Ordinary gallbladder carcinoma (adenocarcinoma) develops in a gallbladder that has undergone secondary changes, often due to long-standing cholelithiasis and associated alterations. Gallbladder carcinoma is detected in about 2–3 % of all cholecystectomy samples and accounts to approximately 60 % of all cancers of the extrahepatic biliary system. The neoplasm can be associated with epithelial precursor lesions and presents with various macroscopic growth patterns. Part of the tumors show, similar to cholangiocarcinomas, a marked desmoplastic stromal reaction and cause a circumscribed or diffuse thickening of the gallbladder wall. Other tumors grow a nodular lesion, sometimes large and obstructing the gallbladder lumen, or present in the form of polyps that grow into the lumen. Histologically, most of the neoplasms are glandular adenocarcinomas with various levels of cellular differentiation. The tumors can grow through the gallbladder wall, show perineural invasion, extend into the gallbladder bed, and invade, depending on stage, into the liver and adjacent organs.

Introduction

In the WHO classification of tumors, carcinoma of the gallbladder (CG) is defined as a malignant neoplasm, usually with biliary, intestinal, foveolar, or squamous differentiation, arising in the gallbladder (Alobores-Saavedra et al. 2010). In most cases, CG develops in an orthotopic gallbladder that may have undergone secondary changes, often due to long-standing cholelithiasis and associated alterations. Rarely, CG develops in gallbladder remnants after incomplete gallbladder resection (Cowley and Wood 1964; Tanga et al. 1973). In the present chapter, emphasis is placed in adenocarcinomas of the gallbladder, special types such as mucinous and squamous cell carcinomas being treated in another chapter. Carcinoma of the gallbladder and its relationship with gallstone disease and chronic cholecystitis have been studied since long.

Epidemiology

CG is an important cancer of the gastrointestinal tract, with an estimated 6,000 new cases per year in the USA. In old autopsy series from a time period with a low rate of gallbladder surgery, the prevalence of CG in necropsies ranged from 5 % to 6 % (Kaumann 1909). In a more recent large autopsy series from Japan, CG was found in 2.1 % (Kimura et al. 1989). In a series of 540 consecutive cholecystectomies from Japan, CG was detected in 2.2 % (Terada 2013). Around 60 % of all cancers of the extrahepatic biliary system arise in the gallbladder (Narula 1971). There are marked differences in incidence from one region of the world to the other. Based on cancer registry data, it was found that the highest CG incidence rates worldwide were reported for women in Delhi, India (21.5/100,000); South Karachi, Pakistan (13.8/100,000); and Quito, Ecuador (12.9/100,000), and high incidences were found in Korea, Japan, and some Central and Eastern European countries (review: Randi et al. 2006). There are also differences in prevalence within

one the same country, due to ethnic variables. In North America, CG is more frequent in American Indians and Hispanic Americans than in whites or African Americans. In an autopsy series of 287 patients with CG, the ratio of men to women was 1:2.64–1:3.7 (Gupta et al. 1980; Sons et al. 1985), but in older series an even higher female preponderance was found (Kaufmann 1909). The average age of women at the time point of diagnosis was 70 years, and that of man, 69.5 years (Sons et al. 1985). The disease occurs on the average at a younger age in females than in males (Gupta et al. 1980). In part of patients, CG is diagnosed as an unsuspected lesion in cholecystectomy specimens (incidental CG; Varshney et al. 2002; Mazer et al. 2012). In a Korean study of 527 patients with gallbladder resection for benign biliary disease, unsuspected CG was found in 1.89 %, 50 % of these patients showing early CG with invasion confined to the mucosa (stage T1) (Kwon and Chang 1997). In a French registry of 218 cases of incidental CG, 67 patients were male and 151 female, with a median age at presentation of 64 years (Fuks et al. 2011). In a systematic review of 30 publications, 276 CGs were detected in Western studies reporting a total of 61,542 cholecystectomy specimens (prevalence of 0.4 %), and of these, 65 % were expected pre- or intraoperatively, while 344 cases of CG were found in 37,365 specimens from Asian studies (prevalence of 1.2 %), with 45 cases being expected pre- or intraoperatively (Swank et al. 2013). In one study analyzing cases of laparoscopic cholecystectomy, the ratio between incidental and non-incidental was 9 out of 19 (Cavallaro et al. 2012).

Clinical and Imaging Features

Dominating symptoms and signs in patients with CG are upper abdominal discomfort or pain, weight loss, jaundice, fatigue, and a palpable mass (Illingworth 1935; Cooper 1937; Kelly and Speed 1946; Danzis 1948; Sainburg and Garlock 1948; Arminski 1949; Cooke et al. 1953; Fortner and Pack 1958; Gerst 1961; Bossart et al. 1962; Chandler and Fletcher 1963; Polk 1966; Robertson and Carlisle 1967; Hardy and Volk 1970; Tanga and Ewing 1970; Solan and Jackson 1971; Krain 1972; Adson 1973; Ohlsson and Aronsen 1974; Donaldson and Busuttil 1975; Melson et al. 1976; Richard and Cantin 1976; Piehler and Crichlow 1977; Arnaud et al. 1979; Jönsson and Pettersson 1982; Pandey et al. 2001; Xu and Zou 2007; Giang et al. 2012). Jaundice was detected in CG patients in up to 58 % (Arnaud et al. 1995), suggesting that invasion and obstruction of extrahepatic bile ducts is a common feature of CG. Part of the increased gallbladder mass may be due to hydrops or hemocholecyst. CG can cause rupture of the gallbladder, eventually followed by biliary peritonitis (Bakaleinik 1976). Very rarely, mucus secreted by CG can accumulate in bile duct lumens and cause obstruction of the common bile duct (Hughes et al. 1997). CG can synchronously occur in conjunction with other neoplasms of the biliary tract, such as carcinoma of the common bile duct (Fujii et al. 2004).

CG can readily be identified by various ultrasonography and other imaging techniques (Pettersson 1974; Olken et al. 1978; Yeh 1979; Fultz et al. 1988; Franquet et al. 1991; Kumar and Aggarwal 1994; Rooholamini et al. 1994; Ohtani et al. 1996; Pandey et al. 2000; Levy et al. 2001; Schwartz et al. 2002; Oikarinen 2006; Lee et al. 2009). Invasive CG presents as wall thickening or polypoid growths in conventional and CT images (Melson et al. 1976; Levy et al. 2001; Levy et al. 2002) and ultrasonography images (Olken et al. 1978; Allibone et al. 1981). In contrast to advanced invasive CD, early CG may be difficult to identify by ultrasonography/US (Nilsson et al. 1989). In one study of 15 patients with pT1 and pT2 disease, US allowed diagnosis in only 5 patients (Kapoor et al. 1996). At US, CG may present as lumen-filling tumors, polypoid masses, or infiltrating masses (Kumar et al. 1990). On both US and CT images, distinguishing the protruding type of CG from polypoid adenomas may be difficult, but benign neoplasms have a more homogeneous texture, spaces between the lesion and the gallbladder wall, and a relatively normal configuration of the gallbladder wall (Jin et al. 2013). The depth of

invasion can be assessed by the use of endoscopic ultrasound/EUS. EUS examination of CG resulted in four distinct phenotypes of cancer growth, i.e., Type A (a pedunculated mass with a fine-nodular surface in an intact wall), Type B (a broad-based mass with an irregular surface and intact outer hyperechoic layer of adjacent wall), Type C (irregular outer hyperechoic layer due to mass echo), and Type D (outer hyperechoic layer disrupted by a mass echo). Each of these types correlated well with the histologically determined depth in cancer invasion (Fujita et al. 1999). CT images in CG show various patterns, including lesions classified as "massive," "thickened wall," or "intraluminal" (Itai et al. 1980).

Pathology

Macroscopy

In their macroscopic presentation, CGs markedly differ between early and advanced cancers. The examination and documentation of macroscopic and other findings in cases of CG have been standardized (Henson et al. 2000).

Early carcinomas, which now comprise tumors of stages T1a and T1b (Cangemi et al. 2006), are usually manifest in the form of circumscribed thickenings of the mucosa or, less commonly, as small polypoid lesions having an adenoma-like morphology. The main gross presentations of early CG comprise flat, superficial-raised, sessile, or pedunculated lesions (Figs. 1, 2, 3, and 4; Tsuchiya 1991). Another classification divided early carcinomas into protruding or superficial lesions, whereby protruding tumors were further subdivided into pedunculated or sessile neoplasms, whereas superficial tumors were subdivided into elevated, flat, or depressed lesions. Among protruding tumors, the majority are sessile, and 88 % of these sessile tumors were accompanied by superficial elevated and/or flat tumors. Overall, 86 % of these early CGs were T1a and 14 % T1b (Wakai et al. 2012). Japanese investigators described that early carcinomas display granular, flat, or gastric area-like mucosal

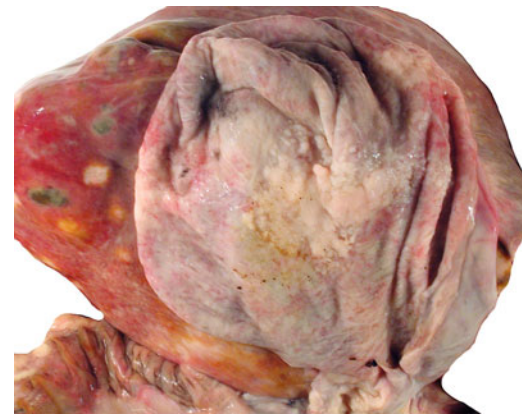

Fig. 2 Same specimen as in Fig. 1, after removal of stones. The gallbladder wall shows carcinoma in the form of a nodular plaque (*center*). Several liver metastases are seen (necropsy specimen)

patterns, which are however not specific for CG, as they may also occur in non-tumorous conditions of the gallbladder. Stereomicroscopic analyses of gallbladders with early CG of the flat type revealed three distinct patterns, i.e., grooved, pitted, or papillary, each of which further subdivided into regular or irregular. The frequency of the grooved (52.2 %) and papillary (52.2 %) patterns was significantly higher in CG than in nonneoplastic lesions, mostly with an irregular subtype, while there was no significant

Fig. 3 Carcinoma of the gallbladder with a component growing into the lumen. The large tumor has massively invaded the liver substance

Fig. 4 Carcinoma of the gallbladder. Transmural cancer growth, marked extension of the carcinoma into the liver, and intrahepatic metastatic disease are seen

difference for the pitted pattern (Ryozawa et al. 1997). In contrast to invasive CG, its precursor lesions, including high-grade dysplasia, are not detectable macroscopically (Renshaw and Gould 2012), and also early CG is detectable pre- and/or intraoperatively in 24 % of cases only (Wakai et al. 2012).

The main growth patterns found in advanced CG are a circumscribed form and a diffuse form of cancer. The circumscribed form presents in four patterns, i.e., a platelike pattern characterized by a firm, more or less delineated plaque causing wall thickening; a nodular pattern with soft or firm tumor nodules effacing the wall and eventually bulging into the lumen; a polypoid pattern with exophytic tumor masses growing into the lumen, forming cauliflower-like masses; and so-called scar cancer, where a grossly ill-defined cancer is situated in scar tissue found in a shrunken gallbladder containing impacted stones. Circumscribed tumor masses within the lumen are usually ulcerated at their surface. Large tumors with necrosis can cause gallbladder perforation. In the diffuse growth pattern of CG, the entire gallbladder wall is firm and sometimes thickened, due to diffuse cancer cell infiltration, without a visible tumor mass. Whereas circumscribed tumors can cause significant enlargement of the gallbladder, diffuse CG is often associated with gallbladder shrinkage. Infiltrative CG can invade the infundibulum and the cystic duct, causing effacement and destruction of the cystic duct, which may no longer be found at gross examination. In case the cystic duct is still open, the gallbladder contains bile and mucus, while complete cystic duct obstruction can result in gallbladder hydrops, but only in non-shrunken gallbladders. Among 287 autopsy cases, most tumors (67.7 %) showed a diffuse infiltrative growth and 32.3 % a polypoid-exophytic growth (Sons et al. 1985). Polypoid tumors were, however, not always found at a high frequency; in one report of 173 cases of CG, only 10 % showed a polypoid pattern (Tragermann 1953).

As CG often develops in gallbladders with long-standing inflammatory change, the organ can show pericholecystic scarring or is sometimes embedded in scar tissue filling the gallbladder fossa. The fibrous adhesions may contain accumulations of pus or even true abscesses, the latter most often in case of perforation, while gallbladder empyema is rather an uncommon CG (Zenker 1889; Haribhakti et al. 1997). CG presents a characteristic local invasion and metastatic pattern. Large cancers often show invasion of the liver substance, and infiltration of neighboring organs can be observed, most often transverse colon and duodenum, and less frequently stomach and pancreas. Rarely, the tumor protrudes through the gallbladder neck and cystic duct into the extrahepatic bile duct system, where it can produce a

tumor thrombus in the common bile duct (Xin-Wei et al. 2013). CG can invade the anterior abdominal wall. In very advanced CG, the tumor can form a large conglomerate inseparably situated between the liver, abdominal wall, stomach, pancreas, and colon, encroaching upon and stenosing large bile ducts and blood vessels, including the portal vein. Owing to its invasive features, CG can produce fistulations between the gallbladder and invaded neighboring organs, most often vesicocolonic fistula, and much rarer vesicoduodenal or vesicogastric fistulas.

Locoregional lymph node metastases may cause impressive lymphadenomegaly. CG commonly produces hepatic metastases, which are manifest as macroscopic metastases of micrometastases. Micrometastases are defined as discrete nodular hepatic lesions, having a diameter of less than 5 mm, or as metastatic deposits located within venous vessels of the liver. Micrometastases are more frequent within 1 cm of the gallbladder bed than 1–2 cm from it, suggesting cancer spread through the vascular network of the gallbladder fossa. Micrometastases showed a strong correlation with the extent of blood vessel invasion around the primary tumor and were often detected in patients with a primary tumor localized on the hepatic side and with more than 3 cm of subserosal invasion (Endo et al. 2004). Although CG invades the entire gallbladder wall and reaches the subserosal space, peritoneal spread (peritoneal carcinomatosis) is not a common feature and is preferentially seen in the diffuse (scirrhous) growth pattern of CG.

Histopathology

Gallbladder carcinoma presents with a wide spectrum of histologies, whereby tubular and solid adenocarcinoma (the "classical" types of CG) predominates (Figs. 5, 6, and 7; Albores-Saavedra et al. 2010; Table 1). The current WHO classification is based on previous classifications published by the WHO and by the Armed Forces Institute of Pathology/AFIP in 2000.

In fact, adenocarcinoma with various proportions of tubular, solid, and/or diffusely growing components is found in most cases (84.6 % in a large autopsy series; Sons et al. 1985). Adenocarcinoma usually grows in the form of nodular or polypoid masses, but diffuse mucosal carcinoma has also been described (Haratake et al. 2002).

Adenocarcinoma, Biliary Type

This is the most common adenocarcinoma of the gallbladder, and these neoplasms are usually well- to moderately differentiated lesions. Biliary-type adenocarcinoma consists of tubular gland-like structures of variable length, lined by columnar cells of varying height and cuboidal cells. The

Small cell carcinoma
Undifferentiated carcinoma
Pleomorphic carcinoma
Carcinomas with sarcomatoid features

cells resemble the cells lining bile ducts and can reliably be identified in fine needle aspiration material (Yadav et al. 2013). Part of the neoplastic cells contain mucin that is sometimes secreted into the tubules, but not forming "mucin lakes" that characterize colloid carcinomas. Approximately a third of well-differentiated biliary-type CG shows focal intestinal differentiation, sometimes with formation of goblet cells. Part of gallbladder adenocarcinomas may contain cell types other than columnar cells, such as Paneth cells, and/or neuroendocrine cells (Koga et al. 1991). Some tumor contains numerous neuroendocrine cells that are reactive for peptide hormones and/or serotonin. Argentaffin cells as a component of CG are a rather uncommon finding, and only a few cells have been detected in one study (Azadeh and Parai 1980). A variant of well-differentiated adenocarcinoma of the gallbladder can mimic minimal deviation adenocarcinoma of the cervix (Tashiro et al. 2000). The nuclei of invasive CG are generally larger than those of in situ lesions, a phenomenon that has been objectively proven by the use of stereologic estimation of mean nuclear volume (Elpek et al. 1999). Classical adenocarcinoma of the gallbladder exhibits variable degrees of desmoplasia (stromal reaction), however, usually without the massive sclerosing stromal reaction characterizing Klatskin tumors. Similar to desmoplastic areas in cholangiocarcinomas, the stroma of CG can undergo secondary changes, including advanced fibrosis/sclerosis, hyalinization, and rarely osseous metaplasia (Cavazza et al. 1999), the latter discussed in more detail in a separate paragraph. In comparison with biliary-type carcinomas of the extrahepatic bile duct, desmoplasia of CG is usually less pronounced. CG may undergo necrosis, hemorrhage, and calcification (Parker and Joffe 1972; Rogers et al. 1973; Hori et al. 2008). Calcification of CG (see below) seems to be an inherent, albeit not yet clarified, feature of some forms of CG, as calcification can also occur in lymph node metastases of these carcinomas (Yun et al. 2011).

Adenocarcinoma, Intestinal Type

Intestinal-type CG is less common than CG and presents under two phenotypes. The more frequent one is characterized by tubular gland-like structures closely resembling those found in

colorectal carcinomas, composed of tall columnar cells with pseudostratified elongated or ovoid nuclei, with mitotic figures having left the basal position and found higher up in the cancer epithelium. Nuclear debris or apoptotic bodies may be found in the epithelial lining. The second, less common variant contains numerous goblet cells, intermingled with Paneth cells and neuroendocrine cells. Immunohistochemically, both variants are typically reactive for MUC2, CEA, and the transcription factor CDX2 (review: Albores-Saavedra et al. 2010).

Adenocarcinoma, Gastric Foveolar Type

This is a rare variant of well-differentiated adenocarcinoma that consists of tall columnar cells with abundant cytoplasm containing mucin and basally placed nuclei. The tumor cells are usually reactive for MUC5A. This carcinoma either occurs as a pure form or exists in combination with other adenocarcinoma variants.

Papillary Carcinoma of the Gallbladder

Papillary adenocarcinoma of the gallbladder is a distinct variety of CG characterized by a papillary growth pattern, a tendency for exophytic growth, and a more favorable biology of disease (Egeberg et al. 1949; Frank and Spjut 1967; Hart et al. 1972; Gunn and Dyte 1985; Akiyama et al. 1995; Onuma et al. 2013). Papillary carcinoma is rare and has been observed in only 4.2 % of all CG (Nuzzo et al. 2005). It has also been found in the setting of anomalous pancreaticobiliary junction (Nuzzo et al. 2005). The intraluminally growing component of papillary carcinomas is well-differentiated and consists of slender papillae covered by columnar cells. Less or even poorly differentiated cell populations have been noted at the base of the papillary structures by some authors (Glenn and Hays 1954; Lund 1960). Large papillary carcinomas may suffer from poor vascularization and undergo marked necrosis (Onuma et al. 2013). Previously, noninvasive and invasive forms of papillary carcinoma were lumped together. In a comparative analysis, it surfaced that noninvasive papillary carcinoma is a distinctive variant occurring more often in females, predominantly showing a biliary phenotype and rarely an intestinal phenotype, associated with cholelithiasis in the majority of cases, and revealing no metastasis and an excellent prognosis. In contrast and similar to ordinary CG, invasive papillary CG can produce lymph node metastasis and is associated with poor prognosis (Albores-Saavedra et al. 2005). A more favorable outcome thus depended on lymph node dissection (Wolma and Lynch 1961).

Intestinal-Type Carcinoma of the Gallbladder

Intestinal-type CG is a variant of well-differentiated adenocarcinoma of the gallbladder characterized by the presence of intestinal features (Albores-Saavedra et al. 1986). Part of these neoplasms resemble colorectal carcinoma, whereas others exhibit a composition characterized by absorptive columnar cells, numerous goblet cells, Paneth cells, and some neuroendocrine cells. The latter may be reactive for serotonin, somatostatin, cholecystokinin, and/or pancreatic polypeptide. The carcinomas are sometimes associated with intestinal metaplasia of the uninvolved mucosa (Albores-Saavedra et al. 1986).

Adenocarcinoma of the Gallbladder with Marked Desmoplasia

In contrast to Klatskin tumors, desmoplasia in CG is usually of moderate degree. There exists, however, a subset of gallbladder adenocarcinomas having marked stromal fibrosis (Wang et al. 2006). In these neoplasms, ultrasound shows that the gallbladder wall is irregularly thickened or exhibits nodosity, but the growth pattern is usually diffuse. A second form of CG associated with copious connective tissue formation is carcinoma

associated with porcelain gallbladder or hyalinizing cholecystitis. Carcinomas developing in this form of cholecystitis did not form distinct tumor masses or a significant wall thickening, but showed widely scattered and bland-appearing glands embedded in the thin band of hyaline stroma, often with microcalcifications and granular intraluminal debris (Patel et al. 2011).

Carcinoma In Situ

Carcinoma in situ (CIS) occurs in the gallbladder either as an isolated lesion or as a lesion associated with invasive carcinoma (Kott and Urca 1974; Albores-Saavedra et al. 1980). Similar to other organs, CIS of the gallbladder is considered to be a malignant neoplasm in its preinvasive phase of evolution. However, in a given case, it cannot be reliably judged whether CIS would have switched to an invasive phenotype in the future or rather persisted as a stable lesion. Among 200 consecutive cholecystectomy specimens removed for cholelithiasis or cholecystitis, CIS was identified in 3.5 %. CIS was also found in the mucosa adjacent to invasive CG in 79 % of surgical cases and in 52.9 % of autopsy cases (Albores-Saavedra et al. 1980). In an analysis of 18 cases of CIS of the gallbladder, all patients were females with an age range of 29–83 years at diagnosis (mean, 55 years). Macroscopically, the CIS lesions could not be distinguished from chronic cholecystitis, with one exception. Histologically, CIS presents as either a papillary lesion or a more common non-papillary lesion. CIS of the gallbladder may extend from the surface epithelium to invaginations and then to antral-type glands, the latter being associated with CIS in more than half of the cases (Albores-Saavedra et al. 1984).

Rare Variants of Gallbladder Carcinoma

A small fraction of CG is characterized by a histology different from adenocarcinoma. These rare carcinoma variants mostly share features with similar neoplasms occurring in other organs (Albores-Saavedra et al. 1981, 1996). The diverse forms of tumors are treated in separate chapters.

Mixed Carcinomas

A minority of CG shows more than one histologic component. Mucinous CG with a separate nodule of anaplastic carcinoma was observed (Mizuno et al. 1999), and there is a very rare reported case of gallbladder adenocarcinoma associated with a choriocarcinoma, sometimes with immunoreactivity for beta-HCG (Albores-Saavedra et al. 1981; Abu-Farsakh and Fraire 1991).

Invasion Patterns

Perineural invasion is a typical feature of CG, and this neoplasm shares this important prognostic alteration with carcinomas of the extrahepatic bile ducts. Cancer cell spread along perineural spaces follows the distinct anatomy of gallbladder nerves. These nerves form a mucosal plexus resembling the intestinal Meissner's plexus, transmural branches, and a nervous plexus on the exterior surface of the gallbladder, the latter plexus also containing ganglion cell clusters (Hermann 1952). Perineural invasion may be mimicked by florid pyloric gland metaplasia of the gallbladder, where the perineural space and the intraneural compartment may be infiltrated by cytologically bland cuboidal or columnar mucin-containing cells (Albores-Saavedra and Henson 1999). Invasive CG has a strong tendency to extend from the mucosa of the gallbladder, where the neoplasm takes its origin in most instances, into the muscle layer and from there into the subserosal space. In part of patients, invasive CG and also CIS were found to extend into Rokitansky-Aschoff sinuses (Albores-Saavedra et al. 2004). Similar to cholangiocarcinomas of the extrahepatic ducts, perineural invasion is a characteristic feature of CG. This type of invasion was identified in 10 of 14 CG (Nagakawa et al. 1993), and perineural

invasion extended to the extramural biliary or pancreatic nerve plexuses in part of cases.

Lymph Node Metastases

Lymph node metastases in CG are either of the macrometastatic or micrometastatic variant and are frequent events of spread. They prevail in the nodular infiltrative form of CG with a histology of moderately differentiated adenocarcinoma, but are less common in papillary adenocarcinoma (Sumiyoshi et al. 1991). In a study of 135 patients with CG undergoing radical resection, lymph node metastasis was found histologically in 44 % (Shirai et al. 2012). In case of micrometastases, the identification of small clusters of carcinoma cells spread to lymph nodes may be difficult by conventional histologic examinations. The detection rate depends in the size and geometry of micrometastases. Tiny aggregates of cancer cells can be detected by means of cytokeratin immunohistochemistry in histologically negative lymph nodes (Yokoyama et al. 1999; Natarajan et al. 2005; Sasaki et al. 2006). In one study, 7 out of 255 HE-negative lymph nodes (2.7 %) were found to be positive for micrometastases by the use of cytokeratin immunostaining (Tajima et al. 1999).

Lesions Associated with Gallbladder Carcinoma

In part of CG with transmural invasion, associated inflammatory infiltrates or populations of immunological effector cells may spill over into the liver substance of the gallbladder bed. Similar to other cancers, CG contains tumor-infiltrating lymphocytes (TILs). High levels of CD4(+) and CD8(+) cells were detected in 51–1 % and 37.8 % of CG cases, respectively, and also infiltrates of natural killer cells were observed (Nakakubo et al. 2003). Part of TILs are FoxP3+ and IL-17-producing T cells that affect tumor progression and prognosis in CG after surgery (Goeppert et al. 2013; Zhang et al. 2013). CG also contains tumor-associated macrophages (TAMs), but these cells are less frequent than TILs. The hepatic bed remaining after cholecystectomy can show various alterations, including granulation tissue, remnants of adherent adipose tissue with lipogranulomas, and sometimes foreign body-type granulomas. Rarely, eosinophil-containing necrotizing granulomas have been observed in the hepatic bed following tumor cholecystectomy, associated with peripheral eosinophilia (Ohtsuki et al. 2012).

Ultrastructural Findings

SEM pictures of well-differentiated CG revealed that CG cells are irregularly shaped columnar cells with less developed and pleomorphic microvilli, whereas transmission EM demonstrated well-developed cytoplasmic organelles, variably differentiated mucus granules, abundant lysosomes, and chromatin changes shared with other malignancies (Koga et al. 1991). In classical CG, mucin-producing secretory columnar cells predominate, intermingled with narrow and dark-staining pencil-like cells (Larraza-Hernandez et al. 1984).

Immunohistochemistry

CG, including its lymph node metastases, is consistently positive for cytokeratins 8 and 18 (Yokoyama et al. 1999). Part of CG are immunoreactive for CK7 and, less often, CK20 (Kalekou and Miliaras 2011). An entire panel of immunohistochemical stains, including cytokeratins, vimentin, epithelial membrane antigen, and carcinoembryonic antigen, is required to reliably diagnose poorly differentiated and undifferentiated forms of gallbladder carcinomas (Diebold-Berger et al. 1995). A significant fraction of CG expresses the mucins, MUC1 and MUC4. High MUC1 expression was correlated with more differentiated neoplasms, whereas a high MUC4 expression was correlated with a negative nodal status (Kim et al. 2012). However, a relationship between MUC1 expression and differentiation was not detected in another

investigation (Ghosh et al. 2005). MUC4 is preferentially expressed in the apex of cancer cells (Miyahara et al. 2008). Expression of CA 242 seems to be a promising marker in CG diagnosis (Rana et al. 2012). Intestinal-type CGs express an intestinal goblet cell marker (Hughes and Bhatal 2013), and CGs with features of pyloric gland metaplasia are reactive for class II mucins (Tatematsu et al. 1988). The majority of CGs express p53 protein in the nuclei (The et al. 1994; Doval et al. 2014). CGs express EGFR, Cox-2, and cyclin D1 (Doval et al. 2014). Part of CG expressed estrogen and progesterone receptors (Gupta et al. 2012). Other immunoreactivities in CG that may be useful in diagnosis of CG include CD151 (a member of the tetraspanin family; Matsumoto et al. 2014), CD117/c-Kit (Langner et al. 2004), EphB1 and Ephrin-B (Yuan et al. 2014), the von Hippel-Lindau gene product, maspin, IMP3, and S100P (Shi et al. 2013). Aberrant maspin expression was noted in focal and patchy areas of gallbladder epithelium and intestinal metaplasia of the gallbladder in patients with cholelithiasis (Maesawa et al. 2006); its expression seems to be involved in early carcinogenesis of CG (Kim et al. 2010). Maspin (mammary serine protease inhibitor) is a member of the serine protease inhibitor/non-inhibitor superfamily and plays a role in the biology of several cancers, where it is downregulated or overexpressed, suggesting differential roles in various cell types. Selectively increased cell adhesion by the expression of maspin is thought to contribute to the inhibition of metastatic spread (review: Berardi et al. 2013). CG shows variably elevated proliferation indices when examined by the use of PCNA or Ki-67 immunohistochemistry (Roa et al. 1993).

Secondary Changes of Gallbladder Carcinoma

CG can undergo marked necrosis, preferentially the exophytically growing forms (Sakurai et al. 2001; Hori et al. 2008). Due to necrosis/infarction, polypoid lesions may detach from the stalk and freely float in the lumen. Necrosis and/or accumulation of mucin, or exudate, can lead to the formation of cystic structures with carcinoma, eventually mimicking adenomyosis/adenomyomatosis at imaging (Tian et al. 2003; Yoshimitsu et al. 2005). Intratumoral cystic components were found in 3 of 35 proven CG by MR examination. All these tumors were well-differentiated adenocarcinomas and cystic changes were caused by abundant mucin production, mucin being accumulated in dilated Rokitansky-Aschoff sinuses (Yoshimitsu et al. 2005). In case of vesicointestinal, and particularly vesicocolonic fistulation, entry of intestinal bacteria into tumor can lead to puriform liquefaction or gangrene of cancer and, rarely, gas gangrene.

As already noted above, gallbladder carcinoma can undergo extensive calcification (Parker and Joffe 1972; Rogers et al. 1973): two main patterns of calcification occur. Calcified carcinomas may have calcium salt deposits mainly in the stroma, numerous mineralization grains being placed between stromal cells and/or along connective tissues fibers. The incidence of this change is not known, but may be more frequent in case one would test for microcalcifications by the use of the von Kossa stain. The second pattern is characterized by sometimes marked calcification in CG with high mucin content (Parker and Joffe 1972; Tian et al. 2003). In rare cases, calcification present in the primary tumor is also found in lymph node metastases (calcified nodal metastasis; Parker and Joffe 1972; Yun et al. 2011) or in liver metastases (Nakadaira et al. 2008). Calcifications and/or osseous metaplasia occurs on malignant gallbladder neoplasms other than CG, e.g., carcinosarcoma with calcified or bony components (Grote and Kaemmerer 1986; Ishida et al. 2012). Calcifications can also develop in mucinous cholangiocarcinoma (Nagakura et al. 1999).

A very rare secondary change in CG is osseous metaplasia (heterotopic ossification), which develops within tumor stroma and is characterized by the formation of immature bony tissue or osteoid within the spindle cell background (Cavazza et al. 1999). Heterotopic ossification in tumors may be induced by production of bone morphogenetic proteins (Imai et al. 2001; Komai et al. 2006). Carcinosarcomas of the gallbladder

can contain foci of osseous metaplasia (Nakagawa et al. 1996).

Precursor Lesions

Several investigations indicate that CGs derive from a foregut cell lineage and that at least a large part of CGs develop in the setting of a hyperplasia/metaplasia-dysplasia-carcinoma in situ-invasive carcinoma sequence, or a cascade leading from gallbladder adenoma with or without significant atypia to carcinoma (Sawyer 1970; Albores-Saavedra et al. 1980; Kozuka et al. 1982; Laitio 1983; Yamagiwa 1987; Yamamoto et al. 1989a, b; Aldridge and Bismuth 1990; Kim et al. 2001; Adsay 2007; Stancu et al. 2007; Trivedi et al. 2008; Feng et al. 2011; Hughes and Bhathal 2013; Segovia Lohse and Cuenca Torres 2013; Kijima et al. 2014).

The overall prevalence of metaplastic changes developing in chronic inflammatory gallbladder disease varies considerably among different studies and was higher than 25 % in some analyses. Metaplastic changes appear to be more frequent in cases with microlithiasis and are associated with chronic gallbladder wall thickening (Seretis et al. 2014). Intestinal metaplasia, in part with goblet cells, was found at rates of 4.0 % and 30.6 % in cases without and with cholelithiasis, respectively. Metaplasia was detected at rates of 69.8 % and 61.1 % in cases with dysplasia and carcinoma, respectively, suggesting that intestinal metaplasia of the gallbladder may precede dysplastic changes (Yamagiwa and Tomiyama 1986). The prevalence of dysplasia varies as a function of genetic background of patients, presence or absence of risk factors such as stone disease and chronic cholecystitis, and definitions/criteria employed to identify dysplasia. Overall, incidental gallbladder dysplasia (IGBD) seems to be a fairly common incidental histologic finding after cholecystectomy for gallstone disease (Solaini et al. 2014). In a Japanese study of 200 gallbladders removed for presumed benign disease, dysplasia was present in 14.5 % (12 % mild dysplasia, 2.5 % moderate to severe dysplasia), while epithelial hyperplasia was diagnosed in 27 % of cases (Mukada et al. 1985). In one analysis, over 80 % of invasive CG presented areas adjacent to flat dysplasia and carcinoma in situ (Rao et al. 2006). There is evidence that K-RAS mutations play a role in the development of premalignant gallbladder lesions and early carcinogenesis (Kim et al. 2000). In contrast to flat dysplasia, an adenoma-carcinoma sequence does not seem to be a pathway for gallbladder carcinogenesis as common as that of dysplasia, as adenomas are uncommon (less than 1 % of cholecystectomies), and adenomatous remnants in the neighboring mucosa to early CG were detected less than 3 % of cases (Roa et al. 2006). However, adenomatous residues were found in up to 19 % of invasive CG (Kozuka et al. 1982). In part of cases of CG, the invasive neoplasm is spatially associated with carcinoma in situ/CIS. CIS disclosed a superficial extension into Rokitansky-Aschoff sinuses and mucous glands (Yamaguchi et al. 1992). CG is known to occur in the setting of gallbladder papillomatosis (Kunisch et al. 1997). What is the time period required for the transformation of dysplasia to frank carcinoma? There is still scarce information regarding the timely evolution of gallbladder precursor lesions, owing to the fact that dysplastic lesions are silent, and early CGs are usually asymptomatic. In an investigation on resected gallbladders, the mean age of patients showing gallbladder dysplasia was 46.3 years, that of early CG 57.5 years, that of advanced CG 59 years, and that of CG with metastases 61.1 years (Roa et al. 1996), suggesting that the carcinogenic progression from dysplasia may require at least 15 years. In addition to precursor lesions, the role of cancer stem cells in the carcinogenesis of CG has been discussed. CG can contain CD133-positive cells classified as self-renewing potential carcinoma stem cells (Shi et al. 2011).

CG was identified in close spatial relationship with adenomyomatosis (Paraf and Potet 1988), but a causal relationship between adenomyomatosis and carcinogenesis remains uncertain. A recent investigation showed that the status of adenomyomatosis in gallbladders with CG was significantly associated with T stage, nodal metastasis, distant metastasis, and shorter survival, and

that adenomyomatosis-positive CG is more often diagnosed clinically in the advanced stages (Kai et al. 2011). CG can also arise in Rokitansky-Aschoff sinuses (Terada 2008), but such relationships are difficult to assess, as invasive CG and CIS can secondarily involve these sinuses (Albores-Saavedra et al. 2004).

Differential Diagnosis

CG may histologically be confounded with an entire spectrum of nonneoplastic lesions, including diverse forms of metaplasia, adenomyomatosis foci with atypia, regenerative changes in previously damaged Rokitansky-Aschoff sinuses, and hyperplastic Luschka ducts (Singhi et al. 2011; Giang et al. 2012). Mass-forming adenomyomatosis of the gallbladder may be masquerade as CG (Shimoji et al. 2001; Ray et al. 2012). Mucin-containing Rokitansky-Aschoff sinuses with extracellular mucin deposits may mimic mucinous adenocarcinoma of the gallbladder (Albores-Saavedra et al. 2009). Pseudotumorous lesions, e.g., intramural gallbladder hematomas (Tan et al. 2005) and gallstone granulomas (Tham and Ng 2001; Jung et al. 2011), may also mimic CG. Rare mass-producing specific inflammations of the gallbladder can produce presentations similar to that of cancer, including gallbladder tuberculosis (Hegler 1925; Ramia et al. 2006; Soufi et al. 2011; Verma et al. 2012), brucellosis (Ögredicie et al. 2010), and actinomycosis (Hefny et al. 2005; Lee et al. 2007).

Paraneoplastic Organ Changes in Gallbladder Carcinoma

A small subset of CG is associated with paraneoplastic features/syndromes (Table 2). The disorders comprise acanthosis nigricans (Lam 1940; Lichtenstein and Tannenbaum 1940; Campbell 1941; Werko 1945; Jacobs and Rigel 1981), bullous pemphigoid (Post et al. 1973), exfoliative dermatitis/erythrodermia (Kameyama et al. 2005), polymyositis (Adli et al. 2013), dermatomyositis (Yiannopoulos et al. 2002; Ni et al. 2013), neuropathy (Mitobe et al. 1970), paraneoplastic opsoclonus (Corcia et al. 1997), Guillain-Barré syndrome (Phan et al. 1999), erythrocytosis (Manigand et al. 1971), thrombocytosis (Wakabayashi et al. 1978), leukemoid reactions (Pozza et al. 1966), hemolytic anemia (Barletta et al. 1989; de la Sierra et al. 1989), Sweet's syndrome (Jindal et al. 2012), production of granulocyte colony-stimulating factor (Takahashi et al. 1985; Takeda et al. 1990; Furihata et al. 1999; Suzumura et al. 2014), hypercalcemia (Vilabona et al. 1986; Watanabe et al. 1989;), Cushing's syndrome (Brickner et al. 1961), synthesis and secretion of chorionic gonadotropin/beta-HCG (Fukuda and Ohnishi 1990; Sato et al. 2010), and AFP-producing CG (Sugaya et al. 1989) which is discussed in a separate paragraph. Paraneoplastic disorders of the CNS in CG should

Table 2 Paraneoplastic syndromes/disorders in gallbladder carcinoma

Cutaneous alterations
Acanthosis nigricans
Bullous pemphigoid
Erythrodermia
Soft tissue alterations
Dermatomyositis
Polymyositis
Hematological alterations
Erythrocytosis
Thrombocytosis
Leukemoid reactions
Production of granulocyte colony-stimulating factor
Autoimmune hemolytic anemia
Hemolytic microangiopathic anemia
Sweet's syndrome
Paraneoplastic thrombosis
Neuromuscular alterations
Neuropathy (sensory, mixed)
Opsoclonus
Guillain-Barré syndrome
Metabolic alterations
Paraneoplastic hypercalcemia
Cushing's syndrome
Syndrome of inappropriate secretion of antidiuretic hormone (SIADH)
Paraneoplastic hyponatremia
AFP production

not be confounded with effects of metastases, e.g., myelopathy due to spinal metastases (Newman et al. 1977).

Adenocarcinoma of the Gallbladder: Biology of Disease, Prognosticators, and Staging

148

Contents

Abstract

Biology of disease and progression of ordinary gallbladder carcinoma depends on several factors. For local spread, perineural and intraneural invasions are important risk factors. Gallbladder carcinoma often extends beyond the organ boundaries and invades the gallbladder bed, liver, and adjacent soft tissues. Lymph node metastasis is a characteristic feature of gallbladder carcinoma and a significant prognostic factor. Pericholedochal nodes are a common metastatic site, followed by the cystic node. There is a relationship between T stage and the incidence of locoregional lymph node metastases. The prognostically significant patterns of gallbladder cancer spread to the liver include hepatic bed type, hepatic hilum type, bed and hilum type, lymph node type, cystic duct type, and localized type. Gallbladder carcinoma can spread through intraluminal bile duct invasion. It produces a distinct pattern of distant metastases, although extraabdominal metastasis is overall uncommon in gallbladder carcinoma. Important prognosticators for tumor progression are tumor stage, lymph node stage, radicality of resection, perineural invasion, and the histologic grade.

Biology of Disease

The natural course of CG is characterized by a high tendency for invasion, spread, and metastasis (Fahim et al. 1962). Most of the patients with CG present with advanced disease at the time point of diagnosis, precluding curative resection resulting in dismal prognosis (Dutta 2012). In some series, almost half of patients showed metastatic disease at the time point of diagnosis (Hamrick et al. 1982). The overall 5-year survival for patients with CG having undergone R0 curative resection was reported to range from 21 % to 69 % in diverse studies (review: Lai and Lau 2008).

Local Invasion

Perineural and intraneural invasions are important modes of local spread in CG. The incidence ranged from 22 % to more than 50 % (Vadheim et al. 1944; Kuwayti et al. 1957; Fahim et al. 1962; Ouchi et al. 1987; Nagakawa et al. 1993). Perineural cancer invasion has to be distinguished from perineural invasion observed in benign conditions, such as adenomyomatous hyperplasia (Albores-Saavedra et al. 2007) and pyloric gland metaplasia (Albores-Saavedra and Henson 1999). There is a correlation between the prevalence of perineural invasion and higher histologic grade (Fahim et al. 1962). CG often extends beyond the organ's boundaries and invades the gallbladder bed, the liver, soft tissues surrounding the bile ducts, and the hepatoduodenal ligament. In bile ducts located to the hepatoduodenal ligament, perineural invasion in the setting of bile duct infiltration is a sign of aggressive tumor disease (Kaneoka et al. 2003). Pathogenetically, expression of the neural cell adhesion molecule/NCAM by carcinoma cells seems to play an important role as a neurotrophic mechanism (Seki et al. 1995). The direct extension of CG tumor cells from the primary tumor to adjacent organs and structures is only partially elucidated. One mechanism involves mucosal and submucosal lymphatic vessel networks that connect neighboring organs. In patients with CG, cancer cells spread through lymphatic vessels in the submucosal layer of the common bile duct (Chikamoto et al. 2009). CG frequently invades blood vessels, in particular veins. The anatomy of the venous drainage of the gallbladder has been studied in detail (Habighorst et al. 1965; Halvorsen and Myking, 1971 9). The first authoritative investigation based on injection methods dates from 1932 (Karlmark 1932). This author demonstrated that the venules and small veins of the gallbladder form a continuous plexus localized to the adventitia of the organ. This plexus is, via venous bridges, connected with a similar plexus of the extrahepatic bile ducts. The plexus system is in turn drained by a variable number of cholecystic veins showing diverse types of arrangement. On the hepatic side of the gallbladder, the number of cholecystic veins ranges from 2 to 20, and these veins terminate in the quadrate lobe of the liver adjacent to the gallbladder bed. In contrast, the peritoneal side of the gallbladder shows usually only one cholecystic vein (rarely two). This vein drains either into the liver or into the periductal venous plexus, which in turn is connected to the veins of the quadrate lobe. In part of cases, this vein drains into the portal vein (review: Fahim et al. 1962). The significance of portal vein drainage is underlined by the observation of dilated gallbladder veins or gallbladder varices in the setting of portal hypertension (Marchal et al. 1985; Ralls et al. 1988; Kainberger et al. 1990). Veins that enter the quadrate lobe form a plexus of small vessel that finally drain into the hepatic vein of this lobe (Petrén 1932). Small veins of the cystic duct join at the neck of the gallbladder to form either single or double cystic veins which accompany the cystic duct to connect to the periductal veins (review: Fine 1997). This anatomical substrate suggests an important pathway for CG spread both into the region of the extrahepatic bile ducts and the hepatoduodenal ligament and the right-sided liver. In a study of 155 cases of CG, involvement of gallbladder vessels was identified in 13.9 %, invasion involving venules having a diameter of 500–1,200 μm to larger veins with a thick muscular wall. In large veins, traffic of cancer cells through the wall seems to take place via transmural invasion and/or extension along vasa

vasorum (Fahim et al. 1962). CG cancer cells can spread through lymphatic vessels in the submucosa of the common bile duct (Chikamoto et al. 2009).

Lymph Node Metastasis

Lymph node metastasis is a characteristic feature of CG that represents a significant prognostic factor. The incidence of lymph node metastasis in CG varies from 35 % to 75 % in diverse studies (Cooper 1937; Vadheim et al. 1944; Jones 1950; Willis 1953). Lymphatic spread may show a distinct distribution pattern, with the pericholedochal nodes being the most commonly affected, followed by the cystic node. Lymph node metastasis by CG cab develops in the absence of involvement of the liver (Cappell and Tudhope 1934). This distinct pattern results from the specific anatomy of the lymphatic drainage of the gallbladder. By means of Prussian blue injection into human fetuses 8–9 months old, Clermont (1909) had studied the lymphatic vessels of the gallbladder and gallbladder-associated lymph nodes in detail. The gallbladder wall harbors lymphatic plexus that traverses the entire wall and enters lymphatic collecting trunks that are mainly located on the inferior surface of the gallbladder. They are arranged like the letter "N," as they are present on both the left and the right borders and diagonally toward the left side of the gallbladder neck (Fahim et al. 1962). The left-sided collecting trunks empty into the cystic node which is situated in the acute angle formed between the cystic duct and the common hepatic duct, while the right-sided collecting trunks pass along the right border of the gallbladder neck and extend uninterrupted to empty into the pericholedochal nodes (reviewed by Fahim et al. 1962). Also the lymph from the cystic node ends in the pericholedochal nodes. The latter are usually two lymph nodes, termed the node of the hiatus and the superior pancreaticoduodenal node. The node of the hiatus was a constant finding in Clermont's investigation. It is situated to the right of the common duct, its lower pole being at the level of the attachment of the lesser omentum behind the superior portion of the duodenum. The node of the hiatus also receives lymph from the extrahepatic bile ducts and from the right liver lobe. Three to four efferent lymphatic vessels of the node of the hiatus continue to reach the superior pancreaticoduodenal node, which is located along the superior surface of the pancreas to the right of the common duct (summarized in Fahim et al. 1962). Efferent lymphatics of this node continue either to the preaortic peri-celiac nodes or to the three to four posterior pancreaticoduodenal nodes which are located around the vessel arcade in the posterior pancreaticoduodenal groove. From here, the lymph flows to the nodes around the superior mesenteric artery. Clermont (1909) found lymph nodes along the hepatic pedicle in relation to the hepatic artery, draining the left liver lobe only, but he did not find any Quénu-type hepatic hilar lymph nodes (proposed to exist by Edouard André Victor Alfred Quénu, 1852–1944, French surgeon active in anatomy and surgical pathology). Clermont's studies referred to human fetuses and infants and the situation in adults may differ from findings obtained in the prenatal and pediatric age group. The lymphatic system of the gallbladder was subject to more recent investigations on adult individuals. Ito and coworkers (1991) divided gallbladder lymphatic drainage into three pathways, i.e., the cholecystoretropancreatic pathway (the main pathway), having two routes, namely, one running spirally and posteriorly from the anterior surface of the common bile duct to the right and the other one running almost straight down from the posterior surface of the common bile duct. These routes end at a retroportal lymph node, termed by the authors the principal retroportal node. A second route connected the gallbladder with the celiac nodes, and a third ran in front of the portal vein to the superior mesenteric nodes.

There is a relationship between the T stage and the incidence of locoregional lymph node metastases. In one study, none of 15 patients with stage pT1 tumors had lymph node metastasis, while 60 of 96 patients with pT2-4 tumor disease had lymph node metastases. pT3-4 tumors displayed more lymph node involvement and significantly higher N2:N1 ratios (2.5) than pT2 tumors.

Patients with N2 disease had a worse prognosis than those with N1 (Tsukada et al. 1997). Overexpression of microRNA-155, associated with inflammation-induced carcinogenesis, in CG is closely correlated with the emergence of lymphatic metastasis and poor prognosis. In vitro assays revealed that aberrant expression of miRNA-155 enhanced CG cell proliferation and invasion (Kono et al. 2013).

Invasion of the Liver and Intrahepatic Metastasis

Among early sites of metastasis, the liver is often involved. In fact, hepatic metastasis is the most frequent mode of recurrence of advanced CG after radical resection, and microscopic liver metastases in CG are an independent prognostic factor (Endo et al. 2004). Infiltration and/or metastatic involvement of the liver was detected in up to 89 % of cases (Lam 1940; Vadheim et al. 1944; Glenn and Hays 1954; Burdette 1957; Sons et al. 1985). It may, however, sometimes be difficult to distinguish hepatic metastases in segments close to the gallbladder from direct invasion of the liver substance. The pathways leading to true hepatic metastases have been discussed, emphasis being placed on the anatomic relationships between gallbladder veins and the anterior portal vein (Shirai et al. 1995; Yoshimitsu et al. 1997, 2001; Ohtsuka et al. 1998; Lin et al. 2005; Table 1). The extent of microscopic angiolymphatic portal tract invasion correlated with the gross depth of direct invasion of the liver (Shirai et al. 1995).

Table 1 Patterns of gallbladder carcinoma spread to the liver

***Kondo system* (2002)**

Hepatic hilum type
Bed and hilum type
Lymph node type
Cystic duct type
Localized type
***Wakai system* (2010)**
Direct invasion through the gallbladder bed
Portal tract invasion
True hepatic metastatic nodules

Kondo and coworkers (2002) identified six types of CG spread. In the hepatic bed type, a large mass in the fundus and body of the gallbladder invaded the liver substance through the gallbladder bed. In the hepatic hilum type, CG of the gallbladder neck infiltrates the hepatic hilum causing obstructive jaundice. In the bed and hilum type, huge masses occupying the entire gallbladder involve both the gallbladder bed and the hepatic hilum. In the lymph node type, enlarged metastatic lymph nodes are the most prominent feature. In the cystic duct type, a small mass arising from the cystic duct involves the common bile duct. In the localized type, tumor spread is localized to the gallbladder and presents at the earliest stage of any type (Kondo et al. 2002). In another study, the mode of hepatic spread was classified into three patterns, i.e., direct invasion through the gallbladder bed, portal tract invasion, and true hepatic metastatic nodules. A significant proportion of cases with portal tract invasion revealed invasion of hepatic lymphatic vessels as shown by D2-40/podoplanin immunohistochemistry (Wakai et al. 2010).

Intraductal Spread of Gallbladder Carcinoma

CG can spread through intraluminal invasion of the extrahepatic biliary tract. It was found in up to 4 % of cases (Fahim et al. 1962). Rarely, CG showed intraluminal implantation into bile ducts (so-called implantation metastasis or formation of intraluminal tumor "thrombi" or "emboli"; Hollings 1963; Al-Qudah 1994; Evans 1994; Midorikawa et al. 2000). In case intraluminal CG metastasis involves the confluence or the common bile duct, obstructive jaundice ensues (Hollings 1963; Midorikawa et al. 2000).

Distant Metastasis

CG produces a distinct pattern of distant metastases, although extraabdominal metastases are

overall uncommon in CG. The most common metastatic site is the lung (Tokunaga et al. 2005; Jeyaraj et al. 2013), followed by the central nervous system (Takano et al. 1991; Tayo et al. 2005), ovaries (Singh et al. 2010), soft tissues, and breast (Khangembam et al. 2013). In rare instances, pulmonary metastasis of CG presents with a lepidic growth patterns, i.e., cancer cells lining alveolar spaces (Tokunaga et al. 2005). Similar to carcinomas of the extrahepatic bile ducts, CG can produce ovarian metastases that sometimes present as Krukenberg tumors (Andrieux et al. 1972; Chicos et al. 2007). Solitary metastases to the skeleton occur, but are rather uncommon (Rominger et al. 1961; Prakash et al. 2010; Chaudhari et al. 2014; Puranik et al. 2014). Multiple osseous metastases are even less common (Commandre et al. 1965; Misra et al. 1997). Subcutaneous metastasis is also rare in CG, but may present as a rapidly progressive cancer disease (Heavey et al. 2014). Other rare sites comprise the orbita (Puglisi et al. 2005), heart (Gunjiganvi et al. 2013), adrenal gland (Sahoo et al. 2014), and uterus (Martinez-Roman et al. 2005; Kefeli et al. 2009).

The mechanisms leading to early and widespread metastasis in CG are only partially known. CG shows an upregulation of the prometastatic microRNA-20, closely associated with local cancer invasion and distant metastasis. A markedly increased level of TGF-beta1 is responsible for the elevation of microRNA-20a, which in turn promotes epithelial-mesenchymal transition thought to promote metastasis (Chang et al. 2013).

Implant Metastasis

Implant metastasis of CG can develop in cholecystectomy scars (Merz et al. 1993). In some patients, metastases of CG have been found at the port site (Karayannakis and Knight 1997; Reber et al. 1998; Ohmura et al. 1999; Winston et al. 1999; Nakagawa et al. 2000), trocar site (Copher et al. 1995), or umbilicus (Clair et al. 1993; Kessler and Mihaljevic 1994; Jacobi et al. 1995; Jeon et al. 1999) following laparoscopic cholecystectomy. The incidence of recurrence of incidental CG at the port site following laparoscopic cholecystectomy was 14 % in one study and was similar whether the primary tumor was confined to the gallbladder (T1/T2) or locally advanced (T3/T4; Z'graggen et al. 1998). In an international survey, it was found port site recurrence was identified in 17.1 % of 409 patients with a median of 180 days following laparoscopic cholecystectomy for nonapparent CG (Paolucci et al. 1999). Laparoscopic cholecystectomy with the finding of unsuspected CG may be followed by cutaneous seeding (Kim and Roy 1994), and laparoscopic removal of CG may cause peritoneal cancer dissemination (Pezet et al. 1992; Sailer et al. 1995; Marmorale et al. 1998; Ohtani et al. 1998; Shirai et al. 1998). Cancer spread to the peritoneum in the setting of laparoscopic cholecystectomy was mainly found in the presence of T3 tumors (Wysocki and Krzywon 2000). Rarely, CG gave rise to umbilical metastasis, alias Sister Mary Joseph's nodule, in the absence of laparoscopic surgery (Rousselot et al. 1964; Bork et al. 2002; Renner and Sticherling 2007). Sister Mary Joseph's nodule refers to a palpable tumor nodule bulging into the umbilicus due to a metastasis from an abdominal or pelvic malignancy. The eponym is related to Sister Mary Joseph Dempsey (1856–1939), surgical assistant of Dr. William J. Mayo at St. Mary's Hospital in Rochester, who drew Dr. Mayo's attention to the phenomenon of umbilical metastasis, the metastatic pathway probably involving lymphatics along the obliterated umbilical vein. Laparoscopic cholecystectomy can also be complicated by parietal seeding of carcinoma (Barsoum and Windsor 1992) or by seeding into the gallbladder fossa (Evrard et al. 1996). Seeding of CG along the intervention tract was observed following percutaneous transhepatic choledochoscopy (Yamakawa et al. 1983).

Prognosticators

A growing list of factors affecting prognosis of CG have been identified, relating to growth factors and their receptors, factors regulating

proliferation and apoptosis, adhesion molecules, factors regulating cell motility and locomotion, enzymes involved in tissue invasion, and angiogenic factors (review: Gomez-Roel et al. 2007).

Stage

Tumor stage (T stage) and lymph node metastases (N stage) are important prognosticators in CG. The T category is a decisive factor for predicting outcome (Kayahara and Nagakawa 2007; Cho et al. 2012). Early CG, limited in its extension to the intramucosal compartment (pT1a), is usually an incidental finding, but this stage is associated with good prognosis (Albores-Saavedra et al. 2011). The presence of lymph node metastases is an important predictor of outcome, whereby the number in involved lymph nodes independently determines prognosis after tumor resection (Sakata et al. 2010; Shirai et al. 2012). Distant positive lymph nodes have a particularly adverse effect on outcome (Meng et al. 2011). There is increasing evidence that the lymph node ratio (LNR) is an important prognostic factor for CG patients. LNR was a powerful predictor of disease-free survival in curatively resected patients, specifically in stage IIIB disease (Negi et al. 2011; Choi et al. 2013). In another investigation, however, the number of positive lymph nodes better predicted patient outcome after resection than LNR or location of positive nodes (Shirai et al. 2012). The presence of lymph node metastases in CG is associated with expression of the high molecular weight glycoprotein, DF3 (MUC 1). Lymph node metastasis was frequently found in the cytoplasmic DF3- and stromal DF3-positive CG, suggesting that DF3 expression plays important roles in cancer cell growth and metastasis of CG (Kashiwagi et al. 2000). The prognostic significance of nodal micrometastases in CG is not yet known in detail, but was shown to have an impact on survival (Sasaki et al. 2006) or even be an independent prognosticator for poor outcome (Nagakura et al. 2001). In one investigation, nodal micrometastases were found in 2.3 % of lymph nodes that were macrometastasis negative at conventional examination. Micrometastases correlated with non-micro-lymph node metastases on conventional tissue sections and were a significant prognostic factor, although they may reflect cancer cell spread to the whole body rather than an initial event of cancer spread (Tanabe et al. 2012). Distant metastases are a decisive factor for prognosis in patients with CG. Hepatic metastasis is the most common mode of recurrence of advanced CG after radical resection. Both macroscopic and microscopic liver metastases are involved in progressive disease and dismal prognosis.

Radicality of Resection

The presence or absence of carcinoma in the resection margin significantly affects outcome (Chakravarty et al. 2009). Carcinoma spread to the cystic duct is a prognosticator which indicates poor prognosis in CG patients, probably also linked to a high proportion of associated perineural invasion and lymph node metastasis (Nakata et al. 2007). It should be mentioned that high-grade dysplasia may rarely occur in the cystic duct margin in the absence of invasive CG (Bickenbach et al. 2011). Intraoperative frozen section is a common method to evaluate resection margins in the setting of cholecystectomies performed for CG, but has some interpretational drawbacks due to the presence of gallbladder structures that may be confounded with cancer, including glands and (atypical) Rokitansky-Aschoff sinuses. It has been demonstrated that frozen section and permanent diagnoses of the bile duct margin in CG may be inconsistent in up to 25 % of cases due to overdiagnosis in frozen sections and the “appearance” of carcinoma in permanent histology slides (Yamaguchi et al. 2005).

Incidental Versus Non-incidental CG

A significant fraction of CGs are incidental tumors detected in cholecystectomy specimens obtained via resection of suspected benign disease. Patients with incidental CG (IGC) had a longer survival rate compared to patients with

non-incidental CG (NIGC). In one study, the majority of patients with potentially curable disease had IGC (D'Hondt et al. 2013).

Histologic Type

With few exceptions, the histologic type of CG did not affect biology of disease (Glenn and Hays 1954). In a comparative study, well-differentiated or moderately differentiated tubular adenocarcinomas were associated with a longer survival time than poorly differentiated carcinomas, the latter also having a higher incidence of hematogenous metastases (Egawa et al. 2004). Most CG shows the histology of adenocarcinoma, and the relatively few neoplasms with distinct morphologies different from ordinary adenocarcinoma mainly comprise papillary and colloid carcinomas. In comparison with all other histologic types, papillary CG had the most favorable prognosis, in some series found in patients with long survival (Fahim et al. 1963; Frank and Spjut 1967; Hart et al. 1972; Ouchi et al. 1986; Henson et al. 1992).

Histologic Grade

Dedifferentiation is often observed in CG and is associated with poor prognosis. In an ECOG study on 30 patients with advanced CG divided into either low-grade or high-grade lesions, the 13-week low-grade CG patient survival was significantly longer than the 7-week high-grade CG patient survival (Johnson et al. 1987). In part of CG, less differentiated tumor cells form isolated single cells or clusters of fewer than five cancer cells at the invasive front. Similar to the respective situation in colorectal carcinomas, this phenomenon is termed tumor budding, a lesion that reflects prognosis, particularly for T2 tumors (Kai et al. 2011).

Invasion Patterns

The presence of perineural invasion is a negative prognosticator in patients with CG (Nagakawa et al. 1993; Yamaguchi et al. 2002; Noshiro et al. 2003; Nakata et al. 2007). In one study of 68 patients with CG, perineural invasion was demonstrated in 71 % of patients. The incidence of invasion was correlated with invasion of extrahepatic bile ducts, which was the only independent factor associated with perineural involvement. The 5-year survival rate of patients with perineural invasion was 7 % in comparison with 71 % of patients without detectable perineural invasion (Yamaguchi et al. 2002). Bile duct involvement portends poor prognosis in resected CG (Chan et al. 2005; Eil et al. 2013). In early CG, intraepithelial extension into Rokitansky-Aschoff sinus is an adverse prognostic factor (Roa et al. 2013). As in other carcinomas, vascular invasion is a negative prognostic factor in CG. Expression of vascular endothelial growth factor-C/VEGF-C was expressed in 63 % of CG, and this expression was associated with lymphatic vessel invasion and lymph node metastasis, suggesting that VEGF-C is involved in tumor progression through lymphangiogenesis and facilitation of lymphatic vessel invasion (Nakashima et al. 2003). Invasion of the hepatic artery is an important prognostic factor in patients with CG, as infiltration of this artery confers high risk and a poorer prognosis (Kobayashi et al. 2012).

Oncogene and Tumor Suppressor Gene Expression and Factors Involved in Chromatin and DNA Metabolism

A significant proportion of CG expresses p53. Fifty-eight percent of these cancers were immunoreactive for p53 in one analysis, seen more often in moderately or poorly differentiated neoplasms (Washington and Gottfried 1996). No significant correlation was found between p53 overexpression and T stage, lymph node metastasis, prognosis, or recurrence in patients with CG, but p53 overexpression was correlated with aneuploidy (Ajiki et al. 1996). p53 nuclear overexpressions in CG were not related to cancer differentiation, depth of gallbladder wall invasion, or patient survival (Hidalgo Grau et al. 2004).

Lack of correlation between p53 expression in CG and survival was found in another investigation (Washington and Gottfried 1996). On the other hand, other investigations reported a role of p53 gene mutation in the transition from premalignancy to malignancy (Ajiki et al. 1996; Moreno et al. 2005) and a correlation between p53 expression in CG and poor survival (Takagawa et al. 2005). An important regulator of chromatin, involved in silencing tumor suppressor genes, is the histone deacetylase (HDAC) system. The Myc oncogene pathway seems to be involved in carcinogenesis and progression of CG. N-myc downstream-regulated gene 1 (NDRG1), a member of the N-myc downstream-regulated gene family, is associated with inhibition of tumor metastasis and tumor suppression. In CG, NDRG1 was expressed in 63.8 % of cases, specifically at the invasive front of the tumors, but not in normal gallbladder epithelium. This expression was significantly associated with high histologic grade, advanced T stage, positive nodal metastasis, venous/lymphatic invasion, and poor survival (Zhang et al. 2012). In CG, overexpression of HDAC 2 in tumor cell nuclei is correlated with higher histologic grade, and predicts unfavorable prognosis (Du et al. 2013a). There is evidence that factors involved in chromatin replication and chromatin remodeling are altered in CG and affect biology of disease. Rsf-1/HBXAP, a nuclear protein with histone chaperon function and member of the remodeling and spacing factor complex which mediates ATPase-dependent chromatin remodeling, is expressed in CG, and its overexpression confers aggressiveness and is associated with disease-specific survival (Chen et al. 2011a). Decreased expression of the chromodomain helicase DNA-binding protein 5 in CG cells is correlated with a higher lymph node metastasis rate and shorter disease-free survival and overall survival (Du et al. 2013b). Dicer and Drosha, two enzymes critically involved in the processing of microRNA, are significantly less expressed in CG than in dysplastic gallbladder epithelia and were less expressed in poorly differentiated carcinomas with lymph node metastases in comparison with well-differentiated adenocarcinomas. Loss of expression of Dicer and Drosha was associated with decreased overall survival (Shu et al. 2012).

Transcription Factors and Associated Protein Signaling Networks

SOX4, a member of the SRY-related HMG-box (SOX) transcription factor family, plays a significant role in carcinogenic pathways of various malignancies. SOX4 was expressed in 75 % of CG, but in normal gallbladder epithelium. SOX4 expression in CG was significantly associated with low histologic grade, low pathological T stage, early clinical stage, and better disease-free and overall survival (Wang et al. 2012a).

Sonic hedgehog, its receptor, patched, and its downstream transcription factor, Gli1 protein, are overexpressed in CG. The expression of these factors was significantly correlated with stage, lymph node metastasis, venous and lymphatic invasion, liver invasion, and lower survival rates (Li et al. 2012). Expression of the N-myc downstream-regulated gene 2 (NDRG2), a protein that may reduce the metastatic potential of cancers, was detected in 37.6 % of CG. Tumors with downregulation of NDRG2 more often had lymph node metastases and lymphovascular invasion and tended to have higher TNM stage; the patients also had poor prognosis (Song et al. 2012). Caudal-related homeobox protein (CDX2), a homeodomain protein which plays an important role in the regulation of cell proliferation and differentiation of glandular epithelia and which is a regulator of intestinal metaplasia, is absent from the normal gallbladder, but is expressed in part of CG, mostly in well-differentiated tubular adenocarcinomas of the intestinal type (Wu et al. 2005).

Cell Cycle Regulation

High proliferative activity is generally associated with an aggressive phenotype of CG (Hui et al. 2002). CG expresses various factors involved in cell cycle regulation, including cyclin E (Mishra et al. 2009), cyclin D1, and p16 (Xuan

et al. 2005; Srivastava et al. 2013). The expression rate of cyclin D1 (68.3 %) in CG was significantly higher than in nonneoplastic disorders of the gallbladder, whereas the expression rates of p16 and retinoblastoma/Rb protein were significantly lower in CG compared to those in cholecystitis and adenoma (Ma et al. 2005). Cyclin D1 overexpression is a critical event in CG carcinogenesis and independently predicts decreased patient survival (Hui et al. 2000; Itoi et al. 2000). Loss of p16 in CG and bile duct cancers is associated with reduced survival of patients (Karamitopoulou et al. 2008), whereby loss of p16INK4 protein is correlated with overexpression of the retinoblastoma/Rb protein (Shi et al. 2000). In contrast, overexpression of cyclin E was not associated with depth of tumor invasion, tumor stage, or patient prognosis (Eguchi et al. 1999). p27 is a tumor suppressor protein which inhibits both Cdk2/cyclin E and Cdk2/cyclin A complexes and prevents transition to the S phase of the cell division cycle. Expression of p27 is expressed in CG and was correlated with clinical stage of CG (Xuan et al. 2005; Alsheyab et al. 2007), and low p27Kip1 expression in CG is an independent prognostic factor associated with poor prognosis (Filipits et al. 2003). The expression pattern of p27 is critically modulated by two SCF(Skp2) ubiquitin ligase-related proteins, Skp2 and cyclin-dependent kinase subunit 1/Cks1, which are involved in the posttranscriptional degradation of the p27 tumor suppressor. Reduced p21(WAF1/CIP1) expression is an early event in CG carcinogenesis and is of prognostic significance (Li et al. 2001; Puhalla et al. 2007). Expression of Skp2 was found to be an important and independent adverse prognosticator in CG (Li et al. 2007). Cyclooxygenase-2 (COX-2) plays a role in promoting cell proliferation, growth, and metastasis of carcinoma cells. Intense immunostaining of COX-2 was found in hyperplastic gallbladder lesions (65 %), pT2 CG (76 %), and advanced stage CG (64 %), including the associated stroma. In pT2 CG, expression of COX-2 in the stroma adjacent to the carcinoma cells in the subserosal layer correlated with aggressiveness of disease, including the tendency for distant metastasis (Kawamoto et al. 2002). The mammalian target of rapamycin (mTOR), a serine/threonine kinase, plays an essential role in the regulation of cell growth and is frequently deregulated in cancers. In CG, phospho-mTOR is an overexpression in early phases of cancer evolution, associated with poor prognosis (Leal et al. 2013). The sphingosine-1-phosphate receptor 1 (S1P1) is overexpressed in CG, and higher levels of S1P1 were significantly correlated with tumor differentiation, tumor mass, lymph node metastasis, invasion, and decreased survival time (Yuan et al. 2013). S1Ps are a class of G protein-coupled receptors that are a signaling target of sphingosine-1-phosphate and that are involved in the regulation of cell proliferation, cytoskeletal organization, and cell migration.

Other Factors Involved in Proliferation and Differentiation of Cells

Astrocyte elevated gene-1 is overexpressed in CG and is strongly correlated with the differentiation degree, stage, Ki-67 proliferation index, and liver invasion. Expression of this protein in CG is an independent prognostic marker for CG progression (Sun et al. 2011). Expression of connective tissue growth factor/CTGF in CG was correlated with better survival in two studies (Alvarez et al. 2008; Garcia et al. 2013), while in another investigation a role of CTGF expression in CG progression was found (Garcia et al. 2013). Part of CGs produce several classes of mucins (see below). Univariate analysis showed that MUC4 expression was significantly associated with poor survival, while expression of MUC1 and MUC2 was not correlated to survival. Backward stepwise multivariate analysis exhibited that MUC4 expression was a significant risk factor for poor outcome (Lee et al. 2012a). Expression of the multifunctional redox protein, human thioredoxin-1 (TRX-1), and its reducing enzyme, thioredoxin reductase (TRX-R), in CG affects tumor biology. Specifically, nuclear TRX-1 expression in cancer cells at the invasion front of CG is a significant prognostic marker (Nagano et al. 2012). Estrogen receptors (ERs) are

expressed in part of CG cells (Gupta et al. 2012). ERbeta isoform was expressed in most specimens, but preferentially in central tumor parts. Absent ERbeta expression at the invasive front was significantly associated with lymph node metastasis, advanced stage, lymphatic invasion, and poor prognosis (Sumi et al. 2004).

Chemokines, Cytokines, and Other Factors Involved in Immune Responses

Chemokine (C-X-C motif) ligand 12 (CXCL12), important for the progression of various malignancies, was differentially expressed in CG tissue, together with its receptor CXCR4, and the magnitude of expression was associated with high histologic grade and nodal metastasis, and expression was a significant risk factor for survival. CXCL12 increased anchorage-dependent and anchorage-independent growth, adhesiveness, and migration and invasive properties of CG cells (Lee et al. 2012b). Toll-like receptors (TLRs), which play a crucial role in inflammatory reactions, including chronic cholecystitis, are also operational in various pathways involved in carcinogenesis. TLR4 is mainly expressed in the glandular and luminal epithelia of the gallbladder. TLR4 expression was lower in CG in comparison with chronic cholecystitis and normal gallbladder (Huan et al. 2012).

Mechanisms of Apoptosis

There are intimate relationships between CG and apoptosis (Zhang et al. 2003). Positive rates of Fas were not significantly different among CG, dysplasia, and gallbladder adenoma, but positive rates of Fas ligand/FasL in carcinoma were significantly higher than that in chronic cholecystitis, suggesting that FasL expression in CG permits tumor cells to escape from immune surveillance by inducing apoptosis in lymphocytes infiltrating CG tissue (Xu et al. 2005). Higher expression of Bcl-2 in CG is considered to affect growth and progression of the tumors via inhibition of apoptosis (Mikami et al. 1999; Karamitoupoulou et al. 2008). Expression of the cellular Fas-associated death domain-like interleukin-1-converting enzyme inhibitory protein (c-FLIP), an antiapoptotic protein, is upregulated in CG, potentially conferring a growth advantage (Zong et al. 2009). Expression of p53-upregulated modulator of apoptosis (PUMA) was significantly higher in adenocarcinoma of the gallbladder than in adenoma and chronic cholecystitis, whereby PUMA expression was lower in small (less than 2-cm diameter) and well-differentiated CG with N0 than in poorly differentiated larger (>2 cm) CG with lymph node metastasis and invasion of surrounding tissues (Cai et al. 2013). Receptor-binding cancer antigen expressed on SiSo cells (RCAS1), a protein that induces apoptosis in immune effector cells expressing the RCAS1 receptor, was overexpressed in 70 % of CG, but not in precursor lesions. RCAS1 expression was associated with depth of tumor invasion, venous involvement, perineural invasion, tumor stage, and the presence of metastases (Oshikiri et al. 2001). Expression of heat shock protein 70-interacting protein (CHIP), a U-box-type E3 ubiquitin ligase, in CG is associated with poor prognosis (Liang et al. 2013).

Cell Adhesion and Motility

Deranged cell-to-cell or cell-to-matrix contact mediated by adhesion molecules plays a crucial role within the invasion cascade. Several factors involved in adhesion are altered in CG. Epithelial cell adhesion molecule (Ep-CAM) is overexpressed in almost two thirds of CG, and overexpression of this factor is related to decreased overall survival and is an independent prognostic factor (Varga et al. 2004; Prince et al. 2008). The L1 adhesion molecule, associated with prognosis in several malignancies, is not expressed in normal gallbladder epithelium, but was detectable in 63.8 % of CG, specifically in cells located to the invasive front of the neoplasm. Expression of L1 in CG cells was correlated with high histologic grade, advanced T stage, and venous and lymphatic invasion and was an independent negative prognosticator in multivariate

analysis (Choi et al. 2011). Expression of nectin-2, an adhesion molecule involved in calcium-independent cell adhesion, in CG is correlated to high T stage and poor prognosis (Miao et al. 2013). Thrombospondin-1 (TSP1), an extracellular glycoprotein that affects cell adhesion, motility, and growth, is mainly expressed in CG stromal cells and less so in cancer cells. Stromal expression of TSP1 increased as a function of increasing stage and was associated with lymph node metastasis and venous involvement, suggesting that TSP1 plays a role in CG spread and metastasis (Ohtani et al. 1999). Fascin, a protein interacting with thrombospondin-1, shows a marked overexpression in advanced CG, associated with aggressive clinical features and poor overall survival. Fascin, thrombospondin-1, and syndecan-1 interact to mediate this aggressive phenotype of CG (Roh et al. 2009). Syndecan-1 expression itself was detected in 58.1 % of CG, and syndecan-1-positive neoplasms more frequently showed lymph node metastasis and tended to have a deeper invasion depth and significantly shorter survival (Roh et al. 2008). Significant differences of E-cadherin and beta-catenin expression were detected between normal, inflamed, and cancerous gallbladder tissues (Puhalla et al. 2005). Loss of E-cadherin expression is high in CG (Priya et al. 2010), an alteration that may contribute to failure of intercellular adhesion, individualization of cells, and promotion of an invasive phenotype. N-cadherin and P-cadherin are biomarkers for invasion and metastasis in CG (Yi et al. 2014). Alterations of beta-catenin signaling are frequent events in CG, but these alterations seem to be minor contributors to CG carcinogenesis, but may be related to progression via loss of E-cadherin function (Kimura et al. 2003). Expression of the integrin-linked kinase (ILK) was found to be an independent poor prognostic predictor in CG (Li et al. 2013). CD97, a member of the EGF-TM7 adhesin family binding to its cellular receptor, CD55, plays an important role in invasiveness and aggressiveness of malignancies. It is a complement regulatory protein expressed by cells to protect them from bystander complement attack. CD97 and CD55 are absent or weakly expressed in normal gallbladder epithelium, but are overexpression CG, this expression being associated with high histologic grade, advanced T stage, angioinvasion, and reduced overall survival (Wu et al. 2012). CD44, a molecule involved in the metastatic pathway of cancers, exists in several variants or isoforms, including CD44s (standard variant), variant 3 (CD44v3), and variant 6 (CD44v6). CD44s is present in normal gallbladder epithelium and exhibits membranous immunostaining. In CG, CD44s is stained as strongly as normal epithelium, but reactivity for CD44v3 and CD44v6 was also found. CD44s is significantly less expressed in well-differentiated CG in the invasive component of the tumor than in the intramucosal part, and both CD44v3 and CD44v6 are more strongly expressed in poorly differentiated CG than in well-differentiated CG, but these expression patterns were not associated with outcome (Yanagisawa et al. 2001). Trefoil factor family protein 1/TFF1 (pS2), a factor that interacts with mucins to protect gastrointestinal epithelial cells and which promotes epithelial cell migration, is expressed in low-stage CG, and expression decreases as a function of increased grade and stage. Patients with TFF1-positive CG revealed a more favorable outcome compared with TFF1-negative neoplasms (Kornprat et al. 2005). As other carcinomas, CG displays alterations of the cytoskeleton and cytoskeletal proteins, changes that affect cell motility and cancer cell migration as a component of the invasion cascade. Cofilin-1, an actin-modulating protein that depolymerizes filamentous F actin and inhibits the polymerization of monomeric G actin, is expressed in CG, whereby expression was significantly associated with large tumor size, high T stage, lymph node metastasis, and decreased overall survival (Yang et al. 2013).

Mechanisms of Invasion and Spread

CG cells express several members of matrix metalloproteinases (MMPs), enzymes that have a central role in the tumor invasion cascade, as they facilitate the egress of cancer cells from the primary tumor and the locomotion and migration of

tumor cells in invaded tissues (Fan et al. 2002). MMP-9 and MMP-14 play a role in CG tumorigenesis (Karadag et al. 2008). MMP-1 and protease-activated receptor-1 are expressed in approximately 70 % of CG. CG expressing these two proteins more often showed lymph node metastasis, a deeper invasion depth, and more frequently lymphovascular invasion (Du et al. 2011). Expression of MMP-2 negatively affected the survival rate (Wu et al. 2009). In mucinous CG, which has a biology different from that of ordinary CG, MMP expression is lower (Karadag et al. 2008). The transcription and expression of MMPs in CG modulated by the neural precursor cell expressed developmentally downregulated 4-lik (Nedd4L) protein. Overexpression of Nedd4L in CG regulates the expression of MMP1 and MMP13 (Takeuchi et al. 2011). ADAM proteins, a multifunctional gene family of membrane proteins having a disintegrin and metalloprotease domain and involved in the metastatic cascade, are overexpressed in CG, this feature being associated with poor prognosis (Wu et al. 2011).

Expression of Differentiation Antigens and Factors Related to Cancer Cell Metabolism

Carcinoembryonic antigen (CEA), which may function as a metastatic potentiator via modulation of intercellular adhesion and cell migration, is expressed in CG cells and CG stromal cells. Lymph node metastasis was frequently found in cytoplasmic and stromal cell CEA-positive CG (Dowaki et al. 2000). Stromal expression of the mucin MUC1 in CG is associated with tumor aggressiveness and a tendency to form distant organ metastases (Kashiwagi et al. 2001; Kawamoto et al. 2004), while expression of MUC2 was not significantly related to lymphatic invasion, lymph node metastasis, or prognosis (Kashiwagi et al. 2001). Tumor-associated glycoprotein 72 is expressed more frequently in CG of larger size, with lymph node metastasis, with higher stage, and with poor differentiation, suggesting that expression of this antigen is a marker of CG aggressiveness (Ouyang et al. 2010). CD24, a small surface protein, is a marker of malignancy and poor prognosis in CG (Liu et al. 2011). Part of CGs express the hepatocyte antigen (Hep). Expression of Hep was negatively correlated to the grade of differentiation, tumor size, and lymph node metastasis, and elevated Hep expression was associated with increased overall survival, Hep expression being an independent prognostic predictor (Li et al. 2011). Forced expression of LAPTM4B in a CG cell line increased the invasive potential (Zhou et al. 2007, 2010). CG expresses neurotrophin, nerve growth factor, and the receptor TrkA (Artico et al. 2010), but the biologic significance of this expression has not yet been elucidated. Glucose uptake is generally augmented in cancer cells. The glucose transporter, GLUT1, is expressed in CG, and this elevated expression is strongly associated with cancer progression (Kim et al. 2002).

Angiogenesis and Lymphangiogenesis

Angiogenesis of tumors, induced and controlled by complex signaling pathways involving VEGF, plays a significant role in tumor progression, including CG (Giatromanolaki et al. 2002; Harino et al. 2008). Increased tumor vascularization caused by angiogenic mechanisms plays a significant role in cancer progression. A high microvessel density in CG determined by Chalkley counting was associated with worse prognosis (da Rocha et al. 2009). In CG, microvessel density was found to increase as a function of depth of invasion, suggesting a role of angiogenesis in the invasive process (Kalekou and Miliaras 2011). Microvessel density correlated with tumor stage and liver metastasis (Chen et al. 2011b). However, microvessel density was not an independent prognosticator in multivariate analysis (Sugawara et al. 1999). Average microvessel counts were lower in cases of well-differentiated carcinoma, small tumor size (less than 2-cm diameter), and negative nodes,

while higher microvessel counts and expression of CD146 in CG were associated with poor survival (Wang et al. 2012b). In a fraction of CG showing augmented angiogenesis, vascular endothelial growth factor/VEGF is expressed (Yamamoto et al. 1998; Giatromanolaki et al. 2003). The presence and expression level of VEGF were associated with tumor size, lymphatic invasion, and advanced disease stage (Okita et al. 1998; Letelier et al. 2014). Expression of platelet-derived endothelial growth factor/thymidine phosphorylase was detected in 63 % of CG, while hyperplastic epithelia or adenomas did not show significant expression. However, the magnitude of expression did not correlate with angiogenesis, but with depth of invasion, lymph node metastasis, and tumor stage (Yamamoto et al. 2000). Cyclooxygenase-2, which affects the expression of VEGF, induces angiogenesis in CG and is associated with poor prognosis (Zhi et al. 2005). A similar effect was found for the expression of inducible nitric oxide synthase (Niu et al. 2004). Tumor endothelial marker 8 (TEM8) protein is highly specific to angiogenesis in malignant neoplasms and is not required for normal adult angiogenesis. TEM8 is expressed in endothelial cells of CG, and its expression increased significantly with increasing CG stage (Maurya et al. 2011). TGF-beta, a protein with multiple functions, also promotes angiogenesis and is expressed in CG, where it augments angiogenesis and is associated with tumor progression (Kitamura et al. 2003).

CG shows vigorous lymphangiogenesis mediated by VEGF-C. TNF-alpha promotes formation of lymphatic vessels in CG through NF-kappaB-mediated upregulation of VEGF-C (Qiang et al. 2014). Expression of vascular endothelial growth factor-D in CG promotes growth, lymphangiogenesis, and lymphatic metastasis in CG and plays a role in CG progression (Lin et al. 2012).

Vasculogenic mimicry, a phenomenon associated with increased tumor-related mortality in several cancers, was observed in CG cell lines cultured in a 3D matrix, and vasculogenic mimicry in these cells was stimulated by HIF-1alpha. In CG analyzed in vivo, vasculogenic mimicry was also observed, and HIF-1alpha expression and vasculogenic mimicry were associated with poorer overall survival (Sun et al. 2012). Vasculogenic mimicry in CG is mediated by signaling pathways that involve PI3K/MMPs/Ln-5gamma2 and EphA2/FAK/paxillin networks (Lu et al. 2013).

Tumor Ploidy

Abnormal DNA contents were observed in 51 % of CG, whereby 44.4 % of tumors were aneuploid. In comparison, aneuploidy was detected in 81.3 % of metastatic lesions (Roa et al. 1993), suggesting effects of progressive genomic instability. Aneuploidy of CG was significantly associated with poorly differentiated adenocarcinoma, higher T stage, and a high mitotic index. A significant advantage in terms of 5-year survival was found in patients with diploid neoplasms in comparison with those having aneuploid tumors (Sato et al. 1993). In contrast, cytometric determination of DNA ploidy provided no prognostic information in CG as compared to conventional tumor staging in other studies (Yamamoto et al. 1990; Baretton et al. 1994).

MicroRNAs

MicroRNA-34 is associated with poor prognosis in CG through the regulation of telomere length in stem cells (Jin et al. 2014). An increased expression of microRNA-335 in CG predicts a favorable prognosis, but this miRNA is downregulated in the majority of CG, being one factor that may determine the aggressive biology of this cancer (Peng et al. 2013). Upregulation of the prometastatic microRNA-20a was closely associated with local invasion, distant metastasis, and poor prognosis (Chang et al. 2013). MicroRNA-155 was overexpressed in CG in comparison with nonneoplastic gallbladder, associated with the presence of nodal metastases and poor prognosis (Kono et al. 2013).

Staging

Determination of tumor stage is a decisive factor in prognostication of CG. However, up to 40 % of CG cases are diagnosed at an advance stage of disease (Henson et al. 1992), limiting the differential estimation of outcome as a function of stage. The current staging system formulated by the AJCC is shown in Table 2. It corresponds to the UICC system (Fong et al. 2006; Gore and Shelhamer 2007; Edge et al. 2010).

The advantages of pitfalls of the AJCC/UICC have recently been discussed (Adsay et al. 2012). The gallbladder does not have the distinct layering as other gastrointestinal organs do. Therefore, it was stated that the definitions of Tis/T1a/T1b may lack practicability, and therefore, the "early gallbladder carcinoma" category proposed in high regions may have to be recognized instead. Furthermore, it was proposed that documentation of hepatic versus serosal involvement should be performed in cases of advanced tumors (Adsay et al. 2012).

In addition to T stage, which describes depth of invasion and extension into adjacent organs and/or structures, other modes of invasion have been proposed as prognostically relevant parameters. T2 carcinomas with subserosal invasion form a distinct group of gallbladder cancers that may profit from radical surgery including resection of the gallbladder bed (Chijiiwa et al. 2001). In T2 tumors, free resection margins and the absence of perineural invasion and of lymph node metastasis are related to good prognosis. The depth of subserosal invasion in pT2 tumors has an impact on outcome in patients with pT2 neoplasms (Wakai et al. 2003). Depth of invasion of the subserosal layer was divided into three categories, i.e., ss1, ss2, and ss3, representing invasion of the upper, middle, or lower thirds of the subserosal layer, respectively (Sasaki et al. 2005). Expression of N-acetylglucosaminyl-transferase V, an enzyme that catalyzes the beta1-6 branching of N-acetyl-glucosamine on asparagine-like oligosaccharides of cellular proteins and enhances the malignant features of cancer cells, is expressed in CG located to the subserosal layer and correlates with postsurgical survival in pT2 tumors (Onuki et al. 2014). Expression of MUC1 mucins in the subserosal layer correlated with postsurgical prognosis (Kawamoto et al. 2001). A further prognostic feature related to stage is the mural invasion

Table 2 AJCC staging of gallbladder carcinoma (7th edition; Edge et al. 2010)

T			
TX	Primary tumor cannot be assessed		
T0	No evidence of primary tumor		
Tis	Carcinoma in situ		
T1	Tumor invades the lamina propria or muscular layer		
T1a	Tumor invades the lamina propria		
T1b	Tumor invades the muscular layer		
T2	Tumor invades perimuscular connective tissue; no extension beyond the serosa or into the liver		
T3	Tumor perforates the serosa (visceral peritoneum) and/or directly invades the liver and/or one other adjacent organ or structure, such as the stomach, duodenum, colon, pancreas, omentum, or extrahepatic bile ducts		
T4	Tumor invades the main portal vein or hepatic artery or invades at least two extrahepatic organs or structures		
N			
NX	Regional lymph nodes cannot be assessed		
N0	No regional lymph node metastasis		
N1	Metastases to nodes along the cystic duct, common bile duct, hepatic artery, and/or portal vein		
N2	Metastases to periaortic, pericaval, superior mesenteric artery, and/or celiac artery lymph nodes		
M			
M0	No distant metastasis		
M1	Distant metastasis		
Anatomic stage/prognostic groups			
Stage	*T*	*N*	*M*
0	Tis	N0	M0
I	T1	N0	M0
II	T2	N0	M0
IIIA	T3	N0	M0
IIIB	T1-3	N1	M0
IVA	T4	N0-1	M0
IVB	Any T	N2	M0
	Any T	Any N	M1

Generally, CGs of stages T1 and T2 are classified as early CG

There are some notable differences between the UICC staging system and the staging system of the Japanese Society of Biliary Surgery (JSBS) staging system (Japanese Society of Biliary Surgery 2001; Table 3)

Table 3 Gallbladder cancer extension classified according to the 2001 version of the classification of biliary tract carcinoma of JSBS (2001)

T (tumor categories)	
T1	S0, Hinf0, Binf0, PV0, A0
T2	S1, Hinf1, Binf1, PV0, A0
T3	S2, Hinf2, Binf2, PV1, A1
T4	S3, any Hinf, Binf3, PV2,3, A2,3
S (grade of serosal invasion)	
S0	No invasion of the serosa
S1	Doubtful invasion of the serosa
S2	Definite invasion of the serosa
S3	Invasion of other organs or structures
Hinf (grade of hepatic invasion)	
Hinf0	No direct invasion of the liver
Hinf1	Doubtful direct invasion of the liver
Hinf2	Definite direct invasion of the liver and invasion around the gallbladder bed
Hinf3	Mass formation because of direct invasion of the liver
Binf (grade of hepatoduodenal ligament (bile duct) invasion	
Binf0	No invasion of the hepatoduodenal ligament
Binf1	Doubtful invasion of the hepatoduodenal ligament
Binf2	Definite invasion of the hepatoduodenal ligament
Binf3	Severe invasion of the hepatoduodenal ligament
PV (grade of portal vein invasion)	
PV0	No invasion of any of portal veins
PV1	Doubtful invasion of portal veins
PV2	Definite invasion of portal veins
PV3	Severe invasion of portal veins (narrowing or constriction)
A (grade of hepatic artery invasion)	
A0	No invasion of any of hepatic arteries
A1	Doubtful invasion of hepatic arteries
A2	Definite invasion of hepatic arteries
A3	Severe invasion of hepatic arteries (narrowing or constriction)
N (lymph node involvement)	
N0	No evidence of lymph node metastasis
N1	Lymph node involvement in a primary lymph node group close to tumor
N2	Lymph node involvement in a secondary lymph node group
N3	Lymph node involvement in a tertiary lymph node group
N4	Lymph node involvement in the fourth lymph node group

Table 3 (continued)

Staging system			
Stage I	T1	N0	M0
Stage II	T1	N1	M0
	T2	N0, N1	M0
Stage III	T1, T2	N2	M0
	T3	N0, N1, N2	M0
Stage IVA	T4	N0, N1, N2	M0
	Any T	N3	M0
Stage IVB	Any T	N4	M0
	Any T	Any N	M1

pattern of CG. Two intramural invasion patterns were defined as the infiltrative growth type (IG, infiltrative growth in the muscle layer without destruction) and a destructive growth type (DG, massive growth with destruction of the muscle layer; Okada et al. 2009a). Scirrhous growth was found more often in DG lesions, and the overall survival rate of patients with DG tumors was significantly lower than that of patients with IG tumors (Okada et al. 2009a). A negative effect of the DG pattern was also found in pT2 CG with a subserosa-invasive growth pattern (Okada et al. 2012). Tumors with a DG growth pattern show a higher proliferative activity, a poorer differentiation, a stromal laminin-5gamma2 chain expression, and a distant lymph node metastasis (Okada et al. 2009b).

Adenocarcinoma of the Gallbladder: Risk Factors and Pathogenic Pathways

149

Contents

Abstract

For ordinary adenocarcinoma of the gallbladder, several risk factors have been identified. The most important risk factors are cholelithiasis, female gender, advancing age, and an elevated maximum body mass index. Gallstones and associated inflammatory gallbladder disease are the most common risk factors for gallbladder cancer. At least three quarters of patients with gallbladder carcinoma have gallstones at the time point of diagnosis, but cholelithiasis seems to be a cofactor for carcinogenesis. There is a relationship between gallbladder carcinoma and chronic inflammatory disease of the gallbladder, including xanthogranulomatous cholecystitis. Also chronic sclerosing and hyalinizing cholecystitis with or without calcification is associated with gallbladder carcinoma. Other carcinogenic associations include anomalous pancreaticobiliary junction and an increasing number of genetic, epigenetic, and molecular alterations.

Cholelithiasis

The most important risk factors for carcinoma of the gallbladder (CG) are cholelithiasis, female gender, advancing age, and elevated maximum body mass index (Strom et al. 1995; Sheth et al. 2000; Pandey 2003; Miller and Jarnagin 2008; Rustagi and Dasanu 2012). Gallstones and

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_149

associated inflammatory gallbladder changes are the most common risk factors for CG (Slade 1905; Fawcett and Rippmann 1913; Luelsdorf 1926–1927; Goldschmidt 1963; Wenckert and Robinson 1966; Hardy and Volk 1970; Hart et al. 1971; Balaroutsos et al. 1974; Beltz and Condon 1974; Arnaud et al. 1979; Hamrick et al. 1982; Vitetta et al. 2000; Tazuma and Kajiyama 2001; Chen et al. 2014; Cariati et al. 2014). It is estimated that three quarters of patients with CG have gallstones at the time point of diagnosis (Balaroutsos et al. 1974). Piehler and Crichlow (1978), in a review of the literature, found a 73.9 % incidence in 2,000 cases. Overall, the risk of CG is approximately four to five times higher in patients with gallstones than in patients without gallstones (reviews: Lowenfels et al. 1985; Lowenfels et al. 1999). Currently, it is considered that gallstones as such are a cofactor for carcinogenesis, but formal proof that they directly cause CG is lacking (review: Shrikhande et al. 2010).

Chronic Inflammatory Gallbladder Disease

There is a relationship between CG and chronic inflammatory disease of the gallbladder, including xanthogranulomatous cholecystitis (Zhuang et al. 2013). Chronic sclerosing and hyalinizing cholecystitis with or without wall calcification (porcelain gallbladder) is associated with CG (Polk 1966; Berk et al. 1973; Stephen and Berger 2001; Khan et al. 2011; Patel et al. 2011; Gupta and Jauhari 2012; Wong and Weissglas 2013). Porcelain gallbladder is a rare condition which was found in only 0.06–0.80 % of cholecystectomy specimens. It is more common in female patients. A recent investigation demonstrated that the risk of harboring CG in patients with porcelain gallbladder is lower than recently anticipated (Schnelldorfer 2013), and in one study, no association between porcelain gallbladder and CG was identified (Towfigh et al. 2001). The significance of gallbladder polyps in predisposing to CG is probably overstated (Pilgrim et al. 2013). Environmental agents, such as heavy metals, have been proposed to be related to gallbladder carcinogenesis (Pandey 2006). In earlier times, thorotrastosis was a well-recognized cause of CG (Hashizume et al. 1980), but most patients who had been investigated by the use of Thorotrast are now no longer alive. Rarely, CG has been found in the setting of primary sclerosing cholangitis (Lewis et al. 2007). There is an association of higher CG risk and chronic salmonellosis (Welton et al. 1979; Caygill et al. 1995; Kumar et al. 2006; Andia et al. 2008; Tewari et al. 2010; Walawalkar et al. 2013). Chronic *Salmonella* carriage is a well-known feature in this infection, and *Salmonella* can form robust biofilms on gallbladder epithelium, the bacterium being able to adhere to and invade polarized gallbladder epithelial cells apically (Gonzalez-Escobedo and Gunn 2013; Gunn et al. 2014). *Salmonella* carriage can induce a smoldering inflammation promoting carcinogenesis and *Salmonella* secretes a genotoxic toxin (Nath et al. 2010). A case-control study in the USA showed that chronic typhoid carriers died of hepatobiliary cancer six times more often than matched controls (Welton et al. 1979). Also in Northern India, a potential association between chronic typhoid fever carriage (*Salmonella typhi* and *Salmonella paratyphi* A) and CG was observed (Nath et al. 1997, 2008).

Differences of CG frequencies in various populations suggest effects of genetic factors. Also familial CG supports a role of genetic mechanisms. In addition, there is evidence that genetic factors are involved in the pathogenesis of gallstone disease, therefore indirectly affecting gallbladder carcinogenesis.

Anomalous Pancreaticobiliary Junction

In Eastern countries, specifically in Japan, anomalous pancreaticobiliary junction is considered to be an important risk factor for CG (Kimura et al. 1985; Lin et al. 1988; Ozmen et al. 1991; Chijiiwa et al. 1993; Tseng et al. 1993; Hanada

et al. 1996; Uetsuji et al. 1996; Yang et al. 1997; Egami et al. 1998; Chao et al. 1999; Yoshida et al. 1999; Ng 2000; Elnemr et al. 2001; Nakayama et al. 2001; Sakurai et al. 2001; Yano et al. 2001; Takayashiki et al. 2002; Hu et al. 2003; Kang et al. 2007; Noda et al. 2007; Hori et al. 2008; review: Tsuchida et al. 2003). In an investigation of the Japanese Study Group of Pancreaticobiliary Maljunction (PBM), PBM was found in 52 (3 %) of 1,722 patients investigated with ERCP, and of these, 14 patients had developed CG (Egami et al. 1998). This association was identified in Western patients at a much lower frequency (Tuech et al. 2000). Detailed histologic studies have demonstrated that CG carcinogenesis in the presence of maljunction proceeds along a complex pathway, starting with hyperplastic mucosal changes in the gallbladder associated with upregulated cell kinetics, followed by various grades of metaplasia, dysplasia, and transition to carcinoma (Yamamoto et al. 1991; Sai et al. 2005; review: Hanada et al. 1999a). Epithelial cell proliferation of the gallbladder is increased in patients with maljunction (Hanada et al. 1996; Yang et al. 1997). Maljunction-induced increased gallbladder cell proliferation may be an event initiated early in life, as increased proliferative activity of mucosal epithelia was detected in children with maljunction (Tanno et al. 1999; Tokiwa et al. 1999). The mechanisms involved in the induction of this sequence of events are only partially known, but it is suggested that pancreatic juice reflux into the biliary tract followed by inflammation, epithelial cell loss, and consecutive hyperregeneration play a significant role (review: Chao et al. 1999). In fact, CG has been found in association with pancreaticobiliary reflux in the absence of maljunction (Sai et al. 2006). This pathway was found to be accompanied by p53 gene mutations and mutations in codon 12 of the K-RAS gene (Iwase et al. 1997; Chao et al. 1999; Hanada et al. 1999a, b; Masuhara et al. 2000). Point mutations of the K-RAS gene in CG have also been found in tumors that had developed in patients with congenital biliary dilatation (Tomono et al. 1996).

Genetic and Molecular Alterations

In CG, an array of genetic abnormalities has been identified, often involving chromosomes 3p, 8p, 9q, and 22q (Wistuba et al. 2002a; Malik 2004; Srivastava et al. 2011; Andrén-Sandberg 2012; Boutros et al. 2012; Maurya et al. 2012). Also aberrations of other chromosomal sites, including chromosomes 1p, 3p,4, 5p, 8p21, 9p, 9q, 13q, 16q, 17p, and 18q21, are considered to play pathogenic roles (Wistuba and Albores-Saavedra 1999; Kuroki et al. 2005; Dixit et al. 2012). Microsatellite instability was detectable in 17 % of CG patients (Yoshida et al. 2000). LOH at a locus on chromosome 3p is associated with abnormalities of the fragile histidine triad gene in CG (Wistuba et al. 2002a,b; Riquelme et al. 2007). Microsatellite instability (MSI) was detected in 17 % of CG, and there was an inverse correlation between MSI and the presence of LOH in CG (Yoshida et al. 2000).

Whole-exome and targeted gene sequencing of CG identified recurrent mutation in the ErbB pathway. Mutated ErbB signaling pathways were found in 36.8 % of CG samples (Li et al. 2014). Several investigations indicate that abnormalities in the TP53 (chromosome 17p13) and p16(Ink4)/CDKN2 (chromosome 9p21–22) gene loci are early and frequent events in the carcinogenesis of CG. The role of p53 gene alterations in CG is still not clarified (Ajiki et al. 1996b; Jonas et al. 1997; Kim et al. 2001a,b; Quan et al. 2001; Koda et al. 2003; Wang et al. 2006; Ghosh et al. 2013, review: Rai et al. 2011). Overall, p53 is expressed in CG with a high frequency (Fujii et al. 1996; da Rocha et al. 2004; Kalekou and Miliaras 2004; Wang et al. 2006). There is evidence that p53 expression is more prevalent in the gallbladder with gallstones in patients with CG (Misra et al. 2000). One subset of CG seems to develop de novo in the setting of predominant p53 gene mutations, with low rate of K-RAS mutations (Itoi et al. 1996). The expression rate of p53 seems to reflect the dysplasia-carcinoma sequence (Agrawal et al. 2010). p53 expression was found in 32.4 % of dysplastic lesions, 44.7 % of CIS, and 65.4 % of invasive carcinomas (Wistuba et al. 1996). Mutations of the TP53 locus seem to be associated with

the growth pattern of CG, as the incidence of p53 immunoreactivity was greater in flat CG than in polypoid CG (Hanada et al. 1997). In contrast to CG, p53 expression was not detectable in gallbladder adenoma but in carcinoma arising in adenoma (Takei et al. 1996). Mutations in the K-RAS gene have been identified in patients with CG, however, at a low frequency, in contrast to adenomas (Saetta et al. 1996; Saetta 2006; Pai et al. 2011; Javle et al. 2014). There is evidence that such mutations may occur either early or later in the carcinogenic pathway. In contrast to other studies, no mutations in K-RAS were found in adenoma or gallbladder dysplasia in one study, but in 20 % of established CG (Kim et al. 2001a). Conversely, an earlier investigation reported K-RAS gene mutation even in gallbladder dysplasia at an incidence similar to that in CG (Ajiki et al. 1996a). There is evidence that alterations in DNA repair genes may be involved in CG carcinogenesis (Srivastava et al. 2010). Altered gene expression patterns involved in CG carcinogenesis are also promoted by aberrant promoter hypermethylation as epigenetic mechanism (House et al. 2003; Takahashi et al. 2004; Garcia et al. 2009). The acquisition of epigenetic alterations of several gene promoter sites of tumor suppressors may contribute to carcinogenic pathways in chronic cholecystitis and dysplastic changes (House et al. 2003). A gene that frequently undergoes epigenetic inactivation in CG is 3p, which is therefore considered a site of candidate tumor suppressor genes (Riquelme et al. 2007).

Apart from the nuclear genome, CG also showed alterations in the mitochondrial genome. Mutation analysis of this genome, in particular the D-loop, showed a wide range of point mutations and polymorphisms in the mitochondrial genome of CG (Maurya et al. 2013).

Factors Involved in Growth and Cell Cycle Regulation

Proliferative activity of CG cells is correlated with overexpression of several factors regulating the cell division cycle, including cyclin E (Eguchi et al. 1999; Mishra et al. 2011). Nuclear expression of the p16(INK4a) gene product was expressed in 39.1 % of CG and 31.6 % of high-grade dysplastic gallbladder epithelia, but not in normal epithelium (Lynch et al. 2008). Inactivation of p16 in CG occurs through two pathways, i.e., via LOH at 9p21–22 and through homozygous gene deletion, the latter being a combination of LOH and promoter hypermethylation (Tadokoro et al. 2007). Cell proliferation in CG is also regulated by a novel member of the Krüppel C2H2-type zinc finger protein family, zinc finger X-chromosomal protein, which promotes growth, but also migration, of CG cells (Tan et al. 2013). Cell proliferation of CG cells is induced by the morphogen, hepatocyte growth factor/HGF (Li et al. 1998; Yang et al. 2012), whereby the cancer cells express the HGF receptor, c-Met (Sasaki et al. 2012). In CG, c-Met is immunohistochemically localized in the cell membrane (Sanada et al. 2010). CG also showed an aberrant activation of the Sonic hedgehog signaling pathway (Xie et al. 2014). ErbB2 signaling in CG is linked to MUC4 expression, as ErbB2 interacts with MUC4 at the carcinoma cell apex, associated with hyperphosphorylation of erbB2, MAPK, and Akt, and with the overexpression of cyclooxygenase-2. Experimentally, MUC4 amplifies cell proliferation in the presence of heregulin through potentiating the phosphorylation of ErbB2 and its signaling pathways (Miyahara et al. 2008).

Wnt/Beta-Catenin Signaling Pathway

In contrast to gallbladder adenomas, altered expression of beta-catenin, such as nuclear or cytoplasmic expression and loss of cell membrane expression, is not a common feature in gallbladder dysplasia and CG, but cytoplasmic and nuclear expression of beta-catenin in CG was correlated with a less aggressive behavior of the neoplasms (Chang et al. 2002).

Apoptosis

Apoptosis is a common phenomenon in CG and is regulated by diverse pro- and antiapoptotic factors. The frequency of apoptosis may increase

with CG progression (Sasatomi et al. 1996). One protein regulating apoptosis is p53. p53 gene mutations are a rather common event in CG and were observed in up to 35.7 % of cases (Kim et al. 2001b). There seems to be a positive correlation between expressions of p53 and Bcl-2 (Sasatomi et al. 1996). 65.4 % of CG revealed a decreased expression of Bax-interacting dactor-1/Bif-1, suggesting that loss of Bif-1 might play a role in gallbladder tumorigenesis (Kim et al. 2008). TSG101, a protein involved in resistance against apoptosis, is overexpressed in CG (Liu et al. 2011).

Invasion and Spread

As already specified above (paragraph on prognosticators), several types of matrix metalloproteinases (MMPs) are expressed in CG and are involved in the initiation and progression of the invasion cascade. Genetic variants of MMP-2, MMP-7, and MMP-9 are associated with higher susceptibility of gallbladder cancer (Sharma et al. 2012). Heparanase is a further enzyme playing a role in invasion and metastasis (Dutta and Poomachandra 2008; Wu et al. 2008). Heparanase is an endo-beta-glucuronidase which splits heparan sulfate and is frequently expressed in CG. Trophinin, an adhesion molecule that was first identified in human trophoblast cells and involved in embryo implantation, promotes cancer cell invasion in CG cells (Chang et al. 2009). Trophinin interacts with tastin and bystin, cytoplasmic proteins required for trophinin's activity as an adhesion molecule (Fukuda and Sugihara 2012). Invasive features of CG cells are also promoted hepatocyte growth factor/HGF interacting with the membranous c-Met receptor (Li et al. 1998). Part of CG exhibit overexpression of c-Met in cells of the invasive component, in association with expression of beta-catenin and cyclooxygenase-2 (Moon et al. 2005). However, other subsets of CG that have been analyzed revealed lack of c-Met expression in the invasive part of the tumor (Sanada et al. 2010).

Angiogenesis

As in other carcinomas and non-epithelial malignancies, tumor-induced angiogenesis is a critical mechanism in the setting of tumor growth and progression. A major driving force that induced angiogenic pathways is tumor hypoxia. Hypoxia-inducible factors 1alpha and 2alpha are upregulated in many CG, and this upregulation is strongly associated with increased expression of vascular endothelial growth factor/VEGF and augmented angiogenesis (Giatromanolaki et al. 2006). However, lower expression of hypoxia-inducible factor-1alpha and elevated expression of the von Hippel-Lindau (VHL) gene in CG are important markers for tumor progression, in that highly invasive tumors show decreased HIF-1alpha expression (Yang et al. 2011). VEGF-C, which has a central role in neoplastic lymphangiogenesis and angiogenesis through VEGF receptor 3 and VEGF receptor 2, respectively, expressed in endothelial cells, promotes progressive growth and invasion of CG (Chen et al. 2010). A further factor involved in tumor angiogenesis in CG is cyclooxygenase-2. Overexpression of this enzyme in CG cells is associated with increased angiogenesis, which in turn affects tumor progression and patient survival (Legan et al. 2009). Basigin (EMMPRIN/CD147), a multifunctional membrane glycoprotein involved in invasion and angiogenesis of diverse malignancies, is overexpressed in CG, expression pattern being correlated with stage and survival rate (Xiao and Tang 2009).

DOI 10.1007/978-3-319-26956-6_150

Abstract

The most common adenocarcinoma of the gallbladder is derived from the glandular epithelium. In addition, there are several variants of adenocarcinoma that are distinguished from the standard form by variant differentiation patterns. One form of gallbladder adenocarcinoma is characterized by abundant production and secretion of mucin, resulting in extracellular mucin lakes. This is mucinous carcinoma, a rare tumor of which only relatively few reports are published, mainly occurring in older patients. In contrast to ordinary gallbladder carcinoma, female preponderance is not present. A second variant of adenocarcinoma with mucin production is associated with deficient mucin secretion, resulting in signet-ring cells. Signet-ring cell carcinoma is a very rare gallbladder cancer with a highly aggressive course. There are several other, very rare variants of gallbladder adenocarcinoma. They include cribriform carcinoma, micropapillary carcinoma, cervix carcinoma-like carcinoma, carcinoma with morule-like features, clear cell carcinoma, carcinoma with lymphoid stroma, and undifferentiated carcinomas.

Mucinous Carcinoma of the Gallbladder

ICD-O code 8480/3

Introduction

In the WHO classification of tumors, mucinous adenocarcinoma of the gallbladder (MCG, mucoid adenocarcinoma, colloid carcinoma) is defined as a carcinoma in which more than 50 % of the tumor contains extracellular mucin. In case the extracellular mucin constitutes a predominant component of the tumor, with scattered tumor cells floating in mucin lakes, the terms colloid carcinoma or gelatinous carcinoma (carcinoma gelatinosum) are employed. MCGs are more common in the gallbladder than in the extrahepatic

bile ducts (Albores-Saavedra et al. 2010; Dursun et al. 2012; Yadav et al. 2013).

Epidemiology

MCG is a rare tumor, of which only relatively few reports are available. In a Japanese study of 540 consecutive cholecystectomies, 12 adenocarcinomas were detected, and of these only one was an MCG (Terada et al. 2013a). In an investigation of 606 primary gallbladder carcinomas, 2.5 % qualified for MCG according to the WHO criteria. The mean age was 65 years, and the female-to-male ratio was 1.1, i.e., clearly different from ordinary CG, where female patients prevail (Dursun et al. 2012).

Selected References Zamecnik et al. 1946; Hirsch et al. 1964; Parker and Joffe 1972; Rogers et al. 1973; Ishibashi et al. 1986; Araida et al. 1996; Tian et al. 2003; Huang et al. 2006; Yamamoto et al. 2010; Dursun et al. 2012; Jindal et al. 2012.

MCG seems to develop in connection with the same risk factors as in ordinary adenocarcinoma and has also been diagnosed in the setting of porcelain gallbladder (Joo et al. 2003) and sclerosing cholangitis in association with ulcerative colitis (Noda et al. 2009).

Clinical and Imaging Features

The clinical presentation of MCG is usually not different from that of other gallbladder adenocarcinomas, signs and symptoms being nonspecific in part of cases. However, some patients exhibit marked enlargement of the gallbladder, and viscous mucin accumulated in the gallbladder lumen may cause obstruction with jaundice and pain (Ishibashi et al. 1986; Ozeki et al. 1991; Tian et al. 2003). In one study, 67 % of patients presented with the clinical picture interpreted as acute cholecystitis (Dursun et al. 2012). Excessive drainage may require specific management (Hirsch et al. 1964).

On CT and MR images, the tumor often presents as a thickened gallbladder wall, a polypoid or cauliflower-like mass with a soft-tissue density, small calcified spots, and some laminated high viscosity fluid inside the gallbladder cavity (Nobusawa et al. 1994; Levy et al. 2001; Huang et al. 2006). Linear or curvilinear streaks seen in MR and MR cholangiopancreatography images are typical findings in MCG (Ishiguro et al. 2012). Cystic areas in an enlarged gallbladder are also a feature of MCG (Tian et al. 2003; Yoshimitsu et al. 2005).

Pathology

Macroscopy

Macroscopically, MCG presents under an entire spectrum of lesions, but nodular and polypoid tumor masses of sometimes large size predominate. In MCG with a very high content of mucin, the tumors are grossly gelatinous or glassy-transparent, whereby this feature is best visualized on cut surfaces. When cutting through the tumor, mucin typically sticks to the knife, and a thin mucin thread can be spun when slowly removing the knife from the tumor cut surface. The maximum of gelatinous features is found in colloid carcinoma, which may be associated with accumulation of viscid mucinous material in the gallbladder lumen. Mucin can be dislocated to the gallbladder neck and the cystic duct, causing obstruction and gluing eventual gallstones together to form a conglomerate mass. In the study of Dursun and coworkers (2012), mean and median tumor diameters were larger than those of conventional adenocarcinomas (4.8 cm and 3.4 cm vs. 2.9 cm and 2.5 cm, respectively; Dursun et al. 2012). Lymph node metastases and tumor deposits in a perineural location may also present as transparent, glassy nodules.

Histopathology

Mucinous adenocarcinoma shows mucin-forming tubular, cribriform, and solid components of

carcinomatous epithelium admixed with extracellular mucin deposits, the latter per definition amounting to more than 50 % of the tumor. The stromal reaction is usually not pronounced. In a minority of cases, well-defined stromal mucin nodules or mucin lakes with scanty tumor cells floating in the mucin (colloid carcinoma) are found, and there are cases that also show signet-ring cells (Dursun et al. 2012). Part of the cases, mainly those with an intraluminally growing component, show a papillary growth pattern at the surface and microcystic alterations with mucin lakes or nodules at the bottom of the lesion. In MCG with cystic components, the substrate of cysts are markedly enlarged gland-like structures containing mucin, which then leaks out and forms mucin lakes (Yoshimitsu et al. 2005). As often large neoplasms, MCG can undergo extensive necrosis. Rarely, MCG undergoes extensive calcification (Parker and Joffe 1972; Rogers et al. 1973;), as mucin accumulations represent a material that favors deposits of calcium salts. Within amphophilic or slightly basophilic extracellular mucus masses, tiny granules of strongly basophilic mineralizations are found, positive in the von Kossa stain, and these granules may coalesce to larger mineral deposits with cracks and fissures and, sometimes, a concentric structure.

Immunohistochemistry

MCG shares markers with ordinary adenocarcinomas of the gallbladder. Among 15 MCG, 57 % were CK7 positive, 29 % were CD20 positive, and 57 % expressed MUC1, 86 % MUC2, and 86 % MUC5AC, but none expressed MUC6 (Dursun et al. 2012). The MUC1 core mucin, which is often present in well-to-moderately differentiated gallbladder carcinomas, is a mucin that can leak out of the cells (Yamato et al. 1999).

Combined Gallbladder Carcinomas Containing a Mucinous Component

Combined neuroendocrine adenocarcinomas (MANEC, see the respective paragraph) may contain mucinous adenocarcinoma. In a 59-year-old male, a 4 cm-sized gelatinous and cauliflower-like gallbladder tumor was found, composed of biphasic large-cell neuroendocrine carcinoma and pure mucinous carcinoma (Russo et al. 2012).

Differential Diagnosis

MCG has to be distinguished from mucin-containing adenocarcinoma with less than 50 % mucin content and from signet-ring cell carcinoma. In some cases, mucocele of the gallbladder may mimic MCG. Mucin in mucoceles or in mucin-containing Rokitansky-Aschoff sinuses can leak upon rupture and elicit a vigorous macrophage reaction (mucophages), sometimes resembling neoplastic signet-ring cells. Numerous mucophages may accumulate to form nodules (mucin granulomas) that can be confound with mucin-containing tumor nodules. In case of doubt, immunohistochemistry by use of anti-CK antibodies (carcinoma cells are positive) and CD68 (macrophages are positive) is helpful to clarify the situation.

Signet-Ring Cell Carcinoma of the Gallbladder

ICD-O code 8490/3

Introduction

Signet-ring cell carcinoma (SRCC) is a rare and highly aggressive variant of adenocarcinoma characterized by accumulation of mucins within the cytoplasm of cancer cells. Due to a purported secretion defect, mucin is retained in the cell in the form of a large glycoprotein body that displaces and deforms the nucleus, resulting in a picture resembling a signet ring. SRCC occurs in several organs but most commonly develops in the stomach (linitis plastica), accounting for 15–30 % of all gastric cancers (Kim et al. 1994; Adachi et al. 2000). SRCC arising in the gallbladder is a highly uncommon neoplasm.

Epidemiology

The exact prevalence of SRCC among carcinomas of the gallbladder is not known, but the tumor is considered to be a rare lesion (Brandt-Rauf and Branwood 1980; Nishida et al. 1997; Krunic et al. 2007; Karabulut et al. 2008; Czyszczon and Alatassi 2010; Mondal 2010; Pavic et al. 2010; Pudasainin et al. 2011; Snyder et al. 2012; Agergaard et al. 2012). The lack of detailed data is in part due to the fact that histological typing was not performed in many published series and to the difficulty of identifying signet-ring cells in conventional histology preparations. In a Japanese series of 57 gallbladder carcinomas, 6 were of the SRCC type (Tatematsu et al. 1988). Among seven gallbladder adenocarcinomas, one was found to be SRCC (Khoo and Nurul 2008). SRCC of the gallbladder is usually a tumor of elderly individuals, but rare examples of SRCC occurring in young individuals are also known (22 years; Czyszczon and Alatassi 2010; 32 years; Mondal 2010). Males are more often affected than with ordinary gallbladder adenocarcinoma. The cancer was found in gallbladders with or without stone disease with associated chronic cholecystitis. In one patient, gallbladder SRCC was observed in the setting of anomalous pancreaticobiliary ductal union (Yamauchi et al. 2000).

Clinical and Imaging Features

Clinical presentation and imaging features are the same as those described for ordinary gallbladder adenocarcinoma, with the exception that SRCC are diffusely infiltrating neoplasms that do not give rise to polypoid lesions at imaging.

Pathology

Macroscopy

SRCC of the gallbladder is usually a mass-forming lesion associated with thickening of the gallbladder wall owing to diffuse infiltration. In one patient, the color of the tumor was described as yellowish white (Pudasainin et al. 2011).

Histopathology

The typical feature of SRCC is, similar to its gastric counterpart, a diffuse growth with sheets of signet-ring cells spreading laterally through the lamina propria of the mucosa and the muscle layer. The tumor cells are medium-sized to large, often about the size of a macrophage, with a well-defined surface membrane, a cup-shaped nucleus displaced to the cell periphery, and a slightly foamy (microvesicular) or clear, large vacuole that stains with PAS, mucicarmine, alkaline Alcian blue, and the Genta stain (Genta et al. 1994; El-Zimaity et al. 1997). In some cases, extracellular mucin is also visualized, representing a mixture of mucin-producing cells that either store or secrete the glycoproteins. Transmural growth with invasion of the subserosal space and infiltration of the gallbladder bed are found. SRCC can also give rise to tumor emboli, sometimes translocated to small pulmonary arteries, followed by pulmonary tumor thrombotic microangiopathy (Ohno et al. 2014).

Immunohistochemistry

SRCC of the upper gastrointestinal tract are generally immunoreactive for CKAE1/3 (100 %), CAM5.2, CK7, and EMA, rarely for CK19 and CK20, and not for CK14 (Pavic et al. 2010; Bazan et al. 2011; Terada 2013b). In SRCC of the stomach, reactivity for EMA was found in 57 %, CEA in 100 %, CA19-9 in 100 %, and p53 in 83 % (Terada 2013c), and the most frequently expressed mucins were MUC5AC and MUC6 (Terada 2013d). In gastric SRCC, variable proportions of tumors are positive for CDX-2 (Chu and Weiss 2004; Terada 2013b), but there are yet no respective data for SRCC of the gallbladder.

Signet-Ring Cell Carcinoma In Situ

This lesion is very rare and was not recognized on gross examination, but was found incidentally on microscopic analysis. Histologically, the alteration was very similar to that of in situ and intramucosal signet-ring cell carcinoma of the stomach. The neoplastic cells were confined to superficial parts of the mucosa, mainly to epithelial lining and epithelial invaginations, in the absence of dysplastic changes of the adjacent epithelium (Albores-Saavedra et al. 1996).

Combined/Composite Tumors Containing a SRCC Component

Gallbladder adenocarcinomas rarely contain components of neuroendocrine neoplasms (MANEC) and in this context may contain SRCC (Olinici and Vasiu 1991).

Biology of Disease

SRCC of the gallbladder is an aggressive and diffusely growing neoplasm that, similar to SRCC in other organs, tends to produce multiple lymph node metastases and distant metastases, often to the liver in a first phase of the disease (Mondal 2010; Bazan et al. 2011). Apart from pure SRCC, also other carcinomas with a component of signet-ring cell carcinoma (mixed SRCC carcinomas) may be expected to show a more aggressive course, as demonstrated for stomach tumors (Huh et al. 2013). In contrast to ordinary gallbladder adenocarcinoma, SRCC may metastasize to unusual sites, including the skin (Krunic et al. 2007). Similar to other SRCC (mainly those of the stomach), SRCC of the gallbladder can give to ovarian Krukenberg tumors (Unterweger et al. 1999; Ayhan et al. 2001; Jain et al. 2006; Kiyokawa et al. 2006). In study performed in Thailand, 7 % of metastatic ovarian tumors had their origin in the gallbladder/extrahepatic bile ducts (Khunamornpong et al. 2006).

Nonneoplastic Signet-Ring Cells in the Gallbladder (Benign Signet-Ring Cell Change)

Signet-ring cell change is a nonneoplastic condition that morphologically simulates SRCC (Wang et al. 2003). Nonneoplastic signet-ring cells or cells closely resembling malignant signet-ring cells have been observed in several organs under various pathologic conditions, including pseudomembranous colitis (Michal et al. 1998; Abdulkader et al. 2003), cholangitis (Dhingra and Wang 2011), and acute erosive gastropathy (Dimet et al. 2004). Rarely, focal collections of signet-ring cells both on the mucosal surface lining and within the lumen of glands or tubules have been detected in the gallbladder, in the absence of evidence for malignancy. In one case, the gallbladder epithelium exhibited multilayering, and part of the epithelial cells showed a small round basal or eccentric nucleus and a vacuolated Pas-, mucicarmine-, and Alcian blue-positive cytoplasm, resulting in a signet-ring cell appearance (Suri et al. 2001). Nonneoplastic signet-ring cells were found in ulcerative lesions of the gallbladder (Michal et al. 1998). In another investigation, the cells were immunoreactive for keratin AE1/AE3 and were regarded to be disrupted mucosal goblet cells with degenerative changes (Ragazzi et al. 2009).

Differential Diagnosis

Rarely, signet-ring cell carcinoma of the stomach or other parts of the gastrointestinal tract may metastasize to the gallbladder (Bilicli et al. 2012). SRCC has to be distinguished from other neoplastic conditions forming signet-ring cells, specifically signet-ring cell lymphomas that may occur in the gastrointestinal tract. SRCC must not be confounded with the presence of nonneoplastic signet-ring cells that may occur in several organs, including the gallbladder (see above; Suri et al. 2001; Ragazzi et al. 2009).

Pathogenic Pathways

Molecular pathways involved in the pathogenesis of gallbladder SRCC are largely unknown, but it may be anticipated that mechanisms operational in other SRCC also apply to the gallbladder counterpart. In colorectal SRCC, chromosomal instability manifested by LOH was a nearly universal finding, including cases with high-level microsatellite instability, associated with BRAF V600E mutation (Kakar et al. 2012). Gastric SRCC exhibited copy number alterations of MYC and TP53, and this feature was associated with aggressive biology at early and advanced stages (Sonoda et al. 2013). In gastric carcinomas, heat shock protein 70 (HSP70) expression is high in intestinal-type cancers with an aggressive course but not in SRCC (Lee et al. 2013). Gastric SRCC and mucinous carcinomas overexpress the COL4A3 protein, which belongs to the type IV collagen family and plays a role in cancer progression (Nie et al. 2013). Gastric SRCC reveal distinct patterns of epigenetic alterations, associated with overexpression of DNA methyltransferase 1 and decreased expression of DNA methyltransferase 3A, suggesting that these neoplasms may produce complex patterns of aberrant DNA methylation (He et al. 2013). A subset of pulmonary adenocarcinomas with signet-ring cell morphology is characterized with rearrangements of the ALK gene (ALK+ lung adenocarcinomas; Nishino et al. 2012).

Cribriform Carcinoma of the Gallbladder

Introduction

Cribriform carcinoma (carcinoma cribrosum) is defined as a low-grade infiltrating carcinoma with a cribriform pattern. A cribriform (sievelike) growth shows round or angular masses of cells embedded in a desmoplastic stroma, sharply punched out round spaces, and a nuclear grade I in at least 90 % of cells. Cribriform carcinoma has chiefly been observed in the breast (Page et al. 1983; Wells and Ferguson 1988; Venable et al. 1990; Stutz et al. 1994; Nishimura et al. 2005). In the breast, invasive cribriform carcinoma is a histologic subtype with the same excellent prognosis as that of invasive tubular carcinoma (Page et al. 1983). It now forms a distinctive clinicopathologic entity (Venable et al. 1990).

Cribriform Carcinoma of the Gallbladder

Cribriform carcinoma has been identified as a rare subtype of gallbladder adenocarcinoma (Albores-Saavedra et al. 1996). In a series of seven patients, five patients were female and two male, whose ages at diagnosis ranged from 31 to 72 years (average, 57 years), i.e., younger than patients with conventional adenocarcinomas of the gallbladder. Five patients had cholelithiasis. Estrogen or progesterone receptors were not detected in these tumors. Three patients having tumors with high nuclear grade died as a result of the neoplasm which had infiltrated the liver by direct extension, while three patients with low nuclear grade tumors confined to the gallbladder wall survived 4–7 years after cholecystectomy (Albores-Saavedra et al. 2008). It seems that cribriform carcinoma of the gallbladder differs from its counterpart in the breast by a more aggressive biology.

Micropapillary Carcinoma of the Gallbladder

Introduction

Micropapillary carcinoma is a distinct variant of adenocarcinoma histologically characterized by very delicate papillary structures often surrounded by a clear, “empty” halo. This lesion was first described in the breast and has since been observed in various organs. This neoplasm has been mentioned to have an aggressive behavior with a high propensity for lymphovascular invasion, multiple lymph node metastases, and poor clinical outcome.

Micropapillary Carcinoma of the Gallbladder

Among a series of 90 gallbladder carcinomas, 20 cases (22.2 %) showed small foci with the typical features of micropapillary carcinoma. Of these 20 cases, 17 also showed lymph node metastases, which was more frequent than in ordinary adenocarcinomas, showing that the presence of this features, even in a focal distribution, is a predictor of lymph node metastasis (Hara et al. 2010).

Cervix Carcinoma-Like Carcinoma of the Gallbladder

Introduction

Among well-differentiated adenocarcinomas of the gallbladder, a small subset is characterized by cell lineages different from biliary-type cells or intestinal-type cells. One very rare variant is adenocarcinoma mimicking minimal deviation adenocarcinoma of the cervix (Tashiro et al. 2000). Minimal deviation adenocarcinoma of the cervix (synonym, adenoma malignum) is a rare form of invasive adenocarcinoma characterized by well-differentiated, but abnormally shaped glands lined by mucin-containing columnar cells with basal nuclei (Gusserow 1870; Silverberg and Hurt 1975; Gilks et al. 1989). The per se contradictory term "adenoma malignum" was chosen to denote a histologic appearance of "adenoma" associated with an aggressive phenotype with fatal progression ("malignum").

Pathology

The index patient was a 71-year-old Japanese male undergoing cholecystectomy for suspected cancer. The resected gallbladder showed a small polypoid mass of 12 mm diameter. Histologically, the neoplasm was a well-differentiated adenocarcinoma composed of columnar cells with a clear or slightly eosinophilic cytoplasm, with ovoid-to-slightly elongated nuclei being basally placed, and with expression of gastric-type mucin. The carcinoma had infiltrated the gallbladder wall in the form of well-developed glands associated with slight desmoplastic reaction (Tashiro et al. 2000).

Carcinoma of the Gallbladder with Morule-Like Features

Introduction

Several types of carcinomas in various organs are characterized by the development of so-called morules, spherical clusters of small cells with clear ("empty") nuclei and a distinct immunophenotype (from Latin, morus: mulberry; the term is redundantly used, as morula or morule is already used as a term denoting the solid cellular mass of blastomeres formed by cleavage of a zygote). Papillary thyroid carcinoma (Camaselle-Teijeiro and Chan 1999; Hirokawa et al. 2010; Cetta et al. 2011, 2012; Schaeffer et al. 2011), colorectal carcinoma (Sarlin and Mori 1984; Ueo et al. 2005), endometrial carcinoma (Saegusa et al. 2007), papillary lung carcinoma (Moran et al. 2004), bronchioloalveolar carcinoma (Fornelli et al. 2003), well-differentiated fetal adenocarcinoma of the lung and pulmonary blastoma (Sekine et al. 2003; Makishi et al. 2006), intraductal papillary mucinous neoplasm of the pancreas (Tateno et al. 2012), and gallbladder carcinoma (Sakai et al. 2008). Morular features rarely also develop in benign neoplasm, including pulmonary sclerosing hemangioma associated with familial adenomatous polyposis (Hosaka et al. 2004).

Gallbladder Carcinoma with Morule-Like Features

A very rare variant of gallbladder carcinoma is characterized by tumor-associated lymphoid stroma and morule-like features (Sakai et al. 2008). A 53-year-old man showed a polypoid gallbladder tumor with a thin stalk, measuring 1.3 × 0.5 cm. Histology revealed a well-

differentiated tubular adenocarcinoma accompanied by multiple spindle cell nodules forming morules as a putative metaplastic reaction. The stroma of the carcinoma exhibited a dense lymphoid cell infiltration.

Pathology

Histopathology

Histologically, morules observed in several carcinoma localizations are well-defined spherical structures composed of small, oval-to-short spindle-shaped cells with bland nuclei, frequently accompanied by intranuclear clear inclusions or optically clear nuclei that are positive for biotin and biotin-binding enzymes, i.e., pyruvic acid carboxylase and propionyl-CoA carboxylase (Okamoto et al. 1995; Gamachi et al. 2003; Ueo et al. 2005). In addition to several types of carcinoma, morules with biotin-containing optically clear nuclei have also been found in benign epithelial neoplasms, e.g., colonic tubular adenoma (Sasaki et al. 1999). Morules are morphologically and qualitatively different from squamous metaplasia (Chinen et al. 2004) and do not express features of epithelial cells in part of these tumors, while they are cytokeratin positive in others.

Immunocytochemistry

Carcinomas with morule-like features developing in other organs display distinct immunophenotypes. Cells of morules fail to express epithelial and oncofetal markers (Makishi et al. 2006). Cytoplasmic expression of CD10 is a characteristic marker of morule-forming tumors in different organs, CD10 being a factor involved in morular metaplasia (Chiarelli et al. 2006; Cameselle-Teijeiro et al. 2008). Cells of the cribriform-morular carcinomas, including the morular variant of papillary thyroid carcinoma (Hirokawa et al. 2010; Koo et al. 2011), endometrial carcinoma (Saegusa et al. 2007), and colorectal carcinoma (Ueo et al. 2005), consistently demonstrate nuclear and cytoplasmic expression of beta-catenin. Aberrant beta-catenin expression is regarded as a common denominator for morular formation, and beta-catenin accumulation co-localizes with estrogen receptor-beta, suggesting a cross talk between beta-catenin signaling and Wnt signaling pathways (Nakatani et al. 2004). The morules in endometrioid proliferations of the uterus and ovary consistently express the intestinal transcription factor CDX2 (Houghton et al. 2008), which is also expressed in pyloric gland adenoma of the gallbladder (Wani et al. 2008). CDX2, which overlaps with nuclear expression of beta-catenin, has a functional role in beta-catenin signaling in the course of transdifferentiation in endometrial adenocarcinomas (Saegusa et al. 2007). In morular differentiation of endometrial carcinomas, SOX4 functions as a positive regulator of beta-catenin signaling (Saegusa et al. 2012). Morular cells also express cyclin D1 and p63 and display a low Ki-67 labeling index, i.e., less than 1 % (Ueo et al. 2005). Marked nuclear expression of beta-catenin was also detected in gallbladder carcinoma with morule-like features (Sakai et al. 2008).

AFP-Producing Carcinoma of the Gallbladder

Introduction

Similar to certain cholangiocarcinomas, a small subset of gallbladder carcinomas have been shown to produce alpha-fetoprotein/AFP (Bernades et al. 1972; Miyasaka et al. 1978; Haruta et al. 1987; Maruiwa 1987; Maruiwa et al. 1988, 1996; Sugaya et al. 1989; Brown and Roberts 1992; Ikeda et al. 1992; Watanabe et al. 1993; Ng and Ng 1995; Cocquyt et al. 1996; Ono et al. 1996; Tanigawa 1996; St Laurent et al. 1999). This rare tumor should not be confounded with AFP-producing hepatoid carcinoma of the gallbladder.

Clinical and Imaging Features

The clinical presentation is that of other gallbladder malignancies, i.e., upper right quadrant pain, a

palpable mass, weight loss, and eventually jaundice. The salient feature of these neoplasms is elevated serum AFP levels (above 1,000 ng/ml), sometimes leading to misinterpretations as to the nature of the tumor. Typically, serum AFP levels drop to normal following resection of the tumor (Brown and Roberts 1992). In some of the cases, proteins other than AFP have been produced by gallbladder adenocarcinomas, e.g., carcinoembryonic antigen and antigen 19-9 (Sugaya et al. 1989; Ono et al. 1996).

AFP-producing adenocarcinomas of the gallbladder are aggressive lesions that invade the liver substance and give rise to multiple metastases, in particular of the liver, causing hepatic failure in part of the patients (Ono et al. 1996). A more aggressive behavior of these neoplasms has also been detected in nude mouse models of tumor transplantation (Maruiwa 1987; Maruiwa et al. 1996).

Pathology

Macroscopy

Macroscopically, AFP-producing carcinomas of the gallbladder show the same growth pattern as other adenocarcinomas, including polypoid, pedunculated, or fungating lesions (Ikeda et al. 1992; Ng and Ng 1995).

Histopathology

AFP-producing gallbladder tumors are adenocarcinomas with a tubular, tubulo-papillary, or papillary growth pattern, not different from that of non-AFP-secreting carcinomas, but papillary adenocarcinoma seems to predominate (Ikeda et al. 1992; Ono et al. 1996). Other morphotypes have rarely been noted, e.g., undifferentiated carcinoma (Ng and Ng 1995; St Laurent et al. 1999) or carcinoma with a component of pleomorphic cells and giant cells (Ng and Ng 1995). In part of the cases, increasing production of AFP may be associated with morphological dedifferentiation of the carcinomas. In one patient with recurrent gallbladder carcinoma, serum AFP increased as a function of tumor progression, with dedifferentiation of the tumor in its metastases in comparison with the primary tumor (Cocquyt et al. 1996). AFP production has been found in a clear cell carcinoma of the gallbladder with neuroendocrine differentiation (Sentani et al. 2014).

Immunohistochemistry

The cells of the adenocarcinoma are immunoreactive for AFP, showing that AFP is in fact produced by this cell type (Haruta et al. 1987; Ikeda et al. 1992; Ng and Ng 1995).

Differential Diagnosis

Differential diagnosis includes other hepatic tumors showing a glandular phenotype and AFP production, including mixed hepatocellular carcinoma-cholangiocarcinoma and purely acinar hepatocellular carcinoma. Carcinosarcoma of the gallbladder has been found to sometimes produce AFP (Shimada et al. 2009)

Clear Cell Carcinoma of the Gallbladder

ICD-O code 8310/3

Introduction

Clear cell carcinoma (clear cell adenocarcinoma) of the gallbladder is an uncommon variant of carcinoma recognized in the World Health Organization classification of tumors of the gallbladder and extrahepatic bile ducts (Albores-Saavedra et al. 2010). Gallbladder clear cell carcinoma is composed predominantly of glycogen-rich clear cells with well-defined cell borders and central hyperchromatic nuclei (Bittinger et al. 1995; Vardaman and Albores-Saavedra 1995; Nomura et al. 1996; Piana et al. 2002; Sartelet et al. 2004;

Vaillo et al. 2004; Tajiri et al. 2006). Most of the cases showed a single morphology ("pure" clear cell carcinoma), but the tumor has also been described in combination with small cell carcinoma of the gallbladder (Piana et al. 2002).

Clinical and Imaging Features

Biologically, little is known about the natural history of these neoplasms, which in similar or the same phenotypes also occur in several other organs, including the extrahepatic bile ducts and the liver. In a series of seven cases, the clinical presentation was similar with conventional adenocarcinomas of the gallbladder, signs and symptoms including right upper quadrant pain, a palpable mass, jaundice, nausea, signs of obstruction, and/or signs of metastatic disease. Almost all cases were associated with cholelithiasis (Vardaman and Albores-Saavedra 1995). All these seven patients were females, and age at diagnosis ranged from 56 to 68 years (mean, 62 years). Two patients had elevated serum CEA levels, explained by the presence of conventional adenocarcinomas together with clear cell carcinoma. This component is usually CEA positive by immunohistochemistry and is presumably the source of the oncofetal antigen in serum. The prognosis of patients with clear cell carcinoma of the gallbladder is poor and related to the pathologic stage (Vardaman and Albores-Saavedra 1995).

Pathology

Macroscopy

Clear cell carcinoma may present as a solid growth, similar to gallbladder adenocarcinoma, but polypoid variants with endoluminal growth have also been observed (Sartelet et al. 2004). Of a series of seven cases, the anatomic location was known in five, and these neoplasms were located in the fundus and body of the gallbladder and infiltrated the full thickness of the wall. Four tumors extended into the liver, two had metastasized to locoregional lymph nodes, and one to the omentum and multiple peritoneal sites. Size of the primary tumor ranged from 5.4 to 7 cm in diameter (Vardaman and Albores-Saavedra 1995).

Histopathology

The tumor cells are of intermediate size and impress by their very well-defined cytoplasmic borders and a clear (sometimes water clear) cytoplasm. The clear cell aspect is caused by accumulation of abundant glycogen. Therefore, the cells display PAS-positive diastase-labile cytoplasmic granules but are consistently mucin negative. In contrast, foci of conventional adenocarcinoma intermingled with clear cell carcinoma in part of cases show mucin-containing cells. There are tumors where columnar cells show subnuclear and supranuclear vacuoles similar to those found in epithelia of secretory endometrium. The clear cells are arranged in sheets, nests, cords, trabeculae, and glandular structures. A papillary variant has also been reported (Sartelet et al. 2004). The sheets and cords are separated by collagen bundles and show a reticulin network of variable density. A minority of cases showed a predominantly glandular pattern (Vardaman and Albores-Saavedra 1995). Focal papillary structures consisting of cuboidal or columnar clear cells lined up on fine fibrovascular stalks are also found, and one variant of clear cell carcinoma shows a predominantly papillary growth pattern (Vardaman and Albores-Saavedra 1995; Sartelet et al. 2004). In the cases of Vardaman and Albores-Saavedra (1995), the majority of cases contained areas of conventional adenocarcinoma that represented 5–40 % of the neoplasms, but may not be present in metastatic deposits. A clear cell component can also occur in squamous cell carcinoma of the gallbladder (Vardaman and Albores-Saavedra 1995). In a patient with adenocarcinoma of the cystic duct, clear cell change was only found in lymph node metastases (Tajiri et al. 2006). Diagnosis of clear cell carcinoma

has been performed by use of fine needle aspiration cytology (Vaillo et al. 2004).

Immunohistochemistry

Clear cell carcinomas of the gallbladder share the immunophenotype, specifically the cytokeratin expression pattern, with adenocarcinoma of this organ (Bittinger et al. 1995). The tumor cells are reactive for epithelial membrane antigen/EMA but negative for vimentin (Sartelet et al. 2004). Staining was focally positive for CEA in the clear cells in a minority of cases (Vardaman and Albores-Saavedra 1995).

Alpha-Fetoprotein-Producing Clear Cell Carcinoma

Clear cell carcinomas that produce alpha-fetoprotein have been observed in the extrahepatic bile ducts (Miyazawa et al. 2006) and, very rarely, in the gallbladder. A metastasizing clear cell tumor of the gallbladder showed hepatoid areas with a trabecular growth pattern, sinusoid-like vascular channels, and immunoreactivity for AFP and CEA, associated with elevated serum AFP levels. The hepatoid components predominated in the metastases (Vardaman and Albores-Saavedra 1995). In another patient, AFP-producing clear cell carcinoma of the gallbladder was associated with adenocarcinoma showing neuroendocrine differentiation, poorly or undifferentiated carcinoma, and carcinoma in situ in the surrounding gallbladder mucosa (Sentani et al. 2014).

Differential Diagnosis

The predominant differential diagnosis of clear cell carcinoma primary to the gallbladder is renal cell carcinoma of the clear cell type. Renal cell carcinomas tend to metastasize to unusual sites, and among metastases occurring in the gallbladder, renal cell carcinoma holds the first position, followed by malignant melanoma (see the respective chapter). Intra-abdominally, the pancreas is a preferred location (Kassabian et al. 2000; Wente et al. 2005), but several reports also document renal cell carcinoma metastasis to the gallbladder (Satoh et al. 1991; Brasseur et al. 1999; Kechrid et al. 2000; Aoki et al. 2002; Nojima et al. 2008; Kücükakin et al. 2009). In one patient, an intraluminal polypoid metastasis of renal cell carcinoma mimicked a gallbladder polyp (Fang et al. 2010). Metastatic renal cell carcinoma may grow as a polypoid mass in the gallbladder (Botting et al. 1963; Satoh et al. 1991), a growth pattern also known for primary clear cell carcinoma. In such cases, immunohistochemistry will serve to solve the diagnostic difficulty. A more remote differential diagnosis is other clear cell neoplasms, e.g., clear cell carcinoid tumor of the gallbladder (Sinkre et al. 2001).

Carcinoma of the Gallbladder with Lymphoid Stroma

Carcinomas of the gallbladder are associated with an immune response of the host, presenting as a mainly lymphocytic infiltration in the tumor stroma. These infiltrates are usually low-density reactions and are discussed in a separate paragraph. Exceptionally, the infiltrates are dense or very dense, a phenomenon known from other carcinomas (e.g., certain breast carcinomas) and called lymphoid stroma. Carcinoma of the gallbladder with lymphoid stroma was first reported in 1984 (Muto et al. 1984), followed by two cases several years later (Kijima et al. 1999; Sakai et al. 2008).

Histologically, the tumor reveals adenocarcinoma with an expended stromal component. The latter contains a dense infiltrate chiefly composed of small lymphocytes, but plasma cells, macrophages, and eosinophils may also be seen in much lower numbers. As in other tumors with a lymphoid stroma, lymph follicles with germinal center can develop. Whether the presence of a lymphoid stroma regularly implies a more favorable prognosis is, owing to the few reported cases, not yet established.

Undifferentiated Carcinoma of the Gallbladder

ICD-O code 8020/3

Introduction

Apart from poorly differentiated adenocarcinoma, a small subset of gallbladder carcinoma are composed of cell lineages with a highly deviating, undifferentiated phenotype, rendering a distinction between carcinoma and sarcoma difficult in some cases. Undifferentiated carcinoma (UDC) is more frequently encountered in the gallbladder than in extrahepatic bile ducts. In the current WHO classification, UDC also comprises spindle cell carcinomas, small cell non-endocrine carcinoma, giant cell carcinomas (including those with osteoclast-like giant cells), and a nodular/lobular type superficially resembling breast carcinoma (Albores-Saavedra et al. 1996). These different variants have been described in several reports (Guo et al. 1988; Nishihara and Tsuneyoshi 1993; Kubota et al. 2000; Tanaka et al. 2002; Takahashi et al. 2004; Badmos et al. 2013). Spindle cell carcinomas of the gallbladder seem to form at least two morphological groups, one with an undifferentiated phenotype sometimes difficult to separate from carcinosarcomas of the gallbladder and the other characterized by a bland-looking population of spindle cells. Epithelial spindle cell tumors of the gallbladder are therefore further discussed in a separate paragraph, except the undifferentiated variant which is treated in the present paragraph. As gallbladder carcinomas comprising a combination of bona fide epithelial cells, transition forms, and vimentin-positive spindle cells, the mechanism of epithelial-to-mesenchymal transition may pathogenetically be involved, probably calling for a reappraisal of UDC definition in the future.

Pathology

Macroscopy

UDCs as rapidly growing neoplasms tend to form bulky tumors with often extensive necrosis, hemorrhage, and accumulated tumor debris and coagulated blood masses in the gallbladder lumen. Tumor hemorrhage can cause hemobilia (Kubota et al. 2000). The growth pattern is either mass forming, diffusely infiltrating, or endoluminal polypoid. Protruding forms with a tumor pedicle were also described (Takahashi et al. 2004).

Histopathology

The undifferentiated tumor cells in UDC may coexist with small neoplastic cells of the non-neuroendocrine type (Takahashi et al. 2004). Part of UDC contains an immature-looking epithelial component, either adenocarcinoma or squamous cell carcinoma or combined, and a highly atypical spindle cell component (undifferentiated spindle cell carcinoma; Nishihara and Tsuneyoshi 1993; Akatsu et al. 2005; Badmos et al. 2013). In variants with a squamous cell/keratinocyte lineage, a gradual transition between the squamous cell carcinoma and the spindle cell component was observed (Nishihara and Tsuneyoshi 1993). Spindle cell components in UDC have also been termed pseudosarcomatous type of carcinoma (Guo et al. 1988; Diebold-Berger et al. 1995). Part of UDC contains highly atypical giant cells of the non-osteoclast type (Manouras et al. 2009). A very rare variant of UDC histologically mimics lobular carcinoma of the breast (Albores-Saavedra et al. 1996).

Immunohistochemistry

Almost all spindle cell UDCs were positive for at least one of the epithelial markers (mostly AE1/AE3 and EMA, less often CEA), but part of the cells were also reactive for vimentin (Guo et al. 1988; Nishihara and Tsuneyoshi 1993).

Differential Diagnosis

UDCs with a prominent atypical spindle cell component have to be distinguished from "true" carcinosarcomas of the gallbladder.

Pleomorphic Carcinoma of the Gallbladder

ICD-O code 8020/3

Introduction

Pleomorphic carcinoma (pleomorphic giant cell carcinoma) is one of the least common primary cancers of the gallbladder, and only few cases have been reported (Appelman and Coopersmith 1970; Willén and Willén 1982; Alpers and Smuckler 1984; Takeda et al. 1990; Caruso et al. 1991; Omura et al. 1999; Kubota et al. 2000; Shimada et al. 2012). Some authors have classified pleomorphic carcinoma as a variant of undifferentiated carcinoma of the gallbladder (Guo and Enjoji 1988). The clinical presentation is that of other invasive carcinomas of the gallbladder. The neoplasm may be associated with a paraneoplastic syndrome, i.e., production of granulocyte colony-stimulating factor, causing leukocytosis in the peripheral blood (Takeda et al. 1990; Omura et al. 1999). Leukocytosis disappears immediately after cholecystectomy. Due to the small numbers of reported cases, no reliable data regarding outcome are available, but pleomorphic gallbladder carcinomas are highly aggressive lesions with a tendency to invade the liver and adjacent organs and poor prognosis.

Pathology

Macroscopy

As other high-grade carcinomas, pleomorphic carcinoma of the gallbladder produces ill-defined invasive masses with necrosis and hemorrhage. Polypoid tumors protruding into the gallbladder lumen have been described (Caruso et al. 1991).

Histopathology

The histology of these carcinomas is characterized by a growth that lack architectural cohesiveness and the organoid features of typical adenocarcinomas. The neoplastic cells are mononuclear or multinucleated (giant cells) and are generally large or at least of intermediate size, with an eosinophilic or amphophilic cytoplasm. Nuclei are highly irregular and pleomorphic, sometimes lobulated, with a coarse chromatin and large nucleoli. Numerous and in part highly atypical mitotic figures are noted. Some of the tumors contain atypical and pleomorphic spindle cells and squamous cells (Appelman and Coopersmith 1970; Alpers and Smuckler 1984; Shimada et al. 2012). The stroma is usually poorly developed. Extensive necrosis, apoptosis, and leukocyte-tumor cell phagocytosis are often present.

Immunohistochemistry

The tumor cells are reactive for cytokeratins, EMA, and carcinoembryonic antigen (Caruso et al. 1991), demonstrating the epithelial nature of this poorly differentiated neoplasm.

Differential Diagnosis

Due to the presence of multinucleated giant cells, pleomorphic carcinoma may be confounded with other giant cell neoplasms, specifically carcinoma with osteoclast-like giant cells. In the latter neoplasms, the giant cells possess more and isomorphic nuclei, and the cells lack pleomorphism. Pleomorphic carcinomas with a spindle cell component may resemble carcinosarcomas.

Undifferentiated Giant Cell Carcinoma (Anaplastic Carcinoma) of the Gallbladder

Undifferentiated carcinoma giant cell type is a rare variant of carcinoma that also occurs in the biliary tract (Dowaki et al. 2003; Oikawa et al. 2007; Ide et al. 2012).

In the very uncommon gallbladder tumors showing this morphology, it has been assumed

that anaplastic giant cell components may probably represent dedifferentiation of a preexisting adenocarcinoma.

Abstract

In addition to the common glandular carcinomas (adenocarcinoma) of the gallbladder, few other types of carcinoma can develop in this organ. Squamous cell carcinoma is a rare type of gallbladder malignancy clinically characterized by a more rapid and aggressive growth with infiltration of the liver and adjacent organs, but less frequent lymph node metastases in comparison with adenocarcinoma. This tumor accounts for only few percent of all gallbladder cancers. Macroscopically, squamous cell carcinoma usually produces large bulky lesions that efface the gallbladder wall. Adenosquamous carcinoma of the gallbladder is also rare and is diagnosed with an incidence similar to that of squamous cell carcinoma. Hepatoid carcinoma of the gallbladder is a rare variant of extrahepatic carcinoma which in several respects mimics hepatocellular carcinoma. Only few well-documented cases were reported for the gallbladder. These cancers are rapidly growing and highly aggressive lesions, similar to their counterparts in other organs. Very rare primary carcinomas of the gallbladder consist of small cells in the absence of neuroendocrine markers. Other very rare primary carcinomas of the gallbladder include anaplastic and pleomorphic carcinoma variants.

Squamous Cell Carcinoma of the Gallbladder

ICD-O code 8070/3

Introduction

Squamous cell carcinoma (SCC; epidermoid carcinoma) of the gallbladder is a rare type of carcinoma characterized by a more rapid and invasive, aggressive growth with infiltration of the liver and adjacent organs, less frequent lymph node metastasis in comparison with adenocarcinoma, and poorer outcome.

Epidemiology

SCC is a rare primary carcinoma of the gallbladder, accounting for only 0.5–12.7 % of all gallbladder malignancies. This neoplasm is predominantly seen among females between the fourth and sixth decades of life. In a clinicopathological review of 68 primary carcinomas of the gallbladder, SCCs amounted to 4.4 % (Donaldson and Busuttil 1975). In an autopsy study of 287 patients with gallbladder carcinoma, 3.7 % were SCCs (Sons et al. 1985). In a series of 29 non-adenocarcinoma types of gallbladder carcinoma, one lesion was SCC and 28 were adenosquamous carcinomas (Oohashi et al. 2002). Among 124 gallbladder malignancies observed in one center, 5 were SCCs (2.41 %), with a mean age at diagnosis of 50.2 years and a female/male ratio of 1.5:1 (del Pozo et al. 2005). A series of nine gallbladder carcinomas detected in 1,122 cholecystectomies contained one case of SCC (Khoo and Nurul 2008). A more recent clinicopathologic analysis of 606 gallbladder carcinomas revealed 41 tumors with a squamous cell differentiation, and eight of these neoplasms were pure SCC. The average patient age of the tumors with squamous cell differentiation was 65 years, with a female/male ratio of 3.8 (Roa et al. 2011). The relatively large range of incidence extracted from literature data is probably related to variable prevalences of risk factors, in particular chronic cholecystitis associated with stone disease. Another factor explaining marked differences in incidence is related to the fact that, in some reports and series, adenosquamous carcinoma, mucoepidermoid carcinoma, and secondary SCCs were lumped together with true primary SCC of the gallbladder. SCC of the gallbladder has been found in the setting of low-dose methotrexate use (Azad et al. 2009). SCC of the gallbladder may be combined with other primary gallbladder malignancies, e.g., adenocarcinoma (Hanada et al. 1986) or angiosarcoma (Kumar et al. 1994).

Clinical and Imaging Features

The most important symptom is abdominal pain, occurring in 66 % of patients. The patients may present with colicky pain (mainly in those with stone disease), a right hypochondrial mass, or jaundice. The tumor may present as acute cholecystitis (Gupta et al. 2004; Damian et al. 2011) or gallbladder empyema (Kamat et al. 2001). Due to its invasive features, SCC can cause fistulations, e.g., biliary-colic fistula (Khaira et al. 1995). In one patient, SCC of the gallbladder was found to produce granulocyte-colony-stimulating factor (Murata et al. 2001). CT images reveal a thick-walled gallbladder (Rekik et al. 2011).

Pathology

Macroscopy

SCC of the gallbladder usually forms large bulky lesions that efface the gallbladder wall. On cut surfaces, the tumors are whitish and friable lesions, associated with often extensive necrosis and hemorrhage. In a minority of cases, the tumors display an endophytic and polypoid growth pattern, with formation of several vegetations sometimes extending from the fundus to the neck of the gallbladder (Mingoli et al. 2005) or with the tumor mass sometimes filling the dilated gallbladder lumen (endophytic carcinomas; Khan et al. 2012). Among 41 cancers with a squamous cell differentiation, including eight pure SCCs, 6 % of the tumors were polypoid (Roa et al. 2011). Very small lesions (minute SCC) have been described, e.g., in the form of a small and firm nodules incidentally found during cholecystectomy (Roppongi et al. 2000). In advanced-stage disease, the tumor invades the gallbladder fossa and the liver substance.

Histopathology

SCC of the gallbladder is an invasive lesion growing in the form of solid components which consist of a layered keratinocyte epithelium. The squamous cell cords are often several cells thick and grow along preexisting structures of the gallbladder wall, specifically blood vessels and nerves. In the cords, smaller cells prevail at the periphery, while more mature-looking keratinocytes predominate in central parts of the cords. In some cases, the smaller and peripherally placed cells show basaloid features. In the centers of the cords, the keratinocytes may form concentrically arranged clusters ("pearls"), with or without keratinization. The latter is seen as dyskeratosis or parakeratosis, while areas with formation of a stratum granulosum are less commonly seen (Xu et al. 2012). SCC can be present as early gallbladder carcinoma, with an intramucosal extension (Albores-Saavedra et al. 2011). Desmoplasia (stroma formation) is usually not pronounced. Large necrosis can occur,

associated with ulceration of the tumor. Peri-and/or intraneural invasion may be noted. Within the tumors and in the adjacent tissue, a cellular mixed infiltrate is noted. In a systematic study, tumor-infiltrating eosinophils were more frequent in SCCs and adenosquamous carcinomas than in adenocarcinoma (Roa et al. 2011). SCC of the gallbladder can be diagnosed by preoperative fine-needle aspiration cytodiagnosis (Gupta et al. 2000; Gupta and Gupta 2012).

SCC is sometimes associated with squamous cell metaplasia of the gallbladder surface epithelium or with squamous cell metaplastic changes situated in crypts or deeper parts of the glandular mucosa (Hanada et al. 1986; Roa et al. 2011). Among 41 gallbladder carcinomas with squamous cell differentiation, squamous cell metaplasia of adjacent mucosa was detected in 12 % of cases (Roa et al. 2011). These metaplastic areas may be located in gallbladder parts, showing mucosal atrophy and fibrosis in case of stone disease, and the metaplasia may in fact be found in flattened mucosae underlying an impacted stone. In squamous metaplasia, various degrees of keratinocyte dysplasia can occur, sometimes representing squamous cell carcinoma in situ. Such lesions may be in direct contact with invasive carcinoma, suggesting a dysplasia-carcinoma in situ-invasive carcinoma sequence or may exist as separate lesions, distant from otherwise invasive carcinoma components. SCC may also originate from metaplasia taking place in adenocarcinoma, as observed in some advanced cases of gallbladder carcinoma (Miyazaki et al. 1995; Tomono et al. 2000).

Biology of Disease

SCC of the gallbladder is aggressive and highly invasive neoplasms with an outcome that is poorer than that of adenocarcinoma, although they display a lower rate of locoregional lymph node metastasis, even in the presence of large primary tumors (Soyama et al. 2011; Chakrabarti et al. 2014). Gallbladder SCC can infiltrate the gallbladder bed, grow into the liver substance, and may be manifest in other sites (Kais et al. 2014). The biology of disease resembles that of adenosquamous carcinoma. Generally, SCC and adenosquamous carcinoma of the gallbladder present, in comparison with conventional adenocarcinoma, with a larger tumor size, a higher T stage, and a higher incidence of adjacent organ involvement, but a lower incidence of locoregional lymph node involvement (Kalayarasan et al. 2013). Whereas 5-year survival rates of adenocarcinoma have been reported to be in the range 32–38.5 % (Henson et al. 1992), the rarer SCC and adenosquamous carcinomas have shown 2-year survival rates of 10–22.3 %. This feature reflects what is known for other organs, where squamous and adenosquamous carcinomas showed a more unfavorable biology than adenocarcinoma, e.g., stomach and lung. The squamous component had a higher proliferative activity than the glandular component in gallbladder carcinomas (Nishihara et al. 1994b). Invasion of adjacent organs is a typical feature of SCC (Karaswa et al. 1981; Miyazaki et al. 1995; Mingoli et al. 2005; Khan et al. 2012). Like adenosquamous carcinoma, SCC is often diagnosed at an advanced stage, resulting in non-curative surgical resection and a poorer prognosis than in conventional gallbladder carcinoma (Kim et al. 2011). However, in a recent study where follow-up was available in 31 patients, the survival of patients with SCC/adenosquamous carcinomas was significantly worse than that of gallbladder adenocarcinomas, and this adverse prognosis persisted when compared with stage-matched advanced gallbladder adenocarcinoma cases (Roa et al. 2011).

Differential Diagnosis

Differential diagnosis mainly includes adenosquamous carcinoma with a predominant squamous cell component, invasion by a hepatic squamous cell carcinomas, and the very rare gallbladder metastasis of a squamous cell carcinoma situated elsewhere.

Pathogenic Pathways

SCC of the gallbladder was found to have coamplification of the HST1 and INT2 genes,

HST1 previously been found to be amplified in over 40 % of SCCs of the esophagus (Tsuda et al. 1989).

Adenosquamous Carcinoma of the Gallbladder

ICD-O code 8560/3

Introduction

Adenosquamous carcinoma of the gallbladder (ASC; synonym: adenoacanthoma) is a rare type of primary carcinoma of this organ. It is defined as an adenocarcinoma containing a squamous cell (keratinocyte) component constituting 25–99 % of the tumors. Adenocarcinomas containing less than 25 % squamous cells are classified as adenocarcinoma with focal squamous change. In older reports, the term adenoacanthoma was employed (Bartocci and Carratu 1964; Occhionero and Ricci 1964; Zambianchi 1965).

Epidemiology

ASC is a rare histologic type of gallbladder carcinoma, accounting for an estimated 5.3–10.6 % of all gallbladder carcinomas (Henson et al. 1992; Nishihara et al. 1994b; Albores-Saavedra et al. 1998). In an early analysis of 271 surgically resected gallbladder cancers, 20 patients had ASC (7.4 %; Nishihara et al. 1994a). In a study on 606 resected invasive gallbladder carcinomas, 41 cases (7 %) showed squamous differentiation, and 26 of these were ASC (Roa et al. 2011).

ASC is a tumor of older patients, most patients being older than 60 years at diagnosis. In the 20 patients with gallbladder ASC reported by Nishihara et al. (1994b), the mean age at diagnosis was 66.9 years. In a series of primary ASC and squamous cell carcinomas of the gallbladder, the average patient age at diagnosis was 65 years/range, 26–81 years, with a female/male ratio of 3.8 (Roa et al. 2011).

Selected References Kusakina and Nigmatulina 1980; Sato et al. 1981; Muto et al. 1982; Otsuka et al. 1982; Suster et al. 1987; Stamatiadis et al. 1989; Fukuda and Ohnishi 1990; Kojima et al. 1994; Nishihara et al. 1994b; Mingoli et al. 1995; Miyazaki et al. 1995; Nishihara et al. 1995; Shimoi and Ohkusa 1996b; Wagreich et al. 1998; Ercolani et al. 1999; Saito et al. 1999; Kondo et al. 2002; Oohashi et al. 2002; Ramia et al. 2002; Akcali et al. 2005; Fujita et al. 2005; Mingoli et al. 2005; Noske and Pahl 2006; Chan et al. 2007; Lada et al. 2007; Farah-Klibi et al. 2008; Horio et al. 2009; Bagdasaryan and Miroshnichenko 2011; Roa et al. 2011; Rustagi et al. 2011; Kim et al. 2012

Clinical and Imaging Features

Gallbladder ASC usually presents with upper abdominal pain, nausea, vomiting, and weight loss (Lada et al. 2007). In a comparative study, the clinical presentation of ASC was not different from that of adenocarcinoma. However, tumor stages in both ASC and squamous cell carcinomas of the gallbladder were significantly advanced and often included liver involvement (Chan et al. 2007). In a study of ten patients with ASC and four patients with squamous cell carcinoma, presentation with vomiting and an abdominal lump was more common than in patients with adenocarcinoma, and these tumors also presented with a larger tumor size, advanced T stage, and a higher incidence of adjacent organ involvement (Kalayarasan et al. 2013). ASC of the gallbladder may mimic Mirizzi syndrome. In one patient, the nodular growth pattern of the ASC was responsible for the finding of a benign-looking bile duct stenosis on examination by ERC (Horio et al. 2009). ASC of the gallbladder tends to invade not only the liver but also adjacent organs, sometimes with fistula formation, e.g., cholecysto-duodenal fistulas (Saito et al. 1999) or bilio-biliary fistulas (Ercolani et al. 1999). As a complication of ASC, tumor rupture has been described (Rustagi et al. 2011). Exceptionally, ASC of the gallbladder was associated with a paraneoplastic syndrome, e.g., a tumor producing

human chorionic gonadotropin (Fukuda and Ohnishi 1990).

Abdominal ultrasonography, CT, and MRI usually reveal an irregularly shaped solid mass with or without extension beyond the organ limits (Wagreich et al. 1998; Fujita et al. 2005). At endoscopic ultrasonography, ASC has been found to present with gallbladder wall thickening, similar to adenocarcinomas (Kim et al. 2012). In one patient, ASC was associated with congenital dilatation of the common bile duct (Otsuka et al. 1982).

Pathology

Macroscopy

Patients with ASC most often present with a large, non-cystic, and advanced-stage tumor mass replacing the gallbladder wall and the gallbladder fossa (Nishihara et al. 1994b; Mingoli et al. 1995; Miyazaki et al. 1995; Roa et al. 2011). In a minority of cases, a polypoid (endophytic) growth pattern is noted. Invasion of the liver substance and adjacent organs, mainly the duodenum, extrahepatic bile ducts, stomach, transverse colon, and pancreas, is a common finding at diagnosis. In ulcerated tumors, the surface of the defect is replaced by a gray-white, shaggy tumor mass. In stone disease, this mass may contain scattered, embedded calculi.

Histopathology

The typical histopathology of ASC is a tubular or papillary adenocarcinoma containing foci of squamous cells, often already visualized at low magnification. The transition between the adenocarcinoma components and the squamous cell components may be continuous or, more often, abrupt. For correct diagnosis, several fields have to be investigated, as the definition of ASC requires more than 25 % squamous cell components; otherwise the tumor is classified as adenocarcinoma with focal squamous change. As in pure squamous cell carcinomas, ASC tends to develop necrosis, sometimes extensive. The development of desmoplastic stroma is highly variable. Part of the tumors show a considerable desmoplasia, but scirrhous forms are the exception. In very rare cases, the desmoplastic stroma of ASC contained multinucleated giant cells of the osteoclast type (Grosso and Gonzalez 1992). ASC can present as early cancer with invasion limited to the proper muscle layer (Sato et al. 1981). ASC of the gallbladder can be diagnosed cytologically based on fine-needle aspiration (Yadav et al. 2013).

Variants of ASC of the Gallbladder

Probably due to the involvement of more than one lineage of cells differentiating in various directions, ASC can contain unusual cellular features in addition to the development of keratinocytes. A rare variant of ASC of the gallbladder is characterized by components showing atypical columnar epithelium with pseudostratification, mimicking gastric foveolar epithelium (Nishihara et al. 1995). Extensive spindle-cell transformation has been found in one case of ASC of the gallbladder. In areas showing interwoven fascicles of fusiform and poorly differentiated cells, keratin-positive cells were seen to merge with areas showing glandular and squamous cell features (Suster et al. 1987). ASC of the gallbladder was found in combination with other tumors, including pure squamous cell carcinoma or large-cell neuroendocrine carcinoma (Noske and Pahl 2006).

Immunohistochemistry

The glandular-type cells are positive for cytokeratins, epithelial membrane antigen, and carcinoembryonic antigen (Grosso and Gonzalez 1992). These cells express class II mucins (Nishihara et al. 1995). The squamous cells were positive for CK34BE12 and p63 (Rustagi et al. 2011). CD44 (standard) and CD44 variant members of a transmembrane glycoprotein adhesion molecule family are good markers of squamous epithelial differentiation (Georgolios et al. 2006) and can be used to detect a squamous cell lineage within an adenocarcinoma, including ASC (Ylagan et al. 2000). In ordinary gallbladder

adenocarcinoma, CD44 variant overexpression was associated with tumor dedifferentiation (Yanagisawa et al. 2001). In a PCNA study, a positive rate for immunostaining was larger in the squamous cell areas (mean 20.55 %) than in adenocarcinoma areas (11.40 %), suggesting a greater proliferative activity of the squamous component (Nishihara et al. 1994b).

Differential Diagnosis

The most important differential diagnosis is adenocarcinoma with focal squamous change, defined as an adenocarcinoma with less than 25 % squamous cell components. This distinction is properly made in large biopsies or resection specimens, while needle biopsies are problematic for the estimation of percentual representations, owing to marked sampling errors. A second potential differential diagnosis is metastatic ASC.

Biology of Disease

Similar to squamous cell carcinoma, ASC of the gallbladder is a tumor that is more invasive and more aggressive than ordinary adenocarcinoma, with a poor prognosis (Nishihara et al. 1994b; Ramia et al. 2002; Mingoli et al. 2005; Lada et al. 2007; Roa et al. 2011). It has been proposed that ASC of the gallbladder warrants resection only if curative resection is feasible (Oohashi et al. 2002). In fact, long-term survival following radical resection has been noted even in patients with advanced disease (Fujita et al. 2005).

Hepatoid Carcinoma of the Gallbladder

ICD-O code 8576/3

Introduction

Hepatoid adenocarcinoma (HAC; synonym: hepatoid carcinoma) is a rare variant of extrahepatic adenocarcinoma which mimics hepatocellular carcinoma (HCC) morphologically and in its functionality. Similar to HCCs, HACs produce and secrete alpha-fetoprotein (AFP), sometimes with very high serum levels (Akiyama et al. 2003; Su et al. 2013). HAC occurs in several organs, but most cases were observed in the stomach, followed by other parts of the gastrointestinal tract (including the pancreas), female genital tract, and lungs (Matsuta et al. 1991; Ishikura et al. 1997; Antonio et al. 2004). In fact, the first AFP-producing extrahepatic carcinoma with features of hepatic differentiation was observed in the stomach and termed hepatoid adenocarcinoma (Ishikura et al. 1985). HAC makes part of a complex group of non-HCC AFP-producing carcinomas. Not all carcinomas producing AFP are HAC. In the stomach, these lesions are generally classified as AFP-producing gastric cancer (AFPGC; Liu et al. 2012). AFPGC presents four histologic types: hepatoid, enteroblastic (fetal type), yolk sac tumor, and common adenocarcinoma type (Motoyama et al. 1993; Kinjo et al. 2012). Similar to gastric tumors, there is a distinct group of AFP-producing gallbladder carcinomas, lacking the histologic features of HAC. These lesions are discussed in a separate chapter.

HAC primary to the gallbladder is a very rare tumor with only relatively few well-documented cases (Katsuragi et al. 1989; Watanabe et al. 1993; Nishiwaki et al. 1997; Nakashima et al. 2000; Maitra et al. 2001a; Sakamoto et al. 2004; Sakamoto et al. 2005; Gakiopoulou et al. 2007; Koswara et al. 2007; van den Bos et al. 2007; Ellouze et al. 2011; Lee et al. 2011).

Clinical and Imaging Features

Patients with HAC present with abdominal discomfort or pain and a mass in the upper right abdominal compartment. HAC is associated with high levels of serum AFP in part of the cases (Katsuragi et al. 1989; van den Bos et al. 2007), but there is also HAC of the gallbladder lacking AFP production (Nakashima et al. 2000).

HAC is rapidly growing and highly aggressive, chemoresistant neoplasms that extensively metastasize to the liver, locoregional lymph nodes, and remote organs (Antonio et al. 2004; Lee et al. 2011). It has been proposed that hepatoid carcinomas, whether AFP producing or not, tend to fare worse than other AFP-producing carcinomas (Wee et al. 2004). On T1-weighted gradient-echo images, the tumor was hypointense to the adjacent liver substance, while fat-suppressed T2-weighted fast spin-echo images showed hyperintensity of the tumor. After injection of non-liver-specific gadolinium chelate, the lesion enhanced predominantly in the periphery (van den Bos et al. 2007).

Pathology

Macroscopy

The tumors are either solid growths of whitish color and firm consistency, or they present as large intraluminal polypoid masses.

Histopathology

Histologically, HAC displays a HCC-like trabecular pattern, the plates and nests composed of large cells with an eosinophilic and slightly granular cytoplasm and distinct cell borders. Nuclei are large and vesicular, often with an ovoid shape and prominent amphophilic or basophilic nucleoli. Part of the cells are PAS positive and stain with Victoria blue (Koswara et al. 2007). Due to these features, HAC often has a striking resemblance with HCC. Mitotic figures are regularly found and are sometimes present in large numbers, reflecting the rapid growth behavior of these neoplasms. In contrast to HCC, a sinusoidal vascular network is usually lacking. Desmoplasia is highly variable, but most tumors show only a delicate stromal component. HAC can consist of an HCC-like neoplasm in its entirety, but it may also be combined with typical adenocarcinoma, either intermingled or in the form of combined tumors (Sakamoto et al. 2004; Koswara et al. 2007; Ellouze et al. 2011) and with high-grade dysplasia of the gallbladder epithelium (Ellouze et al. 2011).

Immunohistochemistry

HAC shows marked reactivity for CK7 and CK19, mainly in components resembling adenocarcinoma, whereas CK20 is negative. Focally, CD10 is positive, suggesting focal canalicular differentiation (van den Bos et al. 2007; Ellouze et al. 2011). The neoplastic cells are reactive for AFP in part of the tumors (Katsuragi et al. 1989; Koswara et al. 2007; van den Bos et al. 2007). AFP reactivity is not restricted to HCC-like tumor cells but may also be detectable in glandular neoplastic cells (Koswara et al. 2007). In part of the cases, the cells have been shown to be positive for Hep Par1, suggesting a hepatocyte-like lineage (Maitra et al. 2001; Sakamoto et al. 2004; Ellouze et al. 2011). In other HAC, reactivity for glypican-3 was observed (Ushiku et al. 2010).

In HAC developing in organs other than the gallbladder, reactivity for P-glycoprotein and multidrug resistant-associated proteins (MRP) 1, 2, and 6 was significantly higher than in adenocarcinoma (Kamata et al. 2008). A marker distinguishing gastric HAC from HCC is the stem cell marker SALL4, which is diffusely expressed in HAC but is completely lacking in HCC (Ushiku et al. 2010; Ikeda et al. 2012).

Molecular Markers

In HAC located to other organs, novel markers distinguishing HAC from HCC have been investigated. Nasal epithelium carcinoma-associated protein/PLUNC has been shown to distinguish gastric HAC from primary HCC (Sentani et al. 2008).

Differential Diagnosis

HAC of the gallbladder has to be distinguished from HCC invading this organ or HCC metastasizing to the gallbladder (Tamura et al. 1993;

Han and Kim 2005; Murakami et al. 2008; Ando and Sakamoto 2009; Ryu et al. 2009). Since there is no peritoneal covering between the gallbladder and the liver fossa, gallbladder carcinoma easily and often invades the liver, whereas HCC rarely invades the gallbladder. Metastasis of HCC to the gallbladder can present massive intraluminal growth mimicking a primary gallbladder tumor (Terasaki et al. 1990) or may induce hemocholecyst (Chang et al. 1998). Gastric HAC often metastasizes to the liver and may eventually involve the gallbladder.

Pathogenic Pathways

The pathogenesis of HAC has not been clarified. One view suggests that adenocarcinoma acquires hepatic differentiation during tumor progression, while another hypothesis proposed that bipotential (progenitor) cells differentiate along two lineages, glandular and hepatoid (Sakamoto et al. 2004). There is molecular evidence of identical origin of gastric HAC with coexistent adenocarcinoma (Akiyama et al. 2003). It has been proposed that gastric AFP-producing carcinomas develop as common adenocarcinoma or enteroblastic carcinoma in the mucosa, which differentiate into HAC during the process of tumor invasion and proliferation, acquiring AFP production ability (Kinjo et al. 2012). HAC shares with HCC immunoreactivity for Hep Par1, regarded as a hepatocyte marker. Focal positivity for Hep Par1 was detected in 6/7 HAC of the gastrointestinal tract. This finding is no proof of a common cell lineage, but just underscores the fact that Hep Par1 expression is not unique to primary hepatocellular neoplasms (Maitra et al. 2001). Differential expression of transcription factors involved in hepatogenesis may be involved in the pathogenesis of HAC. In an AFP-producing lung carcinoma, expression of an important hepatogenic transcription factor, hepatocyte nuclear factor-4a, was restricted to hepatoid foci located in the tumor (Kishimoto et al. 2008).

Small Cell Carcinoma of the Gallbladder

Introduction

Small cell carcinoma (SCC; synonyms: small cell undifferentiated carcinoma, oat-cell carcinoma) of the gallbladder is an uncommon, aggressive malignancy that metastasized early and is associated with a poor prognosis. This tumor entity was first described in 1981 (Albores-Saavedra et al. 1981). Most SCC share with their bronchopulmonary counterpart the presence of neuroendocrine features (NE-SCC), but there seems to be small subset of undifferentiated SCC of the gallbladder that lack such features (non-neuroendocrine SCC; NNE-SCC). The exact origin and cell lineage of NNE-SCC are currently unknown, but this uncommon tumor is briefly discussed in descriptive terms.

Epidemiology

Overall, SCC of the gallbladder accounts for approximately 0.5 % of gallbladder carcinomas, according to SEER data (Henson et al. 1992), but higher incidences have been reported in other studies, e.g., 3.5 % (Moskal et al. 1999). In a further study of 284 cases of gallbladder carcinoma, eight were of the small cell type (Guo et al. 1988). Among 159 gallbladder carcinomas, 5 had the histology of small or oat-cell carcinoma (Albores-Saavedra et al. 1981). Small cell carcinoma (oat-cell carcinoma) of the gallbladder typically occurs in elderly women with cholelithiasis (Albores-Saavedra et al. 1984; Sons et al. 1985; Fujii et al. 2001), with a biology that is clearly different from that of gallbladder carcinoid tumors (Albores-Saavedra et al. 2009). Among 22 published cases, 86 % were women and 14 % males (female to male, 6:1). The mean age of the women was 64 years and of the men 60 years. Cholelithiasis was present in 91 % (Johnstone et al. 1993). In a review of 73 reported cases (Mahipal and Gupta 2011), age at diagnosis ranged from 25 to 86 years (median age: 67 years), with a clear female predominance (66 % female,

34 % male). In one study of 12 cases, the difference in gender was less prominent, i.e., female/male ratio of 5:7 (Maitra et al. 2001). The majority of tumors was associated with cholelithiasis (review: Moskal et al. 1999). In 72 % of the cases, the tumors were pure SCC, while 28 % of cases showed a combined morphology. In 68 % of the patients, the tumor was associated with cholelithiasis. From the National Cancer Institute's SEER program (1973–2005), 54 cases of SCC of the gallbladder were identified. The female/male ratio was 2.2, and the mean age at diagnosis was 67.5 years.

Clinical Features

The biology of disease is characterized by a rapidly progressing course, with frequent metastases to locoregional lymph nodes (70 %), liver (64 %), and lung (10 %) (Ron et al. 1992; Moskal et al. 1999; Matsuo et al. 2000; Mithal et al. 2000; Pavithran et al. 2001; Bahadur et al. 2005; Usmani et al. 2010; Mahipal and Gupta 2011). The 10-year survival for these tumors was 0 % (Albores-Saavedra et al. 2009). The mean survival is less than 7 months (Johnstone et al. 1993). In a later review of 73 cases, the median survival was 9 months (range: 1–198 months; Mahipal and Gupta 2011). However, successful treatment by surgery and adjuvant chemotherapy has been reported (Imai et al. 2008). Similar to SCCs of the lung, gallbladder SCC may be associated with paraneoplastic syndromes (Albores-Saavedra et al. 1981, 1984), e.g., paraneoplastic sensory neuropathy (Uribe-Uribe et al. 2009) or paraneoplastic hyponatremia (Ng et al. 2010).

General Pathologic Features

Macroscopically, small cell carcinoma tends to grow as protruding tumors that detach from the gallbladder wall, owing to extensive necrosis (Guo et al. 1988).

The neoplasms are similar at light and electron microscopic levels to those developing in other anatomic locations. The tumors consist of both small, round cells and elongated, spindle-shaped cells with a scarce, ill-defined cytoplasm and hyperchromatic nuclei with plump chromatin ("salt and pepper chromatin"). The tumors may contain multinucleated cells and foci of adenocarcinoma. The round cells are arranged in compact, solid sheets, with poor stroma. Rosette arrangements may occur. There is extensive necrosis with preservation of intact tumor tissue around blood vessels, as seen in other locations. The characteristic crush artifacts are seen (Albores-Saavedra et al. 1981; Guo et al. 1988; Johnstone et al. 1993; Muraina et al. 1996; Moskal et al. 1999; Matsuo et al. 2000). Intestinal metaplasia may develop (Kuwabara and Uda 1998). Immunohistochemically, part of the tumors are positive for cytokeratins and/or vimentin (Guo et al. 1988). Most of the tumors are typically positive for neuroendocrine lineage markers, especially chromogranin A (Matsuo et al. 2000; Nau et al. 2010) and synaptophysin and neuron-specific enolase (Cavazza et al. 1991). Ultrastructurally, the tumor cells contain typical, round neurosecretory granules (Albores-Saavedra et al. 1981; Larraza-Hernandez et al. 1984; Cavazzana et al. 1991). All small cell carcinomas of the gallbladder demonstrated inactivation of the pRB/p16 pathway; 67 % showed loss of pRB expression, and the other 33 % lost p16 expression. 83 % of the tumors accumulated high levels of p53, whereas activating K-ras mutations were not found (Parwani et al. 2003). For the gallbladder, several examples of mixed carcinomas consisting of adenocarcinoma and small cell carcinoma have been described (Muto et al. 1984; Duan et al. 1991; Nishihara et al. 1994a; Okamoto et al. 2003; Oshiro et al. 2008). Small cell carcinomas of the gallbladder may contain foci of adenosquamous carcinoma (Iida and Tsutsumi 1992). Squamous differentiation has been observed in small cell neuroendocrine carcinoma of the ampulla (Sugawara et al. 2004). Small cell carcinoma of the gallbladder was found to be combined with unusual other malignancies, such as clear cell carcinoma (Piana et al. 2002) or sarcomatoid carcinoma (Takahashi et al. 2004).

Non-neuroendocrine Type of Small Cell Carcinoma (NNE-SCC)

Small cell carcinoma of the gallbladder of the non-neuroendocrine type (NNE-SCC) forms an enigmatic and probably heterogeneous tumor group. Many of the examples of NNE-SCC described in the pre-immunohistochemistry era would now be reclassified as small cell neuroendocrine carcinomas (see below), but there remains a small group of neoplasms that represent undifferentiated carcinomas composed of small cells with scant cytoplasm in the absence of neuroendocrine marker expression. These neoplasms may exist as "pure" lesions or develop in combination with adenocarcinomas (Nishihara et al. 1994a; Moskal et al. 1999). Small cell carcinoma of the gallbladder may be situated in, or surrounded by, well-differentiated adenocarcinoma (Nishihara et al. 1994a), suggesting the emergence of an undifferentiated subclone.

Neuroendocrine Type of Small Cell Carcinoma (NE-SCC)

NE-SCC has first been described in 1981 by use of the term oat-cell carcinoma (Albores-Saavedra et al. 1981). Less than 100 cases have been reported since. These neoplasms are further discussed in the paragraph on neuroendocrine neoplasms of the gallbladder.

Carcinoma of the Gallbladder with Osteoclast-Like Giant Cells

Introduction

Carcinomas with osteoclast-like giant cells are rare extraskeletal neoplasms composed of carcinoma of variable differentiation and numerous multinucleated giant cells in the stroma. This type of carcinoma most often occurs in the breast and in the pancreas, but it also develops in the extrahepatic bile duct system, including the gallbladder (Grosso and Gonzalez 1992; Ito et al. 1992; Amarapurkar et al. 2005; Akatsu et al. 2006; Albores-Saavedra et al. 2006). Carcinoma with osteoclast-like giant cells has to be distinguished from giant cell tumor with osteoclast-like giant cells or extraskeletal osteoclastoma, a benign neoplasm consisting of a mononuclear cell population and osteoclast-like giant cells, in the absence of carcinoma. Tumors located in the gallbladder may grow to relatively large and protruding lesions. As only very few cases have been documented, the biology of disease has not been systematically clarified. In one patient, the tumor metastasized to the liver, and this metastasis consisted predominantly of giant cells, with only a minor component of adenocarcinoma (Ito et al. 1992). The presence of giant cells in metastatic lesions has been confirmed in another study (Grosso and Gonzalez 1992).

Pathology

Histopathology

Histologically, the tumors reveal a basic proliferation of carcinoma being the main biologic feature of the neoplasm and an interstitium containing large multinucleated cells that are regarded as benign. The carcinomatous components were described as well-differentiated adenocarcinoma

(Ito et al. 1992) or adenosquamous carcinoma (Grosso and Gonzalez 1992; Akatsu et al. 2006). The carcinomatous components are spatially associated with monocytoid or macrophage-like mononuclear cells and multinuclear giant cells. The giant cells, representing fused macrophages, display a pale and slightly eosinophilic cytoplasm and contain dozens to more than 50 regularly structured nuclei which are ovoid and show a fine chromatin pattern, very much resembling nuclei of histiocytes. These osteoclast-like giant cells are usually distributed uniformly throughout the neoplasm. In the patient described by Ito and coworkers (1992), liver metastasis of the gallbladder carcinoma also showed osteoclast-like giant cells.

Immunohistochemistry

As in tumors with osteoclast-like giant cells located in other organs, the giant cells are reactive for markers of the monocyte/macrophage lineage, i.e., CD68 and HAM, whereas the macrophage-like mononuclear cells are CD163 positive (Albores-Saavedra et al. 2006).

Differential Diagnosis

Osteoclast-like giant cell tumor of the pancreas, where this lesion typically occurs, can metastasize to liver but also gallbladder (Sun et al. 1998). A second differential diagnosis is undifferentiated gallbladder carcinoma, giant cell type (Manouras et al. 2009), but the giant cells in this neoplasm are not osteoclast-like, CD68-positive elements, but epithelial tumor cells having a neoplastic character.

Carcinoma of the Gallbladder with Rhabdoid Features

Carcinomas with rhabdoid features are defined as usually poorly differentiated carcinomas containing a cell lineage resembling rhabdoid cells. In the gallbladder, a sarcomatoid carcinoma with rhabdoid features has been described. The tumor occurred in an elderly woman and presented macroscopically as a firm, solid, yellowish-gray, and granular mass with areas of necrosis. Histologically, the neoplasm was a biphasic sarcomatoid carcinoma consisting of pleomorphic cells, part of which of rhabdoid cell type, and neoplastic mucin-producing glandular structures. The rhabdoid cell co-expressed cytokeratins and vimentin, and ultrastructural examination revealed the typical cytoplasmic whorls of intermediate filaments. The tumor displayed an aggressive biology, with multiple intrahepatic metastases and omental seedings (Kim et al. 2003).

Differential Diagnosis

Differential diagnosis comprises metastases of other malignancies with rhabdoid features or the very rare primary rhabdoid tumor of the gallbladder (Suri et al. 2003).

Contents

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_152

Abstract

The gallbladder can be the primary site of rare cystic and mixed neoplasms. Cystadenoma and cystadenocarcinoma, now termed mucinous cystic neoplasms, very rarely develop in the wall of the gallbladder. These neoplasms can be restricted to the gallbladder or extend into the hepatoduodenal ligament. The malignant variant, cystadenocarcinoma, is an exceptionally rare neoplasm in the gallbladder. Sarcomatoid carcinomas, characterized by low differentiation and a marked spindle cell component, and various forms of carcinosarcoma can also develop as primary tumors in the gallbladder.

Cystadenoma and Cystadenocarcinoma of the Gallbladder

Introduction

Hepatobiliary cystadenoma and cystadenocarcinoma are rare primary neoplasms of the hepatobiliary tract, located in the liver substance of the extrahepatic biliary tract. Exceptionally, these tumors develop in the gallbladder. Cystadenomas and their malignant counterparts are characterized by conglomerates of macroscopically cystic lesions, the cysts being lined by a usually mucinous, much less often serous biliary-type epithelium. Underneath this epithelial lining, a cellular stroma may be in evidence, similar to the morphology found in other hepatobiliary cystadenomas and cystadenocarcinomas.

Cystadenoma of the Gallbladder

Relatively few reports documented the development of cystadenoma in the gallbladder (Botticelli and Ferrari De Gaetani 1968; Milicevic and Ostojic 1972; Mättig et al. 1982; Simmons et al. 1989; Devaney et al. 1994; Spector et al. 2003; Rooney et al. 2005; McCague et al. 2008; Gokalp et al. 2010). Similar to cystadenomas of the liver, gallbladder cystadenomas seem to prevail in females. Clinically, the tumors have caused upper abdominal pain, nausea, and vomiting, similar to other gallbladder tumors. Few patients experienced jaundice and/or fever. Cystadenoma may be limited to the gallbladder itself, producing a mass effect and sometimes massive gallbladder hydrops, but the neoplasms may also extend into the hepatoduodenal ligament and induce extrahepatic biliary obstruction (Mättig et al. 1982; Simmons et al. 1989). Sonography reveals medium-sized to large cystic lesions with multiple septal structures and sometimes papillary projections. On CT images, cystadenomas present as multilocular, multiseptated cystic structures originating from the gallbladder fossa. Low-density lesions (<30 H) with internal septa and nodules may be seen on CT.

Macroscopy

Macroscopically, gallbladder cystadenoma presents as well-delineated multicystic tumors with rather thin septa dividing the cysts from each other. In rare instances, cystadenoma formed a large polypoid mass that may prolapse into the common bile duct (McCague et al. 2008). The cysts contain a clear or opaque fluid that is sometimes viscid and with a positive spinning phenomenon (mucin-containing fluid). Some cysts may contain a hemorrhagic fluid or a coagulated proteinaceous matter.

Histopathology

Histologically, cysts are lined by a single layer of biliary-type epithelium or a pseudostratified biliary epithelium. Small papillary projections may develop. The cells are cuboid to prismatic, with a basally placed nucleus and a clear cytoplasm toward the cellular apex. In PAS and alkaline Alcian blue stains, the apical half of the cytoplasm shows accumulation of mucin. The nuclei resemble in shape and structure to cholangiocyte nuclei,

but they are slightly larger and may show a more coarse chromatin pattern, but nuclear atypias are usually of minor degree, and mitotic figures are hardly found. The subepithelial stroma is either poorly developed or may show the cellular features known from other hepatobiliary cystadenomas occurring in female patients.

Immunohistochemistry

Immunohistochemically, the tumor cells share an immunophenotype with cholangiocytes, being positive for cytokeratins 7 and 19. Whether stromal cells express sex steroid receptors, as seen in other hepatobiliary cystadenomas, is not known.

Cystadenoma Associated with Multiseptate Gallbladder

Gallbladder cystadenoma with transition to carcinoma has been found in conjunction with a multiseptate gallbladder, resulting in a unique clinico-radiologic phenotype (Sugawara et al. 2001). Multiseptate gallbladder is an extremely rare congenital anomaly characterized by multiple thin septa dividing the gallbladder lumen and sometimes resulting in a honeycomb appearance. The septa contain a muscular layer than is continuous with muscle of the gallbladder wall (Okuda et al. 1979; Isomoto et al. 1990; Strauss et al. 1993; Sugawara et al. 2001).

Cystadenocarcinoma of the Gallbladder

Cystadenocarcinoma of the gallbladder is even less common than cystadenoma. This phenomenon reflects what is known for other hepatobiliary cystadenomatous tumors, where carcinoma is an exceptional finding. In part of the cases, the tumor was clinically circumscribed, without evidence of malignancy, and diagnosis of carcinoma was found at histopathologic examination only (Nakagawa et al. 1990; Sistla et al. 2009). However, there are also observations documenting a clinically aggressive behavior of these neoplasms. In a 75-year-old man a multicystic tumor of 16 cm diameter was detected, showing the histology of cystadenocarcinoma. The neoplasm was invasive and had caused locoregional lymph node metastases. After extended resection, the patient remained without evidence of recurrence 12 months after surgery (Waldmann et al. 2006). In one patient, cystadenocarcinoma was associated with gallbladder cystadenoma (Terada et al. 2003), suggesting an adenoma-carcinoma sequence. In this case, dysplastic mucinous cells malignant papillotubular cells and invasive carcinoma cells were observed in the center of the tumor, while the cystadenoma component was localized to peripheral parts of the tumor. No ovarian-like stroma was detectable.

Differential Diagnosis

Radiologically, cystadenomatous tumors of the gallbladder may be mimicked by cystic gallbladder lymphangioma (Shikano et al. 2008), markedly cystic dilatation of Aschoff-Rokitansky sinuses, epithelial cysts of the gallbladder (Matsumoto et al. 2002), and hydatid gallbladder disease (Pitiakoudis et al. 2006). Very rarely, cystadenoma develops on the peritoneal surface and may involve the gallbladder niche (Krstic et al. 2005).

Spindle Cell Carcinoma (Sarcomatoid Carcinoma) of the Gallbladder

Introduction

Undifferentiated spindle cell carcinoma (SpCC) or sarcomatoid carcinoma of the gallbladder is a rare primary gallbladder malignancy. The nomenclature and classification of this type of carcinoma was complex and in part confusing, because at least three terms have been employed to denote this neoplasm, viz., spindle cell carcinoma, undifferentiated carcinoma (in part), sarcomatoid carcinoma, and carcinosarcoma. All three terms are based on the observation

that these carcinomas contain a spindle cell component that looks mesenchymal, suggesting the synchronous presence of an epithelial and non-epithelial cell lineage. This view has been changed by immunohistochemistry showing that the spindle cells co-express epithelial and mesenchymal markers. The finding of a bimodal differentiation pattern has led to the hypothesis that the spindle cell component is the dedifferentiated offspring of typical adenocarcinoma that co-occurs with spindle cell carcinoma in these lesions. A novel interpretation suggests that these neoplasms involve epithelial-mesenchymal transition.

In the present chapter, only carcinomas showing a spindle cell component, and not other heterologous components, are discussed. In addition, spindle cell carcinomas briefly discussed here are not those that are classified as "undifferentiated carcinoma" (Badmos et al. 2013; see the respective paragraph), although a marked overlap exists. The term carcinosarcoma should be reserved to malignancies in which the sarcomatous components consist of atypical mesenchymal elements other than cytokeratin-positive spindle cells, e.g., myosarcomatous, fibrosarcomatous, or osteosarcomatous components. The more precise definition of gallbladder carcinomas with a spindle cell component has to await novel criteria, including molecular features.

Epidemiology

Less than 20 cases have been reported, mostly involving patients older than 50 years, with females being more often involved than males (Iezzoni and Mills 1993; Nishihara and Tsuneyoshi 1993; Hotta et al. 2002; Arakawa et al. 2004; Takahashi et al. 2004; Akatsu et al. 2005; Kubota et al. 2006; Liu et al. 2009). In a study on 11 patients (8 women, 3 men), age at diagnosis ranged from 59 to 80 years (mean, 66.5 years) (Nishihara and Tsuneyoshi 1993). In a group of six patients, age at diagnosis ranged from 51 to 66 years (median, 58 years); five were females, one male (Liu et al. 2009).

Clinical and Imaging Features

Similar to other carcinomas of the gallbladder, the clinical presentation is nonspecific and consists of upper abdominal pain and fullness, weight loss, fever, and other systemic signs and symptoms of malignancy. On CT images, a thickening of the gallbladder wall is seen, similar to what is found on other invasive carcinomas of the gallbladder (Akatsu et al. 2005). SpCC are aggressive tumors with a poor outcome, even after curative resection and postoperative chemotherapy (Nishihara and Tsuneyoshi 1993; Liu et al. 2009).

Pathology

Macroscopy

The few cases where macroscopic features have been documented illustrate solid tumors with necrotic centers or polypoid lesions with an endoluminal growth pattern (Kubota et al. 2006).

Histopathology

The diagnostic feature of SpCC is hypercellular areas consisting of spindle cells that proliferate in a whirling or interlacing pattern. These elongated cells have a slightly eosinophilic or amphophilic cytoplasm and ovoid or oblong nuclei with minor atypia. Mitotic figures may be noted. SpCC may contain components of adenocarcinoma, with a gradual transition between the two different components (Akatsu et al. 2005). Foci of adenocarcinoma were detected in 8 out of 11 patients in one study. Two of the cases also had small foci of neoplastic squamous epithelium (Nishihara and Tsuneyoshi 1993). A case with undifferentiated small cell carcinoma was also described (Takahashi et al. 2004).

Immunohistochemistry

The neoplastic spindle cells are immunoreactive for cytokeratins, showing their epithelial character, but the cells also co-express vimentin

(Nishihara and Tsuneyoshi 1993; Kubota et al. 2006). In the largest published series (11 patients), AE1/AE3 was positive in nine, EMA in nine, and vimentin in eight cases (Nishihara and Tsuneyoshi 1993). The proliferative activity, as detected by Ki-67 immunostaining, was higher for spindle cells than for adenocarcinoma cells (Kubota et al. 2006).

Pathogenic Pathways

A common origin of spindle cells and conventional adenocarcinoma cells has been proposed, with spindle cells originating from carcinoma through dedifferentiation (Akatsu et al. 2005). A pluripotent progenitor cell may also be involved, similar to what has been proposed for carcinosarcomas (Ajiki et al. 2002). In SpCCs, homogeneous allelic losses (chromosomes 5q, 11q, 17p, and 18q) were identified in both the carcinomatous and sarcomatoid components, suggesting that SpCC had a single clonal origin (Arakawa et al. 2004). This hypothesis has also been formulated to explain the concurrent development of epithelial and mesenchymal cell lineages in carcinosarcomas. As the spindle cells in SpCC exhibit an epithelial immunophenotype, epithelial-mesenchymal transition (EMT) may also represent a pathogenic pathway operational in spindle cell carcinomas occurring in various organs.

Gallbladder Carcinoma with Osseous Stromal Metaplasia and Calcified Gallbladder Carcinoma

Introduction

Stromal osseous metaplasia (SOM) denotes an alteration in certain carcinomas characterized by the development of bone, mainly osteoid trabecules, within the fibroblastic (desmoplastic stroma), this bone being reactive rather than neoplastic. An alternative term is metaplastic stromal ossification. SOM has been found in several types of carcinomas, including colorectal carcinoma (Arnal Monreal et al. 1992; Pai et al. 1993), breast cancer (Kijima et al. 2006; Tsukuda et al. 2009), squamous cell carcinomas (Marioni et al. 2004), renal cell carcinoma (Kuroda et al. 2005), urothelial carcinoma (Mege-Lechevallier et al. 2007), ovarian carcinoma (Mukonoweshuro and Oriowolo 2005), and hepatocellular carcinoma (Leger et al. 1980; Maeda et al. 1986).

Stromal Osseous Metaplasia in Gallbladder Tumors

Extensive osseous metaplasia was observed in metastases of a gallbladder adenocarcinoma (Cavazza et al. 1999).

Differential Diagnosis

The main differential diagnosis are carcinosarcomas of the gallbladder having an osteosarcomatous component (Nakagawa et al. 1996). These lesions can be distinguished based on the atypical bone formation with malignant osteoblasts, while metaplastic bone in tumor stroma is reactive and presents as any immature normal bone.

Pathogenic Pathways

Tumor stroma cell populations contain mesenchymal stem cells that harbor an osteoprogenitor cell lineage. This type of pluripotent mesenchymal cells seems also to be present in the gallbladder wall, as bone metaplasia may occur in chronic cholecystitis and other reactive chronic gallbladder disorders (Indyk and Shipton 1957; Duchini 1967; Yosepovich et al. 2002).

Calcified Carcinoma of the Gallbladder

Calcified carcinoma is a very rare entity characterized by the presence of extensive calcification within an adenocarcinoma. In one case of calcified gallbladder carcinoma, the calcified deposits were

located within or replaced the glandular structures of the carcinoma, but were not detectable in the stroma. Extensive cancer calcification was also found in lymph node metastases (Yun et al. 2011).

Carcinosarcoma and "Malignant Mixed Tumors" of the Gallbladder

ICD-O code 8980/3

Introduction

Carcinosarcoma of the gallbladder is a very rare and highly aggressive tumor of unknown histogenesis characterized by malignancy of both epithelial and mesenchymal components of the same tissue, forming a complex mixture of neoplastic lineages. The term, carcinosarcoma, was coined in 1864 by Rudolf Virchow (1864). Carcinosarcomas can occur in almost all organs, but they are most common in the uterus. The first case of carcinosarcoma of the gallbladder was reported in 1907 by Landsteiner, who identified this type of tumor in a museum specimen (Landsteiner 1907). Since then, less than 100 cases have been reported in the literature.

Epidemiology

Carcinosarcoma of the gallbladder is one of the rarest malignancies of this organ and is reported to account for 1.7 % of all malignant gallbladder tumors (Born et al. 1984). The tumor is usually associated with cholelithiasis (present in 83 %; Roth et al. 1972) and mainly occurs in females in the sixth decade of their lives, the age range at diagnosis being from 45 to 91 years. In a review as of 2009 (Kohtani et al. 2009), only nine patients reported up to 2009 were older than 80 years at diagnosis, eight females and one male. After the first description in 1907 there was a time gap before very few additional tumors were reported (Kritsch 1925; Kleinknecht et al. 1931), followed by more cases to be described after the 1950s.

Clinical and Imaging Features

Clinical features include an upper abdominal mass, pain in the right hypochondrium (sometimes colicky pain, chiefly in the presence of stones), fever, malaise, and weight loss. Colicky pain may sometimes be due to the synchronous presence of gallstones, cholecystolithiasis being present in more than 70 % of patients. Carcinosarcoma of the

gallbladder can invade the extrahepatic bile duct system and form obstructing bile duct tumor thrombi (Wang et al. 2013). Carcinosarcoma may produce marked hemorrhage and cause hemobilia (Sadamori et al. 2012). Carcinosarcoma of the gallbladder may rarely produce paraneoplastic syndromes. Leukocytosis caused by secretion of granulocyte colony-stimulating factor by the tumor was observed (Shimada et al. 2009).

Carcinosarcoma of the gallbladder is a highly aggressive neoplastic disorder with a dismal prognosis which, so far, is usually treated by surgery, as optimal adjuvant chemotherapy and/or radiotherapy protocols are not yet available. In a literature review of 36 published cases of tumors treated with surgical resection, the 3-year overall survival rate was only 31.0 % and the median survival time was 7.0 months (Okabayashi et al. 2009). However, single cases with more favorable outcome following surgery and chemotherapy have also been reported (e.g., no evidence of disease 48 months after surgery; Kohtani et al. 2009). Currently, carcinosarcoma cannot yet stratified as to risk of progression and poor outcome, but tumor size seems to be a prognosticator, as tumors which were smaller than 5 cm in diameter were associated with long survival (Zhang et al. 2008). On the other hand, TNM stage is not a predictor of outcome. In studies comparing T stages II–IV it turned out that mean survival time was low regardless of the T status (Lumsden et al. 1988; Fagot et al. 1994; Liu et al. 2009).

Ultrasonography, CT, and ERCP usually disclose large and sometimes ill-defined gallbladder masses with or without associated gallstones (Hotta et al. 2002). A solid mass containing cystic patencies is sometimes seen on abdominal ultrasonography (Uzun et al. 2009). CT often shows a dilated gallbladder with irregular thickening of the wall and an intraluminal mass (Born et al. 1984; Eriguchi et al. 1999). Calcification within the tumor may be noted (Grote and Kaemmerer 1986) and may in fact lead to diagnosis (Ishida et al. 2012). On CT, the pericholecystic mass may invade adjacent organs, e.g., the hepatic flexure of the colon (Huguet et al. 2005). Rarely, the tumor presented with a huge cystic lesion (Emmoto et al. 1993).

Pathology

Macroscopy

Gallbladder carcinosarcomas are typically large and friable masses of whitish-gray color, showing variable degrees of hemorrhage and necrosis. The tumor can present with endophytic growth, forming polypoid masses (Bousquet et al. 1986; Inoshita et al. 1986; Lumsden et al. 1988; Fagot et al. 1994; Ajiki et al. 2002; Takahashi et al. 2004; Uzun et al. 2009). In tumors with chondroid and/or osteoid differentiation, cartilaginous components may be visualized as pale and transparent parts that are more form than the other tissues, while osteosarcoma may be seen as whitish and firm speckles with or without gross calcifications. In rare cases, the tumor can invade the bile duct system, forming bile duct tumor thrombi resulting in biliary obstruction (Wang et al. 2013).

Histopathology

The epithelial component is usually adenocarcinoma with variable tubular components, but squamous cell carcinoma and mixed adenocarcinoma and squamous cell carcinoma are also known (Herrera-Goepfert et al. 1987; Krishnamurthy et al. 2011; Park et al. 2012). Rarely, the carcinomatous component consisted of small cells and undifferentiated cells (Takahashi et al. 2004). At least at certain places, the diverse types of carcinoma cells blend more or less continuously with sarcoma cells, a characteristic feature of carcinosarcomas.

A frequent mesenchymal component are dense accumulations of spindle cells (Fagot et al. 1994; Hotta et al. 2002; Takahashi et al. 2004; Kubota et al. 2006; Uzun et al. 2009). This cell type is sometimes closely intermingled with epithelial cells forming tubules, or shows apparent transition to epithelial cells, suggesting epithelial-mesenchymal transition. In few cases, the spindle cell component has been termed, fibrosarcoma

(Von Kuster and Cohen 1982; Born et al. 1984). Spindle cell sarcoma has been found in combination squamous cell carcinoma (Kitagawa et al. 1992; Huguet et al. 2005). Chondroid neoplastic tissue is a well-known heterologous component (Mansori and Cho 1980; Von Kuster and Cohen 1982; Ajiki et al. 2002; Oberoi et al. 2006). These components appear as small and in part nodular islands of chondroid tissue with variable amounts of cartilage matrix and atypical chondroblasts. These foci sometimes show a direct transition into adenocarcinoma, a phenomenon that has led to terms such as adenocarcinoma with chondrosarcomatous component (Zheng et al. 2006). In contrast to the presence of chondroid/chondrosarcomatous tissue, an osteosarcomatous component is rare (Aldovini et al. 1982; Nakagawa et al. 1996). The tumor described by Aldovini et al. (1982) showed close intermingling of epithelial and mesenchymal components and malignant osteoblasts representing osteosarcoma and was interpreted as malignant mixed mesodermal tumor of the gallbladder. In gallbladder carcinosarcoma, adenocarcinoma can coexist with rhabdomyosarcoma of variable differentiation. In one case, the rhabdomyoblastic cells were immunoreactive for myoglobin, myosin, and muscle actin, and ultrastructurally they showed various stages of rhabdomyoblastic differentiation (Ishihara et al. 1990).

Leiomyosarcoma is a very rare component, or has at least only rarely identified as such (Yamagiwa 1971), what may be related to the lack of immunohistochemical techniques in older studies. In a minority of cases, the mesenchymal component presents as undifferentiated sarcoma with round and/or pleomorphic cells (Herrera-Goepfert et al. 1987). The presence of rhabdoid tumor tissue components in gallbladder carcinosarcoma is an exceptional finding. In one tumor observed in a 61-year-old female, the neoplasm revealed a biphasic sarcomatoid carcinoma with diffusely arranged pleomorphic cells, focally showing rhabdoid features, and neoplastic glands with focal mucin production. Immunohistochemically, the rhabdoid cells co-express cytokeratin and vimentin (Kim et al. 2003). Cases with combined heterologous elements are known, e.g., osteoid, cartilage, and rhabdomyoblasts. In one of such tumors, the metastases only showed a combination of adenocarcinoma and rhabdomyosarcoma (Inoshita et al. 1986).

Immunohistochemistry

In the light of the dual differentiation of carcinosarcomas, immunohistochemical investigations are an inevitable method for diagnosis and differential diagnosis. Spindle cell components are reactive for both cytokeratins and vimentin (Hotta et al. 2002; Uzun et al. 2009), suggesting that this cell lineage has undergone mesenchymal-epithelial transition (MET), although cytokeratin reactivity of spindle cells is sometimes weak (Kubota et al. 2006), and there are tumors in which spindle cells exclusively express vimentin (Khanna et al. 2013). Also the cells found in chondroid components express, in addition to vimentin, cytokeratins (Ajiki et al. 2002).

Variants of Carcinosarcoma of the Gallbladder

Exceptionally, synthesis and secretion of AFP was detected in these tumors, a phenomenon also present in subsets of bile duct and gallbladder carcinomas. In a 69-year-old male patient with elevated serum AFP, gallbladder carcinosarcoma was immunoreactive for AFP. This tumor also produced granulocyte colony-stimulating factor associated with peripheral leukocytosis as a paraneoplastic syndrome (Shimada et al. 2009).

Malignant Mixed Tumors of the Gallbladder

Several examples of malignant gallbladder neoplasms characterized by complex mixtures of carcinomatous and various mesenchymal components have previously been described by use of the terms, malignant mixed tumor or malignant

mixed mesodermal tumor. These lesions should now be classified as carcinosarcomas (Sagi and Gyori 1972; Higgs et al. 1973; Mansori and Cho 1980; Aldovini et al. 1982; Carlson and McPherson 1982; Von Kuster and Cohen 1982). However, some of the neoplasms exhibit a highly complex composition and appear as multilineage tumors. For example, mixed adenoneuroendocrine carcinoma of the gallbladder also showed squamous cell carcinomatous and osteosarcomatous differentiation (Shintaku et al. 2013).

Differential Diagnosis

Carcinosarcoma has to be distinguished from carcinomas with a spindle cell component, a feature also seen in variants of undifferentiated carcinoma of the gallbladder.

Pathogenesis

The histogenesis of carcinosarcoma has not been elucidated. Some authors proposed an origin from mesenchymal (stromal) cells present in adenocarcinomas and other types of carcinomas (Kadono et al. 2005). Potential pathogenic mechanisms also include epithelial-mesenchymal transition resulting in diverse types of heterologous components. Epithelial-mesenchymal transition has been documented in pulmonary carcinosarcoma (Thomas et al. 2012) and in uterine carcinosarcoma, where a role of the Akt/beta-catenin pathway (Saegusa et al. 2009) and of several species of microRNA (Castilla et al. 2011) has been discovered. Finally, an origin from a pluripotent tumor stem or progenitor cells capable to be primed for several cell lineages may be anticipated.

Abstract

The gallbladder epithelium can give rise to a spectrum of adenomatous, borderline, and dysplastic lesions. Adenomas of the gallbladder are benign neoplasms of the glandular epithelium, often with various forms of differentiation. These tumors are usually small and solitary lesions that are asymptomatic in the majority of cases and often associated with cholelithiasis. Tubular, papillary, and tubulopapillary growth patterns are distinguished. Differentiation patterns include biliary type, pyloric-gland type, intestinal type, and foveolar type. Part of these neoplasms can contain Paneth cells, keratinocytes, neuroendocrine cells, or oncocytes. One special form is characterized by a solitary or diffuse papillary growth (gallbladder papilloma), a lesion sometimes associated with papillomatosis of the cystic duct and extrahepatic bile ducts. A small subset of preinvasive neoplastic gallbladder polyps show a complex mixture of papillary and tubular patterns and are termed intracholecystic papillary-tubular neoplasm.

Adenoma of the Gallbladder

ICD-O codes:

Adenoma	8140/0
Tubular Adenoma	8211/0

Introduction

Adenomas of the gallbladder (AG) are benign neoplasms of the glandular epithelium of the gallbladder, typically with various forms of differentiation. AG are usually small and solitary lesions that do not cause signs or symptoms in the majority of persons, but AG are significant as a potential origin of malignancy. Most AG are associated with cholelithiasis, in contrast to adenomas in the large bile ducts (reviews: Christensen and Ishak 1970; Albores-Saavedra et al. 1993, 2010, 2012; Zhang et al. 1994; Levy et al. 2002.

Epidemiology

AG is a rare lesion, whereas gallbladder polyps are relatively common alterations. Gallbladder polyps are found in approximately 5 % of the worldwide population (Myers et al. 2002; Lee et al. 2004). In a study of 194,767 asymptomatic patients undergoing ultrasonographic examinations, 10,926 patients revealed gallbladder polyps (5.6 %; Okamoto et al. 1999). The prevalence of AG is much lower, but the exact prevalence is not known. Some authors estimated that 95 % of gallbladder polyps are nonneoplastic (i.e., cholesterol polyps or inflammatory/hyperplastic polyps and polypoid adenomyosis), while AG are estimated to account for about 5 % of gallbladder polyps (Lillemoe 2006). Among 123 polyps, four cases of AG (3.2 %) were histologically diagnosed (Escalona et al. 2006). In one study, AG were found in 10 % of patients with gallbladder polyps (Ito et al. 2009).

An early investigation (Wellbrock 1934) showed AG in 69 gallbladders among a series of 9,550 cholecystectomies. Within a series of 1,847 cholecystectomies, 34 AG were identified (1.8 %). Nine carcinomas in situ developing in adenomas were found, and in 8 AG, invasive carcinomas were detected (all of well-differentiated types). Patients with carcinomas in AG were on average older than those with benign adenomas (Lee et al. 2010). In another study of 2,600 surgical specimens of cholecystectomy, an incidence of AG of 0.55 % was found (Zhou 1985). Farinon et al. (1991) found 9 AG among 2,145 cholecystectomies (0.4 %). AG occur more often in female patients (Zhou 1985; Albores-Saavedra et al. 2012). Very rarely, AG had been observed in the pediatric age group (Mogilner et al. 1991; Stringer et al. 2003; Ersöz et al. 2004).

Clinical and Imaging Features

Most AG, and in particular small lesions, are asymptomatic, but few patients experience abdominal pain or discomfort (Tanous et al. 1960; Perazo 1967; Botticelli et al. 1968; Hultén et al. 1970; Sawyer 1970; Brambs et al. 1986;

Logani et al. 1995; Terzi et al. 2000). In a minority of cases, large polypoid lesion may cause obstruction of the gallbladder outlet and is associated with recurrent biliary colic (Pila et al. 1991). Polypoid lesions of the gallbladder are commonly found on ultrasonography and CT images, and part of these lesions are polypoid AG that project into the gallbladder lumen (Kumagai et al. 2006; Tomic et al. 2011). AG can reliably be identified by MR, whereby a high b-value DWI (diffusion-weighted MR imaging) may be useful for differentiating between benign and malignant polypoid gallbladder lesions (Irie et al. 2011).

Pathology

Macroscopy

AG are usually flat, sessile, or pedunculated/polypoid lesions. They are commonly solitary tumors, but multiple AG are found in up to 10 % of cases (Lin and Hägerstrand 1983). In a study of 201 AG, 91 % were single lesions, but one gallbladder showed 102 adenomas (Albores-Saavedra et al. 2012). Most AG have a diameter of less than 20 mm. Most tubular AG display a lobular or globular contour, in contrast to the cauliflower-like configuration of papillary adenomas. The tumors show either a smooth or finely granulated surface and a whitish to pinkish or yellowish color. Large lesions can show superficial ulceration and/or small hemorrhages. The majority of AG have been found in association with cholelithiasis. In rare situations, tubulopapillary adenoma may cause intrabile duct tumor thrombus in the absence of malignancy (Yamamoto et al. 2014).

Histopathology

The histopathology of AG has been described and reviewed in detail (Table 1; Yamamoto et al. 1988; Ono and Masamune 1996a; Katabi 2010; Albores-Saavedra et al. 2010, 2012). AG can be divided into three types based on their growth pattern: tubular, papillary, and tubulopapillary.

Table 1 Growth patterns and differentiation patterns of adenomas of the gallbladder

Growth patterns
Tubular
Papillary
Tubulopapillary
Differentiation patterns (including "metaplasia")
Biliary type (normal counterpart of gallbladder epithelium)
Pyloric-gland type (pyloric-gland adenoma)
Intestinal type (intestinal-type adenoma)
Foveolar type (foveolar-type adenoma)
Other cellular components
Spindle cells
Paneth cells
Squamous epithelial cells (keratinocytes)
Neuroendocrine cells
Oxyphilic cells
Oncocytic cells

The papillary variant of AG is discussed in a separate paragraph. The main histologic differentiation patterns include pyloric-type, intestinal, foveolar, and biliary morphologies. Pyloric and intestinal adenomas are more common that in the extrahepatic bile ducts.

Pyloric and intestinal adenomas typically show a tubular-glandular growth pattern. In a large part of AG, a pyloric gland-type histology predominates (*tubular adenoma*, *pyloric-gland type*; *pyloric-gland adenoma*; Fig. 1), the most important member of so-called metaplastic adenoma (Yu and Kim 1985; Vieth et al. 2003; Constantea et al. 2008; Belekar et al. 2009). Small lesions have a globular or lobular shape, while large lesion develops a pedicle or stalk and project into the gallbladder lumen as polypoid lesions. Similar to colorectal adenomas with "metaplastic" changes, the question as to whether the occurrence of pyloric-type or intestinal-type epithelia in AG reflects true metaplasia is not yet settled. Pyloric-gland adenoma displays lobules of densely packed glands consisting of cells closely resembling the cells of pyloric glands, typically situated underneath a normal-looking biliary-type surface epithelium. Some of the glandular structures are cystically dilated. By definition, pyloric-

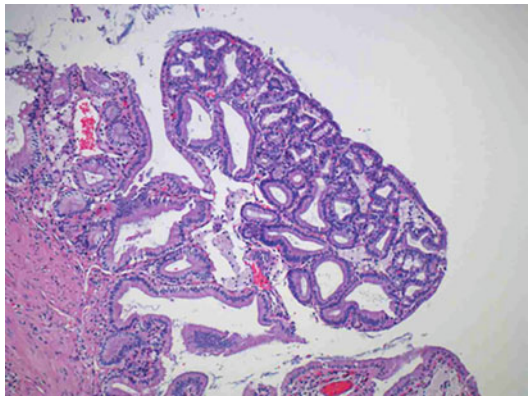

Fig. 1 Tubular adenoma of the gallbladder with polypous growth (hematoxylin and eosin stain)

gland AG have at least low-grade intraepithelial neoplasia, and particularly large lesions may show high-grade dysplasia or even carcinoma in situ or early invasive adenocarcinoma. In the study of Albores-Saavedra and coworkers (2012), high-grade dysplasia/carcinoma in situ was found in 27 % of 165 pyloric-gland adenomas and low-grade dysplasia in 15 %. In contrast, high-grade dysplasia was detected in 46 % of 28 intestinal adenomas, and foveolar adenomas only showed low-grade dysplasia.

The intestinal type of AG (*intestinal-type adenoma*) is less common than its pyloric counterpart. It is characterized by the presence of columnar intestinal cells arranged in a fashion closely resembling colorectal adenomas, often associated with dysplastic alterations. *Foveolar-type AG* is composed of tall columnar cells with basally placed hyperchromatic nuclei and a mucin-rich cytoplasm that expresses MUC5AC and MUC6. It is of importance to note that a biliary cell lineage (*biliary-type adenoma*) is involved in only a minority of cases of AG. Among 201 AG, 82 % were classified as pyloric, 14 % as intestinal, 2.4 % as foveolar, and 1.4 % as biliary (Albores-Saavedra et al. 2012).).

In addition to these main morphologies, some AG can contain other cellular elements of intestinal lineages, e.g., Paneth cells. Oxyphilic cells (Albores-Saavedra et al. 2012) and oncocytic elements (Lespi 1997) may occur. In tubular adenoma, squamous metaplasia was observed (Colovic et al. 2006). In some of these cases, the squamoid cell component undergoes a spindle cell change (Nishihara et al. 1991; Kushima et al. 1996). Rarely, spindle cell components lack intercellular bridges and signs of cytoplasmic keratinization (Yim et al. 1998). The latter type of AG is characterized by closely packed tubules of variable size arranged in lobules. Within these areas, spindle cell metaplasia is found in the form of solid morular foci of blunt spindle cells forming hypercellular nests and whirling arrangements situated between tubular profiles. Immunohistochemically, the spindle cells were reactive for one or more cytokeratins, but for vimentin (Yim et al. 1998), suggesting their epithelial lineage or the effect of epithelial-to-mesenchymal transition.

Immunohistochemistry

In contrast to adenocarcinoma, AG have a low level of MUC1 expression, whereas expression of MUC5AC is higher in AG than in gallbladder carcinoma cells (Xiong et al. 2012). In pyloric gland-type AG, 30 % or more of the epithelial cells were reactive for mucin MUC5AC in 38 % of the tumors, for human gastric mucin in 50 %, MUC6 in 100 %, and M-GGMC-1 in 93 %, while MUC2 was not detectable, supporting the presence of a pyloric-type cell lineage (Nagata et al. 2007). In the large study of Albores-Saavedra et al. (2012), MUC5AC and MUC6 labeled 95 % of pyloric gland-type adenomas, while MUC2 was found in 33 % of intestinal-type adenomas.

Immunohistochemically, part of AG share expression features with gallbladder carcinomas, but in regard to several markers, there is a marked difference between AG and gallbladder adenocarcinoma, and these differences also refer to molecular features (Wistuba et al. 1999). A subset of AG show nuclear reactivity for the tumor suppressor, p53 (Takei et al. 1996; Billo et al. 2000). In one analysis, expression of p53 was found in 16.6 % of AG, while it was seen in 83.3 % of gallbladder carcinomas (Arevalo et al. 2007). A similar figure was reported from another investigation (17.6 %; Wang et al. 2006). The pathways leading to p53 expression in AG are not yet known, as no p53 gene mutations were detectable in AG

(Kim et al. 2001). AG showed a significantly stronger cytoplasmic and nuclear expression of beta-catenin than gallbladder carcinomas, and beta-catenin exon 3 mutations were observed in 62.5 % of AG, but only 4.8 % of carcinomas, suggesting that abnormalities of the beta-catenin pathway may not play a central role in gallbladder carcinogenesis (Yanagisawa et al. 2001). Similarly, AG more commonly exhibit mutations in the RAS/RAF/MAP kinase signaling pathway than gallbladder carcinomas (Pai et al. 2011). S100A8 is overexpressed in gallbladder carcinomas in comparison with AG and other benign epithelial neoplasms (Wang et al. 2013). Expression of annexin A1 (ANXA1) and annexin A2 (ANXA2) is significantly higher in adenocarcinoma than in benign lesions, and benign gallbladder lesions such as AG with positive ANXA1 and/or ANXA2 expression show mild to severe epithelial atypia, suggesting that ANXA expression is a marker of progressive cancerization (Yang et al. 2010). Gallbladder carcinomas display a higher expression of the neurotrophic factor, brain-derived neurotrophic factor/BDNF than AG (Xiong et al. 2013), and more often express cyclin E than AG (Jin et al. 1997). In contrast to carcinomas, no decrease in expression of p27 (Kip1) was found in AG (Hui et al. 2000). Immunostaining for ERK1/2 was detected in 20 % of polypous AG, in contrast to 58.3 % in gallbladder adenocarcinoma (Li and Yang 2009). The progression along an adenoma-carcinoma sequence is associated by expression of cyclooxygenase-2 (Seki et al. 2002). Estrogen receptors can be detected in the gallbladder in various disease states, including AG (Yamamoto et al. 1990).

Gallbladder Adenoma and Carcinogenic Pathways

Pyloric-gland AG have, by definition, at least low-grade intraepithelial neoplasia. However, fraction of AG show severe epithelial dysplasia or carcinoma in situ, suggesting that there exists an adenoma-carcinoma sequence in the gallbladder (Kozuka et al. 1982; Pradines et al. 1988; Yamamoto et al. 1988; Nakajo et al. 1990; Chang et al. 1997; Watanabe et al. 1999; Sasatomi et al. 2000; Turrini et al. 2007; Ciurea et al. 2008; Trivedi et al. 2008). In fact, over 80 % of invasive gallbladder carcinomas present areas adjacent to epithelial dysplasia or carcinoma in situ (Roa et al. 2006). In a study of 17 AG, 72.7 % of metaplastic adenomas and 33.3 % of non-metaplastic adenomas showed foci of atypical gland proliferation (Nakajo et al. 1990). In patients with primary sclerosing cholangitis, gallbladder polyps were reported to be frequently malignant (Buckles et al. 2002). Whether these malignancies arising in or manifesting as polyps tend to originate from adenomas is not known.

Differential Diagnosis

In the setting of imaging approaches, the differential diagnosis between AG and cholesterol polyps based on ultrasonography may be difficult (Park et al. 2013). Apart from AG, sessile lesions are sometimes hyperplastic polyps (Sato et al. 1985).

Pathogenic Pathways

Polypous AG has been observed in Gardner's syndrome (Brevet et al. 2007) and in juvenile polyposis syndrome caused by SMAD4 mutation (Schwetz et al. 2012).

Villous Adenoma: A Rare Markedly Exophytic Variant of Papillary Adenoma

Introduction

Villous adenoma, a term still found in the literature, can be classified as a solitary papillary adenoma with a prominently exophytic growth mode. Similar to the large bile ducts, villous adenoma of the gallbladder is a very rare solitary adenoma with an arborizing papillary structure resembling the long villous structures seen in the respective colorectal adenomas (Kimura et al. 1994;

Nagahama et al. 1997; Krstic et al. 2007; Jin et al. 2013). Villous adenoma is a very rare lesion and was found only twice among 533 cholecystectomies (0.38 %) and in 1 patient among 1,300 randomly selected autopsies (0.08 %) (Kimura et al. 1994). There is overlap between lesion termed "villous" and those termed "papillary" (see below), the most important distinguishing features being the distinct gross presentation and the long finger-like projections in the former.

Pathology

Macroscopy

Villous adenoma is a solitary, polypoid tumor that may exceed a diameter of 5 cm and occupy a large part of the gallbladder lumen. It usually reveals as stalk and an exophytically growth part with a granular, cauliflower-like surface resembling villous adenomas of the colorectal region.

Histopathology

Villous adenoma displays a villous architecture with a regular arborization of long papilliform and densely crowded structures having a delicate fibrovascular stromal axis lined by a single layer of tall columnar cells with basally placed nuclei. The stromal axis may show apical edema (Krstic et al. 2007). Low-grade nuclear atypia is a common finding, but focal high-grade dysplasia or even carcinoma in situ have been reported (Krstic et al. 2007). The principal lesion may be accompanied by small tubular adenomas (Krstic et al. 2007). In villous adenoma with nuclear atypia, immunoreactivity for CEA and CA 19-9 was detected (Kimura et al. 1994).

Differential Diagnosis

Differential diagnosis includes papillary adenomas that do not show the elongated villous profiles of villous adenoma, although there is an overlap between the two lesion groups.

Solitary and Diffuse Papillary Adenoma (Papilloma): A Rare Form of Gallbladder Adenoma

ICD-O Code 8260/0

Introduction

Papillary adenoma (PA; synonyms: papilloma, villous papilloma, villous tumor) is a very rare form of adenoma of the gallbladder, characterized by a predominantly papillary growth pattern forming solitary or diffuse lesions in the gallbladder mucosa. Possibly or probably part of large (>1 cm) papillary lesions described in the literature rather belong to the novel category of preinvasive tumors called intracholecystic papillary-tubular neoplasms (see below).

Epidemiology

The incidence of papillary variants of gallbladder adenoma is not known, as most published observations referred to single cases. PA was apparently first described in 1899 (Ringel 1899). After this report, few other cases were published (Hansson 1905; Pels-Leusden 1906). PA of the gallbladder was described and classified in more detail in 1910 based on one case observed among 365 resected gallbladders (MacCarthy 1910). In a series of 2,168 gallbladders examined between 1907 and 1915, 85 specimens with one or more papillary lesions were seen, however without specifying the histopathologic features (Irwin and MacCarthy 1915). Abell found two PA among 288 cholecystectomies (Abell 1923). Swinton and Becker found 4 PA among 4,553 resected gallbladders (Swinton and Becker 1948). Relatively few observations were published in the first half of the twentieth century (Dominici 1911; Mayer 1911; Mayo 1915; Scoenlank 1915; Hruska 1916; Mölle 1916; Henry 1933; Phillips 1933; Kerr and Lendrum 1936; Brown and Cappell 1937; Greenwald 1944; Miller 1946; McHardy and Edwards 1948). In 1936, only 7 observations

of confirmed gallbladder PA were listed Kerr and Lendrum (1936). PA was since increasingly reported, with or without associated biliary tract papillomatosis.

Solitary lesions are much more common than the multicentric/diffuse forms, which represent a rare gallbladder pathology which was first described in 1911 (Dominici 1911). Further cases were described, only in part confirmed with histologic examination (Henry 1933; Brown and Cappell 1937; Marek 1955; Griffiths 1956; Cantey and Josey 1958; Morrison and Stewart 1956; Daneo and Rosso 1963; Graziani et al. 1965; Almagro 1985; Arunabh et al. 1988; Nakajo et al. 1988). In most cases, solitary or diffuse PA develops in the absence of preexisting underlying hepatobiliary disease, albeit a rare example of diffuse PA of the gallbladder was observed in the setting of ulcerative colitis and sclerosing cholangitis (Almagro 1985).

Clinical and Imaging Features

The clinical presentation depends on the growth patterns and the size of papillary lesions. Small solitary PA are often asymptomatic and are identified incidentally in the setting of cholecystectomy performed for other reasons. Large solitary villous lesions are sometimes associated with abdominal pain (Kao and Ruchim 1990) and acute abdomen (Mohandas et al. 1972) or may cause obstruction of the gallbladder outlet and lead to hydrops or even mucocele (Bazira et al. 1998), or biliary colic (Niv et al. 1986). In case of large PA, part of the tumor may detach, translocated distally as a floating fragment, and cause obstruction of the bile duct (Molina et al. 1988). Large lesions may rarely cause compression of the bile duct confluents and result in intermittent jaundice (Izinger 1964). Multiple PA often fill the entire gallbladder and can become symptomatic. Multiple PA of the gallbladder are most commonly symptomatic in patients where these lesions are associated with generalized bile duct system papillomatosis. PA has been observed in conjunction with regurgitation of pancreatic juice through an abnormally shaped pancreatobiliary union (Yamaguchi et al. 1989).

One of the early reports of gallbladder PA described a variant with intestinal-type epithelium and chloride secretion Kerr and Lendrum (1936). This papilloma deviated considerably in its histologic phenotype from ordinary gallbladder papillomas, in that it contained a partially intestinal cell lining with Paneth cells and enterochromaffin cells. In one patient, diffuse gallbladder PA was complicated with tuberculosis and granulomatous cholecystitis (Nakajo et al. 1988). In PA, abdominal sonography and imaging reveal characteristic filling defects caused by the exophytic mucosal lesions (Hilliard 1956; Pohlandt 1957; Carter et al. 1978; Porta et al. 1981). In case of diffuse biliary tract papillomatosis with involvement of the gallbladder, the exophytic lesions are visualized by use of endoscopic ultrasound and endoscopic retrograde cholangiopancreatography/ERCP (Kliment et al. 2011).

Papilloma and Papillomatosis of the Gallbladder: Biology of Disease and Status as a Preneoplastic Disorder

PA can remain unchanged for long time periods after a growing phase and behave in a benign

manner. Exceptionally, they undergo circulation disorders followed by spontaneous amputation (Goinard and Pelissier 1958). However, similar to other forms of gallbladder adenoma, PA can undergo dysplastic changes resulting in carcinoma in situ and then invasive carcinoma, reflecting an adenoma-carcinoma sequence (Hruska 1916; Tabah and McNeer 1953; Ochsner and Gage 1956). Transformation into adenocarcinoma, sometimes of the papillary and exophytically growing type, was mainly found in patients with diffuse, multicentric gallbladder papillomatosis (Interlandi and Minchio 1979; Nakamura et al. 1987; Kunisch et al. 1997; Kosemehmetoglu et al. 2011). Either adenocarcinoma is detected as synchronous lesion (Khan and Singh 2012) or carcinoma is found in patients with gallbladder adenomas known or suspected for longer time periods, the latter situation being uncommon.

Pathology

Macroscopy

Solitary PA are sessile or polypoid lesions of gray to whitish or pinkish color measuring from a few mm to more than 1 cm in size. Larger lesion typically shows a finely granular surface caused by the clustered tips of the papillary structures. Large villous adenomas can reveal a gross morphology similar to that of colonic adenomas. In the diffuse (multicentric) form, the gallbladder mucosa is studded with numerous, mostly small papillary and sometimes racemose growths that may cover the entire mucosal surface, resulting in a velvety texture in early disease and ending up in a diffusely villous surface. Sometimes, few papillary lesions may be larger, resembling solitary villous adenomas.

Histopathology

Based on the prevailing cellular differentiation, four major patterns can be distinguished in gallbladder adenomas, i.e., biliary type, pyloric-gland type, intestinal type, and foveolar type. Overall, intestinal- and pyloric-type patterns are more common in gallbladder adenomas than in the extrahepatic bile ducts (Albores-Saavedra et al. 2010). Biliary- and pyloric-type epithelial lineages seem to be more prevalent in exophytically growing, papillary tumors, but they can contain other and sometimes rare components, such as Paneth cells and neuroendocrine cells Kerr and Lendrum (1936). In rare instances, gastric-type mucosa has been detected in PA (Ansari 1954; Almagro 1985). In rare cases of diffuse PA, Paneth cells were found to be numerous (Nakajo et al. 1988).

A rare variant of PA of the gallbladder shows signs of mucin hypersecretion, similar to one variant of large bile duct papillomatosis (mucin-hypersecreting papillomatosis). This variant can occur as a solitary lesion (Lauwers et al. 1995), or develop as a diffuse PA (Chung et al. 2006). Histologically, mucin-secreting PA shows a lining of papillary structures by a single layer of tall mucinous cells with a delicate fibrovascular stroma. Focal cellular tufting and nuclear atypia may be present. The columnar cells are Alcian blue-positive, but do not stain with the mucicarmine stain.

Papillary Adenoma and Papillomatosis of the Cystic Duct

PA is an even less common lesion in the cystic duct, as is mostly occurring as a solitary PA. Solitary PA of the cystic duct may rarely cause biliary colic (Loh et al. 1994). Similar to PA of the gallbladder, PA of the cystic duct may develop dysplasia and carcinoma, but these are exceptional observations (Lombard et al. 1967).

Differential Diagnosis

Macroscopically, large solitary PA may be confounded with exophytically growing papillary adenocarcinoma.

Intracholecystic Papillary-Tubular Neoplasm of the Gallbladder

A small subset of preinvasive neoplastic gallbladder polyps with a diameter of more than 1 cm display a complex mixture of tubular and papillary growth patterns associated with a broad spectrum of dysplasia. As these neoplasms have marked histologic similarity with intraductal papillary neoplasms of pancreas and bile duct and show similar cell lineages and mucin core protein expression, these tumors are proposed to be called intracholecystic papillary-tubular neoplasm or ICPN (Adsay et al. 2012; Jang 2014). Among the 123 cases reported by Adsay and coworkers (2012), the patients were predominantly female (2:1) with a mean age of 61 years and a medium tumor size of 2.2 cm. Pathologically, the main pattern was papillary in 43 %, tubulopapillary in 31 %, and tubular in 26 %. The predominant cell lineage was biliary in 50 % (66 % MUC1-positive), gastric foveolar in 16 % (all MUC5AC-positive), gastric in 20 % (almost all MUC6-positive), intestinal in 8 %, and oncocytic in 6 %. Among cases of a pyloric-gland adenoma pattern, 88 % had at least focal high-grade dysplasia and 18 % showed associated invasive carcinoma. Overall, factors significantly associated with invasive neoplasm were extent of high-grade dysplasia, a biliary or foveolar cell type, and the presence of papilla formation. ICPN rarely protrude into the large bile duct and thus cause obstructive jaundice (Hashimoto et al. 2014).

Fibroadenoma of the Gallbladder

Fibroadenoma of the gallbladder is an extremely rare tumor, histologically characterized by a polypoid endoluminal growth, a filamentous pedicle, and glandular epithelial structures embedded in abundant, loose, and edematous-looking connective tissue (Ochsner and Carrera 1959; Eguchi et al. 2001). Fibroadenoma can grow to large size (more than 11 cm) and fill the gallbladder lumen (Magata et al. 2009). Grossly, the polypoid masses exhibit a gray to reddish color, but they can also be greenish owing to bile stain.

Fibroadenoma of the Gallbladder with Borderline Malignancy

In one case of large fibroadenoma, histology showed hyperchromatic nuclei in part of the glandular cells, associated with disturbed polarity and nuclear immunostaining for p53 protein. Part of the stromal component revealed hypercellularity with irregular nuclei, increased proliferative activity, and p53 positivity (Magata et al. 2009). This very rare tumor may be related to carcinosarcoma of the gallbladder.

Hyperplastic Lesions and Metaplastic Changes of the Gallbladder 154

Contents

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_154

Abstract

Various types of hyperplastic lesions and metaplastic changes can develop in the gallbladder. Adenomatous hyperplasia of the gallbladder is a condition characterized by a hyperplasia of metaplastic pyloric-type glands and of deep-seated glands in the absence of cellular atypia. Macroscopically, this alteration presents in the form of a thick and nodular gallbladder mucosa, particularly in its diffuse form, but it can also produce polypoid lesions. The epithelial surface of the gallbladder and glandular epithelial can undergo focal to diffuse hyperplastic changes. In one rare form, papillary hyperplasia is present, usually in a diffuse pattern. Adenomyomatous hyperplasia is a reactive alteration characterized by hyperplastic and cystic changes in deep parts of the gallbladder mucosa associated with smooth muscle hypertrophy. This distinct hyperplasia exists in diffuse, segmental or annular, and localized or focal patterns. The gallbladder epithelium can be subject to various metaplastic changes, including pyloric gland metaplasia, antral gland metaplasia, intestinal metaplasia, and squamous cell metaplasia.

Adenomatous Hyperplasia of the Gallbladder

Introduction

Adenomatous hyperplasia of the gallbladder (AHGB) is a condition characterized by a hyperplasia of metaplastic pyloric-type glands and of deep-seated glands in the absence of cellular atypia. AHGB is sometimes interpreted as a pseudotumor of the gallbladder and has no known malignant potential so far (Christensen and Ishak 1970; Lee et al. 2004). The lesion has been included in the spectrum of cholecystitis glandularis proliferans, but AHGB can clearly develop in the absence of inflammatory change of the gallbladder (Kikiros et al. 2003).

Epidemiology

AHGB is often considered to be a rare lesion, but the incidence is difficult to assess owing to the lack of a consensus regarding diagnostic criteria (Piegza et al. 1978; Farinon et al. 1991; Tyagi et al. 1992; Baig et al. 2002; Kikiros et al. 2003; Stokes et al. 2007). Christensen and Ishak (1970) reviewed 180 tumors and pseudotumors of the gallbladder and identified AHGB in 18 cases/10 %. Elfving et al. (1969) reported the gallbladder mucosal hyperplasia was present in 22 % of their 104 patients who had presented with calculous cholecystitis. In a morphologic investigation of 415 cholecystectomy specimens, AHGB was detected in 10.1 % of the gallbladders (Tyagi et al. 1992). In a series of 40 patients from India with cholelithiasis undergoing cholecystectomy, a detailed histologic examination with numerous sections revealed five cases of AHGB. In a retrospective study evaluating gallbladder wall thickening in 342 patients who had undergone MR cholangiography prior to cholecystectomy, 144 patients revealed wall thickening defined as a wall thickness of 3 mm or more, and among these, no case of AHGB was found (Jung et al. 2005). The lesion is much rare in men than in females, with an estimated male to female ratio of 1:13 (Tyagi et al. 1992). Interestingly, AHGB was not seen in gallbladders containing pigment stones, but found in gallbladders containing mixed or cholesterol stones (Baig et al. 2002). AHGB has been observed in the pediatric age group (Kikiros et al. 2003).

Pathology

Macroscopy

Macroscopically, AHGB has been described as lesion with a thick and nodular gallbladder mucosa, at least in the diffuse form (Stokes et al. 2007). It can present as polypoid lesions (Farinon et al. 1991; Kikiros et al. 2003), the polyps being usually small but sometimes clustered to small groups of exophytic lesions.

Histopathology

AHGB is a focal or diffuse lesion (Tyagi et al. 1992). Histologically, the mucosa reveals elongated papillary folds with a fibrotic core and a mild lymphocytic infiltrate. The surface shows hyperplasia of metaplastic pyloric-type glands, while branching mucous glands are found in deeper layers, focally filling the lamina propria. Numerous deep-seated Rokitansky-Aschoff sinuses are common (Stokes et al. 2007). In contrast to adenomyomatosis, hypertrophy of the muscularis is not a feature in AHGB. Cellular atypia is consistently lacking. Tyagi and coworkers (1992) distinguished two types of AHGB: (1) spongious type described as prolonged but coalesced villi and (2) villous type, characterized by abnormally long and ramifying villi. In their material of 415 cholecystectomy specimens, 33.3 % were type 1, 52.4 % were type 2, and 14.3 % were mixed types.

Differential Diagnosis

Adenomyomatosis of the gallbladder resembles in several aspects AHGB, but shows hypertrophy of the muscle layer and extensive Rokitansky-Aschoff sinuses.

Mucosal Hyperplasia of the Gallbladder

Introduction

The surface epithelium and glandular epithelia of the gallbladder mucosa can undergo focal to diffuse hyperplastic changes that may be confounded with precursor lesion of cancer.

Papillary Hyperplasia of the Gallbladder

Introduction

Papillary hyperplasia of the gallbladder (PHGB) is a rare mucosal change characterized by a usually diffuse benign papillary proliferation of gallbladder epithelia (Albores-Saavedra et al. 1990). PHGB comes in two forms, i.e., primary PHGB and secondary PHGB often associated with pancreaticobiliary maljunction. As, in addition to the gallbladder, other parts of the biliary tract can be involved, PHGB may represent an organ-specific manifestation of a systemic biliary disorder. PHGB is usually not found in cholecystolithiasis.

Primary PHGB is a disorder that develops in the entire gallbladder mucosa in the absence of relevant background chronic inflammation-related gallbladder or bile duct disease. It has first been reported in 1990 based on the observation of a young female patient with a papillary hyperplastic lesion involving the mucosa of the entire gallbladder and the cystic and common bile ducts (Albores-Saavedra et al. 1990). Few other descriptions of this condition have since appeared (Celoria et al. 1994; Huang et al. 2001; Stringer et al. 2001; Umudum et al. 2006; Baba et al. 2014). The etiology of primary PHGB is not yet known.

Secondary PHGB is well known to develop in patients with pancreaticobiliary maljunction (PBMJ) (Yamato et al. 1999; Yamaguchi et al. 2009). PHGB in PBMJ exhibits senescent features including expression of p16(INK4A) and senescent-associated beta-galactosidase, low expression of the polycomb group protein EZH2, and low or increased proliferative activity. In contrast, secondary PHGB in PBMJ showing transformation into cancer showed upregulation of EZH2 (Yamaguchi et al. 2009).

Pathology

Macroscopy

Macroscopically, the gallbladder mucosa may be thickened and exhibits an increased granularity of its surface or a diffuse velvety structure, sometimes with tiny frond-like excrescences. In the investigation of Albores-Saavedra et al. (1990), the gallbladder mucosa was pink-yellow and bore numerous small papillary projections ranging from 0.2 to 0.8 cm in height.

Histopathology

Histologically, mucosal folds of the gallbladder are close to one another and taller than normal (Albores-Saavedra et al. 1990). The folds present a villous or papillary pattern with abnormal branching. The hyperplastic-hypertrophic folds are lined by normal-looking-well-differentiated columnar epithelial cells, usually without atypia in primary PHGB. The nuclei are basally or centrally placed. Part of cells exhibit subnuclear vacuoles, and an increased number of pencil-like cells are admixed with the columnar cells. Paneth cells, goblet cells, or argyrophilic cells are not present. In secondary PHGB, focal cellular and nuclear atypia/dysplasia can be found, precursor lesions of papillary gallbladder carcinoma associated with PBMJ (Kinoshita et al. 2002). In the vicinity of papillary to papillary-tubular carcinoma in PBMJ, atypical epithelial hyperplasia was described (Ohta et al. 1990). The nonneoplastic epithelium of secondary PHGB in PBMJ can express mucin core protein MUC1, similar to gallbladder carcinoma (Yamato et al. 1999). It has been proposed that reflux of pancreatic juice caused by maljunction may induce a distinct form of chronic inflammatory change in the gallbladder favoring the development of hyperplasic, dysplastic, and finally neoplastic alterations.

Differential Diagnosis

Differential diagnosis of PHGB includes papillomatosis of the gallbladder, multiple villous adenomas, and highly differentiated papillary carcinoma.

Glandular Hyperplasia of the Gallbladder

Glandular hyperplasia is a rare form of mucosal hyperplasia. It was observed in a small child with choledochal cyst, where the gallbladder mucosa displayed cribriform proliferation of the gland base of the mucosa, associated with the presence of hyperplastic glandular structures within lymph vessels, but in the absence of malignant change (Hirayama et al. 2009).

Adenomyomatous Hyperplasia

Introduction

Adenomyomatous hyperplasia/adenomyomatosis of the gallbladder (synonyms: diverticular disease of the gallbladder, adenomyosis of the gallbladder, cholecystitis glandularis proliferans, intramural diverticulosis of the gallbladder) is a well-recognized reactive alteration of the gallbladder, characterized by hyperplastic and cystic changes of deep parts of the mucosal epithelium associated with muscle hypertrophy. Together with cholesterolosis, adenomyomatosis has been allocated to a group of disorders termed hyperplastic cholecystoses, a term denoting reactive, benign alterations sharing a hyperplastic reaction of mucosal cells (Jutras 1960; Halin 1964; Feltner 1966; Jelaso et al. 1967; Lubera et al. 1967; Govoni 1981; Berk et al. 1983). It seems that most of the cases previously described as cholecystitis cystica in fact represent adenomyomatosis.

Selected References Eiserth 1938; Akerlund and Rudhe 1950; Caroli et al. 1951; King 1952, 1953; Zinober 1952; Burt and Masel 1955; Ross et al. 1955; Le Quesne and Ranger 1957; Rush et al. 1957; Goldberg and Dodgson 1958; Ludin 1960; Halpert 1961; Verhage and Van der Werff 1964; Brown et al. 1966; reviews: Owen and Bilhartz 2003.

Classification

Based on the distribution pattern and the extension of the lesions, adenomyomatosis is divided into three major types (Table 1).

Mass-forming lesions in localized or segmental adenomyomatosis are sometimes termed adenomyoma (Eiserth 1938; Maderna and Tritto 1959; Young 1959; Andrei and Nobile 1960; Caldone Firrao 1960; Ochsner 1962; Bricker and Halpert 1963; Jutras et al. 1964; Levesque

Table 1 Types of adenomyomatosis

Diffuse (generalized) adenomyomatosis, in which the entire gallbladder mucosa is involved
Segmental (annular) adenomyomatosis, whereby only one gallbladder segment is involved, with a ringlike involvement of one gallbladder part
Localized (focal) adenomyomatosis, whereby only a circumscribed part is involved, most often in the gallbladder fundus

et al. 1964; Tompkins 1967; Inoue and Matsuda 1978; Herrmann and Saul 1986). An adenomyoma is defined as a nodular mural lesion composed of fascicles of smooth muscle cells and clusters of dilated, hyperplastic biliary-type glands. The term is misleading insofar as "adenomyomas" developing in the setting of adenomyomatosis are not true benign neoplasms, but reactive nodular lesions. Focal/isolated adenomyomas mostly occur in the gallbladder fundus (Eiserth 1938).

Epidemiology

Lesions of the adenomyomatosis spectrum were first described by Sutherland (1898) and Eiserth (1938) under the term adenomyoma of the gallbladder. Since then, this entity has been further characterized in numerous reports. It seems that adenomyomatosis is detectable in 2–5 % of all cholecystectomies. In a study of 4,704 consecutive cholecystectomies, adenomyomatosis was detected in 2.4 % (Kim et al. 2010). In a further analysis of 30 patients, age at diagnosis ranged from 22 to 77 years (mean, 52.3 years), and the male to female ratio was 8:7. Twelve cases were segmental, ten were diffuse/generalized, and eight were fundal lesions. In 20 patients, the lesions were associated with gallstones (Kasahara et al. 1992). Gallbladder adenomyomatosis also occurs in the pediatric age group (Alberti et al. 1998; Zani et al. 2005; Akçam et al. 2008).

Selected References Colquhoun 1961; Katz and Rickard 1963; Fotopoulos and Crampton 1964; Seyss 1966; Bevan 1970; Heald 1970; Davies 1971; Frommhold and Lagemann 1971; McCormick and Lang 1971; Skapinker 1971; Ram and Midha 1975; Muto et al. 1978; Hidalgo and Lewicki 1980; Meguid et al. 1984; Kidney et al. 1986; Williams et al. 1986; Costa-Greco 1987; Halpert et al. 1989; Kasahara et al. 1992; Yang et al. 1996; Chang et al. 1998; Secil et al. 2005; Boscak et al. 2006; Dirks et al. 2006; Lin et al. 2011; Ray et al. 2012.

Clinical and Imaging Features

In most patients, adenomyomatosis is clinically silent. Some patients report vague abdominal pain or occasional colics, but these may be caused by accompanying gallstone disease. In fact, adenomyomatosis is often associated with cholecystolithiasis. Specifically, the segmental variant of adenomyomatosis seems to predispose to cholecystolithiasis (Nishimura et al. 2004). Among 64 cases of adenomyomatosis, 38 had black pigment stones, alone ($N = 22$) or in association with singe ($N = 12$) or multiple ($N = 4$) cholesterol gallstones. At least in initial phases of stone formation, Rokitansky-Aschoff sinuses were found close to small intraparietal vessels, and sometimes they contained black pigment microstones (Cariati and Cetta 2003). A subset of gallbladder adenomyomatosis is associated with anomalous pancreatobiliary ductal union (Wu et al. 1995; Chang et al. 1998). The fundal (localized) type of adenomyomatosis seems to differ from the other types in several respects. It has a lower frequency of gallstones and a lower inflammatory grade (Kim et al. 2010).

Sonographically, the main feature is a localized or generalized thickening of the gallbladder wall with a generally smooth outer contour. Small intramural cysts are identifiable in part of the cases, and gallbladder contractility is preserved, in contrast to malignancy (Rice et al. 1981; Raghavendra et al. 1983; Sagar and Naik 1984; Izumi et al. 1985; Fowler and Reid 1988; Brambs et al. 1990; Gerard et al. 1990; Hwang et al. 1998). The intramural foci may show "comet tail" reverberation artifacts, indicative of cholesterol crystals within Rokitansky-Aschoff sinuses. These

"comet tails" extend from the near wall into the anechoic lumen (Boscak et al. 2006; Mariani and Hsue 2011). Postcontrast CT images demonstrate the characteristic rosary sign or necklace sign, formed by the enhanced epithelial structures in the intramural diverticula surrounded by the non-enhancing hypertrophied muscle tissue (Chao et al. 1992; Zissin et al. 2003; Ching et al. 2007; Poonam et al. 2008; Stunell et al. 2008). The rosary or necklace signs are mostly found in the diffuse form of adenomyomatosis, while the segmental form often presents as a dumbbell-shaped gallbladder, and the localized form either presents as a polypoid structure or a nodular mass lesion ("adenomyoma"). The so-called pearl necklace sign is a typical feature of adenomyomatosis and is also well visualized at magnetic resonance cholangiopancreatography (MRCP; Haradome et al. 2003). The pocket-like wall lesions are best seen on CT in the fundal type of adenomyomatosis (Klose et al. 1991). In marked adenomyomatosis, CT imaging may result in findings mimicking gallbladder carcinoma (Agrawal et al. 2012). On MR, T1-weighted images reveal a diffusely thickened gallbladder wall and intramural cavities, which are hyperintense on T2-weighted images. The cavities represent Rokitansky-Aschoff sinuses (Yoshimitsu et al. 1999; Boscak et al. 2006). The phenotype of nonneoplastic and neoplastic gallbladder disease as displayed on MR images has been divided into four layered patterns, viz., type 1 shows two layers with a thin hypointense inner layer and thick hyperintense outer layer; type 2 has two layers of ill-defined margin; type 3 reveals multiple hyperintense cystic spaces in the gallbladder wall; and type 4 shows a diffuse nodular thickening without layering. Adenomyomatosis was correlated with type 3, while types 1 and 2 were typical for chronic and acute cholecystitis, respectively, and type 4 was a characteristic for gallbladder carcinoma (Jung et al. 2005).

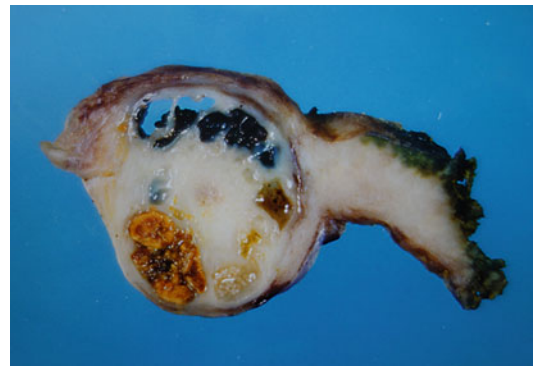

Fig. 1 Adenomyosis of the gallbladder. The cystic spaces contain black stones, and a brown concrement is impacted in scar tissue

Fig. 2 Adenomyosis of the gallbladder with slit-like or microcystic spaces radially arranged around the gallbladder lumen

Pathology

Macroscopy

In most cases, the gallbladder wall is markedly thickened, up to 2 cm or even more. On sections, the wall shows multiple pockets or intramural cystic structures, which may contain gallstones, stone fragments, or glittering accumulations of cholesterol crystals (Figs. 1 and 2). Fundic adenomyomatosis can bulge with excessive subserosal fat tissue of the gallbladder, producing a mass lesion (Miyake et al. 1992; Shimoji et al. 2001).

Histopathology

Adenomyomatosis is characterized by hyperplastic mucosal pockets, cystically dilated Rokitansky-Aschoff sinuses, which are embedded

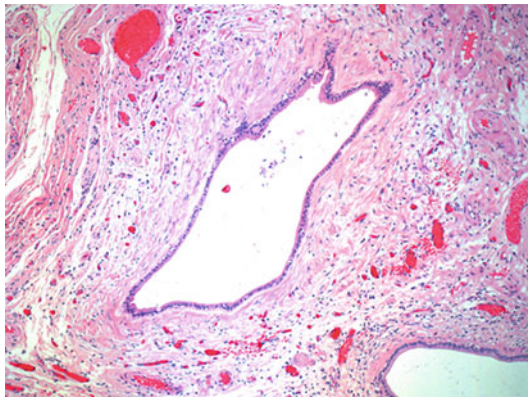

Fig. 3 Adenomyosis of the gallbladder. Cystic spaces are lined by a regular epithelium and surrounded by smooth muscle cells and a fibroblastic tissue (hematoxylin and eosin stain)

in a hyperplastic-hypertrophic muscle layer, usually with only minor or no inflammatory infiltrates, but with some fibrotic changes in advanced stages of the disease (Fig. 3). In part of the cases, Rokitansky-Aschoff sinuses are very prominent and appear as elongated and dilated, sometimes cystic epithelial pockets resembling diverticula. Hyperplastic changes may also be noted in more superficial epithelia of the mucosa. The mucosal pockets (Rokitansky-Aschoff sinuses) often contain inspissated bile, in part of the cases intermingled with stones, stone fragments, and/or cholesterol crystals. Adenomyoma, mostly seen in the fundal variant of adenomyomatosis (Ozgonul et al. 2010), is characterized by a nodule, predominantly fundic, of hypertrophic smooth muscle cells, containing distorted and in part cystically dilated glandular structures.

Differential Diagnosis

Radiologically, gallbladder cancer with intratumoral anechoic foci can be a mimic of adenomyomatosis (Ishizuka et al. 1998). Well-differentiated gallbladder adenocarcinoma with intratumoral cystic components and abundant mucin production may mimic adenomyomatosis (Yoshimitsu et al. 2005).

Is Adenomyomatosis a Precancerous Lesion?

So far, it is not known whether adenomyomatosis has any clinical significance and whether it will truly lead to inflammation or even cancer (Chan-Wilde et al. 1990). Based on the observation of dysplastic changes and the association of gallbladder carcinoma with adenomyomatosis, it has been suggested that adenomyomatosis might represent a premalignant condition (Bevan 1970; Aldridge et al. 1991; Funabiki et al. 1993; Kurihara et al. 1993; Imai et al. 2011). Diffuse adenomyomatosis was found to be associated with dysplastic gallbladder adenoma (Di Carlo et al. 2010). There is one reported case of papillary mucinous adenoma arising in adenomyomatous hyperplasia of the gallbladder (Lauwers et al. 1995). Early gallbladder adenocarcinoma has been found in association with adenomyomatosis (Fujita et al. 1988). A causal relationship between adenomyomatosis and carcinoma has been suggested based on a close spatial relationship of the two lesions (Paraf and Potet 1988). In one case, noninvasive carcinoma of the gallbladder was found in the mucosa overlying localized type of adenomyomatosis with a papillary adenoma in one of the cystic structures (Katoh et al. 1988). There is some evidence that the segmental form of adenomyomatosis predisposes to gallbladder carcinoma (Ootani et al. 1992; Kai et al. 2011). In a study of 4,560 consecutive patients undergoing cholecystectomies, 60 clinically noncancerous gallbladders with segmental adenomyomatosis were examined for epithelial alterations. Histology revealed previously unrecognized carcinoma in 6.6 % of cases, while the other types of adenomyomatosis did not show any significant increase in the incidence of gallbladder cancer, suggesting that segmental adenomyomatosis may represent a high-risk condition for carcinoma, especially in elderly patients (Nabatame et al. 2004).

Pathogenic Pathways

Etiology and pathogenesis of adenomyomatosis are not known. A pathogenic role of an increased

intra-gallbladder pressure has been suggested, with a pressure-induced dilatation and proliferation of Rokitansky-Aschoff sinuses, but this mechanistically oriented hypothesis fails to have any support.

Rokitansky-Aschoff Sinuses

Rokitansky-Aschoff sinuses (RAS or crypts), already discussed in the previous paragraph as a component of adenomyomatosis, are intramural diverticulum-like invaginations of gallbladder epithelium with an associated sheath of fibroblastoid cells with extracellular matrix. RAS extend down the gallbladder wall through smooth muscle gaps. The deep-most reaching RAS reach the peri-/extramuscular connective tissue (Zinober 1952; Ross et al. 1955; Rush et al. 1957; Halpert 1961; reviews: Albores-Saavedra and Henson 1984; Albores-Saavedra et al. 1998). In addition to their role in adenomyomatous hyperplasia, RAS are commonly found in gallbladder resection specimens irrespective of the presence of bona fide adenomyomatosis. In a Japanese series of 540 consecutive cholecystectomies, RAS were detected in 65 % of cases (Terada 2013).

Histologically, RAS are pocket-like, long, and often tortuous invaginations lined by a single layer of biliary-type columnar cells. At the bottom, RAS may show considerable branching, mainly at the gallbladder outlet and the first part of the cystic duct, causing crowded epithelial tubular clusters that may be confounded with well-differentiated adenocarcinoma. However, in contrast to carcinoma, epithelia of RAS lack any relevant atypia, reveal no increased mitotic activity, are in continuation with the mucosal surface, show an organoid/lobular texture, and lack the cellular stroma characterizing carcinoma. In addition, cells of RAS are not reactive for p53 protein and exhibit a very low proliferative activity based on MIB1 immunostaining (Dorantes-Heredia et al. 2013). RAS may accumulate mucin in their lumina which sometimes escapes into the extracellular space, simulating mucinous carcinoma of the gallbladder, but again the participating cells are p53 negative and low proliferative (Albores-Saavedra et al. 2009). In the course of chronic fibrosing cholecystitis, the necks of RAS may be stenosed or even obliterated, causing fluid stasis followed by cystic dilatation, sometimes with trapping of thickened bile, cholesterol crystals, or stones in the lumina. The etiology and pathogenesis of RAS are not yet known, although factors such as increased luminal pressure and weakness of the muscle layer have been discussed. It has also been proposed that chronic cholecystitis may weaken mural muscle bundles and hence reduce their capability to resist to outpouchings (Stalker et al. 1955).

Metaplastic Changes of the Gallbladder

Introduction

Similar to other organs of the gastrointestinal tract, the mucosa of the gallbladder can undergo several types of epithelial metaplasia, gastric metaplasia and intestinal metaplasia being the most common forms (Pessel et al. 1950). Apart from its differential diagnostic importance, metaplasia plays a role as a potential precursor lesion for carcinogenic pathways (Yamagiwa and Tomiyama 1986; Inada et al. 1989; Duarte et al. 1993; Lewis et al. 2007; Meirelles-Costa et al. 2010), an issue further discussed in the chapter on gallbladder carcinoma.

Gastric Metaplasia

General Features

Gastric gland metaplasia of the gallbladder is defined as the presence of gastric-type glands, either single or in groups, within the mucosa (lamina propria) or, less commonly, in the muscularis of the gallbladder. The areas of gastric metaplasia can contain pyloric, antral or mucous glands, or mixtures thereof. Neuroendocrine cells may also occur (Yamamoto et al. 1986). The frequency of gastric metaplasia of the gallbladder varies considerably among reports, ranging from 66 % to more than 80 %. The metaplastic changes

are often associated with chronic cholecystitis, and formation of lymph follicles (cholecystitis follicularis) has been found in association with metaplasia, but mainly in cases with *H. pylori* infection (Misra et al. 2007). Gastric metaplasia may also occur within adenocarcinomas of the gallbladder (Azadeh and Parai 1980).

Pyloric Gland Metaplasia

Pyloric gland metaplasia (pseudopyloric gland metaplasia) is identified in several parts of the gastrointestinal tract, including the gallbladder. PGM seems to be a common metaplastic change of the gallbladder (Fig. 4). Among 540 consecutive cholecystectomy specimens, PGM was detected in 54 % of cases (Terada 2013). PGM was classified into complete and incomplete types on the basis of mucin expression and immunoreactivities for pepsinogens I and II. The complete type of PGM is characterized by neutral mucins and weak pepsinogen I and strong pepsinogen II activities, like normal pyloric gland cells. The incomplete type contains acid mucins and was further subdivided into an incomplete type 1, having pepsinogen II but no pepsinogen I activity, and an incomplete type 2, with no pepsinogen activity (Tatematsu et al. 1987). The cells of PGM are reactive for the apomucin MUC6 (Sasaki et al. 1999). Interestingly, PGM can extend into the muscular wall and serosa of the gallbladder. In this florid PGM, metaplastic glands composed of cytologically bland cuboidal or columnar mucin-containing cells may show perineural and/or intraneural invasion, an intriguing alteration that can be confused with adenocarcinoma. The pathogenesis of this alteration has, similar to corresponding changes in other organs, not yet been clarified (Albores-Saavedra and Henson 1999). This metaplasia seems to develop from epithelial zones with increased proliferative activity (a transitional zone), and as this zone enlarges, shallow pits become apparent, containing pepsinogen II-positive cells and then the pits becoming deeper as the process advances, until the zone gradually resembles that of the normal gastric pylorus mucosa (Shimizu et al. 1996). PGM must not be confounded with pyloric gland adenoma of the gallbladder, which represents a small circumscribed tumor of the gallbladder mucosa composed of pyloric glands and sometimes aberrantly expressing an intestinal cell marker, Cdx2 (Sakamoto et al. 2007; Wani et al. 2008).

Antral Gland Metaplasia

In antral gland metaplasia (AGM), the metaplastic island consists of cuboidal to rather short columnar cells with cytoplasmic and nuclear features of antral cells (Fig. 5; Laitio 1976). The metaplastic antral glands contain sulfated and non-sulfated acid mucins (Buitrago Salassa and Javier Lespi

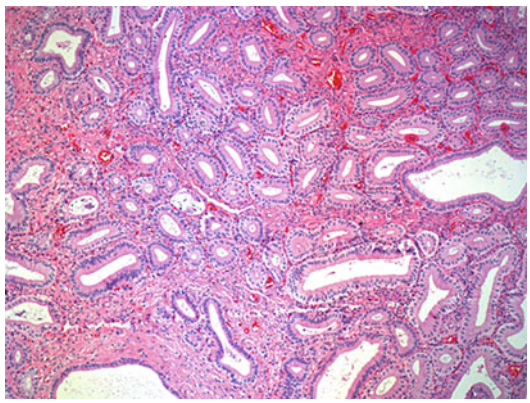

Fig. 4 Pyloric gland metaplasia of the gallbladder (hematoxylin and eosin stain)

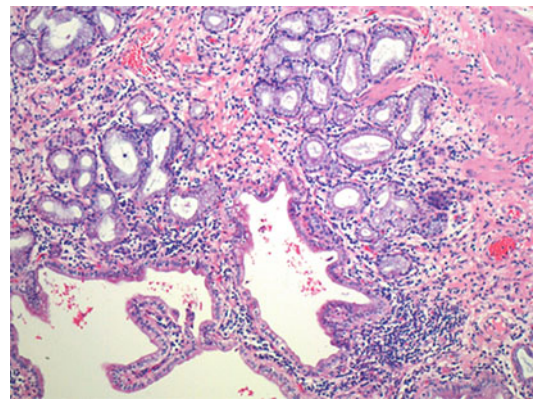

Fig. 5 Antral gland metaplasia of the gallbladder (hematoxylin and eosin stain)

2007). AGM may be mixed with pyloric gland metaplasia. Some reports described the presence of *Helicobacter pylori* in areas of gastric metaplasia (Misra et al. 2007), while other authors failed to detect *H. pylori* in these metaplastic lesions (Arnaout et al. 1990).

Gastric Heterotopia Versus Gastric Metaplasia

In contrast to metaplasia, which is an acquired condition, gastric heterotopia of the gallbladder is a rare congenital lesion that was first described in 1934 (Egyedi 1934). The lesion is discussed in more detail in a separate paragraph and may be confounded with gastric metaplasia of the gallbladder (Yamamoto et al. 1989). The diagnosis requires the identification of a focus composed of an entire (full-thickness) gastric-type mucosa, usually fundic, with PAS-positive foveolar cells, chief and parietal cells, and sometimes abundant pyloric glands (Isik et al. 2002; Ben Brahim et al. 2011). Gastric heterotopia often forms a bulged mucosal area or a polypoid lesion and less commonly an intramural nodular mass (Boyle et al. 1992; Vallera and Dawson 1992; Uchiyama et al. 1995; Leyman et al. 1996; Hamazaki and Fujiwara 2000; Sciumè et al. 2005; Cöl et al. 2007), whereas metaplastic lesions are commonly flat. Furthermore, gastric heterotopia is detected more frequently in younger adults and is mostly found in the gallbladder neck or even in the cystic duct (Isik et al. 2002), whereas metaplasia shows a more extended distribution. Gastric heterotopia may be associated with focal intestinal metaplasia with goblet cells in the surrounding gallbladder mucosa (Xeropotamos et al. 2001; Isik et al. 2002; Tavli et al. 2005).

Intestinal Metaplasia

Intestinal metaplasia (IM) of the gallbladder is characterized by the presence of areas composed of intestinal columnar cells, goblet cells, neuroendocrine cells and Paneth cells, and a distinct mucin expression mode (Ganesh et al. 2007). Complete IM was found in 9.8–85.7 % of gallbladders with gallstone disease, mainly in patients less than 40 years of age (Järvi and Laurén 1967; Kozuka and Hachisuka 1984; Dowling and Kelly 1986; Yamagiwa and Tomiyama 1986; Yamagiwa 1989; Jukemura 1996; Ghiur et al. 1997; Mukhopadhyay and Landas 2005; Fernandes et al. 2008; Sakamoto et al. 2009; Khan et al. 2011), but there are also reports with markedly lower frequencies of IM in cholelithiasis, e.g., 5.4 % (Jukemura 1996). Apart from geographical and genetic differences, variations in criteria used to identify IM may play a role for these marked differences. It was claimed that the frequency of IM increases as a function of increasing age, but this was not confirmed in all reports. Specifically, one study found a peak in incidence in individuals younger than 40 years (Fernandes et al. 2008). Histologic features consistent with IM were also identified in the pediatric age group, where the presence of intestinal gallbladder features seems to be a physiological trait (Zen et al. 2011). On the other hand, IM of the gallbladder in children has also been observed in the setting of pancreaticobiliary maljunction (Ono et al. 2011). Goblet cells are a feature of IM, but their mere presence as such does not suffice for a diagnosis of IM. Goblet cells were detected in more than half of gallbladder specimens in one study (Laitio 1980). Sporadic goblet cells commonly occurred in so-called goblet cell areas which, as small lesions, are usually located in the tops of gallbladder mucosal folds. IM develops when goblet cells also involve deeper parts of folds, associated with a change from sulfated mucins to non-sulfated mucins and the emergence of intestinal-type columnar cells and eventually enterochromaffin cells (Laitio 1975; Laitio and Nevalainen 1975a). Less commonly, IM can also contain Paneth cells (Laitio and Nevalainen 1975b). Ultrastructurally, intervening columnar cells (enterocyte-like cells) contain cytoplasmic mucin granules (Laitio and Nevalainen 1975b). IM cells express large intestinal mucin antigen/LIMA and small intestinal mucin antigen/SIMA (De Boer et al. 1981). Cells of IM are reactive for the transcription factor, Cdx2 (Sakamoto

et al. 2007, 2009). Based on the absence of the presence of endocrine cells, Albores-Saavedra and coworkers (1986) divided IM into two groups. The gallbladder with IM lacking endocrine cells contained isolated or small clusters of mature goblet cells, while those with endocrine cells, in addition to goblet cells, contained argyrophil and argentaffin cells and, less frequently, Paneth cells and gland-like structures resembling colonic crypts. Both groups showed pyloric gland and superficial gastric-type epithelium. The most common endocrine cells were serotonin-positive elements. Based on these findings, the involvement of an endodermal stem cell was suggested (Albores-Saavedra et al. 1986).

Squamous Cell Metaplasia

This is, in comparison with other forms of metaplasia, one of the least common variants. It is characterized by the replacement of a glandular gallbladder epithelium by a stratified squamous cell epithelium (keratinocytes) with or without keratinization (Fig. 6). Massive and diffuse squamous cell metaplasia with keratinization can result in a pseudoepidermoid cyst of the gallbladder, mimicking a gallbladder tumor (Teo et al. 2005). Extended squamous cell metaplasia of the gallbladder with dysplastic changes can occur in association with squamous cell carcinoma (Hanada et al. 1986). A component of squamous cell metaplasia was found in gastric heterotopia of the gallbladder (Daud et al. 2007) and in a tubular adenoma (Colovic et al. 2006).

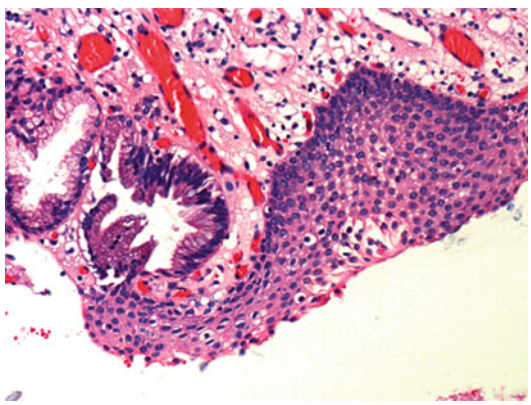

Fig. 6 Squamous cell metaplasia of the gallbladder (hematoxylin and eosin stain)

Other Forms of Epithelial Gallbladder Metaplasia

Ciliated gallbladder epithelium has been observed in a patient with duplication of the gallbladder (Raeburn 1969).

Mesenchymal Metaplastic Changes of the Gallbladder

Osseous metaplasia (or heterotopic bone) is a very rare alteration of the gallbladder, sometimes associated with chronic cholecystitis (Il'chenko et al. 2011; Rege and Vargas 2011). This type of metaplasia can present as a focal hyperdense lesion that may be confounded with a gallstone (Nelson and Kahn 2009). Osseous gallbladder metaplasia was observed in association with polypoid cholesterolosis (Ortiz-Hidalgo and Baquera-Heredia 2000). A similar type of metaplasia rarely develops in the stroma of gallbladder carcinomas (stromal osseous metaplasia; Cavazza et al. 1999).

Pathogenesis

Similar to other organs having a glandular mucosa, metaplastic changes in the gallbladder are thought to be caused, or their development favored, by chronic inflammatory disease, but the exact pathogenic pathways are not yet elucidated. There is recent evidence that several enterohepatic *Helicobacter* (*H.*) species can occur in inflammatory disorders and gallstone disease of the gallbladder and may play a pathogenic role, including *H. hepaticus*, *H. bilis*, *H. pullorum*, and *H. pylori* (Apostolov et al. 2005; Kobayashi et al. 2005; Hamada et al. 2009; Karagin et al. 2010; Lee et al. 2010; Boonyanugomol et al. 2012; Attaallah et al. 2013; Javed et al. 2013). *Helicobacter* infection of gallbladder mucosa in patients with chronic

cholecystitis was associated with metaplasia (Zhou et al. 2013). In one study, *H. pullorum* was only found in gallbladders with metaplasia (Karagin et al. 2010).

DOI 10.1007/978-3-319-26956-6_155

Abstract

Similar to the hepatobiliary tract, the gallbladder is a well-known origin of diverse types of neuroendocrine tumors. Previously, most of these neoplasms were classified as carcinoid tumors, irrespective of their grade of malignancy and differentiation. Today, the same classifications as used as in other anatomical locations are employed for gallbladder neuroendocrine tumors. As malignant neuroendocrine neoplasms, including those that arise in the hepatobiliary tract, can metastasize, the distinction between primary and metastatic gallbladder lesions may be difficult. Generally, solitary lesions and those with an endoluminal growth may more commonly represent primary neoplasms. As in other locations, grading of neuroendocrine neoplasms of the gallbladder is performed in accordance with the ENETS scheme.

ICD-O codes
Neuroendocrine tumor (NET)
NET G1 (carcinoid) 8240/3
NET G2 8249/3
Neuroendocrine carcinoma (NEC) 8246/3
Large cell NEC 8013/3
Small cell NEC 8041/3
MANEC 8244/3

Introduction

As in other locations, including the ampullary region and the extrahepatic bile ducts, neuroendocrine tumors primary to the gallbladder were preferentially termed carcinoids or carcinoid tumors, irrespective of their grade of malignancy and differentiation. The term carcinoid is now reserved for well-differentiated neuroendocrine tumors, according to the 2010 WHO classification (NET G1), while other forms of neuroendocrine tumors are allocated to distinct entities that are different from carcinoids. The novel WHO classification defines neuroendocrine neoplasms of the gallbladder as neoplasms with neuroendocrine differentiation, including NET, neuroendocrine carcinoma (NEC), and mixed adenoneuroendocrine carcinoma (MANEC) (Komminoth et al. 2010).

Classification of Neuroendocrine Neoplasms

Following the widely employed 2000 WHO classification of neuroendocrine tumors, the novel 2010 classification introduced new categories and nomenclatures, summarized in Table 1. The designation "neuroendocrine" instead of "endocrine" is now adopted to indicate that cell lineages involved in the neoplastic process express neural markers. The term, neuroendocrine neoplasm, can be employed as a synonym of neuroendocrine tumor.

The difference between WDET and WDEC was defined according to staging features in the WHO classification. The novel category, NET G2, does not necessarily translate into WDEC of the WHO 2000 classification. NEC should not be termed, NET G3, as NET is per definition a well-differentiated neoplasm.

Grading of Neuroendocrine Neoplasms

As in other locations, grading of gallbladder neuroendocrine tumors is now performed in accordance to the ENETS scheme (Rindi et al. 2006, 2007). The criteria are listed in Table 2. Pillars for this proliferation-based grading system are the mitotic count and the proliferation fraction assessed through the Ki-67 index. This grading

Table 1 WHO classifications (2000 and 2010) of neuroendocrine neoplasms

WHO 2000	WHO 2010
1. Well-differentiated endocrine tumor (WDET)	1. NET G1 (carcinoid)
2. Well-differentiated endocrine carcinoma (WDEC)	2. NET G2
3. Poorly differentiated endocrine carcinoma/small cell carcinoma (PDEC)	3. NEC (large cell or small cell type)
4. Mixed exocrine-endocrine carcinoma (MEEC)	4. Mixed adenoneuroendocrine carcinoma (MANEC)
5. Tumor-like lesions (TLL)	5. Hyperplastic and preneoplastic

Table 2 ENETS grading of neuroendocrine tumors

G1: Mitotic count <2 per 10 HPF and/or < = 2 % Ki-67 index
G2: Mitotic count 2–20 per 10 HPF and/or 3–20 % Ki-67 index
G3: Mitotic count >20 per 10 HPF and/or >20 % Ki-67 index

requires mitotic counts in at least 50 high-power fields (HPF), 1 HPF representing 2 mm^2 of tissue. Grading may, therefore, be difficult or not reliable in very small biopsy samples. The determination of the Ki-67 index (MIB1 immunostaining) requires the analysis of 500–2,000 tumor cells assessed in areas of homogeneous and strongest nuclear labeling (so-called "hot spots"). In case differences in grade determination between mitotic count and Ki-67 index occur, it is proposed that the higher grade be assumed.

Staging Systems for Neuroendocrine Neoplasms of the Gallbladder

In contrast to other gastrointestinal sites harboring neuroendocrine tumors, there is still no proposal for a TNM/staging classification of neuroendocrine neoplasms of the gallbladder. It has therefore been suggested that, for definitely malignant neuroendocrine neoplasms of the gallbladder, and in particular for NEC, the TNM system used for gallbladder adenocarcinomas be employed. Table 3 shows the TNM7 staging system for cancers of the gallbladder.

Epidemiology

Neuroendocrine tumors of the gallbladder are rare lesions that represent only 0.5 % of all gallbladder tumors and 0.2 % of all gastrointestinal neuroendocrine neoplasms (MacDonald 1956). Well-differentiated NETs (carcinoids) have a lower age at presentation in comparison with other gallbladder tumors (Godwin 1975), while NECs occur in an older category of patients.

Table 3 TNM7 Staging system for malignant neoplasms of the gallbladder

T			
TX	Primary tumor cannot be assessed		
T0	No evidence of primary tumor		
T1	Tumor invades the lamina propria or muscle layer		
T1a	Tumor invades the lamina propria		
T1b	Tumor invades the muscle layer		
T2	Tumor invades the perimuscular connective tissue, no extension beyond the serosa or into the liver		
T3	Tumor perforates the serosa (visceral peritoneum) and/or directly invades the liver and/or one other adjacent organ or structure, e.g., stomach, duodenum, colon, pancreas, omentum, extrahepatic bile ducts		
T4	Tumor invades the main portal vein or hepatic artery or invades two or more extrahepatic organs or structures		
N			
NX	Regional lymph nodes cannot be assessed		
N0	No regional lymph node metastasis		
N1	Regional lymph node metastasis		
M			
MX	Distant metastasis cannot be assessed		
M0	No distant metastasis		
M1	Distant metastasis		
Stage grouping			
Stage 0	Tis	N0	M0
Stage IA	T1	N0	M0
Stage IB	T2	N0	M0
Stage IIA	T3	N0	M0
Stage IIB	T1, T2, T3	N1	M0
Stage III	T4	Any N	M0
Stage IV	Any T	Any N	M1

General Clinical and Imaging Features

NET located to the distal part of the gallbladder can cause obstruction and may thus be associated with acute cholecystitis. Acute cholecystitis has also been observed in carcinoid tumor metastatic to the gallbladder, in the absence of stones (Saxton 1983). Even though NETs can synthesize a wide array of endocrine/neuroendocrine peptides, hormonal syndromes caused by these neoplasms are rare and include Zollinger-Ellison syndrome (Bernades et al. 1972) and ACTH secretion

syndrome (Spence and Burns-Cox 1975). Abdominal sonography and CT at admission usually reveal either intramural gallbladder masses, polypoid lesions (Salimi and Sharafuddin 1995), or tumors protruding into the gallbladder lumen, the latter morphology being rather typical for NEC (Chuang et al. 1999). In high-grade tumors, liver invasion is often seen at imaging.

Biology of Disease

In regard to biology of disease and tumor disease progression, neuroendocrine neoplasms of the gallbladder can be divided into two major groups that markedly differ in regard to tumor aggressiveness. The first group consists of NET showing a wide spectrum of behavior ranging from relatively bland tumors to metastasizing lesions, while the second group, the NEC, invariably shows a highly malignant phenotype with rapid evolution and high morbidity and mortality. In the NET group, the risk of malignant behavior depends on tumor size and proliferative activity (grade). NETs measuring 0.3–0.5 cm usually do not develop metastases, while gallbladder NETs with a diameter exceeding 2 cm often invade the liver and/or produce metastases. The overall risk for NET to cause regional or distant metastases is estimated to be 44 % and 11 %, respectively, with a 5-year survival rate of 41 %, based on the SEER database (reviewed in Komminoth et al. 2010). Patients with the aggressive NEC exhibit signs of disseminated disease at the time point of diagnosis in 40–50 %. MANEC tumors are considered to behave similar to ordinary gallbladder adenocarcinomas.

Neuroendocrine Tumor G1 (NET G1; Carcinoid) and NET G2 of the Gallbladder

Introduction

Well-differentiated neuroendocrine tumors (NET G1 and NET G2) are rare tumors. The first case has been reported in 1929 (Joel 1929), and a recent listing of the SEER database has 278 cases of gallbladder NET. However, only a minority of well-differentiated (G1) NETs are listed in this database, suggesting that G1 lesions may be very rare in the gallbladder, most gallbladder neuroendocrine neoplasms belonging to aggressive lesions discussed below (Eltawil et al. 2010; Lee et al. 2010). The female/male ratio of gallbladder carcinoids was 2.4, and the mean age at diagnosis was 64.5 years (Albores-Saavedra et al. 2009). NET may be detected incidentally, in the setting of cholecystectomies performed for other reasons, or are diagnosed because they are symptomatic lesions.

Selected References (Bosse 1943; Barnes 1952; Lanza et al. 1965; Nizze 1973; Gaffney and Coyle 1978; Sommariva et al. 1988; Yamamoto et al. 1989; Mochizuki 1991; Betancourt et al. 1992; Naseer and Kabir 1992; Porter et al. 1992; Deehan et al. 1993; Khetan et al. 1995; Kawaguchi et al. 1996; Nishigami et al. 1996; Psathakis et al. 1996; Lovera et al. 1997; Machado et al. 1998; Kaiho et al. 1999; Yokoyama et al. 2000; Angelini et al. 2003; Ozawa et al. 2003; Arjaneyulu et al. 2007; Geo et al. 2007; Virzi et al. 2008; Baikoussis et al. 2009; Kanakala et al. 2009; Zou et al. 2010; Ghosh et al. 2011; Lee et al. 2011; Mezi et al. 2011).

In principle, symptomatic gallbladder NETs are indistinguishable from gallbladder cancer (Tewari et al. 2009), and the carcinoid syndrome is estimated to occur in only 1 % or less of patients (Salimi and Sharafuddin 1995). A minority of gallbladder NETs are associated with the production and eventual secretion of hormonal peptides, including pancreatic polypeptide, somatostatin, gastrin, or ghrelin (Tanaka et al. 1992; Heymann et al. 1997; Walter et al. 2009), sometimes associated with Zollinger-Ellison syndrome (Barone et al. 1992). Angiographically, gallbladder carcinoids are hypervascular lesions fed by a sometimes dilated and finely neovascularized cystic artery, and this hypervascular phenotype is recapitulated in hepatic metastases (Kitagawa et al. 1986). NET with a differentiation grade G1 or G2 may

probably and in part be translated in what was previously called typical carcinoid. In a group of 101 gallbladder tumors diagnosed as carcinoid, 81 cases were "typical" and 20 cases were "atypical" carcinoids, the latter containing less differentiated neoplasms (Soga 2003).

Only well-differentiated NETs of the gallbladder are expected to have a better prognosis (Iype et al. 2009). Some authors defined "variant endocrinomas" developing in the gallbladder. "Classical" carcinoids were different from the variant group by exhibiting a younger average age, a higher incidence of associated cholelithiasis, a higher incidence of small tumors 50 mm or less, a smaller average tumor size, and a lower rate of metastases (Soga 2003). For classical gallbladder carcinoids, the 10-year survival rate was 36 % (Albores-Saavedra et al. 2009).

Pathology

Macroscopically, NETs are nodular or polypoid tumors of whitish, yellow, or tan color. Part of the lesions show an infiltrative growth into the gallbladder wall at macroscopic examination already. The neoplasms are usually small, less than 2 cm diameter in most cases, but they may grow to sizes exceeding 5 cm. Early lesions that measure only a few mm may be missed at gross examination (Porter et al. 1992). Most NETs are solitary lesions, but rare instances of multifocality exist. Rarely, tumors appear as clearly pedunculated lesions with a well-identifiable stalk (Oku et al. 2008).

In "typical" carcinoid (NET G1), small "endocrine type", uniform cells are arranged in the form of anastomosing trabecular, solid, nested, or alveolar structures surrounded by a richly vascularized stroma. Some NETs show tubular structures. The cells exhibit a slightly eosinophilic cytoplasm and round to oval nuclei with inconspicuous nucleoli. NET G2 has more cellular and nuclear unrest, with more frequent deviation of nuclear size and shape from the round endocrine nuclei and more frequent mitotic figures (see the paragraph on grading). Grimelius staining is variably positive (Nishigami et al. 1996), but Fontana-Masson staining is usually negative.

Ultrastructurally, the neoplastic cells contain typical and sometimes numerous neurosecretory granules in the cytoplasm (Kaiho et al. 1999). Immunohistochemically, NETs are strongly reactive for chromogranin A, synaptophysin, neuron-specific enolase, and CD56/N-CAM. The tumors can express cytokeratins (AE17AE3 and CK7), serotonin, and several hormonal peptides, including somatostatin, gastrin, and pancreatic polypeptide (Kaiho et al. 1999; Zou et al. 2010; Mezi et al. 2011).

Variants of Gallbladder NET/Carcinoid Tumors

One variant of NET G1 is characterized by a composition of clear cells (lipid-rich/clear cell neuroendocrine tumor; clear cell NET G1). Similar to their counterparts occurring in the pancreas (Ordonez and Silva 1997; Hoang et al. 2001), which may occur in the setting of von Hippel-Lindau disease (Singh et al. 2006) or in MEN I (Fryer et al. 2012), clear cell tumors of neuroendocrine lineage of the gallbladder can develop in von Hippel-Lindau disease (Sinkre et al. 2001), but clear cell NET G1 of the gallbladder can occur in the absence of this genetic disorder (Konishi et al. 2003; Ishida et al. 2012). These tumors are composed of cells with a cytoplasm that contains lipid droplets and sometimes displays a foamy structure. The clear aspect of the neoplastic cells is not caused by glycogen accumulations, as PAS staining gives a negative result. Similar to ordinary carcinoids, clear cell NET G1 are immunoreactive for chromogranin A and synaptophysin and may also express several neuroendocrine peptides, including somatostatin, gastrin, and pancreatic polypeptide (Konishi et al. 2003). Clear cell NETs associated with von Hippel-Lindau disease, but not sporadic cases, are reactive for alpha-inhibin (Sinkre et al. 2001; Konishi et al. 2003; Ishida et al. 2012). A very rare variant of NET G1 is signet-ring cell carcinoid, characterized by a neoplastic proliferation of numerous signet-ring cells admixed with chromogranin A-positive clear cells (Papotti et al. 1990). Goblet cell adenocarcinoid has been found as a component of a composite tumor (Muto et al. 1984).

Neuroendocrine Carcinoma (NEC) of the Gallbladder

Introduction

Neuroendocrine carcinomas (NECs) of the gallbladder are rare neoplasms, and patients with such lesions have a poor prognosis. NECs exhibit early and often numerous locoregional lymph node metastases and distant metastases, in a first round frequently to the liver (Bosl et al. 1980; McLean and Pedersen 1991; Kumar et al. 1992; Yoshizumi et al. 1992; Mizukami et al. 1998; Bhutani et al. 2001). However, modern chemotherapy schemes can now result in long-term remission in part of patients (Mizukami et al. 1998; Shimono et al. 2009; Elahi et al. 2013).

Small Cell NEC (SCNEC)

Small cell neuroendocrine carcinomas (SCNECs) of the gallbladder represent the more common variant of NEC and share many features with their counterparts developing in other organs, particularly those in the lung (see above; paragraph on small cell carcinomas). Gallbladder small cell NECs were also termed oat cell carcinoma (Albores-Saavedra et al. 1984). The prevalence of SCNEC of the gallbladder is estimated to be 1–5 % of all gastrointestinal neuroendocrine neoplasms (Albores-Saavedra et al. 1984). Similar to SCNEC of the ampullary region, patients with gallbladder SCNEC are older at presentation than those with NET/carcinoids, with a median age at diagnosis of 65 years (in one study, 69 years; Maitra et al. 2001). There is a female preponderance (76 % are female), and the tumors are often associated with cholelithiasis (72 %).

Selected References (Cavazzana et al. 1991; Ron et al. 1992; Nishihara and Tsuneyoshi 1993; Muraina et al. 1996; Chuang et al. 1999; Moskal et al. 1999; Matsuo et al. 2000; Fujii et al. 2001; Maitra et al. 2001; Lane et al. 2002; Jun et al. 2006; Imai et al. 2008; Nishime et al. 2008; Uribe-Uribe et al. 2009; Lee et al. 2010; Nau et al. 2010; Ng et al. 2010; Mahipal and Gupta 2011; Benkel et al. 2012; Chen et al. 2014).

Similar to LCNEC, SCNECs are very aggressive lesions with poor outcome (Lee et al. 2010). Seventy-five percent of the tumors had metastasized or extended locally beyond the gallbladder at surgery (Maitra et al. 2001). In an analysis of 28 pure SCNEC and 8 MANEC containing SCNEC, the tumors metastasized to lymph nodes in 88 %, the liver in 88 %, the lung in 23 %, and the peritoneum in 19 % (Moskal et al. 1999). In an analysis of 12 patients, mean survival was 10.7 months, with a range of 3–25 months (Maitra et al. 2001). Similar to other small cell undifferentiated carcinomas, SCNECs are sometimes associated with paraneoplastic syndromes, e.g., hyponatremia (Ng et al. 2010) or sensory neuropathy (Uribe-Uribe et al. 2009).

Pathology

Macroscopy

Macroscopically, the tumors are usually bulky lesions of whitish to tan color that may protrude into the gallbladder lumen. In one study of 12 cases, the neoplasms had an average size of 3 cm (Maitra et al. 2001). On cut sections, the tumors have a fleshy consistency or are friable masses. The carcinomas have been described as ill-defined or nodular gray-white to whitish masses showing hemorrhagic necrosis (Chuang et al. 1999). The tumors are often large at the time point of diagnosis and show a propensity for submucosal growth (Albores-Saavedra et al. 1984). SCC may also present as small nodular lesions of the gallbladder, but even small tumors can metastasize to local lymph nodes (Uribe-Uribe et al. 2009), again a feature also known for SCC of the lungs

Histopathology

Histologically, SCNECs exhibit loosely cohesive tumor cells that diffusely infiltrate the gallbladder wall, may form sheets and cords, and can show

extensive lymphovascular invasion. The tumor cells are small to medium sized, mostly somewhat larger than quiescent small lymphocytes, i.e., like oat cells of lung carcinoma. Apart from round cells, spindled, fusiform, or polygonal cells also occur. The cytoplasm is scanty and slightly eosinophilic to amphophilic. The nuclei are ovoid, spindle shaped, or indented, with the characteristic "salt and pepper" chromatin structure with either no visible nucleoli or two to three small nucleoli. Characteristic nuclear "moulding" (also written "molding") is seen on high-power examination. Nuclear "moulding" is a helpful artifact due to the flexible nuclear membrane: the nucleus of one tumor cell appears to be bumping into another nucleus, causing the two nuclei to look like part of a jigsaw puzzle. Many and in part abnormal mitotic figures are noted, as well as apoptotic bodies and foci of necrosis. There may be tingible bodies reflecting phagocytosis of nuclear debris, and emperipolesis of apoptotic bodies may be found. Prominent necrosis is usually found, with accumulations of shadow cells. Similar to small cell carcinoma of the lung, the tumors display the diagnostically helpful nuclear "crushed" artifact caused by section preparation and may show the Azzopardi phenomenon, i.e., basophilic chromatin containing damaged DNA coating vessel walls following liberation of chromatin/DNA from dead cells (Albores-Saavedra et al. 1984; Takei et al. 2007; Nau et al. 2010). Part of SCNECs may show rosette-like structures and tubules. The latter should represent definitively less than 30 % of the tumor, otherwise MANEC has to be considered (see below). In a series of 12 patients, invasion of the muscularis propria and perimuscular connective tissue was detected in 90 % (Maitra et al. 2001). Association with intestinal metaplasia of the gallbladder mucosa has been found, with goblet cells, pseudopyloric glands, and Paneth cells (Kuwabara and Uda 1998). Argyrophilic cells may be found in the Grimelius stain (Iida and Tsutsumi 1992; Nishihara and Tsuneyoshi 1993).

In more than a quarter of cases, SCNEC is combined with adenocarcinoma, squamous cell carcinoma, or other types of carcinoma (Duan et al. 1991; Iida and Tsutsumi 1992; Nishihara et al. 1994; Okamoto et al. 2003; Mahipal and Gupta 2011). In the series of 12 patients published by Maitra et al. (2001), half of the cases were combined with other neoplasms. Four had foci of adenocarcinoma, one had a component of squamous cell carcinoma, and one had a focus of carcinosarcoma. Combined SCC and clear cell carcinoma of the gallbladder have been observed (Piana et al. 2002). Sarcomatoid carcinoma of the gallbladder was found to have an SCC component (Takahashi et al. 2004).

Ultrastructurally, neurosecretory-type cytoplasmic granules were detected (Cavazzana et al. 1991; Fujii et al. 2001). Immunohistochemically, the tumor cells express neuroendocrine lineage markers, above all synaptophysin and chromogranin A (Cavazzana et al. 1991; Chuang et al. 1999; Mahipal and Gupta 2011). Synaptophysin expression is usually diffuse, whereas chromogranin A tends to involve scattered cells. In some cases, focal reactivity for epithelial markers was detectable, including cytokeratins, EMA, and CEA (Cavazzana et al. 1991). SCNEC may express serotonin, but this is a rare feature. Relatively few tumors expressed neuroendocrine peptides, such as somatostatin, or ACTH. On a molecular level, 100 % of SCNEC of the gallbladder demonstrated inactivation of the pRB/p16 pathway, and 67 % of these tumors accumulated high levels of p53, while activating K-ras mutations were not found (Parwani et al. 2003).

Large Cell NEC

Among NECs of the gallbladder, the large cell variant (LCNEC) is the less common in comparison with its small cell counterpart (Papotti et al. 2000; Jun et al. 2006; Shimono et al. 2009; Furrukh et al. 2013; Okuyama et al. 2013; Samad et al. 2013). LCNEC has been found in association with anomalous union of the pancreaticobiliary duct (Yoon et al. 2009). Exceptionally, LCNECs were associated with paraneoplastic syndromes, e.g., Cushing's syndrome caused by

production of ACTH by the tumor (Lin et al. 2010).

Macroscopically, the tumors resemble the phenotype described for SCNEC. Histologically, the neoplasms display an organoid growth pattern and consist of large cells with an amphophilic or slightly eosinophilic cytoplasm and large vesicular nuclei with prominent nucleoli. These cells are arranged in a diffuse, solid, or focally nesting pattern. In fine-needle aspiration preparations, rosette-like structures may be encountered in a background showing extensive necrotic debris (Samad et al. 2013). In some tumors, the cell size is situated between large and small cells (intermediate cell NEC; ICNEC), a tumor not listed as such in the 2010 WHO classification. Immunohistochemically, the tumor cells are reactive for synaptophysin, chromogranin A (Okuyama et al. 2013), and at least part of the cells are reactive for epithelial markers (AE1/AE3; Samad et al. 2013). The proliferation fraction (Ki-67 index) is high or very high (Okuyama et al. 2013; Samad et al. 2013).

Mixed Adenoneuroendocrine Carcinoma (MANEC) of the Gallbladder

Introduction

In the 2010 WHO classification, mixed adenoneuroendocrine carcinomas (MANECs) are defined as composite neoplasms in which areas of adenocarcinoma or squamous cell carcinoma intermingle with areas of neuroendocrine tumor (NET) or neuroendocrine carcinoma (NEC), each component comprising at least 30 %, or exceeding 30 %, of the neoplasm. In the light of the different cell lineages involved, a role of stem cells has been proposed as a pathogenic mechanism (Paniz Mondolfi et al. 2011).

The first description of a gastrointestinal tumor with an exocrine and a neuroendocrine component dates in 1924 (Cordier 1924). Tumors having a synchronous presentation of adenocarcinoma and (neuro)endocrine components were previously called adenocarcinoid, a term first coined in 1978 based on tumors of the appendix (Warkel et al. 1978; Cooper and Warkel 1978). In 1987, Lewin suggested to classify such neoplasm into three different subtypes: collision tumors, combined tumors, and amphicrine tumors (Lewin 1987). According to the WHO classification of tumors, these lesions are now termed mixed adenoneuroendocrine carcinoma or MANEC (synonyms: adenoendocrine carcinoma; mixed/composite glandular-endocrine cell carcinoma; composite carcinomatous and carcinoid tumor; carcinoid tumor with adenocarcinomatous differentiation). The neuroendocrine components display features overlapping those described in pure NETs or NECs, being formed by solid and/or trabecular structures with argyrophilic cells that are immunoreactive for neuroendocrine markers. The identification in adenocarcinoma of scattered neuroendocrine cells by immunohistochemistry does not qualify for the definition of MANEC. The spectrum of lesions ranges from pure NE tumors to pure non-endocrine carcinomas, as discussed in a review as of 2006 (Volante et al. 2006), and MANECs form a distinct window in this spectrum. The nomenclature and classification of these tumors has recently been refined (La Rosa et al. 2012; Table 4). Gastrointestinal MANECs, including those of the gallbladder, can be stratified in different prognostic categories according to grade of malignancy of each component. High-grade malignant MANECs are malignant composite or combined tumors formed by an adenomatous or carcinomatous component and by a poorly differentiated (small, intermediate, or large cell type) neuroendocrine carcinoma. Intermediate-grade malignant MANEC includes mixed adenocarcinoma-neuroendocrine carcinoma and amphicrine carcinoma. The first category consists of adenocarcinoma, and the neuroendocrine component is represented by a

Table 4 Classification of MANEC and related tumors (La Rosa et al. 2012)

High-grade malignant MANEC
Intermediate-grade malignant MANEC
Mixed adenocarcinoma-neuroendocrine tumor (adenocarcinoma-NET)
Mixed adenoneuroendocrine tumor (MANET)
Adenoma-neuroendocrine tumor (adenoma-NET)

differentiated neuroendocrine tumor which can show grade 1 (NET G1) or grade 2 (NET G2) differentiation. Amphicrine carcinoma represents a peculiar neoplasm in which exocrine and neuroendocrine features are coexpressed by the same neoplastic cells. Mixed adenocarcinoma-neuroendocrine tumor (adenocarcinoma-NET) is a composite tumor consisting of areas of adenocarcinoma and areas of grade 1 or grade 2 NET (synonyms: mucin-producing carcinoid; composite carcinoid-adenocarcinoma, composite carcinoid tumor, mixed adenocarcinoid tumor, and composite glandular-neuroendocrine mixed tumor). Mixed adenoneuroendocrine tumors or MANETs include neoplasms formed by well-differentiated neuroendocrine and exocrine cells which behave in an indolent manner. Adenoma-neuroendocrine tumor (adenoma-NET) is a very rare neoplasm characterized by both an adenomatous and a NET component (synonym: glandular-carcinoid tumor). It has to be emphasized that adenocarcinoma having cells showing immunoreactivity for neuroendocrine markers (adenocarcinoma with neuroendocrine features) in the absence of neuroendocrine cells should not be classified as MANEC.

MANEC and similar lesions are rare primary tumors of the gallbladder, less than 30 cases having been reported.

Selected References (Wisniewski and Toker 1972; Ito et al. 1980; Wada et al. 1983; Kotake et al. 1984; Muto et al. 1984; Noda et al. 1989; Fish et al. 1990; Peraza et al. 1990; Duan et al. 1991; Olinici and Waslu 1991; Iida and Tsutsumi 1992; Ohmori et al. 1993; Nishihara et al. 1994; Resnick et al. 1994; Eriguchi et al. 2000; Yannakou et al. 2001; Piana et al. 2002; Shimizu et al. 2006; Sosnik and Sosnik 2006; Tsuchiya et al. 2006; Oshiro et al. 2008; Sato et al. 2010; Paniz Mondolfi et al. 2011; Harada et al. 2012; Rastogi et al. 2012; Russo et al. 2012).

The rarity of reported cases of MANEC may be related to the lack of immune-histochemical studies in older studies. Among 49 gallbladder cancers of a recent investigation using immunohistochemistry for neuroendocrine markers, a neuroendocrine component occupying more than 30 % of the entire tumor was found in 5/49 cases/10 % (Harada et al. 2012), MANECs develop without recognizable association with preexisting disease in the large majority of cases. In one patient, an association with pancreaticobiliary maljunction was found (Oshiro et al. 2008).

Clinical and Imaging Features

The clinical presentation of MANECs is nonspecific and mainly consists of upper abdominal pain and a right upper abdominal mass. Signs of carcinoid syndrome are lacking. In MANEC cases containing aggressive neuroendocrine components, chiefly small of large cell parts, patients may present with advanced stage disease and associated symptoms and signs of cancer disease, including weight loss and fever. MANECs with small cell NEC (SCNEC) and large cell NEC (LCNEC) components have a poor outcome, whereas the biology of disease in MANECs having a carcinoid component is dominated by the adenocarcinoma component of the tumor (La Rosa et al. 2012). Exceptionally, MANECs are associated with hormonal hypersecretion, e.g., pancreatic polypeptide (Marrano et al. 1999).

Pathology

Apart from solid and nodular tumors, MANECs of the gallbladder are relatively often endophytically growing lesions, with a polypoid pattern. On cut surfaces the tumors are grayish or white or whitish-yellow to tan, depending on the proportion of adenocarcinoma vs. neuroendocrine components. MANEC may be deeply invasive lesions, penetrating the entire gallbladder wall and even infiltrating the fossa and the liver substance proper.

The histology of MANEC is characterized by adenocarcinoma and neuroendocrine elements randomly distributed through the gallbladder wall, closely juxtaposed, but also with transitions between the two components. Several combinations of morphologies have been described

Table 5 Types of adenocarcinoma and neuroendocrine tumors combined in MANEC and mixed adenocarcinoma-NET of the gallbladder

Adenocarcinoma, carcinoid tumor	(Wisniewski and Toker 1972; Wada et al. 1983; Kotake et al. 1984; Noda et al. 1989)
Undifferentiated carcinoma, carcinoid tumor	(Ito et al. 1980)
Adenocarcinoma, signet-ring cell carcinoma, ICNEC	(Olinici and Waslu 1991)
Tubular adenocarcinoma, ICNEC	(Eriguchi et al. 2000; Yannakou et al. 2001)
Adenocarcinoma, SCNEC	(Duan et al. 1991; Iida and Tsutsumi 1992; Nishihara et al. 1994; Okamoto et al. 2003; Shimizu et al. 2006; Tsuchiya et al. 2006; Elahi et al. 2013)
Clear cell carcinoma, SCNEC	(Piana et al. 2002)
Mucinous adenocarcinoma, SCNEC, LCNEC	(Oshiro et al. 2008; Russo et al. 2012)
Tubular adenocarcinoma, LCNEC	(Sato et al. 2010)
Papillary adenocarcinoma, LCNEC	(Paniz Mondolfi et al. 2011)

LCNEC large cell neuroendocrine carcinoma, *SCNEC* small cell neuroendocrine carcinoma, *ICNEC* intermediate cell neuroendocrine carcinoma

(Table 5). The differentiation and mucin production patterns of the adenocarcinoma component vary considerably among cases, and some adenocarcinomas may only show florid neuroendocrine cell nests (Sakaki et al. 2000). The reticulin pattern differs between the two parts, being dense in adenocarcinoma and delicate in the neuroendocrine parts. MANEC may contain a component of goblet cell adenocarcinoid as a rare differentiation mode (Muto et al. 1984). Where the two components merge, so-called transitional tumor cells showing both histological and cytological features may be seen. In these areas, argyrophil granules and mucin can be found in the same cells (Wada et al. 1983). One MANEC showed extensive Paneth cell metaplasia (Sakakai et al. 2000). The adenoid component of a small cell NEC-type MANEC may only be manifest in the form of intestinal metaplasia (Kuwabara and Uda 1998). Some of the tumors show necrosis and/or fibrosis.

The tumors may be associated with erosion or ulceration of the overlying mucosa, and hyperplastic epithelial changes are sometimes seen in the adjacent intact mucosa. Ultrastructurally, individual tumor cells were shown to have overlapping features of neuroendocrine and glandular differentiation (Paniz Mondolfi et al. 2011).

The adenocarcinoma cells express a marker pattern typical of ordinary gallbladder adenocarcinoma, while neuroendocrine tumor cells are reactive for neuron-specific enolase (NSE), chromogranin A, and synaptophysin (Noda et al. 1989; Eriguchi et al. 2000; Shimizu et al. 2006; Tsuchiya et al. 2006; Sato et al. 2010). So-called transitional tumor cells display common immunoreactivity for CEA, cancer antigen 19-9, CK19, epithelial cell adhesion molecule, and CD117 (Paniz Mondolfi et al. 2011).

Pathogenic Pathways

The histogenesis of MANEC has not yet been clarified, but several hypotheses of their pathogenesis have been proposed. One view consists of the coincidental neoplastic change in two different cell lineages; the other suggests the involvement of a progenitor cell developing into an endocrine and a glandular cellular phenotype. The second hypothesis is sometimes favored owing to the fact that so-called transitional cells are detectable in part of the tumors.

DOI 10.1007/978-3-319-26956-6_156

Abstract

The gallbladder is the primary site of numerous types of mesenchymal tumors, but all these neoplasms are rare. Many of the small and solitary lesions are asymptomatic and are detected as incidental lesions in the setting of cholecystectomy for other reasons. Benign tumors include lipoma, various fibrous tumors, leiomyoma, gastrointestinal stromal tumor, schwannoma, neurofibroma, granular cell tumor, hemangioma, and lymphangioma. Several types of sarcomas were diagnosed in gallbladder specimens, in particular spindle cell sarcomas, myosarcomas, and angiosarcoma. Part of sarcomas show an endoluminal growth pattern, sometimes with formation of large polyps filling the gallbladder lumen. Part of sarcomatous gallbladder neoplasms described in the older literature are difficult to classify. Rarely, lymphomas develop in the gallbladder wall, in the apparent absence of manifestations elsewhere.

Lipoma of the Gallbladder

Introduction

Gallbladder lipoma is a rare benign adipocyte tumor that has been observed few times as an incidental finding in the course of cholecystectomy or as a slowly growing tumor that caused filling of the gallbladder or obstruction (Hillemand and Debbasch 1961; Bonandrini et al. 1970; Tokoro et al. 1991; Furukawa 1996; Takagi et al. 1996). Gallbladder lipoma may be associated with multiple lipomas of the gastrointestinal tract (Tokoro et al. 1991).

Pathology

Macroscopically, gallbladder lipomas are well-circumscribed, roundish yellow tumors of the soft consistency; these neoplasms also show elsewhere in the body. The histology is the same as in other lipomas, sometimes with small necrosis and

the formation of lipogranulomas. The slowly growing tumors can cause atrophy of the adjacent muscular layer of the gallbladder.

Differential Diagnosis

The principal differential diagnosis of gallbladder lipoma is the more common reactive increase of gallbladder-associated normal adipose tissue, i.e., lipomatosis (Miyake et al. 1987). On a biopsy, these two conditions may not be distinguishable.

Lipomatosis of the Gallbladder

Introduction

Lipomatosis of the gallbladder is defined as either a proliferation of mature adipose tissue in the subserosa of the gallbladder (the common variant) and/or an infiltration of the muscular wall of the gallbladder by adipose tissue, associated with myatrophy (the rare variant). Lipomatosis is one form of Jutras's hypertrophic cholecystosis, a group of disorders or abnormalities of the gallbladder different from inflammatory disease (Jutras et al. 1960). Gallbladder lipomatosis can be associated with adenomyomatosis (Miyake et al. 1992). Subserosal gallbladder lipomatosis is visualized on CT and MR images, with a typical mural stratification, the subserosal fatty layer being the last layer before the serosa stratum (Miyake et al. 1987; Oishi Tanaka et al. 2002).

Pathology

Macroscopically, a thick and lobulated layer of adipose tissue is found in the subserosal gallbladder space in the common form of lipomatosis. In this variant, the adipose tissue does not extend into the muscle layers. In contrast, the much less common transmural form shows lobules of fatty tissue also in the muscularis. Histologically, mature and normal-looking adipose tissue is the hallmark.

Differential Diagnosis

In contrast to the rare gallbladder lipoma, lipomatosis is not a nodular solitary lesion but forms a band-like accumulation of fatty tissue with a diffuse or lobular pattern.

Liposarcoma of the Gallbladder

Introduction

Liposarcoma is a member of the least common sarcomas developing in the gallbladder, together with rhabdomyosarcoma, angiosarcoma, and synovial sarcoma. Only few cases have been reported (Bader and Vallon 1983; Hamada et al. 2006). The tumors tended to invade adjacent structures and to spread within the abdominal cavity.

Pathology

As in other compartments of the body, gallbladder liposarcoma can grow to large or very large sizes. In one patient, the tumor measured 25 cm in diameter, with a weight of 3,300 g, and extended into the right liver lobe and the peritoneal cavity (Hamada et al. 2006). Several histologic types of this sarcoma were identified, including myxoid liposarcoma (Bader and Vallon 1983) and pleomorphic liposarcoma (Hamada et al. 2006).

Differential Diagnosis

Spindle cell components occurring in liposarcoma may lead to the erroneous diagnosis of fibrosarcoma or other spindle cell sarcomas. In liposarcoma lacking large droplet adipocytes, fat stains on frozen sections will lead to the correct diagnosis.

Leiomyoma of the Gallbladder

Introduction

Gallbladder leiomyomas either develop as sporadic and very rare benign tumors, or they occur in immunosuppressed individuals with or without

Epstein-Barr virus (EBV) infection. Sporadic leiomyomas of the gallbladder are usually small- or medium-sized nodular lesions that are mostly found incidentally in the course of cholecystectomies for other reasons (Gava and Cinti 1968; Christensen and Ishak 1970; Shou et al. 1987; Furukawa 1996; Palade et al. 2006; Wachter et al. 2010; Segura-Sampedro et al. 2012). Gallbladder leiomyomas of immunosuppressed patients, including children, were observed in HIV infection (Toma et al. 1997) and in EBV infection (Monforte-Muñoz et al. 2003). Monforte-Muñoz and associates reported an 8-year-old girl with SCID and bone marrow transplantation, who developed multiple gallbladder leiomyomas (leiomyomatosis) associated with other leiomyomas in the liver, spleen, pancreas, intestinal tract, and lung. The patient was EBV infected and developed extensive EBV-associated polymorphic lymphoproliferative disorder/PTLD. Pediatric HIV- and EBV-associated smooth muscle cell tumors of the gallbladder have been described in another clinical investigation (Mahlobo et al. 2012).

Pathology

Macroscopically, gallbladder leiomyomas are solitary or multiple nodular and whitish tumors of medium to high consistency, with a fibrillary or fasciculated texture on the cut surface. Histology typically shows fascicles of faintly eosinophilic and elongated smooth muscle cells with blunted nuclei. Mitotic figures are very rare, and necroses are usually absent. Immunohistochemically, the cells are markedly reactive for alpha-smooth muscle actin and vimentin but not for S100 protein.

Differential Diagnosis

Leiomyoma of the gallbladder may be confounded with other rare spindle cell tumors of this organ, including fibroma, myofibroblastic neoplasms, neurofibroma, well-differentiated leiomyosarcoma, and GISTs. The differential diagnostic separation of leiomyoma from GIST may be difficult and requires immunohistochemistry, leiomyomas being negative for CD117 and positive for smooth muscle actin.

Leiomyosarcoma of the Gallbladder

Introduction

Among gallbladder malignancies, primary leiomyosarcoma is one of the most infrequent types, with only relatively few reported cases. The first case may have been reported in 1893 (Schmidt 1893). By 1984, leiomyosarcoma accounted for 7 % of 105 cases of primary gallbladder sarcomas (Newmark et al. 1986). The tumor is mostly found in female patients in the sixth decade who have cholecystolithiasis (Yasuma and Yanaka 1971). Main symptoms and signs comprise pain radiating to the back or to the right lower quadrant, resembling cholecystitis. Gallbladder leiomyosarcoma carries a poor prognosis. It can invade the gallbladder fossa and the liver hilum and metastasizes to the liver (Garcia Marin et al. 2010).

Selected References Dello Russo and Paladino 1960; Gonzalomendoza and Aguilar 1963; Duchini 1965; Friedland 1971; Yasuma and Yanaka 1971; Willén and Willén 1982; Heitzman 1985; Newmark et al. 1986; Tarasov et al. 1987; Gutstein et al. 1988; Egorov 1989; Fotiadis et al. 1990; Yoshida et al. 1990; Muñoz et al. 1992; Kumar et al. 1993; Tocchi et al. 1993; Ikuno et al. 1996; Zeig et al. 1998; Danikas et al. 2001; Bernardos et al. 2004; Perez-Montiel et al. 2004; Palomeque et al. 2005; Elkaoui et al. 2008; Al-Daraji et al. 2009; Husain et al. 2009; Garcia Marin et al. 2010; Savlania et al. 2012.

Pathology

Gallbladder leiomyosarcomas usually form large, rubbery, or firm masses replacing the gallbladder. The neoplasms can grow to impressive sizes,

having a diameter of 17 cm and a weight of 3,100 g in one case (Palomeque et al. 2005). Large tumors often show central necrosis and hemorrhage. Part of the tumors display an endophytic growth, sometimes with large polypoid endoluminal masses with or without dilatation of the gallbladder lumen (Newmark et al. 1986; Perez-Montiel et al. 2004). Histology shows bundles and fascicles of eosinophilic spindle cells with elongated or blunt nuclei, variable nuclear atypias, and a usually slightly to moderately elevated mitotic count. However, poorly differentiated epithelioid leiomyosarcoma was also observed (Danikas et al. 2001). Immunohistochemically, the tumor expresses alpha-smooth muscle actin and vimentin (Garcia Marin et al. 2010).

Differential Diagnosis

Differential diagnostically, other spindle cell sarcomas and atypical hypercellular leiomyomas have to be considered.

Angioleiomyoma of the Gallbladder

Introduction

Angioleiomyoma (angiomyoma; vascular leiomyoma) is a benign myoid tumor that chiefly occurs in the soft tissues of the extremities, mostly the lower extremity (Hachisuga et al. 1984). The tumor was first described in 1868 by Aufrecht. It produces well-circumscribed nodules consisting of smooth muscle cells which have an intimate relationship to blood vessels. These tumors account for 5 % of all benign neoplasms of soft tissues. In the skin, angioleiomyoma is usually a solitary lesions, but multiple forms also occur. Histologically, angioleiomyoma is classified into three types, i.e., capillary or solid, the most common form characterized by the presence of numerous thin-walled slit-like vascular channels that rarely represent abortive arterial vessels; venous type, with vessels having thick walls; and the rare cavernous type, with dilated vessels that are rather poor in muscle cells. Due to the arterialization in a minority of cases, angioleiomyomas may present as pulsatile nodules. Less commonly, angioleiomyoma develops in inner organs, particularly intestine, genitourinary tract, and dura. Angioleiomyoma also occurs in the skeletal system.

Pathology

Angioleiomyoma rarely develops in the gallbladder (Aschl et al. 1999). Histologically, the nodular lesions are composed of a proliferation of smooth muscle cells forming bundles that surround numerous, thick-walled vessels with partially patent lumina.

Differential Diagnosis

The chief differential diagnosis is leiomyoma, a benign tumor that is well known to occur in the extrahepatic biliary tract.

Infantile Myofibromatosis of the Gallbladder

Exceptionally, gallbladder involvement with infantile myofibromatosis, a rare disorder discussed in another chapter, has been observed (Goldberg et al. 1988). This disorder is characterized by a proliferation of fibroblasts or and/or myofibroblasts which already appears at birth and progressively involves several organs and tissues. In the case reported by Goldberg and associates (1988), gallbladder infiltration was associated with involvement of the common bile duct, causing obstructive jaundice.

Fibroma of the Gallbladder

Primary fibroma of the gallbladder is among the most uncommon tumors of this organ, with only one report available (Furukawa 1996).

Fibrosarcoma and Not Further Specified Spindle Cell Sarcomas of the Gallbladder

Introduction

Primary fibrosarcoma of the gallbladder is a very rare malignancy (Landsteiner 1904; Lyons 1950; Daneo 1954; Chauvenet 1955; Longo and Ferraris 1957; Marrano and Freyrie 1963; Roselli et al. 1964; Tanga 1970; Mena and Montebruno 1971; Tamaki et al. 1971; Yasuma and Yanaka 1971; Vaittinen 1972; Chudacek 1973; Rose 1978; Willén and Willén 1982). In the light of revised classifications of fibroblastic and myofibroblastic sarcomas, it is difficult to judge as to how the tumors reported in the older literature would be classified today. Part of the cases may have represented myxofibrosarcoma or myofibroblastic sarcoma, tumors that are known to occur in the gallbladder (Husain et al. 2009), or myogenic sarcomas. Gallbladder fibrosarcoma was observed in conjunction with gallbladder carcinoma (Chudacek 1973).

Pathology

Macroscopically, fibrosarcomas are large and firm tumors with a fasciculated cut surface, sometimes with central necrosis and/or hemorrhage (Fig. 1). Histologically, the lesions present the same pattern as their soft tissue counterparts, i.e., a dense collection of fibroblastoid spindle cells forming bundles or fascicles, with variable degrees of nuclear atypia and usually a low mitotic count. Part of sarcomas derived from a fibroblastoid lineage show marked pleomorphisms and a low degree of differentiation (Fig. 2).

Myxofibrosarcoma is one of the most common sarcomas in the extremities of patients of older age, and is clinically characterized by a high prevalence of local recurrence, but a rather low overall risk of distant metastases. Primary visceral myxofibrosarcoma is an uncommon variant of this neoplasm. So far, there is a single observation of myxofibrosarcomatoid lesion in the gallbladder, with a fibromyxoid sarcoma-like/Evans-like morphology (Al-Daraji et al. 2009). Differential diagnostically, myxofibrosarcoma can metastasize to the intra-abdominal compartment, including the liver (Murahashi et al. 2012).

Differential Diagnosis

As already outlined above, fibrosarcoma has to be distinguished from other spindle cell sarcomas, in particular myofibroblastic sarcoma and myxofibrosarcoma. Inflammatory pseudotumors (inflammatory myofibroblastic tumors) of the gallbladder may histologically mimic spindle

Fig. 1 Sarcoma of the gallbladder with an endophytic, "phyllodes-like" growth pattern. The neoplasm exhibits marked necrosis

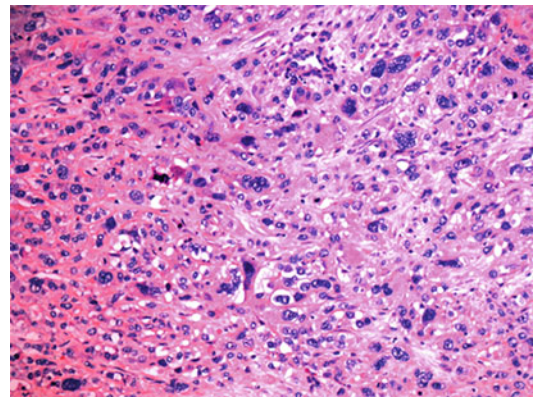

Fig. 2 Pleomorphic, poorly differentiated sarcoma of the gallbladder with tumor giant cells (hematoxylin and eosin stain)

cell sarcoma. Few cases of chronic cholecystitis can develop a marked, fasciitis-like and sometimes mass-forming connective tissue reaction that must not be confounded with sarcoma.

Schwannoma (Neurilemmoma) of the Gallbladder

Introduction

Schwannoma (neurinoma) is a common soft tissue tumor derived from Schwann cells of diverse types of nerves. Apart from soft tissues and the central nervous system, schwannoma develops in several visceral organs, including the hepatobiliary tract. In contrast to large extrahepatic bile ducts, schwannoma of the gallbladder is an uncommon neoplasm.

Pathology

Few cases of schwannoma primary to the gallbladder have been reported, and most were incidental findings obtained with cholecystectomy specimens (Debray et al. 1956; Christensen and Ishak 1970; Yamagiwa et al. 1991; Colovic et al. 2003; Ohta et al. 2010). In one patient, the lesion manifested as jaundice, and a diagnosis of bile duct cancer was considered, but cholecystectomy disclosed schwannoma of the gallbladder (Yamagiwa et al. 1991). In the patient reported by Ohta and associates (2010), laparoscopic cholecystectomy was performed due to a preoperative diagnosis of cholecystolithiasis. The surgical specimen revealed stones and chronic cholecystitis, associated with a small tumor that was manifest as wall thickening of the fundus. Histology showed the typical features of schwannoma.

Differential Diagnosis

Histologically, schwannoma of the gallbladder may be confounded with neurofibroma or traumatic neuroma. In small or damaged lesion, immunohistochemistry for S100 protein expression is helpful to detect the characteristic arrangement of Schwann cells in schwannomas.

Neurogenic Sarcoma of the Gallbladder

There is a single published observation of neurogenic sarcoma primary to the gallbladder (Rabinovitch and Trinidad 1952).

Granular Cell Tumor of the Gallbladder

Granular cell tumors (granular cell schwannomas) are lesions that are well known to occur in the extrahepatic bile duct system (see the respective chapter). In contrast, only few cases of granular cell tumor originating in the gallbladder have been observed (Ishii et al. 1977; Yamaguchi et al. 1985; Murakata and Ishak 2001). In one patient, the tumor was situated in the cystic duct and had caused mucocele of the gallbladder (Yamashina and Stemmermann 1984). As in other locations, the tumors are reactive for S100 protein and inhibin-alpha.

Neurofibroma and Neurofibrosarcoma of the Gallbladder

Introduction

Neurofibroma is a rare benign mesenchymal tumor of the gallbladder that develops with or without preceding neurofibromatosis type 1. In a review of seven published cases, age at presentation ranged from 44 to 77 years (average 61.6 years), with a slight female preponderance (Acebo et al. 1998). Most tumors are located in the gallbladder body and are detected incidentally in gallbladders resected for cholecystolithiasis (Arbab and Brasfield 1967; Christensen and Ishak 1970; Eggleston and Goldman 1982; Ilie and Behar 1985; Morizumi et al. 1988; Fuller and Williams 1991; Zhang 1991; Albores-

Saavedra et al. 1993; King and Williamson 1995; Acebo et al. 1998; Sucandy et al. 2010). Apart from asymptomatic lesions, a case presenting as chronic epigastric pain was reported (Sucandy et al. 2010).

Pathology

Macroscopically, solitary neurofibroma either presents as an intramural nodular tumor of whitish color that is well delineated and exhibits a rather form consistency or as and endophytically growing polypoid tumor. Among seven reviewed cases, five tumors appeared as the mural nodular variant, and two showed intraluminal growth. The size of the lesions ranged from 0.3 to 5.3 cm, with a mean diameter of 1.3 cm (Acebo et al. 1998). Gallbladder neurofibroma can present as multiple mural nodules (Sucandy et al. 2010). Histologically, diffuse or plexiform growth patterns occur, as seen in other neurofibromas.

Differential Diagnosis

Gallbladder neurofibroma may be confounded with neurinoma in the absence of immunohistochemical stains.

Neurofibrosarcoma

Malignant variants of neurofibroma, or neurofibrosarcoma, are extremely rare neoplasms of the gallbladder (Liu et al. 2013). In a 72-year-old female patient described by Liu et al. (2013), the gallbladder revealed a tumor with a maximum diameter of 7 cm that had reached the visceral surface of the organ. Histologically, the neoplasm was composed of fusiform to round cells with a slightly eosinophilic cytoplasm, with a fasciculated and weaving pattern. One to three mitoses per HPF were noted. Immunohistochemically, the cells were vimentin(++), NSE(+), S100 protein (+), and SMA(−).

Neuroma and Neuromatosis of the Gallbladder

Introduction

Neuromas (traumatic neuroma; amputation neuroma) are reactive proliferations of nerves that develop at the distal ends of proximal segments of severed nerves. They are characterized by a neural enmeshment of a disorganized overgrowth of axons, Schwann cells, and perineural cells, forming fascicles of variable dimension embedded in a fibrocollagenous tissue and representing an attempt for regeneration (Masson 1942; Stembridge 1951). Neuromas of the biliary tract and the gallbladder derive from the sympathetic and parasympathetic fibers arising from the greater and lesser splanchnic nerves. It has been shown that the area of the common bile duct bifurcation with the cystic duct is a particularly nerve-rich region (see the respective paragraph in the chapter of bile duct tumors).

Neuroma of the Gallbladder

Neuroma of the body of the gallbladder is a very rare lesion. A polypoid traumatic neuroma was incidentally found in a gallbladder resected for cholelithiasis. This neuroma was suggested to have developed following injury to the gallbladder during an unsuccessful cholecystectomy many years previously (Sano et al. 1985). In another patient, abdominal imaging revealed a protuberant lesion of the gallbladder, histologically representing neuroma in the absence of previous surgery and cholelithiasis (Matsuoka et al. 1996). There are also rare instances of cystic duct neuroma in the absence of previous surgery (Peison and Benisch 1985). More extensive involvement of the gallbladder, i.e., neuromatosis, has been described (Cosmacini et al. 1967). Traumatic neuroma had been found in a patient with double gallbladder, the lesion being present in the second gallbladder after removal of the first (Lefemine and Lazim 2009).

Postcholecystectomy Neuromas

Neuromas most commonly develop in the cystic duct after cholecystectomy, both open and laparoscopic, are the best known example of traumatic biliary tract neuroma, and develop with a highly variable delay following trauma, after cholecystectomy ranging from several months to more than 40 years (Hume and Buxton 1954; Gold 1962; Christensen and Ishak 1970; Bodner et al. 1978; Grigorjew 1981; Stibenz et al. 1984; Elhag and al Awadi 1992; Nagafuchi et al. 1998). The lesions occurred in up to 10 % of postcholecystectomy patients at autopsy in one study (Pickens et al. 1999). Neuroma of the cystic duct stump is a known cause of postcholecystectomy pain/postcholecystectomy syndrome. Cystic duct can extend into the wall of the large extrahepatic bile ducts and cause biliary obstruction (Iannelli et al. 2003).

Osteoma of the Gallbladder

A 39-year-old woman showed multiple osteomas in her gallbladder. She had presented with right upper quadrant abdominal pain, and ultrasonography displayed three small intraluminal gallbladder lesions with no apparent mobility. Pathological examination revealed three small polypoid osteomas covered with normal-looking mucosa (Chen 1994).

Osteosarcoma and Chondrosarcoma of the Gallbladder

Osteosarcoma

Extraskeletal osteosarcoma is a rare high-grade sarcoma which accounts for approximately 1 % of all malignant soft tissue neoplasms. The extrahepatic biliary tract is one of the least common sites for these tumors.

Pathology

Very few cases of osteosarcoma primary to the gallbladder have been described (Sartorio Riganti et al. 1959; Olgyai et al. 2006). Macroscopically, a bony consistency of the tumor mass may be recognizable. Histologically, a spindle cell sarcoma with interspersed neoplastic osteoid is found, with some CD68-positive osteoclasts (Olgyai et al. 2006).

Differential Diagnosis

The main differential diagnosis is variants of gallbladder carcinosarcoma containing tumor osteoid or even osteosarcoma-like components (Inoshita et al. 1986; Ishida et al. 2012; Parreira et al. 2012; Sadamori et al. 2012).

Chondrosarcoma

Edmondson (1967a) mentioned the possible existence of a chondrosarcoma of the gallbladder.

Synovial Sarcoma of the Gallbladder

Introduction

Synovial sarcoma is a high-grade soft tissue sarcoma that mostly develops in the extremities but also occurs in inner organs, including the gastrointestinal tract. In the hepatobiliary system, synovial sarcoma has been observed as a primary liver tumor several times, while a primary location to the gallbladder is an exceptional finding.

Pathology

There is a single report on synovial sarcoma primary to the gallbladder and common bile duct (Qayum et al. 2008).

Rhabdomyosarcoma of the Gallbladder

Introduction

Very few cases of gallbladder rhabdomyosarcoma (RMS) occurring in adult patients have been reported (Edmondson 1967b; Yasuma and Yanaka 1971; Willén and Willén 1982; Ben Rejeb et al. 1987, 1994; Al-Jaberi et al. 1994; Al-Daraji et al. 2009). Similar to hepatobiliary embryonal RMS in children, gallbladder RMS can grow with a botryoid pattern, i.e., with exophytic polypoid masses (Willén and Willén 1982). In the review of Ben Rejeb et al., it was specified that among seven patients described until 1994, six were females. Three tumors were of the embryonal type, three were of the alveolar type, and one was RMS NOS. In the pediatric age group, hepatobiliary rhabdomyosarcoma involving extra- and intrahepatic bile ducts is a well-recognized entity. However, only relatively few children presented with gallbladder RMS (Mihara et al. 1982). The case of Mihara and coworkers (1982) seems to be a combined RMS of both the common bile duct and the gallbladder, with formation of a polypoid filling defect in the duct and three RMS polyps in the gallbladder.

Pathology

In adult patients, gallbladder RMS can present as a large mass (up to 10 cm diameter; al-Jaberi et al. 1994), extensive necrosis, and hemorrhage in central parts of the mass being frequent. Histologically, embryonal, mixed embryonal, alveolar, and pure alveolar types were identified, the tumor cells being reactive for desmin and vimentin (Al-Jaberi et al. 1994). In pediatric gallbladder RMS, a polypoid/botryoid phenotype prevails, and the tumor is usually embryonal RMS (Mihara et al. 1982).

Differential Diagnosis

Apart from RMS, other gallbladder tumors can show rhabdomyoblastic or rhabdomyomatous differentiation, including carcinosarcomas and malignant stromal tumors (Furihata et al. 2005).

Gastrointestinal Stromal Tumor of the Gallbladder

Introduction

Gastrointestinal stromal tumor (GIST) chiefly develops in the GIT, mesentery and omentum, and much less commonly in the hepatobiliary tract (reviews: Steigen and Eide 2009; Liegl-Atzwanger et al. 2010; Foo et al. 2012). Only few reports have documented GIST primary to the gallbladder (Ortiz-Hidalgo et al. 2000; Mendoza-Marin et al. 2002; Jong et al. 2004; Peerlinck et al. 2004; Palomeque et al. 2005; Petrou et al. 2011; Kostov and Kobakov 2012). GISTs have been proposed to take their origin from interstitial cells of Cajal (ICCs) because of the expression of c-KIT (Sircar et al. 1999). ICCs (pacemaker cells of the GIT) are identified by their combined reactivity for CD117, CD34, and vimentin in the gut. In the first two reports on gallbladder GIST, emphasis had been placed that these neoplasms had the phenotype of ICCs (Ortiz-Hidalgo et al. 2000; Mendoza-Marin et al. 2002).

Gallbladder GIST can be divided into low-risk and high-risk categories, as proposed for other GISTs (Miettinen et al. 1999), and can show a malignant behavior (Mendoza-Marin et al. 2002; Jong et al. 2004; Park et al. 2004; Petrou et al. 2011), with invasion of the gallbladder fossa, the extrahepatic bile ducts, and the duodenum, and delayed metastasis to the liver (Park et al. 2004).

Pathology

Similar to GIST developing in the GIT, gallbladder GIST can grow to a large size and encase the entire gallbladder. Histologically, a spindle cell population predominates, with a morphologic pattern similar to that of GIST localized elsewhere. In malignant gallbladder GIST, tumor necrosis and a high rate of mitotic figures have been noted

(in one case more than 20/50 HPF; Park et al. 2004), i.e., showing the high-risk phenotype according to the risk of aggressive behavior of GIST proposed in the NIH consensus symposium of GIST (Fletcher et al. 2002).

Immunohistochemically, most gallbladder GISTs showed reactivity of the tumor cells for CD117/C-KIT, CD34, and vimentin (Ortiz-Hidalgo et al. 2000). However, rare cases with immunoreactivity for PDGFRA in the absence of CD117 staining have also been described, associated with a mutation of the PDGFRA gene involving codon 824 (Petrou et al. 2011).

"Gastrointestinal Stromal Tumor" with Rhabdmyomatous Differentiation of the Gallbladder

Furihata and coworkers (2005) described a malignant stromal gallbladder tumor, observed in a 68-year-old woman, histologically characterized by a spindle cell population showing a rhabdomyomatous differentiation in the absence of desmin immunostaining. The neoplastic cells were diffusely positive for CD117(c-KIT, suggesting an unusual variant of GIST derived from a mesenchymal stem cell capable to follow a rhabdomyomatous cell lineage.

Differential Diagnosis

By conventional histology, the most important morphologic differential diagnoses of gallbladder GIST comprise nerve sheath tumors and smooth muscle cell tumors.

Stromal Tumor of the Gallbladder with Phenotype of Interstitial Cells of Cajal

Stromal tumor of the gallbladder with the phenotype of interstitial cells of Cajal is a novel entity (Ortiz-Hidalgo et al. 2000; Mendoza-Marin et al. 2002). The first case was detected in a 69-year-old woman who had cholelithiasis and chronic cholecystitis. The gallbladder wall showed a hypocellular nodule of 2.4 cm diameter, composed of spindled cells that were immunoreactive for vimentin, CD34, and CD117. The CD117-positive cells were fusiform with elongated bipolar projections or dendritic-like cytoplasmic projections, representing interstitial cells of Cajal (ICC). In the uninvolved gallbladder wall, numerous CD117-positive ICCs were noted, suggesting that the tumor might have originated from ICC hyperplasia (Ortiz-Hidalgo et al. 2000). A malignant counterpart of this tumor was later observed in a 34-year-old woman who had suffered from upper quadrant abdominal pain. The gallbladder had a thickened wall and showed a polypoid growth arising in the neck region. In addition to the features described above, histology revealed numerous mitotic figures and necroses (Mendoza-Marin et al. 2002).

Hemangioma of the Gallbladder

Introduction

In contrast to the liver, where hemangioma is the most common benign tumor, primary hemangioma of the gallbladder is a very rare lesion. In most patients with this lesion, hemangiomas were incidentally discovered in the course of abdominal ultrasound and CT imaging performed for other reasons. Few patients with gallbladder hemangioma showed abdominal pain or signs mimicking cholangitis or choledocholithiasis.

Epidemiology

Hemangioma of the gallbladder was first mentioned in the 1960s in Robbins' textbook of pathology, but the first formal description of a hemangioma of the gallbladder area was that of Arbab and Brasfield (1967), who however reported on a cavernous hemangioma found in the gallbladder fossa in the course of a reoperation due to postcholecystectomy syndrome. Gallbladder hemangiomas are very uncommon lesions. In a review of benign gallbladder tumors, only

1 hemangioma was detected among 465 cases (Melson 1976). In a review of reported patients, the average age at presentation was 52.5 years, with a female to male ratio of 3:1 (Mayorga et al. 1997). In a more recent review of eight patients, six were male and two female, with an age at diagnosis ranging from 11 to 62 years (Crucitti et al. 2005). Cavernous hemangioma of the gallbladder was observed in conjunction with liver hemangioma (Moffat 1973) or was also identified in the setting of multiple visceral angiomatosis (Cabrera et al. 1977).

Clinical and Imaging Features

The clinical presentation of gallbladder hemangiomas is variable, signs and symptoms depending on the size of the lesions and their location within the organ. In part of cases, the lesion was asymptomatic and detected in the course of screening examinations. In the female patient described by Crucitti and coworkers (2005), abdominal ultrasound performed for screening revealed a solid and fixed echogenic mass arising from the gallbladder fundus, 2.8 × 2.2 cm in size, bulging into the lumen. In a compilation of eight cases, abdominal, epigastric, or back pain or discomfort, often vague, was experienced in six patients (Crucitti et al. 2005). However, gallbladder hemangioma of the cavernous type may also grow to impressive size and hence becoming symptomatic, causing voluminous enlargement of the organ and the clinical impression of a cystic mesenteric tumor (Mayorga et al. 1997).

Pathology

Macroscopically, gallbladder hemangiomas are nodular or polypoid and sometimes pedunculated, spongy, or bosselated tumors of red to blue-red color. Histologically, several types of hemangiomas were detected in the gallbladder wall, including cavernous hemangioma (Sewell and Miron 1969; Moffat 1973; Mayorga et al. 1997; Crucitti et al. 2005), arteriovenous hemangioma (Furukawa et al. 1997), and venous hemangioma (Jones et al. 1987). In the most common cavernous variant of hemangioma, histology disclosed densely packed dilated vascular channels with a lobular texture.

Differential Diagnosis

The most relevant differential diagnosis of gallbladder cavernous hemangioma are gallbladder varices, which may develop in the setting of portal hypertension or as a complication of other causes of gallbladder venous outflow disorders (Saigh et al. 1985; Chawla et al. 1994; Radhi 2003; Mishin 2005; Venerito et al. 2006; Besa et al. 2012; Moubarak et al. 2012). Dilated portosystemic collateral vessels of the gallbladder in liver cirrhosis make part of the inferior vena cava group (Moubarak et al. 2012). Similar to hemangiomas, gallbladder varices may undergo hemorrhage, even with associated rupture (Kevans et al. 2009). Other differential diagnoses comprise hypervascular tumors of the gallbladder or of the liver, close to the gallbladder fossa. Hepatic hemangioma located to the fossa region may masquerade as the gallbladder in case of gallbladder agenesis (Stephenson et al. 2010). Exceptional situations mimicking angiomatoid lesions of the gallbladder include mural and extramural proliferations of collateral vessels caused by gallbladder venous and arterial thrombosis in the setting of essential thrombocythemia (Picon-Coronel et al. 2011).

Angiosarcoma of the Gallbladder

Introduction

Among gallbladder sarcomas, primary angiosarcoma (AS) is among the least common malignancies. As in other localizations, gallbladder AS is a highly aggressive neoplasm (Delaini 1954; Vangelista 1954; Belelli 1956; Rosansky and Mullens 1982; Kawai et al. 1989; Kumar et al. 1989, 1994; Hittmair et al. 1991; Byers and McMahon 1994; White and Chan 1994; Costantini et al. 2005; Odashiro et al. 2005; Al-Daraji et al. 2009; Husain et al. 2009). gallbladder AS is usually an isolated lesion that is not associated with preexisting gallbladder lesions,

although one case of AS synchronously associated with squamous cell carcinoma was reported (Kumar et al. 1994).

Pathology

Macroscopically, gallbladder AS form nodular and often hemorrhagic lesions in the wall, or in outer parts of the gallbladder, sometimes extending into the gallbladder fossa. In the course of disease, widespread metastases mainly to the liver, spleen, and peritoneal surface develop (Odashiro et al. 2005). Histopathologically, gallbladder AS present the phenotype known from other locations of this tumor. A dominant proportion of gallbladder AS was of the epithelioid type (Byers and McMahon 1994; White and Chan 1994; Costantini et al. 2005).

Lymphangioma of the Gallbladder

Introduction

Intra-abdominal cystic lymphangiomas, including those developing in the gallbladder, are rare lesions that can be difficult to diagnose, because they radiologically mimic other cystic intra-abdominal alterations. Intra-abdominal lymphangiomas account for less than 5 % of all lymphangiomas. The most common site is the mesentery, followed by the omentum, mesocolon, small intestine, pancreas, liver, spleen, and retroperitoneal space. Approximately 60 % of the patients are younger than 5 years at presentation; the remaining cases do not manifest until the adult age group (Takiff et al. 1985; Roisman et al. 1989). Lymphangioma primary to the gallbladder is a rare lesion, with only few cases having been reported in the literature (Ohba et al. 1995; Amadori et al. 1999; Chung et al. 1999; Choi et al. 2002; Yang et al. 2003; Noh et al. 2005; Kim et al. 2007; Woo et al. 2007; Shikano et al. 2008; Boskovski et al. 2012; Bridda et al. 2012). Gallbladder lymphangioma has also been observed in the pediatric age group (Han et al. 2011).

Clinical and Imaging Features

The clinical presentation of gallbladder lymphangioma is non-specific and mainly consists of right upper quadrant pain, nausea, biliary pain, and sometimes a palpable mass. Owing to a pressure effect, biliary sludge may accumulate in the gallbladder, followed by gallbladder dysfunction. Ultrasonography and CT usually reveal cystic septated masses in the gallbladder wall or in the gallbladder fossa, in part of the cases with calcifications (Ohba et al. 1995), but sometimes the entire gallbladder is replaced by a multicystic mass effacing the gallbladder anatomy. T2-weighted MRI images reveal the septated aspect of most of the cystic lesions (Choi et al. 2002; Noh et al. 2005; Kim et al. 2007). Different signal intensities on T1- and T2-weighted images are due to different fat and fluid ratios within each cyst. Septa are enhanced on the delayed images, while the cystic portions are not. The gallbladder and its lumen may be compressed by the tumor. ERCP illustrated that there is no communication between the gallbladder lumen and the cystic spaces of the tumors (Choi et al. 2002). Angiography showed that the tumors are supplied by a branch of the cystic artery (Ohba et al. 1995).

Biology of Disease

Lymphangiomas are classified as simple, cavernous, or cystic tumors. The prognosis of gallbladder lymphangioma is generally good after complete surgical excision.

Pathology

Macroscopy

Most reported lymphangiomas of the gallbladder were cystic lesions of three morphotypes (Table 1). Multiloculated cystic lesions are grape-like masses with a sponge-like or honeycombed appearance. The cysts displace or replace the preexisting wall structures of the gallbladder and may bulge to the gallbladder lumen,

Table 1 Macroscopic presentation of gallbladder lymphangiomas

Multilocular cystic	Ohba et al. 1995; Shikano et al. 2008
Multiseptated cystic	Choi et al. 2002; Noh et al. 2005
Cystic	Yang et al. 2003; Kim et al. 2007; Woo et al. 2007; Boskovski et al. 2012

associated with atrophy of the mucosa and/or collapse of the lumen. In some of the thin-walled cysts, a fine vascular tree can be noted in the cyst walls. The cysts are sometimes under pressure; following incision, fluid may ooze out copiously. The wall of the cystic tumors can contain calcifications. In case hemorrhage into the spaces takes place, the cysts may have a bluish appearance.

Histopathology

Simple and cavernous lymphangiomas show lymphatic vascular channels that resemble, in their configuration and lumen width, to those found in capillary and cavernous hemangiomas. Cystic lymphangiomas consist of large cystic and usually globose spaces and exhibit a flat endothelial lining of the cystic spaces, whereas simple and cavernous tumors may show a cuboidal or flat lining. Cyst walls are often composed of connective tissue consisting of edematous fibrous tissue, and may contain few myocytes/myofibroblasts and a lymphocytic infiltrate, sometimes with lymph follicles. The lumina of the lymphatic channels contain a pale eosinophilic material (rich in protein, lymph) which can contain lymphocytes and sometimes a few erythrocytes.

Immunohistochemistry

The endothelial lining is reactive for factor VIII-associated antigen and CD31 (Woo et al. 2007). The cells are usually not reactive for CD34. Cells of lymphangiomas are reactive for podoplanin/D2-40 (Sinzelle et al. 2000; Kalof and Cooper 2009) and express VEGFR-3 (Norgall et al. 2007), but this has not yet been analyzed with gallbladder lymphangiomas.

Differential Diagnosis

The chief differential diagnoses comprise echinococcal cysts, lymphangiectasias, mixed cavernous hemangiomas, and wall cysts of the gallbladder.

"Hemangiopericytoma" and Related Tumors of the Gallbladder

Introduction

Hemangiopericytomas were originally described to be neoplasms derived from Zimmermann's pericytes. However, most of the tumors previously classified as hemangiopericytomas do not originate from pericytes, and most of the lesions are in fact solitary fibrous tumors (see the respective chapter on soft tissue tumors of the liver). However, there remains a small group of neoplasms of a truly pericytic lineage, i.e., myopericytomas, lesions that are related to myofibromatosis, glomangiopericytoma, and angioleiomyomas (Fletcher 1994; Granter et al. 1998).

Pathology

A single case of malignant hemangiopericytoma of the gallbladder has been described (Gupta et al. 1983). The tumor showed a pattern typical for this vascular neoplasm and displayed areas of necrosis, an increased mitotic activity, and metastases in locoregional lymph nodes and the right ovary. A giant cell-rich solitary fibrous tumor of the gallbladder was observed (Lazure et al. 2007). This well-demarcated tumor protruded into the lumen and showed a whorled and fibrous structure of the cut surface. The neoplasm was composed of uniform short spindle cells, often aligned like strings of beads between bands of hyalinized collagen. Myogenous sarcoma of the gallbladder

with a hemangiopericytomatous pattern was observed (Nestler et al. 2007).

Malignant Fibrous Histiocytoma (Undifferentiated Pleomorphic Sarcoma) of the Gallbladder

ICD-O code 8830/2

Introduction

Malignant fibrous histiocytoma (MFH) is a rare neoplasm with a high propensity for an aggressive biology. The original concept of MFH by Stout as his associates has undergone extensive changes, and today MFHs are classified as undifferentiated (high-grade) pleomorphic sarcoma/HGUPS (Erlandson and Antonescu 2004; Randall et al. 2004; Matushansky et al. 2009; Henderson and Hollmig 2012). The term MFH is still employed in this paragraph in order to refer to previous observations of this tumor in the gallbladder, all these lesions having been diagnosed as MFH.

Pathology

Few cases of MFH primary to the gallbladder were reported, showing the typical histology with spindle cells arranged in a storiform pattern, intermingled with pleomorphic tumor cells (the storiform pleomorphic pattern). The tumors were usually diagnosed in old patients and tended to metastasize to the liver (Kristofferson et al. 1983; Sasada et al. 1988; Sreekantaiah et al. 1992; Miyakawa and Hamano 1996; Orii et al. 1998; Tomono et al. 1998; Gruttadauria et al. 2001; Al-Daraji et al. 2009; Husain et al. 2009). Also the inflammatory variant of MFH has been observed in the gallbladder (Kato et al. 2002). The neoplasm was found in 70-year-old Japanese man and histologically consisted of ordinary MFH with xanthogranulomatous components, lymphocytes, foamy macrophages, and plasma cells. The tumor cells were reactive for granulocyte colony-stimulating factor, and it was suggested that part of the inflammatory reactions was due to this paracrine mechanism (Kato et al. 2002). In one case of ordinary MFH of the gallbladder, cytogenetic analysis revealed several chromosomal structural abnormalities, including reciprocal translocations and deletions, and chromosomes involved in rearrangements comprised chromosomes 1, 3, 10, 12, 4,16, and 19, while trisomies involved chromosomes 2, 8, 10, and 20 (Sreekantaiah et al. 1992).

Abstract

The gallbladder is involved by a wide variety of non-epithelial tumors, apart from mesenchymal neoplasms. Visceral malignant melanoma develops in the biliary tract, including the gallbladder. As both primary and metastatic gallbladder melanomas may show similar of the same growth patterns, the differential diagnosis between these two conditions is often difficult. Primary gallbladder melanoma is more likely if the tumor shows a polypoid or lobulated and in particular papillary growth pattern, is a solitary lesion, and is associated with junctional activity in the adjacent mucosa. In contrast, metastatic lesions are more commonly multiple, flat, and without junctional changes. Apart from neuroendocrine tumors, other neuroectodermal neoplasms can develop as primary tumors in the gallbladder. Rare primary neoplasms in this organ include germ cell tumors, rhabdoid tumors, perivascular epithelioid cell tumors, and hemolymphatic neoplasms. Apart from malignant melanoma, numerous other malignancies can metastasize to the gallbladder, renal cell carcinoma being a particularly common metastasizing tumor.

Malignant Melanoma of the Gallbladder

Introduction

Visceral malignant melanoma is known to develop in the biliary tract (see the respective chapter) and also occurs as primary neoplasm in the gallbladder, albeit this is a rare malignancy. It has apparently first been reported in 1907 (Wieting and Hamdi 1907), and relatively few cases have since been reported.

Selected References Thayer et al. 1955; Walsh 1956; Jones 1961; Raffensperger et al. 1963; Debiec et al. 1966; Gabriele and Jouffre 1969; Tanga and Ewing 1970; Balthazar and Javors 1975; Peison and Rabin 1976; Sierra-Callejas and Warecka 1976; Hatae et al. 1978; Carle et al. 1981; Baumann et al. 1982; Anderson et al. 1983; Borja et al. 1984; Naguib and Aterman 1984; Seul and Lüchtrath 1984; Rudolph et al. 1985; Verbanck et al. 1986; Heath and Womack 1988; Guerini et al. 1990; Zhang et al. 1991; Habeck 1993; Hatanaka et al. 1993; Velez et al. 1995; Longwitz et al. 1996; Safioleas et al. 2006; Colaneri et al. 2010; Korkmaz et al, 2010; Gligorijevic et al. 2011; Pitlovic et al. 2011.

The morphology and clinical presentation of proven metastatic malignant melanoma of the gallbladder may closely mimic that of "true" or purported primary melanoma of the gallbladder, so that distinguishing these two situations is difficult and has led to the question whether primary malignant melanoma of the gallbladder exists (Higgins and Strutton 1995; Safioleas et al. 2006). Thus, at least part of the published primary gallbladder melanomas may in fact represent metastatic lesions. What are the criteria allowing the diagnosis of primary malignant melanoma of the gallbladder? The following criteria have been proposed: (1) Tumors must be solitary and arise from the mucosal surface of the gallbladder; (2) the lesions must either be papillary or polypoid; (3) they must either display junctional activity or have any other primary sites excluded by history taking, examination, and investigation (Heath and Womack 1988). By applying these criteria, part of the published cases may be deleted and reclassified as unrecognized metastatic lesions. However, also the criteria listed may be misleading, as it is, e.g., known that also metastatic gallbladder melanomas can grow with a polypoid pattern.

Clinical and Imaging Features

The clinical presentation is nonspecific, in particular as many cases remain clinically silent for longer time periods. In case the lesion becomes symptomatic and is suggestive of malignancy, gallbladder carcinomas are usually suspected. As with other gallbladder tumors encroaching upon the gallbladder outlet and/or the cystic duct, acute obstructive cholecystitis may occur in gallbladder

melanoma (Balthazar and Javors 1975). Acute cholecystitis in malignant melanoma may be severe and fulminant, associated with perforation of the gallbladder and biliary peritonitis (Heath and Womack 1988). Primary malignant melanoma of the gallbladder metastasizes to the liver, remote organs, and lymph nodes (Walsh 1956), but unusual metastasis pathways also occur, e.g., to the common bile duct (Verbanck et al. 1986).

Pathology

Macroscopy

Macroscopically, most primary gallbladder melanomas present as circumscribed nodular to lobulated black, friable masses. The growth pattern is characterized by large endophytic, polypoid, and friable masses in most of the reported cases, sometimes with a discrete vascular stalk. Polypoid formations with a papillary surface may form cushion-like structures or large vegetations. This phenotype is in contrast to the gross appearance of metastatic lesions which are more commonly flat, smaller, and multiple lesions (Willis 1948). In the study of metastatic lesions published by McFadden and coworkers (1979), the metastatic lesion was solitary in four cases, multiple in four cases, and diffuse in one case. Primary malignant melanomas of the gallbladder are also larger than most metastatic nodules, the polypoid formation having a diameter of sometimes more than 7 cm, while metastatic nodules described by Willis (1948) were often only a few mm in diameter. Part of the tumors display ulcerated nodules and show necroses in the center, where the tumors may be paler and hemorrhagic, but blackish necroses or black tumor fragments in the gallbladder lumen may also be encountered. In some cases, the gallbladder was filled with blackish sludge or with bile having suspended pigmented fragments and debris.

Histopathology

Histologically, malignant melanoma of the gallbladder shows the phenotype known from melanomas of the skin or other visceral melanomas. Spindled tumor cells with varying amounts of pigment granules (melanosomes) may dominate, but there are also tumor with large and polygonal, epithelioid cells of pleomorphic cells. Numerous and in part atypical mitotic figures are present. In larger nodules, extensive necrosis is noted. The tumors can contain numerous melanophages, mainly around necroses, where liberated melanosomes are phagocytosed by macrophages (Hatae et al. 1978). Small clusters of pigment granules as well as individual pigmented tumor cells may be noted within the columnar epithelial of the mucosa. A junctional activity may be present in lesions spreading within the gallbladder mucosa, characterized by pigmented cells situated between and beneath epithelia cells in small clumps or in isolation (Walsh 1956; Peison and Rabin 1976; Carle et al. 1981). This apparent junctional change has been proposed to be an argument for the primary nature of the tumor (Carle et al. 1981). In the gallbladder mucosa around the site of tumor attachment, and particularly in polypoid lesions having a stalk, there may be scattered single pigmented and in part dendritic cells between epithelial cells. The tumor invades the wall of the gallbladder, with pigmented nodules in the muscle layer and sometimes melanoma nodules in a subserosal position.

Immunohistochemistry

Both primary melanomas of the gallbladder and melanomas metastatic to the gallbladder display the immunohistochemical profile typical for malignant melanomas localized to other organs, including reactivity for HMB45/gp100, melan A, and MITF (Gassler et al. 2004).

Differential Diagnosis: Malignant Melanoma Metastatic to the Gallbladder

Malignant melanoma can metastasize to virtually any organ, most prominent metastatic sites being the lungs, liver, brain, and colon. Gastrointestinal

metastases of malignant melanoma have previously been thought to be uncommon, only 2–4 % of patients with malignant melanoma being diagnosed with gastrointestinal metastases during the course of their disease. However, through improved diagnostic techniques, more aggressive operative and diagnostic interventions, gastrointestinal involvement is now known to be more common. The most common sites of GIT metastases of melanoma include the small bowel (35–67 %), colon (9–15 %), and stomach (5–7 %). Malignant melanoma relatively often metastasizes to the gallbladder, a metastatic pattern that lacks a pathogenic explanation. Among patients with melanoma metastatic to the gastrointestinal tract, around 15 % showed metastases to the gallbladder (Das Gupta and Brasfield 1964). In a review of cases reported until 1979, the interval from diagnosis of the primary tumor until presentation with gallbladder metastases ranged from 3 to 13 years, with a mean of 5.8 years (McFadden et al. 1979).

Selected References Pautler and Gallavan 1951; Henriques 1955; Kazmann 1956; Zemlyn 1966; Gabriele and Jouffre 1969; Shimkin et al. 1972; McFadden et al. 1979; Daunt and King 1982; Vantomme et al. 1984; Murphy et al. 1987; Agosti et al. 1989; Stutte et al. 1989; Goldin 1990; Avila et al. 1994; Seelig and Schönleben 1997; Dong et al. 1999; Cellerino et al. 2000; Kohler et al. 2000; Guida et al. 2002; Gogas et al. 2003; Crippa et al. 2004; Gassler et al. 2004; Swiatoniowski et al. 2004; Rehani et al. 2006; Romero et al. 2006; Varsamidakis et al. 2006; Katz et al. 2007; Marone et al. 2007; Nelms et al. 2007; Tuveri and Tuveri 2007; Samplaski et al. 2008; Hamodat and Alhumidi 2009; Matsubayashi et al. 2012.

As already mentioned above, the similarity of presentation renders the diagnosis of primary gallbladder melanoma vs. metastatic melanoma difficult in a proportion of the cases. Melanoma metastatic to the gallbladder can cause acute, obstructive cholecystitis (Henriques 1955; Ostick and Haggani 1976; Langley et al. 1997; Vernadakis et al. 2009) or masquerading as cholelithiasis (Herrington 1965). Also hemobilia and biliary fistulae have been reported (Daunt and King 1982). However, most cases of gallbladder melanoma metastases are clinically asymptomatic during the patient's lifetime, also illustrated by the discrepancy in case reports vs. detection rates at autopsies (Das Gupta and Brasfield 1964; Goldin 1990; Dong et al. 1999). Overall, the prognosis of metastatic malignant melanoma to the gallbladder is dismal, with a median survival of 6–9 months, and long-term disease-free survival is achieved in only 1–2 % of patients (Dong et al. 1999; Gogas et al. 2003). In a more recent study of 13 patients, the median survival was 12 months following diagnosis, and only 1 patient survived more than 42 months (Katz et al. 2007).

Pathogenic Pathways

Few melanocytes are present in the normal gallbladder mucosa, and it has been suggested that malignant melanomas take their origin from these cells that have spread from the neural crest to the gallbladder during oncogenesis.

Primitive Neuroectodermal Tumor (PNET) of the Gallbladder

Introduction

Primitive neuroectodermal tumor (PNET)/extraosseous Ewing sarcoma most frequently develops in the soft tissues of the extremities and the paravertebral region, but is also known to occur in inner organs. Only one PNET originating in the gallbladder has been reported so far (Song et al. 2004).

Pathology

Histologically, the tumor reported by Song and associates (2004) showed monotonous round cells with a formation of Homer-Wright rosettes, with a morphology typical for PNET occurring elsewhere. The tumor cells were immunoreactive for MIC2/CD99 as well as for synaptophysin and

neuron-specific enolase. A chromosomal translocation, such as t(11;22)(q24;q12) or t(21;22)(q22;q12), was not detectable.

Differential Diagnosis

Differential diagnosis on conventionally stained sections mainly includes other small cell tumors occurring in the gallbladder, e.g., small cell carcinoma or lymphoma.

Paraganglioma of the Gallbladder

Introduction

Extraadrenal paragangliomas are uncommon neoplasms that have been reported in many locations, including the organ of Zuckerkandl, kidney, urethra, urinary bladder, prostate, uterus, vagina, retroperitoneal space, and gastrointestinal tract. While paragangliomas in the head, neck, and mediastinal regions are commonly associated with the parasympathetic system and are chromaffin negative and functionally inactive, retroperitoneal paragangliomas usually originate from the sympathetic nerve system. In the GIT, the duodenal ampulla is a predilection site, specifically for the gangliocytic variant of paraganglioma, whereas the hepatobiliary tract is seldom affected. Few reports documented paraganglioma primary to the gallbladder (Miller et al. 1972; Wolff 1973; Freschi and Sassi 1990; McDonald 1990; Hirano 2000; Cho et al. 2001; Mehra and Chung-Park 2005; Rodriguez-Merchan et al. 2006). The first three patients that had been described (Wolff 1973) were all woman aged 32, 52, and 59 years, respectively, at diagnosis. Gallbladder paraganglioma can develop in the setting of familial multiple endocrine neoplasm syndrome (Mehra and Chung-Park 2005).

Clinical and Imaging Features

Clinically, the tumor may be asymptomatic and detected during cholecystectomy performed for other reasons or may produce vague right upper quadrant pain or gastrointestinal bleeding (Mehra and Chung-Park 2005). In one patient, hemorrhagic gallbladder paraganglioma had caused cholecystoduodenal fistula (Miller et al. 1972). Associated cholecystitis, mostly chronic, was documented in several cases (Wolff 1973; Cho et al. 2001; Mehra and Chung-Park 2005). None of the gallbladder paragangliomas reported so far presented signs and symptoms related to the sympathetic system.

Pathology

Macroscopy

In the few reports where gross features were specified, the tumors were usually located in a subserosal position and were small and well-circumscribed masses, with a beefy, red to brown or red-tan and sometimes spongy cut surface, sometimes with small hemorrhages or necrotic foci (Cho et al. 2001; Mehra and Chung-Park 2005). There was no predilection of site within the gallbladder.

Histopathology

The histopathology of gallbladder paraganglioma is the same as that for other such tumors. The neoplasms are highly vascularized lesions with an expanding growth mode and are surrounded by a complete or incomplete fibrous capsule. The tumor cells are medium-sized, round to polygonal, with an eosinophil or amphophilic, finely granular cytoplasm. Few PAS-positive cytoplasmic globules may be present. The nuclei are ovoid, centrally placed, with a characteristically stippled ("salt-and-pepper") chromatin and small nucleoli. Very few mitotic figures are found. These cells are arranged in small islands or nests (Zellballen). This alveolar-like nesting pattern is best visualized in reticulin stains. Discrete cytoplasmic argyrophilia was detected in the Grimelius stain (Mehra and Chung-Park 2005).

Immunohistochemistry

The large cells forming nests are immunoreactive for chromogranin A, synaptophysin, and neuron-specific enolase, intermingled with S100 protein-positive sustentacular cells. The endothelia of intervening vascular channels are CD34 reactive (Mehra and Chung-Park 2005).

Differential Diagnosis

Gallbladder paraganglioma may occur as a component of multiple paragangliomas, involving the common bile duct and the liver in addition to the gallbladder (Ferrell et al. 1990).

Ganglioneuromatosis of the Gallbladder

Introduction

Ganglioneuromatosis is a well-recognized component of multiple endocrine neoplasia (MEN) type 2b (Carney et al. 1978). Ganglioneuromatosis of the gastrointestinal tract may precede pheochromocytoma and medullary thyroid carcinoma in patients with MEN 2b (Carney et al. 1976). Primary ganglioneuromatosis of the gallbladder is a very rare condition that may develop as an isolated tumor or occur as an extended infiltration of the organ (Carney et al. 1976; Chetty and Clark 1993; Sakuma et al. 2011). In one patient with extensive gallbladder ganglioneuromatosis, additional ectopic pheochromocytoma at the liver hilum was found (Sakuma et al. 2011).

Pathology

Macroscopically, the gallbladder shows a thickened wall and ropy, nodular appearance of the serosal surface (Chetty and Clark 1993). Histologically, the gallbladder wall contains numerous large and prominent nerve-like plexiform structures containing ganglion cells and associated proliferating Schwann cells. The mucosal surface is intact, and the neuroid structures are situated in deeper layers of the gallbladder. Some of the nerve-like profiles are dumbbell-shaped, simulating plexiform neurofibroma (Chetty and Clark 1993).

Differential Diagnosis

In the absence of easily detectable ganglion cells, e.g., due to a sampling error, the lesion may be misinterpreted as plexiform neurofibroma.

Malignant Rhabdoid Tumor of the Gallbladder

Malignant extrarenal rhabdoid tumors are well known to occur in the gastrointestinal tract and the liver, but are very uncommon in the biliary tract. The gallbladder is probably the least common primary site, with only few cases reported so far (Kim et al. 2003; Suri et al. 2003). In one case, the tumor was found in a 46-year-old man who had been operated on for cholelithiasis with chronic cholecystitis. Macroscopic examination of the gallbladder revealed a slight thickening in the body wall, in an area measuring about 1 cm in diameter. Histology showed rhabdoid tumor. The histopathologic presentation is that of rhabdoid tumors of other locations. Gallbladder carcinomas can rarely show a rhabdoid tumor component (Kim et al. 2003).

Germ Cell Tumors of the Gallbladder

Introduction

Similar to other parts of the hepatobiliary tract, germ cell tumors of various types can develop as primary tumors in the gallbladder. In the course of germ cell progenitor migration, some of the

progenitors may be integrated into the budding gallbladder primordium to later give rise to germ cell tumors.

Teratoma of the Gallbladder

Immature teratoma has been observed in the gallbladder of a 9-month-old girl who had presented with an abdominal mass. CT revealed a huge heterogeneous mass with cystic, solid, and calcified components, occupying the upper abdominal cavity and originating from the gallbladder. This teratoma was associated with gliomatosis peritonei in the presence of unaltered ovaries (Torikai et al. 2007).

Choriocarcinoma of the Gallbladder

Non-gestational choriocarcinoma can rarely originate in the gallbladder, similar to other parts of the hepatobiliary tract. Like choriocarcinomas located elsewhere, gallbladder choriocarcinoma displays a rapidly progressive course, with formation of hepatic metastases (Abu-Farsakh and Fraire 1991; Wang et al. 2001). Primary gallbladder choriocarcinoma has been found in conjunction with gallbladder adenocarcinoma (Abu-Farsakh and Fraire 1991).

Dermoid Cyst of the Gallbladder

A single observation described dermoid cyst arising in the gallbladder wall (Falcao and Leal 1975). It cannot be decided in this case whether this lesion was a component of a mature teratoma.

Differential Diagnosis

Gestational and non-gestational choriocarcinomas can widely metastasize within the abdominal cavity, including the gallbladder. Rare gallbladder adenocarcinomas with choriocarcinoma-like areas have been observed (Albores-Saavedra et al. 1981).

Perivascular Epithelioid Cell Tumors (PEComas) of the Gallbladder

Several types of perivascular epithelioid cells tumors (PEC tumors, PEComas) are known for the liver and its ligaments, angiomyolipomas being the most common. In contrast, only very few examples of gallbladder PEComas have been reported.

Among 35 cases of PEComa of the gastrointestinal tract, only 1 case was detected in the gallbladder (Doyle et al. 2013). Also malignant PEComa was observed as a primary neoplasm of the gallbladder (Zhao and Anders 2014). In an elderly male patient, a malignant PEComa of the urinary bladder had metastasized to the gallbladder (Sendo et al. 2013).

Myeloid Neoplasms of the Gallbladder

Alterations of the Gallbladder in Acute or Chronic Myeloid Leukemias

Acute myeloid leukemia can be a complicated by acute acalculous cholecystitis, with or without associated neutropenia (Hurley et al. 1992; Topeli et al. 1996). Acute cholecystitis is sometimes the presenting manifestation of acute myeloid leukemia (Bloom et al. 2002) and can develop in relapsing acute leukemia (Azin et al. 2014). In part of the cases, leukemic infiltration with immature myeloid cells of the gallbladder wall causes significant wall thickening and is causally linked to the initiation of acute inflammation (Bessmel'tsev and Abdulkadyrov 1992; Bloom et al. 2002; Shimizu et al. 2006; Solak et al. 2013). In part of cases, gallbladder infiltrates in the setting of acute myeloid leukemias can produce nodular lesions mimicking gallbladder carcinoma (e.g., in acute myelomonocytic leukemia; Tissot et al. 1981). Patients with chronic myeloid leukemia have a higher prevalence of gallstones (Ates et al. 2009).

Myeloproliferative Disorders

In the course of myelofibrosis, myeloproliferative infiltrates (myeloid metaplasia) can develop in the

gallbladder wall, causing wall thickening (Payan et al. 1989; Geddy and Wedgwood 1996; Thorns et al. 2002; Sahasrabudhe and Davenport 2005). Histologically, the gallbladder wall shows focal segmental or transmural infiltrates resembling extramedullary hematopoiesis, however with numerous immature myeloid cells and often with scattered or clustered atypical (dysplastic) megakaryocytes. A diffuse myeloid infiltrate can efface the architecture of the wall, however sometimes with sparing of the mucosa. The infiltrate can be associated with a reticulin fibrosis, similar to that in myelofibrosis of bone marrow (Geddy and Wedgwood 1996). Essential thrombocythemia can be complicated by multiple venous and arterial thrombosis of the gallbladder causing acute cholecystitis (Picon-Coronel et al. 2011).

Solid Myeloid Neoplasms of the Gallbladder (Extramedullary Myeloid Tumor)

Extramedullary myeloid tumor (EMMT); granulocytic sarcoma or chloroma has been observed in the gallbladder, forming solid tumors of variable size that can grossly resemble gallbladder carcinoma. Immunohistochemically, the neoplasms are reactive for myeloperoxidase, CD15, CD43, and CD117/c-Kit (Tuset et al. 1995; Ojima et al. 2005; Ukkola-Pons et al. 2010). Disseminated EMMT of organs including the gallbladder has also been found in the absence of bone marrow disease (Bartley et al. 2007).

Paraneoplastic Hematological Features of Gallbladder Carcinoma

Similar to other hepatobiliary cancers, carcinoma of the gallbladder can rarely induce paraneoplastic hematological syndromes, e.g., leukemoid reaction (Kumar et al. 2013). In one patient, severe thrombocytosis developed, in the autoptically proven absence of a myeloproliferative disorder (Wakabayashi et al. 1978).

Non-Hodgkin's Lymphomas of the Gallbladder

Introduction

The gallbladder is a rare site of primary non-Hodgkin's lymphoma (NHL) and Hodgkin's lymphomas (HL). In most cases of lymphomatous involvement of this organ, infiltration takes place from the liver (either primary or secondary liver lymphomas extending into the gallbladder via the gallbladder fossa), or gallbladder infiltration is the manifestation of generalized lymphomatous disease. In certain situations, and in the absence of proof through autopsy, it is difficult to decide whether gallbladder lymphoma is truly a primary neoplasm or a manifestation of an otherwise not yet diagnosed lymphoma situated elsewhere.

Epidemiology

NHLs of the gallbladder are uncommon neoplasms that have mostly been published as single case reports. Among 1,452 gallbladder specimens examined over a 5-year period, only one case of lymphoma was found (Darmas et al. 2007).

Clinical Features

Clinically, gallbladder lymphomas often present as cholecystitis (Tishler et al. 1987; Huang et al. 2007) or a space-occupying lesion in the right upper abdomen, but part of the neoplasms are asymptomatic and are detected in the setting of cholecystectomy performed for other reasons. In one study, 92 % of gallbladder NHL presented with symptoms and signs of cholecystitis, cholelithiasis, or jaundice (Mani et al. 2010).

Types of NHL and Pathology

Almost all known types of NHL have been described for the gallbladder, but the type

distribution mirrors that of NHL of the gastrointestinal tract. From the literature it turned out that the most common NHLs (apparently) primary to the gallbladder were NHL of MALT, diffuse large B-cell NHL(DLBCL), and follicular lymphoma. The macroscopic presentation is often that of bulky and sometimes necrotic and/or hemorrhagic masses in the gallbladder wall and/or protruding into the lumen, i.e., a pattern formerly described as "lymphosarcoma." Less common is a presentation in the form of a diffuse infiltration of the wall with wall thickening (Botha and Kahn 1974; Neal et al. 1994; Chatila et al. 1996; Murakami et al. 1996; Bernardini et al. 2000; Gravel et al. 2001; Yokoe et al. 2003; Yamamoto et al. 2005; Ono et al. 2009; Willingham et al. 2009; Shah et al. 2011; Batur and Odev 2014). In a study of 13 cases, transmural involvement by lymphoma was identified in 71.4 %, while 28.6 % showed relative mucosal sparing with predominant smooth muscle and extramuscular involvement (Mani et al. 2010). Rarely, NHL presents as a gallbladder polyp (Mani et al. 2010; Acharya et al. 2014). The cystic lymph node and other locoregional lymph node may or may not be enlarged and involved (Mani et al. 2010). B-cell NHL was also diagnosed in the cystic duct (Jho et al. 2007).

Cases in which the type of gallbladder NHL can be identified from literature data include a broad spectrum of lesion (Table 1).

Table 1 Types of non-Hodgkin's lymphomas (NHLs) observed as primary or secondary lesions in the gallbladder

MALT NHL
Diffuse large B-cell NHL
Small B-cell NHL
Lymphoplasmacytic NHL
Follicular NHL
Extranodal marginal zone NHL
Mantle cell NHL
B-lymphoblastic NHL
Plasmablastic NHL
Burkitt's NHL
Primary effusion NHL
Intravascular large B-cell NHL
Peripheral T-cell NHL
T-cell lymphoblastic NHL
True histiocytic NHL

MALT NHL is the most common primary NHL of the gallbladder. It can form tumorous masses in the gallbladder, mimicking carcinoma, or present as a diffuse infiltration of the gallbladder wall. The histology and immunophenotype are the same as MALT lymphomas developing in other regions of the gastrointestinal tract (Mosnier et al. 1992; McCluggage et al. 1996; Stephen et al. 1998; Abe et al. 1999; Bickel et al. 1999; Tomori et al. 1999; Tsuchiya et al. 2001; Chim et al. 2002; Rajesh et al. 2003; Takano et al. 2004; Koshy et al. 2008; Bisig et al. 2009; Bagwan et al. 2011; Appukutty et al. 2013; Martinez Pérez et al. 2015; Mitra et al. 2014). The second most common NHL of the gallbladder is diffuse large B-cell NHL/DLBCL. It can produce bulky masses in the gallbladder, effacing the wall and sometimes filling the lumen, often with extensive necrosis. The tumor can infiltrate the gallbladder bed and extend into the liver. These are the neoplasms called "lymphocytic lymphosarcoma" or just "lymphosarcoma" in the older literature. The neoplastic cells are a medium-sized to large lymphoid cell with prominent nucleus, showing a B-cell phenotype. As in other locations, this NHL exhibits numerous mitotic figures and a high to very high proliferation fraction (Van Slyck and Schuman 1972; Tishler et al. 1987; Friedman et al. 1993; O'Boyle 1994; Huang et al. 2007; Kato et al. 2008; Sezgin et al. 2009; Mani et al. 2010; Tomonori et al. 2011; Kojima et al. 2014). DLBCL of the gallbladder can occur in combination with MALT NHL (Gardini et al. 2009). The third most common NHL of the gallbladder is follicular NHL, which is characterized by a B-cell population forming follicular structures with a distinctive immunophenotype (Ferluga et al. 2003; Jelic et al. 2004; Mani et al. 2010). The gallbladder can be involved in the setting of chronic lymphocytic leukemia and small B-cell NHL, characterized by a focal to diffuse and sometimes transmural

lymphoid cell infiltrate, the lymphocytes being small but slightly larger than normal unstimulated lymphocytes (Zhang 1985; Chatila et al. 1996; Sato et al. 2001; Psarras et al. 2014). Apart from secondary involvement, small B-cell NHL was also found as a primary gallbladder NHL (Psarras et al. 2014; Zelones and Coimbra 2014), but a not yet diagnosed generalized lymphoproliferative process is difficult to exclude in such cases. Rarely, lymphoplasmacytic NHL/Waldenström's macroglobulinemia was found in the gallbladder (Lin et al. 2003). The other NHLs listed in the table are rare to exceptional findings and include extranodal marginal zone lymphoma (Mani et al. 2010); mantle cell NHL that may develop as a primary gallbladder neoplasm, but also occurs as a metastatic process (Mani et al. 2010; Pherson et al. 2014); B-lymphoblastic NHL (Ozawa et al. 2012); primary (Kim et al. 2014), plasmablastic lymphoma (Mani et al. 2010); primary effusion lymphoma (Mani et al. 2010); intravascular large B-cell lymphoma (Duan et al. 2011; Yadav et al. 2014); Burkitt's lymphoma (Balonga et al. 1996; Gonzalez Lopez et al. 2010); T-cell lymphoma (Farah et al. 2012); T-cell lymphoblastic NHL (Mitropoulos et al. 2000); and true "histiocytic" lymphoma (Sagi and Györi 1972; Gillespie et al. 1977). A very unusual lymphoproliferative process that has been detected in the gallbladder is angiotropic lymphoma (formerly malignant angioendotheliomatosis). Angiotropic (intravascular) lymphoma (originally described as "angioendotheliomatosis proliferans systematisata; Pfleger and Tappeiner 1959) is a rare and mostly fatal neoplasm in which malignant T- or B-lymphoid cells proliferate within the lumina of small blood vessels, whereby B-cell populations predominate. The lesion was also termed intravascular malignant lymphomatosis and often involves the skin and the central nervous system (Wick et al. 1981; Keahey et al. 1982; Bhawan et al. 1985; Mori et al. 1985; Wrotnowski et al. 1985; Carrol et al. 1986; Dominguez et al. 1986; Sheibani et al. 1986; Theaker et al. 1986; Otrakji et al. 1988; Piérard et al. 1988; Fredericks et al. 1991; Helm et al. 1992; Periciario et al. 1995; Erös et al. 2002; Mandal et al. 2007). This malignancy primarily occurs in the skin and the central nervous system, but visceral forms have also been described. The term, malignant angioendotheliomatosis had formerly been employed to denote this neoplastic process, but this term is misleading for lymphomas, as the tumor cells are not endothelial cells, and true neoplastic angioendotheliomatosis is now restricted to rare forms of intravascularly disseminated angiosarcomas (Lin et al. 1997). Few cases of this rare tumor have been described in the gallbladder. Capillaries and other small vessels were filled with, and distended by, large round to oval lymphoid cells with a vesicular nucleus with one or more nucleoli. The mitotic rate was low (Laurino and Melato 1990; DiGiuseppe et al. 1994; Duan et al. 2011). In one case, gallbladder involvement developed in the course the Asian variant of intravascular lymphoma (Kuroda et al. 2007).

Differential Diagnosis

The main differential diagnosis of primary NHL of the gallbladder is metastasis/manifestation of NHL originating elsewhere (Arista Nasr and Lome-Maldonado 1993; Nakai et al. 2011). The gallbladder is sometimes involved in patients with acute lymphoblastic leukemia (Kosucu et al. 2012) or chronic lymphocytic leukemia (Bessmel'tsev and Abdulkadyrov 1991; Chim et al. 2001; Dasanu et al. 2010; Imenpour et al. 2011). Gallbladder involvement by large cell NHL was diagnosed in a patient witch Richter's syndrome (Maryniak and Konecki 1991). The time interval between diagnosis of the primary NHL and its later manifestations in the gallbladder may be long, e.g., 12 years in a patient with follicular NHL (Viswanathan et al. 2011). Very rarely, the gallbladder is the site of reactive lymphocytic proliferations forming a mass, i.e., pseudolymphoma (Hussain et al. 1976). This issue is treated below. Chronic cholecystitis can be associated with lymphoid hyperplasia, often with lymph follicles and germinal centers (Albores-Saavedra et al. 1989; Hayasaka et al. 1996). This lesion, which can

mimic follicular NHL, is termed lymphofollicular (follicular) cholecystitis (Estrada et al. 1960; Hatae and Kikuchi 1979).

Plasmacytoma of the Gallbladder

Plasmacytoma can occur as an apparently primary malignancy of the gallbladder (Hwang et al. 2010). Extramedullary plasmacytoma was also observed in the gallbladder fossa, several months following cholecystectomy (Majerovic et al. 2012). Medullary and extramedullary plasmacytomas can rarely metastasize to the gallbladder (Kondo et al. 1995; Schuster et al. 2007).

Castleman's Disease of the Gallbladder

Castleman's disease as a primary lesion was observed in the gallbladder fossa (Lee et al. 1991).

Langerhans Cell Neoplasms of the Gallbladder

A 74-year-old woman with Langerhans cell sarcoma primary to the gallbladder, associated with involvement of regional lymph nodes, has been described. The neoplastic cells were reactive for CD1a, langerin, and S100 protein, but electron microscopic examination failed to demonstrate Birbeck granules (Zhao et al. 2009). Xanthoma disseminatum can involve the gallbladder (Knobler et al. 1990), with formation of mucosal xanthomas.

Hemophagocytic Lymphohistiocytosis of the Gallbladder

Predominantly in the pediatric age group, hemophagocytic lymphohistiocytosis is known to involve the gallbladder, clinico-radiologically presenting with thickening of the gallbladder wall (Chateil et al. 1999; Fitzgerald and MacClain 2003; Schmidt et al. 2004).

Hodgkin's Lymphoma

Only very few reports have specified involvement of the gallbladder in patients with Hodgkin's disease (HD). In a 44-year-old male patient, acalculous cholecystitis developed due to HD. At surgical exploration, the gallbladder was thickened, erythematous, and tense. An enlarged lymph node was detected in Calot's triangle, and the cystic duct was thickened, leathery, and firm, causing gallbladder obstruction. Histologic examination showed infiltration of the gallbladder by HD at the level of the cystic duct (Dainko 1970). In a second case, HD of the gallbladder presented as a complex mass detected by CT (Orton and Saigh 1996). Involvement of locoregional lymph nodes can cause compression of the cystic duct with non-visualization of the gallbladder (Wee et al. 1970). Apart from the cystic duct, HD is known to infiltrate other parts of the extrahepatic bile duct system, associated with obstructive jaundice (Justin-Besançon et al. 1963; Ochoa and Keene 1970).

Pseudolymphomas and Lymphoid Hyperplasias of the Gallbladder

There is group of conditions of the gallbladder characterized by a reactive proliferation of lymphoid cells, sometimes mimicking a tumor and specifically lymphoma. Part of the lesions show a focal to diffuse hyperplasia of lymphocytes, while others are characterized by nodular lesions or tumor-like masses.

Lymphoid hyperplasias and pseudolymphomas are manifest as one of few patterns compiled in Table 2.

Reactive lymphoid hyperplasias of the gallbladder have been reported several times (Hayasaka et al. 1996). Lymphoid hyperplasia may be associated with chronic cholecystitis, but the etiology remains, with few exceptions, unknown. A marked lymphoid hyperplasia of the gallbladder wall has been observed in chronic cholecystitis caused by *Salmonella* Typhi (chronic typhoid cholecystitis; Mallory and

Table 2 Patterns of pseudolymphomas and lymphoid hyperplasias of the gallbladder

Follicular lymphoid hyperplasia
Focal pattern
Diffuse pattern
Non-follicular lymphoid hyperplasia
Focal pattern
Diffuse pattern
Nodular lymphoid hyperplasia (pseudolymphoma)

Lawson 1931). In the majority of cases, lymphoid hyperplasia presents in the form of a focal or diffuse production of lymphoid follicles with or without germinal centers (Perrin 1953; Estrada et al. 1960; Pennino and Avallone 1965; Hatae and Kikuchi 1979; Albores-Saavedra et al. 1989; Rana et al. 2014). This condition has also been termed, "follicular cholecystitis." In one study, "chronic follicular cholecystitis" was detected in 6.2 % of cholecystectomy specimens (Tyagi et al. 1992). Macroscopically, the mucosa was described as velvety, granular, or nodular (Albores-Saavedra et al. 1989). In few cases, follicular hyperplasia results in polypoid mucosal lesion growing to a size of up to 0.9 cm, resembling gallbladder adenomas (Albores-Saavedra et al. 1989). In contrast to polypoid non-Hodgkin's lymphomas, polypoid follicular pseudolymphomas are lined by a normal-looking, non-damaged gallbladder epithelium. In follicular lymphoid hyperplasia, the gallbladder wall is histologically studded with lymphoid follicles with germinal centers. The follicles may occupy the mucosa or show a transmural distribution. Large follicles can bulge into the gallbladder lumen. Typically germinal centers display macrophages with phagocytosed pycnotic nuclei (tingible bodies). In part of the cases, this follicular reaction is the sign of an immune response to unknown antigens in the absence of a true cholecystitis. However, other cases showed an associated inflammation and fibrosis of the gallbladder wall. In such situations, the follicles are accompanied by an infiltrate that contains plasma cells, neutrophils, and eosinophils (Albores-Saavedra et al. 1989).

Lymphoid hyperplasia can result in nodular lesions in the gallbladder wall (nodular lymphoid hyperplasia; Sauerbrei and Castelli 1979). Nodular lymphoid hyperplasia appears as solitary or multiple nodules composed of dense lymphoid infiltrates. In a minority of cases, lymphoid hyperplasia is detectable as single mass within the gallbladder wall. Such nodules are usually well demarcated and lack a capsule. Histologically, nodular mass lesions are either diffuse lymphocyte proliferations or, more commonly, lesions that consist of numerous lymphoid follicles with germinal centers (Hussain et al. 1976; Yamamoto et al. 2012). In contrast to follicular non-Hodgkin's lymphomas, germinal centers in lymphoid pseudotumors exhibit a typical arrangement of germinal cells and macrophages with tingible bodies.

Differential Diagnosis

The main differential diagnosis is primary non-Hodgkin's lymphoma of the gallbladder, the main follicular variants. Also chronic lymphocytic leukemia can cause an infiltration of the gallbladder wall that may be confounded with lymphoid hyperplasia (Dasanu et al. 2010).

Metastatic Disease of the Gallbladder

Introduction

Metastases to the gallbladder are unusual lesions (Botting et al. 1963). In a series of 1,000 autopsies, metastatic involvement of the gallbladder was detected in only 5.8 % of patients (Abrams et al. 1950). Among a series of 417 gallbladder malignancies in Korea, 4.8 % were metastases of diverse cancers (Yoon et al. 2009). Gallbladder metastases most commonly occur in patients with malignant cutaneous melanoma, renal cell carcinoma, and breast carcinoma (Khan et al. 2010). The reasons why these three malignant neoplasms so clearly dominate metastatic gallbladder disease are currently unknown. At gallbladder imaging, alterations that raise suspicion for gallbladder

metastases include polypoid endoluminal lesion, multiplicity of these vegetations, a broad base of polyps, only limited mural thickening, presence of contrast enhancement, absence of gallstones, and gallbladder bed infiltration (Abacheril and Metzger 2008; Barretta et al. 2011).

Common Types of Metastases

Malignant Melanoma

Cutaneous malignant melanoma (MM) can metastasize to virtually any organ, but organs and structures most typically involved are the regional lymph nodes, lungs, liver, brain, and the lower gastrointestinal tract. The gallbladder, due to still unknown reasons, is one of the most frequent metastatic sites of MM in the upper abdominal visceral system and accounts for about 50 % of all metastases to the biliary tract. Autopsy investigation have demonstrated that gallbladder metastases occur in up to 15 % of patients with metastatic MM of the GI tract, while gallbladder metastases are less often diagnosed during lifetime (Das Gupta and Brasfield 1964). This discrepancy is thought to be due to the observation that MM metastatic to the gallbladder seldom causes symptomatic disease. Gallbladder metastasis of MM may represent the first metastatic site of this neoplasm (Gwynne and Abbas 2008) and can also occur in stage I cutaneous MM (Cellerino et al. 2000). Gallbladder metastasis of MM can occur after a delay of 10 years or more (Gawenda et al. 1995). Owing to its polypoid growth pattern, metastatic gallbladder MM may be suspected by use of imaging examinations (Rehani et al. 2006), including ultrasonography (Zemlyn 1966; Miselli et al. 1988; Stutte et al. 1989; Hahn et al. 1993; Avila et al. 1994; Bedo et al. 1996; Holloway and King 1997; Vesnin et al. 1999; Andreano et al. 2010). Probably due to tumor necrosis and an associated inflammatory reaction, metastatic MM can cause, or be associated with, acute cholecystitis (Henriques 1955; Ostick and Haggani 1976; McFadden et al. 1979; Bundy and Ritchie 1982; Bugnon et al. 1987; Langley et al. 1997; Vernadakis et al. 2009). Similar to other gallbladder metastases, MM can cause gallbladder obstruction, sometimes inducing gallbladder colic (Paolini et al. 1999; Ligeron-Esbrayat and Guillot 2002; Nelms et al. 2007). The prognosis of metastatic MM to the gallbladder is poor, with a median survival time of 6–9 months (Langley et al. 1997; Dong et al. 1999; Katz et al. 2007), but postcholecystectomy survival times of up to 13.5 months have been reported (Dong et al. 1999).

Selected References Henriques 1955; Gavala and Nicolo 1960; Herrington 1965; Bertheussen and Hansen 1971; Shimkin et al. 1972; Arnaud et al. 1978; Orbuch et al. 1981; Vantomme et al. 1984; Murphy et al. 1987; Agosti et al. 1989; Goldin 1990; Guerini et al. 1990; Abdelli et al. 1996; Seelig and Schönleben 1997; Sparwasser et al. 1997; Kohler et al. 2000; Guida et al. 2002; Gogas et al. 2003; Qu et al. 2003; Crippa et al. 2004; Gassler et al. 2004; Swiatoniowski et al. 2004; Romero et al. 2006; Varsamidakis et al. 2006; Tuveri and Tuveri 2007; Samplaski et al. 2008; Alimova et al. 2009; Cicin et al. 2009; Matsubayashi et al. 2012.

Renal Cell Carcinoma (RCC)

RCC metastatic to the gallbladder is, as such, a rare manifestation of this malignancy that usually occurs in men, but is the second most frequent gallbladder metastasis after malignant melanoma. Gallbladder metastasis of RCC may develop after considerable delay, sometimes exceeding 6–10 years (Kechrid et al. 2000; Ricci et al. 2008). In a large series, 58.3 % of the lesions were metachronous deposits that were diagnosed at an average of 9.1 years after primary diagnosis of RCC (Ishizawa et al. 2006). RCC metastases to the gallbladder may either be the only metastatic manifestation of this cancer, or it may occur in conjunction with RCC metastases in other organs (Ricci et al. 2008). Furthermore, gallbladder metastases can occur synchronously or metachronously (Kücükakin et al. 2009; Chung et al. 2012). In analogy with other types of metastases, RCC metastatic to the gallbladder can induce, or mimic, acute cholecystitis (Golbey et al. 1991; Sand et al. 2009). Due to tumor

ulceration and necrosis, hemobilia can develop (Fullarton and Burgoyne 1991). Macroscopically, RCC metastases often show a polypoid or pedunculated configuration, resembling endoluminal gallbladder carcinomas and sometimes freely floating in the gallbladder lumen (Nagler et al. 1994; Nojima et al. 2008; Patel et al. 2009; Fang et al. 2010). The lesions may radiologically mimic gallbladder calculi (Lajolo et al. 2005). In a minority of cases, intraluminal growth is massive, with marked enlargement of the gallbladder (Terasaki et al. 1990). As the renal primary tumor, clear cell RCC metastasis of the gallbladder usually has a yellow color, with focal hemorrhage and necrosis (Ghaouti et al. 2013). Histology showed that the most common type of RCC metastatic to the gallbladder is the clear cell (hypernephroid) type (Nojima et al. 2008). In contrast to primary clear cell carcinoma of the gallbladder, RCC clear cells are negative for CK7 and CEA (Nojima et al. 2008).

Selected References Botting et al. 1963; Osman et al. 1978; Harder and Heindorff 1983; Fullarton and Burgoyne 1991; Golbey et al. 1991; Nagler et al. 1994; Coskun et al. 1995; King et al. 1995; Pagano et al. 1995; Lombardo et al. 1996; Uchiyama et al. 1997; Celebi et al. 1998; Brasseur et al. 1999; Aoki et al. 2002; Limani et al. 2003; Park et al. 2003, 2007; Ishizawa et al. 2006; Pandey et al. 2006; Nojima et al. 2008; Kawahara et al. 2010; Decoene et al. 2011; Chung et al. 2012; Collin and Sabbagh 2012; Robledo et al. 2012; Ghaouti et al. 2013; Jain and Chopra 2013.

Breast Carcinoma

Breast carcinoma is a malignancy that often shows widespread metastasis, specifically the lymph nodes, lung, bone, pleura, brain, and soft tissues, whereas the gastrointestinal and hepatobiliary tracts are less often involved. In the bile duct system, the gallbladder is the most commonly affected organ (Beaver et al. 1986; Rubin and Tate 1989; Pappo et al. 1991; Crawford et al. 1996; Shah et al. 2000; Doval et al. 2006; Manouras et al. 2008; Jones et al. 2009; Herrera et al. 2010; Di Vita et al. 2011; Riaz et al. 2012). Gallbladder metastasis in disseminated breast cancer was reported to occur in 4–7 % of patients (Lee 1983), with a delay between breast cancer diagnosis and gallbladder metastasis ranging from 18 months to more than 10 years (Zagouri et al. 2007). Most patients are asymptomatic in regard to the gallbladder (Riaz et al. 2012), but breast cancer metastasis to gallbladder can cause hydrops of the gallbladder (Essola et al. 2012) or acute cholecystitis (Beaver et al. 1986; Crawford et al. 1996; Boari et al. 2005; Doval et al. 2006; Zagouri et al. 2007; Al-Rawi et al. 2012), and in part of these patients, acute cholecystitis is the presenting feature of breast cancer (Manouras et al. 2008). Breast cancer metastasis can also induce obstructive alterations (Pappo et al. 1991) followed by hydrops (Murguia et al. 2006) or biliary colic (Rubin and Tate 1989).

Interestingly, most cases of breast cancer metastatic to the gallbladder are histologically lobular carcinoma of the breast (Di Vita et al. 2011). In a review of 13 cases extracted from the literature, 8 were lobular carcinomas (Khan et al. 2010). Less often, ductal carcinoma of the breast was found as gallbladder metastasis, including the papillary subtype (Murguia et al. 2006).

Hepatocellular Carcinoma

Apart from direct invasion of the gallbladder fossa and the gallbladder itself, hepatocellular carcinoma (HCC) is known to produce true hematogenous gallbladder metastases (Maruo et al. 1994; Nishida et al. 1997; Lane and Walker 2002; Han and Kim 2005; Terashima et al. 2007; Ando and Sakamoto 2009; Murakami et al. 2010; Kanzaki et al. 2011; Monden et al. 2011; Wakasugi et al. 2012). There seems to be a relationship between the intrahepatic site of HCC and gallbladder metastasis. The majority of reported cases had a primary tumor in segments S4 or S5, and most cases had portal vein thrombosis, suggesting a role of distinct vascular relationships (review: Wakasugi et al. 2012). Four possible routes for the trafficking of HCC cells to the gallbladder have been proposed: a hematogenous route via the portal venous system (mostly

associated with portal vein thrombosis), a lymphatic route, a route through direct invasion from the liver, and a route using pathways via peritoneal dissemination (Nakashima et al. 1983). These authors suggested that the portal vein system route was the most important metastatic pathway for the gallbladder. In fact, all gallbladder veins enter the right anterior branch of the portal vein system through the liver bed of the gallbladder via Carnot's triangle (Sugita et al. 2000), suggesting a backward venous spread to the gallbladder in case of HCC-associated portal vein thrombosis. Differential diagnostically, HCC metastases to the gallbladder have to be distinguished from direct invasion of the gallbladder by HCC from tumors that are situated close to the gallbladder bed (Ueno et al. 2001; Namkoong et al. 2004; Ryu et al. 2009).

Rare Types of Metastases

Uncommon metastases to the gallbladder include prostate carcinoma (Colombat et al. 1999; Maxwell et al. 2009), gastric carcinoma (Bellucci 1967; Bilici et al. 2012), rectal carcinoma (Abacheril and Metzger 2008), squamous cell carcinoma of the lung (Jeong et al. 2012), pulmonary large cell carcinoma (Tanaka et al. 2009) and other non-small cell carcinomas of the lung (Nassenstein and Kissler 2004), osteoclast-like giant cell tumor of the pancreas (Sun et al. 1998), carcinoma of the uterine cervix (Martinez-Roman et al. 2005), medullary plasmocytoma (Schuster et al. 2007), and perivascular epithelioid tumors (Sendo et al. 2013). Similar to more common types of metastases, rare metastatic gallbladder neoplasms can also cause acute cholecystitis, e.g., carcinoma of the stomach (Bilici et al. 2012).

Tumor-Like Inflammatory Changes of the Gallbladder

158

Contents

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_158

Abstract

Several forms of tumor-like inflammatory lesions develop in the gallbladder. Similar to the liver and bile ducts, inflammatory pseudotumors can develop in the gallbladder. They include inflammatory myofibroblastic tumors, with clonal and reactive variants, inflammatory tumors developing as a foreign body reaction, and pseudotumors in the setting of IgG4-related sclerosing disease. Inflammatory pseudotumors of the gallbladder can grow to a size exceeding 10 cm and mimic cancer. Reactive endoluminal inflammatory processes of the gallbladder are called inflammatory polyps, a rather common complication of cholecystitis. Histologically, granulation polyps and inflammatory fibroid polyps are distinguished. A gallbladder inflammation that may closely resemble a malignant process is xanthogranulomatous cholecystitis, a chronic inflammatory and sometimes destructive process characterized by massive accumulation of lipid-containing macrophages and other leukocytes, later followed by a fibrosing lesion. Xanthogranulomatous cholecystitis is associated with gallbladder carcinoma in part of the patients. Another distinct form of cholecystitis with a fibrosing reaction and wall thickening is lymphoplasmacytic sclerosing cholecystitis.

Inflammatory Pseudotumor (Inflammatory Myofibroblastic Tumor) of the Gallbladder

Introduction

Inflammatory pseudotumors (myofibroblastic inflammatory tumors) are well-defined tumorous lesions of the hepatobiliary tracts (see the respective chapter), but are very uncommon alterations of the gallbladder. As in other locations, pseudotumors can be divided into several entities, as summarized in Table 1.

Clinical and Imaging Features

The clinical features of inflammatory gallbladder tumors are known from relatively few case reports only (Shou et al. 1987; Ikeda et al. 1990; Corsi and Bosman 1995; Behranwala et al. 2005; Jain et al. 2005; Mssrouri et al. 2011; Muduly et al. 2012; Rammohan et al. 2012). Inflammatory pseudotumor may clinically present as active cholecystitis, i.e., epigastric or right upper quadrant pain, nausea, vomiting, and fever. In case of large lesions, an upper abdominal mass may be in evidence. In the serum, elevated inflammatory markers are found. The lesions clinicoradiologically mimic gallbladder carcinoma or other gallbladder malignancies in part of the cases (Jain et al. 2005) and sometimes initially present as a gallbladder neoplasm (Behranwala et al. 2005).

Apparently, clonal myofibroblastic tumors of the gallbladder may be HIV and EBV associated and can present as multifocal lesions in the pediatric age group (Mahlobo et al. 2012). Reactive inflammatory pseudotumor has been observed secondary to spilled intra-abdominal gallstones, i.e., as an excessive inflammatory foreign body-type reaction. The lesion may cause extensive adhesions between the diaphragm and the parietal wall with the gallbladder (Rammohan et al. 2012). Gallbladder pseudotumors developing in the setting of IgG4-related disease are sometimes large and ill-defined lesions that mimic gallbladder cancer (Lee et al. 2013).

Table 1 Clinicopathological forms of inflammatory pseudotumors of the gallbladder

Inflammatory myofibroblastic tumor (most of the previously reported cases of inflammatory pseudotumor)
Localized (mass-forming) and diffuse forms
Clonal versus reactive variants
Inflammatory pseudotumors. In the setting of marked foreign body-type reactions
Pseudotumors in the setting of IgG4-related sclerosing disease
Calcifying fibrous pseudotumor

Pathology

Macroscopy

Inflammatory pseudotumor of the gallbladder presents as localized or diffuse thickening of the gallbladder wall or as a mass resembling gallbladder cancer. The masses may exceed 10 cm

in diameter (Behranwala et al. 2005). In case of marked accumulation of lipid-laden macrophages (pseudoxanthomatous reaction), the cut surface shows yellowish spots; otherwise, the tissue is grayish-red, depending on its vascularization.

Histopathology

The histology of inflammatory pseudotumors has been outlined in detail elsewhere. Part of the tumors correspond to clonal myofibroblastic tumors as described in more detail in another chapter. These lesions consist of a proliferation of myoid spindle cells with or without ALK positivity. Reactive forms are chiefly characterized by a proliferation of fibroblasts and myofibroblasts, intermingled with an inflammatory infiltrate containing various numbers of lymphocytes, macrophages (in part foam cells), plasma cells, and granulocytes. In some cases, numerous CD68-positive macrophages were detected (Ozsan et al. 2013). One variant of reactive pseudotumor of the gallbladder is characterized by calcifications (calcifying fibrous pseudotumor; Mourra et al. 2004).

Differential Diagnosis

The most important differential diagnosis of inflammatory pseudotumor of the gallbladder is the group of myofibroblastic and other spindle cell sarcomas.

Inflammatory Polyps of the Gallbladder

Introduction

Inflammatory polyps of the gallbladder are reactive endoluminal lesions which are either sessile or have a short stalk and head and mainly consisting of granulation tissue or fibrovascular tissue with variable amounts of leukocytic infiltrate cells (Majeski 1986; Albores-Saavedra et al. 1993; Owen and Bilhartz 2003). As their size can reach one cm in diameter, inflammatory polyps can produce pseudotumorous lesions that mimic gallbladder neoplasms, in particular polypoid carcinoma. Most inflammatory polyps are associated with chronic cholecystitis.

Epidemiology

The overall prevalence of gallbladder polyps as assessed by ultrasonography in a European population was 4.6 % in men and 4.3 % in women (Jorgensen and Jensen 1990). Among apparently healthy Japanese, the prevalence of gallbladder polyps was highest in middle-aged men, but this observation mainly related to cholesterol polyps (Segawa et al. 1992). Bland inflammatory polyps of the gallbladder are uncommon lesions, however with variable published incidences (Christensen and Ishak 1970, Kubota et al. 1995; Terzi et al. 2000; Myers et al. 2002; Wu et al. 2003; Sun et al. 2004; Ito et al. 2009; Zielinski et al. 2009; Terada 2013).

In a histologic examination of polyps found in 72 patients, cholesterol polyps were in present in 47, adenomas in 8, cancers in 16, and an inflammatory polyp in 1 (Kubota et al. 1995). Among 40 patients with pathologically confirmed polypoid lesions of the gallbladder and mean age of 43.9 years, 57.5 % had cholesterol polyps, 12.5 % inflammatory polyps, 10 % adenocarcinomas, 7.5 % xanthomatous polyps, and 5 % papillary adenomas, and 1 each of the patients had mixed polyp, neurofibroma, and adenomatoid proliferation polyp (Zhang 1991). Terzi et al. (2000) registered no inflammatory polyp among their 74 reported benign polypoid lesions of the gallbladder. A Japanese study documented 7 inflammatory polyps among 70 surgical cases of small polypoid lesions (Sadamoto et al. 2002). In a Chinese series of 260 cases of polypoid gallbladder, 4 lesions were inflammatory polyps (Wu et al. 2003). Roa et al. (2004) noted a prevalence of 2 % inflammatory polyps among 219 gallbladders with polyps of Chilean patients. In an investigation from Korea referring to 396 patients with

confirmed polypoid lesions of the gallbladder, inflammatory polyp accounted for 1.7 %, in comparison with 51.2 % cholesterol polyps (Kwon et al. 2009).

Classification

Several forms of inflammatory polyps of the gallbladder can be distinguished on morphologic and/or molecular grounds. The polyp types are summarized in Table 2. Most inflammatory polyps are bland lesions that correspond in their morphology to reactive polypoid lesions occurring elsewhere in mucosa-containing organs (so-called granulation polyps; Liao et al. 1996).

In the gastrointestinal tract, inflammatory polyps with hyperplastic epithelial changes and having juvenile-like features were found in the setting of neurofibromatosis type 1. Similar lesions may be expected to occur in the gallbladder.

Clinical and Imaging Features

As inflammatory polyps of the gallbladder are small lesions usually not exceeding 10 mm in diameter, they do per se not cause clinical signs and symptoms, the latter being related to underlying gallbladder disease, in particular cholecystitis and stone disease (Christensen and Ishak 1970). Inflammatory polyps are often hypoechoic solitary lesions (Hallgrimmsson and Skaane 1988). On CT, small polypoid lesions, i.e., those less than 10 mm in size, may not be detectable in unenhanced images (Furukawa et al. 1995). Inflammatory polyps may radiologically mimic early polypoid carcinoma (Kyokane et al. 1994; Maeyama et al. 1998; Susumu et al. 2009). A polyp size exceeding 10 mm and age over 60 years suggest malignancy (Koga et al. 1988; Yang et al. 1992; Sugiyama et al. 1999; Yeh et al. 2001; Lee et al. 2004).

Table 2 Types of inflammatory polyps of the gallbladder

Ordinary inflammatory polyp (granulation polyp)
Pyogenic granuloma of the gallbladder
Inflammatory fibroid polyp
Polypoid lesions in xanthogranulomatous cholecystitis

Pathology

Macroscopy

Inflammatory polyps are mostly solitary and sessile lesions. Similar to cholesterol polyps, they generally have a diameter of less than 10 mm, while most cancerous polyps exceed 10 mm in size at the time point of diagnosis (Kubota et al. 1995). In contrast to inflammatory polyps, cholesterol polyps are multiple lesions in about two thirds of cases (Sun et al. 2004). In fresh state, the polyps are reddish to grayish-brown, depending on the grade of hyperemia, density of leukocytes infiltration, and eventual hemosiderosis. The surface of the polyps is either granular, as in any granulation tissue growing out of a mucosal surface, or glistening in case of epithelial covering.

Histopathology

Early lesions show the typical features of a highly vascular granulation tissue with only poor fibroblastic/myofibroblastic reaction (Fig. 1). The vascular stroma of older polyps is typically edematous and displays a cellular infiltrate dominated by lymphocytes, macrophages, and plasma cells. Toward the surface of the polyp, neutrophils may be encountered, and the surface itself is often covered by a thin layer of fibrin-containing exudate. The new formed vessels may show neutrophil leukodiapedesis. Part of polyps show a partial or, less commonly, complete lining of their surface by a columnar epithelium with signs of cell damage, leukocytes transmigration, and regenerative alterations. The epithelial cells are usually flat and can show nuclear atypia related to regeneration.

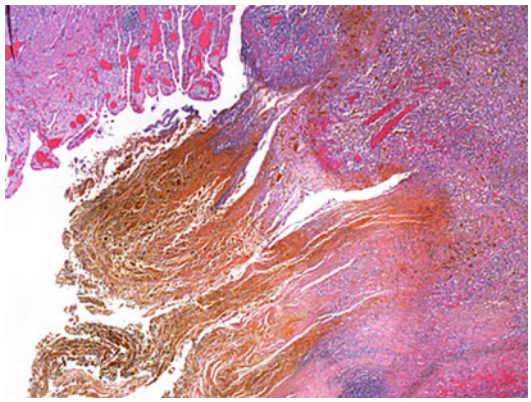

Fig. 1 Inflammatory polyps of the gallbladder. The granulation tissue polyps are covered with bile-containing exudate (hematoxylin and eosin stain)

Inflammatory Fibroid Polyp of the Gallbladder

Inflammatory fibroid polyps (IFP; Vanek's polyp) are benign lesions occurring in the gastrointestinal tract, specifically in the stomach and small bowel, but IFP also occur in the colon, rectum, esophagus, and gallbladder (Morales-Fuentes et al. 2011; Liu et al. 2013). The lesion was first described by Vanek in 1949, using the term "submucosal granuloma." In contrast to ordinary inflammatory polyp, IFP may grow to larger size and can develop a nodular surface (Kim et al. 2003; Liu et al. 2013). IFP are polypoid lesions consisting of a fibrovascular tissue infiltrated by several classes of inflammatory cells, including eosinophils and mast cells. About half of cases show perivascular onion skinning, and part of the lesions reveal a short fascicular growth pattern, and eosinophilia of the lesion was present in 94 % in one study (Liu et al. 2013). IFP developing in stomach and small bowel commonly show mutations in platelet-derived growth factor receptor alpha (PDGFRA), similar to some GISTs, a finding that was suggested to indicate a neoplastic nature of IFP (Schildhaus et al. 2009; Bjerkehagen et al. 2013). Activating PDGFRA mutations occur in exons 12, 14, and 18, whereby exon 12 mutations prevailed in the small intestine, while exon 18 mutations occurred frequently in the stomach (Huss et al. 2012). IFP is a very rare lesion in the gallbladder (Fogt et al. 1998; Kim et al. 2003). In one patient with IFP of the gallbladder, a PDGFRA mutation was detected, similar to its gastrointestinal counterparts (Martini et al. 2013).

Gallbladder Polyps in Acromegaly

Patients with uncontrolled acromegaly have an increased mortality rate compared with the general population, cardiovascular disease accounting for about 60 % of the mortality. These patients also bear an increased risk of developing several types of neoplasms, both benign and malignant, such as carcinomas of breast, colorectum, and prostate, and other types of epithelial tumors, approximately 15 % of mortality being due to cancer. In a retrospective analysis of 140 patients with active acromegaly, colon carcinoma was found in 10, thyroid cancer in 5, breast cancer in 4, and gastric cancer in 2. The risk of developing these cancers was significantly higher than that for a matched control group (Kurimoto et al. 2008).

Patients with acromegaly also reveal a higher incidence of benign lesions, including gallbladder polyps, which were found in up to 14 % of patients (Kurimoto et al. 2008). In another investigation on newly diagnosed acromegaly, the relative risk for gallbladder polyps in acromegaly patients was 6.29, mostly for patients older than 50 years of age and higher growth hormone serum levels (Annamalai et al. 2011). The histopathology of these polyps has not been determined, however with one reported patient with a villous gallbladder adenoma (Krstic et al. 2007).

Differential Diagnosis

Hemobilia with a blood clot in the gallbladder lumen, e.g., subsequent to needle biopsy, may sonographically mimic a polyp (Kwon et al. 2002; Lin et al. 2005). Polypoid benign tumors with a fibrous component may be confounded with a reactive polyp, e.g., polypous

neurofibroma (Morizumi et al. 1988) and polypoid adenomyoma (Sasatomi et al. 1997). Exceptionally, a pseudopolyp-like lesion of the gallbladder was found following penetration of a biopsy needle into the gallbladder, the penetrating needle causing an elevation of the inner gallbladder layer at the entrance site, sonographically mimicking a polyp (Barzilai et al. 1997).

Xanthogranulomatous Cholecystitis

Introduction

Xanthogranulomatous cholecystitis (XGC) is a chronic inflammatory and sometimes destructive process of the gallbladder characterized by massive accumulation of lipid-containing macrophages (foamy macrophages), rendering the tissue macroscopically yellowish as in xanthomas, later followed by fibrosis and eventually extension into neighboring organs. In the context of tumors, XGC is important for two reasons. First, it may clinico-radiologically mimic gallbladder cancer. Secondly, XGC is associated with gallbladder carcinoma in part of the patients, although a role of XGC as a premalignant condition is not settled.

Epidemiology

XGC was first described in 1970 as "fibroxanthogranulomatous inflammation" (Christensen and Ishak 1970). Since then, numerous cases have been reported for adult patients, first under a variety of names, including "ceroid or ceroid-like histiocytic granuloma of the gallbladder." Takahashi and coworkers (1976) reported the incidence in Japan to be 1–2 % of all surgically removed gallbladders. In a retrospective 3-year study, 13 cases of XGC (7 females, 6 males) were identified in 724 gallbladders (1.8 %), with an estimated incidence of 1.7 cases per 100,000 population per year (Roberts and Parsons 1987). Among 1,425 cholecystectomies, 35 cases of XGC were identified (2.4 %; Cardenas-Lailson et al. 2005). In a recent review of 29 studies from Europe, India, Far East, and Americas, covering 1,599 patients, the overall incidence of XGC was 1.3–1.9 %, with the exception of India where it was 8.8 % (Hale et al. 2014). Analysis of clinical data of 39 patients with XGC revealed a male to female ratio of 30:9 and an average age at diagnosis of 62.2 years. There was an association with gallbladder stones in 94.9 % (Han and Chen 2012). In other studies, a female preponderance was found (74 %; Cardenas-Lailson et al. 2005). Rarely, XGC develops in the pediatric age group and has even been diagnosed in infants (Kim et al. 2013).

Selected References: (Takahashi et al. 1976; Amazon and Rywlin 1980), and "biliary granulomatous cholecystitis" (Mehrotra and Bhatnagar 1982), later followed by the term now consistently employed, XGC (Bluth et al. 1979; Goodman and Ishak 1981; Reyes et al. 1981; Fligiel and Lewin 1982; Parsons et al. 1986; Hanada et al. 1987; Roberts and Parsons 1987; Franco et al. 1990; Ladefoged and Lorentzen 1993; Houston et al. 1994; Dixit et al. 1998; Eriguchi et al. 2001; Pinocy et al. 2003; Guzman-Valdivia 2004; Kansakar et al. 2008; Wang et al. 2009a; Rastogi et al. 2010; Cecava and Andrews 2011; Singal et al. 2011; Han and Chen 2012; Jain et al. 2012).

Clinical and Imaging Features

XGC may present with atypical clinical manifestations and is sometimes difficult to diagnose, although many patients show a clinical presentation that is similar to ordinary cholecystitis (Han and Chen 2012). XGC can undergo an aggressive inflammatory course (Psarras et al. 2012), with extension into adjacent organs, above all the liver and transverse colon, and development of cholecystoenteric fistulas (Parsons et al. 1986; Fu et al. 2012). XGC may be associated with xanthogranulomatous changes in other organs, e.g., xanthogranulomatous gastritis (Guarino et al. 1993). In one patient, XGC was associated with primary sclerosing cholangitis (Mori et al. 2010).

Sonography delivers characteristic features in patients with XGC, including a diffuse or focal thickening of the gallbladder wall and oval or flat wall nodules of low echogenicity, the latter ranging in size from 5 to 12 mm (Bluth et al. 1979; Kim et al. 1998; De Gaetano et al. 1985; Parra et al. 2000; Cecava and Andrews 2011; Ueda et al. 2011). On CT images, gallbladders in XGC are homogeneously enhanced in the early vascular phase and remain enhanced for more than 1 min, gallbladder enhancement being either smooth and regular as in ordinary cholecystitis or coarse and irregular (De Gaetano et al. 1985; Cossi et al. 1987; Hanada et al. 1987; Casas et al. 1996; Chun et al. 1997; Kim et al. 1999; Parra et al. 2000; Bhattacharya et al. 2011; Ueda et al. 2011). Part of the cases exhibit a disrupted mucosal line, this feature being more often associated with liver infiltration (Zhao et al. 2013). On contrast-enhanced CT images, intramural hypoattenuating nodules occupying more than 60 % of the gallbladder wall were suggestive of XGC (Jain et al. 2012). XGC can produce masses of the gallbladder that radiologically closely resemble malignancy (Agarwal et al. 2013).

Pathology

Macroscopy

Macroscopically, gallbladders with XGC usually show a marked increase in wall thickness. There may be adhesions on the serosal surface, and the gallbladder is sometimes adherent to the liver and difficult to dissect with the fossa. On cut surfaces, the organ shows a yellowish, patchy discoloration, sometimes with formation of yellowish nodules that bulge into the mucosa. The nodular infiltrate disrupts the mucosal surface, sometimes with ulceration. Large-nodule yellow lesions are soft in the center, due to partial necrosis. Three distribution subtypes of the lesions have been proposed, i.e., multinodular, focal, and diffuse (Franco et al. 1990). In case of marked inflammatory nodularity and fibrotic changes, an inflammatory pseudotumor can result. XGC can result in fistula formation, predominantly cholecystoenteric fistulas.

Histopathology

The histopathology of XGC has been described in detail (Roberts and Parsons 1987; Dao et al. 1989; Singh et al. 1989; Franco et al. 1990). The lesion is chiefly characterized by a dense focal to disuse and sometimes nodular infiltrate composed of numerous foamy macrophages, lymphocytes, and plasma cells, with only a minor participation of granulocytes. The lipid-laden macrophages appear in two forms, i.e., round to oval and large macrophages with a foamy to spongy cytoplasm and spindle-shaped macrophages/histiocytes with elongated nuclei and a granular cytoplasm, which can contain ceroid (Gal et al. 1984; Roberts and Parsons 1987). Giant cells of the Touton type may occur. Foci of xanthogranulomatous tissue are often centered at Rokitansky-Aschoff sinuses. Tumor-like nodules predominantly consist of spindle-shaped cells. Large accumulations of inflammatory cells can result in full-thickness, destructive lesions of the gallbladder, with variable extension into subserosal fat and eventual extension into the gallbladder fossa and beyond the serosal lining. The inflammatory process can also involve the mucosa, with formation of ulcers and mucosal xanthogranulomatous nodules. In most cases, depositions of cholesterol crystals with or without formation of cholesterol granulomas, hemosiderosis, and extravasated bile are present (Roberts and Parsons 1987). Progressively, the inflammation is accompanied by fibrosis which may be patchy or segmental, with formation of sclerosed masses.

Immunohistochemistry

As in other chronic inflammatory disorders, macrophages in XGC are reactive for CD68 and CD163. Inflammatory cells in this cholecystitis are positive for GLUT-1 and GLUT-3. As glucose transporter-1 mediates the transport of fluorodeoxyglucose/(18)F-FDG through GLUT-3, this expression pattern may explain the positive result on F-FDG PET imaging (Sawada et al. 2013).

Differential Diagnosis

The principal clinico-radiological differential diagnosis is gallbladder cancer.

Xanthogranulomatous Cholecystitis and Gallbladder Cancer

As XGC results in an increase of tissue mass, a thickening of the gallbladder wall, a reduced gallbladder contractility, invasion of adjacent organs, and increased cancer marker levels in serum, it may clinically and radiologically mimic gallbladder cancer.

Selected References: (Düber et al. 1984; Maeda et al. 1994; Ros and Goodman 1997; Yoshida et al. 1997; Adachi et al. 1998; Enomoto et al. 2003; Baykara and Karahan 2004; Rao et al. 2005; Spinelli et al. 2006; Clarke et al. 2007; Makino et al. 2009; Sharma et al. 2009; Chang et al. 2010; Rastogi et al. 2010; Maker and Maker 2012; Martins et al. 2012; Zhang et al. 2012; Agarwal et al. 2013).

XGC can present with right upper quadrant pain associated with jaundice, and with an enlarged and firm gallbladder adherent to adjacent organ, in particular with an unclear border between gallbladder and liver, resulting in the clinico-radiological aspect of malignancy during cholecystectomy (Martins et al. 2012). The increase of tissue mass can result in chronic inflammatory pseudotumor (Howard et al. 1991; Roels et al. 1999). As inflammation can markedly extend beyond the gallbladder limits in XGC, an invasive process with infiltration of liver and colon can result (Pinocy et al. 2003). XGC can also be associated with liver abscess suggesting metastasis of gallbladder cancer (Eriguchi et al. 2002). At gallbladder imaging, there is an overlap between the two conditions, but there are also some features serving to distinguish the two entities (Uchiyama et al. 2009; Goshima et al. 2010; Shetty et al. 2012). In a study of 68 patients with XGC, focal thickening of the gallbladder wall as seen on CT images, early enhancement of the gallbladder, and lymph node enlargement were seen more often in coexisting gallbladder cancer. In contrast-enhanced CT images of XCG, the mucosal lining is intact and enhancing, while it is disrupted in cancer (Jain et al. 2012). Fine needle aspiration cytology can distinguish between XGC-mimicking cancer and bona fide malignancy (Hijoka et al. 2010).

XGC may be associated with gallbladder carcinoma, raising the question whether XGC is a premalignant condition (Benbow and Taylor 1988; Benbow 1989; Lopez et al. 1991; Lee et al. 2003; Kwon and Sakaida 2007; Ghosh et al. 2011; Al-Abed et al. 2012). In an immunohistochemical investigation 65 cases of XGC, epithelial nuclear reactivity for p53 protein was found in 3 % of XGC in comparison with 52 % in gallbladder carcinoma, suggesting that XGC is not a premalignant condition (Ghosh et al. 2011). Another study showed that 16 % of gallbladder cancers were associated with XGC, but failed to show p53 protein expression in epithelia of XGC lesions (Agrawal et al. 2010). In one case of XGC, no p53 gene mutation was found by use of PCR and single-strand conformational polymorphism analysis (Takada et al. 2002). A recent global study found that the incidence of gallbladder carcinoma associated with XGC was lowest in European studies (3.3 %), varying from 5.1 % to 5.9 % in the other regions analyzed (India, Far East, the Americas).

Etiology and Pathogenesis

XGC may result from an excessive inflammatory response to mostly unknown antigens, mainly involving an increased cell-mediated immune response with massive recruitment of monocytes/macrophages (Nakashiro et al. 1995). Based on the accumulation of large amounts of lipids in macrophages, a role of biliary lipids has been proposed, e.g., through an inflammatory response to extravasated bile from ruptured

Rokitansky-Aschoff sinuses (Christensen and Ishak 1970; Takahashi et al. 1976; Fligiel and Lewin 1982). Certain infections may promote the development of XGC, e.g., *Candida albicans* infection in immunosuppressed patients (Brown et al. 1996) and *Escherichia coli*. The role of *E. coli* in the pathogenesis of XGC was found to involve scavenger receptor class A and CXCL16-CXCR6 interaction (Sawada et al. 2007).

Lymphoplasmacytic Sclerosing Cholecystitis

Introduction

Lymphoplasmacytic sclerosing cholecystitis (LPSC) is a rare and in part mass-forming inflammatory gallbladder disease that is most often associated with distinct other pathologies, i.e., IgG4-related sclerosing disease, autoimmune pancreatitis, and primary sclerosing cholangitis (PSC) (Kamisawa et al. 2006; Wang et al. 2009b; Kazantsev and Lishchuk 2011). LPSC developing in the setting of IgG4-related sclerosing diseases is a distinct entity and is different from sclerosing cholecystitis related to PSC. Alterations of the gallbladder resembling IgG4-related sclerosing disease and above all occurring in patients with autoimmune pancreatitis are increasingly observed and have in part been termed IgG4-associated cholecystitis (Wang et al. 2009b; Kawakami et al. 2010; Leise et al. 2011).

In patients with PSC, one or more gallbladder abnormalities were found in 41 % of patients, cholecystitis amounting to 25 % (Said et al. 2008). Diffuse lymphoplasmacytic acalculous cholecystitis is a distinctive form of chronic cholecystitis associated with PSC (Jessurun et al. 1998) and also occurs in patients with ulcerative colitis (Herzog and Goldblum 1996). Among 72 gallbladders from 100 consecutive liver explants for PSC, lymphoplasmacytic chronic cholecystitis was present in 49 % (Lewis et al. 2007), but this form of inflammation is not associated with an increase in the number of IgG4-positive plasma cells. Diffuse lymphoplasmacytic chronic cholecystitis is also a distinct alteration in extrahepatic biliary disease (Abraham et al. 2003).

Pathology

Thickening of the gallbladder was detected 75 % (Kamisawa et al. 2006). Histologically, dense lymphoplasmacytic infiltrates either involve the gallbladder mucosa or form a transmural alteration. These infiltrates are associated with a marked fibrosclerosis of the wall. Eosinophilia, phlebitis, and extramural inflammatory nodules are further morphologic features of LPSC. In LPSC associated with IgG4-related sclerosing disease or autoimmune pancreatitis, the plasma cell population contains a significant fraction of IgG4-positive cells (Kamisawa et al. 2006; Leise et al. 2011).

LPSC can be localized and result in a gallbladder pseudotumor. In a patient with autoimmune pancreatitis, ultrasound examination revealed a mass at the fundus of the gallbladder, and CT scans showed a well-enhanced mass. Histologically, the tumor-like nodules consisted of lymphoplasmacytic infiltrates, irregular fibrosis, numerous IgG4-positive plasma cells, and adenomyomatosis (Kawakami et al. 2010).

Noninfectious Granulomatous Cholecystitis

Apart from granulomas or granuloma-like lesions occurring in xanthogranulomatous cholecystitis, sometimes with formation of so-called ceroid granulomas, other conditions of the gallbladder can contain epithelioid granulomas (Table 3).

The gallbladder is rare site of sarcoidosis, with formation of typical fibrosclerosing granulomas having giant cells and eventually Schaumann bodies (Lloyd-Davies and Forbes 1965; Mert et al. 2004). In rheumatoid arthritis, rheumatoid nodules with central fibrinoid necrosis and peripheral palisading histiocytes were found (Sandhu

Table 3 Granulomatous disorders of the gallbladder

Xanthogranulomatous cholecystitis
Sarcoidosis
Rheumatoid nodules (rheumatismus nodosus visceralis)
Granulomas in other autoimmune disorders (systemic lupus erythematosus, polyarteritis nodosa, granulomatous vasculitis)
Crohn's disease
Ulcerative colitis (IBD)
Cholesterol granulomas
Ceroid granulomas
Foreign body granulomas

and Choy 2013). In autoimmune vasculitis/angiitis, granulomas can accompany the vascular inflammatory process, e.g., in polyarteritis nodosa and necrotizing granulomatous vasculitis/Churg-Strauss syndrome (Lasser and Ghofrany 1976). The gallbladder is a well-known site of polyarteritis nodosa (PN) and is sometimes the only localization of isolated PN (Kumar et al. 2003; Juliano et al. 2009). Systemic lupus erythematosus is also known to manifest in the gallbladder (Vergara-Fernandez et al. 2009). Crohn's disease can rarely involve the gallbladder.

Macroscopically, the mucosa is often granular and nodular, with broad longitudinal ulcers and a thickened wall. Well-formed noncaseating granulomas can be found from the lamina propria to the subserosa (McClure et al. 1984; Bouteloup et al. 1997; Rettally et al. 2003; Andoh et al. 2006). Chronic granulomatous cholecystitis has been observed in the setting of chronic ulcerative colitis (Goldgraber and Kirsner 1960). In gallbladders with ulcerous inflammation, cholesterol-containing fragments of stones come into contact with mucosal macrophages, leading to cholesterol granulomas. Ceroid accumulating in the gallbladder mucosa can induce epithelioid cell induction followed by ceroid granuloma formation. Ceroid granulomas are in part associated with chronic cholecystitis and may produce a mass effect mimicking gallbladder cancer. Macroscopically, they are characterized by intramural or mucosal yellow-brown nodules. Mucosal ulceration or rupture of Rokitansky-Aschoff sinuses with bile leakage has been implicated as a pathogenic mechanism (Duarte et al. 1994).

Emphysematous Cholecystitis, Pneumocholecystitis, Pneumobilia, and Gallbladder Pneumatosis

Introduction

Few gallbladder disorders are characterized by the accumulation of gas in the gallbladder lumen and/or the gallbladder wall. As gangrenous inflammations play to most significant role, such lesions associated with an increase of gallbladder mass may be confounded with necrotic malignancy complicated by gas-forming infection.

Emphysematous Cholecystitis

Emphysematous cholecystitis (the "effervescent gallbladder") is a life-threatening variant of acute cholecystitis characterized by the presence of gas in the lumen and the wall of the gallbladder associated with necrotizing inflammation. The disorder has previously also been termed pneumocholecystitis or gangrenous pneumocholecystitis (Heifetz and Senturia 1948; Abel and Rousselot 1952; Lemmens and Louyest 1969). Infection with gas-forming bacteria, such as *Clostridium* species, *E. coli*, and *Salmonella* Derby, plays a decisive role. Predisposing conditions include ischemic gallbladder wall damage (atherosclerosis, cholecystic arterial thrombosis, thromboembolism, vasculitis, systemic hypoperfusion, gallbladder torsion), diabetes mellitus, and old age. CT images show gas in the gallbladder lumen (with an air-fluid level) and within the wall. Air may extensively dissect the gallbladder wall and escape into the abdominal cavity, with formation of pneumoperitoneum (Ohtani et al. 1996; Modini et al. 2008; Carrascosa and Salcines-Caviedes 2012). Luminal gas may also be transported into lower segments of the biliary tract, causing pneumobilia (Harley et al. 1978; Johnson et al. 1984). Emphysematous cholecystitis still has a high mortality (up to 15 %; Moanna et al. 2006).

Selected References: (Friedman and Poster 1955; Mentzer et al. 1975; Harley et al. 1978;

Goodman 1979; McMillin 1985; Gerritsen 1986; Nemcek et al. 1988; Lorenz and Steffen 1990; Ohtani et al. 1996; Garcia-Sancho Tellez et al. 1999; Ise et al. 2002; Konno et al. 2002; Lallemand et al. 2003; Chiu et al. 2004; Bouras et al. 2005; Moanna et al. 2006; Safioleas et al. 2006; Tanaka et al. 2007; Modini et al. 2008; Papavramidis et al. 2008; Uesaka et al. 2009; Wu et al. 2010; Verbeeck et al. 2011; Carrascosa and Salcines-Caviedes 2012; Kurguzov et al. 2012).

Histologically, necrosis or even extensive infarctoid changes are found, usually with a rather poor infiltration owing to limited access of leukocytes owing to vascular occlusion. However, diffuse granulocytic infiltrates (phlegmon) may occur. In longer-standing disease, eosinophilia and a gas reaction with macrophages and giant cells may ensue (Hino et al. 1989).

Gallbladder Pneumatosis

Gallbladder pneumatosis (pneumatosis cystoides), similar to its counterpart in the intestinal tract, is a rare condition characterized by the presence of gas bubbles in the mucosa or deeper parts of the gallbladder wall (Goudet et al. 1995). Gas situated in the tissue may elicit a foreign body-type reaction with accumulation of macrophages and multinucleated giant cells at the transition zone between gas and tissue (the so-called gas reaction). The pathogenesis of gallbladder pneumatosis has not been clarified, but it may develop from the ascent of gas from intestinal pneumatosis, following diagnostic interventions, or as a late change after emphysematous cholecystitis.

DOI 10.1007/978-3-319-26956-6_159

Abstract

The gallbladder can be subject to an entire spectrum of noninflammatory tumor-like changes. A typical example is cholesterolosis of the gallbladder, defined by a mucosal lesion characterized by accumulation of cholesteryl esters and triglycerides in foamy macrophages. Multiple mucosal yellowish to white lesions produce a macroscopically striking lesion termed strawberry gallbladder. Large accumulations of foamy cells give rise to cholesterol polyps that may protrude into the gallbladder lumen and mimic a neoplastic polyp. These polyps may undergo ulceration followed by secondary inflammatory changes. The adipose tissue situated around the gallbladder can undergo steatonecrosis followed by formation of numerous lipogranulomas. The gallbladder is rarely involved with malakoplakia, a reactive lesion more commonly occurring in the urogenital tract. Gallbladder malakoplakia presents in the form of yellowish plaques or nodules and histologically consists of large macrophages with distinct calcifications, the Michaelis-Gutmann bodies. The gallbladder is the site of endometriosis, endometrioma, several types of metaplasia, and tissue ectopias, whereby misplaced pancreatic tissue is the most common variant.

Cholesterolosis of the Gallbladder

Introduction

Cholesterolosis (synonyms: cholesterosis, cholesterinosis) is defined by a mucosal lesion of the gallbladder characterized by accumulation of cholesteryl esters and triglycerides in macrophages, which show the morphology of foam cells. Cholesterolosis was first described by Rudolf Virchow in 1857 (Virchow 1857). Typically, cholesterolosis displays a multifocal mucosal distribution, with multiple yellowish and sharply delineated foci distributed on the dark red-green background of the mucosa, a phenotype which somewhat resembles the morphology of the skin of a strawberry ("strawberry gallbladder"). Cholesterolosis can, however, produce endophytic lesions manifest as polyps, lesions that may radiologically mimic true gallbladder tumors.

Epidemiology

Cholesterolosis of the gallbladder is a common lesion. In a study of 633 consecutive necropsies, 134 strawberry gallbladders (diffuse cholesterolosis), 61 polypous forms, and 29 combined forms were found. None of the persons was under 15 years, and only three were under 20 years of age (Mentzer 1925). In a study of 1,000 surgical cases of cholesterolosis of the gallbladder, 26 % of the stone-free and 82 % of the gallstone cases occurred in females. The age incidence in the two groups was essentially alike, the greatest number of cases in each group occurring between the ages of 35 and 40 years (Judd and Mentzer 1927a). In 1,323 cholecystectomy preparations, cholesterolosis was detected in 15.6 % of cases (Celoria et al. 1994). In a more recent hospital-based retrospective study, 549 patients underwent cholecystectomy and hepatic resection for hepatocellular carcinoma, the prevalence of cholesterolosis of the gallbladder was 6.6 %, and the prevalence of cholesterol polyp of the gallbladder was 0.9 % (Lai 2011).

Among 549 consecutive patients who had cholecystectomies for various gallbladder disorders, 13.4 % had cholesterolosis. Cholesterolosis with coexistent gallstones was documented in 63.3 %, and 85.1 % of the cases were reported to have abnormally high fasting serum cholesterol levels (Khairy et al. 2004). The prevalence of cholesterolosis is higher in obese patients, being 38 % in obese vs. 6 % in nonobese patients in one study (Dittrick et al. 2005) and 37 % in another

(Csendes et al. 2003). In a study of 1,000 cases of gallbladder cholesterolosis, stones were present in half of the specimens, and multiple stones were found in 69 %, 99 % of the stones being cholesterol stones. Cholesterolosis alone, as the typical strawberry gallbladder, was the diagnosis in 53 % of the stone-free group and in 82 % of the stone group, and polypous cholesterolosis was detected in 47 % and 18 %, respectively. Diffuse and local/polypous forms were combined in 34 % of the stone-free and in 10 % of the stone-containing specimens (Judd and Mentzer 1927b).

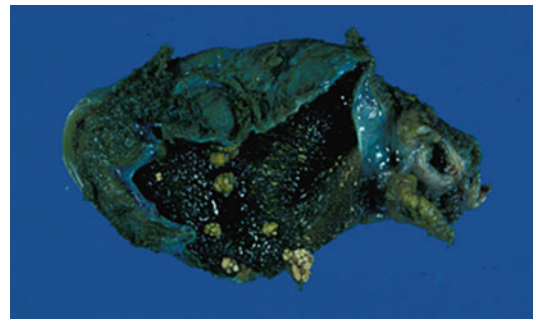

Fig. 1 Cholesterolosis of the gallbladder with cholesterol polyps

Clinical and Imaging Features

Isolated cholesterolosis is clinically silent in most cases. In the era preceding CT and MRI studies, imaging for cholesterolosis using X-ray was associated with a high percentage of errors (Judd and Mentzer 1927b; Damore et al. 2001), although other authors consider ultrasonography as an efficient tool (Price et al. 1982; Sandri et al. 2003). In an ultrasonography study of 853 patients who underwent laparoscopic cholecystectomy, 56 had gallbladder polyps, including cholesterolosis polyps, 75 % of them being smaller than 10 mm. Overall US-based diagnosis of gallbladder polyp was inaccurate in 82 % (Akyürek et al. 2005).

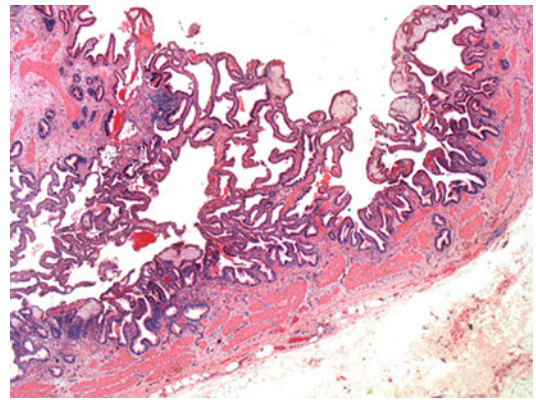

Fig. 2 Cholesterolosis of the gallbladder. Foamy, lipid-rich macrophages have accumulated in the tips of mucosal folds (hematoxylin and eosin stain)

Pathology

Macroscopy

Macroscopically, cholesterolosis of the gallbladder shows small yellowish elevations when the mucosa is inspected in the fresh specimen (Fig. 1). These elevations form circumscribed lesions or coalesce to form short bar-like or hook-like structures or an incomplete network reflecting the fine mucosal fold pattern of the gallbladder (Cooke 1931; Lewis and Peterson 1943; Feldman and Feldman 1954). The lesions, which occupy the tips of mucosal ridges, are 1 mm in diameter or less. Seventy-eight percent of cases showed grossly visible fatty changes (cholecystosteatosis) in the wall of the gallbladder (Judd and Mentzer 1927a).

Histopathology

The histology of gallbladder cholesterolosis has been studied in detail (Guerra et al. 1963). The lamina propria of the mucosa and in particular the tips of the delicate mucosal folds are densely infiltrated by large and clear, markedly vacuolated macrophages (foamy cells, Figs. 2 and 3). Cholesterolosis is often associated with papillary epithelial hyperplasia of the gallbladder (Elfving et al. 1968; Celoria et al. 1994) and sometimes with adenomyosis (Helpap and Huegel 1988). The foamy macrophage accumulations can develop regressive changes, associated with release of cholesteryl esters into the extracellular

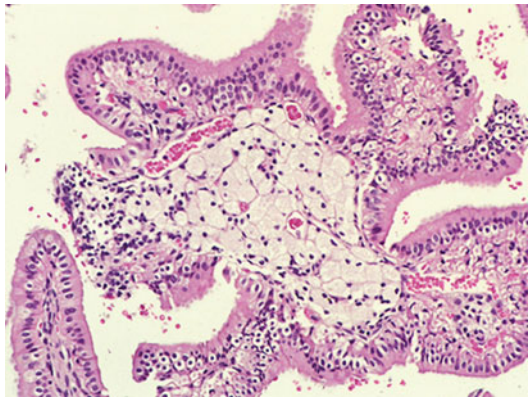

Fig. 3 Cholesterolosis of the gallbladder at higher magnification (hematoxylin and eosin stain)

space, an inflammatory response of the foreign-body type, and formation of cholesterol crystals and cholesterol granulomas, with foreign-body giant cells apposed to crystals (Womack and Haffner 1944). In old lesions, collections of cholesterol granulomas, sometimes in band-like formations, may be noted in deep layers of the gallbladder, in part of the cases associated with formation of lymph follicles and germinal centers. This process can induce mucosal ulceration, granulation tissue, and scarring, sometimes followed by inspissated bile depositions and dystrophic calcifications of the gallbladder wall (Womack and Haffner 1944). Exceptionally, osseous metaplasia can develop in such lesions (Ortiz-Hildalgo and Baquera-Heredia 2000). Released cholesterol and its esters may be transported to locoregional lymph nodes, where they can form "metastatic" cholesterol granulomas in the subcapsular sinus (Womack and Haffner 1944). Rarely, cholesterolosis has been found in association with carcinoma in situ (Akiyama et al. 1996).

Electron Microscopic Findings

Cholesteryl ester-laden macrophages in cholesterolosis show numerous protruded processes, which also contain organelles, lipid droplets, and abundant lysosomes. In foam cells, the cytoplasm is filled with large lipid droplets containing cholesteryl esters. Adjacent epithelial cells also show ultrastructural signs of high cholesterol content, with small lipid droplets and a well-developed agranular endoplasmic reticulum (Nevalainen and Laitio 1972; Koga 1985; Satoh and Koga 1997). Epithelial cells of the cystic duct in cholesterolosis of the gallbladder showed mucous secretory granules that appear dilated, and peculiar intracellular cholesterol deposits are detectable in the apical and subapical region of cells and around condensed mitochondria (Gilloteaux et al. 1997), suggesting that the cystic duct mucosa may participate in cholesterolosis of precursor lesions of this condition.

Tumor-Like Cholesterol Polyps of the Gallbladder

In clinico-radiologic work-ups, tumorous lesions of the gallbladder larger than 10 mm have a high incidence of malignancy. In rare instances, cholesterol polyps of the gallbladder can grow to sizes exceeding 1 cm, forming large papillary masses with a diameter of up to 3 cm and thus mimicking gallbladder cancer (Kaido et al. 2004).

Pathogenesis

Cholesterolosis of the gallbladder is considered to be multifactorial, and first ideas about pathogenic pathways date back to more than 50 years (Graham and Elman 1932). As part of investigations documented a correlation between high serum cholesterol levels and the prevalence of cholesterolosis of the gallbladder (Khairy et al. 2004), excess of cholesterol production was regarded as a pathogenic factor. However, in a study on 446 patients with cholesterolosis associated with gallstones and 190 patients without stones, cholesterolosis was not associated with high plasma cholesterol levels (Méndez-Sanchez et al. 1997). In patients with cholesterolosis, a positive correlation was obtained between the cholesterol saturation of bile and the content of

esterified cholesterol in the gallbladder mucosa (Sahlin et al. 1995). Free sterols can be transferred from bile to the gallbladder mucosa (Tilvis et al. 1982), where free cholesterol is esterified within cells, mainly mucosal macrophages. Cholesteryl ester accumulation is not caused by reduced efflux of cholesterol due to a defective sterol 27-hyroxylase mechanism (Strömsten et al. 2004). There is evidence that cholesteryl ester synthesis of gallbladder mucosa might play a role in the pathogenesis of cholesterolosis, as the activity of acylCoA-cholesterol ester acyltransferase is increased (Watanabe et al. 1998).

Steatonecrosis, Panniculitis, and Lipogranulomas of the Gallbladder

Severe transmural and specifically fistulating and perforating cholecystitis can induce necrosis and inflammation in the pericholecystic adipose tissue (panniculitis). This process can lead to numerous and in part cystic lipogranulomas, eventually producing a mass effect. Fat necrosis (steatonecrosis, adiponecrosis) of the gallbladder is uncommonly found in patients with acute pancreatitis (Chitkara 1995). It presents as whitish flecks or patches in the subadventitional adipose tissue, identical to the lesions found in peripancreatic adipose tissue. Steatonecrosis of the gallbladder may be marked and associated with direct extension from fat necrosis of the hepatoduodenal ligament, causing an ill-defined mass (Schein et al. 1993). A rare instance of membranous fat necrosis of the gallbladder has been reported (Ohtsuki et al. 2012). Membranous fat necrosis (synonyms: membranocystic change, lipomembranous panniculitis) is usually observed in skin-related diseases but may become a systemic alteration. The tissue contains wavy sudanophilic fluffy membranes that can elicit vigorous foreign-body reactions with giant cells. Gallbladder panniculitis can rarely be a manifestation of the panniculitis disorder, Weber-Christian disease (Ishida et al. 1993).

Cholecystosteatosis (Nonalcoholic Fatty Gallbladder Disease)

Obesity may cause fatty infiltration of multiple internal organs, including liver, heart, kidney, and pancreas, associated with organ and tissue dysfunction. Adipose tissue and tissues having fat overload form a dynamic endocrine organ regulating energy expenditure and adipokine turnover. Obesity is also associated with cholecystosteatosis. Cholecystosteatosis (synonym: nonalcoholic fatty gallbladder disease, NAFGBD) denotes increased fat deposition in the gallbladder wall (review, Pitt 2007). Increased gallbladder tissue lipids comprise free fatty acids, phospholipids, and triglycerides (Goldblatt et al. 2006; Mathur et al. 2008). It has been found that there is a relation between the type of cholecystitis and total gallbladder wall fat. Patients with acalculous and calculous cholecystitis have increased gallbladder fat compared to nondiseased controls, and this increased fat may lead to poor gallbladder emptying and biliary symptoms and signs (Al-Azzawi et al. 2007). Increased lipids enhance inflammatory reactions of the gallbladder (steatocholecystitis) resulting in an abnormal wall structure and decreased contractility (review: Tsai 2009).

Malakoplakia of the Gallbladder

Malakoplakia is a rare and unusual inflammatory process first described in the early 1900s (see the chapter on malakoplakia of the liver). Very few cases of gallbladder malakoplakia have been reported (Hanada et al. 1981; Charpentier et al. 1983; Hide et al. 2001; Agnarsdottir et al. 2004; Di Tommaso et al. 2005; Vaiphei et al. 2012). Gallbladder malakoplakia has been found in association with diabetes mellitus type 2 (Vaiphei et al. 2012). Macroscopically, yellowish plaques or nodules were noted. Histopathologically, accumulation of large macrophages with von Kossa-positive Michaelis-Gutmann bodies, associated with lymphocytic infiltration, is the hallmark. In

hematoxylin and eosin-stained sections, Michaelis-Gutmann bodies appear as targetoid cytoplasmic inclusions, and these bodies are PAS positive with and without diastase treatment and are also positive for the colloidal iron stain.

In the presence of typical targetoid, von Kossa-positive Michaelis-Gutmann bodies, the macrophage-rich lesions can hardly be confounded with other granulomatous inflammatory lesions.

Endometriosis and Endometrioma of the Gallbladder

Introduction

Endometriosis is defined as the presence of functioning endometrial tissue outside the uterine cavity. The prevalence of endometriosis has been estimated to be between 8 % and 18 % in young women. Endometriosis outside the pelvic cavity and ovaries mainly involves the abdominal wall, the gastrointestinal tract, and the urinary tract. Rare locations include muscle tissue, inguinal canal, umbilicus, mediastinum, bronchi, pleura, and even nasal region (nasolacrimal endometriosis). Endometriosis, which is well documented for the liver (see the respective paragraph), very rarely occurs in the gallbladder (Saadat-Gilani et al. 2007; Saldaña et al. 2010; Iafrate et al. 2013). Clinically, gallbladder endometriosis was manifest as chronic and vague or colicky abdominal pain, most severe in the right hypochondrium and accentuated during menstruation, and eventually an upper abdominal mass (Iafrate et al. 2013). The cyclic pain is thought to be caused by intrafocal bleeding during menstruation. Gallbladder endometriosis may be an isolated manifestation of this disorder or may be accompanied by endometriotic nodules situated elsewhere, e.g., the abdominal wall (Iafrate et al. 2013).

Pathology

Macroscopically, endometriotic foci may be situated in any part of the gallbladder but predominate in the fundus. The foci may adhere to the gallbladder surface or form internal nodules. The lesions may grow to macroscopic size and mimic cancer (gallbladder endometrioma; Saldaña et al. 2010). Histopathologically, endometriotic foci show preserved or markedly altered endometrial tissue consisting of endometrial glands in various phases of proliferation or secretion and the typical cellular stroma. Secondary changes mainly comprise fresh and old hemorrhage, with accumulation of hemosiderin-containing macrophages and free hemosiderin granules, necrosis, and fibrosis.

As endometriosis is an estrogen-dependent disease, endometriotic foci express estrogen receptors, a phenomenon which may help in the correct classification of stromal foci in the hepatobiliary tract (review: Burns and Korach 2012). Biologically, active estrogens are available to endometriotic tissue via several mechanisms, specifically aromatase activity. The rapid estrogen effects on endometriotic tissue are mediated by both membrane-associated estrogen receptors alpha and G protein-coupled receptor 30/GPER (Plante et al. 2012; Samartzis et al. 2012). Estrogen receptor-beta levels are more than 100 times higher in endometriosis than in normal endometrial tissue (Bulun et al. 2012). Also the estrogen-regulated genes, GREB1, c-MYC, and cyclin D1, are overexpressed in endometriotic foci (Pellegrini et al. 2012).

Differential Diagnosis

Endometriosis occurs in the liver and can be situated close to the gallbladder. Endometriosis sometimes develops on the undersurface of the diaphragm (Triponez et al. 2010).

Osseous Metaplasia of the Gallbladder

Introduction

Osseous metaplasia (heterotopic bone) denotes a tissue alteration characterized by the development of immature and/or mature bone within

connective tissue of various organs. Osseous metaplasia of the gallbladder wall is an uncommon finding and has mainly been observed in the setting of chronic fibrosing cholecystitis (Indyk and Shipton 1957; Duchini 1967; Yosepovich et al. 2002; Nelson and Kahn 2009; Rege and Vargas 2011).

Pathology

Histologically, one most often notes a delicate network of osteoid trabecules lined by osteoblasts, embedded in a collagenous matrix with or without associated lymphocytic infiltration ("cholecystitis ossificans"). Mature mineralized bone may also develop in part of the cases. Osseous metaplasia sometimes exclusively involves the gallbladder mucosa (Nelson and Kahn 2009). In one patient with cholecystitis and cholelithiais, osseous metaplasia of the gallbladder wall was associated with a fasciitis-like fibroblastoid proliferation containing osteoclast-like giant cells (Rege and Vargas 2011).

Differential Diagnosis

Ossifications occur in part of gallbladder carcinosarcomas (Nakagawa et al. 1996). Impacted calcified gallstones may mimic circumscribed osseous metaplasia.

Pancreatic Ectopia of the Gallbladder

Introduction

Misplaced pancreatic tissue (ectopic pancreas, heterotopic pancreas) can occur in the wall of the gallbladder. This alteration was first described by Poppi in 1916. Since then, numerous descriptions of this clinicopathologic entity have appeared in the literature.

Selected References: Mutschmann 1946; Elfving 1959; Monfreda et al. 1967; Dolan et al. 1974; Qizilbash 1976; Ben-Baruch et al. 1986; Lai and Tompkins 1986; Collard et al. 1989; Jarde et al. 1989; Murakami and Tsutsumi 1989; Jeng et al. 1991; Hadzi-Nikolov et al. 1997; Kondi-Paphiti et al. 1997; Bhana and Chetti 1999; Mboti et al. 2003; Meshikhes et al. 2003; Pilloni et al. 2006; Beltran et al. 2007; Elpek et al. 2007; Neupert et al. 2007; Shiwani and Gosling 2008; Bromberg et al. 2009; Al-Shraim et al. 2010; Cerullo et al. 2011; Gucer et al. 2011; Klimis et al. 2011; Sroczynski et al. 2013.

Instead of pancreatic heterotopia or ectopia, the term pancreatic choristoma of the gallbladder is employed to denote this lesion (Beltran et al. 2007). At least half of the cases are located to the gallbladder neck, which embryologically is more close to the pancreas anlage.

Clinical Features

In the majority of cases, heterotopic pancreatic tissue in the gallbladder is an asymptomatic, incidentally found alteration. In part of patients, the lesion can induce, or be associated with, acute or chronic cholecystitis in part of patients (Bhana and Chetty 1999; Mboti et al. 2003; Elpek et al. 2007; Shiwani and Gosling 2008; Bromberg et al. 2009; Al-Shraim et al. 2010; Klimis et al. 2011; Elhence et al. 2012; Sroczynski et al. 2013). Cholecystitis may be related to obstruction, as it was found in pancreatic heterotopia located to the gallbladder neck (Weppner et al. 2009; Limaiem et al. 2012). The lesion rarely presents with symptoms and signs of pancreatitis, as the ectopic pancreatic tissue can undergo acute inflammation, similar to the orthotopic organ (Qizilbash 1976; Pilloni et al. 2006). Sometimes, pancreatic heterotopia gives rise to a suspicious tumefaction (Collard et al. 1989; Foucault et al. 2012), and in one patient, the heterotopia was associated with hypertrophic ectopic pancreatic ducts mimicking an adenomyoma (Pilloni et al. 2006). One case with malignant change of pancreatic heterotopia of the gallbladder was reported (Jeng et al. 1991). The lesion may be associated with high levels of

amylasuria (Klimis et al. 2011) or may cause an elevation of pancreatic enzymes in gallbladder bile (Sato et al. 2012).

Pathology

Macroscopically, pancreatic heterotopia is usually manifest as a mere thickening of the gallbladder wall, with circumscribed nodules of pancreatic tissue embedded in fibrous stroma. The heterotopia can, however, also present as gross, tumor-like nodules of 1 cm diameter or even more (Mboti et al. 2003). Histologically, all cellular systems of the normal pancreas can be present, including acinar cells, duct cells, and endocrine islet-type cells or fully developed islets of Langerhans with expression of insulin and somatostatin (Pilloni et al. 2006; Beltram et al. 2007). In some cases, large parts of the gallbladder wall are involved by pancreatic exocrine tissue, the pancreatic ductules and ducts resembling Rokitansky-Aschoff sinuses (Pilloni et al. 2006). Pancreatic heterotopia can be associated with synchronous heterotopic gastric mucosa of the gallbladder (Jaerve and Meurman 1964).

Ectopic Liver of the Gallbladder

Introduction

Ectopic liver tissue (liver choristoma, accessory liver, hepar succenturiatum) is a rare condition that most often involves the pancreas, stomach, gastrohepatic ligament, umbilical ligament, gallbladder, omentum, adrenal glands, esophagus, and thoracic cavity, including mediastinum, lung, and heart. Ectopic liver of the gallbladder is a rare clinical entity that is usually asymptomatic and observed incidentally in the setting of laparoscopy, cholecystectomy for other reasons, or autopsy. Ectopia of liver tissue in the gallbladder wall was first described in 1922 under the term supernumerary liver lobe implanted on the inferior surface of the gallbladder (Corsy 1922).

Epidemiology

Overall, the incidence of ectopic liver in the abdominal and thoracic cavities has been estimated from 0.24 % to 0.47 %. The incidence of ectopic liver of the gallbladder is probably low but seems to be the most common intra-abdominal site of liver ectopia (Griniatsos et al. 2002; Algin et al. 2008; Triantafyllidis et al. 2009). In a study of 5,500 autopsies, only three cases were detected (0.05 %; Eiserth 1940). In a more recent investigation on 1,060 laparoscopies, three cases were identified (0.28 %; Watanabe et al. 1989).

Clinical Features

Most cases of ectopic liver of the gallbladder are incidental findings without symptoms and signs. However, ectopic liver can produce a mass lesion that may be confounded with a gallbladder tumor (Hamdani and Baron 1994). In unusual situations, ectopic liver can undergo secondary changes that are symptomatic, including torsion of pedunculated lesions, acute hemorrhage, compression, obstruction of the gallbladder, or malignant transformation.

Selected References: Eiserth 1940; Klein 1955; Bassis and Izenstark 1956; Horanyi and Fuesy 1963; Ashby 1969; Costero et al. 1975; Collan et al. 1978; Torchio and Maconi 1978; Natori et al. 1986; Fellbaum et al. 1987; Tejada and Danielson 1989; Watanabe et al. 1989; Castro Viera et al. 1990; Iacconi and Masoni 1990; Svane and Knudtzon 1991; Hamdani and Baron 1994; Kodama and Yokoyama 1996; Sato et al. 1998; Djuricic et al. 1999; Acar et al. 2002; Griniatsos et al. 2002; Sakarya et al. 2002; Lundy et al. 2005; Wang and Liu 2006; Koh and Hunt 2007; Triantafyllidis et al. 2009; Catani et al. 2011; Dettmer et al. 2011; Nagar et al. 2011; Martinez et al. 2013.

Pathology

Macroscopy

Most cases of liver ectopia of the gallbladder showed liver tissue attached to the outer surface of the organ. The lesion may be pedunculated and forming a polypoid structure, with a thick or thin stalk of variable length connecting it with the gallbladder and containing blood vessels (Lundy et al. 2005; Triantafyllidis et al. 2009). Very few reports documented the presence of ectopic liver tissue in inner parts or the gallbladder wall (intramural ectopia) or even the mucosa (Torchio and Maconi 1978; Natori et al. 1986). Ectopic liver tissue of the gallbladder usually manifests as small brownish nodules measuring from a few mm to 1 or 2 cm (Natori et al. 1986), but lesions measuring several cm in diameter have also been observed (Lundy et al. 2005). Due to circulation failure, ectopic liver tissue can undergo necrosis associated with acute hemorrhage, the lesion presenting as a dark red nodule on the gallbladder surface (Nagar et al. 2011).

Histopathology

Histologically, the ectopic liver tissue usually shows a normal architecture, although the lobules may be deformed and/or undersized (Griniatsos et al. 2002). In at least part of the cases, ectopic liver contained portal tracts with small bile ducts, arteries, and venous branches. The ectopic liver tissue is sometimes cholestatic, with accumulation of bile in canaliculi (Svane and Knudtzon 1991). Interestingly, these livers or liverlets do however not always show cholestasis, although a connection to the gallbladder lumen or the cystic duct cannot, or not easily, be identified. Hepatocytes located in ectopic liver may undergo changes similar to that of orthotopic hepatocytes, apart from cholestasis, such as fatty change (Eiserth 1940), hemosiderosis (Tejada and Danielson 1989), and cirrhosis (Watanabe et al. 1989). In one case of ectopic liver localized to the gallbladder fundus, retention of alpha-1-antitrypsin was detected in the ectopic hepatocytes (Dettmer et al. 2011).

Ectopic Liver and Malignancy

Ectopic liver tissue has a propensity to develop hepatocellular carcinoma/HCC, especially in oriental patients (see the respective chapter; Arakawa et al. 1999; Caygill and Gatenby 2004; Leone et al. 2004). In the study of Arakawa and coworkers (1999), which focused at ectopias other than those of the gallbladder, 22 out of 48 cases developed HCC. HCC can also develop in ectopic liver of the gallbladder (Tamura et al. 1985; Arakawa et al. 1999). Interestingly, the incidence of HCC is much lower in ectopic liver tissue of the gallbladder: only one of 33 cases developed cancer (Arakawa et al. 1999). The reason for this striking difference is unknown. Ectopic liver of the gallbladder may have less time to undergo carcinogenesis, because the involved gallbladders may be removed early. It has also been suggested that the difference might be related to the finding that ectopic liver attached to the gallbladder is an anomaly occurring later in ontogenesis and is thus well differentiated and composed of more stable tissue (Griniatsos et al. 2002).

Pathogenic Pathways

It is assumed that ectopic liver of the gallbladder arises from residual liver primordial cells located in the caudal part of the liver primordium.

Thyroid Ectopia of the Gallbladder

In the course of thyroid anlage descent, groups or clusters of thyrocyte precursors can lodge at various non-eutopic sites and thus give rise to ectopic tissue. The most common sites of ectopic thyroid tissue are lingual, sublingual, thyroglossal, laryngotracheal, and lateral cervical sites. Thyroid ectopia in the gallbladder wall has been reported few times (Harach 1998; Ihtiyar et al. 2003; Venditti

et al. 2007; Cassol et al. 2010; Liang et al. 2010; review, Klubo-Gwiezdzinska et al. 2011).

Macroscopically, thyroid ectopia can produce a gallbladder mass (Liang et al. 2010), but this is a highly unusual event as ectopic thyroid tissue is usually detected histologically as an incidental finding. Histology is characterized by normal-looking thyroid tissue, with or without a lobular texture, follicles sometimes being embedded in a collagenous matrix. A potential differential diagnosis of thyroid ectopia is gallbladder metastasis of well-differentiated follicular thyroid carcinoma.

Pathogenic Pathways

Similar to thyroid ectopia in the liver (see the respective paragraph), ectopic thyroid tissue in the gallbladder wall is thought to arise via aberrant migration of thyroidocyte progenitors in the course of the thyroid anlage descent from the foramen cecum to the mediastinum. The descending thyroid anlage is, in a certain phase of embryogenesis, in close contact with the mesenchyme of the future septum transversum, and cell exchange may occur during this developmental phase.

Adrenocortical Ectopia

Very rarely, ectopic adrenal cortex was found in the form of small nodular structures in the subserosal space of the gallbladder (Busuttil 1974).

Gastric Mucosal Heterotopia in the Gallbladder

Introduction

Gastric mucosal heterotopia (GMH) of the gallbladder is a congenital abnormality characterized by the presence of usually circumscribed areas of gastric mucosa replacing the original gallbladder mucosa. Gallbladder GMH was first described in 1934, based on a polypoid lesion (Egyedi 1934), and relatively few observations have been documented since.

Selected References: Williams and Humm 1953; Curtis and Sheahan 1969; Summers et al. 1970; Bentivegna and Hirschl 1972; Keramidas et al. 1977; Mooney et al. 1979; Adam et al. 1989; Pradines et al. 1989; Boyle et al. 1992; Vallera et al. 1992; Schimpl et al. 1994; Uchiyama et al. 1995; Hamazaki and Fujiwara 2000; Inoue et al. 2000; Xeropotamos et al. 2001; Isik et al. 2002; Lombay et al. 2003; Madrid et al. 2003; Sciumè et al. 2005; Cöl et al. 2007; Triki et al. 2008; Hayama et al. 2010; Bulus et al. 2012; Liang et al. 2013.

GMH of the gallbladder is an uncommon condition, while pseudopyloric or pyloric gland metaplastic epithelium in the gallbladder is a common finding, detectable in 66–84 % of cholecystectomy specimens, whereas intestinal metaplasia is present in 12–52 % of gallbladders and is often associated with pyloric metaplasia (review, Xeropotamos et al. 2001). Gallbladder GMH is almost equally distributed among sexes, with an age range at diagnosis of 6–77 years, a considerable proportion of cases being reported for the pediatric age group. In almost a third of cases, gallstones were present. GMH can lead to mucosal defects, including peptic ulcerations (Kehrer and De Minjer 1951; Larsen et al. 1985), sometimes causing massive hemobilia (Adam et al. 1989; Yoon et al. 2005), and hematemesis and melena (Larsen et al. 1985). GMH may occur in gallbladders with preexisting anatomical abnormalities, including duplicate gallbladder (Bailie et al. 2003), or anomalous union of the pancreatobiliary duct (Wakiyama et al. 1998). Apart from the gallbladder, GMH can develop in the cystic duct (Orizio et al. 2011). GMH and intestinal metaplasia of the gallbladder are considered to be precancerous (Yamagiwa and Tomiyama 1986). Etiology and pathogenesis of gastric mucosal heterotopias are not known.

Pathology

Macroscopy

Macroscopically, gallbladder GMH can present as a flat or plaque-like lesion, but GMH growing

as pedunculated or sessile polypous masses is also well known (Yamamoto et al. 1988, 1989; Schimpl et al. 1994; Uchiyama et al. 1995; Leyman et al. 1996; Sciumè et al. 2005; Hayama et al. 2010). In case of polypoid lesions, gallbladder carcinoma may suspected based on imaging results (Hayama et al. 2010), also because polypous GMH may grow to a size exceeding 2 cm. Gallbladder GMH can also present as a firm nodular mass or as a multiloculated lesion (Xeropotamos et al. 2001). Large GMH masses can cause symptom-producing tumors (Bentivegna and Hirschl 1972). On CT images, GMH appears as a slightly high density area which is intermediately enhanced early after bolus injection of contrast medium (Inoue et al. 2000). The lesions are often located in the gallbladder fundus, but GMH also occurs in the gallbladder neck (Sciumè et al. 2005).

Histopathology

Histologically, GMH reveals a gastric-type superficial epithelium and associated gastric glands, including pyloric glands, corpus glands, and fundic glands, chief cells and parietal/oxyntic cells being present (Runge et al. 1978). The epithelium overlying the glandular structures may show hyperplastic changes. Neuroendocrine/APUD cells have been found in part of the cases (Vallera et al. 1992). GMH can be associated with extensive adjacent pyloric and/or pseudopyloric metaplasia, staining red with the Alcian blue-PAS stain (Xeropotamos et al. 2001), or intestinal gallbladder metaplasia (Tavli et al. 2005). It can undergo secondary changes, such as cystic change (Popkharitov et al. 2008) or squamous metaplasia (Daud et al. 2007). Gallbladder GMH can be associated with other types of heterotopia/ectopia, such as pancreas and thyroid tissue (Murakami and Tsutsumi 1999), or with adenoma of the gallbladder (Summers et al. 1970). On gastric-type epithelium of the gallbladder, no *Helicobacter pylori* was detected (Arnaout et al. 1990).

Table 1 Types of gallbladder ectopia

Retroposition of the gallbladder
Intrahepatic gallbladder
Left-sided gallbladder (transposition)
Gallbladder interposition
Extraabdominal gallbladder

Ectopic Gallbladder

Ectopic gallbladder, albeit a rare condition, has clinical significance because it can lead to misdiagnosis and misinterpretation as a tumorous lesion. Several types of gallbladder ectopia are known (Table 1).

A retroposed gallbladder (retrohepatic gallbladder) may suggest the presence of a cystic tumor on the underside of the liver (Feldman and Venta 1988; Chowbey et al. 2004). A retrohepatic gallbladder can be contained in the coronary ligament (Principe et al. 1979). Ectopic gallbladder may be situated within the liver substance, with or without stones (Glasionov 1961; Schulz et al. 1975; Velchik and Noel 1987; Lobo et al. 2007), and can mimic an intrahepatic cystic tumor (Schneider et al. 1979). If it is situated away from the peritoneum, signs of acute cholecystitis may be absent. In some cases, ectopic gallbladder has an own mesenterium (mesovesicula) containing feeding vessels (Popli et al. 2010), the ectopic gallbladder then being a hanging lesion that can undergo torsion and gangrenous infarction (the "floating gallbladder"; Havrilla et al. 1978). A floating gallbladder on a long "mesovesicula" can also herniate through the foramen of Winslow into the lesser sac, with signs of strangulation (Blanton et al. 1974). In rare instances, the gallbladder is situated in a suprahepatic position (Faintuch et al. 1979; Youngwirth et al. 1983; Sheu et al. 1995), sometimes associated with malformations of the right liver (Hsu et al. 1994) or inverted liver (Hibbs and Ahmad 2010). It can also occur intrathoracically (Labitzke 1991), and in few instances, the gallbladder was transposed to the left underside of the liver (gallbladder transposition; Duimstra and Greenfield 1977; Keller et al. 1982; Wong et al. 2001; Dhulkotia et al. 2002) or was malpositioned in the

region of extrahepatic bile ducts (gallbladder interposition; Walia et al. 1986). The gallbladder can be situated on the left side of the common bile duct and the cystic duct, arising from the right hepatic duct (Chung et al. 1997).

Reactive Vascular Mass Lesions of the Gallbladder

Introduction

Similar to extrahepatic and intrahepatic bile ducts, the gallbladder can be involved in a variety of reactive vascular alterations that may produce mass effects or pseudotumors mimicking neoplastic disease. The most important changes include gallbladder varices and pseudoaneurysms of the cystic artery.

Gallbladder Varices

In part of patients with portal hypertension, ectopic varices (varicose veins) as dilated venous collaterals can develop in the wall of the gallbladder.

Selected References: Malusev 1951; Salam et al. 1979; Lebrec and Benhamou 1985; West et al. 1991; Chawla et al. 1994, 1995; Safadi et al. 1996; Gabata et al. 1997; Palazzo et al. 2000; Chu et al. 2002; Radhi 2003; Ito et al. 2009; de Alcantara et al. 2013.

It is estimated that the incidence of gallbladder varices in cirrhotic and non-cirrhotic portal hypertension amounts to up to 30 % (West et al. 1991; Chawla et al. 1994; Helbich et al. 1994; Rathi et al. 1996). Gallbladder varices have also been described in the pediatric age group (Helbich et al. 1994; Rathi et al. 1996). The varices may or may not be associated with extrahepatic portal vein occlusion (West et al. 1991) but are sometimes associated with portal vein cavernoma (Lebrec and Benhamou 1985). Varices cause fixed filling defects (Rosen and Wilson 1980) and thickening of the gallbladder wall suspicious of malignancy (Saigh et al. 1985). Rupture of varices leads to variceal bleeding, sometimes followed by life-threatening or fatal abdominal hemorrhage (Holmlund and Lundström 1977; Chu et al. 2002; Kevans et al. 2009; Vilallonga et al. 2012). The dilated gallbladder veins can be visualized by means of color Doppler sonography (Kainberger et al. 1990; Helbich et al. 1994; Safadi et al. 1996; Mishin 2005). A direct communication of the varices to intrahepatic portal vein branches can be demonstrated by Doppler sonography and CT (Gabata et al. 1997).

Aneurysmatic Changes and Related Vascular Disorders

The most common alteration in this group is cystic artery pseudoaneurysm (CAP). Pseudoaneurysms (synonyms: false aneurysm, aneurysma spurium, aneurysma falsum) are characterized by a periarterial hematoma following a tear in the arterial wall involving intima and media but leaving the adventitia intact in classical cases. However, in some of these aneurysms, the hematoma will break through the adventitia with time. CAP is most often observed in the setting of acute cholecystitis (Machida et al. 2008; Hague et al. 2010; Dewachter et al. 2012; Fung et al. 2013) and can develop as a complication of xanthogranulomatous cholecystitis (Ahmed et al. 2010). CAP can protrude into the gallbladder lumen, producing masses of up to 2 cm in diameter (Ahmed et al. 2010). This vascular lesion can cause acute internal hemorrhage (Fung et al. 2013) and hemoperitoneum (Ghoz et al. 2007), sometimes with fatal outcome (Olbrycht 1965). Pseudoaneurysms can also develop in the right hepatic artery and rupture into the gallbladder (Schubert et al. 1980; Lin et al. 2010). Percutaneous liver biopsy can be complicated by arterial-portal fistula causing a gallbladder polyp as a manifestation of hemorrhage (Lin et al. 2005).

Arteriovenous and Other Vascular Malformations of the Gallbladder

Arteriovenous malformations of the gallbladder are very unusual alterations characterized with the presence of serpentine around and within the gallbladder wall. Angiographically, dilated and tortuous cystic artery branches, a racemose vascular network, and early filling branches of the cystic vein have been noted (Tajima et al. 1997; Osada et al. 2007). The gallbladder is rarely involved in the setting of Osler-Weber-Rendu disease, with multiple telangiectasias in the gallbladder wall (Baba et al. 1995).

Gallbladder Hemorrhage and Hematoma

Introduction

Gallbladder hematomas can occur under various conditions, including trauma, inflammation, coagulation disorders, vascular accidents, and malignant neoplasms. More commonly, blood accumulates within the gallbladder lumen and produces a hemocholecyst, but various conditions also cause intramural gallbladder bleeding which results in wall thickening, mass effect, and sometimes extensive wall dissection. Gallbladder hemorrhages and hematomas can be divided into several anatomical categories (Table 2).

Hemorrhagic Cholecystitis

Gallbladder hemorrhage is a relatively rare complication of hemorrhagic cholecystitis (Parekh and Corvera 2010) and is sometimes associated with pathological coagulopathy or the administration of anticoagulative therapies (Morris et al. 2008; Chen et al. 2010), uremia (Lai and Tarng 2009), or cytostatic therapy. Hemorrhagic cholecystitis can result in hemobilia (Bazzoni et al. 1993) or in gallbladder rupture with massive intraperitoneal bleeding (Tavernaraki et al. 2011). Hemorrhagic cholecystitis, with its alteration in wall structure and contractility, may simulate gallbladder carcinoma (Gremmels et al. 2004).

Table 2 Categories of gallbladder hemorrhage and hematoma

Hemorrhagic cholecystitis
Intraluminal hematoma (hemocholecyst, hematocele)
Intramural gallbladder hematoma
Hemorrhagic tumors

Intraluminal Hematoma (Hemocholecyst)

Acute or continuous bleeding into the gallbladder lumen causes the formation of a blood clot that may completely fill the lumen (hemocholecyst, gallbladder hematocele, Scharling and Geisinger 1993) and which reveals characteristic sonographic and CT features (Grant and Smirniotopoulos 1983; Kauzlaric and Barmeir 1985). Intraluminal blood masses may be mixed with bile, gallstones, mucus, exudate, and tissue debris. Intraluminal blood escapes through the cystic duct and hence causes hemobilia in more distal parts of the biliary tract. In severe and rapidly progressing hemorrhage, gallbladder rupture may result. Important causes of hemocholecyst mainly comprise blunt trauma with gallbladder contusion (Sandblom 1948; Saad et al. 1979; Fröschle et al. 1990; McNabney et al. 1990; Erb et al. 1994), gallbladder malignancy (Faure et al. 1969; Uchiyama et al. 1998; John et al. 1999; Heise et al. 2000; Kubota et al. 2000), coagulation disorders (e.g., hemophilia; Shimura et al. 2000), complications of anticoagulant therapy (Brawner et al. 1966; Mikou et al. 2004; Zangrandi et al. 2009), chemotherapy, radiofrequency ablation therapy of malignant liver tumors (Yamamoto et al. 2003; Shin et al. 2011), benign tumors and polyps (Cappell et al. 1993), hemorrhagic cholecystitis (Ku et al. 2004), ruptured artery and venous aneurysms and pseudoaneurysms (Barzilai and

Kleckner 1956; Hakami et al. 1976; Miura et al. 1998), and venous hemorrhage in portal hypertension (Krustev et al. 2002). In the setting of portal hypertension, gallbladder varices may develop, followed by variceal hemorrhage (Chu et al. 2002; Kevans et al. 2009). Intraluminal gallbladder hematoma was also induced by percutaneous liver biopsy (Kwon et al. 2002). Hemocholecyst can present as a tumorous mass and may mimic a gallbladder neoplasm (Jung et al. 2011).

Intramural Hematoma

Intramural hematoma of the gallbladder is less common than hemocholecyst (Tesler and Cantor 1957; Pilling 1979). Hematoma confined to the wall results in a mass that exerts pressure. The hematoma may remain confined to the wall or may rupture into the gallbladder lumen or through the serosal covering into the peritoneal cavity. Hematoma of the gallbladder wall may be associated with infiltrating hematoma of the hepatic pedicle (Dao et al. 1989). Intramural hematoma as a "pushing" or infiltrating mass can mimic a gallbladder neoplasm on sonographic, CT, or MR images (Tan et al. 2005; Jung et al. 2011).

Hemorrhagic Tumors

Malignancies of the gallbladder can give rise to hemorrhage, both hemocholecyst and mural hematomas at the site of the tumor, whereby the tumors themselves may be hemorrhagic (Petrin 1966; Faure et al. 1969; Piotrowski et al. 1975; Calmat et al. 1979; Fourdan et al. 1994; Osawa et al. 1996; Jones et al. 1997). Metastases to the gallbladder also cause hemorrhage and hemobilia, e.g., metastases of renal cell carcinoma (Fullarton and Burgoyne 1991) or of hepatocellular carcinoma (Chang et al. 1998). In addition to malignant tumors, also benign gallbladder neoplasms can give rise to tumor hemorrhage (Cho et al. 2001).

Pathology

Macroscopy

In acute hemorrhagic cholecystitis, the gallbladder wall is thickened, with edema and bleeding in the extramuscular tissue. The mucosa has lost its fine texture and appears as a dark red to blackish surface with overlying blood coagula and exudate on ulcerated parts. On cut sections, the wall has lost its layers and is visualized as a dark red and often friable tissue. Hemocholecyst is macroscopically characterized by liquid or coagulated blood filling the gallbladder lumen. In recently developing cases, the blood is easily removable from the mucosa, while with time the coagulated blood may adhere to the mucosal surface. In formalin-fixed specimen, the blood forms a dark and hard mass that usually falls off when cutting through the organ. Intramural hematomas, which are either an isolated phenomenon or are combined with hemocholecyst, appear as blood masses of variable size that dissect the gallbladder wall and may bulge into the lumen, mimicking a hemorrhagic tumor.

Cysts of the Gallbladder 160

Contents

Abstract

The gallbladder is the site of various types of cysts that can mimic cystic neoplasms. Gallbladder cysts have been classified as congenital, acquired, and neoplastic cysts. Congenital cysts mainly include congenital simple epithelial cysts, ciliated foregut cyst, dermoid cysts, cystic choristomas derived from ectopic gastric mucosa, mesothelial cysts, duplication cysts, and bronchogenic cysts. Simple cysts may have a muscular wall but are not communicating with the gallbladder lumen. Acquired cysts are retention cysts, dilated Rokitansky-Aschoff sinuses, adenomyomatosis, cystic changes of fistulas, cystic abscesses, inflammatory pseudocysts, and parasitic cysts. Retention cysts are caused by obstructive gallbladder changes induced by stones, tumors, or sludge.

General Remarks and Classification

Cysts of the gallbladder wall represent a heterogeneous group of lesions that may be confounded with other alterations characterized by cyst formation, including necrotic tumors and abscesses. Gallbladder cysts have been classified as congenital, acquired, and neoplastic cysts, as summarized in Table 1 (Jacobs et al. 1991).

Table 1 Congenital and acquired cysts of the gallbladder

Congenital cysts
Congenital simple epithelial cyst
Ciliated foregut cyst
Dermoid cyst
Mesothelial cyst
Cystic choristoma
Gallbladder duplication cyst
Congenital cystic malformation
Bronchogenic cyst
Acquired cysts
Retention cyst
Dilated Rokitansky-Aschoff sinuses
Adenomyomatosis
Cyst from traction of a peridiverticular adhesion
Cystic change of fistula
Cystic abscess
Pseudocyst
Parasitic cyst
Neoplastic cysts

Congenital Cysts of the Gallbladder

Congenital cysts of the gallbladder are very rare lesions that are characterized by a muscle layer and lack of communication with the gallbladder lumen (Cureton and Newcombe 1961). Such cysts sometimes contain a simple cholangiocellular epithelium without further differentiation (simple epithelial cyst; Ochsner and Blalock 1964; Fitzer 1978; Jacobs et al. 1991; Asada et al. 1993; Fujisawa et al. 1995) and are either unilocular or multilocular (Cureton and Newcombe 1961). Epithelial gallbladder cysts may be associated with preneoplastic changes and adenocarcinoma (Matsumoto et al. 2002). Congenital cysts are thought to be caused by incomplete development of a second gallbladder primordium (formation of aberrant vesicles), isolation of a congenital diverticulum, or cystic transformation of a Luschka duct. Part of congenital epithelial cysts with a muscularis are lined by a ciliated epithelium containing variable amounts of goblets cells, thus corresponding to the type of ciliated cyst found in the liver (ciliated foregut cysts of the gallbladder; see the respective paragraph). Further types of congenital cyst characterized by an abnormal epithelial differentiation are the very rare dermoid cyst (Falcao and Leal 1975) and mesothelial cyst (Hoffman et al. 1989). Heterotopic gastrointestinal mucosa of the gallbladder has been found to form a cystic choristoma (Popkharitov et al. 2008). Intra-abdominal bronchogenic cyst has been detected alongside the gallbladder (Kim et al. 2004). A congenital cystic change of the gallbladder can also be caused by duplication of the gallbladder, one component of the double organ undergoing cyst formation (Kothari et al. 2005). An unusual lesion of unknown cause is giant congenital cystic malformation of the gallbladder (Lobe et al. 1986).

Congenital cysts also develop in the cystic duct (congenital cystic duct cyst; cystic malformation of the cystic duct; Pracy 1949; Bode and Aust 1983; Champetier et al. 1987; Serena Serradel et al. 1991) and are sometimes associated with an anomalous pancreaticobiliary junction (Weiler et al. 2003).

Acquired Cysts of the Gallbladder

Acquired cysts can develop following obstructive changes, e.g., by a tumor (retention cyst; Sworn and Gay 1975; Yamada et al. 1996). Retention cysts can occur following cholecystectomy and are located proximal to the stump (Prudkov and Titov 2001). Part of the acquired retention cysts may contain bile, gallstones, or stone fragments such as cholesterol crystal clusters.

Rokitansky-Aschoff sinuses may, especially in cases of sinus neck obstruction, undergo marked cystic change. Cysts are also a feature of gallbladder adenomyomatosis; these cysts may grow to a size detectable by sonography (Hwang et al. 1998; Brambs et al. 1990). Very rare are pseudocysts following pancreatitis (Jelen et al. 1974). In case of extensive squamous metaplasia of the gallbladder mucosa developing in chronic cholecystitis, a pseudoepidermoid cyst can arise (Teo et al. 2005).

Parasitic Cysts

A rather frequent cause of acquired gallbladder cysts is echinococcosis, forming hydatid cysts in

the gallbladder wall or cysts attached to the gallbladder adventitia (Soldevilla 1950; Cabanie and Lamy 1960; Rigas et al. 1979; Safioleas et al. 2004; Pitiakoudis et al. 2006). Hydatid cysts of the gallbladder may undergo marked calcification, sometimes mimicking porcelain gallbladder (Benedetti-Valentini 1954; Krasniqi et al. 2010) and may develop a cholecysto-hydatid fistula (Murtaza et al. 2008; Sabat et al. 2008).

Differential Diagnosis

Differential diagnosis of gallbladder cysts includes hydrops of the gallbladder, mucocele, cholecystocele (Deshmukh et al. 1999), gallbladder diverticulum, gallbladder varicosis (Saigh et al. 1985), cystadenoma of the gallbladder (Spector et al. 2003), and gallbladder lymphangioma (Choi et al. 2002).

Epithelial Cysts of the Gallbladder

Introduction

Apart from ciliated foregut cyst, which is treated in a separate chapter, several other types of congenital or acquired gallbladder cysts are recognized, cystic lesions that have to be distinguished from cystic neoplasms of the gallbladder.

Non-ciliated Epithelial Cysts

Non-ciliated epithelial gallbladder cysts (synonym: epithelial inclusion cyst) are congenital malformative lesions that are thought to result from the segregation of a part of the gallbladder anlage during ontogenesis. In contrast to true diverticula, these cysts do not communicate with the main gallbladder lumen (Cureton and Newcombe 1961; Ochsner and Blalock 1964; Sworn and Gay 1975; Fitzer 1978; Berulava 1980; Jacobs et al. 1991; Asada et al. 1993; Fujisawa et al. 1995; Mori et al. 2002). Most of these cysts are unilocular, but multilocular cysts have also been described (Cureton and Newcombe 1961). Solitary cysts are located within the gallbladder wall, are attached to the outside of the gallbladder (e.g., the fundus), or protrude into the gallbladder lumen. Histologically, the cysts are lined by a single layer of non-ciliated columnar epithelium of the biliary type. The cyst epithelium can undergo dysplastic changes and development of carcinoma in situ (Sworn and Gay 1975). Extensive congenital cystic changes can exceptionally result in giant congenital cystic malformation of the gallbladder (Lobe et al. 1986).

Ciliated Foregut Cyst of the Gallbladder

Introduction

Ciliated foregut cysts form a minority of epithelial gallbladder cysts. These cysts are either an incidental finding in abdominal ultrasound examinations or may produce a mass effect in the right upper abdominal compartment, without acute inflammatory signs (Raeburn 1969; Kakitsubata et al. 1995; Nam et al. 2000; Hirono et al. 2002; Muraoka et al. 2003; Koletsa et al. 2005; Bulut and Karayalçin 2010).

Pathology

Macroscopically, ciliated foregut cysts are thin-walled cysts with a fibrous wall and glistening inner surface, the lumen containing a clear or slightly blurry but viscous fluid. The cysts can protrude into the gallbladder lumen (Kakitsubata et al. 1995; Muraoka et al. 2003), but most cysts are in fact located to the level of the submucosa. A communication to the gallbladder lumen is usually lacking, with few exceptions (Koletsa et al. 2005). Histologically, a fibrous wall is lined by a pseudostratified columnar ciliated epithelium with interspersed goblet cells (magenta stained in the PAS stain), sometimes with an underlying layer of smooth muscle cells.

Differential Diagnosis

As in the liver, old and secondarily altered ciliated foregut cysts can show loss of differentiated ciliated cells, the lining being replaced by a simple biliary-type cuboidal epithelium. Such lesions may look like any epithelial cyst, not otherwise specified. The presence of smooth muscle cells in the cyst wall favors a diagnosis of ciliated foregut cyst, even in the absence of ciliated cells.

Pseudoepidermoid Cyst

The gallbladder mucosa is known to undergo squamous metaplasia, which rarely results in the formation of pseudoepidermoid cysts clinically mimicking a gallbladder tumor (Teo et al. 2005).

Duplication Cyst

Congenital duplication of the gallbladder, caused by doubling of the gallbladder anlage, can give rise to cyst lined by the same type of epithelium as the gallbladder partner itself (Kothari et al. 2005).

Bronchogenic Cyst of the Gallbladder

Bronchogenic cysts are cystic lesions derived from ontogenically misplaced bronchial anlages and are characterized by an epithelial lining of ciliated respiratory epithelium with or without associated other bronchial wall components. Bronchogenic cysts prevail in the intrathoracic compartment but may also occur intra-abdominally. Rare examples have been observed in the gallbladder (Kim et al. 2004).

Apart from bronchogenic cyst developing in the gallbladder, such lesions also emerge at the inferior surface of the liver, next to the gallbladder, mimicking a cystic gallbladder tumor (Kim et al. 2004). There are several reports on subdiaphragmatic bronchogenic cysts (reviewed in Kim et al. 2004).

Retention Cyst of the Gallbladder

Marked stenosis or obstruction of the gallbladder causes dilatation of the organ (hydrops), sometimes with accumulation of mucin-rich fluid (mucocele). These mechanisms can give rise to acquired epithelium-lined cysts or retention cysts (Yamada et al. 1996).

Acquired Honeycomb Gallbladder

Honeycomb gallbladder is an acquired, rare form of pseudo-multiseptate gallbladder associated with chronic calculous cholecystitis. Ultrasonography shows a hyperechoic collection with acoustic shadowing on the inferior surface of the liver. Macroscopically, multiple septum-like structures arise from the gallbladder wall and bridge the lumen from side to side, resulting in a honeycomb pattern caused by inflammatory interfold adhesions and synechia (Sasaki et al. 2004).

Congenital Cysts of the Cystic Duct

A deranged development of the cystic duct in the phase of its canalization can result in the formation of a congenital cystic dilatation of this duct, forming a large cyst, eventually containing calculi (cystic malformation of the cystic duct; Pracy 1949; Champetier et al. 1987; Serena Serradel et al. 1991). It has been proposed that cystic malformation of the cystic duct may be classified as type VI cyst in Todani's classification of biliary tract cysts (Maheshwari 2012).

Mesothelial Cyst of the Gallbladder

Apart from gallbladder cysts with either a simple or a ciliated epithelium, few cysts have a mesothelial lining and are termed mesothelial gallbladder cyst (Hoffman et al. 1989).

Differential Diagnosis

Solitary gallbladder cysts may mimic hydrops of the gallbladder (Ghosh and Meyers 1990; Panico et al. 2011), mucocele (Escobar and Neel 2011), true gallbladder diverticulum, diaphragm of the gallbladder (St-Vil et al. 1992), or hydatid disease (Krasniqi et al. 2010). Solitary cysts have also to be distinguished from ciliated foregut cysts of the gallbladder (Kakitsubata et al. 1995) and from carcinomas undergoing marked cystic change (Hiraki et al. 2010). Multilocular epithelial cysts must be distinguished from other multicystic lesions, including echinococcosis, cystadenoma, and cystic lymphangioma. Cysts located in the vicinity of the gallbladder may radiologically be confounded with gallbladder cysts or with the gallbladder itself, e.g., omental cysts (Giyanani et al. 1986).

Tumor-Like Infections and Infestations of the Gallbladder (Infectious and Parasitic Pseudotumors)

161

Contents

Abstract

Similar to liver and bile ducts, the gallbladder can be subject to several types of tumor-like infections and infestations. The gallbladder is a well-known site of actinomycosis. Gallbladder actinomycosis presents with the clinical picture of acute or subacute calculous cholecystitis. The inflammation is an aggressive process and can extend into the gallbladder fossa and from there to the liver substance. Tuberculosis can involve the gallbladder, but is one of the rarest forms of abdominal tuberculosis. It can present as an ulcerating cholecystitis or a tumor-like granulomatous process mimicking cancer. Other bacterial infections of the gallbladder with mass lesions comprise brucellosis and several types of mycosis. The gallbladder is sometimes involved in hydatid disease and other parasitoses.

Actinomycosis of the Gallbladder

Introduction

Actinomycosis is an important infectious disease of the hepatobiliary tract, discussed in a separate chapter. However, the gallbladder is the least common anatomical site of hepatobiliary actinomycosis, with only few single cases having been reported. Gallbladder actinomycosis can cause extensive destruction of the organ and is

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_161

associated with an invasive process that may closely mimic gallbladder malignancy.

Microbiology

The microbiological features of *Actinomyces* (*A.*) are discussed in detail elsewhere. In gallbladder actinomycosis, *A. israelii* and *A. naeslundii* have been identified as causative agents.

Clinical Features

Gallbladder actinomycosis usually presents with the symptoms and signs of acute or subacute calculous cholecystitis, with abruptly starting upper quadrant abdominal pain and fever (Coleman et al. 1969; Marrie et al. 1977; Smithers et al. 1983; Freland et al. 1987; van Steensel and Kwan 1988; Gerich et al. 1990; Mutter et al. 1993; Acevedo et al. 2008; Lee et al. 2009). Sonography showed a thickened and edematous gallbladder wall, as in other forms of acute cholecystitis (Hefny et al. 2005). The inflammatory process may extend into the gallbladder fossa and from there to the liver, causing liver abscess (Brewer and Allen 1980). Due to the tissue-destructive feature of the infection, fistulas between the gallbladder and common bile duct, duodenum, or stomach may develop (Bledsoe et al. 2008). Clinically and radiologically, gallbladder actinomycosis can mimic gallbladder malignancy (Lee et al. 2007), but gallbladder actinomycosis has also been observed in association with gallbladder adenocarcinoma (Merle-Melet et al. 1995; El Amine et al. 2013). Actinomycosis can also develop in the cholecystic duct remnant following cholecystectomy (Ormsby et al. 1998).

Pathology

Macroscopy

In gallbladder actinomycosis, the serosa is hyperemic and sometimes coarsely granular due to the presence of actinomycotic colonies, the so-called sulfur granules. This phenomenon is caused by the destructive growth of the infectious process, invading the gallbladder wall in a cancer-like manner to reach the serosal surface. The gallbladder wall itself is thickened and edematous or hemorrhagic, with foci of purulent exudate. Extension to the serosa can cause fistulation, with escape of purulent bile onto the serosal surface.

Histopathology

Histomorphology is dominated by a severe suppurative and later granulating inflammation, often with destruction of the preexisting layers of the gallbladder wall and extension into adjacent tissues. Microabscesses may be seen (Hefny et al. 2005). In the purulent exudate, typical microbial drusen forming sulfur granules are present (Lee et al. 2009); for more details, see the respective chapter on liver actinomycosis. These bacterial colonies are composed of Gram-positive, filamentous organisms.

Differential Diagnosis

Radiologically, retroperitoneal actinomycosis, e.g., associated with dropped gallstones (Ramia et al. 2004), can mimic the destructive process characterizing gallbladder actinomycosis.

Tuberculosis of the Gallbladder

Introduction

Abdominal tuberculosis is one of the most common forms of extrapulmonary tuberculosis, with a prevalence in developing countries as high as 12 %. Abdominal localizations of the infection increase in number during the last years, mainly due to acquired immunodeficiency, intravenous drug abuse, and the emergence of virulent mycobacterial strains with multiresistance. Among

abdominal manifestations of tuberculosis, tuberculosis of the gallbladder (cholecystitis tuberculosa) is one of the rarest forms but is still diagnosed in endemic areas. It was estimated that gallbladder tuberculosis accounts for about 1 % of all cases of abdominal tuberculosis (Goyal et al. 1998). The rarity of gallbladder tuberculosis, in comparison with the much more common tuberculosis of the liver, has been proposed to be due to a protective effect of bile against mycobacterial infection.

Epidemiology

Gaucher is said to be the first to have reported gallbladder tuberculosis in 1870 (cited in Lazarus and Eisenberg 1934). Gaucher's patient had, at necropsy, pulmonary tuberculosis and tuberculous involvement of several inner organs, including the liver. The gallbladder showed a hazelnut-sized tuberculous mass.

The first histologically proven case of gallbladder tuberculosis was, however, only reported in 1894 (Heddaeus 1894). This author described a 44-year-old female who presented with a fistulating tumor in the right upper abdomen. The fistula was surgically explored and revealed a connection with the gallbladder which contained caseous necroses. In 1908, Simmonds summarized five cases observed to this time point (Braquehaye 1901; Kisch 1902; Beitzke 1905; Knotte 1907), and reported his own case, a 9-month-old child suffering from miliary tuberculosis and showing miliary foci in the gallbladder mucosa (Simmonds 1908). The 41-year-old female patient described by Braquehaye (1901) is probably the first case of isolated gallbladder tuberculosis. The patient had no evidence of other sites of tuberculosis and was healed following cholecystectomy alone. In the patient of Kisch (1902), a 57-year-old female patient, gallbladder tuberculosis was associated with nodular hepatic tuberculosis and generalized organ tuberculosis and had led to a cholecystocolonic fistula. Several other cases were reported in the first 20 years of the twentieth century, only in part with histologic confirmation (Calabrée 1910). A first extensive compilation of cases appeared in a thesis as of 1922 (Altmeyer 1922). In 1955, 36 proven cases of gallbladder tuberculosis have been compiled, together with a series of questionable cases (Weitz 1955).

Whereas gallbladder tuberculosis is very rarely seen in western countries, studies from southern, southeast, and east Asia document that this disorder is more common in these regions, mainly in patients with abdominal tuberculosis. In a study from India covering the time period between 1996 and 2010, seven out of 209 patients who had undergone biliary tract surgery with a preoperative diagnosis of gallbladder carcinoma or carcinoma of the common bile duct in fact had biliary tract tuberculosis (Govindasamy et al. 2011). Gallbladder tuberculosis develops most often in women over 30 years of age (Duan et al. 1992; Abu-Zidan and Zayat 1999). In the majority of cases, it develops in the setting of abdominal tuberculosis, but rare cases of isolated gallbladder tuberculosis are also known (Lazarus and Eisenberg 1934; Piper et al. 1987; Gupta et al. 1998; Ruhl et al. 2003). The presence of gallstones is detected in more than 90 % of cases of gallbladder tuberculosis, cholelithiasis therefore considered as a condition favoring tuberculous infection of the gallbladder (Bergdahl and Boquist 1972; Ziarek et al. 1975). Rarely, gallbladder tuberculosis has also been diagnosed in patients with pulmonary tuberculosis (Rozmanic et al. 2001) and has been observed in a gallbladder affected by biliary papillomatosis (Nakajo et al. 1988).

Clinical and Imaging Features

The clinical and imaging features of gallbladder tuberculosis have been described in numerous reports, mostly on the basis of single cases. Simmonds (1908) divided gallbladder tuberculosis into two forms: (a) acute gallbladder tuberculosis, characterized by multiple mucosal

ulcerations containing acid-fast bacilli and/or miliary tubercles/granulomas, and (b) chronic granulomatous cholecystitis. Leader (1952) proposed to distinguish a diffuse or miliary form from a local form, the latter being subdivided into a focal or nodular form, consisting of single or multiple conglomerate tubercles forming tumor-like tuberculomas, and a tubular form, also involving the intrahepatic bile ducts. Weitz (1955) proposed four clinical groups of gallbladder tuberculosis, i.e., (a) acute or subacute miliary tuberculosis in children having ulcerated tubercles of the gallbladder mucosa; (b) gallbladder tuberculosis in patients with severe generalized tuberculosis, often with extensive pulmonary phthisis, tubercles in mediastinal and mesenterial lymph nodes, splenic tuberculosis, tuberculous lesions in the intestinal tract and liver, and terminal miliary spread with leptomeningitis; (c) isolated gallbladder tuberculosis; and (d) other or miscellaneous forms. Another clinical classification with four forms distinguishes (a) involvement of the gallbladder as a component of miliary tuberculosis in children and adults, (b) gallbladder tuberculosis as a component of disseminated abdominal tuberculosis, (c) isolated gallbladder tuberculosis in the absence of tuberculous disease elsewhere, and (d) involvement of the gallbladder in the setting of immunosuppression.

Clinically, gallbladder tuberculosis may present with a right hypochondrial mass, jaundice, findings suggestive of gallbladder empyema, and low-grade fever/fever of unknown origin. In 70–90 % of cases, gallbladder tuberculosis was associated with the presence of gallstones (Bergdahl and Boquist 1972; Ziarek et al. 1975; Rouas et al. 2003). Gallbladder tuberculosis may present as acute abdomen caused by gallbladder perforation (Hahn et al. 1995), and tuberculosis of the gallbladder neck may be a cause of cholecystitis. In the course of imaging studies, the preoperative diagnosis is often confused with various other gallbladder diseases (Ramia et al. 2006). Sonographic and CT studies revealed several typical patterns of tuberculous gallbladder disease, including micronodular lesions of the gallbladder wall, diffuse or circumscribed wall thickening, and a tumor-like gallbladder mass (Ben et al. 1995; Jain et al. 1995; Abu-Zidan and Zayat 1999; Xu et al. 2011).

Pathology

Macroscopy

Cholecystectomy specimens in gallbladder tuberculosis show a markedly thickened wall, mainly of the fundus. The serosal surface may show adhesions and sometimes tiny white to gray nodules representing caseating granulomas (miliary lesions). Cut surfaces of the gallbladder wall show small to large caseiform necrosis of ovoid to highly irregular shape. Typically, and in contrast to pyogenic abscesses, these necroses are cream-white instead of dark-yellow, have the consistency of a thick and viscous fluid, and stick to the knife and to the gloves. In rare cases, tuberculous necrosis is not whitish in color but shows a

quince-yellow tinge. In cases with extensive gallbladder destruction, theses caseating masses may fill the gallbladder lumen or may protrude through transmural defects of the gallbladder wall. In long-standing disease, the necrosis becomes compact and putty-like, with or without calcifications. Large and in particular conglomerated lesions may resemble a necrotic malignancy of the gallbladder.

Histopathology

The histology of the lesions is that of a granulomatous inflammation with caseating necrosis and the presence of Langhans giant cells, as in other forms of tuberculosis. Tuberculosis can cause transmural destruction of the gallbladder wall, with extension to the peritoneal surface (Peritonitis tuberculosa), invasion of the gallbladder fossa, and gallbladder perforation with development of bilomas (Hahn et al. 1995). In acute forms of gallbladder tuberculosis, mucosal ulcerations with a necrotic center develop, these lesions containing numerous acid-fast bacilli and representing an anergic reaction. Gallbladder tuberculosis is sometimes associated with tuberculous lesions of the liver, including miliary hepatic tuberculosis (Mirski and Zielinski 1972). The tuberculous infection can involve tissues in the draining area of the gallbladder, including lymph vessels and perilymphangial tissues. Following cholecystectomy, the tuberculous inflammation may continue from these remaining tissue compartments, eventually giving rise to postoperative fistulas (Gupta et al. 1998).

Tuberculosis of Lymph Nodes Associated with Gallbladder

As in other organs, tuberculosis of the gallbladder undergoes lymphogenous spread to locoregional lymph nodes, sometimes forming a primary complex. Lymph nodes that are typically involved comprise the cystic node, lymph nodes of the hepatoduodenal ligament, and peripancreatic lymph nodes (Remmele and Lennert 1957; Vojtisek and Zrustova 1965). In case the cystic node is affected by tuberculosis, the gallbladder is almost always infected (Prasad and Pandey 2001). Tuberculosis detected in these lymph node systems is, however, not always associated with gallbladder tuberculosis. Rarely, isolated cystic duct tuberculosis was diagnosed (De Melo et al. 2004; Sidhu et al. 2007), and isolated peripancreatic tuberculous lymphadenitis was found as a rare manifestation of abdominal tuberculosis (Huang et al. 2013).

Gallbladder Tuberculosis as a Disorder Mimicking Gallbladder Malignancy

As gallbladder tuberculosis can form large necrotic mass lesions (tuberculomas), this specific inflammation may clinically and radiologically mimic malignant neoplasms of the gallbladder, specifically gallbladder carcinoma (Hegler 1925; Rankin and Massie 1926; Ben et al. 1995; Garg et al. 2001; Bikhchandani et al. 2005; Verma et al. 2012). Conglomerate tuberculous lesions with confluent caseating necrosis can replace the gallbladder, invade the gallbladder fossa, and may involve the liver substance. Such aggressive mass lesions are termed pseudotumoral gallbladder tuberculosis (Soufi et al. 2011).

Differential Diagnosis

The “classical” histological presentation of tuberculosis can hardly be confounded with other disease processes, except certain rare mycoses.

Pathways of Infection

It seems that gallbladder tuberculosis is often associated with abdominal extra-gallbladder tuberculosis (Xu et al. 2011), suggesting that the gallbladder is secondarily involved via so far not

well-known routes of microbial spread. It has been proposed that the gallbladder becomes involved by the contiguous spread of mycobacteriosis from adjacent infected lymph nodes and lymph vessels, the peritoneum, an enterohepatic route, or via a hematogenous route (review: Abu-Zidan and Zayat 1999). An interesting finding is the observation of gallstones in up to 90 % of patients with gallbladder tuberculosis, suggesting a pathogenic role of lithiasis in biliary tract tuberculosis (Bergdahl and Boquist 1972; Ziarek et al. 1975).

Brucellosis

Species of *Brucella*, in particular *Brucella melitensis*, can cause acute acalculous or calculous cholecystitis (Morris et al. 1979; Fasquelle et al. 1999; Miranda et al. 2001; Kanafani et al. 2005; Al-Otaibi 2010). Exceptionally, mass lesions ("brucellomas") caused by *Brucella* infection develop in the gallbladder. A female patient who had had febrile brucellosis developed, after a period of 19 years, right upper quadrant pain. CT examinations revealed a mass contiguous with the gallbladder and extending intrahepatically, suspicious of cancer. The resection specimen showed mass-forming granulomatous cholecystitis and PCR of tissue resulted in the diagnosis of *Brucella* infection (Ögredici et al. 2010).

Mycoses of the Gallbladder

Due to the induction of purulent inflammation and a granulomatous response, fungal infections of the gallbladder may rarely induce infectious pseudotumors. However, most fungal infections of the gallbladder are characterized by acute cholecystitis. Fungi that causes gallbladder disease include *Candida albicans*, *Candida lusitaniae*, *Candida famata*, *Candida tropicalis*, *Mucor*, and *Torulopsis glabrata* (Warren and Marsh 1982; Diebel et al. 1996; Santos et al. 2004; Yildirim et al. 2008; Lacarrière et al. 2011; Jajoo et al. 2012; Araujo et al. 2013). In the course of fungal septicemia, *Candida tropicalis* produced gallbladder masses (Jajoo et al. 2012). In the setting of gastrointestinal basidiobolomycosis (*Basidiobolus ranarum*), tumor-like lesions mimicking malignancy relatively often develop in liver and gallbladder (Vikram et al. 2012).

Echinococcosis of the Gallbladder

Introduction

Echinococcosis, which presents in two forms caused by two species, i.e., hydatid disease and alveolar echinococcosis, is endemic in certain regions of the world and is known to typically involve the hepatobiliary tract. However, and in contrast to the liver, gallbladder echinococcosis is a very rare disease, even in endemic areas. Secondary involvement of the gallbladder by echinococcosis of the liver is more frequent than bona fide primary gallbladder echinococcosis. The reason for the uncommon involvement of the gallbladder is currently unknown. Gallbladder involvement may result in tumor-like masses that are sometimes confounded with malignancy.

Hydatid Disease of the Gallbladder

Echinococcus granulosus/*hydatidosus* is the more common species to involve the gallbladder, several reports having described the clinicopathological features of this rare entity (Putnik and Ciric 1953; Ansimov 1962; Khrokhlov 1967; Greida 1973; Rigas et al. 1979; Bacciu et al. 1980; Raza et al. 2003; Safioleas et al. 2004; Pitiakoudis et al. 2006; Krasniqi et al. 2010). Among 183 patients with abdominal hydatid cysts, only 12 patients had only extrahepatic abdominal involvement (6.5 %), involvement of the gallbladder amounting to only 0.6 %, being as rare as adrenal echinococcosis (Wani et al. 2005). The gallbladder may secondarily be involved via expansion of bile duct hydatidosis into the gallbladder following rupture of hydatids (Yücesoy and Poçan 2014). Ultrasonographically, the cysts

typically produce an annular pattern with undulating membranes and signs of membrane detachment (Ivanis et al. 1994; Kapoor et al. 2000). The cystic parasite elicits a marked inflammatory and fibrosing reaction in the gallbladder wall, sometimes with acute cholecystitis or even gallbladder phlegmon (Makokha 1961; Mizaushev and Emuzov 1979), leading to an ill-defined cystic mass lesion that may mimic gallbladder malignancy (Soldevilla 1950). Gallbladder hydatid cysts may undergo suppuration associated with gallbladder empyema (Celoria et al. 1980).

Echinococcus alveolaris of the Gallbladder

Primary alveolar echinococcosis of the gallbladder is a very rare manifestation of this parasite (Pautov 1964).

Pathology

Macroscopy

Echinococcus hydatidosus/granulosus of the gallbladder manifests as a monocystic or multicystic parasite similar to other localizations, in particular the liver. The cyst walls are firm and fixed by connective tissue with adjacent wall components. The cysts usually grow extramucosally, but they can markedly narrow the gallbladder lumen, as they bulge into the gallbladder cavity. Upon opening of the cysts, a jelly-like material appears, containing whitish lamellae that form complex and sometimes concentric structures. Secondary daughter cysts and grape-like, milky-white collections of embryonal parasites forming coralliform colonies are often seen. In the wall of the cysts, patchy calcifications are often noted (Tkebuchava 1966; Krasniqi et al. 2010). Hydatid cysts of the gallbladder can sometimes undergo massive calcification, with calcium salt deposits involving entire cysts and the pericystic tissue, resulting in a gross presentation resembling porcelain gallbladder (Benedetti-Valentini 1954).

Histopathology

The histopathology of gallbladder echinococcosis is the same as that of other hepatobiliary manifestations of this parasite.

Differential Diagnosis

The most important differential diagnosis is echinococcosis of the liver encroaching upon, invading, or rupturing into the gallbladder (Ivanov 1957; Cangiotti et al. 1994; Abou-Khalil et al. 1996; Murtaza et al. 2008; Rabbani et al. 2011). Fistulous communications between hepatic hydatid cysts and the gallbladder are described (Kumar et al. 2004; Adaletli et al. 2005; Murtaza et al. 2008). Hepatic hydatid cysts may rupture into the gallbladder, with subsequent obstruction of the cystic duct by a daughter cyst acting as a ball valve and causing acalculous cholecystitis (Abou-Khalil et al. 1996). Bile sludge can radiologically mimic hydatid cyst membranes (Kara et al. 2010). Rupture of hepatic hydatid cysts into the biliary tract may elicit eosinophilic cholecystitis (Alfaro et al. 1995).

Pathogenic Pathways

Apart from the portal circulation, it has been suggested that echinococcus embryos can spread via other routes to the gallbladder, including the biliary tract (Cangiotti et al. 1994; Raza et al. 2003), the peritoneal cavitary pathway (Cangiotti et al. 1994), or the lymphatic system via lymphatic transport of oncospheres from the intestine to the gallbladder (Rigas et al. 1979; Safioleas et al. 2004). Based on the observation of hydatid cysts located inside the gallbladder, two groups proposed dissemination of embryos (brood capsules) through the biliary tract/cystic duct, but such a pathway has never been proven (Cangiotti et al. 1994; Raza et al. 2003; reviewed in Krasniqi et al. 2010).

Other Infestations of the Gallbladder

Schistosomiasis (bilharziosis) often involves the gallbladder in certain endemic areas, and deposition of eggs with schistosomulae causes granulomatous schistosomal cholecystitis (Rappaport et al. 1975, Sharara et al. 2001). The gallbladder can be infested by *Ascaris lumbricoides*, a nematode parasite that can ascend bile ducts and migrate through the cystic duct (review: Khanduri et al. 2014). A very rare parasitosis of the gallbladder is cysticerosis (Punia et al. 2010). Paragonimiasis, a common parasitosis of the lungs, exceptionally infests the hepatobiliary tract, including the gallbladder (Salinas et al. 1999).

Abstract

Adenocarcinoma of the cystic duct is a neoplasm that takes its origin from the mucosa of the cystic duct. The tumor is sometimes classified as a distinct subtype of gallbladder carcinoma. It is a rare malignancy which accounts to only 2–6 to 12.6 % of all extrahepatic bile duct malignancies. The neoplasm mainly occurs in male and in persons older than 60 years of age. Individuals with this tumor less commonly have gallstones in comparison with gallbladder cancer patients. For diagnosis, the tumor must be restricted to the cystic duct, with no evidence of a neoplastic process in gallbladder or other bile ducts. There are attempts to classify cystic duct carcinoma in regard to growth patterns and spread, including a hepatic hilum type and a cystic confluence type. There are other very rare primary neoplasms of the cystic duct, including neuroendocrine tumors and various types of mesenchymal neoplasms.

Carcinoma of the Cystic Duct

ICD-O code 8140/3

Introduction

Carcinoma of the cystic duct is an adenocarcinoma taking its origin from the mucosa of the cystic duct. It is a rare malignancy, for which preoperative diagnosis is often difficult (Hellner 1925; Farrar 1951). Some authors considered cystic duct carcinoma as a distinct subgroup of gallbladder carcinoma (Nakata et al. 2009).

Anatomy and Physiology of the Cystic Duct

The cystic duct connects the gallbladder with the extrahepatic bile ducts, and its point of insertion into the extrahepatic duct marks the division between the common hepatic duct and the common bile duct. Normally, the cystic duct measures 2–4 cm in length, with a diameter of 1–5 mm, and often shows a serpentine or tortuous course. In 49.9 % of cases, the cystic duct enters the extrahepatic duct from the right lateral aspect, in 18.4 % from the medial aspect and in 31.7 % from an anterior or posterior position. The cystic duct runs parallel to the extrahepatic duct and spirals around the duct. It has a parallel course relative to the extrahepatic bile duct in 10.6 % of patients and varies in length from 1.5 to 9.5 cm (mean, 3–4 cm). Of these parallel cystic ducts, 17 % have a spiral course (Turner and Fulcher 2001). Variants with a longer cystic duct and a lower insertion exist. The anatomy of the cystic duct is variable, with five main macroscopic variations (formation of a fibrous mesocysticum; long cystic duct with low entry into common hepatic duct; cystic duct joining the common hepatic duct on its left; accessory right hepatic duct, and absence of cystic duct, the gallbladder neck directly joining the common hepatic duct). Very rare variations include situations where the cystic opens directly into duodenum and where the cystic duct is absent due to the two hepatic ducts directly entering the gallbladder (Flint 1923; McGregor 1950; Toufeeq 1953). The cystic duct is fed by the cystic artery, which has many possible origins, with the right hepatic artery being the most common (Hugh et al. 1992; Chen et al. 2000; Balija et al. 2001; Mlakar et al. 2003). The topographic relationships between the cystic artery and the cystic duct have been analyzed in detail, with the formulation of distinct group patterns (Ding et al. 2007). Group I or the Calot's triangle type consists of cases with a classical single cystic artery originating from the right hepatic artery within Calot's triangle and of double cystic artery, with a single cystic artery from the right hepatic artery dividing into anterior and posterior branches. In Group II, the cystic artery approaches the gallbladder outside Calot's triangle, with four subgroups: (a) cystic artery originating from the gastroduodenal artery, (b) cystic artery originating from the variant right hepatic artery, (c) cystic artery originating directly from the liver parenchyma, and (d) cystic artery originating from the left hepatic artery. Group III is the compound cystic artery type according to Ding

et al. (2007). This group includes cases where a single cystic artery is accompanied by several types of additional arteries approaching the cystic duct and cases with multiple cystic arteries.

The cystic duct is a complex conduit that allows low-viscosity hepatic bile to enter the gallbladder under low pressure and the expulsion of a more viscous gallbladder bile. It was assumed that the spiral valve of Heister has the central role in these mechanisms, but there are novel findings illustrating that this view has to be revised. The spiral mucosal folds or valves of Heister have first been described in 1732, and the role of these folds remains somewhat obscure (Mentzer 1926; Dasgupta and Stringer 2005). The spiral folds contain muscle cells responsive to neural and hormonal stimuli and considered to play a role in bile transport (Dasgupta and Stringer 2005). Based on cholangiographic 3D models of the inner geometry of the cystic duct, it was found that the most significant geometric parameter affecting resistance was the baffle clearance (lumen size), followed by the number of baffles (the number of folds in the valve of Heister (Ooi et al. 2004). However, the term spiral valve may be misleading, as in over half of casts, spiraling was not the dominant feature of the cystic duct, and a "valve" implies active resistance of flow in one direction, while the internal baffles of the cystic duct serve to regulate bile flow in both directions (Bird et al. 2006). Hydrodynamically, the lumen of the cystic duct seems to serve as a passive resistor striving to provide a constant amount of resistance to control the flow of bile out of the gallbladder (Al-Atabi et al. 2012). In addition, modifications of the bile remaining in the gallbladder for a certain time and admixed with new bile entering the gallbladder alter bile rheology, thus affecting flow through the cystic conduit.

Definitions and Classifications

Diagnostic criteria for carcinoma restricted to the cystic duct have been worked out by Farrar (1951): the tumor must be restricted to the cystic duct; there must be no neoplastic process in the gallbladder, hepatic, or common bile ducts; and histologic examination must confirm the presence of carcinoma. The Farrar definition excludes advanced carcinoma originating from the cystic duct and only applies to tumors originating from the cystic duct and being limited to this part of the extrahepatic duct system (Nakata et al. 2009). As part of the cancers taking their origin in the cystic duct later extend into the gallbladder neck and/or the hepatic ducts, the Farrar definition has practical limitations. As an alternative definition, cystic duct carcinoma has been described as a gallbladder tumor, the center of which is located in the cystic duct (Ozden et al. 2003).

Table 1 Classifications of cystic duct carcinoma

Type I
Type II
Type III

[a]Types defined in the following paragraph

There are recent attempts to classify cystic duct carcinomas in regard to their locoregional spread (Table 1).

Cystic duct carcinomas extending into adjacent tissues and hence no longer fulfilling the Farrar criteria principally show two patterns of invasion: the hepatic hilum pattern (hepatic hilum type) and the confluence invasive pattern (cystic confluence type). In the first pattern, carcinoma invades structures in or around the hepatic hilum, whereas the second pattern is characterized by extension of tumor into the common hepatic duct and the confluence region (Kubota et al. 2008; Yokoyama et al. 2008). Dividing cystic duct carcinoma with extraductal extension into these two types has clinical and biological implications. Perineural and vascular invasion were more common in the hepatic hilum type, which more often occurred in female patients and was associated with a poorer prognosis than that of the cystic confluence type, the later occurring more frequently in males (Yokoyama et al. 2008). Kim and coworkers (2007) defined three types of cystic duct

carcinoma, based on the extent of infiltration. Type I is characterized by a carcinoma confined within the cystic duct (the original Farrar-type carcinoma); in Type II, carcinoma having its center located in the cystic duct extends to the gallbladder neck and infundibulum or bile duct of the cystic duct side, without obstructive jaundice; in Type III, carcinoma with its center in the cystic duct extends up to the gallbladder body or bile duct on the contralateral side of the cystic duct opening, causing obstructive jaundice.

Epidemiology

Carcinoma of the cystic duct is the least common carcinoma of the extrahepatic biliary tract. It amounts to only 2.6–12.6 % of all extrahepatic bile duct malignancies (Glenn and Hill 1955; Nakata et al. 2009). The tumor usually strikes elderly men, and many patients were more than 60 years old at diagnosis. In a review of Western and Japanese cases, mean age at presentation was 62 years, with a male to female ratio of 3.5:1 (Chijiiwa and Torisu 1993). Patients with this form of cancer have a much lower rate of accompanying gallstones than gallbladder carcinoma patients. Few cases were diagnosed in the setting of pancreaticobiliary maljunction (Kawarada and Das 2001; Sato et al. 2001). Rarely, carcinoma of the cystic duct has been found in the setting of hepatobiliary fluke disease, e.g., opisthorchiasis (Chainuvati et al. 1976), or in association with xanthogranulomatous cholecystitis (Abue et al. 2011). Cystic duct carcinoma rarely occurs in conjunction with gallbladder carcinoma (Itoh et al. 2008).

Clinical and Imaging Features

The clinical features of carcinoma of the cystic duct are usually nonspecific and consist of right upper abdominal discomfort or pain, sometimes colicky, and a palpable right hypochondrial mass, which may either be due to the tumor itself or due to enlargement of the gallbladder. In a review of 23 published cases, 81 % presented with right upper quadrant abdominal pain, 41 % with abdominal mass, and a minority with other symptoms and signs (Baraka et al. 1990). Few patients presented with acute cholecystitis (Chan et al. 2005). Part of the cases were identified incidentally, e.g., in the course of abdominal examinations due to the suspicion for other disease. The massive stenosis or obstruction of the cystic duct caused by the tumor can lead to gallbladder hydrops (Pack and Teng 1968), eventually perforation of the gallbladder (Parker 1965) and induction of limy bile (Takahashi et al. 2007). Hydrops in the presence of cystic duct carcinoma was misinterpreted as gallbladder empyema (Rivkind et al. 1989). In some patients, the tumor had mimicked Mirizzi syndrome (John et al. 1982; Walker and Kanzer 1982). In few cases, the carcinoma infiltrated the region of the extrahepatic duct confluence and thus caused stenosis and obstructive jaundice (De Waele et al. 1984; Baraka et al. 1990; Radin et al. 1990; Holzinger et al. 1998; Nemoto et al. 2003). Obstructive jaundice was mainly detected in patients with extended tumor disease, i.e., with tumors not fulfilling Farrar's criteria for restricted cystic duct carcinoma. In a group of 15 patients, among whom 13 had cancer that did not fit Farrar's criteria, 67 % had jaundice (Nakata et al. 2009).

Selected References (Hellner 1925; Farrar 1951; Irons 1955; Rabinovitch et al. 1960; Smith et al. 1962, 1967; Vaittinen 1972; Geoffroy and Maffioli 1975; Nishimura et al. 1975; Manabe and Sugie 1978; Kogire et al. 1985; Radin et al. 1990; Galler et al. 1991; Napolitano and Morgana 1992; Nari et al. 2001; Kim et al. 2007; Yokoyama et al. 2008; Kiu et al. 2009; Aoki and Nara 2010).

Abdominal ultrasound often shows a distended gallbladder or swelling of the gallbladder, mostly without stones (Kubota et al. 2008). Less commonly, atrophy of the gallbladder was noted. Endoscopic ultrasonography reveals a stenosing and infiltrative tumor which extends into the gallbladder, the extrahepatic bile ducts, or both (Shiba et al. 2011). ERCP reveals a stenosis or block at the level of the cystic duct, sometimes associated

with dilated bile ducts (Borghese et al. 1999; Takahashi et al. 2007). Transhepatic cholangiography revealed a curvilinear compression along the lateral aspect of the common hepatic duct, a picture similar to that found in Mirizzi syndrome (Baraka et al. 1990). The mass replacing the cystic duct and the gallbladder neck is visualized by means of CT and MRCP (Furukawa et al. 1999; Abe et al. 2003).

Pathology

Macroscopy

In most cases, cystic duct carcinomas are firm masses of whitish color that obstruct the duct or, due to markedly invasive growth, efface the duct (Abe et al. 2003). In cases fulfilling the Farrar criteria for restricted cystic duct cancer, the tumors are nodular lesions without infiltration of adjacent tissues. Cystic duct carcinoma can protrude into the common bile duct through the orifice of the cystic duct (Shibata and Toyoda 1995), sometimes forming an intraductal tumor thrombus (Aoki and Nara 2010). The gross description of cystic duct cancer based on resection specimens is sometimes not an easy task, specifically in cases with extension of disease into the junctional area or to the hepatic hilum or in situations where anatomic variations of the duct are present (see above).

Histopathology

The majority of cases with documented histology showed moderately to well-differentiated adenocarcinoma with variable desmoplasia (Fig. 1; Yamaguchi et al. 1991; Ozden et al. 2003; Takahashi et al. 2007). A subset of carcinomas are mucin-producing lesions (Nemoto et al. 2003). Less commonly, exophytically growing tumors with a papillary phenotype were observed (Shibata and Toyoda 1995). There is a relationship between the two main histologic presentations of cystic duct carcinoma and the local extension mode. In cases restricted to the cystic duct (typical Farrar-type lesions), tubular and papillary adenocarcinomas prevail, while those neoplasms which extend

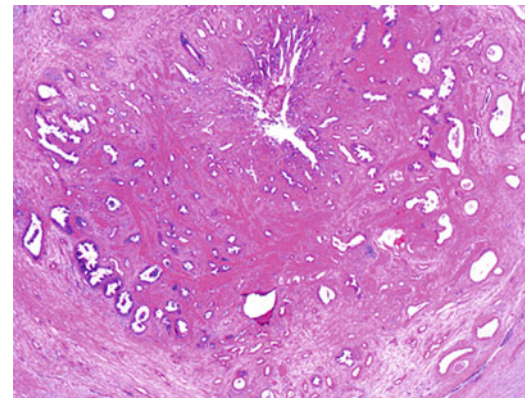

Fig. 1 Adenocarcinoma of the cystic duct. The lumen is severely stenosed by a concentrically growing tubular carcinoma with desmoplasia (hematoxylin and eosin stain)

beyond the cystic duct are chiefly composed of moderately to poorly differentiated adenocarcinoma (Kubota et al. 2008). Exceptionally, clear-cell adenocarcinoma was identified (Tajiri et al. 2006), a phenotype also occurring in other parts of the biliary tract, including the gallbladder. Similar to carcinomas of other parts of the extrahepatic biliary system, cystic duct carcinoma reveals a high rate of perineural invasion. The tumor can also spread superficially to the gallbladder (Sasaki et al. 2011). A sarcoid granulomatous reaction in lymph nodes has been found in a patient with cystic duct carcinoma, similar to granulomatous reactions identified in patients with other adenocarcinomas (Klein et al. 1994).

Precursor Lesions

Carcinoma in situ and dysplastic epithelial changes were rarely observed in the cystic duct (Gilloteaux and Combetta 2005). Typical cholecystocytes were associated with pleomorphic cells of poor differentiation and cells ultrastructurally containing modified mucus vesicles with heterogeneous fatty deposits. Development of carcinoma from papilloma or papillomatosis of the cystic duct has been reported (Lombard et al. 1967; Kosemehmetoglu et al. 2011). In one patient, papillary adenocarcinoma was found to have arisen within a pedunculated cystic duct polyp (Lebovics et al. 1993).

Rare Other Carcinomas of the Cystic Duct

Very few other apparently primary malignancies of the cystic duct have been described. In contrast to the gallbladder (see below), very few published cases of small-cell carcinoma primary to the cystic duct are known (Sonoda et al. 2003). The clinical presentation may be complex, as cystic duct malignancies tend to involve the hepatic ducts or the common bile duct and hence cause signs related to these structures. In a male patient presenting with pain and jaundice, imaging showed a small nodule in the cystic duct invading the common bile duct, with dilatation of the proximal biliary system (Sonoda et al. 2003).

Differential Diagnosis

Carcinomas arising in the distal part of the gallbladder or the gallbladder neck may be confounded with cystic duct carcinoma. A considerable proportion of gallbladder carcinomas show cancer spread to the cystic duct. Among 42 patients operated for advanced gallbladder carcinoma, 31 % revealed cancer spread to the cystic duct (Nakata et al. 2007).

Staging

Staging of cystic duct cancer is performed as for gallbladder carcinoma. About half of patients revealed advanced stage disease at the time point of diagnosis. In a series of 31 cases, stage at presentation was T2 in 3, T3 in 12, and T4 in 16 patients, and 42 % of patients had lymph node metastases (Ozden et al. 2003).

Biology of Disease

In comparison with gallbladder cancer and carcinomas of other parts of the extrahepatic biliary tract, carcinoma restricted to the cystic duct has an outcome that is superior to that of other cancer locations (Benchellal et al. 2008; Berretta et al. 2010). In particular, patients with early-stage disease and undergoing complete resection may show a favorable course (Yamaguchi et al. 1991). Patients who present with higher stage at diagnosis have a poorer outcome. In a study of 31 patients, of whom 16 had stage T4 tumor disease, actuarial 5-year survival rate excluding hospital deaths was 22 % (Ozden et al. 2003). Similar to gallbladder cancer, carcinoma of the cystic duct may show early local recurrence or, in some patients, follow an aggressive course, sometimes with systemic spread (Redmond and Majeranowski 1954; Holzinger et al. 1998). Locoregional lymph nodes are found in a fraction of patients. In one study, five of eight patients displayed lymph node metastases along the hepatoduodenal ligament (Chan et al. 2005), and a second investigation found lymph node metastases in 42 % (Ozden et al. 2003).

Benign Epithelial Neoplasms of the Cystic Duct

Introduction

Very few examples of benign primary epithelial tumors of the cystic duct are known from the literature. These lesions are homologous to those found in other parts of the hepatobiliary tract.

Bile Duct Adenoma of the Cystic Duct

Bile duct adenoma (biliary adenoma) of the cystic duct is a very uncommon neoplasm that is very similar, if nor identical, to biliary adenomas situated elsewhere in the bile duct system (Yopp et al. 2008). Adenomas of the cystic duct can cause duct obstruction or, very rarely, Mirizzi syndrome (Kunisaki et al. 2005). Macroscopically, these adenomas are usually small and well-circumscribed nodular lesions. Histologically, they are characterized by densely packed tubular profiles composed of bland-looking bile duct epithelial cells, but variants with dysplastic changes have also been found (Satoh et al. 1999).

Papillary Adenoma of the Cystic Duct

Papillary adenoma of the cystic duct is a very rare benign neoplasm that shares morphologic features with its counterpart in the large extrahepatic bile ducts and the gallbladder (Loh et al. 1994; Ho and Lee 2006). Due to its exophytic growth, papillary adenoma can cause duct obstruction followed by biliary colic (Loh et al. 1994).

Pyloric Gland Adenoma of the Cystic Duct

Pyloric gland adenoma of the cystic duct, histologically characterized by closely packed pyloric-type glands lined by mucus-secreting cells, has been observed in a 62-year-old male patients who presented with a 2 cm-sized protruding tumor of the cystic duct (Schaefer et al. 2012).

Neuroendocrine Tumors of the Cystic Duct

Introduction

In contrast to the remaining parts of the biliary tract, only very few cases of neuroendocrine neoplasms primary to the cystic duct have been reported in the literature. For the current classification of neuroendocrine tumors, see the other chapters treating these neoplasms. Cystic duct neuroendocrine tumors included somatostatinoma (Goodman et al. 1984), carcinoid tumor (Nicolescu and Popescu 1986; Chittal and Ra 1989; Rugge et al. 1992; Shah et al. 1998; Hermina et al. 1999), and well-differentiated neuroendocrine carcinoma (Felekouras et al. 2009).

Clinical Features

Cystic duct neuroendocrine tumors may be asymptomatic (Aronsky et al. 1999; Stavridi et al. 2007; Ioannidis et al. 2012), but neoplasms growing to a certain size may cause duct obstruction followed by a painfully distended gallbladder (Goodman et al. 1984) or colicky pain crises (Rugge et al. 1992).

Biology of Disease

Most of the few cases reported showed a benign course of the disease, but metastasis in the cystic node was found in one patient (Hermina et al. 1999). In one patient, a 60-year-old female, a malignant variant in the form of a well-differentiated neuroendocrine carcinoma was observed (Felekouras et al. 2009).

Pathology

Macroscopy

As in other locations, neuroendocrine tumors of the cystic duct are well-circumscribed, firm roundish nodular tumors of a yellow to tan color. Most lesions are small and do not exceed 1 cm in diameter, while malignant variants may grow to larger size (Felekouras et al. 2009).

Histopathology

Similar to other locations in the biliary tract, neuroendocrine tumors of the cystic duct are composed of medium-sized cells with an eosinophilic and slightly granular cytoplasm and finely stippled nuclei ("slat-and-pepper" pattern). The tumor cells were reported to be argentaffin (Goodman et al. 1984). The cells arranged in the form of nests and solid structures, with intervening thin-walled vascular channels.

Electron Microscopy

In one case of somatostatinoma of the cystic duct, the tumor cells contained relatively few dense granules (Rugge et al. 1992), measuring 135–475 nm in a case of somatostatinoma (Goodman et al. 1984).

Immunohistochemistry

The neoplasms express neuroendocrine lineage markers (chromogranin A, synaptophysin, neuron-specific enolase; Rugge et al. 1992) and, in case of specific differentiations, certain hormones (Goodman et al. 1984).

Lymphomas of the Cystic Duct

Very few examples of malignant non-Hodgkin's lymphomas (NHL) apparently primary to the cystic duct have been described. The NHL histologically included extranodal follicular lymphoma (Ferluga et al. 2003) and diffuse large B-cell lymphoma, anaplastic variant (Jho et al. 2007). In other patients, the cystic duct was involved in the setting of NHL affecting other organs and tissues, e.g., histiocytic lymphoma (Tartar and Balfe 1990). In one patient, Hodgkin's lymphoma of the cystic duct node was found as a cause of non-visualization of the gallbladder (Wee et al. 1970).

Granular Cell Tumor of the Cystic Duct

Introduction

Granular cell tumor (GCT; granular cell schwannoma; formerly termed granular cell myoblastoma or Abrikossoff's tumor) is an uncommon benign neoplasm of unknown histogenesis, morphologically characterized by solid growth of large cells with a strikingly granular cytoplasm. Apart from skin, oral cavity, and soft tissues, the biliary tract is one of the more common localizations, but GCT of the cystic duct is a very unusual tumor that almost exclusively occurred in women (Fialho and Hilario 1952; Serpe et al. 1960; Goldman et al. 1967; Mackay et al. 1968; Christensen and Ishak 1970; Abt et al. 1971; LiVolsi et al. 1973; Reul et al. 1975; Barber 1984; Yamashina and Stemmermann 1984; Hobbiss et al. 1987; Timberlake and Tachovsky 1988; Ferri Romero et al. 1994, Karakozis et al. 2000). In a review of 15 patients, 14 were female and 1 was male, with an age range at presentation of 15–61 years (Savage and Devitt 1977).

Clinical Features

Symptomatic GCT of the cystic duct has only been reported as a rare finding, mostly presenting as nonspecific right upper quadrant pain or epigastric pain (Fialho and Hilario 1952; Serpe et al. 1960; Goldman et al. 1967; Mackay et al. 1968; Christensen and Ishak 1970; Abt et al. 1971; LiVolsi et al. 1973; Reul et al. 1975; Ferri Romero et al. 1994). The tumor can induce recurrent biliary colic and cholecystitis (Barber 1984; Karakozis et al. 2000), and cystic duct stenosis can result in gallbladder mucocele (Yamashina and Stemmermann 1984).

Pathology

Macroscopy

The tumors are small and roundish, often yellow to tan, and rather well-circumscribed lesions, but ill-defined and seemingly invasive forms are also encountered. In case of cystic duct stenosis caused by the tumor, the gallbladder may be dilated and show a thickened wall due to chronic cholecystitis. Hydrops or mucocele may be present (Reul et al. 1975; Yamashina and Stemmermann 1984).

Histopathology

GCT consists of a proliferation of large polygonal or elongated cells with markedly granular and eosinophilic cytoplasm and often centrally placed, small, round, and dark nuclei. The cytoplasmic granules are strongly positive with the PAS reaction. The tumor cells are embedded within a loose fibrous stroma rich in mucopolysaccharides and sometimes

encircle prominent nerve fibers or are even located within nerves.

Immunohistochemistry

GCT are immunoreactive for S100 protein, alpha-inhibin, and calretinin (Murakata and Ishak 2001; Fine and Li 2003).

Differential Diagnosis

GCT also occurred above the junction of the cystic duct and the common hepatic duct and can infiltrate the cystic duct (Bilanovic et al. 2008). Due to granular and eosinophilic cytoplasm, GCT may be confounded with other neoplasms having these features, such as neuroendocrine neoplasms and paragangliomas. GCT are consistently negative for neuroendocrine markers.

Metastatic Disease and Cancer Invasion of the Cystic Duct

Introduction

A variety of malignancies can metastasize to the biliary tract and the gallbladder and rarely also to the cystic duct. Metastases to the gallbladder are dominated by renal cell carcinoma, malignant melanoma, hepatocellular carcinoma, and breast cancer, and similar preferences have been noted for the cystic duct. Reported cystic duct metastases included breast cancer (Andry et al. 1986), malignant melanoma (O'Connell et al. 1984), rectal carcinoma (Wakahara et al. 2011), and hepatocellular carcinoma (Clark and Schulz 1947).

Clinical Features

As with other tumors located to the cystic duct, metastases can lead to duct stenosis or obstruction followed by acalculous cholecystitis or biliary colic (Andry et al. 1986).

Differential Diagnosis

Metastasis to the cystic duct has to be distinguished from direct invasion of the duct by cancers, including gallbladder carcinoma (Nakata et al. 2007), which can result in cystic duct obstruction (Miyayama et al. 2003). The presence of two cystic lymph nodes (Sekaran and Anwar 2008) can be confounded with a primary or secondary cystic duct tumor. The same diagnostic problem may arise metastatic disease of the cystic node (Arai et al. 1997), in tuberculosis of the cystic duct lymph node (de Melo et al. 2004), or in various inflammatory alterations of this node (Williams and Whittaker 1965).

Tumor-like Inflammatory Changes of the Cystic Duct

There are very few reported instances of acute or chronic inflammatory changes of the cystic duct resulting in tumor-like tissue mass augmentation. These lesions include primary chronic inflammation of the cystic duct of unknown cause (Labo and Rosa 1965; "primary cystic duct cholangitis"), inflammatory cystic duct polyps (Roig Vila et al. 1995), malakoplakia (Sahel et al. 1976), and manifestations of Kawasaki disease (Liebmann et al. 1982).

Primary cystic duct inflammation ("chronic cysticitis," Labo and Rosa 1965)

This is the most important inflammatory change of the cystic duct, and owing to fibroplasia, it can result in pseudotumoral thickenings of the duct. It has been proposed that primary inflammation of the cystic duct may be more common than generally supposed. It may arise at the same time as a chronic diffuse cholecystitis or be the initial stage of it. Or it may also be associated with cholelithiasis (Labo and Rosa 1965). The usually painful lesions radiologically present as a threadlike duct, rigid duct, rosary-like duct, pearl lace duct, or in the form of a swan neck, sometimes associated with a hypotonic gallbladder (Labo and Rosa 1965). Histologically, both atrophic chronic cysticitis and hypertrophic chronic cysticitis have been described, whereby

the latter can be associated with fibrous pericysticitis. In some cases, these inflammatory changes are accompanied by cystic duct cholesterolosis (Labo and Rosa 1965).

Heterotopias in the Cystic Duct

Introduction

Heterotopias and metaplastic alterations are rather common pathologies in the gallbladder, but are much less frequently encountered in the cystic duct. Heterotopias include heterotopic pancreatic tissue (Inceoglu et al. 1993; Bhana and Chetty 1999; Mrak et al. 2010; Lee et al. 2013), gastric mucosa (Lamont et al. 1991; Orizio et al. 2011), and heterotopic duodenum (Galloway 1984).

Clinical Features

Heterotopias in the cystic duct can, due to their mass-forming effect, lead to stenosis, obstruction, inflammatory changes, including cholecystitis, and eventually biliary colic. This phenomenon has, e.g., been observed in pancreatic heterotopia (Inceoglu et al. 1993; Bhana and Chetty 1999; Mrak et al. 2010).

Pathology

The macroscopic and histologic features of cystic duct heterotopias are the same as those of the gallbladder (see the respective paragraph). Pancreatic heterotopia may be exocrine or mixed exocrine-endocrine, sometimes with islets in normal proportion, and was in one patient associated with segmental adenomyomatosis of the gallbladder (Lee et al. 2013). The heterotopic pancreatic tissue can localize to the mucosa and submucosa, forming a nodule or a polypoid lesion, but it can also be situated deeply, in an intramural location (Mrak et al. 2010). Heterotopic gastric mucosa can contain all gastric mucosal cell types (Lamont et al. 1991).

Cystic Alterations of the Cystic Duct

Few examples of congenital and acquired cystic alterations of the cystic are known and enter the differential diagnosis of cystic neoplastic processes of the extrahepatic biliary tract. Very rare are congenital cystic dilatations solely confined to the cystic duct (Bode and Aust 1983). Congenital cystic duct dilatation is sometimes associated with an anomalous pancreaticobiliary ductal junction (Weiler et al. 2003). Among acquired lesions, stone disease with impaction of a calculus in the cystic duct can cause marked inflammatory dilatation of the cystic duct mimicking a cyst (Tanaka et al. 2008). Cystic dilatation was also diagnosed following cholecystectomy (Dhanjal et al. 2005).

Tumors of the Cystic Duct Remnant

Introduction

The cystic duct remnant, which has variable lengths and residual mucosal surfaces, can undergo several types of secondary changes, mostly inflammatory, but several types of tumorous lesions can also develop.

Carcinoma of the Cystic Duct Stump

Cystic duct remnant carcinoma is a very rare complication (Phillips and Estrin 1969; Dixon and Christensen 1971; Gabata et al. 2003). Adenocarcinoma of the stump can show widespread invasion along the common bile duct wall, causing wall thickening (Gabata et al. 2003). Invasion may also extend beyond the limits of the extrahepatic biliary tract, e.g., into the transverse colon (Noji et al. 2003) or the duodenum (Eum et al. 2008). After cholecystectomy, high-grade dysplasia of the cystic duct margin has been observed in the absence of malignancy in the gallbladder (Bickenbach et al. 2011).

Amputation Neuroma of the Cystic Duct Stump

Postsurgical amputation neuromas can develop at the cystic stump and are a typical form of nonneoplastic tumor-like lesion (Rosenberg and Matzner 1957; Loutsch 1961; Palagiano and D'Addato 1963; Mattler et al. 1965; Joske and Finlay-Jones 1966; Berge and Haeger 1967; Maheshwari and Agarwal 1969; Doberauer and Kühlmayer 1973; Bodner et al. 1978; Prinz et al. 1979; Cimaschi et al. 2006).

Pseudotumors of the Cystic Duct Stump

Mass-forming pseudoaneurysm arising from the cystic artery stump was detected following laparoscopic cholecystectomy (Nakase et al. 2008). Granuloma at the cystic remnant-common bile duct junction was found in one patient (Farkas et al. 1980). Empyema of the cystic duct stump may be confounded with a tumor-like mass (Brodman and Ghazi 1971).

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_163

Abstract

The parietal and visceral peritoneum, including the serosal surface covering the liver, is subject to various neoplastic and nonneoplastic alterations. In part of these lesions, tumors and tumor-like processes can involve the liver and cause differential diagnostic problems. Depending on the type of lesions, circumscribed focal masses or a diffuse process associated with thickening of the liver capsule can develop. Several types of primary peritoneal malignancies are known, including primary papillary serous carcinoma, primary psammocarcinoma, primary peritoneal clear cell carcinoma, anaplastic giant cell carcinoma, hepatoid carcinoma, mesodermal (Müllerian) adenosarcoma, and malignant mesothelioma. A distinct neoplastic process known to involve the liver is pseudomyxoma peritonei most frequently associated with mucinous malignancies of the appendix and ovaries. Gliomatosis peritonei may involve large parts of the serosal surface. Numerous forms of reactive alterations of the peritoneum can give rise to small tumor-like lesions. They mainly include various types of metaplasia, granulomas, endometriosis, and deciduosis.

Introduction

The parietal and visceral peritoneum is subject to various neoplastic and nonneoplastic alterations. Inner organs, including the liver and the gallbladder, can be involved when the visceral surface of the peritoneum is affected. In such situations, tumors and tumor-like lesions can be found on the liver capsule, the free surface of the gallbladder, in the gallbladder fossa, and in the subdiaphragmatic space. Depending on the type of lesions, discrete focal masses or a diffuse process resulting in a thickening of the liver capsule may ensue. In this chapter, several entities primarily involving the peritoneum are discussed.

Primary Papillary Serous Carcinoma of the Peritoneum

Introduction

Primary papillary serous carcinoma of the peritoneum (PPSCP; synonyms: extraovarian primary peritoneal carcinoma, EOPPC; extraovarian pelvic serous tumor; multifocal extraovarian serous carcinoma; peritoneal carcinomatosis of unknown primary tumor site) is an uncommon primary low-grade carcinoma of the peritoneal surface that is histologically indistinguishable from papillary serous carcinoma of the ovaries. PPSCP typically develops a diffuse peritoneal growth pattern, while it spares or only superficially invades the ovaries. In the first description of this neoplasm, the author thought it to be a mesothelioma of the pelvic peritoneum (Swerdlow 1959), but the distinction between peritoneal carcinoma and mesothelioma was emphasized in 1977 (Kannerstein et al. 1977).

Epidemiology

PPSCP was first described in 1959 (Swerdlow 1959) and is a disease of females of the middle-aged to older group (Foyle et al. 1981; Lele et al. 1988). Among the cases reported in the literature, around 10 % of females diagnosed with serous ovarian carcinoma actually suffered from PPSCP. PPSCP is an exceptional finding in males (Shah et al. 1998; Shmueli et al. 2001). In the context of peritoneal cancer work-ups, more and more cases of primary peritoneal carcinomas have been identified.

Selected References Raju et al. (1989), Chew et al. (1995), Trauner et al. (1995), Zhou et al. (1995), Taus et al. (1997), Chopra et al. (2000), Koutselini et al. (2001), Morita et al. (2004), Puvaneswary and Proietto (2004), Nakao et al. (2009), Agarwal et al. (2010), Bhuyan et al. (2010), Hwang et al. (2010), Liu et al. (2011). In three studies, the mean age at presentation was 53.3 years (range, 46–59) (Chew et al. 1995), 56 years (range,

40–74 years) (Zhou et al. 1995), and 63 years (range, 44–74 years) (Iavazzo et al. 2008).

Clinical Findings

The tumor presentation is characterized by peritoneal, omental, and mesenterial masses of an exophytically growing tumor in the absence of a primary ovarian malignancy (Liu et al. 2011). The most common presenting features are abdominal pain and distention, and almost all patients present with ascites, often massive (Chew et al. 1995). The serum CA125 levels are markedly elevated (Rosen et al. 1992; Zhou et al. 1995; Furukawa et al. 1999; Iavazzo et al. 2008; Bhuyan et al. 2010). Similar to papillary serous ovarian carcinoma, rising longitudinal levels of CA125 may be significant in the detection of PPSCP (Skates et al. 2003). PPSCP may extend beyond the abdominal cavity and involve the pleural surface (Suh et al. 2008). The carcinoma can metastasize to locoregional lymph nodes and remote organs, including the bronchopulmonary tract (Nakao et al. 2009) and the brain (Sakakibara et al. 2011). The outcome of PPSCP seems to strongly depend on disease extension and amount of residual disease after therapy. In a study of 18 patients, the median overall survival time was 10 months, the figure reflecting the extent of spread of the disease at diagnosis and the relatively limited proportion of patients profiting from optimal cytoreductive surgery (Taus et al. 1997).

Imaging Findings

Patients with PPSCP present with an imaging picture that resembles that of diffuse peritoneal ovarian cancer spread, often associated with massive ascites (Chopra et al. 2000; Morita et al. 2004; Puvaneswary and Proietto 2004). On CT images, the parietal peritoneum of the pelvis showed diffuse enhancement with nodular thickening, and omental caking was seen in the majority of patients with advanced disease. Some of the tumors, i.e., those with psammoma bodies, reveal multiple calcifications (Stafford-Johnson et al. 1998). Typically, the ovaries exhibit a normal size but may display a fine enhancing surface nodularity owing to tumor growth on the ovarian surface (Chopra et al. 2000). The tumor often involves the tissues surrounding the sigmoid colon (Zissin et al. 2001) and may in fact mimic sigmoid cancer (Chand et al. 2007). In the course of disease, PPSCP extends into the upper abdominal compartment (Taus et al. 1997), where involvement of the transverse colon associated with omental tumor formation develops (Furukawa et al. 1999). Upper abdominal involvement can be associated with pleural effusions (Zissin et al. 2001), sometimes massive and bilateral (Kaira et al. 2006).

Pathology

Macroscopy

Macroscopically, the visceral and parietal peritoneums are studded with more or less prominent whitish to reddish nodules with a granulated surface. This pattern is seen at laparoscopy (Trauner et al. 1995). These nodules are commonly 2–5 mm in diameter, but few larger nodules may be noted, especially within the infiltrated omentum. In the intra-abdominal adipose tissue, nodules may coalesce and form an omental cake and/or a firm mesenterial plaque. The small bowel and colon (particularly the sigmoid) may be engulfed by thick and nodular tumor masses, causing a conglomerate of firmly adherent loops. In part of the cases, small cysts filled with a gray and partially gelatinous material are present. The exophytic growths extend into the subdiaphragmatic space (Chew et al. 1995) and to the liver surface. PPSCP can metastasize to the liver (Shmueli et al. 2001).

Histopathology

The histopathology resembles that of papillary serous carcinoma of the ovary. The papillary structures consist of medium-sized serous cells. Part of the cells contain mucin, and even signet ring cells may be noted. One subset of PPSCP

are high-grade neoplasms often showing high mitotic rate, invasion, and necrosis (Truong et al. 1990). However, part of PPSCP are low grade (grade 1), and histologically these tumors mimic the invasive implants of ovarian serous borderline tumors, lack high-grade nuclear atypia, show tissue and/or lymphovascular invasion, and have significant solid epithelial proliferations (Weir et al. 1998). Within the papillary growth, small calcifications or even psammoma bodies may be noted (Liu et al. 2011). The tumor can be diagnosed by use of fine needle aspiration combined with immunocytochemistry (Alberti et al. 2007).

Immunohistochemistry

The tumor cells are positive for cytokeratins (cytokeratins 7 and 20 but not keratins 5/6), epithelial membrane antigen (EMA), Lewis Y antigen, CD15, and placental alkaline phosphatase (Zhou et al. 1995; Shmueli et al. 2001). There is marked positivity for CA125 (Furukawa et al. 1999). The tumor cells are reactive for Ber-EP4, MOC-31, CA19-9, and Leu-M1 (Ordonez 2006). About a third of the tumors are vimentin-positive (Truong et al. 1990). Similar to other carcinomas situated in the peritoneum, but in contrast to mesothelioma, PPSCP is positive for claudin 4 (Facchetti et al. 2007). A large proportion of tumors was found to be positive for estrogen receptors (Barnetson et al. 2006). There is usually no or only limited immunoreactivity for polyclonal CEA or monoclonal CEA (Raju et al. 1989; Truong et al. 1990). Immunostaining for Leu-M1, calretinin, thrombomodulin, or CD44H is negative (Attanoos et al. 2002). The tumors exhibit marked nuclear positivity for p53 protein (Nishimura et al. 2000).

Variants of PPSCP

Primary Peritoneal Serous Borderline Tumors

Peritoneal serous micropapillomatosis of low malignant potential (serous borderline tumor of the peritoneum) is a variant of PPSCP with no detectable invasive growth (Biscotti and Hart 1992). Serous borderline tumors histologically resemble the noninvasive implants of ovarian serous borderline tumors, lack invasion, and do not show nuclear atypia of the degree seen in grade 2 or grade 3 serous carcinoma. Clinically, it is usually manifest at an earlier age than PPSCP. In 19 patients with this neoplasm, mean age at diagnosis was 48 years (Weir et al. 1998).

Primary Psammocarcinoma of the Peritoneum

Primary psammocarcinoma of the peritoneum is a serous carcinoma characterized by the presence of large deposits of psammoma bodies and low-grade cytologic atypia (Whitcomb et al. 1999; Bilgin et al. 2006). This variant of carcinoma was diagnosed at earlier age, i.e., 40 years in one study (Weir et al. 1998). The diagnosis requires the presence of at least 75 % psammoma bodies, no more than moderate cytological atypia, tissue or lymphovascular space invasion, and rare epithelial solid proliferations less than 15 cells across (Weir et al. 1998). Similar to PPSCP, the tumor can be associated with elevated serum CA125 (Whitcomb et al. 1999). Primary peritoneal psammocarcinoma revealed a favorable outcome in part of the patients, resembling the biology of low malignant potential tumors of the ovaries, but examples with an aggressive course are also known, with recurrent disease and metastasis (Poggi et al. 1998; Akbulut et al. 2007; Bodnar et al. 2009).

Differential Diagnosis

The chief differential diagnosis is serous papillary ovarian cancer with peritoneal spread. Histologically, the two neoplasms are in principle indistinguishable. Therefore, diagnosis of PPSCP requires that the ovaries are free of tumor, except the involvement of the ovarian peritoneal surface by a noninvasive papillary

tumor growth in PPSCP. A second important differential diagnosis is papillary peritoneal mesothelioma in females, which can mainly be distinguished by use of immunohistochemistry, as mesotheliomas, but not PPSCP, are positive for calretinin, thrombomodulin, and podoplanin (Zhou et al. 1995; Koutselini et al. 2001; Attanoos et al. 2002; Ordonez 2006). In contrast to PPSCP, peritoneal mesotheliomas do not express estrogen receptors (Barnetson et al. 2006).

Pathogenic Pathways

PPSCP is thought to originate from extragonadal mesothelial cell systems which have a Müllerian differentiation potential. Already in 1972, the female peritoneum was described as a part of the secondary Müllerian system (Lauchalan 1972). A Müllerian potential of peritoneum is supported by the observation of extraovarian malignant mixed Müllerian tumors arising from the peritoneum (Mira et al. 1995; Kanis et al. 2011). Another hypothesis proposed that pathways leading to serous carcinogenesis of the ovaries and the peritoneum involve the traffic of preneoplastic/neoplastic cells from the tubal fimbria, originating from serous tubal intraepithelial carcinomas (STICs), or mediated by a generic secretory cell outgrowth (SCOUT) in the fallopian tube that is associated with altered PAX2 expression (Mehra et al. 2011). Whether the multiple nodules and papillary formations in PPSCP are monoclonal or oligo/polyclonal growths is not yet known. In one study, DNA sequence analysis of the p53 gene showed diverse point mutations at codons 167 and 192 in two of four anatomically different tumors, suggesting polyclonality of some PPSCP neoplasms (Nishimura et al. 2000). The proportion of p53 immunoreactive cells was higher in cases of high-grade pelvic serous neoplasms, reflecting to importance of p53 gene mutations in this subset of neoplasms (Chang et al. 2011). Rare situations have shown familial papillary serous carcinomas of the cervix, peritoneum, and ovary (Kaplan et al. 1998).

Primary Peritoneal Clear Cell Carcinoma

Introduction

In the abdominal cavity, clear cell carcinoma is mostly derived from the ovaries and often associated with endometriosis. The neoplasms are characterized by clear epithelial cells containing abundant glycogen and the presence, at least at some places, of hobnail cells. Very few clear cell carcinomas involving the peritoneal surface in the absence of a genital tract tumor have been described (Lee et al. 1991; Ichimura et al. 2001; Terada and Kawaguchi 2005; Takano et al. 2009; Muezzinoglu et al. 2011). All patients were women 45 years of age or older at diagnosis. The tumors are interpreted to have a Müllerian derivation.

Clinical Features

The tumors presented with upper abdominal and pelvic tumor masses, sometimes associated with ascites. The tumors can grow around intra-abdominal organs such as the stomach and the spleen (Terada and Kawaguchi 2005). The neoplasm may be associated with elevated serum CA19-9 levels (Ichimura et al. 2001).

Pathology

Macroscopy

Macroscopically, part of the described tumors were solid growths with cystic parts, encapsulated by fibrous tissues (Terada and Kawaguchi 2005).

Histopathology

The neoplasms consist of proliferations of polygonal cells arranged in solid nests, tubular, or papillary patterns, the latter sometimes with a hobnail appearance. At least half of the cell populations showed cells with a clear cytoplasm, prominent

cell borders, and round hyperchromatic nuclei with prominent nucleoli. PAS-positive intracytoplasmic hyaline globules were recognized in a few areas (Terada and Kawaguchi 2005). The stromal axes of papillary structures contain an Alcian blue-positive myxoid substance. Histologically, associated endometriosis was either present (Muezzinoglu et al. 2011) or absent (Takano et al. 2009).

Immunohistochemistry

In a study of two tumors, the neoplastic cells were positive for cytokeratin AE1/AE3, polyclonal cytokeratin, cytokeratin MNF116, cytokeratin 34betaE12, epithelial membrane antigen (EMA), CA125, CA19-9, and p53 protein, whereas no reactivity for vimentin and for steroid hormone receptors was found (Terada and Kawaguchi 2005).

Primary Peritoneal Anaplastic Giant Cell Carcinoma

This is an extremely rare type of a primary peritoneal carcinoma that was observed in a 72-year-old woman who had presented with lower abdominal pain. CT revealed a diffuse omental thickening (omental cake). Pathologic examination of resection specimens revealed extensive omental replacement by tumor but only superficial surface cortical involvement of both ovaries, and the neoplasm was composed of diffusely arranged anaplastic tumor giant cells (Lu et al. 2008).

Diffuse Hepatoid Adenocarcinoma of the Peritoneal Cavity

Hepatoid adenocarcinoma is a rare malignancy that occurs mostly in the gastrointestinal tract and the ovaries. A primary localization in the peritoneal surface is very rare and was observed in a 68-year-old man presenting with massive ascites and markedly elevated serum and ascitic AFP levels. CT revealed multiple nodular lesions disseminated exclusively in the peritoneal cavity. Laparoscopic biopsy displayed the morphology of diffuse hepatoid adenocarcinoma (Kitamura et al. 2006).

Primary Peritoneal Mesodermal (Müllerian) Adenosarcoma

Introduction

One–3 % of all female genital tract tumors are stromal malignancies, and of these mesodermal (Müllerian) mixed tumors or adenosarcomas account for 8–10 % of cases (Clement and Scully 1974). Histologically, the neoplasms contain a neoplastic but benign-looking or mildly atypical epithelial element and a sarcomatous, usually low-grade stromal component. Müllerian adenosarcomas are typically neoplasms arising in the corpus of the uterus, but the tumor also occurs in the uterine cervix and ovary and more rarely in the vagina and fallopian tube (review: McCluggage 2010). A small fraction of the tumors originate from the peritoneum, including the pouch of Douglas (Kerner et al. 1989; Ohno et al. 1989; De Jonge et al. 1995; Thylan 1996; Kato et al. 2000; Visvalingam et al. 2001; Kanngurn et al. 2005; Magro et al. 2005; Gong et al. 2008; Patrelli et al. 2011). In part of the cases, the tumor was associated with endometriosis (Dincer et al. 2002; Huang et al. 2009).

Clinical and Imaging Features

The clinical presentation is dominated by the effects of tumor masses occupying the peritoneal surface in diverse sites of the abdominal cavity. Patients usually have pain in the lower or upper abdomen. CT images document the often large solid masses that encroach upon and invade intra-abdominal organs (Gong et al. 2008).

Pathology

Macroscopy

The gross presentation is that of bulky tumors that protrude from the peritoneal surface and cause tumorous adhesions between the peritoneum and organs and between involved organs.

Histopathology

Typically, adenosarcomas show a biphasic pattern and a low-power phyllode-like architecture with leaflike projections consisting of a neoplastic stroma, lined by a variety of benign-looking Müllerian-type epithelia, including cuboid to prismatic glandular epithelium and squamous epithelium. The epithelium lines slit-like or antler-shaped cavities situated between the phyllode-like stromal projections. The glandular epithelium may show a variety of metaplastic changes, including ciliated and strongly eosinophilic cells. A characteristic feature are intraglandular stromal protrusions. The stroma exhibits a rather low cellularity, but cell density is typically higher close to the epithelial linings, causing the development of a so-called cambium. To be classified as sarcomatous, the stroma should show two or more mitotic figures per 10 HPFs (Verschraegen et al. 1998; review: McCluggage 2010). In regard to stromal predominance, Müllerian adenosarcomas exist as lesions without sarcomatous overgrowth (MA-NSO) or with sarcomatous overgrowth (MA-SO). The stroma is usually low grade and of the endometrial or fibroblastic type, but high-grade sarcomatous components also occur, e.g., the sarcomatous component may show an extensive rhabdomyosarcomatous element (Kato et al. 2000). Within the neoplastic stromal tissue, fetal-type cartilage can develop (Kanngurn et al. 2005). Adenosarcomas with an important component of mesenchymal tumor tissue may be difficult to diagnose, because large areas can display a low cellularity and infrequent mitotic figures.

Immunohistochemistry

The epithelial cell populations are cytokeratin-positive, while the stromal cells are reactive for vimentin, alpha-SMA, desmin, CD10, WT1, and steroid hormone receptors. Expression of estrogen receptors predominates in MA-NSOs and I much less common in MA-SOs (Soslow et al. 2008; Gallardo and Prat 2009).

Pseudomyxoma Peritonei

Introduction

Pseudomyxoma peritonei (PMP) was first described by K.F. Rokitansky in 1842 and is a complex life-threatening intra-abdominal disease or syndrome characterized by multifocal to diffuse peritoneal epithelial implants derived from mucinous tumors, secreting copious mucin, and causing dissecting gelatinous ascites (Yan et al. 2001; Jacquemin and Laloux 2005; Buell-Gutbrod and Gwin 2013). PMP is a serious condition that may show a very aggressive course, however depending on the type of disease (see below; Touloumis et al. 2013; Wang et al. 2014). Most primary tumors causing PMP formerly seemed to be located to the appendix or the ovaries (Young 2004; Jacquemin and Laloux 2005; Lee et al. 2008; Smeenk et al. 2008). Less common lesions that can give rise to PMP comprise intraductal papillary mucinous neoplasm of bile ducts (Jhuang and Hsieh 2012), neoplastic mesenteric cysts (Zappa and Sugarbaker 2010), ruptured mucinous cystadenoma of the spleen (Kapoor et al. 2007), mucinous adenocarcinoma of the urachus (Yan et al. 2006), malignant transformation of tailgut cyst (retrorectal hamartoma; Zappa et al. 2009), and colonic polyps (Goldstein et al. 2006).

The identification of primary mucinous ovarian tumors as origin of PMP is hampered by the fact that a considerable fraction of the patients have concurrent mucinous appendiceal tumors, leading to the concept that in most patients ovarian involvement is in fact a secondary

phenomenon, i.e., following an appendiceal primary tumor (Ronnett et al. 1995a, 1997; Pai and Longacre 2005). The pathogenic pathway leading to this distinct mode of peritoneal spread of the disease is only partially known. Recent studies show that PMP is, in principle, a disease of MUC2-expressing goblet cells. Secreted MUC2 accounts for the voluminous deposits of extracellular mucin, typically with a mucin-to-cell ratio exceeding 10:1. Primary epithelial cell cultures derived from PMP express MUC2 whose levels can be epigenetically regulated and are upregulated in response to *Pseudomonas aeruginosa*. Importantly, the levels of mucin deposition are not related to the grade of malignancy but rather reflect the constitutive levels of expression observed in normal goblet cells of the appendix (O'Connell et al. 2002). The neoplastic goblet cells of PMP strongly express a member of the human Reg protein family, the regenerating protein (Reg)-like protein (REPL, Reg IV), a secreted protein of C-lectin type (Heiskala et al. 2006). Reg proteins are involved in regeneration, proliferation, and differentiation of cells in the pancreas, liver, and gastrointestinal mucosa. PMP may involve extended areas of the peritoneal surface and as such can grow onto and eventually into the liver. In 5.4 % of patients, PMP showed pleural extension (Pestieau et al. 2000).

Classification

Based on systematic clinicopathologic studies, PMP is now viewed as three pathologically and prognostically distinct disease processes (Table 1; Ronnett et al. 1995b).

The first type (the classical clinical syndrome of PMP) is *disseminated peritoneal adenomucinosis* (*DPAM*) characterized by copious mucinous ascites and histologically bland peritoneal mucinous tumors. The morphology shows bland to low-grade adenomatous mucinous epithelium associated with abundant extracellular mucin and fibrosis. In most cases, DPAM is causally attributed to a ruptured appendiceal mucinous tumor and usually follows a rather indolent clinical course when surgically treated but may recur over months to years. The second type is *peritoneal mucinous carcinomatosis* (*PMCA*) characterized by copious and diffuse peritoneal mucinous carcinoma. Clinically resembling DPAM, histology shows invasive mucinous adenocarcinoma derived from the GIT. PMCA has a significantly more aggressive course. The third type, *peritoneal mucinous carcinomatosis with intermediate or discordant features* (*PMCA I/D*), displays intermediate or discordant histologic features and is derived from well-differentiated mucinous adenocarcinomas associated with adenomas but manifests a clinical course very similar to cases of pure peritoneal carcinomatosis (Ronnett et al. 1997). In a study of 101 patients with PMP of appendiceal origin, 58 patients had DPAM, 23 had PMCA, and 20 had PMCA I/D, and DPAM and PMCA I/D exhibited a roughly equal incidence of parenchymal (beyond the serosa) organ invasion (Bradley et al. 2006). For patients with PMP of appendiceal origin, a new classification system has recently been proposed, a three-tiered grading system designated PMP1, PMP2, and PMP3 (Shetty et al. 2013). PMP1 included many patients with abundant extracellular mucin and columnar nonstratified epithelium without atypia or dysplasia. In PMP3 cases, part of the lesions contained any percentage of signet ring cells, the presence of signet ring cells having an impact on survival.

Table 1 Classification of pseudomyxoma peritonei (PMP)

Disseminated peritoneal adenomucinosis (DPAM)
Peritoneal mucinous carcinomatosis (PMCA)
Peritoneal mucinous carcinomatosis with intermediate or discordant features (PMCA I/D)

Liver Involvement in PMP

Macroscopy

PMP lesions that develop around the liver usually result in a characteristic scalloping of the liver and spleen margins and often in omental thickening, with production of a so-called omental cake. In the setting of upper abdominal PMP, the liver can directly be involved in part of the patients (Youssef and Moran 2011). Notches of myxoid tumor tissue

can form on the surface of the liver (Qi et al. 2015). During laparotomy or laparoscopy, or at necropsy, liver involvement by PMP is manifest as transparent and viscous masses overlying the liver capsule (Nikolic et al. 2012). In case of hemorrhage or infection, the mucoid material may change from a transparent aspect to brownish-red or yellowish masses. Owing to the organ movements, the material may be pushed into ridges or granular structures. In advanced stages, only a fibrosclerotic thickening of the liver surface is seen. In rare cases, PMP can produce intrahepatic metastases (Lang et al. 1995; Serrano Lira et al. 1995; Gupta et al. 2000), characterized by mucinous adenocarcinoma deposits. Recurrent appendiceal PMP and its mucus may accumulate at the liver hilus/porta hepatis. Among 140 patients with recurrence of appendiceal PMP following complete cytoreduction, 5 % had disease recurrence in and around the porta hepatis (Sugarbaker and Bijelic 2008). PMP was found to originate from low-grade intraductal papillary mucinous neoplasm of bile duct (Jhuang and Hsieh 2012).

Histopathology

PMP tissue and mucinous material covering the liver surface in case of DPAM show lakes of mucus dissecting fibrous tissue, sometimes with a lymphocytic reaction and the formation of macrophage accumulations or mucus granulomas. Suspended in the mucus masses one notes aggregates or "flakes" of well-differentiated mucinous epithelium, sometimes with goblet cell features. The mucus-induced dissection may extend into the subserosal compartment, what is difficult to distinguish from tumor invasion. In case of PMCA, epithelial formations of mucinous adenocarcinoma are seen, and subserosal invasion is easily detectable.

Immunohistochemistry

Immunohistochemically, the PMP tissue is diffusely reactive for cytokeratin 20, CDX-2, MUC2, and MUC5AC. CDX-2 is a useful marker to confirm the appendiceal origin of PMP (Nonaka et al. 2006). MUC2 expression was found to be highest in the PMCA type of PMP and was found to be associated with enteric bacteria in PMP tissue (Semino-Mora et al. 2008). Expression of MUC5AC by the atypical goblet cells is not specific for PMP (O'Connell et al. 2002).

Biology of Disease

As already mentioned above, the classes/types of PMP have an impact on prognosis of the disease. Patients with the DPAM type of PMP have a significantly more favorable prognosis than patients with PMCA, having 5-year and 10-year survival rates of 75 % and 68 %, respectively. In contrast, patients with PMCA I/D had 5-year and 10-year survival rates of 50 % and 21 % and those with PMCA 14 % and 3 %, respectively (Ronnett et al. 2001). Negative prognostic determinants after complete cytoreduction and hyperthermic intraperitoneal chemotherapy of PMP comprised previous chemotherapy, the PMCA pattern, and elevated serum CA125 (Baratti et al. 2009). The biology of PMP seems to be influenced by its inflammatory microenvironment, in particular the expression of IL-6. This cytokine response may be linked to a core microbiome associated with PMP, in that 16S amplicon-based sequencing, direct in situ hybridization analysis, and culturing methods identified numerous bacterial taxa that were consistently present in all PMP patients tested (Gilbreath et al. 2013).

Gliomatosis Peritonei

Introduction

Gliomatosis peritonei (GP), first reported under this name in 1906 (Neuhäuser 1906) but already described in 1905 (Fleischmann 1905), is characterized by the emergence of numerous peritoneal, or more precisely subperitoneal, foci consisting of glial tissue. This is a rare, mostly benign condition occurring both in children and in adults and

chiefly associated with immature and mature teratomas of the ovary (Fortt and Mathie 1969; Robboy and Scully 1970; Okamoto et al. 2007) and sometimes with teratomas located elsewhere. Exceptionally, GP is associated with growing teratoma syndrome (so-called chemotherapeutic retroconversion; Amsalem et al. 2004). The highest incidence of GP was found in the first two decades of life in regard to the time point of first tumor (teratoma) operation (average age based on a literature review, 15.4 years; Müller et al. 2002). GP, particularly in the presence of numerous and large glial foci, is known to cause ascites, of unknown pathogenic mechanism (Hsieh and Liu 2009). Rarely, ovarian teratoma-based GP is associated with both ascites and pleural effusion (hydrothorax). This is termed Pseudo-Meigs' syndrome in GP (Khan et al. 2005). The complex biology of disease of gliomatosis peritonei (GP) is usually a benign condition, and immature teratomas, when associated with mature glial implants within the peritoneum, have a better prognosis irrespective of the original tumor grade (Robboy and Scully 1970). However, there are descriptions of cases of mature gliomatosis peritonei which seem to have evolved into malignancy (Shefren et al. 1991).

Gliomatosis Peritonei of the Liver Surface

An involvement of the liver surface has already been observed in the first patient reported (Fleischmann 1905). The nodules are usually composed of mature-looking glial tissue and either form macroscopically visible nodules of up to 3.5 cm size (*nodular GP*; Harms et al. 1989; average, 0.26 cm; Müller et al. 2002) or microscopic foci found in random peritoneal biopsies (miliary GP). There may be signs of chronic inflammation or immune reaction, perifocal fibrosis, calcifications, or psammoma bodies. The cells of the foci are immunoreactive for GFAP, vimentin, S100 protein, and NSE (Harms et al. 1989; Müller et al. 2002). In part of the cases, a close spatial relationship between a teratoma and GP was found. In the case described by Torikai and coworkers (Torikai et al. 2007), a 9-month-old girl had a cystic and partly calcified immature teratoma hanging beneath the liver and in continuity with the fundus of the gallbladder. In the adjacent omentum and peritoneum, numerous nodules up to 2 mm in diameter were seen, histologically characterized by mature gliomatous tissue. The tridermal primary tumor also contained immature neural tissue.

Pathogenic Pathways

In regard to the causes of GP, at least five theories of pathogenesis have been proposed, viz., implants representing all three germ layers, with survival of glial tissue; immature neural tissue spreading in the abdominal cavity, with subsequent glial differentiation; extrusion from a teratoma of mature glial tissue itself; the differentiation of pluripotent Müllerian stem cells along a glial cell pathway; and primary multiplicity of lesions as a so-called field effect (Müller et al. 2002). A lymphatic spread of target cells is suggested by the observation of nodular/nodal gliomatosis involving locoregional lymph nodes. The complexity of pathogenic pathways in GP is underlined by the morphologic unity, soft tissue gliomatosis, where glial tissue foci occur at diverse sites, with or without association with teratomas or sequestered encephaloceles (McDermott et al. 1996). The glial implant theory of GP is suggested by the observation that GP can occur as a complication of a ventriculoperitoneal shunt, in the absence of any ovarian lesions (Lovell et al. 1989), suggesting an implantation pathway also known to work for peritoneal manifestations of malignant intracranial tumors in patients with such shunts.

Molecular studies have put the implantation theories of GP into question. In investigations employing polymorphic microsatellite loci as markers, it turned out that glial implants in GP seem to arise from cells within the peritoneum (presumably Müllerian stem cells) and not from associated ovarian teratomas (Ferguson et al. 2001; Kwan et al. 2004). Another microsatellite marker study of tumors of immature ovarian

teratoma and its recurrences, and GP, demonstrated mutually exclusive genetic differences among the lesions, establishing the lineages as genetically distinct (Best et al. 2004).

Metaplastic and Tumor-like Lesions of the Hepatic Peritoneum

Introduction

The peritoneum, including that covering the liver, can undergo a multitude of reactive changes that are characterized by focal or multiple mass-producing lesions that can mimic a neoplastic process. In case these alterations are markedly expressed on the hepatic serosa, multiple tumor-like lesions mimicking, e.g., metastatic disease can develop.

Epithelial Metaplasia, Hyperplasia, and Related Lesions of the Mesothelium

Squamous Cell Metaplasia

The peritoneal mesothelium can undergo squamous cell metaplasia, with or without keratinization (Schatz and Colgan 1991). This metaplasia was most often found in chronic peritonitis, e.g., in patients with peritoneal tuberculosis. It has also been observed in patients on continuous ambulatory peritoneal dialysis/CAPD (Selgas et al. 1995) and is sometimes followed by the development of benign glandular inclusions thought to derive from totipotential subcoelomic mesenchymal cells (Chen 1981).

Peritoneal Keratin Granulomas

In cases with keratinization, cornified cells can detach from the epithelial, enter the subserosal space, and elicit a vigorous foreign body reaction, with formation of keratin granulomas. Such granulomas can, however, also develop in the setting of peritoneal spread of squamous cell neoplasms or after rupture of ovarian dermoid cysts.

In general, release of cornified squamous epithelial cells from the "sealed" epithelial into connective tissue elicits a vigorous foreign body reaction mediated by activated macrophages and their fused offspring, multinucleated foreign body giant cells. This response results in the formation of granulomas that contain decaying cornified squamous cells and keratin lamellae, the keratin granuloma. In some situations, these granulomas also contain cholesterol crystals with adherent giant cells (mixed keratin and cholesterol granulomas). Keratin granulomas are well known to occur in the setting of squamous cell carcinomas, e.g., following radiation therapy or chemotherapy where damaged or dead cancer cells induce a local granulomatous reaction (Safall and Azar 1966; Reddy et al. 1975; Westra et al. 1998), but the granulomas may also be found in the vicinity of squamous cell carcinomas in the absence of therapy (Leshin et al. 1992). Keratin granulomas also occur in the neighborhood of benign lesions, e.g., ruptured epidermoid/trichilemmal cysts and dermoid cysts. In this situation, a lipogranulomatous reaction can emerge, directed against the fatty cyst contents.

Apart from squamous cell metaplasia, keratin granulomas situated in the peritoneal surface mainly occur in patients with gynecological cancers containing a squamous component (Chen 1999). In these instances, squamous cancer cells can either leave the tumor when it invades the peritoneum or escape through the Fallopian tube. Peritoneal keratin granulomas, sometimes multiple, have been observed in the context of uterine adenoacanthoma (Chen et al. 1978), endometrioid adenocarcinoma with squamous differentiation (Kim and Scully 1990; Wotherspoon et al. 1989; van der Horst and Evans 2008; Uehara et al. 2011), ovarian carcinomas with squamous differentiation (Wu et al. 2006), and ruptured ovarian teratoma (Phupong et al. 2004). Oil-containing peritoneal keratin granulomas were found as a complication of ovarian dermoid (Kurrein and Fothergill 1961). In male patients, peritoneal keratin granulomas can be related to peritoneal squamous metaplasia or peritoneal inclusion cysts with squamous metaplasia. Following rupture of such cysts, large inflammatory

tumor-like lesions containing keratin granulomas can develop, also involving the liver surface (Tripathy et al. 2010).

Mucinous Metaplasia

Mucinous metaplasia of the peritoneum is a very rare condition, characterized by the presence of mucin-producing glandular or prismatic cells lining the peritoneal surface (Saran et al. 2008).

Mesothelial Hyperplasia

The mesothelial covering of the peritoneal surface can, under several circumstances, develop adenomatoid epithelial structures that may pose diagnostic difficulties in regard to the exclusion of malignant disease (Michal 1997). Hyperplasia of the peritoneal mesothelium is a reactive process that presents in the form of nodular, papillary, tubular, or mixed mesothelial growths (Rosai and Dehner 1975; Clement and Young 1993; Churg et al. 2000; Lee et al. 2014). The alteration can occur in association with a variety of gynecological disorders (Oparka et al. 2011) but can also occur in the setting of peritoneal inflammatory disorders. This alteration is usually characterized by linear arrays of widely spaced and horizontally oriented, simply constructed and non-branching tubules and nests of mesothelial cells, sometimes embedded in a stroma-like connective tissue. The lesions are more commonly found in the tunica vaginalis ("florid mesothelial hyperplasia"; Lee et al. 2014). Mesothelial hyperplasia may be confounded with mesothelioma, in particular benign papillary mesothelioma (Goepel 1981), but whereas the latter express insulin-like growth factor II messenger RNA-binding protein 3/IMP3, reactive hyperplastic mesothelial cells do not (Shi et al. 2011).

Endometriosis

The peritoneum is a rather common site of extragenital endometriosis, either with grossly detectable lesions or in a microscopic form (Khan et al. 2014). Peritoneal endometriosis has a high lymph vessel density associated with the expression of lymphatic growth factors (VEGF-C/VEGF-D) in stromal cells and macrophages (Reichelt et al. 2012). Apart from locally induced and activated stromal cells, macrophages play a significant role in the pathogenesis of peritoneal endometriosis, via secretion of a distinct set of cytokines (Beste et al. 2014). Endometriosis can transform into a mucinous epithelium with eventual development of dysplastic changes (Mai and Burns 1999) and may in some instances resemble a placental site nodule or placental site (Santos et al. 1999). A variant of peritoneal endometriosis is peritoneal stromal endometriosis, characterized histologically by small nodules or plaques of endometrium-type stroma, sometimes with a whorled pattern, increased vascularity, and red cell extravasation. The stromal foci are situated in the submesothelial tissue and protrude above the surface. The lesions may be accompanied by circumscribed mesothelial hyperplasia (Boyle and McCluggage 2009). Stromal endometriosis occurs either in conjunction with classical endometriosis, or as a lesion of its own.

Endosalpingiosis

Endosalpingiosis denotes the presence of endosalpingeal, Fallopian tube-type prismatic, and at least in part ciliated epithelia in extratubal tissues, including the peritoneum. The cells can form multiple simple glands that are lined by a single layer of cells, sometimes with development of cystic structures.

Strumosis Peritonei

Strumosis (synonyms: metastatic ovarian strumosis, strumatosis) is defined as the presence of implants of mature follicular thyroid tissues in the peritoneal tissue. The source of peritoneal strumosis is struma ovarii in ovarian teratoma (Brogsitter et al. 2004; Muallem et al. 2012; Navarro et al. 2012), struma ovarii in connection

with other ovarian tumors (Sibio et al. 2010), and isolated struma ovarii (Balasch et al. 1993; Karseladze and Kulinitch 1994). Peritoneal strumosis can cause thyrotoxicosis (Kim et al. 2009) and may be difficult to differentiate from spread of highly differentiated follicular thyroid carcinoma (Roth and Karseladze 2008).

Sertoli Cell Tumor Implants

In very cases, Sertoli cell tumor of the ovary produced benign peritoneal implants (Onida et al. 2010).

Deciduosis of the Peritoneum

Associated with pregnancy, the peritoneal covering of the liver may be involved in ectopic decidual change, a lesion termed deciduosis or ectopic decidual reaction (deciduosis peritonei), and thought to result from the differentiation of extrauterine stromal cells to a decidual cell lineage (Kwan and Pang 1964; Zaytsev and Taxy 1987; Buttner et al. 1993; Fenjvesi and Zivkovic 2005; Kinra et al. 2006; Shukla et al. 2008; Bolat et al. 2012; Stewart 2013). In part of cases, the peritoneal surface and the omentum are studded with numerous whitish grain-like lesions, varying in diameter from 1 to 5 mm. Peritoneal deciduosis can cause hemorrhage (Hulme-Moir and Ross 1969). It may grossly mimic peritoneal tubercles or miliary peritoneal tuberculosis (Shukla et al. 2008) or metastatic nodules (Piccinni et al. 2002). Hepatic peritoneal deciduosis has, however, not yet been specified in the reports on peritoneal decidual change. Deciduosis has been observed to be accompanied by lipofuscinosis peritonei (White and Chan 1994). A decidual reaction of the peritoneum sometimes results in mass lesions (gross deciduosis, pseudotumoral deciduosis), even obstructing labor (Malpica et al. 2002).

Peritoneal deciduosis, in particular pseudotumoral deciduosis, has to be distinguished histologically from deciduoid mesothelioma (Mourra et al. 2005).

Peritoneal Stromal Luteinization

The submesothelial stromal cells of the peritoneum can undergo functioning extraovarian stromal luteinization (Aneiros-Fernandez et al. 2010).

Melanosis Peritonei

Melanosis peritonei (MP) is a very rare condition characterized by the presence of melanin-containing cells, either melanocytes or – more commonly – melanin-containing macrophages (melanophages, melanophores) in the subperitoneal tissue, including that of the liver. In MP, the peritoneal surface shows a grossly gray to black pigmentation, in a focal to multifocal or even diffuse distribution pattern. Focal melanosis may grossly mimic deposits of malignant melanomas in the course of laparotomy or laparoscopy. MP has most often been encountered in association with melanin-containing lesions covered by peritoneum, such as inflammatory processes (particularly peritoneal tuberculosis), Addison's disease, ovarian dermoid cysts/mature teratoma, ovarian cystadenomas, and gonadal melanogenic neoplasms (Crampton 1832; Gluge 1841; Afonso et al. 1962; Lee and Pontifex 1975; Fukushima et al. 1984; Kagiya et al. 1990; Hesseling and De Wilde 1998; Jaworski et al. 2001; Kim et al. 2002, 2010; Liu et al. 2007). Exceptional associations are melanophage-containing enteric duplication cysts (Jung et al. 1996; Nada et al. 2000) and gastric triplication (De la Torre Mondragon et al. 1997). In MP associated with ovarian teratomas, a spread of germ cell derivatives has been suggested. In non-teratomatous cysts, a gastrointestinal-type squamous epithelium may be a target structure for melanocyte homing, similar to the epidermis. Melanophages are thought to be transferred to the peritoneal/subperitoneal tissue via lymphatic spread, to mainly form perivascular and perineural accumulations of melanosome-containing macrophages, sometimes with formation of pigment cell nodules (Jung et al. 1996). Also a (phagocytic?) uptake of melanin granules by mesothelial cells has been

described (Kim et al. 2002). A condition macroscopically resembling MP is the peritoneal deposition of iron-containing pigments (Jaworski et al. 2001).

Melanotic Peritoneal Cyst

There is a report on a patient having a multilocular cyst lined by heavily pigmented mesothelial cells. Light and electron microscopy revealed that this pigment was melanin, and underneath the pigmented lining there were scattered melanocytes with a dendritic shape. This type of pigmented cyst may represent a manifestation of primary melanosis peritonei (Drachenberg and Papadimitriou 1990).

Melanotic Alterations of the Peritoneum in Neoplastic Melanocyte Processes

Malignant melanocytic neoplasms can induce melanotic lesions of the peritoneum (Hefaiedh et al. 2009; Lim et al. 2012). These lesions may result from accumulations of melanophages having phagocytosed melanosomes escaped from decayed melanoma cells or represent foci of regressed melanoma metastases. More frequent are growing, i.e., non-necrotic melanin-containing peritoneal metastases of melanoma, with primary lesions both in extra-abdominal and intra-abdominal sites (Gao et al. 2010; Lim et al. 2012), including ocular melanoma (Knapp 1868). Peritoneal deposits of malignant melanoma can develop after a long delay, occurring 10 or more years after diagnosis of the primary tumor (Lee et al. 2003). Apart from malignant melanoma, neurocutaneous melanocytosis and malignant meningeal melanosis can give rise to peritoneal metastases (Kurokawa et al. 2013), in part via tumor cell spreading from ventriculoperitoneal shunting for the treatment of hydrocephalus occurring in this disorder (Faillace et al. 1984; Gattuso et al. 1995; Cajaiba et al. 2008).

Peritoneal Pigmentation in Peutz-Jeghers Syndrome

Apart from its gastrointestinal hamartomatous polyposis phenotype, Peutz-Jeghers syndrome is characterized by circumscribed mucosal pigmentations, especially in the intraoral area. In rare cases, peritoneal pigmentation has been observed (Hirasawa et al. 2012).

Non-melanin Pigmentations of the Peritoneum

Multiple black patches of the peritoneum grossly resembling endometriosis and caused by focal accumulation of carbon particles ("peritoneal tattoos") have been observed following spillage and spread of India ink from preoperative endoscopic tattooing (Algoe et al. 2008; Cappell et al. 2010; Tutticci et al. 2010; Stemmer and Shurshalina 2014).

Reactive Peritoneal Cysts

Peritoneal inclusion cysts are a relatively common finding. They mostly develop following a peritoneal insult and occur in a wide age range and mostly in females (82.5 %; Veldhuis et al. 2013). There are rare instances of multilocular peritoneal inclusion cyst, small but grossly visible thin-walled cysts being lined by a single layer of flat mesothelial cells. The cysts may contain retained ovarian fluid (Bharwani and Crofton 2013). Part of the lesions are accompanied by mural mesothelial proliferations. These lesions have to be distinguished from primary peritoneal serous borderline tumor (PPSBT) (Go et al. 2012), multicystic peritoneal mesothelioma (Vallerie et al. 2009), and primary or secondary peritoneal hydatidosis (echinococcosis; Goel et al. 2010; Kushwaha et al. 2012; Hegde and Hiremath 2013; Lissandrin et al. 2013). Part of peritoneal pseudocysts are caused by accumulation of cerebrospinal fluid due to ventriculoperitoneal shunts (Lejeune et al. 1984; Chandra et al. 1992).

Granulomatous and Other Inflammatory Reactions in Peritoneal Tissues

Numerous inflammatory, infectious, and neoplastic conditions can induce a granulomatous peritoneal reaction (peritonitis granulomatosa), e.g., miliary tuberculosis. Granulomas with a necrotic but not caseating center are seen secondary to diathermy ablation of endometriotic peritoneal lesions. Lost gallstones or gallstone fragments can settle in the peritoneum and elicit a vigorous inflammation, sometimes with gallstone granulomas (so-called gallstone peritonitis). A peritoneal macrophage/histiocytic reaction (histiocytic nodules, histiocytic nodulosis, mucicarminophilic histiocytosis) occurs in association with the deposition of oxidized regenerated cellulose (Gonzalez-Campora et al. 1997; Tang et al. 2009). Nodular macrophage/histiocyte aggregates of the peritoneum have also been observed in patients with ovarian cancer (Lv et al. 2012).

Chronic peritonitis can cause circumscribed, tumor-like plaques of fibrosis or scarring. A distinct variant of fibrosing peritonitis is sclerosing peritonitis, a condition mimicking a desmoplastic tumor manifestation. As a specific entity or syndrome, sclerosing peritonitis can be associated with luteinized thecomas/thecomatosis of the ovary (Clement et al. 1994; Iwasa et al. 1996; Werness 1996; Staats et al. 2008; Levavi et al. 2009; Mellembakken et al. 2010), ovarian fibromatosis (Frigerio et al. 1997), and benign cystic ovarian teratoma (Stenram 1997). Sclerosing peritonitis can also be induced by foreign material, e.g., talcum powder, and also occurs as an idiopathic lesion (Burstein et al. 1990). In part of patients, sclerosing peritonitis presents as an encapsulating fibrosis or "abdominal cocoon" (Wirnsberger et al. 1992; Serafimidis et al. 2006).

Myxoglobulosis of the Peritoneal Cavity

Myxoglobulosis (von Hansemann) is a distinct pathology of the vermiform appendix, characterized by the presence of small globules within thickened, viscous mucus, their size ranging from millet grains to sago seeds (Hentz 1932; Uhle and Wilkinson 1954; Navarrete-Reyan et al. 1969). Myxoglobulosis can manifest in the peritoneal cavity, the form of whitish-gray nodules or globules measuring up to 1 cm in diameter. Many of these lesions were filled with mucinous material. Electron microscopically, the globules were covered by mesothelial cells with microvilli (Tanimura and Imachi 1989).

Peritoneal Changes in Mucinous Ascites

Mucinous ascites is an uncommon condition characterized by accumulation of mucin in the peritoneal cavity in the absence of pseudomyxoma peritonei. It is caused by leakage of mucin from ruptured mucin-producing lesions of the gastrointestinal tract or the ovaries, usually a benign appendiceal mucocele. Mucinous ascites can be differentiated from the ominous pseudomyxoma peritonei microscopically by the absence of epithelial cells amidst mucin pools in the former. Rarely, mucinous ascites is caused by mucinous metaplasia of the mesothelial peritoneal lining (Saran et al. 2008).

Abstract

The main risk factors for the development of hepatocellular carcinoma (HCC) include chronic fibrosing liver disease and cirrhosis. Hepatic fibrosis and cirrhosis are most commonly caused by hepatitis virus infection and numerous nonviral factors. Worldwide, hepatitis B virus and hepatitis C virus infections play a central role as etiologic factors for liver cirrhosis and associated HCC, but in addition to their pro-cirrhosis effect, these viruses can also act as oncogenic agents. A second group of important hepatic inflammatory conditions that increase risk for HCC are various forms of nonalcoholic steatohepatitis and associated metabolic disorders. Hepatotoxic factors that increase HCC risk include alcohol (alcoholic liver disease, in part associated with fibrosing inflammation), aflatoxin, iron (mainly in hemochromatosis), pesticides, and a large spectrum of other toxic molecules. Certain drugs, in particular sex steroids and their derivates, can augment liver cancer risk. Apart from the various types of hemochromatosis, other inborn errors of metabolism bear an increased HCC risk, including Wilson's disease, glycogenoses, and tyrosinemia.

Introduction

The main risk factors for the development of HCC include chronic fibrosing liver disease and cirrhosis, most commonly caused by hepatitis viruses and a long list of nonviral factors involved in human hepatic carcinogenesis (reviews: Jaskiewicz et al. 1991; Okuda 1995; Kew 2000; Anzola 2004; Abdel-Hamid 2009; Dragani 2010; Tsai and Chung 2010; Hamed and Ali 2013; Njei et al. 2015; Table 1). Although more than 80 % of HCC develop in cirrhotic livers, there is a substantial fraction of tumors that are detected in non-cirrhotic livers, with a high variable background of underlying liver changes (Brancatelli et al. 2002).

Hepatitis B Virus (HBV) Infection: A Major Cause of Hepatocellular Carcinoma

Introduction

The hepatitis B and C viruses belong to the most important etiologies for HCC worldwide. In regions with high-level endemicity of HBV infection, HBV as a cause of HCC exceeded HCV as a cause of HCC by a factor of about four. HCCs related to HBV or HCV differ epidemiologically. In a large nationwide Korean cohort ($N = 4{,}630$), the annual incidence rate of HBV-related HCC peaked at the 50–59 age group, whereas the annual incidence rate of HCV-related HCC increased gradually to the =>70 age group. In HBV-related cancers, large tumors and portal vein invasion at timepoint of diagnosis were more frequent, whereas tumor multiplicity was more

common in the HCV group. In addition, HBV-related stage IV tumors were associated with poorer survival than HCV-related stage IV cancers (Sinn et al. 2014).

Hepatitis B Virus (HBV) and HBV-Induced Infectious Disease

Hepatitis B virus (HBV) is a very common member of the *Hepadnavirus* family. The viral particle has been described in detail, as have its protein components which are instrumental in the virus's interaction with host cells and are important antigens for immune reactions raised by the host. The HBV genome is a partially double-stranded DNA with a sequence of about 3,200 nucleotides and a minus strand and a plus strand. The minus strand harbors four open reading frames, encoding pre-S/S envelope proteins, core (pre-C/C) proteins, and X protein.

HBV infection is markedly influenced and regulated by several human genes which affect viral cell binding and entry, synthesis and release of virions, and induction of a host response (review: Zeng 2014). The HBV virion seems to interact with a putative hepatocyte receptor via a myristoylated N-terminal preS1-domain of the HBV large envelope protein/HBV-L (Schieck et al. 2013). Upon binding to host cells, the HBV genome is transferred to the nucleus where it becomes a covalently closed circular DNA, which then serves as a template for transcription of viral DNA through the action of reverse HBV polymerase, to be translated into viral proteins. HBV polymerase is devoid a proofreading ability, and is error prone in its transcribing activity, this being a major reason for the development of HBV genome mutations. HBV exists in the form of several genotypes which have distinct clinical and treatment implications (review: Lin and Kao 2011). There exists a relationship between HBV genotypes and HCC development. HBV genotype C strains with spontaneous YMDD mutations were an independent risk factor for HCC in cirrhotic patients (Yang et al. 2013).

In HBV infection, hepatocytes can show ground-glass changes caused by the cytoplasmic deposition of HBsAg. In comparison with those without HCC, cases with HCC had a significantly higher prevalence of type II ground-glass hepatocytes, with a geographically clustered pattern, and associated with higher grades of hepatic fibrosis. It was suggested that this phenomenon might represent clonal proliferation of hepatocytes with mutated hepatitis B surface antigen (Mathai et al. 2013). Infection of HCC cells can result in the cytoplasmic expression of HBV surface antigen (HBsAg; Wu and Lam 1979). Two patterns of distribution and staining of HBsAg in HCC cells were recognized, i.e., confinement of reactivity to solitary or small groups of positive cells where a large HBsAg-positive body resembling a ground glass inclusion was found and a larger area in HCC where all cells show a diffuse peripheral or perinuclear staining of the cytoplasm (Wu 1979).

HBV Infection and Hepatocellular Carcinoma

HBV infection is one of the most important hepatocarcinogenic factors worldwide (reviews: Tarocchi et al. 2014; Trépo et al. 2014). It is estimated that more than 50 % of HCCs arise in HBV carriers. At least 350 million people worldwide are chronically infected with HBV and are at high risk of HCC. Of all HCCs, 80–90 % develop in cirrhotic livers. As, depending on the viral type, 20–50 % of patients will develop hepatic cirrhosis, cirrhosis is the main liver alteration promoting HCC, which manifests at an annual rate of 1–7 % in HCV-infected patients and 3–8 % in HBV-infected patients (Kew and Popper 1984; Arbuthnot and Kew 2001; Raptis et al. 2003; Lee and Lee 2007; Kew 2010b; Tsai and Chung 2010). HBV induces HCC mainly through two pathways, i.e., induction of inflammation and cirrhosis, a carcinogenic pathway shared with other factors inducing HCC, and via a direct mechanism involving genomic integration and expression of the HBx gene product and other HBV-encoded proteins. HBV also affects

carcinogenic pathways by inducing epigenetic changes through methylation on genes regulating cell proliferation, cell adhesion, and several signaling pathways, including p16INK4A, GSTP1, E-cadherin, RASSF1A, and p21WAF1/CIP1 genes (Rongrui et al. 2014).

Chronic active hepatitis induced by HBV and HCV causes chronic fibrosing hepatopathy ending up in cirrhosis. In the setting of this apparently linear process, hepatocyte regeneration is continuously turned on and results in a probably stepwise emergence of clonally aberrant liver cell populations that start to accumulate transforming mutations due to a complex selection process. This pathway can be histologically followed as a hyperplasia-dysplasia sequence . A crucial step in the hepatocarcinogenic capabilities of HCV is its genomic integration into the host cell genomes. Integration of the HBV genome into the human genome is present in over 80–90 % of HBV-related HCCs and in most instances precedes HCC development. HBV genomic integration is also found in non-tumorous liver in patients with chronic HBV infection. HBV genome integrants have a complex pattern of position in the human genome and were considered to be either random or nonrandom. Integrants prefer fragile sites in the genome or regions which are prone to instability. HBV integration promotes several genetic alterations in the human genome, including deletions, translocations, fusion transcripts, amplifications of genes, and genomic instability. Integration of HBV DNA does not seem to compromise or affect cellular oncogenes or tumor suppressor genes directly, but integrants are often situated close to human repetitive sequences and are capable to transpose to other chromosome regions through reintegration. Generally, integration-induced genomic instability may cause misexpression of oncogenes, tumor suppressors, growth factors, and microRNAs, contributing to cell transformation and carcinogenesis. Frequent targets of HBV genome integration comprise cyclins, PDGFR, calcium signaling gene products, retinoic acid receptor beta, and telomerase. Most HCCs with genomic HBV integration have the integrated HBV X gene and/or truncated pre-S/S genes.

Selected References (Kew et al. 1980; Mori et al. 1980; Beasley et al. 1981; Linsell 1984; Beasley 1988; Chen and Chen 1999; Reeves and DeMatteo 2000; Coleman 2003; Wang et al. 2004; Feitelson and Lee 2007; Lee and Lee 2007; Tsai and Chung 2010; Ng and Wu 2012; Sung et al. 2012; Bai et al. 2013; Bharadwaj et al. 2013; Guerreri et al. 2013; Tarocchi et al. 2014).

Among HBV genome-encoded proteins, the HBV X protein (HBX) plays a central part in the regulation of viral gene expression and replication by transactivating promoters and enhancers that are important for persistent viral infection. The HBX gene often remains functional following integration of HBV DNA into the host cell genome in the course of hepatocarcinogenesis. However, as the HBV DNA is prone to numerous mutations due to the proofreading failures of HBV polymerase, the HBX protein is also subject to mutations which play a role in hepatocarcinogenesis and HCC progression (Xie et al. 2014). The HBX protein is a 154 amino acid residue protein that generally functions as a promiscuous transcriptional activator of polymerase II and III promoters (Henkler and Koshy 1996). HBX and its mutated forms can interfere with numerous cellular processes, including cell cycle induction and progression, apoptotic pathways, signal transduction, transcription regulation, protein degradation, and oxidative stress responses. Part of these HBX-induced deregulations, modified by mutations, plays a role in hepatocarcinogenesis in a complex manner that is only partially understood (reviews: Ali et al. 2014). HBX transactivates numerous cytoplasmic signaling components, including Ras/Raf/MAPK, JNK, PKC, JAK/STAT, PI3K, AP-1, AP-2, Smad, and Wnt, and interferes with cellular calcium signaling (Liu et al. 2011). It causes inactivation of negative growth regulators, inhibition of cell senescence factors, and promotion of telomerase. HBx also acts as an antiapoptotic protein. On the other hand, expression of HBx can induce the expression of the Fas/Fas ligand system. HBX also disrupts a balanced expression of circadian

rhythm genes in HCC. Integration of wild-type and mutated HBV into the host genome markedly compromises genomic stability. Subsequent to integration into host DNA, HBX induces genomic instability mainly via compromising excision repair that is dependent on p53. HBx leads to transcriptional repression of the p53 gene and therefore inactivates several cell pathways that depend in p53, including apoptosis, cell cycle progression, DNA repair, and tumor suppression. The HBx protein modulates the expression of PTEN by inhibiting the function of p53 which promotes PTEN expression via p53-mediated transcription.

Selected References (Su et al. 1998; Murakami 2001; Wu et al. 2001; Chung et al. 2003; Wang et al. 2003; Chan and Oi-Lin Ng 2005; Tanaka et al. 2006; Kew 2011; Ng and Lee 2011; Gong et al. 2013; Motavaf et al. 2013; Xu et al. 2013; Amaddeo et al. 2014; Ji et al. 2014; Tong et al. 2014; Yang et al. 2014; Park 2015).

HBX protein is involved in a distinct feature of HCCs associated with previous or actual hepatitis B virus infection, i.e., ploidy and cell nuclearity. Significantly higher DNA ploidy values with a reduction in the percentage of binucleated hepatocytes were detected in such HCCs (Gramantieri et al. 1996). HBX activates mitogenic Polo-like kinase 1 attenuating DNA damage checkpoint and DNA repair resulting in partial polyploidy (Studaeh et al. 2010).

HBx protein also interacts with distinct sets of microRNAs (Xu et al. 2013). It inhibits tumor suppressor miR-205 through inducing hypermethylation of miR-205 promoter to enhance carcinogenesis (Zhang et al. 2013b). There is also evidence that HBx can cause epigenetic modifications via modulation of methyltransferase transcription (review; Kew 2011). A transactivational function is also exerted by truncated pre-S/S integrated gene products. These proteins can transactivate various host cell genes, such as c-Myc, c-Fos, and Ras (Schluter et al. 1994; Luber et al. 1996), and can upregulate human telomerase. Mutant large pre-S protein can activate endoplasmic reticulum stress-induced oxidative DNA damage and by this promote genomic instability.

Hepatitis C Virus (HCV) Infection

HCV Virus: Its Genotypes, Viral Genome, and Gene Products

Hepatitis C virus (HCV; genus *Hepacivirus* in the family *Flaviviridae*) is a small RNA virus with a genome of about 9.6 kb length. HCV infection is a leading factor in etiology and pathogenesis of chronic liver disease, with about 170–200 million persons infected worldwide, and is a major cause of chronic hepatitis, liver steatosis, and cirrhosis. It has been estimated that HCV infection accounts for 27 % of cirrhosis and 25 % of HCC worldwide (Alter 2007; Rustgi 2007; Banerjee et al. 2010; Jang and Chung 2011; Wang et al. 2012; Thomas 2013; Koike 2014; Lee et al. 2014). The microbiology of HCV is complex, as the virus exists as seven genotypes, 67 subtypes, and numerous so-called pseudo-species (Messina et al. 2015). Distinct genotypes are now recognized to induce characteristic phenotypes of HCV-induced disease. For example, genotype 1 is associated with aggressive disease, increased insulin resistance, and higher risks for cirrhosis and HCC, while genotype 3 is associated with increased risk of steatosis and fibrosis (review: Ripoli and Pazienza 2011). In a meta-analysis, patients infected with HCV genotype 1b had almost double the risk to develop HCC than those infected with other genotypes, mainly in patients with early stage of disease (Raimondi et al. 2009). Recent studies showed that also the HCV genotype 3 is independently associated with a higher HCC incidence in patients with ongoing HCV-induced cirrhosis (Nkontchou et al. 2011). Genotype 5 was neither more nor less hepatocarcinogenic than other HCV genotypes (Kedda et al. 1997). HCV prevalence is highest in Egypt, and China has the largest number of HCV-infected individuals (an estimated 29.8 million; Hajarizadeh et al. 2013). Acute HCV infection is often not detected, due to its generally asymptomatic nature. About 25 % of HCV-infected persons with acute infection

undergo spontaneous clearance, but the majority, i.e., 75 %, progress to chronic HCV infection, which is a major risk factor for liver cirrhosis, and chronic HCV infection is an established risk factor for HCC. The biology of HCV-induced liver disease is also influenced by the fact that, according to recent views, HCV infection must be regarded as a systemic disease rather than a disorder limited to the liver (reviews: Antonelli et al. 2008; Craxi et al. 2008). The estimation of HCV-related risk is complex, because this type of viral infection is associated with other risk factors occurring in HCV-infected patients, including HBV infection, alcoholic liver disease, iron toxicity, and HIV infection (Dimitroulis et al. 2013).

The genome of HCV harbors a long reading frame flanked by untranslated 5′ and 3′ sequences. The positive-strand RNA of the virus encodes a single large polyprotein that is processed by viral and host proteases into at least ten structural and nonstructural proteins. Proteins derived from the NH2-terminal third of the polyprotein provide three structural components of HCV, i.e., core and two envelope glycoproteins, E1 and E2. The core protein is the principal building block of the nucleocapsid, has RNA-binding activity, and exists in several forms with varying molecular weights. The nonstructural protein N2 is involved in polyprotein processing and virus assembly, while five other nonstructural proteins (NS3, NS4A/4B, NS5A/5B) operate in viral RNA replication. NS3 is a serine protease capable of cleaving the polyprotein at four distinct sites and is also an RNA helicase and a component of the RNA replicase complex. Replication of HCV is modulated by several microRNAs (Hou and Bonkovsky 2013; Lee et al. 2014; Li et al. 2014), whereby the most important is the liver-specific microRNA-122 (miR-122). Binding of miR-122 to HCV genomic RNA stabilizes the RNA against nucleolytic degradation in an Argonaute protein-dependent manner, but interaction of miR-122 with HCV RNA also promotes viral RNA translation directed by the internal ribosome entry site located downstream of the miR-122-binding site (Conrad and Niepmann 2014).

Infection Mode of HCV

HCV molecular biology, replication features, and immune responses induced by the virus have been studied in detail and reviewed (Irshad and Dhar 2006; Perrault and Pécheur 2009; Ashfaq et al. 2011; De Giorgi et al. 2013; Kim and Chang 2013). In the liver, hepatocytes are the main reservoir of HCV. HCV enters host cells through a complex mechanism mediated by the viral E2 envelope glycoprotein core structure (Kong et al. 2013). Cell entry requires at least three host cell molecules, i.e., the tetraspanin CD81, scavenger receptor BI (SR-BI), and the tight junction protein claudin1. The highly conserved large extracellular loop of CD81 binds the HCV envelope protein complex E1/E2 (Helle and Dubuisson 2008; Ahmad et al. 2011; Houldsworth et al. 2014). Envelope proteins E1 and E2 interact in a cross talk that is involved in membrane fusion and modulation of the E1/E2 binding to entry receptors (Douam et al. 2014). The expression of viral entry receptors is augmented via cell polarization, whereby tight junctions provide a barrier for viral access to receptors (Mee et al. 2008). On the other hand, HCV infection reduces hepatocellular polarity in a VEGF-dependent manner, in that VEGF depolarizes hepatocytes (Mee et al. 2010). Claudin1 is highly expressed in hepatocytes during HCV infection and has high potential for phosphorylation and O-glycosylation (Ahmad et al. 2011). Claudin1 and CD81 form a complex that is localized to the basolateral surface of polarized cells (Harris et al. 2010). However, claudin use for HCV entry is isolate dependent, and differential claudin1 usage by HCV isolates may evolve based on variable expression of claudins in human liver cells (Haid et al. 2014). There is recent evidence that transferrin receptor 1 plays a role in HCV infection at the level of glycoprotein-mediated entry and acts after CD81, as it is involved in HCV particle internalization (Martin and Uprichard 2013). Infection of the liver with HCV is promoted by factors produced from sinusoidal endothelial cells/SEC. SEC secrete bone morphogenetic protein4/BMP4 as an endothelial-expressed proviral factor that facilitates HCV

infection of the liver. BMP4 expression in SEC is negatively regulated by vascular endothelial growth factor-A/VEGF-A through a VEGFR2-primed activation of p38 MAPK (Rowe et al. 2014).

Hepatocellular Carcinoma in Hepatitis C Virus Infection

Chronic HCV infection is a major risk factor for the development of HCC, and the involved pathogenic pathways have been studied and reviewed in detail.

Selected References (Hasan et al. 1990; Kew 1994; Branda and Wands 2006; Levrero 2006; Jin 2007; Ashfaq et al. 2011; Zheng et al. 2011; Bühler and Bartenschlager 2012; Jeong et al. 2012; Selimovic et al. 2012; Hoshida et al. 2014; Koike 2014; Shlomai et al. 2014; Lin et al. 2015).

In particular, HCV genotype 1b increases the cumulative lifetime risk of HCC (Lee et al. 2014). HCV infection alone can promote the development of HCC, although there is also evidence that risk factors not directly related to the virus modify cancer development, such as age, male gender, severity of liver disease, alcohol abuse, and other viruses (Bruno et al. 2011). Epstein-Barr virus/EBV may act as a helper virus by promoting replication of HCV in the infected liver (Akhter et al. 2003). HCV viral components are operational in several phases or steps of the HCC hepatocarcinogenesis pathway, including the induction of inflammation and genotoxic effects, as HCV can directly or indirectly induce DNA damage (Idilman et al. 1998; Jahan et al. 2012; Rusyn and Lemon 2014; Shawki et al. 2014).

HCV and its viral proteins promote hepatocarcinogenesis through the induction of chronic liver inflammation and hepatic cirrhosis, a main risk factor for liver cancer (Jin 2007). The chronic inflammatory response induced by HCV is not only a crucial element in the pathway leading to cirrhosis, but also affects signaling pathways that promote hepatocarcinogenesis, e.g., TGF-beta signaling (Matsuzaki et al. 2007). Inflammatory responses followed by fibrosis and hepatocarcinogenesis induced by HCV are also modulated by oxidative stress caused by HCV. HCV manipulates the pro- and antioxidant balance in cells and tissues, in part by its influence on lipid metabolism and lipoxigenation (review: Paracha et al. 2013). HCV can also cause hepatic iron overload, which contributes to cell damage and inflammation and is associated with poor prognosis (Drakesmith and Prentice 2008). In HCV-infected cirrhotic livers, leptin receptor somatic mutations are frequent and associated with HCC. Such mutations could disrupt leptin receptor signaling and increase susceptibility to liver carcinogenesis (Ikeda et al. 2014).

HCV infection can elicit a distinct type of hepatic steatosis that may be complicated by inflammatory changes (Syed et al. 2010; Filipe and McLauchlan 2015). As outlined in later paragraph, steatosis and steatohepatitis are now well-established risk factors for the development of HCC. Overall, 6 % of HCV patients have steatosis/steatohepatitis, more often in the presence of HCV genotype 3. HCV-induced steatosis/steatohepatitis is mainly observed in the setting of a distinct spectrum of metabolic abnormalities, comprising insulin resistance, hyperuricemia, reversible hypercholesterolemia, arterial hypertension, and expansion of visceral adipose tissue, a constellation termed hepatitis C-associated dysmetabolic syndrome/HCADS (review: Lonardo et al. 2014). The mechanisms involved in HCV-induced hepatic steatosis and steatohepatitis are not fully clarified, but include downregulation of very low-density lipoproteins/VLDLs, inhibition of adipose triglyceride lipase-mediated lipid mobilization, upregulation of lipoprotein and cholesterol receptors, upregulation of master regulator sterol response element binding protein, HCV core protein interaction with lipid droplet accumulation, HCV interaction with microsomal triglyceride transfer protein/MTP, and attenuated mitochondrial lipid beta-oxidation.

Apart from inducing a necroinflammatory response and hepatic fibrosis, HCV and its diverse viral-specific proteins directly interfere with

numerous functions and signaling pathways of the host cell, and this complex interactome is now considered to play an important role in hepatocarcinogenesis (review: Jin 2007). Four HCV components, namely, HCV core, NS3, NS4B, and NS5A, have been demonstrated to exhibit transformation potential in cultured cells (review: Banerjee et al. 2010). HCV viral proteins cause beta-catenin stabilization as an important carcinogenic pathway. Both HCV core and NS5A induce an accumulation of wild-type beta-catenin known to be involved in HCC pathogenesis (review: Levrero 2006). Beta-catenin-mediated transcriptional activity is elevated by NS5A protein (Milward et al. 2010), and this protein inactivates a component of the beta-catenin signaling pathway, glycogen synthase kinase-3beta, and increases the subsequent accumulation of beta-catenin in HCC cells (Park et al. 2009). HCV interferes with the tumor suppressor, PML/promyelocytic leukemia protein, a central component of PML nuclear bodies (Herzer et al. 2014). HCV proteins trigger numerous stress responses of host cells, including endoplasmic reticulum stress (unfolded protein responses), apoptosis, autophagy, and cell cycle arrest (review: Ke and Chen 2012). By inducing the production of reactive oxygen species (ROS) via affecting the levels of the mitochondrial chaperone, prohibitin, and blunting of antioxidant system, HCV markedly exacerbates oxidative stress, an effect involved in the development of HCC (Fujinaga et al. 2011). There is evidence that HCV viral proteins directly affect the cell division cycle of infected cells. In HCV-infected hepatoma cells, a decrease in the proportions of cells in G1 and S phases and an increase of cells in the G2/M phase were detected, associated with marked decreases of mitosis markers, such as phosphohistone 3. The presence of HCV and its proteins seems to cause cell cycle arrest at the level of initiation of mitosis (Kannan et al. 2011). HCV protein NS5A participates in the oncogenic transformation of hepatocyte precursors and induces epithelial-mesenchymal transition (Akkari et al. 2012). The NS5A protein also promotes genomic instability through downregulation of the spindle gene Aspm, thus inducing an aberrant mitotic cell cycle (Wu et al. 2008). Part of HCV's effects on signaling pathways regulating cell proliferation, apoptosis, and cell migration is mediated by a deregulated expression of microRNAs operational in the HCV viral life cycle (Shrivastava et al. 2013). Similar to HBV, HCV also exerts direct effects on cellular mechanisms via epigenetic changes, causing aberrant methylation on SOCS-1, Gadd45beta, MGMT, STAT1, and APC (Rongrui et al. 2014). The HCV core protein also epigenetically silences the Wnt antagonist, secreted frizzled-related protein/SFRP, causing activation of the Wnt signaling pathway and contributing to HCC aggressiveness via induction of epithelial-mesenchymal transition (Quan et al. 2014).

Nonalcoholic Fatty Liver Disease (NAFL) and Nonalcoholic Steatohepatitis (NASH)

NAFL and NASH are associated with hepatocellular carcinoma.

Both NAFL and NASH may cause progressive liver fibrosis and cirrhosis, followed by HCC in part of the patients, both in Western and Eastern countries (metabolic syndrome-associated HCC).

Selected References (Cotrim et al. 2000; Bugianesi et al. 2002; El-serag et al. 2006; Siegel and Zhu 2009; Blonski et al. 2010; Starley et al. 2010; Kawai et al. 2011; Welzel et al. 2011; Baffy et al. 2012; Jain et al. 2012; Rosmorduc and Fartoux 2012; Sun and Karin 2012; Torres and Harrison 2012; Michelotti et al. 2013; Rahman et al. 2013; Rosmorduc 2013; Yilmaz et al. 2013; Alzahrani et al. 2014; Dongiovanni et al. 2014; Kikuchi et al. 2014).

HCCs developing in NAFLD belong to the category of the so-called non-B, non-C HCC (Nishikawa and Osaki 2013) and have become the most rapidly growing indication for liver transplantation in patients with HCC in the USA (Wong et al. 2014). With a current epidemic of the metabolic syndrome, the number of patients with

NAFL/NASH increases, and it is expected that this increase will translate into an increased incidence of HCC (reviews: Hashimoto and Tokushige 2012; Mangia and Ripoli 2013; Rahman et al. 2013). In a nationwide Japanese survey of 14,530 HCC patients, NAFLD was the cause in 2.0 % and alcoholic liver disease in 7.2 % (Tokushige et al. 2011). As NAFL and NAFLD are strongly linked to obesity with or without diabetes mellitus, obesity-related HCC is regarded as an entity of major worldwide concern (Caldwell et al. 2004; Regimbeau et al. 2004; Shen et al. 2012; Michelotti et al. 2013). HCC in patients with active NASH is either a large solitary mass or a multifocal tumor and may precede clinically advanced disease (Iannaccon et al. 2007, Chagas et al. 2009). There is now strong evidence that HCC can develop already in simple fatty liver, i.e., in the absence of significant fibroinflammatory disease or cirrhosis (Chagas et al. 2009; Ikura et al. 2011; Alexander et al. 2013). However, a systematic review of available data showed that NAFLD or NASH cohorts with few or no cases of cirrhosis had a minimal risk for HCC, while cohorts of NASH and cirrhosis had a consistently higher risk, but the HCC risk was lower than that in cohorts with HCV-associated cirrhosis (White et al. 2012). In patients with NAFLD-associated HCC, the tumor disease is often accompanied by signs of metabolic disorders (Duan et al. 2012). In particular, metabolic disease associated with diabetes mellitus increases the risk of HCC (review: Blonski et al. 2010).

Apart from the procarcinogenic effect of liver cirrhosis as a late sequela of NAFL/NASH, the pathogenic pathways leading from fatty liver with or without associated inflammation to HCC are only partially known. There is evidence that mechanisms causing hepatocarcinogenesis in the metabolic syndrome involve interactions between several signaling pathways deregulated in insulin resistance, including oxidative stress, adiponectin actions, inflammatory cytokine networks and oncogene activation, and insulin resistance as such (review: Siddique and Kowdley 2011). There is also a complex relationship between NAFLD-induced chronic liver damage and hepatocyte injury caused by diabetes mellitus. Diabetes as such also increases the risk of HCC, such a risk correlated with long duration of diabetes (Hassan et al. 2010). The abnormal lipid metabolism characterizing NAFLD, with the emergence of unusual fatty acids, may as such be involved in hepatocarcinogenesis. Metabolites derived from excessive glucose, lipid, and insulin cause oxidative stress, which compromise genomic stability and promote pathologic polyploidization (Gentric et al. 2015). These metabolites also perturb epigenetic gene regulation via DNA methylation, RNA interference, and histone modifications (Tian et al. 2013). In steatosis, histone macroH2A1 isoforms undergo changes in HCC, with macroH2A1.2 specifically upregulated in steatosis-associated HCC (Rappa et al. 2013). NFLD is associated with a profound change in the life history of hepatocytes, consistent with hepatocyte senescence caused by shortening of hepatocyte telomeres (Aravinthan et al. 2013). In murine HCC models, proteomic and lipidomic signatures were different between HCC and NASH, with a significantly altered fatty acid profile in HCC characterized by a conversion of saturated fatty acids to monounsaturated fatty acids (Muir et al. 2013). During hepatocarcinogenesis from NASH, silencing of microRNA-122 through hypermethylation is an early event (Takaki et al. 2014).

HCC developing in livers with NAFLD or NASH often shows a phenotype not different from HCC emerging in other conditions. However, as specified in a separate chapter, part of the tumors exhibit a steatohepatitic morphology (steatohepatitic HCC), being more frequent in patients with NAFLD-associated cirrhosis and significantly associated with metabolic risk factors (Salomao et al. 2010, 2012; Gupta et al. 2014).

NAFL, NAFLD, and NASH: Frequent Hepatic Disorders with Complex Clinical Sequelae

NAFL (nonalcoholic fatty liver), NAFLD (nonalcoholic fatty liver disease), and NASH (nonalcoholic steatohepatitis) are considered to

be hepatic manifestations of the metabolic syndrome, and therefore a novel term has been coined, MAFLD (metabolic syndrome-associated fatty liver disease; Balmer and Dufour 2011). NAFLD encompasses a wide spectrum of disease pathology, ranging from the seemingly benign accumulation of neutral fat (simple hepatic steatosis; NAFL) to progressive NASH associated with necroinflammation and fibrosis (Sugimoto and Takei 2011; Farrell et al. 2012; Mak et al. 2012; Lomonaco et al. 2013). In Western countries, NAFLD is a relatively frequent disorder and has become the most common chronic hepatic disease, with an estimated prevalence of 20–30 % (reviews: Milic and Stimac 2012; Loomba and Sanyal 2013).

The pathogenic mechanisms involved in NAFLD are still incompletely elucidated (Watanabe et al. 2007; Koo 2013; Schuppan and Schattenberg 2013). On a higher homeostatic level, interactions between hepatocytes, hepatic stellate cells, hepatic macrophages, and progenitor cells are involved in a complex cross talk that regulates signaling pathways of lipid metabolism and the hepatic metabolome (Beyoglu and Idle 2013; Carpino et al. 2013). There is genetic predisposition for NAFLD (Anstee and Day 2013), genome-wide association studies having identified several genetic modifiers, including the patatin-like phospholipase domain-containing 3 (PNPLA3; adiponutrin) gene variant I148M (Trépo et al 2011; Dongiovanni et al. 2013; Ezzikouri et al. 2014). Alterations in PNPLA3 expression may be related to hepatocarcinogenesis. A higher risk of HCC was observed for subjects with a homozygous genetic variation in PNPLA3 (Hassan et al. 2013). Carriage of the PNPLA3 rs 738409 C>G polymorphism confers an increased risk of NAFLD-associated HCC (Guyot et al. 2013; Liu et al. 2014). In the pathogenesis of steatosis, the main pathways include excessive availability of plasma fatty acids, increased lipogenesis from carbohydrates, decreased lipolysis, and sequelae of oxidative cell and tissue damage. Lipogenesis from glucose is a crucial process that depends on insulin action and is under the control of a specific transcription factor, sterol regulatory element binding protein 1c (SREBP-1c), activated by insulin and carbohydrate response element binding protein (ChREBP) activated by glucose. SREBP-1c, which is proteolytically activated in the endoplasmic reticulum by the maturating action of insulin, itself activates glycolytic and lipogenic gene expression (Ferré and Foufelle 2010). Lipid metabolism in adipocytes and hepatocytes is critically regulated by the action of adipocytokines, in particular adiponectin (Gatselis et al. 2014). Lack of a major member of this group, adiponectin, as observed in NAFLD, drives steatosis and inflammation, while its presence has an antitumor property and is thought to counteract hepatocarcinogenic pathways (review: Wieser et al. 2012). NAFLD and NASH are associated with significant oxidative stress, whereby lipoperoxidation plays an important role. Through formation of oxidated nucleotides such as 8-hydroxy-2'-deoxyguanosine, this stress response can cause oxidative DNA damage which may be involved in carcinogenesis (Tanaka et al. 2013).

There is a complex link between NAFLD and HCV infection, and in pathways leading to HCC, both disorders may contribute in a concerted manner (Ohata et al. 2003; Pekow et al. 2007; Patel and Harrison 2012). Part of patients with HCV-induced chronic hepatitis exhibit hepatic steatosis, in particular those with the genotype 3. HCV infection is also associated with hypobetalipoproteinemia and hypocholesterolemia (Felmlee et al. 2013). The procancerogenic effects of HCV and cirrhosis are thought to be augmented by the effects of fat accumulation, including lipoperoxidation, action of oxygen radicals, and persistent activation of peroxisome proliferator-activated receptor-alpha, the latter causing marked changes in the lipid metabolism and oxidative stress (review: Koike et al. 2010). Although there is a strong relationship between HCV infection, the metabolic syndrome, and NAFLD, the metabolic syndrome is also associated with cryptogenic HCC, i.e., not related to either HBV, HCV, or alcoholic liver disease (Lee et al. 2013). The progression of NAFLD and hence the occurrence of cirrhosis and HCC are influenced by gut microbiota, through a pathway involving NLRP6 and NLRP3 inflammasomes and the

effector protein interleukin-18, which negatively regulate progression of fatty liver disease (Henao-Mejia et al. 2012).

Other Inflammatory Disorders Promoting Hepatocarcinogenesis in Humans

Introduction

The distinct cellular and molecular environment that develops in the liver in various inflammatory diseases is considered an important factor favoring the emergence of liver cancer (Berasain et al. 2009). Numerous types of chronic hepatic inflammation share common pathways favoring hepatocarcinogenesis. They include ongoing enhanced hepatocyte or cholangiocyte regeneration with an increased risk of accumulating cancerogenic mutations, remodeling of hepatic parenchyma with altered vascular relations, accumulation of immunologic effector cells that secrete cytokines and chemokines favoring abnormal cell growth and angiogenesis, and local induction of oxidative stress associated with genotoxic radical release.

Autoimmune Hepatitis

HCC developing in patients with autoimmune hepatitis (AIH) is a rare situation (Pauwels et al. 1987; Thung et al. 1990; Park et al. 2000; Hardee et al. 2003; Ward et al. 2008; Watanabe et al. 2009; Trivedi and Cullen 2011; Wong et al. 2011; Yamamoto et al. 2011). In some patients of earlier reports of probable autoimmune disease-related HCC, the old term lupoid hepatitis was employed (Satake et al. 1988; Motoo et al. 1989). It is difficult to judge the significance of this association in older reports, because part of them were published before the era of HCV screening, suggesting that part of patients had HCV infection associated with autoimmune features or frank AIH (Geramizadeh et al. 2013). The frequency of HCC in patients with AIH and cirrhosis is estimated to range from 1 % to 9 %, with an annual incidence in cirrhotic patients of 1.1–1.9 % (Wong et al. 2011; Czaja 2013). In Japan, survey results showed that HCC developed in 5.1 % of patients with AIH, with cirrhosis of the liver observed in elderly individuals (Ohira et al. 2013). In Japanese AIH patients, hepatic cirrhosis at presentation was predictive of the development of HCC in AIH (Hino-Arinaga et al. 2012; Migita et al. 2012). In some patients, AIH-associated HCC developed in a liver with cirrhosis and precancerous lesions (Ward et al. 2008), suggesting a dysplasia-HCC pathway in part of AIH patients. HCC was also observed in the setting of IgG4-associated de novo AIH after liver transplantation (Zhao et al. 2013).

Primary Biliary Cirrhosis

Patients with primary biliary cirrhosis (PBC) reveal an increased risk of HCC (Krasner et al. 1979; Mallet et al. 1981; Silveira et al. 2008; Watanabe et al. 2009; Kuiper et al. 2010; Macaron et al. 2010; Imam et al. 2012; Floreani and Farinati 2013). Reported risk factors for HCC comprise age, male sex, cirrhosis, and portal hypertension. Among 210 patients with PBC who were followed up for a median period of 8.5 years, 11 patients (5.2 %) developed HCC (Tomiyama et al. 2013). In studies from Spain and Italy, the prevalences were 3.34 % and 3.36 %, respectively (Cavazza et al. 2009). In surveys from Japan, the incidence and mortality of HCC in PBC patients were significantly higher as compared with the general Japanese population. Among 179 PBC patients, 13 developed HCC (Hosonuma et al. 2013). Using data from two Japanese national surveys, it turned out that 71/2,946 patients with PBC, or 2.4 %, developed HCC. HCC patients associated with PBC showed a significantly poorer prognosis than those without (Harada et al. 2013). In a review of 29 cases, more than 70 % of patients were aged over 65 years, the resected tumors were solitary in 79 %, and the median maximum tumor diameter was 37 mm (Sasaki et al. 2014).

Primary Sclerosing Cholangitis

Primary sclerosing cholangitis (PSC), which develops in about 8.5 % of patients with Crohn's disease, is typically complicated by cholangiocarcinoma, a neoplasm which arises in 10–20 % of patients with long-standing PSC. Rarely, HCC has been found as a late complication of PSC. The prevalence of HCC in patients with PSC is estimated to be around 2 % (Ismail et al. 1991; Votte-Lambert et al. 1993; Guckelberger et al. 1998; Leidenius et al. 2001; Oya et al. 2004; Demarchi et al. 2007). PSC patients with cholangiocarcinoma had a shorter median duration of PSC compared with PSC patients having HCC (Leidenius et al. 2001). HCC also developed in small-duct PSC, a disorder in which the disease either starts in or exclusively involves the small intrahepatic bile ducts (Ali and Shah 2010). HCC has been observed in Crohn's disease in the absence of signs of PSC (Ishida et al. 2010). In addition to ordinary HCC, fibrolamellar hepatocellular carcinoma was observed in a patient with ulcerative colitis and PSC (Snook et al. 1989), and also combined hepato-cholangiocarcinoma was found in association with PSC (Wee et al. 1985). HCC was also observed in the setting of other autoimmune disorders, e.g., Sjögren's syndrome (Yan et al. 2013).

Sarcoidosis

Sarcoidosis of the liver can be complicated by HCC, but sarcoidosis-associated HCC is a rare condition (Askling et al. 1999; Wong et al. 1999; Chalasani et al. 2005; Pila Pérez et al. 2007; Ogata et al. 2010; Arai et al. 2014). As hepatic sarcoidosis can induce hepatic fibrosis and remodeling, this process may be an important risk factor for liver cancer. In one patient with sarcoidosis, HCC was associated with established liver cirrhosis (Chalasani et al. 2005). On the other hand, HCC can elicit a sarcoid granulomatous reaction in the liver (Adachi et al. 1993).

Toxic Compounds as Etiologic Agents for HCC

Aflatoxins

Aflatoxins (AF) are secondary difuranocoumarin-derived mycotoxins produced by a polyketide pathway by the fungi, *Aspergillus flavus* and *Aspergillus parasiticus*. Together with *Fusarium*, *Aspergillus* is the mycotoxigenic genus of greatest concern (Bhatnagar et al. 2002; Kew 2010a, 2012, 2013; Felizardo and Camara 2013; Woloshuk and Shim 2013). The two *Aspergillus* species are widely spread and grow in large numbers in grain and seed products and in vegetable staple food, in particular stapled maize, rice, sorghum, and ground nuts. The two fungi produce AF best at temperatures ranging from 25 to 32 centigrades, a relative humidity of 85 %, and a moisture of greater than 12 % but less than 16 %, illustrating that optimal conditions will exist in certain subtropical and tropical countries. High risks for AF production by contaminating fungi are also related to suboptimal storage facilities, food drying, routine food and staple monitoring, and mold exposure control, due to infrastructural and/or financial shortcomings. In developing countries, staple food is often restricted to few types of vegetables (e.g., rice) that provide the principal food, resulting in the chronic intake of large mycotoxin amounts in case of staple food contamination (review: Kew 2013). Among AF, the most potent carcinogenic agent is AFB1. Exposure of AFB1 in parts of Asia and Latin America and chiefly in Africa may begin early in life (already in utero), followed by episodes of intoxication in adulthood. These episodes are markedly influenced by geographical factors, seasonal factors, agricultural and crop storage practices, and individual food preparation and preference habits (review: Bosch and Peers 1991).

The toxic effects that occur following AFB1 ingestion are summarized under the term aflatoxicosis (Williams et al. 2004). Depending on utilized food sources with variable prevalence of fungal contamination, it is estimated that more than four billion persons living in developing

countries are chronically exposed to largely uncontrolled amounts of this toxin (Enwonwu 1984; review: Williams et al. 2004). Apart from the promotion of liver cancer, AFB1 causes several other toxic effects in man and animals and modulates the course of several diseases in humans, including infections such as HIV infection, because AFB1 affects the function of the immune system.

The hepatocarcinogenic effect of AFB1 has been demonstrated in numerous investigations, case reports, and reviewed several times (Linsell and Peers 1972, 1977; Lutwick 1979; Yuen et al. 2009; Hamid et al. 2013; Kew 2013). It is estimated that between 25,000 and 155,000 persons with HCC worldwide have attracted this cancer due to AFB1 exposure and that about 40 % of these persons live in sub-Saharan Africa (review: Kew 2013). Reviews of available results revealed a high degree of positive correlation between calculated ingestion levels of AFB1 and the adult incidence rates of HCC (Peers and Linsell 1977). AFB1 is also the most potent experimental hepatocarcinogen. Reduced AF exposure (diminished maize consumption) associated with universal HBV vaccination caused a decline in liver cancer mortality in an endemic Chinese region (Chen et al. 2013). In the body, AFB1 is metabolized by the cytochrome P450 system to highly active metabolites, including AFB1-8,9-exo-epoxide, which is in turn converted into 8,9-dihydroxy-8-(N7) gualnyl-9-hydroxy AFB1 adduct. This adduct is then metabolized into AFB1 formamidopyrimidine adduct. These adducts are mutagenic and also alter p53 by inducing an arginine to serine mutation at codon 249. AFB1 negatively regulates the WNT/beta-catenin signaling pathway, a pathway critically involved in hepatocarcinogenesis, via activating miR-33a, a microRNA that downregulates beta-catenin (Fang et al. 2013). The destabilizing action of AFB1 metabolites on DNA is modified by differential expression of the DNA repair genes, XRCC4 and XRCC5, linked to genetic polymorphisms (Long et al. 2013). One mechanism of AFB1-mediated carcinogenesis is its induction of a global DNA hypomethylation, suggesting that AFB1 affects epigenetic pathways (Zhang et al. 2012). There are interactions between AFB1 and dietary iron overload in hepatic mutagenesis, in that the two agents exert a multiplicative effect (Asare et al. 2007).

The carcinogenic effects of AF as such are difficult to assess as many individuals with AF exposure also have other hepatic disorders promoting liver cancer, mainly hepatitis virus infections and in particular HBV infection (Peers et al. 1987). The potency of AFB1 in HBsAg+ individuals is substantially higher (with a factor of about 30) than in HBsAg-negative persons (Henry et al. 2002). The cellular changes induced by hepatitis viral infection are thought to modify the hepatocytes' ability to handle AFB1. For example, it was proposed that HBV-infected hepatocytes are predisposed to AFB1-induced DNA damage and that a combination of viral infection and AFB1 toxicity augments the overall cellular oxidative stress (Wild and Montesano 2009).

Ochratoxin A

Apart from AF, another potential contributor to high incidences of HCC in Asia and sub-Saharan Africa is dietary exposure to ochratoxin A (OTA). OTA is an isocoumarin-derived mycotoxin produces by the fungus, *Aspergillus ochraceus*. This fungus chiefly grows on stapled barley, corn/maize, or wheat, but OTA can be found in a wide array of other foods and beverages, including cereals, beer, wine, coffee, cocoa, and spices. Even some meat and milk products were found to contain OTA. OTA is potent immunosuppressive and carcinogenic agent that induces liver and kidney tumors in experimental animals. However, no epidemiological data are available so far to prove the role of OTA in human HCC (review: Felizardo and Camara 2013).

Alcohol Toxicity and Alcoholic Liver Disease

Chronic alcohol intake and alcoholic liver disease (ALD) are a major risk factor for HCC worldwide

(Marrero et al. 2005; Persson et al. 2013; Purohit et al. 2013; reviews: Morgan et al. 2004; Borro and Testino 2013). Heavy alcohol consumption particularly increases the incidence of HCC in patients infected with hepatitis viruses (Lin et al. 2013). It is estimated that heavy alcoholic consumption for at least 5 years increases the risk of HCC by nearly fivefold, and the risk seems to be roughly proportional to the amount of alcohol consumed (Donato et al. 2002; Munaka et al. 2003). However, the risk of HCC in individuals who consume low or moderate amounts remains unknown.

The pathogenesis of alcohol-associated HCC is complex and involves abnormal regenerative hepatocyte responses following chronic liver cell injury, liver cirrhosis as a general HCC risk factor, induction of inflammation with production of procarcinogenic cytokines, and activation of carcinogenic signaling pathways. In majority of ALD patients with HCC, liver cirrhosis was present (Schütte et al. 2012). A further pathogenic group involves patients who have, in addition to ALD, chronic HCV and/or HBV infections which per se can promote carcinogenesis (Kudo et al. 2014). Hepatitis virus infections can modulate the progression of ALD and may thus exert an impact on hepatocarcinogenesis. For example, the presence of HBV core antibody was associated with more advanced liver disease in alcoholic patients with cirrhosis (Zhang et al. 2013a). Metabolites of alcohol are highly active substances that interfere with numerous cellular pathways. A major catabolic product of ethyl alcohol, acetaldehyde, is known to form DNA adducts, the best known being the mutagenic N(2)-ethyl-2′-deoxyguanosine, a genotoxic molecule (Brooks and Theravathu 2005). In the alcohol-preferring rat model of hepatocarcinogenesis, alcohol activated the hedgehog signaling pathway and the associated downstream gene targets (Chan et al. 2014). There are also epigenetic events in liver cancer associated with alcoholic liver disease. Ethanol exposure can alter the histone acetylation status and interact with regulating miRNAs that control transcriptional events (French 2013).

Occupational Toxins

Occupational exposure to chemicals may be a risk factor for HCC development, although relatively few studies have addressed this problem. Potential occupational substances having a hepatocarcinogenic effect include vinyl chloride, organic solvents, pesticides, polychlorinated biphenyl, and arsenic (review: Uccello et al. 2012).

Drugs and Hepatocellular Carcinoma

Androgens

Sex steroids play an important role in hepatic tumorigenesis, albeit mainly for benign hepatocytic tumors and tumor-like lesions (review: Giannitrapani et al. 2006). HCC, sometimes associated with peliosis hepatis, occurs or occurred as a complication of androgen therapy applied for several indications, including Fanconi's anemia (hereditary aplastic anemia), osteoporosis, and body building (Bernstein et al. 1971; Johnson et al. 1972; Henderson et al. 1973; Ziegenfuss and Carabasi 1973; Meadows et al. 1974; Anthony 1975; Farrell et al. 1975; Holder et al. 1975; Kew et al. 1976; Abbondanzo et al. 1986; Kosaka et al. 1996; Gelfand and Wiita 1997; Velazquez and Alter 2004; Ozenne et al. 2008). However, apart from a role of androgen therapy, Fanconi anemia patients may also have a higher HCC risk due to hepatic iron overload (Ozenne et al. 2008). Liver cell tumors following androgen administration and interpreted as "hepatoma" may not always had been "true" ordinary HCC, as some of the lesions regressed after discontinuation of the drug (Farrell et al. 1975). There is evidence that the synthetic androgenic substance, oxymetholone, used for the treatment of aplastic anemias and osteoporosis, is most often associated with HCC, sometimes after a delay of more than 10 years (Linares et al. 1991; Kosaka et al. 1996; Velazquez and Alter 2004). However, HCC in patients with Fanconi's anemia has been observed in the pediatric age group (Abbondanzo et al. 1986).

HCC has also been observed in individuals treated with danazol (Buamah 1985; Weill et al. 1988; Crampon et al. 1998; Confavreux et al. 2003). This relatively weakly androgenic substance is a derivative of the synthetic steroid, ethisterone, a modified progesterone (17-alpha-ethinyl testosterone), and acts by suppressing the increase of luteinizing hormone during the mid-menstrual cycle. It had been or is used for the treatment of fibrocystic breast disease, hereditary angioedema, and endometriosis, but its use in endometriosis has largely been replaced by other drugs.

Androgens, which are converted to estrogens in the liver by the action of aromatase, bind to specific hepatic androgen receptors. Part of human HCC express androgen receptor (Nagasue et al. 1995), in one study 67.7 % (Vizoso et al. 2007). Androgens binding to the androgen receptor enhance HCC cell growth and apoptosis resistance via activation of PEG10 (paternally expressed gene 10; Jie et al. 2007). Activation of the androgen receptor signaling pathway is thought to play a role in carcinogenesis. In HCC cell lines, activation of androgen receptors promotes cell migration and invasion, in part via expression of the metastasis-promoting gene, ID1 (Ao et al. 2012). The cell cycle-regulated kinase (CCRK) is a direct androgen receptor-regulated gene that drives beta-catenin-dependent hepatocarcinogenesis (Feng et al. 2011). The androgen pathway of hepatocarcinogenesis involves upregulation of miRNA-216a and a subsequent suppression of the tumor suppressor in lung cancer-1 (TSCL1) gene (Chen et al. 2012). Differential functions and expression patterns of androgen receptors are considered to play a role in the striking sexual dimorphism of HCC, with males clearly predominating, also in HBV-associated HCC (Kalra et al. 2008; Yeh and Chen 2010). A cooperation of HBV X (HBVx) protein with androgen receptor signaling pathways contributes to this dimorphism. HBVx correlates with high levels of androgen receptor in HCC and induces androgen receptor expression by stimulating its transcription in a promoter methylation-independent manner (Zhu et al. 2011). HBVx protein enhances the transcriptional activity of the androgen receptor through c-Src and glycogen synthase kinase-3beta kinase pathways (Yang et al. 2009). On the other hand, the androgen pathway can increase the transcription of HBV via direct binding to the androgen-responsive elements sites in viral enhancer I, a possible explanation for a higher HBV titer in male carriers and an increased risk of HCC (Wang et al. 2009). In addition to HBV, HCV infection also affects androgen receptor metabolism, in that HCV viral proteins engage in cross talk with the androgen receptor signaling pathway. HCV core protein activates STAT3, which in turn enhances androgen receptor-mediated transcription (Kanda et al. 2008). Androgen-mediated facilitation of HCC depends on Foxa1/Foxa2, suggesting that Foxa factors and their targets are central for the sexual dimorphism of HCC (Li et al. 2012). Irrespective of the role exerted by androgens in hepatocarcinogenic pathways, all antiandrogenic clinical trials failed in advanced HCC. There is now evidence that hepatic androgen receptor expressions in mice play dual yet opposite roles to promote HCC initiation but suppress HCC metastasis. Hepatic androgen receptors can enhance anoikis and suppress migration of HCC cells through suppression of p38 phosphorylation/activation and the nuclear factor kappB/MMP-9 pathway, respectively (Ma et al. 2012).

Estrogens

HCC has also been observed following long-term estrogen therapy (Sotaniemi et al. 1975) or oral contraceptive use (Davis et al. 1975; Glassberg and Rosenbaum 1976; Henderson et al. 1976; Balasz et al. 1977; Leclère et al. 1977; Pryor et al. 1977; Schmidt 1977; Christopherson et al. 1978; Menzies-Gow 1978; Trias et al. 1978; Amtrup et al. 1980; Shar and Kew 1982; Henderson et al. 1983; Neuberger et al. 1986). In one patient, HCC was diagnosed in pregnancy associated with earlier oral contraceptive administration (Christensen et al. 1981). There are observations of liver cell adenoma associated with oral contraceptive use transformed

into HCC (Gyorffy et al. 1989; Korula et al. 1991). There were indications that oral contraceptive use may increase the risk of HCC in countries with extremely low rates for HCC (Palmer et al. 1989; Prentice 1991). However, the question as to whether there is an etiologic relation between oral contraceptives and HCC is complex, in contrast to benign liver tumors (Baum et al. 1973). Even in early investigations, an etiologic association of HCC and oral contraceptives was not found, an apparent association being interpreted as probably coincidental (Goodman and Ishak 1982). Older studies were, at least in part, not based on carefully selected patient groups and were based on patients using pills that are no longer employed. WHO collaborative multinational case-control studies provided no evidence that short-term use of oral contraceptives enhances the risk of liver cancer in countries where the determinants of this neoplasm are similar to those observed in the countries where the analysis was performed (Anonymous 1989; Thomas 1991). An eventual effect of oral contraceptives on HCC risk may be related to the type of preparation used. There is evidence that a potential association with liver cancer is smaller for recent low-dose preparations (La Vecchia and Bosetti 2009). In the multicenter international liver tumor study (MILTS), a small subgroup of HCC cases without liver cirrhosis and with negative serology for HBV and HCV, there was evidence of an association with duration of oral contraceptive use, but no such trend was observed in the group employing preparations containing cyproterone acetate. Altogether, there was no evidence for an increased risk of HCC associated with cyproterone acetate or cyproterone acetate-like oral contraceptives (Thomas et al. 1997). In an inception cohort study from the UK, comparing 339,000 woman years of observation for never oral contraceptive users and 744,000 woman years for ever users, oral contraception was not associated with overall increased risk of cancer (Hannaford et al. 2007). However, female sex steroid use may alter the pathology and behavior of HCC, in that there is some evidence that such a therapy or administration may induce hypervascularity of tumors and a tendency for bleeding (Hromas et al. 1985). In a literature search published in 2009, no systematic study of contraceptive use among women with hepatocellular adenoma or with malignant liver tumors was identified (Kapp and Curtis 2009).

Hepatocellular Carcinoma in Non-cirrhotic Nodular Lesions of the Liver

A considerable fraction of HCC develops in non-cirrhotic liver, but a minority of them are found in association with other hepatocytic nodular lesions. There are few observations suggesting that HCC can arise in a background of nodular regenerative hyperplasia/NRH (Nzeako et al. 1996; Russmann et al. 2001). An analysis of 804 patients with non-cirrhotic HCC resulted in 23 patients having NRH (Nzeako et al. 1996). A higher incidence of HCC was observed in patients with obstruction of the inferior vena cava in the hepatic portion in chronic Budd-Chiari syndrome, a cause of hepatic venous outflow obstruction (HVOO). Hepatic parenchymal lesions are reported in up to 40 % of patients with Budd-Chiari syndrome, and the most common benign nodular lesions are large regenerative nodules and nodular lesions resembling focal nodular hyperplasia (Zhou et al. 2000; Ibarrola et al. 2004; Newerla et al. 2012). In more than 50 % of patients with chronic Budd-Chiari syndrome, thrombotic events in the portal vein occur (Cazals-Hatem et al. 2003), followed by increased arterial flow compensating low portal venous flow, a hemodynamic situation favoring large regenerative nodules (Tanaka and Wanless 1998). The reported time lag from diagnosis of Budd-Chiari syndrome and HCC ranged from several years to several decades. The pathogenesis has not been clarified, but may be linked to ongoing hepatocyte damage caused by HVOO followed by abnormally increased cell turnover (Nakamura and Takezawa 1982; Havlioglu et al. 2003; Jang et al. 2003; Walldorf et al. 2009). The fact that several types of nodular regenerative lesions commonly develop in Budd-Chiari syndrome supports the view that continuously increased hepatocyte regeneration is a

typical feature of this condition. In two patients Budd-Chiari syndrome complicated by HCC was associated with hepatic fibrosis and liver cirrhosis, respectively (Takayasu et al. 1994). The vena cava can show diverse types of membranous obstruction (MOVC) that most commonly involve the infra-or retrohepatic portion of the vein (Kimura et al. 1965), but less frequently, suprahepatic MOVC occurs (Gips et al. 1972; Suchato et al. 1977). Similar to chronic Budd-Chiari syndrome, MOVC causes hepatic hyperregeneration with nodular lesions (Gips 1972). MOVC, caused by postthrombotic fibrous stricture or a congenital web, is a disorder complicated by Budd-Chiari syndrome (Ciesek et al. 2010; Chen et al. 2011). It is often complicated by HCC, but as this vascular abnormality is rare, it contributes with only a minor fraction to the overall causes of HCC (Nakamura 1982; Okuda 1982; Simson 1982; Hautekeete et al. 1990; Seo et al. 1998; Katoh and Shigematsu 1999; Karia et al. 2000; Matsui et al. 2000; Takamura et al. 2004; Kew and Hodgkinson 2006; Mohan et al. 2009; Srinivas et al., 2012). MOVC has mainly been found in South Africa, India, and Japan and overall seems to be complicated by HCC in 3.7–47.5 % of patients, depending on the populations studied (reviews: Hautekeete et al. 1990; Mohan et al. 2009). Subjects affected are often younger and have a poorer prognosis. In a Korean study of 98 patients with MOVC, liver nodules were detected in 37 patients (38 %), 23 of whom had HCC and 14 of whom had benign nodules. The cumulative incidence of HCC at 1, 5, and 10 years was 7.3 %, 13.5 %, and 31.8 %, respectively (Gwon et al. 2010). In a South African series of patients, 6 of 15 individuals with membranous caval obstruction had concomitant HCC (40 %; Kew et al. 1989). Another investigation on 44 black patients with membranous caval obstruction from South Africa found HCC in 47.5 % of these patients (Simson 1982).

Contents

Abstract

Chronic iron overload causes a broad array of cell and tissue injuries and is an important cause of hepatocellular carcinoma (HCC). Among inborn errors of metabolism, hereditary hemochromatosis with its massive iron overload is the most important risk factor for HCC. In addition to hemochromatosis and few other, rare congenital disorders if iron metabolism, there are several acquired conditions with chronic iron overload of the liver, including transfusional iron overload, metabolic syndrome, dietary iron overload in sub-Saharan Africa, and other forms of nutritional iron overload. Hereditary hemochromatosis exists in several types caused by mutations of the genes for HFE, hemojuvelin, hepcidin, transferrin receptor 2, and ferroportin. Patients with cirrhotic hemochromatosis have approximately a 20–200 times higher risk of developing HCC than a non-cirrhotic control group. In this disorder, the annual incidence of HCC is 4 % once cirrhosis has established, illustrating the important role of cirrhosis as an HCC risk factor. Typically, HCC that develops in hemochromatosis does not store stainable iron, resulting in iron-free nodules or masses in an iron-overloaded cirrhotic background.

Chronic Iron Overload of the Liver as a Hepatic Carcinogen

Introduction

Iron is a critical metal for numerous cellular processes and holds a central position in oxidative phosphorylation. As a toxic element, body iron must be tightly regulated (reviews: Fleming 2005; Anderson and Frazer 2006; Siah et al. 2006; Wang and Pantopoulos 2011). Several hereditary and acquired disorders of iron homeostasis result in chronic iron overload known to cause chronic liver disease and cirrhosis (reviews: Franchini 2006; Siah et al. 2006; Table 1).

Genetically caused hepatic iron overload includes hereditary hemochromatosis (reviews: Beutler 2006; Franchini and Veneri 2005; Adams 2009; Allen 2010; Babitt and Lin 2011; Pietrangelo et al. 2011; Kanwar and Kowdley 2013), thalassemias, hereditary spherocytosis, hemoglobin H disease (Chim et al. 1998), and 3-oxo-delta-steroid 5beta-reductase deficiency (Ueki et al. 2009). Hemochromatosis was already described in the nineteenth century, and its hereditary nature was described in 1935 by Sheldon. Hereditary hemochromatosis is caused by several genetic defects affecting critical proteins involved in iron homeostasis (Babitt and Lin 2011; Pietrangelo et al. 2011; Santos et al. 2012; Table 2).

Table 1 Causes of chronic iron overload

Congenital disorders
Hereditary hemochromatosis (several types)
Inborn errors of metabolism associated with iron overload
Neonatal hemochromatosis (gestational alloimmune liver disease)
Congenital non-hereditary disorders with iron overload (e.g., Pearson's syndrome)
Acquired disorders
Transfusional iron overload (transfusion siderosis)
Metabolic syndrome
Dietary iron overload in sub-Saharan Africa (African iron overload)
Other forms of nutritional iron overload

Type 1 Hereditary Hemochromatosis

The most common defect in hereditary hemochromatosis is deficiency of the HFE protein, mostly caused by the C282Y mutation. Males that are homozygous for C282Y often develop iron overload-related disease, but this effect is less common in females (Allen et al. 2008). Inappropriately low secretion of the iron hormone, hepcidin, which negatively regulates iron absorption, is considered the mechanisms for iron overload in this disorder (Alexander and Kowdley 2009). As the most common form of hemochromatosis is type 1, caused by HFE mutations, this is also the form with the highest number of patients with HCC. Patients with cirrhotic hemochromatosis have approximately a 20–200 times higher risk of developing HCC than a non-cirrhotic control group. In hereditary HFE hemochromatosis, the annual incidence of HCC is 4 % once cirrhosis has been established (review: Villanueva et al. 2010). In HFE-related hemochromatosis, there is a relationship between types of mutations and risk for HCC. Meta-analysis of nine studies showed that the Y allele of C282Y was associated with HCC risk (Jin et al. 2010). However, data regarding the relationship between the genotype and HCC incidence vary from one study to the other, some analyses failing to show that HFE mutations increase the risk for HCC, except C282Y homozygosity (Cauza et al. 2003). In a study of 66,000 cases, the odds ratio for HCC in homozygous C282Y patients was 11 (Ellervik et al. 2007). In a meta-analysis of nine studies, it turned out that Y allele of C282Y was associated with HCC in European alcoholic liver cirrhosis patients (Jin et al. 2010). In one study from the UK, only a very small proportion of HFE C282Y homozygotes developed HCC (Willis et al. 2005), and another investigation demonstrated that the C282Y heterozygous genotype was significantly more common in HCC patients, suggesting that this genotype plays a more important role in hepatocarcinogenesis (Hellerbrand et al. 2003). Patients with homozygous or heterozygous C282Y mutations combined with homozygosity for the transferrin receptor Ser allele showed an increased risk for HCC (Beckman et al. 2000).

Table 2 Types of hereditary (primary) hepatic iron overload

Disease	Transmission	Defect	Locus	OMIM
HH type 1	ar	HFE	6p21	235200
HH type 2A	ar	Hemojuvelin	1q21	608374

Abbreviations: *HH* hereditary hemochromatosis, *TF* transferrin, *ODSBR* 3-oxo-delta-steroid 5beta-reductase, *ALAS* aminolevulinate synthase, *ar* autosomal recessive, *ad* autosomal dominant

There is an association between heterozygosity for HFE gene mutations and hepatitis viruses in HCC, in that multivariate analysis reveled that C282Y heterozygous males were 3.8-fold more likely to be HBV positive and that H63D heterozygous females were 6.0-fold more likely to be HCV positive than wild-type subjects. These associations may modulate hepatocellular iron accumulation and oxygen stress responses (Fracanzani et al. 2005).

HCC in hereditary hemochromatosis is usually associated with liver cirrhosis (Tiniakos and Williams 1988). Iron-storing liver cirrhosis has been described in the early twentieth century already, in part using the terms pigment cirrhosis or, in French, cirrhosis bronzée (Achard and Leblanc 1921; Flinn and von Glahn 1929; Lubarsch 1929; Wegelin 1929; Rosenthal 1932). However, the absence of relevant chronic fibrosing liver disease or cirrhosis was observed part of hemochromatosis patients with HCC (Fellows et al. 1988; Sheehan et al. 1989; Kew 1990; Goh et al. 1999; Köhler et al. 1999; Britto et al. 2000; Pellisè et al. 2001; Von Delius et al. 2006; Hiatt et al. 2007; Singh et al. 2012). In a literature review of 2012, 14 case reports of hemochromatosis patients with HCC in the absence of cirrhosis were found; ten of them had evidence of hepatic iron overload, and the remaining patients lacked significant iron storage in their livers (Singh et al. 2012). However, there are also reports that did not find any patient with HCC in non-cirrhotic hemochromatosis (Fargion et al. 1994). In a non-cirrhotic HFE hemochromatosis patient with HCC, HBV DNA integration in tumor tissue was found (Pollicino et al. 2013), suggesting that occult viral infection may contribute to hepatocarcinogenesis in non-cirrhotic hemochromatosis patients. Primary HCC in hemochromatosis was observed in spite of adequate iron removal through multiple phlebotomies (Hurst et al. 1961; Hines et al. 1971) or after reversal of cirrhosis (Blumberg et al. 1988), suggesting that, at least in part of patients, a basic hepatic defect caused by iron overload may persist even after elimination of risk factors.

Type 2 Hereditary Hemochromatosis (Juvenile Hemochromatosis)

Hereditary hemochromatosis type 2, or juvenile hemochromatosis, is a group of autosomal recessive disorders that affects females and males equally, clinically characterized by early-onset iron overload followed by severe organ dysfunction usually before the age of 30 years. The clinical spectrum is similar to that in HFE-related hemochromatosis, but the signs of organ involvement appear much earlier and progression is more

rapid. In untreated disease, manifestations of heart involvement predominate, with cardiac failure being the most important cause of premature death. Type 2 hemochromatosis appears in two forms, subtype 2A and subtype 2B.

Subtype 2A Hereditary Hemochromatosis

Subtype 2A hemochromatosis (OMIM 608374) is caused by mutations in the hemojuvelin gene. Hemojuvelin plays a central role in iron homeostasis via the hemojuvelin-hepcidin axis, whereby the function of hepcidin as a master regulator of iron handling interacts with hemojuvelin (Zhang 2010). Hemojuvelin belongs to the repulsive guidance molecular family (RGM family), members including RGMa, RGMb (Dragon), and RGMs (hemojuvelin). The regulation of hemojuvelin expression is only partially known. Hemojuvelin is anchored to the cell membrane via GPI, binds the proteins neogenin and BMP2 and BMP4, and can be shed from membranes, this shedding being inhibited in response to iron via the action of neogenin (Zhang et al. 2007). TNFalpha downregulated hemojuvelin expression through transcription suppression within the hemojuvelin promoter (Salama et al. 2012). Hemojuvelin is degraded by matriptase-2, an enzyme that belongs to the family of type II transmembrane serine proteases (Meynard et al. 2011; Wysocka et al. 2014), and by the furin family of protein convertases. Matriptase-2 is directly upregulated by hypoxia-inducible factor-1 (Maurer et al. 2012) and is a negative regulator of hepcidin expression (Silvestri et al. 2008). Matriptase-2 also downregulates BMP/SMAD signaling and via this pathway directly regulates iron homeostasis (Finberg et al. 2010). RGM family proteins exhibit differential BMP-binding properties, whereby membrane-anchored hemojuvelin preferentially binds to BMP6 (Wu et al. 2012), an interaction that is important in the regulation of systemic iron homeostasis in that hemojuvelin-BMP-binding enhances hepcidin expression in hepatocytes. Loss of matriptase-2 increases bone morphogenetic protein-dependent signaling. Downregulation of hemojuvelin prevents inhibitory effects of bone morphogenetic proteins 4 and 6 on iron metabolism, in particular hepcidin expression in HCC (Maegdefrau et al. 2011). Hemojuvelin expression is increased in adipocytes of obese individuals (Luciani et al. 2011), suggesting a signaling pathway for abnormal iron homeostasis occurring in obesity and the metabolic syndrome.

Subtype 2B Hereditary Hemochromatosis

Subtype 2B hemochromatosis (OMIM 606464) is caused by mutations in the HAMP gene encoding the protein hepcidin. Only few cases of this subtype have been reported. Hepcidin has a central role in iron homeostasis and is the most critical systemic iron-regulating hormone (Nemeth and Ganz 2006; Ganz 2007; Lee and Beutler 2009; Camaschella and Silvestri 2011; Kaplan et al. 2011; Singh et al. 2011; Ganz and Nemeth 2012; Adams 2014; D'Anna and Roque 2013; Wu et al. 2013; Zhao et al. 2013; Ruchala and Nemeth 2014). Hepcidin modulates systemic iron balance through a limitation of dietary iron absorption and release of iron from macrophage stores. The pathway for hepcidin-dependent regulation of tissue and plasma iron distribution involved the induction by hepcidin of the degradation of its receptor, the cellular iron exporter ferroportin (Nemeth et al. 2004; Lee and Beutler 2009; Preza et al. 2013). Ferroportin exports iron into plasma from enterocytes, from macrophage iron stores, and from hepatocytes that store liver iron (review: Ganz and Nemeth 2012). Hepcidin synthesis is under the control of serine protease, TMPRSS6 (matriptase-2), an iron sensor (Du et al. 2008; Lee et al. 2009), and is mediated by the bone morphogenetic protein/BMP type I receptors ALK2 and ALK3, and hepcidin induction in response to inflammatory reactions requires cooperative BMP signaling (Finberg 2013), BMP4 and BMP6 being a key endogenous regulator of hepcidin expression (Andriopoulos et al. 2009). BMP4-induced hepcidin expression in turn requires a hemojuvelin-neogenin interaction (Zhang et al. 2009). SMAD7 is a potent inhibitor of hepcidin expression and abolishes hepcidin activation by BMPs (Mleczko-Sanecka et al. 2010). Expression of hepcidin is also under

control of innate immune and infectious stimuli (Armitage et al. 2011) and interleukin-22 (Smith et al. 2013), but hepcidin expression is also subject to an autoregulatory pathway in which prohepcidin regulates expression of the hepcidin gene via binding of prohepcidin to the inflammation-regulated STAT3-binding site in the hepcidin gene promoter (Lane et al. 2013). The proteins HFE, transferrin receptor 2, and hemojuvelin form a membrane-associated multiprotein complex with hepcidin (D'Alessio et al. 2012). Interaction of HFE protein with the transferrin receptor 2 is required for transferrin-induced hepcidin expression. In the autosomal dominant iron storage disorder, ferroportin deficiency, mutant ferroportin is resistant to hepcidin-mediated internalization, whereby an alteration at C326 produces the most severe interaction defect (Fernandes et al. 2009).

Type 3 Hereditary Hemochromatosis

Type 3 hereditary hemochromatosis (OMIM 604250) is caused by mutations in the transferrin receptor 2 (TfR2) gene and is an autosomal recessive disorder (review: Chen and Enns 2012). Transferrin receptors regulated to homeostasis of the transferrin ligand and have a central role in iron metabolism (Gkouvatsos et al. 2012). It is characterized by a phenotype that is close to that of HFE hemochromatosis and exhibits a variable age of onset and a widespread geographical distribution (McDonald et al. 2013; Radio et al. 2014). TfR2 is selectively expressed in the liver and is a homologue of TfR1 and is a molecule with a central role in iron homeostasis, but the details of its function are only partially known. TfR2 is crucial for iron sensing in human hepatocytes (Rapisarda et al. 2010). TfR2 and HFE form a stable complex at the cell surface which increases cellular uptake of transferrin-bound iron (Waheed et al. 2008). The HFE-TfR2 interaction is also required for transferrin-induced hepcidin expression (Nemeth et al. 2005; Girelli et al. 2011). HFE and transferrin receptor 2 regulate furin expression through mitogen-activated protein kinase/extracellular signal-regulated kinase (MAPK/Erk) signaling, indicating that transferrin receptor 2 and HFE are involved in holotransferrin-dependent signaling for the regulation of furin, which in turn may control hepcidin expression (Poli et al. 2010). In contrast to wild-type TfR2, which is expressed both in endocytic structures and on the cell surface, mutated TfR2 is retained in the endoplasmic reticulum and is, therefore, not available as a surface receptor (Wallace et al. 2008).

Type 4 Hereditary Hemochromatosis

Ferroportin 1 (IREG1/MTP1) mutations are the cause of hemochromatosis type 4 (also called ferroportin disease; Détivaud et al. 2013). Ferroportin is a transmembrane channel protein involved in the exit control of iron out of macrophages, erythrocytes, and hepatocytes. The macrophage-monocyte system holds a central role in iron homeostasis (Kong et al. 2013). Ferroportin forms a characteristic transport channel, the ferroportin pore, with a critical tryptophan residue at position 42 of the extracellular end of the pore (Gac et al. 2013). Ferroportin is regulated by its interactions with other iron proteins and by iron-responsive microRNA-485-3p (Sangokoya et al. 2013). In contrast to other types of hemochromatosis, ferroportin disease is an autosomal dominant disorder. It is characterized by failure of iron release from macrophage stores and marked accumulation of stainable iron in hepatic Kupffer cells. Patients with ferroportin disease show early increase in serum ferritin in spite of low transferrin saturation and a decreased availability of iron for circulating transferrin. They also display marginal anemia with low tolerance to phlebotomy. Anemia leads to compensatory increase of iron absorption, which in concert with deficient iron release from cells contributes to iron overload, a "more in-less out" effect (Devalia et al. 2002; Wallace et al. 2004; reviews: Pietrangelo 2004; De Domenico et al. 2006; Mayr et al. 2010). In advanced disease (third and fourth decades of life), parenchymal iron overload becomes significant, but the clinical phenotype is generally milder than that in HFE-related hemochromatosis.

Ferroportin disease can be followed by HCC development (Corradini et al. 2007; Rosmorduc et al. 2008). Ferroportin mutations not only occur in Western countries, but were also detected in the Asia-Pacific region (Solomon Islands; Arden et al. 2003). Ferroportin overexpression in murine macrophages significantly impaired macrophage-mediated cellular immunity, associated with impaired nitric oxide/NO production in response to antigenic stimulation (Johnson et al. 2010). HCC tissue showed a lesser expression of ferroportin than noncancerous liver tissue, and ferroportin levels declined along with the progression of liver cancer (Wang et al. 2013).

Pathology of Hepatocellular Carcinoma in Hemochromatosis

HCC as a complication of chronic hepatic iron overload has most often been observed in the various forms of hereditary hemochromatosis.

Selected References Hibbs 1927; Keith and McNair 1930; Orr 1930; Rosenthal 1932; Point et al. 1957; Nash and Kaung 1962; Cliff 1969; Seshadri et al. 1982; Toyokuni 1996; Willis et al. 1997; Pleass and Garden 1998; Fargion et al. 1994; Beckman et al. 2000; Deugnier and Turlin 2001; Fargion et al. 2001; Haddow et al. 2003; Huang 2003; Lwakatare et al. 2003; Kowdley 2004; Harrison and Bacon 2005; Kew and Asare 2007; Ko et al. 2007; Edgren et al. 2008; Adams 2009; Chen and Chloupkova 2009; Kew 2009; Toyokuni 2009; Blonski et al. 2010; Villanueva et al. 2010; and Gan et al. 2011.

But it also occurs in congenital hemochromatosis (Quante et al. 2011), patients with thalassemic syndromes (Parfrey and Squier 1978) and spherocytosis (Barry et al. 1968; Takegoshi et al. 1984). Irrespective of cause, chronic hepatic iron overload leads to fibrogenesis and progressive hepatic fibrosis ending up with cirrhosis and, in part of patients, cirrhosis-associated HCC (reviews: Chen and Chloupkova 2009; Kew 2009). HCC developing in hemochromatosis is known for more than 100 years (Runte 1901; Loehlein 1907).

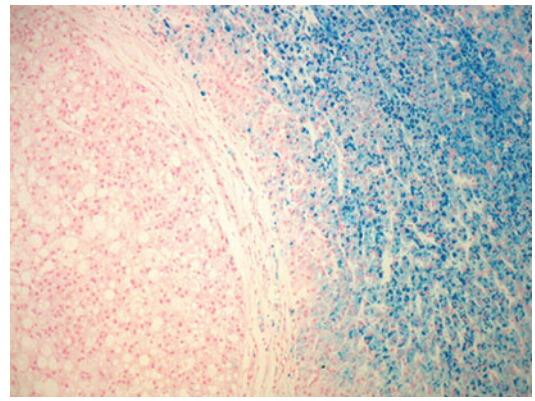

Fig. 1 Hepatocellular carcinoma developing in hereditary hemochromatosis. In this iron stain, the HCC is devoid of stainable iron (*left* of figure), in contrast to marked iron overload of the liver (Perls iron stain)

In most cases, HCC developing in hemochromatosis does not store stainable iron, while the adjacent cirrhotic or non-cirrhotic liver tissue exhibits marked to massive cytoplasmic iron overload (Fig. 1; Bothwell et al. 1965).

Macroscopically, the pale or greenish tumors are easily recognized on a background of a chocolate-brown cirrhotic liver. Iron overload in cirrhotic liver in hemochromatosis has a characteristic distribution and pattern, easily detectable in liver biopsies (Bassett et al. 2011). The stainable iron found in iron-storing hepatocytes is mainly hemosiderin, a structure constructed of crystalline lattices containing ferritin (Richter 1958), but cells may also show a diffuse nongranular background staining in Perls stain, thought to be due to the accumulation of ferritin, an iron/oxygen biomineral contained in protein nanocages (the ferritin nanocage protein superfamily; Andrews 2010; Bevers and Theil 2011; Zhang and Orner 2011; Theil 2013). In some cases, iron-containing nuclear inclusions are found (Altmann 1977). There are few and intriguing exceptions in the form of HCC in hemochromatosis that accumulate significant amounts of stainable iron. In rare cases, accumulation of stainable iron in HCC tissue may be caused by intratumoral hemorrhage (Runte 1901). In one

investigation, HCC arising in hemochromatosis showed frequent biliary differentiation (Morcos et al. 2001). The liver in hereditary hemochromatosis frequently shows sublobular nodules of hepatocytes that are free of stainable iron or displaying much less iron than the adjacent tissue of pigment cirrhosis. These lesions were called iron-free foci. In a study of 185 patients with untreated hereditary hemochromatosis, such lesions were observed in 7.6 % of patients, all men, with an age range of 38–76 years, with hepatic fibrosis or cirrhosis. Ten of these patients had dysplastic features in the iron-free foci, and the foci disclosed increased proliferative activity, suggesting that the foci are preneoplastic lesions (Deugnier et al. 1993).

The molecular mechanisms leading to the exclusion of iron accumulation in HCC cells are only partially clarified. Expression for most of the iron regulatory genes, including hepcidin, transferrin receptor 2, transferrin, ceruloplasmin, and iron regulatory protein 1/IRP1, was significantly downregulated in HCC tissue (Tseng et al. 2009). Also the expression of hepcidin mRNA was uniformly suppressed in HCC (Kijima et al. 2008), suggesting that a reduction of hepcidin in iron-depleted HCC cells reflects a physiologic consequence of the demand for iron in rapidly growing neoplastic cells. A very small subset of HCCs in HCC have shown iron overload of tumor cells, due to so far unknown reasons.

Hepatocellular Carcinoma in Other Genetic Disorders that Affect Iron Metabolism

HCC can develop in patients with thalassemia minor, thalassemia intermedia, and thalassemia major (OMIM 604131) (Borgna-Pignatti et al. 1986, 2004, 2014; Mancuso et al. 2006; Mancuso 2010; Restivo Pantalone et al. 2010; Musallam et al. 2012; Gomatos et al. 2013). Among 36 reported cases of thalassemia-associated HCC, 61 % were found in thalassemia intermedia (Maakaron et al. 2013). HCC emerging in thalassemic syndromes is a rather recent development that is linked to the now longer survival of thalassemic patients (Borgna-Pignatti et al. 2004). A prospective study estimated that the HCC incidence in beta-thalassemia is approximately 2 %, but a more recent study on 144 patients reported an HCC incidence of 5.3 % (Triantos et al. 2013). HCC was found in thalassemia with HCV infection also in the absence of liver cirrhosis (Mancuso et al. 2005). Currently, it is still difficult to judge as to what role iron overload as such is played in HCC of thalassemic patients, because these patients are, due to numerous blood transfusions, often infected with hepatitis viruses, in particular HCV (Ansari et al. 2013; review: Mancuso 2010). In a review of 22 cases of HCC occurring in patients with thalassemic syndrome, 86 % of the patients had been infected with HCV (Borgna-Pignatti et al. 2004), whereas a Greek investigation reported 57/144 patients infected with HCV (Triantos et al. 2013). In regard to the potential role of iron in thalassemia-associated HCC, it was proposed that the main risk factor for HCC was HCV infection in thalassemia major patients but iron activity in thalassemia intermedia patients (Fragatou et al. 2010). HCC was observed in association with hemochromatosis developing in hereditary spherocytosis (Takegoshi et al. 1984), hemoglobin H disease (Chim et al. 1998), and 3-oxo-delta-steroid 5beta-reductase deficiency (Ueki et al. 2009). Hereditary hematologic disorders requiring multiple transfusions can develop transfusion-induced secondary hemochromatosis followed by HCC, e.g., congenital hypoplastic anemia or Blackfan-Diamond syndrome (Steinherz et al. 1976). Several other inborn errors of metabolism are associated with hepatic iron overload, including Δ-aminolevulinate synthase mutations (Lee et al. 2009) and hereditary xerocytosis (dehydrated hereditary stomatocytosis with or without pseudohyperkalemia and/or perinatal edema), characterized by hemolytic anemia, primary erythrocyte dehydration, and iron overload in several organs (Assis et al. 2013). The disorder is caused by gain-of-function mutations in the inactivating eukaryotic cation-selective mechanosensitive ion channel, PIEZO1 (Zarychanski et al. 2012; Albouisson et al. 2013).

Hepatocellular Carcinoma in Acquired Chronic Iron Overload

There are several disorders characterized by acquired iron overload. They include transfusional iron overload, neonatal hemochromatosis, mainly caused by gestational alloimmune liver disease (Bonilla et al. 2012; Whitington 2012; Lopriore et al. 2013) but also found in rare chromosomal anomalies, such as duplication of 16p (Schwaibold et al. 2014), alcoholic liver disease, NAFLD, and dietary iron overload. HCC can develop in acquired forms of iron overload. In general, the risk for HCC development is higher in any type of cirrhosis with increased iron levels (Jaskiewicz et al. 1997; Ito et al. 1999). NAFLD caused by or related to the metabolic syndrome is often associated with hepatic iron overload (Fujita and Takei 2011) and is known to be complicated by HCC. Iron overload in NASH leads, similar to other iron overload situations of the liver, to oxidative DNA damage (Fujita et al. 2009) which in turn results in a promutagenic situation. Patients with other forms of secondary hemochromatosis, e.g., those with hematologic disorders, may also develop HCC (Chung et al. 2003). A further type of chronic overload that may be complicated by HCC is dietary (nutritional) iron overload of rural sub-Saharan Africa, a condition that had previously been termed "Bantu siderosis" or "siderosis in the Bantu" and is now termed African iron overload (Strachan 1929; Bothwell and Bradlow 1960; Gangaidzo and Gordeuk 1995; Mandishona et al. 1998; Moyo et al. 1998; Kew and Asare 2007). The term "Bantu siderosis" would imply that this disorder is restricted to Bantu ethnics; however, significant African iron overload is also known from Uganda, East Africa, Ghana, and Nigeria (review: Gangaidzo and Gordeuk 1995). In former times, severe iron overload was common in sub-Saharan Africa, with a prevalence of more than 10 % in some populations, mainly in South Africa (Gordeuk et al. 1986; Gordeuk 1992). The pathogenesis of African iron overload is not fully clarified. The traditional view has it that this form of dietary iron overload is linked to the consumption of local alcoholic fermented beverage brewed in iron-rich containers (Bothwell et al. 1964). However, the pathogenesis is probably more complex with genetic factors playing a role. There is strong evidence that African iron overload in fact augments the risk for HCC (Mandishona et al. 1998). In an original autopsy series on 114 subjects, 8.8 % with markedly increased hepatic iron storage died from HCC in comparison with 1 patient out of 159 patients (0.6 %) without iron overload (Strachan 1929). In a rural-based liver biopsy study in the Transkei, South Africa, a combination of cirrhosis and severe hepatic iron overload was detected in 38 % of 203 biopsy specimens from 246 patients with HCC (Jaskiewicz et al. 1991).

Iron and Hepatocarcinogenic Pathways

Apart from cirrhosis as an established risk factor for HCC, iron accumulation as such is considered to play a hepatocarcinogenic role, as excess cell and tissue iron has known mutagenic and proliferative effects (reviews: Deugnier et al. 2008; Fargion et al. 2011). The pathogenic pathways of iron-induced HCC are complex. Iron acts as a modulating cofactor in chronic liver disease and is known to accelerate the development of hepatocyte damage (Tirnitz-Parker et al. 2013), but also seems to be a cofactor in tumor cell proliferation (Steegmann-Olmedillas 2011). Free ionized iron is a potent inducer of reactive oxygen species (ROS)/intermediates causing disruption of the cellular redox balance. Via this mechanism, free iron-related oxidative stress causes lipoperoxidation, the resulting highly reactive metabolites leading to DNA injury with formation of mutagenic aberrant nucleotides, such as 8-hydroxy-2′-deoxy-guanosine, which causes G:C to T:A transversions, DNA unwinding, and DNA strand breaks (Asare et al. 2006; Toyokuni 2008; Kew 2009). In hemochromatosis, polymorphism of the patatin-like phospholipase domain-containing-3 (PNPLA3) gene, a gene involved in the pathogenesis of steatosis and hepatic fibrosis, may represent a permissive factor for progression (Valenti et al. 2012). This polymorphism also plays a role fibrosis progression and steatosis in chronic hepatitis C (Trépo et al. 2011) and in the

severity of NASH (Rotman et al. 2010; Speliotes et al. 2010). The genetic alterations occurring in hereditary hemochromatosis lead to epigenetic changes which are already found in nonneoplastic hepatocytes (Lehmann et al. 2007). It also to be expected that mitochondria, with their central role in apoptosis, participate in the regulation of iron metabolism in carcinogenic pathways. Mitochondria possess several proteins involved in iron homeostasis, including mitoferrins 1 and 2; mitochondrial ferritin; ABCBs 6, 7, and 10; and frataxin (Shaw et al. 2006; Richardson et al. 2010; Huang et al. 2011).

Hepatocellular Carcinoma in Inborn Errors of Metabolism Other than Hemochromatosis

Introduction

Several inborn errors of metabolism are risk factors for the development of HCC (Table 3). However, due to the low incidence of most of these congenital disorders, the overall contribution of inborn metabolic diseases to hepatocarcinogenesis is relatively weak.

Table 3 Inborn errors of metabolism complicated by hepatocellular carcinoma

Disorders of copper metabolism

Tyrosinemia
Type II citrullinemia
Alpha-1-antitrypsin deficiency
Dubin-Johnson syndrome
Cholestatic disorders

Wilson's Disease and Other Disorders of Copper Metabolism

Several disorders of copper metabolism are known, both inborn errors of metabolism and acquired disorders (Table 4). Wilson's disease (OMIM 277900) is a rare autosomal recessive disorder of copper transport and metabolism, with an incidence of approximately 1 in 40,000 live births, caused by mutations in the ATP7b gene located to chromosome 13q14.3 (Samuel Alexander Kinnier Wilson, 1912; reviews: Kodama et al. 2012; Broussolle et al. 2013; Kaler 2013; Trocello et al. 2013). The gene product is called ATPase Cu(2+)-transporting beta polypeptide (review: Cox and Moore 2002). Most patients with Wilson's disease are compound heterozygotes in regard to mutated ATP7b gene, a phenomenon which complicates the establishment of genotype-phenotype correlations.

Copper that is an essential element is required for the production of cuproenzymes that include cytochrome C oxidase, lysyl oxidase, dopamine β-hydroxylase, one type of superoxide dismutase, tyrosinase, ascorbic acid oxidase, and ceruloplasmin (Lalioti et al. 2009). As copper is a toxic metal, uptake, transport, storage, and elimination are tightly controlled. Copper transport is accomplished by two ATPases, ATP7a and ATP7b, of which ATP7b is mainly expressed in hepatocytes and mutated in Wilson's disease (review: Rosencrantz and Schilsky 2011). In hepatocytes, copper is delivered to the trans-Golgi network by ATOX1 and then transported across the Golgi through the action of ATP7b which is located in the trans-Golgi membrane (Hasan et al. 2012; Huster et al. 2012). Copper accumulated in the trans-Golgi compartment via this mechanism is incorporated into apo-ceruloplasmin, reduced to holo-

Table 4 Disorders of copper metabolism

Inborn disorders		
Disorder	*Gene involved*	*OMIM number*
Wilsons' disease	ATP7b	OMIM 277900
Menkes disease	ATP7a	OMIM 309400
Occipital horn syndrome	ATP7a	OMIM 304150
X-linked distal hereditary motor neuropathy	ATP7a	
MEDNIK syndrome	AP1S1	
Aceruloplasminemia	Ceruloplasmin	OMIM 604290
Congenital cataracts, hearing loss, and neurodegeneration	SLC33A1	OMIM 614482
Acquired disorders		
Idiopathic copper toxicosis		

ceruloplasmin, and then transported as ceruloplasmin into the blood. The transport of copper to bile also requires ATP7b. In addition to this ATPase, the COMM domain-containing protein1/COMMD1 (previously termed MURR1; Sarkar and Roberts 2011) is also active in biliary excretion of copper. Failure of ATP7b function leads to markedly impaired copper transport out of hepatocytes and copper storage in these cells (review: Kodama et al. 2012).

The histopathologic spectrum of liver lesions caused by Wilson's disease is very variable, ranging from minor cellular alterations associated with the presence of stainable copper to cirrhosis with or without marked hepatocellular injury (reviews: Johncilla and Mitchell 2011; Sini et al. 2013). Wilson's disease is known to be associated with HCC, usually in the setting of Wilsonian liver cirrhosis (Vachon et al. 1973; Kamakura et al. 1975; Wilkinson et al. 1983; Guan et al. 1985; Polio et al. 1989; Cheng et al. 1992; Kumagi et al. 2005; Xu et al. 2007; Ikegawa et al. 2011), albeit controversial informations have been presented referring to HCC incidences. In one study, HCC in Wilson's disease was reported as an extremely rare event (Cheng et al. 1992), while another study arrived at an opposite conclusion (Sternlieb 2000). HCC in the setting of Wilson's disease can already develop in childhood and may occur in non-cirrhotic livers (Thattil and Dufour 2013). As copper is a metal that generates reactive oxygen species, oxidative cell injury may be a crucial mechanism involved in carcinogenesis. Copper (Cu2+) causes apoptosis of several cell systems, including erythrocytes (eryptosis; Lang et al. 2012).

Mutations of the second copper-transporting ATPase, ATP7a, causes Menkes disease (kinky hair disease or steely hair disease, OMIM 309400), occipital horn syndrome, and X-linked distal hereditary motor neuropathy. Similar to ATP7b, the Menkes copper transport protein ATP7a is located to the trans-Golgi network and is an intestinal copper transporter (Dierick et al. 1997). Hepatic copper storage is also a feature of the MEDNIK syndrome, characterized by mental retardation, enteropathy, deafness, neuropathy, ichthyosis, and keratoderma. The disorder is caused by AP1S1 gene mutations. This gene encodes delta-1A, the small subunit of the adaptor protein 1 complex critically involved in clathrin coat assembly and regulation of trafficking between trans-Golgi network, endosomes, and the plasma membrane (Montpetit et al. 2008; Martinelli et al. 2013).

There are several acquired disorders of copper metabolism, including idiopathic copper toxicosis (Hayashi et al. 2012). A distinct situation is the complex of disorders summarized under the term Indian childhood cirrhosis (ICC). ICC is a distinct disease that has been endemic in most parts of India and interpreted to be the result of excess dietary copper intake. ICC presents with a phenotype similar to that of Wilson's disease, but is not caused by ARTP7 gene mutations. ICC has now disappeared from most areas of India, but still exists in Andhra Pradesh and other parts of India

(Singh et al. 1959; Pandit and Bhave 1996; Tanner 1998; Sriramachari and Nayak 2008; Nayak and Chitale 2013; Patra et al. 2013). A clinically related disorder is North American Indian childhood cirrhosis (NAIC, OMIM 604901), described in aboriginal children from northwestern Quebec and characterized as distinct form of neonatal familial cholestasis, severe fibrosis, and marked involvement of bile ducts (Drouin et al. 2000). NAIC is associated with mutations of the human ribosome biogenesis factor, hUTP4/Cirhin (Chagnon et al. 2002; Richter et al. 2007; Freed and Baserga 2010). Cirhin is localized to the nucleolus (Yu et al. 2005) and is a component of the small ribosomal subunit processome and interacts with Cirip, a functional, alternative splice variant of the HIVEP1 protein. An interaction factor of Cirhin is a nucleolar protein, NOL11, required for pre-rRNA transcription and processing (Freed et al. 2012). The function of Cirhin in the development of the hepatobiliary system has been studied in a zebra fish gene knockdown model (Wilkins et al. 2013). An Indian childhood cirrhosis-like condition has also been observed in Japan (Nagasaka et al. 1999). A form of non-Indian childhood cirrhosis (NICC) with copper storage has been observed in Europe and proposed to be associated with exogenic infantile copper intoxication (Müller et al. 1999; Müller-Höcker 1999). A further variant is endemic Tyrolean childhood cirrhosis which was observed in more than 130 infants and children in western Austria between 1900 and 1974. The disorder has disappeared from this area since 1974 and is not an allelic variant of Wilson's disease but may represent a disease requiring both genetic and environmental factors in the sense of an ecogenetic disorder (Müller et al. 1996; Wijmenga et al. 1998; Tanner 1999; Pandit and Bhave 2002).

Porphyrias

Several forms of porphyria are associated with HCC in part of involved patients, including acute intermittent porphyria, variegate porphyria (an acute porphyria caused by partial deficiency of protoporphyrinogen oxidase), hereditary coproporphyria, and sporadic porphyria cutanea tarda.

Selected References Andant et al. 1997; Bengtsson and Hardell 1986; Berman and Braun 1962; Bjersing et al. 1996; Cassiman et al. 2008; Deybach and Puy 2011; Lim and Mascaro 1995; Lithner and Wetterberg 1984; Salata et al. 1985; Schneider-Yin et al. 2010; and Stewart 2012.

In patients with porphyria cutanea tarda, the pathogenesis of liver tumors is particularly complex, as this form of porphyria is associated with HCV and HBV infection, hemochromatosis/iron overload, and specifically alcoholic liver disease, known causes of HCC (Ryan Caballes et al. 2012). Relatively few patients develop HCC in porphyria cutanea tarda, with a yearly incidence of less than 1 % per patient year of follow-up (Kordac 1972; Packe and Clarke 1985; Gisbert et al. 2004; Whittle et al. 2010), and risk factors for HCC were the presence of liver cirrhosis, male sex, and age over 51 (Salata et al. 1985). Porphyria cutanea tarda can occur in combination with hereditary hemochromatosis, the condition being complicated with HCC (Mogl et al. 2007). On the other hand, HCC can induce pseudo-porphyria through production of large amounts of porphobilinogen (Pierach et al. 1984; Ochiai et al. 1997) or porphyrins, resulting in acquired cutaneous porphyria (Keczkes and Barker 1976).

Glycogen Storage Diseases

A minority of the many types of glycogen storage disease can be associated with HCC. Most observations documenting such an association refer to glycogenosis type Ia, an autosomal recessive disorder caused by deficiency of glucose-6-phosphatase (von Gierke's disease, OMIM 232200).

Selected References Zangeneh et al. 1969; Grossman et al. 1981; Limmer et al. 1988; Conti and Kemeny 1992; Bianchi 1993; Franco et al. 2005; Okuda et al. 2009; Manzia

et al. 2011; Ochi et al. 2011; Bashir et al. 2012; and Mikuriya et al. 2012.

Glycogenosis type Ia is a very rare disorder, with an incidence of 1 in 100,000 to 1 in 300,000 live births, and is chiefly characterized by hepatomegaly, a rounded doll-like face, growth retardation, hypoglycemia during fasting, and a hemorrhagic diathesis caused by impaired platelet aggregation. A well-known and common hepatic complication of this glycogenosis is the emergence of liver cell adenoma, which was detected by sonography in up to 73 % of patients (Talente et al. 1994). In contrast, HCC and focal nodular hyperplasia (FNH) are less common events. In one study of 22 patients with glycogenosis type Ia and liver tumors, liver cell adenoma, HCC, FNH, and hepatoblastoma accounted for 16, 3, 2, and 1 case, respectively (Sumimoto et al. 1988). HCC in patients with glycogenosis type Ia can synchronously be associated with other hepatic nodular lesions, e.g., focal nodular hyperplasia (Mikuriya et al. 2012). In part of reported HCC in patients with the type Ia disorder, transition from liver cell adenoma to HCC was observed, in one report in 50 % of cases (Bianchi 1996). For both adenoma and HCC occurring in glycogenosis, the pathogenic pathways of tumorigenesis are not known.

Other glycogenoses sometimes complicated by HCC are glycogenosis type III (debrancher enzyme deficiency, Cori or Forbes disease, OMIM 232400; Shimizu et al. 1982; Haagsma et al. 1997; Siciliano et al. 2000; Cosme et al. 2005; Demo et al. 2007), glycogenosis type IV (brancher enzyme deficiency, Andersen disease, OMIM 232500; de Moor et al. 2000; Onal et al. 2009), and glycogenosis type VI (phosphorylase deficiency, Hers disease, OMIM 232700; Manzia et al. 2011). In glycogenosis type III, development of HCC may be related to liver cirrhosis known to occur in a subset of patients of this disorder, although hepatic involvement is considered mild and self-limiting in most patients (Haagsma et al. 1997; Siciliano et al. 2000; Demo et al. 2007). In some patients with glycogenosis, potential nodular precursor lesions developed, including adenomatous hyperplasia in a female patient with glycogenosis type VIII (phosphorylase kinase deficiency, OMIM 306000; Shiomi et al. 1989).

Lipid and Glycolipid Disorders

Among disorders of lipid and glycolipid metabolism, Gaucher's disease (glucocerebrosidosis) is sometimes complicated by HCC (Arends et al. 2013). Familial hypobetalipoproteinemia (OMIM 615558) is characterized by fatty liver and is in most cases caused by defects in the APOB gene, encoding a short apolipoprotein B-48 and a longer apolipoprotein B-100. In most APOB mutations, both of these apolipoproteins are short versions which fail to transport fat and cholesterol. Three genetic forms are known, i.e., premature stop codon specifying mutations of APOB, a form linked to a susceptibility locus on chromosome 3p21, and a form linked neither to APOB nor to chromosome 3p21 (Schonfeld et al. 2005). There are several reports documenting associated liver cirrhosis and hepatocellular carcinoma (Lonardo et al. 1998; Cefalu et al. 2013). A related disorder is caused by mutations in the ANGPTL3 gene (angiopoietin-like 3 protein), associated with combined hypolipidemia, extremely low levels of serum low-density lipoprotein cholesterol, low high-density lipoprotein cholesterol, and low triglycerides (Musunuru et al. 2010; Noto et al. 2012). HCC was found in patients with cholesterol ester storage disease (Riva et al. 2008) and Niemann-Pick's disease (Pennington et al. 1996; Birch et al. 2003).

Amino Acid and Protein Disorders

Tyrosinemia

Tyrosinemias form a group of hereditary disorders characterized by elevated serum tyrosine levels and, dependent on the type of disease, several patterns of clinical sequelae. Hereditary tyrosinemia type I (tyrosinemia I, OMIM 276700) is an autosomal recessive disorder caused by deficiency of fumarylacetoacetase, the

last enzyme of tyrosine catabolism. Tyrosinemia I causes progressive liver disease that results in micro- and macronodular cirrhosis in early childhood and is associated with secondary renal tubular dysfunction leading to hypophosphatemic rickets (Fanconi syndrome) (review: Russo et al. 2001). HCC occurs in about a third of patients with the chronic form of hereditary tyrosinemia I (Gentz et al. 1969; Weinberg et al. 1976; Day et al. 1987; Dehner et al. 1989; Castilloux et al. 2007). In chronic tyrosinemia I, HCC may develop after a long delay, e.g., in a patient aged 37 years, despite a favorable biological environment in the liver (Kim et al. 2000), and in the presence of so-called "silent" tyrosinemia (Castilloux et al. 2007). In a review performed in 1976, 16 cases of HCC in patients surviving beyond 2 years of age (37 %) had been reported in 43 patients with tyrosinemia I. This incidence was considerably higher than that known for the development of HCC in adults with macronodular liver cirrhosis, suggesting additional factors playing a role in the pathogenesis of HCC (Weinberg et al. 1976). The morphology of HCC in tyrosinemia is not different from other HCCs.

Livers in tyrosinemia I may show multiple hepatic nodules that are not HCC (Day et al. 1987; Shteyer et al. 2011). These nodules appear as high-attenuation hepatic foci on CT scans, but may not be visualized on sonograms. Pathologically, the lesions are regenerating nodules (Day et al. 1987). In acute tyrosinemia type I, hepatic remodeling with micronodularity of the liver may develop. This alteration is sometimes associated with focal fatty change, resulting in multiple intrahepatic mass lesions mimicking HCC (Tazawa et al. 1990). Hepatoblastoma has been found in a patient with tyrosinemia I following treatment with NTBC (Nobili et al. 2010).

Alpha-1-Antitrypsin Deficiency

HCC is a reported complication of alpha-1-antitrypsin deficiency (AATD; Kew et al. 1978; Köhnlein and Welte 2008). AATD is now classified as a serpinopathy, a group of disorders characterized by inappropriate conformational change and self-association or polymerization of serpin (serine proteinase inhibitor) molecule within the endoplasmic reticulum (Knaupp et al. 2010). AATD is a rather common congenital metabolic disorder characterized by numerous mutations, however, with the Z allele being predominantly associated with liver disease. PiZZ homozygotes occur in about 1 in 2000–5000 births in Western countries (review: Teckman 2013). HCC in AATD chiefly occurs in male patients and develops in several AATD genotypes. HCC was found as a complication of ATAD in the PiZZ phenotype, but there are also reported cases for the MZ phenotype, heterozygous ATA deficiency regarded as a cofactor for chronic liver disease and HCC, in the PiSZ genotype, and the Mmalton variant. The prevalence of HCC in patients with ATA deficiency was comparable to that of HCC in patients with cirrhosis of other etiologies. Apart from HCC, AATD may also confer genetic risk for cholangiocarcinoma.

Selected References Eriksson and Hägerstrand 1974; Rawlings et al. 1974; Schleissner and Cohen 1975; Palmer and Wolfe 1976; Rubel et al. 1982; Reid et al. 1987; Propst et al. 1994; Elzouki and Eriksson 1996; Zhou and Fischer 1998; Zhou et al. 2000; Rudnick and Perlmutter 2005; Mihalache et al. 2011; and Perlmutter and Silverman 2011.

The pathogenic pathways leading to HCC in ATA deficiency are incompletely known, but cirrhosis and other cirrhosis-related risk factors and the associated chronic augmentation of liver cell turnover are proposed to be involved (Perlmutter 2006; Topic et al. 2012). Patients with ATA-related cirrhosis showed a high prevalence of hepatitis viral infection (Propst et al. 1992). The abnormally folded AAT polymers that accumulate in the cisterns of the endoplasmic reticulum impair luminal protein mobility and sensitize the cell to endoplasmic reticulum stress (Ordonez et al. 2013), a factor known to be involved in neoplastic transformation. In fact, continuously augmented cell loss and compensatory hepatocyte regeneration are considered a driving force for carcinogenesis in AATD (Perlmutter 2006). The

cytotoxic effects exerted by the abnormally folded serpin are counteracted by the degeneration of the abnormal proteins by both proteasomal and autophagic pathways (Kamimoto et al. 2006), and these pathways may fail in the course of abnormal regeneration. In the course of disease, ATA undergoes stepwise changes in the degree of fucosylation ending up with a HCC-specific modification (Comunale et al. 2010).

Citrullinemia

HCC was found as a complication of asymptomatic adult-onset type II citrullinemia caused by mutations in the SLC25A13 gene and associated with citrin deficiency (Hagiwara et al. 2003; Tsai et al. 2006; Soeda et al. 2008). Downregulation of citrin, a mitochondrial aspartate-glutamate carrier primarily expressed in hepatocytes, is associated with hepatocyte apoptosis through the mitochondrial death pathway (Sawada et al. 2007), and this deregulation of cell survival and compensatory mechanisms may be involved in carcinogenesis. On the other hand, citrullinemia type II causes hepatic steatosis (Tsai et al. 2006), which as such is a known risk factor for HCC.

Inborn Cholestatic Syndromes and Disorders of Bilirubin Metabolism

Congenital disorders associated with severe cholestasis are known to be a risk factor for HCC, including progressive familial intrahepatic cholestasis/PFIC (Ugarte and Gonzalez-Crussi 1981; Knisely et al. 2006; Davit-Spraul et al. 2010), Alagille syndrome (Kim et al. 2005; Tsai et al. 2010), biliary atresia (Hol et al. 2008; Hadzic et al. 2011), and congenital liver fibrosis (Adams 1986). In PFIC, PFIC2 caused by mutations in ABCB11 encoding the bile salt pump/BSEP has a higher risk of HCC in comparison with PFIC1 (Davit-Spraul et al. 2010). Several types of disorders of bilirubin metabolism can be complicated by HCC, e.g., Dubin-Johnson syndrome (Okamura et al. 1980; Sakamoto et al. 1987; Shikada et al. 2004).

Etiology and Pathogenesis of Hepatocellular Carcinoma: Chromosomal Alterations, Oncogenes, Tumor Suppressors, and Associated Signaling Networks

166

Contents

Abstract

In addition to the common viral and nonviral causes of hepatocellular carcinoma (HCC), etiology and pathogenesis of this malignancy depend on a wide array of chromosomal alterations, oncogenes, tumor suppressors, and associated signaling networks. HCC is associated with various recurrent chromosomal aberrations that are in part detectable in early-stage HCC already. Certain of these aberrations occur at high frequency and are alterations that can be employed in a diagnostic setting, e.g., chromosomal loci 8p and 8q, and several other loci with gains or losses. The loci defined by these LOH patterns harbor genes involved in hepatocarcinogenic pathways. The main gene products encoded by these genes include transcription factors (e.g., p53), receptor tyrosine kinases and other kinases, GTPases (such as Ras), components of the Wnt/beta-catenin signaling pathway, TGF-beta1 and associated signaling proteins, PTEN, and the Hedgehog signaling pathway.

Hepatocellular Carcinoma in Chromosomal Breakage Syndromes

Several progeroid disorders are characterized by early development of a phenotype of premature aging resembling "old man" appearance, a lipodystrophy phenotype, and the emergence of malignancies at young age. These features are

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_166

particularly characteristic for neonatal progeroid syndrome or Wiedemann-Rautenstrauch syndrome (OMIM 264090; review: Hou 2009), while adult progeria or Werner syndrome is characterized by a thin body. HCC can develop in progeroid syndromes (Ruijs et al. 2003) and in adult progeria/Werner syndrome, which has a defect in fibulin 3 expression (Okano et al. 2011).

Familial Clustering of Hepatocellular Carcinoma

There are relatively few reports documenting familial clustering of HCC, apart from cases related to inborn errors of metabolism as outlined above. Familial primary HCC was first reported to occur in three adult male siblings in 1965 (Kaplan and Cole 1965), and a second observation referred to three brothers with HCC, aged 11, 22, and 31 years, at diagnosis (Hagstrom and Dee Baker 1968). Familial occurrence of early-onset HCC was observed in patients showing a new segmental progeroid syndrome with genomic instability. The patients showed biallelic germline mutations in SPRTN (also termed C1orf124, DVC1, or Spartan), a protein involved in the prevention of DNA replication stress during general DNA replication and replication-related G2/M checkpoint regulation (Lessel et al. 2014). DNA-protein cross-links (DPCs) are highly toxic compounds which interfere with DNA transactions. Such cross-links can be repaired by Spartan (SprT-like domain-containing protein)/DVC1 (DNA damage protein targeting VCP), a protease of the eukaryotic DPC protease family which allows translesional DNA synthesis, a DNA damage tolerance process allowing DNA replication machinery to replicate past nucleotide lesions. Spartan/DVC1 is deficient in a progeroid syndrome and is a PCNA (proliferating cell nuclear antigen)-interacting protein. Binding to PCNA is a crucial step in lesion repair, because DNA damage-induced PCNA ubiquitination serves as a molecular mark to orchestrate postreplication repair. Spartan is directed to sites of DNA damage in a mechanism dependent on PCNA ubiquitination, PIP box, and UBZ domain, and Spartan interacts with Rad18, the E3 ubiquitin ligase that modifies PCNA (Centore et al. 2012; Ghosal et al. 2012).

Oncogenes, Tumor Suppressors, and Other Molecular Features in Hepatocarcinogenesis

Introduction

Liver cancers, in particular HCC, are subject to multiple genetic/genomic changes that involve genes that regulate growth, differentiation, apoptosis, and invasion and involved in hepatocarcinogenic pathways. The molecular signatures that are progressively identified in liver cancers will result in novel molecular classification that can serve for improved treatment stratifications.

Selected References Buendia 2002, 2007; Feitelson et al. 2002; Coleman 2003; Dufour et al. 2007; Martin and Dufour 2008; Wong and Ng 2008; Feo et al. 2009; Hoshida et al. 2009; McGivern and Lemon 2009; Merle and Trepo 2009; Totoki et al. 2011; van Malenstein et al. 2011; Calvisi et al. 2012; Li and Mao 2013; Nishida and Kudo 2013; Ramakrishna et al. 2013; Kirstein and Vogel 2014; Zhang et al. 2014.

Chromosomal Loci Involved in Hepatocarcinogenesis

HCC is characterized by a wide array of recurrent chromosomal aberrations that are sometimes detectable in early-stage HCC already (Piao et al. 1998; Homayounfar et al. 2013). Certain of these aberrations occur at high frequency and are, therefore, leading alterations that can be employed in a diagnostic setting, e.g., the loci 8p23 and 8q (Nagai et al. 1997; Chang et al. 2002). Recurrent losses of several loci in HCC mainly involve chromosome arms 1p, 4q, 6q, 8p, 9p, 10q,13q, 16q, and 17p, and chromosomal gains mainly involve 1q, 6p, 8q, 17q, and 20q, whereby loss of 4q and 16q seems to occur

predominantly in HBV-related HCC (Laurent-Puig et al. 2001; Nishida et al. 2003). LOH of 8p is already detectable in nodular precursor lesions (dysplastic nodules) HCC at relatively high frequency, and less often, dysplastic nodules display LOH of other chromosomes, such as 11p13 (Kahng et al. 2003). The loci defined by these LOH pattern harbor genes that play important roles in hepatocarcinogenic pathways. In the following paragraphs, reference is made for some of these loci in case the respective genes have been studied in detail.

Genetic Alterations in Hepatocellular Carcinoma: Genomic Signatures as an Instrumentarium for Risk Stratification and Personalized Treatments

HCCs show distinct patterns of recurrent gene alterations that involve several regulation and signaling pathways and include numerous (hundreds) altered genes. Patterns, e.g., comprise changes of tumor suppressors, growth regulators, the p53 pathway involved in apoptosis, chromatin remodelers, and components of the Wnt pathway. The detailed analysis of such genomic alterations and the evaluation of diverse omics result in the formulation of mutational landscapes of HCC and characteristic molecular signatures that may serve for improved cancer stratifications, transcriptome classifications, and future therapies.

An array-based comparative genomic hybridization (AB-CGH) study revealed 722 dysregulated genes in HCC (Skawran et al. 2008). Liver cancers develop in the setting of complex mutation patterns of tumor oncogenes and tumor suppressor genes. The broad array of tumor suppressors, growth factors, and signaling pathways operational in HCC pathogenesis and biology have been reviewed, and important genes are summarized in Table 1 (Ozturk 1999; Dufour et al. 2007; Pang and Poon 2007; Wong and Ng 2008).

Deregulation of Receptor Tyrosine Kinases in Hepatocarcinogenic Pathways

Introduction

HCC is, in its development and progression, characterized by abnormal expression and deregulation of several receptor tyrosine kinases (RTKs). RTKs are cell surface receptors for numerous growth factors, hormones, and cytokines and represent at least 58 of the 90 tyrosine kinase genes of

Table 2 Classes of receptor tyrosine kinases

Receptor	
RTK class I (EGF receptor family/ErbB family)	
	EGFR/Erb-1
	ErbB2/Her2
	ErbB3/Her3
	ErbB4/Her4
RTK class II (insulin receptor family)	IGF1R
RTK class III (platelet-derived growth factor receptor (PDGFR) family)	PDGFRA
	PDGFRB
	CSF1R/Fms
	Kit/CD117
RTK class IV (fibroblast growth factor receptor (FGFR) family)	FGFR1-4
RTK class V (VEGF receptor family)	VEGFR1-3
RTK class VI (HGF receptor family)	
RTK class VII (Trk (tropomyosin receptor kinase) family)	
RTK class VIII (Eph (ephrin receptor family))	
	EphA1-8
	EphB1-6
RTK class IX (AXL receptor family)	
RTK class X (LTK receptor family)	
RTK class XI (TIE receptor family/angiopoietin receptors)	Tie1, Tie2
RTK class XII (ROR receptor family)	
RTK class XIII (DDR receptor family)	
RTK class XIV (RET receptor family)	
RTK class XV (KLG receptor family)	
RTK class XVI (RYK receptor family)	
RTK class XVII (MuSK receptor family)	

the human genome. In contrast to non-receptor tyrosine kinases, RTKs contain a typical hydrophobic transmembrane domain composed of 25–38 amino acid residues, an N-terminal extracellular region, and an intracellular C-terminal region. The conserved C-terminal domain acts as the kinase proper that catalyzes receptor autophosphorylation followed by interaction with downstream targets. The kinases are divided into almost 20 classes (Table 2).

Hepatocyte Growth Factor and c-Met in Hepatic Carcinogenesis

Hepatocyte growth factor (HGF; scatter factor; gene on chromosome 7q21.11) is an important morphogen that regulates growth, cell migration, the construction of distinct tissue structures in development, regeneration, and wound healing. HGF binds to its receptor, c-Met.

HGF belongs to the plasminogen subfamily of S1 peptidases, however, without peptidase activity, and is produced as an inactive precursor that is cleaved by a serine protease into an alpha chain and a beta chain that unite to form an active heterodimer via disulfide bond formation. The processing serine protease of HGF is termed HGF activator (HGFA), which is itself regulated by two Kunitz-type serine proteinase inhibitors, HGFA inhibitor type 1/HAI-1 (SPINT1) and type 2/HAI-2. The HGF-HGFA system is located in a pericellular compartment and tightly regulates the HGF/c-MET interactome. HGF is usually secreted by mesenchymal and stromal cells in a paracrine fashion and acts as a multifunctional cytokine mainly on cells with epithelial lineages (Nakamura 1991; Matsumoto and Nakamura

1992; Kankuri et al. 2005). In addition to diverse types of epithelial cells, HGF also acts on hematopoietic cells and endothelial cells. It promotes angiogenesis both in normal vessel systems and in vascular tumors and has an effect on endothelial barriers (Higginbotham et al. 2014; Sanders et al. 2014; Young et al. 2014). c-Met (MET; hepatocyte growth factor receptor (HGFR); on chromosome 7q31.2) is a receptor tyrosine kinase encoded by the MET gene (MET proto-oncogene). The receptor kinase is produced as a single-chain precursor protein that is posttranslationally processed to yield alpha and beta subunits which are linked to form a mature receptor for HGF. The alpha subunit is an extracellular highly glycosylated domain, while the beta subunit is the transmembrane domain. HGF is the only ligand for c-Met.

The HGF/c-Met receptor signaling pathway is involved in development, growth, and progression of HCC and other malignancies (Suzuki et al. 1994; Ueki et al. 1997; Whittaker et al. 2010; Gao et al. 2011; Ang et al. 2013; Chu et al. 2013; Goyal et al. 2013; Graveel et al. 2013; Lee et al. 2013). HGF promotes experimental hepatocarcinogenesis in part via c-Met autocrine activation in transgenic mice (Horiguchi et al. 2002). The expression patterns of c-Met in HCC and fibrolamellar carcinoma are variable, in that both increase or decrease were found (Schoedel et al. 2003), but its expression tends to be higher in high-grade HCC (Zhao and Zimmermann 1998). HCCs with a c-Met-related expression signature display an aggressive phenotype (Kaposi-Novak et al. 2006). c-Met-positive HCC more often showed portal vein invasion and were associated with lower recurrence-free survival rates (Kondo et al. 2013). Epigenetic upregulation of HGF and c-Met promotes EMT and an aggressive phenotype in HCC (Ogunwobi et al. 2013).

The mechanisms involved in HGF/c-Met-induced hepatocarcinogenesis are complex and proceed along several pathways. HGF induces c-Met expression through upregulation of the c-Met promoter activity. A second pathway involves osteopontin in HCC, induced by the frequently overexpressed transcription factor late SV40 factor (LSF), osteopontin thereby activating c-Met through an interaction between osteopontin and its cell surface receptor CD44 (Yoo et al. 2011). In its oncogenic action for HCC, upregulated c-Met is synergistic to inactivation of the Ras/MAPK pathway negative regulator, Sprouty2 (Lee et al. 2008, 2010). In HCC cells, the HGF/c-Met signaling system also acts via an epigenetic regulator, mixed-lineage leukemia (MLL), which is required for invasion and metastatic spread of HCC (Marquardt and Thorgeirsson 2013; Takeda et al. 2013). In hepatocarcinogenesis, the HGF/c-Met signaling pathway interacts with MUC1 expression in cancer cells. Co-expression of c-Met and MUC1 was associated with the differentiation status of HCC, whereby HGF-induced c-Met phosphorylation downregulated MUC1 expression (Bozkaya et al. 2012). HGF binding to c-met can induce epithelial-mesenchymal transition (EMT), a process modulated by a frequently mutated tumor suppressor, CMTM8 (Zhang et al. 2012). The action of c-Met in HCC is antagonized by an HCC tumor suppressor, leukocyte cell-derived chemotaxin 2 (LECT2), which suppresses HCC vascular invasion by recruitment of protein tyrosine phosphatase 1B (Chen et al. 2014). HGF signaling is regulated by chromatin remodeling and associated factors. Histone deacetylation regulates chromatin remodeling and activates HGF signaling by repressing microRNA-449 in HCC cells, c-Met being a target for this microRNA (Buurman et al. 2012).

Epidermal Growth Factor Receptors in Liver Cancer

The EGFR family is a receptor tyrosine kinase family of four structurally related proteins. These surface receptors bind members of the epidermal growth factor/EGF family of extracellular protein/growth factor ligands. Marked overexpression of EGFRs is a hallmark of several cancers, excessive EGFR signaling being a strong driving force for tumorigenesis and cancer progression. EGFR or ErbB1 (gene on chromosome 7p11.2) binds EGF and TGFalpha and several other ligands. Upon binding of a ligand, the monomeric receptor is

activated to become an active homodimer. The receptor can also pair with other members of the family to generate activated heterodimers, such as Erb2/Her2/neu. Dimerization of EGFR activates the intracellular kinase domain to produce autophosphorylation of the C-terminal domain of the receptor. This is followed by activation of numerous downstream target proteins that is associated with the phosphorylated tyrosine residues of EGFR via their phosphotyrosine-binding domains. This interaction promotes downstream signaling along diverse signal transduction pathways, including MAPK, JNK, and Akt pathways, which are the final mediator for the regulation of cell proliferation and differentiation.

EGFR has a complex role in HCC biology, because its function not only affects HCC cells themselves but also stromal cells, vascular cells, and leukocytes infiltrating the tumor. The EGFR signaling system is situated within an extensive network of interactions and cross-talks with other signaling pathways, including other growth factors, cytokines, and inflammatory mediators (Berasain et al. 2011; Berasain and Avila 2014). EGF signaling promotes hepatic fibrosis and the development of cirrhosis and can, via these tumorigenic conditions, favor the development of liver cancer (Fuchs et al. 2014). EGFR/Erb-1 is overexpressed in many HCCs, in some analyses correlated with tumor cell differentiation and an aggressive tumor phenotype (Buckley et al. 2008). Distinct patterns of EGF/EGFR gene polymorphisms were related to the risk of HBV- and HCV-associated HCC (Abu Dayyeh et al. 2011). HER2/EGFR2 is also overexpressed in part of HCC, albeit at much lower frequency than Erb-1 (Hsu et al. 2002; Bacaksiz et al. 2008). HER2 was detected in HBx-expressing HCCs and was associated with poor prognosis. HBx augments HER2 protein levels in HCC cells through promotion of HER2 mRNA stability, mediated by induction of the RNA-binding protein HuR (Hung et al. 2014). In HCC cells, an direct interaction between cell surface beta1, 4-galactosyltransferase 1, and EGFR inhibits EGFR activation (Tang et al. 2013). Expression of EGFR in HCC is suppressed by the activity of microRNA-302b which directly targets EGFR and is frequently downregulated in HCC (Wang et al. 2013). This downregulation is a major cause of high EGFR expression levels in HCC. EGF signaling can induce cytokeratin 19 expression in HCC, an effect that is associated with higher growth abilities and a more aggressive phenotype (Yoneda et al. 2011).

The EGF/EGFR signaling platform is situated at a critical node between hepatocarcinogenic pathways and inflammatory signals (Berasain et al. 2009). EGF/EGFR induces a pro-inflammatory niche in HCC through induced production of CXCL5 and CXCL8 from HCC cells (Huang et al. 2014). In human HCC, EGFR is expressed in tumor-associated macrophages (TAMs). Based on murine HCC models, it turned out that EGFR is required for TAMs to transcriptionally induce IL-6, which is then involved in stimulation of hepatocyte proliferation and carcinogenesis. In humans, presence of EGFR-expressing TAMs is associated with more aggressive tumor biology and poor survival (Lanaya et al. 2014). TNF-alpha, which is produced by macrophages, triggers shedding of the EGFR ligand in HCC, amphiregulin, by the sheddase ADAM17, highlighting a further link between inflammation and liver cancer. ADAM17 is upregulated in the course of hepatocarcinogenesis (Berasain et al. 2012).

The Hippo Signaling Pathway in Hepatocellular Carcinoma

The Salvador-LATS-MST1/2 (Hippo) pathway is a complex kinase signaling platform that comprises the kinases Hippo and LATS1/LATS2 (warts in *Drosophila*), the adaptor proteins Salvador (AV1) and Mats, the transcriptional coactivator YAP (Yorkie in *Drosophila*), the Hippo activator Willin/Expanded, the upstream regulator KIBRA, and several Hippo-associated proteins. The Hippo pathway plays a key role in the control of cell number, tissue mass, and organ size in development and adults but also affects other cell functions, such as cytokinesis and cytoskeletal rearrangement (Genevet et al. 2010). The core of the signaling platform consists of a kinase

cascade in which Hippo (MST in humans) phosphorylates the nuclear DBF-2-related kinase LATS, which in turn phosphorylates and inactivates YAP/Yorkie. The phosphorylation of these proteins is influenced by an upstream effector of the Hippo pathway, KIBRA. YAP (Yes-associated protein) is a transcriptional coactivator that binds to the transcription factor TEAD (TEAD1-4 in humans, Scalloped in *Drosophila*) in its inactive, unphosphorylated form to promote cell growth and inhibit apoptosis via activation of transcriptional targets. The Hippo pathway affects cytokinesis and cell proliferation also through its effect on spindle formation and is involved in the generation of apico-basal cell polarity (Genevet and Tapon 2011). The mammalian (MST2) sterile 20-like kinase 2 and the scaffold protein SAV1 (Salvador) directly interact with the Nek2 kinase, a NIMA (never in mitosis A)-related kinase implicated in disconnecting the centrosomes via disjoining the linker proteins C-Nap1 and rootletin (Mardin et al. 2010).

Through its role in growth control and regulation of cell population and organ size, Hippo signaling exerts an influence on cancerogenesis and tumor progression (Harvey and Tapon 2007; Grusche et al. 2010). YAP, a target of Hippo, is an important oncogenic driver in liver carcinogenesis (review: Liu et al. 2010). YAP interacts with the Notch signaling cascade as it upregulates Jagged-1 and activates the Notch pathway and a proliferative response in human HCC (Tschaharganeh et al. 2013). Apart from the main components of the Hippo kinase platform, associated proteins are also involved in hepatic carcinogenic pathways. KIBRA, a protein acting upstream of the Hippo pathway, functions as a tumor suppressor that regulates Hippo signaling in conjunction with Merlin and Willin, forming a complex localized to the apical domain of epithelial cells and directly binding to Hippo/LATS (Yu et al. 2010). Several Hippo-associated proteins have functions that may mediate invasive features of cancer cells and by this modulate cancer by mechanisms other than growth control. Zyxin is a regulator of Hippo signaling in invertebrates and mammals. Zyxin is overexpressed in HCC and upregulates its motile phenotype, as in other cancers (Sy et al. 2006; Yamamura et al. 2013). The function of zyxin in cell motility is linked to its being a component of epithelial podosomes (Spinardi et al. 2004) and to its role in FAT signaling (Grusche et al 2010; Rauskolb et al. 2011). The four FAT proteins in mammals (FAT 1–4) associated with two Dachsous proteins (Dachsous 1–2) are very large cell adhesion molecules/cadherins that regulate planar cell polarity (Sharma and McNeill 2013) and are involved in cancer development. FAT4 which is critically involved in maintenance of planar cell polarity and inhibition of cell proliferation is recurrently mutated in HCC (Katoh 2012). Cell polarization is a prerequisite for cell locomotion and is regulated by other proteins that are linked to the Hippo pathway, including Crumbs, Par/partitioning defective, and Scribble, of which the apical polarity protein Crumbs controls the activity of YAP, the progrowth target of the Hippo kinase cassette (Grzeschik et al. 2010; Ngok et al. 2014; Ribeiro et al. 2014). Crumbs appears to act as a potential tumor suppressor involved in the regulation of epithelial-mesenchymal transition in cancer (Laprise 2011). The Hippo activator Willin (a FERM-domain protein like merlin) and the polarity protein Par3 regulate epithelial apical constriction involved in polarized phenotype (Ishiuchi and Takeichi 2011). On the other, elements of the cytoskeleton influences the function of the Hippo pathway. The cilia-associated protein NPHP4, mutated in one form of nephronophthisis, acts as a potent negative regulator of Hippo signaling, directly interacting with kinase LATS1 and inhibiting LATS1-mediated phosphorylation of YAP (Habbig et al. 2011).

Wnt/Beta-Catenin Signaling

Introduction

The Wnt/beta-catenin signaling pathway is a key regulation platform for numerous cellular functions, both in normal cells and in cancer. The pathway is initiated by binding of Wnt ligands to their frizzled (Fz) receptors. Wnt signaling comprises 19 Wnt ligands in humans. These ligands

are highly conserved secreted glycoproteins that bind to ten types of frizzled receptors and play a central role in cell fating, priming of progenitor cells, induction of differentiation, and tissue homeostasis.

The Wnt signaling cascades include three pathways. In the canonical pathway, Wnt ligands activate target genes through stabilization of beta-catenin followed by its nuclear translocation and activation of distinct target genes. The canonical pathway is mediated by Wnt1 class ligands, comprising Wnt1, Wnt3, Wnt3a, Wnt7a, Wnt7b, and Wnt8a. In two noncanonical pathways, Wnt ligands promote activation of RhoA and Jun kinase, while a third pathway involves intracellular calcium release and activation of protein kinase C/PKC and calmodulin-dependent protein kinase II (review: Lee et al. 2006). In the canonical pathway, formation of a Wnt/Fz complex is followed by phosphorylation-mediated activation of the cytoplasmic protein Dishevelled, which regulates the activity of an intracellular signaling complex composed of beta-catenin, glycogen synthase kinase 3beta (GSK3beta), Axin, and the adenomatous polyposis coli/APC protein. The scaffolding protein Axin promotes proteasomal degradation of beta-catenin, a step that requires phosphorylation of beta-catenin by GSK3beta. Activated Dishevelled binds to Axin and promotes its binding to GSK3beta, thus preventing its beta-catenin phosphorylation, leading to bypassing proteasomal degradation of beta-catenin and nuclear beta-catenin translocation. This sequence of events leads from Wnt-receptor binding to the transcriptional activation of several target genes. In the noncanonical Wnt pathways such as Wnt/frizzled-PCP (planar cell polarity) signaling, Dishevelled signals via Daam1-Rho axis and the Rac1 axis, whereby Dishevelled has also important functions in Wnt-microtubule signaling (Gao and Chen 2010).

Wnt/Beta-Catenin Signaling in Liver Cancer

The Wnt/beta-catenin signaling cascade is critically involved in cancer development, including hepatocarcinogenesis, and may represent a future treatment target (Morin 1999; Prunier et al. 2004; Lee et al. 2006; Dahmani et al. 2011). This signal pathway exerts a strong influence on growth and expansion of the hepatocyte lineage, including neoplastic hepatocytes. Activated beta-catenin drives the expression of target genes required for cell cycle progression and proliferation. In the liver, Wnt/beta-catenin signaling holds a central position of growth regulation of the hepatocyte lineage and its precursor cells, including EpCAM(+) hepatic stem cells (Yamashita et al. 2007). HGF-mediated and beta-catenin-mediated pathways cooperate in hepatocyte proliferation during ontogenesis and regeneration (Apte et al. 2006; Nejak-Bowen et al. 2010), and transgenic mice expressing an oncogenic form of beta-catenin develop hepatomegaly caused by uncontrolled hepatocyte growth (Cadoret et al. 2001). In transgenic HCC mice, 50 % of hepatic tumors had somatic mutations within the beta-catenin gene, leading to deregulated Wnt/beta-catenin signaling (de la Coste et al. 1998). There is strong evidence that a deregulated Wnt/beta-catenin pathway is strongly involved in hepatocarcinogenesis in humans, both HCCs and hepatoblastomas.

Selected References Huang et al. 1999; Kondo et al. 1999; Legoix et al. 1999; Nhieu et al. 1999; Wong et al. 2001; Taniguchi et al. 2002; Ban et al. 2003; Cui et al. 2003; Toan et al. 2005; Cavard et al. 2008; Kim et al. 2008; Takigawa and Brown 2008; Nejak-Bowen and Monga 2011; Pez et al. 2013; Lu et al. 2014.

Specifically, the canonical Wnt signaling is often activated due to overexpression and/or somatic mutations in components of the Wnt signal cascade in HCC (de la Coste et al. 1998; Miyoshi et al. 1998). An aberrant nuclear accumulation of beta-catenin, detectable with immunohistochemistry, already occurs in early phases of hepatocarcinogenesis and is a frequent finding in HCC, more often in poorly differentiated than in moderately or well-differentiated tumors (Terris et al. 1999; Murata et al. 2001; Wong et al. 2001; Tien et al. 2005; Wang et al. 2009;

Li et al. 2011). Nuclear beta-catenin accumulation in HCC is associated with increased cell proliferation (Nhieu et al. 1999). Nuclear reactivity for beta-catenin is also present in tumorous lesions undergoing transformation to HCC, such as telangiectatic adenoma (Hechtman et al. 2011). HCC with exon-3 mutations represented a distinct phenotype characterized by a higher percentage of large tumor size and macro- and microvascular invasion (Cieply et al. 2009). Intracellular accumulation of beta-catenin was correlated with cyclin D1 expression and a higher proliferation index (Ueta et al. 2002). Mutational activation of beta-catenin signaling in HCC is correlated with induction of glutamine synthetase, glutamate transporter-1, and G-protein-coupled receptor 49 but not ornithine transcarbamylase (Zucman-Rossi et al. 2007; Austinat et al. 2008; Cieply et al. 2009). Distinct distribution patterns of beta-catenin in HCC are associated with E-cadherin expression, affecting cell adhesion features of neoplastic cells, mechanism of epithelial-to-mesenchymal transition (EMT), and biology of disease (Ihara et al. 1996; Garcia et al. 1998; Nuruki et al. 1998). Beta-catenin undergoes a complex cross talk with snail to induce EMT in HCCs, a process requiring activity of the ERK1/2 signaling pathway (Zucchini-Pascal et al. 2013). Decreased E-cadherin expression on HCC cells is associated with beta-catenin mislocalization and HCC invasion and metastasis (Du et al. 2009), suggesting a role of reduced cell adhesion for tumor cell individualization and spread. Nuclear beta-catenin expression is correlated with the Edmondson-Steiner grade (Wang et al. 2009). Approximately 20 % of human HCC harbor activating mutations with exon 3 of the beta-catenin gene (Kondo et al. 1999; Fujie et al. 2001; Yuan et al. 2011). Expression of beta-catenin in HCC is more abundant in late-stage tumors, neoplasms with a high proliferative rate, and metastatic HCCs (Lai et al. 2011). Deregulation of beta-catenin expression may be associated with other carcinogenic alterations. Hepatitis C virus (HCV) core protein promotes hepatoma cell growth through enhancement of canonical Wnt/beta-catenin signaling, specifically via inactivation of GSK-3beta, contributing to upregulation of c-Myc, cyclin D1, WISP2, and CTGF (Liu et al. 2011; Higgs et al. 2013). Beta-catenin gene mutations were associated with high exposure to aflatoxin B1 (Devereux et al. 2001), whereby aflatoxin B1 negatively regulates Wnt/beta-catenin signaling through upregulating and activating microRNA-33a, a miR that potently inhibits expression of beta-catenin (Fang et al. 2013). Presence or absence of beta-catenin mutations in HCC may be associated with distinct chromosomal aberrations. Chromosome 1p, 4q, and 16p deletions were associated with the absence of beta-catenin mutations (Legoix et al. 1999).

In addition to the typical alterations of beta-catenin expression, HCCs show various changes of Wnt ligand functions and of Wnt/frizzled signaling (Lee et al. 2006; Bogaerts et al. 2014). Part of these Wnt dysregulations are directly or indirectly caused by factors that drive hepatocarcinogenesis. HCV nonstructural protein 5A activates beta-catenin signaling cascades through inactivation of glycogen synthase kinase 3beta and subsequent beta-catenin accumulation (Park et al. 2009). HCV core protein can activate the Wnt signaling cascade through upregulation of gene expression of canonical Wnt ligands Wnt2, Wnt3, Wnt3a, Wnt8b, Wnt10a, and Wnt10b and of frizzled receptors 2, 5, 6, 7, and 9 and of LRP5/6 co-receptors (Liu et al. 2011). On the other hand, blockade of Wnt signaling in HCC cells inhibits tumor growth and angiogenesis (Hu et al. 2009). Loss of Wnt5a is downregulated in the majority of HCCs and acts as a tumor suppressor, decreased expression being associated with aggressive tumor biology (Geng et al. 2012), but in part of HCC, Wnt5a mRNA levels were higher than in para-carcinoma tissues (Li et al. 2014). In vitro, overexpression of Wnt5a in human HCC cells was associated with decrease of cell proliferation and migration, suggesting that Wnt5a acts as a tumor suppressor gene in HCC (Bi et al. 2014). HCC can also display altered expression patterns of Wnt/Frizzled receptors. Expression of frizzled-7 is an early event in hepatocarcinogenesis and affects growth and tumor cell migration (Merle et al. 2004, 2005). A functional interaction between frizzled-7 and Wnt3 causes activation

of Wnt/beta-catenin signaling in HCC cells, associated with TCF transcriptional activity and cell proliferation (Kim et al. 2008). Conversely, soluble frizzled-7 receptor protein inhibits Wnt signaling and results in reduced HCC cell viability and growth (Wei et al. 2011). Glypican-3, which is highly expressed in the majority of HCCs, may form a complex with Wnt by stabilizing the interaction between Wnt and the frizzled receptor, leading to activation of downstream signaling pathways (Gao and Ho 2011). There is an increased group of frizzled-related proteins (FRPs) that modulate the Wnt-frizzled receptor system. Secreted FRPs are WNT antagonists that directly bind to Wnt, have a role in the regulation of cell proliferation and differentiation, and act as tumor suppressors because their expression is often downregulated in diverse cancers via promoter hypermethylation (Shi et al. 2007). Epigenetic inactivation of secreted FRPs (SFRPs) is a common finding in HCC (Takagi et al. 2008). SFRP silencing activates the canonical Wnt pathway and increases cell proliferation in HCC (Kaur et al. 2012). The secreted frizzled-related protein 1 (SFRP1) is a tumor suppressor located to chromosome 8p12-p11.1 (a common LOH region in HCC) and a beta-catenin antagonist that is frequently inactivated in tumors via promoter hypermethylation (Wu et al. 2012). Secreted SFRP1 belongs to the FRP family of proteins that possess a cysteine-rich domain homologous to the Wnt-binding site of frizzled proteins. Downregulation of SFRP1 is a common event in HCC (Shih et al. 2006, 2007) and can contribute to oncogenesis of human HCC, while overexpression of this protein inhibits cell growth (Huang et al. 2007). SFRP1 is epigenetically silenced in HCC (Wu et al. 2012). SFRP1 silencing is promoted by HCV core protein, an effect that enhances HCC aggressiveness by inducing epithelial-mesenchymal transition (EMT) (Quan et al. 2014). In patients with HBV-related liver disease, serum levels of secreted frizzled-related protein 5 (SFRP5) differentially decrease as a function of disease status, lowest levels characterizing patients with HCC (Peng et al. 2014). A further protein that interacts with Wnt is the Wnt coreceptor low-density lipoprotein receptor-related protein-6 (LRP6), which forms a signaling complex with Wnt ligand and frizzled receptor to activate a downstream signaling cascade. Upregulation of LRP6 promotes hepatocarcinogenesis and enhances cell invasion (Tung et al. 2012). Apart from beta-catenin dysregulation, other members of the Wnt/frizzled downstream signaling cascade may be altered in liver cancer. Mutations of AXIN1 and AXIN2 have been documented in both HCCs and hepatoblastomas (Clevers 2000; Satoh et al. 2000; Taniguchi et al. 2002). In contrast to beta-catenin activation in HCC, Axin-mutated HCC did not show induction of glutamine synthetase or glutamate transporter-1 (Zucman-Rossi et al. 2007).

Mechanisms

Activation of the Wnt7-beta-catenin signaling cascade causes upregulation of a large set of target genes that play a role in diverse cell functions (Lee et al. 2007). Wnt/beta-catenin signaling may regulate the Ras/MAPK and PI3K/SAPK signaling pathways via regulation of the phosphorylation status of ERK1/2, JNK/SAPK, and Akt1 protein in HCC cells (Wang et al. 2011). The signal pathway regulates cell cycle progression in HCC cells through affecting cyclin A and cyclin E (Wang et al. 2009). Activation of the canonical beta-catenin pathway results in overexpression of the multifunctional protein Cyr61 (CCN1) via binding to the Cyr61 promoter. Cyr61/CCN is a secreted ECM-associated protein of the CCN family. One well-known member of this family is CCN2 or connective tissue growth factor (CTGF). Cyr61 is involved in the regulation of diverse cellular activities, mainly cell adhesion, proliferation, differentiation, apoptosis, migration, and senescence, through interaction with integrin receptors and heparan sulfate proteoglycans. Overexpression of Cyr61 promotes progression of HCC (Li et al. 2012). Oncogenic beta-catenin promotes an inflammatory response characterized by invariant NKT (iNKT) and chemokine-like chemotactic factor leukocyte cell-derived chemotaxin 2 (LECT2) production,

leading to liver tumorigenesis and an aggressive phenotype of HCC (Anson et al. 2012). TGF-beta cooperates with Ras to activate nuclear beta-catenin in the setting of epithelial-mesenchymal transition (EMT) of hepatocytes. Another pathway of EMT in HCC involves SIRT2 (sirtuin2) which mediates EMT through the GSK-3beta/beta-catenin pathway (Chen et al. 2013). Beta-catenin signaling enhances hypoxia-induced EMT in HCC cells through cross talk with HIF-1alpha signaling (Zhang et al. 2013). The nuclear beta-catenin accumulation results in dedifferentiation of hepatocytes to become an early liver progenitor phenotype. This phenomenon also occurs in HCC showing signs of EMT and tumor recurrence (Zulehner et al. 2010). Wnt/beta-catenin signaling activates expression of four microRNA-181 family members in HCC (Ji et al. 2011).

The canonical Wnt pathway is counteracted by several factors that may also operate in HCC. Major inhibitors of beta-catenin signaling are Dickkopf (DKK) proteins, a family of four secreted proteins (DKK1–DKK4) of which however not all members are beta-catenin inhibitors. DKKs modulate beta-catenin signaling in HCC (Fatima et al. 2011). There is a stepwise upregulation of DKK1 in HCC tissues, higher transcript levels associated with more aggressive tumor behavior, venous invasion, and higher stage (Tung et al. 2011). An elevated expression of DKK1 in HCC is associated with cytoplasmic/nuclear beta-catenin accumulation, instead of membrane expression, and aggressive tumor biology (Yu et al. 2009). On the other hand, DKK4 hampers cell proliferation, reduces colony formation and retards cell migration, probably represents a potential tumor suppressor, and is downregulated in many HCCs (Fatima et al. 2012). The transcription factor SOX1 (sex determining region Y-box 1) is frequently downregulated in HCC via promoter hypermethylation and functions as a tumor suppressor in these tumors by antagonizing the WNT/beta-catenin signaling pathway (Tsao et al. 2012). The candidate tumor suppressor SRY-box containing gene 17 (SOX17) negatively regulates beta-catenin signaling and inhibits HCC cell growth (Jia et al. 2010). The Wnt/beta-catenin pathway is inhibited by an inhibitor of a key regulator of the cascade at the APC complex level, Dishevelled, i.e., HDPR1 (Dapper in *Xenopus*). Downregulation of HDPR1 was found in 58 % of HCC, due to epigenetic hypermethylation of the promoter or allelic loss of its locus, and the decrease is associated with accumulation of beta-catenin (Yau et al. 2005). The dishevelled-associated protein Prickle-1 negatively regulates beta-catenin signaling via promotion of Dishevelled ubiquitination and degradation in HCC (Chan et al. 2006). The beta-catenin pathway is also regulated by microRNAs. MicroRNA-214 targets beta-catenin and by this mechanisms suppresses stem cell-like traits, invasion, and recurrence of human HCC (Xia et al. 2012).

Apart from the canonical pathway, HCC can show features of activation of the noncanonical Wnt-mediated signaling pathway. The noncanonical cascade member Wnt11 is downregulated in human HCC cell lines, while upregulated Wnt11 inhibits HCC cell proliferation and migration via activated protein kinase C, which antagonizes canonical signaling through phosphorylation of beta-catenin (Toyama et al. 2010).

Novel Genes and Gene Products Deregulated in Liver Cancer and Representing Valid or Potential Oncogenes/Tumor Suppressors

Retinoblastoma Gene

The retinoblastoma gene (RB1) is relatively rarely mutated in HCC. RB1, localized to chromosome 13q14.2, encodes a protein that is a negative regulator of cell cycle by binding to the transcription factor E2F. However, RB1 showed imprint abnormalities in a high proportion of HCC patients, 40 % of HCC specimens showing hyper- or hypomethylation at the CpG island in intron 2 of the RB1 gene, loss of imprinting representing an important mechanism for RB1 pathway inactivation in HCC (Anwar et al. 2014).

Insulin-Like Growth Factors

Components of the insulin-like growth factor signaling system and associated proteins are altered in HCC and considered to be potential tumor suppressors. Liver cancer development is also influenced by IGF-binding proteins. Insulin-like growth factor-2 mRNA-binding proteins 1, 2, and 3 belong to a conserved protein family of RNA-binding oncofetal proteins involved in cell proliferation, morphology, differentiation, and cell shape control (Bell et al. 2013). One of these factors is IGF2-binding protein 1 (IGF2BP1), a protein strongly upregulated in HCC and involved in the promotion of proliferation (Gutschner et al. 2014). Another IGFBP is insulin-like growth factor-binding protein-7, which is itself downregulated by the oncogene astrocyte-elevated gene 1 (AEG-1) and acts as a potential tumor suppressor in HCC (Chen et al. 2011).

Tumor Suppressors

A factor that is important as a hepatocyte lineage determinant and differentiation factor is hepatocyte nuclear factor 4 (HNF4), which is a marker of HCC progression and might be a tumor suppressor (Lazarevich et al. 2010). LIS1 (human lissencephaly-1 mutated in the Miller-Dieker lissencephaly syndrome) is a gene assigned to chromosome 17p13.3 and frequently altered in liver cancer cells. LIS1 is downregulated in HCC and acts as tumor suppressor (Xing et al. 2011). The gene Ptpn11, which encodes the tyrosine phosphatase Shp2, is a proto-oncogene that is altered in several malignancies, especially several types of leukemia. It has a tumor suppressor function in the liver (Bard-Chapeau et al. 2011). The X-chromosome-linked tumor suppressor TSPX is altered in several cancers. In the setting of hepatocarcinogenic pathways, TSPX interacts with HBV X protein (HBx) and promotes its degradation via a proteasomal pathway, mutations of TSPX predisposing to human liver cancer (Kido et al. 2011). LZAP (C53, Cdk5rap3) is a putative tumor suppressor that is an activator pf p53. Specifically, it inhibits p38 MAPK by facilitating p38 association with wild-type p53-induced phosphatase 1 (An et al. 2011; Zhao et al. 2011). LZAP selectively inhibits NF-kappa B and promotes cell proliferation and an invasive phenotype of cancer cells (Wang et al. 2007). WW domain-containing oxidoreductase (WWOX) is a tumor suppressor with a reduced expression in several cancers. WWOX is downregulated in HCC, associated with cytoplasmic accumulation with beta-catenin and strong nuclear TCF4 expression, suggesting activation of the Wnt/beta-catenin signaling cascade (Li et al. 2013).

Abstract

Etiology and pathogenesis of hepatocellular carcinoma (HCC) involve deregulation of various transcription factors, signal pathways that control cell proliferation, differentiation and apoptosis, and the telomere/telomerase system. A major mutated transcription factor in HCC is the TP53/p53 gene, one of the most commonly mutated gene in human cancer. p53 is a multifunctional transcription factor that plays an important role in the DNA damage response network, cell cycle regulation, DNA repair, cellular senescence, and apoptosis. Other deregulated transcription factors in HCC include Krüppel-like proteins involved in cell and tissue homeostasis and in cell survival, the c-Fos/c-Jun oncogene system, the human FOX gene family, the Myc proto-oncogene, HOX gene product, and the RUNX transcription factor. The multifunctional protein transforming growth factor beta1 (TGF1) and TGF1-related signaling pathways play a significant role in HCC pathogenesis. GTPases and GTPase-related proteins such as DLC1 (deleted in liver cancer 1) and Ras are involved in early hepatocarcinogenic pathways. HCC pathogenesis also involves deregulation of telomeres and telomerases, a system that controls orderly replication, genomic stability, and regulation of cell senescence.

Deregulated Transcription Factors in Liver Cancer

p53, A Major Mutated Transcription Factor in Hepatocellular Carcinoma

The TP53/p53 gene is the most commonly mutated gene in human cancers (Vogelstein et al. 2000; Olivier et al. 2010; Olivier and Taniere 2011; Seton-Rogers 2014). This encodes the p53 protein, a multifunctional transcription factor playing important roles in DNA damage response network, cell cycle regulation, DNA repair, cellular senescence, and apoptosis (Beckerman and Prives 2010). In principle, p53 prevents abnormal proliferation of numerous cell lineages by guarding against cellular stress and genotoxic damage. As a major transcription factor, p53 exerts its effects via transactivation and transrepression of numerous target genes acting in arrest of cell proliferation or induction of cell death, i.e., operating as a factor that determines cell mass homeostasis. p53 is a major proapoptotic factor by its function as a prooxidant molecule and is a major target of certain hepatocarcinogenic substances, in particular aflatoxins (see above). More than 80 % of p53 gene mutations that occur in cancers involve the transcription/DNA-binding domain of the protein, whereby these mutations prevent p53 from binding to DNA. By use of modern techniques, in particular parallel pyrosequencing, also rare or low-abundance p53 mutations are detectable, having led to an important increase in known mutations in many types of cancers. Apart from mutations of the gene, the function of p53 can be blunted by other mechanisms that interfere with the function of wild-type p53. Many factors can cause altered expression, stability, or activity of p53 in cancers in the absence of p53 mutations, i.e., under maintenance of the wild-type transcription factor.

As stringent control of p53 function is necessary for cell growth homeostasis and survival, p53 interacts with several controlling proteins. p53 mainly interacts with two structurally related proteins that counteract the potentially lethal effects of p53, MDM2 and MDM4. MDM2 (E3 ubiquitin-protein ligase homologue) is an oncogene and encodes a protein which is a potent inhibitor of p53 function (Toledo and Wahl 2007; Perry 2010). The MDM2 gene is a target for transcriptional activation by p53, resulting in MDM2-p53 autoregulatory feedback loop that regulates p53 activity. The activity of the inhibitor MDM2 is blocked by microRNA-339-5p which directly targets MDM2 (Jansson et al. 2014). This microRNA is downregulated in tumors harboring wild-type p53. MDM2 is also a direct target of microRNA-221 in HCC, this microRNA therefore activating the p53 axis by inhibiting MDM2 (Fornari et al. 2014). An MDM2 antagonist that may restore p53 function in HCC cells is Nutlin-3.

On the other hand, Nutlin-3 can also downregulate p53 phosphorylation on serine392 and induce apoptosis in HCC (Shi et al. 2014). MDM2 is amplified or overexpressed in numerous human malignancies. Distinct polymorphisms in the MDM2 gene (at codons 285, 309, and 344) are associated with increased HCC risk, showing that MDM2 is a potential oncogene (Peng et al. 2013; Chen et al. 2014a; Rebbani et al. 2014).

Mutations of TP53 are a well-known etiologic feature in human HCC, cause function failure of p53, and abolish the proapoptotic function of p53, resulting in increased tumor cell survival. TP53 mutations in HCC affect tumor biology and are associated with poor outcome (Tannapfel et al. 2001; Peng et al. 2002; Edamoto et al. 2003; Hussain et al. 2007; Tornesello et al. 2013; Zhan et al. 2013). Such mutations can occur spontaneously or are induced by external factor, the best known example being aflatoxin B1 exposure that is associated with a point mutation at codon 249, as discussed above. In HCC, an important mutational hot spot is R249S, a mutation strongly associated with aflatoxin toxicity and high HCC risk. In patients with HCC, TP53 mutations, in particular those involving the hot spots R249S and V157F, are associated with an aggressive course and poor prognosis (Villanueva and Hoshida 2011). When associated with chronic HBV infection, the leading mutation (Ser249) shows a multiplicative effect of HCC risk (Aguilar et al. 1994; Kirk et al. 2005; Qi et al. 2014). p53 activity can be directly abrogated by HBV infection. The HBx protein, critically involved in HBV-associated hepatocarcinogenesis, can specifically bind to the carboxy-terminus of p53 and suppress p53-induced apoptosis. HBx protein can also decrease binding of p53 to proteins involved in nucleotide excision repair, augmenting the risk of further mutations within DNA (Wang et al. 1994). In patients with HVC-related HCC, unusual mutations of TP53 have been detected, e.g., distinct so-called microindel mutations, infrequent mutations resulting in inserted and deleted sequences at the same nucleotide position and causing truncation of the p53 protein with loss of the DNA-binding domain (Long et al. 2013). p53 represses certain proteins involved in apoptosis regulation. For example, the prosurvival function of the cellular apoptosis susceptibility / importin-alpha1 transport cycle is repressed by p53 in HCC (Winkler et al. 2014). The Notch1 receptor, which plays an important role in liver cell fating and growth, differentially regulates oncogenesis by wild-type p53 overexpression and p53 mutation in HCC (Lim et al. 2011). p53 is transcriptionally regulated by the tumor suppressor gene downregulated in HCC, FHL2 (four and a half LIM protein 2), a LIM domain-only protein. FHL2 binds to and activates the TP53 promoter in hepatic cells. The hot spot mutation 747G>T in HCC is potentially associated with a higher expression of FHL2 in HCC tumor tissue (Xu et al. 2014).

Apart from its role in the regulation of apoptosis and its status as a tumor suppressor, p53 induces other pathogenic pathways that may play a role in liver cancer development, in particular proliferation and cell cycle regulation. This is linked to distinct functions of p53 in the transcriptional regulation of genes involved in mitotic entry, centrosome duplication, and cytokinesis. For example, p53 regulates expression of polo-like kinases which are central to the control of these growth processes (Ward and Hudson 2014). Certain mutated p53 proteins may achieve gain of oncogenic functions via production of oxidative and nitrosative stress (Hussain et al. 2007). A rather frequent polymorphism at codon 72 resulting in the change of arginine to proline is correlated with risk for HCC in distinct subpopulations infected with hepatitis viruses (Hu et al. 2014). However, the proline variant was also correlated with HCC in an HCV-independent manner, suggesting the p53 alterations can promote HCC in the absence of other well-established exogenous risk factors (Ezzikouri et al. 2007). Sustained p53 activation subsequent to DNA damage promotes inflammation-associated mechanisms that can lead to carcinogenesis, supporting the view that p53 can act in a dichotomous manner rather than exclusively acting as a tumor suppressor. In HCC models, constant activation of wild-type p53 resulted in pro-tumorigenic inflammation via

induction of the potential inflammatory molecule, high-mobility group protein 1 (HMGB1) (Yan et al. 2013). A protein with a significant homology to p53 and showing functional similarities to p53 is p73. LOH of p73 is observed in a significant proportion of HCC patients, and tumors with p73 LOH were more often detected in livers without cirrhosis and were associated with poorer patient outcome (Aoki et al. 2004).

Krüppel-Like Transcription Factors

The zinc finger transcription factors, Krüppel-like factors (KLFs), form a family with 17 members (KLF1–KLF17) in mammals. KLFs have a central role in regulation of cell and tissue homeostasis under normal and neoplastic conditions and critically affect cell proliferation, differentiation, survival, and stress responses. The factors are also operational in ontogenesis and the development of numerous organs and tissues and are involved in the reprogramming of somatic stem cells into pluripotent stem cells, a mechanism also playing a role in carcinogenic pathways (review: McConnell and Yang 2010).

KLF6 is a major factor among KLFs acting in cancer biology and is frequently mutated in several human cancers and significantly involved in the regulation of growth, angiogenesis, and apoptosis in cancer cells (Yin et al. 2007). Specifically, KLF6 is capable to regulate a group of genes that belong to the carcinoembryonic gene family, involved in carcinogenesis (review: Andreoli et al. 2010). Three splice variants of KLF6 exist, termed SV1, SV2, and SV3. Alternative splicing of KLF6 is mediated by hepatocyte growth factor to promote growth through SRSF1 (Muñoz et al. 2012). Allelic loss of KLF6 was found only in a variable fraction of HCC cases, varying from around 4 % to 49 % of tumors (Kremer-Tal et al. 2004; Pan et al. 2006; Song et al. 2006; Wang et al. 2007a, 2010a; Lee et al. 2010). Downregulation of KLF6 was already detectable in macroregenerative nodules occurring in cirrhosis (Bureau et al. 2008). The SV2 splice variant of KLF6, which displays antiproliferative and proapoptotic functions, is variably expressed in HCC and HCC cells (Hanoun et al. 2010; Zhenzhen et al. 2012). A frequent upregulated downstream transcript of KLF6 is the PTTG1 (pituitary tumor-transforming gene 1; Lee et al. 2010) oncogene, and a further KLF6-mediated pathway is transactivation of the E-cadherin promoter (DiFeo et al. 2006). The expression patterns of KLF6 and its splice variants are in itself regulated by TGF-beta via a Smad3-Sp1/specificity protein1-LKF6 interaction (Botella et al. 2009).

Other members of the KLF family show expression patterns in HCC that differ from those for KLF6. KLF4 is expressed in the cytoplasm of HCC cells, immunoreactivity being correlated with cell differentiation and decreased proliferative activity (Hsu et al. 2014). In HCC cells, KLF4 suppresses a critical epithelial-mesenchymal transition (EMT)-related transcription factor, Slug, thus reverting EMT in these tumors (Lin et al. 2012). KLF8 plays important roles in cell cycle regulation and oncogenic transformation. Expression of KLF8 in HCC is correlated with nuclear beta-catenin expression, suggesting that KLF8 interacts with the Wnt/beta-catenin pathway and induces typical signaling targets, including c-Myc, cyclin D1, and Axin1 (Yang et al. 2012). KLF8 expression in HCC also positively correlated with expression of focal adhesion kinase/FAK and MMP-9, suggesting that KLF8 affects mechanisms that function in tumor invasion (Han et al. 2013). In fact, upregulation of KLF8 in HCC promotes tumor invasion and is associated with poor prognosis (Li et al. 2010).

KLF9, assigned to chromosome 9q13 and inhibitor of cell proliferation and inducer of apoptosis, is downregulated in HCC tissue in comparison with nonneoplastic liver (Fu et al. 2014). KLF15 indirectly affects hepatocarcinogenesis via its role on HBV infection pathways. It activates HBV gene expression (HBs and core protein expression) and viral DNA replication via promoter interaction (Zhou et al. 2011). KLF17, which plays a role in regulating epithelial-mesenchymal transition (EMT), is downregulated in HCC, associated with increased tumor cell motility, invasion capacity, and upregulation of EMT-promoting factors (Liu et al. 2013). The pro-invasive function of KLF17 in HCC is

modulated by microRNA-9 which targets this transcription factor (Sun et al. 2013).

c-Fos/c-Jun Oncogene System

c-Fos (chromosome 14q24.3) is a proto-oncogene and the human homologue of the retroviral oncogene v-fos. It is a member of the FOS family that comprises c-Fos, FosB, Fra-1, Fra-2, and smaller FosB splice variants. The c-Fos basic leucine zipper protein forms a heterodimer with c-Jun to form the AP-1 complex (activator protein-1 complex) which acts as a transcription factor and binds to AP-1-specific sites at promoter and enhancer regions of target genes (Abate and Curran 1990). c-Fos cannot form homodimers. Its expression is stimulated by growth factors, tumor promoters, cytokines, and ultraviolet radiation, expression being characterized as a very early response (immediate early gene). Protein stability is modulated by posttranslational phosphorylation by MAPK, protein kinase A or protein kinase C. The oncogene Jun, the homologue of transforming gene of avian sarcoma virus 17, is assigned to chromosome 1p32.1 and a member of the JUN-FOS family of basic leucine zipper proteins acting as a potent transcription factor.

Together with other oncogenes, Fos is involved in the regulation of liver regeneration (Corral et al. 1985; Thompson et al. 1986; Coni et al. 1990, 1993; Morello et al. 1990; Haritani et al. 1991; Hsu et al. 1992). Fos possesses a tumor-suppressive function in various cancer types (Tulchinsky 2000; Durchdewald et al. 2009) and suppresses HCC development in vivo (Mikula et al. 2003). c-Fos is overexpressed in at least part of HCC in comparison with surrounding liver tissue, often coordinated with expression of c-Jun (Tabor 1994; Yuen et al. 2001), and Fos is upregulated in HCC precursors (Alexandre et al. 1994; Feng et al. 2001). c-Fos expression in HCC is in part regulated by epigenetic promoter methylation (Choi et al. 1996). Fos overexpression in hepatocytes increases their proliferation capacity via stabilization of cyclin D1 (Güller et al. 2008). Elevated Fos is a mediator of c-Myc-induced apoptotic signaling in HCC cells (Kalra and Kumar 2004). Elevated levels of Fos in HCC cells are associated with a metastatic phenotype. In HCC sublines with a high spontaneous metastatic potential show derepression of Fos due to downregulation of microRNA-139 which inhibits Fos by direct targeting (Fan et al. 2013). Fos may also indirectly affect carcinogenic pathways. The protein acts as a positive regulator of hepatitis C virus propagation and may thus favor pathologic processes linked to HCV infection (Kang et al. 2011).

Human FOX Gene Family in Hepatocarcinogenesis

The human forkhead-box (FOX) gene family is a large gene family with more than 40 members. FOX proteins are transcription factors. Members of the FOX subfamilies A–G, I–L, and Q were grouped into class 1 FOX proteins, whereas members of subfamilies H and M–P were grouped into class 2 FOX proteins.

FOX proteins, in part as fusion partners of other proteins, are involved in the regulation of cell proliferation and apoptosis and are dysregulated in cancerogenic pathways of various neoplasms (Fu and Tindall 2008; Kloet and Burgering 2011). FOX proteins are DNA-binding proteins that control the transcription of multiple target genes that regulate genes involved in cell growth, proliferation, differentiation, and survival and control DNA repair (reviews: Katoh and Katoh 2004; Zhang et al. 2011; Katoh et al. 2013). Human O class FOX proteins (FOXO) are transcription factors that are activated in response to numerous stimuli, including several growth factors, insulin, nutrients, and oxidative stress. Their subcellular localization is regulated by phosphorylation and ubiquitination.

Within the FOXO group of transcription factors, FOXO3 located at chromosome 6q21 acts as a tumor suppressor in HCC, inducing the expression or proapoptotic genes or interfering with the Wnt and MAPK signaling pathways (Lu et al. 2009; Xie et al. 2012; Carbajo-Pescador et al. 2014). The tumor suppressor candidate

FOXP1 (chromosome 3p13) is overexpressed in HCC tissue in comparison with nonneoplastic liver, associated with larger tumor size and higher stage (Zhang et al. 2012). FOXP3 (scurfin, on Xp11.23) was found in some hepatoma cell lines and detected immunohistochemically in 48 % of human HCC, expression being related to high risk (Wang et al. 2010b). FOXC1 (6p25.3) is critically involved in regulation of epithelial-mesenchymal transition and cell locomotion/migration, associated with higher Snail expression. It is upregulated in HCC, where it promotes metastatic spread and an aggressive course (Xia et al. 2013). FOXC1 also induces microvascular invasion in HCC (Xu et al. 2012). Presence of detectable FOXJ1 (on 17q.25) in HCC cells was associated with high histologic grade, an elevated proliferative activity, metastatic spread, and poor survival (Chen et al. 2013). FOXM1 (on 12p13.33) is a master regulator of tumor metastasis and is often expressed in HCC (Lin et al. 2010; Raychaudhuri and Park 2011). Its expression in HCC is induced by HBx protein and is correlated with a metastatic phenotype (Sun et al. 2011; Xia et al. 2012). The class I FOX protein FOXQ1 on 6p25.3 is overexpressed in HCC, FOXQ1 expression being associated with large tumor diameter, high serum AFP, later stage grouping, and aggressive tumor biology (Wang et al. 2013).

Myc Gene Expression in Hepatocellular Carcinoma

The Myc proto-oncogene is located on chromosome 8q24.21 and encodes a multifunctional DNA-binding protein activating or repressing transcription of numerous target genes, but predominantly those involved in control of growth and cell cycle progression. c-Myc is also implicated in the regulation of DNA replication. Malignant transformation and growth related to Myc results from a deregulation and altered balance in the expression of targeted gene products under the control of Myc.

The oncogene c-Myc is implicated in development of HCC (Yuen et al. 2001; Wang et al. 2012a). c-Myc interacts with SIRT1 in a positive feedback loop, and the two proteins act synergistically to promote hepatocellular proliferation; in human HCC SIRT1 expression positively correlates with expression of c-Myc and p53 (Jang et al. 2012). c-Myc expression and function in hepatocarcinogenic pathways interact with HBV X protein. HBx protein and c-Myc cooperate to support ribosome biogenesis and cellular transformation (Shukla and Kumar 2012). Amplifications of c-Myc in HCC are late genetic alteration in these neoplasms and are correlated with poor prognosis (Wang et al. 2002). Similar to other cancers, Myc function in HCC is controlled by microRNAs. MicroRNA-744 can target Myc, causing inhibition of cell growth, while decreased expression of this microRNA in HCC promotes Myc-induced cell proliferation (Lin et al. 2014). In HCC, genes and proteins interacting with Myc can also display altered expression patterns. Part of HCC showed upregulation of N-Myc downstream-regulated gene 1 (NDRG1), associated with a more aggressive tumor phenotype and poorer survival (Lu et al. 2014).

HOX Gene Pathways in Liver Cancer

Hox genes (homeotic genes) form a group of related genes that regulate the development of distinct body plans. For example, Hox proteins determine anterior-posterior axis, body segmentation, and symmetries of internal organs. Hox genes encode transcription factors that share a distinct sequence termed the homeobox. Interestingly, the alignment and organization of Hox genes along chromosomes characterized by distinct clusters are the same as the order of expression along the anterior-posterior axis of the organism, a phenomenon called colinearity (Duboule 1998). Colinearity seems to be related by a self-regulation process that determines the precise temporal and spatial expression of clustered Hox genes (Sheth et al. 2014).

Hox gene expression is deregulated in HCC. There is a significant difference in the expression of locus A HOX genes (HOXA genes), located on chromosome 7, between normal liver and HCC. Overexpression of HOXA1 correlates with

aggressive behavior and poor prognosis in patients with HCC, whereas downregulation of HOXA1 inhibits growth, migration, and invasion of HCC cells (Zha et al. 2012). In part of HCCs, a consistent overexpression of HOXA13 occurs, leading to the action of several gene targets that regulate the HCC cell cycle (review: Cillo et al. 2011). Specifically, there is a protein-protein interaction between HOXA13 and elF4E nuclear bodies, affecting the nuclear export of specific mRNA, such as c-Myc, VEGF, and cyclin D1 (Cillo et al. 2011).

RUNX Transcription Factor

RUNX3 (runt-related transcription factor 3) is a tumor suppressor that is downregulated in various cancers and involved in development of HCC. In HCC, RUNX3 expression is frequently decreased or even lost by epigenetic promoter hypermethylation or hemizygous deletion. Decreased expression is associated with the induction of epithelial-mesenchymal transition (EMT), reduced apoptosis, and tumor progression (Shiraha et al. 2011). In HCC cancer cell lines, an inverse correlation was found between RUNX3 expression and JAG ligand, RUNX3 expression via this pathway reducing HCC cancer stem cells (Nishina et al. 2011).

Transforming Growth Factor-Beta Signaling and TGF-Related Pathways in Hepatocarcinogenesis

Transforming growth factor-beta1 (TGF-beta1, chromosome 19q13.2) is a multifunctional protein that regulates proliferation, differentiation, survival, and apoptosis in numerous cell lineages. TGF-beta1 belongs to the TGF-beta superfamily, a large family of structurally related proteins, divided into four families (or subfamilies), i.e., decapentaplegic Vg-related family (bone morphogenetic proteins (BMPs) and growth differentiation factors), activin/inhibin family, TGF-beta family (TGF-beta1, TGF-beta2, and TGF-beta3), and a mixed family. Mature dimeric TGF-beta proteins interact with a conserved family of cell surface serine/threonine-specific protein kinase receptors. These receptors generate signals by use of a family of proteins termed Smads. Smads are intracellular proteins transducing signals from TGF-beta ligands to the nucleus for activating gene transcription. Smads are transcription factors that consist of trimers of two receptor-regulated Smads (Smad1-3, Smad 5 and Smad 8/9) and one co-Smad (Smad 4). TGF-beta1 affects the cell cycle progression by inducing p15 and p21 proteins which block cyclin-CDK complexes required for retinoblastoma (Rb) phosphorylation. Via this pathway, TGF-beta1 blocks progression through the G1 phase of cycle and suppresses expression of c-Mac, a protein required for G1 progression. TGF-beta1 induces apoptosis through the Smad pathway and DAXX (death-associated protein 6) pathway. In the liver, TGF-beta1 is a potent inhibitor of cell proliferation, acts in the termination mechanism of liver regeneration, plays a role in liver fibrosis and cirrhosis, and is frequently overexpressed in HCC (Abou-Shady et al. 1999; Kim et al. 2003; Paik et al. 2003; Ji et al. 2006; Lu et al. 2008; Giannelli et al. 2011). It is an inhibitor of hepatocyte DNA synthesis and may induce apoptosis, but the role of TGF-beta signaling in hepatocarcinogenesis is complex and not yet fully clarified. This may be due to fact that the hepatic action of TGF-beta strongly depends on its balanced expression, in that underexpression or overexpression can cause increased hepatocyte turnover and by that an increased risk of malignant transformation (Rossmanith and Schulte-Hermann 2001).

There is evidence that TGF-beta signaling plays a dichotomous role in hepatic carcinogenesis in that, on the one hand, it seems to suppress HCC development, but on the other hand is retained for HCC survival and maintenance of a malignant and aggressive phenotype (Mu et al. 2013). A procarcinogenic effect of TGF-beta also depends on its association with p53 loss (Morris et al. 2012). The carcinogenic action of TGF-beta in the liver may depend on a "dosage effect" related to differential expression patterns. Notwithstanding its antiproliferative action, overexpression of TGF-beta in HCC is

correlated with the tumor's malignant potential, probably also influenced by TGF-beta-induced stromagenesis/desmoplasia (Yamazaki et al. 2011; Gupta et al. 2014). TGF-beta is capable to induce epithelial-mesenchymal transition in HCC and by this promote spread and metastasis (Giannelli et al. 2005; Reichl et al. 2012). It also triggers HCC invasiveness through promotion of alpha3beta1 integrin expression and motility on laminin 5 substrates (Giannelli et al. 2002). TGF-beta1 phosphorylates beta1 integrin via Smad2 and Smad3, leading to its activation for invasion (Fransvea et al. 2009). On the other hand, blocking of TGF-beta1 upregulates E-cadherin and reduces invasion of HCC cells (Fransvea et al. 2008). Several members of the ECM-related CCN protein family interact with TGF signaling in cancers. Connective tissue growth factor (CTGF, CCN2) is upregulated in HCC cells through stimulation by epidermal growth factor receptor (EGFR) ligands, dependent on YAP expression, and CTGF expression promotes DNA synthesis and cell survival and downregulates TRAIL expression (Abou-Shady et al. 2000; Chu et al. 2008; Jia et al. 2011; Urtasun et al. 2011).

GTPases and GTPase-Related Proteins in Liver Cancer

Deleted in Liver Cancer 1 (DLC1) Tumor Suppressor Gene

The deleted in liver cancer 1 (DLC1) gene is a potent tumor suppressor gene located to chromosome 8p, plays a significant role in hepatocarcinogenesis, and encodes a regulator of the Rho family of small GTPases, i.e., a Rho GTPase-activating protein or RhoGAP. On chromosome 8p, DLC makes part of a cluster of six genes that are involved in liver carcinogenesis. Loss of DLC1 expression mediated by genetic and epigenetic mechanisms has been associated with the development of numerous human cancers, and two related genes, DLC2 and DLC3, may also represent tumor suppressors. DLCs affect growth of normal and cancer cells via their action as regulators of Rho GTPases which are key factors in cell proliferation. Apart from growth regulation, DLC1 also regulates functions of the cytoskeleton and cell motility, important aspects for tumor cell invasion and spread (Durkin et al. 2007; Liao and Lo 2008; Zimonjic and Popescu 2012). DLC1 presents as three isoforms (alpha, beta, and gamma), whereby DLC1 alpha is the most prominent form in normal human tissues. The function of DLC1 and DLC2 is regulated by differential phosphorylation mediated by Akt kinase.

DLC1 repression HCC has an influence on several biologic aspects of this cancer. In HCC, DLC1 negatively regulates Rho/ROCK/MLC pathway and ROCK-dependent actomyosin contractility. DLC1 abrogates Rock-mediated cytoskeletal reorganization, including formation of stress fibers and focal adhesions (Wong et al. 2008). Downregulation of DLC1 therefore favors a motile and invasive phenotype. In vitro, DLC1 overexpression inhibits growth of HCC cells. DLC1 is frequently inactivated in HCC tumors, through hemizygous and homozygous genomic deletion and epigenetic promoter hypermethylation (Wolosz et al. 2014), whereby remnant expression is found in tumor stroma. HCC can also harbor polymorphisms and missense mutation of DLC1 (Park et al. 2003). Similar to DLC1, a second RhoGAP protein, DLC2, has growth suppressor function, is underexpressed in HCC, and is probably involved in liver carcinogenesis (Ching et al. 2003).

Ras Signaling Pathways

Ras family proteins, named after their presence in rat **s**arcoma, are widely expressed in tissues and organs and belong to a superfamily of small GTPases regulating numerous cell functions, but in particular cell proliferation, differentiation, and survival. Human cell lineages possess three Ras genes, termed HRAS, KRAS, and NRAS, located on chromosomes 11p15.5, 12p12.1, and 1p13.2, respectively.

Ras genes encoding Ras proteins are the mostly commonly altered oncogenes in human

malignancies. Ras proteins are G proteins or guanosine-nucleotide-binding proteins, i.e., single-subunit small GTPases, which function as binary signaling switches. In the off position, Ras binds to GDP, while in the on position, they bind to GTP. The shift between GDP and GTP, and therefore the movement of the switch, is accomplished by the inherent GTPase function of Ras. The function of this switch is modulated by guanine nucleotide exchange factors (GEFs) and GTPase-activating proteins (GAPs). GAP stabilizes Ras and accelerates its switch function, while GEF releases GDP from Ras, facilitating Ras activation. The GTP-bound Ras state has affinities to numerous downstream effectors that mediate the signaling effects. Mutations and epigenetic alterations of the Ras-mitogen-activated protein kinase (MAPK) pathway are among the most common changes observed in various cancers. It is estimated that 20–30 % of all human cancers harbor mutations of Ras family genes, whereby mutations cause inappropriate activation of Ras genes. Constitutional overactivation of this pathway is known to cause overlapping syndromes termed RASopathies (Zenker 2011). Altered Ras and Raf oncogenes are also involved in the pathogenesis of genomic instability and aneuploidy (review: Kamata and Pritchard 2011).

The Ras pathway is significantly upregulated in part of HCC compared with nonneoplastic liver, however with markedly varying incidence. The frequency of K-Ras mutations in HCCs varied markedly and ranged from 2 % to more than 90 % (Liu et al. 1994; Colombino et al. 2012). Mutation of H-Ras in HCC amounted to 71 % in one study (Sui et al. 2012). Ras expression is synergized with Notch1 expression to transform hepatic cells (Fan et al. 2011). Ras expression in HCC promotes cell growth by alternative splicing-mediated inactivation of Krüppel-like 6 (KLF6), a tumor suppressor and zinc finger transcription factor that inhibits proliferation by transcriptional activation of p21 (Yea et al. 2008). In HCC cells, the Ras/Raf/MEK/ERK pathway is stimulated by diacylglycerol (DAG) kinase, an enzyme having a key position in the DAG-protein kinase signaling cascade. In particular, DAG kinase alpha is involved in HCC progression by activation of the MAPK pathway (Takeishi et al. 2012). Deregulation of Ras pathway components affects the biology of HCC. Patients with Ras, Raf-1, or pMEK1 overexpression had poorer overall survival (Chen et al. 2011a). Mutations of H-Ras occurred more often in high-risk tumors with metastatic recurrence than in low-risk neoplasms (Sui et al. 2012). In the absence of Ras mutations, inactivation/downregulation of GAPs/Ras GTPase-activating proteins (Ras GAPs), mainly RASAL1, DAB2IP, and NF1, promote unrestrained activity of wild-type Ras in human HCC (Calvisi et al. 2011).

HCCs revealed frequent downregulation of Ras association domain family (RASSF) proteins both in the early and late stages of carcinogenic pathways. Reduced RASSF1A expression is related to TNM stage, metastatic spread, portal vein invasion, and multiple tumor nodes (Hu et al. 2010). Inactivation of RASSF is associated with LOH of 3p21.3 in tumors, including HCC.

Whereas inactivation of the RASSF1A tumor suppressor is a widespread phenomenon in cancers, downregulation of RASSF2 and RASSF5 is so far limited to certain HCC subsets (Calvisi et al. 2012). Inactivation of RASSF1A in HCC is predominantly accomplished by epigenetic mechanisms, in that more than 90 % of HCCs were methylated at the RASSF1A CpG island (Dammann et al. 2005). RASSF1A expression in HCC cells inhibits cell growth via blunted proliferation (Guan et al. 2009). Epigenetic RASSF1A promoter hypermethylation presented as a prognostic marker for HCC (Saelee et al. 2010). A Ras effector gene acting via RASSF1A is the putative tumor suppressor NORE1B which is epigenetically silenced in the majority of HCC (Macheiner et al. 2009). Several proteins that modify the function of the Ras signaling pathway have been identified in HCC. Important modulators of the RTK/Ras/MAPK pathway are Sprouty proteins. Sprouty (SPRY) orchestrates a complex regulatory platform in the cell and mediates the cross talk among different signaling pathways depending on the MAPK/ERK pathway (Masoumi-Moghaddam et al. 2014). SPRY

genes are differentially expressed in HCC, whereby SPRY1, SPRY2, and SPRY3 are probably involved in carcinogenesis (Sirivatanauksorn et al. 2012). SPRY2 is downregulated in many HCC and may therefore represent a tumor suppressor in this malignancy (Fong et al. 2006; Song et al. 2012), and inactivation of SPRY2 accelerates Akt-driven hepatocarcinogenesis through activation of MAPK and PKM2 pathways (Wang et al. 2012b). The negative regulator of the Ras/Raf-1/ERK pathway, Spred2, increases growth in HCC when downregulated, while overexpression augments caspase-3 and apoptosis (Ma et al. 2011). A Ras-related protein is ARHI (aplasia Ras homologue member I or DIRAS3) which is an imprinted tumor suppressor gene with lost expression in certain cancers. ARHI binds to importins and impairs nuclear import of cargo proteins (Huang et al. 2009a), and is frequently downregulated in HCC, where its suppression is associated with tumor growth and angiogenesis (Huang et al. 2009b; Zhao et al. 2010).

PTEN Signaling in Liver Cancers

PTEN (phosphoinositide 3-kinase/phosphatase and tensin homologue, on chromosome 10q 23.31) is an ubiquitously expressed tumor suppressor and important signaling platform that acts through its lipid phosphatase domain and is centrally involved in growth regulation. In this signal node, PTEN operates as phosphoinositide phosphatase terminating PI3K signaling by dephosphorylating PtdIns(3,4)P and PtdIns (3,4,5)P(3). In its function as a regulator of specific gene expression, growth, cytoskeletal organization, integrin-mediated cell adhesion, and apoptosis, PTEN is expected to play a role in carcinogenic pathways (Tamura et al. 1999). PTEN also negatively regulates the MAPK pathway through its protein phosphatase activity.

In the liver, PTEN regulates several functions of hepatocytes and is also involved in the handling of hepatitis viruses by these cells. HCV infection downregulates PTEN and modulates cholesterol metabolism, favoring macrovesicular steatosis of the liver (Peyrou et al. 2013). PTEN is instrumental in the regulation of stem cell biology. In the liver, it controls the expansion of CD133-positive liver cancer stem cells (Rountree et al. 2009). Deregulation of PTEN occurs in various malignancies (review: Peyrou et al. 2010), and PTEN deregulation is a well-known feature of HCC (Wang et al. 2007b; Wu et al. 2007). Generally, failure of the tumor suppressor PTEN is associated with more aggressive malignancies, also high-grade and invasive HCCs (Hou et al. 2014). This pathway depends on nuclear localization of PTEN, a step that is already observed in hepatocytes infected with HCV and depending on transportin-2 depletion (Bao et al. 2014). PTEN is often downregulated in HCC, mainly via point mutations and associated with poor patient outcome (Yao et al. 1999; Hu et al. 2003, 2007; Zhang et al. 2004; Wu et al. 2007; Zhao et al. 2013), but was found to be expressed in other HCC, mostly at low levels in comparison with nonneoplastic liver (Dong-Dong et al. 2003; Wang et al. 2007b). LOH of HCC with downregulated PTEN localizes to chromosomes 10q23.3 (Fujiwara et al. 2000). Loss of PTEN expression in HCC enhanced tumor cell migration and invasion via Akt/Sp-1 transcription factor/MMP-2 activation, illustrating that downregulation of PTEN can confer an invasive and aggressive phenotype (Sze et al. 2011). The expression of PTEN in human HCC is regulated by aberrant expression of microRNA-21, exerting an influence on cell growth, migration, and invasion (Meng et al. 2007).

Hedgehog Signaling in Hepatocarcinogenesis

Sonic hedgehog (SHH) located to chromosome 7q36.6 encodes a secreted protein that is involved in the regulation of cell fates in the course of ontogenesis and produces inductive signals during embryogenesis. Hedgehog signaling pathway also plays a central role in regulation of growth homeostasis in the adult organism. Mammals possess three *Drosophila* hedgehog homologues termed DHH (desert hedgehog), IHH (Indian hedgehog), and SHH (sonic hedgehog), of which

SHH is the most intensively studied homologue. SHH is associated to membrane lipid rafts via covalent attachment of a cholesterol moiety and a palmitic acid, but it can be secreted into the extracellular matrix with the help of the transporter-like protein Dispatched and the glypican family member heparan sulfate proteoglycan Dlp. The SHH ligand binds on target cells to the Patched-1 (PTCH1) receptor, a molecule homologous to the Niemann-Pick disease protein NPC1. In the absence of SHH ligand binding, PTCH1 inhibits the downstream effector smoothened (SMO) via removing oxysterols from SMO through a sterol sensor/sterol pump contained in PTCH1. All three mammalian hedgehog homologues also bind to a second receptor, PTCH2. The effectors of this signaling pathway are the Gli proteins (glioma-associated oncogene homologue), DNA-binding zinc finger domain proteins. Gli transcription factors (Gli1, Gli2, and Gli3) inhibit transcription of SHH targets via binding to Gli-responsive genes. Transcriptional control by Gli proteins is in part tissue specific, with certain Gli proteins preferentially expressed in distinct tissues. An important negative regulator of SHH signaling is the Rab family GTPase, Rab23, which is involved in the regulation of certain development steps during ontogenesis.

The SHH signaling cascade promotes cell proliferation, specifically the growth of progenitor cells located to various tissues, and is involved in hepatic homeostasis. Due to its central role in growth control and regulation of developmental pathways shared by normal and transforming cells, altered and dysregulated hedgehog signaling is firmly linked to cancer development (review: Toftgard 2000). In the liver, early steps of SHH-linked carcinogenesis may strongly depend on dysregulated hedgehog signaling in immature cholangiocytes, stellate cells, and myofibroblasts, as mature hepatocytes lack hedgehog pathway activity. Hedgehog signaling in hepatic stellate cells (HSCs) is embedded in a network of factors linking hepatocytes with HSCs, e.g., glypican 3 which regulates HSC viability in a hedgehog-dependent manner (Magistri et al. 2014). In contrast, hepatoma cell lines in culture show expression of hedgehog species, PTCH1, smoothened, and Gli1. Production and secretion of hedgehog ligands by malignant hepatocytes influences the metabolic function of myofibroblasts and probably stromal cells via stimulation of glycolysis (Chan et al. 2012). Activation of the hedgehog signaling pathway is a frequent event in HCC, whereby expression of SHH, PTCH1, and Gli1 was observed at high rates (Huang et al. 2006; Patil et al. 2006; Sicklick et al. 2006; Calvisi et al. 2012; Che et al. 2012; Zheng et al. 2013). Expression of smoothened was observed in about 60 % of examined HCC, and hedgehog target genes PTCH1 and Gli1 were found in over 50 % of the tumors (Huang et al. 2006). Hedgehog-related hepatocarcinogenesis is in part linked to HBV infection. Blockade of hedgehog signaling delayed liver cancer development induced by HBx protein, suggesting the HBx-promoted carcinogenesis is partially dependent on the activation of the hedgehog pathway (Arzumanyan et al. 2012). In HCC cells, Gli1 activation and Gli1 nuclear localization are stimulated by HbX protein (Kim et al. 2011). The SHH pathway is involved in the generation of epithelial-mesenchymal transition (EMT) in HCC. Gli1 drives EMT in HCC, in part by upregulating caveolin-1, a strong inducer of EMT (Gai et al. 2014). TGF-beta1, which strongly induces EMT in HCC, promotes EMT in this neoplasm by activation of the SHH and Wnt pathways (Steinway et al. 2014), suggesting the presence of a complex interacting hedgehog-TGF-Wnt signaling platform. Gli1 mediates TGF-beta1-driven EMT in HCC through upregulation of the pro-EMT factor SNAI1 (Zheng et al. 2012).

HCC overexpressing components of the hedgehog signaling pathway show increased proliferation and invasiveness (Cheng et al. 2009), while downregulation of Gli1 inhibited HCC cell migration and invasion (Chen et al. 2014b). Gli1 was upregulated in HCCs with high histological grade, advanced nodal stage, and intrahepatic metastases (Zhang et al. 2014). The pro-invasive and pro-metastatic effects of hedgehog signaling in HCC in part depend on increased expression of MMP-9 via an activated ERK pathway (Lu et al. 2012). Expression of PTCH-1 and Gli1

in HCC predicts recurrence of HCC following tumor resection (Jeng et al. 2013). However, among the various components of the hedgehog system, only expression of the transcriptional factor Gli1 was associated with clinicopathologic features of HCC and indicated poor prognosis (Che et al. 2012). The frequent dysregulation of hedgehog signaling components in HCC may render this pathway amenable to novel therapies (Kappler and von Schweinitz 2012). There is recent evidence that cholangiocarcinoma also shows dysregulated hedgehog signaling (Kim et al. 2012).

Telomeres and Telomerase

Introduction

Telomeres are highly important molecular structures that generate the physical ends of linear chromosomes. They function as a cap to protect chromosomal end from "erosion" and from being mistaken as a DNA double-strand break and maintain ordered replication, genomic stability, and the regulation of cell senescence. Telomeres with a proper length protect genes located close to chromosomal ends from being truncated. Telomere dysregulation has direct consequences for aging and cancerogenesis, including hepatic oncogenesis. As a function of senescence and aging, telomere length changes, also reflected by expression levels of the thermogenic skeletal muscle hormone, irisin (Rana et al. 2014). In mammalian cells, telomeres consist of long telomeric double-stranded DNS/ssDNA overhangs composed of six proteins. The six human telomeric proteins TRF1, TRF2, RAP1, TIN2, POT1, and TPP1 have distinct functions and form a telomeric complex termed the telosome or shelterin. The term shelterin was chosen in analogy to other chromosomal protein complexes such as condensin and cohesin (de Lange 2005). This complex is critically required for telomere protection and maintenance and length control (Okamoto et al. 2008; Denchi 2009). A highly controlled interaction between three proteins, TIN2, TTP1, and POT1, in the cytoplasm regulates assembly and function of the telosome in the nucleus (O'Connor et al. 2006; Chen et al. 2007). The human telomere ssDNA overhangs are protected by POT1 and TPP1. Within the telosome, TRF1 and TRF2 are connected to POT1 through TIN2 and TPP1, whereby TIN2 is a key telosome element (Chen et al. 2007). Both in normal cells and neoplastic cells, telomere function is modulated by several controlling factors. Human TEN1 is a component of the mammalian CST complex (telomere-capping complex) containing CTC1-STN1-TEN1. CTC1 and STN1 act in telomere duplex replication and genome-wide restart of replication following DNA fork stalling. The three CST proteins are at the telomere and maintain telomere integrity, and TEN1 is required for G-overhang processing and genome-wide replication restart (Kasbek et al. 2013). During each cell division, telomeres typically shorten due to the fact that DNA polymerase is unable to fully replicate the 3′ end of chromosomes (the so-called end-replication problem), because the synthesis of Okazaki fragments requires RNA primers attaching ahead on the lagging DNA strand. In order to avoid progressive telomere shorting as a function of cell cycling, cells express a reverse transcriptase that maintains telomere length by adding newly synthesized DNA to the shortening ends. This enzyme, the telomerase (hTERT), consists of the transcriptase proper (TERT) and the telomerase RNA component (TERC) employed as a template to produce telomeric DNA.

Telomere Abnormalities in Liver Cancer and Its Precursors

The basic effect of telomere dysregulation in carcinogenic pathways is related to uncorrected or incompletely corrected telomere shortening leading to progressive genomic instability. Both precursor lesions in the liver and HCC accumulate numerous telomere dysfunctions, mainly telomere shortening which affects genomic stability and the balance between immortality and senescence of cancer cells (Ohashi et al. 1996; Huang et al. 1998; Oh et al. 2003, 2005; Ozturk

et al. 2009; Fu et al. 2012; El-Idrissi et al. 2013; Jung et al. 2014). Telomere length varies through chronic liver disease ending up with cancer by predominantly increasing shorter telomeres (telomere shortening effect), whose length is a good indicator for malignant potential (Yokota et al. 2003; Carulli and Anzivino 2014). However, certain subsets of HCC show long telomeres, a feature that is related to higher telomerase activity (see below), cell immortalization, and invasive capacity (Ko and Jung 2014). Shortening of telomeres causes telomere dysfunction; these short telomeres can undergo fusion, producing dicentric chromosomes and breakage-fusion-bridge cycles, finally resulting in large-scale genomic rearrangements and marked genomic instability (Murnane 2006, 2012). Genomic instability caused by telomere shortening in HCC, e.g., shows up in increasing aneuploidy of chromosome 8, a chromosome with common LOH events in HCC (Plentz et al. 2005). In HCC precursor cells, telomere shortening coincided with inactivation of cell cycle checkpoints (Plentz et al. 2007). Telomere shortening in HCC is associated with upregulation of the telomere proteins TRF1, TRF2, and TIN2 (Oh et al. 2005), possibly reflecting a compensatory mechanism. Telomere maintenance in HCC is regulated by the class III histone deacetylase, sirtuin 1, which is upregulated in HCC. Sirtuins are generally involved in senescence and pathogenic pathways of genomic instability (McGuinness et al. 2011). There is a positive correlation between expression levels and advancement in tumor grades. SIRT1 silencing causes telomere dysfunction and the emergence of telomere dysfunction-induced liver foci (Chen et al. 2011b).

Telomerase (hTERT) reactivation in cancers is a mechanism to achieve telomere maintenance and to avoid progressive telomere erosion. HCCs and their nodular precursors show an upregulation of telomerase (hTERT) that may in advanced liver cancer result in long telomeres and effect that plays a role in cancer progression (Huang et al. 1998; Oh et al. 2008). Variations in telomere length may also characterize distinct subsets of HCC. HCCs show TERT promoter mutations that affect telomere length and maintenance (Pinyol et al. 2014). HCCs with stemness-related protein expression, tumors showing a highly aggressive phenotype, display increased telomere length, increased expression of hTERT and shelterin complex proteins, and increased chromosomal instability (Kim et al. 2013). However, telomerase activation was not only found in dysplastic nodules but also in large regenerative nodules occurring in cirrhosis, suggesting that increased telomerase activity is not necessarily a feature of malignancy (Hytiroglou et al. 1998). Telomerase expression in HCC, or its reactivation following hepatectomy, predicted recurrence (Kobayashi et al. 2002). HCC and its precursor lesions revealed a high frequency of hTERT promoter somatic mutations, occurring as one of the earliest recurrent genetic defects (Nault et al. 2013). In one investigation, telomerase activity, telomere length, and hTERT expression in HCC were independent of the hepatitis virus status (Saini et al. 2009). A protein encoded by the DKC1 gene, dyskerin, is an essential nucleolar protein involved in cell cycle regulation and is required for the pseudouridylation of ribosomal RNA and the stabilization of the telomerase RNA component. Overexpression of dyskerin in HCC was correlated with MYC and MIK67 expression and is an unfavorable prognostic factor in patients with HCC (Liu et al. 2012). Leptin expression is highly correlated with hTERT expression levels in HCC, mediated through binding of STAT3 and Myc/Max/mad network proteins on the hTERT promoter (Stefanou et al. 2010). hTERT expression in HCC is also subject to epigenetic regulation via methylation of the hTERT promoter, the CpG island methylator phenotype (Zhang et al. 2008; Iliopoulos et al. 2009).

Etiology and Pathogenesis of Hepatocellular Carcinoma: Epigenetic Mechanisms

168

Contents

Abstract

Etiology and pathogenesis of liver cancer strongly depend on various epigenetic mechanisms that result in gene silencing. By the action of epigenetic processes, heritable changes in gene expression patterns are maintained over numerous cell generation and play an important role in carcinogenic pathways. Major epigenetic mechanisms that operate in hepatocellular carcinoma (HCC) include DNA methylation, histone modifications, chromatin modifiers, microRNAs, RNA editing (RNA editome), and lncRNAs. DNA methylation that involves numerous CpG sites and results in distinct DNA methylome signatures is an important pathway in HCC. In these neoplasms, CpG-methylated sites are predominantly located within gene-promoter regions and CpG islands, and their presence is associated with biology of disease in HCC. Part of HCCs show various types of histone modifications which play a role in hepatocarcinogenesis. HCCs also show distinct deregulations of chromatin modifiers that cause gene silencing, in particular polycomb repressive complexes. Liver cancers exhibit highly complex patterns of microRNA expression, resulting in distinct microRNAomes that will provide diagnostic and stratification signatures.

DOI 10.1007/978-3-319-26956-6_168

Introduction: General Features of the Liver Cancer Epigenome

By the action of epigenetic mechanisms, heritable changes in gene expression patterns are maintained over numerous generations and play an important role in carcinogenic pathways, including liver cancers. Epigenetic mechanisms operational in HCCs include alterations in DNA methylation (methylome), histone modifications, chromatin modifiers, microRNAs, RNA editing (RNA editome), and lncRNAs (reviews: Liu et al. 2012; Liu et al. 2014a; Raggi et al. 2014). Importantly, epigenetically driven changes in gene expression in HCCs are influenced by environmental factors. Specifically, hepatitis virus infections, alcohol toxicity, and fungal hepatotoxins elicit epigenetic alterations of genes through altered promoter methylation, histone modifications, and RNA-mediated gene silencing (Herceg and Paliwal 2011).

DNA Methylation as an Epigenetic Mechanism: Methylation Profiles in Liver Cancer (the HCC Methylome or Methylation Epigenome)

By the use of genome-wide profiling of DNA methylation, numerous CpG sites modified by methylation were identified in HCCs in comparison with the normal or cirrhotic liver tissue (Raggi and Invernizzi 2013; Dong and Wang 2014). CpG-methylated sites are predominantly located within promoter regions and CpG islands, and their presence is associated with biology of disease in HCCs (Zhu 2006; Hernandez-Vargas et al. 2010; Shen et al. 2012; Song et al. 2013; Mah and Lee 2014; Nishida et al. 2014). In one study on patients with HBV- or HCV-associated HCCs, methylation patterns were associated with tumor progression stage and involved distinct genes involved in growth regulation and signaling (APC, RASSFIA, CDKN2A, and FZD7), and certain hypermethylated genes (e.g., NAT2, CSPG2, and DNMT1) were exclusively associated with HBV-related HCC (Hernandez-Vargas et al. 2010). Song and coworkers detected promoter CpG island DNA methylation loci in diverse signaling networks affecting cell development, gene expression, and cell death (Song et al. 2013). Analysis of epigenetic methylation patterns in HCCs results in the detection of methylation-based prognostic signatures based on the identification of relevant hepatocarcinogenic genes (Yu et al. 2002). Certain clusters of methylated genes indicate tumors with progenitor cell features and are potent epidrivers (Villanueva et al. 2015).

Several candidate tumor suppressors for HCC have been identified to be regulated by promoter hypermethylation, including p16INK4 (Roncalli et al. 2002; Qin et al. 2004; Zang et al. 2011), RASSF1A/Ras association domain family 1A gene (Schagdarsurengin et al. 2003), RUNX3 (Yang et al. 2014b), RIZ1/retinoblastoma-interacting zinc finger gene (Zhang et al. 2010), ZIC1 tumor suppressor (Wang et al. 2014a), tumor suppressor DACH1/human dachshund homolog 1 (Zhu et al. 2013), adenomatous polyposis coli gene/APC (Xu et al. 2014), endothelin receptor type B (Hsu et al. 2006), smad-interacting protein-1/SIP1 (Acun et al. 2011), TGF-beta1 target gene and transcriptional repressor HEYL (Kuo et al. 2014), bone morphogenetic protein-6 (He et al. 2014a), and secreted frizzled-related proteins (Lin et al. 2014). DNA methylation can also modify the expression of several microRNAs in HCC, including microRNA-148a, microRNA-195, microRNA-375, and microRNA-378 (He et al. 2015). There is a negative feedback regulatory loop between microRNA-148a and DNMT1 in HCC cell proliferation, in that DNM1, which is a target of this miR, is inversely correlated with the expression of microRNA-148a (Long et al. 2014).

The activity of DNA methyltransferase 1/DNMT1 in human HCC can be upregulated by growth factors, specifically insulin-like growth factor 1 signaling upregulates DNMT1 via an Akt/beta-transducin repeat-containing protein-mediated ubiquitin proteasome pathway (Fang et al. 2015). Cancer gene methylation frequencies in HCC are modulated by hepatitis virus infections

and environmental carcinogenic factors. Generally, HBX induces epigenetic modifications in hepatocarcinogenesis (Park et al. 2007). Hepatitis B virus inhibits the expression of the metastasis inhibitor KAI1/CD82 through hypermethylation of its promoter in HCC cells (Yu et al. 2014) and downregulates the suppressor of cytokine signaling/SOCS1 by hypermethylation (Zhang et al. 2013b). HBX promotes hypermethylation of p16INK4a through upregulation of DNMT1 and DNMT3 (Zhu et al. 2010). A high frequency of RASSF1A hypermethylation in human HCC was associated with aflatoxin B1 exposure (Zhang et al. 2002), and K-Ras and p16 methylation was more common in workers exposed to vinyl chloride (Weihrauch et al. 2001).

Histone Modifications

In nucleosomes, 145 DNA base pairs are wrapped around a histone octamer consisting H2A, H2B, H3, and H4 histones. Histones packed within nucleosome octamers have a protruding tail which is subject to posttranslational modifications, the histone modifications as an epigenetic feature. Histone modifications serve to switch gene transcription on or off. The modifications include methylation and acetylation of lysine and arginine, phosphorylation of serine and threonine, and ubiquitination of lysine. Histone acetylation is mediated by two families of enzymes, the histone acetyltransferases (causing the "on" position of gene transcription) and histone deacetylases (causing the "off" position of gene transcription).

Part of HCCs show various types of histone modifications which play a role in carcinogenesis and are associated with tumor biology (Magerl et al. 2010; Cai et al. 2011a; He et al. 2012; Hung et al. 2014a). For example, a high level of H3 histone lysine trimethylation is correlated with an aggressive course and poor prognosis of HCC (He et al. 2012). The generation of histone modifications in HCCs is also related to epigenetic alterations in chromatin patterning (see the following paragraph).

Chromatin Modifiers (Polycomb Repressive Complexes)

A distinct form of heritable gene silencing is mediated by chromatin-modifying complexes containing polycomb group proteins. Specifically, polycomb proteins generate silencing platforms termed polycomb repressive complexes (PRCs). Two major PRCs are known. PRC1 consists of a core protein (BMI), RING1A and RING1B ubiquitin ligases for the histone H2AK119, and the protein CBX7 which binds to histone H3K27. PRC2 consists of EZH1/EZH2 (a methyltransferase causing gene silencing by trimethylating histone H3K27), SUZ12/suppressor of zeste 12 homolog, EED1, and RbAp48. Deregulation of PRCs and the associated epigenetic alterations are involved in cancerogenesis (Piunti and Pasini 2011; Lin et al. 2011).

HCCs show various aberrations of PRC-based epigenetic mechanisms (Au et al. 2013). In HCCs, expression levels of EZH1/EZH2 are frequently elevated, high expression correlated with aggressive, metastatic features and poor prognosis (Sudo et al. 2005; Cai et al. 2011b). EZH2 as a methyltransferase represses target genes in part through histone modifications in cancers (Simon and Lange 2008). HCCs show EZH2-induced trimethylation of histone H3 lysine 27 (H3K27me3), affecting the expression of several genes, including cyclin-dependent kinase inhibitors and Notch signaling (Gao et al. 2014). Enhanced EZH2 in HCC silences Wnt antagonists, thereby activating Wnt/beta-catenin signaling involved in hepatocarcinogenesis (Cheng et al. 2011). EZH2, together with c-Myc, silences the tumor-suppressing microRNA-101 in HCC (Wang et al. 2013) and multiple microRNAs involved in liver cancer metastasis (Au et al. 2012).

The PRC pathways are connected with effects exerted by HBV X protein. HBX-mediated hepatocyte transformation is associated with downregulation of the PRC2 component, SUZ12 in a polo-like kinase 1-dependent manner (Wang et al. 2011), a mechanism that activates mitogenic polo-like kinase 1 (Studach et al. 2010). Loss of

SUZ12 caused by this mechanism in turn results in derepression of PRC2 target genes involved in stem and progenitor cell biology, including EpCAM, DLK1, DKK2, and BAMBI (Wang et al. 2011; Studach et al. 2012).

MicroRNAs in Hepatocarcinogenesis

General Remarks

MicroRNAs (miRNAs or miRs) are small noncoding RNA molecules with a length of about 22 nucleotides. They are involved in posttranscriptional regulation of gene expression via base-pairing with complementary sequences within processed mRNA molecules. Targeted mRNAs are silenced by this interaction and afterward actively disassembled (target degradation). The human genome encodes more than 1,000 microRNAs with a complex catalog of targets forming a microRNAome. Functional maturation of microRNAs requires a stepwise cleavage of precursor hairpin transcripts by the Drosha and Dicer RNase III enzymes, but there exist at least two alternative (noncanonical) pathways. One is based on a splicing-mediated miR biogenetic mechanisms related to the action of short hairpin introns called mirtrons. In the mirtron pathway, spliceosome-excised introns are direct Dicer substrates (Ruby et al. 2007; Westholm and Lai 2011). A third pathway is, in contrast to mirtrons, independent of Dicer, but requires Drosha for processing (the simtrons; Havens et al. 2012). Both mirtrons and simtrons interact with Argonaute proteins and function in silencing of target transcripts. The microRNAome is the complete set of microRNAs/miRNAs (or a so-called microRNA atlas) of an organism or a certain normal or neoplastic cell lineage (Murray et al. 2010). The whole human microRNAome will be determined in order to arrive at the complete target miRNA network (Satoh and Tabunoki 2011).

The MicroRNAome in Cancerogenesis

MicroRNAs and the microRNAome have an important role in cancer and cancerogenesis, including liver cancer (Koturbash et al. 2011: Khare et al. 2013). MicroRNAs that have a central role in cancer development are termed oncogenic microRNAs or oncomiRs. In the future, distinct microRNA signatures will characterize individual tumors, in the sense of a oncomiRome. MicroRNAomes of neoplasms may serve to develop novel tumor classifications and to arrive at "micromanaging" classifications by creating a map of tumor-specific miRNA signatures (Vilar et al. 2011).

The MicroRNAome in Hepatobiliary Cancer

There is increasing evidence that microRNAs, due to their action on multiple targets, play a significant role in the development of liver cancer, and in HCC progression (review: Gong et al. 2015). In HCC, microRNAs often display aberrant expression profiles and seem to act as oncogenes or tumor suppressors. Certain microRNA species are almost exclusively associated with HCC or related to distinct HCC types and subtypes, implying microRNAs or hepatic oncomiRs a significance for diagnosis and risk stratification. Furthermore, an aberrant expression of HCC oncomiRs generates typical molecular signatures for these tumors, correlated with clinical parameters and potential drug sensitivities (Gramantieri et al. 2008; Ji and Wang 2009; ElHefnawi et al. 2013; Gailhouste and Ochiya 2013; Giordano and Columbano 2013; Greene et al. 2013; Sun et al. 2013a; D'Anzeo et al. 2014; Hung et al. 2014b; Kou et al. 2014; Saito et al. 2014; Table 1). But also important predisposing conditions are markedly influenced by the action of microRNAs. For example, HCV infection, playing an critical role in hepatocarcinogenesis, is regulated on several levels by distinct miR species (reviews: Kumar 2011; Hou and Bonkovsky 2013). In particular, microRNA-122 is highly enriched in the liver infected with HCV and interacts with HCV, suggesting that HCV has subverted the host gene-silencing machinery (Gupta et al. 2014). In cancer cells, microRNA-mediated gene regulation may be interconnected with signaling pathways, e.g., the Wnt/beta-catenin

Table 1 MicroRNAs (miRs) expressed in liver cancer and/or upregulated or downregulated in hepatitis virus-induced hepatocellular carcinoma (Modified after Hou and Bonkovsky (2013), Sun et al. (2013a), D'Anzeo et al. (2014), and Hung et al. (2014))

Upregulated microRNAs	Main target(s)
miR-10a	Eph4, CADM1
miR-17-5p	p38 signaling pathway
miR-18a	ER1alpha
miR-18b	TIMP3
miR-21	PTEN, RhoB, PDCD4
miR-23a	PGC-1a, G6PC
miR-130a	RUNX3
mir-135a	FOXM1
miR-143	FNDC3B
miR-155	SOCS1, DKK1, APC, PTEN
miR-181	TIMP3
miR-182	MTSS1
mirR-210	VMP1, AIFM3
miR-216a	TSLC1
miR-221	CDK inhibitors
miR-224	NF-kappaB pathway, Smad4
miR-301a	Gax
miR-373	PPP6C
miR-490-3p	ERCIC3
miR-519d	CDKN1A/p21, PTEN, Akt 3
miR-550a	CPEB4
miR-590-5p	TGFRII
miR-615-5p	IGF-II
miR-657	TLE1, NF-jB
Downregulated microRNAs	
Let-7a	caspase-3
Let-7b	HMGA2
Let-7c	PPARalpha
miR-1	ETI1
miR-7a	c-Myc, caspase-3, Bcl-xl
miR-26a/b	IL-6, cyclin D2
miR-29a	SPARC
miR-34a	c-Met, CCL22
miR-101	C-Fos, SOX-9, EZH2
miR-122	c-Myc,ADAM-1,Wnt-1 IL-6, TNF,IGF-1R
miR-124	ROCK2, EZH2, CDK6, SMYD3
miR-125a/125b	VEGF-A, Mcl-1, Bcl-2, SIRT7
miR-138	CCND3
miR-139	c-Fos, ROCK2
miR-145	IGF-1R, beta-catenin, IRS1/2
miR-195	VEGF, cyclin D1, CDK6, E2F3
miR-199a/b-3p	c-Met, mTOR, caveolin-2, PAK4
miR-200a	HDAC4
miR-203	ABCE1
miR-206	suppressor of cell proliferation
mirR-214	catenin, HDGF
miR-219-5p	GPC3
miR-223	STMN1
miR-375	AEG-1, ATG7
miR-376a	PIK3R1
miR-449	c-Met
miR-450a	DNMT3a
miR-520e	cyclin D1, MEKK2

signaling cascade (Sun et al. 2013b). Similar to other microRNAs, oncomiRs associated with HCC may be distributed among cells via exosomes/microvesicles, a mechanism potentially involved in the generation of metastatic niches and establishment of cancer fields.

In what follows a selection of the microRNAs listed in the Table are discussed in some more detail. MicroRNA-21, which negatively regulates several targets and involved in the development of several cancers, displays elevated expression levels in HCC, where it regulates multiple programs that enhance proliferation, apoptosis, and invasive pathways by mainly targeting PTEN, PDCD4, and RECK (Liu et al. 2010). MicroRNA-23 may be involved in the onset of HCC, as its expression is correlated with TNM stage and tumor size (Bao et al. 2014). Expression of microRNA-26a in HCC suppresses angiogenesis by targeting the HGF/c-Met signaling pathway (Yang et al. 2014a). MicroRNA-21 is inducible by the HBx protein and favors cell proliferation by targeting programmed cell death protein 4 and PTEN (Bao et al. 2013; Damania et al. 2014). MicroRNA-29c acts as a tumor suppressor by directly targeting a factor involved in cellular senescence and regulation of telomere function, sirtuin 1/SIRT1. MiR-29c potently suppresses SIRT1, and loss of miR-29c expression in HCC causes aberrant SIRT1 expression promoting tumor progression (Bae et al. 2014). MicroRNA-101 is an important tumor-suppressive miR in human HCCs and is

epigenetically repressed by the zeste homolog 2/EZH2 unit of the polycomb repressive complex 2/PRC2 in a c-Myc-mediated manner (Wang et al. 2014b). MicroRNA-106b-25/microRNA-17-92 forms polycistronic clusters that are involved in HCC oncogenesis and are regulated by c-Myc (Tan et al. 2014). MicroRNA-122 is a liver-specific miR which suppresses proliferation and induces apoptosis (Xu et al. 2012) and is significantly downregulated in most HCCs. It regulates hepatic tumorigenesis by targeting Akt3, suggesting that microRNA-122 acts as tumor suppressor (Nassirpour et al. 2013). MicroRNA-148a is a tumor suppressor in HCC and involved in HBV-induced hepatocarcinogenesis. HBV infection promotes expression of this miR through HBx-mediated upregulation of the URG11 gene, URG11 protein modulating the expression of several miRs (Yuan et al. 2012). This microRNA also suppresses epithelial-mesenchymal transition/EMT and metastasis by targeting Met/Snail signaling (Zhang et al. 2014). MicroRNA-657 directly targets transducin-like enhancer protein 1/TLE1 and activates NF-kappaB pathways (Zhang et al. 2013a). MicroRNA-206 is downregulated in HCC. Low levels of this miR are associated with poor tumor differentiation, multiple tumors, advanced stage, and lymph node metastasis. MicroRNA-206 is a suppressor of cell proliferation and promoter of apoptosis (Yunqiao et al. 2014). MicroRNA-218 modulates HCC proliferation through targeting of the PTEN/Akt/PIP3K pathway (Xiao et al. 2014). In several HCC cell systems, microRNA-612 showed inhibitory effects on cell proliferation, migration, invasion, and metastasis, Akt being a direct target. This microRNA also suppresses the stemness of HCC by reducing the number and size of tumor spheres and colony formation in vitro (Tang et al. 2014). Expression of microRNA-657 can be induced by hepatitis viral proteins and is increased in HCC, where it augments proliferative activity. In a miRNA analysis of the human bile, real-time PCR has identified miRNA-9 as a potential diagnostic biomarker for biliary tract cancer (Shigehara et al. 2011). Certain microRNAs can exert an influence in the growth pattern of HCCs. Simultaneous silencing of microRNA-141 and microRNA-200 promoted the development of HCC with bile duct thrombus formation via activation of epithelial-mesenchymal transition (Yeh et al. 2014).

Several microRNAs have been analyzed in regard to their impact on HCC biology and aggressiveness in more detail (reviewed in Sun et al. 2013a). HCC with poor prognosis, or shorter disease-free survival, or shorter overall survival, and aggressive course were characterized by downregulation of miRs let-7g, 19, 22, 26, 29, 99a, 122, 124, 139, 145, and 199b or upregulation of miRs 10b, 21, 17-5p, 135a, 155, 182, 221, and 222. Upregulation of miR-125b was associated with good survival.

Long Noncoding RNAs in Liver Cancer

Long noncoding RNAs (lncRNAs) are functional RNA molecules that are not translated into a protein, but play significant roles in numerous biological processes and in cancerogenic pathways (review: GENCODE consortium v7 catalog of lncRNAs, Derrien et al. 2012). LncRNAs are transcribed as large RNA transcripts with a length greater than 200 nucleotides, i.e., about ten times longer than microRNAs and longer than other short/small noncoding RNAs, such as piRNAs, snoRNAs, and endogenous siRNAs (Deng and Sui 2013; Shi et al. 2013). LncRNAs form a large group of RNAs. It is estimated that at least four times more lncRNAs than coding RNA sequences are present. The FANTOM (Functional Annotation of Mammalian cDNA) project identified approximately 35,000 noncoding transcripts from around 10,000 distinct loci, but this figure may become greater in the future. LncRNAs are transcribed within intergenic stretches and are predominantly transcribed as complex interlaced networks of overlapping sense and antisense transcripts that frequently include protein-coding genes. LncRNAs function in the regulation of life cycles of numerous genes and affect

chromosome remodeling, transcription (via targeting transcriptional activators or repressors and RNA polymerase II), availability of transcription factors, splicing regulation, siRNA-directed gene regulation, posttranscriptional processing, interactions with microRNAs, epigenetic silencing, and imprinting (Rinn and Chang 2012). Via these interactions, lncRNAs regulate cell growth and differentiation. Specifically, numerous lncRNA species that affect differentiation of various cell lineages have been identified (list and review: Hu et al. 2012). In cancer, lncRNAs expression is associated with modulation of invasion, spread, metastasis, and recurrence (Qiu et al. 2013).

Alterations of lncRNA expression play a role in various liver disorders, including cancer and its precursors (Takahashi et al. 2014). Dysregulation of lncRNA has been observed in HCC, whereby both up- and downregulations were observed for numerous (more than 200) lncRNAs (Panzitt et al. 2007; Hou and Bonkovsky 2013; Pan et al. 2013; Wang and Li 2013; He et al. 2014b; Huang et al. 2014; Liu et al. 2014b; Zhao et al. 2014; Zhu et al. 2014b). Mainly in HCV-associated HCC, several species of lncRNA are differentially expressed (Hou and Bonkovsky 2013). LncRNAs are also involved in the biology of hepatitis virus infections. In HBx transgenic mice, a distinct pattern of lncRNA develops compared with wild-type mice. HBx protein downregulates lncRNA-Dreh (for downregulated expression by HBx), which can inhibit HCC growth and metastasis and acts as a tumor suppressor in the pathogenesis of HBV-related HCC. This lncRNA has a human homolog (hDREH), which is often downregulated in HCCs (Huang et al. 2013). The pathways leading from dysregulated lncRNA expression and carcinogenesis are not yet clarified, but modifications in the proliferative behavior of target cells may play a central role. In the setting of liver regeneration, a distinct type of lncRNA termed lncRNA associated with liver regeneration/lncRNA-LALR1 is expressed and accelerates hepatocyte proliferation via activation of the Wnt/beta-catenin signaling cascade (Xu et al. 2013).

RNA Editing and the RNA Editome in Hepatocellular Carcinoma: Diversification of the Tumor Transcriptome

A posttranscriptional modification of RNA is characterized by enzyme-mediated conversion of nucleotides within RNA, processes causing extensive transcriptome diversity. A common RNA editing is adenosine-to-inosine conversion (termed A-to-I editing). A-to-I editing is accomplished by adenosine deaminase/ADA which induces adenosine deamination to yield inosine. The editing process involves both coding and noncoding regions of DNA (Athanasiadis et al. 2004). ADAs that are specific for double-stranded RNA are termed ADAR (adenosine deaminases that act on RNA), forming a family with ADAR1 and ADAR2 being prominent members (George et al. 2014). A second form of RNA editing is characterized by cytidine to uridine conversion, mediated by APOBEC-1. A third form of RNA editing, guanosine-to-adenosine conversion, involves the APOBEC-3 protein.

RNA editing generates considerable RNA and protein diversity, with aberrant diversity patterns in cancers (Schaub and Keller 2002; Paz et al. 2007; Dominissini et al. 2011). During malignant transformation of cells and progression of cancers, A-to-I editing results in complex patterns of RNA modifications, the so-called RNA editome. In HCCs, the editing rate is significantly higher than in adjacent nonneoplastic liver tissues (Kang et al. 2015). The RNA editome of HCC is markedly disrupted and showed hyper-and hypoediting of numerous genes, including not only the recoding editing of exons but also the editing in noncoding chromosomal regions (microRNAs; Alu-repetitive elements; Li et al. 2013; Qi et al. 2014). Genome-wide analysis of editing in HCC revealed several tumor-specific edits in part relating to cancer genes (Kang et al. 2015). HCCs often display a severely disrupted A-to-I RNA-editing balance, mainly caused by differential expression patterns of ADAR1 and ADAR2 (Chan et al. 2014). In HCC, ADA2 mediates the editing of

complementary antisense transcripts as a mechanism regulating the biosynthesis of specific microRNAs (Yang et al. 2006; Liu et al. 2013).

Interspersed Nuclear Elements/ Transposable Elements/Endogenous Retrotransposons in Liver Cancer

Retroposons or transposable elements comprise about 44 % of the human genome (Cordaux and Batzer 2009). Active retroelements come in three classes and can induce mutations. They comprise long interspersed elements (LINEs; around 500,000 copies), short interspersed elements (SINEs; approximately 1.5 million copies), and SVAs (SINE-R, VNTR, Alus; around 3,000 copies). LINE-1 retrotransposons (6.4 kb long) represent mobile genetic elements that account for up to 21 % of the human genome (Adams et al. 1980). LINE-1 retrotransposons have two open reading frames that encode proteins that act in retrotransposition, i.e., a ribonucleoprotein p40 and a reverse transcriptase. These two proteins operate in the "copy and paste" mechanism to generate a new DNA template for further retrotransposition (review: Rahrmann and Largaespada 2013). Novel LINE-1 insertions can change gene functions and by this induce pathological genome expression patterns associated with carcinogenesis. Altered gene expression is linked to the generation, during retrotransposition, of two single-strand breaks that may create the potential for double-strand break, translocations, deletions, or recombinations. Part of endogenous LINE-type retrotransposons are silenced by epigenetic promoter methylation, but active (non-silenced) LINEs have been observed in several normal cell lineages and in cancer cells. LINE-1 alterations (germline retrotransposition events) are involved in HCC and are associated with altered expression of tumor suppressors (Rahrmann and Largaespada 2013; Shukla et al. 2013). Hypomethylation of LINE-1 was detected in a majority of HCCs, but not in nonneoplastic liver tissue (Takai et al. 2000). Epigenetic hypomethylation of LINE-1 in HCC is associated with poor prognosis through activation of c-Met (Zhu et al. 2014a).

General Pathology of Hepatobiliary Tumors: Structural and Functional Changes of Nuclei

Nucleus, Nuclear Structure, and Nuclear Functional Changes in Liver Cancer

169

Contents

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_169

Abstract

Cancers, including those of the hepatobiliary tract, display a wide variety of cellular and nuclear abnormalities that reflect the fundamental biologic disorder, characterizing malignancies. Part of nuclear abnormalities are important for cancer diagnosis and are generally summarized under the term nuclear atypia. The spectrum of nuclear abnormalities in cancer, and the associated mechanisms, is however highly complex. The major forms of nuclear and cellular abnormalities in cancer cells include pleomorphic, anisokaryosis, anaplasia, micronuclei, hyperchromasia, coarse chromatin patterns, chromatin bridges, macronucleoli, irregular nuclear membranes, and abnormal mitotic figures. Generally, the severity of chromatin abnormalities used in histologic and cytologic diagnosis, such as hyperchromasia, coarse chromatin, and changes in nuclear size and shape, depends on the dedifferentiation of cancer cells, the changes gradually increasing in malignancies of higher grade. There are direct causal links between the fundamental derangement of high-order chromatin organization that occurs in and characterizes cancers and the diagnostically important patterns of altered nuclear morphology.

General Aspects of Cancer Cell Morphology

Cellular and Nuclear Abnormalities of Cancer Cells

Cancers, including those of the hepatobiliary tract, show a wide variety of cellular and nuclear abnormalities that reflect the severe biologic disorder characterizing cancer and are useful for diagnosis (Klebs 1889; von Hansemann 1897; Willis 1948; Cameron 1952; Rather 1978; Cohen et al. 1991; Bignold 2003; Bignold 2004; Wee and Nilsson 2003; Bignold et al. 2006b; Rynearson and Sussman 2011). Part of the abnormalities visualized in tissue sections or cytologic smears are described by distinct terms (Table 1).

Pleomorphism, Nuclear Size, and Nuclear Shape

Pleomorphism relates to marked overall changes of the cell body and its cytoplasm and alterations in shape, size, and chromatin pattern of nuclei in cancer cells and usually reflects a mutator phenotype of carcinogenesis (Bignold 2003; Zink et al. 2004). Typical alterations of nuclear in cancer cells comprise malleable nuclei with crush artifacts, grooves, clefts, polylobulation, indentations, folds, and undulations (Figs. 1, 2, 3, 4, 5, 6, and 7).

Apart from frequent and general changes in chromatin structure (Table 1), chromatin changes comprise asymmetric aggregates of heterochromatin, dispersed heterochromatin, and loss of heterochromatin aggregates (Zink et al. 2004). The mechanisms governing nuclear size and shape are still not well elucidated. There is evidence that the control of nuclear size and nuclear shape is coupled in a complex manner (Walters et al. 2012; Jevtic et al. 2014). Nuclear shape, which undergoes dramatic changes in cancer cells, is strongly regulated by the nuclear envelope and its connections with both the cytoskeleton and chromatin. The nuclear envelope can undergo several types of characteristic alterations in cancer cells. In malignant neoplastic cells with genetically stable, near-diploid background, the nuclear envelope can show intranuclear invaginations that contain cytoplasm and are manifest as so-called intranuclear inclusions. Also nuclear grooves found in certain neoplasms are thought to derive from nuclear lamina abnormalities. In genomically highly unstable tumors, severe shape anomalies of the nuclear envelope are more common (Fischer 2014). Cancer cells can show transient nuclear envelope rupturing during interphase, associated with the mislocalization of nucleoplasmic and cytoplasmic proteins and sometimes entrapment of cytoplasmic organelles in the nuclear space (nuclear invaginations;

Table 1 Terminology of cellular and nuclear abnormalities of cancer cells

Pleomorphism	Variable size and shape of cells and/or nuclei in cells of the same type
Anisokaryosis	Variation in nuclear size
Macrokaryosis	Increased nuclear size
Nuclear/cytoplasmic ratio	Increased N/C ratio of 1:2 or more suggests cancer
Anaplasia	Process leading to undifferentiation (von Hansemann definition)
Micronucleus	Small abnormal nucleus forming whenever a chromosome or chromosome fragment is not incorporated into one of daughter nuclei
Broken eggs	Small amounts of genetic material attached to the nucleus by a Feulgen-positive filament
Nuclear buds	Protrusions of nuclei formed from chromatin bridges
Nucleotesimals	Nuclear appendages connected with the nucleus by lamellar bridges
Atypical naked nuclei	HCC nuclei apparently devoid of cytoplasm in cytologic smears
Hyperchromasia	Increased basophilic staining of nuclear components due to a change in structure, density, and/or amount of chromatin
Coarse chromatin pattern	Ropy or cord-like chromatin pattern
Irregular chromatin distribution	Distribution of chromatin particles is different from normal cells of the same lineage (e.g., salt-and-pepper chromatin; irregular granular chromatin)
Chromatin bridge	Stringlike DNA matter connecting nuclei of two daughter cells. Telomeres of sister chromatids fuse and fail to segregate into daughter cells during anaphase (anaphase bridges). The bridge may be seen in the next interphase (interphase bridge)
Macronucleoli	Nucleoli increased in size (diameter of more than 5 μm)
Anisonucleoliosis	Variation in nucleolar shape or size (also within the same nucleus)
Angular nucleoli	Nucleoli have an angular shape or are fusiform, instead of being round or ovoid
Irregular nuclear membrane	Nuclear membrane is wrinkled or shows grooves, gaps, invaginations, or blebs

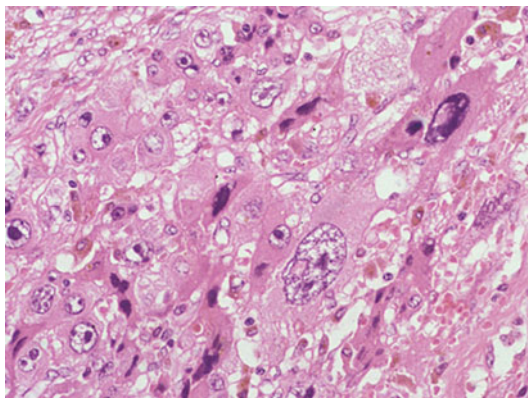

Fig. 1 Marked pleomorphism in a poorly differentiated hepatocellular carcinoma. One of the neoplastic cells shows a polyploid, massively enlarged nucleus; a second cell (to the *top* and *right*) exhibits hyperchromasia and irregular chromatin distribution (hematoxylin and eosin stain)

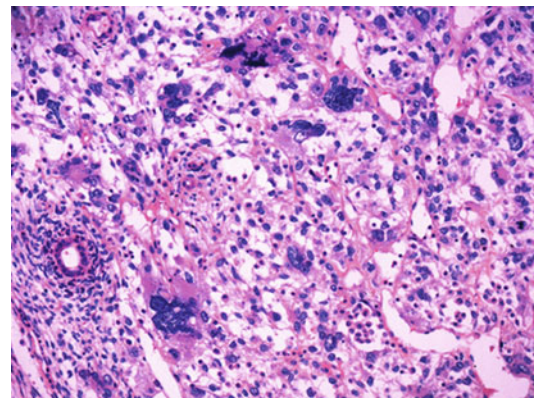

Fig. 2 Nuclear pleomorphism with formation of tumor giant cells (hematoxylin and eosin stain)

Figs. 8 and 9). Through the gaps produced by envelope rupture, chromatin particles can escape, resulting in micronucleus-like structures (Vargas et al. 2012).

Anaplasia

The concept of anaplasia found in malignancies has first been formulated by von Hansemann (1893). David Paul von Hansemann, a German pathologist (1858–1920) and assistant of Virchow

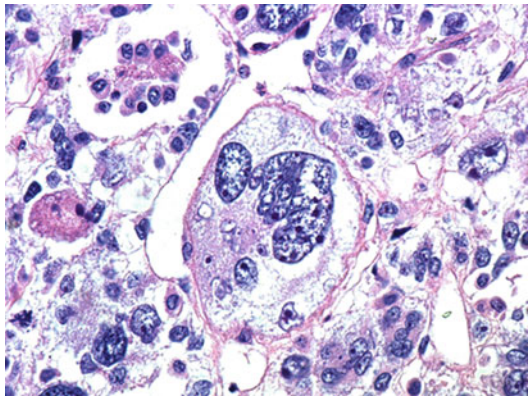

Fig. 3 Striking nuclear pleomorphism with a multilobulated polyploid giant nucleus and production of separate smaller nuclei following endomitosis (hematoxylin and eosin stain)

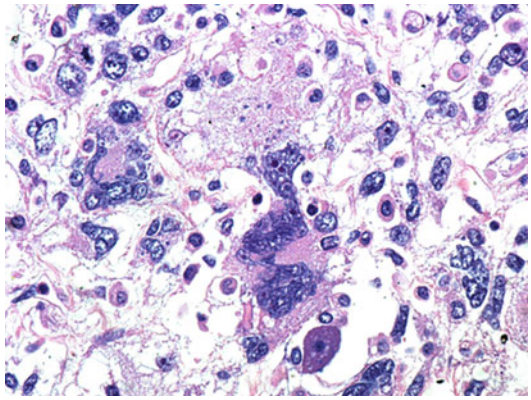

Fig. 4 Massive pleomorphism with incomplete cytokinesis of a tumor giant cell, resulting in a dumbbell-shaped cell, multinuclearity, and micronuclei (hematoxylin and eosin stain)

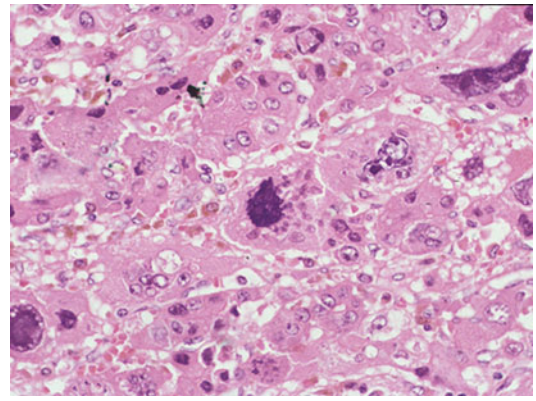

Fig. 5 Hepatocellular carcinoma with cellular and nuclear pleomorphism. A tumor giant cell in the center has an enlarged hyperchromatic nucleus which underwent karyopyknosis due to mitotic catastrophe. This cell displays several small nuclei following endomitosis (hematoxylin and eosin stain)

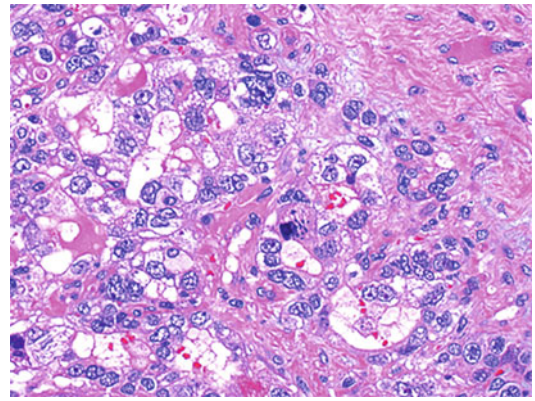

Fig. 6 Several tumor cells show strongly basophilic micronuclei (hematoxylin and eosin stain)

(Wagner 1999), is also known for the Hansemann cells, macrophages containing Michaelis-Gutmann bodies in malakoplakia. As reviewed by Whitman (1919), pleomorphism of cancer cells and the presence of atypical, irregular mitoses had been described before (e.g., Arnold 1880). Von Hansemann found, in a carcinoma of the larynx, hyperchromatism and large numbers of tripolar and multipolar mitotic figures, but also noted so-called hypochromatism caused by an actual reduction in total chromosome number in some cancer cells, in one case with a monaster having only nine chromosomes. Von Hansemann used his term hypochromatism exclusively for cells with a reduced chromosome number, whereas this term is now also employed in a less specific manner for situations with an apparently reduced amount of chromatin, diminished stainability of chromatin, or a loose chromatin structure. The investigator related these abnormalities to delayed chromosomal splitting, resulting in highly asymmetrical division with one daughter cell receiving a reduced chromosome set. Chromosomal splitting failure is supported by the observation that one daughter cell may contain an odd number of chromosomes (Von Hansemann

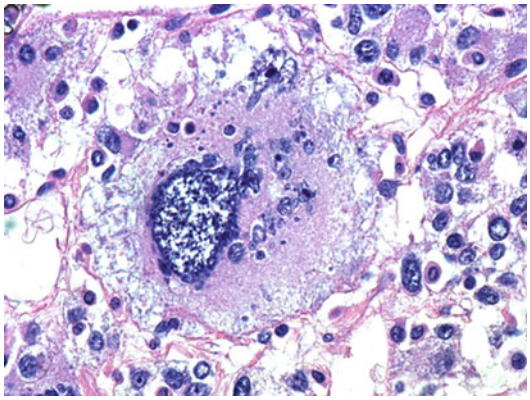

Fig. 7 Highly pleomorphic tumor giant cell with a polyploid nucleus, small separate nuclei, and several condensed micronuclei (hematoxylin and eosin stain)

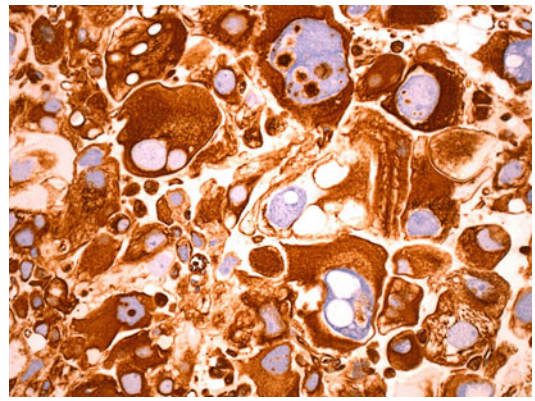

Fig. 9 In this cytokeratin stain, part of nuclear invaginations exhibit a brown reaction product which represents cytoskeletal components of cytoplasm invaginated into abnormal nuclei (cytokeratin immunostain)

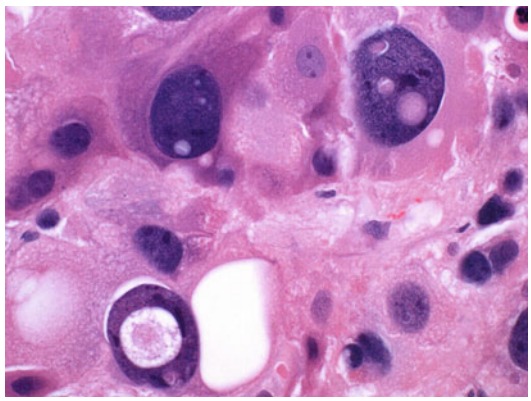

Fig. 8 Pleomorphic neoplasm with polyploid nuclei. Part of the nuclei show one to several so-called nuclear vacuoles, which in most cases are cytoplasmic invaginations caused by abnormal reassembly of nuclei and nuclear membranes (hematoxylin and eosin stain)

1890, 1891). Together with de Vries, von Hansemann believed that asymmetrical mitosis has a strong impact on cell fate due to a disordered distribution of chromosomal constituents that transmit properties of cells and termed pangenes or idioplasmae (now the genes). In 1914, Boveri speculated that malignant transformation and cancer were associated with these chromosomal abnormalities and are therefore credited with the first chromosomal theory of cancer, based on the observations of von Hansemann and others before him (Boveri 1914; Bignold et al. 2006a). The term anaplasia as formulated by von Hansemann is the mere process of disorder leading to undifferentiation and not the nuclear changes due to undifferentiation. This has led to some misunderstandings in the literature (Whitman 1919). Even today, the nuclear changes in undifferentiated cancer cells are called "anaplasia," although the term denotes aberrant growth.

In contrast to anaplasia, metaplasia is a form of cell lineage infidelity that can occur in normal, dysplastic and neoplastic cells and may be related to so-called embryonic reversion of cells. Based on the concept of histologic substitution, the term metaplasia was introduced by Virchow in 1870 (review: Bignold 2005). There is evidence that cancerogenic pathways can proceed through a phase of metaplasia, thus having a preneoplastic or premalignant status under certain conditions, but metaplastic changes found in neoplasms may also exist ab initio, as several tumors characteristically contain "foreign" cell lineages and pathways of differentiation as an inherent feature.

Micronuclei

A micronucleus is small and highly abnormal nucleus that is formed in cells with various types of DNA damage, such as ionizing radiation, genotoxic chemicals, or certain mutations. The

development of micronuclei in malignancies is associated with mutagenetic stresses and, in general, genomic instability (Iarmarcovai et al. 2006; Bolt et al. 2011; Fenech et al. 2011; Samanta and Dey 2012; Bhatia and Kumar 2014). Micronuclei are tiny basophilic spherical extranuclear objects that are seen to budd off daughter cells after mitosis. The bodies are often seen at light microscopy in the vicinity of a large nucleus. Micronuclei can contain non-incorporated chromosomes, chromosome fragments, or chromatids (Heddle et al. 1991; Norppa and Falck 2003). In solid tumors, more than 70 % of micronuclei contained material from unstable chromosomes (Gisselsson et al. 2001). Micronuclei typically show a massive collapse of nuclear membrane associated with irreversible loss of compartmentalization (Hatch et al. 2013). Micronuclei can themselves damage cells and are related to apoptosis (Utani et al. 2010), because micronuclear damaged DNA induces a defective cell cycle checkpoint arrest and DNA repair response (Terradas et al. 2010). Micronuclei are detectable in liver cancers and their precursor lesions (de Almeida et al. 2004). In the course of hepatocarcinogenesis, there is a stepwise increase in the number of micronuclei from normal hepatocytes to atypical cells to HCC cells. Micronuclei increase as a function of decreased differentiation of HCCs (Guido et al. 2008; Wen et al. 2013). An increased rate of micronuclei was found in human hepatoma cells transfected with the HBV HBX gene, suggesting that genomic instability with micronuclei can be driven by hepatocarcinogenic viral products (Livezey et al. 2002).

Micronuclei can form after mitosis from lagging chromatids or chromatin bridges between anaphase chromosomes and can persist for about one cell cycle. If cells containing micronuclei enter mitosis, they produce either daughter cells without micronuclei or, more often, cells with additional micronuclei (Utani et al. 2010). Chromosomal anaphase bridges are an important cause of micronuclei. Micronuclei that develop through this mechanisms have incomplete nuclear pore complexes, nuclear import defects, and a chromatin with greatly reduced transcriptional activity (Hoffelder et al. 2004). In addition, interphase nuclear budding is a chief mechanism for micronucleation, resulting in lamin B1-positive and lamin B1-negative micronuclei. Lamin B1-negative micronuclei located to cytoplasmic blebs are often connected with the nucleus by a thin chromatin stalk, whereby chromatin is extruded through lamina gaps (nuclear herniation, blister formation), suggesting that in micronucleogenesis cytoplasmic membrane blebbing and nuclear budding are coupled (Utani et al. 2011). The pathogenic role of nuclear blebs is supported by the finding that similar to micronuclei they frequently contain unstable chromosomes or parts of them (Gisselsson et al. 2001).

"Broken Eggs" and Nucleotesimals

Broken eggs (BE) are small amounts of genetic material attached to the main nucleus through a Feulgen-positive filament (da Silva et al. 2007). Similar to micronuclei, BE are sensitive markers of genotoxic damage and chromosomal instability. In comparison with normal hepatocytes, BE were significantly more frequent in precursor lesions, with a progressive increase from large regenerative nodules to dysplastic nodules and HCCs (Guido et al. 2008). There are other forms of nuclear fragmentation, resulting in abnormal paranuclear structures. In certain tumors, an amitotic process causes small nuclear appendages connected with the main nucleus via lamellar bridges. Such appendages were called nucleotesimals (Elias and Fong 1978).

Nuclear Morphology and Chromatin Structure in Liver Cancer

General Morphologic Features of Liver Cancer Nuclei

In hepatocellular carcinoma (HCC), alterations of nuclear size, shape, and structure strongly depend on the differentiation grade of these neoplasms. Well-differentiated (grade 1) HCCs display nuclei that resemble those of normal or regenerating

hepatocytes. In early tumors, nuclear anomalies may be minor ("minimum deviation carcinomas"), a phenomenon that causes diagnostic difficulties when assessing small liver nodules. In the course of decreasing differentiation and tumor progression, nuclei become larger and show hyperchromasia of peripheral parts, a more coarse chromatin pattern, and more variable shapes. The abnormal chromatin structure of HCC nuclei is clearly shown in ultrastructural studies (Theron and Mekel 1964; Ghadially and Parry 1966; Toker and Trevino 1966; Ruebner et al. 1967; Schaff et al. 1971; Horvath et al. 1972; Ma and Blackburn 1973). HCC nuclei can show an increase of the granular component (Hruban 1979). In some HCCs, intranuclear invaginations of cytoplasm can be found ("nuclear vacuoles"; Livni et al. 1977). Well-differentiated cholangiocarcinomas exhibit nuclei with a structure that is similar to that of normal cholangiocytes of medium-sized or large bile ducts, whereas moderately or poorly differentiated cancers show a broad array of marked nuclear anomalies similar to those of other adenocarcinomas. Morphologic abnormalities observable in liver cancers can be assessed quantitatively by means of morphometric methods or the determination of fractal dimensions (Kerenji et al. 2000).

Chromatin in Liver Cancer Cells

As outlined above, the often massive derangements occurring in the nuclei of cancer cells are reflected in alterations of chromatin structure and function. As a general rule, the magnitude of chromatin abnormalities, such as hyperchromasia, coarse chromatin, and the associated changes in nuclear shape and size, depends on the dedifferentiation of hepatic tumor cells, chromatin changes being usually minor in benign hepatocyte and cholangiocyte neoplasms and gradually increasing in malignancies of higher grades. In hepatocellular adenomas, the chromatin structure resembles that of normal hepatocytes, but nucleoli may be larger. In contrast, chromatin texture is coarser already in well-to-moderately differentiated HCCs and is highly abnormal in G3 or G4 lesions. In principle, chromatin structure and stainability deviate from those of hepatocytes as a function of higher liver cancer cell grade. Whereas an experienced eye may still recognize the hepatocyte-type nucleus in G1 and G2 HCCs, higher-grade neoplasms have atypical chromatin that may belong to any other poorly differentiated neoplasm, rendering diagnosis more and more difficult.

Part of genotoxic effects that change chromatin structure and function in cancer cells can be counteracted by several mechanisms, particularly the DNA damage response (DDR), a process that coordinately regulates DNA repair in conjunction with cell cycle progression. DDR requires sensing of chromatin injury and a machine that can decompact chromatin to have access to damaged components. This is brought about by posttranslational histone modifications affecting nucleosome accessibility and several ATP-dependent chromatin remodeling systems (Clapier and Cairns 2009; Luijsterburg and van Attikum 2011).

High-Order Chromatin Organization Determines Nuclear Structure, Size, and Shape

As many of the nuclear abnormalities that occur in cancer cells relate to abnormal configurations of chromatin, essential features of diverse forms of chromatin and their definitions are briefly presented. Chromatin is the entire ensemble of genomic DNA and numerous associated proteins (the chromatin proteome), consisting of a highly ordered and dynamic structure confined within the nucleus (review: van Steensel 2011). Basic structures of chromatin that form the building blocks for higher-level structures are the chromatin fiber (diameter of 10 nm; the previous 30 nm fiber is not a constant finding; Maeshima et al. 2014) and nucleosomes, of which about $3 \times 10(7)$ are present per human nucleus. The higher order of chromatin possesses several levels of organization. In the nucleus, chromosomes occupy distinct territories with preferred nuclear locations. There is evidence for a complex suprachromosomal order. Chromosome territories of the nucleus contain

open chromatin compartments having active genes, closed chromatin compartments comprising inactive genes, and interchromatin domain compartments that include complexes for the transcription, splicing, DNA replication, and repair machineries (Cremer et al. 2000). Each of these compartments has a distinct proteome of regulatory and enzymatic proteins. The chromatin proteome accounts for approximately 10 % of the cell's proteins. These proteins form complexes with DNA, RNA, and among themselves, forming an intricate chromatin interactome. To explain the complexity of chromatin self-organization and chromatin folding, models have been developed, e.g., the strings and binders switch model (Barbieri et al. 2012, 2013).

The composition, ordering, and remodeling of chromatin are well-studied features, but notwithstanding this knowledge, the relationships between chromatin and nuclear morphologies have not yet been fully elucidated (Zink et al. 2004; Reddy and Feinberg 2013). Chromatin is a highly dynamic matter regulated by chromatin factors and codes (Zhou and Troyanskaya 2014) and undergoing complex functional and structural changes in cancer cells, whereby cancer-associated chromosomal and genomic changes transcribe into alterations in chromatin structure (e.g., "coarse chromatin pattern"; Zhang et al. 2000). For gene positioning and expression, chromatin is arranged in a basic 30 nm fiber and loops, chromatin loops allowing a long-range physical contact between regulatory DNA sequences and transcribing genes (reviews: Dean 2011; Holwerda and de Laat 2012; Ghirlando and Felsenfeld 2013). Within transcriptional chromatin domains, genes to be transcribed are clustered in transcriptional units called "gene bodies," which are modified in their function via DNA methylation, also in liver cancers (Tischoff and Tannapfel 2008; reviews: Jones 2012; Huh et al. 2013).

Condensed Chromatin

Condensed chromatin is any kind of chromatin occurring in the form of dense particles irrespective of the cause of condensation. Chromatin condensation serves to pack the almost two meters of DNA and associated proteins into nucleosomes, chromatin domains, and chromosome territories, resulting in the high-order structure of chromatin (Grigoryev 2012; Hirano 2012a).

Euchromatin

Euchromatin is defined as a lightly packed chromatin abundant in gene concentration, often in state of active transcription. About 92 % of the human genome is euchromatic. Euchromatin possesses the typical string and nucleosomal pattern, has the 10 nm fibril as the basic structural unit, and appears as light-colored bands (low-compaction structure) in G band preparations, while heterochromatin stains dark. In mammalian cells, condensed euchromatin is detectable in tissue-specific pattern and is also called, "functional heterochromatin." Euchromatin is the active chromatin form engaged in the transcription of DNA into mRNA.

Heterochromatin

Heterochromatin is a chromatin form with tightly packed DNA and exists in two forms, constitutive and facultative heterochromatin. Heterochromatin was first defined by Emil Heitz in 1928 and was later found to predominantly localize to the nuclear periphery and around the nucleolus. Constitutive heterochromatin is repetitive and generates structural functions including telomeres and centromeres and acts as an attractor for expression and repression signals. It can mainly affect the function of genes in its vicinity (position-effect variegation). Heterochromatin plays a role in the maintenance of chromosome integrity (Fadloun et al. 2013). Facultative heterochromatin is not repetitive and may, under certain condition, lose its compact structure and become transcriptionally active. Peripheral heterochromatin provides a "protected area" for epigenetically silent genes and gene-poor DNA. This positioning of chromatin sub-compartments depends on lamina-associated and nucleolus-associated chromatin domains (LADs and NADs; Wu and Yao 2013;

Padeken and Heun 2014). A protein associated with the nuclear lamina, PRR14, participates in the tethering of heterochromatin to the inner nuclear membrane surface. PRR14 binds to anaphase chromosomes via HP1 and then mediates the association with nuclear lamina in telophase (Poleshko and Katz 2014). Heterochromatin in the proper sense denotes constitutive heterochromatin, i.e., a form of chromatin that is always condensed at interphase. The generation of heterochromatin as a dynamic platform strongly depends on histone modifications, specifically it requires epigenetic methylation of histone H3 and the subsequent recruitment of chromodomain proteins, including heterochromatin protein HP1 (Grewal and Jia 2007). HP1 binds lysine 9-methylated histone H3, a hallmark of heterochromatin (Nishibuchi and Nakayama 2014).

Crowded Chromatin

In contrast to organelles with their lipid membranes, intranuclear structures are not separated from each other by membranes but employ other ways for compartmentalization. The compaction mode of chromatin exerts a direct influence on the local crowding state of chromatin and has been suggested to play a role in the generation of distinct chromatin patterns, but crowded chromatin is not sufficient for heterochromatin formation (Walter et al. 2013).

Chromatin Remodeling, Insulation, and Compartmentalization

Chromatin remodeling denotes a complex and dynamical process that serves to modify chromatin architecture to permit access of condensed genomic DNA to the transcription machinery (Clapier and Cairns 2009). Remodeling is mainly mediated by two systems, i.e., covalent histone-modifying complexes and ATP-dependent chromatin remodeling. The latter operates at the level of nucleosome regulation and consists of at least five chromatin remodeling complexes, of which the SWI/SNF complex holds a remarkable place in malignancy because it contains proteins mutated in several cancers (SMARCB1, the hSNF5/INI1 protein). Nucleoplasmin is also involved in chromatin remodeling (Arregi et al. 2011). The term, chromatin insulator, is employed for two nuclear phenomena. On the one hand, chromatin components are compartmentalized by chromatin insulator proteins (Vogelmann et al. 2011). Insulator-related proteins, but not the insulators themselves, colocalize with nuclear speckles and form so-called insulator bodies (Golovnin et al. 2008). Insulator-related proteins found in insulator bodies include the Drosophila Suppressor of Hairy wing (Su(Hw)), modifier of mdg4, and centrosomal 190 kDa/p190. The posttranslational modification of insulator proteins by small ubiquitin-like modifier (SUMO) and intact p190 protein is crucial for insulator body formation, insulator bodies functioning as a depot of sumoylated proteins that are involved in insulation (Golovnin et al. 2012). On the other hand, DNA sequence elements termed insulators are long-range interactors that either barrier elements that block the propagation of heterochromatic structures into adjacent euchromatin (modulators of chromatin domain boundaries; Wei et al. 2005) or enhancer-blocking elements that interfere with interactions between enhancers and promoters when placed between them (Gaszner and Felsenfeld 2006; Bushey et al. 2008; Amouyal 2010; Giles et al. 2010; Vogelmann et al. 2011; Barkess and West 2012; Dixon et al. 2012; Ghirlando et al. 2012; Yang and Corces 2012). Enhancer-blocking elements are DNA elements that disrupt the communication between a regulatory sequence (enhancers or silencers) and a promoter. DNA insulators must reside between an enhancer or silencer and promoter to exert an inhibitory action.

Chromatin Compaction

As visualized by light microscopy of normal and cancer cells, chromatin is compacted in the course of mitosis into discrete mitotic chromosomes. This highly ordered compaction or condensation is brought about by a nonhistone protein complex,

the condensins (Hirano 2012b; Piazza et al. 2013). Condensin forms a multisubunit structural maintenance of chromosome (SMC) protein complex (Cuylen and Haering 2011). Condensin I is required for the establishment of the intrinsic higher-order structure of chromosomes (Gassmann et al. 2004). Condensin II induces axial compaction of interphase chromosomes, disrupts interchromosomal interactions, and promotes the dispersal of pericentric heterochromatin, therefore functioning as a protein that compartmentalizes chromatin into discrete chromosomal territories (Bauer et al. 2012). Condensin is recruited and attracted by monopolin, a protein complex which cross-links multiple kinetochore complexes to prevent merotelic attachments that might cause chromosomal missegregation (Dudas et al. 2011; Burrack et al. 2013).

Segregation of compacted chromosomes depends on a distinct chromatin environment at centromeres. Pericentric heterochromatin controls the histone variant composition of centromeres and hence affects the segregation process (Boyarchuk et al. 2014). In the course of mitosis, the pericentromere becomes a spring consisting of cohesin, condensin, and a rosette of intramolecular chromatin loops, which determine the position of cohesin, radially displaced from condensin (Stephens et al. 2013). Cohesin is the multisubunit complex that produces segregation of compacted chromosomes in the course of mitosis and which mediates cohesion between replicated sister chromatids (Peters et al. 2008; Brooker and Berkowitz 2014; Tapia-Alveal et al. 2014). Components of the cohesin complex can undergo mutations, resulting in cohesinopathies (Cornelia de Lange syndrome; Roberts syndrome) and several types of cancer (Losada 2014; Solomon et al. 2014). In mammalian cells, cohesin interacts with distinct chromosomal sites and colocalizes with a protein that induces long-range DNA interactions, CTCF, thus producing a link between cohesin function and genome organization (Bose and Geron 2010). Through these mechanisms, cohesin also controls gene transcription through multiple mechanisms (Dorsett and Kassis 2014) and affects, in cooperation with CTCF, chromatin architecture (Feig and Odom 2013; Sofueva et al. 2013; Wallace and Bosco 2013; Ball et al. 2014; Zuin et al. 2014). The maintenance of sister chromatid cohesion also depends on the microtubule and kinetochore protein, astrin, which regulates separase activity (Thein et al. 2007). Separase is a cysteine protease that severs the connection of aligned sister chromatids and promotes centriole disengagement at the end of mitosis.

Senescence-Associated Heterochromatin Foci (SAHF)

In senescence of cellular systems, a stable proliferation arrest is associated with profound alteration in chromatin organization. The hallmark of this process is the development of punctate DNA foci in senescent cells, termed senescence-associated heterochromatin foci (SAHF) (Kosar et al. 2011; Aird and Zhang 2013; Chandra and Narita 2013). SAHFs are specialized senescence-associated, highly compacted domains of facultative heterochromatin that largely exclude other domains of chromatin at telomeres and pericentromeres (Zhang and Adams 2007). A distinct form of heterochromatinization in SAHF is a means to maintain a functional chromatin complement in the absence of DNA replication and depends a spatial repositioning of chromatin and on the function of lamin B1 (Corpet and Stucki 2014). SAHFs contain typical heterochromatin-associated proteins, including heterochromatin protein 1, HMGA proteins, and the histone H2A variant macroH2A. A complex of histone chaperones, histone repressor A (HIRA), and antisilencing function 1a (ASF1a) play a key role in the formation of SAHFs (Zhang et al. 2007), and SAHF biogenesis is also promoted by the chromatin remodeling factor acting downstream of the oncogene, BRCA1 (Tu et al. 2013). BRG1 in SAHF formation is preceded by senescence-associated distension of satellites (SADS) associated with higher-order unfolding of satellite heterochromatin (Swanson et al. 2013).

Nuclear Envelope-Limited Chromatin

Nuclear envelope-limited chromatin appears in the form of very thin sheets (envelope-limited chromatin sheets, ELCS). ELCS are a form of condensed chromatin that forms structural units of about 17–30 nm in diameter that forms an ordered layer or several layers of definite geometry at the level of the nuclear envelope (Haynes and Davies 1973; Kuvichkin 2012). TEM cross sections show a picture resembling a sandwich of apposed nuclear envelopes separated by about 30 nm, containing a layer of parallel chromatin fibers (Eltsov et al. 2014). ELCS appears to develop from excessive nuclear envelope growth caused by complex heterochromatin-nuclear envelope interactions (Olins and Olins 2009). ELCS cannot be visualized in normal or cancer cells by the use of light microscopy. The function of ELCS is not well known, but ELCS is predominantly associated with M phase arrest, mitosis restitution, and delayed apoptosis in endopolyploid cells, suggesting that uncoupling of mitosis from DNA replication plays a role in ELCS induction (Erenpreisa et al. 2002).

Lamina-Associated Domains

Lamina-associated domains or LADs consist of a relatively large fraction of mammalian genome that is inactive and organized along the nuclear lamina via interaction of numerous lamina-associated sequences (LASs) enriched in the GAGA motif (Guelen et al. 2008; Bickmore and van Steensel 2013; Luperchio et al. 2014). LADs have a role in the modulation of gene expression, in that lamins generate contacts with gene promoters (Lund and Collas 2013; Collas et al. 2014). Lamina interactions are generated during mitosis and involves localized recruitment of lamin B during late anaphase. LAD is bound by the transcriptional repressor cKrox, suggesting that LAD is a chromatin compartment related to chromatin silencing (Zullo et al. 2012).

Interchromatin and Intrachromatin Connections

Interactions between diverse chromatin domains are mediated by groups of distinct proteins, specifically a set of coiled-coil domain-containing complexes termed cohibin, cohesin, condensin, and monopolin. These complexes perform the regulation of DNA-DNA connections across the genome (review: Poon and Mekhail 2011).

Argyrophilic Nucleolar Organizers and Fibrillar Centers in Liver Cancer

Introduction

Nucleolar organizer regions (NORs) are characterized by loops of ribosomal DNA that are transcribed to ribosomal RNA by RNA polymerase 1; NORs are localized to the short arms of the five acrocentric chromosomes, i.e., chromosomes 13, 14, 15, 21, and 22 in humans (Fakan and Hernandez-Verdun 1986). NORs embed coding genes for the synthesis of 18S and 28S ribosomal RNA. Ultrastructurally, NORs are evident as fibrillar centers within nuclei, associated with the dense fibrillary component of interphase. NORs can be visualized based on their argyrophilic staining features (argyrophilic NORs or AgNORs). These structures are argyrophilic because they are associated with acidic proteins containing sulfhydryl and carboxy groups that precipitate silver ions (Shiro et al. 1993). By the use of silver stains, NORs appear as dark brown or black spots in light microscopy.

Nucleolar Organizer Regions in Liver Cancer

Generally, NORs are more frequently detectable in HCCs and preneoplastic lesions than in normal or cirrhotic liver (Crocker and McGovern 1988; Bufo and Frassanito 1992; Shimizu et al. 1995). NORs are more frequent in HCC than in hepatocytes of normal or cirrhotic liver (Anselmi et al. 1990; Nonomura et al. 1990a; Parveen et al. 2006). The number of NORs in normal human hepatocytes was 1.3–1.7, while it was

2.4–3.5 in cirrhosis and 3.0–7.9 in HCC (Jain et al. 1998). In HCCs, two types of AgNORs were detected, type 1 NORs being large and medium-sized dots with well-defined margins, and these NORs were in close association with nucleoli, and type 2 NORs being fine single dots and clusters without well-defined margins. Smaller and irregular type 1 NORs and more numerous type 2 NORs were associated with decreasing HCC differentiation (Shiro et al. 1993). The presence and number of NORs have an impact on the biology of HCCs. A significant correlation was found between the number of NORs and proliferative activity of HCCs (Nagao et al. 1995). The number of NORs was correlated with tumor grade and size, portal vein invasion, and survival in HCC patients (Shimizu et al. 1995). Also in various types of cholangiocarcinomas, the number of NORs is increased in comparison with normal controls (Nonomura et al. 1990b). Similar to HCC, the number of AgNORs was related to tumor differentiation and size (Hayashi et al. 1995).

Nuclear Envelope and Associated Structures

Nuclear Envelope

The nuclear core is surrounded by a double bilayer termed nuclear envelope. The nuclear envelope was compared to a "cocoon" that harbors and protects all the nuclear and genomic machinery (Chow et al. 2012; Strambio-De-Castilla 2013). In the course of mitosis, the nuclear envelope undergoes extensive structural remodeling, which begins with the retraction of nuclear membranes into the endoplasmic reticulum (ER) at onset of mitosis and finalizing with the re-enclosure of postmitotic chromatin by ER-derived membranes (reviews: Kanoh 2013; Wandke and Kutay 2013). Embedded in the nuclear envelope are the nuclear pore complexes (NPCs) that mediate mRNA transport. However, recent evidence showed that NPCs are not the only gates for mRNA exit, as mRNAs can traverse the double envelope membrane at sites other than NPCs. Important nuclear envelope proteins are the nesprin-1, nesprin-2, nesprin-3, and nesprin-4, which connect nuclei with elements of the cytoskeleton (Rajgor and Shanahan 2013). Nesprin-1/nesprin-2 isoforms tether actin through their N-terminal actin binding domain, while nesprin-3 binds plectin and associated with intermediate filaments. Nesprins affect nuclear size and nuclear shrinkage. Complete nesprin-2 (nesprin-2 giant) overexpression leads to increased nuclear size (Lu et al. 2012).

Nuclear envelope reassembly at the end of mitosis depends on the close gathering of neighboring chromosomes that form a compact cluster. These clusters seem to produce a signal that the new envelope is generated around the entire chromosome mass and not around single chromosomes. This process is mediated by the chromokinesin Kid (kinesin 10) which localizes to the boundaries of anaphase and telophase chromosomes and is involved in the shortening of anaphase chromosome masses along the spindle axis. By this mechanism, Kid prevents the formation of postmitotic multinucleated cells (Ohsugi et al. 2008).

Nuclear Lamina

The nuclear lamina is the inner layer of the nuclear envelope and is mainly composed of a meshwork of several lamins. Nuclear lamins are type V intermediate filaments that are posttranslationally modified and which determine the structure of the nuclear lamina and serve as chromatin-interacting proteins which affect the organization of chromosomes within the nucleus (Dechat et al. 2010). A-/C-type lamins exhibit marked invaginations into the interior of the nucleus, representing channels for the transport of regulatory cargo to and from nuclear and nucleolar compartments. A-type lamin channels interact with polycomb group bodies, genomic regions of DNA repair, heterochromatin proteins, and UBF-positive regions of nucleoli, and A-/C-type lamin channels interact with nuclear pores and PML bodies (Legartova et al. 2014).

Nuclear Pore Complex

The nuclear pore complex (NPC) is a distinct multiunit structural component and the nuclear membrane and mediates the selective passage of certain molecules into and out of the nucleus. As such, the NPC is a highly selective bidirectional transporter for a large number of protein and ribonucleoprotein cargoes (Peters 2009; Wente and Rout 2011; Natalizio and Wente 2013). NPCs play a central role in the transfer of mRNA into ribosomal compartments (Brickner and Brickner 2012; Adams and Wente 2013; Natalizio and Wente 2013). The basket of the NPC is a distinct structure composed of eight specific protein filaments which protrude into the nucleoplasm and converge in a ring distal to the NPC. These basket proteins (nucleoporins; reviews: Doye and Hurt 1997; Wälde and Kehlenbach 2010; Chatel and Fahrenkrog 2011; Burns and Wente 2014) interact with other NPC proteins, the spindle organizer, the proteasome, silencing factors, and components of messenger ribonucleoproteins (mRNPs) (Liashkovich et al. 2012). Nucleoporins with a filamentous domain structure occupy the center and line the diffusion conduit of the NPC and gate protein diffusion across the NPC (Patel et al. 2007). The basket seems to reduce chromatin crowding around the central transporter of the NPC and is considered to be the docking site for mRNPs during nuclear export (Niepel et al. 2013). A further major component of the NPC basket is the nucleoporin translocated promoter region (Tpr), a protein involved in nuclear transport, chromatin organization, and mitosis, and associated with cancer and aging (Rajanala and nandicoori 2012; Snow et al. 2013; Snow and Paschal 2014).

The transport of karyophilic proteins into and from the nucleus is accomplished by a family of specific proteins, the karyopherins (KPNs), which possess nuclear localization signals (NLSs) and belong to the nuclear pore complex family. Generally, karyopherin-mediated protein transfer takes place through nuclear pores. Karyopherins can operate as importins (proteins mediating traffic into the nucleus) and exportins (out of the nucleus). Importin beta facilitates transport of protein cargo in the karyoplasm, whereby it first binds to importin alpha, which attaches cargo in the cytoplasm. Importin alpha exists in six forms, alpha1 to alpha6 (KPNA1 to KPNA6). Importin beta is encoded by the KPNB1 gene. A further beta-karyopherin is transportin-1 which mediates the nuclear import of the RNA-binding protein hnRNP A1. Transportin-3 mediates the nuclear import of splicing factors (Maertens et al. 2014). Nuclear localization of beta-catenin, a Wnt-related signaling protein mutated in HCCs and hepatoblastomas, is mediated by importin beta-5 in cooperation with the IQGAP1 protein (Goto et al. 2013). Importin 8, another beta-karyopherin, regulates the transport of mature microRNAs into the nucleus (Wei et al. 2014). Exportin 5, encoded by the XPO5 gene, mediates the nuclear export of microRNAs (Muqbil et al. 2013).

Nuclear Budding and Blebbing of the Nuclear Lamina in Cancer Cells

Structures protruding from the nucleus in the form of blebs are mainly found in a progeria syndrome and in diverse cancer cells. Blebs have been observed in regions where the fibers in the lamin meshwork have a greater separation (Funkhouser et al. 2013).

Nucleus-Cytoskeleton Connections (LINC Complexes), Chromosome Movements, and Nuclear Positioning

Nucleoskeleton and LINC Complexes

The nuclear envelope is linked to the cytoskeleton via distinct envelope proteins that transfer cytoskeletal forces to the nuclear lamina through a nuclear envelope bridge (the LINC complex). Linker of nucleoskeleton and cytoskeleton (LINC) complexes span the double membrane of the nuclear envelope and provide the machinery that links the nucleoskeleton with the cytoskeleton via a distinct set of proteins (reviews: Ostlund et al. 2009; Zhong et al. 2010; Lombardi and

Lammerding 2011; Simon and Wilson 2011; Rothballer et al. 2013). These proteins comprise SUN (Sad1 and UNC-84), spanning the inner nuclear membrane and KASH (Klarsicht, ANC-1, and Syne/nesprin homology) residing in the outer nuclear membrane (Sosa et al. 2012). These proteins can associate cytoskeletal proteins, including actin, microtubules, intermediate filaments, and centrosomal proteins, with the nuclear surface and the nucleoskeleton (Starr and Fridolfsson 2010). In the lumen of the nuclear envelope, the SUN and KASH domain proteins assemble to form a nuclear envelope bridge which mediates binding to cytoskeletal proteins (Rothballer et al. 2013). Specifically, nesprin-2 giant and nesprin-3 anchor actin cap fibers to the nucleus (Chambliss et al. 2013). The nucleoskeleton itself includes nuclear pore-linked filaments, A-type and B-type intermediate filaments, nuclear mitotic apparatus (NuMA) networks, spectrins, titin, actin variants/isoforms, and more than ten myosin and kinesin motors. This multiprotein system plays an central role in interskeleton signaling, nuclear positioning and movements, and chromosome motility.

Nuclear Positioning

For its proper function and the establishment of nuclear-organelle interactions, the cell must set the nucleus into distinct intracellular positions. Nuclear position is actively regulated by the mechanisms of intracellular nucleus movements, in particular also nuclear rotation (Sleeman 2004; Starr 2011). Movements are chiefly mediated by the microtubular system, but the actin cytoskeleton and dynein are also involved (Wu et al. 2011). Specifically, the actin machine is active during centrosome orientation in polarized cells, where the actin cytoskeleton moves the centrosome to the cell center, while the nucleus is shifted to the cell rear, thus orienting the centrosome between the nucleus and the rear end. The moving nucleus is connected with the actin cytoskeleton by a linear array of nuclear envelope membrane proteins, the transmembrane actin-associated nuclear (TAN) lines, mainly composed of nesprin-2G, Samp1, and SUN2 (reviews: Luxton et al. 2011; Osorio and Gomes 2014). Nuclear movements require the LINC complex components nesprin-2G and SUN2, and Samp1 is required for its association with SUN2 and lamin A/C (Borrego-Pinto et al. 2012). TAN line formation is mediated by the diaphanous formin, FHOD1, which interacts with nesprin-2G (Kutscheidt et al. 2014). A-type lamins anchor TAN lines through the action of a nuclear membrane protein, emerin, which organizes actin flow for nuclear movement (Chang et al. 2013). Nuclear positioning is also mediated by nuclear pore proteins (NUPs), including nucleoporins (Ruben et al. 2011).

Chromosome Movements, Chromokinesins, and Gene Positioning

Genes must be expressed and repressed at the right time and right place. Gene expression and positioning strongly depend on condensed regions of heterochromatin, the latter acting as a subnuclear silencing compartment (Jost et al. 2012). Chromosomes perform directed movements during the cell division cycle (chromosome oscillations; Campas and Sens 2006). The directed movements depend on a proper position within the spindle and are related to the chromosomal passenger complex, a complex driving chromosome segregation and cytokinesis, and composed of Aurora kinase B, INCENP, survivin and borealin, and centralspindlin (Watanabe 2010; Lewellyn et al. 2011; van der Horst and Lens 2014). Several theories have been formulated to explain the mechanisms behind these movements. One direction of thinking involves a machinery similar to that operational in microtubule-kinesin-driven organelle movements. In a second theory, mitotic chromosome motions were correlated with electrostatic forces. Positively charged kinetochore-associated molecules, such as Ndc80/hec1, have been implicated as likely interaction partners for negatively charged microtubule ends to generate electrostatic-dependent poleward forces that drive chromosome motion. This scheme explains dynamic tracking/coupling of kinetochores to microtubules, and the simultaneous

depolymerization of kinetochore microtubules as poleward force is generated (review: Shain and Gagliardi 2011).

The first system of chromosome-associated motors functions conventionally in moving chromosomes along microtubules of the spindle apparatus. The second system of chromatin-associated motors is involved in preventing chromosome loss and spindle formation, via docking microtubules to chromosome arms. A third system involves kinetochore motors which operate in spindle checkpoint activity (review: Brunet and Vernos 2001). Chromosome-associated motors comprise several classes of kinesin motors (chromokinesins; Mazumdar and Misteli 2005; Vanneste et al. 2011). Members of the kinesin-8 subfamily are plus end-directed motors that accumulate at the plus ends of kinetochore microtubules. Kinetochore translocation is strongly coupled at the depolymerizing microtubule end. The so-called Pac-Man hypothesis suggests that poleward movement of chromosomes during anaphase is brought about by disassembly of kinetochore microtubules at the kinetochore, generation of the poleward force taking place exclusively at or very close to the kinetochore, and the required energy coming from coupled disassembly of these microtubules (Pickett-Heaps and Forer 2001). Kinesin 8/Kif18A destabilizes microtubules via its depolymerizing activity and is capable to walk along microtubules for long distances, depending on a non-motor microtubule binding site (Mayr et al. 2011). Kinetochores and their proteins control the movements of duplicated chromosomes by interacting with spindle microtubules during mitosis and meiosis. They create a complex protein interface with microtubules (review: Akiyoshi and Siggins 2012). Kinetochore function in mitosis depends on the identification of microtubule attachment points. At the onset of mitosis, but no longer at metaphase, the protein CLIP-170 localizes to kinetochores and facilitates the formation of kinetochore-microtubule attachments, through direct capture of microtubules at the kinetochore . The polymer end of microtubules is the critical interface to kinetochores and is therefore stringently controlled. A distinct kinesin, mitotic centromere-associated kinesin (MCAK), a member of the kinesin-13 family, is a potent depolymerase of microtubules by removing tubulin subunits from the polymer end. This depolymerization corrects erroneous attachments of microtubule-kinetochore. The expression and activity of MCAK itself are regulated by mitotic kinases, including Aurora A/B, polo-like kinase 1, and cyclin-dependent kinase 1 (Sanhaji et al. 2011). Kinetochore-microtubule attachment during the organization of the mitotic spindle also depends on multiple asters (MAST)/Orbit, a member of a family of non-motor microtubule-associated proteins. MAST/Orbit is required for the maintenance of spindle bipolarity and chromosome congression (Maiato et al. 2002). Kinetochore-microtubule interactions are furthermore regulated by BUB1, BUB3, and BUBR1 proteins, core spindle checkpoint kinases which interact with the CENP-E microtubule motor (Maia et al. 2007). The spindle assembly checkpoint (SAC) presents initiation of anaphase until all chromosomes have been congressed in the spindle plane and have accomplished bipolar attachments within the mitotic spindle, in order to ensure fidelity of chromosome segregation and to strictly avoid eventual chromosome loss during mitosis. BUB1, BUB3, and BUBR1 SAC kinases play a critical role in this crucial process (Logarinho and Bousbaa 2008).

Mitotic Centromere Movements and Their Regulation

At the metaphase plate, alignment of chromosomes takes place, representing a visible signature of metazoan cell division. Centromeres direct the assembly of kinetochores, microtubule attachment sites allowing chromosome segregation in the spindle. The kinetochore-associated protein complex, Ndc80, binds to a centromere receptor of this complex, histone-fold protein Cnn1 (CENP-T), thus coupling chromosome movement to kinetochore-dependent spindle dynamics. In order to arrange chromosomes in the metaphase plane, mechanisms to cancel centromere motion and to arrest centromeres in the spindle midzone plane are required. Restricting centromere

movement to the spindle midzone is linked to centromere attenuation by kinesin-8/Kif18A which promotes microtubule pausing. Kinesin Kif18A is a motile kinesin depolymerase which is crucial for attenuating chromosome oscillations (Gardner et al. 2008), chromosome congression, and dampening of microtubule plus-end dynamics (Du et al. 2010). In addition, polar ejection forces spatially confine chromosomes to the metaphase plane through position-dependent regulation of kinetochore tension and centromere switch rates, and polar ejection forces are antagonistically modulated by chromokinesins.

Chromatin Movements (Chromobility)

The interphase nucleus is functionally compartmentalized, including preferential interior localization of gene-rich and early-replicating chromosome regions versus peripheral localization of gene-poor and late-replicating chromosome regions. The generation of such dynamic compartments in nuclei depends on distinct features of chromatin dynamics, long-range directional movements of target components, gene positioning, and chromosome territory relocation (Hübner and Spector 2010). The genomic DNA in mammalian cells is organized into chromatin domain of about 1 Mbp size which are the basic units for DNA compaction, replication, and transcription. These chromatin domains undergo translational movements and configurational changes. In the interphase nucleus, chromatin and chromatin components move in a constrained random walk, having an impact on genome expression dynamics and DNA-based reactions. In addition to translational movements, chromatin domains exhibit rapid oscillatory motions, early S-phase replicated chromatin domains showing the highest levels of motion, and late S-phase chromatin the lowest. Chromatin mobility is increased at sites of DNA double-strand breaks, a process requiring Mec1, Rad9, and the homologous recombination machinery. The process of chromatin movement is termed chromobility and is thought to be accomplished by the action of nuclear chromatin motors (Bridger 2011). Chromatin parts, gene loci, and entire chromosomal domains can move rapidly, with relocation of parts of the genome within less than 15 min over a number of microns (Bridger 2011).

Interorganelle DNA Migration

In eukaryotic cells, DNA is known to be exchanged between mitochondria, which are endosymbiosis-derived DNA-containing organelles, and the nucleus. This interorganelle DNA migration is a process that began early in evolution and resulted in a massive relocation of organelle genes to the nuclear genome, followed by retargeting of the nuclear gene components to their ancestral compartment, and others now function in new subcellular locations. There is also gene transfer from plastids to the nucleus, a process that played and still plays a role in genome evolution (Bock and Timmis 2008). However, almost all present-day nuclear transfers of mitochondrial or plastid DNA give rise to noncoding sequences, dubbed nuclear mitochondrial DNAs (NUMTs), and nuclear plastid DNAs (NUPTs) (reviews: Richly and Leister 2004; Kleine et al. 2009). Mitochondrial genomes often contain large numbers of plastid DNA (ptDNA)-derived sequences (MTPTs), whereby the intercompartmental transfer of ptDNA is markedly reduced in species with only a single plastid per cell (monoplastidic species) versus those with many plastids per cell (polyplastidic species). This is termed the limited transfer window hypothesis (Barbrook et al. 2006). MTPTs are restricted to the mitochondrial genomes of polyplastidic species and are absent from those of monoplastidic species (Smith 2011). Interorganelle DNA transfer is ongoing and ubiquitous and can produce genetic diversity by reshaping genes through adding novel exons. Plastid or nuclear gene sequences have also contributed to the biogenesis of mitochondrial tRNA genes (review: Leister and Kleine 2011).

Nucleolus

Morphology of Nucleoli in Liver Cancer

The nucleolus is, after chromatin, the most striking nuclear structure seen at light microscopy. Nucleoli occur in cancer cells as single spherical object of variable diameter or as few to several smaller structures of round or ovoid shape. Depending on the relationship between proteins and RNAs, the staining of nucleoli ranges from eosinophilic to amphophilic and slightly basophilic. Apart from their size, shape, and staining features, nucleoli may show typical intranuclear distribution pattern in various cancers. In well-differentiated hepatocellular carcinoma, nucleoli resemble in the shape to those of normal hepatocytes, but they are larger and show a strong eosinophilia (macroeosinophilic nucleoli). As cell differentiation decreases, nucleoli become larger and multiple, and their staining shifts from eosinophilic to amphophilic or even basophilic, the latter in grade 4 lesions. Nucleolar hypertrophy is a typical feature of HCC nuclei and can be quantitatively assess by determination of the nucleolar index. In comparison with normal human hepatocytes, nucleoli with a size of 7 μ^2 or greater were considered to be hypertrophic. The nucleolar index was obtained by calculating the percentage of liver cells having a nucleoli with 7 μ^2 or greater (Trerè et al. 2003). HCCs were significantly more common in the group with a nucleolar index of 2.5 or greater. Nucleoli in HCCs revealed ultrastructural abnormalities, including a condensation of the fibrillar component (Ruebner et al. 1967; Horvath et al. 1972; Smetana et al. 1972; Hruban 1979).

Both HCCs and cholangiocarcinomas can show abnormal expression patterns of the nucleolar protein, dyskerin (Liu et al. 2012; Vasuri et al. 2015). In intrahepatic cholangiocarcinomas, expression of dyskerin was associated with more aggressive tumor biology (Vasuri et al. 2015). Similarly, HCC expressing dyskerin presented with advanced clinical stage and poor patient prognosis (Liu et al. 2012). Dyskerin, a protein mutated in dyskeratosis congenita, is one of the three subunits of the telomerase ribonucleoprotein complex. It is involved in the regulation of telomere length (Gu et al. 2009), but it also possesses functions that are independent on its action on telomeres, including regulation of mitosis (Alawi and Lin 2013; Angrisani et al. 2014).

Nucleolus: Structure

In tissue sections and smears, nucleoli are not homogeneous structures but show a finely granular or homogeneous background with more dense areas. The nucleolus possesses a fine internal network of proteins called the nucleolar matrix or nucleolar skeleton (Zbarsky 1981; Schwarzacher and Wachtler 1993; Chen et al. 1999; Raska et al. 2006). In cell spreads, nucleolar organization shows a network corresponding to the nucleolonema (NCN; Estable 1966; Deltour and Motte 1990; Sato et al. 2005). This network reveals units comparable to the rDNA transcriptional units in length and is associated with tufts of fibrils and granules (Ghosh and Paweletz 1996). Ultrastructural investigations demonstrate that the nucleolus consists of three major components: a dense fibrillar component (DFC), a granular component (GC), and a fibrillar center (FC) (review: Schwarzacher and Wachtler 1993). DFC and FC are integrated in the NCN, whereby FCs predominantly occur in amniote organisms. The NCN is a fundamental substructure of the nucleolus, whereby the DFC corresponds to the matrix of the NCN, and the FC is a counterpart of argyrophilic lacunae localized in the NCN (Mirre and Stahl 1981; Kniebiehler et al. 1983; Sato 1992; Sato et al. 2005). High-voltage electron microscopy in thick sections has shown that argyrophilic FC components in compact nucleoli show a knotted ropelike structure in which knots are constituted of one central fibrillar center surrounded at some distance by loops of the dense fibrillar component and in which the rope is constituted of dense fibrillar component. In reticulated nucleoli, argyrophilic deposits are confined to the surface of the nucleolonema as several strands twisted at the periphery of the fibrillar

component (Ploton et al. 1987). FCs are low-electron density patches within DFCs and change their size and features under different physiological conditions and during the cell cycle. The volume of FCs doubles from G1 to G2 in Ehrlich tumor cells (Lepoint and Goessens 1982), and the number of FCs gradually increases from G1 to G2 (Junera et al. 1995). FCs are depots of inactive rRNA genes. The DFC is present as a network of strands that surround FCs, but DFC can also reach out to the nucleolar periphery. In DFCs, pre-rRNA synthesis and early rRNA-processing events take place, while GC is the site of late rRNA-processing events and assembly of ribosomal particles. There is a clear relationship between the functional status and the morphology and structure of the nucleolus. This has an impact on the understanding of nucleolar changes in cancer cell nuclei. In hyposynthetic cells, i.e., those with a low-level protein synthesis and ribosome biogenesis, nucleoli are small and show a single FC and poor DFC, resulting in ring-shaped nucleoli. In active cells, including growing cancer cells, a large network of DFC contains numerous FCs, and GC occupies peripheral parts (compact nucleoli). Newly stimulated cells exhibit a prominent DFC, but only few and small FCs (reticulate nucleoli; Schwarzacher and Wachtler 1993). During mitosis, the nucleolus is decomposed and postmitotically reassembled by a highly controlled process.

Nucleolus: Nucleologenesis and Function

The biogenesis of nucleoli (nucleologenesis) takes place in the nucleus around distinct genetic loci termed nucleolar-organizing regions (NORs). A typical NOR consists of tandem repeats of ribosomal RNA (rRNA) genes, of which more than 200 clustered copies are present in the human genome on five different chromosomes. Nucleoli play a central role in ribosomal RNA/rRNA synthesis and processing and ribosome subunit assembly (the "ribosome factory"; Boisvert et al. 2007; Cmarko et al. 2008; Bartova et al. 2010; Dundr 2012). Nucleolar ribonucleoproteins are localized to components of the NCN. Non-nucleosomal DNA filaments form roundish agglomerates with a spatial distribution which is superimposable on that of FCs (Derenzini et al. 1983). Ribosomal DNA (rDNA) is specifically localized to the FCs, but rDNA transcription does not seem to take place in these structures. rDNA transcription is localized to the boundary region between FC and DFC, rRNA transcripts being processed outward within the DFC (Sato et al. 2005). This distribution pattern is also reflected by the intranucleolar distribution of fibrillarin, fibrillarin staining shifting from the FCs to adjacent regions (Snaar et al. 2000; Jamison et al. 2010). During S phase of the cell cycle, catalytically active telomerase holoenzyme is initially assembled in DFC. The telomerase RNP is retained in the nucleolus via interaction of hTERT with nucleolin. Following this step, the telomerase RNP is transported to Cajal bodies (Lee et al. 2014).

In the course of ribosome biogenesis, the initial step involves transcription of rRNA genes by two RNA polymerases (pol I and III) within the nucleolus, in association with regulatory proteins forming the preinitiation complex (PIC). The PIC contains promoter selectivity factor (SLI), transcription initiation factors (SLI), and upstream binding factor (UBF). In humans, rRNA genes transcribed in the nucleolus by pol I result in the rRNA transcripts 5.8S, 18S, and 28S, whereas the 5S transcript (a component of the 60S ribosomal subunit) is transcribed by pol III in the nucleoplasm, later to be transferred to the nucleolus. For ribosome biogenesis, different and highly dynamic pre-ribosomal complexes are formed. These complexes contain specific proteins required for the production of the various types of rRNA transcripts. For the 18S transcript, Dbp4 (a DEAD-box RNA helicase), Bfr2, and Enp2 are required, whereby the latter two proteins associate with U3 small nucleolar RNA/snoRNA, the U3-specific protein Mpp10, and various pre-18S ribosomal RNA species. These proteins are components of the small-subunit (SSU) processome (Turner et al. 2009; Soltanieh et al. 2014). The SSU

processome is a large (80S) ribonucleoprotein complex that corresponds to the terminal knobs seen in EM (Bernstein et al. 2004; Phipps et al. 2011; Feng et al. 2013). During transcription of rRNA genes, the highly specific molecular organization of the respective partners in the nucleolus can be visualized. Active rRNA genes are present in the form of characteristic Christmas trees.

Apart from proteins directly participating in the ribosome factory, the nucleolus contains other proteins involved in nucleolar functions (nucleolar proteome). Nucleolin is a phosphoprotein widely distributed in the nucleolus. The protein has numerous functions, and its levels reflect the functional activity of the organelle. It has helicase and ATPase activities and can bind RNA via its RNA recognition motifs (review: Tajrishi et al. 2011). As noted above, nucleolin is also involved in the turnover of telomerase in nucleoli. A further nucleolar protein is fibrillarin, involved in pre-rRNA processing during ribosomal biogenesis and in the maintenance of nuclear shape. Nucleophosmin (B23) is a protein which is predominantly localized in the nucleolus. Nucleophosmin is overexpression in many human cancer cells and plays a regulatory role during differentiation of liver cancer cells (Xu et al. 2014). Nucleophosmin targets the ARF tumor suppressor to the nucleolus and inhibits its function (Korgaonkar et al. 2005). ARF is a nucleolar protein that activates checkpoints in a p53-dependent manner by binding Mdm2, an antagonist of p53. From its position in the nucleolus, ARF acts as a sensor of signals that relate to cell growth and proliferation (Maggi et al. 2014). The nucleolus contains the lipid phosphatase PTEN which plays a role in regulating nucleolar homeostasis and morphology (Li et al. 2014). The nucleolus contains at least ten species of mature microRNAs. Their accumulation in the nucleolus depends on the protein CRM1 which is associated with the trafficking of small nucleolar RNAs (Bai et al. 2014). MicroRNAs can affect nucleolar structure and function. Expression of microRNA-122 in HCC cells results in more prominent nucleoli in these cells (Jin et al. 2014).

Functions of the Nucleolus Other Than the Ribosome Factory

The nucleolus and its machinery are in constant interaction with the nucleoplasm and several nuclear bodies (see below) and act as a complex sensor of various nuclear and cytoplasmic functions (Olson et al. 2002; Sirri et al. 2008; Thiry et al. 2011). The nucleolus is involved in nuclear and chromatin organization, cell cycle regulation, stress responses, and aging. Nucleolar proteins interact with heterochromatin and mediate the organization of heterochromatin around the nucleolus (nucleolus-associated chromatin domains, NADs; Padeken and Heun 2014). The relationship between the nucleolus and the cell cycle is complex, and cell cycle features have a strong influence on both function and size of nucleoli (Derenzini et al. 1998; Tsai and Pederson 2014). During mitosis, the ribosome factory comes to a halt, requiring a sensor system of the nucleolus that monitors the position of the cell with respect to interphase versus cycling.

Abstract

The numerous types of structural abnormalities of cancer cell nuclei are directly associated with functional disorders of nuclear homeostasis, DNA replication and its fidelity, and cell division, this general disorder being a hallmark of malignant transformation. Basically, the nuclear abnormalities seen in cytologic and histologic preparations reflect progressive chromosomal and genomic instability and their effects on the higher-order structure of chromatin. The diverse types of chromatin are organized within the nuclear space in a specific fashion and occupy distinct intranuclear compartments. These patterns are massively altered in progressing cancer cells, involving disturbed arrangement of chromatin fibers, abnormal heterochromatin generation, disordered production of euchromatin strings, failure of nonrandom positioning of interphase chromosomes within the nuclear matrix, abnormal attachment of chromosomes to the nuclear membrane, and anomalies of intranuclear chromosome movements.

Pathogenic Pathways of Structural Nuclear Abnormalities in Cancer: General Aspects

The numerous types of structural abnormalities of cancer cell nuclei are directly associated with functional disorders of nuclear homeostasis, DNA replication and its fidelity, and cell division. In particular, structural nuclear abnormalities reflect chromosomal instability (CIN) and genomic instability (von Hansemann 1893; Boveri 1914; reviews: Cheng and Loeb 1993, 1997; Bignold et al. 2006; Thompson et al. 2010). Apart from abnormal chromosome numbers and asymmetrical division being at the base of von Hansemann's concept of anaplasia, numerous structural anomalies found in the nuclei of cancer cells have not yet been sufficiently explained (review: Bignold 2003). This mainly holds true for chromatin changes found in interphase cancer nuclei and described as "coarse chromatin," "stippled chromatin," "hyperchromatism," and "chromatin clumping."

There is evidence that components of diverse types of chromatin are arranged in distinct and dynamic patterns within the nuclear space. These patterns are strikingly different in living cells in comparison with fixed and stained entire nuclei on smears or cut nuclei appearing in histologic sections. Specifically, unfolded chromosomes occupy domains in the nucleus during interphase, providing a uniform density of fine chromatin fibers throughout the living nucleus. In contrast, interphase chromatin is seen in preparations of fixed cells as coarse clumps (heterochromatin) or strings and fibers (euchromatin) (Bignold 2003). Dynamic chromatin patterns are also caused by a nonrandom positioning of interphase chromosomes within the nuclear matrix, chromosomal attachment to nuclear membrane, intranuclear chromosome movements, orientations of chromosomal domains toward nuclear pores during transcription, and connections between chromatin and components of the cytoskeleton.

Pathogenesis of Chromosomal Instability in Cancer: Disordered Centrosome Cycles and Centrosome Amplification (Polycentrosomy)

Centrosomes and Centrioles as Drivers of Cytokinesis

Centrosomes and centrioles are critical structures in the orderly distribution of chromosomes during cell division. The centrosome holds a chief position in the regulation of division, organization of cell polarity and motility, and cilium-dependent sensing and signaling. The centrosome is the main microtubule-organizing center of cells and templates the assembly of the primary cilium. At mitotic entry, the division cycle involves nucleus-centrosome coupling in prophase, requiring recruitment of dynein to nuclear surface, regulated by the protein Asunder (Jodoin et al. 2012). Cytokinesis requires the interaction of centrosomes and centrosome-associated proteins with other effectors, e.g., centralspindlin, which

connects the mitotic spindle to the plasma membrane (Lekomtsev et al. 2012; White and Glotzer 2012; Glotzer 2013).

It is to be expected that disorders of centrosome function in cancer cells have effects far beyond a mere derangement of cell division. Several factors control the structure and function of centrosomes. Two kinases are particularly essential for centrosome duplication, i.e., polo-like kinase 1 (PLK1) and PLK4. PLK1 has several targets that directly affect centrosome biogenesis and function. PLK1 phosphorylates the Wnt signaling protein Axin, which dynamically regulates the centrosome's association with gamma-tubulin (Ruan et al. 2012). Liver kinase B1 (LKB1) controls centrosome function mediated by PLK1 and maintains genomic stability (Werle et al. 2014). A further protein involved in the centrosome cycle is the Fanconi anemia protein, FancJ, which activates PLK1 (Zou et al. 2013). PLK4 possesses an autoregulated instability which limits centrosome duplication to once per normal cell cycle (Holland et al. 2010). In addition, the function of PLK4 is regulated via its phosphorylation by stress-activated protein kinase kinase kinases (SAPKKKs), cooperatively with p53 protein (Nakamura et al. 2013).

Centriole duplication is a process by which two new daughter centrioles are produced from preexisting mother centrioles (Browntree and Rogers 2013). Centriole duplication is regulated by the proteins PLK4, centrobin, centrosomal proteins of 152 kDa (CEP152), 192 kDa (CEP192), and 135 kDa (CEP135), STIL (SCL/TAL1 interrupting locus; SIL; Vulprecht et al. 2012), and centrosomal protein 4.1-associated protein (CPAP/CENPJ), whereby the shape and number of centrioles are controlled by a CPAP-centrobin interaction on centrioles (Gudi et al. 2014).

A Damaged Centrosome Cycle Induces Centrosome Amplification

Boveri (1914) had reported that supernumerary centrosomes can cause chromosome missegregation in sea urchin eggs. It is now established that deregulation of centrosome structure and function, and a disordered centrosome cycle, are central to the pathogenesis of chromosomal instability in cancer (reviews: D'Assoro et al. 2002; Lingle et al. 2005; Ganem et al. 2009; Duensing and Duensing 2010). Specifically, mechanisms causing centrosome amplification play the main role in this pathway, whereby numerous chemical carcinogens and ionizing radiation are well known to cause centrosome duplication. Other causes include failure of cytokinesis and alterations of regulators of centrosome structure and function, e.g., via mutations. The fate of cells with such errors depends on whether the centrosome cycle and the chromosome cycle remain coupled or not (Lingle et al. 2005). In case of maintained coupling, cells enter the G2 phase of the cycle with duplicated centrosomes and a 4N chromosome complement. In the uncoupled state, cells go through one or more rounds of centrosome/centriole duplication in the absence of chromosome replication. Subsequent division will result in 4N cells with multiple centrosomes and formation of multipolar spindles and multipolar mitotic figures. This is a mechanism that is frequent in poorly differentiated cancer cells and cancer cells altered by radiotherapy. Centrosome amplification is a key mechanism for the generation of an aneuploid cellular offspring, as further outlined in a following paragraph. The centrosome-driven biogenesis of spindles and spindle pole bodies is directly associated with nuclear function, as spindle pole bodies are inserted in the nuclear envelope (Jaspersen and Ghosh 2012), the latter itself being a chromatin organizer (Zuleger et al. 2011).

Centrosome Cycle Anomalies in Cancer: Centrosome Clustering as a Repair Mechanism Protecting Against Abnormal Centrosome Cycles and Polycentrosomy

As centrosome cycle anomalies and polycentrosomy are ruinous for normal spindle biogenesis and an orderly cell division, centrosome amplification causes cell division failure, chaotic genomes, and cell death in cancer cells.

In general, multipolar spindles are antagonistic to cell viability, however depending on the ploidy status of cells involved. For example, supernumerary centrosomes in aneuploid cancer cells may be unable to nucleate microtubules and thus generate multipolar mitosis, due to lack of functional centrioles. In contrast, diploid cancer cells possess a functional centriole and are capable to nucleate microtubules and create spindles (Ghadimi et al. 2000; Difilippantonio et al. 2009). Can, therefore, cancer cells circumvent the disastrous effects of centrosome amplification ? Even in the presence of two or more centrosomes, part of neoplastic cells can obviously divide in a successful manner, due to suppression of multipolar mitosis (Kwon et al. 2008). This is usually accomplished through clustering of supernumerary centrosomes into bipolar arrays, whereby extra centrosomes undergo coalescence into two functional spindle poles (centrosome clustering; Brinkley 2001; Godinho et al. 2009). Through this mechanism, a clone of aneuploidy cancer cells emerges. Within this aneuploidy clone, selection mechanisms will promote the development of cells with bipolar spindles, e.g., via selective inactivation of extra centrosomes.

Centrosome clustering is a highly complex process that is mediated by APC/C (cyclosome), whereby the motor kinesin Eg5 is a substrate of APC/C-CDH1, inhibition of APC/C resulting in stabilization of Eg5, while increased Eg5 levels prevent centrosome clustering (Drosopoulos et al. 2014). Successful cell division, both of normal and cancer cells, depends on a highly conserved and tightly controlled program that regulates nuclear envelope breakdown, chromosome condensation and alignment, spindle formation, sister chromatid separation, anaphase motors, cytokinesis, and restoration of nuclei. The successful performance of this program not only depends on the switching on of several control and checkpoint proteins but also the selective and timely degradation and elimination of distinct proteins. This is accomplished by the proteasomal pathway and the action of several E-type ubiquitin ligases that generate ubiquitin chains containing target proteins. One of these ligases that are central to cell division is the anaphase-promoting complex. The anaphase-promoting complex or cyclosome (APC/C) is a molecular machine that regulated sister chromatid segregation and the exit from mitosis via catalyzing the ubiquitinylation of several cell cycle regulators, including cyclins. APC/C consist of a large multi-subunit complex of E3 RING-cullin ubiquitin ligase and is constructed of 14 proteins (He et al. 2014; Zhang et al. 2013a, 2014). The function of this complex is controlled by several cofactors, reversible phosphorylation, and distinct inhibitors (review: Barford 2011). A heterotrimeric protein complex, Ska (spindle- and kinetochore-associated protein complex) which is required for anaphase onset, enhances binding of APC/C to chromosomes and promotes exit from mitosis (Sivakumar et al. 2014). The cyclosome is inhibited by the spindle assembly checkpoint/SAC and unattached kinetochores transduce the SAC via the intramitotic production of a APC/C inhibitor. In addition, nuclear pore complexes in interphase cells also inhibit APC/C through assembling a premitotic anaphase inhibitor (Rodriguez-Bravo et al. 2014).

Apart from its effects on mitosis, centrosome amplification has additional effects on cancer cell behavior. Centrosome amplification can, similar to certain mutated oncogenes, trigger cell invasion. The pathway involves augmented centrosomal microtubule nucleation and an increase in Rac1 activity, which disrupts cell-cell adhesion and promotes invasion (Godinho et al. 2014).

Aneuploidy

Polyploidy and Aneuploidy in Normal Hepatocytes

As expected based on findings in other malignant neoplasm, hepatocellular and cholangiocellular neoplasms display various types of aneuploidy. However, also normal hepatocytes can become aneuploid, showing that aneuploidy is not necessarily a feature of malignancy (Gupta 2000). Between 30 % and 90 % of human hepatocytes

were found to be aneuploid, whereby polyploidy and aneuploidy in the liver are closely linked (Celton-Morizur and Desdouets 2010; Gentric et al. 2012; Duncan et al. 2012; Duncan 2013). Polyploidy plays a pivotal role for the development of binuclear hepatocytes (Toyoda et al. 2005; Guidotti et al. 2003), is a sign of terminal differentiation and cell senescence (Gentric et al. 2012), and is induced by partial hepatectomy, which attenuates hepatocyte replication (Sigal et al. 1999). Hepatocytes of mice may become polyploid and then undergo ploidy reversal to become aneuploid, a process termed ploidy conveyor (Duncan et al. 2010).

Aneuploidy in Hepatocellular and Cholangiocellular Malignancies

Aneuploidy is a well-recognized feature of hepatocellular carcinoma (HCC) and has been found in 37 % to more than 70 % of HCCs (Balsells et al. 1996; Eissa et al. 1997), associated with a high count of argyrophilic nucleolar organizer regions (AgNOR). Both higher aneuploidy and AgNOR counts are also detectable in dysplastic HCC precursor lesions (Attallah et al. 2009). On the other hand, there are HCCs with a "minimal deviation phenotype" that are diploid (Nowell and Morris 1969). DNA ploidy in HCCs was not correlated with age, sex, tumor stage, or underlying liver disease (Nagasue et al. 1992; Hamazaki et al. 1993; Ng et al. 1994). However, there is some evidence that aneuploidy is associated with dedifferentiation (Wilkens et al. 2004) and certain differentiation patterns of HCCs. Higher rates of aneuploidy or hyperploidy were detected in HCCs rich in Mallory-Denk bodies in comparison with standard HCCs (Hoso and Nakanuma 1989).

Accelerated mitotic progression is associated with mitotic defects, chromosome missegregation, and aneuploidy in HCC, caused by overexpression of a distinct oncogene, chromodomain helicase/ATPase DNA-binding protein 1-like (CHD1L) gene, which in turn activated its target, and translationally controlled tumor protein (TCTP); TCTP promotes the ubiquitin-proteasome degradation of Cdc25C during mitotic progression, causing the failure in the dephosphorylation of Cdk1 on Tyr15 and decreased Cdk1 activity, which in turn provokes a faster mitotic exit and chromosome missegregation (Chan et al. 2012). A spindle checkpoint protein, CENP-E, which plays a significant role in the function of the spindle organization checkpoint and the process of chromosome separation, displays a reduced expression in HCC, causing chromosome misseparation and hence aneuploidy (Liu et al. 2009). Aneuploid hepatocellular carcinoma cells often harbor gain of 1q and partial loss of 13q, while cholangiocarcinoma cell lines showed loss of 8p in combination with a relative gain of 8q (Wilkens et al. 2012).

Ploidy and -Somy: Definitions and Terms

The term ploidy denotes the number of sets of chromosomes in a cell. Haploid (N) is the number of chromosomes in a gamete, which is also monoploid (see below). The normal human chromosome set is diploid, i.e., the presence of two sets of chromosomes. A monoploid chromosome number is the number of chromosomes in a single (nonhomologous) set and is, therefore, different from the haploid number. The monoploid number is the number of unique chromosomes in a single complete set. An exact multiple of haploid chromosome complement is called euploid, while a chromosome complement showing a chromosome number other than the diploid 46 in humans is termed heteroploid. Specifically, euploidy is a condition in which a cell has an integral multiple of the monoploid number. In humans, the normal set is 46, an integer multiple ($\times 2$) of 23, but a situation of 69 (an integer multiple of 3; $3 \times 23 = 69$) would also be called an euploid state. *Monoploidy* denotes the loss of an entire set of chromosomes. Monoploid organisms with one half of the normal chromosome number are rare in nature due to unmasking of recessive lethal mutations, but there are examples of monoploid invertebrates originating from unfertilized eggs, such as male bees (drones) and worker ants. *Aneuploidy* is defined as an abnormal chromosomal

situation where one or more chromosomes of a normal set are lacking or are present in more than their normal number of copies. In this sense, aneuploidy is any non-euploid state. Missing or extra chromosomes are a frequent cause of birth defects and are well known to occur in cancer cells. The chief mechanism of aneuploidy is failure of proper separation of chromosomes in the course of cell division (see below). Aneuploidy exists in one of several variants. Nullisomy is a condition with loss of both pairs of homologous chromosomes (chromosomal composition = 2N−2). Monosomy is characterized by the loss of a single chromosome (2N−1). In balanced translocations or deletions, partial monosomy can develop. Here, only a portion of the chromosome is present in a single copy. In doubly monosomy, one chromosome from each of two pair of homologous chromosome is missing (2N−1−1). Disomy (the presence of two chromosome copies) is the normal situation for humans, whereas it is abnormal or aneuploid in organisms that normally are triploid or above. Uniparental disomy denotes a condition where both copies of a chromosome derive from the same parent. In trisomy, gain of an extra copy of a certain chromosome takes place (2N+1). A common example is trisomy 21, the cause of Down's syndrome. In tetrasomy, an extra pair of homologous chromosomes is gained (2N +1). Tetrasomy is rarely found in autosomes (nonsex chromosomes). An isochromosome is defined as a chromosome having the same genetic material on both arms. *Polyploidy* is a condition in which cells have multiple sets of chromosomes beyond the normal set. *Clastogenesis* is a mechanism that results in additions, deletions, or rearrangements of parts of the chromosomes.

Mechanisms of Aneuploidy

In general, aneuploidy is caused by mechanisms that cause a deranged separation of chromosomes during cell division. The most important mechanisms are nondisjunction, chromosomal misalignment, multipolar spindles, monopolar spindles, inactive mitotic checkpoints, sister chromatid cohesion, and merotelic attachment. In nondisjunction, a failure of chromosomal alignment control results in a situation where a chromosome pair is not lined up on the mitotic plate in time. During division, this pair lags behind and will not enter a daughter cell. In the condition of multiple spindles, common in cancer cells, more than two spindle poles are generated. This will result in one daughter cell for each spindle pole, each daughter cells having any complement of chromosomes. In malignant cells, multiple and defective spindle may, however, abolish the cell's capacity to divide, resulting in complex endomitotic polyploid states. In the case of a monopolar spindle, only a single daughter cell can emerge, having a double copy of chromosomes. Inactive mitotic checkpoints are responsible for nondisjunction at multiple chromosomes, in some situations of all chromosomes, as these checkpoints normally control the progression of the entire chromosome sets to the mitotic apparatus. Construction, maintenance, and timely removal of sister chromatid cohesion prior to the mitotic act itself are critical processes that are tightly regulated. The main regulator of this process is a protein complex termed cohesion. Failure of cohesion function and nonremoval of sister chromatid cohesion leads to aneuploidy (Barbero 2011). Centromeric chromatin is also involved in the maintenance of a normal karyotype.

Aneuploidy and the Kinetochore

The kinetochore, a large protein complex localized to the centromeric chromatin domain, is the docking site for mitotic spindle microtubules and a target for the controlling action of the spindle checkpoint. In the course of metaphase, spindle microtubules from the two opposing spindle poles capture each pair of sister kinetochores and create tension across sister kinetochores (Jia et al. 2013). The cross-linking of kinetochore components and microtubule attachment sites during anaphase is mediated by the monopolin complex chiefly compose of two proteins (Corbett et al. 2010). The spindle checkpoint serves to detect improper attachments between microtubules and kinetochores, and in case such misattachments happen,

it switches off the anaphase-promoting complex and delays anaphase onset. Failure of the checkpoint leads to premature sister chromatid separation and aneuploidy. Orderly progression through mitosis also depends on a proper interaction between anchoring proteins and mitotic kinases, including the protein gravin which interacts, in its phosphorylated form, with the mitotic kinase PLK1 (polo-like kinase 1). Gravin is closely linked to the mitotic spindle checkpoint protein, CDK1, a protein interacting with Mad2 (Chila et al. 2013). Gravin phosphorylated by CDK1/cyclin B1 localizes to centrosomes and spindle of dividing cells where it acts as a scaffold for PLK1. Depletion of gravin, what occurs in part of malignant neoplasms, impacts mitotic progression, causes misalignment of chromosomes, and induces aneuploidy (review: Canton and Scott 2013). Kinases that perform surveillance of the division process include Aurora kinases (Aurora-A, Aurora-B, and Aurora-C). Deranged expression patterns of Aurora kinases are causally linked with the generation of aneuploidy and cancerogenesis, whereby the expression of these kinases is modulated by de novo synthesis, stability factors, phosphorylation, and ubiquitin-dependent degradation. Aneuploidy can also be induced by epigenetic mechanisms (Herrera et al. 2008).

An intriguing mechanism of aneuploidization is heterotypic tumor/cell-in-cell structure. This mechanism is characterized by the phenomenon that one living and intact cell (and not an apoptotic cell) enters into another living cell, usually occurring between homotypic cancer cells and immunologic effector cells. T and B cells, monocytes, and natural killer cells are known to invade tumor cells, and these cells can penetrate directly into the nucleus of tumor cells, causing multinucleation and thereafter aneuploidy (Chen et al. 2013).

Merotelic Kinetochores as a Source of Aneuploidy

Kinetochores have binding sites for about 20–25 kinetochore microtubules. Kinetochores bound to kinetochore microtubules oscillate between poleward and away-from-the-pole movements. These oscillations are coupled to changes in length of kinetochore microtubules (Amaro et al. 2010; Wan et al. 2012). Kinetochores can become merotelic in prometaphase if they attach to microtubules from opposite poles rather than to just one pole as normal. Merotelic kinetochore orientation is a misattachment of kinetochores in which a single kinetochore is attached to microtubules from both spindle poles instead of just one (Cimini et al. 2004; Gregan et al. 2011). These merotelic attachments, which are not always detected by the mitotic spindle checkpoint, support chromosome bi-orientation and alignment near the metaphase plate, and are a cause of aneuploidy (Cimini et al. 2001). In anaphase initiation, merotelic kinetochores are not properly segregated, may lag behind, or even move in the direction of the wrong pole. This leads to lagging chromosomes in anaphase (Cimini et al. 2002). Therefore, merotelic kinetochores are a major mechanism for the generation of aneuploidy (Salmon et al. 2005). The effect of merotelic kinetochores can be corrected by an increase in the ratio of kinetochoric microtubules attached to the correct versus incorrect pole during pre-anaphase, resulting in eventual kinetochore reorientation. A second correction mechanism seem to involve an increased in microtubule ratio to opposite poles in anaphase, promoting segregation of merotelically oriented chromosomes to the correct pole.

Aneuploidy and Other Causes of Multilateral Genomic Instability and Their Role in Cancerogenic Pathways (Cancer Chromosomal Instability, CIN)

Aneuploidy is consistently found in most, if not all, cancers and is strong driving force for cancerogenic pathways (Duesberg et al. 1998, 1999, 2004; Sen 2000; Duesberg and Rasnick 2000; Duesberg and Li 2003; Weaver and Cleveland 2009; Nguyen and Ravid 2010; Ried et al. 2012; Honma et al. 2014; Ricke and van Deursen 2013; Takeshita et al. 2013; Zasadil

et al. 2013) and may be associated with somatic mosaicism (Sen 2000). Aneuploidy destabilizes the karyotype as it unbalances thousands of genes and causes progressive genomic instability, an altered transcriptome and proteome, and finally a novel cellular phenome (Pavelka and Rancati 2013). Cancer chromosomal instability (CIN) is defined as an excessive rate of numerical and structural genomic changes in neoplasms (Bayani et al. 2007). CIN is associated with aneuploidy and is a major factor for intratumor heterogeneity and is a marker for aggressive tumor biology (Zasadil et al. 2013). Progressive CIN leads to an increasing deviation of the cancer clones from their normal counterparts in regard to genotype and genomics, creating something like a "novel species." CIN is characterized by increased DNA replicating stress and proneness to faulty information copying circumvented by the generation of novel and sometimes thriving copies. Cells in a state of aneuploidy more often acquire mutations that eventually result in their malignant transformation, aneuploidy driving a mutator phenotype (Kolodner et al. 2011). Many of the random novel karyotypes thus induced perish, but part of them survive and give rise to abnormal karyotypes that acquire replicative autonomy and a cancer phenotype – similar to a deviant form of speciation (the speciation theory of carcinogenesis). According to this theory, cancer is a chromosomal disease strongly dependent on the generation of aneuploidy and genomic instability (Duesberg et al. 2005, 2006; review: Duesberg et al. 2011). CIN is normally abolished by the action of CIN-suppressor genes, such as PIGN (MCD4), MEX3C (RKHD2), and ZNF516 (KIAA0222) encoded on chromosome 18q that are often altered in CIN, CIN being associated with aneuploidy (Burrell et al. 2013). Abnormal, aneuploidy genotypes evolving in the course of genomic instability result in the selection of specific clones that gain individuality as autonomously replicating entities (Fabarius et al. 2008). There is increasing evidence that distinct protein groups affecting the fidelity of chromosome separation during mitosis are involved in aneuploidy and genomic instability in cancers. One group of proteins involved in this pathway are mitotic kinases. Aurora kinases link chromosome segregation and cell division to cancer susceptibility. During carcinogenesis, missegregation of chromosomes due to deregulated Aurora kinase activity results in aneuploidy or polyploidization (review: Meraldi et al. 2004). In gastric cancer cells, high Aurora-B kinase expression in nuclei is correlated with aneuploidy and TP53 mutations, but not with microsatellite instability (Honma et al. 2013).

Aneuploidy is not the single mechanism responsible for genomic instability. A mechanism of genomic instability is deregulation of the centrosome cycle, a process that is operational in many cancers (reviews: Fukasawa 2005; Vitre and Cleveland 2012). Centrosome composition is controlled by the tumor suppressor phosphatase and tensin homolog (PTEN) and Akt during mitosis. Specifically, PTEN localization at mitotic centrosomes peaks between prophase and metaphase, paralleling the centrosomal localization of gamma-tubulin (Leonard et al. 2013). Centrosome deregulation is closely linked to centrosome amplification caused by environmental factors such as ionizing radiation, failure of cytokinesis, and activating mutations affecting centrosome structure and function. Centrosome duplication as a first step of amplification promotes cells to enter the G2 phase of the cycle in tetraploid state (4N). But such cells fail to terminate mitosis and tend to reenter the G1 phase of cycle as 4N cells with amplified centrosomes. In case centrosome duplication is uncoupled from chromosome replication, further centrosomal amplification round will result in multipolar spindles that may cause aneuploidy, as outlined above (Lingle et al. 2005). Centrosome amplification is also the cause for polyploid karyotype states occurring in cancers (Duensing and Duensing 2010).

Genomic instability is also thought to be linked to telomere dynamics (Cheung and Deng 2008), specifically to erosion and/or amplification of the TTAGGG repeat sequences present at chromosomal termini. Telomeres are specialized domains at chromosomal ends made up of 5′-TTAGGG-3′ repeats and a number of telomere-associated proteins (the "telomerome"). The telomere is capable to form a loop structure to conceal the DNA end and protecting it from breaks and degradation.

Correct telomere function determines the domain of individual chromosomes within the nuclear compartment and protects chromosomes from damage, telomere failure leading to karyotype destabilization (Cheung and Deng 2008). Amplification of telomeric DNA is associated with aggressive malignancy, in particular metastatic cancers (Pathak et al. 2002).

Mitotic Catastrophe as a Protection Against Aneuploidy

Mitotic catastrophe (MIC) is a mechanism designed to sense mitotic failure leading to cell death or senescence. MIC is a very powerful pathway to circumvent and counteract progressive aneuploidy and genomic instability. Several pathogenic pathways can induce MIC. One mechanism of MIC consists in the generation of non-bipolar mitotic spindles that cause failure of cell division and death. In cancer cells, apoptin, a protein from chicken anemia virus, can cause MIC and selective tumor cell death through failure to progress through anaphase and telophase (Lanz et al. 2013). More details on MIC are presented in the chapter on cell death and apoptosis.

Chromosomal and Genomic Instability as a Driving Force for Cancerogenesis: Further Mechanisms

Introduction

Errors in genome replication fidelity cause chromosome instability (CIN) leading to aneuploidy and the promotion of cancerogenic pathways (see above; Abbas et al. 2013). CIN can promote cancerogenesis through gene amplifications and deletions (structural CIN) and gains and losses of chromosomes (numerical CIN or nCIN) (reviews: Foijer 2010; Thompson et al. 2010). Traditional mechanisms for CIN comprise cohesion defects, supernumerary centrosomes, defects in kinetochore-microtubule attachment dynamics, and defects in cell cycle regulation. Genomic instability in contrast to CIN can be generated via mutational events resulting in sometimes characteristic mutational signatures in cancers (Alexandrov et al. 2013; Helleday et al. 2014). Genomic instability can also develop through localized hypermutations, a disorder called kataegis. Recently, several catastrophic genomic disorders resulting in copy number variation (CNV) have been described (Lupski and Stankiewicz 2005; Zhang et al. 2009; Liu et al. 2011). Several of these disorders lead to "genome chaos" (chaotic genomes), a massive form of CIN found in several types of cancer (Liu et al. 2014). The finding very important for cancerogenesis is that even in the presence of massive and rapidly evolving genome damage, viable clones with unstable genomes can emerge (Lane and Clarke 2012).

Nonallelic Homologous Recombination (NAHR) and Nonhomologous End Joining (NHEJ)

NAHR and NHEJ are two mechanisms that result in a "genome chaos" (Liu et al. 2014). NAHR is a major cause of CNV that occurs when the control of allelic recombination fails (Liu et al. 2012). It can occur on interchromosome, intrachromosome, intrachromatid, and sister chromatid exchange levels. Random rejoining of chromosomal fragments can occur through nonhomologous end joining (NHEJ).

Chromoanagenesis

In chromoanagenesis, large numbers of complex rearrangements occur at one or a few chromosomal loci in a single catastrophic event. The term seems to cover the two events, chromothripsis and chromoanasynthesis (Holland and Cleveland 2012).

Chromothripsis

Chromothripsis (chromosome shattering) describes a distinct form of "acute" genomic

rearrangement occurring in one single massive jump instead of numerous small steps (Stephens et al. 2011). Hence, chromothripsis is a form of CIN that opposes the traditional theory that cancer results from a multistep process. It is a catastrophic one-off event rather than the gradual accumulation of genomic alterations typical for many other oncogenic pathways (Rajapakse et al. 2011; Forment et al. 2012; Jones and Jallepailli 2012; Zhang et al. 2013b; Cai et al. 2014; Kinsella et al. 2014) and is the cause of clustered chromosomal rearrangements in subsets of malignant neoplasms. Some cancer cells can thus contain chromosomes with hundreds or thousands of clustered intra- and interchromosomal rearrangements, which involve a single chromosome or a chromosome arm (Kloosterman et al. 2011), and these rearrangements cause rapid genome evolution. It is currently thought that chromothripsis results from breakage and inaccurate reassembly of chromosomes, i.e., "shattering" of chromosomes followed by aberrant "stitching together" (reviews: Forment et al. 2012; Righolt and Mai 2012). The process shows large numbers of complex rearrangements in circumscribed regions of single chromosomes or chromosome arms, clustering of chromosomal breakpoints, prevalence of rearrangements involving a single haplotype, randomness of joining features, and randomness of DNA fragment order along resulting abnormal chromosomes. However, the exact mechanisms are not yet elucidated, and the view that chromothripsis results from a single event has been criticized (Sorzano et al. 2013). In chromothripsis, mitotic entry takes place before completion of DNA replication within the micronucleus occurred, with a defect in disassembling the micronuclear envelope that encapsulates the chromosome fragments for random reassembly in the following interphase (Holland and Cleveland 2012).

Chromothripsis has been observed in hepatocellular carcinoma (HCC). In one study, chromothripsis was detectable in 5.7 % of HCCs recurrently affecting chromosome arms 1q and 8q (Fernandez-Banet et al. 2014).

Chromoanasynthesis

Chromoanasynthesis is another type of constitutional complex genome rearrangement (Liu et al. 2011). In contrast to chromothripsis, the authors detected frequent copy number gains with interspersed regions containing duplication or triplication of one parental allele, but no LOH, and proposed microhomology, mediated breakage-induced repair as the major mechanism for inducing the translocations. In summary, chromoanasynthesis denotes a genomic disorder in which locally defective DNA replication causes serial, microhomology-mediated template switching resulting in local rearrangements with CNV (Holland and Cleveland 2012; Pihan 2013).

Chromoplexy

Chromoplexy denotes a type of complex DNA rearrangements that occurs in cancer cells. Similar to chromothripsis, chromoplexy is characterized by scrambling of genetic material of one or more chromosomes as multiple strands and then ligated to each other in a new configuration. In contrast to chromothripsis, where one or two chromosomes are involved in the shattering process, chromoplexy involves DNA segments from multiple chromosomes and shows fewer rearrangements than the hundreds or thousands found in chromothripsis. In addition, chromoplexy can occur in multiple subsequent rounds, what does not occur in chromothripsis.

Chromosome Pulverization

Chromosome pulverization is a form of genomic chaos characterized by massive errors in mitotic chromosome segregation that generate DNA breaks through the formation of micronuclei. In case errors produce lagging chromosomes, whole-chromosome-containing micronuclei can develop. These micronuclei cause whole-chromosome aneuploidy because they undergo marked subsequent changes, i.e., defective and

asynchronous DNA replication that results in DNA damage and extensive chromosomal fragmentation ("pulverization") within the micronucleus. As such, pulverization can be regarded as a form of chromothripsis with its genome instability, because micronuclei with fragmented chromosomes can persist and may be distributed to daughter cells (Crasta et al. 2012).

Kataegis

Kataegis (from Greek, "thunder") denotes a pattern of localized hypermutation occurring in certain cancer genomes (Nik-Zainal et al. 2012). Hypermutated regions that occur in kataegis often colocalize with regions of somatic genome rearrangement. Kataegic hypermutation almost exclusively involves cytosine to thymine switches, possibly caused by the action of AID/APOBEC cytosine deaminase (Lada et al. 2012). This cytosine deaminase, when dysregulated, can induce localized hypermutation with simultaneous, closely spaced or clustered multiple mutations (Roberts and Gordenin 2014). Localized hypermutation can also originate from DNA damage (e.g., alkylation) within long single-stranded DNA (ssDNA) formed at resected double-strand breaks and dysfunctional replication forks, clustered mutations emerging along the track of DNA synthesis (Roberts et al. 2012; Sakofsky et al. 2014).

Nuclear Bodies

Introduction

Nuclear bodies comprise a group of distinct structures of the nuclear architecture involved in a wide array of nuclear functions (reviews: Dundr 2011, 2012). The bodies form, as their name implies, morphologically visible, dot-like or point-like structures that, as they may be numerous and associated with distinct chromatin domains or the nucleolus, have an impact on the overall inner texture of the nucleus. The dynamic bodies therefore also contribute to the nuclear changes found in cancer cells, although the bodies are not easily identifiable in conventional sections. Part of the nuclear bodies are involved in the handling of RNA or ribonucleoprotein complexes, while others are distinct multiprotein signalosomes. The principal categories of nuclear bodies are listed in Table 1.

Table 1 Nuclear bodies

Promyelocytic leukemia bodies (PML bodies)
Nuclear speckles
Nuclear paraspeckles
P-bodies (mRNA processing bodies)
S1-1 nuclear bodies
Nuclear stress bodies (nuclear stress granules)
U bodies
Histone locus bodies
Cajal body
DDX1 bodies
Cleavage bodies
Gemini bodies (gems)
Polycomb group bodies
HSF1 granules

Promyelocytic Leukemia Bodies/PML Nuclear Bodies: General Aspects

Promyelocytic leukemia bodies (PML bodies) play an important role in the pathogenesis of diverse malignancies and are therefore treated in some more detail. These bodies are named after their specific component, the promyelocytic leukemia protein (PML). The PML gene was originally found at the t(15;17) translocation site of acute promyelocytic leukemia. The PML protein is the core component of a nuclear substructure that contains more than 70 proteins, the PML body or PML nuclear body (PML-NBs). PML-NBs are also termed nuclear dots, PML oncogenic domains (PODs) nuclear domain 10, or Kr-bodies. PML-NBs represent punctate structures that originally were detected as an autoantigenic target in primary biliary cirrhosis, but they are also found in the nuclei of cancer cells, including liver cancer. Proteins other than PML cover a broad range of protein types, such as Sp100, nuclear matrix proteins, and proteins of

the nuclear pore complex, whereby part of these proteins are SUMOylated, a process involved in PML-NB biogenesis (Shen et al. 2006). PML protein (synonym: TRIM 19) belong to the group of tripartite motif (TRIM) proteins having a coiled-coil region that facilitates oligomerization, a process important for PML body formation (Batty et al. 2012). The PML protein is a scaffold protein with several functions, including the control of cell growth, apoptosis and survival, DNA repair, senescence, telomere maintenance, and nuclear storage of proteins (reviews: Salomoni et al. 2012; Mazza and Pelicci 2013).

PML and PML-NBs serve as DNA damage sensors (Dellaire et al. 2006). The number and size of PML-NBs changes as a function of cell cycle phase and changes in chromatin structures or DNA damage. The number of PML-NBs increases in S phase and, as response to DNA damage, the latter effect being the result of DNA injury sensing. PML protein interacts with chromatin and ATM kinase which in turn phosphorylates the KRAB-associated protein 1 (KAP1), inducing in an increase in PML-NB number (Kepkay et al. 2011). Originally thought to be an exclusively nuclear protein, PML is now known to act in the cytoplasm as well, where it affects several mechanisms of cellular homeostasis (Carracedo et al. 2011; Jin et al. 2014). In particular, PML is a key regulator of cytokine signaling and affects immune responses, inflammation, and cytokine-induced apoptosis (Terris et al. 1995; Maarifi et al. 2014). Differential expression of PML in liver cancers may, therefore, exert an influence on tumor-associated inflammation and antitumor immune reactions. Breakdown of the nuclear envelope during mitosis is associated with formation of stable interactions of PML-NBs with early endosomes and spindle poles, this interaction remaining through mitosis and dissociated in the daughter cells (Palibrk et al. 2014).

PML Nuclear Bodies in Liver Cancer

PML expression has a determinant function in cancer stem cells and carcinogenic pathways, including hepatocarcinogenesis. PML is required for cancer stem cell maintenance (review: Zhou and Bao 2014). In many established solid tumors, immunohistochemical expression of PML is reduced or even absent. Generally, low expression of PML is associated with high-grade morphology, aggressive tumor biology, and poor outcome (Mazza and Pelicci 2013). However, HCCs show an upregulation of PML-NBs. Overexpression of PML was detected in 50 % of HCCs (Chan et al. 1998). The amount of PML and the number and size of PML-NBs increased gradually in the progression from liver cirrhosis, dysplastic nodules, to HCCs, and this overexpression was strongest in HBV-related cancers (Yoon and Yu 2001). However, HCV seems to interfere with the PML tumor suppressor (Herzer et al. 2014). In hepatocarcinogenic pathways, PML protein links DNA damage response and DNA repair to HBV-related tumorigenic pathways. PML deficiency facilitates genomic instability and promotes HBV-induced hepatocarcinogenesis (Chung and Wu 2013), and downregulation of PML also fosters HCV-associated hepatocarcinogenesis, a process associated with impaired expression of the proapoptotic factor TRAIL (Herzer et al. 2012). In HCV-infected cells, the HCV core protein promotes PML localization to PML-NBs where it colocalizes with p53. In PML-NBs, HCV core protein interacts with the PML isoform IV, a key regulator of p53 activity, and via this reaction inhibits the proapoptotic action of p53 (Herzer et al. 2005). Expression of PML and PML bodies in HCC negatively affects apoptosis of cancer cells (Herzer et al. 2014).

Abstract

Within carcinogenic pathways involving abnormal stress responses and deregulation of cell death pathways, mitochondria play a significant role. Apart from their role as the principal energy machines of the cell, mitochondria hold a central role in the regulation of various forms of apoptosis, exert an influence on cell structure and shape, and engage in complex interactions with other cellular organelles. Numerous of these functions can be deranged in the course of malignant transformation of cells, having led to the concept of a mitochondrial malignancy theory. Hepatocellular carcinomas (HCCs) vary in their cellular content of mitochondria and the presence of mitochondrial structural abnormalities. In part of poorly differentiated HCCs, biogenesis and proliferation of mitochondria through fission are impaired, a process that causes mitochondriopenia or sarcopenia. Few HCCs and cholangiocarcinomas show markedly increased numbers of mitochondria, resulting in an oncocytic phenotype. Anomalies in microstructure include diminished cristae, matrix inclusions, density changes of the matrix, altered ratio of short versus elongated cristae, and complex shape changes. At least part of these mitochondrial anomalies are associated with complex alterations of mitochondrial DNA, including losses and mutations.

Introduction: Mitochondrial Malignancy Theory

Apart from the established role of oncogene products (oncoproteins), tumor suppressor proteins, viruses, chemical, and radiation inducing malignant transformation and tumorigenesis, there is evidence that hypoxia, oxygen-induced cell damage, and stress of nutrient deprivation also represent factors capable to promote carcinogenesis. These factors can accelerate senescence, hence exerting a selection pressure on cell systems involved. Cells capable to overcome and escape from cellular senescence form a fit subset of cells

with novel features, including proneness to malignant transformation. In the mechanisms that circumvent hypoxia-induced senescence, mitochondria play a central role.

Mitochondria (the cellular "powerhouse") and mitochondrial dysfunction are involved in cancerogenesis, cancer cell metabolism, growth and differentiation, and apoptosis (Modica-Napolitano et al. 2007; Grandemange et al. 2009; Chatterjee et al. 2011; Scatena 2012; Davila and Zamorano 2013; Gasparre et al. 2013; Wang et al. 2013b). Mitochondria of cancer cells differ in many respects from their counterparts of normal cells, in that they have changed their metabolism, in particular their oxidative phosphorylation, and their interactions with other organelles (Gogvadze et al. 2008). Overall, mitochondrial respiration is decreased in most cancer cells. Increased knowledge of mitochondrial functions in cancer cells will have an influence on the design of anticancer drugs (Tatarkova et al. 2012), including drugs that destabilize mitochondria, e.g., the mitocans (Neuzil et al. 2013).

Cancer Mitochondrioma and Mitochondrial Morphology in Hepatocellular and Cholangiocellular Carcinomas

Hepatocellular carcinomas vary in their cellular content of mitochondria and the presence of mitochondrial structural anomalies (Ghandially and Parry 1966; Schaff et al. 1971; Hruban 1979; Isomura and Nakashima 1980). The deranged functional status of HCC mitochondria, in part related to losses and mutations in mtDNA, manifests in several ways, although many, if not most, of the ultrastructural changes are nonspecific. The alterations include diminished cristae (Schaff et al. 1971), electron-dense mitochondrial inclusions (Schaff et al. 1971), density changes of the mitochondrial matrix, alterations in the ratio of short versus elongated mitochondria, and complex shape changes. In one ultrastructural morphometric study, the mitochondria of HCC cells revealed a higher numerical density and surface density of internal membranes and cristae than mitochondria of hepatocytes in cirrhosis (Wu et al. 1984). A liver cell tumor with large oxyphilic cells that harbor a rich ER and prominent mitochondria is fibrolamellar hepatocellular carcinoma (Caballero et al. 1985). Similar to other oncocytomas, oncocytic HCC is characterized by a marked increase in the number of mitochondria (Fukunaga et al. 1996), but it is not yet known whether this phenomenon is associated with an increased rate of mtDNA mutations. Clear cell HCC showed scarce and ballooned mitochondria (Clayton et al. 2012). In contrast to HCCs, cholangiocarcinomas may show abundant organelles, also in poorly differentiated variants (Alpert et al. 1974; Stitnimankarn et al. 1978).

Proliferative Status and Respiration of Mitochondria in Cancer Cells

In part of poorly differentiated HCC, biogenesis and proliferation of mitochondria are impaired, resulting in mitochondriopenia/sarcopenia. In contrast, fibrolamellar carcinoma is characterized by upregulation of mitochondriopoiesis, probably related to mutations in mtDNA (Vivekanandan et al. 2010). Induction of increased mitochondrial biogenesis and augmentation of oxidative phosphorylation hamper cancer progression through decrease in cell proliferation and invasiveness (Wang and Moraes 2011).

Alterations of Mitochondrial DNA in Liver Cancer

Introduction

Mitochondrial DNA (mtDNA) is a circular, covalently closed, double-stranded, and maternally inherited DNA of which between 100 and 10,000 separate copies exist in human cells, while a single mitochondrion contains two to ten mtDNA copies. MtDNA forms a chromosome equivalent, but it is confined in distinct mitochondrial nucleoids (Tauber et al. 2013). Nucleoids exist in complex clusters containing several accessory proteins, the DNA polymerase gamma complex and its

associated proteins, the DNA-compacting mitochondrial transcription factor A/TFAM, and the core transcription initiation factor TFB2M. The actions of the transcription factors TFAM and TFB2M on promoters and their interaction with mitochondrial RNA polymerase differ from those of the nuclear transcription machinery (Han et al. 2011; Yadav et al. 2014; Agaronyan et al. 2015; Morozov et al. 2015). The two strands of mtDNA differ in their nucleotide composition, the heavy strand (H strand) being guanine rich and the light strand (L strand) being cytosine rich. MtDNA encodes for a relatively small number of mitochondrial proteins, most of the approximately 1500 protein types being encoded by nuclear DNA and imported into mitochondria. In human cells, the H strand encodes 28 genes and the L strand 9 genes for a total of 37 genes, of which 13 genes encode mitochondrial proteins, 22 genes encode transfer RNAs/tRNAs, and two genes encode small and large subunits of ribosomal RNA/rRNA.

mtDNA is replicated by the action of DNA polymerase gamma complex. The catalytic polymerase proper is encoded by the POLG gene and two accessory subunits by the POLG2 gene. This complex associates with the Twinkle helicase and mitochondrial SSB proteins to form the mtDNA replisome (McKinney and Oliveira 2013). Twinkle helicase, a DNA unwinding enzyme mutated in certain mitochondriopathies, is an essential protein required for synthesis of nascent D-loop strands and complete mtDNA replication (Milenkovic et al. 2013). mtSSB protein/single-stranded DNA-binding protein directs origin-specific initiation of mtDNA replication, as it covers the parental heavy strand, which is displaced during mtDNA replication. The SSB protein blocks primer synthesis on the displaced strand and restricts initiation of light-stranded mtDNA synthesis to the specific origin of light-stranded DNA synthesis (Miralles Fusté et al. 2014).

Alterations of mtDNA in Liver Cancer

The maintenance of a function mitochondrial genome is crucial for mitochondrial functions. MtDNA function is compromised by mutations, whereby mtDNA mutates much faster than nuclear DNA. mtDNA point mutations and deletions occur somatically and accumulate with increasing age. Such mutations can occur together with wild-type mtDNA, a condition termed heteroplasmy. Mutant mtDNA can undergo clonal expansion within single cells, giving rise to complex and severe diseases (mitochondriopathies) and eventually cancer (reviews: Gaude and Frezza 2014; Kim 2014; Carelli et al. 2015). Similar to nuclear DNA, mtDNA is subject to base excision repair (Prakash and Doublié 2015). Apart from mtDNA, also mitochondrial tRNAs can under cancerogenic mutations (Wang et al. 2015c).

In cancer, the mtDNA genome undergoes genomic instability which exerts dramatic influences on mitochondrial structure and function (Copeland and Longley 2014; Ju et al. 2014). mtDNA copy numbers are reduced in HCCs (Yin et al. 2004), this reduction being correlated with tumor size and the presence of cirrhosis and with shortened 5-year survival (Yamada et al. 2006), suggesting that severe alterations in mtDNA markedly affect HCC biology. Several types of somatic mitochondrial DNA (mtDNA) alterations, including mtDNA loss, sequence polymorphisms, and mtDNA D-loop mutations, have been identified in cancers, including HCC (Lee et al. 2004; Wong et al. 2004; Yin et al. 2004, 2010; Stuart and Brown 2006; Lu et al. 2009; Gwak et al. 2011; Wang et al. 2011a; Jin et al. 2012; Hsu et al. 2013). It is likely that loss of mtDNA and mtDNA mutations is significantly involved in mitochondrial dysfunction, and mtDNA mutations act as clonal markers in HCC, specifically in multicentric HCC (Nomoto et al. 2002). In solid neoplasms, an elevated expression of normal or mutated mtDNA genes coding for components of the electron transfer machinery may affect the capability of cancer cells to adapt to novel energy situations, in particular hypoxia (Copeland et al. 2002). In HCCs, somatic mtDNA mutations and a general decrease in mtDNA copy number are common events (Hsu et al. 2013). Deletion of mtDNA was also observed in liver changes preceding HCC, i.e., viral hepatitis, liver cirrhosis, and hyperplastic liver nodules (Yamamoto et al. 1992; Nishikawa et al. 2001; Shao et al. 2004). Loss of mtDNA in HCC cells

is associated with angiogenic and invasive potential (Cheon et al. 2010). The link between mtDNA mutations and carcinogenesis, liver cancer cell behavior, and tumor progression is not yet well known (review: Wang et al. 2013b). However, a higher frequency of mtDNA D-loop (displacement loop) mutations was detected in less-differentiated HCCs (Tamori et al. 2004). There is evidence that the inflammatory process induced by hepatitis viruses contributes to the rate of mtDNA mutations (Wheelhouse et al. 2005). Mutations in the mitochondrial genome have also been identified in cholangiocarcinomas (Muisuk et al. 2015).

Epigenetic Alterations of mtDNA and Mitochondrial Gene Expression (Mitochondrial Epigenetics)

Introduction

Expression of nuclear genes is markedly modified by several epigenetic mechanisms which include DNA methylation, histone modifications, chromatin modifiers, and microRNAs. There is increasing evidence that also mtDNA gene expression is subject to such epigenetic mechanisms, potentially playing a role in cancerogenic pathways (mitoepigenetic phenomena in cancer; Ferreira et al. 2015).

Mitochondrial Epigenetic Methylome

Similar to nuclear DNA, gene expression regulation in mtDNA has been suggested to be accomplished by promoter methylation on cytosine residues, a still disputed issue (Maresca et al. 2015). In nuclear DNA, methylation is performed by DNA(cytosine-5)-methyltransferase 1/DNMT1. DNMT1 is responsible for maintaining the nuclear genome methylation patterns during DNA replication and repair. As the great majority of mitochondrial proteins are encoded by nuclear DNA, nuclear methylation gene-silencing patterns are imported into mitochondria. There is, however, some evidence that mtDNA methylation occurs through the action of a mitochondrial isoform of DNMT1 (Iacobazzi et al. 2013). Cytosine methylation of mtDNA has been detected in hepatocytes and was associated with the severity of nonalcoholic fatty liver disease (Pirola et al. 2013).

Epigenetic methylation of certain nuclear genes can affect replication of mtDNA. DNA methylation seems to occur at exon 2 of mtDNA polymerase gamma A/POLGA, and DNA demethylation of POLGA is an essential regulator of mtDNA copy number. Cancer cells are only capable to modulate POLGA DNA methylation and mtDNA copy number in the presence of a DNA demethylation agent that inhibits de novo DNMT activity (Kelly et al. 2012; Lee et al. 2015).

Mitochondrial MicroRNAs/MitomiRs: Translocated Nuclear MiRs and MitomiRs

Certain microRNAs encoded by nuclear DNA (MiRs) are imported into mitochondria where they epigenetically regulate gene expression patterns. Mitochondria are therefore a distinct destination for certain MiR subsets that have been outsourced from nuclei (Bandiera et al. 2011). However, the translocation of microRNAs and other small RNAs to mitochondria and other organelles is not yet clarified (Sripada et al. 2012a). MicroRNA-532-3p regulates mitochondrial fission through targeting apoptosis repressor with caspase recruitment domain (Wang et al. 2015b). Based on the central role of mitochondria in programmed cell death, it may be expected that other microRNAs are involved in apoptosis, what has already been documented for nuclear microRNAs in cancer (Wang and Lee 2009).

In addition to translocation of nuclear microRNAs to mitochondria, there is evidence that mitochondria-specific MiRs (termed mitomiRs) are encoded by mtDNA, in part predicted by respective sequence analysis of mtDNA (Barey et al. 2011; Shinde and Bhadra 2015). MitomiRs are considered to act as vectors that sense and respond dynamically to the changing microenvironments of mitochondria (Bandiera et al. 2013). Several aging-related

mitomiRs may play a direct role in controlling mitochondrial function by regulating mitochondrial protein expression and affecting inflammatory responses (Rippo et al. 2014). Similar to entire cells, it might be expected that mitomiRs can be released as cargo of exosomes. It was shown that stimulated human mast cells can secrete mitochondrial components/particles that can induce inflammatory responses in an autocrine and paracrine manner (Zhang et al. 2012).

Circulating Mitochondrial DNA and Mitochondrial Fragments

Damaged and permeabilized cells of malignant neoplasms, including liver cancer, can release mitochondrial fragments, such as membranes, cristae and matrix components (mitochondremia), and mitochondrial DNA. Circulating free mtDNA reflects tumor cell death and chemotherapeutic effects on cancer cells (Huang et al. 2014). As outlined in more detail below, mitochondria and mitochondrial components released by cells can act as danger signals and provide damage-associated molecular patterns/DAMPs which may provoke inflammatory responses (Maeda and Fadeel 2014). In particular, circulating free mtDNA can act as a specific form of DAMP-termed mitochondrial DNA damage-associated molecular patterns (mtDNA DAMPs).

Mitochondrial Oxygen Stress: A Pathway Involved in Hepatocarcinogenesis

Reactive Oxygen Species (ROS) Production and ROS-Induced Oncogenic Transformation

Oxystress and the production of reactive oxygen species (ROS), including ROS released from mitochondria, contribute to carcinogenesis and cancer biology in general through the induction of DNA damage and the deregulation of signaling pathways (reviews: Wallace 2005; Fang et al. 2007; Fogg et al. 2011; Cardin et al. 2014; Sullivan and Chandel 2014). Oxystress susceptibility versus resistance is in part determined by genetic factors. OSGIN1/oxidative stress-induced growth inhibitor 1 is a tumor suppressor that is downregulated or mutationally altered in human HCC (Liu et al. 2014c). There is increasing evidence that hypoxia is associated with a progressive elevation of mitochondrial production of reactive oxygen species (ROS). Over time this may lead to stabilization of damaged cells through increased hypoxia-inducible factor (HIF)-2alpha, enabling cells to survive with persistently elevated ROS levels (review: Ralph et al. 2010). Apart from HIF, altered redox states of mitochondria are linked to distinct mitochondrial membrane proteins. Reactive oxygen species modulator-1/ROMO1 is a mitochondrial protein and oncomarker associated with control of redox states and cancer growth that acts through induction of NF-kappaB (Shyamsunder et al. 2015). The paradoxial increase of ROS in cancer cells suffering from hypoxia is not fully clarified but is probably related to altered oxygen sensing by mitochondria and changes in HIF availability (Chandel 2010). ROS generated by mitochondrial complex III are required for hypoxic activation of HIF, a mechanism that is involved in ROS handling in hypoxic cancer cells (Guzy and Schumacker 2006; Klimova and Chandel 2008). Through HIF signaling, hypoxia induces enlarged mitochondria in cancer cells. Hypoxic cancer cells undergo HIF-1-dependent and mitofusin-1-mediated alteration in morphology from a tubular network to markedly enlarged organelles. This change protects the cells from apoptotic stimuli as the mitochondria conserve ATP production and transmembrane potential (Chiche et al. 2010).

ROS-induced oxidative stress can be reduced by several protective pathways. HIF-2alpha can counteract DNA mismatch repair, causing the progressive accumulation of mitochondrial ROS-induced oxidative DNA alterations and associated mutations. In case such stabilized cells overcome senescence and maintain proliferative capacity, they may be candidates for malignant transformation (ROS-induced oncogenic transformation; Ralph et al. 2010). A potent anti-oxystress factor is the molecular chaperone,

mortalin, a protein of the HSP 70 family located primarily to mitochondria (Luo et al. 2010; Yang et al. 2011; Flachbartova and Kovacech 2013). Mortalin, together with Tid1, serves as a protein disaggregating machine which carries the scavenging of toxic protein aggregates (Iosefson et al. 2012). In HCCs, mortalin is overexpressed and increases as a function of stage (Chen et al. 2011), suggesting a protection mechanism directed against the deleterious effects of oxidative protein damage. Mortalin also interacts with p53 protein (wild type and mutant types) in HCC cells, inactivating the transcriptional and proapoptotic functions of p53 (Lu et al. 2011b). On the other hand, mortalin silencing in HCC cells promotes apoptosis via disinhibition of p53 (Lu et al. 2011a).

Cell Death Pathways Induced by Mitochondrial Oxystress

Mitochondrial oxystress can induce several cell death pathways both in normal and neoplastic cells, including liver cancer. Mitophagy (mitochondrial autophagy), the controlled elimination of superfluous mitochondria (see below), is involved in the reorganization of the mitochondrial complement in normal and cancer cells. Parts of undifferentiated cancer cells are poor in organelles and may, despite their energy requirements, contain less mitochondria than normal counterparts. Apart from deranged mitochondrial biogenesis, elimination of "unwanted" mitochondria by a selection process may be involved in the process of sarcopenia/mitochondriopenia. An important driving force for mitophagy in neoplastic cells is hypoxia, associated redox disorders, and other stressors (Kim et al. 2011; Frank et al. 2012; Chourasia et al. 2015; Wei et al. 2015). Several proteins mediate hypoxic damage of mitochondria. The hypoxia-inducible BH3-only proteins BNIP3, BNIP3L, and NIX react to hypoxia and potently induce mitophagy in cancer cells (Mellor and Harris 2007; Bellot et al. 2009; Ding et al. 2010; Feng et al. 2013; Ney 2015). Cancer cells subject to hypoxia show increased mitophagy rates induced by the mitochondrial outer-membrane protein FUNDC1, a receptor for hypoxia-induced mitophagy and interacting partner of LC3 (Liu et al. 2012). In HCCs, an autophagy-promoting protein, damage-regulated autophagy modulator/DRAM is translocated to mitochondria and induces mitophagy leading to apoptosis. In such cells, translocation of DRAM is inhibited by phosphorylated Akt, a mechanism protecting HCC cells from apoptosis (Liu et al. 2014b). In addition to mechanisms inherent to cancer cells, factors involved in cancerogenesis itself can affect mitophagy. For example, hepatitis C virus/HCV can modulate mitophagy through mitochondrial translocation of Parkin, a protein critically involved in mitophagy (see below; Kim et al. 2013a; Hara et al. 2014).

Regulation of the Mitochondrial Matrix and Mitochondrial Proteomes in Cancer Cells

In both normal and neoplastic cells, the mitochondrial matrix contains a set of specific proteins that are imported into the matrix by the translocase of the outer membrane, i.e., the TOM complex, and the presequence translocase of the inner mitochondrial membrane, i.e., the TIM23 complex (Albrecht et al. 2006; Qiu et al. 2013). In conjunction with other dysfunctions of cancer mitochondria, the mitochondrial matrix of cancer cells undergoes complex alterations that affect the turnover of mitochondrial proteins and of mtDNA. Proteins located to the mitochondrial matrix are degraded by three specific mitochondrial proteases of the AAA+ superfamily (Lon, ClpXP, and m-AAA proteases). By regulating the quantity and availability of mitochondrial proteins, these proteases exert a strong influence on the assembly of inner membrane and matrix proteins, composition of the oxidative phosphorylation platforms/tablets, nucleoid formation, and mitochondrial network dynamics (Goard and Schimmer 2014). In cancer cells, the expression patterns of matrix proteases are altered, a mechanism that affects numerous mitochondrial functions in cancer.

Mammalian mitochondria contain up to 1400 different proteins which form the mitochondrial

proteome. These proteins are in part produced in the cytoplasm and enter mitochondria via targeting/recognition signals, but other members of the proteome are synthesized by mitochondrial ribosomes (Herrmann et al. 2012). Apart from changes in mitochondrial DNA, liver cancer cells show differential upregulations and downregulation of mitochondrial proteins (Ye et al. 2013). These proteome and subproteome alterations are thought to play a role not only in carcinogenesis but also in tumor cell biology, in particular invasion and spread.

Mitochondrial Alterations Induced by Hepatitis Viruses

Hepatitis Viruses as Inducers of Oxidative Stress

Both hepatitis B and hepatitis C virus infections exert significant effects on oxygen metabolism in mitochondria and are potent mediators of oxidative stress. Through these pathways, HBV and HCV can contribute to oxystress-promoted carcinogenesis. The HBV protein HB X interacts with the inner mitochondrial membrane protein COXIII, causing upregulation of COX III protein and increased activity of cytochrome c oxidase/COX, associated with enhanced production of ROS (Lim et al. 2010; Hino et al. 2014; Zheng et al. 2014; Zou et al. 2015). Via ROS generation, HB X protein affects cell death pathway, but this protein can also directly induce apoptotic pathways (Rawat et al. 2012). Mitochondrial oxidative stress is also mediated by the action of hepatitis C virus/HCV, a virus known to promote mitochondrial dysfunction. Specifically, HCV promotes the mitochondrial production of ROS (Simula and De Re 2010; Brault et al. 2013; Hino et al. 2014). HCV is well known to alter the redox state of hepatocytes, associated with structural changes of mitochondria, and HCV core protein-induced dysfunction of the respiratory chain results in ROS overproduction (Korenaga et al. 2005a, b; Piccoli et al. 2006, 2009). HCV proteins, including core and NS5a proteins, contribute the generation of ROS through mechanisms mediated by binding of these proteins to mitochondria and endoplasmic reticulum/ER. Mitochondrial HCV core protein binding induces calcium uptake, mitochondrial superoxide production, and sensitization of mitochondria to calcium- and ROS-induced membrane permeability transition. HCV core protein redistributes cytochrome c from mitochondrial to cytosolic compartments (Okuda et al. 2002). The core and NS5a proteins of HCV cause ER stress and calcium(2+) release from ER. This results in a shift of calcium from ER to mitochondria, causing mitochondrial electron transport changes followed by increased ROS production (Wang and Weinman 2006, 2013). HCV triggers mitochondrial permeability transition with production of ROS leading to DNA damage (Machida et al. 2006). HCV also affects oxygen metabolism in mitochondria through iron-mediated pathways. Generally, iron accumulation in the liver exacerbates oxidative stress. ROS-mediated oxystress is modulated by proteins that regulate mitochondrial iron homeostasis, including the NEET family of proteins containing 2Fe-2S clusters (Stehlingh et al. 2014; Tamir et al. 2014). HCV core protein enhances mitochondrial iron uptake and ROS generation (Sekine et al. 2015).

Antiviral Effects of Mitochondria

Mitochondria hold an important position in antiviral defense and the generation of antiviral immunity (reviews: Scott 2010; Ohta and Nishiyama 2011). RNA viral components interact with a mitochondrial membrane adaptor protein, mitochondrial antiviral signaling protein/MAVS which is a member of the RIG-I signaling pathway and plays a crucial role in orchestrating the innate host response mediated by interferon-beta/IFN-beta. RIG-I signaling via MAVS involves the NF-kappaB pathways and also coordinates apoptotic and metabolic pathways. This signaling system connects mitochondria with other organelles participating in stress responses, as MAVS is also present in membranes of the endoplasmic reticulum and peroxisomes (Belgnaoui et al. 2011; Zemerli and Arnoult 2012). MAVS

makes part of a defense platform (HCV pathogen-associated molecular patterns/PAMPs) that also comprises Toll-IL-1 receptor domain-containing adaptor inducing IFN-beta/TRIF (review: Heim 2013). HCV as an RNA virus can circumvent the MAVS-induced innate antiviral immune reaction by cleavage and inactivation of MAVS through the viral protease, NS3-4A (Li et al. 2005; Anggakusuma et al. 2015). Another protein is involved in sensing of HCV and inducing innate immunity of the helicase MDA5 (Cao et al. 2015).

Other Mitochondrial Effects of Hepatitis Viruses

HBV affects the turnover of the mitochondrial protein, mitofusin-2, a protein involved in mitochondrial fusion and apoptosis (see below). HB X protein inhibits p53-mediated upregulation of mitofusin-2 in HCC cells (Wang et al. 2012b). This may exert an effect on tumor cell apoptosis, as mitofusin-2 triggers mitochondrial calcium influx from the endoplasmic reticulum to induce apoptosis in HCC (Wang et al. 2015a).

Mitochondria: Role in Inflammasome Biology and Immunity

Introduction

Inflammasomes constitute distinct and large molecular platforms that are activated by stress factors to serve as cell damage sensors and trigger inflammation and an innate immune response through the maturation of pro-inflammatory cytokines to produce IL-1beta and IL-18. Nod-like receptor family protein 3/NLRP3 is the most prominent inflammasome (reviews: Gross et al. 2011; Leemans et al. 2011). Danger signals that can activate the NLRP3 inflammasome include pathogen-associated molecular patterns, the inflammasomes thereby acting as microbial sensors (review: Franchi et al. 2010). Apart from bacterial products, components of parasites such as the malarial hemozoin are also capable to operate as danger signals for the inflammasome (Dostert et al. 2009). Host-derived damaging compounds such as reactive oxygen species/ROS and uric acid crystals also activate the inflammasome (Gasse et al. 2009). Due to their position in mechanisms dealing with cellular stress responses and innate immunity, inflammasomes play an important role in carcinogenic pathways.

Inflammasomes: The Mitochondrial Connection

One of the major common pathways for inflammasome activation is ROS (Tschopp and Schroder 2011). ROS are, e.g., produced through activation of NADPH oxidase upon phagocytosis of exogenous substances such as silica and asbestos (Dostert et al. 2008). A main source of ROS is mitochondria, organelles which are induced to secrete ROS upon various activation stimuli, including membrane damage, hypoxia, and increased metabolic rates (Brookes et al. 2004). In fact, there is a close association between dysfunctional mitochondria and the NLRP3 inflammasome, and inflammasomes are activated by mitochondrial oxystress (Tschopp 2011; Gurung et al. 2015; Usui et al. 2015). ROS produced by mitochondria are endogenous damage-associated molecular patterns/DAMPs (Kapetanovic et al. 2015) and fuel the inflammasome (Sorbara and Girardin 2011). Oxidized mtDNA released during apoptosis from mitochondria directly binds and activates the NLRP3 inflammasome, suggesting a link between apoptosis and inflammasome activation (Shimada et al. 2012; review: Martinon 2012). On the other hand, autophagy proteins inhibit the release of mitochondrial DNA and thus regulate innate immune responses mediated by the activated inflammasome (Kepp et al. 2011). However, not all inflammasomes are linked to organelles. The activated endogenous apoptosis-associated speck-like protein containing a CARD (ASC) pyroptosome is produced in the cytoplasm and co-localizes with NLRP3 and caspase-1, but not with organelles (Wang et al. 2013a).

Inflammasomes, Mitochondria, and Innate Immunity

Through inflammasome activation, mitochondria are linked to, and can trigger, inflammatory responses that operate in innate immunity (West et al. 2011; Cloonan and Choi 2012; Weinberg et al. 2015). Mitochondrial DAMPs/mtDAMPs (mitochondrial danger signals or mitochondrial alarmins) are potent drivers of innate immune reactions through activation of inflammasomes, a process mediated by pattern recognition receptors such as Toll-like receptors/TLRs (Said-Sadier and Ojcius 2012). NLRP3 inflammasomes activated by mitochondria-derived ROS not only generate inflammatory cytokines (interleukin-beta1, IL-18) but also modulate glycolytic and lipogenetic pathways and thus promote the metabolic syndrome (reviews: Tschopp 2011; Salminen et al. 2012). The caspase-1-dependent pro-inflammatory process induced by inflammasomes can activate the innate immune system, initiating pyroptosis (an inflammatory form of programmed cell death; see the respective chapter on apoptosis) and influencing adaptive immunity (Sutterwala et al. 2014).

Necroptosis: A Form of Cell Death Involved in Mitochondria-Induced Inflammation and Innate Immunity

As further discussed in the chapter on apoptosis, necroptosis is a pathway of regulated, caspase-independent necrosis that involves the proteins RIPK1, RIPK3, and MLKL. An alternate pathway to induce necroptosis involves the antiapoptotic protein CFLAR (CASP8 and FADD-like apoptosis regulator) long isoform (CFALRL) (He and He 2013). Necroptosis is induced by death receptors, TNF-alpha, interferons, intracellular DNA and RNA sensors, and, what is important in the setting of immunity, damage pattern recognition receptors such as Toll-like receptors (Kaczmarek et al. 2013; Pasparakis and Vandenabeele 2015). Necroptosis induction is also linked to mitophagy (Mizumura et al. 2014). In the case of TNF-alpha-induced necroptosis, TNF-alpha stimulation leads to the activation of the kinase receptor-interacting protein 1/RIP1, which then binds with and activates RIP3 to form the necrosome. RIP3 interacts with and activates the pseudokinase, mixed lineage kinase domain-like/MLKL, which induces necroptosis through the induction of mitochondrial damage and mitochondrial ROS production, linking mitochondrial dysfunction with necroptosis (Ye et al. 2012; Marshall and Baines 2014). In the course of necroptosis, damaged cells can release part of their organelle inventory into the extracellular space and into circulation. Mitochondria released from necroptotic cells act as danger signals or alarmins (DAMPs) and by this induce inflammatory signaling (Sangiuliano et al. 2014). Such mitochondria are phagocytosed by macrophages and dendritic cells, leading to the modulation of cytokine secretion by macrophages and dendritic cell maturation (Maeda and Fadeel 2014), both processes being instrumental in the induction of inflammation and innate immunity. In liver inflammation and liver cancer, Kupffer cells, monocytes, macrophages, stellate cells, dendritic cells, and endothelial cells form an interacting network of non-epithelial cells that transmit necroptotic death signals into inflammatory responses (Brenner et al. 2013).

Inflammasomes in Liver Cancer

Chronic necroinflammation promoting ongoing hepatocyte regeneration, liver cirrhosis, cell senescence, and telomere shortening is a key process inducing hepatocarcinogenesis. Inflammasomes, and specifically the NLRP3 inflammasome, play an important role in this process. Due to their capability as inflammasome activators, mitochondria rendered dysfunctional by various endogenous and exogenous factors, including hepatitis viruses, hold a critical position in this pathogenic pathway (Ramakrishna et al. 2013). In early carcinogenic steps, HCC evolution may be driven by inflammasome actions, but later phases of HCC are characterized by marked deregulation of the NLRP3 inflammasome, its components significantly downregulated or even lost. This suggests distinct inflammasome and innate immunity

expression patterns along HCC evolution and progression (Wei et al. 2014). In carcinomas, inflammasome regulation also involves cells that are components of the tumor stroma. The stroma contains tumor-associated macrophages/TAMs. In these cells, inflammasomes are activated upon cellular danger signals, including ROS from dysfunctional mitochondria, and initiate cytokine-mediated inflammatory responses that modulate tumor cell survival, growth, motility, and invasion. Mesenchymal stromal cells and mesenchymal stem cells homing to stroma negatively regulate NLRP3 inflammasome activation in macrophages (Oh et al. 2014), suggesting a complex interaction network among stromal cells.

Mitochondrial Biogenesis and Morphogenesis

Mitochondrial Dynamics

Mitochondria constantly fuse and divide. The number and shapes of mitochondria in a given cell are subject to a dynamic process (generally termed mitochondrial dynamics) which changes as a function of diverse metabolic requirements (Chen and Chan 2010; Westermann 2010; Ferree and Shirihai 2012; Wang et al. 2012a; Youle and Van der Bleik 2012). In addition to mitochondrial morphology, mitochondria are also dynamic in terms of organelle turnover and intracellular organelle movements. Mitochondrial dynamics results from a controlled equilibrium between mitochondrial fusion and fission in order to maintain a set of functional organelles (the chondriome) that is capable to meet the metabolic requirements of cells. Cycles of mitochondrial fusion and fission play an important role in organelle homeostasis and in the maintenance of mitochondrial integrity, as the fusion/fission cycle exchanges mDNA, proteins, and lipids of damaged or altered mitochondria with those of "healthy" mitochondria (reviews: Benard and Karbowski 2009; Otera et al. 2013; van der Bliek et al. 2013). Mitochondrial fusion and fission also play an important role in the regulation of the cell cycle (Mitra 2013) and apoptosis (Wasilewski and Scorrano 2009; Karbowski 2010).

Mitochondrial Shaping

The maintenance of a distinct shape is a decisive feature of mitochondrial homeostasis (Scorrano 2013). Dynamic morphogenesis of mitochondria and the establishment of organelle shapes (shaping) depend on the activity of several proteins, including mitofusins (Mfn) 1 and 2, optic atrophy1 (Opa1), and Drp1. Independently of mitochondrial fusion, Opa1 regulates the crista remodeling pathway of apoptosis. Specifically, Opa1 oligomers produced by the inner membrane rhomboid protease Parl are disrupted early during the apoptotic process (Scorrano 2007).

Mitochondrial Fusion

Mitofusin 1, a GTPase mutated in some forms of Charcot-Marie-Tooth disease, is an essential mitochondrial outer-membrane protein and a key mediator of mitochondrial fusion (Cerveny et al. 2007). Mitofusins are related to dynamin, a large GTPase required for vesicle endocytosis. Mitofusins form oligomers and cleave GTP to generate mitochondrial membrane rearrangements resulting in fusion. The two known mitofusins are generally involved in mitochondrial dynamics and can form homo- and heterooligomers, but mitofusin 1 has generally a higher GTPase activity than mitofusin 2. The function of mitofusin-2 is modified by a binding protein, MARCH-V, that also binds ubiquitinated forms of Drp1. Overexpression of MARCH-V promotes the formation of long tubular mitochondria in a manner that depends on mitofusin 2 activity (Nakamura et al 2006). Mitofusin 2 has additional activities, e.g., it is required for axonal mitochondrial transport via its interaction with the Miro/Milton complex (Misko et al. 2010). In damaged mitochondria, Parkin interacts with mitofusin 1 and promotes its enhanced turnover through proteasomal degradation, a process that serves to selectively identify and eliminate injured mitochondria (Glauser et al. 2011). Normal fusion of mitochondria into elongated tubular structures requires the action of the Bcl-2 family proteins, Bax and Bak, whereby Bax seems to induce mitochondrial fusion by activating the assembly of the

large GTPase Mfn2/mitofusin (Karbowski et al. 2006). Mitochondrial fusion and structure biogenesis are also dependent on the protein optic atrophy 1/Opa1. Opa1, a mitochondrial fusion GTPase, independently from mitochondrial fusion regulates the crista remodeling pathway. Oligomers of a membrane bound and a soluble form of Opa1, produced by Parl, an inner membrane rhomboid protease (presenilin-associated rhomboid-like), are disrupted early during apoptosis, leading to remodeling of the mitochondrial cristae (Scorrano 2007). Crista remodeling requires Parl, which participates in the production of a soluble form of Opa1. Parl itself is regulated by proteolysis to generate a cleaved form, which in turn modulates the shape of the mitochondrial reticulum (Pellegrini and Scorrano 2007). Caspases indirectly regulate cleavage of Opa1 (Loucks et al. 2009). The opening of fusion pores by Opa1 exerts an influence on mitochondrial energy conservation events manifesting as so-called mitochondrial flashes associated with fluctuations in mitochondrial membrane potential (Santo-Domingo et al. 2013).

Mitochondrial Fission (Mitochondrial Division)

Fission of the mitochondrial organelle is the crucial mechanism that increases the number of mitochondria per cell and thus regulates the organelle complement of cells relative to their functions. Mitochondrial fission during mitosis is a complex process that is thought to involve sensors deciding about fission dynamics and the proper distribution of mitochondria to daughter cells (Nezich and Youle 2013). The establishment of a certain degree of symmetry of organelle distribution during cell division is in part linked to the interaction of mitochondria with elements of the cytoskeleton, a central pacemaker of mitosis. The main factors for controlled fission of mitochondria are the fission proteins DRP1 (the mitochondrial fission GTPase, dynamin-related protein 1; DRP1-dependent mitochondrial division), which undergoes complex posttranslational regulation (Santel and Fank 2008), Fis1, and the mitochondrial fission factor/Mff (review: Elgass et al. 2013). DRP1 is a self-assembling GTPase that is recruited to both mitochondrial and peroxisomal membranes to execute organelle fission. Dynamins are large GTPases that belong to a protein superfamily which includes classical dynamins, dynamin-like proteins, Opa1, Mx proteins, mitofusins, and guanylate-binding proteins/atlastins. DRP1 is required for the mitochondrial fragmentation taking place during mitosis. Mitotic mitochondrial fission depends on the relocation of DRP1 to the outer mitochondrial membrane to coordinate membrane scission. The transfer of DRP1 to mitochondrial membranes is promoted by Fis1, a docking protein which acts as the DRP1 receptor. The proper placement and assembly of DRP1 at membrane scission sites or the disassembly step of fission complexes is regulated by the mitochondrial E3 ubiquitin ligase, MARCH5 (Karbowski et al. 2007). Docking and SUMOylation of DRP1 are promoted by Bax/Bak (Wasiak et al. 2007). DRP1 undergoes phosphorylation by the mitotic kinase cyclin B-CDK1, a process mediated by the small Ras-like GTPase RALA and its effector RALBP1 (Kashatus et al. 2011). RALA and RALB are activated downstream of oncogenic Ras, whereby RALB is mainly involved in tumor cell survival and metastasis (Kashatus and Counter 2011; Kashatus 2013). The mitotic kinase Aurora A promotes RALA relocalization to mitochondrial membranes, where it recruits the effector RALBP1 and DRP1 (Kashatus and Counter 2011). The two adaptor proteins, MiD49 and MiD51, recruit DRP1 to the mitochondrial surface in a Fis1- and Mff-independent manner (Palmer et al. 2011, 2013; Loson et al. 2013). The enzymatic activity of DRP1 is prompted by binding of mutant huntingtin to DRP1 (Song et al. 2011). The dynamics of DRP1 also depends on its interaction with the PTEN-induced kinase PINK1 (Deng et al. 2008; Liu et al. 2011). The mitochondrial expression of DRP1 is also controlled by a mitochondrial protein that regulates various mitochondrial functions, TRAP1/tumor necrosis factor receptor-associated protein 1 (Takamura et al. 2012). DRP1 activity is inhibited by annexin a6, which binds to DRP1. On the other hand,

binding of $Ca^{(2+)}$ to annexin a6 relieves this inhibition, DRP1 being liberated to induce fission (Chlystun et al. 2013). In viral hepatitis, DRP1 expression is stimulated by HCV, which also induces DRP1 phosphorylation and translocation to mitochondria (Kim et al. 2014).

Fis1 and Mff are DRP1-receptor/effector proteins. Fis1 can, however, also accomplish mitochondrial fission independently of DRP1, via its self-interaction through formation of dimers and oligomers. The fission factor Fis1 fragments mitochondria; downregulation of Fis1 results in mitochondrial elongation reflecting fission failure. Fis1 also affects proper cell division by interplay with the cell cycle machinery at G2/M (Lee et al. 2014). The expression of Fis1 is regulated by microRNA-484 (Wang et al. 2012c). An important mitochondrial fission protein is mitochondrial fission factor/MFF. MFF and Fis1 are both tail anchored in the mitochondrial outer membrane, but they form separate protein complexes (Gandre-Babbe and van der Bliek 2008).

Mitochondrial fission seems to depend on interorganelle interactions and interactions between mitochondria and components of the cytoskeleton. Fission is promoted by ER-mitochondrial interactions. Inverted formin 2/INF2 located to ER membranes can induce actin polymerization, whereby actin filaments accumulate between ER and mitochondria and result in initial mitochondrial constriction, which then allows secondary DRP1-driven constriction and fission (Korobova et al. 2013). For mitochondrial fission to occur, mitochondrial movements must come to a halt. This requires that microtubules connected with mitochondria and their associated proteins/motors stop their traction. In situations, where mitochondrial fission is blocked, the traction of microtubules causes tubular structures extending from mitochondria, the so-called mitochondrial extensions (Bowes and Gupta 2008).

Complex Factor Networks Regulating Mitochondrial Biogenesis and Morphogenesis

Several other proteins are required for mitochondrial function and regulation of the fission/fusion cycle. Leucine zipper EF hand-containing transmembrane protein 1 (LETM1), encoded by the WHSC1 gene deleted in Wolf-Hirschhorn syndrome (Bergemann et al. 2005), is an essential mitochondrial protein that is evolutionarily conserved throughout the eukaryotic kingdom (Schlickum et al. 2004). The tubular shape of mitochondria is maintained by LETM1 via its interaction with the AAA+-ATPase BCS1L, the latter stimulating the assembly of the LETM1 complex (Tamai et al. 2008). Downregulation of LETM1 leads to Drp1-independent fragmentation of the mitochondrial network and to necrosis-like death, without activation of caspases and not protected by Bcl-2 (Dimmer et al. 2008), suggesting that LEMP1 has a central position in the maintenance of mitochondrial network integrity. Functionally, LETM1 acts in a distinct mitochondrial Ca^{2+} uptake pathway (Hajnoczky and Csordas 2010; Waldeck-Weiermair et al. 2011). It also serves as an anchor protein for complex formation with the mitochondrial ribosome protein L36, whereby it regulates mitochondrial biogenesis (Piao et al. 2009). Mitochondrial function is also strongly regulated by huntingtin, mutated forms of which cause Huntington's disease (Bossy-Wetzel et al. 2008). Expectedly, microRNAs affect the morphology and function of mitochondria (Li et al. 2012; Sripada et al. 2012a). Parts of regulatory microRNAs are located to the mitochondria and have been termed mitomiRs, microRNAs that act as vectors that sense and respond to changing cellular microenvironments (Bandiera et al. 2013). In HCC cells, microRNA-122 negatively regulates mitochondrial shape and induces organelle swelling (Jin et al. 2014).

For the construction of mitochondrial cristae, members of the prohibitin family are essential (Merkwirth and Langer 2009). Prohibitins (PHB) form the mitochondrial PHB complex that possesses two homologous subunits, PHB1 and PHB2, which form a high molecular weight complex in the inner mitochondrial membrane. Another protein regulating biogenesis of cristae is mitofilin, a mitochondrial inner membrane protein acting as a membrane anchor (An et al. 2012; Zerbes et al. 2012a). Mitofilin controls cristae remodeling and through this mechanism regulates

cytochrome c release during apoptosis (Yang et al. 2012). Mitofilin is a component of the mitochondrial inner membrane organizing system or MINOS, which consists of three spatially arrayed clusters, i.e., mitofilin, MINOS1, and CHCHD3 (Alkhaja et al. 2012; Jans et al. 2013). MINOS is required for cristae biogenesis and for keeping cristae membranes attached to the inner membrane through so-called crista junctions (Zerbes et al. 2012b). The MINOS clusters interact with a cardiolipin-binding protein facing the intermembrane space, APOOL, involved in cristae biogenesis (Weber et al. 2013). MINOS is also critically involved in protein biogenesis of the mitochondrial outer membrane (Bohnert et al. 2012).

Mitochondrial morphology is controlled by an outer-membrane mitochondria-anchored protein ligase (MAPL). Overexpression of MAPL leads to mitochondrial fragmentation. The protein is also incorporated within unique, Drp1-independent, 70–100 nm-diameter mitochondria-derived vesicles which selectively incorporate their cargo. MAPL-containing mitochondrial vesicles fuse with a subset of peroxisomes, a mechanism involved in the complex mitochondria-peroxisome interaction. A further factor exerting an influence of mitochondrial shape is ubiquitin-specific protease 30 (USP30), a deubiquitinating enzyme that is embedded in the mitochondrial outer membrane. Depletion of USP30 induces elongated and interconnected mitochondria in a mitofusin-dependent fashion (Nakamura and Hirose 2008). Rearrangement of mitochondria networks, mitochondrial segregation, elongation, and unfurling are controlled by Drp1 and Milton, a kinesin-associated protein (Aldridge et al. 2007).

Mitochondria-Endoplasmic Reticulum Interactions

Interorganelle communication is an important aspect of cell biology and depends on distinct organelle distribution patterns, organelle movements, and tethering between different organelles. Mitochondria interact with the endoplasmic reticulum (ER) through a physical association mediated by the mitochondria-associated ER membrane or MAM (Pizzo and Pozzan 2007; Giorgi et al. 2009; Lebiedzinska et al. 2009; Rowland and Voeltz 2012; Wideman et al. 2013). Communications between the endoplasmic reticulum (ER) and mitochondria are important for diverse metabolic mechanisms, but specifically for calcium(2+) homeostasis and lipid biosynthesis. MAM is critically involved in efficient transfer of Ca^{2+} from ER to mitochondria. The MAM is a platform for the intermembrane transport of cholesterol, phospholipids, and ceramides and allows direct calcium transmission to mitochondria (Fujimoto and Hayashi 2011). Proteins that mediate the ER-mitochondria contact include calnexin, calreticulin, ERp44, ERp57, grp75, and the sigma-1 receptor at the MAM (Hayashi et al. 2009). The mitochondrial GTPase, mitofusin-2, localizes also to ER membranes where it interacts with mitofusins located to the outer mitochondrial membrane, thus generating interorganellar bridges (Merkwirth and Langer 2008; de Brito and Scorrano 2009). The mitofusin2-mediated mitochondria-ER contacts are regulated by the mitochondrial ubiquitin ligase MITOL (Sugiura et al. 2013). An ER-mitochondria encounter structure (ERMES) tethering complex has been identified in yeast, which plays a role in phospholipid exchange between the two organelles (Kommann et al. 2009; Kommann and Walter 2010; Michel and Kommann 2012). This organelle tethering system is phylogenetically conserved; in yeast cells, the ER has a role in tethering mitochondria specifically at the tip of the growing bud, and mitochondrial anchoring to the bud tip requires the tethering factor Mmr1 (McBride 2011). In eukaryotic cells, ERMES is also involved in the coordination of mitochondrial protein import, mitochondrial DNA replication, and mitochondrial dynamics. Five ERMES proteins are known in yeast so far, the ER-anchored protein Mmm1 and three mitochondria-associated proteins, Mdm10, Mdm12, and Mdm34, involved in the regulation of mitochondrial protein synthesis and morphology. A fifth component, the calcium 2+-binding Miro GTPase Gem1, is an integral

component of ERMES (Kommann et al. 2011; Stroud et al. 2011; Nguyen et al. 2012). Gem1 regulates the number and size of the ERMES complexes. The metazoan Gem1 ortholog Miro1 localizes to sites of ER-mitochondrial contacts (Kommann et al. 2011). Apart from its central role in intracellular calcium homeostasis, the mitochondria-ER interface is also involved in the regulation of apoptosis (Grimm 2012). The mitochondrial fission protein Fission 1 homologue (Fis1) conveys an apoptosis signal from mitochondria to ER membranes by interacting with Bap31 at the ER. The Fis1-Bap31 complex (ARCosome) forms an ER-mitochondrial bridge and undergoes an association with procaspase-8- (Igasawa et al. 2011). The ERMES complex discussed above is critically involved in mitophagy and the formation of mitophagosomes (Böckler and Westermann 2014).

Mitochondria-Derived Vesicles and the Peroxisomal Connection

The biogenesis and function of mitochondria and peroxisomes are tightly coupled. Their growth and division are mediated by common fission machineries (reviews: Schrader 2006; Delille et al. 2009). hFis1, a tail-anchored membrane protein interacting with the dynamin-like fission protein DLP1, regulates the membrane fission of both organelles (Koch et al. 2005), whereby hFis1 is targeted to peroxisomes through the action of Pex19p, a peroxisomal membrane protein import factor (Delille and Schrader 2008). hFis1 and DLP1 interact with Pex11pbeta, involved in the morphogenesis of peroxisomes (Kobayashi et al. 2007). These complex interactions between mitochondria and peroxisomes also depend on a specific mitochondrial cargo transport system, the mitochondria-derived vesicles/MDVs (review: Andrade-Navarro et al. 2009). MDVs are capable to fuse with peroxisomes and deliver cargo to these organelles (review: Schumann and Subramani 2008). MDVs are formed independently of the known mitochondrial fission GTPase DRP1 and are enriched for a mitochondrial small ubiquitin-like modifier (SUMO) E3 ligase called MAPL. Seventy to 100 nm-diameter MDVs contain MAPL, an outer-membrane mitochondria-anchored protein ligase with a RING-finger domain (Neuspiel et al. 2008). This MAPL seems to have a regulatory function controlling mitochondrial morphology. MAPL-containing MDVs fuse with a subset of peroxisomes. In contrast, MDVs containing TOM20 and lacking MAPL do not fuse with peroxisomes. MDVs involved in the peroxisomal connection transport cargo from mitochondria to peroxisomes. The regulation of MAPL from mitochondria to peroxisomes is itself regulated by the retromer complex, a component of vesicle transport from endosomes to the Golgi complex. Vps35 and Vps36 are found in complex with MAPL, Vps35 being recruited from MDVs (Braschi et al. 2010). The delivery of cargo from MDVs to peroxisomes is selective and does not require mitochondrial depolarization and is independent of ATG5 and LC3, suggesting that vesicle delivery complements mitophagy (Soubannier et al. 2012.

Mitochondrial Ribosomes

Synthesis of respiratory chain complexes depends on the expression of mtDNA-encoded subunits. This protein synthesis is performed by mitochondrial ribosomes inserted into membranes. Mitochondrial ribosomes are involved in the synthesis of only relatively few hydrophobic membrane proteins serving as subunits of the respiratory chain (review: Agrawal and Sharma 2012). Mitochondrial ribosome biogenesis is controlled by the mitochondrial transcription termination factor 3/MTERF3 (Wredenberg et al. 2013). Membrane-bound mitochondrial ribosomes and their specific proteins interact with human mitochondrial RNA polymerase (Surovtseva and Shadel 2013) and distinct ribosome-binding proteins which facilitate mitochondrial translation and include ObgH1, Mtg1, Mdm38, Mba1, and Oxa1 (Bauerschmitt et al. 2010; Kotani et al. 2013). Transfer RNA required for ribosomal protein synthesis travels from cytoplasm to mitochondria (Rubio and Hopper 2011). Protein synthesized by mitochondrial ribosomes leaves the organelle through a specifically tailored

ribosomal polypeptide tunnel (Gruschke and Ott 2010). Ribosome recycling in mitochondria is mediated by mitochondrial ribosome recycling factor/mtRRF (Rorbach et al. 2008). Mitochondrial ribosomes are specifically recognized by the mitochondrial release factor, mtRF1a (Duarte et al. 2012), a factor which recycles stalled ribosomes resulting from truncated stop-codon-less mRNAs (Huynen et al. 2012).

Mitochondrial Calcium Signaling

Calcium(2+) can efficiently be transported into the mitochondrial matrix, whereby hormone-stimulated calcium influx proceeds via open IP3 receptors and ryanodine receptors, resulting in a higher intra-matrix calcium concentration than in the cytosol. Furthermore, an interorganellar tether between the ER (see above) and the outer mitochondrial membrane includes the IP3 receptor and the voltage-dependent anion-selective channel/VDAC providing a shortcut for released calcium to cross the outer mitochondrial membrane (review: Hajnoczky and Csordas 2010). The mitochondrial calcium signaling system is closely linked with the cytoplasm through distinct proteins, including MUCU1, NCLX, and LETM1 (review: Hajnoczky and Csordas 2010).

Movements of Mitochondria (Mitokinesis)

Introduction

The entire set of mitochondria (the chondriome) within a given cell forms a dynamic network, within which individual mitochondria are distributed in a characteristic and function-oriented manner rather than being randomly distributed in the cell. This distinct arrangement of mitochondria in cells requires movements of mitochondria. Intracellular movements of mitochondria affect a variety of cellular behaviors both in normal and neoplastic cells. The cellular functions affected by mitokinesis include proliferation, differentiation, and apoptosis, as well as mitochondrial metabolic activity (Boldogh and Pon 2007; Frederick and Shaw 2007; Fagarasanu et al. 2010). Mitochondrial movements that determine intracellular organelle distribution are also important for the generation of cell polarity and hence for cell motility and invasive properties. Mitochondrial movements take place in all cells studied so far, but the longest distances traveled by mitochondria take place in axonal transport of these organelles. The movement of mitochondria to distinct parts of the cell body not only determines cytokinesis as such but also the strength of the cytokinetic response. An anterior localization of mitochondria in cancer cells, in between the nucleus and the leading edge, correlates with faster cell locomotion and increased directional persistence (Desai et al. 2013). Therefore, mitokinesis has a direct impact on the mode of cancer cell motility and invasion.

Mitokinesis Is Regulated by Distinct Ras Superfamily Components and by the Parkin/PINK1 System

Mitokinesis is critically regulated by members of the Ras signaling pathway. Essential regulators of mitochondrial morphogenesis and calcium-dependent sensors of mitochondrial motility are Miro GTPases, a unique subgroup of Ras superfamily proteins (Reis et al. 2009). Miro interacts with the protein kinase PINK1. Both Miro and Milton associate with mitochondria and regulate mitochondrial attachment to microtubules via the kinesin heavy chain (Koutsopoulos et al. 2010; Kane and Youle 2011). PINK1 and Parkin are Parkinson disease-associated proteins, whereby Parkin acts downstream of PINK1 in maintaining mitochondrial function and integrity. PINK1, a Ser/Thr kinase, translocates Parkin, an ubiquitin ligase, to mitochondria and regulates mitochondrial remodeling processes (review: Koh and Chung 2010). PINK1 forms a multiprotein mitochondrial complex with the adaptor proteins, Miro and Milton, and PINK1 also interacts with mitofilin, suggesting a role for PINK1 in mitochondrial trafficking along microtubular tracks (Weihofen et al. 2009). PINK1 phosphorylates

Miro, a process that activates proteasomal degradation of Miro in a Parkin-dependent manner. The subsequent removal of the adaptor Miro from the mitochondrion detaches kinesin from the mitochondrial surface and therefore arrests mitochondrial motility (Wang et al. 2011b). Mitochondrial motility is linked to distinct components of the cytoskeleton. Mitochondria are specifically connected with several proteins of the cytoskeleton. In budding yeast cells, inheritance of mitochondria into the emerging bud sites is regulated by bidirectional transport along the cytoskeleton (Frederick and Shaw 2007). Mitochondrial movements within cells and cell processes are mediated by three types of molecular motor proteins traveling along the cytoskeletal scaffold. The predominance of cytoskeletal motors varies in different species. In yeast and other fungi and in plant cells, the main engine is based on the actin system (Boldogh and Pon 2006), while in eukaryotic cells mitochondria predominantly move along microtubular tracks (Frederick and Shaw 2007), but the actin system is also involved. In yeast cells, the spatial organization of mitochondria is microtubule dependent (Das et al. 2010). For the function of microtubular track in mitokinesis, two different types of motors are required, viz., dyneins and kinesins. Dyneins deliver mitochondria toward the minus end of microtubules, while kinesins transport the organelles toward both the plus and minus ends of microtubules, depending on the position of the motor domain at the N- or the C-terminus. Among the 14 known families of kinesins, two kinesins are known to operate in mitokinesis: the kinesin heavy chain (KHC; also termed KIF5) and KIF1Balpha (Nangaku et al. 1994; Tanaka et al. 1998). KHC/KIF5 belongs to the kinesin 1 family and exists in three isoforms, two of them restricted to brain cells. KHC/KIF5 docks mitochondria by use of distinct adaptor proteins. In mammalian cells, Miro1/2, OIP106/GRIF-1, and syntabulin are adaptors that allow KHC/KIF5 to associate with mitochondria (Brickley et al. 2005; Cai et al. 2005; Fransson et al. 2006). Miro1 and Miro2 are proteins located in the outer mitochondrial membrane. HUMMR (hypoxia upregulated mitochondrial movement regulator) is a mitochondrial protein which interacts with adaptor proteins Miro1 and Miro2 and therefore affects kinesin interaction with the mitochondria and microtubules (Li et al. 2009). While present in normoxia, HUMMR protein abundance is markedly induced by hypoxia through a HIF-1alpha-dependent mechanism. In axons, HUMMR biases mitochondrial movement in the anterograde direction in response to hypoxia (Li and Rempe 2010). Mitofusin 2, an outer mitochondrial membrane protein, interacts with the Miro/Milton complex and is necessary for transport of axonal mitochondria (Misko et al. 2010). In the nematode *Caenorhabditis elegans*, a further kinesin variant, KLP6, has been identified and shown to regulate morphology and transport of mitochondria in neural cells (Tanaka et al. 2011). The kinesin system is also involved in movements of the Golgi apparatus (Marks et al. 1994). In fission yeasts, an additional microtubule-dependent but motor-independent mechanism for mitochondria positioning has been identified, and the protein mmb1p binds to mitochondria and microtubules by attaching tubular mitochondria to the MT lattice at multiple discrete interaction sites (Fu et al. 2011).

The involvement of the actin system in mitochondrial motility pathway has been documented for several types of mammalian cells, including neurons and their axons. In humans, a myosin, Myo19, functions in actin-based mitokinesis (Quintero et al. 2008). In epithelial cells, the actin cytoskeleton controls the movement of intracellular organelles. Mitochondria and lysosomes moving actively at rest stopped rapidly within seconds after an intracellular Ca^{2+} rise induced by activation of P2Y(2) purinergic receptors in an F-actin-dependent manner (Jung et al. 2012). A third cytoskeletal protein system that affects mitokinesis is the intermediate filament vimentin. In cells lacking vimentin or in which vimentin organization is disrupted, the motility of mitochondria is increased relative to intact cells with normal vimentin networks. A vimentin peptide of residues 41–94 directly binds to mitochondria and links these organelles to other components of the cytoplasm and/or the cytoskeleton (Nekrasova et al. 2011).

Mitoptosis

Introduction

Mitoptosis (programmed destruction of mitochondria) is a mitochondrial suicide process by which cells can deal with impaired, malfunctioning, or damaged mitochondria. It is thought that mitoptosis plays an important role in various disease processes (review: Mijaljica et al. 2010; Apostolova et al. 2011). Mitoptosis was first hypothesized to take place in cells undergoing apoptosis (Skulachev 2002) and to accompany apoptosis as a pathway to eliminate mitochondria in a caspase-independent manner (Karbowski and Youle 2003). Mitoptosis occurs when mitochondria hydrolyze glycolytic ATP instead of producing respiratory ATP (uncoupling of oxidative phosphorylation; "energy catastrophe"). Survival of cells with this type of disorder is associated with selective elimination of "unloved" mitochondria by mitoptosis. Elimination of aged mitochondria through mitoptosis is thought to be regulated by mechanisms related to mitochondrial genome germ line variations that become more relevant and frequent as a function of age (Rose et al. 2002).

Mitoptosis as an Effector of Chondriome Organization: The Mitochondrial Thread-Grain Transition

Mitochondria perform a broad array of interconnected functions and form a dynamic, interconnected network that is intimately integrated with other cellular compartments and organelles (Nunnari and Suomalainen 2012). Mitochondria are now known to play a crucial role in cell signaling events, interorganelle communications, modulating nuclear functions, and regulating cell survival and death. Signaling gates serving as ports of cross-talk include mitochondrial porins, e.g., the voltage-dependent anion channel or VDAC (Shoshan-Barmatz et al. 2010). In many cell systems, the entire set of mitochondria (termed the chondriome) forms characteristic spatial arrangements called the mitochondrial reticulum. The distinct features of this intracellular positioning of individual mitochondria in the reticulum allow the cell to organize a united intracellular power-transmitting system (or a "powerhouse"). In this reticulum, mitochondria also act as important signaling platforms (Tait and Green 2012). As the cell is a dynamic system continuously adapting to novel situations, the mitochondrial reticulum has to be dynamic as well. The reticulum can, e.g., be changed by damage of certain mitochondria or mitochondrial senescence, may alter its network through mitochondrial movements, may change in numbers or shape changes, or may change its organization through interorganelle associations, e.g., with the ER. In these situations, decomposition of extended mitochondria to small and roundish organelles takes place, a process called thread-grain transition (Skulachev et al. 2004). Morphologically, elongated mitochondria undergo a segmentation, bead-like small organelle parts being connected with their neighbors via a thin, threadlike structure. It was assumed that this transition serves to isolate a damaged part of a mitochondrion from the intact parts, the isolated "grain" then undergoing mitoptosis and being engulfed by an autophagosome.

Mechanisms of Mitoptosis

Mitoptosis has been proposed to occur in two variants: inner membrane mitoptosis in which only the internal matrix and cristae are lost while the external mitochondrial envelope remains unaltered and outer-membrane mitoptosis, where only swollen internal cristae are detectable (Tinari et al. 2007). It may be assumed that both of these pathways will then result in mitoptotic organelle loss. Mitoptosis is characterized by a series of distinct steps (Lyamzeav et al. 2008): fission of mitochondrial filaments, clustering of the resulting roundish mitochondria in the perinuclear area, occlusion of mitochondrial clusters by a membrane and formation of the mitoptotic body, decomposition of mitochondria inside the mitoptotic body to small vesicles, protrusion of the mitoptotic body from the cell, and disruption of the boundary

membrane of the body. Mitoptosis is sometimes, but not consistently, associated with mitochondrial autophagy (Kundu and Thompson 2005; Lyamzeav et al. 2008). The increased fragmentation of mitochondria in the initial phase of mitoptosis is due to increased fission via the recruitment of a dynamin-like GTPase Drp1 to mitochondria and to a block of mitochondrial fusion, fission and fusion being counteracting mechanisms. In early mitoptosis, Bax-/Bak-mediated release of DDT/TIMM8a, a mitochondrial intermembrane space protein, into the cytosol occurs, where it binds to and promotes the mitochondrial redistribution of Drp1, a mediator of mitochondrial fission. In a first step, this redistribution causes mitochondrial outer-membrane permeabilization (MOMP), whereby intermembrane space proteins are released, including DDT/TIMM8a and the proapoptotic cytochrome c (Arnoult et al. 2005). In situations of proteasome inhibition, mitoptosis can occur independent from Bax/Bak, in that proteasome inhibitors induce a rapid and simultaneous upregulation of several BH3-only proteins, including BIK, BIM, MCL-1S, NOXA, and PUMA, in the mitochondria, causing mitochondrial membrane permeabilization, degradation of the mitochondrial reticulum, and irreversible changes of the mitochondrial ultrastructure (Lomonosova et al. 2009).

The integrity of mitochondria strongly depends on Ca^{2+} homeostasis within the organelle. This homeostasis depends on calcium transfer from the endoplasmic reticulum (ER) to the mitochondria, via a distinct functional and structural interorganelle association (ERMES; see above). Alpha-synuclein positively affects calcium transfer from the ER to mitochondria, augmenting the mitochondrial Ca^{2+} transients elicited by agonists that induce Ca^{2+} release from the ER. This effect depends on the number of ER-mitochondria interactions in the setting of ERMES (Cali et al. 2012). Reactive oxygen species (ROS) initiate mitoptosis in order to rid the intracellular population of mitochondria from those that are ROS overproducing (Skulachev 2006). Loss of the mitochondrial Lon protease, which catalyzes the degradation of oxidatively modified mitochondrial matrix proteins, chaperones the assembly of inner membrane complexes, and participates in the regulation of mitochondrial gene expression and genome integrity, leads to mitoptosis (Bota et al. 2005).

Protection Against Mitoptosis

As the maintenance of a normally constructed chondriome in its reticulum network is essential for cellular homeostasis, there are physiological mechanisms counteracting mitochondrial decay. During starvation, mitochondria fuse into highly connected networks, protecting mitochondria from damage-induced degradation through an interorganelle rescue mechanism. This distinct alteration of the chondriome is dependent on the inactivation of the fission protein Drp1, through targeting of two different phosphorylation sites. This rapid inhibition of mitochondrial fission, which characterizes one step in mitoptosis, leads to unopposed mitochondrial fusion to form a stable network (Rambold et al. 2011).

Physiological Mitoptosis

Reticulocyte maturation to erythrocytes is the final step of erythropoiesis that occurs in the blood circulation. In the course of reticulocyte maturation, a distinct two-step elimination program takes place, leading to loss or elimination of organelles, including the nucleus (followed by nucleophagy by macrophages), mitochondria, Golgi apparatus, lysosomes, and components of the endoplasmic reticulum. Part of the cellular protein substance of reticulocytes is eliminated by exosome release (Blanc et al. 2005). Close to red cell maturation, a second and last step is a cleaning session that clears the remaining mitochondria via mitoptosis (Géminard et al. 2002).

Mitoptosis in Cancer

Massive mitoptosis can cause cell death due to the intracellular liberation of cell death proteins normally hidden in the intermembrane space of mitochondria.

Mitophagy

Introduction

Mitophagy is the selective autophagic degradation of damaged and/or superfluous mitochondria and is regarded as an essential process for mitochondrial quality and quality control (reviews: Kim et al. 2007; Tolkovsky 2009; Mijaljica et al. 2010; Novak and Dikic 2011; Okamoto and Kondo-Okamoto 2012; Rambold and Lippincott-Schwartz 2011; Wang and Klionsky 2011; Hirota et al. 2012; May et al. 2012; Novak 2012; Zhang 2013; Dengjel and Abeliovich 2014; Liu et al. 2014a; Redmann et al. 2014; Shimizu et al. 2014; Song et al. 2014). Mitophagy is the major instrument of the cell to regulate mitochondrial number and mass, and there is a regulatory cross-talk between mitochondrial function and dysfunction and mitochondrial abundance (Michel et al. 2011), suggesting the presence of a mitochondrial abundance sensor. However, how mitochondria are selected for mitophagy is only partially known, although the mitochondrial permeability transition (MPT) is critically involved in the initiation of the process (Mijaljica et al. 2007). Mitophagy belongs to the group of autophagic processes, which also comprise pexophagy, ER-phagy, ribophagy, golgiphagy, and nucleophagy. Autophagy, as discussed in a separate chapter, serves removing of altered proteins and dysfunctional organelles (Kondo-Okamoto et al. 2012). Mitophagy is an essential component of the regulatory systems controlling mitochondrial numbers and mass. Apart from mitochondrial quality control, mitophagy is an instrument to guarantee the maintenance of adequate mitochondrial abundance (Michel and Kornmann 2012).

Structural Features of Mitophagy

In response to inducers of mitophagy, mitochondria undergo fragmentation. This morphologic alteration accompanies the exposure of so-called "eat-me" signals. These signals result in the engulfment of mitochondria by autophagosomes (Gomes and Scorrano 2013).

Causes of Mitochondrial Injury Leading to Mitophagy

Injury of mitochondrial DNA, e.g., mtDNA mutations, can result in mitophagy (de Gilkerson et al. 2012; De Vries et al. 2012). Mutations in the gene for ATPase type 13A2 (ATP13A2), involved in autosomal-recessive Parkinsonism (Kufor-Rakeb syndrome), are associated with a higher frequency of mtDNA lesions, increased oxygen consumption rates, fragmentation of the mitochondrial network, and mitophagy (Grünewald et al. 2012). Oxygen damage via reactive oxygen species (ROS) as potential mitochondrial damaging agents can normally be neutralized within the mitochondria through enzymatic activity. In case this system is overcharged, mitochondrial damage and mitophagy can occur (Lee et al. 2012). Elimination of mitochondria being overcharged with oxidized proteins via mitophagy is a mechanism suppressing cell damage by mitochondrial oxidative products (Kurihara et al. 2012). But also hypoxia causes mitochondrial injury leading to mitophagy (see above).

PINK1- and Parkin-Mediated Mitophagy

The Parkinson disease-related proteins PINK1 (PTEN-induced kinase 1; a mitochondrially localized serine/threonine kinase) and Parkin (PARK2; a cytosolically localized E3 ubiquitin ligase) are guardians of mitochondrial fidelity, regulate mitochondrial homeostasis (Scarffe et al. 2014), and are essential for targeting mitochondria for mitophagy (Matsuda and Tanaka 2010; Huang et al. 2011; Kane and Youle 2011; Springer and Kahle 2011; Youle and Narendra 2011; Jin and Youle 2012). The mitochondrial turnover of PINK1 and Parkin is tightly controlled. The mitochondrial intramembrane protease PARL cleaves human PINK1 within its conserved membrane anchor. Mature PINK1 is then free to be released into the cytosol or the mitochondrial intermembrane space.

In PINK1-dependent mitophagy and following uncoupling of the outer mitochondrial membrane

potential, the canonical import of PINK1 and PARL-catalyzed processing is blocked, leading to the accumulation of the PINK1 precursor. Accumulation of PINK1 precursor and its targeting to the outer mitochondrial membrane triggers mitophagy (Meissner et al. 2011). Generally, loss of PINK1 function causes oxidative stress via production of ROS and mitochondrial damage (Cui et al. 2011). Endogenous PINK1 forms a 700 kDa complex with the translocase of the outer membrane (TOM) on depolarized mitochondria. Association of PINK1 with TOM complex allows rapid reimport of PINK1 to rescue depolarized mitochondria from mitophagy (Lazarou et al. 2012). In Parkin-dependent mitophagy, PINK1 which is located in the mitochondrial outer membrane recruits Parkin from the cytosol to the mitochondria as a first step leading to autophagous destruction of the organelle. Complexes containing upstream Atg proteins (autophagy-related proteins), including ULK1 (the mammalian homologue of Agt1), Atg12, Atg14, DFCP1, WIPI-1, and Atg16L1, can associate with depolarized mitochondria. Atg9A and ULK1 structures are also recruited to damaged mitochondria as well as to the autophagosome formation site in the earliest steps of mitophagy, while the autophagosomal LC3 (MT-associated protein 1 light chain 3) family of proteins is involved in later stages of mitophagy (Itakura et al. 2012). LC3 interacts with microtubule-associated protein 1S/MAP1S bridging autophagic components with the microtubular system (Xie et al. 2011). In human endothelial cells, targeted mitochondrial damage upregulated the autophagy factors LC3B, Atg5, and Atg12, and this upregulation resulted in an improved mitochondrial membrane potential, enhanced ATP production, and an antiapoptotic effect (Mai et al. 2012). One of the effectors of the mitophagic cascade, Ulk1, is phosphorylated by AMP-activated protein kinase connecting energy sensing to mitophagy (Egan et al. 2011) and is regulated by the Hsp90-Cdc37 chaperone complex (Joo et al. 2011).

Parkin itself as an ubiquitin E3 ligase ubiquitinates intracellular proteins and via this mechanism induces clearance of cellular molecular debris and of organelles, including mitophagy, whereby ubiquitinylated outer mitochondrial membrane proteins, including mitofusins 1 and 2, are targeted for proteasomal degradation (Gegg et al. 2010; Chan and Chan 2011; Karbowski and Youle 2011; Khandelwal et al. 2011). In the pathway of mitophagy, Parkin binds to Ambra1 (activating molecule in beclin 1-regulated autophagy), a protein that promotes autophagy (Van Humbeeck et al. 2011a,b). The function of Parkin in mitophagy is synergistically regulated by the three ubiquitin-conjugating enzymes, UBE2N, UBE2L3, and UBE2D2/3 (Geisler et al. 2014). The autophagy protein beclin 1 interacts with Park2 and regulates Park2 translocation to mitochondria and mitophagy (Choubey et al. 2014). A protein that regulates mitophagy is the diabetes susceptibility factor clec16a, a membrane-associated endosomal protein that interacts with the E3 ubiquitin ligase Nrdp1, a target of the master regulator of mitophagy, Parkin (Soleimanpour et al. 2014). Parkin-induced mitophagy is counteracted by the mitochondrial deubiquitinase USP30, a protein which removes ubiquitin attached by Parkin onto damaged mitochondria (Bingol et al. 2014) and by the deubiquitinase USP15 (Cornelissen et al. 2014). PINK1 and Parkin also exert important effects on mitochondrial motility. PINK1 phosphorylates Miro, a component of the primary motor/adaptor complex that anchors kinesin to the mitochondrial surface. The phosphorylation of Miro activates proteasomal degradation of Miro in a Parkin-dependent manner. By thus stopping mitochondria in their tracks, the PINK1/Parkin pathway may quarantine damaged mitochondria prior to their mitophagic clearance (Wang et al. 2011).

Execution of Mitophagic Pathways

Bnip3 (Nip3-like protein X; NIX), an atypical BH3-only protein causing mitochondrial dysfunction and cell death, can under certain circumstances also protect against cell death by inducing mitophagy. Bnip3 activation is a pro-mitophagic signal, and this pathway involves impairment of mitochondrial oxidative phosphorylation and is independent of apoptosis (Thomas et al. 2011). This response requires

homodimerization of Bnip3, and clearance of mitochondria is mediated in part via binding of Bnip3 to the microtubule-associated protein 1 light chain 3 (LC3) on the autophagosome (Hanna et al. 2012). On the other hand, Bnip3-mediated mitophagy is inhibited by activation of the p53-TIGAR axis (Hoshino et al. 2012). Mdivi (mitochondrial division inhibitor) attenuates mitochondrial division in cells by selectively inhibiting the mitochondrial division dynamin-related protein (Cassidy-Stone et al. 2008). Dynamin-related protein 1 (Drp1) docks at mitochondria, regulating their positioning and activity (Baixauli et al. 2011). Mdivi is also a mitophagy inhibitor that operates via inhibition of Drp1 (Park et al. 2011; Givvimani et al. 2012). FUNDC1, a mitochondrial outer-membrane protein, is a receptor for hypoxia-induced mitophagy. Hypoxia leads to dephosphorylation of FUNDC1 and enhances its interaction with LC3 for selective mitophagy (Liu et al. 2012). Following mitophagy, organelle remnants can enter a lysosomal degradation pathway, whereby a distinct system of mitochondria-derived vesicles (MDVs) generates the contact with lysosomes to deliver degradable cargo (Soubannier et al. 2012).

Other Factors Regulating Mitophagy

The Parkinson disease GWAS risk factor locus SREBF1 (sterol regulatory element-binding transcription factor 1) is a regulator of mitophagy (Ivatt et al. 2014). The ATM gene mutated in ataxia telangiectasia plays a role in mitochondrial homeostasis. Atm-deficient thymocytes in mice show an altered mitochondrial homeostasis, suggesting that ATM plays a role in regulating mitophagy (Valentin-Vega and Kastan 2012). Melatonin, a highly efficient antioxidant, is involved in the control of mitophagy (Coto-Montes et al. 2012). Mitophagy is also mediated by the C2 domain-containing protein, SMURF1 (Orvedal et al. 2011). Mitophagy is also promoted by proteins of the HCV virion (Kim et al. 2014).

Sequelae of Inhibited Mitophagy

It has been shown that inhibition or blockade of mitophagy leads to the accumulation of damaged, ROS-generating mitochondria, which in turn activates the NLRP3 inflammasome, a pathway positively regulated by reactive oxygen species/ROS. The NLR3P inflammasome acts as a sensor of damaged mitochondria, explaining the frequent association of mitochondrial damage and inflammatory diseases (Zhou et al. 2011).

Abstract

Uncontrolled, progressive proliferative growth is a key feature of cancers. The net mass increase of tumors depends, apart from secondary phenomena contributing to mass such as blood vessels and leukocyte infiltrates, on the balance between increase of cell number through proliferation and cell loss caused by apoptosis and necrosis. Cell proliferation of hepatocellular carcinoma (HCC) mimicks the kinetic features known for hepatocytes in the setting of liver regeneration, but critical control mechanisms that operate in normal liver regeneration are no longer active. This already involves a first step of proliferation, i.e priming of cells for cell cycle entry. In contrast to normal hepatocytes, which have to be initiated to cross the cycle checkpoint in depence of cell production demand, HCC cells seem to be capable to pass without stop from one division cycle to the next. This deregulated replication can involve failure in the control of numerous factors orchestrating the cell division cycle, including checkpoint proteins, proteins involved in DNA synthesis and synthesis termination, proteins of the mitotic apparatus and cytoskeleton, and factors preparing daughter cells for a new division round.

Introduction

With respect to proliferative growth of liver cancers, much has been learned by the study of liver regeneration. In fact, normal hepatocyte regeneration is one of the best known examples of regenerative responses, and the cell kinetic and molecular features of this process have been elucidated in rodent models and in the human liver to a high level of detail.

Selected reviews: (Michalopoulos 1990, 2013, 2014; Fausto and Webber 1993; Columbano and Shinozuka 1996; Fausto 2000; Zimmermann 2004; Alison and Lin 2011; Kang et al. 2012).

Previously, most of the knowledge regarding liver regeneration has been employed to better understand the capacity of the human liver to recover and to restitute its cell mass following injury, surgical resection, and transplantation. The time has now come to utilize this wealth of information for the study of abnormal growth and growth control patterns, taking place in liver cancer, and to gain knowledge suitable to generate more efficient anticancer drugs. Both hepatocellular and cholangiocellular cancers share in their growth regulation numerous pathways with their normal counterparts. They very often utilize the same or similar regulatory factors which however are subject to distinct and far-reaching deregulations.

Cell Proliferation in the Normal Resting and Regenerating Liver: Lessons for the Understanding of Liver Cancer Growth

General Aspects

In the normal resting liver, physiologic hepatocyte turnover goes at low pace, with about one cell in 20,000–40,000 cells being in cell cycle at a given time point. In the course of regeneration of the normal resting adult liver, several hepatic cell lineages have to be replaced in accordance with the required liver cell mass. An adjustment of liver mass to the requirements of the entire body may involve a controlling system, the so-called hepatostat (Michalopoulos 2014), an instrument that not only senses the actual state of cell turnover and regulates the compensatory replacement of cells that had been lost but also monitors the size, geometry, and composition of the liver lobules and other structural-functional units of the liver. The functional cell mass of the liver consists of several specialized cell types, of which the hepatocytes form the major part and which differ considerably in their turnover (Paget 1954; Francavilla et al. 1988; Fleig 1998). Hepatocytes are mature and highly specialized cells, but they are not terminally differentiated but are in proliferative quiescence (the G0 phase). In hepatic regeneration, hepatocytes are stimulated to rapidly enter a cell division cycle. This regenerative response involves a sequence of distinctive

phases: (1) an initiation or priming phase, in which G0 hepatocytes enter a state of replicative competence; (2) a proliferation phase, where expansion of the hepatocyte population takes place; and (3) a termination phase, where cell proliferation is suppressed to terminate regeneration at a defined set point. These three "phases" are not independent events, but overlap and are linked in their progression in a complex manner. In addition, proliferation in the expansion phase subsequently requires a distinct remodeling process representing a "fourth phase" of regeneration.

Timely Sequence, Morphology, and Involved Cells of Liver Regeneration

Following the stimulation of regeneration, hepatocyte proliferation starts after an interval of about 24 h, reflecting the priming of G0 cells and the shift from G0 to the G1/S checkpoint and then into the S phase of cycle. In the normal non-cirrhotic liver, regenerative proliferation of hepatocytes starts in the periportal zone 1 of the liver lobule and extends to the pericentral zone 3 by 36–48 h. Tritiated thymidine incorporation into murine hepatocyte nuclei was maximal at 36 h (Lorup 1977). After an initial burst of proliferation, the rate of progression into DNA synthesis in the rat liver is at 3–4 % per hour, whereby most cells divide once and a few twice (Fabrikant 1968). Proliferation of non-parenchymal cells lags behind, the delay amounting to 24–48 h or even later (Fabrikant 1968; Crofton et al. 1978; Bouwens et al. 1986; Wacker et al. 1986; Wake et al., 1989; Table 1).

Most hepatocytes are engaged in proliferation after 3 days (the expansion phase), and this phase is associated with the formation of hepatocyte accumulations of eight to ten cells (the hepatocyte clusters) arranged around immature or disintegrating sinusoidal vascular channels. The emergence of hepatocyte clusters, characterized by cells with an amphophilic to slightly eosinophilic cytoplasm and a partially immature morphology, is closely associated with the effacement of the normal sinusoidal network (Figs. 1 and 2). This is accompanied by loss of a typical space of Disse and a degradation of perisinusoidal extracellular matrix (ECM) through metalloproteinases (Michalopoulos and DeFrances 1997). As the perisinusoidal space with its mesenchymal cells is effaced, hepatocyte clusters are depleted of mature hepatic stellate cells (HSCs), suggesting that hepatocytes might transiently engage in some sort of autonomous proliferation, related to the lack of stop signals released by mesenchymal cells. By 48 h post-partial hepatectomy (PH),

Table 1 Start of proliferation of diverse liver cells following stimulation of regeneration: timescale

Hepatocytes	24 h
Cholangiocytes	48 h
Kupffer cells/macrophages	72 h
Sinusoidal endothelial cells	96 h

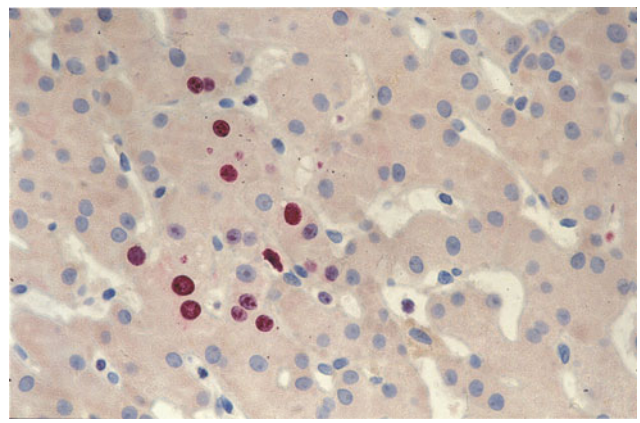

Fig. 1 Proliferative focus in liver regeneration. Several nuclei in a cluster express proliferating cell nuclear antigen (*PCNA*), and also a mitotic figure (metaphase, *close to the middle*) is labeled. Note that in the area of this proliferative cluster, hepatocyte plate architecture is partly effaced (PCNA immunostaining)

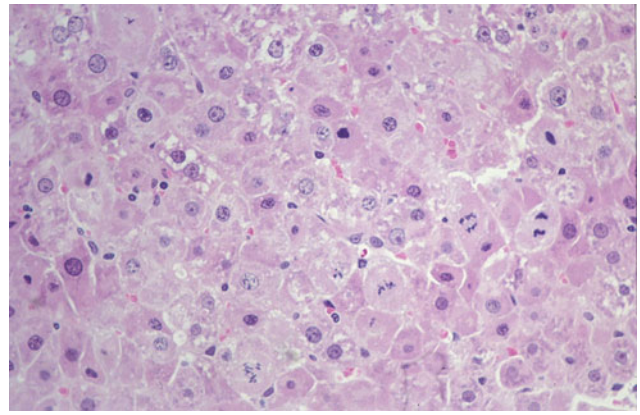

Fig. 2 Liver regeneration in the expansion phase. The liver cell plate structure is effaced and replaced by numerous proliferating hepatocytes (hematoxylin and eosin stain)

insinuation of small vessels ensues (resinusoidalization), associated with resynthesis of ECM proteins, the reconstitution of a space of Disse, and the repopulation of this space with regenerating HSC, which can exert growth control on hepatocytes. The resulting parenchymal unit (the "protolobula") is still oversized, and the final achievement of a normal lobule requires termination of hepatocyte regeneration and remodeling mechanisms depending on apoptosis. It seems that the new liver lobule is reshaped through a "top-to-bottom" control system, i.e., via controlled elimination of superfluous cells until the final dimension of the lobule determined by some master clock is achieved. The fate and functions of non-hepatocyte liver cells in regeneration are outlined in more detail below.

Molecular Regulation of the Initiation Phase of Liver Regeneration

Hepatocytes pass through a priming stage prior to proliferation (Mead et al. 1990). Priming, i.e., the gain of cell cycling competence by quiescent G0 hepatocytes, involves a set of upregulated regulatory factors, including hepatocyte growth factor/HGF, IL-10 mediated by p38MAPK, IL-6 mediated by STAT3, and TNF-alpha and JAK/STAT mediated by Ras/ERK and STAT3 (Fausto et al. 1995; Li et al. 2014). The main cellular sources for IL-6 and TNF-alpha are non-parenchymal cells, i.e., sinusoidal endothelia, Kupffer cells, and hepatic stellate cells (HSCs). ICAM-1-deficient mice exhibit impaired hepatocyte regeneration, because ICAM-1 triggers release of TNF-alpha and IL-6 from Kupffer cells following IL-6 binding to the gp130 receptor. TNF-alpha and IL-6 trigger the arrival at the cell cycle checkpoint and G0/G1 transition of the cell cycle. IL-6-deficient and TNFR-1-deficient animals fail to accomplish initiation and a hepatocyte regenerative response (Streetz et al. 2000). C/EBPbeta also critically controls the G1/S checkpoint. The importance of this pathway is illustrated by C/EBPbeta/NF-IL-6 knockout mice, showing a blunted regeneration. IL-6 can also cause cell cycle arrest and delayed proliferation during the first day of regeneration after partial hepatectomy, associated with activation of DNA repair enzymes to guarantee accurate replication and restoration of hepatic mass (Tachibana et al. 2014). Several mechanisms stimulate the IL-6 surge necessary for initiation. Peroxisome proliferator-activated receptor-alpha (Pparalpha) induces the IL-6R; Pparalpha null mice lack IL-6R gene induction and show delayed liver regeneration (Anderson et al. 2002). C/EBPbeta/NF-IL-6 binds to the IL-6 promoter region and enhances expression of IL-6. Promoter interaction is modulated by C/EBP homologous protein (CHOP), which interferes with NF-IL-6 action insofar as CHOP dimerizes more preferentially with an inhibitory

isoform of NF-IL-6 (LIP, liver-enriched inhibitory protein) than with a positively acting isoform (LAP, liver-enriched activator protein), CHOP upregulating IL-6 production without binding to its promoter (Hattori et al. 2003). The proper timing of G1/S checkpoint transition is controlled by a protein that regulates the Akt and STAT3 signaling pathway, protein tyrosine phosphatase of liver regeneration-1/Prl-1 (Jiao et al. 2015).

Apart from the key initiation factors, there are other pathways that can induce initiation. Rodents with dysfunctional leptin signaling exhibit a profound impairment of liver regeneration. Leptin-deficient ob/ob mice show an exaggerated activation of NF-kappaB and STAT3 during the initiation/priming phase, but an abrogation of TNF-alpha and IL-6 release at the time of G1/S transition (Leclercq et al. 2003). In early phases of liver regeneration, bile acid signaling plays a role in initiation. Bile acids promote regeneration through activating their receptors, farnesoid X receptor (FXR) and G protein-coupled BA receptor 1 (GPBAR1) (Fan et al. 2015). The activity of the farnesoid X receptor itself is regulated by sirtuin 1 (SIRT1), a molecule that controls central metabolic functions such as lipogenesis, protein synthesis, gluconeogenesis, and bile acid homeostasis (Garcia-Rodriguez et al. 2014). Bile acids are involved in a regulatory loop, in that remnant liver primed to undergo regeneration cannot handle bile acids returning via portal circulation (enterohepatic cycle).

Proliferation/Expansion Phase: Checkpoints and Growth Factors

Progression of primed/competent hepatocytes through G1 and subsequent replicative cycling mainly depends on hepatocyte growth factor (HGF) and transforming growth factor-alpha (TGF-alpha) signaling, after which the proliferation process seems to proceed autonomously under the control of cyclins and cyclin-dependent kinases. However, a complex network of other factors regulates the delicate transition of primed hepatocytes into the S phase of the cell division cycle (Fujiyoshi and Ozaki 2011).

Subsequent to priming/initiation, several immediate early-phase genes related to hepatocyte proliferation are induced within 2 h. They comprise c-fos, c-Jun, and others (Taub 1996). c-Jun serves as a major c-Jun-N-terminal kinase (JNK) target in proliferation. JNK is strongly activated minutes after PH; the JNK/c-Jun pathway is a critical component of the early proliferative response and induces the G0 to G1 transition via cyclin D1. A further rapidly induced factor is insulin-like growth factor-binding protein 1 (IGFBP-1). IGFBP-1-deficient mice display reduced and delayed hepatocyte DNA replication after PH (Leu et al. 2003). Some of the proteins involved in priming, expansion, and termination may be modified by enzymes converting (inactive) proproteins via limited proteolysis to the active species. Nine mammalian proprotein convertases have been identified so far, eight belonging to the yeast kexin subfamily of subtilases. A K-like subtilase, neural apoptosis-regulated convertase 1 (NARC-1), peaks on days 2–3 post PH, whereas other convertases (PC5, PACE4, furin) peak on day 1, suggesting that these enzymes are active in the bioavailability of growth factors. Furthermore, the bioavailability of growth factors depends on the liberation of these factors from storage in the ECM by the action of plasmin and plasmin-like enzymes, as found in experiments using mice deficient in urokinase or in plasminogen activator (uPA), showing an impaired liver regeneration.

Expression of HGF has been detected in hepatic stellate cells (HSCs), hepatic macrophages/Kupffer cells, and in sinusoidal endothelial cells. Kupffer cells are capable to simulate HGF secretion by HSCs (Takeishi et al. 1999). As HSCs diminish in number along the regeneration pathway, their stimulatory action is reduced by the end of regeneration, probably contributing to the termination phase. HGF is secreted as an inactive single-chain protein (scHGF), proteolytically cleaved at the Arg-Val-Val site to form the active two-chain HGF (tcHGF). The HGF receptor, c-Met, can bind both forms, but is only activated by tcHGF. Cleavage is accomplished by urokinase-type plasminogen activator (uPA),

tissue-type plasminogen activator, coagulation factor XIIIa, and hepatocyte growth factor activator (HGFA). The activity of HGFA is itself regulated by two Kunitz-type serine protease inhibitors, HGFA inhibitor type 1 (HAI-1) and type 2 (HAI-2), having different roles (Naganuma et al. 2003). TGF-alpha has a central place in the stimulation of hepatocyte proliferation and is regulated by beta-catenin signaling (Torre et al. 2011). Hepatocyte growth is furthermore regulated by H/MFREP-1 (human/murine fibrinogen-related protein-1), a liver-specific protein of the fibrinogen superfamily, eventually acting as a "molecular facilitator" in the regenerative response. Other factors that control hepatocyte proliferation include hepassocin, augmenter of liver regeneration (ALR), a mammalian FAD-dependent sulfhydryl oxidase that also plays a role in HCC (Schaefer-Ramadan et al. 2013; Yu et al. 2014b), EGF, heparin-binding epidermal growth factor-like growth factor (HB-EGF), and lal-1 (liver annexin like-1). Part of these growth factors are modulated by surface molecules on hepatocytes which interfere with growth factor receptor binding, e.g., integrins which can inhibit growth factor signaling (Patman 2014; Speicher et al. 2014).

Cell cycle progression itself is regulated by cyclin expression and activation of cyclin-dependent kinases (CDKs). For example, S-phase entry and progression critically depends on the formation of cyclin E-CDK2 and cyclin A-CDK2 complexes. Cyclin B associates with CDK1 (Cdc2) to achieve progression from G2 to M. CDK-mediated cell cycle progression is modulated by CDK inhibitors (CDKIs). Finally the G2/M transition in hepatocytes is regulated by a cell cycle-dependent nuclear protein, Citron kinase as a downstream target of Rho-GTPase, and Citron kinase loss in knockouts induces apoptosis in a subset of cells (Liu et al. 2003). The orderly expression of cyclin A and the Wee1/Cdc2/cyclinB1 pathway and entry into M phase is regulated by the production of the transcription factor, nuclear factor erythroid 2-related factor 2 (Nrf2), a protein involved in proliferation and apoptosis (Zou et al. 2015).

Termination of the Regeneration Process

Subsequent to the expansion phase, the growth response must finally be terminated. Major factors involved in the termination response comprise transforming growth factor-beta (TGF-beta), the activins, integrin-linked kinase, glypican-3, and Yes-associated protein (YAP) (review: Kang et al. 2012). Loss of proliferative capacity of hepatocytes may also be induced by epithelial-mesenchymal transition, fundamentally altering the epithelial character of hepatocytes (Xue et al. 2013).

TGF-beta and activin regulate hepatic organ mass and tonically inhibit DNA synthesis in hepatocytes. The cation-independent mannose 6-phosphate receptor (CIMPR) is overexpressed in hepatocytes during regeneration. Induction of its gene occurs in mid-G1 phase, and CIMPR mediates latent pro-TGF-beta activation, thus acting by targeting TGF-beta to hepatocytes during the termination response of regeneration (Villevalois-Cam et al. 2003). The action of TGF-beta itself is mediated by Smads serving as intracellular signals in this pathway. Two transcriptional repressors of the TGF-beta/Smad pathway, SnoN and Ski, are upregulated during regeneration, and they antagonize TGF-beta-mediated termination via binding to Smad proteins (Macias-Silva et al. 2002). In addition to an inhibition of hepatocyte proliferation, TGF-beta1 also induces hepatocyte apoptosis by a c-Jun-independent mechanism, and this effect may contribute to the termination response, but may also be involved in lobule remodeling. The TGF-beta family member, bone morphogenetic protein (BMP) 4, is a paracrine inhibitor of liver regeneration (Do et al. 2012) and may be involved in the termination process.

Activins and their receptors and follistatin exhibit a distinctive timely expression pattern during regeneration. Activin A (the homodimer of the inhibin betaA chain) and follistatin (an activin-binding protein) inhibit and promote hepatocyte proliferation, respectively. Activin A is an inhibitor of hepatocyte DNA synthesis, can induce a reduction of liver mass, and promotes apoptosis in hepatocytes, blocked by follistatin (Rodgarkia-

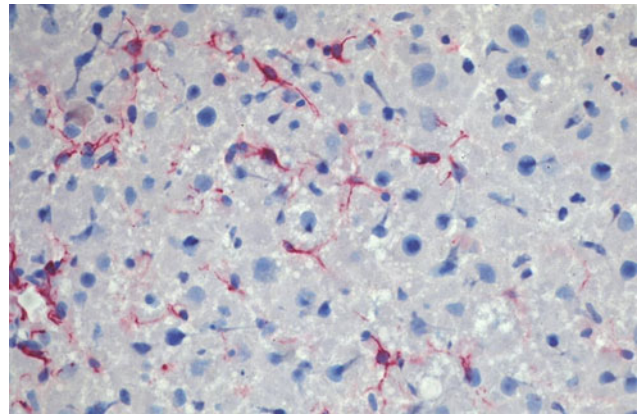

Fig. 3 Liver regeneration in the expansion phase. Desmin-reactive hepatic stellate cells with long processes have populated a proliferating hepatocyte cluster, but a Disse space has not yet been formed (frozen section, desmin immunostaining)

Dara et al. 2006; Kreidl et al. 2009). This response is dependent on activin receptors and on Smad2 protein relocated to the nucleus. Following partial hepatectomy in the rat, expression of betaA- and betaC-activins significantly dropped at 12 h post surgery and remained low until 168 h post hepatectomy, while a peak follistatin expression takes place at 24–48 h, coincident with an increase of hepatocyte mitosis (Gold et al. 2005). After rat liver injury or PH, hepatocyte activin A receptors are downregulated by 24 h and normalize by 72 h (Date et al. 2000), a phenomenon possibly involved in rendering hepatocytes responsive to mitogenic stimuli.

Termination of liver regeneration is also induced by the C/EBPalpha-HDAC1 complex and chromatin-remodeling proteins (Jin et al. 2014). Termination of regeneration is also regulated by proteins that are deregulated in liver cancer, i.e., C/EBP family proteins that interact with chromatin-remodeling proteins (Jin et al. 2015). A fine tuning of proliferation versus proliferative quiescence is also accomplished by Hippo signaling in mammalian liver regeneration. Loss of Hippo signaling, such as in liver cancers, results in ongoing, uncontrolled cell growth. The Hippo pathway includes a core kinase cascade that consists of Ste20-like kinases (in *Drosophila* called Hippo) and the cofactor Salvador, activating the large tumor suppressor Lats1/2 which in turn inhibits two transcriptional coactivators, YAP and TAZ (Hong et al. 2015).

Termination of hepatocyte regeneration requires, and goes in parallel with, the restauration of the normal sinusoidal and littoral phenotypes and the repopulation by hepatic stellate cells

Close to the end of regeneration and linked to termination, insinuation of vascular channels (the later sinusoids, resinusoidalization), formation of the perisinusoidal space of Disse, reequipment of Disse space by HSC (Fig. 3), and the resynthesis of the perisinusoidal extracellular matrix (ECM) take place.

These are processes that are crucial not only for the reconstruction of the regenerated lobule by remodeling but also for the termination of regeneration as such, because sinusoidal and littoral cells are the principal sources of termination signals. The morphogenesis of a sinusoidal system is linked to liver regeneration as such, in that endothelial cell-derived angiopoietin-2 controls regeneration as a spatiotemporal rheostat (Hu et al. 2014). A reconstructed sinusoidal system creates the homing microenvironment for blood-borne monocytes that differentiate into hepatic macrophages/Kupffer cells, a cell system that is involved in regeneration signaling (Chazaud 2014).

Resinusoidalization requires endothelial cell proliferation, exerting an important influence on hepatic regeneration (Wang et al. 2014b). In addition to VEGFs, sinusoidal cell regeneration is in part regulated by semaphorin 3E secreted by damaged hepatocytes (Yagai et al. 2014). The role of endothelial cells increasing in number during resinusoidalization is underlined by the recent finding that mice administered circulating VEGF-A had enlarged livers due to increased

proliferation of hepatocytes and non-parenchymal cells, and the sinusoidal endothelial cell-derived paracrine mediators promoting growth were IL-6 and HGF (LeCouter et al. 2003).

The repopulation of the developing liver lobule by HSC and their differentiated offspring, in particular their homing to the newly formed Disse space in the phase of resinusoidalization, depends on proliferation and migration of these cells. HSC shows a migration response to PDGF-BB, to epithelial growth factor (EGF), and to TGF-beta1, a key molecule of termination, augmenting the chemoinvasive response of HSC to PDGF and bFGF. A resynthesis of the previously degraded perisinusoidal ECM is required for full regeneration, and the ECM is synthesized by HSC transiently differentiated to myofibroblasts. This is illustrated by mice deficient in the Forkhead Box (Fox) f1 transcription factor, showing defective stellate cell activation and abnormal liver regeneration associated with aberrantly elevated TGF-beta1 expression (Kalininchenko et al. 2003). The importance of only a transient and well-controlled ECM increase is documented by observations obtained with mice bearing a mutated collagen-I gene conferring collagenase resistance (r/r mice); these animals exhibit a persistent activation and a reduced apoptosis of stellate cells, a failure of ECM degradation, and a diminished hepatocyte regeneration (Issa et al. 2003). Epithelial cells require contact with ECM to inhibit detachment-induced apoptosis (anoikis), and the reconstitution of a perisinusoidal ECM will therefore stabilize the newly formed hepatocyte population.

The final construction of the liver lobule and its zonation is regulated by the Wnt/beta-catenin signaling pathway (Gebhardt and Hovhannisyan 2010). Wnt signaling is the major upstream effector of beta-catenin activity in pericentral hepatocytes and determines the definition of zone, whereby Kupffer cells are the major source of Wnt secretion (Yang et al. 2014b). Lobule reconstruction also depends on the function of ductules and peribiliary stellate/myofibroblastic cells, ductular/myofibroblastic "units" probably serving as pacemakers of remodeling, similar to processes occurring in pancreatic regeneration (Zimmermann et al. 2002). There is some evidence that the shaping of the future lobule also critically depends on a close interaction between vascular endothelial cells and hepatocytes.

MicroRNAs as Regulators of Cell Proliferation in Liver Regeneration

A complex network of microRNAs regulates hepatocyte proliferation during liver regeneration (Song et al. 2010; Chaveles et al. 2012; Schug et al. 2013; Chen and Verfaillie 2014; Finch et al. 2014). MicroRNAs therefore provide an important instrument for the control of adequate cell replacement in the liver and hence participate in the master clock that determines initiation, progression, and termination of regeneration. In rodent models, microRNAs are subject to marked upregulations or downregulations, depending on the regeneration phases. In post-partial hepatectomy rats, early regeneration (hours, 3–18) was characterized by upregulation of 40 % of microRNAs, while at 24 h, around 70 % of microRNAs were downregulated. It was suggested that upregulation of microRNAs in early regeneration is required for priming of G0 hepatocytes for cell cycle entry (initiation, Shu et al. 2011). MicroRNA-21 is upregulated in the initiation/priming phase and promotes proliferation competence via targeting NF-kappaB signaling (Marquez et al. 2010). In the expansion phase, microRNA-127 is downregulated, facilitating hepatocyte proliferation in rat liver regeneration (Pan et al. 2012). The downregulation of distinct microRNA species in the proliferation/expansion phase reflects a phenomenon that is also observed in liver cancer (see below). Inhibited microRNA expression in the setting of ongoing proliferation includes microRNA-26a, microRNA-150, microRNA-503, and microRNA-663 (Zhou et al. 2012; Salehi et al. 2013), whereas upregulated microRNAs include microRNA-21, microRNA-122, and microRNA-221 (John et al. 2014). MicroRNA-21 targets PTEN (Yan-nan et al. 2014), and its surge in early regeneration facilitates rapid cyclin D1

translation and cell cycle progression (Ng et al. 2012). MicroRNA-221 enhances hepatocyte proliferation by targeting p27, p57, and Arnt (Yuan et al. 2013). Downregulation of microRNA-26a during the proliferative phase of regeneration enhances hepatocyte proliferation through targeting the cell cycle proteins CCND2 and CCNE2 (Zhou et al. 2012). In late regeneration, microRNA-34a is upregulated in hepatocytes of rats and is associated with the suppression of hepatocyte proliferation (Chen et al. 2011), suggesting that this MiR plays a role in the termination phase of regeneration. Similarly, downregulation of microRNA-23b activates TGF-beta17Smad3 signaling and thus contributes to the termination of regeneration (Yuan et al. 2011).

Safeguards of Aberrant Cell Replication During Regeneration

The proliferation of hepatocytes in regeneration is characterized by a massive surge of cell production, a process that ends with termination and zonation of the lobule. As in any markedly upregulated proliferation, like that found in cancers, unlimited cell production bears the risk of replication errors and the production of aberrant cells. Such a danger is not only inherent to cancers, but is also present in the transient, apparently "uncontrolled" growth surge in liver regeneration, where cells are disconnected for a certain time period. The mechanisms protecting proliferating hepatocytes from damage and transformation are incompletely known. One safeguard mechanism counteracting abnormal DNA replication induced by deregulated proliferation stimuli is the replication stress response (RSR), a mechanism leading to cell cycle restriction and/or apoptosis and therefore to a blockade of unwanted cells. In transformed cells, RSR is bypassed giving rise to viable aberrantly proliferating cells, whereas RSR is preserved in normal regenerating hepatocytes. A key component of RSR is the COP9 signalosome, a conserved regulator of cullin ring-type ubiquitin ligases (Panattoni et al. 2014).

Remodeling of the Growing Lobule

As outlined above, the primordial post-regeneration liver lobule is oversized and therefore requires remodeling to achieve its final dimension, which is crucial for metabolic zonation and the generation of proper vascular relationships. The radius of a normal liver lobule has to be controlled tightly in order to maintain an oxygenation gradient and proper oxygen extraction by lobule cells from lobule inflow to outflow. The remodeling of the post-regeneration liver lobules is also closely connected with the reconstitution of metabolic zonation. Metabolic zonation denotes the phenomenon that hepatocytes differ in the type of their metabolic activity and in their biology as a function of the cells' position within the lobule. Periportal hepatocytes differ from pericentral hepatocytes in their enzyme expression patterns. For example, enzymes active in drug metabolism are predominantly expressed in the pericentral zone. This metabolic zonation is not present at the termination phase of regeneration, and hepatocytes have to be programmed to achieve their distinct metabolic signature in the course of lobule remodeling (Torre et al. 2010; Gougelet et al. 2014). The control of liver zonated gene expression is regulated by a convergence of canonical Wnt signaling on hepatocyte nuclear factor (HNF) 4alpha-driven transcription (Colletti et al. 2009; Berasain and Avila 2014). Within the Wnt pathway, beta-catenin is a central molecule regulating zonation and in particular affects zonated lipid metabolism and the pathogenesis of steatosis (Behari et al. 2014). Several pathogenic factors can interfere with metabolic zonation, including hypoxia, toxic agents, and hepatitis C virus proteins (König et al. 2013; Moreau et al. 2015).

It appears that superfluous hepatocytes in the post-regeneration lobule are eliminated through apoptosis. Interestingly, TNF-alpha not only induces regeneration but also apoptosis. TNF-alpha-induced hepatocyte apoptosis is modulated by acidic sphingomyelinase (ASMase), as seen in ASMase knockout mice, by promoting the mitochondrial targeting of glycosphingolipids

(Garcia-Ruiz et al. 2003). Furthermore, hepatocyte cytokeratins/keratins (K) have an impact on cell survival. The K8/K18 system plays a significant role in providing resistance to stress and apoptosis in hepatocytes and in preserving hepatocyte integrity. K8/K18 provides resistance to Fas-mediated apoptosis through a modulation of Fas targeting to the cell surface. K18 is a caspase substrate, and transgenic mice overexpressing mutant human K18 develop hepatocyte fragility via keratin filament disruption, which predisposes hepatocytes to Fas- but not TNF-mediated apoptosis (Ku et al. 2003). The mechanism apparently involved is that K18 may sequester TNFR1-associated death domain protein (TRADD) to attenuate interactions between TRADD and activated TNFR1. The balance between apoptosis and hepatocyte survival is critical for appropriate remodeling of future fully regenerated lobules. Based on IGF-binding protein-1 (IGFBP-1)-deficient mice, it has been shown that IGFBP-1 functions as a hepatic survival factor counteracting the TGF-beta1 proapoptotic signal. Protection against caspase-8-mediated hepatocyte apoptosis is also accomplished by senescence marker protein-30 (SMP30), as based on studies with SMP30-/- mutant mice. A potent antiapoptotic agent against TNF-alpha-mediated liver cell loss is the TNF superfamily member LIGHT binding to lymphotoxin-beta receptor, inhibiting caspase-3 processing on the apoptotic protease cascade.

Liver Regeneration: Role of Stem/Progenitor Cells

In the normal liver, virtually, all newly formed hepatocytes are derived from preexisting mature hepatocytes (Yanger et al. 2014). Notwithstanding the fact that most cells that participate in parenchymal regeneration of a liver with competent cell systems are hepatocytes, stem or progenitor cells come into action in situations where remnant hepatocytes are injured and partially or completely incompetent for regeneration (Haque et al. 1996; Thorgeirsson 1996; Fausto and Campbell 2003; Santoni-Rugiu et al. 2005; Best et al. 2015; Huch 2015). Therefore, facultative hepatic stem cells enter the stage in situations of severe chronic or acute overwhelming liver injury (Itoh and Miyajima 2014; Shin and Kaestner 2014; Than and Newsome 2014). The liver possesses two stem/progenitor cell systems, i.e., fetal progenitor cells derived from foregut endoderm and competent to differentiate into hepatocyte and cholangiocyte lineages and adult hepatic progenitor cells that can contribute to liver regeneration under certain circumstances. Adult hepatic progenitor cells are in part resident cells normally situated within small bile ductules, in part cells derived from circulating stem cells. Circulating progenitor cells in part have the features of mesenchymal stem cells, and also local mesenchymal cells, including myofibroblastic cells, can contribute to the hepatocyte generation (Swiderska-Syn et al. 2014). Adult hepatic stem cells express a set of markers, including delta-like 1 homologue (DLK1), CD13, CD133, and LIV2 (reviews: Kamiya and Inagaki 2015). In rodents, progenitor cells termed oval cells develop in many instances of liver injury, and these cells express hepatic stem cell markers, including CK19 (Chiu et al. 2007).

The role of circulating stem cells derived from the bone marrow in the regenerating liver is not fully elucidated. Apparently, only few hepatocytes originate from circulating stem cells and are mainly generated by cell fusion (Oh et al. 2007). In contrast, circulating progenitor cells are a significant source of sinusoidal endothelial cells and hepatic leukocytes, the latter being an essential production place for growth factors and signaling substances involved in liver regeneration (Grompe 2005). Progenitor cells play an important role in the reconstitution of parenchyma in liver cirrhosis. The repopulation of regions of parenchymal extinction in human cirrhosis proceeds through hepatocyte buds located in broad septa, buds being clusters of cells reflecting a characteristic progenitor pathway and providing a progeny that represents up to 70 % of hepatocytes (Stueck and Wanless 2015). The action of hepatic progenitor cells in the setting of liver regeneration strongly depends on the hepatic microenvironment, where a close

interaction between progenitor cells, recruited inflammatory cells, the ECM and stored growth factors, and signaling factors takes place (Santoni-Rugiu et al. 2005). The capacity of progenitor cells to produce hepatocytes depends on a tight regulatory system, which also involves microRNAs, including microRNA-122 (Tanimizu et al. 2014). Circulating stem cells, including mesenchymal stem cells, can affect hepatocyte regeneration through signals released from stem cell-derived exosomes (Tan et al. 2014).

Fate and Function of Non-parenchymal Liver Cells in Hepatic Regeneration

Cholangiocytes and Bile Ducts

Cholangiocytes are capable of proliferating in the adult organism, however, at a low rate under resting conditions. Nevertheless, the proliferative activity of cholangiocytes in normal livers is higher than that of hepatocytes, suggesting a higher normal cell turnover (Rubin et al. 1995). Proliferation is enhanced in several conditions of liver injury, including inflammation, regeneration, and repair (Sutton and Spurgeon 1966; Marongiu et al. 2014). In the course of liver regeneration, regenerating cholangiocytes of the type normally found in ductules are found as small cell nests or, in some situations, as foci of ductular proliferation. These structures are situated in close association with altered portal spaces and remain there up to 2 weeks post-partial hepatectomy in rodent models (Seres-Sturm et al. 1981). Part of regenerating cholangiocytes enter the regenerating lobule, similar to models of rat liver transplantation (grade IV ductular proliferations, Zhao et al. 1993, 1995), and are in close relation with immature hepatocyte clusters. In the course of lobular remodeling, these proliferations recede and leave a normal complement of ductules, probably accomplished by tightly controlled apoptosis. However, cells of primitive ductules in hepatic injury may also derive from hepatocytes, this conversion depending on Notch-Hes1 signaling (Sekiya and Suzuki 2014). Regenerative proliferation of cholangiocytes is regulated by factors secreted by local monocytes/macrophages and other immune cells, including granulocyte colony-stimulating factor and stem cell factor. These factors also affect remodeling of the biliary system, through the action of S100 calcium-binding protein A4/S100A4 and microRNA-181b (Meng et al. 2012).

Proliferating cholangiocytes can acquire a phenotype of neuroendocrine cells. These cells secrete neuropeptides, hormones, growth factors, and cytokines and participate in a multifaceted cross talk with other liver cells, e.g., during regeneration (Alvaro et al. 2007). Newly formed cholangiocytes can convert into hepatocytes and thus contribute to parenchymal cell replacement (Tanimizu et al. 2013). Regenerating biliary epithelial cells can originate from progenitor cells. The biliary tree harbors multipotent stem cells. In portal tracts, these cells are located in ductules or in von Hering's passages, while in medium-sized to large bile ducts, they are mainly found in peribiliary glands (Cardinale et al. 2010, 2012; Sutton et al. 2012). In peribiliary tubuloalveolar glands, progenitor cells are located at the bottom of glands and are phenotypically heterogeneous, but express liver-specific transcription factors (SOX9/17) and several endodermal markers. In the course of priming/maturation, these cells shift to the bile duct surface, where they can, upon stimulation, become cholangiocytes or hepatocytes (Carpino et al. 2012). Subsequent to specific cell lineage priming, these progenitor cells give rise to cholangiocytes and hepatocytes (Cardinale et al. 2011).

Kupffer Cells/Macrophages

Kupffer cells as hepatic ED2+ macrophages and major component of hepatic littoral cells play an important role in liver homeostasis and regeneration (You et al. 2013). In the course of hepatocyte expansion, the sinusoidal architecture of the liver lobule is desintegrated, and with this the residence and the homing place for hepatic macrophages/Kupffer cells, which is normally situated within the sinusoidal lumen. The repopulation of newly formed sinusoids after the termination phase of liver regeneration is not fully elucidated. Apart from local macrophages that proliferate during

regeneration and find their way to the newly formed vascular channels, homing of circulating monocytes into sinusoids and the subsequent differentiation onto mature hepatic macrophages/Kupffer cells take place. After partial hepatectomy in the rat, ECD2+ cells remaining in the liver increase rapidly from day 2 to 5, with a maximum replicating ED2+ macrophages at day 2 (Ukai et al. 1990). Peak mitotic activity of Kupffer cells following partial hepatectomy in the rat occurred at 48 h (Widmann and Fahimi 1975). In the course of rodent liver regeneration, macrophages first infiltrate the periportal parenchyma and then shift to the pericentral zone, suggesting a hepatic zonation of homing factors (Baier et al. 2005).

Kupffer cells as monocyte-derived hepatic macrophages exert several effects of regenerating hepatocytes (review: Takeishi et al. 1999). Through a paracrine mechanism, Kupffer cells regulate regeneration of hepatocytes via secretion of IL-6 and TNF-alpha. As these two factors hold a key position in liver regulation, innate immune mechanisms mediated by monocytes/macrophages play a significant role (Shiratori et al. 1996; Aldeguer et al. 2002; Iimuro et al. 2007), an interleukin playing a central role in the initiation phase of regeneration (see below). The release of TNF-alpha and IL-6 by macrophages/Kupffer cells is triggered by intercellular adhesion molecule-1 (ICAM-1), which binds to macrophages and recruits leukocytes to the liver (Selzner et al. 2003). Hepatic macrophages can affect the morphogenesis of ductular reactions via macrophage-mediated signaling of TNF-like weak inducer of apoptosis (TWEAK) (Bird et al. 2013). Kupffer cells affect hepatic perfusion during liver regeneration via modulation of vasoactive peptides (Abshagen et al. 2008).

Sinusoidal Endothelial Cells

As outlined in more detail above, the terminal phase of liver regeneration requires the reconstitution of a sinusoidal microvascular bed (the so-called insinuation). Insinuation and angiogenesis mediated by angiopoietin-2 in general play a significant role in complete liver regeneration (Uda et al. 2013; Wang et al. 2014b). Sinusoidal endothelial cells (SECs) originate from local endothelial cells, local progenitors, and circulating precursor cells (Krause et al. 2010; Moniaux and Faivre 2011). The recruitment of progenitor cells of SEC is regulated by a surge of hepatic vascular endothelial growth factor (VEGF) (Wang et al. 2012b). In the early phase of liver regeneration, SECs downregulate their production of angiopoietin-2, which in turn reduces SEC-derived release of TGF-beta1, hence releasing an important hepatocyte proliferation break (Hu et al. 2014). In the later termination phase, this mechanism is reversed (see below). VEGF signaling produced by SECs and epithelial cells has a central place not only in sinusoidal regeneration but also in the generation of the distinct three-dimensional sinusoidal network and in lobule zonation (Mochida et al. 1998; Walter et al. 2014). Sinusoidal regeneration in late liver regeneration is mediated by semaphorin 3E secreted by hepatocytes (Yagai et al. 2014). SECs express vascular endothelial growth factor (VEGF)-A receptor-2/VEGFR2 which promotes hepatocyte proliferation via upregulation of the transcription factor Id1 and release of HGF (Ding et al. 2010). Induction of Id1 also takes place through upregulation of CXCR7 and CXCR4 in sinusoidal endothelial cells, deploying pro-regenerative angiogenic factors (Ding et al. 2014). SEC production and function in liver regeneration are strongly influenced by platelets (Nowatari et al. 2012; Murata et al. 2014). Platelets streaming through an intact sinusoidal system promote SEC proliferation and induce the secretion of IL-6 and VEGF by these cells (Kawasaki et al. 2010). This effect strongly depends on a close interaction between thrombocytes and SECs. SECs avidly bind platelets in an integrin-dependent and immobilized fibrinogen-dependent manner. This binding leads to NF-kappaB activation and cytokine secretion in SECs, and in upregulation of P-selectin, which in turn promotes homing and adhesion of leukocytes (Lalor et al. 2013). This may also be a mechanism resulting in the local recruitment of circulating stem cells.

SECs are engaged in a close interaction with hepatocytes, Kupffer cells, hepatic stellate cells

(HSCs), and Pit cells. SECs and their progenitors directly affect hepatocyte regeneration (Gamble et al. 2011; Wang et al. 2012a). These cells are capable to secrete HGF at low level, but part of their bone marrow-derived progenitors are rich in HGF (Ping et al. 2006; DeLeve 2013). The role of SECs in expansion and termination of regeneration is closely linked to their influence on hepatic angiogenesis (Ding et al. 2010, 2014; Uda et al. 2013; Huebert and Shah 2014). SECs coordinate liver regeneration as vascular pacemakers via angiopoietin-2 (Wang et al. 2014b), forming a spatiotemporal rheostat based on autocrine-acting angiopoietin-2 signaling (Hu et al. 2014). Similar to hepatocytes and HCC cells, endothelial cells are subject to stimulation by various growth factors. The response to growth factor stimulation is negatively regulated in these cells by the expression of four types of Sprouty proteins that are modulators of mitogen-activated protein kinase (MAPK) signaling (Mason et al. 2006; Cabrita and Christofori 2008).

Hepatic Stellate Cells, Myofibroblasts, and Other Hepatic Mesenchymal Cells

As outlined above, hepatic stellate cells (HSCs) repopulate the newly formed perisinusoidal/Disse spaces in the course of resinusoidalization of parenchyma in later phases of regeneration. HSCs proliferate in regeneration, can actively migrate to the perisinusoidal space, and undergo complex interactions with regenerating hepatocytes and SECs. HSC-hepatocyte signaling is associated with formation of direct physical contacts between these two cell types, via generation of tight junction-mediated connections (Mabuchi et al. 2004). The appropriate number of stellate cells after a proliferative surge is controlled by apoptosis. TGF-beta1 and IFN-alpha downregulate apoptosis in stellate cells, whereas CD95/CD95L and p53 protein promote apoptosis. The mechanisms involved include the TRAIL receptor-2/death receptor-5 expressed on activated stellate cells (Taimr et al. 2003). HSCs engage in growth factor-mediated signaling for hepatocytes and promote regeneration (Antoine et al. 2009; Yin et al. 2013). They secrete HGF, a process regulated by the tumor suppressor, cylindromatosis (CYLD) gene (Pannem et al. 2014). HSCs are a specific source of delta-like 1 homologue (DLK1), a protein that regulates cyclins and cyclin-dependent kinases and positively controls regeneration (Zhu et al. 2012). HSCs are central to the generation of a hepatic mesenchyme and extracellular matrix that provides a scaffold and growth factor storage facility for regeneration. Liver regeneration is promoted by trophic factors produced by hepatic mesenchymal cells (Fouraschen et al. 2014), part of which originate from HSCs. A C-type lectin produced by HSCs, endosialin, inhibits hepatocyte proliferation and is upregulated in the liver undergoing fibrosis (Mogler et al. 2015). Part of mesenchymal cells of the hepatic microenvironment are derived from mesenchymal stem cells (MSCs), which therefore play a role in the replacement of mesenchymal cells in the course of liver regeneration. In addition, MSCs can directly affect hepatocyte regeneration through the secretion of factors that promote proliferation (Fouraschen et al. 2012). Part of these MSC-derived pro-regenerative factors are released by exosomes (Tan et al. 2014). As bone marrow-derived stromal/mesenchymal cells with progenitor features can transform into functional hepatocytes, such mesenchymal cells may contribute to liver cell replacement in regeneration (Hang and Xia 2014). There is also evidence that HSCs and myofibroblastic cells can contribute to the production of progenitor cells (Kordes et al. 2014; Swiderska-Syn et al. 2014).

Immune Effector Cells

Whereas the kinetics of the four major cell types listed above are well known in liver regeneration, less information is available concerning blood vessel regeneration and the reconstitution of cells mediating hepatic innate immunity, i.e., natural killer cells/Pit cells and other immune effector cells. Cytokines and chemokines released by immune and inflammatory cells of the hepatic microenvironment can modulate parenchymal regeneration (Budhu and Wang 2006; Dong et al. 2007; Bishayee 2014). Interleukin-17 produced by gamma-delta T cells promotes hepatic

regeneration in a dectin-1-dependent manner (Rao et al. 2014). IL-17 also activates HSCs, which hold a central place in liver regeneration, promotes growth of liver cancer (Ma et al. 2014), and facilitates growth of liver cancer through recruitment of myeloid-derived suppressor cells (Hammerich and Tacke 2014). Elements of the local immune effector cell system secrete other pro-inflammatory cytokines that are important for liver regeneration. Expression of fibroblast growth factor-inducible 14 (Fn14), the receptor for TNF-like weak inducer of apoptosis (TWEAK), is induced early in liver regeneration and remains high throughout the expansion phase (Karaca et al. 2014). This factor is also involved in growth of HCCs (Li et al. 2013a). Adiponectin produced in the hepatic microenvironment is required for an efficient early cytokine response to hepatocyte loss, but is inhibitory to later growth factor actions, suggesting the adiponectin fine-tunes the progression of liver regeneration via modulation of signaling networks (Correnti et al. 2015). Cytokines produced by cells of the inflammatory niche also modulate the function of progenitor cells in the regenerating liver (Lowes et al. 2003; Strick-Marchand et al. 2008). Myeloid-derived suppressor cells are induced from circulating monocytes by activated HSCs in a CD44-dependent manner (Hoechst et al. 2013) and are expanded by HGF/c-Met derived from multipotent human mesenchymal stromal cells (Yen et al. 2013). On the other hand, natural killer cells of the liver can negatively regulate hepatic regeneration (Sun and Gao 2004). NK-mediated overactivation of innate immunity has to be blunted in regeneration in order to reduce its harmful effects. A coinhibitory receptor, T cell Ig and ITIM domain/TIGIT, safeguards liver regeneration via negatively regulating NK cell-hepatocyte cross talk (Bi et al. 2014). In patients with hepatocellular carcinoma, the natural killer response is disarmed by the action of myeloid-derived suppressor cells (Hoechst et al. 2009). The production and secretion of cytokines and chemokines by hepatic immune cells is modulated by factors involved in the regulation of hepatocyte and HCC cell proliferation. Augmenter of liver regeneration (ALR, hepatopoietin; see below) reduces activity of resident NK cells (Tanigawa et al. 2000) and induces a reduction of interferon-gamma in liver-resident NK cells and thus abolishes the inhibitory effects of interferon on hepatocyte regeneration (Polimeno et al. 2000).

The innate immune system of the liver and its effects on liver regeneration are markedly influenced by procedures related to the induction of hepatic regeneration, above all various surgical interventions. Laparotomy/open surgery results in suppression of the Th1 lymphocyte population and enhances the release of cytokines by macrophages. In contrast to laparoscopical surgery, open full laparotomy in a rat model was associated with increased function of peritoneal macrophages and enhanced TNF-alpha production (Lee et al. 2003). Laparoscopy and the associated CO2 pneumoperitoneum affect the function of peritoneal macrophages, with evidence of suppressed macrophage function and reduced secretion of TNF-alpha (Carter and Whelan 2001; Ost et al. 2008).

Effect of Liver Regeneration on Malignant Hepatic Tumors

Primary and metastatic malignancies of the liver develop and grow in normal liver; liver with fatty, other metabolic, or inflammatory changes; or in cirrhotic livers. The presence of a normal liver or a preexistent liver disease significantly affects growth patterns and fates of malignant neoplasms. The different growth mode of metastatic tumors in fatty or cirrhotic livers is discussed in the respective chapter on metastatic liver disease. A specific situation occurs for recurrent liver tumors that emerge in livers post resection with ongoing liver regeneration. Cellular and molecular changes taking place after surgical resection can result in a complex alteration of tumor growth and tumor cell kinetics. Generally, the surge of growth factors, cytokines, chemokines, angiogenic factors, and signaling pathways that are central to liver regeneration can affect growth of tumors (de Jong et al. 1996; Christophi et al. 2008). Liver regeneration following hepatic resection can facilitate tumor growth and activate metastases (Takita et al. 1966; Mizutani et al. 1992; Ikeda

et al. 1995; Harun et al. 2007; Paschos and Bird 2010; Shi et al. 2011; Shi and Line 2014) and can provide a novel microenvironment that may favor the homing of circulating tumor cells. Hepatic resection followed by regeneration is associated with upregulation of cyclin D1, VEGF, and VEGFRs affecting tumor growth (Shi et al. 2011). Activation of the renin-angiotensin system in the regenerating liver can stimulate hepatic tumor growth and recurrence (review: Koh et al. 2010). In murine models, upregulation of c-Met following partial hepatectomy enhanced the yield of hepatic metastases following tumor cell injection (Harun et al. 2014). In addition to the promotion of HCC recurrence, liver regeneration may also favor the development and growth of hepatic metastasis, but such an effect was not found in all animal experimentations (Panis et al. 1990). Liver regeneration and the associated remodeling of parenchyma may favor the homing of circulating tumor cells and/or the activation of dormant tumor cells that had already settled in the pre-metastatic niches of the liver before emergence of regeneration (Paschos and Bird 2010). Following partial hepatectomy, cells of the hepatic microenvironment secrete macrophage inflammatory protein-2 (MIP-2) which contributes to regeneration-induced acceleration of hepatic metastatic tumor growth. MIP-2 stimulates the process of engraftment, but not metastatic growth as such (Kollmar et al. 2006, 2008). Major liver resection and subsequent regenerative responses stimulate stromal cells in the liver and promote the emergence of metastases, in part through the action of upregulated TGF-beta (Momiyama et al. 2012). As important effectors of proliferative signals, cancer-associated fibroblasts (CAFs) modulate the regenerative response of hepatocytes located in peritumoral parenchyma (Cesselli et al. 2011). Liver regeneration following experimental partial hepatectomy also positively affected the yield of lung metastasis after injection of cancer cells, through a so far unknown mechanism (Ikeda et al. 1995). Furthermore, liver regeneration per se promotes accelerated hepatocarcinogenesis through chronic inflammation-induced double-strand DNA breaks (Barash et al. 2010).

Morphology of Proliferating Liver Cancer Cells

Liver cancer cells (HCCs and cholangiocarcinomas) in proliferation show an increased rate of mitotic figures, expressed as mitotic index (MI) (mitoses per N high-power fields). The MI of HCCs varies considerably among different tumors and is, also in G4 tumors, usually lower than many other poorly differentiated carcinomas, e.g., small cell carcinomas. MI correlates with survival in patients with HCC (Chapel et al. 1996). But also nuclear features in interphase cells suggest growth activity, e.g., increased nuclear size and large nucleoli indicating protein synthesis. In HCCs, the nuclear area correlates with cell differentiation and proliferative activity. Subjectively, one may obtain the impression that G3 and G4 HCCs possess smaller nuclei in comparison with better differentiated tumors, but this is flawed by the effects of increased nucleus/cytoplasm ratios. Morphometrically, the mean nuclear area of poorly differentiated HCCs was larger than that of moderately and well-differentiated tumors, and this increase was correlated with elevated proliferative activity (Ikeguchi et al. 1998). Ultrastructurally, HCC cells show persistence of nucleoli throughout all stages of cell division, and the Golgi apparatus retains its discrete entity of laminar and vesicular components during mitosis. Apparent penetration of RER into the mitotic apparatus is seen in metaphase and anaphase (Chang and Gibley 1968).

Cell Kinetics of Hepatocellular Carcinoma and Cholangiocarcinoma

There is a limited number of studies of the cell kinetics of human HCCs. The growth features of experimental HCCs have been studied by use of the assessment of incorporation of tritium-labeled thymidine (MacDonald 1961). In murine hepatoma models, the relative rate of DNA synthesis in individual tumor cells was about one half the relative rate in 21-h regenerating liver cells, and all of the tumors exhibited a H3-TdR-labeling

index between 9.6 and 12.9 (Chang et al. 1968). Tumor volume doubling time (TVDT) is an indicator of tumor growth rate and is associated with tumor biology in HCC. TVDTs in HCC are related to the differentiation grade. In one study, mean TVDTs in Edmondson grades 1–3 were 138.3, 94.9, and 32.2 days, respectively, whereby TVDT is correlated with AFP doubling times (Shingaki et al. 2013). Proliferative activity and tumor doubling times of HCCs were correlated with survival for patients with HCC treated with hepatectomy or in combination with systemic chemotherapy (Silvestrini et al. 1992).

Immunohistochemical Methods To Assess Cell Proliferation: Proliferating Cell Nuclear Antigen (PCNA)

Introduction

Proliferating cell nuclear antigen (PCNA) is a 36-kDa protein that serves as a regulator of the cell cycle. It is a cofactor of DNA polymerase delta in the S phase of cycle and is involved in DNA repair during DNA synthesis (Mozzherin et al. 1997; Prosperi 1997; Li et al. 2013b). A role of PCNA in DNA repair was also observed in HCC (Gramantieri et al. 2003). PCNA also promotes the activity of the DNA damage repair enzyme, DNA polymerase zeta (Garg et al. 2005). PCNA is differentially expressed in the cell cycle phases. It starts to accumulate in G1 to reach the highest expression level in the S phase, to decrease in G2/M. PCNA is a valuable antigen to immunohistochemically estimate the proliferative activity of neoplasms (determination of PCNA labeling index (LI), number of labeled nuclei per 100 nuclei analyzed), but has to be applied with certain cautions (Robbins et al. 1987; Hall et al. 1990; McCormick and Hall 1992). PCNA has, however, a rather slow turnover, leading to the effect that remaining immunoreactivity may persist in the next cycle, causing a potential interpretation artifact.

PCNA Labeling in Hepatocellular Carcinoma

PCNA labeling was detected in 57–100 % of HCCs (Kawakita et al. 1992; Nakopoulou et al. 1995; Shehata et al. 2006; Alenzi et al. 2010; Lai et al. 2014) and increases as a function of increasing tumor grade (Adachi et al. 1993; Ojanguren et al. 1993; Taniai et al. 1993; Wu and Tseng 1994; Suehiro et al. 1995; Hino et al. 1996, 1997), also in small HCCs, where high LIs were correlated with capsular and vascular invasion (Kitamoto et al. 1993). PCNA labeling also reflects higher tumor size (Osada et al. 2004) and the invasive phenotype of large HCCs (Ng et al. 1994), suggesting that proliferative activity exerts an influence on tumor cell invasion. In some studies, the PCNA LI was correlated with biology of disease in patients with HCC: The higher the PCNA LI, the worse the prognosis (Soini et al. 1996; Zeng et al. 2002), whereby tumors with a PCNA LI of less than 15 % had a better outcome (Nishimori et al. 1994). The PCNA LI increases along the hepatocarcinogenesis axis, being lower in nodular precursor lesions than in small HCCs and higher in malignant foci located in the interior of dysplastic nodules (Terada and Nakanuma 1992a; Zhao et al. 1994). PCNA LI in HCCs was positively correlated with increased numbers of tumor foci and advanced tumor invasiveness and stage (Shehata et al. 2006). The PCNA LI is, expectedly, also elevated in the regenerating liver, e.g., in viral hepatitis, whereby there was no difference in PCNA Li between HCV and HBV infections (Nakamura et al. 1993). A high PCNA Li is associated with upregulation of other proteins in HCCs, including the membrane traffic-related molecular alpha-taxilin (Ohtomo et al. 2010), the genomic stability maintenance protein growth arrest and DNA damage 45-alpha (GADD45-alpha) (Gramantieri et al. 2005), and PTEN (Hu et al. 2007). On the other hand, there are proteins that inhibit the function of PCNA, such as the CDK inhibitor, p21(Cip1/Waf1), which also modifies the interaction of PCNA

with other proteins (Oku et al. 1998; Tsurimoto 1999). Expression of the autophagy regulator Beclin-1 in HCC is associated with decreased PCNA labeling (Qiu et al. 2014). The PCNA-dependent DNA replication is mediated through a p21(Cip1)-like PCNA-binding motif in a subunit of DNA polymerase delta (Ducoux et al. 2001).

PCNA Labeling in Cholangiocarcinomas

PCNA is expressed in most or all cholangiocarcinomas, albeit with variable labeling indices (Ohashi et al. 1994; Terada and Nakanuma 1996; Rijken et al. 1998; Batheja et al. 2000). Similar to other neoplasms, proliferative activity is higher in cholangiocarcinomas with lower differentiation. Whereas well-differentiated cholangiocarcinomas showed a mean PCNA LI of 10.8 %, moderately or poorly differentiated tumors exhibited an index of 24.0 % and 26.0 %, respectively. The anatomical location of tumors along the biliary tree had no relation to the PCNA LI (Minato and Nakanuma 1993). The PCNA LI increases from hyperplastic lesions of intrahepatic bile ducts to dysplasia, to adenocarcinoma in situ (Terada and Nakanuma 1992b), a phenomenon also observed in surface epithelium and glands of stone-containing bile ducts (Lee and Sheen 1999), suggesting a gradual increase in proliferation as a function of the carcinogenic pathway. This is also reflected by the expression patterns of interphase nucleolar organizer regions (AgNORs) (Terada et al. 1992b). The number of AgNORs per nucleus of intrahepatic cholangiocarcinoma was related to tumor size and differentiation (Hayashi et al. 1995). The PCNA LI in intrahepatic cholangiocarcinoma varies as a function of the gross growth pattern. PCNA LI was significantly higher in periductal extension and spicula-forming tumor types than in the mass-forming type (Ohashi et al. 1994). In ampullary carcinomas, the rate of PCNA positivity correlated with tumor size (Crucitti et al. 1999).

Immunohistochemical Methods To Assess Cell Proliferation: Ki-67 Antigen

Introduction
