I dedicate this textbook to my wife, Geneviève, who for many years of preparatory work endured much and offered continued interest, help, and compassion while I was creating this work. She accompanied me with great loyalty in this endeavor. I also dedicate this book to my children, Laxmi and Tristan, who have given so much meaning to my life, and to my venerated late teacher in pathology, Professor Hans Cottier.

Preface

This textbook is designed to be a comprehensive assessment of current knowledge regarding the surgical and general pathology of hepatobiliary tumors and tumor-like lesions. The scope of the book is broad and provides an up-to-date source for the wide-ranging tumor pathology of the entire hepatobiliary tract. In the planning phase of this work, the question had arisen as to the purpose and need of such a book, in the light of numerous excellent monographs and textbooks that have been published in this field during the last years, but a major justification for a new book relates to the rapid change in the role of pathology in the investigation of hepatobiliary tumors and related lesions. Therefore, an update of the dramatic changes that have taken place in the discovery and application of several lines of knowledge referring to hepatobiliary tumor pathology in a broader sense was regarded a worthwhile task. Notwithstanding the impressive increase in diagnostic precision of modern imaging and other, in particular various molecular, methods, tumor biopsy and its morphological interpretation based on complex techniques is still a central diagnostic instrument that serves refined diagnosis and classification, risk stratification, and therapy planning, also in the light of future personalized treatment strategies. A combined approach by using conventional, fine structural, immunohistochemical and hybridization morphological studies, and molecular techniques generated a new concept of the tight correlation between structure and function in tumor pathology, contributing to advanced modes of diagnosis. Apart from information on a given diagnostic tumor entity, differential diagnosis is discussed in depth as a most critical issue.

The main reason for integrating several important issues of general pathology is based on the rapidly evolving and continued changes that are occurring in the disciplines of tumor biology, genomics, and associated molecular features that characterize tumors. The concept of the present work in fact aims at concentrating detailed aspects of surgical pathology needed for diagnosis and the pathogenic mechanisms behind disease in one source with ample color illustrations and a detailed reference corpus.

In the light of refined imaging techniques and other modern diagnostic approaches that can uncover a host of previously undetectable hepatobiliary lesions, a significant part of the textbook is dedicated to an extensive range of tumor-like lesions, pathologies that may, in a clinical-radiological setting, be confounded with true hepatobiliary neoplasms. Part of the tumor-like lesions, including mass-forming infections and infestations, are common entities

world-wide, while others may appear as unexpected or incidental findings, or rare and "exotic" disorders.

This text has been planned to serve hepatopathologists, hepatologists, and others interested and involved in this field, and it is the author's hope that the book is a comprehensive account on the surgical and general pathology of hepatobiliary tumors and their tumor-like mimics. The book is also hoped to be a useful source of information for basic scientists active in the field of liver pathophysiology.

To provide a systematic review of the immense field of hepatobiliary tumors and tumor-like lesions, the textbook has been divided into 39 parts, each covering one to several chapters, in order to assist the reader in locating topics of interest. In what follows, brief overviews on the contents of each chapter are presented.

Part 1 starts off with a series of chapters that supply comprehensive information on tumors characterized by a hepatocyte-derived lineage and its precursors. Chapter ▶ 1 deals with the role of hepatic stem and progenitor cells in hepatocarcinogenic pathways. Hepatocytes were perceived to represent the major cells of origin for numerous neoplasms of the liver, but stem and progenitor cells have been identified as important sources. The chapter addresses issues of hepatic stem cell niches, types of stem/progenitor cells found in these niches, interactions of stem cells with other cells, changes of their microenvironment, and mechanisms involved in a stem cell-cancer sequence. As cancer initiating cells and cancer-associated stem cells can circulate in blood, the significance of cycling clonogenic cells with longevity and remote spread for tumor progression is discussed. Chapter ▶ 2 provides an in-depth description of ordinary hepatocellular carcinoma (HCC), including classification of gross phenotypes, macroscopic growth patterns, pertinent histologic and diagnostic features, and tumor grading. In Chap. ▶ 3, the numerous immunohistochemical features characterizing ordinary HCC are discussed in detail. Chapter ▶ 4 focuses on invasion and metastatic patterns of ordinary HCC. Patterns of macrovascular and microvascular invasion and the features of intrahepatic and remote metastasis are explained and illustrated. This part also provides information on risk factors for metastasis and on the presentation and frequency of extrahepatic organ metastases. In Chap. ▶ 5, secondary changes that develop in HCCs, and in particular the interesting phenomenon of spontaneous tumor regression, are highlighted. Progression and recurrence of HCC are major elements of the tumor's biology of disease. Numerous prognostic factors for the natural course of HCC have been delineated, discussed in detail in Chap. ▶ 6. The issues of Chap. ▶ 7 are the various types of HCC precursor lesions that can develop in cirrhotic livers, including small and large cell change, dysplastic foci, and dysplastic nodules. There is a group of ordinary HCCs characterized by small size at the time point of diagnosis, lesions that are more frequently diagnosed due to improved imaging techniques. These intriguing lesions, specifically their morphology, classification, biology, and relationship to early cancer are dealt with in Chap. ▶ 8. The chapters on neoplasms of the hepatocyte lineage are considerably extended to reflect the growing importance of special types of liver cell cancers in the setting of clinical presentation, detectability by modern imaging techniques,

molecular features, and biology of disease (Chaps. ▶ 9, ▶ 10, ▶ 11, ▶ 12, and ▶ 13). Chapter ▶ 9 deals with clear cell HCC, a group of neoplasms that belong to a growing spectrum of epithelial clear cell tumors of the alimentary tract with a distinct biology of disease. A heterogeneous group of HCCs is characterized by the accumulation of neutral fat, including steatotic HCC and its inflammatory variant, steatohepatitic HCC, tumors that also develop in the setting of nonalcoholic and alcoholic fatty liver disease. Part of these tumors are rich in Mallory-Denk bodies (Chap. ▶ 10). A rare group of HCCs is characterized by the presence of an abundant desmoplastic stroma, similar to cholangiocarcinoma (sclerosing and scirrhous HCCs; Chap. ▶ 11). A further unusual subset of HCCs shows dense infiltrates of mononuclear leukocytes (inflammatory HCCs). One variant of these neoplasms reflects a morphology similar to lymphoepithelial carcinoma, with or without association with EBV virus infection, and another rare variant exhibits a plasmacellular infiltrate and signs of regression (medullary HCC; Chap. ▶ 12). Very rare forms of HCCs are characterized by peliotic change, multinucleated giant cells, chromophobe cells, oxyophilic/oncocytic cells, or cells with a Dubin-Johnson-like pigment (Chap. ▶ 13). An interesting group of liver cell tumors displays the presence of progenitor cells or stem-like cells. Part of these HCCs with progenitor cell features express cytokeratin 19, a feature conferring a more aggressive course (Chap. ▶ 14). A clinically and radiologically intriguing situation is produced by HCCs arising in an ectopic, extrahepatic location (Chap. ▶ 15). HCCs also occur in infancy and childhood (pediatric HCC). It is not yet clarified whether these unusual malignancies are the same or different from their adult counterparts (Chap. ▶ 16). A neoplasm that in several respects mimics HCC is hepatoid carcinoma, which can develop in numerous organs, but is usually manifest in the liver in the form of metastases (Chap. ▶ 17). An intriguing variant of HCC is fibrolamellar HCC, a tumor mainly occurring in younger individuals, showing a biology similar to that of ordinary HCC, and associated with a typical recurrent chimeric transcript (Chap. ▶ 18). A rare group of neoplasms composed of immature hepatocyte progenitors (embryonal and fetal hepatocytes) is formed by the various types and subtypes of hepatoblastoma and related neoplasms (Chap. ▶ 19). The majority of these cancers develops in children younger than 5 years, but rarely also develop in adults. Unusual variants of hepatoblastoma with aberrant differentiation patterns are treated in Chap. ▶ 20, including tumors with a bile duct cell differentiation. The focus of Chap. ▶ 21 relates to the biology and prognostic factors of heptoblastoma, while Chap. ▶ 22 treats risk factors and pathogenic pathways of neoplasms of the hepatoblastoma tumor family. An intriguing neoplasm related to hepatoblastoma and associated with an interesting clinical presentation and unique molecular features, nested stromal epithelial tumor, is the theme of Chap. ▶ 23. A benign tumor of the hepatocyte lineage is hepatocellular adenoma, which has recently been subdivided into several molecular subtypes associated with distinct morphologic patterns. The discussion of this important hepatic tumor and its variants is found in Chaps. ▶ 24 and ▶ 25. A rare group of neoplasms containing hepatocyte-like cells is combined hepatocellular-cholangiocarcinoma, malignancies that display a biphenotypic histologic picture. In contrast to HCC, these highly aggressive

neoplasms occur in cirrhotic and noncirrhotic livers with almost the same frequency (Chap. ▶ 26).

Part 2 of the textbook relates to benign and malignant neoplasms of the cholangiocyte lineage. Cholangiocarcinomas (CC) are divided into two major groups, extrahepatic and intrahepatic bile duct cancers. Among the former, hilar and perihilar CC form a distinct clinicopathologic entity different from CC originating in the mid-region and distal parts of the large bile duct. Intrahepatic CC is a malignancy that can present in three major gross growth patterns and originates from both small or large intrahepatic bile ducts. CC are malignancies of adult patients, but very rarely also develop in the pediatric age group (Chaps. ▶ 27, ▶ 28, ▶ 29, ▶ 30, ▶ 31, and ▶ 32). A distinct group of bile duct neoplasms is formed by intraductal neoplasms, tumors that resemble their pancreatic counterparts. They display a phase of intraluminal, often papillary noninvasive growth and a later high risk of transition into invasive CC (Chap. ▶ 33). In addition to classical forms of CC, there are tumors developing in the setting of hepatobiliary cystic disease, or exhibit distinct differentiation patterns different from those observed in ordinary CC (Chaps. ▶ 34, ▶ 35, ▶ 36, ▶ 37, and ▶ 38). A rare subset of bile duct tumors is characterized by cysts lined by a mucin-producing epithelium, frequently associated with a subepithelial ovarian-like stroma and expression of sex steroid receptors. These mucinous cystic neoplasms (MCN) can undergo a dysplasia-carcinoma sequence (Chap. ▶ 39). Both the intrahepatic and extrahepatic biliary tree can be the site of several types of benign epithelial neoplasms and hamartomas, including tubular and papillary adenomas, peribiliary gland hamartomas, biliary microhamartoma, and neoplasms and hyperplasias of peribiliary glands (Chaps. ▶ 40 and ▶ 41).

Part 3 covers a heterogeneous group of liver tumors derived from other epithelial lineages. Some hepatobiliary carcinomas are characterized by varying proportions of squamous epithelial cells, including squamous cell carcinoma, adenosquamous carcinoma, and mucoepidermoid carcinoma, or acinar cell and adenoid cystic components (Chaps. ▶ 42 and ▶ 43). Rare carcinomas of the biliary tract are undifferentiated neoplasms, such as nonendocrine small cell and spindle cell carcinomas, and carcinomas with rhabdoid features (Chap. ▶ 44). In a small group of hepatobiliary neoplasms, the cells of origin are not yet fully clarified. These lesions mainly comprise hepatic adrenal rest tumor and progenitor cell neoplasms (Chap. ▶ 45).

Part 4 of the textbook refers to mixed epithelial-mesenchymal tumors of the hepatobiliary tract. Chapter ▶ 46 highlights an intriguing group of hepatobiliary malignancies that are composed of a complex mixture of various neoplastic tissue types. These tumors are classified as carcinosarcomas and carcinomas with sarcomatoid features. Few primary hepatic tumors are characterized by the presence of multinucleated, osteoclast-like giant cells with a macrophage/histiocyte lineage (Chap. ▶ 47). Apart from carcinosarcomas, rare hepatic tumors present a mixed cellular phenotype that is still difficult to classify, including malignant mixed tumors, adenosarcomas, stromal tumors, and adult-type mixed hepatoblastomas (Chap. ▶ 48).

Part 5 focuses on the predominant group of hepatobiliary mesenchymal tumors, i.e., vascular tumors. The most important type of primary hepatic

vascular neoplasm is cavernous hemangioma with its various phenotypes and associations with extrahepatic vascular tumors (Chap. ▶ 49). Less common hepatic vascular tumors include several forms of hemangiomatosis, hemangioblastoma, epithelioid hemangioendothelioma, infantile hepatic hemangioma/hemangioendothelioma, kaposiform hemangioendothelioma, angiosarcoma, Kaposi's sarcoma, glomus tumors, myopericytoma, and glomangiopericytoma (Chaps. ▶ 50, ▶ 51, ▶ 52, ▶ 53, ▶ 54, ▶ 55, ▶ 56, and ▶ 57). Unusual vascular malformations, which may be part of complex inborn syndromes, can mimic true vascular neoplasms, such as Klippel-Trenaunay syndrome (Chap. ▶ 58). A second group of reactive vascular lesions that can cause tumor-like hepatic manifestations include bacillary angiomatosis and peliosis hepatis (Chap. ▶ 59).

Part 6 refers to tumors and tumor-like lesions of lymph vessels. In the hepatobiliary tract, these are very rare conditions which include cystic and noncystic lymphangioma, capillary lymphangioma, lymphangiomatosis, hepatic lymphangiectasis, and lymphocele (Chap. ▶ 60).

Part 7 is exclusively dedicated to solitary fibrous tumor and tumors with a hemangiopericytoma-like pattern. These lesions now include at least part of the former hemangiopericytomas and are characterized by a distinct somatic fusion of two genes, NAB2 and STAT6 (Chap. ▶ 61).

Part 8 discusses the complex spectrum of nonvascular mesenchymal tumors of the hepatobiliary tract. All these neoplasm are rare lesions and include fibroblastoid and myofibroblastoid neoplasms, leiomyoma and leiomyosarcomas, rhabdomyosarcomas, lipoma, liposarcoma, myelolipoma, hibernoma, tumors with osteosarcomatous and chondrosarcomatous components, gastrointestinal stromal tumors, benign and malignant nerve sheath tumors, granular cell tumors, synovial sarcoma, and undifferentiated high-grade pleomorphic sarcomas (Chaps. ▶ 62, ▶ 63, ▶ 64, ▶ 65, ▶ 66, ▶ 67, ▶ 68, ▶ 69, ▶ 70, and ▶ 71).

Part 9 summarizes tumors with a mesothelial cell lineage. Primary mesotheliomas of the liver are very rare, but characteristic neoplasms mimic mesothelial tumors in other locations. A unique mesothelial tumor occurring also in the liver is adenomatoid tumor (Chap. ▶ 72).

The theme of Part 10 is a heterogeneous group of neoplasms that are derived from, or related to, perivascular epithelioid cells. The liver is the primary site of various perivascular epithelioid cell tumors or PEComas, all with complex cellular compositions. They include PEComa proper, angiomyolipoma with its various subtypes, clear cell myomelanocytic tumors, clear cell and sugar tumors, and lymphangiomyomatosis (Chap. ▶ 73).

Part 11 presents hepatobiliary tumors of neuroendocrine lineages. Chapter ▶ 74 provides pertinent information regarding extraadrenal paraganglioma, neoplasms that also in the liver range in biology from a benign to frankly malignant behavior. In Chap. ▶ 75, the various types and subtypes of hepatobiliary neuroendocrine tumors are treated, emphasis being placed on novel classifications and grading systems.

In Part 12, a rare group of small tumors that also originate in the liver are discussed. The lesions comprise various small cell blue tumors, such as primitive neuroectodermal tumors (PNET), desmoplastic small round cell tumor, NUT midline carcinoma, and hepatic neuroblastoma (Chap. ▶ 76).

Part 13 refers to the interesting group of primary and secondary melanotic tumors of the hepatobiliary tract. Emphasis is placed on primary and metastatic melanoma, in particular also metastatic ocular melanoma, melanotic progonoma, and manifestations of melanoma of soft parts (Chap. ▶ 77).

Part 14 focuses on hepatic tumors with a rhabdoid cell lineage. Liver and bile duct tumors with rhabdoid cell components are, at least in part, associated with absence of the chromatin remodeling factor SRF5/INI1 and include malignant rhabdoid tumor proper, carcinomas with rhabdoid features, and a subset of small cell hepatoblastoma (Chap. ▶ 78).

In Part 15, primary and metastatic germ cell tumors are treated. Most germ cell tumors occurring in the gonads can occur as primary lesions in the liver, but teratomas, yolk sac tumor, and choriocarcinoma prevail, also in the pediatric age group. The liver is a well-known site of metastatic germ cell tumors and can be the site of growing teratoma syndrome (Chap. ▶ 79).

Part 16 summarizes the pathology of hepatic manifestations of myeloid neoplasms. With the exception of granulocytic sarcomas, these neoplasms cause diffuse infiltration of the liver substance. The conditions discussed comprise polycythemia vera, several types of myeloproliferative syndrome, chronic eosinophilic leukemia and idiopathic hypereosinophilia, mast cell neoplasms, acute leukemias, myeloid neoplasms with a monocytoid lineage, and blastic plasmacytoid dendritic cell neoplasms (Chaps. ▶ 80, ▶ 81, ▶ 82, ▶ 83, ▶ 84, ▶ 85, ▶ 86, and ▶ 87).

Part 17 refers to the complex pathology of hepatobiliary Hodgkin's disease. This disorder causes, on the one hand, tumorous hepatic lesions that can clinically be confounded with liver cancer, but on the other hand also reveals associations with paraneoplastic changes, including vanishing bile duct syndrome (Chap. ▶ 88).

Part 18 covers the large field of hepatobiliary non-Hodgkin's lymphomas, other lymphoproliferative disorders, and neoplasms of dendritic and histiocytic cell systems. Major groups comprise B-cell and T-cell neoplasms that occur in numerous extrahepatic sites, but pseudolymphomas, neoplasms of the Langerhans cell and histiocytic systems, dendritic cell neoplasms, and reactive histiocytic syndromes (such as Rosai-Dorfman syndrome) are also discussed (Chaps. ▶ 89, ▶ 90, ▶ 91, ▶ 92, ▶ 93, ▶ 94, ▶ 95, ▶ 96, ▶ 97, ▶ 98, ▶ 99, ▶ 100, ▶ 101, ▶ 102, and ▶ 103).

Part 19 treats mesenchymal hamartoma of the liver and related neoplasms. Mesenchymal hamartoma and undifferentiated embryonal sarcoma of the liver are typical pediatric hepatic neoplasms, but they have rare counterparts in adult patients (Chaps. ▶ 104 and ▶ 105).

Part 20 is a large complex of chapters that relates to the very important issue of metastatic liver disease. The chapters discuss in detail aspects of gross and microscopic pathology of liver metastases in general, a specific chapter on colorectal cancer metastases, other common and rare metastatic cancers, secondary changes that frequently develop in hepatic metastases, secondary spread of metastatic disease into locoregional lymph nodes, associated liver lesions, growth and regrowth of metastases, and pathogenic features of liver metastasis (Chaps. ▶ 106, ▶ 107, ▶ 108, ▶ 109, ▶ 110, ▶ 111, ▶ 112, ▶ 113, ▶ 114, and ▶ 115).

In Part 21, a small theme of liver tumor pathology is addressed, tumors and tumor-like lesions of hepatic ligaments. Falciform and round hepatic ligaments are the site of rare primary benign and malignant neoplasms, metastases, and various types of cysts (Chap. ▶ 116).

Part 22 contains chapters on reactive nodular hyperplastic hepatocyte lesions of the liver. Focal nodular hyperplasia (FNH) of the liver is an important mass-forming regenerative condition that often develops secondary to localized vascular and circulatory abnormalities of the liver. After hemangiomas, FNH is the second most common benign hepatic tumorous lesion (Chap. ▶ 117). A second important regenerative condition of the liver is nodular regenerative hyperplasia, which is associated with a broad array of causative factors (Chap. ▶ 118).

In Part 23, pseudotumors of the hepatobiliary tract are discussed. Pseudotumors and inflammatory pseudotumors form a heterogeneous group of lesions that share spindle cell proliferations and inflammatory infiltrates of variable density. Inflammatory myofibroblastic tumors is a lesion that contains a subset with neoplastic features and aberrant ALK expression (Chap. ▶ 119).

Part 24 relates to nonneoplastic tumor-like lesions of the liver. The liver is the site of tumor-like ectopias and heterotopias, mass-forming malformations, solitary necrotic nodule, various types of dust-induced nodular lesions, tumor-like lesions caused by gallstones and foreign bodies, pseudotumors consisting of reactive proliferations of hematopoietic cells and macrophages, pyogenic liver abscesses mimicking cancer, numerous hepatic bacterial, fungal, and protozoal infections causing tumor-like hepatic masses (tuberculosis, syphilis, brucellosis, and amebiasis representing prominent examples), tumor-like parasitic lesions (mainly echinococcosis), and liver infarcts (Chaps. ▶ 120, ▶ 121, ▶ 122, ▶ 123, ▶ 124, ▶ 125, ▶ 126, ▶ 127, ▶ 128, ▶ 129, ▶ 130, ▶ 131, ▶ 132, ▶ 133, ▶ 134, ▶ 135, ▶ 136, and ▶ 137).

Part 25 refers to reactive cystic lesions of the liver that may mimic cystic neoplasms. They include simple nonparasitic cysts, ciliated foregut cyst, pancreatitic pseudocysts, and cerebrospinal fluid pseudocysts (Chap. ▶ 138).

Part 26 provides information related to hepatic mass lesions caused by noninfectious granulomas. The main disorder is sarcoidosis that can also cause a complex form of sclerosing bile duct disease with bile duct loss. Blau syndrome and complex inflammatory disorders in part involving deregulated inflammasome function are also discussed (Chap. ▶ 139). A small chapter refers to chronic granulomatous disease (Chap. ▶ 140).

Part 27 presents the hepatic pathology of interesting fibrosclerotic disorders. The conditions include idiopathic retroperitoneal fibrosis and its variants, and the complex spectrum of IgG4-associated systemic sclerosing disease (Chap. ▶ 141).

In Part 28, numerous reactive bile duct alterations that can mimic biliary neoplasms are discussed. Intrahepatic and extrahepatic bile ducts can be involved with inflammatory stenosing polyps, granulomatous cholangitis, follicular cholangitis, oriental cholangitis, xanthogranulomatous cholangitis, bile duct cholesterolosis, sclerosing eosinophilic cholangitis, mechanical and anatomical bile duct alterations, bile duct stenosis caused by congenital

anomalies and acquired disorders of the splanchnic arterial tree and the portal vein, and postcholecystectomy changes (Chaps. ▶ 142, ▶ 143, ▶ 144, ▶ 145, and ▶ 146).

Part 29 addresses the important issue of gallbladder cancer and other tumors and tumor-like lesions of this organ. Ordinary gallbladder carcinoma usually develops in a gallbladder that has undergone secondary changes related to longstanding cholelithiasis and associated inflammations. This neoplasm, an adenocarcinoma, can be associated with epithelial precursor lesions and presents in the form of distinct growth patterns (Chap. ▶ 147). Biology of disease, prognosticators, staging, risk factors, and pathogenic pathways of gallbladder carcinoma are treated in more detail in Chaps. ▶ 148 and ▶ 149. Apart from the common ordinary adenocarcinoma of the gallbladder, several rare variants with other differentiation patterns are recognized, including mucinous, signet ring cell, and squamous cell carcinomas (Chaps. ▶ 150 and ▶ 151). The gallbladder is also the site of rare cystic and mixed neoplasms, such as cystadenoma and cystadenocarcinoma (Chap. ▶ 152). As outlined in Chap. ▶ 153, the gallbladder can give rise to a spectrum of adenomatous, borderline, and dysplastic lesions. Of differential diagnostic importance is the observation of various types of hyperplastic and metaplastic lesions in the gallbladder mucosa (Chap. ▶ 154). Similar to the bile duct system and liver, the gallbladder is a well-known origin of diverse types of neuroendocrine tumors, mesenchymal neoplasms, malignant melanoma, and a wide spectrum of other, however very rare, neoplasms (Chaps. ▶ 155, ▶ 156, and ▶ 157). A broad array of reactive, inflammatory, and noninflammatory alterations of the gallbladder can result in mass lesions that mimic neoplasms, and in particular gallbladder cancer (Chaps. ▶ 158, ▶ 159, ▶ 160, and ▶ 161). A rare group of malignant and benign tumors takes its origin in the cystic duct (Chap. ▶ 162).

Part 30 refers to a heterogeneous group of tumorous and tumor-like peritoneal lesions that may involve the liver surface. They include several primary carcinomas and other malignancies, pseudomyxoma peritonei, gliomatosis peritonei, and various forms of metaplasia, granulomas, endometriosis, and deciduosis (Chap. ▶ 163).

Part 31 is the first part of the textbook referring to aspects of general pathology of hepatobiliary tumors, specifically etiology and pathogenesis of hepatocellular carcinoma (HCC). A first chapter discusses in depth inflammatory and toxic causes, in particular the role of hepatitis virus infections, fatty liver and steatohepatitis, and nutritional and other toxins in hepatocarcinogenic pathways (Chap. ▶ 164). The following chapter (Chap. ▶ 165) discusses HCC that arises in the setting of inborn errors of metabolism, in particular various forms of chronic hepatic iron overload. Chapter ▶ 166 focuses on chromosomal alterations, oncogenes, tumor suppressors, and associated signaling networks that are involved in tumorigenesis, while Chap. ▶ 167 puts emphasis on the roles of transcription factors, regulators of growth and apoptosis, and telomere homeostasis. Finally, Chap. ▶ 168 is an overview on the etiologic and pathogenic significance of epigenetic mechanisms in hepatocarcinogenesis (the epigenome).

Part 32 contains an important chapter on the general pathology of structural and functional nuclear changes in hepatobiliary cancer. In Chap. ▶ 169,

relevant diagnostic and theoretical aspects of nuclear and nucleolar abnormalities, anaplasia, and chromatin alterations are addressed. Numerous types of structural abnormalities of cancer cell nuclei are directly associated with functional disorders of nuclear homeostasis, DNA replication, cell division, and organization of chromatin superstructures during interphase. Abnormal heterochromatin generation, a deranged production of euchromatin strings, malposition of interphase chromosomes, and anomalies of intranuclear chromosome movements are hallmarks of nuclear function failure in cancer cells (Chap. ▶ 170).

Part 33 addresses mitochondrial structure and function in normal and malignant neoplastic cells. Apart from their central role in energy production, mitochondria play a significant role within carcinogenic pathways involving abnormal stress responses and deregulation of cell death pathways. This role has led to the "mitochondrial malignancy theory." Mitochondria hold a central position in apoptosis induction, but they also modulate cell shape and engage in complex interactions with other organelles. Cancer cells exhibit various types of structural abnormalities of mitochondria and may show changes in mitochondrial number, mitochondrial fission, and elimination of this organelle. Part of these alterations are associated with losses and mutations of mitochondrial DNA (Chap. ▶ 171).

The contents of Part 34 pertain to tumor growth and its regulation. Uncontrolled, progressive growth is a key feature of cancers. Net mass increase of tumors not only depends on cell proliferation, but also on cell loss caused by various forms of apoptosis and necrosis and the contribution of nonneoplastic tissues and cells accompanying neoplasms, in particular stroma, blood vessels, and leukocytes. Cell proliferation in liver cell cancer reflects features of normal liver regeneration which is therefore discussed in some detail. The aberrant proliferation of liver cancer cells is related to deranged functions of factors orchestrating cell division, checkpoint regulators, proteins involved in DNA synthesis, proteins of the mitotic apparatus, and the numerous components of the cytoskeleton. Similar to the regenerating liver, growth of liver neoplasm is regulated by numerous growth factors and their receptors, including factors produced by platelets and antagonists of proliferation. Furthermore, hepatobiliary cancers reveal abnormal expression patterns of proteins that control entry into and passage through the cell division cycle, including cyclins and cyclin-dependent kinases. Finally, regulation of tumor growth strongly depends on various epigenetic mechanisms, specifically on complex expression patterns of microRNAs and other RNA classes (Chaps. ▶ 172, ▶ 173, ▶ 174, and ▶ 175).

Part 35 informs the reader about important aspects of the necrobiology of hepatobiliary cancer. An intricate process to control tumor cell mass is apoptosis, a complex form of tightly controlled cell death. Growth caused by proliferation is also counteracted by necrosis which, in contrast to traditional views, is a controlled process rather than a passive phenomenon. In liver cancer, apoptosis can be assessed by immunohistochemical and molecular methods. In addition to classical apoptosis, necrobiologic processes active in cancer also include various forms of cell death related to, but not identical with, apoptosis. These pathways may play a significant role for future novel

therapies (Chaps. ▶ 176 and ▶ 177). A special chapter is dedicated to the pathophysiology of classical (passive) necrosis in comparison with regulated necrosis (necroptosis). The latter involves a complex signaling platform, the necrosome, a molecular machine that senses ATP depletion and transmits this signal into kinase execution switches (Chap. ▶ 178). An important role in cancer cell biology is played by autophagy, a process involved in the maintenance of cell and tissue homeostasis, control of the protein composition of cells, aging, senescence, and neoplastic transformation. Autophagy is the instrument to eliminate altered proteins, damaged or superfluous organelles, and pathogens, and is a complex system connected with inflammasome function, inflammation, immunogenic cell death, and cell senescence. Special forms of autophagy in cancer cells include mitophagy and nucleophagy (Chap. ▶ 179).

Part 36 covers several important aspects of cancer invasion and metastasis. Invasion and metastatic spread of cancer cells involve a highly complex sequence of events that comprise tumor cell individualization, tumor cell polarization, migration, and the acquisition of a secretory phenotype, with release of histolytic enzymes. It is not yet fully known how these features are acquired by cancer cells in a seemingly concerted fashion. For being able to locomote, cancer cells, similar to leukocytes, must be able to undergo shape change and polarization, a process that requires numerous cytoskeletal components and specific polarity proteins. The invasive process strongly depends on the generation of invadosomes, including podosomes and invadopodia, matrix-degrading adhesive, and actin-dependent dynamic cellular structures or "organelles" that can also extend through endothelial linings and mediate extravasation of tumor cells. An important role for the invasion of carcinomas is the distinct tumor stroma. Stroma is composed of cancer-associated fibroblasts/CAFs, myofibroblasts, mesenchymal stem cells, stellate cells, blood vessel cells, extracellular matrix, and several classes of infiltrating leukocytes. The interaction of stromal cells with cancer cells affects invasive functions and modulates epithelial-mesenchymal transition (Chaps. ▶ 180, ▶ 181, ▶ 182, and ▶ 183). Metastatic spread of cancer cells, preceded by invasion, is a process that depends on the construction of premetastatic niches, the expression of distinct prometastatic genes and metastasis suppressors, on numerous microRNAs, and on the exchange of cellular information through exosomes and other vehicles that transfer signal cargo and extracellular nucleic acids (Chap. ▶ 184).

Part 37 is reserved for a distinct tumor tissue that affects numerous biologic functions of neoplasms, i.e., tumor stroma. Stroma forms a specific microenvironment that critically regulates the development and behavior of malignant neoplasms. Stromal cells interact with tumor cells directly, in part through cell fusion, and via molecular signals, resulting in a complex signal platform that expands in parallel with tumor growth. Stroma regulates tumor growth, differentiation, invasion, and metastatic spread. The various types of leukocytes present in stroma, in particular tumor-associated macrophages, myeloid-derived suppressor cells, lymphocytes, and neutrophils, create a unique inflammatory microenvironment which, through chemokines and other signal substances, significantly affects tumor biology (Chap. ▶ 185).

Part 38 shows how tumor angiogenesis functions and how it is an essential process in many aspects of liver tumor invasion and progression. Angiogenesis, the formation of new tumor blood vessels, is a critical mechanism for the development and progression of hepatobiliary tumors, which are often highly vascular lesions. In contrast to normal tissues, tumor blood vessels often form highly atypical branching patterns, with irregular diameters and abrupt changes from large to small diameters. The cells mediating tumor angiogenesis are endothelial cells and auxiliary cells that modulate the biology of endothelial cells, in particular perivascular cells, stromal cells, and tumor-associated macrophages and other leukocytes. As in normal tissue, initiation and progression of angiogenesis in tumors involve the action of numerous angiogenic factors, but neoplasms also produce several antiangiogenic factors. Tumor angiogenesis is modulated by epigenetic mechanisms, mainly microRNAs expressed by tumor cells and stromal cells (Chap. ▶ 186). This chapter is supplemented by a chapter that addresses basic questions of vasculogenesis, angiogenesis, and lymphangiogenesis (Chap. ▶ 187).

The last part of the present book, Part 39, provides a summary of current systems of tumor staging. As with other cancers, staging of hepatobiliary cancers is critical for prognostication and optimal treatment planning. Staging is a complex task that depends on multiple factors. In recent years, several staging systems have been developed and markedly improved the methods to arrive at optimal risk stratification procedures. Apart from hepatocellular carcinoma, highly reproducible staging systems have been developed for extrahepatic and intrahepatic cholangiocarcinoma and for hepatoblastoma (Chap. ▶ 188).

Acknowledgments

It is both a great honor and pleasure to thank all those who encouraged me to be involved in this endeavor and offered me continuous advice, support, and help. In fact, the present textbook could only be created thanks to numerous persons who have contributed in several ways to make this work possible. First of all, I express my deep gratitude to my former and venerated teacher in pathology, the late Professor Hans Cottier of the Berne University who, when I was still a beginner in surgical pathology and research, inspired me and filled his young disciple with enthusiasm to engage in a mode of thinking that was strongly based on science. Specifically, it was he who so clearly showed me the uppermost significance of basic science in pathology and, by doing this, kindled my strong desire to follow this path of thinking and acting. Later in my professional life as a pathologist I had the privilege to chair the Berne Institute of Pathology together with an outstanding partner, Professor Thomas Schaffner, whose critical mind in science and the highly stimulating interaction with him as a really good friend will remain unforgettable and irreplaceable. In regard to my early and continued interest in hepatology, I am indebted to all those who uncovered this fascinating field for me, in particular Professors Preisig, Reichen, Lauterburg, and Dufour of the Berne University. In the field of surgery, I have profited a lot from intense contacts with Professors Blumgart and Büchler, with whom I had the great chance to cooperate in various scientific projects and who converted me to bring hepatobiliary pathology to the bedside. In the field of pediatric hepatobiliary oncology, I would like to acknowledge the stimulating influence and help of all my professional friends of the international SIOPEL study group, with whom I had a very fruitful interaction for so many years. Having had access to large numbers of hepatobiliary tumor specimens deserves special thanks for the enthusiasm and tireless work of the laboratory crew of the Berne pathology institute, in particular I remain indebted to the wonderful support I have received from the histopathology staff with its chief, Mary Economou. A hearty thanks also goes to all who so often served me with special methods in diagnostic pathology, particularly Andreas Kappeler and his crew. A central place in the project of this book is held by my outstanding scientific secretary, Erna Kramel. I am highly grateful for the excellent secretarial help and the skillful illustration work performed by Erna, who spared no effort in seeing the preparatory work being completed. I also deeply acknowledge the outstanding librarian work of Sibylle Graf and Irene Marconi who, during many years, competently

provided me with large numbers of scientific articles and books and performed literature search with great motivation and innovation. I extend my appreciation to Alexander Grossniklaus for his continued help in matters of informatics. The significance of the contributions of all these persons cannot be overestimated. The author has been fortunate in having a continued and outstanding relationship with his publisher and his Springer partners associated with and enthusiastically accompanying him in this fascinating project, in particular Daniela Graf who offered continued excellent support and advice. Finally, the creation of this work would have been inconceivable without the continued interest, help, and compassion of my wife, Geneviève, who endured much in all these years of hard work and who accompanied me with great loyalty in this endeavor.

About the Author

Professor Arthur Zimmermann is an internationally known specialist in hepatobiliary tumor pathology. Following his training as MD and pathologist at the University of Berne, Switzerland, he worked in basic research for several years, focusing on tumor cell growth regulation, tumor cell locomotion, and cell cycle mutants of cancer cells. In surgical pathology, he analyzed more than 20,000 liver specimens, described new tumor entities, and was an author or coauthor of more than 500 publications in his field of interest. As chapter author, he participated in several well-known books on liver and biliary tract disease, including the 2010 edition of the *WHO Classification of Tumors of the Digestive System*, and was one of the editors of the book, *Pediatric Liver Tumors* (Pediatric Oncology Series, Springer). Professor Zimmermann developed the pathology review center for the multinational SIOPEL pediatric liver cancer treatment studies and was involved in the formulation of the new classification of pediatric liver tumors.

Abstract

Stem cells are involved in hepatocarcinogenic pathways. In the normal liver, hepatic stem cells are self-renewing cells dwelling in distinct compartments termed stem cell niches. These niches are distinct microenvironments which maintain the balance of slow self-renewal of quiescent stem cells and their priming to become hepatocytes and other differentiated cells. Hepatic stem cells possess plasticity, allowing them to undergo lineage diversification. In hepatocarcinogenesis, tumor stem cells mimick certain features of their normal counterparts. Tumor stem cells in hepatocellular carcinoma (HCC) can act as tumor-initiating cells and tumor-propagating cells that express hepatic stem cell markers and show distinct gene expression profiles. Apart from their role in carcinogenic pathways, cancer stem cells in HCC are considered to play an important role in tumor recurrence and metastasis. The expression of stemness-related markers in HCC confers an aggressive phenotype in these neoplasms. Tumor stem cells in HCC modulate several processes, including maintenance of slowly cycling clonogenic cells having longevity, induction of distinct growth features, and tumor progression. Following removal of HCC and other liver cancers, tumor stem cells can remain in the liver and enter the bloodstream to settle in new stem cell niches, including metastatic niches.

Introduction

Stem cells participate in tumorigenic pathways of numerous neoplasms and have therefore anticipated to be involved in hepatocarcinogenesis. Tumor stem cells (cancer stem cells, CSCs) in hepatocellular carcinoma (HCC) drive carcinogenic pathways and maintain a growing cell population in addition to proliferating nonstem cancer cells, but stem cells are also considered to play a significant role in HCC metastasis and recurrence. Furthermore, and similar to normal stem cells, CSCs exhibit the features of plasticity in regard to their lineage fating, an element that plays an important role in tumor heterogeneity and progressive phenotypic change, e.g., in metastases (reviews: Meacham and Morrison 2013; Sukowati and Tiribelli 2013). Recent research on liver cancer stem cells has also been undertaken with the aim of shedding light on novel treatment directions (reviews: Lee et al. 2009; Pang and Poon 2012). Generally, it is proposed that the expression of stemness-related markers in HCC confers an aggressive phenotype to these neoplasms. As in other organs and tissues, hepatic stem cells are self-renewing cells that dwell in distinct compartments termed stem cell niches, specific microenvironments which provide conditions for maintaining a balance of slow self-renewal of the mostly quiescent stem cells and their priming to become differentiated cell lineages. It is assumed that, following removal of HCC and other malignancies, stem cells involved in maintenance of a neoplastic phenotype remain in the liver and can enter the bloodstream to settle in new stem cell niches, including metastatic niches.

Stem Cells and Progenitor Cells in the Normal Liver: Pacemakers of Hepatic Ontogeny and Regeneration in the Injured Liver

Stem cells are critically involved in liver ontogenesis (reviews: Kamiya et al. 2006; Navarro-Alvarez et al. 2010). After fating of primordial endodermal cells to become liver, hepatic specification produces bipotential hepatic stem cells or hepatoblasts which can differentiate into either hepatocytes or cholangiocytes (reviews: Sangan and Tosh 2010; Parveen et al. 2011; Shin and Monga 2013; Kamiya and Inagaki 2015). Hepatic specification is a highly complex process that not only depends on fated endodermal cells but also on an interaction of several cell types located to endoderm, including the endothelial cell niche which promotes hepatic endoderm expansion and is directly required for liver speciation (Han et al. 2011b). In regard to regeneration of hepatocytes, the liver is in a special situation insofar as most of the cells that repopulate undamaged parenchyma after cell loss (e.g., resection) are the mature hepatocytes themselves, and not stem/progenitor cells, as hepatocytes are in a G0 phase of cycle and can be rapidly recruited into a cell division cycle. Stem cells play a significant role in regeneration of the liver in case of hepatocyte damage, i.e., when metabolic injury and decreased viability precludes a regenerative response of hepatocytes. Two types of hepatic stem cells have been defined, viz. fetal hepatic stem cells and stem cells of the adult liver (oval cells; progenitor cells). Fetal hepatic stem cells can maintain their self-renewal capability in the developing liver (Zheng and Taniguchi 2003). In adult livers, hepatic progenitor cells are present in small numbers and are quiescent stem cells with a low proliferative rate, representing a reserve or "emergency" compartment that is activated in case of marked hepatocyte damage or massive hepatocyte loss (Sharma et al. 2006; Gaudio et al. 2009; "ghosts in the machine"; Darwiche and Petersen 2010). In the normal adult, liver stem cells mainly reside in peripheral parts of portal tracts, in the compartment of canals of von Hering, and ductules (Vessey and de la Hall 2001), but a subset of liver progenitor cells originates from HNF1beta(+) biliary duct cells (Rodrigo-Torres et al. 2014). The progenitor cell response comes in four components, viz. activation/priming, proliferation, migration, and differentiation. In the course of stem cell-mediated regeneration, primed stem cells and their progeny, oval cells in rodents and progenitor cells in humans, form ductular profiles (ductular reaction) that deeply invade the damaged parenchyma and differentiate into focally arranged cell clusters that will generate hepatocytes (reviews: Fausto and Campbell 2003; Vestentoft 2013; Katoonizadeh et al. 2014). These clusters can also form narrow intraparenchymal ductular structures which have been termed parenchymal ductules. The cells forming these ductules have the same immunophenotype as resting stem cells (Papp et al. 2014). Stem cells isolated from fetal liver have the capacity to repopulate up to 10 % of normal liver, while progenitor cell lines from embryonal and adult liver have no significant repopulation activity (review: Dabeva and Shafritz 2003).

Extrahepatic Stem Cells Home to Liver and Liver Cancer and Regulate the Respective Cell Biologies

In addition to resident hepatic stem and progenitor cells, stem cells acting in the liver can also be recruited from extrahepatic organs and tissues. Induced pluripotent stem cells (iPSCs) develop through reprogramming of somatic cells to a pluripotent state by a complex induction process. iPSCs resemble embryonic stem cells/ESCs in several aspects (review: Chiang et al. 2013). iPSCs can, e.g., originate from mesenchymal cells (including mesenchymal stem cells), fibroblasts, adipocytes, and several types of bone marrow derived cells. As iPSCs can undergo tridermal priming/fating and differentiation, they can give rise to several types of hepatic cells. Embryonal

fibroblasts can be reprogrammed by hepatocyte nuclear factor 1 alpha and Foxa3 to bipotential hepatic stem cells (Yu et al. 2013b). Circulating bone marrow and/or adipose tissue-derived hematopoietic and mesenchymal stem cells (MSC) are capable to give rise to hepatic cells enabled to act in hepatic regeneration (Petersen et al. 1999; Grompe 2005; Oh et al. 2007; Guest et al. 2010; Ishikawa et al. 2010; Gong et al. (2013a, b); Stock et al. 2014). MSCs form a heterogeneous population of fibroblastoid cells surrounding blood vessels and are concentrated in the bone marrow and in adipose tissue, from where they can emigrate, circulate in the blood, and home to diverse tissues. Both hematopoietic stem cells and MSCs can home to the liver after hepatocyte loss, populate the remaining liver, and give rise to cells that can regenerate liver. MSCs can also home to tumors, including HCCs, where they exert diverse functions, including contribution to tumor cell development and expansion, generation of metastatic niches, neovascularization, and immunosuppression (review: Reagan and Kaplan 2011). Human fetal hepatic stem/progenitor cells are distinct from, but closely related to, hematopoietic stem cells (Chen et al. 2013d). Bone marrow-derived MSCs homing to liver tumors can, through interaction with tumor cells, increase tumor cell apoptosis and inhibit metastatic spread (Hang and Xia 2014). Homing of hematopoietic stem cells to the liver after hepatectomy requires hepatocyte growth factor (HGF) and stroma-derived factor-1 (SDF-1) (Lehwald et al. 2014), and hepatic differentiation of human adipose tissue-derived stem cells is promoted by distinct microRNAs (Davoodian et al. 2014).

Identification of Liver Tumor Stem Cells: Morphology, Stem Cell Markers, and Their Characteristics

Morphology

In the normal and regenerating liver, at least part of the stem or progenitor cells can morphologically be identified (Alison et al. 2001; Forbes et al. 2002; Fausto and Campbell 2003; Strain et al. 2003; Zheng and Taniguchi 2003; Kuhlmann and Peschke 2006; Bird et al. 2008). Stem cells, which in part are located in the lining of bile ductules, from where they can be recruited and mobilized, have morphological features of oval cells, small basophil cells, and transition cells between cholangiocytes and hepatocytes. Recently, it was reported that also ballooned cells forming Mallory-Denk bodies may have features of progenitor cells (French et al. 2013). Numerous investigations provided strong evidence that hepatic cancer stem cells (CSC) can be isolated from HCC (Chiba et al. 2006; Ma et al. 2007; Kamohara et al. 2008; Sell 2008; Sell and Leffert 2008; Lingala et al. 2010; Tomuleasa et al. 2010; review: Ji and Wang 2012).

Markers of Stem/Progenitor Cells

CSC are characterized by several markers, including CD13, CD24, CD44, CD90, CD133, EpCam (CD326), OV6 (Terris et al. 2010), and numerous others (Table 1).

Stem cells or stem-like cells can also be isolated from HCC cell lines in vitro via isolation of the side population (SP) cells, a cell population

Table 1 Markers for hepatocellular carcinoma-related cancer stem cells

Tudor domain-containing protein 4

capable to exclude Hoechst 33343 dye owing to the capacity of these cells with sufficient ATP-binding cassettes to transport the Hoechst dye out of the cell, while non-SP cells cannot. Due to this difference, tumor SP cells can then be separated from the other cell populations by use of cell sorting, and the resulting SP cells tested for typical stem cell features. Results of such analyses showed that SP cells contain a CSC cell population (review: Sell and Leffert 2008). However, not all cells of side population cell fractions have the characteristic features of CSCs (Nakayama et al. 2014). HCC-CSCs can also be identified by their molecular makeup. Stem cell features of HCC cells are associated with well-established gene alterations conferring an abnormal growth and apoptosis behavior in HCC, such as TP53 mutations (Woo et al. 2011).

CD133: Prominin 1 is a Crucial Molecule in HCC-CSC Biology

CD133 (prominin 1; PROM1) is a well-known stem cell marker (Mizrak et al. 2008; Wu and Wu 2009; Li 2013) which is involved in cell differentiation and polarity (Fargeas et al. 2011), organ morphogenesis (Anderson et al. 2011), cell surface dynamics (Mak et al. 2011), iron homeostasis of various cells (Bourseau-Guilmain et al. 2011), and interactions between cancer cells and stromal cells (Moriyama et al. 2010; Akita et al. 2013a, b). CD133 is expressed in subsets of liver stem cells (Rountree et al. 2011). These cells display a greater colony-forming efficiency and a higher proliferative output (Ma et al. 2007). Expression of CD133 also characterized part of HCC stem cells (Suetsugu et al. 2006; Ma et al. 2008; Song et al. 2008; Yoshikawa et al. 2009; Suetsugu et al. 2010; Zhang et al. 2011; Tsai et al. 2012; Ma 2013), and CD133+/CD44+ cells in HCC are considered to be true cancer stem/progenitor cells that are involved in tumor maintenance and chemoradioresistance (Zhu et al. 2010; Piao et al. 2012). There is evidence that the presence of CD133+ stem cells in HCCs is related to the etiology of HCC. In an area endemic for HBV virus (Taiwan), CD133 expression in HCC was negatively associated with the presence of HBsAg, implicating a non-HBV viral origin of CD133+ HCC (Yeh et al. 2009). In HCC cell lines, expression of CD133 markedly affects the biological features of the tumor cells. Silencing of CD133 expression impaired in vitro HCC cell proliferation, formation of tumor spheres, colony formation, and in vivo tumorigenicity in immunodeficient mice. In addition, knockdown of CD133 reduced cells in G0/G1 and increased tumor cell apoptosis through modulation of Bcl-2 and Bax (Lan et al. 2013). CD133 expression predicted poor disease-free survival independently of p53 expression (Yeh et al. 2009). Expression of CD133 in HCC cells is a predictor of the effectiveness of S1+ pegylated interferon alpha-2b therapy (Hagiwara et al. 2011). CD133 is also expressed in cholangiocarcinoma and gallbladder carcinoma cells (Shi et al. 2010; Fan et al. 2011; Iwahashi et al. 2013), and this expression is correlated with positive tumor margin status and lymph node metastasis (Leelawat et al. 2011).

Other Stem Cell Markers

A well-known second hepatic stem cell marker, OV6, is also present in HCC-associated CSC. OV6+ HCC stem cells are tumor-initiating cells that possess a high capacity to form tumor spheroids in vitro and give rise to tumors in severe combined immunodeficient (SCID) mice (Yang et al. 2012). CD90 characterizes a stem cell lineage in liver cancer, and cells expressing CD90 express several hundred other genes, including glypican-3 (Ho et al. 2012). A further protein expressed in part of stem and progenitor cells is c-Kit (CD117). In one investigation, c-Kit expression was detected in only 2.3 % of HCC, suggesting that c-Kit is not significantly overexpressed in HCC cells (Becker et al. 2007). In another study, immunoreactivity for c-Kit was detectable in 70 % of HCC with different degrees of intensity, illustrating highly variable results in regard to the expression of this stem cell marker in HCC. However, c-Kit reactivity was also found in 90 % of peritumoral cirrhotic and noncirrhotic liver tissue. Similarly, c-Kit

mRNA was identified in 83 % of HCC and 90–100 % of surrounding tissue (Mansuroglu et al. 2009). Sal-like protein 4/SALL4, a member of a family of zinc finger transcription factors, modifier of somatic cells and regulator of organogenesis and pluripotency, is a stem cell marker. SALL4 is expressed in normal human hepatic stem cells, hepatoblasts, HCC, cholangiocarcinoma, and mixed cholangiocarcinoma but is silenced in the normal adult liver. Its expression correlates with cell and tumor growth and an aggressive HCC phenotype (Yong et al. 2013), whereas its suppression results in slowed tumor growth and tumor cell differentiation (Oikawa et al. 2013). SALL4 is a marker for a progenitor subclass of HCC with an aggressive phenotype (Yong et al. 2013). Epithelial cell adhesion molecule (EpCAM) is expressed in several cancer and HCC stem cells and in tumor-initiating cells (TIC) (Yamashita et al. 2009; Terris et al. 2010; Imrich et al. 2012). In subsets of HCC stem cells, EpCAM is coexpressed with another stem cell marker, CD133, and cells with this phenotype represent tumor-initiating cells (TIC; Chen et al. 2012). In a recent investigation, it was shown that the two CSC markers of HCC, EpCAM and CD90, are independently expressed, in that EpCAM positivity characterized epithelial CSC, while CD90+ CSC had features of vascular endothelial cells, suggesting that more than one type of hepatic CSC may occur together and fulfill different functions (Yamashita et al. 2013). Liver cancer stem cells are also characterized by positivity for the Thomsen-Friedenreich core-1 protein, CD176 (Lin et al. 2011). Stemness features of HCC cells were analyzed by analysis of two stem cell characteristics, low proteasome activity and low intracellular reactive oxygen species/ROS. Isolated HCC with these two features demonstrated asymmetric divisions, tumorigenicity and a metastatic phenotype in immunodeficient mice, upregulated chemokine-related genes, and facilitation of macrophage migration in vitro (Muramatsu et al. 2013), suggesting that HCC stem cells not only affect tumorigenesis as such but also features of spread and interactions with tumor-associated cells such as macrophages. In HCC tumor cell lines kept in culture, a minor cell population expresses intercellular adhesion molecule 1 (ICAM-1). These ICAM-1-positive cells, which were also detected in human HCC and as circulating tumor cells in HCC patients, have greater sphere-forming and tumorigenic properties and represent tumor stem cells (Liu et al. 2013a). A second molecule involved in the regulation of cell adhesion is dysadherin. Dysadherin expression in liver cells characterizes a stem-like cell phenotype (Park et al. 2011). Part of HCC progenitor/stem cells are reactive for the 140 kDa isoform of neural cell adhesion molecule (NCAM) (Tsuchiya et al. 2011). A novel HCC stem cell marker is Delta-like 1 protein (Dlk-1), a surface protein expressed on fetal hepatic stem/progenitor cells but absent from mature hepatocytes in neonatal and adult rodent livers (Yanai et al. 2010). Overall, Dlk-1 is expressed in 20 % of all HCC but is even more frequently detectable in HCC diagnosed in young patients (Nishina 2012). Granulin-epithelin precursor (GEP) is a hepatic oncofetal protein expressed in fetal livers, but not in normal adult livers. Fetal liver cells containing GEP coexpress the stem cell-related signaling molecules beta-catenin, Oct4, Nanog, Sox2, and Dlk-1 and the CSC markers CD133, EpCAM, and ABCB5 (Cheung et al. 2011). The polycomb gene product BMI1 is critically involved in the self-renewal of somatic stem cells and participates in several types of tumorigenesis. BMI1 is expressed in subpopulations of HCC stem cells and plays a role in the maintenance of TICs in HCC (Chiba et al. 2008). HCV virus-induced CSC have a molecular signature containing doublecortin and CaM kinase-like-1 (Ali et al. 2011). A stemness-related molecule in HCC is cytokeratin-19 (CK19) (Lee et al. 2012a). Expression of CK19 in HCC confers increased EMT-related protein and mRNA expression and an invasive, aggressive phenotype (Kim et al. 2011; Lee et al. 2012).

HCC-Associated Stem Cells: Self-Renewing Cells with Various Biological Functions

HCC-associated stem cells promote tumor maintenance and progression.

HCCs can possess various self-renewing tumorigenic cell types, including CSCs sensu strictiori. These cells act as tumor-initiating cells (TICs) and tumor-propagating cells that express numerous morphologic and phenotypic features and distinct gene expression profiles (Colombo et al. 2011). CSCs of HCC express typical hepatic stem cell markers, such as CD133 and CD90, and their priming manifests in the expression of HCC lineage markers, as CD90(+) HCC-CSCs can also express glypican-3 (Ho et al. 2012). HCC-associated CSCs or stem-like cells are present in the tumors themselves, but they also occur in increased numbers in chronic liver disease, e.g., HCV-related liver cirrhosis (Behnke et al. 2013). A distinct property characterizing HCC stem cells is that they can initiate tumor growth in syngeneic or immunocompromised recipients. It is, however, difficult to judge whether such tumor-initiating cells are true CSC or non-CSC tumor cells that can give rise to growing tumors after cell transplantation (review: Sell and Leffert 2008). HCC-associated CSCs differ in several respects from other stem cells. In mouse HCC models, HCC progenitor cells give rise to fully developed cancer only when introduced into a liver showing chronic damage and compensatory hepatocyte regeneration, and tumor growth depends on cytokine stimulation, e.g., IL-6 signaling (He et al. 2013). CSCs occurring in HCC affect and modulate several biological functions, including maintenance of clonogenic cells with low proliferative activity but longevity, induction of distinct growth features (also in vitro; sphere formation, colony formation, anchorage-independent growth), and tumor spread and progression. There is also growing evidence that CSC are involved in the process of hepatocarcinogenesis itself, hepatic progenitor cells exposed to carcinogens progressively accumulating genetic alterations and genomic instability, in part acquiring the features of tumor-initiating cells, and finally showing a stably transformed phenotype (Xu et al. 2010; Kim et al. 2014; Machida et al. 2015). CSCs make part of a hierarchic cancer stem cell model for solid tumors such as HCC (review: Tong et al. 2011).

HCC-associated CSCs are not only involved in the initiation and maintenance of a given tumor but are also operational in HCC recurrence (HCC recurrence-associated stem cells, RASCs), the programming and establishment of metastatic niches (niche-associated stem cells, NASCs), and growth of metastases (metastasis-associated stem cells, MASCs). The pathways leading from the expression of stem cell markers to specific cancer cell behaviors are only partially elucidated. For example, expression of the stem cell marker, CD133, in HCC cells is associated with high capacity for tumorigenicity (Suetsugu et al. 2006; Yin et al. 2007) and confers an aggressive and invasive phenotype to HCC cells through the expression of metalloproteinase-1 (MMP-1) and a disintegrin and metalloproteinase (ADAM9; Kohga et al. (2010). Cytoplasmic expression of CD133 is an important risk factor for overall survival in HCC, specifically for stage III and IVA lesions (Sasaki et al. 2010).

HCC stem cells program epithelial-mesenchymal transition (EMT), a process critical for invasion and spread.

Epithelial-mesenchymal transition (EMT) is a process that occurs in many epithelial lineages and tumors derived thereof, characterized by the acquisition of a mesenchymal phenotype. The reverse process, mesenchymal-epithelial transition (MET) is less well known. EMT is driven by a distinct set of non-tissue-specific master transcriptional regulators (review: Cicchini et al. 2014). HCC stem cells are involved in the programming of EMT, a phenomenon which is crucial to invasion and spread of cancer cells and their interactions with the tissue microenvironment. On the other hand EMT creates a niche in which CSCs can settle and undergo differentiation. In this niche, with its features as an inflammatory microenvironment, mesenchymal stem cells can settle and accelerate HCC metastasis via induction of EMT (Jing et al. 2012). In cancers, EMT is chiefly characterized by disruption of intercellular contacts and connections leading to individualization of cells, enhancement of cell motility, and achievement of a primitive cell type capable to integrate into novel microenvironments (Guarino et al. 2007). In human HCC stem-like cells, the EMT promoter Twist2 induces self-renewal of these cells in a CD24-dependent manner (Liu et al. 2014). An EMT phenotype is

induced in hepatic oval cells by downregulation of microRNA-200a via targeting the beta-catenin signaling pathway (Liu et al. 2013b), which in turn affects the expression of cadherin, an important modulator of EMT. MicroRNA-200 upregulates vasohibin2 which in turn induced EMT and promotes HCC transformation (Xue et al. 2014). HCC cells that express the stem cell marker CD133 display more invasive characteristics by upregulation of invasion-associated genes and EMT-associated genes (Na et al. 2011). The relationship between EMT and a more invasive phenotype of cancers is linked to a distinct E-cadherin adhesion molecule repressor interactome in EMT (Hugo et al. 2011). Loss of E-cadherin, a typical feature of EMT, is associated with the acquisition of stem cell signatures and of cell with increased invasiveness (Nakagawa et al. 2014). NANOG, a major transcription factor essential for stem cell self-renewal, regulates self-renewal of CSC through the insulin-like growth factor pathway in human HCC (Shan et al. 2012) and promotes HCC invasion by inducing MEM, via activation of NODAL and CRIPTO-1 to promote SMAD3 phosphorylation and SNAIL expression. Interestingly, NANOG is preferentially expressed at the tumor edge, where invasion is most active (Sun et al. 2013a), suggesting that tumor stem cells may not be randomly distributed in liver cancer, but may rather populate distinct tumor areas. EMT can also be induced by hepatocyte growth factor secreted by hepatic stellate cells (HSCs), associated with upregulation of cancer stem cell-like properties in HCC cells (Yu et al. 2013a). The function of stem cell in the setting of EMT is modulated by tumor-associated macrophages (TAMs). In HCCs, TAMs promote cancer stem cell-like properties through TGF-beta1-induced EMT (Fan et al. 2014).

Stem Cells in HCC: Significance for Invasion, Spread, Stroma Formation, and Angiogenesis

A meta-analysis of HCC demonstrated that the presence of cancer stem cells was significantly associated with poor histological grade and elevated serum AFP levels, but there was no correlation between the presence of cancer stem cells and tumor size, tumor stage, or chronic liver disease/cirrhosis. Cancer stem cells in HCC were significantly associated with poor survival, including overall survival and disease-free survival, suggesting that the analysis of stem cells has an impact on the prognostication of HCC biology (Ma et al. 2013). HCC harboring CD133+ cells showed an aggressive, invasive phenotype, complicated by bile duct tumor invasion and thrombi (Yu et al. 2011). The reason why CSCs in HCC can significantly affect tumor biology and prognosis is related to several CSC-modulated mechanisms involved in tumor growth, invasion spread, and generation of a tumor-specific microenvironment. CSCs interact with and modulate the function of bone marrow-derived stromal stem cells (BMSCs), stem cells that are recruited to form tumor stroma and that are prone to undergo progressive changes similar to that of their cancerous partner cells, including telomere attrition due to telomerase failure (review: Saeed and Iqtedar 2013). CSCs contribute to neovascularization and angiogenesis through the production of proangiogenic factors, transdifferentiation of CSCs into endothelial and myoid cells, and formation of non-endothelium-lined channels called vasculogenic mimicry (reviews: Yu et al. 2010a, b; Barajas et al. 2007; Ping and Bian 2011; Zhu et al. 2012a, b). High expression levels of hepatic stem cell markers are related to tumor angiogenesis and poor prognosis in HCC. HCC with higher levels of CSC displayed higher levels of vascular endothelial growth factor and had an angiogenic pattern characteristic for aggressive tumors (Ho et al. 2006; Yang et al. 2010). Part of angiogenic effects exerted by hepatic CSC are linked to the angiogenic effects of CD133 (Akita et al. 2013a). Expression of CD133 in liver tumor-initiating cells (TIC) promotes tumor angiogenesis, growth, and cell renewal via a neurotensin / interleukin-8/CXCL1 signaling pathway, causing activation of p-ERK1/2 and RAF-1, components of the mitogen-activated protein kinase/MAPK pathway (Tang et al. 2012). A second stem cell factor that affects invasive properties of HCC cells is EpCAM. There is evidence that HCC growth

and invasiveness is dependent on a subset of EpCAM+ stem cells (Terris et al. 2010). In addition to the proangiogenic effect of CSCs, neovascularization /angiogenesis in malignant neoplasms is also accomplished by homing of angiogenic circulating progenitor cells to tumors. These cells are either angiogenic stem cells already primed for endothelial differentiation or homing MSCs that will upon their settling in the tumor be fated to become angiogenic cells (review: Melero-Martin and Dudley 2011). On the other hand, endothelial progenitor cells, through their angiogenic modulation of the tumor niche, affect HCC progression. These cells promote HCC intrahepatic metastasis via monocyte chemotactic protein-1 induction of microRNA-21 (Shih et al. 2014).

Cancer Stem Cells and Vasculogenic Mimicry

Vasculogenic mimicry (VM) was described in 1999 based on the detection of vascular channel formation by human melanoma cells (Maniotis et al. 1999). The term, VM, denotes a phenotype resembling the pattern of embryonic vasculogenic networks and describes the plasticity of cancer cells and their precursors forming de novo vessel-like channels lined by cancerous cells, whereby these channels contribute to perfusion and transport fluid from leaky vessels (Frenkel et al. 2008). Like this, the pseudovascular structures in VM contribute to neovascularization of rapidly growing malignancies in a mode that is independent of classical angiogenesis and vasculogenesis. The development of fluid-transporting spaces in VM facilitates metastatic spread (reviews: Folberg et al. 2000; Folberg and Maniotis 2004; Ping and Bian 2011; Kirschmann et al. 2012; Liu et al. 2012; Seftor et al. 2012). In cancers, two main patterns of VM are recognized, i.e., tubular VM and patterned matrix VM. In tubular VM, fluid-containing spaces are surrounded by tumor cells, while in patterned matrix VM laminin-reactive loops with PAS-positive laminas surrounding packets of tumor cells are seen (laminin-rich looping VM). Mainly in patterned matrix VM epithelial-mesenchymal transition (EMT) induced by Twist1 plays a significant pathogenic role whereby cancer cells can acquire a mesenchyme-like phenotype and may even become endothelial-like cells. In EMT-induced VM, CSCs are important actors, whereby EMT itself is potent for the acquisition and maintenance of stem-like features of cancer cells (Fan et al. 2013). Twist1 involved in EMT can stimulate cancer cell migration (Matsuo et al. 2009) and via this effect facilitates VM which requires tumor cell movements. In hypoxia-induced VM, Bcl-2 can induce a major endothelial adhesion molecule in tumor cells, i.e., VE-cadherin (Zhao et al. 2012). However, VM is resistant to antiangiogenic therapies (Fan and Sun 2010). Apart from factors regulating EMT, several other molecules are active in the promotion of VM, including the PI3-K signaling pathway, matrix metalloproteinases, laminin-5-gamma chain, protein tyrosine kinases, epithelial cell kinase (ECK), focal adhesion kinase, Eph receptors, Nodal, Notch4, hypoxia-inducible factor, galectin-3, bone morphogenetic proteins, cAMP signaling, cyclooxygenase-2, inhibitor of DNA binding 2/Id2, autophagy-related proteins, and VEGF (Hess et al. 2001; Hess et al. 2007; Sun et al. 2007; Lissitzky et al. 2009; Su et al. 2009; Fan and Sun 2010; Hardy et al. 2010; McAllister et al. 2010; Paulis et al. 2010; Che et al. 2011; Han et al. 2011a; Sun et al. 2012; Vartanian et al. 2013; Ding et al. 2014).

Both tubular and patterned matrix VM occur in HCC and is correlated with aggressiveness and poor clinical prognosis (Sun et al. 2006; Zhao et al. 2006; Guzman et al. 2007). Patterned matrix VM in HCC was associated with larger tumor, vascular invasion, high tumor grade, and late stage (Liu et al. 2011b). Similar to other cancers, VM induced by HCC cells is related to the induction of EMT, in that HCC cells in VM express the EMT inducer, Twist1 (Sun et al. 2010). Via EMT, Twist1 directly induces VM in hypoxic HCC cells (Ma et al. 2011) and promotes a metastatic phenotype (Lee et al. 2006). EMT-associated VM induced by Twist1 is stimulated by Bcl-2, which binds to and activates Twist1 under hypoxic conditions (Sun et al. 2011). Various factors present in EMT microenvironments are involved in

VM. The extracellular protease ADAMTS1 is a critical enzyme for cancer cells to acquire endothelial-like properties (Casal et al. 2010), and VM in HCCs is associated with the expression of osteopontin and matrix metalloproteinase-2 (Liu et al. 2011d). In the course of EMT-induced VM, poorly differentiated HCC cells can become CD31 positive and therefore phenotypically resemble endothelial cells (Zhao et al. 2007).

HCC-associated CSCs play a role VM. In the process of VM, a stem cell-like phenotype is involved, whereby cells forming the vascular channels express stemness markers, including CD133 (Yao et al. 2011; Lai et al. 2012; Valyi-Nagy et al. 2012). VM channel formation in HCCs is associated with EMT, dedifferentiation of tumor cells, and increased expression of stemness genes (Lirdprapamongkol et al. 2012). Stem cell-induced VM is particularly prevalent in EMT that develops in hypoxia. Expression of Slug, a potent inducer of EMT, in HCCs promotes the biogenesis and maintenance of a CSC subpopulation that is capable to produce VM (Sun et al. 2013b). EMT itself promotes the formation of HCC cells with stem-like properties via Twist1-Bmi1 signaling, Bmi1 belonging to the polycomb repressive complex 1 (Wu and Yang 2011), and this connection may favor EMT-induced VM mediated by cancer stem cells.

CSCs in Tumor Recurrence and Metastatic Spread: RASCs, NASCs, and MASCs

Tumor recurrence is traditionally viewed as a process that originates from remaining cancer cells that have not been radically removed and/or were resistant to chemo- or radiotherapy. However, within the population of recurrent HCC cells, cells with stem-like features were identified (Yi and Nan 2008; Xu et al. 2010a, b), and it is assumed that such cells contribute to recurrence and significantly modify the recurrence phenotype and pattern. For hepatic recurrence, recurrence-associated stem cells (RASCs) may either represent (a) surviving HCC-CSCs capable to resume growth following therapy, (b) novel stem cell species arising from the recurrent tumor, or (c) stem cells derived from an extrahepatic site and homing to the recurrent tumor with its new microenvironment. Tumor stem cells and their fully malignant offspring play a critical role in the biogenesis of metastatic niches. In human HCCs, expression of the two stem cell markers CD90 and EpCAM was higher in the early recurrence group (Guo et al. 2014). As niche-associated stem cells (NASCs), CSCs undergo a complex crosstalk with normal cells in the prometastatic niche, in that they secrete factors that affect stromagenesis, recruitment of tumor-associated macrophages (TAMs) and tumor-associated endothelial cells (TECs), and angiogenesis (Gupta et al. 2014). These factors include the TGF-beta/Smad system, PDGF, VEGF, and IL-6. Similar to the complex function of the portal fibroblast, which provided a niche for controlled cholangiocyte turnover (Wells 2014), prometastatic niches contain a fibroblastoid population that interacts with NASCs, with a mutual regulation of the cells involved. Part of fibroblastoid cells and angiogenic cells constituting the prometastatic niche are derived from mesenchymal stem cells (MSCs) that circulate in the blood and home to the tumor microenvironment (Wang and Chen 2013), where they interact with tumor cells and NASCs. The mode of this interaction is not yet well known, but MSCs rarely fuse with HCC cells in murine models (Li et al. 2013). HCC cells and their stromal component themselves modulate the migratory behavior of MSCs (Garcia et al. 2011). As the tumor microenvironment is often hypoxic and/or deficient in nutrients, niche-associated tumor cells have developed strategies to circumvent this stress situation. CD133(+) HCC-CSCs showed higher survival, less apoptosis, and higher clonogenicity under hypoxic and nutrient deprivation stress, in part associated with increased autophagy (Song et al. 2013). CD133 is involved in the regulation of autophagy and glucose uptake (Chen et al. 2013d). Following their exit from a primary or recurrent tumor, or a metastatic niche, RASCS and NASCs enter circulation and can become metastasis-associated stem cells or MASCs. There is evidence that circulating HCC stem cell-like cells capable to generate metastatic recurrence (MASCs) express certain markers that allow their identification, such as the stem cell marker CD90 (Yamashita et al. 2013), the oncofetal

marker Lin28B (Cheng et al. 2013), and the G protein-coupled receptor 87/GPR87 (Yan et al. 2013). Expression of CD133 in liver CSC plays a critical role in hematogenous metastasis of HCC (Hou et al. 2012; Chow et al. 2013). CD133-positive CSCs play a role in repeated pulmonary recurrence of HCC (Toshima et al. 2013). In regard to prognostication, the various HCC stem cell markers differ in several respects. While expression of CD133 was more frequently found in small tumors in cirrhotic livers and early stage disease, expression of EpCAM characterized small tumors and poor differentiation and was an independent prognosticator at all stages (Chan et al. 2014). Can circulating CSCs rehome to primary cancers or metastatic niches and modulate the features of their tumor of origin?

Tumor Stem Cells in Nontumorous Liver Tissue

CSC are readily detectable in HCC tissue itself by means of their distinct marker profile, but cells with similar or the same features also occur in the nonneoplastic parenchyma of livers harboring HCC. Cell lines producing colonies in soft agar and showing anchorage-independent growth were isolated form liver resections with HCC, and these cells revealed the marker profile of CSC (Zhang et al. 2010).

Cells with Stem Cell-Like Features in Special Variants of Hepatocellular Carcinoma and in Precursor Lesions

Tumor stem cells seem to be involved in pathogenesis of scirrhous HCC. In this variant of HCC, small neoplastic cells were reactive for cytokeratin 7 and ATP-binding cassette transporter G2. Part of these cells (termed type 1 cells) stained for cytokeratin 19, neural cell adhesion molecule (NCAM), and epithelial cell adhesion molecule, while another subset (termed type 2 cells) did not show this immunophenotype. In type 3 scirrhous HCC, no small tumor cells with stem cell features were present. It was suggested that type 1 and type 2 cells in scirrhous HCC correspond to a side population of cultured cells (Fujii et al. 2008). Apart from conventional HCC, features of stemness are also present in dysplastic hepatocytes (Lingala et al. 2010), fibrolamellar hepatocellular carcinoma (Zenali et al. 2010), and hepatoblastomas (Akita et al. 2013).

Stem Cells in Hepatoblastomas

Hepatoblastomas (HBs) have been shown to contain cells with stem-like features. Hepatoblasts, a putative normal counterpart of HB, show a pattern of proteins shared by hepatic stem cells, i.e., CK19, human epithelial antigen-125/HEA-125, and OV-6 (Crosby et al. 1998). This has in particular been observed in HBs of low differentiation, such as small cell undifferentiated HB (see the respective chapter). In subsets of HB, expression of CK19, Oct-3/4, and EpCAM was observed (Yun et al. 2013). HB cells can express proteins that are present in human fetal liver, including delta-like protein/DLK, a membrane protein of unknown function (Dezso et al. 2008; Yun et al. 2013).

Biogenesis of HCC-Associated Stem Cells

Mechanisms of Stem Cell Formation in the Liver and Liver Neoplasms

Recent findings showed that several mechanisms can elicit tumor stem cells and stem cell signatures in normal liver, regenerating liver, and HCCs. They comprise the expression of transcription factors (Sox2, c-Myc, LIN28, NANOG), several signaling pathways (TGF-beta, Wnt/beta-catenin signaling), factors modulating the cancer microenvironment (Notch signaling), microRNAs, and differential DNA methylation patterns (reviews: Zheng et al. 2013; Bogaerts et al. 2014; Dang et al. 2014). Expression of transforming growth factor beta play an important role in signaling pathways taking place in hepatic and intestinal stem cell niches (review: Majumdar et al. 2012).

Chronic and constant TGF-beta stimulation results in the generation of hepatoma-initiating cells derived from hepatic progenitor cells (Wu et al. 2012), and TGF-beta secreted by HCC cells mediates the crosstalk between cancer cells and the tumor microenvironment (Gupta et al. 2014).

How are the distinct growth and survival features of CSCs regulated, in particular their critical capacity for self-renewal? Overall, the expression of stemness-related proteins by HCC cells is related to increased telomere lengths, increased expression of hTERT and shelterin complex proteins, and increased chromosomal/genomic instability in comparison with conventional HCC (Idrissi et al. 2013). Maintenance of telomeres is compromised in HCCs, and it is expected that a derangement of the telomere platform may be an early event in hepatocarcinogenesis, eventually already involving CSCs (Ye et al. 2010). Specifically, there is evidence that abnormal stem cells may lack telomerase, an enzyme responsible for telomere extension (reviews: Gardano et al. 2013; Saeed and Iqtedar 2013). Telomeres are the terminal elements at the ends of linear chromosomes and are critically involved in the prevention of exonucleolytic degradation, inter- and intrachromosomal fusion, and subsequent chromosomal instability (Ye et al. 2010; Calado and Dumitriu 2013). Telomere integrity is critically required for the unlimited replicative potential of cancer cells. The stability of telomeres depends on the binding of the six-protein subunit complex shelterin to telomeric repetitive DNA sequences (Palm and de Lange 2008; Xin et al. 2008). Further proteins playing a role in telomere stability are the sirtuins (Rodriguez et al. 2013). Telomerase elongates telomeres and is recruited by homeobox telomere-bending protein1/HOT1 (Kappel et al. 2013). Furthermore, the subunit telomerase reverse transcriptase (TERT) has additional functions, including transcriptional regulation and metabolic reprogramming (Low and Tergaonkar 2013). All telomeric proteins involved in telomere function form, together with the telomere proper, the telosome (Liu et al. 2004; Folini et al. 2009).

Epigenetic mechanisms play a central role in the generation of hepatic stem cells and side population cells occurring in HCC. Side population cells of HCC have a high rate of DNA hypermethylation as compared with their corresponding non-side population cells, and the differentially methylated genes in side population cells were involved in numerous signaling pathways (Zhai et al. 2013). Among stem cell molecules regulated by epigenetic mechanisms is CD133, this regulation pathway involving TGF-beta1 which inhibits DNA methyltransferase 1 and DNA methyltransferase 3beta expression and subsequent demethylation of promoter-1 (You et al. 2010). CD133 expression is also promoted by hypoxia, in that hypoxia-inducible factors activate CD133 promoter via ETS family transcription factors (Ohnishi et al. 2013). Certain transcription factors and transcription repressors are preferentially active in stem and progenitor cells and affect epigenetic mechanisms. BORIS (brother of regulator of imprinted sites) is a protein encoded by the CTCFL gene, is a paralog of the transcription suppressor CTCF (Tiffen et al. 2013), and is an ubiquitous 11-zinc finger protein with highly versatile functions, including transcriptional silencing and organization of epigenetically controlled chromatin insulators that regulate imprinted genes in the soma both in normal and cancerous tissues (Klenova et al. 2002; Loukinov et al. 2002; Rosa-Garrido et al. 2012). As BORIS expression in HCC is correlated with expression of the stem cell marker CD90, BORIS may itself be a property of hepatic and HCC-associated stem cells (Chen et al. 2013b).

Pathways from Primed Stem Cells to Differentiated Cells

In parallel to normal stem cells it may be anticipated that CSC can undergo priming to more differentiated neoplastic cells. This is an important study field, because it potentially opens pathways for novel treatment strategies. One factor involved in the switch turning CSC to differentiated cells is the Hippo pathway. Hippo signaling

has a dual regulation of Hippo in liver tumor suppression as well as a transition of oval stem cells to fully differentiated hepatocytes and hepatocyte-like cells in tumors (Zheng et al. 2011). A second crucial pathway involved in the phenotypic shift of CSC to a more differentiated offspring is the WNT/beta-catenin-signaling pathway (Yang and Poon 2008). Expression of beta-catenin is pertinent in hepatic oval cell activation and differentiation (Nejak-Bowen and Monga 2011), and it is expected that the same mechanism is operational in HCC and related neoplasms. As discussed in the respective chapter, immature cells forming undifferentiated clusters in hepatoblastomas are markedly reactive for beta-catenin and seem to give rise to more differentiated but rapidly proliferating offspring surrounding the stem-like cell clusters (Zimmermann 2005).

Regulation of Stem Cells by microRNAs and Other Noncoding RNAs

The function of HCC-associated stem cells is itself regulated by several factors and signaling pathways, including microRNAs (reviews: Chai and Ma 2013; Qi et al. 2013; Chen and Verfaillie 2014). In HCCs and HCC cell lines several and in part specific microRNAs have been identified (Xu et al. 2013). miRNA-130b was shown to promote liver tumor-initiating cell growth and self-renewal through induction of nuclear protein 1 by tumor p53 (Ma et al. 2010). In isolated subsets of side population cells, silencing of microRNA-21 reduced migration and invasion of cancer cells, while overexpression of mRNA-21 drastically inhibited the expression of PTEN, RECK, and PDCD4 proteins (Zhou et al. 2013). MicroRNA-142-3p regulates the expression of the functional hepatic cancer stem cell marker CD133 (Chai et al. 2014). microRNA-181 is highly expressed in embryonic liver tissue and in isolated hepatic stem cells. Specifically, inhibition of microRNA-181 resulted in reduction in EpCAM+ HCC cells and tumor-initiating capacity (Ji et al. 2009). microRNA-150 inhibits human CD133+ liver cancer stem cells through negative regulation of the transcription factor cMyb, associated with downregulation of the cell cycle regulator cyclin D1 and the cell survival regulator Bcl-2 (Zhang et al. 2012). micro-612 suppresses the stemness of HCC CSCs via the Wnt/beta-catenin-signaling pathway (Tang et al. 2014). The tumorigenicity of cancer stem-like cells derived from HCC is regulated by microRNA-145, probably through modulation of the downstream target, the stem cell-related gene Oct4 (Jia et al. 2012; Wang et al. 2013). microRNA-148a inhibits EMT and several CSC properties and by this impairs metastasis of HCC (Yan et al. 2013). Lin-41, a stem cell-specific E3 ligase and a target of the tumor suppressor microRNA let-7 mediates ubiquitinylation and degradation of the microRNA pathway protein Ago2. Lin-41 is overexpressed in HCC, where it is involved in growth control through regulating the RISC complex proteins Ago1 and Ago2 to inhibit microRNA-mediated gene silencing and promoting the expression of oncogenic proteins (Chen et al. 2013a). Lin-41 expression in HCC confers an aggressive phenotype associated with early recurrence and poor survival, suggesting that Li41 is involved in HCC CSC. Hepatic stem cell biology is also affected by long noncoding RNAs. Oncofetal long noncoding RNA PVT1 promotes proliferation and stem cell-like properties of HCC cells by stabilizing NOP2 (Wang et al. 2014).

Modulation of Stem Cell Biogenesis and Function by Microvesicles and Exosomes: Can Cancer Stem Cells "Infect" Other Cells and Transmit Them a Malignant Phenotype?

Mesenchymal stem cells (MSC) as a potential source of hepatic cells possess a complex stem cell secretome that can be transferred to other cell systems through exosomal pathways (Bruno et al. 2013; Kupcova 2013; Xiong et al. 2013). Microvesicles of MSC can serve as trophic shuttles for diverse cell types, including stem cells (Aliotta et al. 2012; Mokarizadeh et al. 2013) and act as a complex paracrine information system within cell interactomes (Quesenberry and

Aliotta 2010), e.g., in regeneration and tissue repair (Camussi et al. 2010; Anthony and Shiels 2013) and the induction of epithelial-mesenchymal transition (Garnier et al. 2013). Via this mechanism, stem cell properties are maintained, while loss of the pathway may result in differentiation of stem cells (Bauer et al. 2011). Specifically, microvesicles released from stem cells confer a stem cell-like phenotype to other stem cells and damaged cells, evoking stem cell maintenance and self-regenerative programs (Herrera et al. 2010; Quesenberry et al. 2012; Camussi et al. 2013), but they may also transfer stem cell-like features to neoplastic cells being in close contact with them (Muralidharan-Chari et al. 2010; Lee et al. 2011; Pap 2011).

A critical property of stem cell microvesicles and exosomes is their genetic information cargo, i.e., they are loaded with microRNAs and mRNAs, genetic information that can be transferred among cells through microvesicle release (Yuan et al. 2009; Deregibus et al. 2010; Lee et al. 2012b). The molecular mechanisms by which genetic information such as microRNAs are loaded into microvesicles/exosomes are not yet well known, but distinct RNA-related zipcode-like sequences seem to act as sentinel sequences for these processes (Bolukbasi et al. 2012). Multipotent mesenchymal stem cells can affect and modulate their partners and other cells through CD133/prominin-1, contained in lipid rafts of these cells, by release of microvesicles. Similarly, cancer cells possess exosomes containing CD133 and numerous other proteins and microRNAs that are involved in metastatic pathways (Rappa et al. 2013). Human liver stem cell-derived microvesicles inhibit HCC growth in immunodeficient mice by releasing antitumor microRNAs (Fonsato et al. 2012). Informational cargo transported and transmitted by exosomes also modulates processes that are associated with and required by stem cell-driven cancer growth and spread. Endothelial progenitor cells located within tumors produce microvesicles that activate an angiogenic program in endothelial cells by horizontal transfer of specific mRNAs (Deregibus et al. 2007).

Systemic and Hepatic Mesenchymal Stem Cells and Stem-Like Cells: Modulation of HCC Biology

In murine models, there is evidence that HCC may originate from genetically mutated MSCs (Gong et al. 2013). MSC interact with HCC cells and modulate their behavior and affect interactions of HCC cells with stromal and vascular cells. In the nude mouse tumor transplantation model, BMSCs could promote the growth of small vessels and increased microvascular density (Gong et al. 2013a, b; Kupcova 2013), and in another murine HCC model, hematogenic MSC could modulate their microenvironment via secreted cytokines that promoted tumor initiation, growth, and homing to tumor sites (Gong et al. 2013). Hepatic stellate cells (HSC) and their precursors are specific mesenchymal cells of the liver that exert a profound impact on growth, differentiation, and morphogenesis of several other hepatic cell systems and neoplasms derived thereof (review: Yin et al. 2013).

Dormant Cancer Stem Cells

Dormant cancer stem cells (D-CSC) are defined as cells that remain intact after apparent eradication of cancer, including HCC, and are capable to maintain a transformed phenotype and to generate recurrent cancer. In one study, such D-CSC were detected in human HCC cell population grown in immunodeficient murine hosts after chemotherapy in the form of human AFP+/CD13+/PCNA cells (Martin-Padura et al. 2012).

Abstract

Hepatocellular carcinoma (HCC) is a malignant neoplasm composed of cells with a hepatocellular differentiation. Most HCCs exhibit a trabecular and/or acinar histologic pattern (ordinary or classical HCC), but there also exist numerous variants with a different morphology and a fibrolamellar variant treated in a separate chapter. HCC is a frequent malignancy and is estimated to be the fifth most common malignancy in males worldwide. Most of the tumors arise in patients with liver cirrhosis caused by various etiologies, hepatitis virus infections, and toxic agents playing a central role. HCC displays specific macroscopic growth patterns. Eggel divided the neoplasms in nodular, massive, and diffuse types, nodular HCC being the most common. This classification has subsequently been extended and refined. HCC frequently invades large and small hepatic vessels and bile ducts, causing distinct clinical disorders. Histologically, hepatocyte-like cells arranged in large plates with an abnormal reticulin pattern and loss of Kupffer cells are the hallmarks of trabecular HCC, whereas pseudoglandular structures are found in other tumors. The grading of HCC has been standardized and is an important prognosticator. Morphological classifications of HCC are currently extended by the use of molecular signatures of these neoplasms.

Introduction

Hepatocellular carcinoma (HCC) is a malignant neoplasm composed of cells with a hepatocellular differentiation. The majority of HCC shows trabecular and/or pseudoglandular/acinar patterns that consist of a hepatocyte-like cell lineage (ordinary, "classical," or "standard" HCC). In addition, there exist numerous variants of ordinary HCC and a distinct entity, fibrolamellar hepatocellular carcinoma, treated in separate chapters.

Eggel (1901) was the first to clearly state that primary liver cell cancer is derived from hepatocytes. Apart from the morphologic resemblance between hepatocytes and hepatoid cells in moderately to well-differentiated HCC, a crucial argument of Eggel was his discovery of bile depositions in 6 of the 117 histologically examined tumors that he compiled from the literature, by adding a case of his own. Identification of bile in and between tumor cells still is a hallmark for the diagnosis of HCC.

Epidemiology

Liver cancer is a frequent malignancy worldwide with an incidence that is particularly high in all low-resource regions of the world, except Northern Africa and Western Asia. It is estimated that 82 % of HCC occur in developing countries (Leong and Leong 2005; Chuang et al. 2009). Estimates from the year 2004 show that HCC is the fifth most common malignancy in males and the eighth in females worldwide (Table 1).

About 564,000 new cases are diagnosed per year, with 398,000 in men and 166,000 in females, illustrating that HCC is two to four times more common in men than in women (reviews: Bosch et al. 2004, 2005). The yearly incidence comprises between 2.5 % and 7 % of patients with liver cirrhosis (Montalto et al. 2002). The highest reported incidence of 100 cases per 100,000 of population annually had been reported from Mozambique, due to high prevalence of HBV infection followed by cirrhosis, aflatoxin

Table 1 Age-adjusted incidence of HCC per 100,000 inhabitants (Llovet et al. 2003; modified)

Area	Age-adjusted incidence (males/females)
Worldwide	14.9/5.5
East Asia	35.4/12.6
Middle Africa	24.2/12.9
Southeast Asia	18.3/5.7
Southern Europe	9.8/3.4
Western Europe	5.8/1.6
South America	4.8/3.6
North America	4.1/1.6
Northern Europe	2.6/1.3

and alcohol toxicity, and possible iron overload. The peak age of onset of HCC is continuously rising worldwide, and there is evidence that the clinical features in the elderly differ from those in younger individuals. In a study of 622 patients with HCC, including 91 patients 70 years old or older, the proportion of females increased, and tumor sizes at diagnosis were smaller in the elderly than in younger patients, whereas clinical stage taking liver function into consideration was similar in the two age groups (Nomura et al. 1994). Whereas an increase in incidence has been noted in certain regions, the incidence of HCC has, e.g., been static over recent decades in the Asia Pacific region (Yuen et al. 2009).

HCC is closely associated with liver cirrhosis (Siegenbeek van Heukelom 1894; Kew and Popper 1984; Gall 1960; Fattovich et al. 2004), the main causes of this chronic liver disease being hepatitis virus infections, alcoholic liver disease, and nonalcoholic fatty liver disease (NAFLD). The development of HCC in a background of cirrhosis varies as a function of underlying disease. Particularly high incidences of HCC in cirrhotic liver are found in HCV infection and hereditary hemochromatosis. HCV infection was found to have the highest HCC incidence in cirrhotic patients, with a 5-year cumulative incidence of 17 % in Western countries and 30 % in Japan. In the cirrhotic stage of hemochromatosis, the 5-year cumulative incidence was 21 %. Lower values are observed in other important causes of cirrhosis, i.e., HBV infection, alcoholic liver disease, and various forms of biliary cirrhosis. In high endemic areas of HBV infection, the 5-year cumulative incidence of HCC is 15 %, while it is 10 % in Western countries. Overall, alcoholic liver cirrhosis has a 5-year cumulative HCC risk of 8 % (review: Fattovich et al. 2004). Male gender and age more than 50 years are risk factors for HCC in cirrhotic patients. A subset of HCC develops in the absence of cirrhosis (Tabarin et al. 1987; Giarelli et al. 1991). In an autopsy study from Japan, non-cirrhotic cases among 618 HCC patients amounted to 10.7 % (Okuda et al. 1989). In Western countries, HCC in non-fibrotic livers was associated with younger age and female sex (Bège et al. 2007).

It seems that the earliest true primary HCC was a case reported in Frerich's series in 1861, followed by a bona fide example of HCC in a cirrhotic liver with invasion of the inferior vena cava, reported in 1876 (Weigert 1876). It is striking to note that in early works on the incidence of HCC in Europe, relatively few cases were found in a clinical setting or in autopsy series in comparison with metastatic liver disease. In his work on liver tumors, Thöle (1913) cites that von Hansemann (a pathologist, assistant of Virchow, who formulated the concept of anaplasia) found 225 metastases and 6 HCC among 258 malignancies observed until 1889 and that Ahlenstiel detected 95 hepatic malignancies in 6,000 autopsies, of which 90 were metastases and 5 primary liver cancer. Similarly, Mau identified, in 1901, 246 hepatic malignancies among 8,587 autopsies performed in Hamburg, Germany, including 242 metastases and 4 primary liver cancers. Riesenfeld (1868) diagnosed liver cancer in 2.3 % of autopsies performed in Berlin between 1864 and 1868. Among 24,400 consecutive autopsies performed at Bellevue Hospital, New York, from 1906 to 1936, 62 cases of primary hepatic carcinoma were identified (Gustafson 1937). Between 1850 and 1950, many publications were written on single cases and small series, and numerous later studies and reviews have then addressed issues of occurrence patterns and epidemiology of HCC.

Clinical Features

General Features

In early HCC, many patients are asymptomatic. In the absence of distinct complications, symptoms and signs in symptomatic patients are nonspecific and in part related to underlying chronic liver

disease, in particular hepatic cirrhosis. They include upper abdominal discomfort or pain, effects of hepatomegaly, malaise, anorexia, weight loss, and anemia (Berman 1959). In one European study, malaise (85 %), weight loss (78 %), anorexia (67 %), and hepatomegaly (84 %) were common findings at presentation (Kaczynski et al. 2005). In advanced disease, signs of hepatic failure and jaundice may ensue. In patients with underlying cirrhosis, sequelae of portal hypertension are often the leading clinical signs. Serologically, several markers for HCC and HCC recurrence have been identified, but AFP and its variants remains the most frequently used tumor marker for the diagnosis of HCC (Vogel et al. 1974; Gonzalez and Keeffe 2011; Nakao and Ichikawa 2013). However, a significant proportion of HCC patients do not show elevated serum AFP levels (low-AFP HCC; Carr et al. 2010). Serum AFP is employed for monitoring patients' response to therapy. Specifically, monitoring of *Lens culinaris* agglutinin-reactive AFP (AFP-L3, the fucosylated variant of AFP) is useful for early detection of recurrent HCC (Okuda 2000; Giannelli and Antonaci 2006). Elevated serum AFP is not only a bystander, but the protein exerts distinct functions. HCC patients with high or very high AFP serum levels show a higher mortality rate, probably related to a tumor growth-promoting activity of AFP (Li et al. 2011). It was earlier reported that AFP has immunosuppressive properties and induces spontaneous T and B lymphocyte responses in HCC patients. These responses are related to distinct immunogenic epitopes of the AFP molecule (review: Bei and Mizejewski 2011). AFP is also capable to activate monocytes and to augment phagocytic capacity of both monocytes and granulocytes (Kong et al. 2012), but abolishes the activation of natural killer cells by inhibiting the function of dendritic cells (Yamamoto et al. 2011).

Assessment of des-gamma-carboxy prothrombin (PIVKA-II), an abnormal prothrombin secreted by HCC, by sensitive assays has an important place in the diagnosis and follow-up of HCC (Takikawa et al. 1992; Bertino et al. 2012). In one study of 116 HCC, PIVKA-II was detected in serum in 54.3 % of patients and the concentration showed a positive correlation with tumor size (Takikawa et al. 1992). Further serum markers for HCC include glypican-3 and Golgi protein 73 (Giannelli and Antonaci 2006; Tian et al. 2011). Serum carcinoembryonic antigen (CEA) is raised in part of HCC patients (Macnab et al. 1978). For small or early HCC, reliable serum markers have not yet been established (Talwalkar and Gores 2004).

Paraneoplastic Syndromes

Hepatocellular carcinomas can be associated with a wide array of paraneoplastic syndromes (Table 2).

Complications

HCC may cause several types of complications. Rupture of HCC is a particularly severe

Table 2 Paraneoplastic syndromes associated with hepatocellular carcinoma

Hematologic paraneoplastic syndromes

Acquired von Willebrand disease
Cryofibrinogenemia
Combined paraneoplastic syndromes
Fever of unknown origin (FUO)

complication of this neoplasm and bears a high mortality. Rupture may occur spontaneously or following blunt abdominal trauma (Ong and Taw 1972; Chearanai et al. 1983; Van Landingham et al. (1985); Clarkston et al. (1988); Kanematsu et al. (1992); Chen et al. (1996); Castells et al. (2001); Chedid et al. 2001; Polat et al. 2005; Lai and Lau 2006; Kim et al. 2008). Spontaneous rupture of HCC can also occur in pediatric HCC (Nejmeddine et al. 2010). Localization of tumor to the left lobe and expansion of HCC outside the liver surface are risk factors for tumor rupture (Chen et al. 1995). Spontaneous rupture of HCC with hemoperitoneum is a rare condition in Western countries (Pombo et al. 1991; Chedid et al. 2001), while over 10 % of patients with HCC may experience tumor rupture in certain regions of Africa and Asia (Nagasue and Inokushi 1979). Spontaneous rupture of HCC was found to be the cause of death in only 3 % of patients in one study of 530 HCC patients (Kaczynski et al. 2005). Disruption of the tumor surface and a tear in a parasitic feeding artery are typical causes of HCC rupture (Chen et al. 1995; Kim et al. 2008). Vascular injuries that favor spontaneous rupture include degradation of collagen in the vascular wall (Zhu et al. 2001, 2002) and immune complex-induced damage of elastic lamellae (Zhu et al. 2004, 2006). Risk factors for HCC rupture included underlying disease such as hypertension and cirrhosis, a tumor size exceeding 5 cm, tumor protrusion from the liver surface, vascular thrombus, and extrahepatic invasion (Miyoshi et al. 2011; Zhu et al. 2012). HCC rupture can cause massive hemoperitoneum (Gibbons and Bell 1963). Parts of HCC present with jaundice, which is a negative prognosticator. In a minority of jaundiced patients, hyperbilirubinemia is due to biliary obstruction caused by the tumor, a situation outlined in more detail below. In the majority of patients, however, jaundice is caused by hepatic insufficiency caused by tumor and/or associated liver cirrhosis. Among 530 HCC patients with clinically detectable jaundice, 481 had jaundice due to hepatic insufficiency and 49 patients had obstructive jaundice. Patients with hepatic insufficiency had extremely poor prognosis, and 90 % of them died within 10 weeks of first presentation (Lau et al. 1997).

Imaging Features

Imaging features of HCC have been described in detail in numerous publications and are not specifically dealt with in this chapter (Okuda 1980a; Vermess et al. 1985; Stevens et al. 1996; Lee et al. 2011). Diagnostic imaging of HCC has recently undergone marked progress, mainly due to the introduction of the ultrasound contrast agent Sonazoid used in contrast-enhanced US (CEUS) and MR techniques employing a liver-specific gadolinium MR contrast agent (Ogawa et al. 2006; Xu et al. 2011; Tanaka et al. 2014; review: Kudo 2011).

Pathology

Introduction

As outlined in the paragraph on classification, HCCs are characterized by several distinct macroscopic patterns. The preparation and documentation of specimens for the identification of gross features has been standardized (Ruby 2000), as has the reporting of tissues removed (Dabbs et al. 2004; Association of Directors of Anatomic and Surgical Pathology 2005). Similarly, the definitions and nomenclature of nodular liver cell lesions has been standardized in a consensus panel (International Working Party 1995). In this paragraph, the morphology of advanced HCC is discussed, while the pathology of early and small HCC (Wanless 2007) is discussed in a separate chapter.

Selected References Rindfleisch 1878; Eggel 1901; Wegelin 1905; Rosenberg and Ochsner 1948; Edmondson and Steiner 1954; Edmondson 1955; Berman 1959; Patton and Horn 1964; Foster and Berman 1977; Mori et al. 1980; Anthony 1999; Kai et al. 2012.

Both the macroscopic growth patterns and the histopathologic presentation of HCC vary as a function of geography and genetic background, and between individual patients (Okuda et al. 1984; Okuda 1997). There are certain geographic specificities in regard to the presentation of diffuse and other variants of HCC and the type of underlying liver disease. This issue has been outlined by Okuda (1997) who emphasized that there are significant global variations of clinicopathologic features of HCCs, based on comparative studies of patients from Japan, Los Angeles, and Pretoria in South Africa (Okuda et al. 1984). For example, most patients from Japan show HCCs growing in an expanding fashion, with formation of a fibrous capsule, while capsule formation was very uncommon in South African Blacks. Depending on its gross growth patterns, primary HCC can involve one liver lobe or both liver lobes, whereby bilobar involvement had been found more frequently in HCC not associated with cirrhosis (Ho et al. 1981).

Classifications

Clinical Classifications

Several classifications of HCC are based on clinical and staging data (Llovet et al. 2003; review: Llovet 2007). The Barcelona Clinic Liver Cancer (BCLC) classification is an important classification for the clinical management of HCC and design of trials, endorsed by EASL and AASLD guidelines. It links stage stratification with a recommended therapy strategy. Other systems include the Cancer of the Liver Italian Program (CLIP) investigators, the Chinese University Prognostic Index (CUPI), and French staging systems, forming scoring systems predicting outcome in patients with advanced-stage disease.

Classifications Based on Macroscopic Presentation and Growth Patterns

Virchow separated primary from secondary liver cancer. However, in the thesis of Riesenfeld performed under Virchow's guidance (1868), gallbladder cancer was still regarded as a primary liver cancer. A fundamental step into the direction of modern pathology classifications of HCCs was the work of Eggel (1901) who divided liver cancers into nodular, massive, and diffuse forms. This and subsequent classifications are discussed in detail in the paragraph on tumor macroscopy.

Originally, primary HCC was divided into two major macroscopic groups, i.e., nodular carcinoma formed of discrete nodules of varying size and massive carcinoma, consisting of one large tumor mass. Hanot and Gilbert (1888) divided HCCs into three forms, i.e., nodular cancer ("cancer nodulaire," several to numerous nodules of varying size), massive cancer ("cancer massif," one large tumor mass), and cancer with cirrhosis, i.e., they proposed a classification based on tumor morphology on the one hand and underlying liver disease on the other hand. This system had

intrinsic inconsistencies of logic and was, therefore, applicable only with difficulty or not at all, because also nodular and massive cancers of course develop in cirrhotic livers. Already Eggel (1901) put his finger on the fact that Hanot and Gilbert themselves allocated one cancer in cirrhosis each to a nodular and a massive tumor.

A major step ahead is based on the novel classification of Eggel (1901), as further outlined below. Early comments on this classification were reviewed by Wegelin (1905). Today we know that HCCs show a characteristic spectrum of macroscopic growth patterns, comprising usual and unusual gross appearances (review: Kai et al. 2012). The macroscopic growth of HCCs can be classified according to several criteria (Table 3).

Table 3 Classification of HCC growth patterns

Eggel's classification (1901):
Nodular HCC
Massive HCC
Diffuse HCC
Kaufmann's classification (1958)
Large massive node
HCC in cirrhotic liver
(a) Multiple nodules
(b) Diffuse growth
(c) Combination of nodules and growth
Okuda classification (1984)
Expanding
Spreading
Multifocal
Surgical classification:
Invading lesions ("invaders")
Expanding lesions ("pushers")
Pedunculated lesions ("hangers")
Classification of the Liver Cancer Study Group of Japan (LCSGJ):
Nodular HCC (distinctly nodular type)
Simple nodular (SN) type
Simple nodular type with extranodular growth (SNEG)
Confluent multinodular type (CMN)
Nodular HCC
Small nodular type with indistinct margins (vaguely nodular type)
Classification according to size:
Small HCC
Solitary large HCC

In Eggel's investigations, nodular HCCs accounted for 64.6 %, massive for 23 %, and diffuse cancers for 12.4 %. Herxheimer in Germany (1930) arrived at similar figures (65 %, 28 %, and 7 %, respectively). In rare instances, a mixture of all three patterns is present. Eggel noted that mainly the massive form of HCC resulted in marked hepatomegaly, but hepatomegaly was in fact found in most of Eggel's original cases. He described a patient with a liver weight of 7 kg, but Herxheimer (1930) cites an observation by Bruzelius and Schwink reporting a liver cancer causing a liver weight of 14 kg. In some of the cases, the macroscopic presentation is dominated by liver cirrhosis, and tumor is only detectable on cut sections.

Eggel (1901) divided HCCs into two histologic groups (carcinoma solidum and carcinoma adenomatosum) and classified the macroscopic growth patterns, also based on the concepts of Hanot and Gilbert, into three patterns, i.e., nodular, massive, and diffuse. Eggel's classification of HCCs, proposed more than 100 years ago (Eggel 1901), was widely used, however, mainly for autopsy studies and less for surgical cases. The nodular type is grossly characterized by single or multiple discrete nodular neoplasms with a clear demarcation. Massive HCCs present as a large mass that almost completely replaces the left or right liver lobe. The diffuse type of HCC is characterized by a diffuse infiltration of the liver by numerous small to minute cancer nodules that macroscopically somewhat resemble cirrhotic nodules. The nodular form is the most common and is, based on data in the literature, present in 64.6 % of cases, while the massive form was found in 23 % and the diffuse form in 12.4 %. The nodular category of Eggel is sometimes applicable to surgical specimens with some difficulties only. For the adequate classification of HCC in hepatectomy specimens, the Liver Cancer Study Group of Japan proposed to divide nodular HCCs in subclasses. In 1984, Okuda and coworkers proposed a simple classification based on gross anatomical features of HCC from three disparate geographic areas, common major patterns being expanding, spreading, and multifocal (Okuda et al. 1984). Growth patterns were used as a stage

classification, e.g., the expansive-invasive-disseminative growth staging classification (Zhu et al. 2013).

Molecular Classifications

Based on the continuously growing recognition of distinct molecular signatures found in HCC, attempts to classify HCC according to molecular features have been and are undertaken (Boyault et al. 2007; Katoh et al. 2007). Katoh and coworkers (2007) found that HCC is composed of several genetically homogeneous subclasses, each having characteristic genetic alterations. Molecular signatures are associated with distinct macroscopic growth patterns. For example, EpCAM was predominantly expressed in the confluent multinodular (CM) type of HCC which is an aggressive phenotype with poor outcome (Murakata et al. 2011). In the setting of an integrative transcriptome analysis, three robust HCC subclasses termed S1, S2, and S3 have been identified, and each of these molecular subclasses correlated with clinical parameters, including tumor size, extent of cellular differentiation, and serum AFP levels. The S1 subclass reflected aberrant activation of the WNT signaling pathway, S2 proliferation, as well as MYC and AKT activation, and S3 was associated with hepatocyte differentiation (Hoshida et al. 2009).

Macroscopic Pathology of Main Gross Patterns of HCC

Size of Hepatocellular Carcinoma

The size of HCC at diagnosis varies markedly, ranging from tumors defined as early or small HCC (see the respective chapter) to very large lesions exceeding 20 cm in diameter and replacing most of the liver. Multinodular tumors with a liver weight exceeding 10 kg have been reported (Cooper et al. 1935), suggesting that, similar to other organs, HCC can grow to enormous size without leading to death through metastatic disease. HCC occurring in normal livers were, at least in part of analyses, significantly larger in average tumor size than those occurring in cirrhotic livers (Kishi et al. 1983).

Nodular HCCs

Nodular cancer in HCCs forms well-circumscribed, more or less spherical masses, mostly in a cirrhotic liver. These nodules most commonly either form simple and firm to friable masses of variable color or are closely grouped or form irregular nodular masses (Berman 1959). The color as seen on cut sections is yellowish, yellow-green, frankly green (in tumors with marked bile accumulation; "green hepatomas"), or gray to reddish. The green color of bile-rich lesions typically becomes more strong after formalin fixation. In cases where nodular cancers form groups or clusters of nodules, the color may vary from one nodule to the other, reflecting variations in differentiation (e.g., bile production) caused by progressive genomic instability or variations in regressive phenomena. Such differences can sometimes be found within one and the same nodule. Frequently, bile-storing green HCC nodules stand out against the non-bile-stained background of the cirrhotic liver. Large nodules can contains extensive hemorrhage, sometimes leaving a dark red-blue nodular lesion resembling a hemangioma (Figs. 1, 2, 3, 4, 5, 6, 7, 8, and 9). Clustered lesions form HCCs of the confluent multinodular type. In some cases, numerous nodules are present, and this presentation may be difficult to distinguish from multiple intrahepatic metastatic spread (Fig. 10). Small nodules are usually more firm than large one. The variable consistency depends on the ratio between preserved or necrotic epithelial cells versus stroma, the latter inducing firmness of the lesions when present in significant amounts. Large nodules are often soft and friable, whereby the centers are softer than the periphery owing to central necrosis. When cutting through large nodules, a creamy matter of necrotic tissue typically sticks to the blade of the knife. Macroscopically, nodular lesions tend to show an expanding growth pattern and therefore display a sharp border, but there also

Fig. 1 Nodular hepatocellular carcinoma in a cirrhotic liver. The tumor mass displays an expanding growth pattern and shows a rather homogeneous cut surface (formalin-fixed resection specimen)

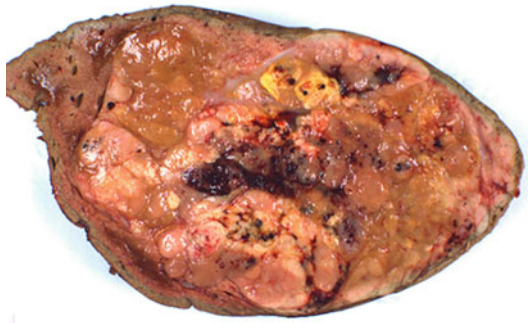

Fig. 2 Nodular hepatocellular carcinoma with an expanding growth pattern in a non-cirrhotic liver. The heterogeneous cut surface shows central hemorrhage and few *yellow* areas with necrosis and fatty change

lesions with a blurred border due to a macroscopically invasive phenotype. Mainly in large tumors, central necrosis, sometimes with cyst formation, is often impressive.

Small HCCs with a diameter of less than about 2 cm are classified into two major types, i.e., small nodular type with indistinct margins (SN-IM, vaguely nodular type) and the distinctly nodular type (SN-DN; Kojiro and Nakashima 1999). SN-IM may, due to its blurred margins, be difficult to distinguish from surrounding cirrhotic nodules and/or nodular precursor lesions. SN-IM are histologically often well-differentiated lesions with so-called replacing growth at the periphery. The tumors can contain portal tracts in markedly reduced numbers. These portal tracts are deformed by invasive growth of HCC, the so-called stromal

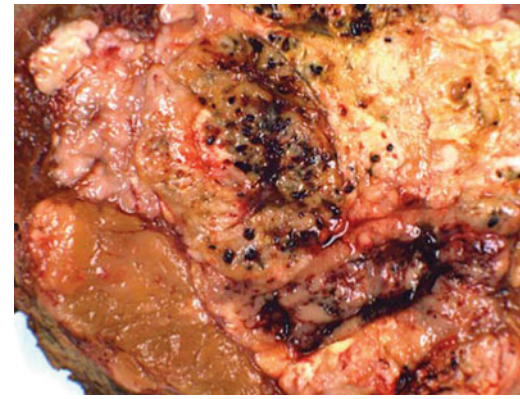

Fig. 3 Cut surface of a nodular hepatocellular carcinoma at higher magnification. This tumor is highly heterogeneous: the *greenish* part to the *left lower corner* exhibits bile accumulation, while the *whitish-pink* parts showed less differentiated neoplastic tissue. This tumor heterogeneity can cause bioptic sampling errors in regard to typing and grading. Extensive necrosis and hemorrhage are observed (*center* and *upper right corner*)

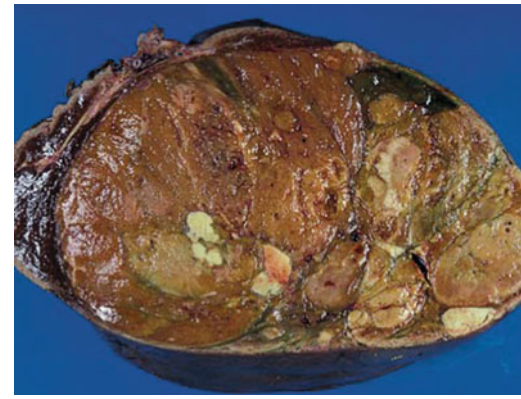

Fig. 4 Large hepatocellular carcinoma, nodular type with multinodular interior composition. The cut surface is characterized by *brown* and *greenish* areas (bile accumulation) and several *white* necrotic foci. In this non-fixed specimen, tumor tissue bulges from the cut surface

invasion, which is a very important diagnostic element. In some studies, these lesions have been termed, early HCC (Kojiro 2007), a lesion further discussed in a separate chapter.

As seen in Table 3, Japanese investigators have subdivided nodular HCCs into three subcategories, in order to cope with imaging findings surgically resected HCCs (The Liver Cancer Study Group of Japan (LCSGJ) 2003). In this

Fig. 5 Nodular hepatocellular carcinoma with an expanding growth pattern and marked bile accumulation. The *green* discoloration of bile-storing HCC becomes more intense in formalin-fixed specimens, as in the present case

Fig. 6 This nodular hepatocellular carcinoma exhibits a striking pattern on the cut surface, with a *green* part rich in bile being well-separated from a *whitish* part histologically less differentiated and showing necrosis and hemorrhage. Several satellite nodules are present

Fig. 7 In this hepatocellular carcinoma, the presence of three separate subunits showing different colors is striking. The *dark-green* part was a well-differentiated HCC with marked bile accumulation, while the *whitish* part revealed moderately differentiated HCC with necrosis. Within this part, a nodule with poor differentiation emerged, suggesting clonal evolution in the setting of progressive genomic instability

Fig. 8 Nodular hepatocellular carcinoma in cirrhotic liver, resection margin. The expanding lesion is situated close to the margin, but exterior surface appears intact (fixed resection specimen)

classification system, SN-DN is further subdivided into three subtypes, namely, the simple nodular type (SN), the simple nodular type with extranodular growth (SNEG), and the confluent multinodular type (CMN). This subclassification has an impact on prognosis. Based on 65 resected HCCs with a diameter of less than 5 cm, the median time to recurrence and duration of disease-free survival were significantly shorter for CMN lesions than in the other two groups (Hui et al. 2000). SN is characterized by a sharply

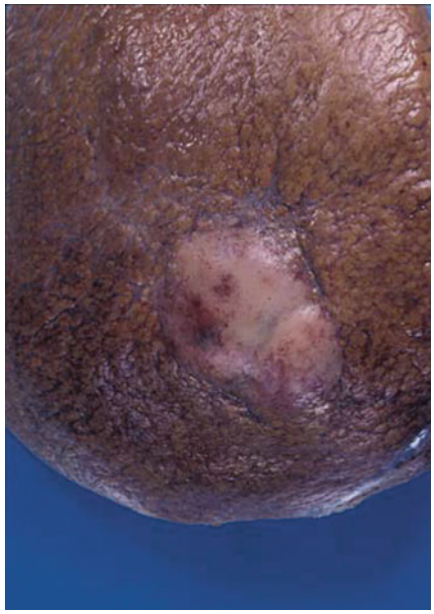

Fig. 9 Nodular hepatocellular carcinoma in a cirrhotic liver. This tumor reaches to the capsular surface of the liver, resulting in slight bulging. The *red-brown* speckles on the tumor are tiny hemorrhages

Fig. 10 Hepatocellular carcinoma with a multinodular growth pattern in a non-cirrhotic liver. In situations with a dominant larger tumor associated with several smaller nodules, intrahepatic metastasis has also to be considered

delineated, more or less spherical nodules, often well differentiated and encapsulated, with no macroscopic evidence of extranodular growth or vascular invasion. SNEG nodules include those with extranodular HCC foci, growing beyond the capsule of the principal nodule, nodules showing vascular invasion, and/or small metastases near

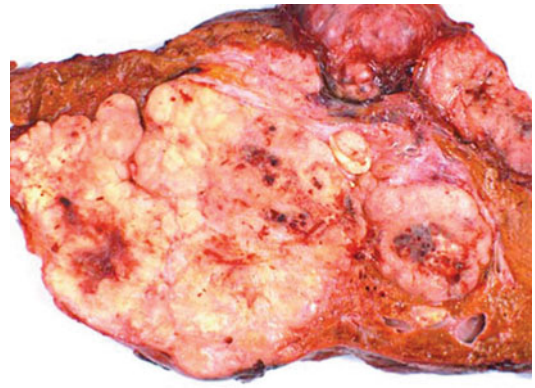

Fig. 11 Hepatocellular carcinoma with a massive growth pattern. The liver is extensively infiltrated by in part confluent tumor nodules that show necrosis and multiple hemorrhages

the main nodule. CMN HCCs result from joining together of few to multiple small tumor nodules. CMN is not encapsulated. Portal tracts are entrapped between the clustered nodules. Vascular invasion and/or intrahepatic metastasis are more common than in the simple subtype.

Massive Hepatocellular Carcinoma

Massive HCC is often found in a markedly enlarged liver that is deformed by large, irregularly shaped tumor masses (Fig. 11). On sections, the involved liver lobe may be almost completely occupied by a usually whitish mass with numerous necroses and hemorrhages, associated with secondary or satellite lesions and gross vascular invasion (Goldberg and Wallerstein 1934; Berman 1959). In part of the tumors, the distinction between a nodular pattern with confluence and massive-type HCC may be difficult. In principle, nodular HCC with multiple nodules and occupying an entire liver lobe becomes a massive-type HCC (Kojiro 2006).

Diffuse Hepatocellular Carcinoma

The diffuse type of HCC is a rare growth variant of this cancer (Okuda et al. 1981). Diffuse HCC is macroscopically characterized by a liver that is

studded with numerous minute, uniformly sized nodules, with homogeneous involvement of the organ. HCC presenting with this patterns is usually poorly differentiated. As diffuse HCC usually develops in cirrhotic livers, the small tumor nodules may macroscopically be confounded with cirrhosis nodules or other small regenerative nodules. In some cases of diffuse-type HCC, the cancer nests can only be detected histologically. The tumor often invaded large portal vein branches and displays invasion of numerous small intrahepatic vessels, suggesting vascular spread as a pathogenic mechanism of the diffuse growth pattern. A prominent clinical feature of diffuse HCC was rapid deterioration of patients' general condition, associated with rapid enlargement of liver size and terminating in hepatic failure (Okuda et al. 1981).

Pedunculated Hepatocellular Carcinoma

Pedunculated hepatocellular carcinoma (P-HCC) is defined as a form of HCC protruding from the liver as a roughly polypoid or spherical mass with or without a clearly delineated vascular pedicle (Anthony and James 1987; Kohno et al. 1987; Nakashima and Kojiro 1987; Tsoulidis et al. 2007; Zhang et al. 2011). Baer and coworkers (1995) defined HCC as pedunculated if they showed a real pedicle with pedicle vessels and as dependent HCC if over 50 % of their surface growth was located extrahepatically. The term dependent was coined by us to describe, in a clinical-surgical setting, tumors that grow with a base adjacent to the free liver edge and hanging in their entirety, rendering these lesions relatively easy to resect (Baer et al. 1989). P-HCC does not differ significantly from other growth patterns with respect to associated liver disease (Yeh et al. 2002a). P-HCC; (HCC with extrahepatic growth; clinically-surgically a "hanging lesion" or "hanger"; Baer et al. 1995) was first described at the end of the nineteenth century (Roux 1897), followed by a report in 1934 (Goldberg and Wallerstein 1934). The term pedunculated HCC was coined in 1954 (Edmondson and Steiner 1954). These authors regarded P-HCC connected with liver and showing extrahepatic growth with a pedicle as an exception, and relatively few cases were reported in the Western literature until recently, but numerous cases of P-HCC have been published from Japan. Okuda reported ten cases of P-HCC among 4,031 cases of HCC observed in Japan (Okuda 1980b). Until 1981, 20 cases were reported from Japan and several other followed (Nishizaki et al. 1993; Yan et al. 2009). In Japan, P-HCC accounts for only 0.24–4.2 % of all HCC (Okuda 1980; Horie et al. 1983; Yeh et al. 2002). It is estimated that P-HCC overall accounts for 0.24–3.0 % of all HCC (Horie et al. 1983).

Macroscopically, P-HCCs are in most cases solitary neoplasms that sometimes grow to a very large size, e.g., having a diameter of 23 cm (Baer et al. 1995). P-HCC is sometimes subclassified into a subtype I with a pedicle and a subtype II lacking a clearly visible pedicle (Figs. 12, 13, 14, 15, 16, and 17; Nakashima et al. 1983). P-HCC is more often observed in the right liver lobe (Nishizaki et al. 1993), and many tumors arise from the hepatic inferior surface or hepatic rim (Horie et al. 1983). Markedly pedunculated subtype I lesions manifest as polypoid masses that freely hang in abdominal cavity, most often the right cavity, large or giant tumors sometimes extending into the right iliac fossa (Karatzas et al. 2011). The size of P-HCC varies considerably, and also nodules having a diameter

Fig. 12 Extrahepatic hepatocellular carcinoma connected to the liver by a thin vascular pedicle (pedunculated hepatocellular carcinoma, type 1)

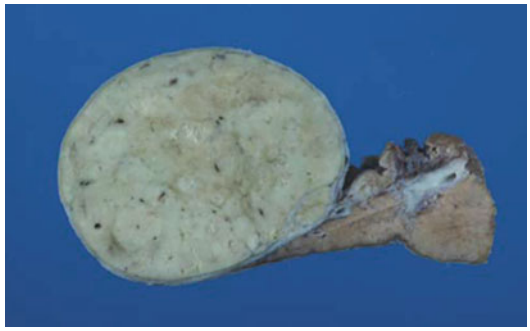

Fig. 13 Cut surface of a pedunculated hepatocellular carcinoma (type 1). The well-delineated, encapsulated tumor nodule is connected to the liver through a stalk or pedicle containing blood vessels

Fig. 14 Hepatocellular carcinoma situated at the anterior margin of the liver, to the left of the gallbladder. Part of the tumor mass is situated outside the cirrhotic liver substance, however, without a vascular pedicle. Such lesions have been termed type 2 pedunculated HCC

of 3 cm can produce an extrahepatic growth, but larger tumors are more common, some reported examples exceeding a diameter of 20 cm. The spherical or dome-shaped tumors are covered by the liver capsule which is smooth and in most cases devoid of adhesions of inflammatory changes, although adhesions to the transverse colon have been found in some cases (Horie et al. 1983). In the subcapsular tissue, dilated veins may be noted, sometimes forming a prominent network of congested vessels. Mainly in cases with well-developed pedicles (subtype I lesions), gross invasion of the liver substance is lacking.

Histologically, P-HCCs share the morphology of other ordinary HCCs. Rarely, the histologic presentation deviates from ordinary HCC, e.g.,

Fig. 15 A large part of this nodular hepatocellular carcinoma in a cirrhotic liver has grown out of the liver substance. A rim of cirrhotic tissue forms a thin collar around the tumor, in the absence of a pedicle. Note the abnormal dilated blood vessels on the tumor convexity

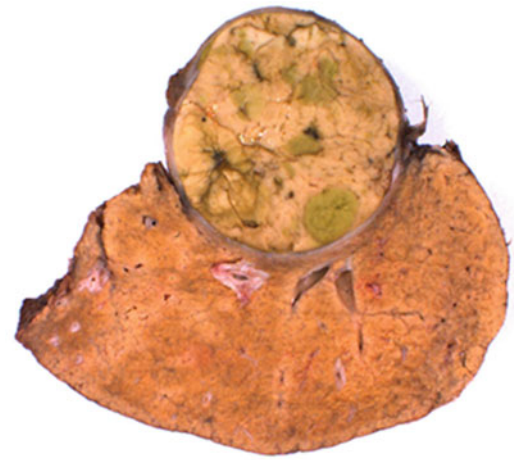

Fig. 16 Cut surface of type 2 pedunculated hepatocellular carcinoma. This tumor is demarcated from the liver substance by a thin pseudocapsule. The *greenish* nodules within tumor are areas with marked bile accumulation

showing a sarcomatoid component or presenting as a combined hepato-cholangiocarcinoma (Noh et al. 2012). In one patient, a giant P-HCC was synchronously associated with a hemangioma interposed between HCC and the liver capsule (Karatzas et al. 2011). P-HCCs were shown to have a more favorable biology of disease in comparison with other growth patterns, in part related

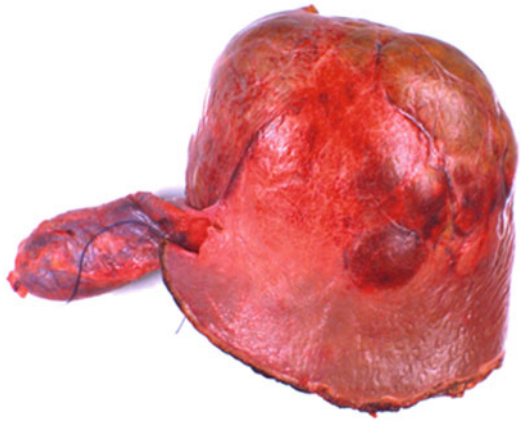

Fig. 17 Some type 2 pedunculated hepatocellular carcinomas reveal a morphology resembling exophytically growing focal nodular hyperplasia. The present tumor developed close to the insertion of the *round* hepatic ligament

to the higher proportion of well-differentiated tumors in the P-HCC group (61 %), the presence of a more prominent capsule, and the relative ease to obtain a wide resection margin (Yeh et al. 2002).

The pathogenesis of P-HCC has not yet been clarified. It has been proposed that this variant of HCC might arise from congenitally displaced lobules situated in Glisson's capsule (Goldberg and Wallerstein 1934). Other authors suggested an origin from accessory liver lobes (Gyotoku et al. 1980), as such lobes are often located to the right liver lobe and to its inferior surface. One theory proposed that some, or perhaps most, of right-sided P-HCCs represent fusion of the right liver lobe and para-adrenal or adrenal metastatic HCC, eventually based on vascular connections caused by adrenohepatic fusion (Okuda et al. 1998). In fact, extrahepatically growing HCC was fed by the adrenal arteries in two patients (Yoshimura et al. 1989; Kaneko et al. 1992). A pedunculated or dependent phenotype not only exists for HCC, but is also encountered with hepatic metastases and certain benign tumors and tumor-like lesions, e.g., focal nodular hyperplasia and giant hemangiomas (Baer et al. 1995).

Satellite Lesions

A series of 149 resected HCC showed satellite lesions in 19 % of cases. HCC with a single nodular type with extranodular growth and the confluent multinodular type more often displayed satellite lesions than the single nodular type or early HCC, and satellite lesions prevailed in tumors with poor differentiation. Most lesions (50 %) were located at 0.6–1.0 cm from the main tumor, whereas 33 % were 0.5 cm or less, and 17 % at 1.1–2.0 cm (Okusaka et al. 2002).

Bile Duct Invasion (Icteric-Type HCC)

A subset of HCC is characterized by bile duct invasion. In part of these patients, obstructive jaundice is a leading sign, but the condition is uncommon, with a reported incidence of 0.5–13 % in patients with HCC. Intrabiliary growth was found in 5.1 % of 257 HCC patients (Ikeda et al. 1997), while in another series of 549 HCC patients, gross evidence of bile duct invasion was present in only ten cases (Wang et al. 1999). Even small or very small HCC can cause intraductal growth (Lee et al. 2001). In case this intraductal tumor extends to the confluence region and/or the choledochus, obstructive jaundice ensues ("icteric-type HCC"; Lin et al. 1975; Lee et al. 2001; Huang et al. 2002).

Selected References Kojiro et al. 1982; Sastry et al. 1996; Yeh et al. 2004; Esaki et al. 2005; Huang et al. 2006; Ikenaga et al. 2009; Liu et al. 2011a; Yu et al. 2011; Paradis 2013b.

Mechanisms of obstructive jaundice comprise either the forming of a growing intraluminal tumor tissue plug, tumor tissue fragments admixed with bile and exudate, or intraductal accumulation of blood or coagulated blood masses derived from necrotic and hemorrhagic intraluminal tumor. Parts of intrabiliary tumors can detach and dislocated to more distal parts (Lam et al. 2009). This is mainly due to the loose texture of the tumors and their tendency to undergo necrosis. Acute tumor bleeding may

favor the detachment of fragments which are then transported along the biliary tract. In case the blood coagulates, tumor fragments are caught in this mass and either decay or continue with their growth, which however requires induction of a new vascular support. Macroscopically, these neoplasms appear as nodular lesions in close associated with a tumor mass located within the lumen of an often dilated intrahepatic bile duct. These intraluminal masses are sometimes called "bile duct thrombi," which is a misnomer. Small nodular or pluglike lesions are usually situated in one or two intrahepatic ducts, while large lesions may present as extensive biliary duct casts that obstruct large parts of ducts and also the biliary confluence. As intraductal tumors tend to further grow along the lumen, without significant infiltration of the duct wall (Yu et al. 2011), the involved segment of the duct is often enlarged into a fusiform shape. The intraductal tumors are usually hypervascular, with a distinct array of feeding vessels and a characteristic imaging presentation, with an early enhancement pattern on contrast-enhanced CT and MR images. In the course of dissection of a specimen, a continuum between the main tumor and its intraductal manifestation is detected in the majority of cases. However, there are few cases of intraductal HCC in which no extraductal tumor could be identified (Makino et al. 2006; Long et al. 2010; Abe et al. 2012). Intrabiliary growth is a risk factor for poor outcome in part of patients (Ueda et al. 1994), but in one investigation there was no significant difference in survival rates between patients with and without bile duct thrombi, although the rate of stage IV or portal vein invasion was significantly higher in patients with biliary tract invasion (Satoh et al. 2000). Even if HCC tumor "thrombus" is detected in major branches of bile ducts, outcome following surgery may be satisfactory in part of patients (Tantawi et al. 1996; Qin and Tang 2003; Qin et al. 2004; Esaki et al. 2005; Ebara et al. 2013; Moon et al. 2013). Intraductal HCC "thrombi" may present in a manner similar to polypoid cholangiocarcinomas. Intraductal ultrasonography can serve to separate these two lesions sharing an intraluminal growth pattern (Tamada et al. 2001). Intraductal HCC may also be mimicked by intraductal clots resulting from hemobilia (Casagrande et al. 1985). HCC invading large bile ducts has to be distinguished from the rare instances of ectopic HCC primarily developing in bile ducts (Hasegawa et al. 2002), and from HCC exerting compression of large duct followed by obstructive jaundice (Lee et al. 1988), or causing extrinsic stricture (Dusenberg 1997).

Histopathology

Introduction

Histologically, HCC presents with a wide array of phenotypes reflecting a complex histogenesis and varying as a function of early versus advanced disease The general or most common histologic features have been described and reviewed in numerous reports (Yamagiwa 1911; Lapis and Johannessen 1979; Schirmacher et al. 2001; Schlageter et al. 2014). In the present chapter, histologic features of classic, conventional, or "standard" HCC are discussed, whereas specific histologic phenotypes are treated in separate chapters. Main histologic and cytologic features of ordinary HCC are compiled in Table 4.

Histology of Well-Differentiated and Moderately Differentiated Hepatocellular Carcinomas

Well-differentiated HCC often grows in the form of liver cell plates that minimally deviate from the normal situation, i.e., having essentially a normotrabecular arrangement or having

Fat droplets (tumor cell steatosis)

trabecules two to three cells thick, or present as macrotrabecular structures with a width sometimes exceeding ten cells. In such situations, criteria that result in a diagnosis of well-differentiated HCC include nuclear crowding, cytoplasmic amphophilia or increased cytoplasmic basophilia, and microacinar formation (Kondo et al. 1989). Apart from cell plates, gyriform to cerebriform structures (Adelheim's gyriform structures), or solid cell nests, can occur. In HCCs, tumor cell plates often anastomose, and there are cell plates with slits, showing exterior palisading. In addition to plates and variant thereof, acinar (pseudoglandular) structures are often seen, the cells lining acini sometimes, but not often being prismatic (Kondo and Nakajima 1987). The lumina of the acini may contain bile, bile-stained fluid, or proteinaceous material. Mixed trabecular-acinar components are often encountered, and some acinar profiles can result in microcystic structures. Cell plates and acini are almost never separated by stromal tissue (Figs. 18, 19, 20, 21, 22, 23, and 24).

Well-differentiated HCC and part of moderately differentiated HCC are characterized by cells that closely resemble normal hepatocytes and by a trabecular growth pattern (Fischer 1903; Oertel 1905; Von Albertini 1974). The size of the cells of ordinary HCC are about the size of normal hepatocytes, sometimes slightly larger or smaller. Cells in the center of nodules may be smaller than those at the periphery. In contrast to normal or regenerating hepatocytes, HCC cells are more often slightly amphophilic, and also pale cells are encountered (Wegelin 1905). Such HCC are the most difficult to diagnose in biopsies, but can also be diagnosed by means of fine-needle aspiration biopsies.

Selected References Jacobsen et al. 1983; Bell et al. 1986; Huang et al. 1996; Soyuer et al. 2003; Wee and Nilsson 2003; Chhieng 2004; Yang et al. 2004; Wee 2005, 2011, 2013.

The morphology of the tumor cells together with a sometimes normotrabecular pattern may render diagnosis of malignancy difficult, and the detection of an infiltrative growth is crucial, as emphasized by Masson in 1956. A high level of differentiation occurs in both advanced and small/early HCC (Tomizawa et al. 1995). Tumor cell nuclei generally retain the basic morphology of hepatocyte nuclei, but they are often enlarged and more vesicular, the chromatin is more coarse, heterochromatin at the nuclear membrane is more prominent, and nucleoli are larger. HCCs display an increased number of binucleated cells and of polyploidy nuclei, whereas well-differentiated HCCs, in contrast to HCCs with a

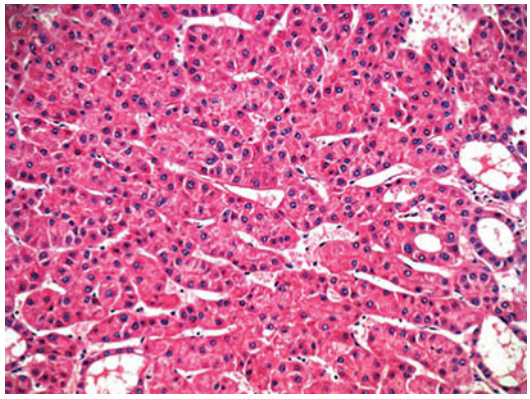

Fig. 18 Hepatocellular carcinoma, predominantly trabecular type. In this well-differentiated neoplasm, tumor cell plates show an abnormal width, although parts of the plates are rather slender. Few acinar/pseudoglandular structures are present (to the *right* and *bottom*). The cell plates are separated by sinusoid-like vascular channels (hematoxylin and eosin stain)

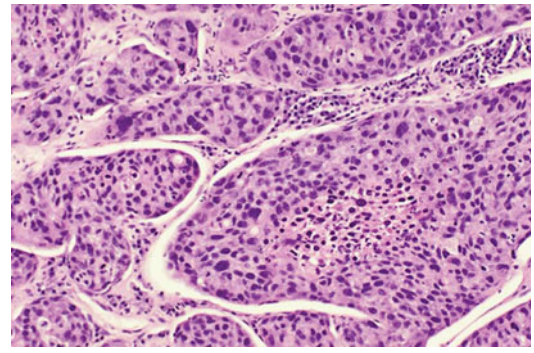

Fig. 20 In trabecular hepatocellular carcinoma with a macrotrabecular pattern, cells in inner parts of the plates may suffer from hypoxia due to a large distance to the next vascular channel, causing focal ischemic necrosis with karyopyknosis and karyorrhexis (to the *right* of the *middle*, hematoxylin and eosin stain)

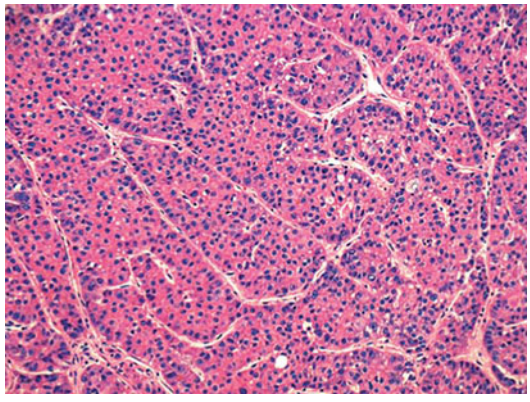

Fig. 19 In this trabecular hepatocellular carcinoma, tumor cell plates are large, sometimes exceeding a thickness of ten cells (macrotrabecular pattern). The neoplastic cells are hepatocyte-like and well differentiated (hematoxylin and eosin stain)

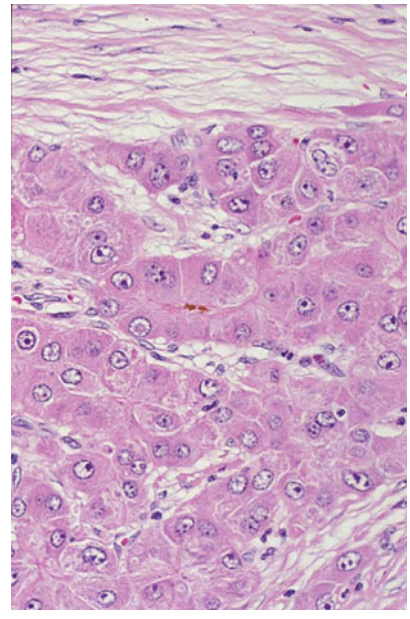

Fig. 21 This well-differentiated trabecular hepatocellular carcinoma with hepatocyte-like cells and abnormally enlarged nuclei shows deposition of *brown-yellow* bile in canaliculus-like structures (close to center of figure, hematoxylin and eosin stain)

grade 3, only rarely show multinucleated cells. Multinucleated cells in HCCs were described in early works on these tumors already (Nazari 1905). Nucleoli are prominent, and two to three of them may be observed (Smetana et al. 1972). Mitotic figures are usually not common in well-differentiated tumors; they are, e.g., less frequently present than in regenerating liver.

Morphometry disclosed that cell size in normotrabecular HCC is slightly reduced in comparison with normal hepatocytes or regenerative hepatocytes (Kondo et al. 1988; Nagato et al. 1991). The tumors may show a slight decrease in the density of the reticulin network,

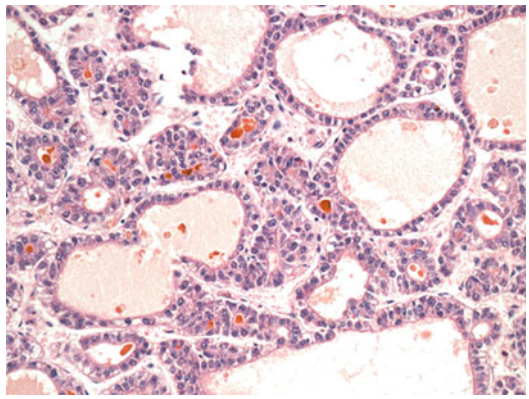

Fig. 22 Hepatocellular carcinoma, acinar/pseudoglandular type. The neoplastic cells form spherical spaces that may contain bile and/or a proteinaceous fluid (hematoxylin and eosin stain)

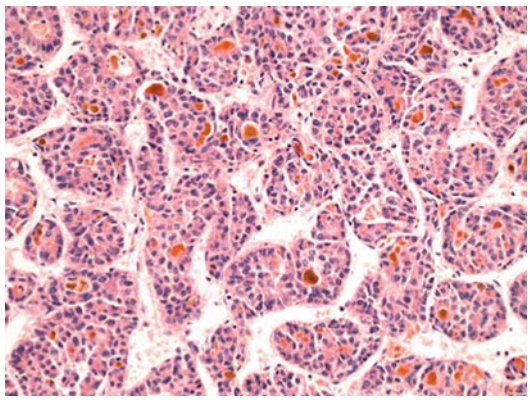

Fig. 23 Hepatocellular carcinoma with incomplete acinus formation. There is marked bile accumulation within dilated canaliculi and protoacini. A prominent sinusoidal vascular network is present (hematoxylin and eosin stain)

irrespective of the absence of macrotrabecular structures. Useful cytology features for well-differentiated HCC included small tumor cell size with an increased nuclear/cytoplasmic ratio; striking similarity of tumor cells to hepatocytes; a monotonous aspect of atypia; the presence of tumor giant cells, intracytoplasmic vacuoles, bile production, acinar formation, and narrow cell plates; a tendency for cell dissociation; and the presence of sinusoidal endothelial cells. In contrast, poorly differentiated HCC were characterized by cell dehiscence, large cells with ovoid nuclei, dyshesive pleomorphic cells, a thickened

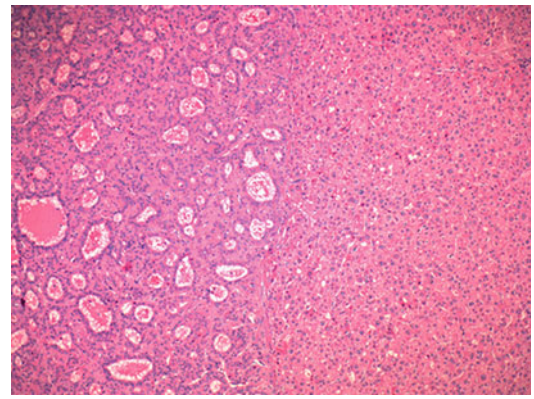

Fig. 24 Mixed acinar and trabecular/solid hepatocellular carcinoma. An acinar area (*left*) exhibits an abrupt transition into a non-acinar area (*right*, hematoxylin and eosin stain)

nuclear membrane, and one or more prominent nucleoli (Wee et al. 1991, 1994). A high level of differentiation sometimes includes large HCC in their entirety, but well-differentiated tumors may with time switch to components of lesser differentiation. This heterogeneity as to differentiation causes a bias in the interpretation of needle biopsies and fine-needle aspirates, due to sampling errors. A differentiation switch may already occur in small lesions. When well-differentiated small/early HCC reach a diameter of 1.0–1.5 cm, areas of lesser differentiation with increased proliferative activity may evolve (Kojiro and Nakashima 1999). It must be emphasized that many if not most advanced HCC are heterogeneous with respect to growth patterns, cellular differentiation, and grade, an observation that was already made by well-known authors of earlier literature (Von Albertini 1974).

Histology of Poorly Differentiated Hepatocellular Carcinoma

In contrast to well-differentiated or moderately differentiated HCC, high-grade HCCs with poor differentiation are less capable to form trabecular structures or plates, and usually no acinar profiles, the neoplastic cells having lost polarity and the junctional apparatus to generate more complex patterns. The cells are heterogeneous as to the

size, shape, and structure. Some tumors consist of small "basophilic" cells and resemble any anaplastic carcinoma, while others have medium-sized cells with an amphophilic cytoplasm, no longer of the hepatocyte type. A minority of tumors show pleomorphic or giant cells with highly atypical nuclei, with prominent nucleoli and numerous, in part abnormal mitotic figures. Poorly differentiated liver cancers may be difficult to classify as hepatocyte cancers, and only immunohistochemistry will solve the problem.

Cytologic Features

Cell Polarity

Well-differentiated and moderately differentiated HCC consists of neoplastic cells that recapitulate, at least in part, the polarized phenotype of normal hepatocytes (Zegers and Hoekstra 1998; Treyer and Münsch 2013). Subsets of tumor cells are oriented with a basolateral domain toward sinusoidal channels, whereas a canalicular-like domain can face the lumen of acinar structures.

Pleomorphism and Giant Cells

The presence of multinucleated or pleomorphic giant cells was already described and depicted in detail in the textbook of Ewing (1922). As outlined below (paragraph on grading), grade 3 HCCs often show enlarged cells with several nuclei. These cells have to be distinguished from the multinucleated and highly abnormal, pleomorphic cells that occur in part of poorly differentiated HCCs.

Tumor Cell Inclusions

Part of HCC cells harbor cytoplasmic globules or inclusions (Figs. 25 and 26). They comprise eosinophilic globules that are either PAS-positive or PAS-negative, hyaline globules, and pale bodies (Keeley et al. 1972; Underwood 1972; Grimelius et al. 1977; An et al. 1983; Wang and Liu 1986; MacDonald and Bedard 1990; Fukunaga et al. 1996; Nayar et al. 2000). These inclusions have to be distinguished from Mallory-Denk bodies (Pappenheimer and Hawthorne 1936). In one study, hyaline intracytoplasmic globules were detected in 15.2 % of HCC cases, mainly in male patients with a mean age in the fifth decade. HCC with hyaline globules more often showed tumor necrosis in comparison with HCC lacking globules (Cohen 1976), but the presence of hyaline globules was not related to tumor differentiation (Nayar et al. 2000). It was assumed

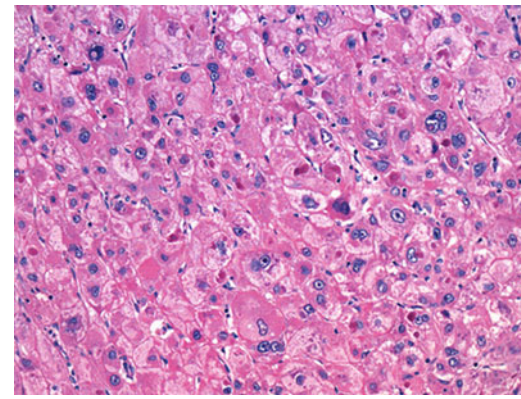

Fig. 25 Trabecular hepatocellular carcinoma with several types of cytoplasmic inclusions. Apart from pale eosinophilic inclusions, several Mallory-Denk bodies are observed. The latter appear as dark and homogeneous, dense eosinophilic bodies with irregular shape (hematoxylin and eosin stain)

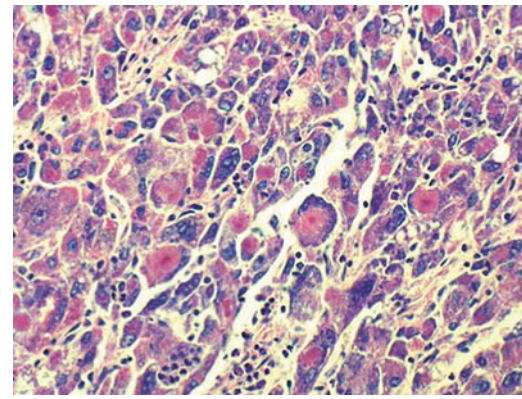

Fig. 26 Hepatocellular carcinoma with numerous eosinophilic inclusions showing a radiated structure (hematoxylin and eosin stain)

that hyaline globules may represent, at least in part, giant lysosomes. Ultrastructurally, hyaline inclusions appeared in two forms, i.e., one form consisting of a lamellar ultrastructure compatible with hyperplastic smooth endoplasmic reticulum and the other consisting of globular non-membrane-limited areas with a fibrillar material. These inclusions can contain p62 protein, a phosphotyrosine-independent ligand of p56lck kinase, similar to Mallory-Denk bodies (Stumptner et al. 1999a, b; Zatloukal et al. 2002). Parts of inclusions in HCC cells have a fibrillar structures and were termed globoid fibrillar inclusions (Huntrakoon and Bhatia 1984) or cytoplasmic fibrillar bodies (Smetana et al. 1972).

A further type of cytoplasmic inclusions or "bodies" are pale bodies which were described in fibrolamellar hepatocellular carcinoma (Craig et al. 1980), but also occur in ordinary HCC. Pale bodies are characterized as a pale amorphous, PAS-negative substance with a distinct margin and occupying a large part of the cytoplasm (Nakashima et al. 1992; Moon et al. 2000). They were detectable in up to 5.7 % of resected HCC (Nakashima et al. 1992). In one study, where these bodies were detectable in 5.5 % of HCC, the pale inclusion was sometime slightly eosinophilic, rarely resembling ground-glass inclusions found in HBV infection. In fact, part of pale inclusions may be caused by deposition of HBsAG, which is detectable in some HCC in HBV-positive patients (Péquignot et al. 1974; Wu and Lam 1979; Stromeyer et al. 1980). Nuclei of tumor cells with pale bodies were often displaced to the periphery of inclusions, leaving only a rime of cytoplasm. Cells with pale bodies may be clustered to small nodules (Moon et al. 2000). Ultrastructurally, pale bodies show a granular or fibrillar material surrounded by a limiting membrane, suggesting a relationship with the rough endoplasmic reticulum (Nakashima et al. 1992; Moon et al. 2000). A variant of pale eosinophilic inclusion in HCC achieve a diameter of about 14 μm and closely resemble ground-glass cells. These inclusions are thought to represent deposition of secretory proteinaceous material (Nakanuma et al. 1982). Various types of globular inclusions are also detectable in metastatic HCC (Haratake et al. 1990). HCC cells can contain bona fide Mallory-Denk bodies, sometimes associated with cell ballooning similar to that seen in alcohol toxicity (Hoso and Nakanuma 1990). In some subsets of HCC, Mallory-Denk bodies are very common; this variant of nonstandard liver cancer is treated in a separate paragraph. Part of HCC developed in the setting of alpha-1-antitrypsin deficiency can contain cytoplasmic PAS-positive globules similar to those found in nonneoplastic hepatocytes (see below). In contrast, the cytoplasmic hepatocyte inclusions seen in porphyria cutanea tarda are not present in the cells of HCC arising in this condition (Fakan et al. 1998).

Bile Accumulation

Depending on cell differentiation and the expression of bilirubin and bile acid transporters, HCC can extract bile components from blood, accumulate it in cytoplasm, and eventually secrete bile into the cavities of canaliculi and acini. Bile is seen as a yellow to green homogeneous material, droplets in the cytoplasm, and plugs in lumina of canaliculi. Older bile depositions in acini appear as a golden or brown matter. The identification of bile in a given tumor is diagnostic, or at least a very strong argument for HCC. Accumulation of bile is also found in part of HCC metastases (Nappi et al. 1992; Yu et al. 2013).

Accumulation of Neutral Fat (Fatty Change, Steatotic Change) and Other Cytoplasmic Changes

Part of HCC accumulate neutral fat (triglycerides) in their cytoplasm, visualized as small to large fat droplets ("fatty HCC"; fatty metamorphosis of HCC; steatotic HCC; Itai et al. 1987; Yoshikawa et al. 1988; Ueda et al. 1989; Kutami et al. 2000). In part of these neoplasms, steatosis of tumor cells is associated with inflammatory changes similar to those encountered in nonalcoholic or alcoholic steatohepatitis (steatohepatitic HCC, SH-HCC;

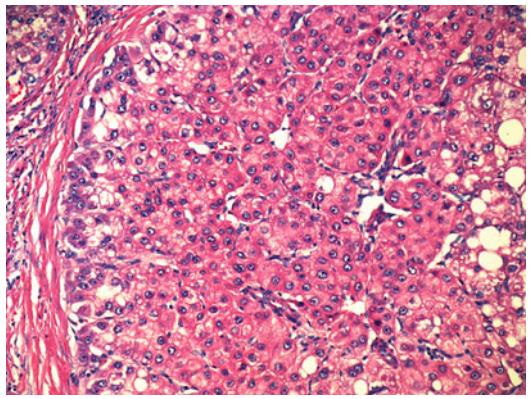

Fig. 27 At the interface between tumor and adjacent liver, HCC cells may show a morphology different from that in central tumor parts, i.e., with a clear cell change in this case (*left* part of figure, hematoxylin and eosin stain)

Salomao et al. 2010, 2012b). These tumors are further discussed in a separate chapter. HCC can show a focal clear cell change, not to be confounded with clear cell HCC which is a distinct variant (Fig. 27).

Reticulin Fiber Patterns

The production of a reticulin network is a characteristic feature of most non-squamous cell carcinomas. This feature was formerly summarized under the term reticulum (review: Tureen and Seelig 1933) and was first shown to consist of distinct fibrils by Henle in 1859. The demonstration of the reticulin fiber network by use of silver stains has proved useful in the differential diagnosis between HCC, in particular trabecular types, and benign hepatocellular nodules (Ferrell et al. 1992; Stahl and Voyvodic 2000; Wee and Nilsson 2003; Yao et al. 2013). The demonstration of a reticulin framework reliably allows to estimate the thickness of liver cell plates, which are normally two to three cells wide, while in HCC plates exceed a thickness of three cells (Ferrell et al.1993). Several studies arrived at the conclusion that, in contrast to normal or cirrhotic liver, well-differentiated HCC has either absent or markedly reduced reticulin, or an abnormal reticulin staining pattern with increased distances between mature reticulin fibers, the presence of

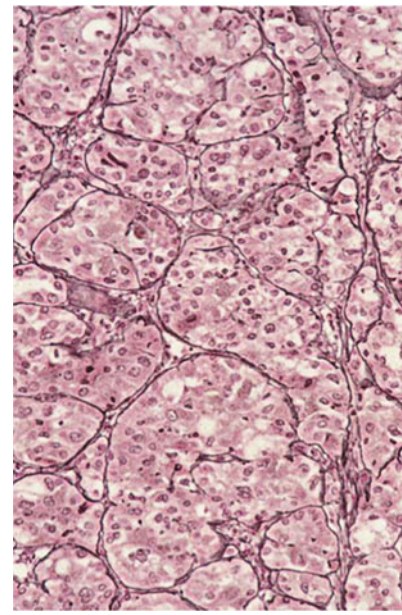

Fig. 28 Reticulin stain of a trabecular hepatocellular carcinoma. In contrast to normal liver tissue, the reticulin fibers are widely spaced due to macrotrabecular plates. By the use of the reticulin stain, the abnormal patterns of HCCs are readily visualized, this stain therefore being a very helpful method in diagnosis and differential diagnosis (Gomori *silver stain*)

abnormally short reticulin fibers, or an increased amount of very fine and loosely arranged fibers (Fig. 28).

There are rare exceptions in which HCC show a preserved reticulin framework (Wilkens et al. 2006; Hong et al. 2011). In the cases reported by Hong and coworkers (2011), a preserved reticulin framework was found to surrounding groups of neoplastic cells or individual neoplastic hepatocytes, a finding which is atypical both for HCC and benign liver cells tumors.

Reticulin loss is seen in early HCC undergoing stromal invasion (Kondo 2009, 2011), the invading cell cords not being accompanied by a typical reticulin framework (Miyao et al. 1999), and a lack of a reticulin framework distinguishes small HCC from macroregenerative nodules in cirrhotic livers (Ferrell et al. 1992). Reticulin loss also characterizes fine-needle aspirates of HCC (Gagliano 1995; Bergman et al. 1997; Wee and Nilsson 2003, Yang et al. 2004). It is thought that the phenomenon of loss of the reticulin framework is either due

to a "true" loss of reticulin fibers in the course of growth of HCC cells and the generation of abnormal sinusoid-like channels that are not surrounded by a normal, reticulin-containing perisinusoidal space or to an apparent reticulin loss due to the wider spacing of reticulin fibers owing to the presence of large tumor cell plates. Reticulin loss (defined as a loss similar to that seen in HCC) was also detected in benign fatty liver. For mild steatosis, reticulin loss was rare; however, loss increased for moderate steatosis and was most prominent in marked steatosis. An almost identical situation was found in cases of nonalcoholic steatohepatitis (NASH). In liver cell adenomas, reticulin loss was only seen in areas of steatosis (Singhi et al. 2012).

Loss of Kupffer Cells (Hepatic Macrophages) in Hepatocellular Carcinoma

Kupffer cells are reduced in HCC and display an altered intrasinusoidal distribution (Kranz et al. 1980; He et al. 2002; Liu et al. 2003). In contrast, Kupffer cells are present in liver cell adenoma, although their number may be less than in surrounding normal liver (Goodman et al. 1987). It has been claimed that loss of Kupffer cells is a general feature of HCC. However, there is a relationship between intratumoral Kupffer cell numbers and the differentiation grade and stage of tumors. By the use of the CD68 immunostain, it was found that the average number of Kupffer cells in well-differentiated HCC tissues less than 1 cm in diameter was not statistically different from that in noncancerous liver tissue, whereas the number of Kupffer cells decreased in HCC as tumor size increased and the histologic grade decreased (Tanaka et al. 1996). In an investigation on 48 cases, the number of Kupffer cells decreased as tumor size increased, and the lowest values were found in poorly differentiated neoplasms (Liu et al. 2003). CD68-reactive Kupffer cells were observed in early HCC, but were absent in advanced HCC (Wakasa et al. 1997). A loss of Kupffer cells in HCC was also found electron microscopically (Tabarin et al. 1986). In cytology smears, the presence of vimentin-positive, spider-shaped Kupffer cells is helpful in distinguishing HCC from other carcinomas (Wu et al. 1996). A reduced set of Kupffer cells in HCC is a substrate for the efficiency of modern imaging techniques, such as superparamagnetic iron oxide-enhanced MR, which reflects Kupffer cell numbers in hepatic tumors (Imai et al. 2000; Asahina et al. 2003; Shimofusa et al. 2010). Superparamagnetic iron oxide particles are sequestered by Kupffer cells under normal conditions, but are not retained in lesions lacking Kupffer cells such as HCC (Wang 2011).

It has been suggested that depletion of Kupffer cells as a distinct population of hepatic macrophages is linked to decreased hepatic immune surveillance favoring carcinogenic pathways (Manifold et al. 1983). Kupffer cells which are the differentiated offspring of bone marrow-derived monocytes are important in several host defense mechanisms, including clearance of microorganisms transported from gastrointestinal tract to liver and antitumor activities (Chen et al. 2001). Kupffer cells are thought to execute tumor cell control through increased production of chemokines and cytokines, specifically TNF-alpha and interferon-gamma, and via pathways involving nitric oxide. By these macrophage-derived factors, apoptosis of tumor precursor cells and cancer cells is induced (Zhu et al. 2000). A disordered defense milieu is already present in cirrhotic livers, as the number of Kupffer cells is reduced in hepatic cirrhosis. In addition, the ischemic-hypoxic situation present in sinusoids of cirrhotic nodules may incite Kupffer cells to produce and secrete, like tumor-associated macrophages (TAMs), cytokines that may promote tumor growth and metastasis (Liu et al. 2011b).

Grading of Hepatocellular Carcinoma

Previous histologic descriptions of HCC already related to various forms of differentiation, resulting in the terms trabecular carcinoma (carcinoma hepatocellular trabeculare, often grade

Table 5 Differentiation grades of hepatocellular carcinoma (grading, based on the Edmondson and Steiner grading system, 1954, modified and extended)

Grade I
Grade I is reserved for those areas in HCC of grade II where the difference between neoplastic cells and normal or hyperplastic hepatocytes is so minor that a diagnosis of HCC rests upon the demonstration of more aggressive growth in other parts of the tumor
Grade II
In grade HCC, the cells display marked resemblance to normal hepatocytes. However, the nuclei are larger and more hyperchromatic than normal, but the cytoplasm is abundant and eosinophilic; the cell borders are often sharp and clear-cut. Acini (pseudoglandular structures) are frequent; their lumina vary in size from tiny canaliculi to large thyroid-like spaces. The lumina of the acini are often filled with bile or a proteinaceous material
Grade III
In grade III HCC, the nuclei are usually larger and more hyperchromatic than in grade II cells. These nuclei occupy a relatively greater proportion of the cell (the nuclear-to-cytoplasm is increased). The cytoplasm is granular and eosinophilic as in grade II, but usually less so. Sometimes there is segregation of the granular cytoplasm toward the end of the cell bordering a lumen that usually does not contain bile. Acini are less common and less often contain bile or proteinaceous material. Tumor giant cells are most numerous in this grade
Grade IV
In grade III HCC, the nuclei are intensely hyperchromatic and occupy the greater part of the cell (markedly elevated nuclear-to-cytoplasm ratio). The cytoplasm is variable in amount, is often scanty, and contains fewer granules. The growth pattern is medullary in character, trabecules are difficult to find, and cell masses seem to lie loosely without cohesion between or in vascular channels. Only rare acini are found. Giant cells are not conspicuous. Spindle cell areas are seen in some of the tumors. Short plump cell forms, resembling oat cell carcinoma of the lung, are seen in some grade IV tumors

1 or 2), vesicular carcinoma (carcinoma hepatocellular vesiculare, now acinar HCC), and anaplastic carcinoma (carcinoma hepatocellulare anaplasticum, grade 4; Von Albertini 1974). A major breakthrough for HCC grading arrived when Edmondson and Steiner proposed their four-level grading system, which is now generally termed Edmondson-Steiner grading (Edmondson and Steiner 1954). Grading can be performed by the use of fine-needle aspiration biopsies (Ali et al. 1986). The grading includes nuclear and cytoplasmic features and growth patterns. Definitions of tumor grades are compiled in Table 5.

Most HCC are either grade 2 or grade 3, grade 2 being more common than grade 3, while grade 1 is less common, and grade 4 is the least common (Chapel et al. 1996). It is still difficult to judge what forms of HCC are "true" grade I neoplasms, and whether "pure" grade I HCCs exist, as grade I makes part of grade II lesions in the Edmondson-Steiner system. There are examples of well-differentiated small or early HCC that seem to consists exclusively of a grade I pattern, and there are also large solitary HCC with these features. Grade III HCC is relatively easy to recognize, owing to the typical presence of multinucleated tumor giant cells, that are however not pleomorphic. Due to the scant cytoplasm, which may be amphophilic or even slightly basophilic, the high or very high nucleus-to-cytoplasm ratio, the associated nuclear crowding, and the medullary-like growth pattern with effacement of plates and prominent sinusoid-like vessels, grade IV HCC resemble anaplastic carcinomas and may, without immunohistochemistry, sometimes be difficult to diagnose as HCC (Sasaki et al. 2014; Figs. 29, 30, 31, 32, 33, 34, 35, 36, 37, and 38).

Stroma Formation (Desmoplasia) in Hepatocellular Carcinoma

Stroma is formed in HCC to variable degrees, with some variants being markedly desmoplastic (scirrhous HCC). However, apart from special forms of HCC, desmoplasia is usually less prominent than in many cholangiocarcinomas. Stromagenesis in hepatic malignancies is a distinct biologic feature affecting growth and spread (Sivridis et al. 2004), that is discussed in a separate chapter in more detail. Specifically, tumor stroma, even in cases where it is sparsely developed, displays a distinct gene expression signature that has a marked impact on growth, differentiation, and invasive properties of cancer cells embedded or migrating in it (Gao et al. 2011). Stromal cells engage in complex interaction with epithelial tumors cells that affect cancer cell behavior (review: Shtilbas

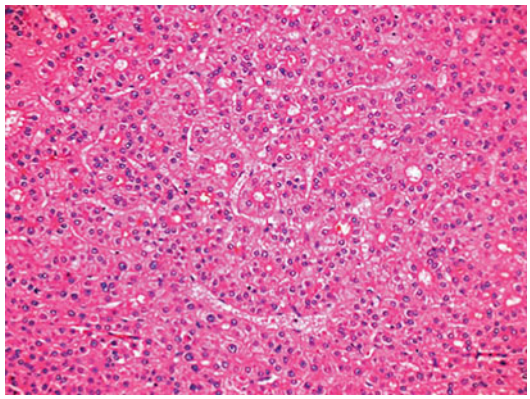

Fig. 29 Grading of hepatocellular carcinoma. This mixed trabecular and acinar neoplasm reveals a homogeneous population of hepatocyte-like cells and is grade 1 (hematoxylin and eosin stain)

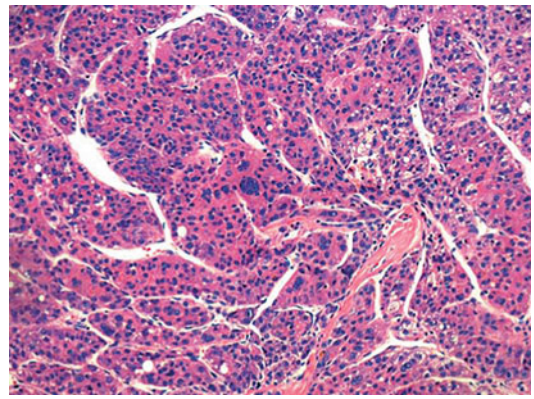

Fig. 31 Trabecular hepatocellular carcinoma with an increased proportion of atypical hepatoid cells and presence of multinucleated tumor cells, corresponding to grade 3 (hematoxylin and eosin stain)

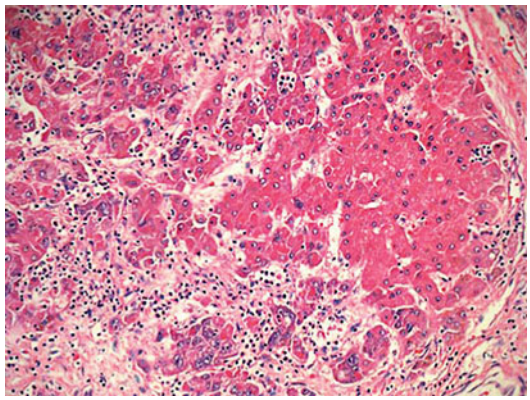

Fig. 30 Trabecular hepatocellular carcinoma of mixed grade, G1 and G2. The large hepatocyte-like cells to the *right* show only minor deviation from normal and are G1, while the neoplastic cells to the *left* exhibit increased nucleus-to-cytoplasm ratio and more pronounced nuclear atypia, representing G2 (hematoxylin and eosin stain)

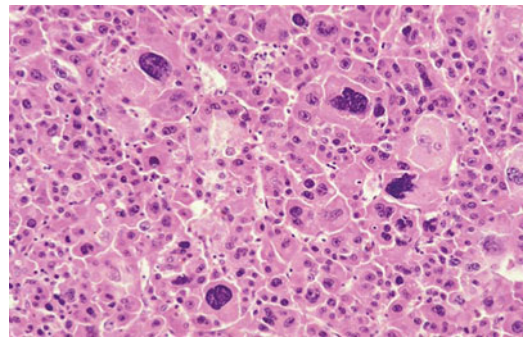

Fig. 32 In some hepatocellular carcinomas with otherwise grade 2 or grade 3 morphology, highly atypical and pleomorphic tumor cells can occur (hematoxylin and eosin stain)

2013). The tissue space between cancer cell plates and endothelia of intervening vascular channels is occupied by stromal spindle cells that have, on the one hand, the features of fibroblasts (stromal fibroblasts, review Li et al. 2012), while on the other hand a significant fraction of these spindle cells are reactive for alpha-smooth muscle actin and, less often, vimentin, but negative for desmin. These stromal cells therefore have the features of myofibroblasts (Enzan et al. 1994; Terada et al. 1996; review: Hinz 2010).

Vascular Patterns (Angioarchitecture) of Hepatocellular Carcinoma

HCCs are highly vascular tumors that possess a distinct angioarchitecture that in part mimics the microvascular system of normal liver, i.e., a sinusoid-like vessel pattern. In the course of

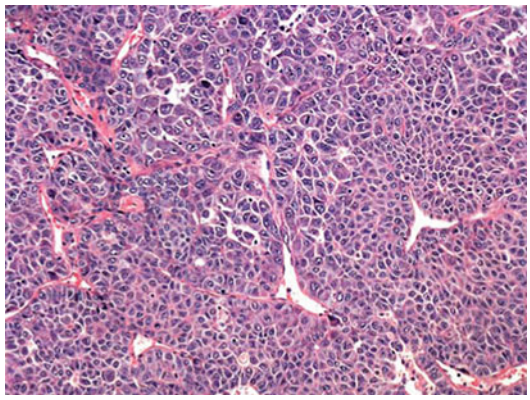

Fig. 33 In this trabecular hepatocellular carcinoma, almost all neoplastic cells display a markedly increased nucleus-to-cytoplasm ratio, resulting in a "blue cellular tumor," a feature typical for poorly differentiated HCCs (grade 4, hematoxylin and eosin stain)

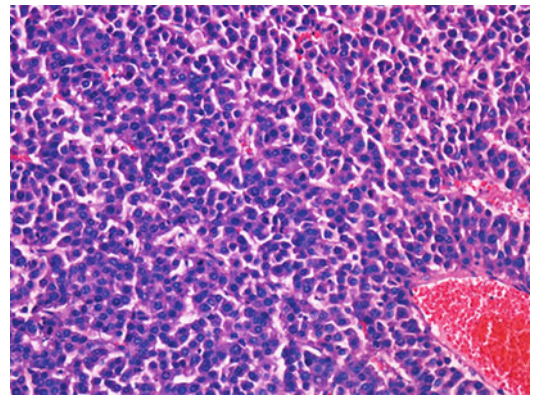

Fig. 35 Grade 4 hepatocellular carcinoma with predominance of small cells and diffuse growth pattern. Such "anaplastic" neoplasms are difficult to diagnose, requiring immunohistochemical and/or molecular methods (hematoxylin and eosin stain)

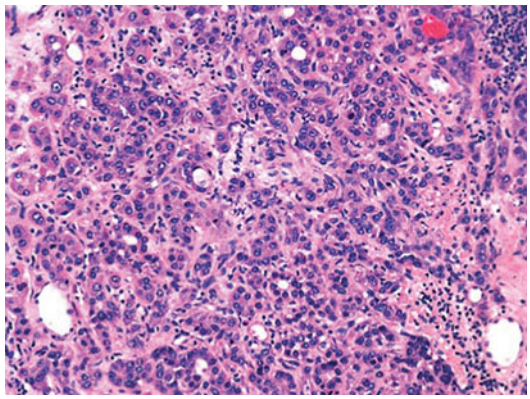

Fig. 34 Poorly differentiated grade 4 hepatocellular carcinoma may be dominated by clusters of medium-sized to small cells in the absence of a trabecular or acinar pattern, rendering diagnosis of HCC difficult without immunohistochemistry (hematoxylin and eosin stain)

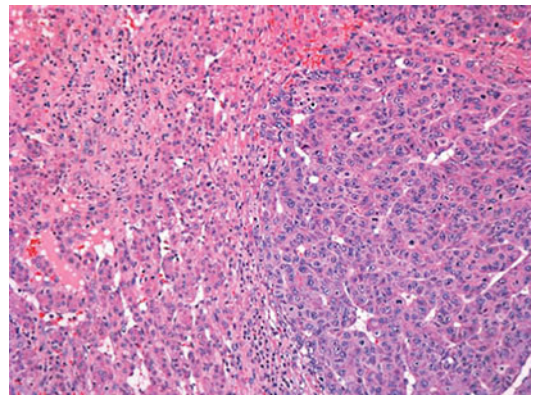

Fig. 36 Trabecular hepatocellular carcinoma of mixed differentiation. Some HCCs exhibit heterogeneity in regard to differentiation. In the present tumor, well-differentiated components (G1 and G2, *left*) are separated from a focus showing G3 and G4 (hematoxylin and eosin stain)

growth an invasion, this vascular system is continuously constructed in the setting of tumor angiogenesis, outlined in a separate chapter. HCCs show two predominant patterns of microvessels, capillary-like and sinusoid-like microvessels, these two patterns having an impact on tumor biology (see above; Chen et al. 2011). A fraction of HCC contain abnormal/aberrant arteries and display a lack of portal tracts with hepatic artery and portal vein branches. On CT images during arterial portography and CT during hepatic arteriography, these abnormal vascular patterns can be visualized in vivo. In the course of hepatocarcinogenesis in cirrhotic livers, abnormal arteries (intranodal arterial supply through newly formed abnormal arteries) gradually increase (Hayashi et al. 2002; Matsui 2004). However, the number of arteries in HCC varies as a function

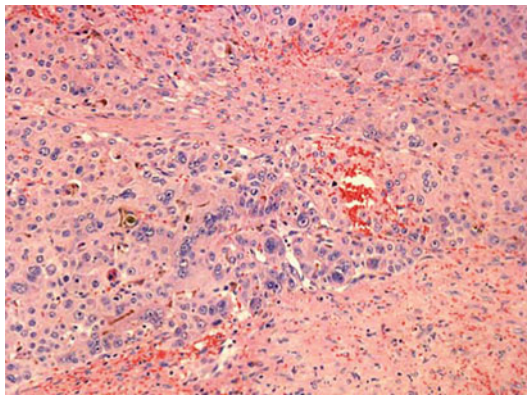

Fig. 37 Trabecular hepatocellular carcinoma of mixed differentiation. On a background of grade 2 tumor tissue, one focus is characterized by increased nuclear atypia and multinuclearity, being grade 3 (hematoxylin and eosin stain)

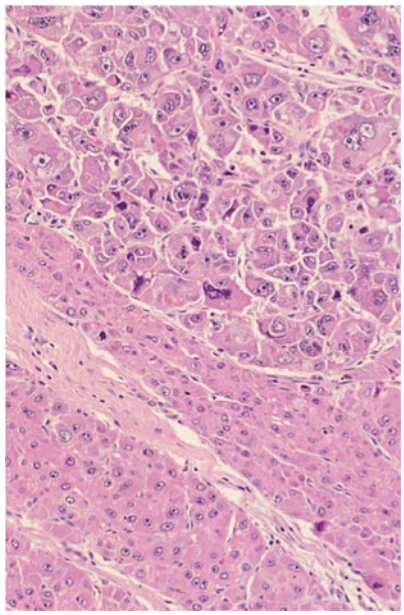

Fig. 38 Trabecular hepatocellular carcinoma of mixed differentiation. Well-differentiated HCC (G1/2) can contain poorly differentiated and pleomorphic components, reflecting tumor heterogeneity also observed at a macroscopic level (hematoxylin and eosin stain)

of tumor differentiation. There is a low-arterial vessel group of HCC with moderate differentiation and a more aggressive course (Fujita et al. 2010).

Encapsulation (Pseudocapsule or Capsule Formation)

Introduction

The formation of an incomplete or complete pseudocapsule (often termed capsule or encapsulation) has predominantly been found in non-small HCCs showing a nodular growth pattern. The reported prevalence of a pseudocapsule in nodular HCCs ranges from 10.3 % to 86.4 %, depending on geographic factors, diagnostic criteria used, and size and type of tumors studied (Okuda et al. 1977; Nakashima et al. 1982; Hsu et al. 1985; Tanaka et al. 1985; Kemeny et al. 1989; Fekete et al. 1990; Ng et al. 1992). Encapsulation of HCC may be more often observed in Japan in comparison with tumors studied in Western countries (Nakashima et al. 1983), but this was not confirmed by a later investigation (Kemeny et al. 1989). In a Japanese autopsy study on 26 cases of encapsulated HCCs, the mean age of the patients at diagnosis was 64.1 years, which was significantly older compared with that of 143 cases of nonencapsulated HCCs (Okuda et al. 1977). In an analysis of 154 HCC with adequate histology, encapsulation was identified in 46.8 %, the thickness of the capsule ranging from 0.13 to 3.09 mm (mean: 0.87 mm). Tumors with a capsule showed a much lower incidence of liver invasion, tumor microsatellites, and venous invasion (Ng et al. 1992). In an investigation of patient survival in HCC in relation to age, younger patients (<50 years of age) had less often pseudocapsules and a more advanced tumor stage (Ng et al. 1996). The incidence of tumor pseudocapsules did not increase or decrease with tumor size (Ng et al. 1992), but pseudocapsules are more common in pedunculated HCCs (Yeh et al. 2002) and are also found in early HCCs and small HCCs (Hsu et al. 1985; Kojiro 1998; Zheng et al. 2007). In one study, small nodular HCCs with distinct margins had thin fibrous pseudocapsules in more than half of the cases (Kojiro 1998). There seems to be a relation between the presence or absence of cirrhosis and tumor encapsulation. In a study of 74 cases of

non-cirrhotic HCC, only 50 % of the tumors were encapsulated (Liu et al. 2013).

Pathology

When strongly developed, tumor pseudocapsules are grossly visualized as a whitish to gray-white rim surrounding an expansively growing tumor, either complete, incomplete, or fragmented (Fig. 39).

A fragmented encapsulation is more often found in grossly invasive neoplasms that invade the liver substance. The whitish rim of a capsule is particularly well observable in pedunculated HCC. The liver parenchyma adjacent to the pseudocapsule may by atrophic, this atrophy zone sometimes reaching a thickness of more than 10 mm. This zone is slightly reddish, and on sections through a fresh specimen, the zone is often sunken with respect to more distant parts of parenchyma. Beneath the pseudocapsule, calcifications may develop, visualized as ring calcification on CT images (Fukuya et al. 1999).

Histologically, the pseudocapsule consists of a dense connective tissue that contains spindle cells (fibroblasts and myofibroblasts) and collagen fiber bundles (Fig. 40).

In contrast to tumor stroma, capsular tissue usually does not have a matrix rich in glycosaminoglycans and is therefore slightly eosinophilic. The capsule is strongly stained with the Van Gieson and trichrome stains and may be slightly PAS-positive, depending on the amount of glycoproteins such as fibronectin and laminin. The capsule is vascularized, whereby younger capsules usually contain more blood vessels than old, sclerosed ones. The fibrous tissue of pseudocapsules is traversed by few S100-positive nerve fibers in contact with blood vessels (Terada and Matsunaga 2001). The pseudocapsule may be invaded by HCC cells, which tend to follow perivascular spaces to reach the adjacent hepatic parenchyma. Immunohistochemically, many of the capsular spindle cells are reactive for alpha-smooth muscle actin (SMA) and therefore represent myofibroblasts that may have been recruited from local hepatic stellate cells, which are known to also occur in tumor stroma.

Fig. 39 Encapsulated hepatocellular carcinoma. The small tumor is sharply demarcated from cirrhotic liver tissue by a fibrous pseudocapsule

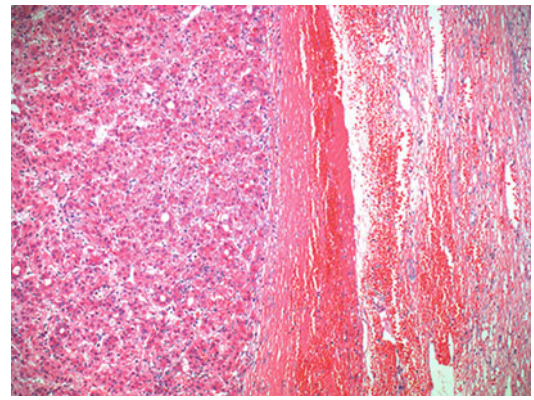

Fig. 40 Encapsulated hepatocellular carcinoma. The well-differentiated neoplasm is surrounded by a sheath of collagenous, hypocellular connective tissue (hematoxylin and eosin stain)

Biologic Significance of HCC Pseudocapsules

The presence of a pseudocapsule in HCC is one of the factors exerting a positive influence on outcome (Okuda et al. 1977; Ng et al. 1992; Iguchi

et al. 2009; Lin et al. 2010; review; Qin and Tang 2002; Lu et al. 2013). It has been suggested that the pseudocapsule acts as barrier or barricade preventing the spread of cancer cells, although this may be a mechanistic view that not adequately describes the function of a complex pseudocapsule. In a study of 189 surgically resected HCCs, 46.8 % of the cases had tumor encapsulation. Tumors with such a pseudocapsule showed a much lower incidence of direct liver invasion, tumor microsatellites, and venous permeation when compared with HCCs without pseudocapsule. Disease-free and actuarial survival times were significantly better in patients with encapsulated tumors (Ng et al. 1992). In a multivariate analysis of patients having undergone curative resection of HCC, only the presence of a tumor pseudocapsule was significantly associated with long-term survival without recurrence (Tsai et al. 2000). The absence of a complete tumor pseudocapsule is correlated with several high-risk prognostic factors in HCC. The lack of an intact tumor pseudocapsule was correlated with bile duct tumor thrombi, a lesion conferring an extremely dismal prognosis (Yu et al. 2011). The biological significance of tumor cells invading liver tissue beyond the pseudocapsule has been studied in detail. A study on 88 HCCs with a diameter of 5 cm or less compared an extracapsular infiltrating type, in which HCC cells infiltrated outside the pseudocapsule and touched the extratumoral liver parenchyma, and an intracapsular infiltrating type, in which the infiltrating HCC cells stayed inside the pseudocapsule. The analysis showed that the former type revealed a poorer outcome for the overall survival and disease-free survival, and this type was an independent prognostic factor for disease-free survival (Iguchi et al. 2008).

Pathogenesis of Pseudocapsules

Most HCCs develop in livers with cirrhotic change, but the development of a fibrous tumor pseudocapsule does not seem to be directly related to cirrhosis, as such pseudocapsules also arise around HCCs in non-cirrhotic livers (Fekete et al. 1990). The cellular source of pseudocapsules are mainly fibroblasts and myofibroblasts (Kojima et al. 1999; Ishizaki et al. 2001). The pseudocapsule of HCCs contains numerous stromal spindle cells expressing high molecular weight caldesmon, a highly specific marker for smooth muscle cells (Nakayama et al. 2004). Alpha-SMA-positive myofibroblasts are also observed in fibrous capsules around hepatic metastases, e.g., of colorectal carcinoma (Lunevicius et al. 2001; Gulubova and Vlaykova 2006). Procollagen alpha1(I) mRNA colocalized to alpha-SMA-positive stellate cells/myofibroblasts within regions of increased collagen deposition in HCC pseudocapsules, suggesting that hepatic stellate cells differentiated into myofibroblasts are responsible for pseudocapsular matrix production (Ooi et al. 1997). The fact that the CD34-negative cells of HCC's tumor stroma also express SMA and are myofibroblasts (Enzan et al. 1994; Terada et al. 1996; Faouzi et al. 1999) suggests that the stroma may participate in the morphogenesis of a pseudocapsule.

Differential Diagnosis of Ordinary Hepatocellular Carcinoma

Both radiologically and pathologically, HCC with its diverse differentiation patterns and grades has to be distinguished from other nodular hepatocellular lesions, specifically liver cell adenoma, several types of nodular hepatic precursor lesions, and focal nodular hyperplasia (Hytiroglou and Theise 1998). Unusual nodular hepatocyte lesions with large cell change and formation liver cell rosettes occur in primary biliary cirrhosis and may be confounded with well-differentiated HCC (Nakanuma and Hirata 1993).

Abstract

Although the histological and cytological features of differentiated hepatocellular carcinomas (HCC) usually allow a reliable diagnosis, poorly differentiated HCCs and tumors found in small samples require immunohistochemical confirmation. Generally, cells of HCCs share with normal hepatocytes a rather wide array of lineage markers. These include Hep Par1, arginase 1, and glutamine synthetase, which are expressed in many, but not all, HCCs. A majority of HCCs are positive for the heparan sulfate proteoglycan, glypican-3. Many HCCs express and secrete typical export proteins, of which alpha-fetoprotein is the best-known example. Part of HCCs show reactivity for the canalicular domain markers, polyclonal CEA and CD10. The tumors share with hepatocytes the expression of cytokeratins 8 and 18, and sometimes 19, the latter defining a tumor subset with poor prognosis. In addition, HCCs express, however in a variable manner, markers of cellular differentiation, cell adhesion molecules, oncogenes, tumor suppressors, and a host of other markers related to various biochemical and metabolic functions.

Introduction

Immunohistochemistry has an important role in the diagnostic approach to HCC and for tumor monitoring (Varma and Cohen 2004; Wee 2006; Lo and Ng 2011; Masuda and Miyoshi 2011; Minguez and Lachenmayer 2011). The field of HCC markers is very active and the number of markers is steadily growing (Marrero and Lok 2004). The most important markers are compiled in the Table 1.

Hepatocyte Lineage Markers

As part of HCC consists of cells that are similar to normal or hyperplastic hepatocytes, immunohistochemical methods are useful for the diagnosis of these neoplasms (reviews: Varma and Cohen

Table 1 Markers for hepatocellular carcinoma

Hepatocyte/HCC cell lineage markers
Hep Par1
Arginase 1
Glutamine synthetase
Heparan sulfate proteoglycan expressed by hepatocytes/HCC cells
Glypican-3
Hepatocyte/HCC-typical export proteins
Alpha fetoprotein (AFP)
Alpha-1-antitrypsin (AAT)
Ferritin
Abnormal prothrombins (PIVKA-II)
Canalicular domain markers
CD10
Polyclonal CEA (pCEA)
Intermediate filaments
Cytokeratin 8
Cytokeratin 18
Cytokeratin 19
Wnt/beta-catenin signaling pathway
Beta-catenin
Markers of proliferative activity
PCNA
Ki-67
Cyclin D1
Markers of cellular differentiation
DEC1 (in part of HCCs)
MUC1 (in part of HCCs)
Squamous cell carcinoma antigen (SCCA; in part of HCCs)
Cell adhesion molecules and cytoskeletal proteins
CD44
N-cadherin (in part of HCCs)
EpCAM (epithelial cell adhesion molecule; in part of HCCs)
NCAM (neural cell adhesion molecule; in part of HCCs)
Clathrin heavy chain
Oncogenes and tumor suppressor genes
p53
p73
Other markers (expressed in part of HCCs)
Heat shock protein 70 (HSP70)
HCC-specific gamma-glutamyltransferase
Kazal type 1 proteinase inhibitor (SPINK1)
CD147 (EMMPRIN)
SALL4
Osteopontin
Osteonectin/SPARC
Importin-alpha1
Aldo-keto reductase 1

2004; Wee 2006). There are several markers of the hepatocyte cell lineage that can be employed in HCC diagnosis, including antibodies directed against hepatocyte antigens and proteins exclusively expressed in hepatocytes (review: Roncalli et al. 2011).

HepPar1

Hep Par1 is a reliable hepatocyte lineage marker and is also regarded as a potent tool in the differential diagnosis of hepatocellular tumors (Leong et al. 1998; Zimmermann et al. 2001; Chu et al. 2002; Siddiqui et al. 2002; Lamps and Folpe 2003; Saad et al. 2004; Varma and Cohen 2004; Wang et al. 2006; Karabork et al. 2010; Al-Muhannadi et al. 2011; Shibuya et al. 2011). The antigen for Hep Par1 was reported to be the hepatocytic urea cycle enzyme, carbamoyl phosphate synthetase 1 located in mitochondria (Butler et al. 2008). Hep Par1 has a sensitivity for HCC of around 80–100 % and generally reflects hepatocyte-like differentiation in tumors. The reactivity manifests as a diffuse cytoplasmic granular staining pattern in normal and neoplastic hepatocytes (Figs. 1 and 2).

The frequency of Hep Par1 positivity depends on the tumor's grade. In an analysis of 96 cases of HCC, all 50 cases of nuclear grade 1 and nuclear grade 2 HCC were positive for Hep Par1, while only 84 % with grade 3 and 50 % with grade 4 were positive, and a positive result was more common in HCC with a trabecular, pseudoacinar, or scirrhous growth pattern than in those with a compact pattern (Chu et al. 2002). Apart from differences related to grade, not all HCC show uniform Hep Par1 staining. Tumors containing steatotic, clear cell, or oncocytic components show reduced or lacking reactivity in these areas. Hep Par1 reactivity is also detectable in metastases of HCC and seems to be a prognostic factor (Mondada et al. 2006). As Hep Par1 is expressed in hepatoid adenocarcinoma and it metastases (Pitman et al. 2004), and hepatoid carcinomas histologically are more or less identical to HCC, Hep Par1 will not serve to distinguish these two entities. However, not all HCC stain uniformly, and not all Hep Par1-positive tumors are of hepatocyte lineage or arise in the liver (review; Wee 2006). In one analysis, 3/19 HCCs showed <5 % Hep Par1 immunostaining, and variable Hep Par1 positivity was detected in part of gastric carcinoma, cholangiocarcinoma, colorectal carcinoma, lung carcinomas, ovarian carcinomas, and adrenocortical carcinomas (Fan et al. 2003), but also in reactive lesions such as intestinal metaplasia (Chu et al. 2003).

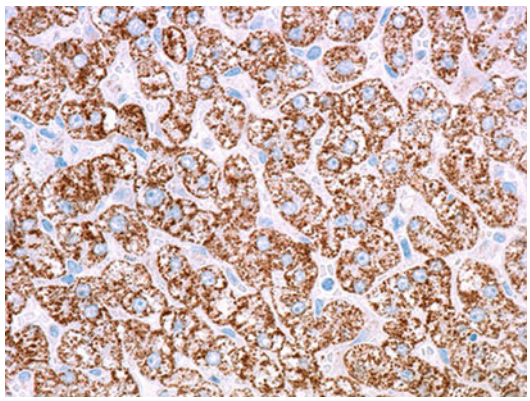

Fig. 1 Well-differentiated hepatocellular carcinoma with expression of Hep Par1 in a cytoplasmic granular pattern (Hep Par1 immunostain)

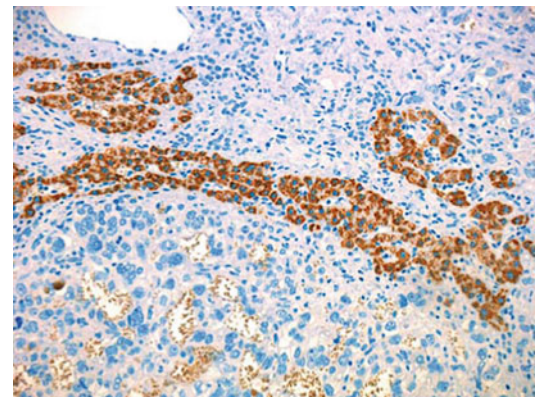

Fig. 2 Poorly differentiated hepatocellular carcinoma may downregulate expression of Hep Par1. In the present case, pleomorphic HCC cells (lower half of figure) are Hep Par1-negative, in contrast to compressed and partially atrophic hepatocytes (Hep Par1 immunostain)

Arginase-1

An important marker of the hepatocyte enzyme category comprises arginase-1 which is reactive in HCC (Yokoyama et al. 2004; Yan et al. 2010; Radwan and Ahmed 2012). Arginase-1 reactivity was demonstrated as a reliable marker of HCC in fine needle aspirates (McKnight et al. 2012) and was found to be superior in sensitivity to Hep Par1 and glypican-3 (Fujiwara et al. 2012). Arginase-1 reactivity was also useful in the diagnosis of scirrhous HCC (Krings et al. 2013). However, expression of arginase-1 is not restricted to hepatocytes and hepatocytic neoplasms, as this enzyme is expressed in myelocytes/metamyelocytes and localized in gelatinase granules of human neutrophils (Jacobsen et al. 2007).

Glutamine Synthetase

Expression of glutamine synthetase (GS) is an early marker for HCC based on immunohistochemical and proteomic analyses (Matsuno and Goto 1992; Dal Bello et al. 2010; Long et al. 2010; Shin et al. 2011) and is expressed in most of these neoplasms. GS expression is regulated by ubiquitin-dependent proteolysis (Osada et al. 1999). GS immunostaining is characterized by diffuse reactivity of the cytoplasm. GS showed an increased expression and phosphorylation in well-differentiated HCC, GS-positive cells sometimes growing in nodule-in-nodule manner (Kuramitsu et al. 2006). GS staining was correlated with large tumors, low histologic grade, formation of pseudoacini, bile deposition, and reduced specific and overall mortality (Del Bello et al. 2010). On the other hand, there is evidence that GS expression may enhance the metastatic potential in HCC (Osada et al. 1999, 2000). GS immunostaining is also present in focal nodular hyperplasia/FNH, regardless of size or a steatotic component. However, the staining pattern is different from that of HCC in that it is not diffuse, but characteristically anastomosed in a map-like cytoplasmic pattern (Bioulac-Sage et al. 2009).

Glypican-3

Glypican-3 is a valuable marker for hepatocyte-derived malignancies, including HCC and hepatoblastoma (Zhu et al. 2001; Coston et al. 2008; Wang et al. 2012b; Filmus and Capurro 2013; Krings et al. 2013; Witjes et al. 2013) but also for several other malignancies. Immunostaining for GPC3 can distinguish HCC from benign liver cell neoplasms, preneoplastic lesions, cholangiocarcinoma, metastases, and hyperplastic cells of cirrhosis. That enhanced GPC expression differentiates the majority of HCCs from non-HCC lesions has been shown by us in 2001 (Zhu et al. 2001) and has since been confirmed several times (Nakatsura et al. 2003; Filmus and Capurro 2004; Man et al. 2005; Liu et al. 2010; Suzuki et al. 2010; Yan et al. 2011; Yorita et al. 2011; review: Kandil and Cooper 2009; Fig. 3).

In contrast to HCCs, which show an upregulation of GPC3 in the majority of cases, GPC3 is downregulated in cholangiocarcinomas (Man et al. 2005) and nonmalignant hepatocellular lesions (Enan et al. 2013). Expression of GPC3 is a valuable diagnostic element in early HCC (Chen et al. 2014) and in HCC that are negative for AFP (Li et al. 2013). Immunohistochemically,

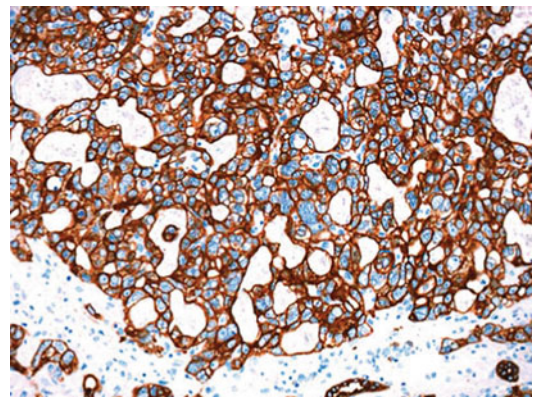

Fig. 3 Glypican-3 expression by HCC cells (glypican-3 immunostain)

GPC3 is visualized as a more or less diffuse cytoplasmic staining of cells in moderately and well-differentiated HCCs. In poorly differentiated HCC, membranous GPC3 immunostaining is seen, and membranous staining is also prevalent in metastatic lesions of HCC when compared with the primary tumors (Suzuki et al. 2010). HCC patients with circumferential cell surface GPC3 immunostaining revealed worse prognosis of their tumor disease (Yorita et al. 2011). This immunophenotype of HCCs is also visualized in needle biopsies (Kandil et al. 2007). The yield of GPC3 positivity in HCCs may exceed 85 % (Wang et al. 2006). In a microarray study of 54 HCCs and adjacent liver tissue, GPC3 staining was observed in 90 % of 21 HCC cases with cirrhosis and in 64 % of 28 HCC cases associated with non-cirrhotic liver. In cases with adenomas, only malignant foci were positive. Among 94 macronodules, GPC3 immunostaining was noted in 48 % of high-grade dysplastic nodules or early HCCs and in only 3 % of benign or low-grade dysplastic nodules (Wang et al. 2006).

Similar to classical HCC, fibrolamellar hepatocellular carcinoma (FL-HCC) can express GPC3 (Shafizadeh et al. 2008; Abdul-Al et al. 2010; Ward et al. 2010; Ward and Waxman 2011). In a comparative immunohistochemical study of 26 cases of FL-HCC and 62 classical HCCs, 39 % of HCC and 59 % of FL-HCC cases were positive for GPC3 (Ward et al. 2010). In contrast to this study, another investigation found that GPC3 was more often and more strongly expressed in HCCs (72 %) than in FL-HCCs (17 %) (Abdul-Al et al. 2010). Immunoreactivity for GPC3, together with that of Hep Par1, was detected in lymphoepithelioma-like hepatocellular carcinoma (Nemolato et al. 2008). GPC3 is also involved in the biology of hepatic cells other than hepatocytes and neoplasm derived thereof. M2-polarized tumor-associated macrophages which promote the progression and metastasis of HCC are recruited by CCL5, CCL3, and CSF1 under involvement of GPC3 (Takai et al. 2009).

Glypican-3 (GPC3) is a member of the membrane-anchored heparan sulfate proteoglycan glypican family. Glypicans are linked to the cell surface membrane by a glycosylphosphatidylinositol (GPI) anchor. So far, six members of this family (GPC1 – GPC6) have been identified in mammals, and two in *Drosophila*. All glypicans share the same basic structure, characterized by a core domain, an N-terminal secretory signal peptide, and a hydrophobic domain required for the addition of the GPI anchor (review: Filmus and Selleck 2001). Glypican-type heparan sulfate proteoglycans are coordinators of several cell functions (reviews: David and Bernfield 1998; Tumova et al. 2000; De Cat and David 2001; Fransson 2003), represent important mediators of developmental processes, and play distinctive roles in carcinogenic pathways. GPC3 has an important role in several developmental processes. Loss of GPC3 function causes growth factor-dependent defect in cardiogenesis (Ng et al. 2009), and loss-of-function mutations of the GPC3 gene (localized to chromosome Xq26) are the cause of Simpson-Golabi-Behmel syndrome type 1 (SGBS1; OMIM 312870, synonyms: Bulldog syndrome, Golabi-Rosen syndrome, Simpson dysmorphia syndrome; dysplasia gigantism syndrome, X-linked). Silencing of the glypican-3 gene regulates invasion and migration of human HCC cells (Qi et al. 2014). GPC3 is normally expressed in fetal tissues, including fetal liver and placenta, but not in the normal adult human liver. In the postnatal liver, GPC3 mRNA is repressed by the transcription factor, zinc fingers, and homeoboxes 2 (Zhx2) (Morford et al. 2007). In the liver, GPC3 is involved in hepatocyte proliferation and regeneration. GPC3 mainly operates in pathways regulating cell proliferation and the function of the cytoskeleton. The expression of GPC3 itself is regulated by the action of specific microRNAs (miRs; Maurel et al. 2013). miR-96, belonging to the miR-182/183 cluster, downregulates GPC3 expression by targeting its mRNA 3′-untranslated region and interacting with the predicted site.

Glypican-3 is also the source of a potential peptide vaccine (Sawada et al. 2012, 2013) and for recombinant humanized antibodies to treat HCC (Zhu et al. 2013). Glypican-3 is particularly useful in the diagnosis of well-differentiated

HCC (Sakamoto et al. 2008; Shafizadeh and Kakar 2011). In HCC patients, glypican-3 can circulate in the blood, and it is comparable to AFP as a serum marker for the diagnosis of HCC (Liu et al. 2013; Xu et al. 2013; Yao et al. 2013b) or for monitoring tumor recurrence (Fu et al. 2013). GPC3 has been considered as a potential target for the antibody therapy of liver cancer (reviews: Ho 2011; Feng and Ho 2014). By use of RNA interference it was shown that suppression of GPC3 in cultured HCC cells inhibited cell proliferation with cell cycle arrest at the G1 phase, associated with upregulation of TGF-beta2 (Sun et al. 2011). GPC3 can be targeted to HCC cells using multifunctional nanoparticles (Park et al. 2011) or liposomes containing GPC-3-targeting peptide ligands (Lee et al. 2011).

Heat Shock Protein 70

Expression of heat shock protein 70/HSP70 has proven to be a reliable marker for HCC (Di Tommaso et al. 2009). In one series, HSP70 was found in 71.9 % of HCC (Shin et al. 2011). HSP70 can synchronously be co-expressed with AFP in HCC cells (Wang et al. 2007).

Alpha-Fetoprotein (AFP) and Other Proteins Secreted by Hepatocytes

Alpha fetoprotein (AFP), an embryonal/fetal type of albumin, is produced and secreted by the majority of HCC (Fig. 4). AFP can be visualized in HCC cells both by immunofluorescence and immunohistochemistry methods (Purtilo and Yunis 1971; Nishioka et al. 1972; Thung et al. 1979; Espinoza et al. 1984; Imoto et al. 1985; Roncalli et al. 1985; Okushin et al. 1987; Brumm et al. 1989; Hurlimann and Gardiol 1991).

Also AFP messenger RNA is detectable in human HCC expressing the AFP gene (Di Bisceglie et al. 1986). In cases with AFP positivity, AFP is not present in distinct cell populations but rather shows a randomly heterogeneous distribution (Kinoyama et al. 1986). By use of immune-electron microscopy, intracellular AFP was mainly found in perinuclear space, cisternae of the rough endoplasmic reticulum, Golgi complex, and secretory vesicles (Okada et al. 1987). It was reported that the number of positive cells and the intensity of cytoplasmic AFP staining was roughly proportional to serum AFP levels in most cases (Kojiro et al. 1981), but depending on the preservation status of tissue and antibodies used, this phenomenon is not always observed. Expression patterns for AFP may be related to tumor grade, although reported percentages of positivity per a given grade vary considerably. In small HCC with a diameter of <3 cm, AFP immunoreactivity was less frequent than that of vitamin K absence or antagonist II/PIVKA-II. There is evidence that AFP-positive HCC are biologically more malignant than those neoplasms that are AFP-negative or PIVKA-II-positive (Fujioka et al. 2001).

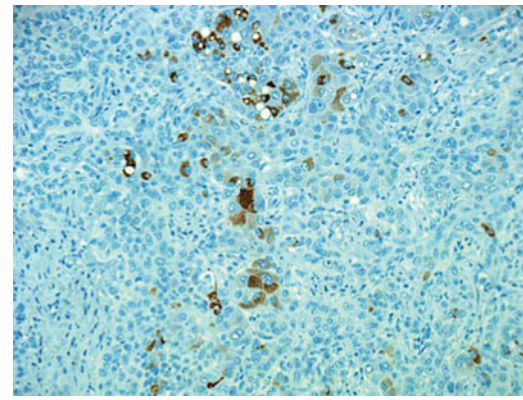

Fig. 4 A subset of hepatocellular carcinoma cells are reactive for alpha-fetoprotein (*AFP*) in a highly variable pattern (AFP immunostain)

Part of HCC cells are reactive for alpha-1-antitrypsin (AAT; Palmer and Wolfe 1976; Thung et al. 1979; Cohen et al. 1982; Nakopoulou et al. 1982; Fernandez-Izquierdo and llombart-Bosch 1987). In a series of 63 HCC cases, AAT reactivity of cancer cells was found in 82.5 % (Busachi et al. 1986). Some HCC showed atypical PAS-positive diastase-resistant globules resembling those in Z-gene AAT deficiency, and these globules were in part reactive for AAT (Palmer

and Wolfe 1976; Palmer et al. 1977; Reintoft and Hägerstrand 1979). In one investigation, atypical AAT-positive globules were found in 5.4 % of HCC, whereas a diffuse fine granular pattern of AAT distribution was detected in 31 % of HCC cases (Nakopoulou et al. 1982). A second study described AAT positivity in tumor cells in a finely granular pattern in 73 % of cases (Thung et al. 1979). In contrast to globules in normal hepatocytes in inherited AAT deficiency, where the inclusions are round and regular and show a ringlike AAT immunoreactivity, AAT inclusions in HCC were both intracellularly and extracellularly as round, but often distorted and less uniform globules (Palmer et al. 1980). However, other studies failed to detect AAT globules in HCC cells in patients with AAT deficiency who had inclusions in normal hepatocytes (Blenkinsopp and Haffenden 1977).

HCC cells are capable to synthesize and secrete ferritin. Serum ferritin concentrations are elevated in up to 100 % of patients with HCC. In part of these cases, ferritin can immunohistochemically be demonstrated in tumor tissue (Cohen et al. 1984). However, high serum ferritin in patients with HCC can also be caused by associated hepatic iron overload. Immunohistochemically, reactivity for ferritin was found in up to 70 % of cases, but predominantly in well-differentiated neoplasms (Imoto et al. 1985). HCC show an upregulated expression of transferrin receptors (Sakurai et al. 2014). PIVKA-II, an abnormal prothrombin, is secreted by part of HCC and serves as a serum marker for this neoplasm. About half of HCC showed cytoplasmic reactivity for PIVKA-II (Koda et al. 1993).

HCC-Specific Gamma-Glutamyltransferase

HCC cells can express a tumor-specific form of gamma-glutamyltransferase (GGT; hepatoma-specific GGT; HS-GGT; Yao et al. 2004). Analysis of HS-GGT bands in serum can serve as a diagnostic means for HCC (Yao et al. 1998). Overexpression of HS-GGT in HCC may be related to an altered methylation status of the HS-GGT gene (hypomethylation of CCGG sites; Yao et al. 2000).

Canalicular Domain Markers and Organelle Markers

CD10 (other names : neprilysin, CALLA/common acute lymphoblastic leukemia antigen, atriopeptidase, endopeptidase 24.11, enkephalinase, fibroblast metalloelastase, kidney-brush-border neutral peptidase, membrane metalloproteinase A, neutral endopeptidase; MEROPS peptidase code M13.001) is thermolysin-like zinc metalloendopeptidase of the neprilysin/NEP family that can also act as a secretase and plays an important role in tuning off peptide signaling events at the surface of several cell types, targets including enkephalins, tachykinins, chemotactic peptides, natriuretic peptide, and Alzheimer beta-amyloid peptide (Turner et al. 2001; Xiao et al. 2001). The canalicular domain, which is usually present in well-differentiated HCC, is immunoreactive for CD10 (CD1can), similar to polyclonal CEA antibody (Borscheri et al. 2001; Wee 2006). CD10 was detectable in 52 % of HCC cases (Chu et al. 2002), and is more often expressed by moderately to well-differentiated HCC cells than poorly differentiated HCC cells (Dragovic et al. 1997; Lau et al. 2002; Ahuja et al. 2008). Reactivity for CD10 is suitable to distinguish HCC from metastatic carcinomas resembling liver cancer (Ahuja et al. 2008). Expression of CD10can (but not its cytoplasmic counterpart, CD10cyt) in HCC was found to be a favorable prognostic factor (Mondada et al. 2006). Similar to CD10, polyclonal CEA antibody (pCEA) stains the canalicular domain of moderately to well-differentiated HCC (Varma and Cohen 2004), and reactivity was found in up to more than 80 % of cases (Wee and Nilsson 1997; Morrison et al. 2002; Al-Muhannadi et al. 2011). pCEA expression is related to tumor grade, in that canalicular staining becomes infrequent and irregularly distributed with increasing anaplasia. However, pCEA immunostaining did not separate

malignant, dysplastic, or benign hepatocytes (Wee and Nilsson 1997).

Intermediate Filament Expression Patterns

HCC cells can be distinguished from normal hepatocytes by differing patterns of organellogenesis, including mitochondria (Fig. 5).

Cytokeratins

Cytokeratins 8 and 18

HCC cells are strongly and consistently stained by CAM 5.2, which reacts with keratins of molecular weights 50, and 43, corresponding to cytokeratins 8 and 18 (Fig. 6; Hurlimann and Gardiol 1991; Wee 2006). Fifty-five percent of pure, classical HCC expressed cytokeratins of the hepatocyte lineage (D'Errico et al. 1996). In one study, intensity and extent of CMA 5.2 immunostaining did not correlate with the histologic grade of HCC (Johnson et al. 1988). In contrast to the strong expression of lineage-typical cytokeratins, most HCC do not show reactivity for vimentin, but vimentin may be positive in poorly differentiated HCC with ambiguous cell lineages. In HCC cells, the vimentin gene is aberrantly methylated (Kitamura et al. 2011), causing silenced expression via an epigenetic mechanism.

Cytokeratin 19

Part of HCC are reactive for cholangiocyte markers, including CK7 and CK19, a phenomenon probably related to transdifferentiation (Van Eyken et al. 1988; Shibuya et al. 2011). Expression of CK19 can also be found among morphologically pure HCC (D'Errico et al. 1996). Expression of CK19 in HCC as a stemness feature associated with high-risk biology (HCC of progenitor cell type). Expression of cytokeratin 19 (CK19; Keratin 19) is a feature typical for many adenocarcinomas, in particular also cholangiocarcinomas, while it was formerly held that CK19 is not a feature characterizing hepatocellular carcinomas (HCC). A subset of HCCs is characterized by the expression of stemness-related markers, including CK19 (Kamohara et al. 2008) and ezrin (Okamura et al. 2008). Such tumors have been termed, "dual-phenotype HCC/DPHHCC" (Lu et al. 2011). However, expression of CK19 in HCCs not only represents

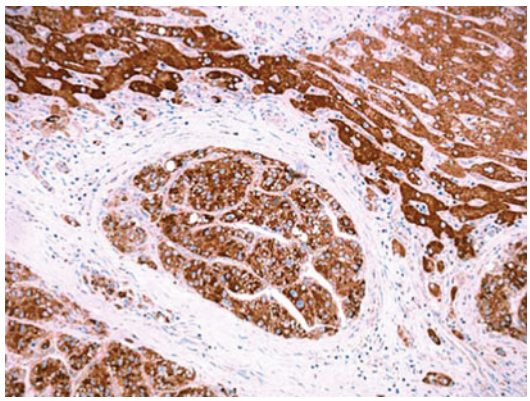

Fig. 5 Similar to normal hepatocytes, HCC cells contain variable amounts of mitochondria and are therefore reactive for a mitochondrial antigen (tumor focus in the center of the figure). The adjacent, strongly positive hepatocytes exhibit perifocal atrophy (mitochondrial antigen immunostain)

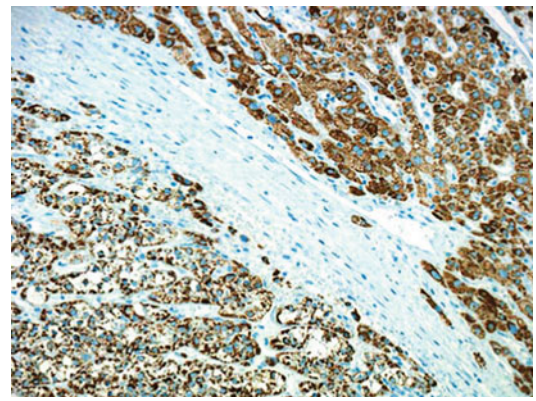

Fig. 6 Hepatocellular carcinoma cells (*left bottom corner*) show strong positivity for cytokeratins 8 and 18, but the granular reaction product is less compact than that of normal hepatocytes seen to the right and top (CAM 5.2 immunostain)

the acquisition of a biliary phenotype but is also related to stemness features. It has been proposed that HCC expressing a cholangiocyte phenotype is a novel subtype of HCC with a highly aggressive behavior. CK19 expression predicts accelerated progression of HCC and poorer survival (Uenishi et al. 2003; Yang et al. 2008; Yamada et al. 2011; van Malenstein et al. 2012; Wang et al. 2012a; Greenhill 2013; Lee et al. 2013; review: Izumi 2012). Among 155 HCCs, tumors with CK19 expression accounted for 10.1 %, and patients with this type of neoplasm a significantly lower overall survival and recurrence-free survival (Lu et al. 2011). 35.7 % of 210 surgically resected HCCs were CK19-positive, and this feature predicted early tumor recurrence and poor prognosis (Yuan et al. 2011). CK19-expressing HCCs with stemness-related marker expression demonstrated more frequent large vessel invasion, increased tumor size, microvessel invasion, poor tumor encapsulation, and poor survival (Kim et al. 2011). The adverse effect of CK 19 on prognosis, with early tumor recurrence, has also been found in small HCC after curative resection (Zhou et al. 2010), and particularly small HCCs (diameter <3 cm) additionally expressing mucin as an indicator for biliary differentiation form a high-risk group (Aishima et al. 2007). CK19-positivity in HCCs is an independent risk factor for developing lymph node metastasis (Ding et al. 2004; Zhuang et al. 2008). Part of HCCs expressing CK19 and showing aggressive behavior coexpress other stemness-related markers, such as CD133, nestin, CD44, and ATP-binding cassette subfamily G member 2/ABCG2 (Yang et al. 2010). In one investigation, CK19 was most frequently expressed in combination with at least one other stemness-related marker, such as CD133, EpCAM, and c-kit. HCC expressing CK19 in part also expressed Yes-associated protein 1, a potential oncogene known to promote stem cell proliferation (Kim et al. 2013). Expression of CK19 was also significantly associated with expression of proteins characterizing epithelial to mesenchymal transition (EMT), including vimentin, S100A4, uPAR, and ezrin (Kim et al. 2011). There is a significant inverse correlation between the expression of the organic anion transporter peptides (OATP) 1B1 and 1B3 and of CK7 and CK19, in that all HCCs expressing OATP 1B1/1B3 were CK7/CK19 negative (Vasuri et al. 2011). One stemness-related marker, epithelial cell adhesion molecule (EpCAM), is highly expressed in premalignant hepatic tissues and in a subset of HCCs (De Boer et al. 1999). EpCAM-positive HCCs display a distinct molecular signature with features of hepatic progenitor cells (Yamashita et al. 2008). The aggressive phenotype of EpCAM-positive HCCs may be related to the observation that expression of EpCAM shifts the state of cadherin-mediated adhesions from strong to weak (Winter et al. 2003). The reason why expression of CK19 is associated with higher aggressivity of HCCs is not yet known. From other tumor models there is evidence that CK19 and other intermediate filaments play an important role in tumor cell migration, invasion, and metastasis (Hendrix et al. 1996). Keratin 19-positive HCC highly expressed invasion-related/metastasis-related markers and showed expression of members of the miRNA 200 family. Furthermore, primary human keratin 19-positive HCC showed increased invasiveness in vitro (Govaere et al. 2014). HCC expressing "stemness"-related proteins were characterized by increased telomere length, augmented expression hTERT, and shelterin complex proteins, associated with increased chromosome instability, alterations favoring an aggressive tumor phenotype (Kim et al. 2013).

Proliferative Activity

Proliferative activity of HCC cells is usually assessed by means of determination of the mitotic index or immunohistochemical assessment using PCNA or Ki-67 (MIB1) staining (Figs. 7 and 8; Grigioni et al. 1989; Ojanguren et al. 1993; Ng et al. 1995). The proliferative activity of HCC assessed through PCNA and MIB1 labeling is significantly related to tumor differentiation (Ng et al. 1995). Whereas PCNA immunostaining of normal and regenerative livers showed no or only a minimal proliferative activity, even well-differentiated HCC exhibited a labeling index

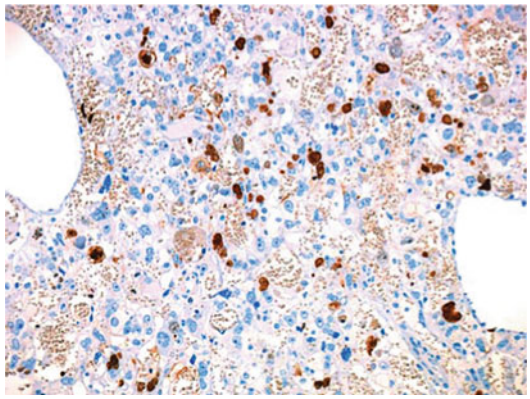

Fig. 7 Hepatocellular carcinoma, grade 3. There is increased proliferative activity (MIB1 immunostain)

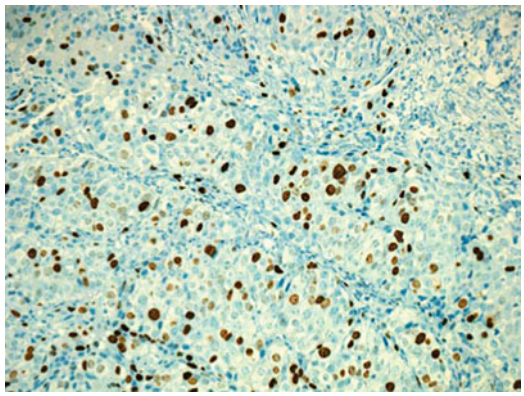

Fig. 8 This hepatocellular carcinoma with a diffuse growth pattern and grade 4 differentiation exhibits a markedly increased proliferative activity (MIB1 immunostain)

exceeding 15 % (Ojanguren et al. 1993). Ojanguren and coworkers (1993) classified PCNA labeling into several categories, i.e., absent; minimal, <5 % positive nuclei; grade 1, 1.5–25 % positive nuclei; grade 2, 26–50 % positive nuclei; grade 3, 51–75 % positive nuclei; and grade 4, 76–100 % positive nuclei. These categories are now known as Ojanguren grades. In cirrhotic liver harboring HCC, the PCNA labeling index was higher in perineoplastic cirrhotic liver than in perineoplastic non-cirrhotic liver (Mun et al. 2006). Based on Ki-67 immunostaining, HCC had a proliferative index ranging from 15 % to 50 %, dependent on Edmondson-Steiner grade (Grigioni et al. 1989). HCC express factors involved in the promotion of cell proliferation, such as cyclin D1 (expression associated with tumor progression), other cyclins (Choi et al. 2001), and S100A6 (Hua et al. 2011).

Markers of Cellular Differentiation

Apart from the synthesis and secretion of certain distinct proteins, such as AFP, other proteins produced by HCC cells reflect variable grades of differentiation and lineage features. The protein, differentiated embryo chondrocyte 1/DEC1, is expressed in the cytoplasm of hepatocytes and HCC, but well-differentiated HCC cells also display nuclear reactivity of DEC1, while low DEC1 expression indicates poor histologic differentiation (Shin et al. 2011). A subset of HCC expresses mucin core protein 1 (MUC1). In one study, MUC1 immunoreactivity was demonstrated in 85/186 HCCs, and MUC1 positivity in HCC was significantly associated with serum AFP concentrations, tumor differentiation, bile duct invasion, lymph node metastasis, cytokeratin 19 expression, and higher rate of first recurrence, suggesting that MUC1-expressing HCC form a high-risk group of neoplasms (Ichikawa et al. 2006). HCC express the squamous cell carcinoma antigen (SCCA) or variants/isoforms thereof, a protein that is also secreted into serum (Pontisso et al. 2004; Guido et al. 2008; Schmilovitz-Weiss et al. 2011). Immunohistochemically, the antigen is expressed in the cytoplasm of HCC cells, with an uneven distribution of positive tumor cells within HCC nodules, either scattered or in irregular clusters (Guido et al. 2008). A further expression pattern reflecting cell differentiation is the production of intercellular junctions and the associated proteins. Tight junctions are involved in numerous important processes in hepatocytes and cholangiocytes (reviews: Lee and Luk 2010; Lee 2012). In the course of carcinogenesis, including hepatocarcinogenesis, tight junction components undergo marked alterations which allow cancer cells to individualize and to dissociate, prerequisites for invasion (Swift et al. 1983). While occludin and ZO-1, two typical tight junction components, are

strongly expressed in canalicular domains of normal hepatocytes, they are not expressed in HCC cells. As colorectal metastases show strong occluding and ZO-1 expression, analysis of these two proteins may be diagnostically helpful (Orban et al. 2008). Tight junction proteins can be used in differential diagnostic approaches. Claudins have a complex role in liver cell function and play a role in HCV biology. Claudins are members of the tetraspanin family of proteins. During HCV infection, claudin-1 is highly expressed in liver and is required for HCV entry (Ahmad et al. 2011). Claudin-1 and claudin-4 are highly expressed in colorectal cancer metastasis, but claudin-1 has low expression in HCC and claudin-4 is virtually absent (Holczbauer et al. 2013). Lack of claudin-4 expression in HCC and high expression in cholangiocarcinoma has been described in another analysis (Lodi et al. 2006). Conversely, claudin-7 was expressed in HCC cells (Brokalaki et al. 2012). High expression of claudin-10 in HCC determined by molecular methods was associated with tumor recurrence (Cheung et al. 2005). Claudin-5 is expressed in sinusoidal endothelial cells, portal vein, and arteries, but not central veins, while it is downregulated in tumor vessels of HCC (Sakaguchi et al. 2008). Claudins play a role in acquisition of an invasive phenotype. For example, claudin-1 acts through a c-Abl-protein kinase C delta signaling pathway to promote cell invasion (Yoon et al. 2010).

Markers Related to Adhesion Molecules, Cytoskeletal Structures, and Tumor Cell Organelles

HCC express diverse cell adhesion molecules in differential patterns. Normal hepatocytes express E-cadherin but are only weakly stained for alpha-catenin, whereas bile duct cells show high-level expression of alpha-catenin. Conversely, E-cadherin and alpha-catenin expression is often reduced in HCC (Kozyraki et al. 1996; Zhao and Zimmermann 1998). Loss of E-cadherin expression on the surface of HCC cells is mainly found in poorly differentiated neoplasms (Shimoyama and Hirohashi 1991). Part of HCC express neural cadherin/N-cadherin, whereby overexpression of this adhesion molecular is a negative prognosticator (Seo et al. 2008). Epithelial cell adhesion molecule (EpCAM) is expressed by part of HCCs and is regarded as a stem cell marker in these neoplasms. EpCAM was preferentially expressed in HCC with a nodular growth pattern and high tumor grade (Bae et al. 2012). HCCs with progenitor cell features express the adhesion molecule, NCAM (Tsuchiya et al. 2011). A cell surface glycoprotein called MOC31 is consistently positive in cholangiocarcinomas and metastatic adenocarcinomas, but is negative in HCC (Proca et al. 2000).

An adhesion molecule that plays a significant role in HCC is CD44. The CD44 (cluster differentiation 44) isoform group is a conserved family of several transmembrane glycoproteins serving as cell surface adhesion molecules. CD44 mainly acts as a receptor for hyaluronan, but can also bind other glycosamino-glycans, glycoproteins, and proteins with lower affinity, including chondroitin sulfate, fibronectin, serglycin, and osteopontin. CD44 as an adhesion molecule is widely expressed in lymphoid cells, other leukocytes, and epithelial cells, and is an important component of lymphocyte homing. The cytoplasmic domain of CD44s interacts with several components of the cytoskeleton via ankyrin and proteins of the ezrin-moesin-radixin family. Upon binding of hyaluronan, CD44 activates the Rho GTPase signaling pathway. Interaction of CD44 isoform with cytoskeletal proteins is required for cell locomotion and plays a critical role for cell migration, specifically in cancer cell systems. Cells expressing CD44v(3,8–10) are capable to form membrane spikes or invadopodia required for locomotion, and CD44v(3,8–10) is closely associated with the actomyosin contractile system and with the active form of metalloproteinase-9. The activity of two metalloproteinases, MMP-2 and MMP-9, was stimulated by the interaction of the variant CD44, CD44st, with hyaluronan, associated with an invasive phenotype (Fang et al. 2011). Expression of CD44s is a well-known prognostic factor in various cancers, based on its functions as a tumor growth factor and adhesion

molecule affecting tumor cell invasion and spread. CD44 is not expression by normal hepatocytes (Mathew et al. 1996), but is expressed in HCCs in a membranous staining pattern (Washington et al. 1997;). CD44 expression in HCCs depends of differentiation and is an important progniticator. In a tissue array study of 260 HCC samples employing a primary mouse CD44s monoclonal antibody, expression of CD44s correlated with poor differentiation of HCC (high grade in Edmondson-Steiner grading) and shorter disease-free survival time (Ryu et al. 2011). A correlation with higher tumor grade was found in other studies (Beckebaum et al. 2008). In contrast, use of an antibody that does not distinguish between standard CD44 and splice variants did not show a correlation between CD44 expression and HCC grade (Washington et al. 1997), and reactivity for CD44 was not correlated with the proliferation index of HCC cells (Mathew et al. 1996). Immunoreactivity of CD44 in HCC is significantly correlated with vascular invasion (Mathew et al. 1996) and extrahepatic metastasis (Ogawa et al. 2004). CD44s expression in HCC is associated with higher cancer stage and the presence of lymph nodes metastases (Beckebaum et al. 2008). Apart from CD44 effects mediated by the modulation of tumor cell adhesion, the altered biologic behavior of HCC cells expressing CD44 and its variants may also be caused by a different cellular composition of CD44-expressing HCCs. Cancer stem cells/progenitor cells are highly enriched in CD133+/CD44+ populations of HCC (Zhu et al. 2010; Chan et al. 2014), suggesting the emergence of distinct cell lineages in these tumors.

Clathrin heavy chain positivity is a marker for HCC that already works in the diagnosis of small HCC (Di Tommaso et al. 2011). Golgi protein 73 (GP73) is expressed in HCC (Yao et al. 2013a) and appears in serum, whereby there is evidence that serum GP73 has a either a comparable or lesser accuracy to AFP for the diagnosis of HCC (Ozkan et al. 2011; Zhou et al. 2012). In contrast to cholangiocarcinomas, HCC cells are not reactive for epithelial membrane antigen/EMA, positive cases representing mixed hepato-cholangiocarcinomas (Sacho et al. 1991).

Oncogenes and Tumor Suppressor Genes

A majority of HCC revealed nuclear reactivity for p53 protein related to p53/TP53 gene mutations (Fig. 9; Cohen and DeRose 1994; Zhao et al. 1994; Kang et al. 1998).

The TP53 gene encodes a tumor suppressor protein, p53, composed of several domains, including transcriptional activation, DNA-binding, and oligomerization domains. P53 protein is a cellular stress response protein that regulates the expression of several genes affecting cell proliferation, apoptosis, DNA repair, and cell senescence. In a recent whole-genome sequencing analysis, TP53 was the most frequently mutated tumor suppressor in HCC (35.2 %; Kan et al. 2013). Mainly in East Asia and southern Africa, p53 protein expression is linked to a mutational hot spot at codon 249 of the p53 gene (Murakami et al. 1991; Debuire et al. 1993). However, p53 protein overexpression is frequent in European HCC largely independent of the codon 249 hotspot mutation (Volkmann et al. 1994). The TP53

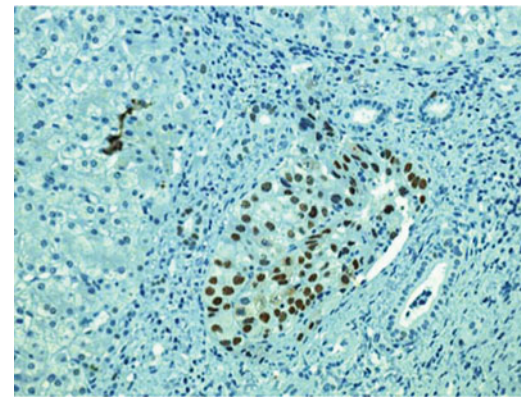

Fig. 9 This hepatocellular carcinoma, which has invaded a venous branch in a portal tract, shows strong nuclear reactivity for p53 protein. The lesion is surrounded by several small interlobular bile ducts (p53 immunostain)

gene mutational hot spots R249S and V157F were significantly associated with worse prognosis (Villanueva and Hoshida 2011). The patterns of p53 mutations have been shown to vary among tumors within the same liver (Tullo and Sbisa 2002), suggesting the emergence of several clones with a different genomic composition. Immunohistochemically, p53 protein reactivity presents as a strong nuclear positivity that may be patchy or diffuse. Nuclear staining restriction depends on the antibody used and was mainly found with the antibody CM-1, whereas other antibodies may also result in variable degrees of cytoplasmic staining (Zhao et al. 1994). There was no relationship between p53 immunostaining and type or grade of HCC (Zhao et al. 1994). However, one study showed a correlation between p53 reactivity and significantly higher Ki67 scores (D'Errico et al. 1994).

HCCs can express a tumor suppressor protein related to p53, p73 (Herath et al. 2000). The p73 gene is located at chromosome 1p36.3. Similar to p53, p73 is involved in the regulation of apoptosis. HCC which express p73 protein belong to a aggressive, high-risk group (Tannapfel et al. 1999).

Components of the Wnt/Beta-Catenin Signaling Pathway

Whole-genome sequencing demonstrated that beta-catenin, a key component of the Wnt signaling pathway, is the most frequently mutated oncogene (15.9 %; Kan et al. 2013). There is a tight correlation between beta-catenin gene mutations and the expression of Wnt target genes in HCC. In one investigation, 36 % of HCC displayed beta-catenin immunostaining, and this immunophenotype was associated with certain signification features, including a homogeneous microtrabeculo-acinar pattern, low-grade cellular atypia, and cholestasis, the latter visualized in the form of numerous bile plugs in acinar or canaliculus-like lumina (Audard et al. 2007). Abnormal beta-catenin reactivity in the cytoplasm and/or nuclei of HCC cells was also found at higher rates, e.g., 72.9 % (Fig. 10; Li et al. 2014).

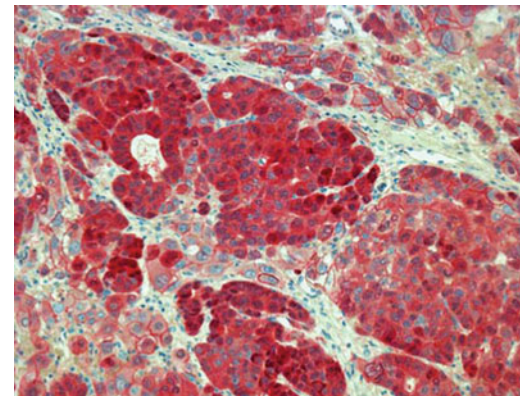

Fig. 10 Hepatocellular carcinoma with mixed cytoplasmic, membranous, and nuclear reactivity for beta-catenin (beta-catenin immunostain)

Similar to hepatoblastoma, overexpressed beta-catenin is correlated with cytoplasmic overexpression of cyclin D in HCC, and is associated with increased proliferative activity of tumor cells (Ueta et al. 2002). HCC that harbor exon-3 mutations of the beta-catenin/CTNNB1 gene showed a distinct phenotype with frequent macro-and microvascular invasion, a larger tumor size, a less common association with cirrhosis, and an aggressive behavior, as beta-catenin plays a significant role in the metastatic cascade (Cieply et al. 2009; Lai et al. 2011). In comparison with normal liver, HCC show much less reactivity for Wnt-5a (Li et al. 2014).

Extracellular Matrix of HCC

HCC possess, depending on the amount of stroma formation, a complex extracellular matrix which shares many proteins and glycoproteins with the normal hepatic matrix. Typical components of this matrix include interstitial collagens and mucopolysaccharides, basement membrane proteins (laminin, type IV collagen, nidogen, fibronectin), tenascin, protein receptors such as laminin receptors, and proteases and growth factors that are stored in

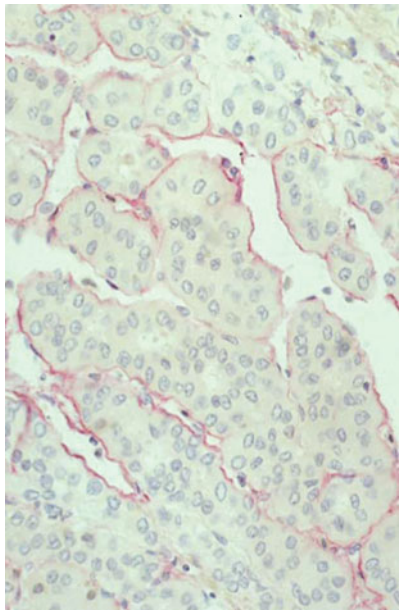

Fig. 11 This trabecular hepatocellular carcinoma shows a thin rim of peritrabecular extracellular matrix, situated between tumor cell plates and vascular channels. This matrix reveals reactivity for laminin (*red* reaction product; laminin immunostain)

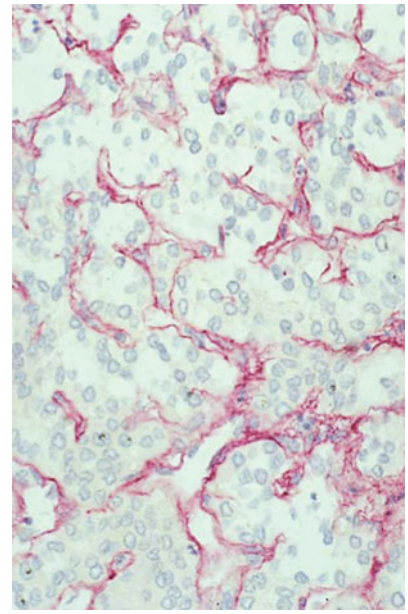

Fig. 12 As a marker for tumor extracellular matrix there is reactivity for tenascin in the peritrabecular space of this hepatocellular carcinoma (*red* reaction product; tenascin immunostain)

the matrix. Part of these proteins are present both within cancer cells and in the extracellular space, e.g., fibronectin (Okushin et al. 1987; Figs. 11 and 12).

The composition of the extracellular matrix affects the biologic behavior of HCC cells (Grigioni et al. 1991). Type IV collagen is predominantly present along sinusoid-like vascular channels in well-differentiated HCC, whereas laminin and type IV collagen in poorly differentiated HCC is mainly restricted to large intratumoral vessels (Grigioni et al. 1987). Most HCC show expression of tenascin, this expression being stronger than that of accompanying cirrhosis (Zhao et al. 1996) and the basement membrane protein nidogen (Cheng et al. 2012). Proteins of basement membrane substance, including type IV collagen and laminin, are differentially expressed in various types of HCC. As the extracellular matrix is less well developed in poorly differentiated HCC, such neoplasms showed a reduced expression of type IV collagen (Zhao et al. 1996). Agrin, a basement component, is a multifunctional heparan sulfate proteoglycan, is present in minor amounts in hepatic blood vessel walls and around bile ducts, but is upregulated in cirrhosis and HCC (Tatrai et al. 2009; Somoracz et al. 2010), the source probably being myofibroblasts (Tatrai et al. 2006). The stroma of HCC can contain heparan sulfate proteoglycans, e.g., syndecan-3 and perlecan, proteoglycans that may be involved in angiogenesis (Roskams et al. 1998). HCC can express various types of matrix metalloproteinases and their inhibitors. Tissue inhibitor of metalloproteinases (TIMP) is detectable in myofibroblasts, smooth muscle cells and endothelial cells of blood vessels, and bile ducts cells of normal livers, and is strongly expressed in the capsule of HCC (Fukuda et al. 1991). HCC also express factors involved in the production of an extracellular matrix, including several types of fibrokines and their regulators.

CD34 Expression in Vascular Endothelial Cells: An Important Diagnostic Feature

In normal liver tissue, CD34 immunostaining is restricted to portal tracts and few sinusoids in the periportal zone 1 of the lobule; whereas in HCC a diffuse and strong endothelial cell reactivity is present (Figs. 13, 14, 15, 16, and 17; Tanigawa et al. 1997).

CD34 immunostaining is in fact a highly sensitive method for the diagnosis of HCC, as it clearly outlines the abnormal growth pattern of

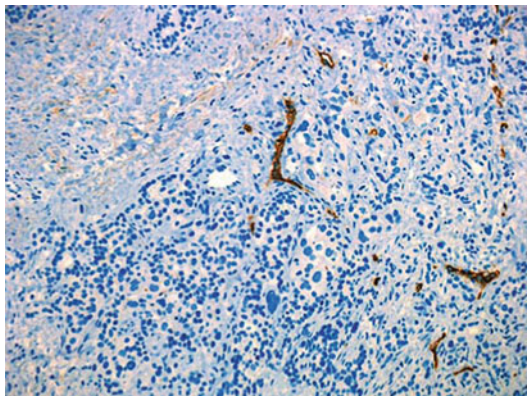

Fig. 13 CD34-reactive small feeding vessels at the periphery of hepatocellular carcinoma (CD34 immunostain)

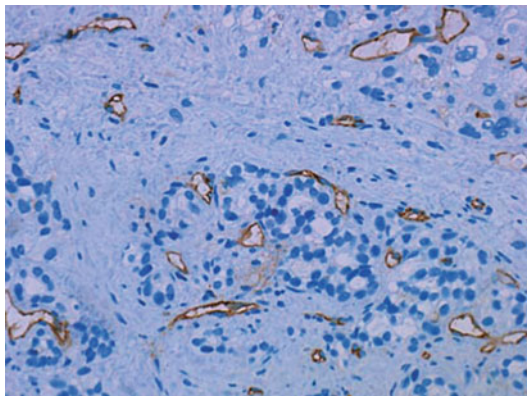

Fig. 14 Angiogenesis in hepatocellular carcinoma results in an intricate relationship between small tumor vessels (*brown*) and clusters of tumor cells (CD34 immunostain)

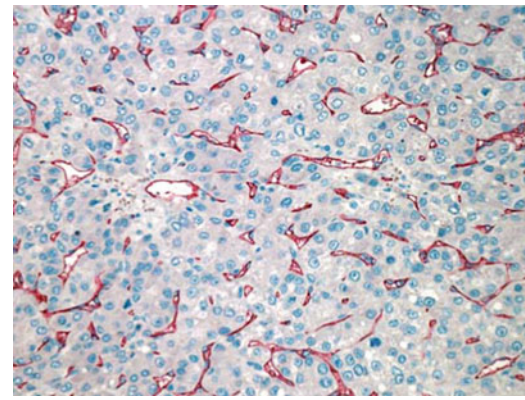

Fig. 15 The vascular channels of this trabecular hepatocellular carcinoma are lined by diffusely CD34-positive endothelial cells (CD34 immunostain)

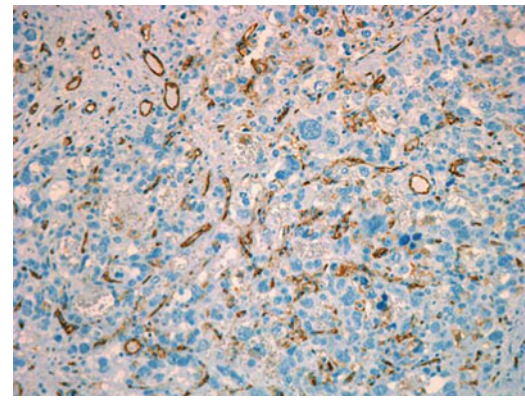

Fig. 16 At the invasion front of this hepatocellular carcinoma (upper third of figure), vigorous angiogenesis has taken place (CD34 immunostain)

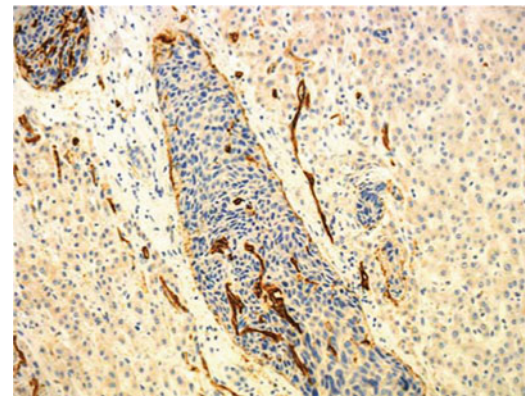

Fig. 17 An intravascular plug of hepatocellular carcinoma ("tumor thrombus") is secondarily vascularized by CD34-positive vascular sprouts (CD34 immunostain)

HCC, mainly well or moderately differentiated forms (Gottschalk et al. 1998; Wee and Nilsson 2003; Varma and Cohen 2004; Coston et al. 2008; Tatrai et al. 2009; Yao et al. 2013a). However, diffuse CD34 immunostaining is not specific for HCC, as it also occurs in part of liver cell adenomas and focal nodular hyperplasia (de Boer et al. 2000). These authors proposed that the reticulin stain may be superior to CD34 immunostaining in the diagnosis of HCC. There is evidence that CD34-positive endothelial cells may play a significant role in hepatocarcinogenesis. These cells may, at least in part, originate from circulating progenitor cells capable to transform into a distinct population of endothelial cells (Ohmori et al. 2001).

Markers Related to HCC Angiogenesis

As described in more detail in a separate chapter, angiogenesis is a prominent feature of HCC and exerts a strong influence on tumor biology (Semela and Dufour 2004; Fernandez et al. 2009). Angiogenesis in HCC is derived from endothelial cells of feeding arteries and sinusoid-like vascular channels, but liver-specific pericytes also play a role, mainly as mediators of sinusoidal remodeling (Lee et al. 2007). Several factors involved in angiogenesis are expressed, or upregulated, in HCC. Vascular endothelial growth factor/VEGF is expressed in HCC cells, but also in hepatocytes and vascular endothelial cells, but VEGF expression in endothelial cells is numerous times more common in HCC than in the surrounding liver, suggesting that VEGF plays an important role in tumor angiogenesis (An et al. 2000). CD105 (endoglin) is strongly expressed in tumor vessels and is related to prognosis (Duff et al. 2003; Yang et al. 2006). Endoglin is a co-receptor for several TGF-beta family cytokines, is expressed in dividing endothelial cells alongside ALK1 and ACVRL1, and is required for BMP9 (bone morphogenetic protein 9)/pSMAD1 signaling in endothelial cells. Endothelial cells of HCC, and mainly those of microvessels, are reactive for the chemokine receptor, CXCR7 (Monnier et al. 2012).

Other Markers

Part of HCC cells revealed reactivity for thrombospondin in the cytoplasm, but were also present in accompanying fibroblasts and endothelial cells (Hayashi et al. 1997). Reactivity for serine peptidase inhibitor, Kazal type 1 (SPINK1), was found in more than 90 % of HCC, but was not detectable in normal or cirrhotic liver tissues and in dysplastic nodules (Marshall et al. 2013). Early HCC were found to be reactive for CD147 (EMMPRIN) (Mamori et al. 2007). Few cases of HCC were immunoreactive for inhibin (McCluggage et al. 1997; Vrettou et al. 2005), inhibin as such not being a marker of the hepatocyte lineage or of most HCC, and positive results usually being caused by endogenous biotin (Iezzoni et al. 1999). Part of HCC are reactive for the transcription factor SALL4, which is a well-known marker for yolk sac tumor. In contrast to yolk sac tumor, which displays as diffuse finely granular nuclear staining pattern, HCC show a distinct punctuate/clumped nuclear pattern of SALL4 staining (Gonzalez-Roibon et al. 2013). Part of HCC express osteopontin, a secreted phosphoprotein implicated in cancer progression and metastasis (Pan et al. 2003; Hua et al. 2011), and osteonectin/SPARC, which is mainly expressed in stromal fibroblasts of HCC showing a high grade (Le Bail et al. 1999). Importin-alpha1 is produced by HCC cells and is a factor associated with progression of disease (Yoshitake et al. 2011). Aldo-ketoreductase family 1 member B10 (AKR1B10) reactivity seems to be promising diagnostic marker for HCC (Schmitz et al. 2011). Subsets of HCC are reactive for multidrug resistance-conferring transporters. Multidrug resistance-associated protein 1 (MRP1) expression was high in HCC with poor differentiation, large tumor size, and microvascular invasion and may reflect tumors with progenitor cell features and an aggressive biology (Vander Borght et al. 2008). Another immunohistochemical marker associated with poor tumor differentiation is p21 (Schoniger-Hekele et al. 2005). The PTEN phosphatase was expressed in 64–5 % of HCC, but immunoreactivity was lower and weaker than that in

surrounding non-neoplastic liver tissues (Wu et al. 2007). Prothymosin alpha, normally positive in the nuclei of bile duct cells but not in quiescent hepatocytes, is intensely expressed in regenerating hepatocytes and HCC cells, confirming that this protein is related to the regulation of liver cell proliferation (Fraga et al. 1993). Expression of the insulin-like growth factor-I receptor may participate in hepatocarcinogenesis (Yan et al. 2013). HCC, but also regenerating hepatocytes, overexpress hepatic prothymosin alpha, which may be a marker for this neoplasm. Reactivity is exclusively present in nuclei (Fraga et al. 1993; Wu et al. 1997).

Immunohistochemical Panels Serving for Diagnosis of HCC

The specificity of lineage marker expression can be augmented by combining the most efficient markers, namely arginase-1, Hep Par1, heat shock protein 70, glutamine synthetase, and glypican-3 (Sakamoto et al. 2008; Shin et al. 2011; Timek et al. 2012; Tremosini et al. 2012; Lagana et al. 2013), and eventually other markers. Histologic diagnosis of well-differentiated HCC can be difficult, especially in biopsies, as tumor cells may only slightly deviate in their morphology from normal hepatocytes or benign hepatocellular tumors. Apart from a careful analysis of cell morphology, reticulin patterns, and vascular architecture, panels of immunohistochemical stains are helpful in critical situations. A panel including glypican-3, heat shock protein 70, and glutamine synthetase have proven to be of use in the diagnosis of HCC, including small and well-differentiated HCC (Di Tommaso et al. 2009), early HCC (Tremosini et al. 2012), and to distinguish low-grade HCC from hepatocellular adenoma (Lagana et al. 2013). For the distinction of small HCC from dysplastic nodules, a combination panel of aminoacylase-1, glypican-3, and sequestosome-1 has been proposed (Jin et al. 2013). For separating HCC from intrahepatic cholangiocarcinoma, a combination of glypican-3 and CK19 was proposed as a first-line marker, with an accuracy rate of 73.5 %, and adding claudin 4 and MOC31 increased this rate to 88.5 % (Ryu et al. 2012), MOC31 mainly serving to distinguish HCC from cholangiocarcinoma and metastatic adenocarcinoma (Porcell et al. 2000).

Abstract

Hepatocellular carcinoma (HCC) is a highly invasive malignancy that frequently invades small and large blood vessels, the liver substance, and bile ducts. In contrast to cholangiocarcinoma, perineural and intraneural invasion is a less common invasion mode of HCC. Invasion of the portal vein, with or without associated venous thrombosis, is a typical feature of HCC and plays a central role in intrahepatic tumor spread. Hepatic microvascular invasion is more frequently observed in HCCs with a lower degree of differentiation and confers an aggressive tumor biology. HCCs with extranodular growth and contiguous multinodular growth patterns are prone to microvascular invasion. HCCs give rise to intrahepatic and remote metastases with high frequency. Risk factors for metastasis comprise macro- and microvascular invasion, large tumor size, multifocality, and poor histologic differentiation. Intrahepatic metastases, which may occur in more than 80 % of large tumors, appear as macro- or micrometastases. Extrahepatic metastases are predominantly found in the lung, bone, lymph nodes, and brain, followed by the gastrointestinal tract and other sites.

Invasion Patterns of Hepatocellular Carcinoma

Phenotypes of Invasion

HCCs are highly invasive neoplasms that have a marked tendency to invade small and large hepatic blood vessels, perivascular compartments (interstitial invasion), and bile ducts. As outlined in the analyses of small HCC, interstitial invasion can microscopically be classified into three patterns, i.e., a crossing type, in which HCC cell invades across fibrous septa of tumor nodules; a longitudinal type, in which HCC cells grow longitudinally within fibrous septa; and an irregular type, in which portal areas are irregularly invaded by cancer cells (Kondo et al. 1994). Intrahepatic neural invasion has been noted in HCC (Ueda et al. 1991), but this feature is probably less common in HCC than cholangiocarcinomas.

Blood Vessel Invasion

HCC has a strong tendency to invade large and small hepatic blood vessels (macrovascular and microvascular invasion; Figs. 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, and 12).

Invasion-induced thrombosis of portal vein branches can result in organization and cavernous transformation. On the other hand, portal vein obstruction may be followed by perivenous collateral networks forming cavernous vasculatures (Terada et al. 1989). Terminal portal vein invasion, a crucial finding of early HCC, can be assessed by the use of Victoria blue staining (Kobayashi et al. 2012a). Microvascular invasion

Fig. 1 Hepatocellular carcinoma with invasion of the extrahepatic portal vein. The vein is longitudinally opened and contains friable, greenish tumor masses in the absence of a thrombus (necropsy specimen)

is a common feature mainly in less well-differentiated HCC and is a parameter that confers aggressive tumor biology (Rodriguez-Peralvarez et al. 2013). Independent predictors of microvascular invasion were tumor size exceeding 4 cm or 5 cm and a high tumor grade (Kim et al. 2008; Esnaola et al. 2002). High-risk macroscopic growth patterns, i.e., single nodular type with extranodular growth and contiguous multinodular type, are strong predictors of microvascular invasion (Nagano et al. 2008). Patients with Edmondson-Steiner grade 1 and a tumor diameter of less than 5 cm had no microvascular invasion, while those with grade 2 or higher had higher incidences of microvascular invasion, even in small tumors (Kim et al. 2008). Apart from tumor size, high serum AFP and high levels of des-gamma-carboxyprothrombin in serum are significant factors in identifying microvascular invasion (Eguchi et al. 2010).

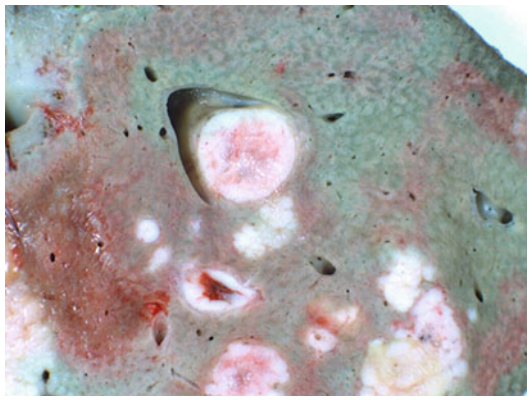

Fig. 2 A dilated intrahepatic portal vein branch shows an eccentrically placed HCC nodule that invaded the vein, forming a bulging mass. The tumor nodules in the vicinity may have resulted from intravenous cancer spread

Lymph Vessel Invasion

In the light of locoregional lymph node metastases, HCC will often invade intrahepatic lymph vessels, although it is difficult to identify invaded intrahepatic thin-walled vessels without immunohistochemistry. Lymphovascular invasion is more easily detectable in extrahepatic structures, e.g., the hepatoduodenal ligament, where also lymphangitis carcinomatosa is found. Lymphangitis carcinomatosa was first described by the French physician, Gabriel Andral, in 1824 (cited in Doyle 1989) and later studied in detail by Virchow. It is not an inflammatory change, as the term would suggest, but the presence of cancer cells in lymph vessels, sometimes associated with thrombus-like masses. Cancer cells, including HCC cells, can proliferate within lymph vessels and can produce nodule-like lesions that cause saccular lymph vessel dilatation. As with other malignancies, the mechanisms of lymphatic invasion and spread are complex and in part depend on tumor-induced lymphangiogenesis (review: Achen and Stacker 2008).

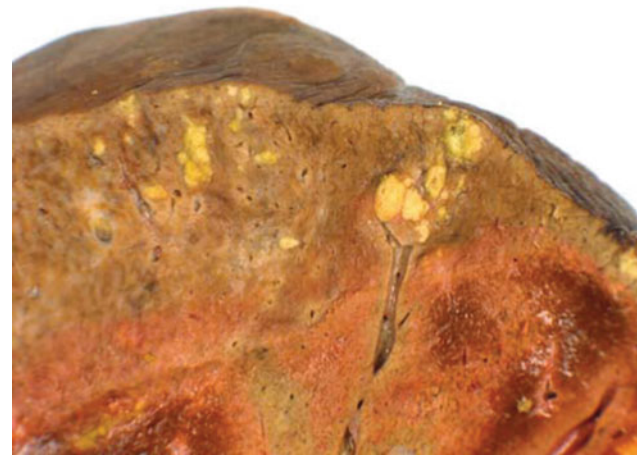

Fig. 3 Intrahepatic portal vein invasion by HCC can result in peripheral intrahepatic spread, causing numerous metastatic tumor nodules with a distribution reflecting the vascular tree

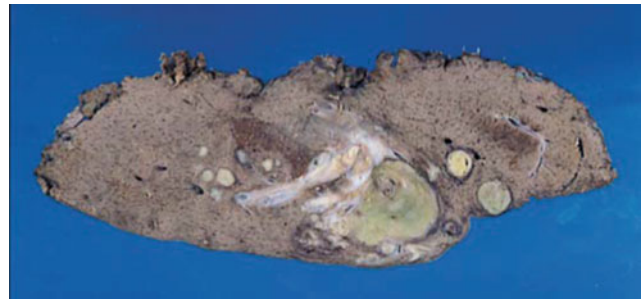

Fig. 4 A large hepatocellular carcinoma (greenish tumor nodule) invaded an adjacent large portal vein branch, followed by intravenous tumor spread with several intravenous tumor casts

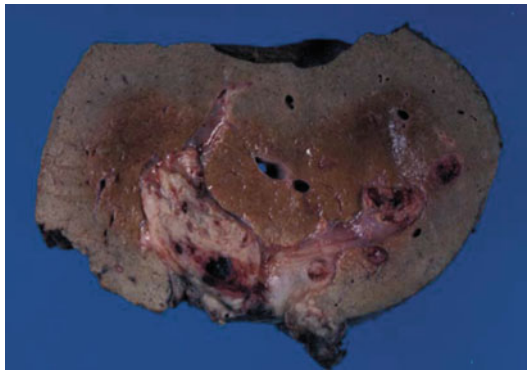

Fig. 5 Massive HCC invasion of hepatic veins. Note that the intravenous tumor displays hemorrhage and necrosis

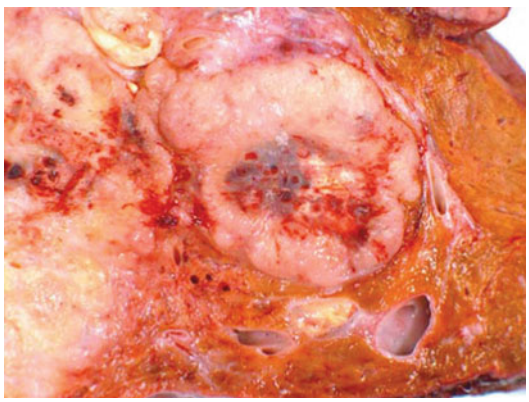

Fig. 6 Intrahepatic portal vein invasion by hepatocellular carcinoma (*center* of figure). The large tumor has completely obturated the dilated vein, but a probe could still be inserted between tumor and venous wall

Vasculogenic Mimicry

HCC cells with a metastatic phenotype can produce in vitro the chord-like structures that represent vasculogenic mimicry (VM). VM is

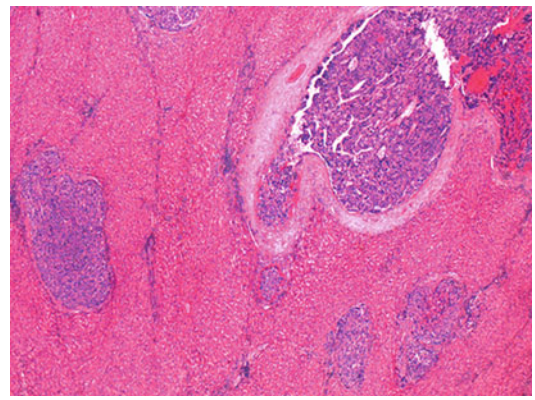

Fig. 7 Intravascular hepatocellular carcinoma ("tumor thrombus" of HCC) in a portal vein branch is accompanied by several smaller intravascular tumor foci, suggesting intravascular spread for the larger tumor focus (hematoxylin and eosin stain)

morphologically characterized by vessel-like channels lined by tumor cells. It is thought that VM plays an important role in invasion and spread within tumor stroma (Kirschmann et al. 2012). The establishment of VM depends on the activity of several factors in HCCs, including Twist1 (Ma et al. 2011; Sun et al. 2011), Slug (Sun et al. 2013b), ROCK signaling (Zhang et al., 2014a), Notch1 (Zhu et al. 2014), and autophagy mechanisms (Ding et al. 2014). The process of VM in HCC is critically regulated by osteopontin, probably through activation of matrix metalloproteinase 2 and urokinase-type plasminogen activator (Liu et al. 2011).

Interstitial Invasion Patterns

HCCs invade hepatic parenchyma, perivascular spaces, bile ducts, and periductal sheaths by

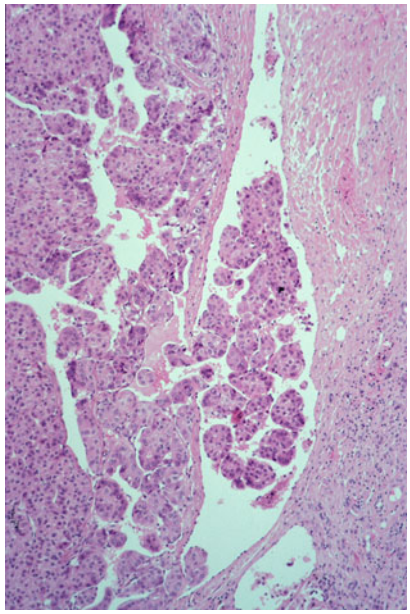

Fig. 8 In this hepatocellular carcinoma, tumor tissue invasion of an intrahepatic portal vein branch caused a break or gap in the venous wall (*middle* of figure; hematoxylin and eosin stain)

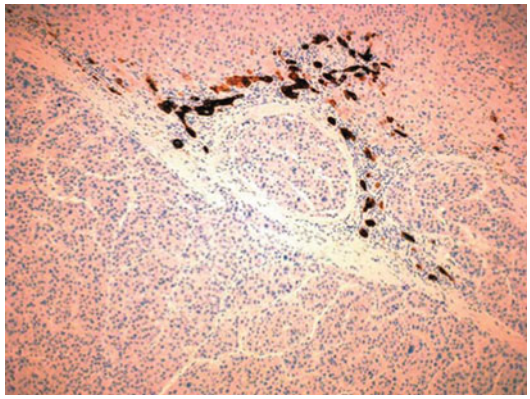

Fig. 9 This hepatocellular carcinoma underwent invasion of a small intrahepatic portal venous branch (*middle* of figure). This invasion is associated with a perifocal ductular reaction (brown profiles; cytokeratin 19 immunostain)

invasion mechanisms discussed in a later chapter. Infiltration of normal tissue via histolytic mechanisms allows the tumor to transgress tissue barriers and to reach peritumoral tissue compartments, including resection margins (Figs. 13 and 14).

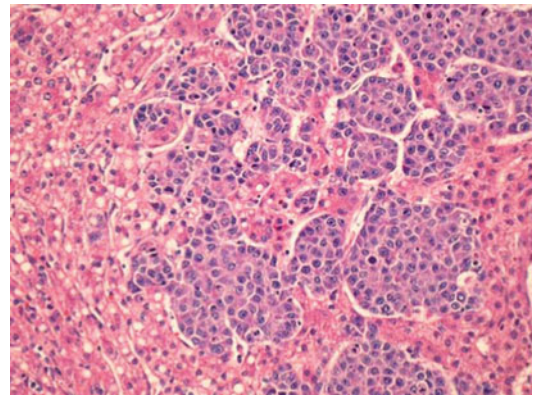

Fig. 10 Hepatocellular carcinoma, intrasinusoidal spread. Tumor cells grow within the dilated sinusoids, sometimes causing atrophy of hepatocyte plates (hematoxylin and eosin stain)

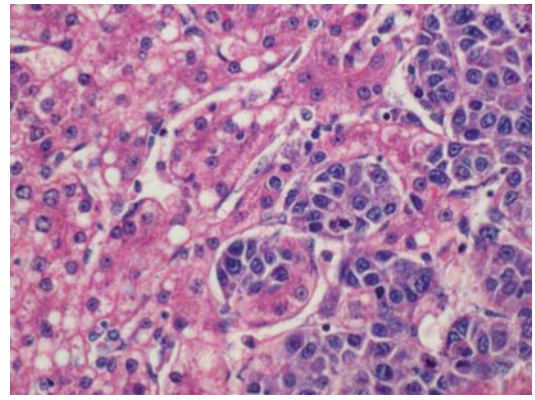

Fig. 11 Hepatocellular carcinoma, intrasinusoidal invasion. Neoplastic cells can invade hepatocyte plates, facilitating direct contact between tumor cells and liver cells (*below center* of figure). Heterologous cell interactions of this type play a role in tumor growth, invasion, and progression (hematoxylin and eosin stain)

Epithelial-Mesenchymal Transition (EMT) in Hepatocellular Carcinoma

Epithelial-mesenchymal transition (EMT) plays a central pathogenic role in the generation of a tumor microenvironment that favors an invasive phenotype. In addition, HCC cells and other tumor cells undergoing EMT become cells with a certain plasticity required for spread and homing at remote places. HCC EMT affects biology of disease, in that tumors showing EMT exhibit a

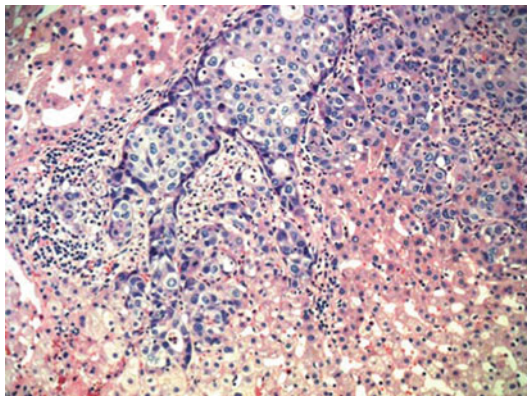

Fig. 12 Intrasinusoidal invasion of HCC cells is associated in this case with tumor cell presence in inlet veins and portal venous branches (hematoxylin and eosin stain)

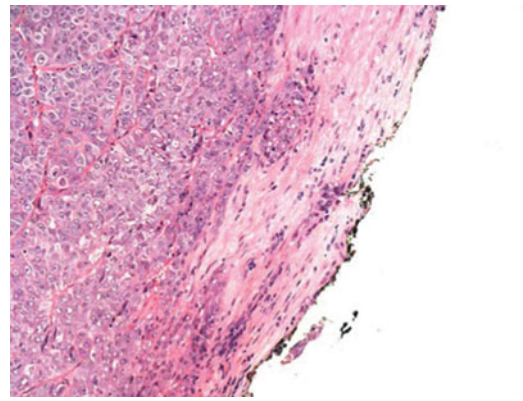

Fig. 14 Hepatocellular carcinoma, inked resection margin (*black* particles). Note that invading neoplastic cells have reached the inked surface at one place (hematoxylin and eosin stain)

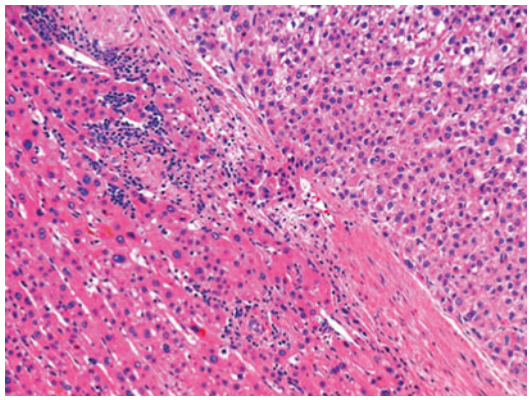

Fig. 13 A well-differentiated hepatocellular carcinoma (*right half* of figure) has perforated its fibrous pseudocapsule to invade adjacent liver tissue (*center*; hematoxylin and eosin stain)

more aggressive course (Yamada et al. 2014). Similarly, abnormal expression of EMT-related proteins such as S100A4, vimentin, and E-cadherin is correlated with prognosis in HCC (Zhai et al. 2014). Reduced E-cadherin expression indicates poor prognosis for patients with HCC (Chen et al. 2014).

EMT in HCCs is induced and controlled by numerous factors. EMT is promoted by the transcription factors ZEB1 and ZEB2, the expression of which is suppressed by p53 protein via upregulation of microRNA-200, which in turn represses ZEB1/ZEB2 expression (Kim et al. 2011). Periostin, an extracellular matrix protein involved in the regulation of EMT, is expressed in the stroma and epithelia of a subset of HCC and indicates aggressive biology of disease (Riener et al. 2010). Astrocyte elevated gene-1 (AEG-1) is a biomarker of EMT in HCC and seems to be involved in tumor progression (Zheng et al. 2014). HCC invasion depending on EMT is promoted by RANKL which induces NF-kappaB-mediated EMT (Song et al. 2014). In HCC cells, protocadherin 9 inhibits EMT and cell migration through activation of the GSK-3beta pathway situated within Wnt-beta-catenin signaling system (Zhu et al. 2014). A factor involved in the regulation of cell proliferation and differentiation, mammalian sterile-20-like kinase 4/MST4, promotes HCC EMT and metastasis through activation of the p-ERK pathway (Lin et al. 2014). EMT in HCCs is regulated by several microRNA species (review: Yang et al. 2014). The microRNA-200 family plays an important role in the regulation of EMT (Mongroo and Rustgi 2010). Downregulation of microRNA-200a induces EMT in hepatic stem cells through targeting the beta-catenin signaling pathway (Liu et al. 2013a). MicroRNA-141 suppresses HCC progression by targeting the EMT factor ZEB2 (Wu et al. 2014). Vasohibin 2, a factor involved in EMT and angiogenesis in HCCs, is upregulated by microRNA-200. Vasohibin 2 promotes EMT through the ZEB1/ZEB2 signaling pathway (Xue et al. 2014).

MicroRNA-122 triggers EMT in HCC, but suppresses cell motility and invasion by targeting RhoA (Wang et al. 2014). MicroRNA-26b inhibits EMT in HCC by targeting the 3′UTR of USP9X, which in turn affects EMT via Smad4 and the TGF-beta signaling pathway (Shen et al. 2014).

Metastatic Patterns of Hepatocellular Carcinoma

Introduction

Hepatocellular carcinoma is a malignancy with a high capacity for metastatic spread, critically linked to its frequent invasion (intravasation) of small and large hepatic blood vessels (Fig. 15).

Apart from intrahepatic metastases, which are the key feature of recurrent disease, HCCs can metastasize to remote organs, albeit with distinct metastatic patterns (reviews: Zhou 2002; Tang et al. 2004).

Factors Influencing HCC Metastasis

Risk factors for HCC metastasis mainly comprise vascular invasion, larger tumor size, multifocality, and poor histologic differentiation (Si et al. 2003).

Fig. 15 Intrahepatic metastasis of hepatocellular carcinoma. Most of the metastatic nodules are situated close to the primary tumor in the left lobe, while fewer nodules are found on the contralateral side

Early microvascular invasion followed by tumor cells distribution in the circulation is regarded as the most important step for metastatic spread and plays a central role in hepatic recurrence (Imamura et al. 2003). Vascular invasion by HCC cells is not only an inherent features of motile and histolytic cancer cells but is also regulated by distinct genes that affect metastatic spread, including metastatic tumor antigen 1 (MTA1) which directly promotes vascular invasion (Moon et al. 2004; Ryu et al. 2008), and the actions of microRNAs involved in metastasis regulation, e.g., microRNA-135a (Liu et al. 2012). The presence of circulating tumor cells (CTC) has been confirmed in several studies, and these cells are associated with metastasis and prognosis in HCC patients (Guo et al. 2007; Yang et al. 2008; Chiappini 2012; Zhang et al. 2012a).

Subsets of CTC express epithelial cell adhesion molecule (EpCAM), intercellular adhesion molecule 1 (ICAM-1), and/or SALL4 and therefore have features of HCC progenitor cells (Liu et al. 2013c; Sun et al. 2013a). EpCAM-positive CTC as a biomarker of systemic disease are significantly associated with survival (Schulze et al. 2013). Epithelial-mesenchymal transition (EMT), which plays a significant role in metastatic spread of malignancies, is involved in promoting the blood-borne dissemination of primary HCC cells (Li et al. 2013). CTC in HCC consist of several subgroups with varying epithelial, mesenchymal, liver-specific, and mixed features, whereby the representation of these subgroups affects distinct clinical patterns (Nel et al. 2013). Epigenetic upregulation of HGF and c-Met in CTC drives metastatic spread in HCC patients (Ogunwobi et al. 2013). CTC can be detected in early phases of spread by analyzing their molecular signatures, e.g., through analysis of the MAGE-3 and MAGE-4 genes (Hussein et al. 2012). The spread of the "HCC disease" in blood circulation is also assessable via analysis of surrogate markers of circulation entry by the tumor, e.g., endoglin/CD105 (Yagmur et al. 2007). Interestingly, there is also evidence that endothelial cell progenitor is present in the circulation of HCC patients, and the presence of such cells is associated with poor survival,

suggesting a role in tumor spread (Shao et al. 2011). How is the fate of CTC regulated? It is likely that only part of CRC remain viable, are capable to home to distinct vascular beds, perform egress into tissue, and can resume proliferation and growth to metastatic nodules. Subsets of CTC are subject to host defense mechanisms and undergo cell death. Resistance to anoikis is an important mechanism for metastatic spread. It has been shown that formation of cell aggregates by HCC cells mediates anoikis resistance (Zhang et al. 2008b). An important role in the elimination of spreading cancer cells is held by CD56-positive natural killer cells (NK cells). HCC patients showed a significant reduction of NK cells both in blood and tumors, and both peripheral and tumoral NK cells exhibited poorer capacity to produce IFN-gamma and kill target cells (Cai et al. 2008). Apart from NK cells, cytotoxic CD8 T cells are important mediators of anticancer cell activity. CD8 T-cell impairment occurs in HCC and is associated with poor survival. The pathway of impairment involves increased regulatory CD4 (+) T cells which counteract the effector function of CD8 T-cell and thus promote disease progression (Fu et al. 2007).

In addition to invasion of blood vessels, infiltration into and spread within lymphatic channels and lymph vessels play a significant role in HCC spread. This metastatic pathway is often associated with intralymphatic growth of cancer cells, i.e., carcinomatous lymphangiosis. This condition is sometimes massive in the pulmonary lymph vessel bed (Molina and Valente 2003) and may cause pulmonary dysfunction. Epithelial-mesenchymal transition (EMT) is a mechanism that plays a crucial role in the initiation and completion of a metastatic cascade. In HCC, Twist overexpression correlates with metastasis through the induction of EMT associated with downregulation of E-cadherin and hence cell adhesion (Lee et al. 2006).

Intrahepatic Metastases

HCC frequently undergoes intrahepatic intravascular dissemination that results in intrahepatic metastasis. The incidence of intrahepatic metastases in advanced HCC may exceed 80 % (Sugino et al. 2008). Intrahepatic HCC metastases appear as macrometastases or micrometastases. In small HCC with a diameter less than 3 cm, the presence of intrahepatic micrometastases is associated with distinct gross patterns. No micrometastases or portal vein invasion were found in the vaguely nodular type of small HCC. Tumors of the single nodular type with extranodular growth and of the confluent multinodular type showed a higher frequency of intrahepatic micrometastasis than the single nodular type (Nakashima et al. 2003). In solitary resected HCC with an appropriate resection margin, micrometastases were found at a distance of 0.05–6.1 cm from the main tumor, with a decreasing frequency gradient from areas close to the tumor to more remote from the tumor (Shi et al. 2004). Intrahepatic spread of HCC is based on both invasion of small liver blood vessels and invasion of large vessels, in particular branches of the portal vein. In an autopsy study, it was found that the metastatic process was initiated by vascular involvement whereby nests of neoplastic cells are surrounded by sinusoidal-like vessels and extend into portal and hepatic veins. This is associated with the formation of endothelium-coated tumor cell clusters that enter circulation to form emboli in liver and distant organs (Sugino et al. 2008). Apart from the widespread intrahepatic distribution of metastatic cells, there are situations where micrometastases develop in the tissue directly surrounding primary tumors. These microsatellites are detectable at various distances from their source. In one study, they were found with a range of 0.05–6.10 cm (Shi et al. 2004). The phenomenon of distances exceeding 1 cm is of great importance for the assessment of resection margins and requires the search for microsatellites in the setting of radical judgments. How can intrahepatic metastases of HCC be distinguished from multicentric HCC? The two situations are often difficult to separate (Yasui et al. 1997).

The morphology of intrahepatic metastases of HCC can differ from that of the primary tumor. At least part of the metastatic lesions exhibit a

less differentiated phenotype, but in other situations, primary and metastatic tumors may look almost the same. In one investigation, the part of the metastatic nodules showed well-differentiated, normotrabecular patterns, sometimes with a central core of less differentiated HCC, resulting in nodule-in-nodule lesion (Kondo and Wada 1991).

Portal Vein Invasion

Portal vein invasion with or without associated thrombosis is a frequent complication of HCC and was found in up to 37.8 % of patients (Olubuyide 1991). A literature survey of 1,497 patients with HCC revealed portal vein involvement in 35 % of patients (Lee and Geer 1987). Even in the presence of thrombosis, patients with portal vein involvement may remain asymptomatic, but part of them manifest signs of hepatic inflow failure, associated with ischemic hepatopathy, mainly in situations of general hypotension, and some patients will experience portal hypertension.

Extrahepatic HCC Metastases: General Aspects

Depending on the level of differentiation, HCC is a tumor which extensively metastasizes to various organs and structures. Extrahepatic metastatic disease in HCC is a condition associated with poor prognosis (Okusaka et al. 1997; Natsuizaka et al. 2005; Uka et al. 2007; Yang et al. 2007a). In an autopsy study, extrahepatic metastases were identified in 68 % of cases (Terada and Maruo 2013). Particularly frequent metastatic sites include the liver, lungs (at least 50 % of cases), bone (up to 40 %), and lymph nodes, followed by the gastrointestinal tract, adrenal glands, peritoneal surface, skin, brain, and muscle (Berman 1958. 1959; Anthony 1973; Linder et al. 1974; Nakashima et al. 1983; Lee and Geer 1987; Yuki et al. 1990; Katyal et al. 2000). In a mixed clinical and autopsy study of 137 patients with primary HCC, involvement of regional lymph nodes and other intra-abdominal organs was noted in 10.2 %, while distant metastases were recorded in 30.8 %, with the lung, bone, and brain being the most common metastatic sites (El-Domeiri et al. 1971). Among 1,573 HCC patients, the incidence rate of extrahepatic metastases, as detected during the lifetime after medical treatment of HCC, was approximately 13 % at 5 years (Kanda et al. 2008). In a study of 403 consecutive US patients with HCC, the most common extrahepatic metastatic site was the lung (55 %), followed by abdominal lymph nodes (41 %) and bone (28 %; Katyal et al. 2000). In an autopsy study of 490 HCC cases observed in a low-endemicity area (Sweden), metastases especially involved the lymph nodes (42 %), lungs (18 %), and skeleton (17 %), and metastases were associated with multinodular growth of the primary tumor, involvement of both liver lobes, low grade of differentiation, and vascular invasion (Kaczynski et al. 1995). There is a clear relationship between tumor size, tumor stage, and invasive features of the primary tumor and the prevalence of extrahepatic metastasis. In an autopsy study of 240 consecutive cases of HCC, the incidence of extrahepatic tumor spread was significantly higher for tumors measuring more than 5 cm in diameter (Yuki et al. 1990). Among 148 patients with extrahepatic metastases, 86 % had either intrahepatic stage IVA tumor (76 %) or an intrahepatic stage II tumor (11 %; Katyal et al. 2000). In a study of 65 patients with extrahepatic HCC metastases, 73.8 % of the patients with extrahepatic metastases had tumors with intrahepatic TNM stages T3 or T4, while only 28.5 % of patients without extrahepatic metastases had T3 or T4 stage disease. Macrovessel invasion was also more frequent in the group having extrahepatic metastasis (Natsuizaka et al. 2005). It is important to keep in mind that, albeit seldom, also very small or so-called minute HCCs can give rise to extrahepatic metastases (Kim et al. 1998). In most cases, extrahepatic HCC metastasis develops through intravascular spread, a mechanism that is also operational in intrahepatic metastases. In rare cases, metastasis-like spread occurs following invasion of organs and tissues adjacent to the liver, e.g., right-sided pedunculated HCC

caused by adrenal metastasis extending into the liver (Okuda et al. 1998), or through abnormal connections between the liver and neighboring organs, e.g., adrenohepatic fusion (Okano et al. 2004).

Invasion of Large Hepatic Veins and Associated Outflow Structures: Pathways for Pulmonary Spread

HCC has an important propensity to invade large veins. Invasion into major hepatic veins and the inferior vena cava occurs, but is less common than involvement of the portal vein (Culpepper and von Haam 1934; Close and Uri 1989; Okuda 1997). Although HCC can induce impressive intravascular tumor plugs, patients can survive such tumor manifestations for longer time periods. Following caval invasion, HCC may grow to the right atrium and produce intra-atrial growth (Gregory 1939; Kojiro et al. 1984; Barbero et al. 2012) and can even cross the tricuspid valve (Ohwada et al. 2008). Through such pathways, HCC can form pulmonary artery tumor thrombi and embolize to large- and medium-sized pulmonary artery branches (Blanloeil et al. 1983; Main et al. 1984; Willett et al. 1984; Harada et al. 1988; Putterman et al. 1994; Wilson et al. 2001; Gutiérrez-Macias et al. 2002; Papp et al. 2005; Jäkel et al. 2006). These complications can cause pulmonary hypertension (Brisbane et al. 1980), pulmonary infarction (Shinzato et al. 1990), and fatal pulmonary embolism (Chan et al. 2000; Kwok et al. 2003; Schmidt-Mutter et al. 2003; Wu et al. 2013).

Locoregional Lymph Node Metastasis

In comparison with intra- and extrahepatic cholangiocarcinomas, there are less numerous studies having analyzed the metastatic status of locoregional lymph nodes in patients with HCC (Tanaka et al. 1985; Lee and Geer 1987; Arakai et al. 1988; Olubuyide 1991; Toyoda et al. 1996; Efremidis et al. 1999; Uenishi et al. 2000; Ercolani et al. 2004; Sotiropoulos et al. 2007; Uchino et al. 2011; Ueda et al. 2012; Utsumi et al. 2012; Awazu et al. 2013). It is suggested that HCC cells obtain access to lymph nodes either via invasion of intrahepatic lymphatics (Nomura and Ohnishi 1991), or through secondary pathways involving invasion of the hepatoduodenal ligament. Incidences of abdominal lymph node metastases in HCC vary considerably among the analyses from different geographical areas, factors for this phenomenon including differences in stage and biology of tumors, therapy modalities, and the genetic background of patients. Lymph node metastases are more frequent in large primary tumors and those with poor differentiation (Uenishi et al. 2000; Lee et al. 2011a). Furthermore, nodal metastasis is more common in massive and multinodular nonencapsulated HC types than in encapsulated HCC (Abe et al. 2002). The clinicopathologic features of lymph node metastases have been investigated in 660 consecutive autopsy cases in Japan. Lymph node metastases were noted in 25.5 % and was more often found in massive than in nodular tumor types and, interestingly, most frequent in patients with pedunculated HCC. No locoregional lymph node metastases were detected in patients with tumor less than 3 cm, i.e., early or small HCC (Watanabe et al. 1994). In a literature review of 1,497 patients with HCC, portal lymph node metastases were registered in 27 % (Lee and Geer 1987). A US investigation on 403 patients found abdominal lymph node metastases in 41 % of patients. In this study, periceliac and portohepatic lymph nodes were the most commonly involved, and peripancreatic, aortocaval, and retrocaval were the least common (Katyal et al. 2000). Distant lymph node metastases were detected in 12 % of patients. There are investigations with markedly lower figure for nodal metastasis incidence. Among 968 patients from China with operable HCC, only 5.1 % showed lymph node metastasis (Sun et al. 2007). There is a relationship between the frequency of lymph node metastases and the growth patterns of primary tumors, being lowest in single nodular tumors and highest in diffuse and contiguous multinodular types (Yuki et al. 1990). Intra-abdominal nodal metastases can be

visualized intraoperatively by means of indocyanine green fluorescent imaging (Satou et al. 2013). Typically, HCC metastasizes to supradiaphragmatic lymph nodes, including mediastinal nodes (Tanaka et al. 2005), Virchow-Troisier's node (Schwarz et al. 1982), cervical lymph nodes (Kobayashi et al. 2012b; Terada and Maruo 2013), and supraclavicular nodes (Lau et al. 2000). Mediastinal, pretracheal, and cardiophrenic lymph node metastases were most frequent (Katyal et al. 2000). Extrahepatic extrathoracic model involvement is less frequent and chiefly occurs in patients with large, advanced, and poorly differentiated tumors. Rare nodal metastatic sites include mesenteric, axillary, pharyngeal, internal mammary, perirectal, retrocrural, iliac, and paraspinal lymph nodes, but in principle almost any nodal station can be involved (multiple systemic lymph node metastases; Ciriza et al. 1996; Toyoda et al. 1996; Alison et al. 2000). In rare situations, extraabdominal nodal metastasis occurs also in the presence of small primary tumors (Toyoda et al. 1996; Uehara et al. 2003).

Lymph node metastases negatively affect outcome. Hilar lymph node metastases had a negative prognostic value for both tumor recurrence and survival (Sotiropoulos et al. 2007). Among 523 HCC patients, those with nodal metastases had tumor recurrence in 82.05 %, versus 57.64 % in those without nodal metastasis (Xiaohong et al. 2010). Spontaneous rupture of metastatic peripancreatic lymph nodes can cause massive peritoneal bleeding (Terada et al. 2003), and spontaneous rupture of a metastatic mediastinal lymph node can cause hemothorax (Oh et al. 2013) or cardiac tamponade (Seki et al. 2001). The risk factors for locoregional lymph node metastases in HCC have not yet fully worked out. Expression of CK19 and matrix metalloproteinase 2 predicts lymph node metastasis in HCC (Xiang et al. 2011). Immunopositivity of CK19 and OV-6 in HCC with lymph node metastasis was higher than in those without, and the CK19(+) group had a shorter median survival, expression of CK 19 being an independent prognostic factor for overall survival in HCC with lymph node metastasis (Zhuang et al. 2008). The Axl receptor and its ligand growth arrest-specific 6/Gas6 are components of a signaling system involved in the pathogenesis of several malignancies. In HCC patients, differential expression of Axl was correlated with lymph node metastasis (He et al. 2010). Increased expression of vascular endothelial growth factor C, which is involved in lymphangiogenesis, is correlated with lymph node metastasis and poor prognosis in HCC (Xiang et al. 2009). There is also evidence that there is a characteristic gene expression signature for nodal metastasis, as observed in genome-wide analysis for metastasis-associated genes (Lee et al. 2009).

Gallbladder: A Neighboring Site for Invasion and Metastatic Spread

HCC, mainly right-sided tumors, can invade or metastasize into this organ (Murakami et al. 2008; Ryu et al. 2009; Kanzaki et al. 2011; Terada and Maruo 2013). Invading tumors macroscopically form a nodule that originates in the liver substance close to the gallbladder fossa and which extends into the gallbladder wall, with effacement of the wall structures. Invading HCC can result in polypoid intraluminal gallbladder masses mimicking primary gallbladder cancer (Ueno et al. 2001). In rare cases, the entire gallbladder may be integrated within a large and partially necrotic tumor mass. Metastatic HCC foci either present as discrete mural nodules or as large tumor masses not in continuity with the liver substance.

Pulmonary Metastasis

Among extrahepatic metastasis of HCC, the lung is the most commonly affected organ, with frequencies in Western countries in the range of 18.1–62 % (Tsai et al. 1984; Katyal et al. 2000; Zhang et al. 2008a; Terada and Maruo 2013). Radiologically, multiple nodulation and pleural effusion are the main findings, but miliary lesions and signs of carcinomatous lymphangiosis are also found (Tsai et al. 1984). In a Japanese investigation of 98 autopsy cases of HCC, extrahepatic

hematogenous metastasis was found in 64 %, and the lung was the most frequently involved (62 %). There was close relationship between hepatic vascular tumor invasion, in particular the rate of portal vein invasion, and pulmonary metastasis. Furthermore, the rate of pulmonary metastasis was lower in patients with well-differentiated tumors, HCC with an expanding growth pattern, and tumors with a diameter of less than 10 cm (Sawabe et al. 1987). Pulmonary spread of HCC may present as extensive lymphangiosis carcinomatosa, clinically causing shortness of breath and exertion dyspnea (Molina and Valente 2003). Involvement of the pleura is a well-known phenomenon that can cause hemothorax (Takagi et al. 1996).

Hepatocellular tissue histologically resembling well-differentiated HCC can be found within the pulmonary artery tree following traumatic liver tissue embolism (Johnston 1959; Voitk and Munkittrick 1986; Tozzini et al. 2004).

Bone and Skeletal Metastasis

HCC can metastasize to the skeleton which is the second most common extrahepatic organ site after the lungs. Incidences for bone metastasis of HCC ranged from 3 % to 20 % (Kaufmann 1922; Moon 1929; Bolker et al. 1937; Hedrick 1937; Okazaki et al. 1985; Fukutomi et al. 2001; Seong et al. 2005; Kim et al. 2007; Longo et al. 2014; Santini et al. 2014). Moon (1929) cites old reports describing this distinct clinicopathologic situation, e.g., reports by Schmidt (1897), Blumberg (1912), and Catsaras (1921). In a study of 211 deceased HCC patients with evidence of bone metastasis, the median time to the onset of bone metastasis was 13 months; 64.9 % of patients had multiple bone metastases, and the spine was the most common site (59.7 %). 82.4 % of the metastatic lesions were osteolytic (Santini et al. 2014). Other common sites for HCC metastases are the pelvis and the rib cage. In very rare cases, painful bone metastasis is the first manifestation of HCC (Ayan et al. 2013). Bone metastasis can be the initial presentation of HCC (Ruiz-Morales et al. 2014). In rare cases, disseminated carcinomatosis of bone marrow can develop (Honda et al. 2015).

Typically, the neoplastic cell masses fill the marrow spaces, associated with effacing of hematopoiesis, rarefaction of trabeculae of cancellated bone, and erosion of the outer shell of compact bone (osteolytic metastasis; Moon 1929). HCC tissue may break through the bony shell subsequent to massive bone lysis, forming a metastatic, invasive plaque between bone and periosteum. This may be followed by bleeding and marked inflammatory changes. Frequently, osteolytic metastases are followed by the formation of expansile soft tissue masses, which can result in an oncologic emergency (Kim et al. 2007; He et al. 2009; Seo et al. 2011). Small extensions of HCC tissue may follow the tracts of bone veins perforating the periosteum. The tumor tissue can contain bile, an important element for diagnosis, but it is sometimes difficult to distinguish an HCC metastasis from other granular cell tumors, immunohistochemistry being mandatory. Rarely, bone metastasis of HCC may present as massive osteoplastic metastases (Ohno et al. 1986). The pathogenic pathways involved in bone metastasis of HCC are not yet clarified. Osteolytic metastases are mediated by parathyroid hormone-related protein (PTHrP), interleukins 8 and 11, and vascular endothelial growth factor (VEGF), while osteoplastic metastases are induced by tumor-secreted endothelin-1, bone morphogenetic proteins, platelet-derived growth factor, connective tissue growth factor (CTGF), stanniocalcin, and adrenomedullin (Zhang et al. 2014b). Elevated serum levels of VEGF indicate advanced disease in HCC patients (Schoenleber et al. 2009). Immunoreactivity for VEGF was detectable in both primary HCC and its bone metastases (Iguchi et al. 2002), suggesting that secretion of VEGF by the tumor can induce bone resorption in situ.

Adrenal Gland

The adrenal gland was estimated to be the second most common site of extrahepatic hematogenous metastasis of HCC, although this mode of metastasis is less commonly diagnosed in a clinical

setting (Li et al. 1990; Ohwada et al. 1998; Yamamoto et al. 2002; Zeng et al. 2005; Yamakado et al. 2009; Chua and Morris 2012; Tariq et al. 2012; Zhang et al. 2012b; Ma et al. 2013).

In a series of 174 HCC patients undergoing hepatectomy, adrenal metastasis was found in 2.3 % (Popescu et al. 2007). Adrenal metastasis can cause severe retroperitoneal hemorrhage (Yang et al. 2007b), may be the first manifestation of HCC (Tsalis et al. 2005), and is sometimes diagnosed after long delay, e.g., 8.5 years after liver resection (Kuromatsu et al. 1993). In the part of patients, both adrenals are synchronously involved (Mundada et al. 2003), a situation that can cause adrenal insufficiency (Takamura et al. 1999). A subset of adrenal HCC metastasis seems to develop via adrenohepatic fusion which provides a bridge for the spread of HCC cells (Okano et al. 2004). Periadrenal HCC metastasis supplied by the hepatic artery has been described (Iwamoto et al. 1997). Also this situation is probably caused by preexisting adrenohepatic fusion. Adrenal HCC metastasis may be confounded with a primary adrenal neoplasm, including adrenocortical adenoma and adrenocortical carcinoma (Ohwada et al. 1998; Yasaka et al. 2013). The clinical and radiological presentation of adrenal metastases of HCC has been specified in numerous reports (Sai et al. 1982; Nakamura et al. 1989; Takayasu et al. 1989; Kitagawa et al 1996).

Peritoneal Metastases

Peritoneal metastasis (implant metastases, peritoneal seeding, intraperitoneal drop metastases) of HCC in a focal or diffuse seeding pattern is well known, although uncommon complication of this malignancy which occurs both synchronously and metachronously (Castro Fernandez et al. 1985; Kim et al. 1994; Kosaka et al. 1999; Yunoki et al. 1999; Kurachi et al. 2002; Uenishi et al. 2002; Yeh et al. 2002; Yoshida et al. 2002; Takahashi et al. 2004; Miyake et al. 2007; Otsuka et al. 2007; Matsukuma and Sato 2011). Peritoneal metastasis may appear as a solitary implant, but multiple nodules are more common (Kim et al. 1996). A special form of peritoneal seeding is omental seeding (Blandino et al. 1997). Among 749 patients with HCC recurrence after hepatic resection, 3.4 % developed isolated peritoneal implantation (Yeh et al. 2002). In an autopsy study, peritoneal seeding was detected in 9.4 % of cases, whereby the majority of patients exhibited a local peritoneal spread, most often involving the diaphragm followed by the omentum and the visceral serosa. Peritoneal spread was significantly associated with HCC rupture, direct diaphragmatic invasion, and locoregional lymph node metastasis (Matsukuma and Sato 2011). The correlation with lymph node metastasis may suggest a role of lymphatic spread in the pathogenesis of peritoneal seeding. Rupture of HCC is considered to be a special and independent risk factor for peritoneal seeding (Sonoda et al. 1989; Lin et al. 2006; Hung et al. 2008; Kwak et al. 2012). A severe complication of peritoneal HCC metastasis is tumor rupture (Yeh et al. 2002; Ishikawa et al. 2005), which may cause massive hematoperitoneum. Peritoneal metastasis can also occur following therapeutic interventions, e.g., after microwave coagulation therapy (Sato et al. 1999). Peritoneal seeding can occur after tumor biopsy or resection of ruptured HCC (Ryu et al. 2004), and after percutaneous ethanol injection therapy (Kurl et al. 1997; Miki et al. 2000). Generally, peritoneal metastasis follows a progressive course, but rare instances of apparently spontaneous regression have been reported (Terasaki et al. 2000). When other risk factors, such as age, sex, Child-Pugh score, and intrahepatic tumor stage, were matched, peritoneal metastasis failed to independently affect overall survival (Lin et al. 2009; Kwak et al. 2012).

Histologically, early implantations appear as tiny accumulations of cancer cells in the submesothelial tissue, sometimes associated with intravascular tumor deposits (carcinomatous hemangiosis and lymphangiosis). This finding suggests a spread to subserosal tissue compartments via small vessel and lymph vessel spread. In case seeding in fact develops in this way, the term implant would be a misnomer. Already early metastases are associated with a stromal reaction. The overlying mesothelium is still preserved in

early and very small lesions, whereas in later phases it reacts in the form of papillary microprojections or shows erosions, followed by a perifocal fibrinous peritonitis. Similar findings have been obtained in animal models (van de Molengraft et al. 1989).

Gastrointestinal Tract Metastasis

Involvement of the gastrointestinal tract from HCC uncommonly occurs, being observed in 0.5–6 % of cases (Anthony 1973; Nakashima et al. 1983; Chen et al. 1990). The most common site of involvement is the stomach, followed by duodenum and colon, usually via direct invasion, hematogenous metastasis, or through peritoneal seeding (Park et al. 2002). In one study, the most common clinical presentation was frank gastrointestinal bleeding, becoming evident in all cases. The median time between diagnosis of primary HCC and metastases was 4.5 months, and the sites of involvement were stomach, duodenum, and jejunum (Chen et al. 1990).

Several reports document metastasis of HCC to the esophagus, often with formation of large polypoid and even pedunculated lesions and often associated with tumor bleeding (Kume et al. 2000; Sohara et al. 2000; Cho et al. 2003; Tsubouchi et al. 2005; Yan et al. 2007; Fukatsu et al. 2012). Polypoid esophageal metastasis seems to progress from submucosal tumor masses (Choi et al. 2008). As tumor thrombi can be found in esophageal varices in HCC patients with cirrhosis (Arakawa et al. 1986), at least part of esophageal metastases may develop from such intravascular deposits. Gastric metastases of HCC tend to bleed (Maruyama et al. 1999) and are proposed to develop via a retrograde hematogenous pathway, spread eventually being promoted by a frequent tumor-associated portal vein thrombosis (Lin et al. 2000; Hu et al. 2010). On the other hand, due to its infrahepatic position, the stomach may also be directly invaded by HCC (Kimura et al. 2008). The duodenum, which is rather frequently affected by HCC in comparison with other parts of the GI tract, is either involved by hematogenous spread (eventually via a retrograde pathway in case of splanchnic vein/portal vein thrombosis), or through direct invasion (Yamada et al. 1998). Direct invasion mostly occurred from HCC located to the right liver lobe (Liang et al. 2012). The majority of duodenal HCC metastasis and invasion are complicated by duodenal bleeding (Humbert et al. 1987; Hung et al. 1998; Yamada et al. 1998). Small bowel metastases of HCC is a well-known complication often causing occult or frank hemorrhage (Narita et al. 1993; Yang et al. 1987; Kunizaki et al. 2012) or intussusception (Kim et al. 2006). HCC, by extending beyond the organ's limit, can directly invade the transverse colon or the right hepatic flexure, leading to sometimes large tumor masses that frequently tend to bleed (Chen et al. 1997; Hirashita et al. 2008). Apart from direct colonic invasion, true hematogenous HCC metastases to the colon have been observed (Fukui et al. 1993; Lin et al. 2000; Kaibori et al. 2007; Nozaki et al. 2008; Yoo et al. 2010). Similar to other GI tract sites of HCC metastasis, colonic metastases often cause hemorrhage, sometimes massive and life-threatening (Cosenza et al. 1999; Hwang et al. 2008).

Splenic Metastases

HCC metastasizes to the spleen in part of patients, and sometimes this is the only identifiable intra-abdominal metastasis. A splenic metastasis may be diagnosed in a patient with an otherwise asymptomatic HCC (Jain et al. 1997). However, splenic metastasis is sometimes synchronously associated with other metastases of HCC in abdominal or extraabdominal organs, small intestine, lungs, or adrenals (Yamamoto et al. 1986; Katoh et al. 1994; Hanada et al. 2004; Hayashi et al. 2006; Nakamura et al. 2006; Iwaki et al. 2008). Splenic metastases of HCC can cause spontaneous splenic rupture

(Horie et al. 1982) or associated with metachronous rupture of the splenic metastasis and the hepatic primary tumor (Sumiya et al. 2007) and may produce very large tumor masses (Fujimoto et al. 1990).

Overall, hematogenous metastasis of HCC to spleen is rare, with a reported incidence of 0.7–0.8 % in HCC patients.

Selected References Senenko and Glutbarg 1966; Fujimoto et al. 1990, 1992; Imada et al. 1991; Nakamuta et al. 1992; Filik et al. 2003; Yan et al. 2009; Duggal et al. 2010; Yu et al. 2011; Liu et al. 2013b.

Oropharyngeal Region

HCC is known to metastasize to the gingiva and oral mucosa, sometimes with formation of multiple metastatic nodules (Lund et al. 1970; Marker and Clausen 1991; Llanes et al. 1996; Maiorano et al. 2000; Shen et al. 2009; Terada 2011), and gingival metastasis may be the first manifestation of this malignancy (Terada 2011). However, oral cavity metastasis of HCC is less common than the three most frequent cancers metastasizing to this compartment, namely, lung carcinoma, breast carcinoma, and renal cell carcinoma. Clinically, gingival HCC metastases may present as hyperemic nodules morphologically resembling pyogenic granuloma (Ramon Ramirez et al. 2003).

Salivary Glands

Metastatic involvement of the parotid gland is uncommon, but nevertheless comprises up to 8 % of all parotid gland malignancies (Markowski et al. 2005; Nuyens et al. 2006), including very few instances of metastasis of HCC (Vitale et al. 2009; Yu et al. 2013). HCC metastatic to the parotid gland was diagnosed by the use of fine-needle aspiration biopsy (Dargent et al. 1998; Romanas et al. 2004). Due to the typical granularity of cytoplasm, metastatic HCC of the parotid gland was misinterpreted as salivary gland acinic cell carcinoma in a needle core biopsy, corrected after Hep Par1 immunostaining (Moore et al. 2010).

Renal Metastasis

HCC is well known to metastasize to the kidneys, although HCC metastatic to the kidneys is a rather rare event. In most cases reported so far, the primary liver tumor and renal metastasis were synchronous (Hsu et al. 1994; Fukushima et al. 1996; Mezawa et al. 2001; Sanz Mayayo et al. 2003; D'Antonio et al. 2010). In case of metastatic clear cell HCC, distinction from renal cell carcinoma of the clear cell (hypernephroid) type may be difficult, and metastatic HCC may mimic renal oncocytoma, but metastatic HCC lacks the typical nesting pattern of oncocytoma (D'Antonio et al. 2010). Renal metastasis of HCC may undergo spontaneous rupture (Mezawa et al. 2001), resembling the common hemorrhagic feature of renal cell carcinoma.

Gonadal Metastasis

The first case of ovarian metastasis of HCC was published in 1983 (Oortman and Elliott 1983). Since, several studies documented HCC metastases to the ovaries (Young et al. 1992; Khunamompong et al. 1999; de Groot et al. 2000; Kim et al. 2004; Kim 2005; McCluggage and Wilkinson 2005; Lee et al. 2011b). In a review of eleven cases published until 2011, the mean age at diagnosis was 45.6 years, and 3/11 patients showed bilateral ovarian metastases (Lee et al. 2011). The metastases can form large cystic masses, associated with a progressive elevation of serum AFP levels (Lee et al. 2011), or sometimes present as a large solitary mass (de Groot et al. 2000). As peritoneal seeding is usually absent, hematogenous spread has been

considered (Lee et al. 2011). HCC metastatic to the liver has to be distinguished from primary hepatoid carcinoma of the ovary (Lazaro et al. 2007; Pandey and Truica 2011). The ovary is a typical site for hepatoid carcinoma, and this neoplasm and HCC are difficult to distinguish, as both lesions share a common histology, and both are positive for AFP and Hep Par1. Hepatoid yolk sac tumor of the ovary may also be confounded with HCC metastasis. In cases of doubt, the presence of bile in or between tumor cells is a strong argument for HCC. In contrast to the ovary, HCC metastasis to the testis is an exceptional finding (Wang and Yang 2006).

Other and Rare Metastatic Sites

HCC metastases have been reported for the skin, orbit, heart, nasal cavity, external auditory canal, breast, and skeletal muscle (Nappi et al. 1992; Kim et al. 2000a; Royer et al. 2008; Terada and Sugiura 2010). Cutaneous metastasis may be the first and precocious manifestation of HCC (Royer et al. 2008).

Tumor Cell Seeding Following Percutaneous Approaches

Tumor seeding of HCC (implantation metastases following iatrogenic displacement of malignant cells, needle tract seeding, needle tract implantation) along the needle tract after percutaneous diagnostic core biopsies and fine-needle aspiration biopsies is a well-known complication that has been reported numerous times. Needle tract seeding is a severe or even catastrophic complication, in particular in patients that are transplantation candidates.

Selected References Sakurai et al. 1983; Smith 1991; Huang et al. 1996; Chapoutot et al. 1999; Kim et al. 2000b; Pelloni and Gertsch 2000; Takamori et al. 2000; Durand et al. 2001; Llovet et al. 2001; Chhieng 2004; Kosugi et al. 2004; Chang et al. 2005, 2008; Liu et al. 2007; Pavan et al. 2007; Perkins 2007; Rowe et al. 2007; Tung et al. 2007; Qua et al. 2008; Cabibbo and Craxi 2009; Silva et al. 2008; Robertson and Baxter 2011.

Needle tract seeding has an estimated frequency ranging from 0.6 % to 5.1 % of cases. However, in many reports, the incidence was lower than 3 %. In a literature review, it turned out that the incidence is 2.7 % overall or 0.9 % per year (Silva et al. 2008). In a large series of sonographically guided percutaneous biopsy of HCC, the overall frequency of needle tract implantation was 0.76 % (Chang et al. 2005). Implants following needle biopsy develop with sometimes considerable delay, with a reported range of 1 month to up to 72 months (Pelloni and Gertsch 2000; Liu et al. 2007). The implants usually appear as one or few, seldom numerous, round- to oval-shaped or lobular-enhancing nodules with a well-circumscribed margin along the needle tract on CT images, ranging from cutis or subcutis to intercostal and abdominal muscles to the subserosal space (review: Chang et al. 2008). There is evidence that biopsy using a coaxial cutting needle technique markedly reduces the risk of seeding, as the use of a needle introducer that remains in position during multiple passes protects normal tissue along the tract (Maturen et al. 2006).

Needle tract seeding also occurs in percutaneous ethanol injection, but is a rare complication in this procedure (Cedrone et al. 1992; Goletti et al. 1992; Yano et al. 2001; Arrivé et al. 2002; Kosugi et al. 2004; Almeida et al. 2008). Percutaneous radiofrequency ablation (PRFA) is a well-established alternative to percutaneous ethanol injection for single nonsurgical HCC. This procedure can be followed, similar to other percutaneous techniques, by HCC seeding (Llovet et al. 2001; Shirato et al. 2002; Espinoza et al. 2005; Jaskolka et al. 2005). Among 32 PRFA patients followed up in one study, 12.5 % showed biopsy-proven needle tract seeding detected between 4 and 18 months. Neoplastic seeding was related to subcapsular tumor location, poor differentiation, and baseline AFP levels (Llovet et al. 2001). In a review of

200 patients, 4 % were identified with needle tract seeding, based on imaging findings or surgical reintervention (Jaskolka et al. 2005).

Metastasis of HCC into Other Tumors and Metastasis of Other Tumors into HCC

In rare situations, and similar to other malignancies, HCC metastasizes into other neoplasms, e.g., medullary carcinoma of the thyroid (Sung et al. 2011). Exceptionally, extrahepatic cancers metastasized to primary HCC, e.g., esophageal carcinoma (Doihara et al. 1989), colorectal cancer (Maruyama et al. 1990), and Hodgkin's lymphoma (Utsunomiya et al. 2009).

Growth of Hepatocellular Carcinoma in the Regenerating Liver

The question as to whether growth and recurrence of HCC following resection is influenced by the regenerative status of the hepatocyte population is an important issue, as it may be anticipated that signaling pathways regulating hepatocyte regenerating might also favor the growth of surviving tumor cells. In a rat model of HCC, whereby hepatoma cells were implanted into livers following various degrees of partial hepatectomy, liver regeneration significantly facilitated the growth of microscopic HCC. The largest liver resections were also associated with HCC spread to the lungs (Shi et al. 2011).

Secondary Alterations of Hepatocellular Carcinoma

5

Contents

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_5

Abstract

Hepatocellular carcinoma (HCC) can undergo spontaneous or induced secondary tissue changes. HCCs, and particularly large tumors and those of poor differentiation, are prone to necrosis. This can be followed by dystrophic calcifications, which sometimes result in macroscopically and radiologically visible deposits. Tumor calcifications are also found following hepatic dearterialization. In some HCCs, calcifications present are peripheral sickle- and ring-shaped calcifications mimicking parasitic hydatid disease. Rarely, stromal calcifications are observed. Other secondary changes include spontaneous tumor regression and immune reactions of the host directed against the tumor. Induced secondary alterations of HCC are well known after microwave coagulation therapy or radiofrequency ablation. The lesions are characterized by coagulative necrosis with shadow cells and faded nuclei, a rim of palisading histiocytic/epithelioid cells, a foreign body-type giant cell reaction, and sometimes destruction of adjacent bile ducts.

Secondary Tissue Changes of Hepatocellular Carcinoma

Necrosis

Hepatocellular carcinomas (HCCs) can undergo extensive necrosis, mainly of their inner (core) parts which predominantly suffer from ischemia and hypoxia (Figs. 1, 2, 3, 4, and 5).

Hemorrhage

Necrosis of cancers, including HCC, can involve several types of tumor blood vessels, followed by tumor hemorrhage and eventually tumor rupture. In HCC, also the marked angioinvasive phenotype can favor vascular injury and hemorrhage (Figs. 6, 7, and 8).

Apoptosis

Apart from various types of necrosis, HCCs can undergo apoptosis as a secondary alteration, further discussed in a separate chapter (Fig. 9).

Calcifications

Part of HCCs show calcifications, which are therefore not always an indicator of fibrolamellar carcinoma (Scatarige et al. 1983; Chin et al. 1986; Teefey et al. 1987; Friedman 1988; Stevens et al. 1994; Bezerra et al. 2003; Kawada et al. 2008). This alteration has been found in up to 15.3 % of HCC (Scatarige et al. 1983). Calcifications may present as circumscribed small collections of basophilic corpuscles, usually within necrotic areas of the tumor, or may sometimes appear as larger deposits that become macroscopically detectable as yellowish or whitish speckles. At imaging, HCC calcifications are usually located eccentrically within a complex heterogeneous mass (Stoupis et al. 1998). Calcifications prevail in larger lesions, but have also been noted in small or even minute HCC (Muramatsu et al. 1985). Tumor calcifications were also seen following hepatic dearterialization (Bengmark 1989). In few tumors, calcifications are present as sickle-shaped alterations underneath the tumor capsule, appearing as so-called ring calcification or rim calcification on CT images, mimicking hydatid disease (Mitchell et al. 1994; Fukuya et al. 1999; Kawada et al. 2008). Ring calcifications also occur in encapsulated small HCC where they have been suggested to result from a circulatory disturbance caused by a high internal pressure exerted by the fibrous capsule (Murakami et al. 2013). Apart from calcifications involving the tumor substance as such, there are rare instances with calcification in the tumor stroma. Small stromal calcifications were seen in two carcinomas out of 60 primary HCCs (Patton and Horn 1964). In one case, viable tumor cells were detectable between the calcified stromal components (Moenandar 1974). Linear portal vein calcification was observed in a patient with HCC

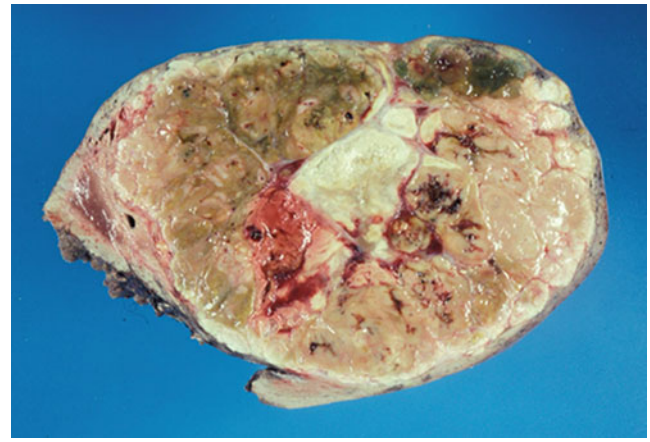

Fig. 1 Large hepatocellular carcinoma with an expanding growth pattern. This tumor has undergone partial necrosis, seen as a central white, rather well-delineated and shrunken focus. A second smaller area shows hemorrhagic necrosis, and small bleedings are also found in part of tumor nodules (*dark red speckles*)

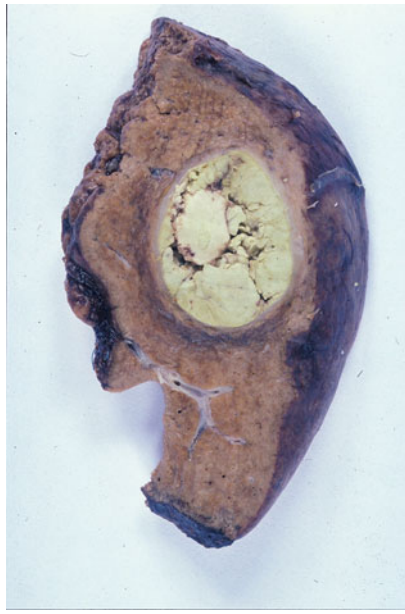

Fig. 2 In case of extensive necrosis of hepatocellular carcinoma, the tumor tissue becomes highly fragile. Typically, formalin-fixed tissue exhibits fissures and cracks upon sectioning

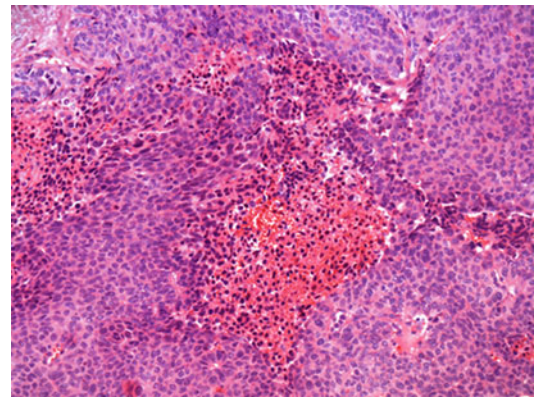

Fig. 3 Focal necrosis of poorly differentiated hepatocellular carcinoma (*center* and to the *top left*). Within eosinophilic decayed tissue areas, pycnotic nuclei and nuclear debris are found. In necrotic foci, dystrophic calcification can develop (hematoxylin and eosin stain)

associated with liver cirrhosis and portal hypertension (Del Val et al. 1991). Calcified primary HCC has to be distinguished from hepatic metastases undergoing calcification (Takahashi et al. 1971; Bernadino 1979) and from rare instances of calcification of cholangiocarcinoma (Hall et al. 1970). In very rare cases, calcification of HCC is associated with metaplastic ossification (ossified HCC; Maeda et al. 1986).

Pathology of HCC Following Nonsurgical Treatments

Several types of nonsurgical therapies of HCC can result in distinct morphologic patterns of tumor damage (Figs. 10, 11, and 12).

Histopathologic changes after microwave coagulation therapy or radiofrequency ablation of HCC are characterized by a tumor coagulative necrosis

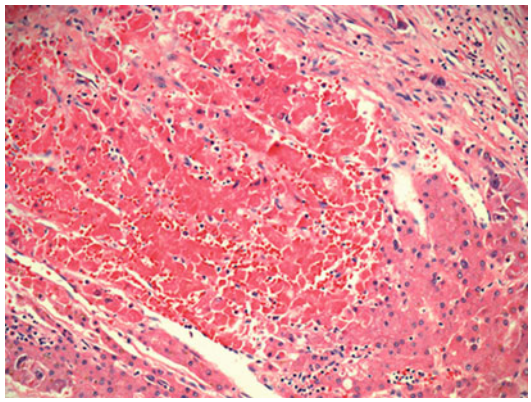

Fig. 4 In this trabecular hepatocellular carcinoma (G1/G2), an abrupt transition into almost complete necrosis is seen. The necrotic tumor tissue area exhibits shadow cells and shadow trabecules. This type of lesion is usually caused by hypoxia/ischemia (hematoxylin and eosin stain)

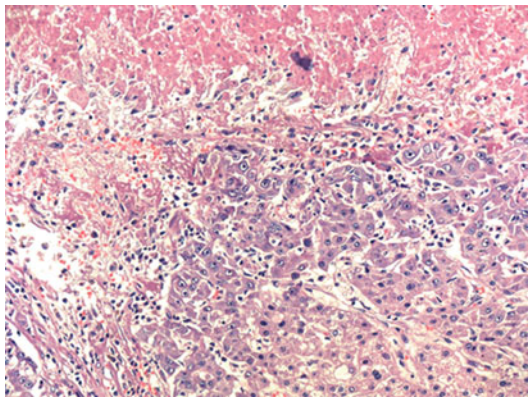

Fig. 5 Cancer regrowth following necrosis of hepatocellular carcinoma can be associated with increased cellular and nuclear atypia (*center of figure*; hematoxylin and eosin stain)

with eosinophilic shadow cells and faded nuclei and a rim of palisading, histiocytic, giant cell, inflammatory reaction associated with fibrotic bands (Yamashiki et al. 2003; Kim et al. 2004). Rarely, massive hepatic infarction can develop (Poggi et al. 2004; Chuang et al. 2005; Chiu et al. 2009). Foreign bodies may develop that can mimic disseminated tumor recurrence (Takahashi et al. 2008). The often marked necrosis after thermal ablation may cause destruction of bile duct walls followed by hemobilia (Enne et al. 2004) or hemocholecyst (Shin et al. 2011).

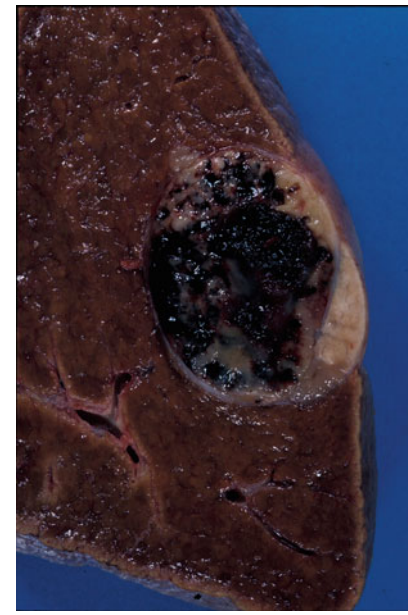

Fig. 6 Subcapsular nodular hepatocellular carcinoma with extensive fresh hemorrhage. Even in lesions with a pseudocapsule, as in the present case, massive hemorrhage can result in tumor rupture followed by hematoperitoneum

Following transcatheter arterial embolization (TAE), small HCC showed complete necrosis in up to 80.2 % of cases, but was much less frequent in large neoplasms, with viable tumor cells remaining in central parts in large tumors. Necrosis in large HCC after TAE is usually patchy, forming several necrosis units. Subsequent to TAE, most tumor capsules were affected by tumor necrosis and the following reparation process, resulting in a thick secondary capsule (Higuchi et al. 1994). Several patterns of changes take place following transarterial chemoembolization (TACE). Polyvinyl alcohol particles can reach and occlude distal arterioles and capillaries, but rarely leak into non-tumorous hepatic sinusoids (Lee et al. 2012). Part of the tumors undergo complete necrosis associated with a nonspecific inflammatory reaction at the periphery of the necrotic tumor mass. In part of tumors with remaining viable neoplasia, a change of differentiation was observed, with formation of cholangiolar, glandular, or spindle cell areas suggestive of a mixed hepatocholangiocellular phenotype and occurrence of cells with progenitor cell features, including CD133 positivity. CD133

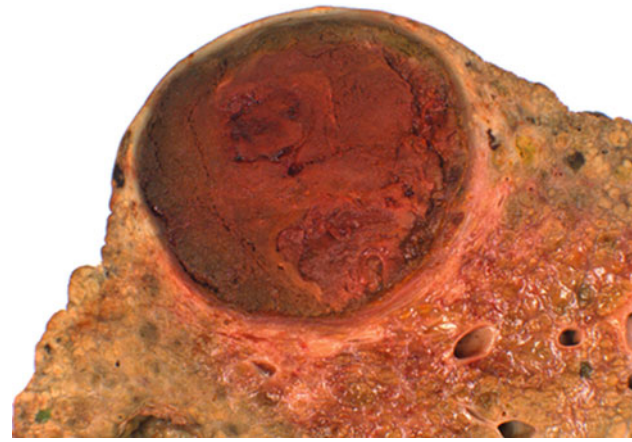

Fig. 7 This nodular hepatocellular carcinoma underwent complete hemorrhagic infarction. Tumor tissue is replaced by a clot of fresh blood surrounded by a pseudocapsule. Adjacent liver tissue shows cirrhosis

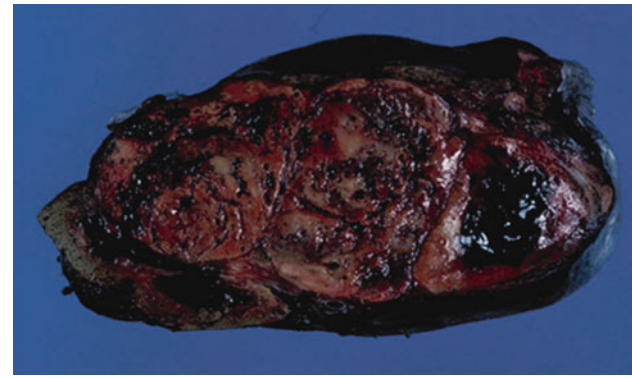

Fig. 8 Highly aggressive and poorly differentiated hepatocellular carcinoma with a massive growth pattern can show extensive hemorrhage, resulting in intratumoral hematoma, as seen in the right part of the figure. Such areas are prone to rupture

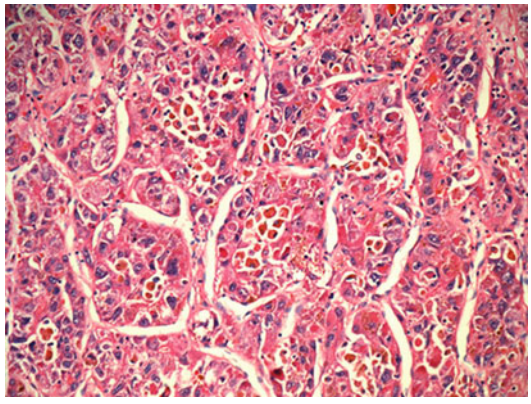

Fig. 9 Trabecular hepatocellular carcinoma with prominent apoptosis of neoplastic cells. Inner parts of trabecules show numerous, strongly eosinophilic and dense apoptotic bodies (hematoxylin and eosin stain)

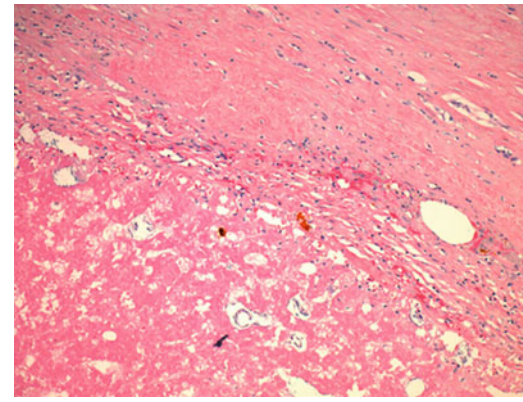

Fig. 10 Apparently total tumor necrosis following chemoembolization of hepatocellular carcinoma. Only eosinophilic shadow structures remain, with basophilic dots representing dystrophic microcalcifications (hematoxylin and eosin stain)

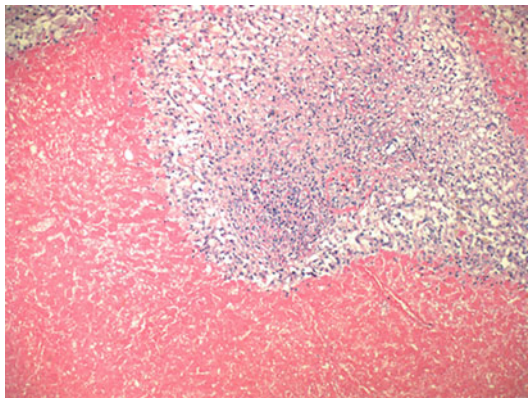

Fig. 11 Necrosis of hepatocellular carcinoma following chemoembolization. In this case, necrotic tissue is organized by a large tuft of vascularized granulation tissue (*upper part of figure*; hematoxylin and eosin stain)

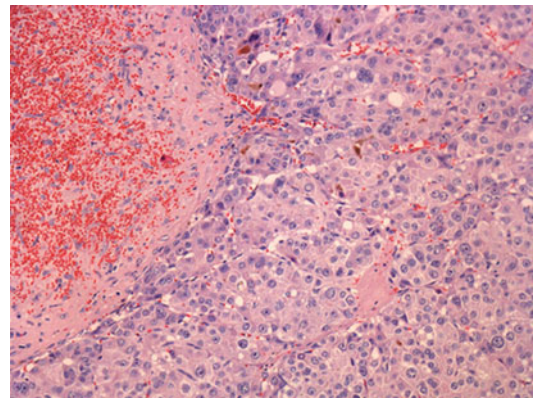

Fig. 13 Hepatocellular carcinoma with a spherical defect caused by needle biopsy (*left of figure*). Biopsy caused hemorrhage and necrosis which are now repaired by granulation tissue (hematoxylin and eosin stain)

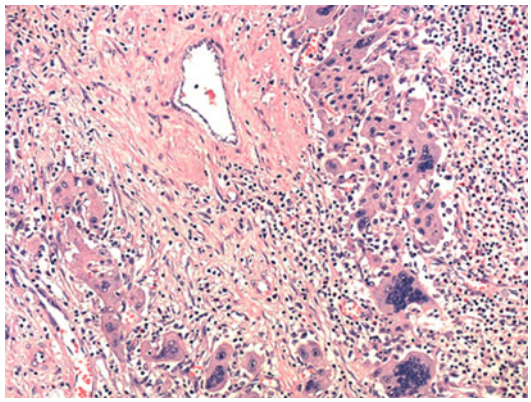

Fig. 12 Injected material in chemoembolization can, following leakage into tissue, elicit a vigorous foreign body reaction with multinucleated giant cells. In the present case, foreign material may have leaked from the blood vessel to the top that shows thinning of its wall at one place (hematoxylin and eosin stain)

reactive cells frequently coexpressed CK19, EpCAM, or NCAM. Patients with CD133-positive post-TACE HCC showed a higher recurrence rate (Zen et al. 2011). Arterial chemoembolization can cause fatal pulmonary oil embolism (Kwok et al. 2003; Czauderna et al. 2005). Tumor and/or hepatic infarction also occurs after pure ethanol injection (Chiu et al. 2009; Da Ines et al. 2010). A spectrum of changes in HCC is induced by therapy with the multikinase inhibitor, sorafenib, acting on several tyrosine protein kinases (VEGFR and PDGFR) and Raf kinases (Moeini et al. 2012; Chow et al. 2013; Di Marco et al. 2013; Dufour et al. 2013; Yang et al. 2014). The main alterations are necrosis, tumor cell apoptosis, cell junctional anomalies, reduced cell proliferation, and reduced angiogenesis. Distinct changes are also induced by transarterial radioembolization (TARE) with yttrium 90-impregnated microspheres (Dhingra et al. 2014).

As mentioned above, diverse nonsurgical treatments of HCC can induce epithelioid cell reaction and the formation of granulomas. However, a rare subset of HCC may contain granulomas induced by immune reactions (Tomimatsu et al. 1982). Apart from a foreign body reaction induced by necrotic tumors following diverse treatment modalities, granulomas in HCC were also induced by lipiodolized SMANCS, a polymer-conjugated derivative of neocarzinostatin (Ichikawa et al. 2002). Epithelioid cells induced within HCC by therapeutic measures or immune reactions of the host may appear in fine-needle aspirates and cause false-negative diagnostic results (Mourra and Flejou 2001).

A special situation of secondary change of HCC is tumor damage due to needle biopsy (Fig. 13).

Pathologic Changes in the Peritumoral Liver Substance

Liver tissue surrounding HCC nodules displays complex alterations, including formation of a distinct perinodular stroma consisting of an expanded fibrous matrix and a ductular reaction. Cytokeratin 19 expression in this perinodular stroma varies according to the underlying liver disease, being complex around cirrhotic nodules, attenuated around dysplastic nodules, and absent around HCC (Bioulac-Sage and Balabaud 2011). It was proposed that these patterns represent marked cellular alterations in cellular identity as an underlying mechanism that parallels progressive stages of intranodular hepatocarcinogenesis (Lennerz et al. 2011). In the absence of liver cirrhosis, a belt-like liver tissue zone surrounding HCC shows abnormal expression patterns of CD10 and CD105/endoglin expression. Compared with the background tissue, peritumoral liver parenchyma revealed significantly decreased CD10 staining, irrespective of HCC or metastatic carcinoma, and exhibited belt-like CD105 expression in 66.7 % of cases of metastatic carcinoma and in 88.6 % of those with HCC (Nakamura 2009).

Spontaneous Regression of Hepatocellular Carcinoma

Introduction

Spontaneous regression of malignant neoplasms (also termed spontaneous remission, spontaneous healing, or vanishing tumor; review: Everson and Cole 1968) is an intriguing phenomenon characterized by the apparently spontaneous and unexpected disappearance of a malignant lesion expected to behave in a progressive or aggressive manner. Spontaneous disappearance of tumors was already described in 1938 (Chamberlain 1938). In their seminal publication on numerous examples of spontaneous regression, Everson and Cole (1968) defined spontaneous regression of a tumor as the partial or complete disappearance of a malignant tumor in the absence of all treatment or in the presence of therapy which is considered inadequate to exert a significant influence on neoplastic disease. In principle, this is a definition that had previously been proposed (Stewart 1952), but the second part of the definition may have to be revised in the light of the development of therapies since 1968. The incidence of spontaneous tumor regression is difficult to judge; it has previously been estimated to occur in about 1 in 100,000 cancers (Everson and Cole 1968), but it may either be less common or more common (review: Challis and Stam 1990).

The first case of complete regression of malignant melanoma was reported in 1899 (Bennett 1899; cited in Papac 1998). Two years later, William Osler reported on *The Medical Aspects of Carcinoma of the Breast, with a Note on the Spontaneous Disappearance of Secondary Growths* (Osler 1901). A first series of cases was published in 1918 (Rohdenburg 1918). The author listed 302 cases, of which however only 70 cases with temporary or permanent regression were analyzed in detail. Interestingly, this series revealed that most cases with regression occurred following incomplete tumor removal or an acute febrile illness, suggesting a role of a systemic inflammatory response (see below). In a review of cases identified in the world literature from 1900 to 1960, and under exclusion of squamous cell carcinoma of the skin, leukemia, and Hodgkin's disease, the four most common examples of regression were renal cell carcinoma, neuroblastoma, malignant melanoma, and choriocarcinoma (Everson and Cole 1968).

Spontaneous regression of HCC is defined as vanishing of primary HCC in the absence of a specific therapy. It is a rare and fascinating phenomenon that delivers informations that may be employed for the development of more potent treatment modalities (Randolph et al. 2008). From published reports, the actual incidence of spontaneous regression of HCC can hardly be estimated, but the phenomenon may be more common that formerly anticipated. In most reports, the tumors were standard (ordinary) HCCs, but spontaneous regression was also observed in variants, e.g., clear-cell hepatocellular carcinoma (Stoelben et al. 1998; Jeon et al. 2005).

The rate of spontaneous objective partial regression among patients with HCC was estimated as 0.406 % (Oquiñena et al. 2009). Histologic proof of HCC prior to tumor regression is available for only part of the reported cases, the remaining tumors being diagnosed as HCC based on serum AFP elevation and imaging findings. It cannot, therefore, be excluded that a subset of the cases showing regression may not have been ordinary HCCs or other malignant hepatocellular tumors. In part of the tumors with regression, the neoplasm histologically revealed complete necrosis of the coagulative type (Lebon et al. 1950). Regression can also occur in HCC metastases or as an abscopal effect after therapy of metastases (Okuma et al. 2011).

Selected References Gottfried et al. 1982; Lam et al. 1982; Sato et al. 1985; Suzuki et al. 1989; Ayres et al. 1990; reviews of the literature: Postow et al. 2012; Yokoyama et al. 2012; Kermiche-Rahali et al. 2013; Okano et al. 2013; Sasaki et al. 2013; Saito et al. 2014.

Regression of Solitary HCCs Versus Multicentric HCC

Most reports on spontaneous regression of HCC refer to regression of solitary tumors with or without associated remote metastases. Several reports describe regression of rather small HCCs, i.e., with a diameter of 6 cm or less, but regression of large tumors has also been reported (Morimoto et al. 2002; Alqutub et al. 2011; Maejima et al. 2011). Typically, regression of HCC is accompanied by a reduction or normalization of serum AFP levels (Del Poggio et al. 2009; Alqutub et al. 2011). Regression of HCC has been found to coincide with shrinkage of the liver with a rise of SGOT to sometimes relatively high levels (Lam et al. 1982). Whether this phenomenon is related to a compromised portal circulation is not known, although regressing HCC has been found in association with portal vein thrombosis (Iiai et al. 2003). So far, there are no factors allowing to predict spontaneous regression. In particular, there seems to be no relationship between the type of underlying chronic liver disease and spontaneous regression of HCC. On ultrasonography and CT images, a significant reduction in tumor size is typical (Del Poggio et al. 2009; Yokoyama et al. 2012), either with a remaining small nodule with denser structure of cyst formation or with complete radiological vanishing of the tumor. In case of remnant tumor, the term spontaneous partial regression has been used (Meza-Junco et al. 2007). In residual nodules, an enhancing rim may persist over long time periods (Del Poggio et al. 2009). Apart from spontaneous regression of solitary HCCs, there are rare instances of regression involving several HCC nodules, i.e., multicentric HCC (Blondon et al. 2004). In one patient with alcohol-related liver cirrhosis and multiple HCC nodules, spontaneous regression of all tumor masses but one occurred, associated with normalization of serum AFP (Blondon et al. 2004). The finding of one HCC nodule not undergoing regression is of particular interest and may suggest immune-mediated mechanisms, with one nodule eventually not expressing the relevant antigens and thus being spared.

Recurrence After Regression

Is spontaneous regression of HCC a durable phenomenon? In several cases, follow-up exceeding 24 months has documented that regression may be followed by long-term remissions (Lin et al. 2004; Ohtani et al. 2005). However, after apparently complete regression, HCCs can recur, associated with the emergence of gross tumor nodules and rising serum AFP values (Magalotti et al. 1998; Lee et al. 2000). Recurrence may be characterized by rapid growth (Nakajima et al. 2004).

Regression of Metastasizing Hepatocellular Carcinoma

There are rare reported situations where spontaneous or therapy-induced regression of HCC was associated with regression of remote metastases. This phenomenon has also been observed with

several other tumor types (Everson and Cole 1968). HCC cases published so far include lung metastases (Toyoda et al. 1999; Ikeda et al. 2001; Kojima et al. 2006; Harimoto et al. 2012), skull metastases (Nam et al. 2005), other skeletal metastases (Sato et al. 1985), and splenic and peritoneal metastases (Terasaki et al. 2000). Complete regression of pulmonary HCC metastases has been seen following hepatectomy for HCC. In this patient, lung metastases developed after hepatectomy, with rising AFP levels, and the metastases regressed after 5 months in the absence of any therapy (Harimoto et al. 2012). Regression of multiple lung metastases of HCC has been observed following regression of the primary tumor after transcatheter arterial embolization (Heianna et al. 2007). It has been proposed that anti-metastasis immune reactions initiated by regression of the primary tumor and liberation of tumor antigens may play a role for metastasis regression (Heianna et al. 2007). In one reported patient, lung metastases remained regressed even though the hepatic primary continued to grow (Ikeda et al. 2001).

Abscopal Regression

Exceptionally, spontaneous regression of primary HCC occurs through an abscopal effect. The abscopal effect, coined by Mole (Mole 1953), denotes the impact that therapeutic irradiation of a tissue has on remote nonirradiated tissues. For example, irradiation of a tissue has been followed by regression of tumors located in a remote nonirradiated compartment. It has been proposed that this effect is mediated by a radiation-induced increase in circulating cytokine levels, such as TNF-alpha or IL-18 (Ohba et al. 1998; Nakanishi et al. 2008). However, there is increasing evidence that local radiotherapy elicits an immune response, mediated by T lymphocytes, which may then attack neoplastic cell populations in a remote site (review: Kroemer and Zitvogel 2012). For HCC, one report described a patient with an HCC that regressed after radiotherapy for thoracic vertebral bone metastasis. Serum levels of TNF-alpha increased after radiotherapy (Ohba et al. 1998).

Pathology of Spontaneous Regression of Hepatocellular Carcinoma

Macroscopically, complete regression may leave an atrophic region in the liver, with or without a central fibrous area. The regressed tumor may, however, also be visible as a demarcated necrotic mass with a rim of granulation tissue. Regression of HCCs may result in the formation of cysts filled with a clear or sanguinolent fluid (Nakajima et al. 2004). Histologically, complete necrosis of the tumor is present in part of the cases.

Selected references: Andreola et al. 1987; Ozeki et al. 1996; Stoelben et al. 1998; Izuishi et al. 2000; Lee et al. 2002; Li et al. 2003; Ohta et al. 2005; Ohtani et al. 2005; Arakawa et al. 2008; Maejima et al. 2011.

In regressed HCCs showing apparently complete necrosis, histology reveals a "dirty" necrotic background with shadow cells and few scattered, naked and irregular, damaged nuclei (Lee et al. 2002; Li et al. 2003). The necrotic tumor may be encircled by a dense inflammatory reaction, with infiltrates of granulocytes, lymphocytes, and macrophages (Arakawa et al. 2008). In part of the cases, this perinodular inflammation is followed by a rim of fibrosis, sometimes with formation of a fibrous pseudocapsule (Yokoyama et al. 2012). Postregression liver biopsy from the site of the previous tumor showed uninflamed liver tissue without dysplasia (Lam et al. 1982). The area of the liver previously occupied by HCC may be replaced by regenerating non-dysplastic liver parenchyma (Lam et al. 1982).

Differential Diagnosis of Tumor Regression

Spontaneously regressing HCC may be confounded with other liver cell tumors that may undergo regression, e.g., liver cell adenoma and focal nodular hyperplasia (FNH) (Siegel and Hartmann 1987).

Pathogenesis of Regression

Numerous pathogenic mechanisms for HCC regression have been proposed, including tumor hypoxia following thrombosis of feeding arteries, intratumoral bleeding, antitumoral immune reactions, blood transfusion, alcohol withdrawal, infection, hemorrhagic shock, tumor inhibition by growth factor and/or cytokines, induction of differentiation, angiogenesis inhibition, deranged telomere and telomerase metabolism, induction of massive apoptosis, and the use of herbal medicine (reviews: Cole 1976, 1981; Firminger 1976; Thomas 1976; Singh and McKinney 1979; Stoll 1992; Kaiser 1994; Papac 1998; Kaiser et al. 2000; Bodey 2002; Nelson and Ganss 2006). In a review of 75 cases described in the English literature, the most common mechanisms claimed to have caused regression were tumor hypoxia (28.0 %) and a systemic inflammatory response (33.3 %). In 38.7 %, no possible cause was mentioned (Huz et al. 2012).

Total necrosis owing to massive tumor hypoxia has been reported (Andreola et al. 1987; Lee et al. 2002; Ohta et al. 2005). This hypoxia may be caused by spontaneous occlusion of the tumor's feeding artery (Imaoka et al. 1994; Lee et al. 2002), thrombotic occlusion of intratumoral arteries (Yokoyama et al. 2012), artery stenosis due to subintimal injury (e.g., incurred by hepatic angiography; Takayasu et al. 1986), sustained systemic hypotension (Huz et al. 2012), and a steeling phenomenon caused by peritumoral arterioportal shunt deviating blood from the tumor (Misawa et al. 1999). Spontaneous remission of HCC has, e.g., been observed after massive gastrointestinal hemorrhage (Tocci et al. 1990; Bastawrous et al. 2012) and following portal vein thrombosis (Kermiche-Rahali et al. 2013). Intratumoral bleeding can cause hemorrhagic necrosis followed by regression of the tumor (Nakajima et al. 2004).

There is evidence that systemic inflammatory responses may cause or at least induce mechanisms finally resulting in complete regression of HCCs. Such responses included trauma, endotoxin shock, cholangitis, and systemic cytokine storms (e.g., with elevated levels of interleukin-18; Abiru et al. 2002). There is indirect evidence that antitumor immune reactions of the host induce HCC regression. In one patient, recurrent HCC after segmentectomy was first treated with transarterial embolization (TAE), followed by tumor growth and spontaneous regression 1 year later (Nakai et al. 2001). It may be theorized that TAE-induced tumor damage had facilitated contact of tumor antigens with the host's immune system, followed by a strong immune response directed against the recurrent tumor. As regressing HCC may be associated with dense lymphocytic infiltrates (a so-called lymphoid stroma; Park et al. 2009) or dense lymphocytic and plasmacellular infiltrates (resembling the phenotype of medullary breast cancer; Zimmermann et al. 2002), immune responses directed against tumor-associated antigens have been proposed to play a role in spontaneous regression of HCC (Park et al. 2009).

Immune Reactions and Inflammatory Changes in Hepatocellular Carcinoma

Introduction

The tumor microenvironment of HCC is characterized by the presence of immunologic effector cells that perform an immune response of the host directed against the tumor (Figs. 14 and 15).

The immunologic functions of tumor microenvironments of the liver are influenced or even determined by the unique immunologic features of this organ, forming some sort of tertiary lymphoid structure (Crispe 2009; Goc et al. 2013). The immune effector cells and associated cells involved in anti-liver cancer responses comprise several well-defined categories, namely, tumor-infiltrating lymphocytes (TILs), regulatory T cells (TREGs), monocytes and tumor-associated macrophages (TAMs), natural killer cells, dendritic cells, myeloid-derived suppressor cells, granulocytes, and mast cells (Bianchi et al. 2011; Chan et al. 2011; Zhao et al. 2012b; Lindau et al. 2013).

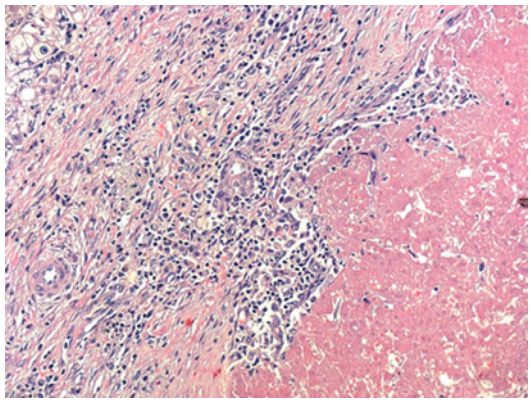

Fig. 14 Necrotic hepatocellular carcinoma is associated with an immune reaction characterized by lymphocytes and other immunologic effector cells. Part of these cells are in direct contact with necrotic tumor tissue (hematoxylin and eosin stain)

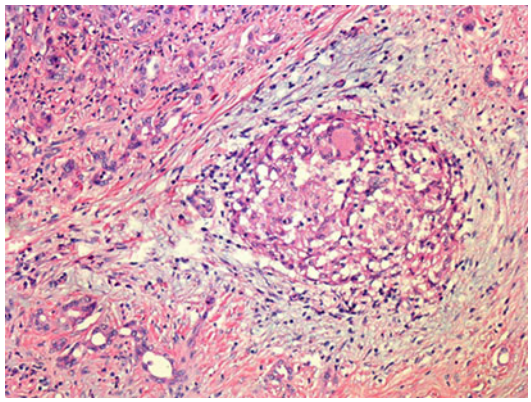

Fig. 15 In and around hepatocellular carcinomas, activated tumor-associated macrophages (TAMs) can transform into epithelioid cells and generate epithelioid cell granulomas, sometimes with Langhans-type giant cells (hematoxylin and eosin stain) (Reviews: O'Beirne and Harrison 2004; Berasain et al. 2009; Keibel et al. 2009; Korangy et al. 2010; Zamarron and Chen 2011; Guo et al. 2012; Leonardi et al. 2012; Nakagawa and Maeda 2012; Qin 2012; Senovilla et al. 2012; Aravalli 2013; Candido and Hagemann 2013; Fridman et al. 2013; Greten et al. 2013)

Lymphoid Cells: TILs and TREGs

Tumor-infiltrating lymphocytes (TILs) are a well-known phenomenon in HCC, albeit the density of TILs in HCCs is usually rather low (Shirabe et al. 2010). The density of TILs may increase as a function of tumor progression (Flecken et al. 2012). TIL accumulation is an early event in HCCs that determines long-term survival (Chew et al. 2012), whereby CD8(+) T cells located in the tumor stroma play a central role (An et al. 2014). Similar to dendritic cells, TILs are attracted to liver cancer through the action of locally released chemokines (Ben-Baruch 2012), but their recruitment is also influenced by interactions with other immune cells, in particular monocytoid cells (Kuang et al. 2010). Higher numbers of TILs are, however, relatively rare in HCCs and cholangiocarcinomas, but the presence of mixtures of CD3(+), CD4(+), and CD8(+) cells can affect prognosis (Shirabe et al. 2010). The calculated density of immune cells in tumor tissue was higher in the HCC group for which the prognosis was favorable, suggesting that lymphocyte density in HCC is a prognostic marker (Kawata et al. 1992). In few HCCs, the density of lymphoid cell or plasmacytoid infiltrates is excessively high, resulting in carcinoma with lymphoid stroma (Emile et al. 2000; Szekely 2001) or carcinomas resembling medullary carcinoma of the breast (Zimmermann et al. 2002).

A distinct and important category of lymphoid cells found in liver tumors are regulatory T cells (TREGs). TREGs were formerly known as suppressor T cells and constitute a subpopulation of T lymphocytes that modulate various immune responses, cause immune suppression of T cell-mediated responses, are involved in the inhibition of autoimmune reactions, play a role in cancer control, and maintain tolerance to self-antigens (Yu and Fu 2006; Wang and Wang 2007; Kosmaczewska et al. 2008; Wang 2008; Shirabe et al. 2010). In general, TREGs abrogate immune reactions of other immunologic effector cells (the so-called self-check mechanism). Based on the expression of several markers, TREGs come in several subpopulations, but the most important category has the phenotype, CD4(+), CD25(+), and Foxp3. The expression of Foxp3 is not specific for TREGs, as also recently activated non-TREG T lymphocytes express this transcription factor. TREGs make part of populations of immunologic effector cells in HCCs and are increased in part of the tumors (Yang et al. 2006;

Flecken et al. 2014). In one study, TREGs comprised 8.7 % of TILs (Unitt et al. 2005). TREGs infiltrating human HCCs promote, through their immunosuppressive function, immune evasion of these neoplasms (Pedroza-Gonzalez et al. 2013). Gamma/delta T cells infiltrating HCCs are functionally impaired by TREGs in an interleukin-10- and TGF-beta-dependent manner (Yi et al. 2013). TREG-induced immunosuppression also requires activation of Toll-like receptor 4/TLR4 signaling pathways (Yang et al. 2012). The presence of TREGs in HCCs is related to more aggressive biology, a highly invasive phenotype, and poor outcome (Gao et al. 2007; Zhou et al. 2009). Infiltration by Foxp3(+) TREGs in HCCs correlated with CD8(+) T cell impairment and was associated with portal vein tumor thrombosis and poor prognosis (Shen et al. 2011; Huang et al. 2012; Wang et al. 2012), whereby high Foxp3 expression levels were the most prominent predictors of poor outcome (Lin et al. 2013). Interestingly, TREG subsets with a different functional status are heterogeneously distributed in tumors and peritumoral tissues. In HCCs, intratumoral TREGs displayed higher frequencies and more suppressive phenotypic functions than those in the peritumoral compartment (Wu et al. 2013b).

Apart from T cells, B lymphocytes are also active in immune responses directed against HCCs. Specifically, infiltrating CD20(+) B lymphocytes are preferentially accumulated at the invasive front of the tumors (margin-infiltrating CD20(+) B cells). High densities of these cells were positively correlated with small tumor size, absence of vascular invasion, and increased density of CD8(+) T cells. Furthermore, high levels of margin-infiltrating B cells at the tumor invasion margin and penetrating the tumor capsule were associated with improved overall and recurrence-free survival (Shi et al. 2013).

Tumor-Associated Macrophages

Tumor-associated macrophages (TAMs) form an important group of immune effector cells that express a variety of tumor-promoting factors and factors that promote stroma formation, angiogenesis, and lymphangiogenesis.

Selected references: Van Loveren and Den Otter 1974; Biswas et al. 2008; Nardin and Abastado 2008; Yuan et al. 2008; Coffelt et al. 2009; Mantovani et al. 2009; Siveen and Kuutan 2009; Thelen et al. 2009; Sica 2010; Lawrence 2011; Fukuda et al. 2012; Wu and Zheng 2012; Biswas et al. 2013; Capece et al. 2013; Galdiero et al. 2013a; Long and Beatty 2013; Mano et al. 2013; Richards et al. 2013; You et al. 2013; Chazaud 2014.

TAMs form an important cell population in the inflammatory microenvironment of HCCs (Capece et al. 2013) and are mainly located to the tumor stroma where they undergo complex interactions with invading cancer cells, stromal myofibroblasts, endothelial cells, and other infiltrate cells, predominantly diverse classes of immunologic effector cells. TAMs are derived from circulating monocytes which in turn are produced in the bone marrow. TAMs promote cancer stem cell-like properties in HCCs through TGF-beta1-induced EMT (Fan et al. 2014).

TAMs, including those in liver cancers, form several functionally different subpopulations. TAMs basically present as fully polarized M1 cells and M2 or alternatively activated cells, with M1 and M2 cells forming the extremes of a continuum of functional TAM states (Sica and Mantovani 2012; Mantovani and Locati 2013). Classically activated M1 macrophages are also termed inflammatory macrophages, while alternatively activated M2 cells are termed regenerative macrophages (Zhou et al. 2014). Macrophages that infiltrate cancer tissues and become TAMs are usually driven by T cell-derived cytokines to acquired and alternative polarized of M2 phenotype (Mantovani et al. 2002). In most cancers, TAMs show properties of an alternative polarization phenotype (M2 TAMs) characterized by the expression of various chemokines, cytokines, and proteases that promote immunosuppression, tumor cell proliferation, and spreading of cancer cells (review: Través et al. 2012). TAMs affect EMT by downregulating the expression of E-cadherin

in HCC cells via an NF-kappaB/Slug pathway (Wang et al. 2014). The cells can also secrete angiogenic factors, e.g., vascular endothelial growth factor (VEGF), interleukin-8, matrix metalloproteinases (MMPs), and prostanoids, and through these products modulate the tumor microenvironment, pre-metastatic niche, and angiogenesis (Ono 2008). M2-polarized TAMs are preferentially present in glypican-3-positive HCCs (Takai et al. 2009). Inflammatory macrophages in liver are fibroblast-specific protein 1 positive and form a subpopulation that shows increased expression of COX2, osteopontin, inflammatory cytokines, and chemokines but reduced expression of MMP-3 and TIMP-3 compared with Kupffer cells and other macrophages (Österreicher et al. 2011). TAMs produce interleukin 6 and signal through STAT3 to promote expansion of HCC stem cells (Wan et al. 2014). c-Myc is expressed in TAMs and regulates their phenotype and function (Pello and Andrés 2013). The chemotactic cytokine CX3CR1 receptor contributes to TAM survival in cancers (Zheng et al. 2013). PD-L1-expressing monocytes/TAMs suppress tumor-specific T cell responses and hence promote tumor growth and progression (Kuang et al. 2009). As other macrophages, TAMs are derived from a bone marrow-derived monocyte lineage. Apart from mature TAMs, tumors including HCCs contain distinct types of monocytes that affect tumor behavior. Specifically, HCCs contain monocytes that express TIE2 (tyrosine kinase with Ig and endothelial growth factor (EGF) homology domain 2) (DePalma et al. 2013). These TIE2-expressing monocytes or TEMs are a marker for HCCs and modify growth and invasion of these neoplasms (Dapas et al. 2014). In particular, TEMs, through expression of the angiopoietin receptor TIE2, convey pro-angiogenic signals in HCCs (Germano and Daniele 2014).

HCC cells can trigger a transient activation of monocytes in stroma, whereby these cells acquire surface expression of PD-L1/B7-H1 molecules. This response is strengthened by the autocrine production of TNF-alpha and interleukin-10 released from activated monocytes, and the two factors themselves induce expression of PD-L1, thus forming an autocrine loop. Homing of TAMs to HCCs is mediated by upregulation of B7-H1, which mediates HCC immune escape (Chen et al. 2012). NF-kappaB has a central role in the recruitment and function of TAMs (Biswas and Lewis 2010; Mancino and Lawrence 2010; He and Karin 2011). In the cross talk between HCC cells and TAMs, NF-kappaB, STAT-3, and HIF-1 signaling pathways play a significant role (Capece et al. 2013; Mano et al. 2013). Expression of B7-H1 in HCC cells is associated with TAM infiltration of the tumors, whereby TAMs themselves induce B7-H1 expression in HCCs (Chen et al. 2012). In HCCs and peritumoral tissues, CD163(+) TAMs are more common than CD68(+) TAMs, but the density of CD68 (+) TAMs in peritumoral tissue was associated with better prognosis, but not of CD163(+) TAMs in peritumoral tissues (Kong et al. 2013). In HCCs, TAMs have complex functions that include antigen presentation, cytotoxicity directed against HCC cells, promotion of apoptosis, remodeling of cancer tissue and stroma, removal of dead cells and debris, and mediation of immune reactions. By these mechanisms, TAMs exert a marked influence on HCC progression (reviews: Shirabe et al. 2012). Proangiogenic TIE2(+)/CD31(+) TAMs are the predominant TAMs in metastatic lymph nodes (Kim et al. 2013b).

Granulomas and Sarcoid Reaction

In rare situations, TAMs in HCC are activated to become epithelioid cells and form granulomas (Cunningham et al. 1982; Tomimatsu et al. 1982). Granulomas have also been found in dysplastic nodules (Phelan and Nolan 2008). Similar to other visceral carcinomas, HCCs are sometimes associated with a marked granulomatous reaction in locoregional lymph nodes, a condition termed sarcoid reaction and caused by a strong cell-mediated immune reaction with transformation of activated macrophages into epithelioid cells (Adachi et al. 1993; Fong et al. 2012).

Natural Killer Cells and Pit Cells

Apart from B and T lymphocytes and macrophages, natural killer (NK) cells are involved in immune surveillance of liver tumors (Gao et al. 2008, 2009; Gao and Bertola 2011; Stojanovic and Cerwenka 2011; Desbois et al. 2012; Narni-Mancinelli et al. 2012; Bassiri et al. 2013; Cariani and Missale 2013; Tian et al. 2013; Vanherberghen et al. 2013). NK cells are abundant in the liver and serve as a central innate immune response component against a wide array of auto- and foreign antigens. It is estimated that NK cells, including pit cells, constitute 30–50 % of all hepatic lymphoid cells. Apart from regulation of immune responses, hepatic NK cells are also involved in reactions to acute or chronic liver damage, regeneration, and fibrotic processes (review: Cariani and Missale 2013). Homing of NK cells, including the liver, is subset specific, as visceral organs are preferentially populated by CD56(bright) CD16(neg/dull) noncytotoxic NK cells (Carrega and Ferlazzo 2012), whereby the cells are regulated by distinct microRNAs (Leong et al. 2012). There is evidence that tumor-associated NK cells become downregulated during tumor progression (Stojanovic et al. 2013). Tumor invasion and metastasis are regulated by an ubiquitin E3 ligase that plays an important role in the cytolytic activity of NK cells, NK lytic-associated molecule (NKLAM) (Hoover et al. 2012). Increased numbers of NK cells in HCCs and activated by monocytes can predict improved survival (Wu et al. 2013a). The anergy of NK cells is induced by cancer-expanded myeloid dendritic cells through membrane-bound TGF-beta1 (Li et al. 2009). Myeloid-derived suppressor cells (MDSCs) inhibit NK cells in HCC patients through the NKp30 receptor (Hoechst et al. 2009). A distinct population of hepatic large granular lymphocytes are the pit cells, a cell population that is critically involved in hepatic immune responses. In the course of liver regeneration, pit cells undergo a burst of proliferation followed by differentiation (Xu et al. 2011). In liver tumors there is an increase of large granular NK cells expressing the 12o kDa LAK-1 molecule (Stefanini et al. 1989).

Dendritic Cells

Dendritic cells (DCs) accumulate in the normal and inflamed liver (Lau and Thomson 2003; Ilkovitch and Lopez 2009). In comparison with liver cirrhosis, HCCs contain less DCs, in particular less CD83(+) DCs (Chen et al. 2000). In the course of hepatocarcinogenesis, DCs appear relatively late (Kapanadze et al. 2013). DCs in the nonneoplastic liver and in HCC consist of several categories, i.e., conventional DCs with intact antigen-presenting activity, functionally defective DCs with impaired motility and low ability to process and present antigens, and regulatory DCs with a high capacity to suppress T cell proliferation, induce the differentiation of regulatory T cells, or support immune tolerance (Umansky and Sevke 2013; Shurin et al. 2013). DCs serving as antigen-presenting cells accumulate in HCC tissues in variable numbers, and their presence affects local immune responses and tumor biology. HCC cells can inhibit the differentiation and maturation of DCs together with stimulating the production of TREGs (Li et al. 2007). A strong infiltration of DCs in HCCs is closely related to prognosis after surgical resection (Ido et al. 1994; Yin et al. 2003; Cai et al. 2006). DCs can be recruited to liver cancers and their microenvironments by the action of chemokines, cytokines, and chemotactic factors. The recruitment of dendritic cells is accomplished by the chemoattractant function of chemerin. Decreased chemerin expression in HCCs is associated with reduced DC accumulation and poor prognosis (Lin et al. 2011). HCC with low chemerin expression levels showed a more aggressive course and poorer survival (Lin et al. 2011), suggesting a role of the chemerin dendritic cell regulation loop. The function of tumor-associated dendritic cells is modulated by factors derived from HCC cells. Tumor-derived AFP impairs the differentiation and T cell stimulatory activity of dendritic cells (Pardee et al. 2014).

Myeloid-Derived Suppressor Cells (MDSCs)

Myeloid-derived suppressor cells (MDSCs) are a heterogeneous group of early or immature myeloid cells of different stages of differentiation that are potent inhibitors of diverse immune reactions, mainly adaptive immune responses mediated by CD4(+) and CD8(+) T cells and cytotoxic effects of NK cells.

Reviews: Pan et al. 2008; Ostrand-Rosenberg and Sinha 2009; Lechner et al. 2010; Natarajan and Thomson 2010; Greten et al. 2011; Hu et al. 2011; Younos et al. 2011; Cohen et al. 2012; Ostrand-Rosenberg et al. 2012b; Chandra and Gravekamp 2013; Nagaraj et al. 2013; Zhong et al. 2013; Jackaman and Nelson 2014.

In the context of the present chapter, it is important that MDSCs suppress antitumor immune responses, hence contribute to tumor immune evasion (circumvention of tumor immunosurveillance), but these cells also promote cancer cell invasion, angiogenesis, and metastatic spread (Haile et al. 2012; Monu and Frey 2012; Qu et al. 2012). MDSCs are marrow-derived elements that originate from distinct stem/progenitor cell populations and which occur in two main lineages, i.e., granulocytic (or granulocyte/neutrophil-like) MDSCs, accounting for 80–90 % of all MDSCs, and monocytic (or monocyte-like) MDSCs, accounting for 10–20 %. Granulocytic MDSCs or neutrophil/G-MDSCs share many features with neutrophils, with which they have a complex relationship (review: Brandau et al. 2013). The immunophenotype of MDSCs, which can also be assessed in normal and tumor tissues, presents several subcategories of MDSCs. A common immunophenotype is CD33(+) CD11b(+) CD15(+)CD14(−)MHC class II(−), but a subset of MDSCs is CD(+)HLA-DR(−/low). Intracellular markers comprise arginase and iNOS2. For an Internet poster depicting important aspects of MDSCs, see www.nature.com/nci/poster/mdscs. Both G-MDSCs and M-MDSCs are able to polarize from a classically activated phenotype (M1) to an alternatively activated one (M2), similar to TAMs (Yang et al. 2013). From their precursors, MDSCs can be recruited and expanded by various factors, including the HGF/c-met signaling pathway and STAT-3 (Yen et al. 2013). MDSCs mainly consists of cells derived from neutrophilic and monocytic lineages (Duffy et al. 2013; Schmid and Varner 2012). However, MDSCs can also be induced from NK cells in tumor microenvironments (Park et al. 2013). Accumulation of MDSCs in tissues involves TNF signaling (Zhao et al. 2012c), uPA and uPA receptor-dependent pathways (Ilkovitch et al. 2012), and the action of SIRT1 (Liu et al. 2014). The accumulation of MDSCs is stimulated by the proinflammatory S100 proteins, S100A8 and S100A9 (Sinha et al. 2008). The development of functional MDSCs is promoted by microRNAs-155 and microRNAs-21 (Li et al. 2014). In tumor tissues, immature MDSCs are modulated in their differentiation and function through a complex interaction with the tumor microenvironment (Gabrilovich et al. 2012; Ostrand-Rosenberg et al. 2012b). The survival of MDSCs is controlled by apoptosis via caspase family proteins and the Fas/FasL pathway (Ostrand-Rosenberg et al. 2012a). MDSCs express Fas receptor and undergo apoptosis in response to T cell-expressed Fas ligand/FasL (Sinha et al. 2011). On the other hand, deregulation of Bcl-xL and Bax in MDSCs contributes to their apoptosis resistance (Hu et al. 2013).

MDSCs exert their immunosuppressive functions through several pathways. The express cytoplasmic arginase and nitric oxide synthase 2/NOS2, which together block the translation of the T cell CD3 zeta chain, in part through nitrotyrosine, thus inhibit T cell proliferation and promote T cell apoptosis. MDSCs also stimulate the production of immunosuppressive TREGs and secrete immunosuppressive cytokines. Circulating MDSCs correlate with immunosuppression and inflammation in patients with cancer (Ohki et al. 2012). The immunosuppressive function in cancer, which is important for the failure of immunosurveillance, is based on MDSC effects exerted on several immune cell systems, including

the activation of TREGs (Hoechst et al. 2008; Kalathil et al. 2013) and the downregulation of NK cells and dendritic cells (Haile et al. 2012; Monu and Frey 2012; Solito et al. 2012). In cancers, MDSCs also promote epithelial-mesenchymal transition (EMT) and tumor cell invasion and dissemination (Toh et al. 2011). Similar to TAMs, MDSCs in part mediate their effects on other cells through exosomal pathways (Burke et al. 2014).

CD14(+) MDSCs are an important immunomodulatory cell subpopulation in the liver and in hepatic tumors (Ren et al. 2012). The mechanisms of MDSC recruitment to the liver are not yet fully understood. As the name implies, the majority of these effector cells originate from the bone marrow. MDSCs can be induced from circulating monocytoid cells/monocytes by activated hepatic stellate cells (HSCs) (Chou et al. 2011; Hoechst et al. 2013). This process operates in a CD44-dependent manner. MDSCs accumulate in the liver in the setting of chronic viral infection, particularly chronic HCV infection (Velazquez et al. 2012). In the liver, upregulated MDSCs impair dendritic cell function and promote hepatocarcinogenesis (Hu et al. 2011).

Patients with HCCs display the common subset of MDSCs, but they also show the population of MDSCs characterized by CD14(+)HLA-DR(−/low) and increased in the blood. These MDSCs promote immunosuppression through the induction of CD4(+)CD25(+)Foxp3(+) TREGs (Hoechst et al. 2008). In one investigation, almost one third of hepatic CD11(+) myeloid DCs were CD14(+) MDSC (Kelly et al. 2014). Increased numbers of CD14(+) MDSCs in HCCs are correlated with tumor progression (Arihara et al. 2013). The most important mechanism for the promotion of tumor progression is probably related to the immunosuppressive function of MDSCs, abolishing antitumor immune reactions and favoring tumor immunoevasion. MDSCs inhibit NK cells in patients with HCC (Hoechst et al. 2009), but this effect is not found with all subsets of MDSCs, as, e.g., RAE-1-positive mononuclear MDSCs activate NK cells (Nausch et al. 2008). The activity of MDSCs in HCCs is associated with a downregulation of anticancer dendritic cell function (Hu et al. 2011). Tumor-infiltrating monocytic MDSCs mediate CCR5-dependent recruitment of TREGs (Schlecker et al. 2012), a further immunosuppressive mechanism. In mice, upregulated MDSCs promoted HCC development through impairment of dendritic cell function (Hu et al. 2011).

The development and function of myeloid cells in HCC and other cancers is also regulated by stromal cells. Myofibroblasts are involved in the upregulation of S100A8 and S100A9 and the differentiation of myeloid cells (Kim et al. 2012). A novel subset of MDSCs are so-called fibrocytes, a term that was previously preoccupied by the mature offspring of fibroblasts. Fibrocytes according to the new definition are hematopoietic stem cell-derived MDSCs that bear the phenotypic and functional hallmarks of fibrocytes and are implicated in chronic inflammation and fibrosis. Fibrocytes from cancer patients suppressed anti-CD3-mediated T cell proliferation (Zhang et al. 2013).

Granulocytes

Neutrophils interact with the substratum of the extracellular matrix of tumors in a complex way which affects various aspects of tumor cell behavior, in particular invasion (Dumitru et al. 2013). Neutrophil granulocytes, apart from the role as acute cellular reactants to cell and tissue injury and bacterial infection, can interact with several cell populations and secrete numerous cytokines and signaling molecules (review: Galdiero et al. 2013b). Neutrophils from patients with HCC differ from other neutrophils in that they can produce CCL2, the amount of CCL2 produced being a function of the tumor load. The survival rate of HCCs having high-level CCL2 production by neutrophils was significantly lower than that for other patients (Tsuda et al. 2012). Although eosinophil granulocytes can be found in the stroma of both HCCs and cholangiocarcinomas, relatively few informations are available regarding their function, in contrast to other neoplasms. There is evidence that eosinophils can exert antitumor cytotoxic activity

directed against HCCs. Experimental expression of eotaxin in HCC cells affected the growth of these cells, and eosinophils producing TNF-alpha could kill tumor cells (Kataoka et al. 2004).

Mast Cells

HCCs and cholangiocarcinomas can contain mast cells in their stroma, but the density of this cell type is usually low (Cervello et al. 2005). In HCCs, mast cell density did not correlate with age or sex of patients, tumor stage, or grade (Grizzi et al. 2003). Mast cells can mobilize myeloid-derived suppressor cells and TREGs in the tumor microenvironment via the IL-17 pathway (Yang et al. 2010). Mast cells and Foxp3(+) TREGs often accumulate in the peritumoral tissue or peripheral stromal components, and the combined presence of these two cell types predicts prognosis (Ju et al. 2009). Infiltrating mast cells in HCCs can promote tumor angiogenesis (Peng et al. 2005) and may be involved in capillarization of sinusoidal vascular channels (Grizzi et al. 2003). In human HCC cell lines, histamine and spontaneously released mast cell granules affect cell growth, in that histamine downregulated the expression of beta-catenin, associated with caspase-3 activation (Lampiasi et al. 2007).

Hepatic Stellate Cells

An important hepatic cell population that is involved in immune mechanisms in the liver are the hepatic stellate cells (HSCs), cells that are activated by overexpression of c-myc in hepatocytes (Nevzorova et al. 2013) and probably also HCC cells. HSCs have immunosuppressive properties, enhance the expression of cytokines, and promote proliferation and migration of cancer cells. HSCs accomplish these functions, which are thought to affect HCC behavior, through the induction of T cell hyporesponsiveness, accelerated activated T cell apoptosis, increase in the number of Treg cells, and inhibition of T cell-mediated cytotoxicity. They may therefore induce T cell anergy and by this facilitate the immunologic escape of HCC cells (Zhao et al. 2012a). Intratumoral HSCs influence the progression of HCC, and their presence in greater numbers was an independent factor for overall and recurrence-free survival in HCC patients (Sun et al. 2013).

Communication of Immune and Inflammatory Cells in Liver Tumors Through Exosomes and Related Vehicles

As discussed in more detail in the chapter of liver metastases, exosomes as distinct extracellular vesicles released from normal and tumor cells play an important role in intercellular communication. Exosomes and related vehicles carry a cargo that contains signal substances, growth factors, microRNA and other short RNAs, and DNA.

Reviews: Royo and Falcon-Perez 2012; Vickers and Remaley 2012; Bai et al. 2013; Crescitelli et al. 2013; Kim et al. 2013a; Rayner and Hennessy 2013; Wendler et al. 2013; Voloshin et al. 2014.

Exosome-mediated exchange of informations is increasingly recognized as a critical mechanism in tumor cell fating and in tumor-associated immune and inflammatory reactions, including those found in HCCs and cholangiocarcinomas. Exosomal cargo delivery may play a role in the overall function of the immunological synapse (Delon and Germain 2000). A particularly important role is played by microvesicle-/exosome-transported microRNAs (Boon and Vickers 2013). Myeloid-derived suppressor cells produce exosomes carrying signal substances (Burke et al. 2014), and microRNAs make part of the cargo of T cell exosomes (Mittelbrunn et al. 2011) and can be transferred from TAMs to HCC cells (Aucher et al. 2013). MicroRNA transfer from human macrophages to HCC cells inhibits proliferation of these cells (Aucher et al. 2013). Apart from a modulation of immune responses, exosomal microRNA derived from macrophages can also stimulate invasive features of cancer cells (Yang et al. 2011). It may be assumed that the physiological capability of

macrophages to locomote and invade tissues can be adopted by cancer cells via exosomal information transfer. Furthermore, promotion of growth of HCC cells can be acquired by exosomal microRNA exchange (Kogure et al. 2011). Immune cell-derived microparticles/exosomes can facilitate HCC metastasis by transferring integrin alpha(M)beta2 to tumor cells (Ma et al. 2013). Macrophages not only transmit exosomal signals to tumor cells but also communicate among each other through this pathway, a mechanism involved in the regulation of macrophage differentiation (Ismail et al. 2013). Hepatic exosomes are also involved in the transmission of HCV to induce productive infection (Cosset and Dreux 2014). Exosomes originating from normal liver cells can, through the transport of signal substances, affect other hepatic ells. E.g., microparticles from liver cells can activate hedgehog signaling in hepatic endothelial cells (Witek et al. 2009). Exosomal information transfer can also occur from extrahepatic sources to the liver. Exosomes from intestinal mucosal cells can carry prostaglandin E2 and suppress the activation of liver NK cells (Deng et al. 2013).

A distinct mode of vesicle-mediated transfer is found in neutrophils, also those acting in tumor microenvironments. Neutrophils can produce tubulovesicular extensions termed cytonemes ("cell threads," membrane tethers) anchored to the substrate of extracellular matrix via an L-selectin-dependent, beta1- and beta2-independent mechanism. This attachment has an important role in neutrophil function, specifically adhesion, secretory processes, and phagocytosis (Galkina et al. 2005, 2013). In principle, cytonemes are specialized filopodia which in turn are cellular protrusions implicated in numerous types of mechanosensory processes. Cytonemes are critically involved in the handling and dispersion of diverse morphogens (review: Kornberg 2014) and mediate important steps in cell-to-cell signaling (Gradilla and Guerrero 2013). It may be anticipated that crucial interactions between leukocytes present in the stromal niche and tumor cells depend on the function of cytonemes acting as signal-transporting nanotubes and related structures.

Hepatocellular Carcinoma: Prognostic Factors

6

Contents

Abstract

Hepatocellular carcinoma (HCC) as a highly invasive and aggressive neoplasm displays a high rate of recurrence following surgery or ablation procedures. Numerous factors affect recurrence and prognosis. Among these, tumor stage is the most important prognosticator. Small and early HCCs have a better outcome than larger tumors. In addition to tumor size, the number of tumors (multiplicity) affects tumor biology. The status of the resection margin exerts a strong influence on prognosis. Future methods to evaluate the resection margin with respect to minimal residual cancer include molecular and nanosystem approaches. Other parameters of prognostic significance comprise distinct growth patterns in the liver, satellite lesions, large vessel invasion, presence of a pseudocapsule, tumor grade, microscopic invasion patterns, tumor angiogenesis, and a growing number of molecular features. The identification of distinct molecular signatures defining high-risk groups will become an important prognostic instrument in the future.

Introduction

In about 70 % of patients with HCC treated with surgery or ablation procedures, disease recurs within 5 years. Numerous factors affecting recurrence and prognosis have been identified and

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_6

discussed in surveys (reviews: Qin and Tang 2002a; Llovet et al. 2003; Mann et al. 2007).

Stage

Stage still is the most important prognosticator in patients with HCC (Hanazaki et al. 2001; Qin and Tang 2002b). This issue is further discussed in a separate chapter. Generally, tumor size exerts a variable influence on outcome in HCC. Large or very large HCC, i.e., those with a diameter of 10 cm or more, commonly showed recurrence following resection, but in some analyses overall survival was not different from patients with resected smaller lesions (Shah et al. 2007). Apart from tumor size, the number of tumors affects biology of disease (Germani et al. 2011). Apart from the general effects of stage, there are distinct T stage-related variants of HCC that differ from other cancers in regard to outcome. Generally, small and early HCCs have a better prognosis than larger HCC (Jwo et al. 1992; Hu et al. 2003). Solitary large HCC (SL-HCC) is a specific subtype of HCC which was associated with good outcome after hepatic resection (Yang et al. 2009), but the concept of SL-HCC has yet to be validated (Zhou et al. 2011).

Resection Margin

A negative resection margin was a favorable prognostic marker, and a positive margin a negative prognosticator, in part of investigations (Yoshida et al. 1989; Lai et al. 1990; Yamanaka et al. 1990; Matsutani et al. 1994; Chau et al. 1997; Young et al. 2007), while a clear resection margin $<$10 mm was a negative prognostic factor (Tralhao et al. 2007), and some analyses failed to show a significance of a clear resection margin in non-small HCC (Masutani et al. 1994). In HCC, the optimal liver resection margin is still a matter of controversy. It has been proposed that a resection margin of 2 cm is associated with a decreased recurrence rate and improved survival outcomes (Salloum and Castaing 2008). For large HCC, the presence of microsatellites and multiple nodules was associated with increased risk of positive resection margins. As such small lesions may often occur in a peritumoral rim of several mm width (Lai et al. 1993; Shi et al. 2002), resection with a margin of less than 5 mm was not regarded advisable (Lai et al. 1991; Zhou et al. 2007). In series of 288 HCC patients, the width of the resection margin did not affect postoperative recurrence rates. A positive margin was associated with a higher incidence of recurrence, but in most patients this was related to microsatellites and venous invasion (Poon et al. 2000). In a systematic review and meta-analysis of several randomized controlled trials and non-randomized trials, it turned out that there was no significant difference between the group with a margin $<$1 cm and the group with a margin $=>$ 2 cm in recurrence rate, one-year survival, 3-year survival, and 5-year survival (Tang et al. 2012). A clear resection margin is difficult or impossible to achieve in the presence of microsatellites and/or histologic venous permeation close to the primary tumor (Lai et al. 1993).

For a most optimal assessment of resection margins, novel mapping systems will be available to clearly identify margins and their orientation with respect to the resected liver, e.g., resection map systems (Lamata et al. 2010), image guidance systems (Kingham et al. 2012), and computer-assisted virtual liver resection planning (Mise et al. 2013). A special challenge is the detection of small clusters of residual tumor cells in the tissue of the resection margin (minimal residual cancer, MRC). Apart from histologic assessment of resection margins, including intraoperative frozen section, novel and in particular molecular and nanosystem approaches are developed to increase diagnostic sensitivity and to be employed in a theranostic setting (Braakhuis et al. 2010; Casciaro 2011). The aim of novel techniques, which make part of the concept of a theranostic and potentially personalized oncology (Omidi 2011; Kalia 2013; Yang et al. 2013), is to improve spatial resolution of cancer spread through molecular imaging of residual cancer cells or components thereof in resection margins (Alberti 2012). They include detection of tumor-associated proteins by tissue microarray

techniques (Li et al. 2011); methylation-based molecular margin analysis with microarrays (Zhang et al. 2006), e.g., with the CDKN2A methylation status as target (Yang et al. 2005); detection of promoter methylation of p16(INK4A), cytoglobin, E-cadherin, and transmembrane protein with EGF-like and two follistatin-like domains 2 (TMEFF2) (Shaw et al. 2013); tumor margin detection using quantitative near-infrared fluorescence (NIRF) molecular imaging targeting epithelial cell adhesion molecule (EpCAM) (NIRF-labeled anti-EpCAM antibody detection; Zhu et al. 2013); assessment of tissue by the use of molecular fluorescence imaging employing activatable cell-penetrating peptides as probes that may also be linked to nanoparticles (Nguyen et al. 2010; Olson et al. 2010); ultrasound-mediated transmembrane injection of labels contained in liposomal nanobubbles/bubble liposomes (Suzuki et al. 2013) or polymersomes (Thevenot et al. 2013); analysis through photothermal imaging of immune-targeted gold nanoparticles (Jakobsohn et al. 2012) or other nanocarriers; reconstruction of the spatial distribution of tumor cells using mass spectrometry (Gholami et al. 2011); assessment of tumor-associated genes in margins through quantitative RT-PCR analysis (de Carvalho et al. 2012); and detection of cancer-associated gene expression (e.g., TP53) via ligated DNA amplification (Poeta et al. 2009).

Other Morphologic Parameters

Important macroscopic morphologic parameters that are associated with more aggressive tumor biology include tumor size >2 cm, presence of satellite lesion, and large vessel invasion (Hanazki et al. 2001; Yeh et al. 2002; Hu et al. 2003; Kim et al. 2010). Tumor size in HCC predicts vascular invasion and histologic grade (Pawlik et al. 2005). Among three macroscopically nodular types of HCC, the single nodular type with extranodular growth (SNEG type) showed higher rates of portal vein invasion, intrahepatic metastasis, and poor differentiation (Shimada et al. 2001). Size is a dismal prognostic factor only in part, but not all HCC. A subset of solitary large HCC, a novel subtype with high-level differentiation, shows favorable prognosis (Zhou et al. 2011). Tumors with a thick capsule (marked encapsulation) had a better prognosis than those without (Franco et al. 1990; Ng et al. 1995), and encapsulation was found to be an independent prognosticator for longer disease-free survival (Lai et al. 1990). A favorable effect of the presence of a tumor capsule is not restricted to HCC but has also been found in other tumors, e.g., liver metastasis of colorectal cancer (Lunevicius et al. 2001). Also the macroscopic growth patterns have an impact on outcome. Among three nodular types of HCC, the single nodular with extranodular growth (SNEG) group revealed the worst survival, whereas there was no difference in outcome between single nodular and confluent multinodular groups (Shimada et al. 2001). In another study, the rate of microscopic invasion significantly increased from single nodular type to single nodular type with extranodular growth to contiguous multinodular type (Hui et al. 2000). Associated liver cirrhosis has an impact on outcome. Postoperative recurrence is frequent in cirrhotic patients (Takada et al. 2003). HCC without cirrhosis led to better overall and disease-free survival compared to cirrhotic HCC after curative liver resection (Nagasue et al. 2001; Grazi et al. 2003), but outcome in the non-cirrhotic group depends on preoperative hepatic function, margin status, and tumor multiplicity (Chen et al. 2003). Hypovascular HCC was biologically less aggressive, but evolved into a more aggressive malignancy in the course of further growth an increase of vascularity (Takayasu et al. 2013).

Different ground-glass hepatocyte patterns harbor specific HBV pre-S deletion mutants and are preneoplastic lesions in chronic HBV infection. The presence of a clustered ground-glass hepatocyte pattern in non-tumorous liver tissue was significantly associated with decreased local recurrence-free survival (Tsai et al. 2011). The presence of distinct phenotypes of small vessels in HCC has an impact on the tumor's biology of disease. HCCs display two main microvessel types, capillary-like and sinusoid-like vascular

channels. Patients with capillary-like vessel predominant HCC had a better disease-free and overall survival than those with sinusoid-like predominant tumors (Chen et al. 2011).

Tumor Grade and Differentiation Parameters

Tumor differentiation reflected as grade is an important prognostic factor in HCC and a crucial parameter for prognostication after therapy. In patients with advanced and sometimes mixed histologic grade, the worst histologic grade was found to determine prognosis after resection (Wu et al. 1996; Yamanaka et al. 2000; Zhou et al. 2011; Han et al. 2013). It was found that any proportion of poorly differentiated components is associated with poor prognosis in HCC patients after hepatectomy (Sasaki et al. 2014). Tumor grade can be combined with other parameters in order to obtain a combined prognosticator. For example, nuclear grade 1 with or without microvascular invasion and nuclear grade 2 without microvascular invasion formed a fair prognosis group, whereas nuclear grade 2 with microvascular invasion and nuclear grade 3 with or without microvascular invasion formed a poor prognosis group (Lauwers et al. 2002). Normal hepatocytes and HCC cells reveal cytoplasmic expression of the differentiation marker, DEC1 (human differentiated embryo chrondrocyte 1). HCC cells also show nuclear expression of DEC1, whereby high levels are found in well-differentiated HCC, whereas poorly differentiated HCCs fail to accumulate DEC1 in their nuclei (Shi et al. 2011). HCC with a progenitor cell phenotype, characterized by expression of cytokeratin 7 and/or 19, exhibited a higher rate of recurrence and a worse prognosis (Wu et al. 1996; Durnez et al. 2006; Lee et al. 2012). Arginase-1 as an enzyme that is typical for the hepatocyte lineage is an indicator of hepatocyte differentiation. HCC patients with higher arginase-1 expression showed less aggressive tumor features associated with higher cell differentiation, less vascular invasion, and lower TNM stage (Mao et al. 2013). Reduced levels of MUC15 in HCC are associated with shorter survival times of patients and reduced time to disease recurrence (Wang et al. 2013).

Parameters Related to Proliferation, Apoptosis, and Autophagy

The proliferation rate of HCC is generally elevated in comparison with normal and cirrhotic liver tissue and is roughly correlated with the differentiation grade. The Ki-67 labeling index of HCC with a diploid DNA pattern was significantly lower than that in aneuploid HCC, and HCC with an index exceeding 10 % showed a lower disease-free and overall survival (King et al. 1998). Microtubule-associated protein 1 light chain 3A (LC3A), a protein involved in autophagy, is differentially expressed in human malignancies. LC3A is highly expressed in HCC, and high expression in a “stone-like” pattern was correlated with poor differentiation, vascular invasion, and unfavorable prognosis (Xi et al. 2013). Abnormal spindle-like microcephaly-associated protein (ASPM) involved in the regulation of cell proliferation is overexpressed in subsets of HCC, associated with enhanced invasive and metastatic potential (Lin et al. 2008). Expression levels of TRAIL (the proapoptotic TNF-related apoptosis-inducing ligand) are downregulated in HCC in comparison with normal liver tissue (Piras-Straub et al. 2015), and expression of TRAIL receptors has prognostic relevance for HCCs (Kriegl et al. 2010). The biology of HCCs is also modulated by distinct expression patterns of apoptosis-inducing caspases. Cytosolic and nuclear caspase-8 have opposite impact on HCC biology and progression (Koschny et al. 2013).

Parameters Related to Tumor Invasion and Angiogenesis

Tumor invasion as a prerequisite for metastatic spread is a negative prognosticator in all cancers. The survival of HCC patients with macroscopic portal vein invasion and tumor thrombosis is poor (Zhou et al. 2006). Microscopic invasion of portal

venous branches is associated with poor differentiation of HCC, higher serum AFP levels, larger tumor size, and intrahepatic metastasis (Fujita et al. 2011). There is now evidence that microvascular invasion, including microscopic venous invasion, in patients with HCC is one of the most important risk factors affecting recurrence and survival (Tsai et al. 2000; McHugh et al. 2010; Hayashi et al. 2011; Lim et al. 2011; Rodriguez-Peralvarez et al. 2013). The presence of this feature is associated with greater tumor size, poor histologic grade, and intrahepatic micrometastasis (Ramos et al. 2006; Sumie et al. 2008; Eguchi et al. 2010; Gouw et al. 2011) and with an AFP level of more than 100 (McHugh et al. 2010).

Several factors and markers characterizing an invasive phenotype are altered in HCC, including several adhesion molecules (E-cadherin, N-cadherin, catenins, ICAM-1, and CD44 and its variants) (Endo and Terada 2000), tissue proteases, and angiogenesis regulators (review: Qin and Tang 2004). Adhesion-associated molecules ("adhesins") are altered in their cellular expression in early phases of the invasion cascade, and altered expression patterns reflect the mode of tumor cell invasion. Downregulation of E-cadherin in HCC is correlated with an invasive and metastatic phenotype (Endo et al. 2000; Guo et al. 2008), and E-cadherin expression is reduced in single nodular-type HCC with extranodular growth and in the contiguous multinodular type associated with increased invasion and high risk of recurrence (Inayoshi et al. 2003). Investigations on the expression patterns of N-cadherin in HCC provided controversial results. Reduced N-cadherin expression was associated with poorer tumor differentiation, increased cell migration, vascular invasion, and a metastatic phenotype in one study (Zhan et al. 2012), and also discontinuous N-cadherin immunostaining was associated with high risk of recurrence (Cho et al. 2008), while overexpression of neural cadherin (N-cadherin) was a predictive marker for early postoperative recurrence in HCC in another analysis (Seo et al. 2008). In HBV-related carcinogenesis, reduced or absent expression of E-cadherin as an important mechanism of cell contact loss is accomplished by epigenetic repression through histone deacetylation of CDH1 and downregulation of microRNA-373 (Arzumanyan et al. 2012). Also molecules associated with adhesion molecules are involved in this process and affect biology of disease. Serglycin, a proteoglycan, is overexpressed in HCC, and this overexpression is correlated with absence of E-cadherin and a poor prognosis (He et al. 2013), an aggressive invasive phenotype probably being linked to reduced cell-to-cell adhesion of tumor cells and their subsequent individualization. Interestingly, also absent expression of E-cadherin in noncancerous liver was associated with recurrence of HCC after curative resection (Minata et al. 2013a). Enhanced tissue remodeling mediated by matrix metalloproteinases affects the invasion process in a positive way. Tumor recurrence was associated with upregulation of matrix metalloproteinase-2 (MMP-2) in HCC (Théret et al. 2001). An association of E-cadherin and matrix metalloproteinase expression is correlation with HCC progression (Gao et al. 2006).

Tumor invasion requires tumor cell motility and locomotion linked to distinct functions of the actin-containing cytoskeleton. Control of fibrous actin formation involves several proteins, including formin-like 2, a member of the diaphanous-related formin family. Transfection of formin-like 2 into cells suppresses cell motility. Downregulation of formin-like 2 predicted poor prognosis in HCC (Liang et al. 2011), possibly via a mechanism favoring cell motility and migration. Filamin A is highly expressed in HCC cells and may be related to a metastatic phenotype (Ai et al. 2011). Expression of fascin (an actin-bundling protein) and cortactin was associated with poor prognosis in HCC (Iguchi et al. 2009; Huang et al. 2012). A factor stabilizing adherens junctions, MAGI1, suppresses invasion and metastasis. Downregulation of this factor in HCC is associated with aggressive disease and poor prognosis (Zhang et al. 2012). A factor involved in invasion is discoidin domain 1 receptor, showing a higher expression in HCC with recurrent disease (Jian et al. 2012). Overexpression of invasion-associated proteases

plays a role in recurrence and tumor spread. For example, poor prognosis of HCC was associated with overexpression of matrix metalloproteinase-12 (MMP-12) (Ng et al. 2011). On the other hand, TIMP-3 expression is associated with malignant behavior of HCCs (Gu et al. 2014). SERPINB3, a member of the family of serine protease inhibitors, is overexpressed in HCCs with an aggressive course and early recurrence (Pontisso 2014). A higher rate of vascular invasion and poor survival of HCC was correlated with the expression of the metastasis-associated colon cancer 1 (MACC1) gene (Qiu et al. 2011). An invasive phenotype of HCC was also associated with expression of the p53 gene (Hsu et al. 1993).

Pathways leading to an invasive and spreading phenotype in cancer are closely linked with tumor angiogenesis. Tumor angiogenesis is a major and critical event for HCC progression, recurrence, and metastasis. As angiogenesis is based on endothelial cell proliferation and the construction of a new microvessel networks, molecules serving as endothelial cell markers have been studied in HCC angiogenesis in detail, such as CD34 and CD105. The determination of tumor microvessel count appears to be useful prognostic marker for predicting HCC recurrence and patient survival (Nanashima et al. 2004). It is, therefore, to be expected that factors determining angiogenesis affect tumor progression. Strong expression of vascular endothelial growth factor (VEGF) was significantly associated with prognosis (Guo et al. 2006) and with metastatic recurrence following curative resection of HCC (Minata et al. 2013b). Expression of angiopoietin-2 in HCC correlated both with significantly shorter progression-free survival and overall survival (Miyahara et al. 2013). Similarly, expression of the proangiogenic factor endoglin (CD105), a co-receptor for several TGF-beta family cytokines, is correlated with increased postoperative recurrence and metastasis in patients with HCC (Yang et al. 2006). CD105 (endoglin) is overexpressed in microvessels emerging in the peritumoral nonneoplastic tissue as an angiogenic response, and this expression pattern is correlated with tumor recurrence and poorer prognosis (Ho et al. 2005; Yao et al. 2007; Wang et al. 2010). Part of the CD105-reactive endothelia of peritumoral liver are located in the sinusoid-like vessels (Yu et al. 2007). CD105 locally produced in the peritumoral angiogenic belt promotes the migration of HCC-derived endothelial cells (Benetti et al. 2008), suggesting a complex endotheliopoietic system involving the tumor and its peritumoral vascular network. Expression of claudin-10, closely related to angiogenesis, in HCC was correlated with poor prognosis (Huang et al. 2011). The hypoxic angiogenic zone surrounding HCC is a niche of endothelial progenitor cells and is an area overexpressing hypoxia-inducible factor-1 alpha, vascular endothelial growth factor A, and endostatin (Yu et al. 2010). Tumor-derived endothelial cells possess an increased angiogenic capability and are more resistant to angiogenesis inhibitor (Xiong et al. 2009). Expression of carcinoembryonic antigen-related cell adhesion molecule 1 (CEACAM1) in HCC is closely related with angiogenesis and poorer relapse-free survival after curative resection (Zhu et al. 2011).

Parameters Related to Epithelial-Mesenchymal Transition (EMT)

Acquiring a mesenchymal phenotype by HCC epithelial cells is a critical feature of epithelial-mesenchymal transition (EMT), a phenomenon that has multiple important impacts on tumor cell behavior, including HCC cells (Marijon et al. 2011). Several mechanisms are involved in the transition of a primarily epithelial tumor cell to a mesenchymal cell, characterized by becoming vimentin positive. CD44, a major adhesion molecule in the extracellular matrix, promotes the neo-expression of vimentin in HCC cells and a downregulation of E-cadherin expression. This pathway is associated with a spindled morphology of cancer cells, an increased invasiveness, and a more aggressive course (Mima et al. 2012). Smad-interacting protein 1 (SIP1, ZEB2) is critically involved in EMT as a repressor of E-cadherin and is overexpressed in several cancers (Oztas

et al. 2010). Claudins are tight junction-associated proteins that affect important cell functions in HCC, including the regulation of epithelial-mesenchymal transition. In HCC, claudin-10 levels were higher than in normal tissue, and expression was correlated with microscopic venous invasion and shorter overall survival (Huang et al. 2011). ZEB1, a member of the ZFH protein family (zinc finger E-box binding homeobox), plays an important role in epithelial-mesenchymal transition in carcinogenesis. Overexpression of ZEB1 in HCC was correlated with advanced stage, intrahepatic metastasis, vascular invasion, and frequent early recurrence (Zhou et al. 2012). Snail, which plays an important role in EMT, is capable to suppress E-cadherin expression in HCC and characterizes poorly differentiated tumors (Woo et al. 2011). Krüppel-like factor 8 promotes EMT, besides effects on proliferation and apoptosis. Upregulation of this factor in HCC promotes tumor invasion and indicates poor prognosis (Li et al. 2010).

Effects of Host Defense Against Tumor

There is strong evidence that the density of tumor-infiltrating immune cells is a predictor of intrahepatic recurrence and survival in patients with HCC. Lymphocyte infiltration of HCC is an early event that is driven by chemokines (CXCL10, CCL5, CCL2) and that determines long-term survival (Chew et al. 2012). In one analysis, the density of CD45RO(+) memory T cells was lower in HCC in comparison with the surrounding liver, while the CD57(+) senescent T cell density was higher in the tumor. The infiltrating memory/senescent T cell ratio predicted extrahepatic metastasis of HCC (Gao et al. 2012).

Ploidy and Chromosomal Aberrations

HCCs, but also the cirrhotic livers in which they develop and precursor lesions, display alterations of ploidy. In patients with liver cirrhosis who developed HCC within 3 years, the DNA ploidy was widely spread from diploid to hyperpolyploid, with a small peak of triploid cells and differences of ploidy among the two nuclei of binucleated cells (Koike et al. 1982, 1985). Initially, HCCs are either diploid or aneuploid neoplasms or contain a mixture of diploid and aneuploidy, e.g., hypotetraploid cells (Saeter et al. 1988). Single HCCs are homogeneous with respect to ploidy in the majority of cases (Ng et al. 1994), while complex tumors may contain mixed ploidy patterns. However, intratumoral heterogeneity as to ploidy was not found in all analyses. Some tumors show several aneuploidy peaks (multiple aneuploidy; Iwao et al. 1993). HCC metastases may show similar or different ploidy pattern (Kuo et al. 1987; Ding et al. 1992), while second (metachronous) HCC lesions developing in the liver can show a ploidy pattern different from that of the first tumor (Ishizu 1989; Nagasue et al. 1992). In some metastases, a DNA ploidy reduction was noted (Yoshida et al. 1992). In the course of progressive genomic instability, the ploidy patterns within a given tumor become more and more heterogeneous. This might be the reason why DNA ploidy patterns were not a useful indicator for the prognosis of HCC (McEntee et al. 1992), although ploidy patterns were well correlated with the Edmondson-Steiner grade (Hamazaki et al. 1993) and with tumor size, vascular invasion, and the presence of intrahepatic metastases (Fujimoto et al. 1991). In a study of small HCCs with a diameter of less than 3 cm, 73.3 % were diploid, while 84.6 % of large HCC were aneuploid (Cong and Wu 1990).

HCCs with multiple allelic losses were less often associated with hepatitis viral infection, were more frequently poorly differentiated, had higher serum AFP levels, and were of higher stage. Patients with more than one loss of heterozygosity (LOH) exhibited poorer 3-year disease-free survival than those with one LOH or none, suggesting that cumulative LOH is a useful prognosticator (Tamura et al. 1997) and that comprehensive allelotyping and comparative genomic hybridization are an important approach for

prognostication (Nagai et al. 1997; Piao et al. 1998; Wong et al. 1999; Lau and Guan 2005; Moinzadeh et al. 2005; Homayounfar et al. 2009; Longerich et al. 2012). In addition, distinct chromosome losses were identified with a more aggressive course. Allelic losses on 8p are common in HCC and confer aggressive biology (Chan et al. 2002). Allelic loss on 13q may play an important role in contributing to a more aggressive feature of HCC (Wong et al. 2002).

Molecular Parameters

An increasing number of molecular features are currently defined to play a significant role in HCC biology, molecular classifications, outcome of disease, and prognostication (Table 1).

Selected References Sheu 1997; Qin and Tang 2002a; Qin and Tang 2004; Thorgeirsson et al. 2006; Boyault et al. 2007; Mann et al. 2007; Pang and Poon 2007; Tommasi et al. 2007; Roessler et al. 2010; Chang et al. 2011; Gehrau et al. 2011; Hoshida 2011; Murakata et al. 2011; Van Malenstein et al. 2011; Villanueva et al. 2011; Walther and Jain 2011; Zhang et al. 2011; Singhal et al. 2012; Nault et al. 2013.

HCCs display distinct molecular signatures, e.g., TP53 pathway (Hoshida 2011; van Malenstein et al. 2011). The tumors also show differential expressions of gene products involved in metastatic cascades, including the prometastatic metastasis-associated protein 1 (Moon et al. 2007) and the metastasis suppressor gene, KAI1, which is reduced in metastatic HCC (Guo et al. 1998). However, not only molecular signatures expressed in HCC play a significant role in tumor progression. Gene expression patterns in non-tumoral liver tissue surrounding the primary tumor affect outcome, analysis of these tissue providing insights into the pathobiology of HCC recurrence. The biology of HCCs is markedly regulated by epigenetic mechanisms (promoter DNA methylation) and the differential expression of microRNAs (review: Anwar and Lehmann 2014).

Table 1 Molecular features of hepatocellular carcinoma negatively affecting prognosis

	Effect(s)
Oncogene/suppressor gene expression patterns	
Low p57 expression	Aggressive phenotype
FAT10 oncogene expression (6q21.3)	Tumor progression
HTPAP transcription variant-1 downregulation (8p)	Metastasis, poor survival
SOX9 overexpression	Tumor progression
N-myc downstream-regulated gene 1 expression	Metastatic phenotype
Growth/cell cycle regulation factors	
DNA topoisomerase II alpha overexpression	Aggressive phenotype
Akt overexpression	Metastatic spread
SMAD3L expression	Shorter RFS
Notch1 expression	Shorter DFS
RECK gene polymorphism	Distant metastasis
Cytoskeletal/motility factors	
Talin overexpression	Poor prognosis
Wnt signaling pathway	
BCL9 expression	Aggressive phenotype
Invasion- and metastasis-associated factors	
Matrix metalloproteinases	Invasion
Serine protease inhibitors/SERPINS	Invasion
Expression of colon cancer 1/MACC1	Tumor progression
Epithelial-mesenchymal transition	
p300 expression	Shortened OS
Transcription factors	
FOXJ1 expression	Poor prognosis
FOXM1 expression	Aggressive phenotype
BRP/POZ-domain gene	Poor prognosis
Proinflammatory factors	
CXCL5 expression (neutrophil recruitment)	Tumor progression
CXCR6 upregulation (inflammatory ME)	Metastasis promotion
CXCR7 expression	Distant metastases
S100 calcium-binding protein expression	Proinvasive effects
Osteopontin overexpression	Poor prognosis
Hypoxia and hypoxia-inducible factors	
HIF-1alpha expression	Tumor recurrence
Senescence factors	
Downregulation of fibulin-3	Poor prognosis
Nuclear traffic factors	
Importin-alpha 1	Metastatic phenotype
MicroRNAs	
MiR-18b expression	Malignancy grade
MiR-130b expression	Poor prognosis
MiR-224 upregulation	Tumor progression
MiR-372 expression	Tumor progression
Drug resistance factors	
Expression of asparagine synthetase	Poor prognosis

DFS disease-free survival, *RFS* recurrence-free survival, *OS* overall survival, *ME* microenvironment

DOI 10.1007/978-3-319-26956-6_7

Abstract

In cirrhotic livers, several types of precursor lesions of hepatocellular carcinoma (HCC) have been identified. These lesions include both hepatocellular changes characterized by distinct atypias (small cell change and large cell change, previously termed small liver cell dysplasia and large liver cell dysplasia) and circumscribed dysplastic lesions that are either invisible on gross examination (dysplastic focus) or visible with the naked eye (dysplastic nodules). A dysplastic focus consists of a group of hepatocytes having dysplastic features, incidentally detected in histologic specimens and usually showing a diameter of less than 1 mm. Dysplastic hepatocytes in a dysplastic focus mostly show small cell change. Dysplastic nodules are single or multiple nodules ranging in diameter from few mm to 15 mm or even more. They are divided into two variants, low-grade dysplastic nodule and high-grade dysplastic nodules, depending on the degree of atypia. Dysplastic nodules have to be distinguished from large regenerative nodules (macroregenerative nodules).

Introduction

It was recognized since long that cirrhotic livers can contain hepatocellular nodules that differ from usual cirrhotic nodules both in their size and the cellular features. Based on these characteristics and parallels with nodules detected in murine models of hepatocarcinogenesis, such nodules were considered to be precancerous lesions (reviews: Okuda 1992; Kojiro 2000). These macroscopically visible nodules were variably termed "liver cell atypia," "hyperplastic nodule," "macroregenerative nodule" (MRN; Furuya et al. 1988; Hytiroglou et al. 1995), "adenomatous" or "adenomatoid" hyperplasia (Edmondson 1976; Sakamoto et al. 1991), "hepatocellular pseudotumor" (Nagasue et al. 1984), "dysplastic nodules" (Wada et al. 1988), and "atypical liver nodes" (Berman and Moore 1996). It was early recognized that the distinction between these oversized atypical nodules and early hepatocellular carcinoma (HCC) may be difficult (Higginson and Steiner 1961). Based on the presence or absence of cytologic and/or architectural atypias, MRN were classified into two types, i.e., nodules without atypia or type I MRN ("ordinary adenomatous hyperplasia") and nodules with atypia or type II MRN ("atypical adenomatous hyperplasia"; Furuya et al. 1988; Nakanuma et al. 1990, 1993). In part of type II MN, alterations suggestive for the diagnosis of early HCC may be found; for these lesions with an uncertain malignancy, the term "borderline nodule" had been proposed (Ferrell et al. 1993). Precancerous nodules may consist of two components, with a nodule of different cellular composition being surrounded by an MRN nodule with or without atypia ("nodule-in-nodule" patterns). Recently, precancerous lesions of the liver have been redefined, the diagnostic features standardized, and a consensus nomenclature worked out (Ferrell et al. 1993; International Working Party 1995). This had led to the replacement of the former type I MRN by the term, large regenerative nodules (LRN), and type II MRN by the term, dysplastic nodule, as discussed in more detail in the following paragraph (Anthony et al. 1973; Schwartz 1998).

Modern Concepts of Precursor Lesions: Definitions and Classification

In general pathology, dysplasia is defined as a condition that either refers to alteration of single cells, group of cells, or entire multicellular tissues. In the latter case, which is best known from dysplasia of cervical squamous epithelium, a distinct tissue compartment is replaced by immature and atypical cells associated with a decrease of normally differentiating cells. In contrast to metaplasia, atypia or even anaplastic changes must be present in dysplasia, which denotes not only a change in differentiation as in metaplasia but a disorder of growth and differentiation that represents a premalignant alteration. In contrast to dysplastic tissues (e.g., an epithelial lining of a mucosa), dysplasia is less well defined for single cells or groups

Table 1 Classification of precursor lesions of hepatocellular carcinoma (International Working Group 1995)

Cellular alterations
Small cell change (small liver cell change (SLCC))
Large cell change (large liver cell change (LLCC))
Focal and nodular lesions
Dysplastic focus (DF)
Dysplastic nodule (DN)
Low-grade dysplastic nodule (LGDN)
High-grade dysplastic nodule (HGDN)

of cells, such as found in the liver. This is due to the fact that, contrary to an epithelial lining, architectural features (including the effacement of a typical cellular gradient from bottom to top) are not evident, emphasis therefore being placed on cellular and nuclear atypia, as already specified in a classical publication on liver cell dysplasia (Anthony et al. 1973).

As compiled in Table 1, precursor lesions of the liver include both hepatocellular changes characterized by distinct atypias (small cell change, large cell change, and iron-free foci) and hepatocellular dysplastic lesions that are either invisible on gross examination (dysplastic focus; DF) or visible with the naked eye (dysplastic nodule; DN) (Crawford 1990; International Working Party 1995; Tannapfel and Wittekind 2001; Roncalli et al. 2007, 2008). The features of these lesions have recently been reviewed in the 2010 WHO Classification of Tumours of the Digestive System (Theise et al. 2010).

Small Cell Change

Small cell change (small liver cell change; SLCC) was originally described as small cell dysplasia or small liver cell dysplasia (Watanabe et al. 1983; Dumortier and Scoazec 2001). SLCC is defined as an alteration of hepatocytes characterized by decreased cell size/volume, increased nuclear-cytoplasmic ratio, mild hyperchromasia and nuclear atypia, cytoplasmic basophilia or amphophilia, and nuclear crowding (Fig. 1; see below). SLCC, which can exist as small groups of cells, foci, or components of DN, morphologically

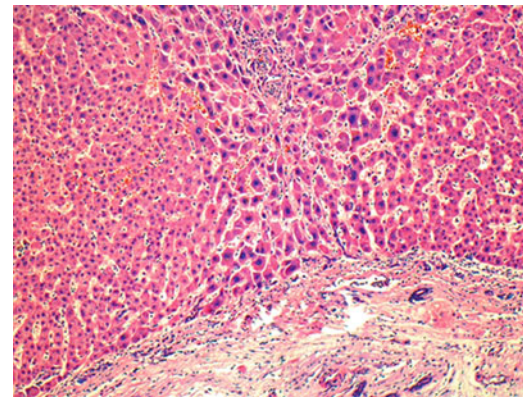

Fig. 1 A small area in a cirrhotic liver is occupied by abnormal hepatocytes with amphophilic cytoplasm and atypical nuclei (small cell change/small cell dysplasia; hematoxylin and eosin stain)

resembles early HCC and shares with HCC chromosomal and genomic alterations. The latter issue is discussed in more detail in the paragraph of pathogenic pathways.

Large Cell Change

Large cell change (large liver cell change, LLCC) was previously termed large cell dysplasia or large liver cell dysplasia (Anthony et al. 1973). In a histologic investigation of HCC associated with liver cirrhosis in Uganda, Anthony and coworkers (1973) defined LLCC as cells with cell body enlargement, nuclear pleomorphism, and multinucleation, occurring in cell groups or occupying entire cirrhotic nodules. Hepatocytes with LLCC display enlargement of both the cell body and the nucleus, with a preserved nuclear-cytoplasmic ratio. Nuclei show a moderate to marked hyperchromasia and sometimes multinucleation (Figs. 2, 3, and 4; see below histopathology).

There is evidence that LLCC exists in two forms regarding pathogenesis and biologic significance, i.e., a reactive form mainly occurring in cholestatic liver disease, and probably representing cellular senescence associated with polyploidization (Lee et al. 1997), and a form that is probably a true dysplastic, preneoplastic cell change and typically occurring in the setting of HBV infection (see below). Currently, there is consensus that LLCC

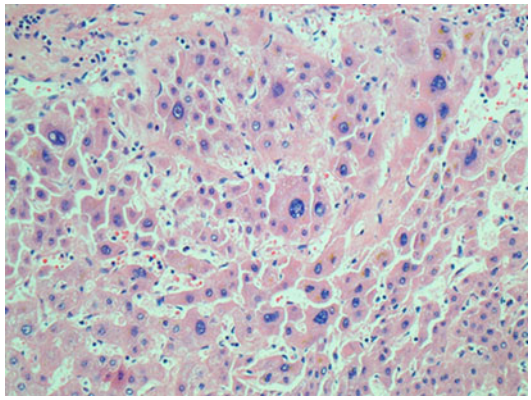

Fig. 2 In contrast to normal-sized hepatocytes in the lower part of the figure, the markedly enlarged cells show highly atypical nuclei and an irregular arrangement (large cell change/large cell dysplasia; hematoxylin and eosin stain)

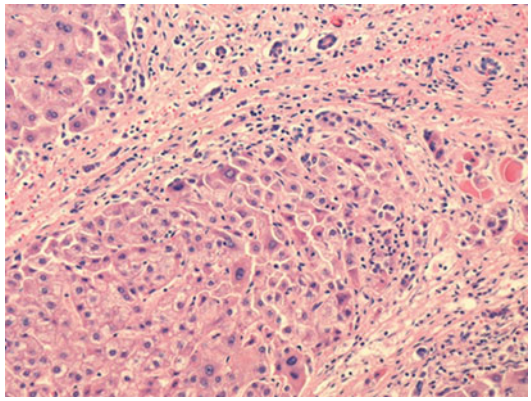

Fig. 3 This cirrhotic nodule exhibits a mixture of small and large dysplastic cells (small and large cell change combined; hematoxylin and eosin stain)

reflect acute to chronic cell injury that may predispose to a carcinogenic pathway.

Dysplastic Focus

The term dysplastic focus (DF) was proposed in the setting of a consensus meeting on nodular hepatic lesions (International Working Party 1995). DF is defined as a group or groups of hepatocytes having dysplastic features, incidentally found in histologic specimens and not macroscopically visible, in contrast to DN (Figs. 5 and 6). In the original definition,

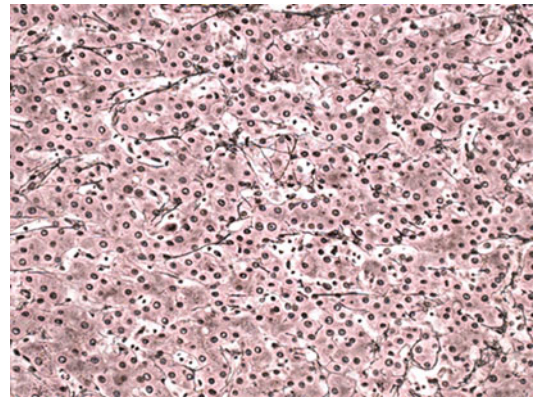

Fig. 4 Hepatocyte dysplasia (small and large cell change) leads to some cellular unrest in reticulin stains, but the general trabecular morphology is preserved (Gomori silver stain)

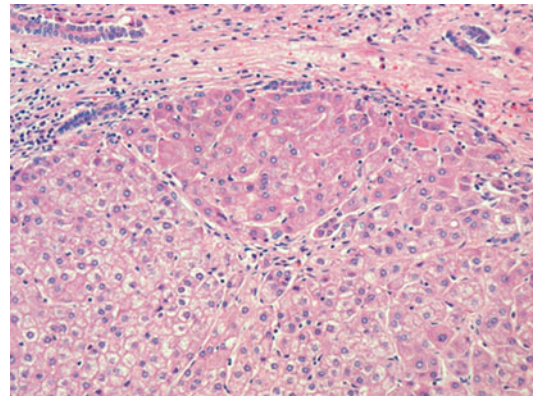

Fig. 5 Dysplastic focus. The nest of cells situated in the periphery of a cirrhotic nodules shows a cell morphology clearly different from that of adjacent hepatocytes (hematoxylin and eosin stain)

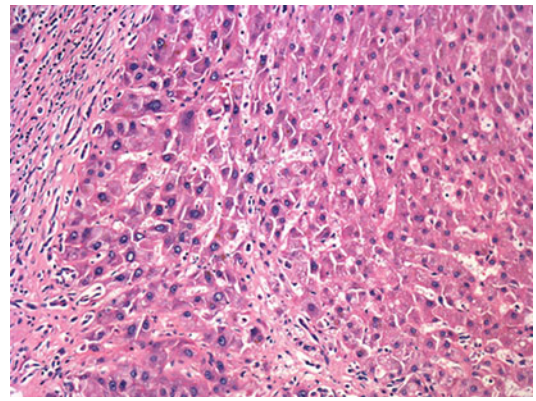

Fig. 6 This dysplastic focus shows a higher degree of cellular and nuclear atypia (hematoxylin and eosin stain)

DF is a lesion with a diameter lesser than 1 mm. This is an arbitrary size definition, which is related to the fact that DF occurs in a single liver lobule or within a cirrhotic nodule (Theise et al. 2010). As described below, DF usually consists of hepatocytes with SLCC, and DF with iron exclusion typically occurs in livers with hemochromatosis.

Dysplastic Nodule

Dysplastic nodules (DN; International Working Party 1995) are nodular lesions that have previously been termed adenomatous hyperplasia. In contrast to DF, DN are macroscopically visible, as single or multiple nodules with a diameter usually ranging from few mm to 15 mm or more, most DN however being smaller than 15 mm in diameter. DN differ from cirrhotic nodules in texture, color, and bulging activity. They are divided into two variants, low-grade DN (LGDN) and high-grade DN (HGDN), depending on the degree of atypia (Figs. 7, 8, 9, 10, 11, 12, and 13; International Working Party 1995). The histologic features are outlined in more detail below. There are certain differences or discrepancies between Eastern and Western interpretations of dysplastic nodules, in that Eastern specialist often identify "borderline nodules" as early HCC, while Western pathologists tend to term these lesions more commonly HGDN. It is expected that distinct molecular

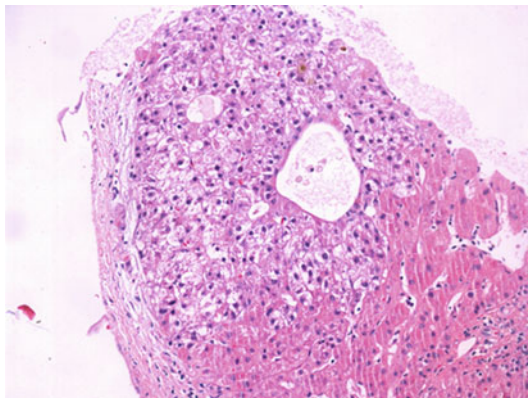

Fig. 12 Dysplastic nodules can contain clear cells and acinar structures (hematoxylin and eosin stain)

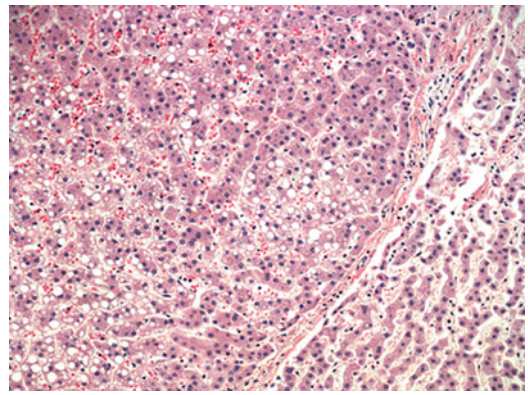

Fig. 14 Macroregenerative nodule. The nodule is well delineated and composed of normal-looking hepatocytes forming slender plates. There is focal fatty change. Note the perifocal parenchymal atrophy (hematoxylin and eosin stain)

signatures will help to better stratify these lesions as to their malignancy status (review: Roncalli et al. 2008).

Large Regenerative Nodules

In the consensus working formulation proposed in 1995 (International Working Party), the term large regenerative nodule (LRN) has replaced the former macroregenerative nodule type I or macronodule. LRN are larger than cirrhotic nodules occurring in micronodular cirrhosis and have a diameter of at least 5 mm (Fig. 14).

LRN mostly occur close to large portal tracts and are composed of hepatocytes without nuclear atypia. In contrast to DN, LRN are not considered to be precursor lesions of hepatic malignancy, as at the molecular level they do not differ from hyperplastic cells found in cirrhotic nodules, although they may, in the setting of their growth status, be different from normal hepatocytes in non-cirrhotic livers (Roncalli et al. 1999; Tiniakos and Brunt 1999; Borzio et al. 2003). The finding of monoclonality in LRN, assessed by use of X

chromosome inactivation-based techniques, is no longer considered to be an argument for a precursor of malignancy status, as this technique also identifies monoclonal cell patches or fields that normally occur during hepatic ontogenesis and may grow to mm size in the course of liver regeneration.

Iron-Free Hepatocyte Foci and Siderotic Foci and Nodules (Siderotic Dysplastic Nodules)

Livers with iron overload, and in particular livers of patients with hereditary hemochromatosis, can contain hepatocyte foci that do not accumulate stainable iron and are capable to exclude iron overload. Such foci are called iron-free foci and are considered to have a growth advantage due to reduced iron toxicity (similar to HCC) and to be precursor lesions for HCC which is a common complication of hepatic iron overload (Hirota et al. 1982; Terada and Nakanuma 1989; Deugnier et al. 1993). Iron-free nodules can also show persistent glycogen stores (Williams 1976), what is of interest with respect to glycogen-storing foci mainly known from animal experimentation (see below).

In contrast to iron-free foci, cirrhotic livers in the absence of generalized iron overload can contain hepatocyte nodules with marked iron overload/hemosiderosis, e.g., also in the setting of chronic viral hepatitis (Murakami et al. 1989; Mitchell et al. 1991; Lefkowitch et al. 1998; Krinsky et al. 2001; Zhang and Krinsky 2004; Cappellesso et al. 2013). Macroscopic nodules with marked iron accumulation are termed iron-rich nodules, siderotic regenerative nodules, or siderotic nodules. Iron-rich foci or nodules can be detected by means of CT and MR, showing nodules of high density or with heterogeneous regions of high density (Murakami et al. 1992), specifically with susceptibility-weighted MR imaging (Chen et al. 2012). MR imaging was used to distinguish between regenerative and dysplastic siderotic nodules (Krinsky et al. 2000). Iron-rich foci that are only found microscopically also occur but are less common alterations (Lefkowitch et al. 1998; Krinsky et al. 2001). Siderotic nodules come in two forms, i.e., those without atypia (regenerative siderotic nodules) and those with various degrees of atypia, termed high-grade siderotic DN and being precursors of HCC. Even low-grade siderotic nodules should be considered premalignant lesions as, similar to DN, they display marked architectural abnormalities, including a high rate of unpaired arteries (Krinsky et al. 2002). Within siderotic nodules, HCC can develop under the sign of a nodule-in-nodule lesion (Mitchell et al. 1991), and the occurrence of HCC may be associated causally with iron deposition in regenerative nodules in patients with cirrhosis (Ito et al. 1999). The reasons why subsets of HGDN are capable to accumulate large amounts of iron are currently unknown.

Glycogen-Storing Foci

In the setting of rodent models of hepatocarcinogenesis, early lesions are characterized by the emergence of clusters or foci of hepatocytes differing from normal parenchymal cells (foci of altered hepatocytes; FAH). Altered hepatocytes appear in several variants, namely, clear glycogen storage cells with a dislocation and relative reduction of granular endoplasmic reticulum, acidophilic glycogen storage cells with hypertrophy of the granular endoplasmic reticulum, fat-storing cells, and basophilic cells poor in glycogen and rich in ribosomes (Bannasch 1976). In these animal experiments, FAH have the features of precursor lesions in a hepatocarcinogenic pathway. Hepatocytes of these early lesions display distinct metabolic alterations, i.e., (a) focal excessive glycogen storage (termed glycogenosis) in hepatocytes giving rise to malignant neoplasms poor in glycogen and (b) an accumulation of mitochondria in hepatocytes, leading to an oncocytic cell lineage (Bannasch et al. 1984, 1997a, b). Clear and acidophilic glycogenotic cells precede the development of neoplastic nodules by weeks and months in mice (Bannasch 1976).

In the human liver, the occurrence and significance of FAH and glycogenic foci are less well studied. Glycogen-storing foci (GSF) and oncocytic foci have sometimes been observed in

human liver, mainly in chronic liver disease with or without associated HCC (Lefkowitch et al. 1980; Su et al. 1997; Libbrecht et al. 2000). However, other types or variants of FAH, as found in rodent models, have not reproducibly been detected in human livers. GSF in human livers are predominantly found in cirrhosis associated with HCC. The potential preneoplastic role of GSF in humans is not clarified. Part of GSF showed clusters of cells with SLCC, but whether there is really a sequence from GSF via liver cell dysplasia to HCC, as proposed, is still an open question (Su et al. 1997). It has also to be emphasized that liver cell dysplasia in cirrhosis, including the preneoplastic SLCC, is a rather common finding, while GSF are much rarer events (Libbrecht et al. 2001).

Hyperplastic Foci and Abnormal Regenerative Alterations

Japanese investigators reported on the occurrence of hyperplastic cell populations often containing small cells, termed hyperplastic focus (HPF; Shuto et al. 1999; Kato et al. 2001). Comparisons of the morphologic features of HPF and other small cell lesions suggest that HPF may be the same lesion as a small cell dysplastic focus, at least for a good part of cases. HPF are markedly proliferative lesions and were found to be an indicator of tumor recurrence following hepatic resection for small HCC (Shuto et al. 1999) and might, therefore, rather be precursor lesions instead of reactive, regenerative lesions. From a terminological point of view, HPF would therefore not be a suitable term, as hyperplasia implies a benign, reactive change.

In the Japanese literature, a distinct form of abnormal regeneration has been described under the term "irregular regeneration" (Shibata et al. 1998). Irregular regeneration is characterized by anisocytosis of hepatocytes (variations in cell size), pleomorphism of hepatocytes, bulging of parenchyma, and distinct homogeneous populations of liver cells separated from each other by a sharp border or outline. This pattern results in what was termed a "maplike distribution." Irregular regeneration was graded and severe forms regarded as a risk factor for the evolution of HCC. To date, the relationship between irregular regeneration and other forms of potential precursor lesions has not yet been clarified.

Epidemiology

The incidence of dysplastic changes and of dysplastic nodules in several types of liver cirrhosis varies considerably among reported case series, not the least caused by different definitions of precursor lesions in older studies in comparison with analyses performed after the consensus agreements and the novel definition of dysplasia, dysplastic foci, and dysplastic nodules (Karhunen and Penttilä 1987; Lefkowitch and Apfelbaum 1987). In a classical investigation (Anthony et al. 1973), liver cell dysplasia was found in only 2 of 200 patients with normal livers (1 %), in 3 of 43 (6.9 %) of patients with normal livers harboring HCC, 35 of 175 (20.3 %) of patients with cirrhosis, and in 80 of 124 (64.5 %) of patients with cirrhosis and HCC, suggesting an increase of dysplastic alterations in livers involved in a carcinogenic pathway. Liver cell dysplasia was identified in 60 % of 558 cases of cirrhosis with and without HCC in necropsies of Chinese individuals in Hong Kong from 1963 to 1978 (Ho et al. 1981). In liver tissues of 223 autopsy cases of cirrhosis and HCC, liver cell dysplasia was found in 94 or 42.2 % of cases, 37 from cases with cirrhosis only, and 53 from cases of cirrhosis with HCC. Cases with dysplasia disclosed significantly less frequently positivity for HBsAg (Akagi et al. 1984). In a study of 86 lesions of "macroregenerative" nodules, defined as nodular lesions exceeding 10 mm in diameter, the incidence of dysplastic changes (67.3 %) was significantly higher than that in cases without MRN (40.9 %), and the average size of MRN was greater in macronodular cirrhosis than in micronodular cirrhosis and greater in cirrhosis associated with HCC than in livers

without HCC (Furuya et al. 1988). Terada and coworkers found adenomatous hyperplasia in 21.5 % of 209 cirrhotic livers, and atypical adenomatous hyperplasia (type 2 lesions) were seen in 5.7 %. Among 38 cases of atypical adenomatous hyperplasia, 19 cases contained overt malignant hepatocellular foci (Terada et al. 1993b). In an autopsy series of 150 cases with cirrhosis, nodules of "adenomatous hyperplasia" were detected in 60 cases (40 %), and most patients belonged to the age group 30–60 years (Vaiphei et al. 1999). Rarely, nodular precursor lesions were diagnosed in old individuals, e.g., 82 years old (Gindhart et al. 1979).

Liver cell dysplasia and DN can develop in hepatic conditions known to be complicated by HCC. In regions with a high prevalence of HBV infection, the presence of dysplastic liver lesions is an important predictor of HBV-related HCC (Paterson et al. 1989). Large liver cell dysplasia, as it was previously termed, was detected in up to 82 % of adult alpha-1-antitrypsin deficiency (AAT) livers (69 % including infantile patients), and immunoreactive alpha-1-antitrypsin was detected in "dysplastic" cells (Cohen and Derose 1994a), but according to newer findings, large cell change in AAT livers may be related to cholestatic change (see below). In patients with early-stage ZZ AAT (stage 1 liver disease), increased CK-7-positive hepatic progenitor cell proliferation was seen compared to normal liver (Brunt et al. 2010), an alteration that may play a role in development of dysplastic lesions. Liver cell dysplasia is a typical feature of chronic liver disease developing in hereditary tyrosinemia type I, an inborn metabolism with a high rate of HCC development in chronic liver disease. Hepatic regenerating nodules, nests, or clusters of liver cell dysplasia and DN are found in tyrosinemia type I (Day et al. 1987; Dehner et al. 1989; Manowski et al. 1990; Mieles et al. 1990; Zerbini et al. 1992; Esquivel et al. 1994). In patients showing mutation reversion, reverted liver nodules interestingly revealed normal hepatocyte appearance and no dysplasia (Demers et al. 2003). By use of flow cytometry, DNA aneuploidy was detected in 10 % of cirrhotic nodules in this metabolic disorder (Zerbini et al. 1992). It was proposed that intermediates of tyrosine metabolism (maleylacetoacetate and fumarylacetoacetate) induce greatly increased chromosome breaks in tyrosinemia, causing chromosomal instability (Gilbert-Barness et al. 1990).

Clinical and Imaging Features

Dysplastic nodular lesions are in most patients asymptomatic, involved patients showing signs and symptoms of underlying liver cirrhosis. Patients with DN in the absence of frank HCC foci do not show elevated serum AFP levels (Kondo et al. 1990), with very few exceptions where secretion of AFP by dysplastic liver cells was found (Ng et al. 1999). Due to advanced imaging techniques, small nodular precursor lesions are now more easily and reliably detectable (Fukunaga et al. 2007). Ultrasonographically, the echogenicity of DN is variable, being either high or low. Contrast-enhanced Doppler ultrasonography is useful to distinguish precursor nodules from HCC, as the two lesion types markedly differ in their vascularity and hence intralesional arterial blood flow (Borzio et al. 1997; Fracanzani et al. 2001; Giorgio et al. 2011). Similar variability is seen on CT and MR images, but overall, common imaging findings of DN include low echogenicity, low attenuation, and high, low, or homogeneous intensity on T1- and T2-weighted MR images (Matsui et al. 1989; Kondo et al. 1990; Nomura et al. 1993; Choi et al. 1999; Tanaka et al. 2000; Takayasu et al. 2002; Kim et al. 2003; Krinsky 2004; Lim et al. 2004; O'Malley et al. 2005; Xu et al. 2005; Forner et al. 2008; Hanna et al. 2008; Park et al. 2009; Okamoto et al. 2010; Chou et al. 2011; Ouedraogo et al. 2011; Sersté et al. 2012; Iavarone et al. 2013; Quaia et al. 2013). In some studies, DN were not regularly detectable by use of ultrasonography (Libbrecht et al. 2002). In lesions with iron overload, MR imaging did not allow the distinction of regenerative and dysplastic nodules (Krinsky et al. 2000). The progression from dysplastic

changes to HCC is characterized by typical vascular changes (Efremidis and Hytiroglou 2002).

Pathology

Macroscopy

As specified above, only dysplastic nodules (DN) can be diagnosed macroscopically and appear as single or multiple lesions (Vaiphei et al. 1999; Roncalli et al. 2011). DN are usually small nodules which exhibit a diameter of few mm to 2 cm, but most DN have a diameter of less than 1.5 cm: Large and very large nodular lesions are also observed, reaching a diameter of up to 10 cm ("giant macroregenerative nodule"; Gurkan et al. 2001; Chen et al. 2002). In an autopsy study (150 cases of liver cirrhosis), nodular precursor lesions (termed adenomatous hyperplasia) measured 6 mm to 5 cm in diameter (Vaiphei et al. 1999). HGDN or so-called borderline nodules can be multiple and may have a relationship with a multicentric origin of HCC (Terada and Nakanuma 1995a). On cut surfaces, DN may have a color slightly different from that of non-DN cirrhosis nodules in the vicinity, but DN may sometimes be yellow owing to fatty change, are tan to orange stained, or appear as whitish lesions. In case the lesions are greenish due to bile accumulation, suspicion of early HCC should be raised. Bulging of the cut surface in the non-fixed state of the specimen can be recognized macroscopically and is a rather characteristic feature of larger DN with high-grade dysplasia, high proliferative activity, and compression of the adjacent liver substance. There is a tendency for size of nodules to increase in order from LGDN to HGDN to HCC; in one study, all nodules exceeding a diameter of 1.5 cm were HCC (Sakamoto et al. 1991).

Histopathology

As outlined above, hepatic precursor lesions appear in several types and variants, and diagnostic criteria to identify these lesions have been worked out (Table 2).

Small Cell Change (Small Liver Cell Change (SLCC))

SLCC is characterized by hepatocytes with decreased cell volume, markedly increased nuclear-cytoplasmic ratio, and a basophilic or amphophilic cytoplasm (Watanabe et al. 1983; Vaiphei et al. 1999; Su and Bannasch 2003). The decrease of cytoplasmic mass causes nuclei to be closer together than in normal liver cell plates, resulting in so-called nuclear crowding. Cells with SLCC exhibit a higher proliferative activity than cells in surrounding cirrhotic nodules, harbor genomic changes, and are considered to be preneoplastic cell populations. The distinct features of dysplastic cells, particularly the shapes and symmetry of nuclei, can be assessed by use of morphometry (Chen et al. 1984; Giannini et al. 1987; Pollice et al. 1988; Motohashi et al. 1992; Berman and Moore 1993). There was a relationship between the karyometric features of small cells and the features of poorly differentiated HCC (Zhao et al. 1994). Immunohistochemically, more than half of SLCC cell population consisted of small cells with the same immunohistochemical phenotype as putative hepatic progenitor cells, in contrast to LLCC cells (Libbrecht et al. 2000). The proliferative activity of SLCC as assessed by PCNA labeling was similar to that of grade 1 and grade 2 HCC (Adachi et al. 1993). In addition to SLCC elements belonging to a dysplastic cell compartment, hyperplastic small cells also occur in cirrhotic liver (Tezuka and Sawai 1983), giving rising to differential diagnostic problems. Dysplastic liver cells can reliably be identified by use of morphometric analysis (Vertemati et al. 2010).

Large Cell Change (Large Liver Cell Change (LLCC))

Large liver cell change (LLCC) was formerly termed large liver cell dysplasia. Cells with LLCC are oversized hepatocytes with enlarged nuclei, and these large cells are situated within liver cell plates with a normal architecture. In

Table 2 Histologic criteria for nodular precursor lesions of hepatocellular carcinoma (HCC) in comparison with early HCC

	LGDN	HGDN	Early HCC
Architectural features			
Liver cell plates of normal thickness	+[a]	±	–
Liver cell plates with a width of 3 cells	–	±	+
Effacement of reticulin network	–	±	+
Sinusoidal nuclear alignment	–	+	+
Intranodal portal tracts	+	±	–
Unpaired arteries	–	±	+
Growth patterns			
Clonal growth (in part maplike)	±	+	+

LGDN low-grade dysplastic nodule, *HGDN* high-grade dysplastic nodule
[a]Legend: + or – means present or absent, respectively. In the rubric proliferation for SLCC, + means low and ++–+++ means moderate to marked, and for LLCC, 1/– means low or absent

contrast to SLCC, the cytoplasm is usually eosinophilic. Nuclei show atypia and are either hyperchromatic or hypochromatic, what had led to the separation of LLCC into two subtypes (Zhao et al. 1994), but whether this reflects two phenotypes of LLCC or two extremes of LLCC nuclear morphology has to be further clarified. Hepatocytes with large cell change revealed either an unchanged nuclear-cytoplasmic ratio (Vaiphei et al. 1999) or an increased morphometric nuclear-cytoplasmic and nucleolar-cytoplasmic ratio (Roncalli et al. 1988). LLCC, which is still a controversial alteration, refers to lesions that are often encountered in various types of chronic liver disease (Park and Roncalli 2006). There is evidence that LLCC is often a reactive change, often occurring in cholestatic liver disease and related to cellular senescence, and not a cellular alteration within a carcinogenic pathway (Henmi et al. 1985; Kovacs and Elek 1987; Lee et al. 1997). In particular, immunohistochemical studies showed that foci of LLCC did not show a correlation with putative progenitor cells (Libbrecht et al. 2000). The criteria for diagnosing LLCC in fine-needle biopsies have been worked out, and in such biopsies, the incidence of LLCC amounts to as much as 15–20 % of cases of liver cirrhosis (Guettier et al. 2001). The morphometric features of large cells more closely resemble those of regenerating hepatocytes, indicating their hyperplastic character rather than a precancerous phenotype (Matturri and Bauer 1988).

There is a complex relationship between normal hepatocytes, regenerating hepatocytes, and LLCC, depending on the underlying type of liver disease. In HBV-related cirrhosis, the p21,

p27, and p16 cell cycle checkpoint markers were activated in normal-looking cirrhotic hepatocytes but diminished gradually from LLCC, small liver cell change, to HCC, with a progressive increase in p53 expression. Conversely, cholestatic LLCC retained expression of cell cycle checkpoint markers. As HBV-related LLCC had a higher yield of p53 cells, it was suggested that LLCC as such is a heterogeneous condition but that cholestatic LLCC represents a reactive change, while HBV-related LLCC may represent dysplastic elements (Natarajan et al. 1997; Koo et al. 2005; Kim et al. 2009).

Dysplastic Foci (DF)

Dysplastic foci (DF) are macroscopically not identifiable and are usually incidental findings at microscopic examination of cirrhotic liver tissue (International Working Party 1995). DF histology consist of small groups of abnormal hepatocytes, whereby the lesion is per definition smaller than 1 mm in diameter. DF commonly consist of an expansion of proliferating hepatocytes with small cell change, but large cells also occur (Hytiroglou 2004). In hemochromatosis livers, DF often appear as iron-free foci. SLCC is considered to be a more advanced precursor lesion than LLCC (Park 2011), but the premalignant significance of DF has not yet systematically been studied, due to small size and the ill-defined status of these lesions. It is to be expected that modern techniques of cell isolation in situ, e.g., laser capture, will render it possible to analyze genomic changes of isolated DF cells.

Dysplastic Nodules

Dysplastic nodules (DN) are defined as nodular lesions, in which groups of dysplastic hepatocytes (SLCC and/or LLCC) have developed in a cirrhotic nodule or occupy an entire nodule (Anthony et al. 1973; Ferrell et al. 1993; International Working Party 1995). DN mostly occur in cirrhotic livers as solitary or multiple lesions, usually not exceeding a diameter of 15 mm. Generally, DN predominantly composed of SLCC cells in a background of ordinary cirrhotic nodules present as hypercellular lesions with increased cytoplasmic basophilia, nuclear and nucleolar enlargement, nuclear crowding, occasional microacini, and proliferating cells located to septa (Wada et al. 1988). Nuclear crowding is related to a change in the nuclear-cytoplasmic ratios, which are clearly greater in malignant liver cells than regenerative cells, specifically in the frequent small cells (Gallagher 1978; Chang et al. 2010), while the nuclear-cytoplasmic ratio was unchanged in most large cells (Watanabe et al. 1983). DN may show a maplike clonal growth pattern (review: Roncalli 2004). DN having a large proportion of LLCC cells show cellular enlargement, nuclear polymorphisms with hyperchromasia or hypochromasia, and multinucleation, and enlargement of both nuclei and the cytoplasmic body can be two- to threefold in non-small cell dysplastic lesions (Anthony et al. 1973). Large liver cell nodules contained more micronuclei and more often showed nuclear anomalies termed “broken eggs” (de Almeida et al. 2004). In contrast to HCC, liver cell plates are not thickened, and reticulin pattern is usually preserved in LGDN (Nakanuma et al. 1998), while HGDN may show liver cell plates reaching a width of three cell layers, sometimes associated with sinusoidal nuclear alignment characterized by continuous hepatocyte nuclear alignment toward sinusoid-like vascular channels.

According to the propositions of an International Working Party (1995), DN are divided into two variants according to the degree of atypia, i.e., low-grade DN (LGDN) and high-grade DN (HGDN). Both variants show evidence of a clonal expansion of abnormal hepatocytes, but LGDN shows minor nuclear anomalies in comparison with HGDN. In HGDN, focal or diffuse SLCC is particularly common, and while intranodular portal tracts are more common in LGDN, they are rare in HGDN, which however may contain unpaired arteries as a sign of abnormal arterialization. In contrast to LGDN, which show a plate architecture identical to that of normal liver, HGDN can show thickened liver cell plates (up to three cells), associated with formation of

microacini and expansile subnodules (foci; Theise et al. 2010). In HGDN lesions having subnodules, the degree of atypia may vary from one subnodule to the other, suggesting clonal diversification. Part of such subnodules were found to be early HCC (HCC arising in DN; Theise et al. 2010). In part of HGDN, Mallory-Denk body clustering was detected, all such foci being well-circumscribed lesions (Terada et al. 1989b). Small liver nodules can either exclude iron and appear as iron-free lesions or they may also store stainable iron. Iron exclusion is regarded as a typical feature of HGDN and is shared by HCC, which typically show resistance to iron (hemosiderin) accumulation (Hirota et al. 1982). HGDN may show unusual changes. One variant is characterized by marked fatty change, lesions previously termed, and fatty macroregenerative nodules (Terada et al. 1989a). These lesions develop in non-steatotic liver cirrhosis as well-demarcated nodules and show foci of clustering Mallory-Denk bodies, numerous hyaline globules, atypical and hyperchromatic nuclei, abnormal blood vessels, iron exclusion, few intranodular portal tracts, and association with HCC. It was proposed that the presence of Mallory-Denk bodies and hyaline globules are suggestive of neoplasia (Terada et al. 1989b), as these cytoplasmic features characterize HCC (Nakanuma et al. 1981; Nakanuma and Ohta 1986). Whereas HGDN can easily be distinguished from LGDN, the latter is difficult to distinguish from regenerative nodules, due to the minor degree of nuclear anomalies. Molecular signatures will in the future help to separate low-grade dysplastic lesion from mere hyperplasia.

HGDN differ from ordinary cirrhotic nodules with respect to vascular architecture. Both a pathologic arterialization and features of capillarization (capillaries with basement membranes instead of sinusoidal channels) are present in at least part of DN. Whereas as the parenchyma of normal liver, cirrhotic nodules, and large regenerative nodules reveal no or only very few arterial elements, arterial vessels are found in DN and so-called borderline lesions of the former nomenclature (Terada and Nakanuma 1995b). The number of both capillary units and unpaired arteries was significantly increased in HGDN and frank HCC over LGDN and cirrhotic nodules, suggesting that certain angiogenic features segregate HGDN from other nodular lesions (Roncalli et al. 1999). In a morphometric analysis, arteries were slightly more numerous and portal vein branches were slightly less frequent in DN, mainly in HGDN (or type 2 adenomatous hyperplasia nodules) compared with surrounding liver substance, while HCC revealed a number and cumulative luminal area of arteries that was much greater than that of surrounding liver (Ueda et al. 1992). HCC developing in the interior of DN seem to possess a vascular tree different from that of the surrounding DN. Following transarterial embolization, the HCC part can undergo selective necrosis, while the DN was spared (Ueda et al. 1991). In rare instances, adenomatous hyperplasia had a pattern of demarcated nodules with scat-like central fibrosis and a large number of arteries, resembling focal nodular hyperplasia (Terada et al. 1993b).

DN can show abnormalities of the extracellular matrix (ECM) but are usually poor in connective tissue. Areas with SLCC displayed a reduced expression of the ECM proteins, tenascin, and type IV collagen (Zhao et al. 1996). Part of DN exhibit a marked increase in connective tissue fibers and may even show a scirrhous change. Two types of scirrhous change in DN were identified, i.e., a pericellular type related to cholestatic change and Mallory-Denk body formation and a stellate type associated with extensive portal fibrosis. Scirrhous change was not a specific feature of HGDN (An et al. 2003). DN also differ from cirrhotic nodules in their content of non-hepatocytic cells. DN contain fewer hepatic stellate cells (HSC) than ordinary cirrhotic nodules, and HSC are more frequent in peripheral parts than in central parts of DN but still less frequent than in cirrhotic nodules (Park et al. 1997). These findings suggest that DN display a profound alteration of the perisinusoidal space, the dwelling place of HSC, possibly related to monoclonal growth of these lesions. On the other hand, HSC may exert an influence on hepatocarcinogenic pathways, including the morphogenesis of dysplasia. In platelet-derived

growth factor C (PDGF-C) transgenic mice, receptors for PDGF-C were localized on HSC, which upon activation produced growth factors and cytokines, including stromal cell-derived hepatocyte growth factors involved in paracrine induction of liver cell dysplasia (Wright et al. 2013).

Immunohistochemistry

In regard to cytokeratin expression, dysplastic cells and cells of DN do not differ from normal hepatocytes. In contrast to HCC, dysplastic lesions were negative for glypican-3 (Wang et al. 2010), and DN are not reactive for AFP (Tsuji et al. 1999). DN may contain few cytokeratin19-positive cells, both in the form of small intraparenchymal cell clusters being similar to ductules and of peripheral bile ductules, while HCC did not show such cells (Terada et al. 1995). Epithelial membrane antigen/EMA staining was found in a minority of nodular precursor lesions (Tsuji et al. 1999). The proliferative features of dysplastic lesions vary among several studies having addressed this issue. Macroregenerative nodules without atypia did not differ from surrounding cirrhotic liver with respect to PCNA labeling, whereas an increased PCNA labeling was found in nodule-in-nodule lesions, whether atypical or overly malignant (Theise et al. 1996). Hepatocytes with small cell change displayed an increased PCNA proliferation index (Zhao et al. 1994) and an increased Ki-67 proliferation index in comparison with cirrhotic nodules without small cell change (Koskinas et al. 2005). Similarly, DN reveal an increased PCNA index in comparison with regenerative nodules (Terada and Nakanuma 1992; Yamashita 1996; Tiniakos and Brunt 1999), and PCNA staining increased from low-grade to high-grade lesions (Le Bail et al. 1995). There was a gradual increase of Ki-67-reactive nuclei from cirrhosis to HGDN and HCC (Dutta et al. 1998; Yeh et al. 2007). Immunoreactivity for the mitogen, transforming growth factor-alpha, is marked in cirrhotic nodules but is weakly or not expressed in HGDN and HCC (Yeh et al. 2007). p53 protein is rarely expressed in dysplastic liver cells, in contrast to HCC (Cohen and DeRose 1994b), but expression of p53 protein in dysplastic cells was found to be associated with increased apoptosis as assessed with in situ DNA end labeling/ISEL (Zhao and Zimmermann 1997). The hepatocyte growth factor receptor, c-Met, is expressed in about half of HCC, but in dysplastic lesions it was only detectable in small cell change (Zhao and Zimmermann 1998).

There is and was an active search for proteins that immunohistochemically discriminate DN from hepatocytes in normal and cirrhotic liver. While normal hepatocytes show a marked membranous staining for E-cadherin, such a reactivity was not found in SLCC (Zhao and Zimmermann 1998). Reactivity for alpha-methylacyl-coenzyme A racemase (AMACR; P504S) was moderate or marked in HCC and dysplastic lesions but was low in normal hepatocytes (Guzman et al. 2006; Helal Tel et al. 2012). Established HCC express protein-induced vitamin K absence or antagonist II (PIVKA-II), while this protein was not detectable in nodular precursor lesions (Miskad et al. 2001). Immunoreactivity for ubiquitin, which is strong in advanced HCC (also in HCC foci forming the inner part of nodule-in-nodule lesions), was weaker in early HCC and weak in dysplastic nodular lesions, suggesting that ubiquitin staining increases in a stepwise manner from DN to advanced HCC (Osada et al. 1997). Similarly, immunoreactivity for leukocyte cell-derived chemotoxin 2 (LECT2), a protein also synthesized by hepatocytes, revealed a stepwise decrease from hepatocytes to DN to well-differentiated HCC and was negative in advanced HCC (Uchida et al. 1999). The immunohistochemical expression of the organic anion-transporting polypeptide 8 (OATP8) significantly decreased during multistep hepatocarcinogenesis, decreasing from LGDN to HGDN to HCC, which may explain the decrease in enhancement ratio on gadoxetic acid-enhanced MR imaging (Kitao et al. 2011).

Immunohistochemical studies also revealed an abnormal phenotype of endothelial cells and vascular channels present in DN. Expression of the endothelial cell markers, CD31, CD34, and BNH9, was detected in 29.8 % of dysplastic lesions and 47 % of HCC, but not in normal

liver tissue, and the three markers were more often found in areas of small cell than of large cell change (Frachon et al. 2001). CD34 expression was more than 30 % in both DN and HCC (Nascimento et al. 2009). Agrin, which is selectively deposed in HCC microvessels versus sinusoidal walls, shows an expression gradually increasing agrin-negative benign lesions to DN of low and high grade (Tatrai et al. 2009). Sinusoid-like endothelial cells exhibited increased caveolin expression in DN relative to adjacent cirrhotic liver, while HCC vessels did not or only to a minor degree (Yerian et al. 2004).

Differential Diagnosis

HGDN may be difficult to distinguish from established HCC (Hytiroglou and Theise 1998), and in fact there is a considerable morphological overlap between HGDN and small HCC, also in cytology specimens (Berman and McNeill 1988). In particular, a distinction between HGDN and early HCC is sometimes difficult, especially when only imaging techniques are employed (Libbrecht et al. 2005). A decisive feature allowing the distinction of HCC from HGDN is presence of tumor cell invasion into portal tracts included in the interior of the tumor nodule, called "stromal invasion." The detection of "stromal invasion" is particularly helpful in case of well-differentiated HCC with vaguely nodular contours (review: Kojiro 2004). Architectural features of thickened cell plates, formation of trabeculae, and loss of the normal reticulin pattern are typical for HCC and are not, or less often, seen in DN (Crawford 1990; Ferrell et al. 1992). Part of HGDN exhibit fatty change, but this feature is also encountered in up to 40 % of small early HCC, i.e., those with a diameter of about 1.5 cm or less, and is therefore not helpful as a discriminator. Fatty change usually vanished as HCC grows to larger size. Advanced HCC may be surrounded by small hepatic nodules, sometimes numerous, that are usually malignant lesions and not DN (Ezaki et al. 1996). Apart from HGDN mainly containing small cells, other small cell lesions have been described, including so-called hyperplastic foci which are associated with recurrence following hepatic resection for small HCC (Shuto et al. 1999).

Biology of Disease

In early reports, foci of cellular atypia or, as they are called now, dysplastic lesions had not been considered to be premalignant or malignant lesions from the beginning, arguments raised against a premalignant state including a difference in histology of atypical nodules vs. HCC (Steiner and Davies 1957) or that such foci can persist in liver cirrhosis for years without development of HCC (Scheuer 1968). The first report demonstrating the emergence of malignancy in adenomatous hyperplasia nodules appeared in 1986 (Arakawa et al. 1986). Development of carcinoma in nodular precursor lesions was reported 2 years later (Furuya et al. 1988; Tsuda et al. 1988). As DN, and specifically HGDN, contain transformed cells with monoclonal growth and accumulation of cancerogenic gene alterations (Facciorusso et al. 2012), they are prone to progress to HCC, reflecting a premalignant change and a dysplasia-carcinoma sequence.

A strong argument for the premalignant nature of DN is the observation of HCC, sometimes multiple, developing in the interior of such a dysplastic nodule (Itoh et al. 1991; Theise et al. 1993;

Midorikawa et al. 2002) or HCC coexistent with DN (Kurita et al. 1993). In one investigation, 68.4 % of cases with adenomatous hyperplasia evolved toward HCC after 8–31 months (mean 14.2 months; Lencioni et al. 1994). In another early study, foci of overt HCC were found in 11/53 nodules of atypical adenomatous hyperplasia, suggesting that this alteration (now called HGDN) may be a hepatocellular neoplasm, a borderline lesion, or a peculiar form of low-grade HCC, in which overt HCC is likely to develop (Nakanuma et al. 1990). In a prospective study of macronodules with a mean follow-up of 33 months, 31 % of nodules transformed into HCC. The incidence of HCC per 100 person-years of follow-up was 11.3 %, with a malignant transformation rate of 3.5 %, 15.5 %, 31 %, and 48.5 % at 1,2, 3, and 5 years, respectively. HGDN and extranodular large cell change were independent predictors of malignant transformation (Borzio et al. 2003). A morphologically defined progression from DN to HCC was also found in fine-needle aspiration cytology studies of dysplastic lesions (Lin et al. 2008). It was estimated that 30–40 % of HGDN will progress to HCC at 24 months (Di Tommaso et al. 2013), while another investigation documented a yield of 53 % HCC in HGDN vs. 18 % in LGDN (Kaji et al. 2004). However, not all DN will develop into HCC, due to only partially known reasons, and other studies found a lesser progression to HCC. DN may remain as stable lesions or may even regress or disappear (Kondo et al. 1990). In one study of DN less than 20 mm in diameter, 15/33 nodules (45.5 %) disappeared, 14 nodules (42.4 %) remained unchanged, and only 4 nodules (12.1 %) progressed to HCC. The latter four nodules were all hyperechoic on US and were composed of clear cells with fatty change or small cells with increased nuclear density (Seki et al. 2000). Apart from intrinsic features such as the mode of progressive genomic instability, vascular factors seem to play a role in the switching of DN to HCC. Small hepatocyte nodules with arterial hypovascularity and a preserved portal supply had a low risk of transformation (Fukunaga et al. 2007). DN can give rise to both HCC and cholangiocarcinoma (Kwon et al. 2002), suggesting the involvement of bipotential progenitor cells.

Irrespective of all these observations, the exact role played in hepatocarcinogenesis by liver cell dysplasia and DN as such is not yet fully clarified (Henmi et al. 1985). In particular, it is not yet exactly known which features of dysplastic lesions will with the highest probability lead to malignancy. SLCC, less common than LLCC, is accepted to be a precancerous condition (Thung et al. 1995; Szczepanski 1997). In 1 study of 72 consecutive patients with HCV-associated cirrhosis, SLCC was an independent risk factor for HCC (Makino et al. 2000). There is evidence that a DN with an increased ratio of nuclear density, small cell change, clear cell change, and fatty change should be recognized to be a high risk for the development of HCC (Terasaki et al. 1998). A high prevalence of distinct histologic changes, including SLCC, cytoplasmic basophilia, small microacinar structures, peripheral distribution of nuclei, nuclear irregularities, and thickened liver cell plates, was found in cirrhotic nodules located close to HCC (Ojanguren et al. 1997). A high proliferation rate in dysplastic lesions also seems to be a predictor of later malignancy (Borzio et al. 1998). In contrast, the significance of LLCC has been interpreted in variable ways, based on controversial findings. The difficulty in interpreting the cancerogenic significance of LLCC is linked to the fact that large cells occur as reactive alterations, preferentially in cholestatic liver disease. Several studies did not confirm a premalignant phenotype of LLCC (Thung et al. 1995). But there is evidence that large cells are related to dysplasia and hepatocarcinogenesis under certain circumstances (Ganne-Carrié et al. 1996). It may also be assumed that we deal with two or more types or phenotypes of large cell change, part of them being reactive, others preneoplastic, with the same or at least a very similar morphology. Molecular studies are expected to clarify this situation further. Similar to HGDN, extranodular large cell change was an independent predictor of malignant transformation (Borzio et al. 2003). LLCC observed in the setting of chronic HBV infection was one of the

risk factors for HCC (Koo et al. 2008), and cirrhosis and LLCD were independent risk factors for HCC development in viral-induced chronic liver disease (Libbrecht et al. 2001).

Pathogenic Pathways

There is evidence that HGDN contain transformed cell population with clonal features. Early studies demonstrated a higher prevalence of aneuploidy in DN or atypical adenomatous hyperplasia, suggesting transformation (Hoso and Nakanuma 1991; Thomas et al. 1992; Orsatti et al. 1993; Rubin et al. 1994; Eissa et al. 1997). Clonal analysis of DN by methylation pattern of the X-chromosome-linked human androgen receptor gene revealed monoclonality in part of the lesions (Paradis et al. 1998; Okuda et al. 2001). In a study of 26 macronodules, monoclonality detected by this method was found in 54 % of the nodules and in 45 % of LGDN and 60 % of HGDN (Paradis et al. 1998). Clonality of DN was also demonstrated by use of DNA fingerprinting (Aihara et al. 1996). An immortalizing marker suggesting transformation, activity of telomerase, is absent in cirrhotic nodules but was found in up to 86 % of DN. However, also some large regenerative nodules expressed telomerase, suggesting that telomerase activity is not an absolute indicator of malignant transformation in these cell systems (Hytiroglou et al. 1998).

What are the mechanisms involved in the transformation of DN cells? There is evidence that DN exhibit distinct gene and genome alterations giving rise to abnormal growth and survival. Dysplastic liver lesions may show multiple chromosomal abnormalities (Terris et al. 1997; Raidl et al. 2004) and harbor certain patterns of loss of heterozygosity (LOH). LOH of chromosome 1 has been proposed to be an initial event in human hepatocarcinogenesis and is also manifest in dysplastic nodules, mainly involving the 1p36–p34 region, and specifically at loci D1S2843 (1p36.12) and D1S513 (1p34.3) (Sun et al. 2001; van Dekken et al. 2005). LOH of microsatellites showed a stepwise increase from HGDN to well-differentiated minute HCC to large HCC (Dong et al. 2011). LOH of chromosome 8p21.3.p22 (containing platelet-derived growth factor receptor beta-like tumor suppressor gene/PRLTS and deletion in liver cancer-1 tumor suppressor gene) was detected in 40.9 % of DN and LOH of chromosome 11p13 (containing the HBV integration site and the WT1 tumor suppressor gene) in 15.8 % of DN (Kahng et al. 2003). Comparative genomic hybridization revealed several chromosomal abnormalities in liver cell dysplasia as an indicator of the premalignant status of these lesions (Marchio et al. 2001; Tornillo et al. 2002; van Dekken et al. 2003). In HBsAg-transgenic mice, loss of promyelocytic leukemia protein (PML) promoted chromosome breaks in liver cells and accelerated to induction of dysplasia (Chung and Wu 2013). Epigenetic mechanisms seem to be involved in the pathogenesis of dysplastic lesions. DNA methyltransferases (Dmt) are responsible for epigenetic DNA methylation. Nuclear expression of Dmt3 was not detectable in LGDN but was present in HGDN, similar to HCC (Choi et al. 2003). A recently identified target of methylation is RASSF1A, acting in concert with NORE1A in the proapoptotic pathways of RAS signaling and increasingly methylated from normal liver to cancerous lesions (Di Gioia et al. 2006).

The gene alterations involved in the pathogenesis of DN and genomic differences between DN and early HCC are only partially known. It is expected that DN as precursors of malignancy reveal progressive genomic instability affecting several genes. Telomere shortening, chromosomal instability, and inactivation of the cell cycle checkpoint protein p21 (WAF1/CIP1) function occur both in LGDN and HGDN (Lee et al. 2009). Shortening of telomeres and reactivation of telomerase occur in DN during early stages of hepatocarcinogenesis and with a clear increase of the phenomena from LGDN to HGDN (Komine et al. 2000; Oh et al. 2003). There are differences in gene expression between normal liver, dysplastic lesions, and HCC (Nam et al. 2005). In one investigation, 12 genes were significantly and differentially expressed in early HCC compared with DN, namely, TERT, glypican-3, gankyrin, surviving, TOP2A, LYVE1, E-cadherin, IGFBP3, PDGFRRA,

TGFA, cyclin D1, and hepatocyte growth factor (Llovet et al. 2006), and gene expression profiling revealed 24 genes distinguishing dysplasia from cirrhosis (Wurmbach et al. 2007). In cDNA microarrays, numerous genes were consistently deregulated in livers with dysplastic changes, including caveolin-1, semaphorin E, and FMS-like tyrosine kinase 3 ligand, genes that have a putative role in carcinogenic pathways of the liver (Anders et al. 2003). Part of the gene alteration found in dysplastic lesions affect cell proliferation and differentiation. Dysplastic liver cells, and particular nodular lesions, show an increased proliferative activity. Cell proliferation assessed by counting nucleolar organizer region-associated proteins (Ag-NOR) demonstrated a stepwise increment from LGDN and HGDN to nodule-in-nodule lesions and early HCC (Aoki et al. 1994). G1-S cell cycle modulators such as cyclin D1 and p53 are expressed in HCC but were not detected in DN, suggesting that cyclin D1 overexpression and aberrant p53 expression might have a less important role in DN-HCC progression (Choi et al. 2001), and no mutations in the p53 gene were detected in DN (Kang et al. 1998). Abnormalities of the Wnt/beta-catenin signaling pathway are typically found in HCC, but DN did not show nuclear positivity for beta-catenin and no beta-catenin gene mutations (Prange et al. 2003). DN often display abnormalities of the transforming growth factor-beta (TGF-beta) signaling pathways. The expression of TGF-beta1 is progressively decreased in the sequence from dysplastic cells to early and advanced HCC (Paik et al. 2003). Immunoreactivity for Smad7, an inhibitory Smad of the TGF-beta pathway, is present in the majority of advanced HCC but absent in DN and early HCC, suggesting that Smad7 makes part of a resistance mechanism in increased TGF-beta1 in late stages of hepatocarcinogenesis (Park et al. 2004).

The biogenesis and morphogenesis of dysplastic lesions and the involved mechanisms have been investigated in animal models of hepatocarcinogenesis. LLCC, which is often observed in HBV infection, can be reproduced in HBV x transgenic mice. In these animals, LLCC may, in contrast to humans, more frequently be involved in carcinogenesis (Koo et al. 2005). In double transgenic mice expressing the HBx genes, ATX and IRS-1, an increased frequency of dysplastic lesions and HCC was observed, associated with increased insulin growth factor 1, Wnt1, and Wnt3 mRNA levels (Longato et al. 2009). In a c-Myc transgenic mouse model with microdissection of hepatic lesions, c-Myc induction was associated with transcriptional upregulation of candidate genes and the development of liver cell dysplasia (Hunecke et al. 2012).

Abstract

At the time point of diagnosis, subsets of hepatocellular carcinoma (HCC) show a small size. Part of these lesions are early cancers, but there are also small HCCs with a distinct histologic pattern. Lesions with a diameter of 3.5 cm or less were formerly termed minute HCC. Today, early HCC is frequently identified as a nodular HCC measuring 2 cm or less in diameter, the limit of 2 cm having been settled in an international consensus conference. These small neoplasms come in two basic growth patterns, one characterized by vaguely nodular, well-differentiated tumors (small HCC with indistinct margins or vaguely nodular small HCC) and the other by distinctly nodular tumor with the histology of ordinary HCC. Early and small HCCs are usually asymptomatic, but are associated with liver cirrhosis in most patients. At least part of early HCCs show a histological presentation that differs in several respects from that of larger ordinary HCCs, suggesting that some of these small tumors are not simply early stages of a classical HCC progression pathway, but rather represent a distinct variant of HCC.

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,

Introduction

There is a group of hepatocellular carcinomas (HCCs) characterized by small size at the time point of diagnosis. Formerly, such small lesions were mostly detected in resection specimens or in the setting of autopsies, but based on the higher efficiency of modern imaging techniques, small HCC are now commonly diagnosed in a clinical diagnostic setting. Small HCCs have also been termed microcarcinoma of the liver (Köhn 1956). HCCs of small size have previously been described as small HCC, mainly in the Japanese literature. As an international consensus regarding the biological nature of these lesions and their distinction from high-grade dysplastic nodules has been achieved (International Consensus Group for Hepatocellular Neoplasia 2009), recent classifications, including that of the WHO (Theise et al. 2010), now employ the term early HCC (E-HCC) to denote these neoplasms.

Originally, the term "small HCC" defined the neoplasm's size (diameter) and did not necessarily refer to an early stage of hepatocarcinogenesis. The concept of "small HCC" is complicated by several difficulties in regard to further definition and the integration of aspects of tumor biology. Concerning the maximum tumor diameter, the lesions have been defined in various ways, authors accepting tumors as "small HCC" with nodule diameters ranging from 2 cm or less (Yama-shita et al. 2012) to 5 cm. Lesions with a diameter of 3.5 cm or less were formerly also called "minute HCC." Today, E-HCC is usually defined as a poorly defined nodular hepatocellular neoplasm measuring 2 cm or less in diameter ("small HCC with indistinct margins," "vaguely nodular small HCC"; Theise et al. 2010), the limit of 2 cm in diameter having been settled in an international consensus publication (International Working Party 1995).

What are the arguments that "small HCC" are in fact E-HCC vs. "progressed-type" lesions? There is clear evidence that at least part of small tumors measuring 2 cm or less are E-HCC at the time point of diagnosis and may progress to advanced HCC afterward, becoming large lesions in the course of the disease (Grigioni et al. 1991; reviews: Hytiroglou 2004; Roncalli et al. 2010). But there is evidence that at least a fraction of tumors being small at diagnosis will remain small lesions, i.e., will exhibit slow growth or no documentable growth, and will behave in a more favorable manner. However, the fact that these neoplasms have reached a size rendering them visible at imaging or at macroscopic examination means that significant growth has taken place, probably for a long time period, and for still unknown reasons, further growth will not, or only slowly, take place following diagnosis.

Epidemiology

Numerous reports document the existence of small HCCs, in both cirrhotic and non-cirrhotic livers. Together with dysplastic nodules, well-differentiated E-HCCs are often detected in noncancerous liver tissue resected along with HCCs and in explanted cirrhotic livers (Kojiro and Roskams 2005). Part of these small cancers are incidental lesions. In explanted cirrhotic livers of 30 patients, E-HCC was incidentally found in 63.3 % of the livers, varying from microscopic focuses to 2 cm diameter lesions (Caroli-Bottino et al. 2005). In a study of 325 Chinese HCC patients with hepatitis and S-HCC, male gender and young age were typical for smaller tumor mass phenotypes (Carr et al. 2011).

Selected References Okuda et al. 1975; Mahmood and Schatzki 1976; Nakashima et al. 1977; Zhaoyou et al. 1979; Yu et al. 1980; Yamasaki et al. 1981; Chen et al. 1982; Shinagawa et al. 1982; Watanabe et al. 1986; Grigioni et al. 1989; Tang et al. 1989; Sasaki et al. 1996; Kojiro 1998; Fong et al. 1999; Utsunomiya et al. 2000; Toyoda et al. 2001; Sherman 2005; Carr et al. 2011; Kim et al. 2011 and Park 2011.

Clinical and Imaging Features

E-HCCs are usually asymptomatic lesions, but as they are associated with liver cirrhosis in the majority of, or all, patients (Gandolfi et al. 1987;

Zhou et al. 1991), signs and symptoms are dominated by the chronic cirrhotic liver disease. For subcentimeter hypervascular lesions, the clinical impact of individual lesions is limited owing to the longer time interval for tumor growth to reach a critical size, but diagnosis of early HCC shows to be aimed for lesions in the range of 1–2 cm (Yu et al. 2009). E-HCC can cause symptomatic disease in specific situations, e.g., in case the lesion is situated close to the hilum, causing obstructive jaundice (Ise et al. 2004). Serial measurement of serum AFP levels appears to be a very helpful method for detection of HCC at the early stage (Kanematsu et al. 1983; Chen et al. 1984; Dusheiko et al. 1986; Pancoska et al. 2011). In E-HCC with a diameter of 3 cm or less, serum levels of AFP-IgM complexes were higher than in patients with a tumor diameter exceeding 3 cm, suggesting the determination of this complex is of potential benefit for the diagnosis of E-HCC (Jiang et al. 2011).

Ultrasonographic findings in E-HCC have been described, characteristics of sonograms being posterior echoes (posterior acoustic enhancement) of the tumor, mosaic pattern of internal echoes, peripheral hypoechoic halo, and lateral shadows (Makuuchi et al. 1983; Shinagawa et al. 1984; Watanabe et al. 1984; Kanematsu et al. 1985; Itai et al. 1987; Livraghi et al. 1987; Higashi et al. 1988; Choi et al. 1989; Nagasue et al. 1989; Tanaka et al. 1989; Tang et al. 1993; Kanematsu et al. 1999; Jang et al. 2009), but the distinction between very small HCCs and other nodular lesions developing in cirrhotic livers is difficult. In particular, the sonographic features listed above become rare in nodules with a diameter inferior to 2 cm diameter (Makuuchi et al. 1983). However, real-time linear scan US has a detection rate exceeding 90 % even in very small lesions (Watanabe et al. 1986). The typical enhancement patterns of fast-in and fast-out (FIFO) or fast-in and slow-out (FISO) of E-HCC improve the diagnostic ability of ultrasound in cirrhotic livers (Chen et al. 2006). Contrast-enhanced ultrasound (CEUS) has been found to be a potent method to identify E-HCC (Wang et al. 2006; Kim et al. 2011). Assessment of the malignant potential of hypervascular E-HCC is possible by B-mode ultrasonography (Moribata et al. 2011). E-HCC are also identifiable by use of CT and MR (Hosoki et al. 1982; Takashima et al. 1982; Inamoto et al. 1983; Watanabe et al. 1984; Tsunetomi et al. 1989; Hirai et al. 1991; Inoue et al. 1993; Bhattacharjya et al. 2004; Golfieri et al. 2009; Yu et al. 2009; Sanuki-Fujimoto et al. 2010; Sherman 2010; Bartolozzi et al. 2011; Lv et al. 2011), but both portal and delayed phases of dynamic MR imaging had a limited diagnostic values for diagnosis of small hypervascular E-HCC (Yu et al. 2008). Diffusion-weighted sequences did also not improve the diagnostic accuracy (Di Martino et al. 2013). The ring sign detected on MR images is a feature typical for encapsulated E-HCC (Ebara et al. 1986). High-intensity patterns on MR images were associated with tumor steatosis, clear cell formation, and/or copper accumulation (Ebara et al. 1991). Lesions smaller than 20 mm in diameter can reliably be detected by use of 2 mm-pitch reconstruction CT (Teratani et al. 2004), and gadoxetic acid-enhanced MRI has proved to be an efficient method to detect E-HCC in chronic liver disease (Hwang et al. 2012; Kim et al. 2012). Single-photon emission computed tomography (SPECT) was inferior to the initial US screening examination in detecting E-HCC less than 2 cm in size, but its sensitivity was identical to that of the initial screening US study for detecting HCC of 2–5 cm diameter (Kudo et al. 1986).

A large fraction of small nodular lesions representing early or small HCC are hypervascular lesions. Arterial hypervascularity is one of the most sensitive findings in the diagnosis of HCC during dynamic CT or MR imaging, although the specificity is rather limited owing to hypervascular benign lesions occurring in cirrhotic livers. In large HCCs, washout in the venous phase is a highly specific feature in the diagnosis of hypervascular HCC, but the sensitivity of washout is more difficult to assess in small tumors (Jeong et al. 2002; Yu et al. 2008). Imaging enhanced by superparamagnetic iron oxide (SPIO) exhibits a sensitivity for nodular lesions with reduced amounts (or reduced function) of intralesional macrophages/Kupffer cells. HCCs typically harbor reduced numbers of

macrophages, in contrast to benign nodular hepatic lesions (Tang et al. 1999; Ward et al. 2000; Choi et al. 2001; Lim et al. 2001; Pauleit et al. 2002). In many small hypervascular HCCs up to 2 cm in diameter, SPIO-enhanced MR allowed reliable early diagnosis in the absence of washout on dynamic gadolinium-enhanced imaging (Yu et al. 2009). By use of gadoxetic acid-enhanced MR, S-HCC can be distinguished from arterial-enhancing pseudolesions (Sun et al. 2010). On the other hand, it is not yet known how many small arterial phase-enhancing nodules are in fact established S-HCCs. In a follow-up study of patients having such lesions, with a mean of six CT studies for each patient with a mean follow-up of 25 months, 44 % of the lesions were stable, 28 % decreased in size, and 28 % increased in size. These findings suggested that most small (10–20 mm diameter) arterial phase-enhancing nodular lesions seen on triphasic liver CT are not HCCs (O'Malley et al. 2005). Hypervascular lesions are reliably identified by use of conventional hepatic angiography (Ikeda et al. 1994), CT angiography (Ohnishi et al. 2010), and angiography combined with superselective infusion arteriography. In lesions smaller than 2 cm, a so-called tumor stain in the capillary phase was the only abnormality found in most, but not all, cases, unstained areas histologically representing fatty change, necrosis, or fibrosis (Sumida et al. 1986). What is the evidence that small hypervascular enhancing lesions are mostly small or early HCCs? Among 169 enhancing lesions on the arterial phase images of dynamic CT in 67 patients with liver cirrhosis, only 17 % were HCC at the final diagnosis, and these lesions were often early enhancing, centrally placed, and non-wedge-shaped. The low positive predictive value of such lesions requires serial follow-up for examining lesion growth or additional MR techniques (Hwang et al. 2008). It has been shown that rapid central washout after early enhancement of lesions and coronal enhancement surrounding the lesions are highly predictive of small hypervascular HCCs if present at multiarterial phase contrast-enhanced dynamic MR (Ito et al. 2004). How to properly interpret small hypovascular nodular lesions occurring in the setting of cirrhosis? Hypovascular tumors shown to be HCCs demonstrated as hypoattenuating nodules on late-phase CT were often not seen on late-phase MR imaging (Hayashida et al. 2008). Serial imaging of small arterially enhancing liver lesions has shown that lesions that increase in size, convert to hypointense or subsequent T1-weighted images, convert to hyperintense lesions in T2-weighted images, or develop rim enhancement on follow-up MR images are suspicious for S-HCCs (Korpraphong et al. 2009). The hypervascular status of E-HCC can be identified reliably by use of infusion hepatic angiography, which is a method considered to be superior to selective celiac angiography, which is not always able to detect foci with a diameter of less than 2 cm in diameter, owing to vascular proliferation which cannot be distinctly found by conventional angiography (Takashima and Matsui 1980).

Pathology

Macroscopy

Small HCCs measuring 2 cm or less in diameter macroscopically appear as one of several phenotypes (Table 1). They can be vaguely nodular, well-differentiated tumors (the typical "early HCC") and distinctly nodular tumors, with the histologic features of "classic" or "ordinary" HCC (Efremidis et al. 2007). However, transition forms between these two types exist, although some of the E-HCC may remain stable and thus

Table 1 Macroscopic phenotypes and classification of small/early hepatocellular carcinomas

Basic growth patterns
Vaguely nodular, well-differentiated tumors (classical early HCC)
Distinctly nodular tumors with histology of "ordinary" HCC
Kanai classification (Kanai et al. 1987)
Type 1: single nodular type
Type 2: single nodular type with extranodular growth
Type 3: contiguous multinodular type
Type 4: poorly demarcated nodular type

not being true early cancers, but rather a distinct biologic variant of HCC (Figs. 1, 2, and 3).

Kanai and coworkers classified E-HCC as type 1 or single nodular type, being expanding, roughly spherical, and often encapsulated; type2 or single nodular type with extranodular growth, with replacing growth often found in the area of extranodular growth; type 3 tumors or contiguous multinodular type, consisting of small nodules growing in contiguity, often with replacing growth at the periphery; and type 4 or poorly demarcated

Fig. 1 In this liver with incomplete cirrhosis, a slightly bulging nodular lesion representing early hepatocellular carcinoma is observed

Fig. 2 Small hepatocellular carcinoma on a background of complete liver cirrhosis. The tumor bulges from the cut surface. Its slightly greenish discoloration is caused by bile accumulation

Fig. 3 Fresh, non-fixed resection specimen of early hepatocellular carcinoma in a cirrhotic liver

nodular type, showing infiltrative growth at its border (Kanai et al. 1987).

Notwithstanding pattern of growth, E-HCCs are defined as lesions with a diameter of 2 cm or less, part of neoplasms in a probably early phase of disease that have a diameter exceeding 2 cm. In an SEER study including 788 patients with early HCC, median tumor diameter was 3.2 cm, and 20 % of patients had neoplasms measuring 2 cm in diameter or less. Seventy-four percent were solitary nodules, and 82 % had no visible vascular invasion (Nathan et al. 2009). Part of the lesions are encapsulated (Okuda et al. 1977). In one study, 86.4 % of small HCCs were encapsulated, capsule formation being significantly higher in tumors found in cirrhotic livers (96.9 %; Hsu et al. 1985). Macroscopically, sign of gross invasion may be encountered, including invasion of bile ducts with tumor thrombus formation (Liu et al. 2010) or formation of an intrabiliary pedunculated polyp (Terada et al. 1989).

Histopathology

The histopathology of small or early HCC has been described in numerous reports (Table 2; Kondo et al. 1983; Nakashima et al. 1983; Ohno et al. 1990; Choi et al. 1993; Kojiro 2005; International Consensus Group 2009; Roskams and Kojiro 2010; Theise et al. 2010; Roncalli et al. 2011; Wee 2011).

E-HCCs show a histological presentation that differs in several respects from that of "ordinary" HCC (Figs. 4 and 5).

The majority of E-HCC consist predominantly of a G1 phenotype of HCC, with small- to medium-sized hepatocyte-like cells that may merge imperceptibly with the adjacent hepatic parenchyma (Theise et al. 2010), this feature being the reason for the vague-nodularity patterns of some E-HCC. Small and ill-defined lesions were described to have groups of basophilic

Table 2 Histopathologic features of early/small hepatocellular carcinoma

Population of well-differentiated small- to medium-sized hepatocyte-like cells
Merging of tumor cells with adjacent liver parenchyma
Increased nucleus-to-cytoplasm ratio with increased cell density and nuclear crowding
Thin trabecules (normotrabecular pattern rather than macrotrabecular pattern)
Acinar/pseudoglandular structures with or without bile accumulation
Fatty change (usually macrovesicular)
Clear cells with or without Mallory-Denk bodies
Foci of poorly differentiated cells in part of cases (sometimes in nodule-in-nodule lesions)
Copper storage (only in part of cases)
Presence of intratumoral portal tracts

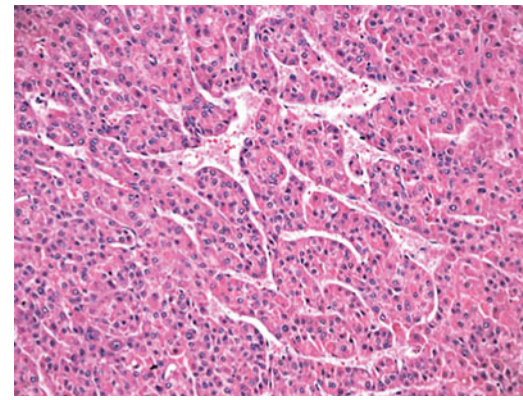

Fig. 4 Histologically, early hepatocellular carcinoma clearly differs from hyperplastic nodular lesions by the abnormal morphology of cell plates, trabecule width exceeding three cells (hematoxylin and eosin stain)

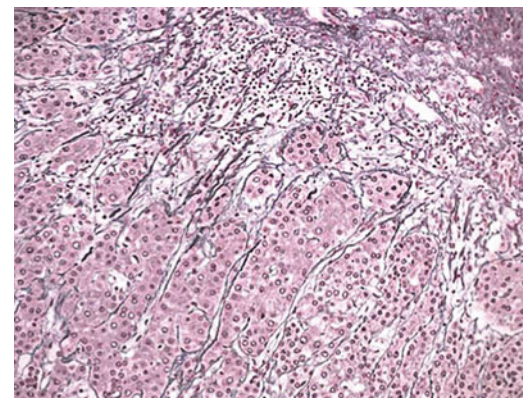

Fig. 5 As in larger hepatocellular carcinomas, early and small HCCs exhibit an abnormal reticulin pattern, reticulin fibers surrounding large tumor cell plates (Gomori silver stain)

cords showing acinar formations, bile congestion, and increased stromal elements with effacement of the sinusoidal network (Kondo et al. 1983). In a study of 21 autopsy cases, 19 tumors showed a trabecular morphology, only 1 was pseudoglandular/acinar, and one was of clear cell type. In at least part of E-HCC, the trabecular pattern is characterized by cell plates of almost normal thickness (the normotrabecular pattern; Kondo et al. 1987; Nakashima et al. 1995), a feature that may be misleading and cause misinterpretation as dysplastic nodule or even adenoma. However, even areas with a normotrabecular pattern typically show nuclear crowding, not observed in benign lesions. Fatty change is often observed in E-HCC and is mostly of the macrovesicular type. Fatty change was found in 40 % of high-grade dysplastic nodules and 75 % of well-differentiated E-HCC but was absent in low-grade dysplastic nodules and large regenerative nodules (Miyaaki et al. 2005). A part of E-HCC contains clear cells with or without Mallory-Denk bodies, in some cases almost all cells being involved (Nakanuma and Ohta 1984). In contrast to dysplastic nodules, E-HCCs usually lack deposits of stainable iron (Miyaaki et al. 2005), but few lesions exhibited excessive copper storage caused by lysosomal accumulation of copper metallothionein (Haratake et al. 1986; Kitagawa et al. 1991). Some E-HCCs show calcifications (Muramatsu et al. 1985). E-HCCs sometimes show intratumoral portal tracts, a feature usually not found in larger HCC. Unpaired arteries also occur in at least part of E-HCC but are less common than in other small HCC of the progressed lesion type. It has to be emphasized that all these histologic features are not specific for E-HCC, but may also be observed in tumors exceeding a diameter of 2 cm. Parts of E-HCC are located within, or are found adjacent to, dysplastic nodules, sometimes as so-called nodule-in-nodule lesions, suggesting a stepwise progression within hepatocarcinogenesis (Rim et al. 1993; Than et al. 1995; Kojiro 2010). This issue is further discussed in a separate chapter. It was found that the microvascular phenotype of E-HCC differs from that of larger lesions. In particular, a capillary-like pattern was more common in E-HCC than a sinusoid-like pattern (capillarization of nodules; Haratake et al. 1992; Chen et al. 2011). In a minority of cases, desmoplasia is prominent in E-HCC, and such lesions are therefore considered to be early scirrhous HCC (Fukii et al. 2007). E-HCCs are in part hypervascular lesions with a distinct vascular pattern that is also detectable by use of imaging. Capillary-like blood vessels are more common in E-HCC and were significantly associated with higher microvessel density (Chen et al. 2011).

Histopathologic Distinction of E-HCC from Other Forms of Small HCC

As already mentioned above, not all small HCCs defined as lesions with a diameter of 2 cm or less are bona fide E-HCC. A part of small HCC resembles in their macroscopic presentation classical or "ordinary HCC" in that they display a distinctly nodular phenotype rather than the vaguely nodular phenotype encountered in E-HCC. These distinctly nodular small lesions present, as a rule, a histology that corresponds to that seen in larger HCC, including macrotrabecular components admixed with acinar structures, variably differentiated cell populations, a well-developed sinusoid-like vascular system, and presence of paired arteries, suggesting that such neoplasms are biologically progressed lesions with a greater propensity for portal vein invasion and intrahepatic metastasis (Theise et al. 2010).

Invasive Features

Invasive features of E-HCC are sometimes difficult to assess, as many tumors are encapsulated. In a study of 28 E-HCC, 17 were encapsulated, and capsular invasion was found in 14 of the 17 encapsulated neoplasms, and vascular invasion was detected in 12 of 28 lesions. This observation illustrates that, even in the presence of a tumor capsule, E-HCC is an invasive lesion, but distant metastasis was seen in only 1 out of these 28 cases (Wakasa et al. 1985). Interstitial invasion in E-HCC was microscopically classified into three

patterns: (1) crossing type, in which HCC was invading across fibrous septa of tumor nodules; (2) longitudinal type, in which neoplastic cells grow longitudinally within fibrous septa; and (3) irregular type, in which the portal tract area was irregularly invaded by HCC. In G1 tumors, type 2 was the most common mode of invasion (Kondo et al. 1994).

Satellite Nodules

An interesting phenomenon in E-HCC that may be related to local spread is the presence of minute satellite nodules. In one investigation on solitary HCC with a diameter of 2 cm or less, 13 % of solitary E-HCCs showed preoperatively undetectable minute satellite nodules measuring 1.5–4.0 mm in diameter. Well-differentiated E-HCC had 1 or 2 min satellite nodules 6 cm or more away from the main lesion, and moderately to poorly differentiated E-HCC had 4 or more minute satellite nodules within 1 cm from the main tumor (Maeda et al. 2000a).

Pretreatment Biopsy Histology as an Element of Diagnosis

Preoperative histology may not be available for E-HCCs larger than 2 cm in diameter arising in cirrhotic livers, because at the EASL Monothematic Conference on HCC (Bruix et al. 2001), it was recommended that lesions larger than 2 cm did not require biopsy if the lesions were shown to be hypervascular on two dynamic radiological studies in the setting of a cirrhotic liver. Conversely, in a non-cirrhotic liver, where the pretest probability of HCC is much lower, biopsy is recommended. At the 2000 EASL Meeting, biopsy was recommended for smaller nodular lesions (diameter $\leq$2 cm) and follow-up for even smaller lesions (Bruix et al. 2001; Bruix and Sherman 2005). However, analysis of 72 liver nodules in 59 patients with liver cirrhosis showed that the noninvasive EASL criteria for diagnosis of HCC are satisfied in only 61 % of small nodules in cirrhosis, suggesting that biopsy is often required, specifically in the setting of small hypovascular lesions (Bolondi et al. 2005).

Grading of Early HCC

In principle, the same grading strategies as employed for large/advanced HCC apply to E-HCC. Many E-ECC are well-differentiated lesions (Edmondson-Steiner grades 1 and 2) and will therefore not produce grading difficulties. However, there are E-HCCs having multiple grades within a single lesion (Kenmochi et al. 1987; Sugihara et al. 1992; Maeda et al. 2000b). Among eight well-differentiated E-HCC, two tumors already contained less-differentiated components (Maeda et al. 2000b). There is evidence that diversification of grades and associated neoplastic cell lineages is a function of tumor progression. In one study, it was observed that, when HCC reach approximately 2 cm in diameter, one-third of them displayed various combinations or more than two cancerous tissues of different histologic grades. In such neoplasms, a core of less-differentiated HCC was almost always surrounded by well-differentiated cancer tissue. This rim of well-differentiated HCC vanished as a function of progression and will be replaced by moderately to poorly differentiated HCC tissue (dedifferentiation of E-HCC as a function of growth to larger lesions; Kojiro et al. 1996). As poorly differentiated components are expected to affect outcome, it was of interest to test whether poor differentiation and hence high-grade lesions may be predicted preoperatively. In a univariate analysis, serum hepatitis B surface antigen positivity, HCV antibody negativity, AFP level, des-gamma-carboxy prothrombin level, and a high contrast-to-noise ratio in T2-weighted MR images were significantly associated with the poorly differentiated type of small-sized HCC (Imai et al. 2009).

Immunohistochemistry

It has been proposed that reactivity for HSP70, CAP2, glypican-3, and glutamine synthetase could serve as molecular markers for early HCC

(review: Sakamoto 2009). Glypican-3 is a potent marker for E-HCC, specifically in combination with CD34 immunostaining (Wang et al. 2012), or in a panel with heat shock protein 70 and glutamine synthetase (Tremosini et al. 2012). In a comparative study of low-grade dysplastic nodules, high-grade dysplastic nodules, FNH-like nodules, and HCCs with a diameter $\leq$3 cm, it turned out that glypican-3 expression, on both immunohistochemistry and RT-PCR, was much higher in E-HCCs than in cirrhosis and other types of focal liver lesions, suggesting that the transition from premalignant nodular lesions to E-HCC is associated with a sharp increase of glypican-3 expression (Libbrecht et al. 2006). Expression of glypican-3 is not only of diagnostic relevance, but it also affects biology of disease: elevation of glypican-3 acted as an adverse indicator for HBV-related small HCC patients after curative resection (Yu et al. 2012). At least a part of E-HCC has cells reactive for glutamine synthetase (Long et al. 2010). In approaches using a panel of immunostains, addition of clathrin heavy chain immunostaining markedly increased the diagnostic accuracy for small HCC/E-HCC, and there was important gain in sensitivity (Di Tommaso et al. 2011). Part of neoplastic cells in E-HCC exhibit nuclear reactivity for p53 protein (Maeda et al. 2000b). Fatty change in cells of E-HCC is associated with immunoreactivity for insulin-like growth factor II, suggesting that this factor is involved in steatogenesis in small HCC (Sohda et al. 1997). E-HCCs generally have a low proliferative activity as estimated with PCNA or Ki-67 staining (Yamagata et al. 1999; An et al. 2001), but it is higher than in dysplastic or regenerative nodules.

Most E-HCCs show a capillarization of small vascular channels, with reactivity of vessel walls for collagen type IV (Dhillon et al. 1992) and laminin (Kin et al. 1994; Yamamoto et al. 1996). E-HCCs can be distinguished from dysplastic nodules by podocalyxin-like protein 1, which in HCCs stains tumor-associated microvasculature endothelial cells, while the protein is not or only focally expressed in vessels of dysplastic nodules (Heukamp et al. 2006). Part of the vascular network of E-HCC is reactive for CD34, whereby hypervascular regions preferentially found on poorly differentiated parts of the tumors are more often CD34 reactive, particularly in nodule-in-nodule lesions, suggesting that capillarization goes in hand with tumor dedifferentiation (Maeda et al. 1995). Podocalyxin-like protein 1 (PCLP1; thrombomucin/MEP21) is a CD34-related sialomucin which is expressed on hematopoietic stem cells (Doyonnas et al. 2005) and is, as an overexpressed protein, an independent factor of poor prognosis in colorectal cancer (Larsson et al. 2011).

Differential Diagnosis

The most difficult differential diagnosis is high-grade dysplastic nodules, which can achieve a size comparable to that of S-HCCs. The diagnostic approach may be complex in situations where E-HCC is situated inside a dysplastic nodule (Ohno et al. 1990; nodule-in-nodule lesion) or adjacent to dysplastic lesions (reviews: Kojiro 2000, 2010). The presence of tumor cell invasion into the intratumoral portal tracts (stromal invasion) is a helpful clue for distinguishing the two lesions (Kojiro 2004; Kojiro and Roskams 2005), and this invasive phenotype has been accepted as a decisive feature in distinguishing high-grade dysplastic nodules from E-HCC in an International Consensus Meeting (review: Kojiro 2010). Foci of E-HCC located in dysplastic nodules revealed a higher proliferative activity (PCNA immunostaining) than dysplastic hepatocytes or hepatocytes of regenerative hyperplasia (Terada and Nakanuma 1992; Seki et al. 1993).

Biology of Disease

General Features

In case that small HCCs are interpreted as E-HCC, it may be expected that such lesions undergo further growth to become non-small-HCC, but they may also remain silent in regard to growth for certain time periods. In fact, there are reports showing that E-HCC remained without

appreciable change in size for many years (Yoshida et al. 1982). Whether such a phenomenon reflects in inherent feature of certain E-HCC, i.e., being characterized by a limited final size, or whether it depends on growth control by the tumor's environment in the liver or antitumor defense of the host is not clear. In case the tumor continues growing, one may extrapolate proliferation features found in larger HCC lesions.

Risk Factors for Recurrence and Spread

Irrespective of their small size, E-HCCs are potentially invasive lesions that infiltrate adjacent liver parenchyma, invade blood vessels, and can even cause subcutaneous seeding following biopsy (Yamada et al. 1993). Furthermore, well-differentiated E-HCC can give rise to extrahepatic metastasis (Kim et al. 1998), sometimes with massive spread in the peritoneum (Kim et al. 2007). However, in a prospective study of 70 patients who had a diagnosis of a single (solitary) HCC 2 cm or less in diameter (stage T1) and curative hepatectomy, follow-up demonstrated that E-HCCs had, in comparison with advanced HCC, a lower rate microscopical regional spread, a longer time to recurrence, and a significantly better overall survival and recurrence-free survival (Takayama et al. 1998).

What are the risk factors that are associated with poorer outcome in certain subsets of G1 E-HCC? Several investigations demonstrated that tumor size and this tumor stage significantly affect biology of disease in E-HCC. Small lesion size in HCC is associated with a lower likelihood of macroscopic vascular invasion (Nakashima et al. 2003), but small HCCs with invasion of the inferior vena cava and the right atrium have been reported (Noguchi et al. 1994). Tumor diameter correlated significantly with poorer overall survival in patients with stage I E-HCC, but a positive survival effect for small lesions was not found in stage II tumors (Ko et al. 2011). Even though E-HCCs are those with, per definition, a diameter of 2 cm or less, a 3 cm cutoff seemed to best determine the biological behavior and clinical prognosis of patients undergoing partial hepatectomy for small HCC (Lu et al. 2011). In a Cox regression analysis study on E-HCC defined as nodules with a diameter of 5 cm or less, tumor size was an independent prognostic factor, a tumor diameter of 3 cm being the cut point that could dichotomize patients into different 5-year disease-free survival and cancer-specific survival risk groups (Chen et al. 2011). In a SEER study of 788 patients with early HCC, tumor size exceeding 2 cm, multifocality, and vascular invasion were independent predictors of poor survival (Nathan et al. 2009).

Similar to its larger HCC counterparts, macrovascular and microvascular invasion are negative prognosticators in E-HCC. Even 2 cm-sized HCC can be associated with microvascular invasion (Nakano et al. 1990; Yamashita et al. 2012). In an analysis of 43 patients with E-HCC, 28.9 % showed microinvasion, associated with poorer outcome, and three independent predictors of microinvasion were identified, i.e., invasive gross HCC type, poor histologic grade, and serum des-gamma-carboxy prothrombin > 100 mAU/ml (Yamashita et al. 2012). Presence of vascular invasion as such, even in tumors less than 2 cm in diameter, is associated with poorer prognosis (Kikuchi et al. 2009). In 80 patients with E-HCCs up to 2 cm diameter who had undergone hepatic resection, the overall survival rates at 3, 5, and 10 years were 83 %, 69 %, and 36 %, respectively. In this patient group, microscopic portal vein invasion, hepatic vein invasion, and intrahepatic metastasis were positive in 15 %, 4 %, and 10 % of the patients, respectively.

Typical E-HCC consists of well-differentiated neoplastic cells (G1), but there are subsets containing high-grade components, rendering grading an important prognosticator. E-HCCs with a diameter of ≤ 3 cm may contain poorly differentiated components, and such tumors more often show microvascular invasion and a worse prognosis. Poorly differentiated E-HCCs may be identified by a high contrast-to-noise ratio (CNR) in T2-weighted MR imaging (Imai et al. 2009). High-grade lesions may be associated with a higher proliferative activity, which itself affects outcome. Doubling times for HCC

obtained through ultrasonography and CT were 119 ± 96 days, the doubling time being shorter in HCC in patients with HBV surface antigen positivity (Yoshino 1983). In another investigation on small untreated HCC (however with a diameter of less than or equal to 5 cm), doubling time ranged from 27.2 days to 605.6 days (median 171.6 days), suggesting that great variability of growth modes exists among small HCC (Barbara et al. 1992). Tumor volume doubling times tended to correlate with mitotic index and were one of the determining factors of survival length (Okazaki et al. 1989). A high proliferative activity as estimated with PCNA immunostaining was closely related to recurrence and reduced survival rate (Kitamoto et al. 1993; Adachi et al. 1995).

Are there other risk factors apart from stage, growth and differentiation, and vascular invasion? Child-Pugh classification and portal vein invasion were independent prognostic factors for survival rate, and tumor differentiation was an independent prognostic factor for disease-free survival rate, suggesting that E-HCC already have the biologic characteristics of more advanced HCCs (Fukuda et al. 2005). A part of E-HCC shows extracapsular invasion in the form of tumor projection seen on CT and MR images (Imaeda et al. 1994). These invasion features may be the causative factor of tumor satellites. Invasion and penetration of the tumor capsule affect prognosis. In contrast to large HCC, invasion through the capsule in small HCC correlated well with recurrence (Hsu et al. 1985). Also, the type of tumor vascularization affects prognosis. E-HCCs more often show capillary-like microvessels, and the presence of such a vascularization type is associated with better prognosis (Chen et al. 2011). Among the two major microvessel types found in HCCs, i.e., capillary-like and sinusoid-like, the capillary-like phenotype was more common in E-HCC, was significantly associated with higher microvessel density, and was significantly correlated with better disease-free survival and overall survival (Chen et al. 2011).

In univariate and multivariate analyses of small HCC, significant risk factors for early recurrence were a tumor diameter greater than 2.2 cm (i.e., greater than the diameter defining E-HCC), intracapsular invasion, a tumor location deep in the liver, macroscopic and microscopic tumor invasion into the portal vein, and intrahepatic metastasis (Shirabe et al. 1991). Risk factor for early recurrence included a serum AFP level $>$ 100 ng/ml., lack of tumor capsule formation, microscopic vascular invasion, high Edmondson-Steiner grade, and cytokeratin-19 expression (Zhou et al. 2010). Another investigation showed that poor Child-Pugh score, tumor diameter exceeding 2 cm, portal vein tumor thrombus, and multiple lesions including satellite lesions were adverse factors affecting postoperative survival (Wu et al. 2005). Fibrosis and AST to platelet ratio (APRI) predict postoperative prognosis for solitary HBV-related E-HCC, minimal fibrosis diagnosed by APRI being associated with a lower incidence of recurrence and better survival (Hung et al. 2010). There are also molecular features of E-HCC that confer a more aggressive course. An elevated expression of osteopontin and glypican-3 acted as adverse indicators for HBV-related E-HCC (Yu et al. 2012).

How do these risk factors translate into outcome following treatment of E-HCC?

A meta-analysis revealed that anatomic liver resection can extend the 3-year disease-free survival rate of patients with E-HCC (Jing-Dong et al. 2011). In a study of 788 patients, the median tumor size was 3.2 cm, and 20 % of the patients had tumors $\leq$2 cm. Following surgery, overall median and 5-year survival were 45 % and 39 %, respectively. After adjusting for demographic factors and histologic grade, tumor size $>$2 cm, multifocality, and vascular invasion remained independent predictors of poor survival (Nathan et al. 2009). Solitary E-HCCs tend to be considered as less aggressive cancers, leading to nonsurgical treatment modalities. In patients with E-HCC $<$2 cm in diameter and solitary lesion, percutaneous ethanol injection treatment led to a local recurrence rate at 3 years of 10 % (Ebara et al. 2005). In patients with cirrhosis, radiofrequency ablation of E-HCC led to higher 2-year disease-free survival in comparison with ethanol injection (Seror et al. 2006). Also, percutaneous image-guided radiofrequency ablation has been shown to be an effective first-line treatment for cirrhotic patients with early-stage

HCC (Lencioni et al. 2005), and experience with percutaneous ethanol injection has accumulated (Vilana et al. 1992; Koda et al. 2000; Pompili et al. 2001; Huang et al. 2005; Kammula 2006; Liao et al. 2006).

Although surgical resection, radiofrequency ablation, or particle radiotherapy of early/small HCC are associated with favorable outcome, the exact biology of disease of E-HCC is still not fully known. Even after treatment, E-HCC may show a special recurrent pattern in the form of bile duct tumor thrombus formation (Liu et al. 2011). As most patients with E-HCC suffer from liver cirrhosis, treatment failure and death are often related to hepatic insufficiency irrespective of the treatment modality (Ohnishi et al. 1987). A more favorable biology disease in E-HCC is thought to be related to an early developmental status of these neoplasms, although one does not yet known how many of initially small lesions will, and during which time interval, progress to large lesions.

Molecular Features and Pathogenic Pathways

S-HCC occurs in a wide array of chronic liver diseases/cirrhosis, including HCV infection and metabolic disorders such as Wilson disease (Kumagi et al. 2005). There is strong evidence for a dysplastic nodule-early HCC sequence (Park 2005). In fact, the evolution of dysplastic nodules to early HCC and fully established nodular HCC with distinct margins within several months to a few years is well established (reviews: Hytiroglou 2004; Kojiro 2005). E-HCC is considered a key step in the development of HCC, and molecular signatures found in such lesions may represent a baseline for molecular alterations occurring later in disease (reviews: Uchida 1995; Effendi and Sakamoto 2010; Suriawinata and Thung 2010; Tan et al. 2012). E-HCCs differ from advanced HCCs by the presence of distinctive pattern of gene expression as assessed via gene expression profiling (Mas et al. 2006). A part of small HCC/E-HCC is aneuploid in DNA analyses (Zeppa et al. 1993). There was a stepwise increasing fractional allelic loss of heterozygosity of microsatellites from high-grade dysplastic nodules to E-HHCs and large HCCs, suggesting that determination of microsatellite LOH is a helpful measure to distinguish dysplastic nodules from E-HCC (Dong et al. 2011). A distinct molecular signature distinguishes dysplastic nodules from E-HCC. In one investigation of HCC arising in HCV-associated liver cirrhosis, twelve genes were significantly and differentially expressed in early HCCs compared with dysplastic nodules; these genes included TERT, glyican-3 (GPC3), gankyrin, survivin, TOP2A, LYVE1, E cadherin, insulin-like growth factor binding protein 3 (IGFBP3), platelet-derived growth factor receptor A (PDGFRA), TGFA, cyclin D1, and hepatocyte growth factor (HGF). A group of three genes (GPC3, LYVE1, survivin) had a discriminative accuracy of 94 % (Llovet et al. 2006). Well-differentiated small hepatocellular tumors, which may represent the precursors of E-HCC, were shown to express the c-Yes oncogene in the nuclei, suggesting that this oncogene is a marker of early-stage HCC (Nonomura et al. 2007). Although E-HCC can metastasize, their more favorable biology is probably related to a lesser propensity for spread and metastasis, and this feature is associated with overexpression of a metastasis-suppressor gene, nm23-H1 (Boix et al. 1994).

Abstract

Clear cell hepatocellular carcinoma (HCC) belongs to a growing spectrum of epithelial clear cell cancers of the alimentary tract. Morphologically, this neoplasm is characterized by a trabecular or solid growth of large cells with a clear cytoplasm. Due to varying diagnostic criteria, the epidemiology of clear cell HCC is complex, frequencies reported in the literature ranging from 0.4 % to 37 %. In case a clear cell component of at least 50 % is accepted, clear cell HCC accounts for 2.2–6.7 % of all HCCs. In contrast to ordinary HCC, females are more often involved, and antecedent liver cirrhosis is a common feature. Clear cell HCC usually presents as a large solitary tumor that shows a pseudocapsule more frequently than other HCCs. Histologically, the differential diagnosis between clear cell HCC and hepatic metastasis of other clear cell tumors may be difficult. Immunohistochemistry is an important diagnostic tool, most clear cell HCCs being positive for the hepatocyte/HCC markers, Hep Par 1 and arginase-1. Clear cell HCC appears to follow a more favorable course than ordinary HCC.+

Introduction

Hepatocellular carcinoma with clear cells (primary clear cell carcinoma of the liver, PCCCL; Liu et al. 2008) has been described in the early

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_9

literature under several and in part misleading names, including hypernephroid tumors and hepatic hypernephroma (Swenson 1917; Williams 1924; Ramsay 1929). Hepatic adrenal rest tumor appeared as a synonym of clear cell HCC in some reports, but this neoplasm seems to be a distinct entity and is dealt with in a separate chapter. Clear cell HCCs as they appear in hematoxylin- and eosin-stained sections have first been reported in 1937 (Bonne 1937). This phenotype later appears in several works (Berman 1951, 1958; Edmondson 1958), until a first series of 13 cases was systematically analyzed (Buchanan and Huvos 1974).

Clear cell HCCs make part of an increasing spectrum of epithelial clear cell tumors of the alimentary tract (Nappi et al. 1997; Ritter et al. 1997), which mainly comprise gastric clear cell carcinomas (pylorocardiac gland cell carcinoma; tubulopapillary clear cell gastric carcinoma, TCCGC), clear cell carcinomas of the bowel, pancreatic epithelial malignancies composed of clear cells, clear cell carcinomas of the hepatobiliary tract, and clear cell well-differentiated neuroendocrine carcinomas (review: Ritter et al. 1997).

Large Clear Cell Hepatocellular Carcinomas

Epidemiology

The epidemiology of clear cell HCC is complex, because the diagnostic criteria employed vary considerably from one study to the other. Thus, the frequency of large clear cell HCC varies in the literature between 0.4 % and 37 % in the largest published series (Lai et al. 1979; Kashala et al. 1990). Some authors have diagnosed this HCC variant when the tumor contained more than 30 % clear cells (Buchanan and Huvos 1974), whereas others considered less than 30 % of clear cells within a given tumor as sufficient for diagnosis (Lai et al. 1979). It seems that tumors entirely composed of clear cells are very rare (Buchanan and Huvos 1974; Pecorella et al. 1994). In case one accepts that the proportion of clear cells must at least be 50 %, clear cell HCC accounts for only 2.2–6.7 % of all HCCs. The diagnosis also depends on what is accepted to be a clear cell (see below). Therefore, clear cell HCC still awaits a reproducible diagnostic definition.

In one series, less than 10 % of HCC showed a clear cell component, but these cases revealed a slightly older mean age of the patients and a male/female ratio of 1.6:1, which is lower than the worldwide ratio of 6.7:1 for ordinary HCC (Buchanan and Huvos 1974). Among 118 cirrhotic patients with HCC, 10 patients (8.5 %) were reported to have clear cell HCC (Emile et al. 2001). In a recent series of 43 patients, the mean age at presentation was 53.6 years, and the male/female ratio was 2.9:1. 30.2 % of the tumors were in the left, 60.5 % were in the right liver lobe, and 9.3 % were bilateral (Liu et al. 2008). In a series from East Asia, 12.5 % of the cases studied were diffuse clear cell HCC (Lai et al. 1979). Among 223 sub-Saharan African HCC cases (from the then Zaire), the clear cell variant accounted for less than 1 % (Kashala et al. 1990). In an autopsy study of 287 HCCs in Hong Kong, there was a significantly higher incidence of bilobar involvement in clear cell HCC (Ho et al. 1981). In one instance, clear cell HCC was detected as a metastasis (Sister Mary Joseph's nodule) in the presence of an occult hepatic primary tumor (Shah et al. 2005).

In a clinicopathologic study of clear cell HCC, such lesions were more often associated with female gender, and antecedent cirrhosis was commoner than that seen with other carcinomas of the liver (90 % vs. 59 %) (Yang et al. 1996). However, the tumor has also been observed in non-cirrhotic livers (Mansinho et al. 1993; Adamek et al. 1998; Takahashi et al. 2008; Clayton et al. 2012). In a clinicopathologic study of 43 patients with clear cell HCC treated with hepatectomy (Liu et al. 2008), there was a positive rate of hepatitis C virus infection and capsule formation in the clear cell HCC group, higher than in common

HCC. On the other hand, the vascular invasion rate was notably lower in the clear cell HCC group. There are very few associations of clear cell HCC with other liver tumors. The lesion has been found to arise 25 years after successful treatment of hepatoblastoma (Basile et al. 2010).

Clinical and Imaging Features

The most common clinical presentation of clear cell HCC is similar to that of ordinary HCC. The clear cell variant is most often associated with liver cirrhosis. Similar to ordinary HCC, clear cell carcinoma can undergo tumor rupture, a complication observed in up to 15 % of cases (Liu et al. 2011). Several and extremely rare metabolic and hormonal disorders complicating clear cell HCC have been reported, albeit only in older publications. Hypoglycemia is a known paraneoplastic complication of HCC. In few cases of clear cell HCC, the tumors were clinically associated with hypoglycemia and hypercholesterolemia (Sasaki et al. 1981; Antoniello et al. 1986). A similar observation referred to a clear cell HCC in a patient who also showed erythrocytosis in addition to hypercholesterolemia and hypoglycemia, the latter having caused sudden death (Ross and Kurian 1985).

At imaging, clear cell HCC was more prone to form a pseudocapsule (Liu et al. 2011; Wang et al. 2014). On pre-contrast CT images, clear cell HCC showed slight hyperattenuation with a hypoattenuation halo, while at hepatic arterial phase, the mass showed early enhancement. Typical HCC enhancement patterns were found in 72.2 % of clear cell HCC in one series (Liu et al. 2011). At the equilibrium phase, the mass presented hypoattenuation with a rim enhancement. On MR images, the tumors were slightly hypointense on T1-weighted images (Liu et al. 2011). On T1-weighted sequences, the tumors are usually well circumscribed, sometimes with a high-intensity part inside, and the tumor may appear as a high-intensity lesion on T2-weighted images (Takahashi et al. 2008).

Pathology

Macroscopy

Grossly, clear cell HCCs usually present as solitary and sometimes large tumors. In the series of Liu and coworkers (2008), 74.4 % of 43 tumors were solitary/single lesions, and their diameter ranged from 2.1 to 22.3 cm (median, 6 cm), and only 37.2 % had a diameter of 5 cm or less than 5 cm. In this study, capsule formation was a prominent feature, observed in 88.4 % of the tumors. In a study of 20 cases, clear cell HCCs were also more prone to form pseudocapsules in comparison with ordinary HCCs (75 % vs. 49.6 %; Liu et al. 2011). The macroscopic growth pattern is not yet sufficiently clarified. In the study of Buchanan and Huvos (1974; $N = 13$), extensive replacement of hepatic parenchyma by invasive carcinoma was the most consistent finding. However, on section tumors tended to closely resemble conventional HCC. The color is described as gray to pale tan, yellow coloration being exceptional (Buchanan and Huvos 1974).

Histopathology

Microscopically, the clear cell phenotype is the hallmark, although the proportion of these cells varies from one tumor to the other. Lai and coworkers suggested that the diagnosis of this neoplasm can be made even when the proportion of clear cells is less than 30 % (Lai et al. 1979), whereas Buchanan and Huvos (1974) proposed that a proportion of more than 30 % is required. Today, there is agreement that diagnosis requires that the proportion of clear cells must be 50 % or more (Kida et al. 2012). Among 175 surgical specimens of HCC, 79 (45.1 %) showed varying amounts of clear cells (Wang and Liu 1986). According to the proportion and distribution of these cells, the authors divided clear cell HCC into three types: (a) scattered type (20.3 %), (b) localized type (54.4 %), and (c) diffuse type (25.3 %). Clear cells were detectable in HCCs of variable differentiation grades, i.e., not restricted to either

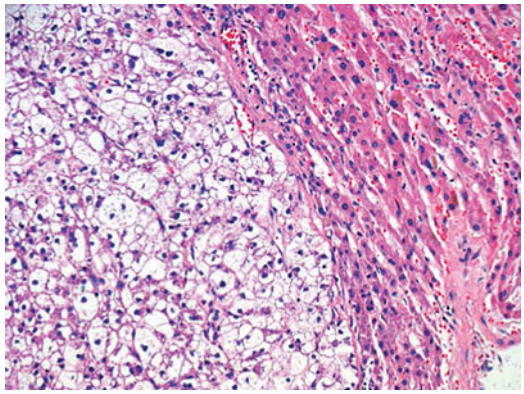

Fig. 1 Hepatocellular carcinoma, clear cell type. Tumor cells are larger than normal hepatocytes and display a water-clear and sometimes slightly spongy cytoplasm and rather small nuclei. The present tumor shows an expanding growth pattern and is associated with perifocal parenchymal atrophy (hematoxylin and eosin stain)

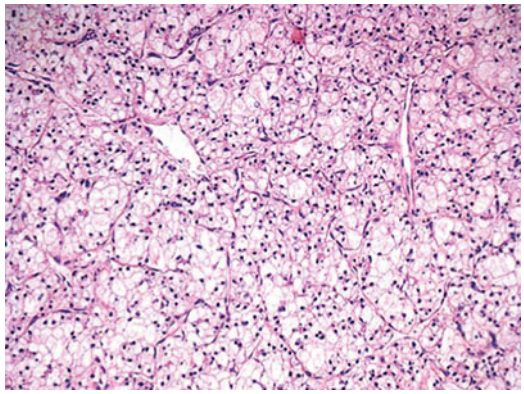

Fig. 2 Hepatocellular carcinoma, clear cell type. Most of these neoplasms exhibit as trabecular or solid growth pattern (hematoxylin and eosin stain)

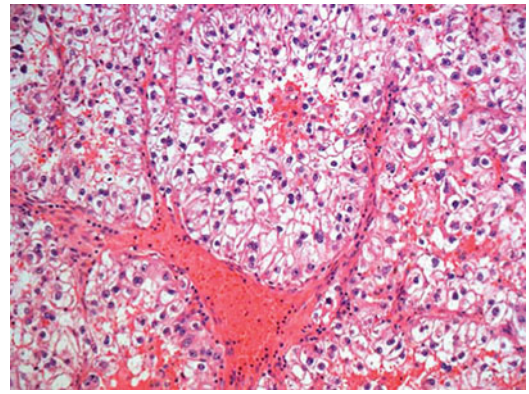

Fig. 3 Clear cell hepatocellular carcinoma. At higher magnification, the trabecular growth pattern is readily observed (hematoxylin and eosin stain)

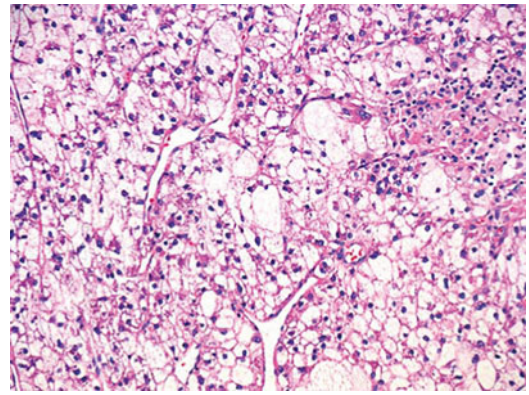

Fig. 4 In clear cell hepatocellular carcinoma, part of neoplastic cells may undergo marked ballooning followed by cell death and karyopyknosis (*center of figure*; hematoxylin and eosin stain)

well, moderately, or poorly differentiated tumors, although in one series of 18 cases, no grade 4 lesion was found in the set of clear cell HCCs (Lao et al. 2006). The clear cells are arranged, similar to ordinary HCC, in trabecular, acinar, or compact patterns (Figs. 1, 2, 3, 4, and 5).

The morphology of individual clear cells varies from apparently empty cytoplasm ("water-clear cells") to vacuolated cells and to foamy cells with a microvesicular pattern. These clear cells may be intermingled with cells that have an eosinophilic to granular cytoplasm. The cells are usually polygonal and may show a fine, granular condensation of cytoplasm, particularly adjacent to the cell membrane (Lao et al. 2006). Nuclei are often centrally placed, but larger lipid droplets may dislocate the nucleus to the cell's periphery. In tumors with variable contributions of clear cells, these cells are often scattered intimately among conventional tumor hepatocytes. The cellular features of clear cell HCC are also detectable in cytological diagnosis of this tumor (Yazdi 1985; Donat et al. 1991; Gupta et al. 1994; Singh et al. 1997; Kilinç et al. 2003). In tumors where the clear cell phenotype is chiefly caused by glycogen accumulation, the cells strongly stain with PAS (Wang and Liu

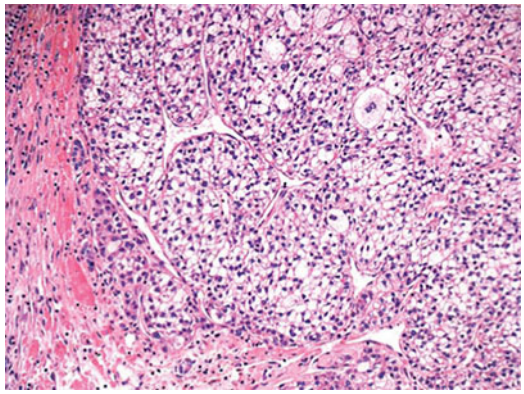

Fig. 5 Notwithstanding their differentiation, clear cell hepatocellular carcinomas show an invasive behavior, with infiltration of adjacent tissues (*left lower corner*; hematoxylin and eosin stain)

1986), the staining being mostly abolished after digestion. Apart from glycogen, lipids are reported to contribute to the clear cytoplasmic phenotype (Lao et al. 2006.

Ultrastructure

Some cases of clear cell HCC have been studied by the use of electron microscopy (Isomura and Nakashima 1980; Audisio et al. 1987; Wang and Liu 1986; Lapis 1988; Kwon et al. 1996; Clayton et al. 2012). In the largest series (seven patients; Audisio et al. 1987), the clear cell phenotype was ultrastructurally found to be caused by accumulation of excess glycogen and lipid droplets, a phenomenon also observed in another study and compared to what is found in precursor lesions of HCC (Wu et al. 1983; see above). In part of the cases, the cytoplasm of the HCC cells had fewer organelles, leading to void appearance, the rough endoplasmic reticulum was rarefied, and mitochondria were swollen. Mitochondria frequently aggregated on one side of the nucleus or near the cell membrane (Wang and Liu 1986). In an investigation of diverse types of clear cell carcinomas, it was found that, in addition to glycogen and/or lipid storage, cell swelling with dilated endoplasmic cisternae, formation of intracellular vacuoles, intracytoplasmic lumens, and organelle paucity are involved in the generation of a clear cell phenotype (Kwon et al. 1996).

Immunohistochemistry

In published cases and series, clear cell HCC lacked expression of cytokeratin 7 (with very few exceptions), of cytokeratin 19, and of epithelial membrane antigen (EMA) (Adamek et al. 1998; Leroy et al. 1998; Murakata et al. 2000; Clayton et al. 2012). In a study of ten cases, no tumor showed immunoreactivity for AFP (Murakata et al. 2000). Distinguishing primary clear cell HCC from hepatic metastases of other clear cell carcinomas may be very difficult and sometimes impossible without additional examinations. Immunohistochemical reactivity for a hepatocyte marker (hepatocyte paraffin 1/Hep Par 1) may be helpful in such situations (Murakata et al. 2000; Shah et al. 2005). Hep Par 1 alone was reported to be 82 % sensitive and 90 % specific in detecting HCC (Wennerberg et al. 1993; Minervini et al. 1997). Clear cell HCC is also reactive for the lineage marker, arginase-1 (Sang et al. 2013). In more than half of the cases of clear cell HCC, canalicular membrane immunostaining was found by the use of a polyclonal CEA (pCEA) antibody (Murakata et al. 2000).

Stromal reactions in clear cell HCC occur to variable degrees, similar to other HCCs, but not much is known about extracellular matrix proteins in these tumors. Fibronectin seems to show abnormal expression in HCC (Torbenson et al. 2002). When testing the expression pattern of fibronectin in HCCs by the use of immunohistochemistry, a marked increase of fibronectin was seen in fibrolamellar HCC, clear cell HCC, and encapsulated HCC (Jagirdar et al. 1985).

Cytogenetic and Molecular Features

In regard to cytogenetic and molecular features, the data for clear cell HCCs are still sparse. In one investigation, 11 cases of clear cell HCC were evaluated for DNA ploidy by means of image

analysis of Feulgen-stained tissue sections. 45.4 % of the tumors analyzed were diploid, and 54.5 % were non-diploid (four aneuploid, one tetraploid, and one multiploid). The non-diploid tumors displayed a moderate to severe degree of pleomorphism and a high mitotic rate (Orsatti et al. 1994). The authors suggested that the divergent data in the literature relating to biology of disease and outcome may be caused by aggressive features of a subset of these lesions.

Biology of Disease

The biology of disease of clear cell HCC is incompletely known so far, but it emerges that the biology of disease is more favorable in patients with clear cell HCC than in those with ordinary HCC (Li et al. 2011, 2013). Some early reports already suggested that the tumor seldom metastasizes and therefore has a rather favorable prognosis (Wu et al. 1983; Pecorella et al. 1994), but metastases known for ordinary HCC, such as bone metastases, are known to occur (Liu et al. 2004), sometimes with an occult hepatic primary tumor (Shah et al. 2005). In a systematic study of prognostic indicators in HCC, it was found that there was a better survival for the patients with clear cell HCC and that the survival figures are directly correlated with the proportion of clear cells within the tumor (Lai et al. 1979). Clear cell HCC may show spontaneous regression of metastases (McDermott and Khettry 1994) or synchronous regression of primary tumor and metastases (Jeon et al. 2005), associated with long-term survival, but spontaneous tumor regression is also known for other types of HCC (Lin et al. 2004). In a study of 64 patients, the median survival in the group having curative surgery was 38 months, while the group with curative resection plus postoperative chemotherapy with calcium folinate and tegafur had a median survival of 41 months. Capsule formation, preoperative liver function, hepatitis C virus infection, large vessel invasion, and multiple tumor recurrences were related to disease-free survival (Ji et al. 2010). Li and coworkers (2011) reported on a total of 214 clear cell HCCs treated by curative resection, and intrahepatic recurrences were classified into early ($\leq$1 year) and late (>1 year) recurrences. It was found that the 1-, 3-, and 5-year overall survival for patients with this tumor were significantly better than those of ordinary HCC patients. A similar result was reported in an alter investigation showing that clear cell HCCs have a favorable grade and longer survival times (Li et al. 2014). In a multivariate analysis, serum ALT and vascular invasion were independent risk factors for early intrahepatic recurrence, while age was the only significant risk factor for late intrahepatic recurrence (Li et al. 2011). In a recent clinicopathologic study of 43 cases, the Kaplan-Meier method showed that the 1-, 3-, and 5-year survival rates were significantly higher in the clear cell HCC group than in common HCC, and the better prognosis of clear cell HCCs was related to capsule formation, vascular invasion, liver cirrhosis, and clear cell ratio, higher clear cell ratios being a prognosticator for better outcome (Liu et al. 2008). In an investigation of 20 clear cell HCCs, no signs of lymph node metastasis were found (Liu et al. 2011). Other studies could not confirm a better outcome of patients with this lesion. An aggressive course of clear cell HCC with rapidly progressive disease has been reported (Audisio et al. 1987; Pecorella et al. 1994). A study of a larger series of patients with clear cell HCC ($N = 215$) documented a worse postoperative 5-year survival for this tumor type, i.e., 33 % vs. 46 % for conventional HCC (Yang et al. 1996). However, there was no difference in the overall long-term prognosis of clear cell HCC when compared with non-clear cell HCC. A similar biology of the two groups was also found in other studies (Kishi et al. 1983; Emile et al. 2001; Lao et al. 2006; Ye et al. 2010).

Small Hepatocellular Carcinomas with Clear Cell Change

In a series of 20 cases of clear cell HCC, small HCCs (diameter 3 cm or less) were found in 25 % (Liu et al. 2011). In a study of 44 small HCCs

defined as lesions with a diameter equal to or smaller than 5 cm, tumor recurrence did not correlate with the presence of clear cells (Hsu et al. 1985).

Clear Cell Formation in Precursor Lesions of Hepatocellular Carcinoma

In rat models of chemical hepatocarcinogenesis, at least four types of altered hepatocytes were recognized in foci of altered hepatocytes (FAH) and neoplastic liver nodules, i.e., clear glycogen storage cells, acidophilic glycogen storage cells, fat-storing cells, and basophilic cells (Bannasch 1976, 1996). A focal excessive storage of glycogen (focal glycogenosis) is a typical step of the sequence of events leading to liver cell neoplasia (Bannasch et al. 1997, 2003) and illustrates that massive glycogen accumulation is a cause of a clear cell phenotype also in HCC precursors. Clear cell foci have also been identified in human livers, lesions resembling those found in rats (Ribback et al. 2013). Electron microscopically, such lesions are characterized by massive glycogen storage, largely due to the reduced activity of the glycogenolytic enzyme, glucose-6-phosphatase. Hepatocytes in human clear cell foci overexpressed the insulin receptor and glucose transporter proteins. The cells exhibited upregulation of AKT/mTOR and Ras/MAPK pathways as well as enzymes of glycolysis, de novo lipogenesis, beta-oxidation, and cholesterol synthesis (Ribback et al. 2013).

Clear Cell Hepatocellular Carcinomas with Marked Stromal Reactions

In some instances, the clear cell variant of HCC is associated with a marked desmoplastic reaction (Buchanan and Huvos 1974). A clear cell HCC with an abundant myxoid stroma was observed in a 55-year-old man who had died of liver cancer (Fukuda et al. 1992). Autopsy revealed a large hepatic tumor located in the right lobe (10 ×10 × 8 cm) and metastatic nodules with a prominent myxoid appearance in multiple organs. Histologically, each tumor manifestation consisted of uniform small tumor cells with clear cytoplasm attributed to abundant accumulation of glycogen, and a rich myxoid stroma was also present. In addition to tumor cells, fibroblastoid cells and stellate cells were found within the myxoid substance. Some of these cells possessed a vacuolated cytoplasm showing similar histochemical findings to the tumor cells. Tumor cells within the myxoid stroma were immunoreactive for fibrinogen, ferritin, and prealbumin.

Clear Cell Variant of Fibrolamellar Hepatocellular Carcinoma

Fibrolamellar hepatocellular carcinoma (FL-HCC) is usually characterized by large and polygonal neoplastic cells that exhibit an eosinophilic and granular, sometimes even oncocytic-looking cytoplasm. Very uncommonly, the cells in FL-HCC have shown a clear cell phenotype (Cheuk and Chan 2001). The tumor described by these authors was incidentally detected in the non-cirrhotic liver of a 59-year-old female patient. The tumor measured up to 5 cm and was a predominantly circumscribed, bosselated, and firm mass situated in the subcapsular area of the right liver lobe. It was light tan and interspersed with concentric whitish streaks on the cut surface. Microscopically, the neoplasm consisted of the typical fibrolamellar structures and small islands of polygonal cells with either the classical FL-HCC phenotype or an abundant, clear, and finely reticular cytoplasm (about 50 % of the cells) highlighted by trichrome stain and immunostaining with an antimitochondrial antibody. The peculiar concentric streaks observed at gross examination were due to coalesced zones of fibrosis, with the collagen fibers being oriented radially. Ultrastructurally, the cytoplasm of the clear cells was packed with empty membrane-bound vesicles that occasionally contained short cristae. These features suggested that the clear cell phenotype resulted from ballooning and rarefactive changes of mitochondria. Clear cell FL-HCC has later been confirmed, also by aspiration cytology (Kaplan and Hoda 2007).

Differential Diagnosis of Clear Cell HCC

Clear cell HCC has to be distinguished from other primary liver tumors characterized by the presence of clear cells, including intrahepatic clear cell cholangiocarcinoma and other clear cell bile duct cancers (Vardaman and Albores-Saavedra 1995; Haas et al. 2007), clear cell papillary carcinoma of the liver (a variant of peripheral cholangiocarcinoma; Tihan et al. 1998), atypical bile duct adenoma, clear cell type (Albores-Saavedra et al. 2001), and variants of angiomyolipoma and other PEComas, including clear cell "sugar" tumors of the liver (Alexandrakis and Kling 1998; Dalle et al. 2000; Chen et al. 2009; Figs. 6 and 7).

A second group of important differential diagnosis comprises metastases of extrahepatic tumors having a clear cell component, such as renal cell carcinomas and clear cell neuroendocrine tumors. These tumors can be distinguished by their different nuclear and cytoplasmic features, by immunohistochemistry and by in situ hybridization, e.g., for albumin messenger RNA (Oliveira et al. 2000). Clear cell HCC may erroneously be interpreted as hepatic metastases of renal cell carcinoma (Hou et al. 2010). Clear cell gallbladder carcinoma was reported to invade the liver substance (Vaillo et al. 2004) and may thus mimic primary hepatic clear cell HCC. Primary peritoneal clear cell carcinoma is a rare entity (Hama et al. 2004) that may involve the liver surface.

Pathogenesis of Clear Cells in HCC

A clear cell change (cytoplasmic clearing; Cheuk and Chan 2001) develops in many different tumor types and is caused by cellular edema with or without organelle damage (ballooning), accumulation of cytoplasmic vesicles, glycogen storage, storage of lipids/glycolipids and/or glycoproteins, organelle (mainly mitochondrial) swelling, or tissue-processing artifacts (Kwon et al. 1996). In clear cell HCC, it has been suggested to be an epigenetic phenomenon, because no genomic changes were found to distinguish it from ordinary HCC (Laurent et al. 2006).

The observation that clear cell formation in clear cell HCCs and other clear cell carcinomas is associated with cellular swelling, vacuole formation, dilated cisternae, and paucity of organelles – features also encountered in hepatocyte ballooning – favors the hypothesis that a disorder of cellular water transport might be involved. The classical role of aquaporins, which are expressed in numerous tissues, including the hepatobiliary tract (review Portincasa et al. 2008), is facilitating transmembrane fluid transport and, for some

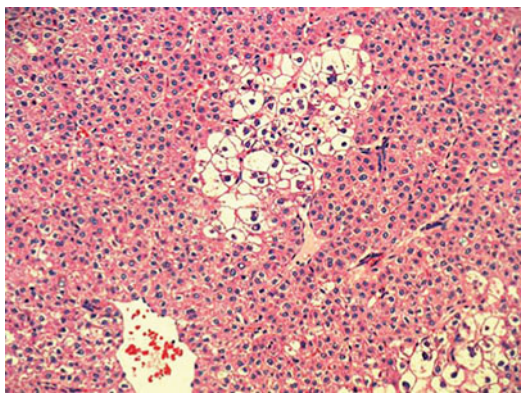

Fig. 6 Ordinary hepatocellular carcinoma rarely contains small foci of clear tumor cells. It is not yet known whether these are precursor lesions of clear cell HCC (hematoxylin and eosin stain)

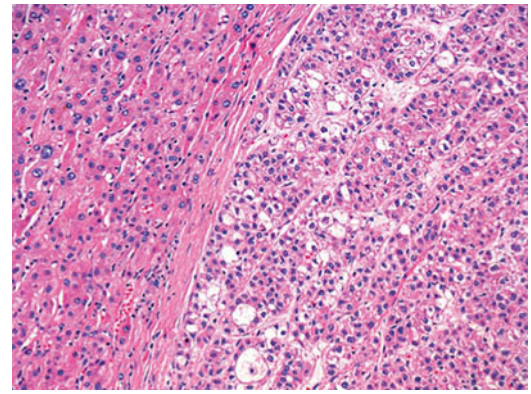

Fig. 7 This trabecular hepatocellular carcinoma contains few enlarged cells with clear cytoplasm and condensed nuclei. These cells represent tumor cell ballooning as a regressive phenomenon and must not be confounded with clear cell type HCC (hematoxylin and eosin stain)

aquaporins, the transport of small solutes such as glycerol. Thirteen aquaporins are known in mammals (aquaporins AQP0–AQP12), and they are subdivided in orthodox aquaporins (AQP0–AQP2, AQP4, and AQP5) and in aquaglyceroporins (the types 3, 7, 9, and 10) which enable the transport of glycerol as well as water. AQP6, AQP8, AQP11, and AQP12 are hardly classified within the above two main groups. AQP6 has permanent intracellular localization and has very low water permeability and shows conductance to inorganic ions upon acidic pH. AQP8 can act as a gate for ammonia and hydrogen peroxide in addition to water. Aquaporins 7 and 9 are glycerol channels in adipocytes and hepatocytes, aquaporin 9 being expressed at the basolateral membrane of the hepatocyte (review: Maeda et al. 2008). AQP9 knockout mice display defective glycerol metabolism (Rojek et al. 2007).

Potentially important for clear cell formation not related to glycogen storage is the fact that aquaporins are also involved in swelling of cells under stress (Verkman 2005).

Some aquaporins affect apoptotic pathways which are associated with organelle swelling. AQP8 and AQP9 have been identified in the inner mitochondrial membrane of various tissues, including the liver, where they mediate water transport associated with organelle and cell volume changes and participate in osmotic swelling induced by apoptotic stimuli (review: Lee and Thövenod 2006). Aquaporins facilitate cell migration, possibly related to facilitated water transport in lamellipodia (reviews: Verkman 2005; Papadopoulos et al. 2008). Aquaporins are involved in several pathologic mechanisms operational in cancer cells and tissues (Verkman et al. 2008), including the facilitation of tumor angiogenesis, endothelial cell migration, tumor cell extravasation, and metastatic spread. AQP0, AQP1, AQP3, AQP8, AQP9, and AQP11 are expressed in liver tissue, and AQP1 and AQP4 are expressed in intrahepatic bile ducts (review Portincasa et al. 2008). In hepatocytes, knockdown of hepatocyte AQP8 induces defective canalicular water transport (Larocca et al. 2009), suggesting that this aquaporin has a central role in hepatocytic water handling. On the other hand, obstructive extrahepatic cholestasis in the rat downregulates AQP9 at the basolateral hepatocyte domain, suggesting that AQP9 channels contribute to bile flow regulation (Calamita et al. 2008). Expression of aquaporin 1, a water channel protein expressed in many epithelial lineages and in endothelium, has been found to be expressed more frequently in clear cell renal cell carcinomas than in other renal cell carcinoma phenotypes and to be a prognostic indicator in clear cell renal cell carcinoma (Huang et al. 2009). It has been suggested that AQP1 is involved in the pathogenesis of certain hepatobiliary disorders, including neoplasias. In an immunohistochemical study, AQP1 staining was detected in 93 % of cholangiocarcinomas compared with 0 % in hepatocellular carcinomas and 30 % in colorectal carcinoma metastases, suggesting that expression of AQP1 is a marker for a differentiated cholangiocellular lineage (Mazal et al. 2005). AQP1 is downregulated in a subset of intrahepatic cholangiocarcinoma, and the downregulation is related to tumor progression and mucin (mucus core protein 5 AC) expression (Aishima et al. 2007). AQP8 and AQP9 expression is significantly decreased in HCC vs. normal liver, leading to increased resistance to apoptosis (Jablonski et al. 2007).

Glycogenotic Hepatocellular Carcinoma with Glycogen-Ground-Glass Hepatocytes

Introduction

Glycogenotic hepatocellular carcinoma with glycogen-ground-glass hepatocytes (GLY-HCC) is a novel phenotype of highly differentiated HCC cytologically and histologically characterized by the presence of glycogen-rich tumor cells with a ground-glass cytoplasm (Callea et al. 2012; Fig. 8).

Glycogenotic ground-glass hepatocytes are also observed in distinct populations of focal precancerous hepatocellular lesions, particularly in preneoplastic focal hepatic glycogenosis/FHG (recent review: Bannasch 2012).

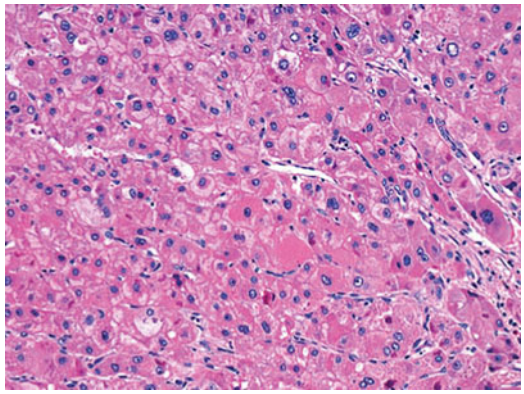

Fig. 8 Hepatocellular carcinoma with glycogen-ground-glass hepatocytes, visualized as large cells with a granular eosinophilic cytoplasm (hematoxylin and eosin stain)

Pathology

GLY-HCC are well-differentiated trabecular HCC with numerous large, glycogen-rich neoplastic cells with a ground-glass cytoplasm, these cells in part admixed with clear cells without a ground-glass cytoplasm (Callea et al. 2012) and eventually "standard" HCC cells. By microchemical analysis, complete deficiency of glucose-6-phosphatase activity was observed in the tumor cells (Callea et al. 2012).

Differential Diagnosis

The clear cell component has to be distinguished from the entity, clear cell HCC. Glycogen storage in HCC can be caused by enzymatic defects of glycogen metabolism (Christiansen et al. 1968).

Abstract

A heterogeneous group of hepatocellular carcinoma (HCC) is characterized by the cellular accumulation of neutral fat (triglycerides), visualized as small, medium-sized, or large cytoplasmic vacuoles. HCCs with significant neutral fat accumulation in the absence of inflammatory changes are termed steatotic HCC. A significant fatty change that is grossly visible and detectable by imaging is a rare finding and is probably found in less than 2 % of all HCCs. Fatty change is more common in small tumors and seems to decrease with an increase of tumor diameter. In a subset of fatty HCCs, inflammatory alterations are observed, with a mixed leukocyte infiltration and sign of cell damage. These lesions are called steatohepatitic HCC. Tumors with this distinct morphology can occur without associated liver disease apart from cirrhosis, but they also develop in the setting of nonalcoholic fatty liver disease, nonalcoholic steatohepatitis, and alcoholic steatohepatitis, conditions known to be risk factors for HCC.

Steatotic Hepatocellular Carcinoma

Introduction

Tumors of the liver containing visible neutral fat accumulation are a heterogeneous group of lesions of both mesenchymal and epithelial lineages (Valls et al. 2006). Similar to normal hepatocytes, hepatocellular carcinomas and their nodular precursor lesions may accumulate visible fat, in the absence of inflammatory changes (fatty hepatocellular carcinoma; steatotic hepatocellular carcinoma; hepatocellular carcinoma with fatty metamorphosis; lipid-rich HCC; Peters 1976; Itai et al. 1987; Yoshikawa et al. 1988; Ueda et al. 1989; Tsai et al. 2006).

Epidemiology

Histologically, HCCs may show varying degrees of fatty change, but detection of gross steatosis on CT is not a frequent feature. In one series, only 1.6 % of the patients (10/600) showed areas of low attenuation consistent with fatty infiltration (Yoshikawa et al. 1988). Microscopically, the incidence of fat accumulation in HCC is much higher. In fine-needle aspirates, lipid vacuoles in HCC cells were found in 14–70 % of the cases (Wee et al. 1991; Das 1999). Fatty change is more frequent in small HCCs and particularly in well-differentiated HCCs (Kutami et al. 2000; Miyaaki et al. 2005; Kim et al. 2007). Generally, the frequency of fatty change in HCC seems to decrease with the increase of tumor diameter (Kutami et al. 2000).

Clinical and Imaging Features

Steatotic HCC/lipid-rich HCC without inflammatory changes can occur in the setting of nonalcoholic steatohepatitis (NASH), e.g., in patients with diabetes mellitus (Orikasa et al. 2001). Steatosis is detectable in well-differentiated HCCs by the use of ultrasonography, tumors with fatty change being frequently hyperechoic on US (Monzawa et al. 1999). Macroscopic fat within HCCs is well demonstrated on CT scans (Itai et al. 1987; Yoshikawa et al. 1988). Fatty change in HCC characteristically causes a low-attenuation area on CT, less than −10 H, and a highly echogenic area on sonography (Yoshikawa et al. 1988). Steatotic HCCs appear hyperintense on T1-weighted images and demonstrate signal intensity drop on chemical shift images (Basaran et al. 2005; Prasad et al. 2005). Some study results suggest that fatty change is the principal cause of hyperintensity on T1-weighted images of some HCCs and that this finding can help in establishing the diagnosis (Martin et al. 1996; Bartolozzi et al. 2001). At imaging, fat in the ablation zone following radiofrequency ablation can persist and does not necessarily indicate treatment failure (Pupulim et al. 2009).

Fatty Change as a Feature of Nodular Precursor Lesions of Liver Cancer

Steatosis, commonly of the macrovesicular type, has been observed in several types of

hepatocytic nodular lesions occurring in the context of liver cirrhosis. Fatty change has been seen in regenerative nodules (Morii et al. 2013) and in macroregenerative nodules (fatty macroregenerative nodules) in non-steatotic liver cirrhosis and suggested to be, at least in part, precursor lesions of a neoplastic process (Terada et al. 1989). Fatty change also develops in dysplastic nodules (Nakanuma et al. 1998) and has been identified as one of several risk factors for the evolution of hepatocellular nodules to HCC (Terasaki et al. 1998). In a study of nodular lesions in HCV-related liver cirrhosis found in 128 resections, fatty change was not seen in large regenerative nodules and low-grade dysplastic nodules, while it was found in 40 % of high-grade dysplastic nodules (Miyaaki et al. 2005). It seems that marked fat accumulation in small nodular hepatic lesions is an indicator of potential malignancy and that "yellow nodules" on the surface of the liver, detected by laparoscopy, may serve in early diagnosis of a neoplastic liver process (Kameda and Shinji 1992).

Fatty Change in Early or Small Hepatocellular Carcinomas

Fatty change is well documented for small or minute, well-differentiated hepatocellular carcinomas, and at ultrasonography, many of these small nodular lesions are hyperechoic, this feature being caused by the fatty change (Tanaka et al. 1983; Yoshikawa et al. 1988; Kanno et al. 1989; Yoshimatsu et al. 1989; Takayasu et al. 1995; Kim et al. 2005). In lesions less than 1.5 cm size, steatosis is usually diffuse, whereas larger well-differentiated tumors usually show patchy fat accumulation (Yoshikawa et al. 1988; Kim et al. 2005; Prasad et al. 2005). In the study of Yoshikawa and coworkers ($N = 10$; 1988), fatty change was diffuse in tumors less than 3.5 cm diameter and focal in tumors larger than 3.5 cm. In a systematic study of 39 histopathologically proven early HCCs with a mean diameter of 1.7 cm, low-density lesions in CT showed mild to moderate fatty change, and isodense lesions showed no or minimal fatty change (Takayasu et al. 1995). Fatty change can be seen in up to 40 % of small HCCs or well-differentiated HCCs in the early stage (Kojiro 2004). In detailed study of 260 HCC nodules 3 cm or less than 3 cm in diameter, fatty change (frequently of the diffuse type) was found in 19.6 %, and the frequency was highest (36.4 %) in the nodules whose diameter was 1.1–1.5 cm. With an increase of tumor diameter, moderately differentiated HCC with less or without fatty change progressively appeared, and focal fatty change in tumors was found more frequently. In HCCs 1.5 cm or less in diameter, the number of intratumoral arteries was significantly smaller in HCCs with fatty change, without any difference in intratumoral portal tracts (Kutami et al. 2000). In an ultrasonography study of 55 hyperechoic and 107 hypoechoic liver nodules less than 20 mm in diameter in patients with chronic liver disease, 76 % of hyperechoic nodules were histologically diagnosed as HCC, and 82 % of hyperechoic HCCs contained fatty change and/or clear cell change (Yamagata et al. 1999). In small HCCs with fatty change that develop in HCV-infected livers, insulin-like growth factor II/IGF-II was found in 80 %, suggesting pathogenic role of IGF-II for tumor steatosis (Sohda et al. 1997). HCV-associated HCC may also share mechanisms that operate in the pathogenesis of HCV-induced hepatic steatosis (review: Zimmermann 2006).

Fatty Change in Larger Hepatocellular Carcinoma

In contrast to small HCCs, where a diffuse steatosis is often noted, larger HCCs more commonly show localized fatty areas (Itai et al. 1987), and the presence of these "patchy" steatotic areas associated with areas of hemorrhage and/or necrosis may contribute to the characteristic mosaic pattern of HCC (Valls et al. 2006; Figs. 1, 2, and 3).

A steatotic phenotype of HCC has been found to persist in metastases, e.g., in peritoneal metastatic spread (Tsai et al. 2006). Marked steatosis of HCC occurs in both solitary and multiple lesions and in a variety of growth patterns of HCC.

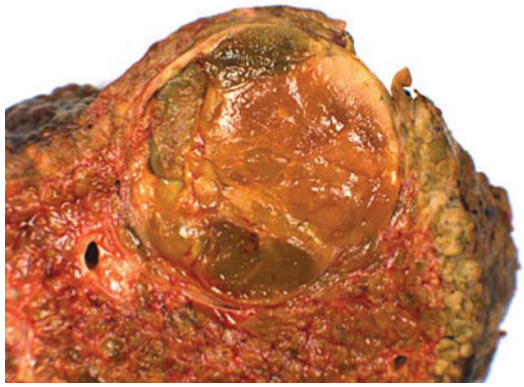

Fig. 1 Hepatocellular carcinoma with fatty/steatohepatitic change. The cut surface of this non-fixed resection specimen is heterogeneous and shows yellowish nodular areas that represent fat accumulation and fresh hemorrhage

Fig. 3 Multinodular steatotic/steatohepatitic hepatocellular carcinoma. Lipid accumulation has led to diffuse yellow discoloration of the neoplasm. The dark areas are hemorrhages altered by formalin fixation

Fig. 2 In this nodular hepatocellular carcinoma in a cirrhotic liver, fatty change is marked, resulting in a yellow nodule that might be confused with metastasis of more common lipid-rich malignancies

However, we more frequently observed significant steatosis (and mainly the macrovesicular variant) in large tumors with an expanding growth pattern. On the cut surface, steatosis may be manifested in the form of a diffuse yellow color of the tissue or in the form of circumscribed yellow-stained sectors or yellow nodules. That is, in some HCC steatosis is a heterogeneous phenomenon that, in case of composite lesions, may only involve a subset of the tumor nodules. In situations where the steatotic HCC also stores bile (cholestatic features of the tumor), the lesion shows a distinct saffron-like or "pistachio" color almost exclusively encountered in such neoplasms. A fatty aspect was also found in metastases of steatotic HCC, e.g., in the pancreas (Nishiofuku et al. 2013).

As already outlined above, visible neutral fat in HCC may have several distribution patterns. In small HCCs, a *diffuse steatosis pattern* prevails, with all or almost all of the tumor tissue being occupied by cells with lipid droplets/vacuoles. In larger tumors, a *focal or patchy steatosis pattern* is more often and seems to roughly increase in frequency as a function of the tumor size. In large steatotic HCCs with intratumoral cholestasis, we noted the phenomenon that at least macrovesicular steatosis is more common in peripheral parts of the tumor (*peripheral steatosis pattern*). Tumor cell steatosis, similar to normal hepatocytes, microscopically ranges from small lipid droplets to classical macrovesicular steatosis, with cells mainly occupied by a large vacuole displacing the nucleus to the cell's periphery (Mathew and Affandi 1989; Mitchell and Sturgis 2009; Figs. 4, 5, 6, 7, and 8).

Both in small HCCs and in larger tumors, steatosis may be associated with clear cell change in the same area, a combination however more often noted in small tumors and well-differentiated HCCs. A second cell alteration seen in tumor steatosis is tumor cell ballooning, with or without formation of Mallory-Denk

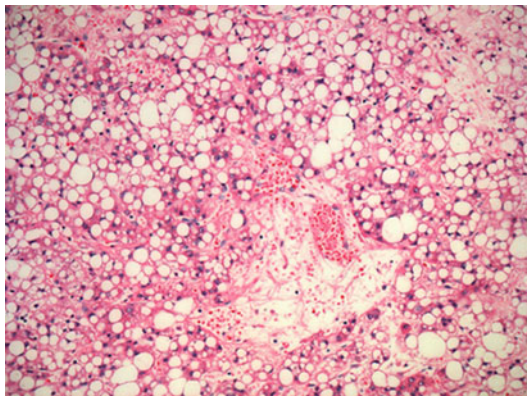

Fig. 4 Steatotic hepatocellular carcinoma (fatty HCC). Most of the tumor cells contain small to large droplets of neutral fat, similar to those observed in macrovesicular hepatic steatosis (hematoxylin and eosin stain)

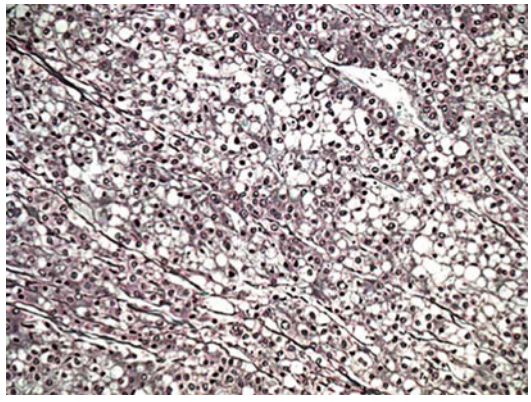

Fig. 5 As fat accumulation in steatotic HCC can efface typical structures of the tumor, the morphology thus resembling hepatic steatosis, a reticulin stain showing abnormally enlarged cell plates is of great diagnostic help (Gomori silver stain)

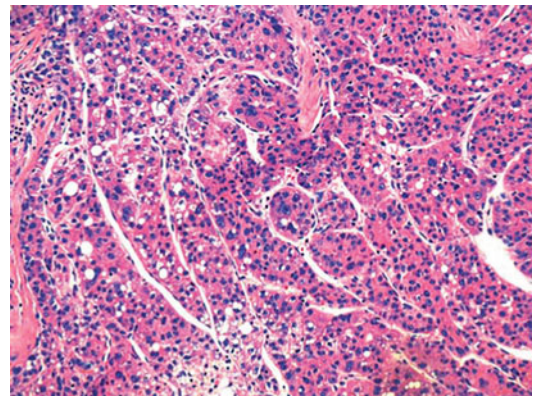

Fig. 6 In this trabecular hepatocellular carcinoma, fatty change is focal and not a prominent feature (hematoxylin and eosin stain)

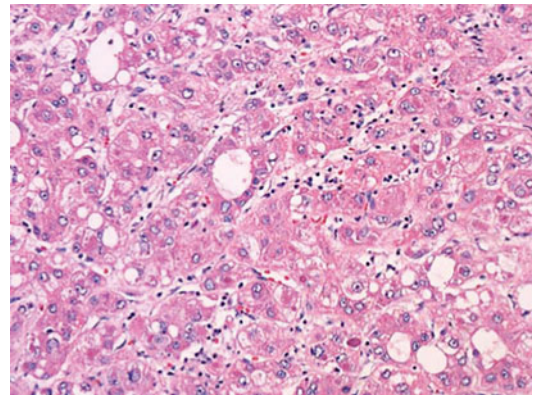

Fig. 7 This hepatocellular carcinoma illustrates that macrovesicular fatty change can also involve neoplastic cells of acinar structures. Few Mallory-Denk bodies are seen (hematoxylin and eosin stain)

bodies. Owing to the enlargement of cells by accumulated neutral fat, the structure of the intervening tumor vascular channels may be effaced, a phenomenon well recognized for massive liver steatosis. In marked tumor steatosis, oil droplets and/or lipogranuloma formation may develop. Accumulation of visible fat in hepatocyte nuclei seems to be restricted to the liver (review: Wegelin 1928). In normal hepatocytes and in HCC cells, nuclear fat is visualized in the form of larger or smaller sudanophilic and osmiophilic fat droplets or their vacuoles within nuclei. The droplets frequently show a clear halo, or they are delimited by a thin basophilic rim, already described by Wegelin in 1928. In the normal liver, Wegelin noted nuclear fat in 14 % of 160 organs examined in detail (Wegelin 1928). Stainable fat is sometimes present in HCC cells as nuclear lipid inclusions. Nuclear fat droplets in hepatocytes have first been described in 1909 (Brandts 1909). This author noted sudanophilic nuclear inclusions of hepatocytes mainly in non-steatotic livers and in those with atrophy and lipofuscinosis. Interestingly, Brandts also mentioned pigment grains within these inclusions, an observation suggesting that the inclusions result from cytoplasmic

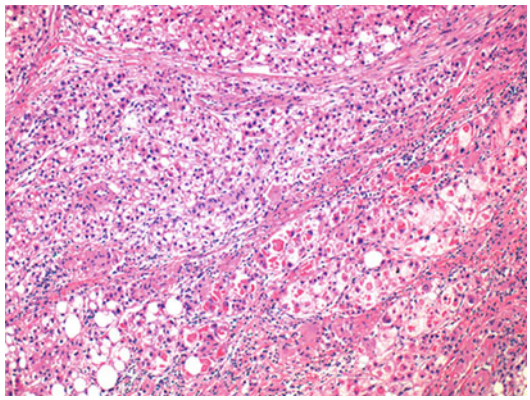

Fig. 8 Mixed hepatocellular carcinoma with focal fatty change and formation of Mallory-Denk bodies (hematoxylin and eosin stain)

invaginations containing fat and lipofuscin. Apart from fat visible at light microscopic examination, small fat droplets have been identified in HCCs by use of electron microscopy (Livni et al. 1977).

Steatohepatitic Hepatocellular Carcinoma (Hepatocellular Carcinoma with Steatohepatitic Features)

Introduction

HCC complicating NAFLD (nonalcoholic fatty liver disease), NASH (nonalcoholic steatohepatitis), or ASH (alcoholic steatohepatitis) is well recognized (Petta and Craxi 2010; Baffy et al. 2012; Rozman 2014; Wong et al. 2014), but many of these tumors developing in these metabolic disorders are histologically ordinary HCCs (Zen et al. 2001; Shimada et al. 2002; Chagas et al. 2009; Kawada et al. 2009). However, in a subset of HCC that are associated with NAFLD or NASH, a so-called steatohepatitic morphology is observed (steatohepatitic HCC, SH-HCC; steatohepatitis in HCC).

Selected References Zimmermann 2002; Salomao et al. 2010, 2012; Jain et al. 2013; Ahuja et al. 2014; Gupta et al. 2014; Shibahara et al. 2014.

In a series of HCCs, SH-HCC represented 13.5 % of cases, all but one case occurred in patients with underlying steatohepatitis, and SH-HCC was diagnosed in 35.7 % of patients with either NASH or ALD/ASH (Salomao et al. 2012). In another series of 101 cases of HCC with various etiologies in explanted livers from adults, the steatohepatitic variant was identified in 18.8 % of cases (Jain et al. 2013). SH-HCC was described to occur in the setting of hepatitis C-related cirrhosis with associated NAFLD/NASH and was detected in 35.5 % of these cases. Patients with SH-HCC were characterized by a higher frequency of diabetes mellitus and hypertension and showed higher serum levels of cholesterol and triglycerides than patients with ordinary HCC (Shibahara et al. 2014). Generally, SH-HCC seems to be a form of HCC strongly associated with metabolic syndrome (Jain et al. 2013).

Pathology

The histologic presentation of SH-HCC closely mimics that of NASH and florid alcoholic liver disease. SH-HCC are characterized by large droplet steatosis, ballooning (frequently associated with Mallory-Denk bodies), and inflammatory infiltrates and fibrosis. The leukocytic infiltrate is dominated by lymphocytes, plasma cells, and neutrophils, and neutrophil granulocytes were often seen aggregated around ballooned tumor cells (Fig. 9).

Inflammatory infiltrates occur in three main patterns. In the first pattern, tumors focally show an infiltrate composed of neutrophil granulocytes, chiefly in tumor areas with ballooned cells and Mallory-Denk body formation. The second pattern is characterized by the focal accumulation of macrophages, sometimes with formation of epithelioid cells (or even granulomas) and lipid-laden foamy cells (lipophages). The third pattern shows a focal infiltrate rich in lymphocytes and plasma cells. It is likely that these infiltration patterns reflect distinct phases of an inflammatory/immune reaction directed against the altered tumor cell population. In areas of florid ballooning, fibrosis is predominantly of the pericellular type, while a

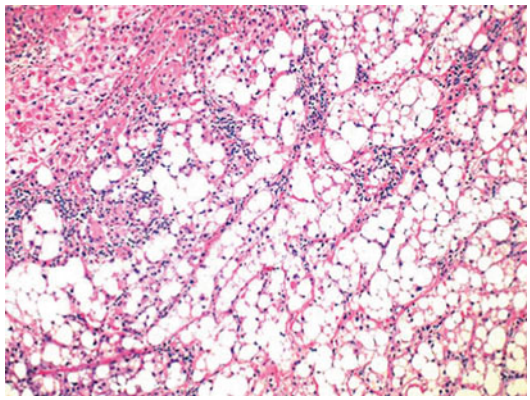

Fig. 9 Steatohepatitic hepatocellular carcinoma. There is marked macrovesicular fatty change, effacing the baseline growth pattern of the tumor. The neoplasm exhibits focal infiltration of inflammatory cells, mainly lymphocytes, and there is focal tumor cell apoptosis (hematoxylin and eosin stain)

bundled type of fibrosis is haphazardly distributed through the tumors (Salomao et al. 2010). In NASH, also large well-differentiated HCC with extensive fatty change can develop (Ishikawa et al. 2013).

Based on Japanese patients, a histologic diagnosis of SH-HCC was made if the tumor fulfilled four of the following five criteria: steatosis >5 % of tumor cells, cell ballooning or Mallory-Denk body formation, interstitial fibrosis, and inflammatory infiltrates (Shibahara et al. 2014).

Lipid-Rich Clear Cell Hepatocellular Carcinoma

Apart from steatotic hepatocellular carcinomas (HCC), which show an accumulation of triglyceride droplets in the cytoplasm of tumor cells (see the respective chapter), there are rare instances of clear cell and lipid-rich HCC which store a more complex mixture of lipids. These neoplasms have been termed lipid-rich clear cell HCC (Orikasa et al. 2001). The first case had been described in a 67-year-old female patient with diabetes mellitus and nonalcoholic steatohepatitis (Orikasa et al. 2001). The patient described by Orikasa and coworkers (2001) showed a hyperechoic liver lesion of 2.5 cm diameter. Biopsy of the nodules revealed HCC of the clear cell type associated with early cirrhosis of the peritumoral liver. The lesion was excised. Macroscopically, the resection specimen showed a nonencapsulated tumor with a maximum diameter of 2.6 cm, with a grayish-yellow cut surface. There was a clear boundary between the tumor and the adjacent liver substance. Histologically, the neoplasm consisted of cell nests, the tumor cells having a clear cytoplasm containing lipid droplets or varying size. The nuclei were rather small and round and lacked pleomorphism. Irregular cytoplasmic, low-molecular-weight cytokeratin-positive inclusions resembling Mallory-Denk bodies were detected. The tumor lacked the sinusoidal-like vascular patterns often seen in HCCs. Electron microscopically, the tumor cells contained numerous lipid droplets, abundant glycogen, and swollen mitochondria. Canalicular profiles with well-developed junctional complexes were in evidence, supporting the hepatocyte lineage of the neoplastic cells. The main differential diagnosis is steatotic HCC, which may sometimes show small lipid droplets in the cytoplasm but lacks clear cell features (Mitchell and Sturgis 2009).

Hepatocellular Carcinoma with Foamy Histiocyte-Like Appearance

Introduction

There exists a group of neoplasms with cells having a finely vacuolated cytoplasm resembling the morphology of foamy macrophages (foamy cells). These neoplasms seem to be capable of storing lipids in the cytoplasm in the form of small or very small lipid droplets (lipid bodies; lipid organelles), visualized in paraffin sections as a sponge-like texture of the cytoplasm. Such neoplasms are derived from several tissues and organs and include secretory breast carcinoma, foamy gland prostatic adenocarcinoma, pancreatic ductal carcinoma with foamy gland pattern, foamy variant of pancreatic intraepithelial neoplasia, certain endocrine neoplasms, sebaceous carcinomas, foamy cell balloon melanoma, foamy cell mesothelioma, foamy cell angiosarcoma, foamy cell

ependymoma, and malignant gliomas with lipidized/foamy tumor cells. Extremely rare forms of hepatocellular carcinoma can also develop a foamy cell phenotype.

Hepatocellular Carcinoma with Foamy Histiocyte-Like Appearance

This variant of hepatocellular carcinoma (HCC) was detected in a 63-year-old man with chronic hepatitis C who developed a tumor in liver segment 7. The hepatic resection specimen showed a tumor measuring up to 4.5 cm in diameter, with a yellow-white cut surface and a white central bulging area. Histology revealed a moderately differentiated HCC of the trabecular subtype. Numerous cells exhibited a foamy phenotype reminiscent of foamy macrophages/histiocytes, but immunohistochemically these cells were CD68-negative and represented cells of a hepatocyte lineage (Noro et al. 2010).

Secondary Fatty Change in Treated Hepatocellular Carcinoma

Several modes of nonsurgical treatment of HCC cause complex patterns of secondary changes, which are outlined in a separate chapter. Fatty change of residual HCC cells was noted following combined radiotherapy and hyperthermia (Seong et al. 1991).

Differential Diagnosis of Fatty Tumors in the Liver

Differential diagnosis of fatty HCC includes other liver masses that accumulate triglycerides, mainly benign fatty hepatocyte nodules, focal fatty change, and angiomyolipoma. Angiomyolipoma of the liver has distinct imaging features but may be confounded with steatotic HCC, mainly in situations of rather low fat content (Chung et al. 2002). On the other hand, hepatic angiomyolipoma may occur in conjunction with hepatocellular carcinoma in the same liver (Chang et al. 2001). Focal fatty change, less common than focal fatty sparing of the liver (Gabata et al. 2001), is typically situated subcapsular in location, has geographic margins, and causes no mass effect, and normal non-distorted vessels are seen inside. However, when focal fatty change has a nodular configuration, it may be difficult to exclude a fatty tumor (Valls et al. 2006). Multifocal hepatic steatosis (multifocal nodular fatty infiltration) has been reported to mimic malignancy in ultrasonography and CT imaging of the liver (Kröncke et al. 2000; Kemper et al. 2002).

Pathogenic Pathways

The pathogenesis of fatty change in HCC is not well understood, but several mechanisms have been suggested, such as metabolic disorders, hypoxia due to insufficient vascular supply, and the effects of hepatitis C virus.

Steatosis in HCC: Genomic and Metabolic Alterations

In a study of 22 nodular liver lesions (9 HCCs, 5 dysplastic nodules, and 8 large regenerative nodules), fatty and clear cell change was not associated with a distinct patterns of the genomic damage fraction/GDF (Laurent et al. 2006). Steatosis in HCC is in part regulated by growth factors. Immunohistochemically, expression of insulin-like growth factor II is more prominent in cells of steatotic HCCs than in ordinary HCCs (Sohda et al. 1997). In HCC, signaling and enzymatic pathways favoring a positive lipid balance are frequent events (Khan et al. 2010; Patterson et al. 2011). For example, HCC shows a coordinate activation of lipogenic enzymes (Yahagi et al. 2005).

An important role in pathogenic pathways leading to HCC steatosis is played by hypoxia and changes in blood circulation. In small HCCs with nodules smaller than 1.5 cm, the number of intratumoral arteries was significantly reduced when fatty change was present, suggesting that fatty change in HCCs is not only related to size but

also to insufficient development of tumor vessels (Kutami et al. 2000). On the other hand, fatty hepatic tissue impairs the liver's microcirculation and promotes ischemic injury (Selzner et al. 2000; Ijaz et al. 2003; Farrell et al. 2008). Free fatty acids delivered from steatotic liver cells sensitize hepatocytes to bile acid-induced apoptosis (Pusl et al. 2008), palmitic acid being more proapoptotic than oleate (Gomez-Lechon et al. 2007). There is a causal relationship between fatty change in normal or malignant hepatocytes and hepatitis C virus infection. Tumor cell lines derived from HCCs of HCV-positive patients progressively accumulated fat droplets in the cytoplasm, and fatty change in these cells seemed to be associated with less proliferative activity than was seen in small HCC cells without fatty change (Seki et al. 2002).

Steatosis and HCV Infection

Hepatitis C virus (HCV) infection is significantly involved in altered lipid metabolism of normal, regenerating, and neoplastic hepatocytes. HCV infection of the liver is frequently associated with fatty change of hepatocytes (reviews: Ramalho 2003; Adinolfi et al. 2005; Sheikh et al. 2008). This HCV-induced hepatic steatosis is associated with insulin resistance, the metabolic syndrome, and a fibrosis pathway in the liver (Cua et al. 2008). There is evidence that fatty change also develops in early liver cancer in patients with HCV infection (Sohda et al. 1997). The direct pathogenic role of HCV in liver steatosis is demonstrated by the association with HCV genotype 3 infection, the correlation between severity of steatosis and HCV replication levels, and the association between response to HCV infection treatment and disappearance of steatosis. It has been shown that the HCV core protein is capable to induce fat accumulation in hepatocytes, likely via interactions with lipid droplets and interference with very-low-density lipoprotein assembly (review: Negro 2006). It seems that PPARalpha activation is essential for HCV core protein-induced steatosis (Tanaka et al. 2008), whereas the PPARgamma/RXRalpha complex is involved, together with the Ku antigen, in the modulation of apolipoprotein C-IV by HCV core protein (Kim et al. 2008). In transgenic mice, the HCV core protein induces hepatic steatosis (Moriya et al. 1997). It has been shown that the HCV core protein is associated with the surface of lipid droplets and the endoplasmic reticulum membranes closely surrounding these droplets (review: Roingeard and Hourioux 2008). It was found that the core protein of both HCV genotypes 1b and 3a binds tightly to the surface of lipid droplets, but cells transfected with genotype 3a contain more neutral lipids in lipid droplets, and more large lipid droplets, than cells transfected with genotype 1b sequences (Piodi et al. 2008). In HCV genotype 3, two polymorphisms in the HCV core gene at positions 182 and 186 correlated with the presence and absence of hepatic steatosis, suggesting that core polymorphism has an important impact on liver cell lipid turnover (Jhaveri et al. 2008).

Induction of Inflammation in Liver and Liver Tumor Steatosis

The inflammatory reaction found in part of steatotic HCCs resembles steatohepatitis. This is of interest insofar as steatohepatitis, and in particular also NASH, is linked with abnormal intercellular matrix production, abnormal hepatocyte regeneration, and hepatic remodeling, eventually resulting in cirrhosis (reviews: Mehta et al. 2002; Choi and Diehl 2005; Farrell and Larter 2006; Gentile and Pagliassotti 2008). Several pathogenic factors are currently discussed to involve specifically the action of fatty acids and their oxidation products, viz., lipotoxicity (reviews: Gentile and Pagliassotti 2008; Greenfield et al. 2008; Malhi and Gores 2008). It has been shown that also oxidized phosphatidylcholine, in part localized to lipid droplets, is associated with the inflammatory activity of NASH (in particular, the number of recruited neutrophils in the liver tissue) and has an impact on the progression of fatty liver disease in humans (Ikura et al. 2006). The reasons as to why an inflammatory cellular infiltrate is established within the

tumor in some cases of steatotic HCC are not well understood, but mechanisms operational in fatty liver disease/NASH may be shared. Excess lipid accumulation in hepatocytes induces sustained hepatic generation of proinflammatory cytokines (review: Lalor et al. 2007), particularly when the hepatic innate immune system becomes Th-1 polarized (review: Choi and Diehl 2005). For example, patients with NASH have elevated serum levels of proinflammatory cytokines, such as interleukin-8 (IL-8; Bahcecioglu et al. 2005), and it has been found that palmitic acid, a component of neutral fat, induces production of IL-8 from steatotic hepatocytes (Joshi-Barve et al. 2007). Similarly, serum TNF-alpha levels are elevated in patients with NASH (Bahcecioglu et al. 2005), and this may be linked to the elevated intercellular adhesion molecule-1 (ICAM-1) levels in NASH (Ito et al. 2007), because TNF-alpha induces a strong expression of ICAM-1 on hepatocytes and/or sinusoidal endothelial cells. Triglycerides also potentiate the inflammatory response in Kupffer cells (Budick-Harmelin et al. 2008). Mallory-Denk bodies (MDBs), which may occur in conjunction with steatosis and tumor cell ballooning in HCCs and contain cytokeratins 8 and 18 (review: Zatloukal et al. 2007), may contribute to inflammatory responses in these neoplasms, similar to steatotic nonneoplastic liver parenchyma. In HCC, the priming events for MDB formation are not known, but MDB production continues in a subset of tumors for longer time periods. In a murine model of MDB reinduction, it has been found that persistent posttranslational chaperone modifications, coupled with protein cross-linking and altered chaperone expression and function, seem to contribute to a so-called toxic memory (Strand et al. 2008). The pathogenic role of one major component of MDBs, cytokeratins 8 and 18, is evident by the observation that CK8/18 germ line heterozygous mutations predispose to end-stage liver disease of multiple etiologies and to liver disease progression in patients with HCV infection (review: Ku et al. 2007). Hepatocytes damaged by fat accumulation and fatty acid oxidation derivatives release cytoskeletal components. For example, cytokeratin 18 fragments are increased in serum of children and adults with nonalcoholic fatty liver disease and are a biomarker for this disorder (Diab et al. 2008; Vos et al. 2008). Release of native or modified cytokeratins from the hepatocyte cytoskeleton may induce a local inflammatory response. There is also evidence that apoptosis-associated activation of caspase-3 activity causes cytokeratin 18 cleavage, resulting in the M-30 aggresome (Amidi et al. 2007), and that this cleavage is associated with milder hepatic inflammation and fibrosis (Valva et al. 2008). On the other hand, inflammatory stress exacerbates lipid accumulation in liver cells and fatty livers of apolipoprotein E knockout mice (Ma et al. 2008). Both alcoholic and nonalcoholic fatty liver disease are associated with increased rates of liver cell apoptosis (review: Feldstein and Gores 2005).

Mallory-Denk Bodies (MDBs) in Hepatocellular Carcinoma and MDB-Rich Hepatocellular Carcinoma

Introduction

Part of hepatocellular carcinomas (HCC) contain Mallory-Denk bodies (MDBs). There is increasing evidence that MDB formation in HCC cells is a heritable phenotype and is related to hepatocarcinogenic pathways. Hyaline intracytoplasmic bodies have been described by the American pathologist Frank Burr Mallory (1862–1941) in 1911 (Mallory 1911) and were later termed Mallory bodies (MB). Helmut Denk and coworkers described the first animal model of MB formation in 1975, feeding mice with griseofulvin (Denk et al. 1975). Based on the impact of these observations, it was proposed to rename MB as Mallory-Denk bodies (MDB; Zaloukal et al. 2007).

As MDBs are associated with liver cell injury (see below), these hyaline inclusions are relatively often seen in various forms of HCC, as HCC cells undergo complex patterns of cell and cytoskeletal damage. The identification of MDB, specifically small or incipient hyaline inclusion bodies, depends in their frequency and hence on sampling and on the methods used to detect them (special

stains; immunohistochemistry). However, there are subsets of HCC that are characterized by large numbers of MDBs that are easily recognized in routine histologic preparations (MDB-rich HCC). There is evidence that MDB formation is a heritable phenotype of certain subsets of HCC (Nakanuma and Ohta 1986).

Epidemiology and Clinical Features

In an autopsy study of 200 consecutive cases, 49 HCC showed MDB. In comparison with the 151 cases without MDB, the MDB group consisted of patients who were older, showed a higher association rate of liver cirrhosis, and had a lesser liver weight. Furthermore, a nodular growth pattern was more prevalent in the MDB group, while the other group had more cases with massive and diffuse growth patterns (Hoso and Nakanuma 1990).

Histopathology

MDB-rich HCC may be otherwise ordinary HCC, but there is also evidence that numerous MDBs occur in small encapsulated HCC (Kondo et al. 1986; Cameron et al. 1993) and in steatotic or lipid-rich HCC that develop in patients with steatohepatitis (Orikasa et al. 2001; Maeda et al. 2008; Figs. 10, 11, 12, and 13). Similar to hepatocytes in alcoholic liver disease of NASH, MDBs in HCC are irregularly shaped and strongly eosinophilic hyaline cytoplasmic inclusions (Norkin and Campagna-Pinto 1968) that have a characteristic ultrastructure (Roschlau and Kemmer 1967) and are composed of intermediate filaments and associated proteins (Virtanen et al. 1979).

MDBs are stainable by the use of the chromotrope aniline blue method (Roque 1953). MDBs are also visualized by the use of phloxine methylene blue staining after Zenker's acetic acid fixation, phosphotungstic acid-hematoxylin/PTAH staining after fixation in 95 % ethanol, and Laqueur's acid fuchsin. In HCC, the ultrastructural features of MDB are the same or similar as in nonneoplastic hepatocytes (Enat et al. 1973; Scotto et al. 1974; Ichida 1983) and closely resemble MDB found in alcoholic liver disease (Keeley et al. 1972). MDBs are more often encountered in well-differentiated HCC (Oda et al. 1972; Cadrin et al. 1990; Nakanuma et al. 1990) and in solitary HCC smaller than 1 cm in diameter (Nakanuma and Ohta 1984; Nakanuma et al. 1986). Based on autopsy cases, three patterns of MDB formation in HCC were recognized, i.e., clustering, diffuse, and sparse types (Nakanuma and Ohta 1986). The clustering type, characterized by formation of groups of MDB-containing carcinoma cells within the

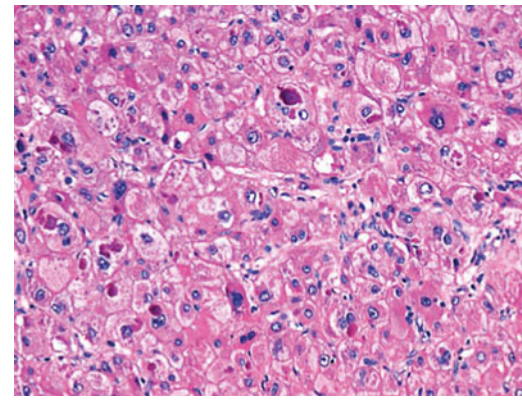

Fig. 10 Hepatocellular carcinoma with several Mallory-Denk bodies, characterized as strongly eosinophilic and dense, irregularly shaped intracytoplasmic inclusions (hematoxylin and eosin stain)

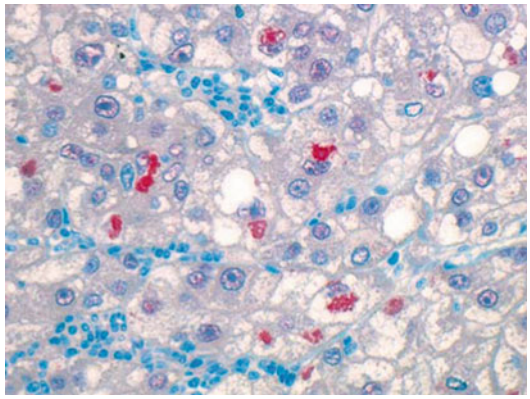

Fig. 12 Mallory-Denk bodies in hepatocellular carcinoma are readily detectable as ubiquitin-positive inclusions (*red bodies*). Mallory-Denk bodies can be associated with cell ballooning (*right lower corner*; ubiquitin immunostain)

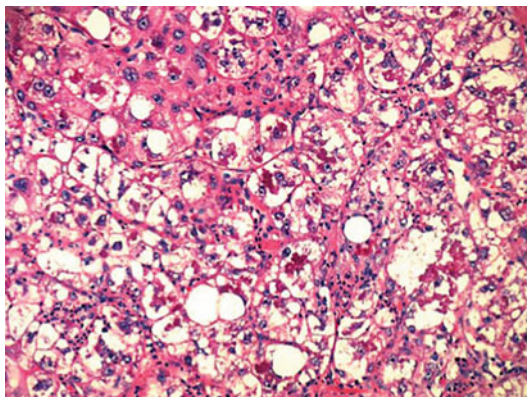

Fig. 13 Mallory-Denk body-rich hepatocellular carcinoma with marked tumor cell ballooning (hematoxylin and eosin stain)

tumor, was the most common and was detected in 21/28 autopsy cases. MDBs were also found in unusual types of HCC, e.g., black HCC with Dubin-Johnson-like pigment storage (Roth et al. 1982).

Both in normal hepatocytes and in HCC cells, MDBs are often associated with a strikingly clear cytoplasm associated with cell body enlargement, a change called ballooning. Ballooning of a hepatocyte containing MDB is already depicted in the original figure of intracellular hyaline published by Mallory in 1911. The clear change of cytoplasm characterizing ballooning is in part due to a shift of stained cytoskeletal components and organelles attached to them into MDB, MDB acting like an "attractor" causing collapse of the organelle network. On the other hand, ballooning is an indicator of a complex pattern of cell injury, with stress-induced changes of the endoplasmic reticulum (SEM), sometimes with fat droplet-associated dilation of the SER cisterns (Caldwell et al. 2010). There is an intricate relationship between cell death, ballooning, and MDB (Machado and Cortez-Pinto 2011).

Immunohistochemistry

Immunohistochemically, MDBs are typically reactive for cytokeratins 8 and 18 and less so for cytokeratins 19, 7, and 20 (Pei et al. 2004). MDBs are usually positive for ubiquitin (Ohta et al. 1988). In griseofulvin-fed mice with MDB, intermediate filaments surrounding mature MDB are decorated with ubiquitin, illustrating the intricate association of cytokeratins and ubiquitin in MDB (Ohta et al. 1988). It was found that MDBs in nonneoplastic liver disease and HCC closely share a common immunophenotype, suggesting a common pathogenic mechanism (Peters et al. 1982).

Intracellular Hyaline Bodies in Hepatocellular Carcinoma

Intracellular hyaline bodies (IHBs) are cytoplasmic inclusions that have hitherto only been observed in HCC cells and in hepatocytes altered by copper toxicosis. In one study, IHBs were found in 8.6 % of HCC cases, whereas both IHB and MDB were detected in 7.5 %. IHB and MDB may simultaneously occur in the same HCC cell. In addition, hybrid inclusions with a position intermediate between IHB and MDB regarding light microscopic morphology, ultrastructure, and composition occur. Both IHB and MDB contain the stress-inducible adaptor protein, p62, but in contrast to MDB, IHBs lack keratins, suggesting that alterations of the keratin cytoskeleton are required to transform IHB into MDB (Stumptner et al. 1999; Denk et al. 2006).

Sequelae and Effects of MDB in Hepatocellular Carcinoma

MDB formation in HCC is accompanied by a constant change in DNA content of HCC cells, in that MDB-containing cells are more often hyperploid or aneuploid (Hoso and Nakanuma 1989). Both in nonneoplastic liver and HCC, MDB can elicit a vigorous granulocyte reaction (Bautista 2002), sometimes with granulocytes forming a cluster or corona surrounding damaged cells containing MDB ("granulocyte satellites"). MDBs release substances that exert a positive chemotactic reaction of granulocytes (Peters et al. 1983). In MDB-rich HCC, inflammatory reactions mediated by neutrophils and, to a lesser degree, lymphocytes and macrophages can elicit a pattern resembling acute steatohepatitis ("steatohepatitis-like HCC"). It is assumed that a strong chemotactic/chemokinetic activity of MDB constituents for neutrophils is responsible for this phenomenon. On the other hand, HCC can induce neutrophil attraction in the absence of MDB. HCC can overexpress and release CXCL5 (epithelial neutrophil-activating peptide 78), a member of a proangiogenic subgroup of the CXC-type chemokine family that mediates neutrophil infiltration (Zhou et al. 2012). Similarly, expression of the chemokine receptor, CXCR6, by HCC is also associated with neutrophil accumulation in the tumor (Gao et al. 2012). MDBs evoke both cellular and humoral immune reactions (Gluud et al. 1981, review: Leevy and Elbeshbeshy 2005). The sometimes strong granulocyte and immune responses can, in both HCC and inflammatory liver disease, elicit tumor cell and hepatocyte apoptosis associated with nuclear DNA fragmentation (Takahashi et al. 2000). There is evidence that degranulation of granulocytes in contact with MDB-containing cells can lead to apoptosis (Jaeschke 2002). But neutrophils can also promote motility of cancer cells through a hyaluronan-mediate TLR4/PI3K activation loop (Wu et al. 2011). Neutrophils accumulating in HCC interact with HCC cells and promote their invasive properties via a paracrine regulation mediated by neutrophil-derived hepatocyte growth factor (Imai et al. 2005). The inflammatory response associated with peritumoral neutrophils fosters angiogenesis in HCC and induces tumor progression (Kuang et al. 2011). The presence of intratumoral neutrophils was a poor prognostic factor for HCC after resection (Li et al. 2011).

Significance of Mallory-Denk Bodies in Precursor Lesions and Hepatocellular Carcinomas

There is evidence that the presence of MDB in hepatocytes is a sign of preneoplasia. In autopsy studies comparing livers with HCC and cirrhotic livers without HCC, the frequency of MDB in nonneoplastic hepatocytes was 40 % in the HCC group with cirrhosis. In HCC-bearing livers with precirrhotic changes, 25 % showed NDB formation by nonneoplastic hepatocytes. HCCs were significantly more frequent in cirrhotic livers with MDB than in those cirrhotic livers without MDB, suggesting that MDB formation in hepatocytes might represent a preneoplastic change (Nakanuma and Ohta 1985). MDB can emerge in nodular hepatocyte lesions that are considered to play a role in hepatocarcinogenesis. MDBs have been found in adenomatous hyperplasia of the liver containing a small HCC in its center (Sakurai et al. 1989). Fatty macroregenerative nodules developing in non-steatotic liver cirrhosis can contain clustered MDB, suggesting that these nodular lesions are preneoplastic alterations (Terada et al. 1989). MDBs have also been demonstrated in large cell dysplasia developing in focal nodular hyperplasia of the liver (Agaimy et al. 2003).

Experimentally, MDB can develop in hepatoma cells induced by dimethylnitrosamine (Borenfreund et al. 1981) and the carcinogenic drug DDC (Nan et al. 2006; Oliva et al. 2008; French et al. 2011b), and MDBs are thus regarded as a marker for a hepatic carcinogenic pathway. Experimentally, hepatocarcinogenic agents induced MDBs in clusters of hepatocytes in mice. In these clusters, fatty acid synthase, ubiquitin B, GPC-3, and AFP mRNA levels significantly increased, suggesting that markers

characterizing HCC are upregulated in hepatocytes forming MDB (Nan et al. 2006). Pathogenetically, the oncogene FAT10 is involved in the pathway leading to MDB formation in chemically transformed hepatocytes, as FAT10 knockout mice fail to develop MDB upon DDC-induced carcinogenesis (French et al. 2012). FAT10 is localized at chromosome 6q21.3, a region frequently amplified in HCC, and is a gene product involved in the regulation of proliferation, apoptosis, and epithelial-mesenchymal transition.

Pathogenesis of Mallory-Denk Bodies in Hepatocellular Carcinomas

MDB as Aggresomes

MDBs are complex cytoplasmic structures and aggresomes composed of several proteins, part of which are components of the cytoskeleton (Denk et al. 1975; Okamura 1976; Osborn and Weber 1989; Jensen and Gluud 1994; Stumptner et al. 2000, 2001; Riley et al. 2002; Strnad et al. 2008, 2012; Omary et al. 2009). These hyaline cytoplasmic inclusions are composed of modified cytokeratins, ubiquitin, heat shock proteins, and protein p62. By the use of immunofluorescence, it was shown that cytokeratins are a key component of MDB (Denk et al. 1979), altered cytokeratins forming unique fimbriated rods of filaments within MDB (Franke et al. 1979). It is currently thought that MDBs serve to clear the hepatocyte from cytoskeletal components altered by oxidative and other stressors (Stumptner et al. 2002), e.g., also in steatosis and steatohepatitis (Nishida et al. 2013). The close relationship between MDB and constituents of the hepatocyte cytoskeleton is also illustrated by the finding that microtubules are required for MDB morphogenesis (Riley et al. 2003). MDBs are related to cytokeratin aggresomes that can be induced by several stressors, but differ from aggresomes both morphologically and in their composition (Riley et al. 2002; Bardag-Gorce et al. 2004). Among the diverse classes of cytokeratins, cytokeratins 8 and 18 are major constituents of MDB (Nakamichi et al. 2002; Fickert et al. 2003). These two keratins are the characteristic cytoskeletal cytokeratins of normal hepatocytes (review: Omary et al. 2002). In mice hepatocytes, overexpression of cytokeratin 8 promotes MDB formation (Nakamichi et al. 2005), and expression of cytokeratins 8 and 18 in MDB can be induced in the setting of CCl4-induced liver damage (Jeong et al. 2005). Cytokeratin aggresomes chiefly result from hyperphosphorylation of cytokeratin 8 by p38 kinase (Nan et al. 2006), cytokeratin 8 phosphorylation regulating its transamidation via cross-linking by transglutaminase-2 (Kwan et al. 2012). In the course of its alteration taking place in aggregates becoming MDB, CK8 undergoes conformational changes from predominantly alpha-helical to cross beta-sheet, while CK18 and p62 do not show such a change (Mahajan et al. 2011). MDB and other aggresomes contain p62, a scaffolding protein that binds polyubiquitin (Zatloukal et al. 2002). p62 plays a role in protein degradation by the proteasome. The significance of p62 in MDB formation is underlined by the observation that overexpression of p62 in drug-primed cultured hepatocytes enhanced MDB formation, and that overexpression of p62 in normal mouse hepatocytes induced MDB-like aggresomes (Nan et al. 2004). As aggresomes, MDBs contain heat shock proteins of the 70b and 90b categories, proteins thought to play an important role in MDB biogenesis (Riley et al. 2003).

Role of the Ubiquitin-Proteasome Pathway

Inhibition of proteasomal degradation of ubiquitinated cytokeratins plays an important role in MDB formation (Bardag-Gorce et al. 2001, 2002; McPhaul et al. 2002). Ethanol induces MDB via inhibition of proteasomal degradation of ubiquitinated cytokeratins (Bardag-Gorce et al. 2006). Inhibition of proteasome function by bortezomib causes intracellular aggregation of serpins and the formation of MDB (Hernandez-Espinosa et al. 2008). Sequestosome1/p62, a

stress-inducible scaffolding and adaptor protein that binds to ubiquitin and polyubiquitinated proteins and is involved in the degradation of proteins by the proteasome, is involved in MDB formation (Nan et al. 2004; Stumptner et al. 2007). Binding of p62 to abnormal cytoskeletal cytokeratins may allow hepatocytes to dispose potentially harmful proteins (Stumptner et al. 2002). Inhibition of the proteasomal pathway causes cytokeratin aggresome formation, these aggresomes however being different from complete MDB (Bardag-Gorce et al. 2004).

Genomic Regulation of MDB Formation

The alterations of cytokeratins 8 and 18 required for MDB formation are genetically regulated (Haybaeck et al. 2012). Gene expression levels required for MDB formation are regulated by the NF-kappaB-p105 signaling pathway through ERK (Nan et al. 2005).

Immune Mechanisms in MDB Formation and the Role of Inflammatory Pathways

Mechanisms mediating inflammatory reactions participate in MDB formation. Toll-like receptors (TLR), in particular TLR2/4 and the downstream signaling components, MyD88 and TRAF-6, are upregulated in the MDB DDC-fed mice model (Bardag-Gorce et al. 2010. In livers with steatohepatitis and in HCC, the immunoproteasome plays a role in MDB formation. In a case of HCC forming NDB in tumor cells, co-localization of FAT10 and ubiquitin with LMP2, LMP7, and MECL-1 within the MDB was found, associated with a shift of the 26S proteasome to the immunoproteasome (French et al. 2010, 2011a). Cytokines such as TNF-alpha and interferon induce the expression of the LMP2, LMP7, and MECL-1 subunits of the immunoproteasome and of a protein overexpressed in HCC, in UbD, and in HCC, an induction mechanism promoting the formation of MDB in HCC (Oliva et al. 2010).

Hepatocyte-Extracellular Matrix Interactions

The formation of MDB in hepatocytes also depends on interactions between hepatocytes and proteins of the extracellular matrix. Laminin-integrin signaling, which activates ERK, triggers MDB formation (Wu et al. 2005).

Fate of MDB in Hepatocellular Carcinoma

It is currently not clear as to how many HCC cells harboring MDB will survive or will enter an apoptotic pathway. In particular, it has not been clarified whether HCC cells containing MDB are capable to divide and to pass the hyaline bodies to daughter cells. It is surmised that cells developing MDB exhibit a severe stress response and damage that might prevent further cell division. In the DDC mouse model of MDB formation, autophagy was shown to be a mechanism for the elimination of cytokeratin 8-containing MDB (Harada 2010).

Contents

Abstract

A rare group of hepatocellular carcinoma (HCC) is characterized by the presence of an abundant desmoplastic stroma, similar to that observed in cholangiocarcinoma. Scirrhous HCC is an uncommon and heterogeneous variant that resembles fibrolamellar HCC and often shows a contiguous multinodular growth pattern. Histologically, scirrhous HCC shows a diffuse pattern of fibrosis with radiating structures. For diagnosis, at least 50 % of the tumor must consist of a scirrhous fibrotic component, but reproducible diagnostic criteria have not yet been worked out.

In sclerosing HCC, tumor cells are embedded in an abundant and sclerosing stroma that does not show a laminated pattern. Part of sclerosing HCCs are associated with paraneoplastic hypercalcemia caused by ectopic production of parathyroid hormone-like peptide or prostaglandin E. Biologically, stroma-rich HCCs seem to behave as ordinary HCCs.

Scirrhous Hepatocellular Carcinoma

Introduction

Scirrhous hepatocellular carcinoma (SHCC) is an uncommon variant of HCC characterized by diffuse fibrosis or diffuse desmoplasia of the tumor. SHCC must not be confounded with tumors called

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_11

"sclerosing hepatocellular carcinoma," a complex group of liver malignancies that develop in the non-cirrhotic liver and are characterized by unique metabolic disorders, in particular hypercalcemia (see the respective chapter). In contrast to SHCC, which is accepted as distinct variant of HCC, "sclerosing HCC" has been deleted from the WHO classification.

Epidemiology

SHCC is a rare lesion. In one study, 3.7 % of HCCs were SHCC, with a male-female ratio of 4:1 (Okamura et al. 2005). In a series of 546 consecutive resected HCCs without preoperative anticancer therapies, 25 SHCC were identified (4.6 %; Kurogi et al. 2006). In the latter study, 72 % of the tumors were located in the right liver lobe. 68 % of the 25 patients had a single tumor, and 32 % showed multiple tumors. In another analysis of 20 cases of SHCC, 15 tumors were solitary lesions and five patients had multiple tumors (Matsuura et al. 2005).

Clinical and Imaging Features

The clinical features of SHCC have previously been reported to not significantly differ from those of ordinary HCCs with regard to age, gender, positive rates of hepatitis viruses, serum AFP levels, Child-Pugh classification, and stage of tumor node metastases (Iha 1994; Matsuura et al. 2005; Kurogi et al. 2006). However, a more recent investigation showed that the SHCC group exhibited less HBV infection, low serum AFP level, less delayed washout during CT, and low usefulness of clinical diagnostic criteria compared with usual HCC. In addition, more portal vein invasion and less liver cirrhosis were noted in the SCC group than in the ordinary HCC group (Lee et al. 2012). In one study of 25 cases, the overall survival rate was significantly higher than the control HCCs (Kurogi et al. 2006), while another investigation of 21 patients with SHCC did not observe statistically significant differences in the 5-year cumulative survival and recurrence rates between SHCC and ordinary HCC (Kim et al. 2009a). Similarly, a recent study of 37 patients with SHCC showed survival rates similar between SHCC and the ordinary HCC control group (Lee et al. 2012).

On ultrasonography, SHCC patterns are mostly hypoechoic, and contrast-enhanced CT and MRI show mostly lesions with a heterogeneous density (Sanada et al. 2007; Kim et al. 2009a). Most SHCCs are radiologically characterized by confluent multinodularity, a location close to the liver capsule, stellate fibrosis, and lack of encapsulation. Furthermore, hypervascularity and an indentation of the liver surface on dynamic CT images seem to be characteristics of SHCC. In a group of 21 SHCCs, common CT features were an ill-defined tumor margin (76 %), peripheral rim-like enhancement on arterial and portal phases (62 %), presence of an area of prolonged and delayed enhancement on equilibrium phase (95 %), and hepatic surface retraction (59 %), whereas the presence of a washout area was uncommon in comparison with ordinary HCC (Kim et al. 2009a; Yachida et al. 2009). Part of small SHCCs may display atypical findings on imaging, with heterogeneous hypervascular nodules in the early-phase CT and a low-density lesion in the late phase (Kim et al. 2009b). Due to its diffuse stromal reaction, SHCC is often misdiagnosed as cholangiocarcinoma, mixed HCC-cholangiocarcinoma, or metastatic carcinoma on diagnostic images (Kurogi et al. 2006). Also on gadoxetic acid-enhanced MRI imaging, SHCCs are similar to intrahepatic cholangiocarcinomas, but the proportion of hyperenhancement of 20 % or more on the arterial phase is a helpful finding in distinguishing SHCC from intrahepatic cholangiocarcinoma (Park et al. 2013). In one study, the majority of SHCCs (88 %) were located close to the liver capsule (Kurogi et al. 2006). Small SHCCs may show a central scar detectable on MR images (Goshima et al. 2002).

Pathology

Macroscopy

At macroscopic examination, SHCCs may resemble mass-forming intrahepatic cholangiocarcinoma or metastatic carcinoma (Suguki

et al. 2009). Some of the tumors have a resemblance to fibrolamellar carcinoma. The tumors are whitish in color, solid and lobulated, and well demarcated and show an expansive growth pattern and are firm, owing to the marked desmoplasia. Matsuura and coworkers (2005) distinguished a more common contiguous multinodular type, in which tumors are formed by a cluster of small contiguous nodules, and a less common single nodular type. In one study of 15 cases, the tumor diameter ranged from 1.8 to 10 cm (Okamura et al. 2005). Most of the tumors (more than 80 %) are situated in the subcapsular area of the liver and may even protrude outside the liver. Among 25 cases, SHCC was located in the right lobe in 72 % (Kurogi et al. 2006). The tumors may show stellate fibrosis (seen in 84 %; Kurogi et al. 2006), are not encapsulated in most cases, and usually do not show grossly detectable hemorrhage or necrosis. In 21 SHCCs studied, tumor capsule formation was found in 29 %, and only 10 % of the cases showed tumor necrosis or hemorrhage, while portal or hepatic vein involvement was significantly more common than in normal HCC (Kim et al. 2009a). In another study, no case of encapsulation was reported (Kurogi et al. 2006); these differences may, apart from different populations with different genetic background studied, also depend on histologic criteria employed. The adjacent liver may show signs of chronic hepatitis, but liver cirrhosis seems to be less commonly associated with SHCC. In a study of 25 cases, liver cirrhosis was present in 28 % (Kurogi et al. 2006).

Histopathology

SHCC shows a diffuse pattern of fibrosis, the fibrotic areas forming radiating structures or being localized along the sinusoid-like vascular channels, as already described above. The histologic diagnostic criteria of SHCC are not yet settled in a satisfactory way. Kurogi et al. (2006) had defined SHCC as malignancy with diffuse fibrotic changes in almost the entire area of the largest cross-section of the tumor and a mean fibrotic area of 39 % compared with only 4.6 % in ordinary HCC. It may, for the moment being, be accepted that the diagnosis of SHCC requires that scirrhous areas exceed 50 % of the tumor area. Based on the pattern of fibrosis, the tumors were divided into radiating and sinusoidal types. The radiating structures are characterized by fibrous scars within the tumor, with thick dense fibrous bands radiating out from the scars to the surrounding tumor tissue. Conversely, the sinusoidal type is characterized by fibrous bands occupying the sinusoidal /perisinusoidal spaces, often with lymphocytic infiltrates. The radiating type of SHCC seems to be associated with larger tumors (Okamura et al. 2005). The stroma of SHCCs is usually not laminated, in contrast to fibrolamellar hepatocellular carcinoma. An important lymphocytic infiltration of the stroma is sometimes found in SHCC (Kurogi et al. 2006) but, as already stated, prevails in the so-called sinusoidal type of SHCC (Okamura et al. 2005). Scirrhous change of HCC can already be found in small tumor lesion (minute SHCC; Fujii et al. 2007; Sanada et al. 2007). In one published case of minute SHCC, the scirrhous well-differentiated HCC was situated in the center of a nodule that showed high-grade dysplasia at the periphery (Fujii et al. 2007). The neoplastic cells embedded in the fibrous stroma are mostly hepatocyte-like cells, as found in ordinary HCC.

In contrast to fibrolamellar hepatocellular carcinoma, an important differential diagnosis, the tumor cells are not different from those of "standard" HCC, which is an important diagnostic feature. The cells are usually moderately to well-differentiated and arranged in the form of cell plates/trabecules. Apart from hepatocyte-like cells, SHCC contains other epithelial cell types, such as cells that show clear cell change (84 % of cases in one study; Kurogi et al. 2006) and contain hyaline bodies. SHCC also shows small neoplastic cells at the periphery of tumor cell nests, which may represent progenitor cells. SHCC has been classified into three types, based on the presence or absence of these cells and their respective immunohistochemical profiles. Type I SHCCs have small cells that are reactive for CK7, ATP cassette transporter G2 (a marker of the side population phenotype), NCAM, and epithelial cell adhesion molecule and display, in addition, reactivity for CK19, NCAM, and epithelial cell

adhesion molecule. Type II tumors have small cells lacking the additional immunohistochemical features, and type III tumors lack small cells (Fujii et al. 2008).

Immunohistochemistry

SHCCs are significantly more often positive for CK7 than ordinary HCC (Matsuura et al. 2005). They share this feature with fibrolamellar carcinoma, where CK7 reactivity is a typical phenotype. The epithelial cells of SHCCs are variably reactive for the hepatocyte marker, Hep (Okamura et al. 2005), but Hep Par 1 reactivity is significantly less common in SHCC than in usual HCC (Matsuura et al. 2005). In one study of 14 cases, 43 % of tumors were Hep Par 1 negative (Suguki et al. 2009). The combination of Hep Par 1 negativity and desmoplasia in SHCC may cause misinterpretation of these neoplasms as adenocarcinomas. However, SHCCs are reactive for glypican-3 and arginase in the majority of cases, this phenomenon thus being an important diagnostic element (Krings et al. 2013). SHCCs express epithelial-mesenchymal (EMT)-related genes (Seok et al. 2012).

The stroma reveals a high density of alpha-SMA-positive myofibroblasts (Okamura et al. 2005; Kurogi et al. 2006; Fujii et al. 2008). Myofibroblasts are sparse in ordinary HCCs (Terada et al. 1996). In the extracellular matrix of the tumors, reactivity for collagen types I and III was detected, but there was no expression of laminin-5 in the stroma of SHCC, in contrast to intrahepatic cholangiocarcinoma (Okamura et al. 2005). Expression of metalloproteinase-7/MMP-7 was higher in SHCC than in ordinary HCC, while expression of tenascin-C was low in SHCC (Okamura et al. 2005).

Differential Diagnosis

Part of SHCCs exhibit a stellate type of fibrosis. A central fibrous scar is sometimes present in part of small scirrhous HCCs and may resemble scar-like structures found in cholangiocarcinomas (Goshima et al. 2002). Dysplastic nodules can develop scirrhous changes (An et al. 2003) and may histologically be confounded with a small and well-differentiated SHCC. Also ordinary HCC can undergo prominent stromal change at certain parts of the tumor and can thus resemble SHCC. HCCs can develop diffuse fibrosis following chemotherapy or chemoembolization.

Sclerosing Hepatocellular Carcinoma

Introduction

Sclerosing hepatocellular carcinoma (SHCC) is an uncommon variant of HCC characterized by tumor cells embedded in a dense fibrous (desmoplastic) stroma. SHCC differs from ordinary HCC by showing a well-developed stroma, lack of any pseudocapsular delineation, and a diffuse growth pattern.

Epidemiology

SHCC seems to have been first described in 1977 (Beaugrand et al. 1977), followed by relatively few reports. The lesion is rare: among a total of 1,390 HCCs observed between 1989 and 2005, six tumors were SHCC (0.43 %; Kim et al. 2006). In a study on 30 patients, there were 14 male and 16 female, with a mean age at presentation of 62.6 years (Omata et al. 1981). Among seven Taiwanese patients with SHCC, age at diagnosis ranged from 26 to 71 years (mean, 42.3 years).

Selected References Omata et al. 1981; Yamashita et al. 1992, 1993; Yoshida et al. 1992; Park and Park 1994; Kakita et al. 1995; Albar et al. 1996; Martinez et al. 1997; Medina Perez et al. 1997; Koyama et al. 1999; Llovet and Miguel 1999; Hong et al. 2001; Yeh et al. 2005; Kim et al. 2006, 2007; Mahoney et al. 2006; Kobayashi et al. 2008a.

Clinical and Imaging Features

The clinical presentation of SHCC does not differ from that of ordinary HCC. In a study of seven patients from Taiwan, abdominal fullness was the most common symptom (Yeh et al. 2005). Part of

SHCCs are associated with a distinct paraneoplastic syndrome, i.e., tumoral hypercalcemia. Paraneoplastic hypercalcemia is caused by secretion of variant forms of parathyroid hormone-like peptide (PTHrP) (Skrabanek et al. 1980; Suva et al. 1987) and is known to occur in any variant of HCC (Belaiche et al. 1975; Halabe et al. 1976; Roche et al. 1979; Polterauer et al. 1980; Oldenburg et al. 1982; Attali et al. 1984; Gentric et al. 1984; Ikeda et al. 1988; Suzuki et al. 1988; Otsuka et al. 1989; Yen et al. 1993; Tamura et al. 1994; Leone et al. 1999; Béchade et al. 2000; Ghobrial et al. 2002). Hypercalcemic HCC may induce hypercalcemia by production of prostaglandin E instead of PTHrP (Ikeda et al. 1988). Patients with SHCCs may or may not show paraneoplastic hypercalcemia (Omata et al. 1981; Martinez et al. 1997; Yamashita et al. 1992; Koyama et al. 1999; Kim et al. 2006; Mahoney et al. 2006). In an early report (Omata et al. 1981), the prevalence of paraneoplastic hypercalcemia in SHCC was 68.8 %. Hypercalcemia caused by SHCC may be a life-threatening disorder (Mahoney et al. 2006). Patients with HCC-associated hypercalcemia show elevated levels of PTHrP in serum (Yen et al. 1993; Koyama et al. 1999). Reduction of the tumor mass at least transiently abolished hypercalcemia, e.g., by transcatheter arterial chemoembolization (Roche et al. 1979; Attali et al. 1984; Suzuki et al. 1988).

On CT images, the tumors are manifest as hypoattenuating masses with peripheral rim enhancement at the hepatic arterial phase, followed by centripetal enhancement progressively during the portal venous and equilibrium phases (Yoshida et al. 1992; Kim et al. 2007). Although the tumors ar2e usually well defined, a pseudocapsule is not seen on CT images (Yamashita et al. 1993). SHCCs are hypervascular lesions that exhibit a corona on CT during hepatic arteriography, this corona representing drainage from the tumor vascular channels to sinusoids of the adjacent liver (Kobayashi et al. 2008a). On MR imaging, the tumors are hypointense on T1-weighted images and hyperintense on T2-weighted images. Characteristic for SHCC on dynamic MR images is a remarkable contrast enhancement, which continues to the delayed phase (Yamashita et al. 1993).

Pathology

Macroscopy

SHCC may either show a nodular growth pattern with formation of a well-delineated mass or show a diffuse growth pattern. The latter tumors are, owing to the lack of a pseudocapsule, ill-defined. The cut surface reveals a whitish and sometimes fasciculated tumor with a firm to hard consistency. Some lesions may show yellowish speckles or stripes, due to pigment accumulation in the sclerosed stroma and/or calcifications. The size of the tumors at diagnosis varies greatly; in one study, the tumor diameter ranged from 2.7 to 11 cm (mean: 7.2 cm; Kim et al. 2007). Scattered satellite nodules may be noted (Albar et al. 1996).

Histopathology

The tumor cell population is arranged in a trabecular or pseudoacinar pattern, although the former seems to be more common. In case of glandular structures, bile accumulation can be noted in the canaliculi or lumina. Typically, the tumor cells are embedded in a copious desmoplastic stroma with usually low cellularity and with thick collagen fiber bundles (Fig. 1).

In contrast to fibrolamellar carcinoma, the sclerosed stroma is not laminated, but rather reveals a “disordered” or fascicular arrangement of the matrix fibers.

Electron Microscopy

Cells of SHCC exhibit a microvillous surface structure, and the cytoplasm contains secretory granules with a diameter of 100 nm (Kitazawa et al. 1999).

Immunohistochemistry

Immunohistochemically, SHCCs present the same general marker patterns as ordinary HCCs. Cells of a subset of SHCCs have been shown to be immunoreactive for PTHrP (Albar et al. 1996; Kitazawa et al. 1999).

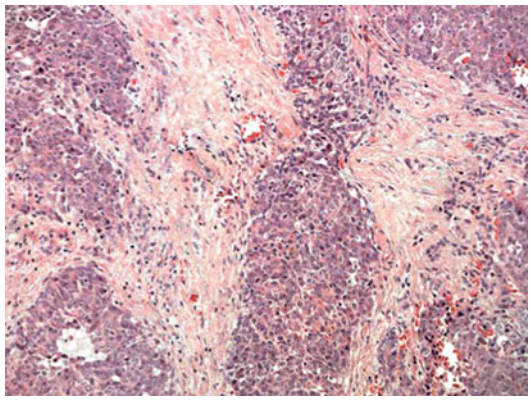

Fig. 1 Sclerosing hepatocellular carcinoma. The trabecular epithelial components are embedded in an abundant fibrosclerotic stroma (hematoxylin and eosin stain)

Molecular Studies

In one case of SHCC, PTHrP transcripts were demonstrated by in situ hybridization using a PCR-derived single-stranded DNA probe (Kitazawa et al. 1999).

Biology of Disease

In a study of six cases with hepatic resection, the prognosis was not worse than that of ordinary HCC (Yeh et al. 2005; Kim et al. 2006), although SHCC may undergo a rapid course (Medina Perez et al. 1997).

Differential Diagnosis

The main differential diagnosis at imaging comprises fibrolamellar carcinoma and desmoplastic intrahepatic cholangiocarcinomas. Fibrolamellar carcinomas are mostly diagnosed in younger individuals, while SHCCs occur in middle-aged to older persons, male predominant (Haratake and Horie 1989). Sclerosing hemangioma may mimic HCC with stroma formation (Lee et al. 2005).

Pathogenesis of Hypercalcemia in Sclerosing Hepatocellular Carcinoma

In the nonneoplastic liver, cells of reactive biliary ductules that express neuroendocrine markers also express PTHrP (Roskams et al. 1993a). The peptide is also detectable and rapidly inducible in human liver cell cultures that have a bile duct phenotype (Roskams et al. 1995). Apart from SHCCs, cholangiocarcinomas are associated with hypercalcemia (Kihara et al. 1973; Zelissen and van Hattum 1986; Trikudanathan and Dasanu 2010) and often express PTHrP (Roskams et al. 1993b; Yamada et al. 2000; Sohda et al. 2006), and PTHrP secretion has been found in primary squamous cell carcinoma of the liver (Asanuma et al. 2002; Saito et al. 2002) and primary adenosquamous carcinoma of the liver (Hayashi et al. 2001) associated with hypercalcemia. Also pancreatic tumors can present with this hypercalcemic syndrome, including adenosquamous carcinoma (Kobayashi et al. 2008b).

Diffuse Cirrhosis-Like Hepatocellular Carcinoma

Introduction

Most hepatocellular carcinomas (HCC) grow in the form of solitary or multiple nodules that are localized to one of few sites within the liver. In contrast, one recently reported rare variant of HCC produces small nodules distributed diffusely throughout the liver, in a cirrhosis-like manner. This unique pattern has been termed diffuse cirrhosis-like HCC/CL-HCC (Jakate et al. 2010). HCC with this growth pattern remains undetected as carcinoma clinically and radiographically and will unexpectedly be discovered in explanted livers in the setting of liver transplantation. In the study of ten patients reported by Jakate et al. (2010), nine were males, and all ten had liver cirrhosis of varying etiology, in the absence of pre-transplant suspicion of HCC. Only three patients had mild elevation of serum AFP, not exceeding 252 ng/mL.

Pathology

Macroscopically, CL-HCC is characterized by the presence of innumerable (sometimes more than 1,000) small HCC nodules measuring 0.2–0.6 cm in diameter scattered among cirrhotic

nodules. Histologically, the nodules showed well or moderately differentiated HCC, often with a pseudoglandular pattern, perinodular sclerotic rims, Mallory-Denk bodies (MDBs), cholestasis, and small vessel invasion. Immunohistochemically, the HCC revealed reactivity for ubiquitin (MDBs) and cytoplasmic and membranous CD10, but not AFP.

Inflammatory Hepatic Carcinomas 12

Contents

Abstract

Rare variants of hepatocellular carcinoma (HCC) show dense infiltrates of several classes of mononuclear leukocytes, mainly lymphocytes and macrophages or histiocytes (inflammatory HCCs). As a sign of an antitumor immune reaction, most ordinary HCCs exhibit lymphocyte and macrophage infiltrates of low density, but this feature does not qualify for a diagnosis of inflammatory HCC. Uncommon HCCs display a massive lymphoid cell infiltration, mostly T cells (HCC with lymphoid stroma). A very rare variant of HCC shows dense plasmacytic infiltrates, associated with tumor cell apoptosis and tumor regression (medullary-like HCC). There are also uncommon HCCs rich in macrophages or histiocytes with or without epithelioid cell reaction. A last group of inflammatory HCCs are lymphoepithelial liver tumors (lymphoepithelial carcinomas) which also occur in the biliary tract and several extrahepatic locations. Part of the latter neoplasms is associated with Epstein-Barr virus infection.

Introduction

Hepatocellular carcinomas (HCCs) almost constantly show a usually loose infiltration by leukocytes, mainly lymphocytes and tumor-associated macrophages (TAM) as signs of an inflammatory/immune response directed against the tumor.

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_12

Table 1 Types of inflammatory hepatic carcinomas

HCCs with low-density leukocyte infiltration
HCCs with lymphoid stroma
HCCs with dense plasmacellular infiltration (including medullary-type HCC)
Macrophage-rich HCCs with or without epithelioid reaction/granulomas
HCC with massive histiocyte infiltration
HCCs with steatohepatitis-like features
Hepatic lymphoepithelial carcinomas

This cellular infiltration is commonly more dense at the tumor border, i.e., in the peripheral contact area between tumor and host, while central parts of the tumors mostly display few round cells infiltrating either the epithelial components or the tumor stroma. In contrast to this "standard" situation, a subset of hepatic carcinomas, including certain HCCs, display a prominent cellular infiltration. These tumors may tentatively be grouped into six categories (Table 1). Similar to carcinomas in other organs, hepatic carcinomas with significant cellular infiltrates might have a more favorable prognosis (Choi and Choi 2008), but the biology of disease is not yet clarified for these rare tumors.

Hepatocellular Carcinomas with Low-Density Leukocyte Infiltration

HCCs are often associated with a low-density infiltration of lymphocytes, macrophages, and plasma cells (Shirabe et al. 1995; Wada et al. 1998). Lymphocyte infiltration of HCC tissue chiefly involves T lymphocytes of both helper and cytotoxic categories and is, at least in part of the cases, associated with an upregulated antitumor response and a more favorable biology of disease (Shirabe et al. 1995, 2010; O'Beirne and Harrison 2004; Zhao et al. 2012). Infiltrates of lymphocytes are often detected in the fibrous/stromal tissue and close to sinusoidal vessels located to the interface between tumor and peritumoral normal liver (Fig. 1).

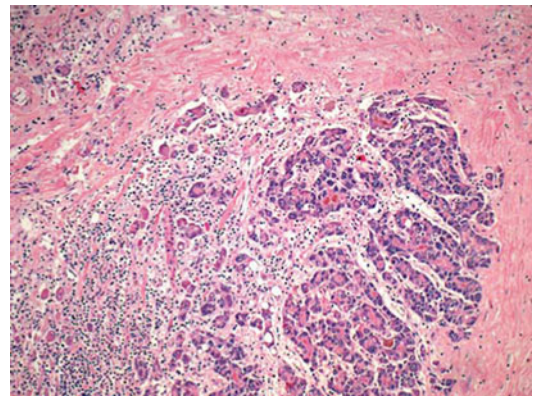

Fig. 1 Hepatocellular carcinoma with lymphocytic infiltration and fibrosis of stroma (hematoxylin and eosin stain)

These infiltrates constitute a mixture of T-cells, B-cells, and natural killer cells, but T-cells usually predominate. The T-cells mostly infiltrate areas in the tumor where endothelial cells strongly express HLA-DR antigen (Shirabe et al. 1995). 70–90 % of tumor-associated lymphocytes were of the antigen-experienced phenotype, and CD4+ CD25+ lymphocytes were more frequent within the tumor proper than in surrounding normal liver, while CD8+ cells predominate at the tumor-host contact site (Chen et al. 2007a). Sixty to seventy percent of the CD4+ or CD8+ lymphocytes in HCCs express the activation markers CD69 and HLA-DR (Chen et al. 2007a). In some HCCs, the peripheral infiltrate forms a band-like zone of lymphocytes with or without associated lymph follicles and sometimes germinal centers. Within the tumor, CD4+ and CD8+ T-cells are scattered among stromal cells, infiltrate the epithelial tumor trabecules or acini, and/or are clustered around tumor blood vessels. Small lymphocytes can be found in direct contact with tumor cells, sometimes with signs of emperipolesis. In most HCCs, the density of intratumoral lymphocytes is lower than that in the peritumoral liver substance and was found in one study to be in average 9.5 cells/HPF versus 17.8 cells/HPF in the noncancerous liver tissue (Ikeguchi et al. 2004). The density of peritumoral lymphocytes is

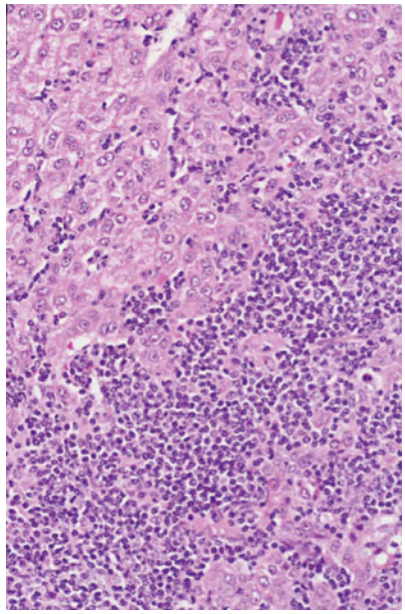

Fig. 2 This hepatocellular carcinoma exhibits a dense lymphocytic and plasmacellular infiltration. Such neoplasms are termed hepatocellular carcinoma with lymphoid stroma (hematoxylin and eosin stain)

modified by the type of underlying liver disease, e.g., being higher in patients with hepatitis C, whereas the density of intratumoral lymphocytes has been found to decrease with increasing tumor stage (Ikeguchi et al. 2004). In addition to lymphocytes, HCCs contain variable amounts of monocytoid cells and macrophages (tumor-associated macrophages, TAMs), discussed in more detail below. Most HCCs contain only small numbers of plasma cells in the stroma. Among tumor infiltrate cells, myeloid and plasmacytoid dendritic cells are also found in HCCs in variable numbers and play an important role in host defense directed against neoplastic cells (Ido et al. 1994; Yin et al. 2002, 2003; Lau and Thomson 2003; Cai et al. 2005, 2006; Kelly et al. 2014). Dendritic cells can engage in close contacts or even fusion with tumor cells, eventually forming "dendritomas" within tumors. However, in part of cases, CD38-positive mature and activated dendritic cells are reduced or lacking in HCC tissue (Chen et al. 2000), and HCC cells can inhibit the differentiation of dendritic cells (Li et al. 2007).

Hepatocellular Carcinoma with Massive Lymphoid Infiltration (Hepatocellular Carcinoma with Lymphoid Stroma)

There are rare instances where hepatic carcinomas are associated with massive lymphoid infiltration, but not representing typical LELC (Emile et al. 2000; Choi and Choi 2008; Park et al. 2009; Fig. 2). In one report, a 57-year-old male patient showed a regressing HCC consisting of a tumor 2.7 cm in size which was composed of two nodules. One nodule was replaced by a massive lymphoid infiltration with insignificant amounts of hepatocyte antigen (OCH1E5)-positive vital tumor cells, while the other nodules demonstrated a small portion of well- to moderately differentiated trabecular HCC, again with marked lymphocytic infiltration. The infiltrate chiefly consisted of CD3+ T lymphocytes, among which CD4+ cells predominated EBV was not detectable by EBER ISH (Park et al. 2009). The predominance of CD4+ cells in the lymphocytic infiltrate is in clear contrast to LELC, where CD8+ cells prevail.

Hepatocellular Carcinoma with Dense Plasmacellular Infiltration and Medullary-Like Hepatocellular Carcinoma

In a classical terminological approach, medullary carcinoma is defined as a carcinoma in which the epithelial component markedly exceeds the stromal component, resulting in a tumor that macroscopically assumes the features and, specifically, the consistency of fresh bone marrow (hence the term, medullary, "marrowish"). In distinct organs, and specifically the breast, other morphologic characters are employed to define medullary carcinoma,

such as a poorly differentiated type of cancer cells, a cohesive growth pattern, and a dense lymphocytic and plasmacytic infiltration of the tumor (Pedersen et al. 1994; Jacquemier et al. 2005; Malyuchik and Kiyamoya 2008; Foschini and Eusebi 2009). Neoplasms histologically resembling infiltrate-rich medullary carcinoma are termed carcinoma with medullary-like features. Medullary carcinomas are very rare in visceral organs. Gastric and colonic medullary carcinomas have been reported (Adachi et al. 1992; Chetty 2012).

In the breast, medullary carcinoma is a member of the so-called basal group which has been classified as tumors with a favorable prognosis in several studies, notwithstanding its high-grade morphology (Rakha et al. 2009; Cao et al. 2013), mainly in patients with so-called typical medullary carcinoma (Nurlaila et al. 2013), but there are also investigations that found no difference in outcome in comparison with invasive ductal carcinoma (Park et al. 2013). The downregulation of genes involved in cellular proliferation, an effective host immune response, enhanced tumor cell apoptosis, and elevated levels of metastasis-inhibiting and low levels of metastasis-promoting factors were suggested to account for the better prognosis (Yakirevich et al. 1999; Bertucci et al. 2006; Weigelt et al. 2008).

In the liver, medullary-like carcinoma has been described (Zimmermann et al. 2002). The liver resection specimen of a 56-year-old male patient with liver cirrhosis contained a 3.5 cm conglomerate of rather sharply delineated, brown-red or tan nodules, focally in close association with intrahepatic veins and with extensive macroangioinvasion. Histologically, the neoplasm consisted of large amphophilic or slightly basophilic cells with a solid and partly syncytial/cohesive, stroma-less (medullary) growth pattern. The tumor tissue was densely infiltrated with lymphocytes and plasma cells. Focally, the neoplasm showed marked tumor cell apoptosis and tumor shrinkage, remnant CK8-positive tumor cell nests situated within the dense round cell infiltrate (Figs. 3, 4, and 5). Immunohistochemically, the tumor cells were reactive for CK8, focally for CK19, and AFP. The proliferation fraction (Ki-67) exceeded 80 %. In contrast to medullary

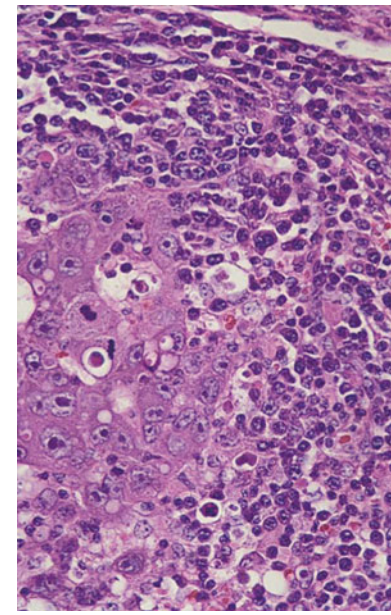

Fig. 3 Hepatocellular carcinoma with dense plasmacytic infiltration and marked tumor cell apoptosis (medullary HCC; hematoxylin and eosin stain)

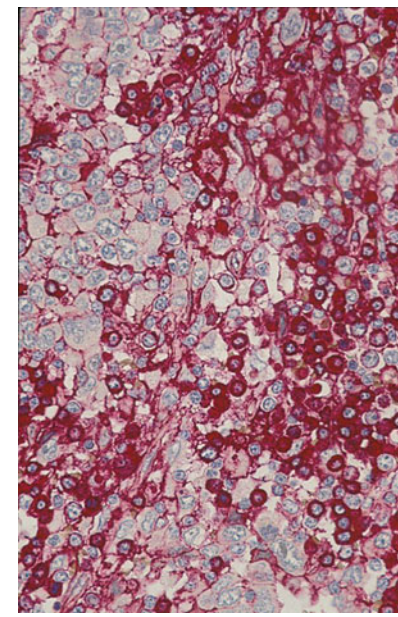

Fig. 4 Plasma cell-rich (medullary) hepatocellular carcinoma. Numerous CD138-positive plasma cells infiltrate this neoplasm (CD138/syndecan-1 immunostain)

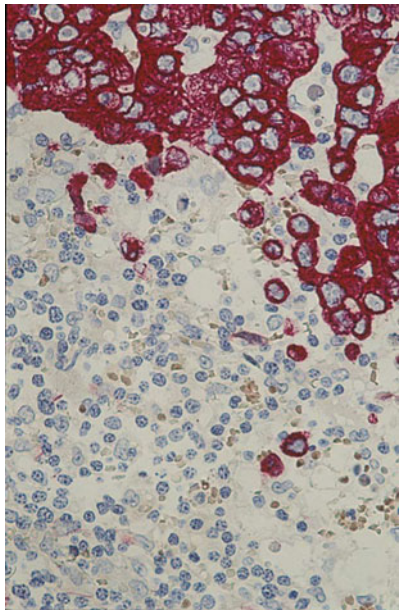

Fig. 5 Dense plasmacytic infiltrates in medullary hepatocellular carcinoma are associated with signs of tumor regression, visualized as loss and atrophy of tumor cells (CAM5.2 immunostain)

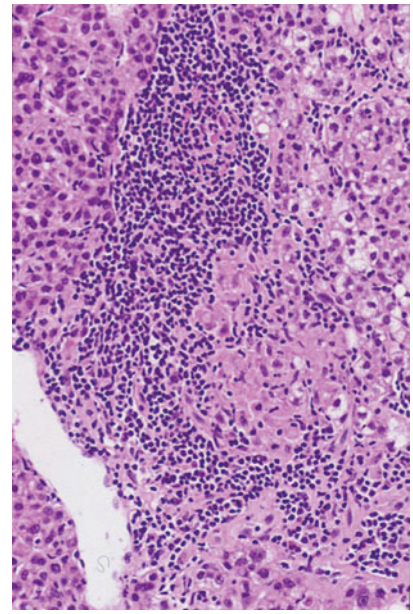

Fig. 6 Part of hepatocellular carcinomas with dense immune cell infiltrates also contain increased numbers of macrophages, sometimes with formation of epithelioid cell granulomas (hematoxylin and eosin stain)

carcinoma of the breast, where a significant proportion shows p53 positivity (Jacquemier et al. 2005), medullary-like HCC failed to show p53 protein reactivity. The plasma cells were strongly CD138 positive, while the lymphocytes were predominantly CD20- and CD79a-reactive B-cells. The tumor contained numerous S100 protein-positive cells with stellate or veiled morphology, probably antigen-presenting cells. Fas was detectable in a subset of lymphoid infiltrate cells, but not in tumor cells. Conversely, part of tumor cells expressed Fas-ligand. This rare type of HCC has subsequently been confirmed (Quist et al. 2014).

Macrophage-Rich Hepatocellular Carcinoma With or Without Epithelioid Cell Reaction

Tumor-associated macrophages (TAMs) play a significant role in tumor biology and are discussed in more detail in another chapter (Shirabe et al. 2012; Mano et al. 2013; Newell et al. 2013). TAMs also occur in most HCCs, but there are examples where this infiltrate cell is present in large numbers (Capece et al. 2013). CD68+ and CD63+ macrophages are present both within HCCs and in the peritumoral liver tissues, but CD163+ seem to predominate (Kong et al. 2013). Cellular immune reactions can be associated with marked macrophage activation resulting in epithelioid macrophages (epithelioid cells), granulomas, and macrophage fusion with formation of multinucleated giant cells (Fig. 6).

In native HCCs, epithelioid cell granulomas occur, as a so-called sarcoid-like reaction, albeit rarely and in small numbers (Neville et al. 1975; Tomimatsu et al. 1982; Mourra and Fléjou 2001). In the case reported by Tomimatsu and coworkers (1982), autopsy showed that the entire left liver lobe of a 55-year-old man was almost completely replaced by a massive poorly differentiated hepatocellular carcinoma. Histologically, granulomas having Langhans-type giant cells and varying numbers of lymphocytes were noted predominantly within the tumor and a few also within tumor thrombi of portal vein branches, but not in the noncancerous liver. However, other

observations documented the presence of granulomas also in livers harboring HCCs. Granulomas have also been found in hepatic dysplastic nodules and shown to contain multinucleated giant cells, in the absence of granuloma formation in associated HCC nodules (Phelan and Nolan 2008). Epithelioid cells and granulomas can be induced in HCCs in the course of therapeutic procedures. For example, granulomas can be induced by lipiodolized SMANCS, a polymer-conjugated derivate of neocarzinostatin (Ichikawa et al. 2002). Histologically, an epithelioid cell reaction in HCCs is seen in the form of small clusters of medium-sized to large and sometimes ovoid or spindle-shaped macrophages/histiocytes which are usually located close to carcinoma cell formations with or without signs of cell damage. Epithelioid cell granulomas in HCCs are often small and always noncaseating, with only a sparse peripherally lymphocyte cuff and often without detectable giant cells; however, few giant cells may be missed in thin tissue sections. Immunohistochemically, both epithelioid cells and granulomas are reactive for CD68.

Hepatocellular Neoplasm with Massive Histiocyte Infiltration

This rare variant of HCC was described based on the observation of a 73-year-old Japanese man presenting with a liver malignancy in the absence of hepatic viral infection. Histologically, the nodule consisted of hepatocyte-like tumor cells and abundant histiocytes with abundant foamy cytoplasm that filled up a sinusoid-like space, associated with central loose fibrosis. Most of the tumor revealed features of adenoma, but a focal HCC-like lesion was also present (Kai et al. 2010).

Hepatocellular Carcinomas with Steatohepatitis-Like Features (Steatohepatitic Hepatocellular Carcinoma)

This variant, further discussed in the chapter of lipid-rich HCCs, is characterized by neutral fat accumulation in tumor cells, tumor cell ballooning with or without formation of Mallory-Denk bodies, and an inflammatory infiltrate consisting of neutrophils, lymphocytes, and macrophages. In several respects, the histologic presentation of these HCCs reflects the morphology of acute nonalcoholic steatohepatitis (NASH), and it is assumed that similar pathogenic mechanisms are involved (reviews: Duvnjak et al. 2007; Perlemutter et al. 2007).

Lymphoepithelial Liver Tumors

Introduction

Lymphoepithelial liver tumors comprise a spectrum of lesions that share the general features of lymphoepithelioma-like carcinoma (LELC; synonym, lymphoid stroma-rich carcinoma). LELC is an undifferentiated carcinoma with a marked and predominantly lymphocytic infiltration, histologically mimicking nasopharyngeal carcinoma (NPC), and being associated with Epstein-Barr virus (EBV) in variable proportions. NPC differs significantly from other cancers of the head and neck anatomic compartments in its occurrence, causes, clinical course, and treatment responses. NPC is vastly more common in certain regions of East Asia, the Middle East, and Africa than elsewhere. In part of the reports referring to NPC and LELC, the term "lymphoepithelial-like" carcinoma has been employed, the designation "-like" denoted the uncertainty as to whether undifferentiated carcinomas with dense lymphocytic infiltration form a homogeneous group or rather a group of unrelated lesions with a similar morphology. Lymphoepithelioma, as it was originally termed, was primarily described in the 1920s by Regaud and Schmincke in the head and neck region of Asian patients. Alexander Schmincke (1877–1953), one of the persons appearing in the eponym, was a German doctor who became a pathologist at the Würzburg University in 1907. In 1921, he accepted to succeed Heinrich Albrecht as a professor in Graz, Austria, moving to the same tenure at Tübingen in 1922 and in 1928 to Heidelberg. He described the neoplasm in question in 1921, under the title, *Lymphoepithelial*

Growths (Schmincke 1921). Claude Regaud (1870–1941) was a French radiologist. He was agrégé for anatomy and pathology from 1901 to 1913 in Lyon and from 1913 onwards professor at the Pasteur Institute and director of the Radiophysiological Laboratory at the Radium Institute at the University of Paris. Apart from the most important localization in the head and neck regions, LELC is now known to develop in a broad array of organs and tissues including the breast, middle ear, oral cavity, major and minor salivary glands, specifically the parotid gland, lacrimal gland, larynx, trachea, lung, thyroid gland, thymus, esophagus, stomach, hepatobiliary tract (see below), pancreas, colon, rectum, renal pelvis, ureter, urinary bladder, ovary, uterine cervix, prostate, and skin. Many of these tumors, but specifically those originating from the nasopharynx, salivary glands, thymus, lung, and stomach show a close linkage with Epstein-Barr virus (EBV) infection (Iezzoni et al. 1995), discussed in more detail below.

Lymphoepithelioma-Like Carcinoma of the Liver

ICD-O 8082/3

LELC of the liver substance proper has been reported under several names, including hepatoma with marked lymphocyte infiltration (Isoda et al. 1982), hepatocellular carcinoma with lymphoid stroma (Emile et al. 2000; Szekely 2001a; Choi and Choi 2008), hepatocellular carcinoma with massive lymphoid infiltration (Park et al. 2009), and lymphoepithelioma-like hepatocellular carcinoma (Chen et al. 2007b; Nemolato et al. 2008; Shinoda et al. 2013; Patel et al. 2014). Lymphoepithelioma-like carcinoma was a term chosen to denote what was interpreted to be hepatocellular carcinoma with lymphoid stroma (Szekely 2001a; Chen et al. 2007b). In fact, the tumors may contain components histologically resembling HCC (Emile et al. 2000), and two reports described LELC with a HepPar1-positive component suggesting the involvement of a hepatocellular cell lineage (Chen et al. 2007b; Nemolato et al. 2008). However, other hepatic LELC lack features of bona fide hepatocellular carcinoma and are epithelial tumors of unknown cellular origin. All in all, relatively few cases of hepatic LELC have been described (Isoda et al. 1982; Wada et al. 1998; Emile et al. 2000; Szekely 2001a; Si et al. 2004; Chen et al. 2007b; Nemolato et al. 2008). Hepatic LELC was not associated with viral marker (HBV, HCV) positivity (Nemolato et al. 2008). LELC of the liver interpreted as HCC has been observed in extrahepatic location, e.g., the suprarenal space (Sturm et al. 2004). The clinical presentation does not differ from that observed in other primary epithelial liver tumors. Hepatic LELC occurs as solitary and single or multiple tumors. The majority of cases was found in cirrhotic livers, but LELC also occurs in the absence of cirrhosis (Nemolato et al. 2008). It is noteworthy that serum AFP is usually normal, in contrast to HCC (Emile et al. 2000). MRI imaging has demonstrated low signal intensity in the T1-weighted images and a moderate signal intensity in the T2-weighted images (Choi and Choi 2008). In dynamic MRI image, enhancement in the late arterial phase and washout in the portal venous phase was found (Choi and Choi 2008). The biology of hepatic LELC is not yet clarified, due to the low number of cases collected so far. In one recent study of eight patients, 37.5 % showed local recurrence (Patel et al. 2014).

LELC of the liver may be associated with Epstein-Barr virus (Si et al. 2004). EBV viral transcripts were detected by in situ hybridization (Si et al. 2004), by enumeration of chromosome 11 copy number (Si et al. 2004), and by polymerase chain reaction (PCR) for EBNA2 (Si et al. 2004) and for LMP1, the LMP1 gene being wild-type in one study. Some hepatic LELC failed to show EBV expression (Emile et al. 2000; Chen et al. 2007b; Choi and Choi 2008; Nemolato et al. 2008). It may be added here that the role of EBV in the pathogenesis of ordinary HCC is controversial, studies finding either no evidence (Akhter et al. 2003; zur Hausen et al. 2003) or detecting positive EBV PCR signals, e.g., in a subset of Chinese patients (Li et al. 2004) or Japanese patients (Sugawara et al. 2000). The pathogenic role of EBV in LELC is outlined in more detail below.

Pathology of Hepatic LELC

The tumors are usually well-circumscribed nodules that bulge from the cut surface and show a white-yellowish color, sometimes with necroses and small hemorrhages (Min et al. 2007). The histopathologic phenotype of the tumor cells in hepatic LELC comes in two main patterns. One pattern is characterized by poorly differentiated cells arranged in nests or solid structures, similar to the morphology of nasopharyngeal carcinoma (Fig. 7).

A cohesive pattern may be observed, but this is usually effaced by the dense lymphocytic infiltration. These cells are most often of intermediate size, at least smaller than normal hepatocytes, with an amphophilic to slightly basophilic and ill-defined cytoplasm and vesicular nuclei with a rather prominent nucleolus. Mitotic figures are regularly seen and may be abundant. The overall presentation is that of a solid growing, poorly differentiated (grade 3) carcinoma which fails to reflect a clear-cut cellular origin. At the interface between the carcinoma and the cellular infiltrate, a zone resembling piecemeal necrosis is often recognized (Choi and Choi 2008), but in fact, this phenomenon does not represent necrosis but rather apoptosis induced by the lymphocytes. Within the solid tumor parts, numerous apoptotic bodies may be seen, and sometimes the vital tumor tissue is markedly regressed owing to apoptotic cell loss. Apart from apoptosis, coagulation-type necrosis of tumor tissue is also found. The second and rarer pattern is that of standard hepatocellular carcinoma of the trabecular and usually moderately to well-differentiated type, either as a sole lesion or combined with the poorly differentiated component (Chen et al. 2007b). In both patterns, the stromal component, which is usually sparse, is not easily seen because it is occupied by a dense cellular infiltrate which is dominated by lymphocytes, but plasma cells and macrophages are also noted in variable numbers (the so-called lymphoid stroma). Lymph follicles, sometimes with germinal centers, are often found (Choi and Choi 2008). Typically, the caps of the germinal centers are randomly oriented. The lymphocytes invade the solid carcinoma tissue and are sometimes in close contact with viable-looking carcinoma cells or with apoptotic bodies. Emperipolesis is observed, and lymphocytes are visualized within vessel lumina, probably reflecting a homing mechanism.

The tumor cells have been shown to be reactive for cytokeratins, including pankeratin (AE1/AE3) and cytokeratins 8 and 18 and sometimes CK19, but a case not staining for cytokeratins 7, 19, and 20 has been reported (Nemolato et al. 2008; Fig. 8).

In the HCC-like pattern, the cells sometimes stain for HepPar1 (Chen et al. 2007b; Nemolato

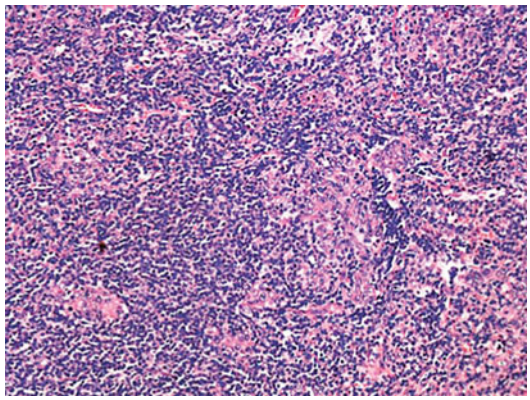

Fig. 7 Lymphoepithelial carcinoma of the liver. The histologic picture is dominated by a lymphocytic infiltrate with interspersed neoplastic epithelial cell nests (hematoxylin and eosin stain)

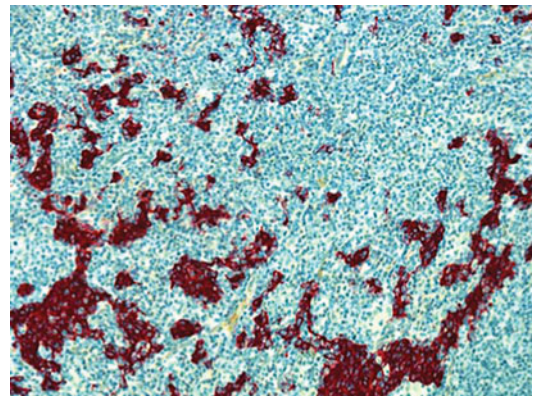

Fig. 8 The epithelial tumor cell nests in lymphoepithelial carcinoma as visualized by cytokeratin expression. Note that part of tumor cells are damaged and atrophic (CAM 5.2 immunostain)

et al. 2008) and for glypican-3 (Nemolato et al. 2008). In the poorly differentiated pattern, the proliferation fraction is very high and may exceed 80 %, as visualized in the Ki-67 immunostain. The lymphocyte population is dominated by T-cells with either a CD8+-dominated immunophenotype (Nemolato et al. 2008) or uniform distribution of CD4(+) and CD8(+) cells (Patel et al. 2014). There is a variable admixture of CD4+ T lymphocytes, CD20+ and CD79a + B lymphocytes, CD38+ polytypic plasma cells, and CD68+ macrophages. The lymph follicles and germinal centers are of B-cell lineage and exhibit the immunophenotype known from other localizations.

EBV Expression in LELC

Similar to other organs, part of hepatic LELC expresses Epstein-Barr virus components (Fig. 9).

In hepatic LELC-expressing Epstein-Barr virus (EBV), tumor cells are reactive for LMP1 and show nuclear signals for EBER in in situ hybridization (Weiss et al. 1989; Korabecna et al. 2003). EBV expression in LELC has been associated with p53 overexpression in the nuclei of EBV-infected tumor cells (Gulley et al. 1998) and with overexpression of Bcl-2 and the proliferation marker, PCNA (Niemhom et al. 2000).

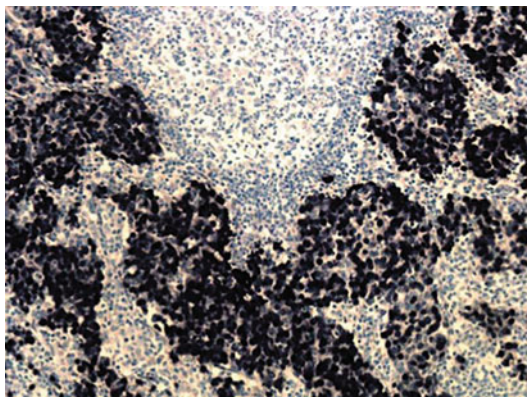

Fig. 9 Part of lymphoepithelial carcinomas of the hepatobiliary tract express Epstein-Barr virus (EBV) antigens. This figure shows strong nuclear reactivity of neoplastic cells for EBER (*black* nuclei). A germinal center is present in the upper part of the figure (in situ hybridization for EBV early RNA/EBER)

Lymphoepithelioma-Like Carcinoma of the Biliary Tract

ICD-O 8082/3

Apart from LELC of the liver substance proper, several reports have documented the occurrence of LELC in either the extrahepatic or intrahepatic bile ducts, however, with clear predominance in the intrahepatic bile duct system.

Selected References Hsu et al. 1996; Vortmeyer et al. 1998; Kim et al. 1999; Pratschke et al. 1999; Ortiz et al. 2000; Chen et al. 2001; Jeng et al. 2001; Szekely 2001b; Huang et al. 2004; Min et al. 2007; Adachi et al. 2008; Henderson-Jackson et al. 2010; Hur et al. 2011; Ishida et al. 2011; Lee 2011; Mao et al. 2011; Xiao et al. 2012.

The majority of individuals developing this cancer were older than 40 years of age, and almost half were more than 60. Females and males are equally affected. Interestingly, the right and left liver lobes were almost equally involved. Very few cases have been identified in the common bile duct (Ishida et al. 2011). Biliary tract LELC is usually not associated with liver cirrhosis, and the serum AFP levels are normal. Most biliary LELC reported so far were associated with EBV infection (Hsu et al. 1996; Vortmeyer et al. 1998; Ortiz et al. 2000; Chen et al. 2001; Jeng et al. 2001; Huang et al. 2004; Min et al.2007; Henderson-Jackson et al. 2010; Xiao et al. 2012; Chan et al. 2014), also tumors in the extrahepatic duct system (Ishida et al. 2011). Several patients, in part older than 60 years at diagnosis, were reported to be EBV negative (Kim et al. 1999; Szekely 2001b; Adachi et al. 2008; Hur et al. 2011; Lee 2011).

The prognosis of biliary tract LELC seems to be better than that of ordinary cholangiocarcinoma (Chan et al. 2014). Based on five cases, one patient died of disease after 4 years, while four patients were alive and free of disease after a period ranging from 2 months to 7 years (Jeng et al. 2001). In a compilation of 11 patients with available follow-up, only 2/11 died of disease and 1/11 died of surgical complications

(Huang et al. 2004). In a review of 13 patients, 4 patients had lymph node metastases, only 1 patient had remote metastases (lung and spleen), and 3 died of disease. With a follow-up ranging from 2 months to 7 years, eight patients were alive without disease (Henderson-Jackson et al. 2010). This better outcome is reflected by a similar biology of LELC located in the stomach (Shibata et al. 1991; Nakamura et al. 1994; Matsunou et al. 1996) and in the lung (Chen et al. 1998).

There are relatively few informations regarding the gross features of these neoplasms. In a patient with LELC of the extrahepatic bile duct, laparotomy revealed a whitish, firm tumor, originating from the common bile duct and reaching to the right hepatic duct (Pratschke et al. 1999). In the literature, the diameter of these lesions ranged from 3.0 to 12 cm. Intrahepatic biliary tract LELC have been described as well-defined, non-encapsulated tumors with a firm or rubbery consistency, and a white to yellowish cut surface and a more or less clear spatial relationship to larger intrahepatic bile ducts (Kim et al. 1999; Chen et al. 2001; Huang et al. 2004; Min et al. 2007; Lee 2011). In one case, serial macroscopic sections revealed that the tumor was located on the route of the hepatic duct and connected to it (Adachi et al. 2008). Large tumors may be associated with hepatic satellite nodules (Hsu et al. 1996). Association with liver cirrhosis has been reported (Kim et al. 1999; Lee 2011) but is uncommon. Lymph node metastases were described in two reports (Vortmeyer et al. 1998; Chen et al. 2001).

Biliary tract LELC has been described to be either composed of the undifferentiated component alone (morphologically corresponding to the undifferentiated subtype of nasopharyngeal carcinoma/NPC) or two components. Undifferentiated carcinoma is the variant in which tumor cells form ill-defined syncytia-like formations infiltrated by small lymphocytes, with irregular large nuclei with vesicular or open chromatin and prominent nucleoli, again similar to NPC. Within the sometimes very dense lymphocytic infiltrate, lymph follicles with or without germinal centers may develop (Vortmeyer et al. 1998; Huang et al. 2004). In the transition region between tumor cells' nests and lymphocyte infiltrates, piecemeal necrosis-like changes may be seen. In mixed forms, undifferentiated carcinoma is combined with moderately differentiated adenocarcinoma forming ductular structures (Henderson-Jackson et al. 2010), sometimes accompanied by a marked desmoplastic reaction, similar to ordinary cholangiocarcinoma (Hsu et al. 1996; Vortmeyer et al. 1998; Ortiz et al. 2000; Chen et al. 2001; Huang et al. 2004), but an association of LELC with intraductal cholangiocarcinoma has also been found. This component had a papillary structure of non-mucinous carcinoma cells, and transitions between the two components were noted (Adachi et al. 2008). The cellular infiltrate of biliary tract LELC may contain large and immunoblast-like forms and, rarely, multinuclear atypical cells somewhat resembling cells in Hodgkin's disease, but with negative results for CD30 reactivity (Pratschke et al. 1999; Szekely 2001b).

Immunohistochemistry

The cells of biliary tract LELC are reactive for pancytokeratin, CK7, CK8, CK22, EMA, and polyclonal CEA, but negative for CD20. CEA was negative in one case (Vortmeyer et al. 1998). Infiltrating lymphocytes form a mixture of phenotypes, but usually with predominance of CD3-reactive cells (Ortiz et al. 2000; Chen et al. 2001; Huang et al. 2004; Henderson-Jackson et al. 2010). Abundant nuclear reactivity for p53 protein has been observed (Ortiz et al. 2000).

EBV Expression in Biliary Tract LELC

Detection of EBV-encoded RNA (EBER1) by in situ hybridization results in nuclear staining, either patchy or diffuse (Ortiz et al. 2000; Huang et al. 2004). Based on PCR, one tumor extract showed EBV nuclear antigen 2 (type II EBNA2) of 400 bp and latent membrane protein (LMP) of 285 bp, due to a 30-bp internal deletion (Huang et al. 2004). PCR analysis for EBV nuclear antigen 2 was consistent with EBV strain type A (Vortmeyer et al. 1998). In the case of Hsu and coworkers, abundant EBV EBER1 was shown in both the LELC and adenocarcinoma component

of the tumor. Southern blot analysis and PCR showed a monoclonal episomal form of EBV, with a genotype characteristic for Chinese EBV strain type 1 (Hsu et al. 1996). In one report, the LMP1 gene was found to be wild type by PCR (Vortmeyer et al. 1998). Negative results for LMP1 immunostaining are reported in the literature (Ortiz et al. 2000). In contrast to these tumors, no EBV-encoded nuclear RNA and LMP1 were detected in 215 cases of intrahepatic cholangiocarcinoma from Japan (Ozaki et al. 2000).

EBV Expression in Hepatocellular Carcinoma

EBV is detectable in a subset of HCCs from hepatitis C-positive patients. This finding has led to the assumption that EBV could play a role in the development of HCV-related HCC (Sugawara et al. 2000).

Abstract

Few hepatocellular carcinomas (HCC) show a morphologic pattern that deviates from the histology of ordinary HCC or established variants thereof, treated in detail in other chapters. Rare tumors show peliotic change with a presence of blood-filled spaces lacking an endothelial lining (peliotic HCC). One variant of HCC is characterized by multinuclear tumor cells resembling syncytial cells in giant cell hepatitis (syncytial giant cell HCC). This unusual neoplasm occurs both in the pediatric age group and in adults. Cells with a smooth chromophobic cytoplasm and clusters of cells with anaplastic changes are diagnostic features of the rare chromophobe HCC. HCCs with strongly eosinophilic and granular cells form the oxyphilic and oncocytic variants of HCC, the latter having increased number of mitochondria, similar to oncocytic tumors in other organs. Very rare HCCs are pigmented due to the accumulation of a Dubin-Johnson-like pigment. Other very rare variants of HCC include pleomorphic giant cell-rich HCC, spindle cell HCC, and ossifying HCC.

Peliotic Hepatocellular Carcinoma

Introduction

Peliosis of the liver is a lesion histologically characterized by the presence of few to multiple blood-filled cavities that lack a complete endothelial lining (see the respective chapter). Numerous causes or associations have been noted for hepatic peliosis. Rarely, peliotic change can also develop within liver tumors, in particular hepatocellular carcinoma.

Hepatocellular Carcinoma with Peliotic Change

Relatively few cases of hepatocellular carcinoma (HCC) with peliotic change (peliotic HCC; pelioid-type HCC) have been described in the literature (Balazs 1991; Moldvay et al. 1991; Chedid et al. 1999; Grazioli et al. 2000; Ji et al. 2001; Kawasaki et al. 2003; Kim et al. 2007a; Watanabe et al. 2008; Hoshimoto et al. 2009; Fujimoto et al. 2010; Ikeda et al. 2011). The exact prevalence of peliotic change in HCC is not yet known, but the alteration may be more common than generally anticipated. In a series of 294 consecutively resected HCC, peliotic change in tumor was observed in 39.5 % (Fujimoto et al. 2010). HCC with peliotic change has been observed under circumstances that also promote peliosis in nonneoplastic liver, e.g., long-term androgenic steroid therapy (Balazs 1991; Moldvay et al. 1991) and intake of oral contraceptives (Ikeda et al. 2011).

Clinical and Imaging Features

From the relatively few reports available, it surfaced that the overall clinical presentation of peliotic HCC is not different from that of other HCC. However, peliotic change in HCC has been suggested to be associated with a better prognosis (Chedid et al. 1999). Abdominal ultrasonography usually reveals hyperechoic lesions with mosaic patterns, and contrast-enhanced harmonic ultrasonography shows hemangioma-like findings, i.e., the peripheral globular enhancing pattern (Kawasaki et al. 2003). Dynamic CT and MR imaging showed early irregular enhancement of the peripheral part of the lesion, with this effect persisting into late phase, spreading into central parts of the tumor (Kim et al. 2007; Hoshimoto et al. 2009). Hepatic angiography showed the “cotton-wool” sign that usually characterizes hemangioma (Hoshimoto et al. 2009). Peliotic HCC may closely mimic hepatic hemangioma on angiography and contrast-enhanced harmonic ultrasonography (Kawasaki et al. 2003). Also in the course of technetium-99 m red blood cell scintigraphy, peliotic HCC may present as a lesion closely mimicking hepatic hemangioma (Ji et al. 2001), because both lesions are characterized by the entrapment of erythrocytes in dilated vessels or blood-filled spaces.

Pathology

At gross examination, peliotic HCC shows focal dark-red areas on cut surfaces, looking like focal hemorrhage (Ji et al. 2001) or presenting as a hemorrhagic honeycomb-like pattern (Fujimoto et al. 2010). In part of the tumors, the grossly visible peliotic change can occupy more than half of the cut surface. Apart from focal peliotic change, there are examples of extensive tumor peliosis, macroscopically showing a diffusely red discoloration and a spongy appearance of the tumor (Hoshimoto et al. 2009). In extensive peliotic change, the tumor grossly resembles giant cavernous hemangioma with hemorrhage (Kim et al. 2007). In contrast to tumor hemorrhage, tumor peliosis is not associated with grossly detectable necrosis. Peliotic HCCs were found to be encapsulated more frequently than in HCC without peliotic change (Kim et al. 2007; up to 93 %, Fujimoto et al. 2010). In one investigation, the mean tumor diameter of HCC with peliotic change was significantly larger than that of control HCC, and large tumor more often showed peliosis (Fujimoto et al. 2010).

Peliotic HCCs display, usually in a focal distribution and more often in central parts other tumor, variably sized spaces containing blood in the absence of a complete endothelial lining (Figs. 1 and 2).

Within large blood-filled spaces, trabecules of HCC seem to be isolated and sometimes fragmented, and there are areas where only cancer cell clusters remain. In marginal parts of the peliotic lesions, spaces with an incomplete endothelial lining may be found, suggesting a transition between the peliotic spaces and the surrounding tumor blood vessels. Peliotic zones in HCC s may, in fact, be surrounded by areas with telangiectasia. In one case, a dense eosinophil infiltration associated with the tumor was found (Watanabe et al. 2008).

Hepatocellular Carcinoma Associated with Peliosis Hepatis

Peliosis hepatis can be synchronously associated with hepatocellular carcinoma (Tocornal and Rosenberg 1981; Russmann et al. 2001).

Differential Diagnosis

On CT images, focal peliosis hepatis may itself mimic hepatocellular carcinoma (Han and Kim 2006; Atila et al. 2007; Kim et al. 2007) or metastatic liver disease (Tateishi et al. 1998; Wannesson et al. 2009). Other hepatic tumors sometimes showing peliosis include liver cell adenoma and angiomyolipoma (Akatsu et al. 2004).

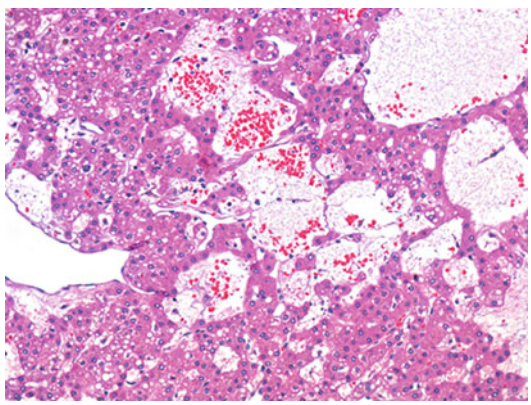

Fig. 1 Peliotic hepatocellular carcinoma. This tumor contains several large blood-filled spaces (hematoxylin and eosin stain)

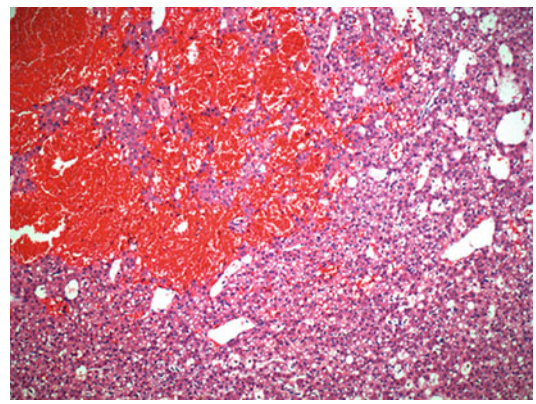

Fig. 2 In this peliotic hepatocellular carcinoma, blood-filled spaces lack an endothelial lining and are associated with tumor cell atrophy (hematoxylin and eosin stain)

Syncytial Giant Cell Hepatocellular Carcinoma

Introduction

Hepatocytes are capable of transforming into multinucleated cells, the syncytial giant cells. In nonneoplastic conditions, this phenomenon is well known to occur in several types of neonatal hepatitis, mainly in those associated with cholestasis (giant cell hepatitis; syncytial giant cell hepatitis) and also in adults (postnatal giant cell hepatitis). Syncytial giant cell formation is known in several types and locations of carcinoma, e.g., clear cell renal cell carcinoma (Lloreta et al. 2002). Hepatocellular tumors with syncytial giant cells are rare lesions that occur both in adult and pediatric patients. The giant cells occurring in these neoplasms are epithelial in nature, in contrast to the mesenchymal features of osteoclast-like multinucleated giant cells occurring in a distinct group of hepatobiliary tumors.

Syncytial Giant Cells in Adult-Type Hepatocellular Carcinoma

A first case of hepatocellular carcinoma with syncytial giant cells was published by Nazari in 1905. The figure published in this work shows a well-differentiated HCC of the trabecular type. At some places, huge multinucleated tumor cells are interspersed between the outer surface of the trabecules and the endothelial lining of intervening sinusoid-like vascular channels. The syncytial giant cells deeply bulge into these vascular spaces and are sometimes covered by a thin endothelial cell layer (Nazari 1905). A second case of multinucleated hepatocellular carcinoma was described in 1925 (Rowen and Mallory 1925). Histology of a malignant tumor in a 57-year-old male displayed hepatocellular carcinoma with a mixed trabecular and acinar growth pattern and bile production. The neoplasm contained numerous and in part very large, multinucleated hepatoid cells. The large cells, with a cytoplasm resembling that of hepatocytes, contained dozens of vesicular nuclei with prominent nucleoli, these nuclei being predominantly arranged at the cell periphery but also forming clusters in central parts of the cells. Some of these cells contained inspissated bile, and few cells had engulfed damaged cells of unknown character (emperipolesis). At least part of pleomorphic giant cell-rich hepatocellular carcinomas can also contain syncytial giant cells, in addition to pleomorphic giant cells with bizarre and lobulated nuclei (Vijay et al. 2011; Lampri et al. 2014).

Pediatric Syncytial Giant Cell Hepatocellular Carcinoma

A marked contribution of large syncytial giant cells was found in an hepatocellular carcinoma of an infant who presented with features of Cushing's syndrome due to bilateral adrenal hyperplasia (Atra et al. 2007). This patient was a 9-month-old girl with bilateral nodular hyperplasia of the adrenal glands and a cystic lesion in the left ovary that in addition showed a 5 cm-sized mass in the right liver lobe. Biopsy of the mass revealed hepatocellular carcinoma consisting of medium-sized hepatocyte-like cells forming both a trabecular and acinar pattern, with bile formation in the acini. The tumor contained numerous multinuclear giant cells of the syncytial type, similar to those seen in infantile giant cell hepatitis (Figs. 3 and 4).

The giant cells displayed the same nuclear atypias as the other HCC cells and were therefore not reactive elements. The adjacent liver did not show any giant cell change. The tumor giant cells were immunoreactive for the hepatocyte marker Hep Par 1 and cytokeratin 8. A mitochondrial immunostain showed that the tumor cells had less mitochondria than normal hepatocytes, except the giant cells, where mitochondria were numerous. Very few tumor cell nuclei were p53 protein positive. Beta-catenin was consistently expressed in both ordinary HCC cells and tumor giant cells, with a predominantly membranous staining pattern. The proliferation fraction of the HCC (Ki-67) was lower than 5 %, and no labeling was found in the nuclei of giant cells.

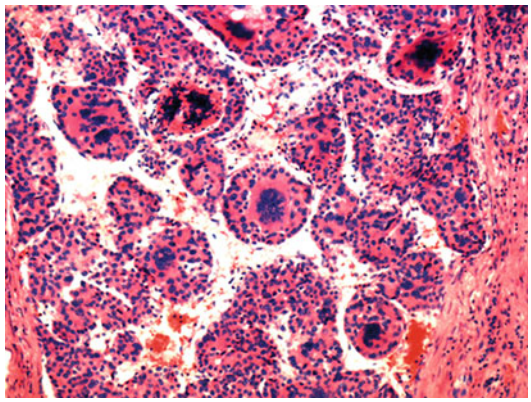

Fig. 3 Syncytial giant cell hepatocellular carcinoma. This trabecular tumor shows multinucleated giant cells situated in the interior of tumor cell plates (hematoxylin and eosin stain)

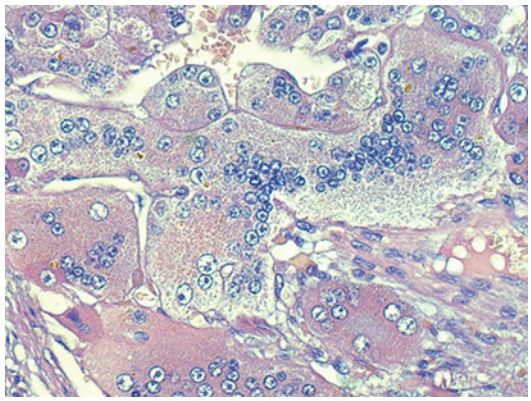

Fig. 4 Giant cells in syncytial giant cell hepatocellular carcinoma can become very large cells with numerous nuclei, the latter sometimes arranged in bands (hematoxylin and eosin stain).

Differential Diagnosis

The most important differential diagnosis of giant cell-rich hepatic carcinomas is hepatobiliary tumors with osteoclast-like giant cells. There are few other hepatic tumors that rarely develop a giant cell component, e.g., epithelioid angiomyolipoma (Alatassi and Sahoo 2009). Many ordinary HCCs display tumor cells with several nuclei, mainly in grade 3 lesions, but these cells are not syncytial-type giant cells.

Pathogenetic Pathways

Under normal conditions, several cell types are capable to change into multinucleated cells, mainly via the mechanism of cell fusion. Well-known examples are osteoclasts (derived from mononuclear preosteoclasts), syncytiotrophoblast, myotubes, and macrophages. Cell fusion has also been found to occur in infantile giant cell hepatitis (Koukoulis et al. 1999) and in adult autoimmune hepatitis with giant cell formation (Hayashi et al. 2011). Cell fusion is a unique phenomenon that is induced and regulated by numerous factors. In osteoclasts, several molecules have been reported to be fusion related, including CD44, CD47, ADAM12, MCP-1, IL-4, IL-13, and CD9. Macrophages can fuse among each other, but may also fuse with somatic cells and tumor cells, forming hybrid fusion products. CD44 expression is highly induced in macrophages at the onset of cell fusion. The intracellular domain of CD44 (CD44ICD) is cleaved in macrophages undergoing fusion, whereby CD44ICD promotes cell fusion via activation of NF-kappaB (Cui et al. 2006). A compound critical for both osteoclastogenesis and the generation of multinucleated macrophages (Langhans giant cells and foreign-body giant cells) is the seven-transmembrane-region receptor dendritic cell-specific transmembrane protein, DC-STAMP (Yagi et al. 2006). Much information has accumulated in studies of respiratory syncytial virus (RSV)-induced giant cell formation. RSV is an important human pathogen that causes severe respiratory infections in infants, the elderly, and immunocompromised hosts. RSV infection induces the activation of RhoA, a small GTPase, in cells, and inhibition of RhoA abolishes syncytium formation, indicating an important role of RhoA signaling in giant cell formation (Gower et al. 2005). Formation of multinucleated cells by liver cell neoplasms may represent a survival strategy. In HCC cells exposed to etoposide-induced DNA damage, resistance to toxicity and survival promoted by Akt/PTEN signaling is associated with multinucleation (Mukherjee et al. 2013).

The numerous nuclei in syncytial giant cells, also in those found in rare HCCs, have an

abnormal position in the cell body and distribution. The nucleus in eukaryotic cells has, on the one hand, a well-defined position in relation to the cytoskeleton, organelles, and cell surface but, on the other hand, can move within the cytoplasm. Positioning and movements of nuclei are controlled by a distinct protein interactome. The integral outer nuclear membrane (ONM) proteins implicated in these processes thus far all contain a conserved Klarsicht/ANC-1/Syne homology (KASH) domain at their C-terminus that associates with Sad1p/UNC-84 (SUN)-domain proteins of the inner nuclear membrane within the periplasmic space of the nuclear envelope (review: Wilhelmsen et al. 2006). ANC-1 consists of two actin-binding calponin domain and a nuclear envelope targeting KASH domain. ANC-1 functions to physically tether the actin cytoskeleton to the outer nuclear membrane, thus linked the nucleus to the cytoskeleton (Starr and Han 2002, 2005). UNC-84 is a SUN protein that is required for both nuclear migration and anchorage. UNC-84 recruits a second UNC protein, UNC-83, and ANC-1 to the nuclear envelope (McGee et al. 2006). In skeletal muscle cells, Syne proteins anchor nuclei at the neuromuscular junction (Grady et al. 2005), and SUN1 and SUN2 play critical but partially redundant roles in anchoring the nuclei.

Chromophobe Hepatocellular Carcinoma

Introduction

In an analysis of 219 Western HCC, a novel subtype of this tumor category was identified, characterized by a generally chromophobe appearance of neoplastic cells and abrupt focal anaplasia. This subtype was identified in 6 % of all HCC analyzed, with almost equal distribution of sexes and an average age of 61 years at presentation. 6/13 cases occurred in cirrhotic livers, with an enrichment of chronic hepatitis B. In contrast to ordinary HCC, where 8 % of cases were associated with the alternative lengthening of telomere (ALT) phenotype (a telomerase-independent mechanism of telomere maintenance), ALT positivity was found in 92 % of chromophobe HCC (Wood et al. 2013).

Pathology

Chromophobe HCC is composed of cells with a smooth chromophobic cytoplasm and of small clusters of tumor cells with marked nuclear atypia that are abruptly separated from the bland chromophobe background, a phenomenon termed abrupt focal anaplasia (Wood et al. 2013).

Oncocytic and Oxyphilic Hepatocellular Carcinoma

Introduction

In contrast to fibrolamellar hepatocellular carcinoma/FL-HCC, which is a well-established hepatic tumor entity characterized by large oxyphilic cells and oncocytes, other primary oxyphilic or oncocytic hepatocellular neoplasms are exceedingly rare (Figs. 5 and 6).

More common are bile duct neoplasms with oncocytic features, treated in a separate chapter.

Oncocytic lesions are characterized by epithelial cells showing an abundance (“proliferation”)

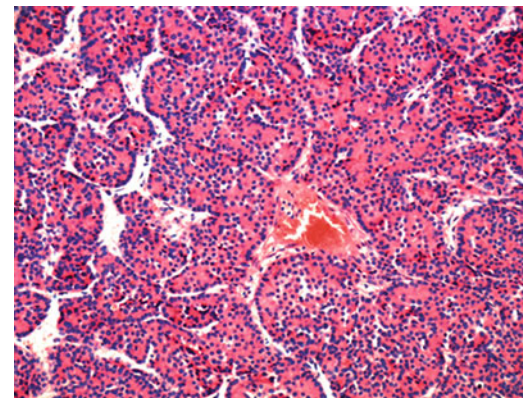

Fig. 5 Rare trabecular hepatocellular carcinomas show predominance of tumor cells with a strongly eosinophilic cytoplasm (oxyphilic hepatocellular carcinoma; hematoxylin and eosin stain)

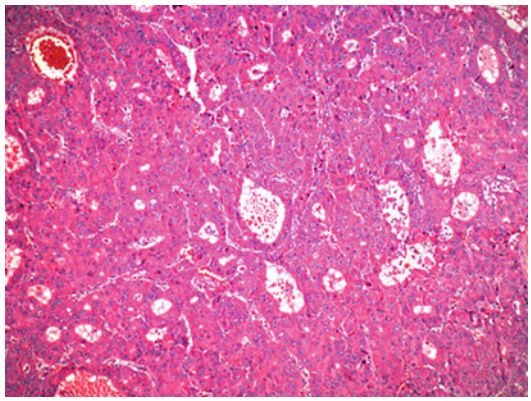

Fig. 6 The cells of this oxyphilic mixed trabecular and acinar hepatocellular carcinoma are enlarged and reminiscent of mitochondria-rich cells/oncocytes (hematoxylin and eosin stain)

of mitochondria (mitochondriosis), the oncocytes. Oncocytes can arise in numerous tissues and organs, both in nonneoplastic and neoplastic cells (reviews: Tallini 1998; Guaraldi et al. 2011). The presence of oncocytes in the liver has been documented for various hepatic conditions in several reports (Sternlieb 1979; Gerber and Thung 1981; Altmann 1990; Tanikawa et al. 2007). Liver cells rich in mitochondria have also been termed oxyphilic granular hepatocytes (Lefkowitch et al. 1980). The use of the term, oxyphilic, for cells that are in fact oncocytes may cause some misunderstandings. True epithelial oxyphilic cells possess their strongly eosinophilic features due to a marked increase of smooth endoplasmic reticulum rather than an increase in mitochondria. Oncocytic hepatocytes reveal mitochondrial DNA dysfunction characterized by significant deficiencies of mtDNA and mtDNA-encoded respiratory chain enzymes (Müller-Höcker 1998; Tanji et al. 2003).

Pathology of Oncocytic Hepatocellular Carcinoma

Only very few bona fide oncocytic tumors primary to the liver have been reported (Baithun and Pollock 1983; El Hag et al. 1994; Fukunaga et al. 1996; Papotti et al. 1999). The tumor described by Baithun and Pollock (1983) was found in the non-cirrhotic liver of a 51-year-old female. Macroscopy showed a well-circumscribed tumor measuring up to 20 cm in diameter, with a central fibrous scar. Histologically, the tumor cells were polygonal-shaped oncocytes embedded in a fibrous stroma. The histology does not seem to correspond to FL-HCC. The case reported by El-Hag et al. (1994) was an 18 cm-sized tumor located to the right liver lobe, in the absence of cirrhosis. Macroscopically, in another reported case, a large tumor occupying almost the entire left lobe was detected in a 67-year-old man with liver cirrhosis. Histopathologically, the tumor consisted of exclusively large, granular eosinophilic cells with moderate nuclear atypia and occasional mitotic figures. The growth pattern was mixed trabecular and pseudoglandular, without lamellar fibrosis. The tumor cells contained numerous, PAS-negative globular hyaline bodies. Ultrastructurally, the cells were rich in mitochondria with electron-dense, ovoid or polyhedral inclusions (Fukunaga et al. 1996). Sometimes, HCC with oncocytic features is identified in its metastases, e.g., in the kidneys, where such a tumor can mimic renal oncocytoma (D'Antonio et al. 2010).

Precursor Lesions with Oxyphilic or Oncocytic Features

Foci of altered hepatocytes (FAH) regarded as very early lesions in the hepatic carcinogenic pathway sometimes show cells with oncocytic features (Su et al. 1997).

Differential Diagnosis

Differential diagnosis mainly includes fibrolamellar hepatocellular carcinoma, oncocytic biliary neoplasms (Tabibian et al. 2008), metastatic oncocytic tumors including oncocytic adrenocortical carcinoma (Argyriou et al. 2008), metastasizing oncocytic endocrine tumors of the pancreas (Volante et al. 2006), and rare forms of

angiomyolipoma of the liver with oxyphilic cell change. Several reports document metastases of renal oncocytoma to the liver (Timbal and Rodier 1984; Aslam et al. 2009), and hepatic metastases of the oncocytic thyroidal Hürthle cell carcinoma have been described (Salvatori et al. 2004). Also the uncommon bile duct adenoma with oncocytic features may cause diagnostic difficulties in biopsies (Arena et al. 2006).

Pigmented Hepatocellular Carcinoma

Introduction

Most instances where a pigment is found in epithelial tumors of the liver are caused by Dubin-Johnson syndrome (DJS; OMIM 237500). This autosomal recessive disorder was independently described twice in the same year, 1954 (Dubin and Johnson 1954; Sprinz and Nelson 1954). The term, black liver disease, was coined in 1958 (Smiley et al. 1958). DJS is a rare benign hereditary (autosomal recessive) disorder of bilirubin metabolism, characterized by conjugated hyperbilirubinemia, a darkly pigmented liver, and the presence of an abnormal pigment in hepatocytes. The disorder is mapped to chromosome 10q24 and is caused by absent activity of a critical conjugate export pump of the hepatocyte, the MRP2 glycoprotein (see below). Several animal models of DJS are known, including mutant Corriedale sheep, and TR- and EHBR mutant rats.

Black Livers and Benign Black Liver Tumors: Dubin-Johnson Syndrome and Related Pigments

Livers of patients with DJS are characterized by the accumulation of a coarse, dark-brown pigment in the vicinity of the canalicular pole of hepatocytes (Arias and Blumberg 1979). The pigment is much darker than ordinary lipofuscin and lacks the golden color of hemosiderin. The pigment stains with the Fontana-Masson stain and has, therefore, been compared with melanin ("melanin-like") but is clearly different from melanin (Swartz et al. 1987).

Histochemically and immunohistochemically, the DJS pigment is very close to the pigment in pseudomelanosis coli (Park et al. 1990). Ultrastructurally, accumulation of membrane-bound, electron-dense lysosomal granules within the cytoplasm of hepatocytes is observed. These bodies are mostly located in the vicinity of the canalicular pole, as is to be expected from light microscopic findings. The same pigment is found in Kupffer cells which phagocytose it after hepatocyte decay (Muscatello et al. 1967; Baba and Ruppert 1972; Ueno et al. 1998; Sobaniec-Lotowska and Lebensztejn 2006). It has been reported that postoperative regeneration of the DJS liver is not different from that of normal livers according to portography and hepatic scintigraphy finings (Nakamura et al. 1984).

Exceptionally, black livers develop in the absence of DJS. In a patient with a black liver, massive accumulation of coarse brown granules was detected in the absence of Schmorl stain positivity of hepatocyte pigment and absent MRP2 mutation. The MRP2 protein was immunolocalized to the canalicular membrane in this liver (Kobayashi et al. 2004). Pigmented liver cell adenoma with extensive deposition of a DJS-like pigment in the pericanalicular cytoplasm of adenoma cells has been observed in patients without DJS (Bernard et al. 2000; Hasan et al. 2000; Ferko et al. 2003; Hechtman et al. 2011; Masuda et al. 2011; Koea and Kua 2012; Vij et al. 2012). In the male patient described by Bernard and coworkers (2000), numerous black tumors of different sizes were seen at laparoscopy, histologically representing liver cell adenomas. The expression of the canalicular multispecific organic anion transporter was decreased in the tumors but normal in the adjacent liver, thus ruling out DJS. In the 28-year-old female patient reported by Ferko et al. (2003), pigmentation of hepatocellular adenoma was interpreted to be caused by long-term use of phenobarbital. In one case, hepatocellular carcinoma developed within a pigmented telangiectatic adenoma with nuclear beta-catenin expression (Hechtman et al. 2011).

Pigmented Hepatocellular Carcinoma

Roth and coworkers (1982) described a unique, largely black hepatocellular carcinoma discovered in a patient without evidence of DJS, i.e., a situation similar to that of black liver cell adenomas. In this 62-year-old male with a mass in the right liver lobe, hepatic arteriogram showed a moderately vascular, 120-cm single intrahepatic tumor. An extended right hepatic lobectomy was performed. The resection specimen revealed a well-circumscribed, bulging tumor with a maximum diameter of 13 cm in a non-cirrhotic liver of normal color. On cut surfaces, about 85 % of the tumor was charcoal gray and the rest tan-brown. An incomplete fibrous capsule was present and fine fibrous strands subdivided the tumor into nodular regions. Foci of necrosis and old hemorrhage were present. Histology disclosed a well-differentiated HCC with a microtrabecular and solid growth pattern. The tumor cells were eosinophilic, with occasional multinucleated forms. Intracytoplasmic, coarse and dark-brown pigment granules were present in the tumor cells and in few sinusoidal cells (probably macrophages). Ultrastructurally, the pigment granules were membrane-bound particles containing clumps of electron-dense material similar to the granules seen in DJS.

Pigmented Hepatocellular Carcinoma, Not Otherwise Specified

Ultrastructural studies have shown that HCCs may contain the endogenous pigment, lipofuscin, in the cytoplasm (Ichida 1983). Ye and coworkers described an HCC characterized by the accumulation of a not otherwise specified pigment, occurring in a 42-year-old woman with a history of 25-year oral contraceptive use (Ye et al. 1999).

Nonpigmented Hepatocellular Carcinoma in Dubin-Johnson Syndrome

Several reports document the development of hepatocellular carcinoma in DJS, so far exclusively from Japan (Okamura et al. 1980; Sakamoto et al. 1987; Sano et al. 1988; Mori et al. 1991; Adachi et al. 1992; Kajikawa et al. 1993; Yakushiji et al. 1995; Ueno et al. 1998; Shikada et al. 2004). Adachi and coworkers (1992) reported that during an observation decade in Japan, 57 patients with DJS had associated cholelithiasis (14 %), chronic hepatitis (10 %), or HCC (3 %). Where documented, the macroscopic color of the tumors is described as pale or yellow, i.e., not like the adjacent darkly pigmented liver (Ueno et al. 1998). Apart from HCC, DJS is rarely associated with multiple hepatic cavernous hemangiomas (Li et al. 2013).

Hepatocellular Carcinoma with Mucin Production

Introduction

Combined hepatocellular and cholangiocellular carcinomas are defined as primary hepatic malignancies that show both hepatocellular and cholangiocellular components in an intricate mixture and usually a stromal reaction accompanying the cholangiocarcinoma components. Much less common are primary liver carcinomas with a dual phenotype, i.e., having a cell lineage expressing both hepatocyte and cholangiocyte features in the same cells, and not representing primary liver of intermediate phenotype. Such a situation, termed hepatocellular carcinoma (HCC) with mucin production has been first described in 2009, based on a 53-year-old Korean man with liver cirrhosis showing on CT a 10 × 9.8 cm heterogeneously enhancing mass in the right liver lobe (Lee et al. 2009). Based on the distinct histopathology of this tumor (see below), the authors classified the lesion as liver tumor of dual differentiation, different from combined HCC/CC.

Pathology

The resection specimen described by Lee et al. (2009) displayed a poorly circumscribed, firm, white to pink nodular tumor. Histopathology

revealed HCC with solid and trabecular components and extensive geographical necrosis. One part of the tumor consisted of hepatoid cells as found in ordinary HCC, while another part was composed of thick trabecules or irregularly shaped tumor island filled with compact or loose mucin-producing glands. These glands consisted of columnar cells with eosinophilic cytoplasm and apical microvilli, and there was intervening desmoplastic stroma. Some of the glandular cells contained PAS-positive mucin bodies, creating signet-ring cells. Immunohistochemically, tumors cells of both trabecular and glandular components were CK19-positive. In some glandular portions, positivity for CK7, EMA, and CEA was noted.

Pleomorphic Giant Cell-Rich Hepatocellular Carcinoma

Introduction

The pleomorphic giant cell-rich variant of hepatocellular carcinoma (PG-HCC) was first described in 1973 (Anthony 1973). Very few cases have been reported since (Chetty et al. 1990; Korkolis et al. 2009; Hu et al. 2010). The tumor is histologically characterized by a pleomorphic phenotype of the neoplastic cells and the presence of numerous highly atypical multinucleated giant cells of the non-osteoclast-like type. Multinucleated giant cells are a features of many HCCs and are a hallmark of Edmondson-Steiner grade 3 lesions, but here they usually occur in smaller numbers and in a focal distribution pattern and are less pleomorphic, while in PG-HCC, the giant cells are numerous, diffusely distributed, and highly pleomorphic.

Pathology

In one case, the tumor was described as an irregularly infiltrative, multifocal, grayish white tumor with necrosis and hemorrhage. The neoplasm had developed in a cirrhotic liver (Vijay et al. 2011). The neoplastic cells are large and pleomorphic and show an abundant eosinophilic cytoplasm. These cells contain one to few highly atypical nuclei with abnormal mitotic figures. These cells are arranged in nests or tiny nodules rather than plates/trabecules, and also solid growth patterns may occur. Numerous tumor giant cells are present, characterized by multiple pleomorphic and in part bizarre nuclei with prominent nucleoli. The cytoplasm of these giant cells may contain cell debris and remnants of phagocytosed neutrophils (Vijay et al. 2011).

Immunohistochemistry

The neoplastic cells are immunoreactive for cytokeratins, vimentin, and alpha-fetoprotein. In contrast to hepatic giant cell tumor with osteoclast-like giant cells, the multinucleated cells are not reactive for CD68 (Vijay et al. 2011).

Differential Diagnosis

The most important differential diagnosis consists of other HCCs showing giant cells, in particular grade 3 tumors which are known to have multinucleated giant cells. Pleomorphic giant cell carcinoma occurs in the pancreas and can metastasize to the liver. The latter tumor can be distinguished from primary PG-HCC by the different morphology of the hepatoid cells in the latter and by immunoreactivity for hepatocyte markers and AFP. Osteoclast-like giant cell tumor of the liver has a clearly different phenotype, the multinucleated cells lacking pleomorphism, with highly regular nuclei, and the cells being CD68-positive.

Spindle Cell Hepatocellular Carcinoma

Introduction

Carcinomas with formation of spindle cells are rare lesions in the hepatobiliary tract and are more often found to belong to the cholangiocarcinoma group and in the gallbladder, whereas most hepatocellular carcinomas with spindle cells

have been classified as carcinosarcomas. Spindle cell carcinomas (also termed metaplastic carcinomas, biphasic carcinomas, or biphasic sarcomatoid carcinomas; Nappi et al. 1994) are well recognized in the aerodigestive tract, in particular involving the oral cavity, the larynx, the thyroid gland, the lungs, and the esophagus. Generally, it seems that spindle cell formation is more common in squamous carcinomas than in adenocarcinomas. In spindle cell carcinomas *sensu strictiori* (metaplastic carcinomas), vimentin reactivity is a consistent feature, but reactivity for several cytokeratins and for epithelial membrane antigen (EMA) is more variable, probably depending on cell differentiation (Adem et al. 2002). It is evident that such developments may require that one redefines what, e.g., a carcinosarcoma is, this term still based on morphologic findings and numerous interpretations dating from the pre-immunohistochemistry era.

Spindle cell carcinomas of the liver have been reported sporadically or in relatively small series, using several terms to designate these uncommon lesions (review: Maeda et al. 1996). Craig et al. (1989) designated sarcomatoid hepatocellular carcinoma as spindle cell HCC. Others employed the term, spindle *variant* of HCC (Ishak et al. 1994). Kojiro and coworkers (1989) classified the sarcomatous appearance of some HCCs into two types: those consisting mainly of spindle-shaped cells ("spindle cell type") and those consisting of tumor cells that lacked mutual contact ("free cell type"). Based on these earlier discussions, Maeda and coworkers, in their study of 15 cases, designated HCCs with a spindle-cell-type *sensu strictiori* (Kojiro et al. 1989) as spindle cell hepatocellular carcinoma (SpHCC). Although carcinosarcomas of the liver are treated in a separate chapter, liver carcinomas with a predominantly spindled mesenchymal component are here discussed separately, under the use of Maeda's terminological proposition, SpHCC.

Clinical and Imaging Features

The clinical und imaging presentations of SpHCC do not differ from those of other HCCs. The biology of disease has not been clarified; specifically, it is clearly known whether SpHCCs behave similar or in a different way in comparison with ordinary HCCs, although few informations suggest that SpHCCs may behave in a more favorable manner (Chedid et al. 1999).

Histopathology

Relatively few examples of HCCs entirely composed of spindle cells (SpHCC *sensu strictiori* or Kojiro's spindle-cell-type HCC; Kojiro et al. 1989) have been reported (Andreola et al. 1987; Chan and Leung 1988; Kojiro et al. 1989; Ishijima et al. 1995; Maeda et al. 1996; Han et al. 1998; Chedid et al. 1999; Maruyama et al. 2002). In most other situations (the second group of spindle cell HCCs), the tumors exhibit foci where the hepatocyte-like tumor cells exhibit transitions to populations of fusiform or spindle cells, or foci of spindle cells are admixed with trabecular and/or pseudoglandular structures (Nam et al. 2006; Yoshida et al. 2013). This complex situation, which may reflect varying effects of EMT, is illustrated by the largest published clinicopathologic and immunohistochemical analysis which described the features of 15 cases (Maeda et al. 1996). The patients showed a mean age at presentation of 58.7 years, and all except one were males. Tumor sizes ranged from 2.1 to 14.0 cm (mean, 6.2 cm), and all tumors except one were located to the right liver lobe. Most tumors were grossly whitish, hard masses demonstrating foci of necrosis and hemorrhages. Two tumors were of the pedunculated growth pattern. Histologically, a gradual transition between the spindle cell component and ordinary HCC was present in some cases. In other cases, however, the spindle cell component and the ordinary HCC component were present separately, or the tumor cells demonstrated features of both spindle cells and ordinary HCC cells. In this series, the spindle cell component represented more than 10 % of the viable tumor in all cases. The tumor cells in the spindle cell component were positive for vimentin in 62 % of the tumors, and almost two thirds of the

tumors showed spindle cells which were also cytokeratin (CAM 5.2)-positive (Maeda et al. 1996).

An unusual and in part spindle cell liver neoplasm was reported by Schmid and coworkers (1979). The patient, a 36-year-old female, had a large mass in her right liver lobe. The surgical specimen contained a spherical tumor, 8.5 × 7.0 cm; a portion of this tumor reached the dome of the liver. This mass, macroscopically well-circumscribed, was mainly composed of a whitish-gray and moderately form tissue with small cystic areas. The surrounding liver was compressed by the tumor. Histologically, the tumor tissue was well demarcated, without sinusoidal infiltration. The lesion consisted of an association of elongated spindle cells, a diffuse and focal infiltration of inflammatory cells (mainly lymphocytes and plasma cells), and large cells, which were extremely pleomorphic, often multinucleated, and some of which were elongated with a ribbon-shaped appearance like skeletal muscle fibers. At the periphery, inflammatory cells were also conspicuous. Ultrastructurally, the neoplastic cells exhibited the features of hepatoid epithelial cells. A similar malignant hepatic spindle cell tumor containing large and multinucleated tumor giant cells was reported Grigsby and coworkers (Grigsby et al. 1987). In this young female patient with a long history of oral contraceptive intake, a liver cell adenoma had developed within this spindle cell carcinoma. The hepatectomy specimen showed a dominant mass of 8.2 cm maximum diameter, surrounded by several smaller satellite lesions. Within this dominant spindle cell tumor part was an oval, 0.9-cm-diameter, well-encapsulated nodule, which was the liver cell adenoma (Grigsby et al. 1987).

This second group has been designated by a variety of terms, including carcinosarcoma or hepatocellular carcinoma with sarcomatous change or sarcomatous appearance (Kakizoe et al. 1987; Tsuji et al. 2001; Koda et al. 2003). Two tumors designated by the latter terms were of interest insofar as immunohistochemistry showed the spindle cells to be positive for both vimentin and keratin (Ellis et al. 1988; Tsuji et al. 2001; Koda et al. 2003), but in one instance, this was also the population later found in metastatic lesions (Koda et al. 2003). In one case, electron microscopic examination showed desmosomes and Mallory-Denk bodies in the spindle cells, taken as an argument for the diagnosis of HCC (Andreola et al. 1987). Neoplasms with features of carcinosarcoma are discussed in more detail in a separate paragraph.

Differential Diagnosis

The histologic differential diagnosis includes several other tumors in the liver that contain a spindle cell population, i.e., carcinosarcomas (review: She and Szakacs 2005), primary or secondary mesenchymal tumors of the liver, inflammatory pseudotumors, and unusual situations such as primary hepatic lymphoma with spindle cell components (Hayashi et al. 2006).

Pathogenesis

It is currently thought that such tumors are monoclonal neoplasms originating from a putative stem cell giving rise to both a frankly epithelial and a spindle cell lineage. The field of carcinomas with spindle cells has generally become more complex based on the possibility of defining cell lineages involved in a much more reliable way, owing to immunohistochemistry and other modern methods. Two concepts have basically altered our understanding of such neoplasms: first, the finding that spindle cells may either show a mesenchymal lineage or may clearly express epithelial markers and addition to mesenchymal markers and, second, the phenomena related to mesenchymal-epithelial transition (MET; epithelial-mesenchymal transition, EMT; Doble and Woodgett 2007; Guarino et al. 2007; Zavadil et al. 2008). MET/EMT has been proposed as a histogenetic mechanism for the development of sarcomatoid carcinomas. The phenomenon has been studied in some detail for squamous cell carcinomas with a spindle cell lineage (Iwata et al. 2009), and markers for detecting several cell lineages in sarcomatoid carcinomas showing

features of MET/EMT have been analyzed (Cates et al. 2008). In these and other tumors, several factors regulate the switch between morphologically epithelial and spindle cells, including the catenin-cadherin signaling pathway; the transcription factors Snail-1, Slug, E47, twist, and single-minded-2/SIM2; notch signaling pathway; hedgehog signaling; stromal cell-derived factor-1alpha/CXCR4; and the Aurora-A kinase (Usami et al. 2008; Wan et al. 2008; Zidar et al. 2008). These factors form an intricate signaling network within EMT pathways. Snail and slug transcription factors promote EMT via beta-catenin-T-cell-factor-4-dependent expression of TGF-beta3 (Medici et al. 2008). Slug-induced EMT alters the expression profile of receptor tyrosine kinases, including discoid domain receptor 2 (Maeyama et al. 2008).

Ossifying Hepatocellular Carcinoma

Introduction

Ossification of liver tumors is a well-known phenomenon in mixed epithelial and mesenchymal hepatoblastomas and certain rare mixed malignant tumors occurring in adult patients. Exceptionally, ossification develops in hepatocellular carcinoma (Leger et al. 1980; Maeda et al. 1986).

Pathology

In one patient, ossification was present in the stroma of a hepatocellular carcinoma that had arisen in a patient with sarcoidosis (Leger et al. 1980). The patient described by Maeda and coworkers (1986) was a 54-year-old man suffering from liver cirrhosis. CT of the liver revealed localized fine conglomerated calcifications in the right liver lobe and arteriography suggested hepatocellular carcinoma. Autopsy showed an encapsulated tumor, 4.5 cm in diameter, with variegated hemorrhagic and necrotic areas. Histology showed partially necrotic hepatocellular carcinoma predominantly of the trabecular type, with focal acinar differentiation and bile production. In a localized area within the tumor, there were bony trabecules. These were surrounded by relatively small immature malignant cells associated with osteoid. Ossification is a feature of part of mixed epithelial and mesenchymal hepatoblastomas of the adult (Altmann 1992), an intriguing group of neoplasms further discussed elsewhere.

Pathogenesis

The pathogenic pathways leading to ossification in liver tumors are not elucidated. Calcification of neoplastic tissue, found in rare hepatocellular carcinomas (Friedman 1988) or hepatic mixed malignant tumors (Ludwig et al. 1975), may induce secondary bone tissue formation, as, e.g., observed in certain forms of ectopic ossification. In hepatocellular carcinomas showing significant calcification, this alteration is sometimes present in the tumor stroma (Moenandar 1974). Ossification occurring in primary epithelial liver tumors has to be distinguished from that in the rare primary osteosarcomas of the liver (Kitayama et al. 1995).

Solitary Large Hepatocellular Carcinoma

Introduction

Large hepatocellular carcinoma (HCC) is often considered to represent advanced disease and to frequently consist of unresectable neoplasms. Recently, a unique type of HCC has been identified, characterized by solitary large tumors with a good outcome after hepatic resection (solitary large HCC, SL-HCC; Yang et al. 2009). In comparison with nodular HCC, SL-HCC showed a better outcome. Disease-free survival of SL-HCC was similar to that of small HCC, whereas poorer overall survival was observed in SL-HCC patients than in patients with small HCC, accompanied by more frequent vascular invasion, more advanced TNM stage, and potentially higher Edmondson-Steiner grade (Zhou et al. 2011).

Pathology

SL-HCCs are solitary bulky tumor masses that usually show an expanding growth pattern. These large neoplasms can show extensive central necrosis. Otherwise, the gross and histologic features do not differ from HCC of smaller size.

Hepatocellular Carcinoma with Progenitor Cell Features

14

Contents

Abstract

Subsets of hepatocellular carcinoma (HCC) can harbor hepatic progenitor cells or stem-like cells (HCCs with progenitor cell features). Stem/progenitor cells were also identified in combined hepatocellular-cholangiocarcinoma. Stem/progenitor cells detectable in HCCs share a marker profile with normal hepatic stem cells, but tumor cells may be deficient in part of the markers. For most progenitor cell features in HCC, the biologic significance is not yet clarified. However, there is strong evidence that expression of cytokeratin 19 as a stemness feature is associated with a high-risk biology of these neoplasms. The incidence of marked cytokeratin 19 expression in HCC cells is only partially known, but may amount to 10 %. Cytokeratin 19 expression in HCC may occur in combination with other stem cell-associated markers and is associated with expression of proteins involved in epithelial-to-mesenchymal transition. Cytokeratin 19 expression in HCCs predicts higher serum alpha-fetoprotein levels, tumor angiogenesis, accelerated tumor progression, early recurrence, and poorer survival.

Introduction

There is increasing evidence that certain subsets of hepatocellular carcinomas (HCCs) harbor cell populations with features of hepatic progenitor

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_14

cells or stem-like cells (Mikhail and He 2011; Tong et al. 2011; Ji and Wang 2012; Behnke et al. 2013; Sainz and Heeschen 2013; Hashimoto et al. 2014; Yamashita and Kaneko 2014; Ye et al. 2014). Stem/progenitor cells are also detectable in combined hepatocellular-cholangiocarcinomas (Ikeda et al. 2013; Sasaki et al. 2014), a phenomenon that influenced modern classifications of liver cancer (review: Lo and Ng 2013). As described in more detail in the chapter referring to hepatic stem cells, progenitor cells present in certain HCCs express a typical pattern in markers, among which CD133, CD90, epithelial cell adhesion molecule(EpCAM), and cytokeratin 19 are the most intensively studied (Jia et al. 2013; Ma 2013; Table 1).

The significance of progenitor cell features of HCCs is not fully clarified. In particular, it is not yet fully established whether the presence of progenitor cells in HCCs is critically related to an origin of these neoplasms from hepatic stem or stem-like cells (tumor-initiating cells (TICs)) or whether progenitor cells form a secondary population of cells with different functions (Lee et al. 2014). It has been proposed that liver progenitor cells present in various subtypes of HCCs are master regulators of HCC initiation, tumor spread, and progression, but this issue needs further in-depth studies (Wu et al. 1996; Oishi et al. 2014; review: Lo and Ng 2013). Markers found in stem or progenitor cells often appear as embryonic markers in cells of cancers undergoing dedifferentiation. The presence of progenitor cells in HCCs is, in fact, not necessarily a constitutive feature, but might represent a phenomenon that is subject to modifications in the course of tumor progression. For example, inflammatory cytokines, signal molecules produced by various cells in the tumor microenvironment, can promote the retrodifferentiation of tumor-derived hepatocyte-like cells to progenitor cells (Dubois-Pot-Schneider et al. 2014). The expansion of CD44 (+) HCC cells, i.e., cells with progenitor features, is promoted by interleukin-6 produced by tumor-associated macrophages (TAMs) located within HCCs via a signal transducer and activator of transcription 3 (STAT3)-dependent mechanism (Wan et al. 2014). TAMs can also promote stem cell-like properties in HCC through transforming growth factor-beta1-induced epithelial-to-mesenchymal transition (Fan et al. 2014). However, the presence of certain progenitor cell markers in HCCs affects the biology of disease, in that HCCs with progenitor cell features may show a high-risk biology and aggressive clinical behavior.

Stemness Markers Expressed in HCCs and Their Significance

Epithelial Cell Adhesion Molecule (EpCAM)

EpCAM (CD326) is a cell surface protein that is present on a subset of normal epithelial and overexpressed in numerous cancers, being a marker of progenitor cells and tumor-initiating cells (review : Imrich et al. 2012). Part of HCCs expresses EpCAM, and this adhesion molecule is

also expressed in precursor lesions of HCC, including dysplastic nodules (Bae et al. 2012a). EpCAM expression was more frequently detected in HBV-associated liver cancers (Kimura et al. 2014). Expression of EpCAM in HCCs defines a distinct progenitor cell signature in these cancers, partially associated with the presence of other stemness markers, such as C-Kit and cytokeratin 19, and an activated Wnt/beta-catenin pathway. Conversely, EpCAM(−) HCCs represent a proliferation of cells that resemble mature hepatocytes. EpCAM(+) and EpCAM(−) HCCs could further be subclassified based on the level of AFP production (Yamashita et al. 2008, 2009). The switch between HCC cells with these progenitor cell features and cells with a mature hepatocyte-like phenotype is in part regulated by microRNAs, especially microRNA-122. HCCs with an EpCAM(+)AFP(+) signature contain self-renewing cell populations that can elicit highly invasive cancers in immunocompromised mice (Yamashita et al. 2009; Terris et al. 2010). Similar to HCCs expressing CK19, tumors with high levels of EpCAM showed a more aggressive course that HCCs without expression of this marker. Specifically, HCCs with marked immunoreactivity for EpCAM were associated with early recurrence and poor overall survival and recurrence-free survival (Guo et al. 2014; Xu et al. 2014), suggesting a potential role of EpCAM-targeted therapy (Ogawa et al. 2014). In one investigation, high levels of EpCAM expression were associated with elevated peritumoral ductular reactions, suggesting upregulation of progenitor cell activation (Xu et al. 2014).

CD133

CD133 is a marker for progenitor cells in several cancers, including HCC. The prevalence of CD133 expression in HCCs varies considerably among tumor collections studied so far (Piao et al. 2012). In HCCs occurring in an area endemic for HBV infection, 15.6 % of tumors were CD133(+), and CD133 expression was negatively correlated with the presence of HBsAg (Yeh et al. 2009). Generally, CD133 expression seems to be more common in HBV-associated HCCs than in HCV-associated tumors (Yilmaz et al. 2014). As with EpCAM expression, the presence of CD133(+) cells in HCCs predicted poor disease-free survival independently of p53 expression (Yeh et al. 2009; Guo et al. 2014; Yilmaz et al. 2014), and CD133(+) stem cells promote repeated recurrence of HCC after liver transplantation (Toshima et al. 2013).

CD90

Part of HCCs shows cell populations that express CD90/Thy-1 (Sukowati et al. 2013). CD90(+) and EpCAM(+) cells reside distinctively, whereby CD90(+) cells have features of vascular endothelial cells and enhance the motility of EpCAM(+) epithelial cancer cells (Yamashita et al. 2013). CD90(+) HCCs showed a more prominent stromal reaction with increased alpha-smooth muscle actin reactivity (Sukowati et al. 2013). HCCs with CD90(+) progenitor cell subsets showed a higher rate of early recurrence and a progression phenotype (Guo et al. 2014).

Other Stem/Progenitor Cells Markers

Expression of the pluripotency transcription factor, Nanog, in HCC is associated with poor differentiation and worse clinical outcome. Only a minority of cells in HCC are Nanog(+), and these cells show enhanced ability of self-renewal, clonogenicity, and tumor initiation, typical features of stem cells (Shan et al. 2012). Subsets of HCC cells express OV6, a marker of hepatic progenitor cells. The presence of OV6-positive cells is associated with tumor-initiating cells, augmented invasion, and metastasis potential (Yang et al. 2012). CD44, a protein associated with vimentin expression in HCC cells, may confer stemness features to HCCs via its known role as a promoter of epithelial-to-mesenchymal transition(EMT) (Mima et al. 2012). A progenitor cell marker present in certain liver cancers is nestin. Nestin-positive hepatic cells are considered to be the source of liver cancer cells in response to

lineage-specific mutations that target Wnt and Notch signaling, whereby expression of nestin is restricted by p53 in an Sp1/3 transcription factor-dependent manner. The loss of wild-type p53 expression, a common feature in diverse liver cancers, would therefore augment nestin expression and drive a progenitor cell pathway (Tschaharganeh et al. 2014). HCC cells with progenitor features can express intercellular adhesion molecule 1 (ICAM1) in humans and mice. ICAM1 is also present in circulating tumor cells (Liu et al. 2013). Another adhesion molecule that characterizes HCCs with progenitor cell features is neural cell adhesion molecule (NCAM). In one investigation, NCAM was detectable in 8.3 % of resected HCCs, and high NCAM levels in tumors were associated with an intrahepatic metastasis phenotype (Tsuchiya et al. 2011a). A subset of HCCs revealed expression of the oncofetal gene SALL4 (Sal-like protein 4), a zinc finger transcription factor that is present in fetal hepatocytes but is silenced in the adult liver. The presence of SALL4 in part of HCCs therefore represents an abnormal reexpression phenomenon that indicates progenitor cells and confers an aggressive behavior (Oikawa et al. 2013; Yong et al. 2013). In vitro, overexpression of SALL4 in cultured HCC cells resulted in increased proliferation, correlating with an increased expression of cytokeratin 19 and EpCAM (Oikawa et al. 2013). In progenitor-like cells of recurrent HCCs, expression of ezrin was found (Okamura et al. 2008). Expression of the transcription factor OCT4 (octamer binding transcription 4) in HCC cells is associated with low differentiation and tumor recurrence and is a stem cell lineage marker (Dong et al. 2012). Fetal liver cells have the surface antigen, Delta-like 1 (Dlk-1), which is then lost in mature adult hepatocytes. Dlk-1 is also expressed in several cancers, including HCC, and is a marker of HCC progenitor cells (Yanai et al. 2010; Nishina 2012; Xu et al. 2012). The hepatic oncofetal protein, granulin-epithelin precursor (GEP), which is expressed in fetal hepatocytes, but not in mature hepatocytes, is a protein that is co-expressed with proteins labeling stem cells, including EpCAM, CD133, Nanog, and Dlk-1. Expression of GEP defines a subset of hepatic cancer stem cells (Cheung et al. 2011). HCC cells with progenitor cell features can express Toll-like receptor 4 (TLR4), which acts as a receptor for lipopolysaccharides. The presence of TLR4 was associated with increased invasiveness and migration capability of HCC cells (Liu et al. 2015). TLR4 expression renders CD133(+) tumor-initiating cells tumorigenic, whereby TLR4/Nanog activation causes p53 protein degradation through phosphorylation of the protecting protein NUMB and its dissociation from p53 by the oncoprotein TBC1D15 (Machida et al. 2015). Zinc finger protein X-linked (ZFX), a member of the ZFY family, is a widely expressed stem cell marker that is also present in subsets of HCC cells, where it promotes self-renewal, colony formation ability, and proliferation (Lai et al. 2014). ATP-binding cassette subfamily G member 2 (ABCG2) is expressed in cancer stem cells of a minor subgroup of HCC and is associated with an aggressive phenotype (Zhang et al. 2013). A marker of hepatic progenitor cells that are involved in the development of embryonal liver cancers such as hepatoblastomas is the CBP/P-300 interacting transactivator 1 (CITED1) (Murphy et al. 2012).

Expression of Cytokeratin 19 in HCC as a Stemness Feature Associated with High-Risk Biology

Introduction

Expression of cytokeratin 19 (CK19) is a feature typical for many adenocarcinomas, in particular also cholangiocarcinomas, while it was formerly held that CK19 is not a feature characterizing hepatocellular carcinomas (HCC). Several types of cytokeratins are present in HCCs (Wee 2006) and in part relate to prognosis and metastatic potential. This specifically holds true for the expression of CK19 by hepatocellular malignancies. It has been proposed that HCC expressing a cholangiocyte phenotype is a novel subtype of HCC with highly aggressive behavior (see below). Such tumors have been termed, "dual-phenotype HCC/DPHHCC" (Lu et al. 2011).

However, expression of CK19 in HCCs not only represents the acquisition of a biliary phenotype but is also related to stemness acquisition.

CK19 Expression in HCCs Is a Stemness-Related Marker

It has been found that a subset of HCCs is characterized with the expression of stemness-related markers, including CK19 (Fujii et al. 2008; Kamohara et al. 2008; Bae et al. 2012b). Durnez and coworkers found a CK19(+)/CK7(−) phenotype in 6 % of HCCs, while a CK19(+)/CK7(+) was identified in 10 %. The distinct features of these HCC subsets suggested a progenitor cell origin (Durnez et al. 2006). In one investigation of these neoplasms, CK19 was most frequently expressed in combination with at least one other stemness-related marker, such as CD133, EpCAM, and c-kit. HCC expressing CK19 in part also expressed Yes-associated protein 1 (YAP1), a potential oncogene known to promote stem cell proliferation (Kim et al. 2013a). Expression of CK19 was also significantly associated with expression of proteins characterizing epithelial-to-mesenchymal transition (EMT), including vimentin, S100A4, uPAR, and ezrin (Kim et al. 2011). There is a significant inverse correlation between the expression of the organic anion transporter peptides (OATP) 1B1 and 1B3 and of CK7 and CK19, in that all HCCs expressing OATP 1B1/1B3 were CK7/CK19 negative (Vasuri et al. 2011).

CK19 Expression in HCC as a Feature Predicting High Risk

CK19 expression in HCCs predicts higher serum AFP levels, tumor angiogenesis, accelerated progression, early postoperative recurrence, and poorer survival (Uenishi et al. 2003; Yang et al. 2010; Kim et al. 2011; Yamada et al. 2011; Lee et al. 2012; van Malenstein et al. 2012; Wang et al. 2012; Greenhill 2013; reviews: Izumi 2012; Kim and Park 2014). CK19 expression in this neoplasm is a significant predictor for overall survival. In a study on 50 HCC patients, CK10 alone or in combination with CK19 expression was associated with a 7-year overall survival of 30.0 %, which was significantly lower than that of CK10−/CK19− patients (56.1 %; Yang et al. 2008). Among 155 HCCs, tumors with CK19 expression accounted for 10.1 %, and patients with this type of neoplasm have a significantly lower overall survival and recurrence-free survival (Lu et al. 2011). 35.7 % of 210 surgically resected HCCs were CK19 positive, and this feature predicted early tumor recurrence and poor prognosis (Yuan et al. 2011). CK19-expressing HCCs with stemness-related marker expression demonstrated more frequent large vessel invasion, increased tumor size, microvessel invasion, poor tumor encapsulation, and poor survival (Kim et al. 2011). In a cohort of surgical specimens, keratin 19 expression revealed the strongest correlation with increased tumor size, decreased tumor differentiation, metastasis, and microvascular invasion (Govaere et al. 2014). Hypovascular HCCs exhibited a significantly higher CK19 expression rate and earlier recurrence rate within 6 months compared to the patients with hypervascular HCCs (Chung et al. 2012). Expression of CK19 in HCC is related to high tumor recurrence after curative radio-frequency ablation (Tsuchiya et al. 2011b). The adverse effect of CK19 on prognosis, with early tumor recurrence, has also been found in small HCC after curative resection (Zhou et al. 2010), and particularly small HCCs (diameter less than 3 cm) additionally expressing mucin as an indicator for biliary differentiation form a high-risk group (Aishima et al. 2007). CK19 positivity in HCCs is an independent risk factor for developing lymph node metastasis (Ding et al. 2004; Zhuang et al. 2008). The expression of CK19 in HCCs is correlated with expression of matrix metalloproteinase 2, and also this co-expression predicts lymph node metastasis (Xiang et al. 2011). CK19 expression in HCCs is also correlated with a higher proliferating cell nuclear antigen (PCNA)-labeling index and lower differentiation (Wu et al. 1996; Zhuang et al. 2008) and expression of matrix metalloproteinase 9 (Zhuang et al. 2008). CK19-positive HCCs demonstrated longer telomeres than CK19-negative HCCs, and

telomere lengthening was associated with poor differentiation and reduced survival (Oh et al. 2008). CK19 expression in regional lymph nodes of livers harboring HCC was associated with lymph node metastasis and very poor outcome (Lee et al. 2013).

Part of HCCs expressing CK19 and showing aggressive behavior co-expresses other stemness-related markers, such as CD133, nestin, CD44, and ATP-binding cassette subfamily G member 2 (ABCG2) (Yang et al. 2010). One stemness-related marker, epithelial cell adhesion molecule (EpCAM), is highly expressed in premalignant hepatic tissues and in a subset of HCCs (De Boer et al. 1999). EpCAM-positive HCCs display a distinct molecular signature with features of hepatic progenitor cells including the presence CK19, c-kit, and activated Wnt/beta-catenin signaling (Yamashita et al. 2008). CK19 mRNA and protein expression correlate with the expression of multidrug resistance-associated protein 1 (MRP1) in HCCs. MRP1, together with MRP3 and BCRP, co-localizes with CK19 in the tumor, and this expression pattern suggests a progenitor cell origin of these aggressive tumors (Vander Borght et al. 2008). The aggressive phenotype of EpCAM-positive HCCs may be related to the observation that expression of EpCAM shifts the state of cadherin-mediated adhesions from strong to weak (Winter et al. 2003).

The reason why expression of CK19 is associated with higher aggressivity of HCCs is not yet known. From other tumor models, there is evidence that CK19 and other intermediate filaments play an important role in tumor cell migration, invasion, and metastasis (Hendrix et al. 1996). Keratin 19-positive HCC highly expressed invasion-related/metastasis-related markers and showed expression of members of the microRNA-200 family. Furthermore, primary human keratin 19-positive HCC showed increased invasiveness in vitro (Govaere et al. 2014). HCC expressing "stemness"-related proteins were characterized by increased telomere length, augmented expression hTERT and shelterin complex proteins, associated with increased chromosome instability, alterations favoring an aggressive tumor phenotype (Kim et al. 2013b).

CK19 Expression in HCCs as a Marker of Biliary Differentiation

A biliary differentiation characterized by the presence of ductal/ductular or glandular profiles and the immunohistochemical reactivity for CK7 and CK19 are typical features of mixed hepatocellular and cholangiocarcinomas. However, it is more difficult to judge whether the expression of CK19 in HCCs lacking morphological features of cholangiocellular differentiation is a marker for a biliary phenotype or rather a stemness-related marker. In one study, part of HCCs expressing CK19 also expressed the mucin core protein-1 (MUC-1) supported the presence of a bona fide biliary phenotype (Lu et al. 2011). Biliary differentiation characterized by positivity for CK19 and mucin expression does occur even in small HCCs and mucin-producing HCC cells and confer a higher risk for aggressive behavior (Aishima et al. 2007). One group of HCCs was classified as tumors with an intermediate (hepatocyte-cholangiocyte) phenotype (Kim et al. 2004) and is discussed in a separate chapter.

CK19 Expression in HCC Precursor Lesions

In a rat model of progenitor cell-derived HCC, microdissected samples of focal lesions, adenomas, and early and advanced HCCs showed that about 50 % of persistent nodules and all HCCs expressed CK19, whereas only 14 % of remodeling nodules were CK19 positive. CK19-expressing lesions displayed a distinct gene expression signature with a predominance of the AP-1/JUN network expression (Andersen et al. 2010).

Pathogenesis of CK19 Expression

The mechanism of the development of CK19 positivity in HCC remains to be studied in more detail. The form of CK19 synthesized and stored in HCC cells may be different from that of other cell systems, because CK19 produced by HCC

cell lines is in part secreted as a fragment, CYFRA 21-1 (Wu et al. 2002). CK19 fragments are also produced and secreted into serum by human HCCs (Nagai et al. 2001). It was demonstrated that the activation of the EGF-EGFR-signaling pathway is associated with the acquisition of CK19-positive HCC phenotype, possibly mediated by EGF-induced phosphorylation of c-Jun N-terminal kinase (JNK)/stress-activated protein kinase (Yoneda et al. 2011). In HCC cells grown in culture, expression of CK19 was in any case associated with the expression of laminin, and laser scanning confocal microscopy demonstrated the concomitant presence of the two molecules in most of the positive cells. In two CK19-negative HCC cell lines, addition of laminin to the culture medium resulted in an induction of CK19 in a dose-dependent manner, suggesting that laminin is an inducer of CK19 upregulation in HCC cells in vitro (Su et al. 2003).

Stemness in HCC cells may be induced by viral factors. In cell culture and murine tumor xenograft models, HCV replicon-expressing hepatoma cells display a high-level expression of the stemness markers, DCAMKL-1 (doublecortin and CaM kinase-like-1) and CK19, suggesting that chronic HCV infection predisposes cells toward a path of acquiring cancer stem cell-like traits (Ali et al. 2011). A higher proportion of CK19 expression was detected in HCCs after preoperative transcatheter arterial chemoembolization (TACE) (Nishihara et al. 2008). Mixed phenotype HCC with expression of CD133, EpCAM, NCAM, and CK19 is more frequent after TACE and liver transplantation (Zen et al. 2011).

Pathogenesis of Progenitor Cell Features in HCCs

The stem cell marker EpCAM is activated by the Wnt/beta-catenin signaling pathway in HCC, whereby the beta-catenin activation target TCF-4 binds to the EpCAM promoter (Yamashita et al. 2007). Stemness of EpCAM(+) HCCs is regulated by the transcription factor SALL4, which also affects the expression of CD44 in these neoplasms (Zeng et al. 2014). In EpCAM-enriched HCC progenitor cells, epigenetic modification of microRNA-429 targets the retinoblastoma binding protein 4/OCT4 axis and contributes to self-renewal of the cells involved (Li et al. 2015). The mechanisms regulating the expression of CD133, a surface glycoprotein, in progenitor cells have in part been elucidated. CD133 expression in CD133(+)HCC cells is inhibited by the transcription factor Ikaros through direct binding to the CD133 P1 promoter, resulting in repression of stemness features in HCCs. Ikaros itself is upregulated by ETS1 regulated by the MAPK pathway (Zhang et al. 2014). Human CD133-positive liver cancer stem cells are inhibited by microRNA-150 via negative regulation of the transcription factor c-Myb (Zhang et al. 2012). Expression patterns of OCT4, Nanog, and EpCAM in HCC cells are modulated by c-MYC, which enhances stem cell marker expression at low expression levels, whereas high c-MYC blunts the stem cell response and induces a pro-apoptotic program (Akita et al. 2014).

Molecular markers of HCC stemness are closely linked with elements of the Wnt/beta-catenin signaling pathway. Beta-catenin activation characterizes a progenitor cell phenotype and is, in experimental models, a strong promoter of hepatocarcinogenesis (Mokkapati et al. 2014). Wnt/beta-catenin signaling in HCC transcriptionally activates microRNA-181 expression (Ji et al. 2011).

The presence of progenitor/stem cell features is linked with tumor cell epithelial-to-mesenchymal transition (EMT). There is strong evidence that cancer cells with EMT traits share numerous features with cancer stem cells. In HCC cells, the transcriptional coactivator with PDZ-binding motif (TAZ), one of the nuclear effectors of Hippo-related signaling pathways, promotes the expression of stem cell markers (OCT4, Nanog, and SOX2) through induction of EMT (Xiao et al. 2014). HCC cells with aberrant cell surface vimentin expression and absent CD133 expression display an EMT phenotype and have stem-like features (Mitra et al. 2014). Cellular features of HCCs, including stemness and EMT promotion, are markedly influenced by various species

of microRNAs (Meng et al. 2012; Chai and Ma 2013; Qi et al. 2013; Anwar and Lehmann 2014). The proportion of stem cells in HCC is augmented by microRNA-200 via upregulation of vasohibin 2 which induces EMT (Xue et al. 2014). EMT is also modulated by microRNAs acting on the Wnt/beta-catenin pathway. Beta-catenin signaling, which is required for EMT, is suppressed by microRNA-612 in HCC cells (Tang et al. 2014).

Ectopic Hepatocellular Carcinoma 15

Contents

Abstract

Ectopic hepatocellular carcinoma (ectopic HCC) is defined as an HCC that arises from intrahepatic or extrahepatic bile ducts, the gallbladder, from liver parenchyma situated in an extrahepatic organ or tissue, or from extrahepatic hepatogenic progenitor cells. In advanced ectopic HCC, the source of the tumor may be difficult to assess, as ectopic liver tissue may have been completely destroyed by the tumor. Ectopic HCC is a very rare neoplasm, as its most common source, ectopic or heterotopic liver, has an estimated incidence of only 0.24–0.47 %. There is a propensity of ectopic liver to give rise to HCC. Ectopic HCC may be suspected in patients with markedly elevated serum alpha-fetoprotein levels in the absence of an orthotopic liver tumor. Ectopic HCC that develops in large bile ducts can show several growth patterns, one of the patterns characterized by endoluminal polypoid growths that cause biliary obstruction. Ectopic HCCs situated outside the liver can be attached to the organ by a vascular stalk. Uncommon tumors occur in visceral abdominal organs, in the peritoneal surface, in the retroperitoneal space, and within the thoracic cavities.

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_15

Introduction

Ectopic hepatocellular carcinoma is defined as HCC arising from intrahepatic or extrahepatic bile ducts, from hepatic parenchyma that is located in an extrahepatic organ or tissue, although preexisting ectopic liver tissue cannot always be identified, or from extrahepatic hepatogenic cells/progenitor cells (Sasaki and Konishi 1995; Arakawa et al. 1999; Le Bail et al. 1999; Caygill and Gatenby 2004). Liver tissue as a source of HCC may be completely destroyed and replaced by cancer, or HCC may have originated from a tiny hepatic ectopia or from hepatogenic cells (progenitor cells) displaced into an extrahepatic, aberrant site. Based on potential pathogenic mechanisms involved, several basic types of liver ectopia have been proposed, i.e., (1) an accessory liver lobe attached to the liver by a vascularized stalk, (2) small accessory liver lobe equivalents ("liverlets") attached to the liver, (3) ectopic liver tissue that is situated outside the orthotopic liver without any connection with it, and (4) microscopic ectopic liver cell foci (Collan et al. 1978). An early displacement of small collections of hepatic progenitor cells to extrahepatic niches is supported by the observation of ectopic HCC relatively remote to the liver, e.g., in the spleen, the pancreas, the jejunum, the abdominal cavity, the diaphragm, or the chest wall.

Epidemiology

The reported incidence of ectopic or heterotopic liver (liver ectopia and liver heterotopia) is only 0.24–0.47 % (Eiserth 1940; Watanabe et al. 1989), and ectopic HCC is even rarer, but there seems to be propensity of ectopic liver to give rise to HCC (Le Bail et al. 1999; Arakawa et al. 1999; Caygill and Gatenby 2004). Out of approximately 100 cases of ectopic liver reported, HCC was detected in 28 of them (Arakawa et al. 1999; Asselah et al. 2001; Kim et al. 2003; Leone et al. 2004). Most cases of reported ectopic HCCs involved Asian patients, and only few Caucasian cases were published (Leone et al. 2004; Toonen and Smilde 2010). The presence of ectopic HCC may be suspected in patients having a markedly elevated serum AFP or other HCC markers in the absence of imaging evidence of a primary liver tumor or other tumors known to secrete AFP. Patients with ectopic HCC do not show the usual risk factors for orthotopic HCC, such as HBV infection and liver cirrhosis (Arakawa et al. 1999; Kubota et al. 2007). In very rare cases, ectopic HCC was associated with other condition, such as pachydermia (Dettmer et al. 2011).

Ectopic Hepatocellular Carcinoma Arising in Bile Ducts

Clinical and Imaging Features

The diagnosis of ectopic HCC in bile ducts requires that no trace of HCC can be detected in the liver, as manifestations of primary hepatic HCC in the biliary tract is well known (icteric-type HCC). Larger lesions cause stenosis of the common duct and obstructive jaundice and hence may mimic icteric-type HCC (Cho et al. 1996; Buckmaster et al. 1994; Kondo et al. 2003; Peng et al. 2004; Tsushimi et al. 2005; Makino et al. 2006; Yigit et al. 2007; Schmelzle et al. 2009). Cholangiography reveals a round defect in the bile duct (Tsushimi et al. 2005) or a circumscribed swelling of the duct wall (Schmelzle et al. 2009).

Pathology

Several types of gross presentation can be distinguished (Table 1). Intramural mass-forming tumors present as fusiform eccentric or concentric lesions that lead to circumscribed stricture or stenosis (Park et al. 1991; Hasegawa et al. 2002). Exophytic spherical tumors can grow as nodular masses or as polypoid masses covered by a capsule and connected with the underlying bile duct mucosa by a vascular stalk (Tsushimi et al. 2005;

Table 1 Gross growth patterns of ectopic HCC of bile ducts

Extrahepatic ectopic HCC of bile ducts
Type 1
Intramural mass-forming fusiform type
Type 2
Intraductal nodular type
Type 3
Intraductal pedunculated polypoid type
Type 4
Intraductal embolus-like type
Intrahepatic ectopic HCC of bile ducts
Type 5
Intrahepatic intramural nodular small type
Type 6
Intrahepatic intraductal polypoid type

Yigit et al. 2007). Embolus-type HCC of the biliary tract in the absence of primary hepatic HCC is an intriguing lesion that may in part derive from ectopic tissue, but failure of diagnosing an intrahepatic tumor has to be taken into account. Intrahepatic intrabiliary ectopic HCCs are small tumors in close association with a lobar or segmental bile duct (Yasui et al. 2004). They may show a pedunculated polypoid growth pattern (Terada et al. 1989).

Metastasis of intrahepatic HCC to bile ducts may grossly mimic these growth patterns. For example, metastatic manifestation of HCC in the hepatic duct was reported to grow as a polypoid mass with a stalk (Narita et al. 2002). Intrahepatic HCCs may chiefly grow in connection with bile ducts close to the liver hilum (Thomsen et al. 1998).

Histologically, ectopic liver tissues may show lobular-like architecture with central veins, in particular when the lesion is macroscopically visible. Microscopic ectopias may, in contrast, only consist of small collections of hepatocytes embedded in a connective tissue, without liver-specific angioarchitecture. A biliary drainage may or may not be present. The ectopic liver tissue can undergo secondary alterations, such as cholestasis, steatosis, inflammatory changes, and fibrosis or even cirrhosis.

Ectopic Hepatocellular Carcinoma in the Gallbladder

As ectopic liver is relatively frequent in the gallbladder, this organ is a common site of ectopic HCC (Tamura et al. 1985; Sarda 2005). Ectopic HCC of the gallbladder presents as nodular or polypoid, intraluminal mass, often in the body and/or fundus. The neoplasm may be confounded with primary gallbladder carcinoma, but an elevated serum AFP concentration should raise suspicion of ectopic HCC.

Ectopic Hepatocellular Carcinoma in Connection with the Main Liver, but Physically Separated from the Main Liver Substance

These are HCCs that form nodules that are separated from the liver, but are connected with the liver through a meso-like structure or by a pouch-like extension of the liver capsule. These tumors arise from liver anlages that have separated from the main organ in the course of the formation of the liver bud or from hepatogenic cell nests having been isolated from the remaining cell populations in the septum transversum. This type of ectopic HCC may be situated close to the inferior vena cava (Fukuda et al. 2009), in the triangular ligament (Kuo et al. 2008; Kanzaki et al. 2010).

Ectopic Hepatocellular Carcinoma in Visceral Abdominal Organs

Ectopic HCCs were found in the abdominal cavity (Matsunaga et al. 2003), on the peritoneum (Liu et al. 2007), the left subphrenic space (Seo et al. 2008), the hepatoumbilical ligament (Zonca et al. 2013), underneath the diaphragm (Takayasu et al. 1994; Kim et al. 2003; Nishikawa et al. 2011), at the lesser curvature of the stomach (Kuo et al. 2008), in the perigastric space (Nakamura et al. 2013), the jejunum (Shigemori et al. 2006), the pancreas (Hayashi et al. 2000;

Cardona et al. 2007; Kubota et al. 2007), and the spleen (Matsuyama et al. 2011).

Multiple Ectopic Hepatocellular Carcinomas in the Abdominal Cavity

In rare cases, multiple brown nodules were found on the peritoneal surface and in the mesentery, sometimes associated with hemorrhagic ascites (Kawahara et al. 1988; Miyake et al. 2012).

Ectopic HCC in the Retroperitoneal Space

Few cases of retroperitoneal ectopic HCC were reported (Horiuchi et al. 1969), sometimes with formation of large masses suspicious of germ cell tumor metastases (Toonen and Smilde 2010). Ectopic HCC has very rarely been observed in the renal hilum, masquerading an adrenal tumor (Singh et al. 2010).

Thoracic Ectopic Hepatocellular Carcinoma

Ectopic HCC was observed on the superior surface of the diaphragm (Moriwaki et al. 1987; Huang et al. 2007; Oldani and Garavoglia 2013), in the chest wall (Kawabata et al. 1996; Asselah et al. 2001; Nenekidis et al. 2011), and has also been diagnosed within the thoracic cavity, including the mediastinum (Rozen et al. 2011).

Differential Diagnosis

The most important differential diagnosis is metastatic HCC, but can be excluded in the absence of an orthotopic primary tumor. Hepatoid carcinoma originating in organs and tissues known to be a site of ectopic liver may resemble ectopic HCC, e.g., hepatoid carcinoma of the pancreas (Marchegiani et al. 2013).

Biology of Disease

In a minority of cases, ectopic HCC later produces recurrence in the main liver (Kawabata et al. 1996; Arakawa et al. 1999; Kim et al. 2003; Leone et al. 2004; Shigemori et al. 2006; Kuo et al. 2008). These situations were usually interpreted as metastases of the ectopic HCC, but a second metachronous primary tumor cannot be excluded with certainty.

Ectopic Liver: Anatomic Sites and Morphology

As ectopic HCC may originate from ectopic liver tissue, sites and morphology of ectopic liver tissue are of interest in this setting. Ectopic and accessory liver tissue has been described already in the old literature on abnormalities of liver development (Jacquemet 1896; Hanser 1930). Liver ectopia outside the bile ducts and the gallbladder is mostly an isolated phenomenon, but it can also occur in conjunction with other congenital abnormalities, including biliary atresia, caudate lobe agenesis, omphalocele, ductal plate malformations, and laparoschisis, Parts of liver tissue nodules sometimes identified as ectopic liver are connected to the orthotopic organ through a vascularized pedicle and are, therefore, not true ectopias but may rather be related to accessory and abortive liver lobes (hepar succenturiatum; Algin et al. 2008; Wang et al. 2012). In comparison with true liver ectopia, accessory liver lobes have been described numerous times (Levi et al. 1969; Pujari and Deodhare 1976; Go et al. 1978; Kuroiwa et al. 1984; Tomooka et al. 1988; Fogh et al. 1989; Massaro et al. 2007; Stattaus et al. 2008; Faraj et al. 2010; Wang et al. 2010; Kostov and Kobakov 2011). Accessory livers may have their own mesentery and, depending on their location, can drain into the biliary system or have no drainage system. Liver tissue connected with the main organ via a vascularized stalk may rarely have an unusual position, e.g., being situated within the suprahepatic part of the inferior vena cava, as a

floating intraluminal polypoid mass (Morris et al. 2012). An accessory liver lobe can be found in exomphalos/omphalocele (Tan and Tan 1971; Pereira et al. 2005). The gallbladder may be embedded in the right-sided inferior accessory lobe (Festen et al. 1988). Accessory liver lobes with a vessel-containing pedicle may undergo torsion, followed by infarction, both in children and adults (Olinde and Boggs 1958; Watson and Lee 1964; Peter and Strohm 1980; Betge 1995; Sanguesa et al. 1995; Koumanidou et al. 1998; Koplewitz et al. 1999; Bedda et al. 2003; Ladurner et al. 2005; Hundal et al. 2006; Pérez-Martinez et al. 2006; Negru et al. 2007; Carrabetta et al. 2009; Umehara et al. 2009; Jambhekar et al. 2010). Other secondary changes of such lobes comprise a rupture due to blunt trauma (Garba and Ameh 2002) and hemorrhage (Vykouril 1989). Accessory liver lobes can protrude through congenital abdominal wall defects (Johnstone 1965) or disturb the closure of the umbilical ring (Ito et al. 1999).

In contrast to accessory liver lobes, true liver ectopia is not connected to the main liver through a vascularized pedicle, but is completely separated from the orthotopic organ. Numerous sites of true ectopic livers have been identified (Table 2).

Most true ectopias are clinically silent. In a minority of cases, the lesions become symptomatic, mostly due to hemorrhage and necrosis, compression of adjacent organs (e.g., stenosis of the gastric outlet), and intraperitoneal or intrathoracic bleeding. The natural course of true liver ectopias is unpredictable. Some of the lesions may disappear postnatally due to atrophy or remodeling processes.

The most important abdominal organ harboring ectopic liver is the gallbladder (Ribbert 1914; Walzel and Gold 1925; Bassis and Izenstark 1956; Angquist et al. 1975; Torchio and Maconi 1978; Natori et al. 1986; Fellbaum et al. 1987; Tejada and Danielson 1989; Watanabe et al. 1989; Castro Viera et al. 1990; Svane and Knudtzon 1991; Hamdani and Baron 1994; Acar et al. 2002; Griniatsos et al. 2002; Sakarya et al. 2002; Lundy et al. 2005; Kyeong et al. 2008; Triantafyllidis et al. 2009; Nagar et al. 2011; Karaman et al. 2012). Macroscopically, ectopic livers of the gallbladder most often present reddish-brown polypoid or bean-shaped nodules that are covered by intact serosa and are connected with the gallbladder wall via a vascularized pedicle. The size of these liverlets usually ranges from few millimeters to 1 or 2 cm, but larger lesions are occasionally seen. The ectopic livers are most often situated at the fundus and corpus of the gallbladder, but some of the lesions were also found in the gallbladder neck. Ectopic liver of the gallbladder wall can mimic a tumor mass (Hamdani and Baron 1994) and may undergo secondary changes, including hemorrhagic necrosis (Nagar et al. 2011), sometimes caused by torsion (Elsayes et al. 2005), cholangitis (Castro Viera et al. 1990), cholestasis (Svane and

Knudtzon 1991), and cirrhosis (Brühl 1926; Lieberman 1966; Angquist et al. 1975; Pesce et al. 1984). In comparison with other ectopic livers, liver ectopia of the gallbladder does seem to less commonly be complicated by HCC. The reason for this phenomenon is still unknown.

Other, much less common localizations include the bile duct system (see above); hepatic ligaments; abdominal cavity (Kawahara et al. 1988); omphalocele (Fock 1963); umbilical region (Nora and Carr 1946); diaphragm (Takayasu et al. 1994; Huang et al. 2007); greater omentum (Orth 1887; Brühl 1926; Elsayes et al. 2005); stomach wall (el Haddad et al. 1985); gastrohepatic ligament (Catani et al. 2011); pancreas (Kubota et al. 2007; Catani et al. 2011); spleen and splenic capsule (Schnyder 1926; Heid and Von Haam 1948; Ball et al. 1971; Matsuyama et al. 2010); parasplenic space (Diez et al. 2009); jejunum (Newland et al. 1989; Shigemori et al. 2006); intrathoracic structures (Rodriguez-Perez 1955; Sehdeva and Logan 1971; Babu and van der Avoirt 2001; Han and Soylu 2009; Kutner et al. 2010; Huang et al. 2011), including the pericardium (Kinnunen et al. 1997), right atrium (Brustmann 2002), and lung parenchyma (Iber and Rintala 1999; Tancredi et al. 2010); retroperitoneum (Pesce et al. 1984; Watanabe et al. 1989); adrenal glands (Honoré 1985; Buck and Koss 1988; Zlatkovic et al. 1998; Catani et al. 2011); testis (hepatogonadal fusion; Ferro et al. 1996); and umbilical cord (Preminger et al. 2001). A supradiaphragmatic liver is commonly disconnected to the main body of the liver (Hudson and Brown 1962; Lasser and Wilson 1975) and may be associated with other malformations, e.g., congenital cardiac anomalies (Shapiro and Metlay 1991) or congenital diaphragmatic hernia (Shah et al. 1987). Thoracic hepatic tissue may be a rare congenital alteration (Luoma and Raboei 2003; Kamath et al. 2010), but it can also develop in the setting of diaphragmatic hernias, either iatrogenic or subsequent to injury (Yoshino et al. 2006). Posttraumatic extension of the liver into the thoracic cavity may cause esophageal obstruction (Jimenez and Hayward 1971). Multiple intrapulmonary liver foci had been observed after orthotopic heart transplantation (Mehta et al. 2010).

The detailed anatomy of ectopic livers is sometimes difficult to analyze, because such liver structures (or "liverlets") are often not fed by a branch of the hepatic artery, do not show a portal venous circulation, and may not be connected to the biliary tract. In contrast to the often polypoid or pedunculated liver ectopias of the gallbladder, ectopic liver in other organs is usually manifest as a macroscopic or microscopic nodule of liver parenchyma surrounded by a capsule-like condensation of connective tissue. Histologically, liver ectopias of the gallbladder, but also those of other organs, consist of a hepatocytic parenchyma that either exhibits a lobular texture with central veins or does not show a lobular architecture, but contains normal-looking hepatocytes. The latter may, however, undergo secondary changes, the most common being cholestasis in cases without biliary drainage. Interestingly, not all ectopias lacking a biliary drainage accumulate the bile. This unexpected phenomenon may be linked to failure of ectopic hepatocytes to clear bilirubin from circulation due to a membrane defect. Most liver ectopias are fed by an autonomous artery that is embryological typical for tissues forming a niche for ectopia. Apart from bile accumulation, other secondary alterations of ectopic liver tissue include steatosis, chronic active inflammation (chronic active hepatitis), granulomatous hepatitis, iron overload, fibrosis, cirrhosis, metastatic disease, hepatocarcinogenesis, and development of non-HCC tumors. For example, ectopic intrathoracic liver contained infantile hemangioendothelioma (Shah et al. 1987) or cystic mesenchymal hamartoma (Antoniou et al. 2012). In very rare cases, alterations resembling congenital hepatic fibrosis were found in ectopic liver, in the absence of corresponding changes in the orthotopic liver (Zlatkovic et al. 1998).

Morphogenetic Pathways

Whereas the pathogenesis of accessory liver lobes can be regarded as a consequence of a segregation or sequestration of liver primordium from the

main liver, resulting in some sort of aberrant lobe connected to the hepatic vascular system and biliary tract, pathogenic pathways leading to true liver ectopias are more difficult to understand. The orthotopic liver develops through a series of reciprocal tissue interactions between the primed or fated embryonic endoderm and nearby mesoderm. Endodermal cells fated to become liver primordium are located in the ventral foregut endoderm, from where the hepatic diverticulum emerges, a pocket of thickened endodermal epithelium adjacent to the developing heart. Endodermal cells primed for a hepatocyte lineage develop into hepatoblasts which delaminate from the endoderm to invade the septum transversum mesenchyme and to form the liver bud. The liver bud is something like a pacemaker that determines, on the one hand, the construction of the later hepatocyte parenchyma and the ductal plate and, on the other hand, the generation of a highly liver-specific vascular system and a system of distinct mesenchymal cells, the hepatic stellate cells and their differentiated offspring. This sequence of events is orchestrated by a strictly controlled system of transcription factors and growth factors, in part expressed in the mesenchymal cells of the septum transversum which form a decisive platform for the stepwise progression of hepatogenesis (Le Douarin 1975; Zaret 2002, 2008; Lemaigre and Zaret 2004; Tremblay and Zaret 2005; Freedman et al. 2007; Lemaigre 2009; Wandzioch and Zaret 2009; Si-Tayeb et al. 2010; Boulter et al. 2013; Shin and Monga 2013; Yin et al. 2013). For ectopic liver tissue localized to organs in the vicinity of the liver, such as the pancreas, spleen, and adrenals, aberrant migration of hepatocyte progenitors having left the liver bud might be considered, but the generation of liver tissue would require the induction of a specific hepatogenic mesenchyme, as in the orthotopic liver. As most intra-abdominal ectopic livers are situated in the upper part of the abdomen, components of the embryonal septum transversum might be available for liver induction at these ectopic places. On the other hand, specification of cell lineages is a potentially bidirectional process, as tissue programming can be reversed (Zaret 2008). For liver ectopias in the thoracic cavity, other mechanisms have to be considered, because these sites are proximal to the hepatogenic endoderm and superior to the septum transversum. Ectopic priming of cells for a hepatocyte lineage proximal to the ventral foregut might play a role. On the other hand, conversion of pluripotent stem cells into endodermal cells or hepatoblasts (Sekine et al. 2012; Xu and Zaret 2012), or even a conversion of mesenchymal cells into hepatocytes, might be taken into account, as there is recent evidence that human adipose stem cells can directly differentiate into functional hepatocytes. Also aberrant, ectopic expression of transcription factors that have a programming role for liver induction, such as Sox9 (Kawaguchi 2013), might be involved.

Pathogenesis of Ectopic Hepatocellular Carcinoma

In the absence of usual HCC risk factors, the pathogenic pathways involved in ectopic HCC are not fully understood. It has been suggested that continuous cell damage with hyperregeneration, chronic cholestasis with bile acid toxicity, and impaired vascularization might play a role. Persistent regeneration of hepatocytes may be induced by cirrhosis developing in ectopic liver tissue, e.g., secondary biliary cirrhosis in the absence of biliary drainage (Pesce et al. 1984).

ICD-O code 8170/3

Contents

Abstract

Pediatric hepatocellular carcinoma (P-HCC) is a malignancy that resembles in many respects adult-type HCC. P-HCC is a highly invasive and aggressive neoplasm with a tendency for early metastatic spread. The tumor frequently develops in the setting of hepatitis B virus infection but also occurs in association with congenital hepatobiliary tract disorders and inborn errors of metabolism. Epidemiologically, P-HCC is rarer than hepatoblastoma. Only about 0.5 % of all pediatric malignancies are P-HCC. The tumor mainly occurs in an age group that is older than that of hepatoblastomas but also develops in infants and small children. The histological presentation of P-HCC appears to be the same as that in adult-type HCC, but future molecular studies will show whether P-HCC and adult-type HCC are in fact the same or different diseases.

Introduction

As in adult patients, hepatocellular of children (P-HCC) is a malignant neoplasm characterized by a proliferation of hepatocyte-like cells. P-HCC is a highly invasive and aggressive neoplasm with a tendency to produce early metastatic disease. Mainly in endemic areas, there is an important etiologic role played by HBV infection. In part of patients, P-HCC develops in the setting of

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_16

congenital disorders and inborn errors of metabolism.

Epidemiology

Overall, P-HCC is an epithelial malignancy that is rarer than hepatoblastoma (Reynolds 2001; Zaman et al. 2011; McAteer et al. 2013; Tanaka et al. 2013; Zhang et al. 2013). It is estimated that about 05 % of all pediatric malignancies are P-HCC, with an incidence of 0.5–1.0 cases per million (Czauderna et al. 2002; Emre and Mckenna 2004; Allan et al. 2014). This has been uncovered in several studies. Among 42 malignant hepatic tumors in children collected from the West Midlands Regional Children's Tumour Registry, UK, 27 were hepatoblastomas and only 3 were HCC, HCC being even rarer in this collection than rhabdomyosarcoma (Mann et al. 1990). However, the incidence of P-HCC is higher in areas with a high and very high endemicity of HBV infection, such as sub-Saharan Africa. Most P-HCCs occur in children that are older than the typical hepatoblastoma age group, i.e., older than 5 years (Chan et al. 2002). Typically, P-HCC manifests between 10 and 14 years, with a median age at diagnosis of 12 years in one study (Bellani and Massimo 1993). There are, however, marked differences in age distribution in different countries, in part due to the frequency and mode of HBV infection (Lee and Ko 1998). In a study of 73 P-HCC and 54 hepatoblastomas, mean age at presentation was 10.6 years for P-HCC versus 2.5 years for hepatoblastomas (Chen et al. 2005). However, P-HCC is also diagnosed in infants and even neonates (Sawyer 1950; Benson 1958; Koch and Bradford 1959; Dalal and Buhariwala 1966; Kumar and Singh 1966; Rao et al. 1967). In cases associated with HBV infection, P-HCC is more often diagnosed in males, whereas P-HCC is associated with congenital disorders and inborn errors of metabolism; the female-to-male occurrence ratio is equal. P-HCC is known to develop in congenital abnormalities and inborn errors of metabolism, part of which are known to result in chronic liver disease and even liver cirrhosis. Most P-HCCs, however, develop as seemingly de novo neoplasms and are apparently not related to preexisting liver disease, in contrast to HCC in adults (Czauderna 2002).

Single cases or small series of HCC have been reported in the last century. In early publications, where sometimes terms such "hepatoma" have been employed, it is in part difficult to judge, specifically in the absence of histology figures, whether we deal with bona fide HCC or with hepatoblastoma. As discussed in more detail in the respective chapter, these two entities were formerly regarded as one, hepatoblastoma being defined at a later time point. In fact, it was Willlis (1960, 1962) who demonstrated that primary malignant epithelial neoplasms of the pediatric liver are to be divided into two groups, hepatoblastoma and HCC. Before these publications, this distinction was not performed, but got acceptance in studies dating from the last fourth of the last century.

Lack et al.1983; Weinberg and Finegold 1983; Bellani and Massimino 1993; Douglass 1997; Chen et al. 1998.

Clinical and Imaging Features

As in adult patients, there are no characteristic signs and symptoms. Frequent findings include tender or non-tender hepatomegaly, dull abdominal pain or discomfort, weakness, anorexia and weight loss, gastric upsets, and diarrhea or constipation (Czauderna 2002). The duration of symptoms is often short, less than 1 month (Ishak and Glunz 1967). Jaundice and ascites are uncommon. In a minority of patients, the tumor disease is manifest as acute abdomen due to tumor rupture and intra-abdominal hemorrhage. In patients with P-HCC, hepatomegaly is probably the most common finding at the time point of diagnosis. In patients with underlying metabolic diseases, the clinical history may often be dominated by the sequelae of these disorders, sometimes hiding the presentations of HCC. Approximately 60–80 % of patients show significantly elevated serum AFP concentrations. Part of patients present at the time of diagnosis with metastatic disease, with locoregional lymph node metastases and distant metastases, most frequently to lungs and bones. In P-HCC with underlying liver cirrhosis, preexisting liver disease may dominate the clinical presentation, e.g., upper gastrointestinal bleeding due to esophageal varices (Jennuvat and Vithayyasai 2011).

By the use of ultrasonography, CT, and MR, P-HCC presents with an imaging pattern that is, in principle, similar to that of the adult counterparts (Margulis et al. 1956; Kaude et al. 1980; Isdale et al. 1982; Miller and Greenspan 1985; de Campo and de Campo 1988; Foulner and Cremin 1991; Das et al. 2009). Modern ultrasound techniques can provide valuable information on tumor extent and resectability (de Campo and de Campo 1988). In a subset of P-HCC, calcified foci are detectable, similar to other primary liver tumors (Kattan et al. 1959).

Is Pediatric HCC Different from Adult-Type HCC, or Is It the Same Disease?

As many types of malignant neoplasms developing in the pediatric age group reveal a biology that is different from that of the adult counterpart, it has been questioned whether P-HCC is a tumor that is different from adult-type HCC. So far, no difference in the macroscopy and histopathologic features have been detected, most P-HCC showing a histology characterized by a trabecular or acinar phenotype of HCC (Ishak and Glunz 1967; Schiodt 1970). Some HCC subtypes regularly found in adults are uncommon in children, such as clear cell HCC and sclerosing HCC, whereas fibrolamellar HCC is more often found in young individuals and older children. Also the aggressive biology typical for adult HCC is reflected in P-HCC, still with a poor overall outcome, and in some studies even worse than in adults (Chen et al. 1998; Czauderna 2002). In a recent investigation, a distinct immunohistochemical pattern distinguished P-HCC from adult-type tumors. All cases of P-HCC were diffusely positive for epithelial cell adhesion molecule (EpCAM), and EpCAM was also positive in fibrolamellar carcinoma and hepatoblastomas, while adult-type HCC EpCAM was only focally expressed in 15 % of cases (Zen et al. 2014). Future cytogenetic and molecular studies may identify novel signatures that serve to distinguish P-HCC from adult HCC. For example, cyclinD1 expression was significantly lower in P-HCC than in adult HCC, and LOH frequency on 13q was relatively higher in P-HCC than adult HCC (Kim et al. 2000).

Pathology

Macroscopy

The macroscopic presentation of P-HCC is the same as or similar to that in adult HCC, with three major growth patterns, i.e., expanding, invasive, or pedunculated tumors, and either with

solitary or multiple masses. In one study, multiple nodules of P-HCC were observed in half of patients (Ishak and Glunz 1967).

Histopathology

The histopathologic presentation of P-HCC corresponds to that of adult HCC in most cases (Ishak and Glunz 1967; Ito and Johnson 1969; Weinberg and Finegold 1983; Geramizadeh et al. 2010; Figs. 1, 2, and 3).

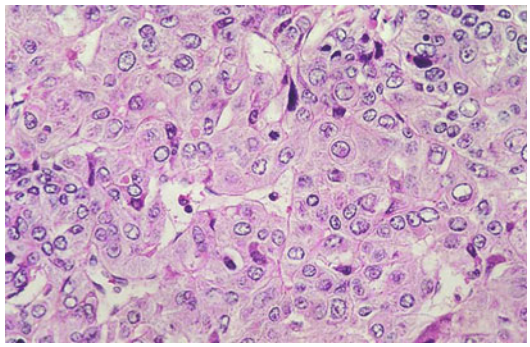

Fig. 1 Well-differentiated pediatric hepatocellular carcinoma (G1). Trabeculae of large hepatocyte-like cells are separated by sinusoidal vascular channels (hematoxylin and eosin stain)

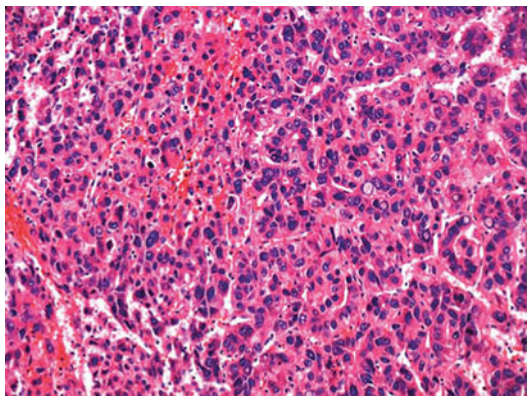

Fig. 2 Pediatric hepatocellular carcinoma, grade 3. Trabeculae are in evidence, but tumor cell nuclei are enlarged, with an increased nucleus-to-cytoplasm ratio (hematoxylin and eosin stain)

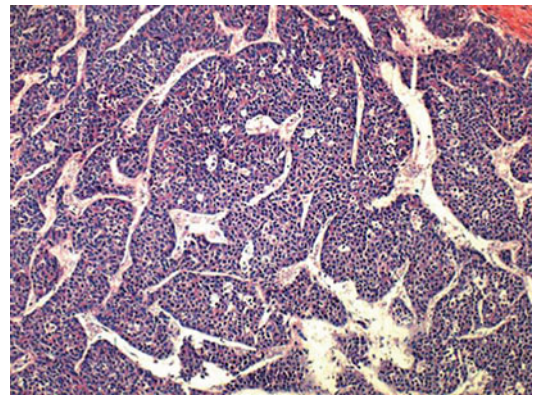

Fig. 3 Pediatric hepatocellular carcinoma, grade 4. This hypercellular "blue" tumor exhibits a solid to trabecular growth pattern, but the sinusoidal vascular pattern is replaced by a vascularized stroma (hematoxylin and eosin stain)

Most tumors show a trabecular pattern, with up to 20 layers of cells in each cell plate. These trabeculae are separated from each other by sinusoid-like vascular channels lined by endothelial cells. Again similar to adult HCC, pleomorphic and multinucleated giant tumor cells occur. Mixed HCC-cholangiocarcinoma may occur, but is very uncommon lesion (Ishak and Glunz 1967). Vascular invasion is usually a prominent feature. Focal calcification can occur (Kattan et al. 1959), probably following necrosis (dystrophic calcification). There is evidence that P-HCC developing in tyrosinemia differs in its histology from HCCs occurring in other etiologic contexts. P-HCC in patients with tyrosinemia 1 exhibit clear cell changes, a solid architecture, and only mild nuclear atypias (Zen et al. 2014).

Immunohistochemistry

Similar to adult-type HCC, P-HCC cells are immunoreactive for hepatocyte markers, glypican-3, cytokeratins 8 and 18, and AFP, the latter only in part of the neoplasms (O'Brien et al. 1989).

Differential Diagnosis

The most important differential diagnoses of P-HCC are certain variants of hepatoblastoma (mainly the macrotrabecular subtype) and transitional liver cell tumor.

Staging

For P-HHC, the PreText staging system mainly developed for hepatoblastomas is now employed in most clinical investigations (see ▶ Chap. 19, "Hepatoblastoma and the Hepatoblastoma Family of Tumors").

Biology of Disease

Already in early reports, it is stated that P-HCC is an aggressive neoplasm with a consistently unfavorable outcome, especially among children older than 4 years and in girls (Exelby et al. 1975; Haas et al. 1989), and this has been confirmed in recent investigations (Pham et al. 2007; McAteer et al. 2013; Zhang et al. 2013), in strong contrast to hepatoblastoma, where modern treatment strategies have brought about a favorable outcome in a large proportion of patients (Czauderna et al. 2002). However, recent treatment strategies start to bring about a change to the better, however, in strong dependence to the stage at the beginning of therapy (Perilongo et al. 1987). Patients with initially resectable HCC have a better prognosis, with an event-free survival for patients with stage I disease being as high as 88 % (Katzenstein et al. 2002). In contrast, outcome was uniformly poor for children with advanced-stage disease, unfortunately still a frequent situation, and due to this stage effect, overall survival for most reported series is still poor, being less than 30 %. Among 40 children with P-HCC, metastases were identified in 31 % and extrahepatic tumor extension, vascular invasion, or both in 39 %, illustrating the advanced disease at diagnosis (Czauderna et al. 2002). In this analysis, partial response to therapy was observed in 18 (49 %) of 37 patients, in only 36 % was complete tumor resection achieved, and overall survival at 5 years was 28 %. There is evidence that liver transplantation in selected patients is a good therapeutic modality for children with HCC (Esquivel et al. 1994; Arikan et al. 2006; Beaunoyer et al. 2007).

Etiology and the Role of Preexisting Liver Disease

Similar to adult-type HCC, numerous etiologic factors or risk factors for P-HCC have been identified (Table 1). Chronic HBV infection plays a significant role as an etiologic factor for P-HCC, mainly in east-southeast Asia and Africa

Table 1 Conditions associated with increased risk of pediatric HCC

Hepatitis B virus infection
Hepatitis C virus infection
Other forms of hepatitis
Infantile giant-cell hepatitis
Congenital abnormalities of the bile duct system
Biliary atresia
Choledochal cyst
Cholestatic disorders
Progressive familial intrahepatic cholestasis (PFIC)
Alagille syndrome
Aagenaes syndrome
Familial adenomatous polyposis
Inborn errors of metabolism
Tyrosinemia
Alpha-1-antitrypsin deficiency
Citrin deficiency (AGC2)
Transaldolase deficiency
Neonatal iron storage disease
Glycogenoses
Niemann-Pick disease
Wilson's disease
Fanconi anemia
Acute intermittent porphyria
Deoxyguanosine kinase deficiency
Mitochondriopathies (MPV17 deficiency)
Other congenital disorders
Neurofibromatosis

(De Potter et al. 1987; Leuscher et al. 1988; Chang et al. 1991; Cheah et al. 1990, 1991; Giacchino et al. 1991; Pontisso et al. 1992; Moore et al. 1997a; Hadley et al. 2004; Ni et al. 2004; Chen et al. 2005). In fact, HBV infection is the main cause of P-HCC in regions hyperendemic for HBV infection (review: Chang 1998). A study from Taiwan has demonstrated that P-HCC developed exclusively in HBV surface antigen carriers and that low positivity rates of serum HBeAg and liver hepatitis B core antigen coupled with a high frequency of liver cirrhosis indicate that an early HBeAg seroconversion to anti-HBe may play an important role in the rapid development of P-HCC (Hsu et al. 1987). A hotspot mutation in the pre-S2 region of HBV may represent a risk factor and prognosticator for P-HCC (Abe et al. 2009). In a Taiwanese series of P-HCC related to HBV infection, pre-S deletion was an independent risk factor for P-HCC and was found in nearly half of the children with HCC, suggesting a causal link between pre-S2 deletion and hepatic carcinogenesis (Huang et al. 2010). HCC can also develop following hepatitis virus infection in pregnancy (Shapiro 1960) or in the perinatal period. In Taiwan, transmission of HBV from the mothers during the perinatal period or early infancy was the most important mode of HBV transmission in P-HCC children (Chang et al. 1989). In an investigation analyzing the development of HCC among 426 prospectively followed Taiwanese children with chronic HBV infection, two boys developed HCC during 6250 person-years, with an incidence of 32 per 100,000 persons (Wen et al. 2004). The significance of HBV infection is underlined by studies showing that the incidence of P-HCC decreases in children following large-scale hepatitis B vaccination (Lee et al. 2003; Hsiao et al. 2009; Tajiiri et al. 2011).

In addition to virus-induced hepatitis, other forms of pediatric hepatitis are associated with HCC, including neonatal hepatitis (Moore et al. 1997b) and giant-cell hepatitis of infancy (Roth and Duncan 1955; Fajers et al. 1960). An increasing group of hepatic inflammatory disorders occurring in the pediatric age group is nonalcoholic fatty liver disease (NAFL)/nonalcoholic steatohepatitis (NASH; Berardis and Sokal 2014). Similar to adult patients, pediatric NAFL/NASH can elicit chronic fibrosing liver disease and cirrhosis (Bozic et al. 2013; Giorgio et al. 2013), whereby oxidative stress is an important component of the pathophysiology of this process, in part counteracted by paraoxonase 1 and catalase (Desai et al. 2014). One might anticipate that in the setting of a worldwide increase of pediatric NAFL/NASH, P-HCC developing in this liver disease will occur. P-HCC has been observed following long-standing total parenteral nutrition (Zen et al. 2014), a condition that can induce NAFL/NASH-like changes in the liver.

Congenital abnormalities of the bile duct system and chronic cholestatic disorders are known to be risk factors for P-HCC, such as biliary atresia (Okuyama 1965; Deoras and Dicus 1968; Iida et al. 2009; Hadzic et al. 2011; Romano et al. 2011), Alagille syndrome (Kaufman et al. 1987; Rabinovitz et al. 1989; Békassy et al. 1992; Bhadri et al. 2005), choledochal cyst (Romano et al. 2011), progressive familial intrahepatic cholestasis/PFIC (Dahms 1979; Ugarte and Gonzalez-Crussi 1981), and Aagenaes syndrome (Ladekarl et al. 2013). In Alagille syndrome, nodular hepatocyte hyperplasia can occur (Tajima et al. 2001), and such nodular can develop in association with P-HCC (Wetli et al. 2010). In chronic progressive familial intrahepatic cholestasis caused by mutations of the bile salt pumps, ATP8B1, encoding FIC1 (PFIC1), and ABCB11, encoding bile salt export pump/BESP (PFIC2), P-HCC is a known complication, around 15 % of patients developing HCC or cholangiocarcinoma (Knisely et al. 2006; Vilarinho et al. 2014). P-HCC is more prevent in the PFIC2 variant (Davit-Spraul et al. 2010).

Several other inborn errors of metabolism are known to be associated with P-HCC, including hereditary tyrosinemia type 1 (Weinberg et al. 1976; Fisch et al. 1978; Russo and O'Regan 1990; Tazawa et al. 1990; Arikan et al. 2006; Castilloux et al. 2007; Romano et al. 2011; review: Erez et al. 2011), glycogenoses (Franco et al. 2005; Romano et al. 2011; Mikuriya et al. 2012), alpha-1-antitrypsin deficiency (Hadzic et al. 2006; Topic et al. 2012),

transaldolase deficiency (Leduc et al. 2014), Niemann-Pick disease (Pennington et al. 1996; Birch et al. 2003), Fanconi anemia (Abbondanzo et al. 1986; Masserot-Lureau et al. 2012), and Wilson's disease (Savas et al. 2006). Tyrosinemia type 1 is an important model to study the effects of an inborn error of metabolism on carcinogenic pathways. Patients with hereditary tyrosinemia type 1 show early nodular regenerative reactions in the liver (Day et al. 1987), liver cell dysplasia (Manowski et al. 1990), and DNA damage caused by the accumulation of abnormal metabolites (Gilbert-Barness et al. 1990) and have impaired DNA repair and genomic stability (van Dyk and Pretorius 2012). Transaldolase deficiency is caused by a defect in the enzyme TALDO1. Children with this deficiency show abnormal metabolites of the pentose phosphate pathway (ribitol, D-arabitol, erythritol, sedoheptitol, sedoheptulose-7P) and liver cirrhosis (Verhoeven et al. 2001; Perl 2007; Qian et al. 2008; Wamelink et al. 2008; Tylki-Szymanska et al. 2009; Leduc et al. 2014) and can develop early-onset HCC (Leduc et al. 2014). Similar to hepatoblastomas, there is some evidence that the Wnt signaling pathway is involved in etiology and pathogenesis of P-HCC. For example, HCC in children has been found to be associated with familial adenomatous polyposis (Gruner et al. 1998).

Although HCC in children is less frequently associated with liver cirrhosis as in adults, chronic fibrosing liver disease and cirrhosis are known predisposing conditions for P-HCC (Kratkova and Masek 1956; Jones 1960; Bhatia et al. 2014). In chronic fibrosing liver disease of adult patients, a distinct spectrum of precursor lesions has been defined (see the respective chapter), in particular liver cell dysplasia, and it was expected that a dysplasia-HCC pathway might also be present in the pediatric age group. In children with liver cirrhosis due to various reasons, liver cell dysplasia was detected in the liver explants in almost half of the cases (Esquivel et al. 1994).

Pathogenetically, less molecular findings are known for P-HCC in comparison with adult-type HCC. In contrast to most adult HCCs, P-HCC have shown somatic mutations in the kinase domain of the c-Met/hepatocyte growth factor receptor gene (Park et al. 1999). p53 was overexpressed in a majority of P-HCC, but this a abnormal p53 expression does not seem to be caused by mutations in the p53 gene (Kennedy et al. 1994).

Hepatoid Carcinomas (Adenocarcinomas with Hepatoid Features)

17

Contents

Abstract

Hepatoid carcinoma (adenocarcinoma with hepatoid features) is a highly aggressive carcinoma occurring in various organs, morphologically characterized by the presence of HCC-like cells that frequently express alpha-fetoprotein, but with a cytokeratin pattern that differs from that of classical HCC, in that tumor cells are often positive for cytokeratins 7 and 20. Similar to HCC, gastrointestinal hepatoid carcinomas can express the hepatocyte marker Hep Par 1. These neoplasms are associated with rapid progression and a poor outcome. Most hepatoid carcinomas found in the liver are metastases of gastric hepatoid carcinomas, the stomach being a frequent primary site. Primary hepatoid carcinomas also occur in bile ducts, the gallbladder, and the ampullary region, but these are uncommon locations. The histogenesis of this neoplasm has not yet been elucidated.

Introduction

Some carcinomas occurring in several organs, but in particular the gastrointestinal tract, can show signs of hepatocellular differentiation, either focally or almost exclusively. These lesions, which are termed hepatoid (adeno)carcinomas or extraheptic tumors with hepatoid features (EHTHF), may be associated with elevated serum AFP levels and an aggressive course

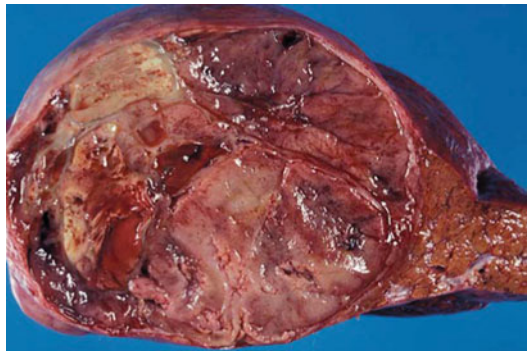

Fig. 1 Hepatoid carcinoma of the liver. These are rapidly growing, aggressive neoplasms developing in non-cirrhotic livers

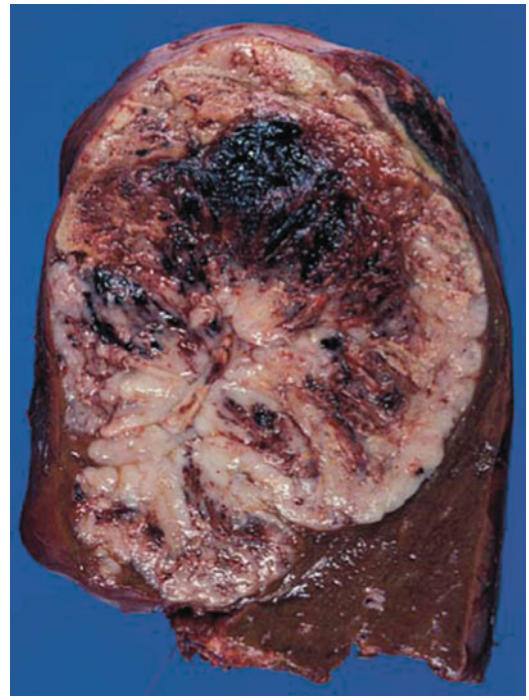

Fig. 2 The macroscopic morphology of hepatoid carcinomas of the liver resembles that of carcinoma metastases. Necrosis and hemorrhages are common features

(reviews: Kishimoto et al. 2000; Su et al. 2013). Typical primary sites of these carcinomas include the stomach (the most common site), esophagus, pancreas, gallbladder, colon, lung, ovary, urinary bladder, renal pelvis, uterus, fallopian tube, and adrenal gland. Hepatoid carcinomas usually have a distinct and unique immunophenotype, characterized by reactivity for cytokeratins 7, 8, 18, 19, and 20, alpha-fetoprotein (AFP), and pCEA (Terracciano et al. 2003). Immunoreactivity for AFP is variable, ranging from absence of staining to marked and diffuse staining of cancer cells, illustrating that not all carcinomas with a hepatoid morphology are producing AFP (Nagai et al. 1993). Many hepatoid carcinomas of the gastrointestinal tract show, similar to hepatocellular carcinomas, reactivity for hepatocyte paraffin 1 (Hep Par 1) antibody, underscoring the fact that Hep Par 1 expression is not unique to primary hepatocellular neoplasms (Maitra et al. 2001). At least part of hepatoid carcinomas are positive for glypican-3, a cell surface heparin sulfate proteoglycan expressed specifically in the fetal liver and in malignant neoplasms of the hepatocyte lineage (Hishinuma et al. 2006). Generally, hepatoid carcinomas are highly aggressive tumors (Figs. 1 and 2).

For example, it has been demonstrated that AFP-producing gastric carcinoma and hepatoid adenocarcinomas of the stomach had a more aggressive biology than that of common gastric cancer and that the prognosis of hepatoid tumors was poorer than that of AFP-producing gastric carcinoma (Liu et al. 2012).

Histologically, hepatoid carcinomas consist of large or medium-sized polygonal cells that are arranged in trabecular fashion or solid nests separated by narrow fibrous stroma bands and sinusoid-like channels (Fig. 3).

Rarely, hepatoid carcinomas showed, apart from the predominant adenocarcinoma, other components, e.g., endocrine carcinoma (Suzuki et al. 2012). It is often difficult to distinguish EHTHF from metastatic hepatocellular carcinoma (HCC) using any kinds of ancillary studies, with the exception of clinical-radiological identification of a hepatic tumor (Kwon et al. 2006).

Some of the extrahepatic carcinomas with morphological resemblance to hepatocellular carcinoma are AFP-negative, but may show positive signals for albumin mRNA in ISH preparations (Supriatna et al. 2005). On the other hand, it has to be emphasized that the mere presence of immunohistochemical markers known to be expressed

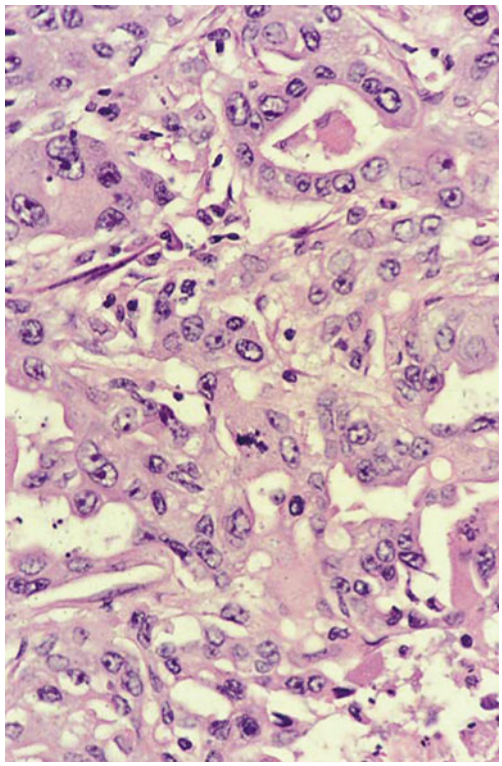

Fig. 3 Hepatoid carcinoma in the liver. The neoplasm consists of cells similar to those in hepatocellular carcinoma, but tubular structures are also encountered, and the tumors are often pleomorphic, with highly atypical nuclei and abnormal mitotic figures (hematoxylin and eosin stain)

in hepatoid cell lineages does not mean that we deal with EHTHF. It has, e.g., been shown that hepatoid carcinoma of the gastrointestinal tract (Maitra et al. 2001) and diverse types of cervical carcinomas (including ordinary adenocarcinoma, adenocarcinoma in situ, and squamous cell carcinomas) can be reactive for Hep Par 1 (Thamboo and Wee 2004) and that Hep Par 1 does not distinguish between EHTHF of the ovary from metastatic HCC (Pitman et al. 2004). AFP-producing adenocarcinoma without morphological hepatoid features may also be positive for glypican 3 (Hishinuma et al. 2006; Oishi et al. 2009). SALL4, a stem cell marker and a marker for fetal gut differentiation, is expressed in the majority of gastric EHTHF, but not in HCCs (Ushiku et al. 2010). On a molecular level, it has been found that foci of hepatoid differentiation in EHTHF show restricted expression of hepatocyte nuclear factor 4 alpha (Kishimoto et al. 2008). Expression of the PLUNC (palate, lung, and nasal epithelium carcinoma-associated protein) gene is a marker for EHTHF (Sentani et al. 2008). PLUNC, also termed lung-specific X protein (LUNX), is a major secreted protein product of the upper respiratory tract, of a still unknown function.

Hepatoid Carcinomas of the Extrahepatic Biliary Tract

Primary EHTHF of the extrahepatic ducts are very rare lesions. In one case, a 67-year-old female suffering from obstructive jaundice had a stenosing mass at the common hepatic duct, mimicking a Klatskin tumor, histologically representing hepatoid carcinoma. The tumor was associated with elevated serum AFP levels (Abdullah et al. 2010). A hepatoid tumor located to the common duct showed all immunohistochemical features characteristic for EHTHF, i.e., positivity for Hep Par 1, CK8, and CK18 (Wang et al. 2013).

Hepatoid Carcinoma of the Gallbladder

EHTHF is known to occur in the gallbladder (Watanabe et al. 1993; Vardaman and Albores-Saavedra 1995; Nishiwaki et al. 1997; St Laurent et al. 1999; Nakashima et al. 2000; Maitra et al. 2001; Sakamoto et al. 2004, 2005; Gakiopoulou et al. 2007; Koswara et al. 2007: van den Bos et al. 2007; Kao et al. 2009; Ellouze et al. 2011). The tumors may be associated with elevated serum AFP levels (van den Bos et al. 2007). In principle, the neoplasms show the same histologic features as those in other locations. Macroscopically, the tumors however often differ from ordinary gallbladder carcinoma by their more nodular and sometimes polypoid growth pattern. In one case of Sakamoto et al. (2005), a 74-year-old female with a long history of cholecystolithiasis exhibited a nodular and elevated gallbladder tumor of 5 cm diameter,

consisting of AFP-positive and Hep Par 1-positive hepatoid cells. Part of the tumors showed cholangiocarcinoma-like components, which also immunostained for AFP (Koswara et al. 2007). In a case reported in 1995, the AFP-producing tumor belonged to the group of clear cell carcinomas of the gallbladder (Vardaman and Albores-Saavedra 1995). Gallbladder carcinomas associated with elevated serum AFP levels are not always hepatoid lesions, but may instead represent other histologies, e.g., standard adenocarcinoma (Brown and Roberts 1992) or undifferentiated carcinoma (Ng and Ng 1995).

Hepatoid Carcinoma of the Ampullary Region

Few cases of primary hepatoid carcinoma of the ampullary/periampullary region have been described (Gardiner et al. 1992; Weng et al. 2009; Palas et al. 2013). The tumor described by Gardiner and co-workers (1992) was located to the papilla of Vater and consisted of a poorly differentiated adenocarcinoma with clear cells containing occasional hyaline droplets and exhibiting bile secretion. Immunohistochemically, AFP, alpha-1-antitrypsin, and CEA were detectable.

Liver Metastasis of Hepatoid Carcinomas

Hepatoid carcinoma of the stomach, the most common localization for this tumor, relatively often metastasizes to the liver, but also other primary intra-abdominal localizations give rise to hepatic metastatic disease (Yoshida et al. 2005; Jo et al. 2012). EHTHF with liver metastasis may mimic HCC (Pan et al. 2011; Jo et al. 2012; Moon et al. 2012), but EHTHF metastases are more commonly positive for CK19 and CK20 and are more often negative for Hep Par 1 than HCCs (Terracciano et al. 2003).

Differential Diagnosis

The main differential diagnoses include metastatic hepatocellular carcinoma and germ cell tumors with marked hepatoid differentiation. HCCs are known to show unusual metastasizing patterns and can, e.g., metastasize to the gallbladder, causing a lesion pattern that may not be distinguishable from primary hepatoid carcinoma (Terasaki et al. 1990). Apart from AFP, embryonal carcinoma has been found to secrete des-gamma-carboxy prothrombin (Hasegawa et al. 2005).

Pathogenic Pathways

Novel observations on the lineage relationships between pancreatic cells and hepatocytes, and their respective precursors, may shed a light on pathogenic mechanisms involved. Of course the liver and the pancreas ontogenically derive from a similar fated endodermal area, but this will not suffice for the understanding of carcinogenic pathways. A key molecule involved in the prenatal development of the stomach and liver is the transcription factor, GATA4. In AFP-producing gastric carcinoma cells, GATA4 expression is silenced via epigenetic histone deacetylation (Yamamura and Kishimoto 2012). Gastric carcinoma producing AFP was shown to share the main histologic features with combined hepatocellular and cholangiocarcinoma, but revealed a different histogenesis with respect to SALL4 expression. Specifically, the germ cell marker SALL4 was expressed in 95 % of AFP-producing gastric carcinomas, including those with a hepatoid component, but was not detectable in combined hepatocellular and cholangiocarcinoma (Ikeda et al. 2012).

Fibrolamellar Hepatocellular Carcinoma

18

Contents

Abstract

Fibrolamellar hepatocellular carcinoma (FL-HCC) is a distinct variant of hepatocellular carcinoma (HCC) that differs from classical HCC at histological, cytological, immunohistochemical, and molecular levels. FL-HCC is typically a tumor of adolescents and young adults, but may also occur in older individuals. In contrast to most HCCs, FL-HCC is not associated with liver cirrhosis. The neoplasm is histologically characterized by strands of large, eosinophilic hepatocyte-like cells embedded in a collagenous stroma forming striking lamellae. Clear cell and glandular variants are known. Clinically, the tumor often presents as a large solitary mass in the absence of elevated serum alpha-fetoprotein levels. FL-HCC may be associated with several metabolic paraneoplastic syndromes that include disorders of vitamin B12-binding protein, sex steroid metabolism, ammonia handling, neurotensin synthesis, and gonadotropin production. In contrast to previous views, there is now evidence that the biological behavior of FL-HCC is not different from that of classical HCC. The neoplasm shows a distinct genomic landscape characterized by a recurrent DNAJB1-PRKACA chimeric transcript arising from a deletion on chromosome 19, but the tumor also showed other molecular abnormalities.

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_18

Introduction

Fibrolamellar hepatocellular carcinoma (FL-HCC) is a distinct malignant liver cell tumor that differs from classical HCC at histological, cytological, immunohistochemical, and molecular levels. It mainly occurs in adolescents and young adults and is histologically characterized by strands of large, eosinophilic hepatocyte-like cells embedded in a fibrous stroma forming collagen-rich lamellae. FL-HCC was first described in 1956 (Edmondson 1956) and subsequently confirmed by Craig et al. (1980) and Berman et al. (1980). The typical clinicopathologic and molecular features of this tumor entity have been reviewed (Soreide et al. 1986; Vecchio 1988; Saab and Yao 1996; McLarney et al. 1999; El-Serag and Davila 2004; Torbenson 2007; Liu et al. 2009; Lim et al. 2014; Darcy et al. 2015a). After the first description, it took a rather long time period until the tumor entity was defined and accepted. Several alternative terms had been employed to denote this lesion, including hepatocellular carcinoma with laminar fibrosis, hepatocellular carcinoma with polygonal cell type and fibrous stroma, oncocytic hepatocellular carcinoma, and eosinophilic hepatocellular carcinoma with lamellar fibrosis.

Epidemiology

FL-HCC accounts for 1–9 % of HCCs overall, this impressive frequency range being caused by markedly variable prevalences in different geographic niches and differences in diagnostic criteria used (Craig et al. 1980; McLarney et al. 1999). Among 46,392 cases of HCC registered in the SEER program between 2000 and 2010, 191, tumors were FL-HCC, with an incidence of clearly less than 0.1 per 100,000 people (Eggert et al. 2013). In contrast to conventional HCC, FL-HCC is not associated with cirrhosis of the liver and other typical risk factors, although a relation to genetic syndromes has been suggested in part of the cases, e.g., Gardner syndrome (Gruner et al. 1998) and Fanconi anemia (LeBrun et al. 1991). FL-HCC is typically a tumor of adolescents and young adults, but rarely also occurs in older individuals. FL-HCC is rare in infants and small children (Cruz et al. 2008), but FL-HCC in older children has more often been encountered (Dellaportas et al. 2011). There is usually no gender predominance, but a predominance of the female gender has also been reported (Chagas et al. 2015). The tumor has been diagnosed during pregnancy (Kroll et al. 1991; Louie-Johnsun et al. 2003). In reviewing studies there is an age range of 5–69 years (mean in Western patients : 23 years), and most patients present in their second and third decades (McLarney et al. 1999). In contrast, conventional HCC is less common than FL-HCC in individuals younger than 40 years (Hernandez-Castillo et al. 2005).

The incidence of FL-HCC is relatively high in Western countries, but is rare in Oriental countries. Analysis of Japanese cases revealed an age range of 15–45 years, with a mean of 21.9 years, findings similar to those in Western countries (Kohno et al. 1988; Haratake et al. 1990; Tanaka et al. 1994; Hoshino et al. 1996; Nojiri et al. 2000; Magata et al. 2001; Yoshimi et al. 2002; Yoshinaga et al. 2002; Kanai et al. 2004; Morise et al. 2005). FL-HCC is apparently not uncommon in sub-Saharan Africa (Moore et al. 2004; Bhaijee et al. 2009) and Latin America (Arista-Nasr et al. 2002).

Clinical Features

FL-HCC characteristically manifests as a large hepatic mass in the absence of liver cirrhosis, elevated serum AFP values, or known risk factors for HCC. In most cases, FL-HCC presents with vague and nonspecific clinical signs and symptoms, often with abdominal discomfort or pain, malaise, and weight loss (Craig et al. 1980; Saab and Yao 1996; Hemming et al. 1997; reviews: Torbenson 2007; Chun and Zimmitti 2013). Due to its mass effect, FL-HCC can cause recurrent obstructive jaundice (Albaugh et al. 1984; Soyer et al. 1991a). It can, similar to ordinary HCC, invade large bile ducts and cause obstructive

Table 1 Metabolic disorders in fibrolamellar hepatocellular carcinoma

Increased serum vitamin B12-binding capacity
Increased neurotensin synthesis with increased serum levels
Paraneoplastic gynecomastia caused by increased aromatase P450 activity
Paraneoplastic production of beta-HCG
Paraneoplastic hyperammonemia with encephalopathy

jaundice, sometimes with subsequent migration of tumor fragments to the common bile duct and distal biliary obstruction (intrabiliary tumor thrombus; Eckstein et al. 1988; Kunz et al. 2002; De Gaetano et al. 2013; Arora 2015). FL-HCC reveals invasion of large liver veins less commonly than conventional HCC, but Budd-Chiari syndrome has been observed as the first manifestation of FL-HCC (Lamberts et al. 1992; Asrani and LaRusso 2012). Caval compression syndrome has been reported as a complication of FL-HCC (Kanai et al. 2004). Additional and usually less common or rare disorders sometimes associated with FL-HCC include severe anemia (Tanaka et al. 1994), nonbacterial thrombotic endocarditis (Vaideeswar et al. 1993), tumor-induced ascites in the case of peritoneal spread (Gupta et al. 1999), a clinical syndrome mimicking hepatic pyogenic abscess (Debray et al. 1994), and cold agglutinin disease (Al-Matham et al. 2011). FL-HCC has been observed in association with ulcerative colitis with primary sclerosing cholangitis (Snook et al. 1989).

FL-HCC patients can show complex patterns of metabolic disorders (Table 1).

The tumor shows abnormalities in the metabolism of vitamin B12 (cobalamin). An increase of serum levels of vitamin B12-binding capacity in patients with FL-HCC has first been reported in 1982 (Paradinas et al. 1982) and confirmed in later analyses (Sheppard et al. 1983; Wheeler et al. 1986; Lildballe et al. 2011). Increasing vitamin B12-binding capacity has been found in postoperative recurrence of FL-HCC (Kanai et al. 2004). However, elevation of vitamin B12 and B12-related proteins seems to be a common feature in HCCs and not only in FL-HCC (Simonsen et al. 2014). Transcriptional profiling of FL-HCC revealed an endocrine signature, in that 4 of the 16 genes most significantly overexpressed in pure FL-HCC were neuroendocrine genes, i.e., prohormone convertase 1/PCSK1, neurotensin, delta/notch-like EGF repeat containing, and calcitonin (Malouf et al. 2014). Serum neurotensin levels (especially levels of the C-terminal part) may be elevated in patients with FL-HCC, caused by secretion of this peptide by the tumor (Collier et al. 1984; Read et al. 1991). Neurotensin was originally isolated from bovine hypothalamus and is an important gastrointestinal regulatory peptide that affects pancreatic secretion, gut motility, gut mucosal growth, and the translocation of fatty acids from the intestinal lumen. The neurotensin gene is expressed in fetal human liver (but not adult liver) and in FL-HCCs (Ehrenfried et al. 1994). In the tumor itself, the neurotensin (6–13) peptide was detectable (Read et al. 1991).

FL-HCC can be associated with gynecomastia (McCloskey et al. 1988; Hany et al. 1997; Agarwal et al. 1998; Sher et al. 1998), mainly in cases of large tumor mass/metastasis. Gynecomastia may be the presenting sign of FL-HCC (McCloskey et al. 1988). Gynecomastia in this tumor is caused by increased aromatase P450 activity in the neoplasm (hyperaromatase syndrome; Hany et al. 1997; Agarwal et al. 1998; Muramori et al. 2011), which gives rise to markedly elevated serum levels of estrone and estradiol-17 beta, suppressing FSH and LH, respectively, and consequently testosterone (Agarwal et al. 1998). Northern analysis indicated the presence of P450 aromatase transcripts in total RNA from FL-HCC but not in the adjacent liver (Agarwal et al. 1998). FL-HCC can rarely produce beta-HCG and by this cause vaginal bleeding (Dahan and Kastell 2002). In part of patients, FL-HCC is associated with a recurrent non-hepatic/non-cirrhotic form of hyperammonemia (paraneoplastic hyperammonemia) complicated by encephalopathy. This complication may mimic a disorder of urea synthesis, e.g., ornithine transcarbamylase deficiency (Sulaiman and Geberhiwot 2014).

Imaging Features

Abdominal imaging shows a well-circumscribed, lobulated, heterogeneous mass that may resemble focal nodular hyperplasia (FNH). CT images document that FL-HCCs are predominantly solitary, well-delineated, and hypervascular lesions which are predominantly hypoattenuating compared with the liver (Bedi et al. 1988; Soyer et al. 1991b; Ichikawa et al. 2000; Marrannes et al. 2005; Selaru et al. 2007; Yen and Chang 2009; Terzis et al. 2010). Almost all tumors were heterogeneous on non-enhanced CT images. In portal venous phase and relative to enhanced liver, FL-HCCs appeared isoattenuating in 48 %, hyperattenuating in 16 %, and hypoattenuating in 36 % (Ichikawa et al. 1999). A central scar resembling the stellate scar seen in FNH is present in CT images in about a third to about 70 % of the cases (the "scar sign"; Kane et al. 1987; Soyer et al. 1991b; Ichikawa et al. 1999). In one study, 82 % of the scars showed a stellate morphology on CT images (Ichikawa et al. 1999). However, central or eccentric scars are also found in conventional HCC, cholangiocarcinoma, and some hepatic metastases (review: Kim et al. 2009). Among 31 cases, CT revealed well-defined margins in 77 % and ill-defined margins in seven cases (Ichikawa et al. 1999). PET-CT scans are a valuable modality in the diagnosis of FL-HCC (Liu et al. 2011). Tumor calcifications in FL-HCC have been reported in 15–68 % of cases at CT and occur in a wide variety of patterns (Soyer et al. 1991b; Stoupis et al. 1998; Ichikawa et al. 1999). Calcifications are more frequent in FL-HCC than in FNH (Caseiro-Alves et al. 1996).

Classification

FL-HCC has been divided into two separate entities, i.e., pure FL-HCC and mixed FL-HCC, differing in clinical presentation and course (Malouf et al. 2012). Pure FL-HCC typically occurs in patients younger than 30 years of age and is often complicated by lymph node metastasis at the time of diagnosis and more frequently shows extrahepatic recurrence. So far, combined or mixed FL-HCC has been regarded as rare lesion. However, in a more recent investigation of 54 patients, the mixed form was found in 25 % of the patients. In contrast to pure FL-HCC, the mixed variant appeared to resemble HCC, occurring in patients aged >40 years, often involving the liver as primary site of disease recurrence, and imparting an increased risk of death (Malouf et al. 2012). Pure FL-HCCs have a distinct transcriptomic signature characterized by strong expression of neuroendocrine genes, including prohormone convertase 1, neurotensin, delta/notch-like EGF repeat containing, and calcitonin, suggesting a complex cellular lineage (Malouf et al. 2014).

Pathology

Macroscopy

The tumors tend to be more common in the left liver lobe (about two thirds of cases; Craig et al. 1980), but relatively often involve both lobes (Ichikawa et al. 1999). In one study, 55 % of the cases had involvement of three or more hepatic segments, and 32 % had involvement of two segments (Ichikawa et al. 1999). Multifocality, gross vascular invasion, and cirrhosis are typically absent, but the tumor often demonstrates aggressive local invasion and nodal and distant metastases (Wong et al. 1982; Friedman et al. 1985; Francis et al. 1986; Gibson et al. 1986; Brandt et al. 1988; Ruffin 1990; Ichikawa et al. 1999; McLarney et al. 1999; Smith et al. 2008). Macroscopically, the tumors are well-delineated masses with a polycyclic border and an expansive growth pattern. A tumor capsule (usually incomplete) is seen in approximately half of the neoplasms. In a study of 31 cases, tumor diameter ranged from 3 to 27 cm, with an average of 13 cm (Ichikawa et al. 1999). In 80–90 % of the

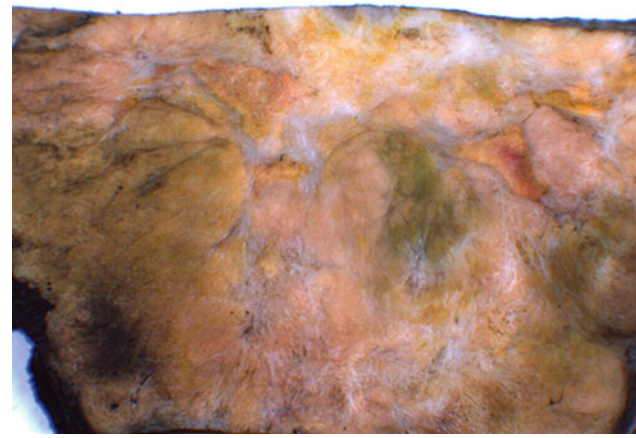

Fig. 1 Fibrolamellar hepatocellular carcinoma. On cut surfaces, the neoplasm exhibits a lobulated texture, lobules, or nodules separated from each other by fibrous septa

cases, a solitary tumor is present. In the remaining cases, there is a mass with small peripheral satellite lesions (10–15 %), a bilobed mass (5 %), or rarely a diffusely/multifocal mass (less than 1 %). Up to 20 % of the tumors show some degree of pedunculation. On cut surfaces, the neoplasms are yellow to tan and often show a nodular or radiated structure caused by radiating fibrous band that originates from central fibrous scar-like areas (Figs. 1 and 2).

In case of marked bile accumulation, a greenish discoloration of the tumor is seen. The neoplasms are encapsulated in about half of the cases, the pseudocapsule being mostly incomplete. A central scar-like structure resembling that seen in focal nodular hyperplasia was detected in about three quarters of cases (Ichikawa et al. 1999). Small necroses and/or hemorrhages may be noted, but are grossly visible in only about 10 %. Rare examples of tumors have revealed massive necrosis and/or hemorrhage, resulting in a multicystic morphology mimicking a primarily cystic liver tumor, but primary multicystic variants of FL-HCC also occur (Pombo et al. 1993). The adjacent liver does not show cirrhosis.

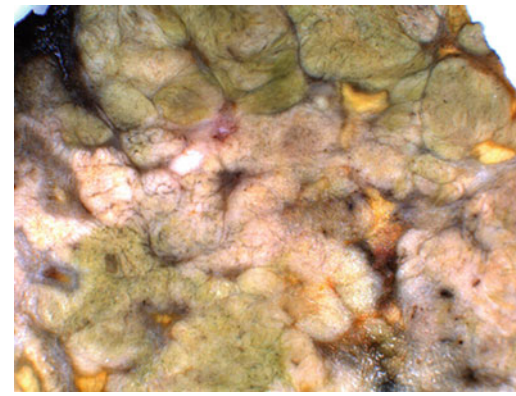

Fig. 2 Nodular structures in fibrolamellar hepatocellular carcinoma can form intertwining ribbons, resulting in a gyriform pattern

Histopathology

The typical cell of FL-HCC is a large polygonal cells having an abundant, deeply eosinophilic, faintly granular cytoplasm and well-defined cell borders . These oxyphilic cells are, however, cytologically different from oncocytes (Altmann 1990). The nuclei are large, round to ovoid and vesicular, and usually single, and they show a peripheral condensation of chromatin and a prominent, centrally placed amphophilic nucleolus. The typical morphologies of the cells and nuclei, together with lamellar fibrosis, are the three main criteria for diagnosis (Figs. 3, 4, 5, 6, and 7).

A part of the nuclei display intranuclear cytoplasmic pseudoinclusions (cytoplasmic invaginations). Large invaginations cause so-called empty nuclei. Mitotic figures are much less common

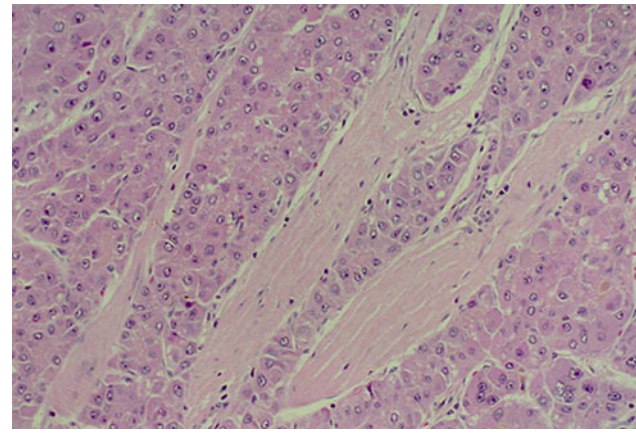

Fig. 3 Fibrolamellar hepatocellular carcinoma. Solid strands and ribbons of large eosinophilic tumor cells are separated by fibrous hypocellular tracks, the fibrolamellae (hematoxylin and eosin stain)

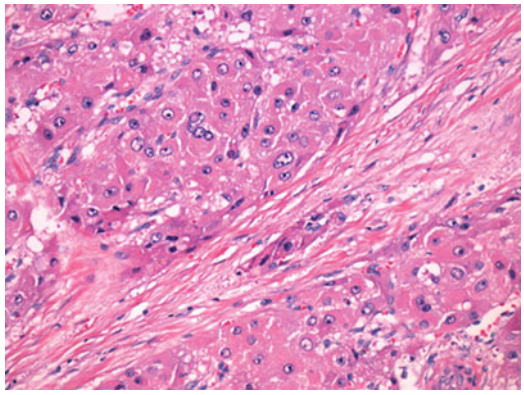

Fig. 4 Fibrolamellar hepatocellular carcinoma. The epithelial tumor cells are in direct contact with collagenous bands, without a visible interposed cellular stroma (hematoxylin and eosin stain)

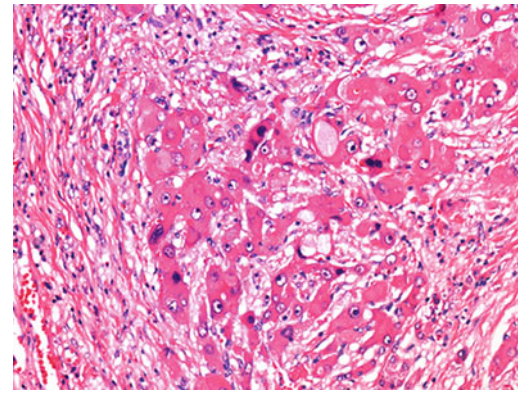

Fig. 5 Fibrolamellar hepatocellular carcinoma. Focally, stroma of slightly higher cellularity can occur, sometimes associated with dissociation of tumor cells (hematoxylin and eosin stain)

than in ordinary HCC (Farhi et al. 1983) and may have previously suggested that the tumor is of low malignancy, what is not the case. Less than 10 % of the cells exhibit PAS-positive globular cytoplasmic inclusions (2–7 μm in diameter; Farhi et al. 1982). About half of the tumor cells contain large ovoid cytoplasmic inclusions that are much less eosinophilic or are amphiphilic, the so-called pale bodies (Fig. 8) .

Pale bodies sometimes show a central hyaline core. Cholestasis is often seen. The tumor cells commonly show canaliculus-like lumina present between adjacent cells containing bile. Tumor cholestasis is, like in ordinary HCC, associated with deposition of copper (copper-binding protein in many cases (Lefkowitch et al. 1983). Small calcifications are sometimes seen, mostly in the central scar and within the fibrous bands. In a minority of FL-HCC, a mild macrovesicular steatosis may be found.

The solid components of medium- to large-sized polygonal cells are irregularly subdivided by connective tissue bands rich in collagen (the "fibrolamellae" that have given the tumor's name). The amount of collagen in the bands varies markedly, ranging from sclerosed bands to bands with a loose texture of tissue rich in glycosaminoglycans and higher spindle cell

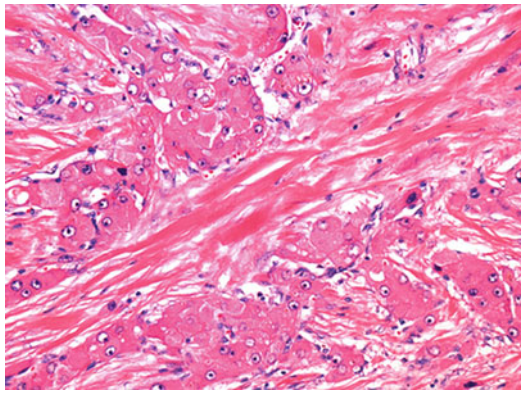

Fig. 6 Fibrolamellar hepatocellular carcinoma. In the fibrous lamellae, collagen-rich connective tissue may undergo hyaline change (hyaline sclerosis of stroma, center of figure; hematoxylin and eosin stain)

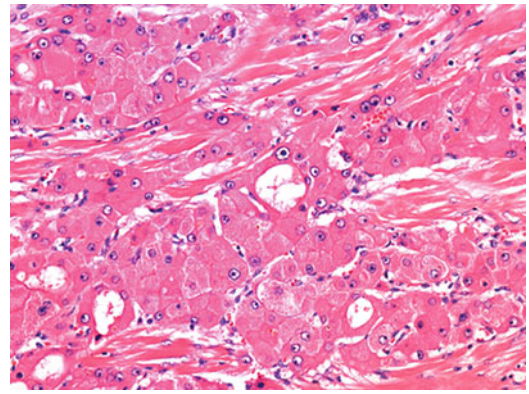

Fig. 7 Fibrolamellar hepatocellular carcinoma. The typical tumor cell is large, with abundant oxyphilic and granular cytoplasm. Nuclei are spherical to ovoid, with a hyperchromatic periphery and less dense center, and with prominent nucleoli. Pseudotubular lumina can be present (hematoxylin and eosin stain)

cellularity. However, it has been shown that the connective tissue content in FL-HCC is overall greater than in other liver tumors (Sarosi et al. 1991). The bands stain red in the van Gieson stain and bright blue with the trichrome stain. In the silver stain, the stroma shows a fine, dense, and complex network of reticulin fibers. The fibrolamellae often end in frayed edges. The fibrous matrix is predominantly composed of collagens I, III, and V, tenascin, and (less abundantly) basement membrane proteins such as laminin. In situ hybridization studies have shown that the fibroblastoid cells embedded in the matrix express collagen III-mRNA (Nerlich et al. 1992). FL-HCC cells may develop apparently intracellular lumina or spaces containing erythrocytes (Fig. 9).

Rare variants of FL-HCC, or certain regions in these tumors, may display a markedly solid component (Kojima et al. 2004). Based on the distinct cellular features and the distinct epithelial-stromal composition of FL-HCC, this neoplasm has been diagnosed by cytological methods (Suen et al. 1985; Perez-Guillermo et al. 1999; Jain et al. 2002; Kunz et al. 2002; Sarode et al. 2002; Mansouri et al. 2006; Gulati and Saran 2009). FL-HCC is an angioinvasive neoplasm that tends to invade large veins. Vascular invasion is present in about 40 % of the tumors (Farhi et al. 1983; Kakar et al. 2005). It was reported that FL-HCC arose in a background of focal nodular hyperplasia (Imkie et al. 2005). In a patient with generalized AA amyloidosis, amyloid was also deposited in the stroma of an FL-HCC (Llortea et al. 1994).

Ultrastructure

The neoplastic cells are rich in organelles and contain nuclei with often prominent cytoplasmic invaginations, the latter corresponding to the clear nuclear pseudoinclusions seen in light microscopy. The cytoplasm frequently contains numerous and densely packed, swollen mitochondria which are uniform in size and shape and often contain dense inclusions, resulting in a picture resembling oncocytes (Andreola et al. 1986). The endoplasmic reticulum is prominent, sometimes with dilated profiles. Dense cytoplasmic inclusions have been noted (Farhi et al. 1982; Andreola et al. 1986; Hasegawa 1996). Fully developed Mallory-Denk bodies are absent, but filamentous material resembling that found in these bodies has been detected (Caballero et al. 1985). Between two adjacent cells, lumina with microvilli can be found, representing abortive biliary canaliculi (Sato et al. 1997). The pale

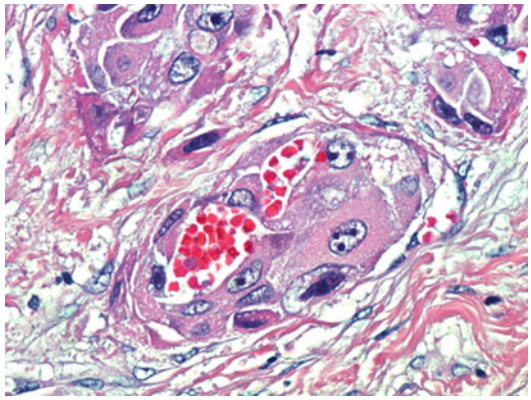

Fig. 9 Fibrolamellar hepatocellular carcinoma. Neoplastic cells can develop apparently intracellular lumina or spaces that contain erythrocytes (hematoxylin and eosin stain)

bodies seen at light microscopy ultrastructurally represent intracellular lumina lined with numerous microvilli. The central hyaline cores seen in part of the pale bodies are depositions of fine granular material (An et al. 1983). In part of the tumors, ultrastructural signs of neuroendocrine differentiation have been found (Payne et al. 1986; Garcia de Davila et al. 1987; Lloreta et al. 1994). The tumor cells are separated by broad, homogeneous bands of dense collagen with characteristic periodicity. The bands of collagen are lined by spindle cells with the features of fibroblasts or myofibroblasts, and these cells are interposed between collagen and tumor cells (Farhi et al. 1982).

Immunohistochemistry of the Epithelial Component

The immunophenotype of epithelial cells in FL-HCC has been analyzed in detail (Caballero et al. 1985; Teitelbaum et al. 1985; Berman et al. 1988). The cells of FL-HCC are positive for HepPar [hepatocyte paraffin 1] (Wennerberg et al. 1993; Klein et al. 2005; Ward et al. 2010; Patonai et al. 2013), suggesting that a hepatocyte-like differentiated cell is involved. Similar to conventional HCC, FL-HCC expresses the heparan sulfate proteoglycan, glypican-3, the positivity rate ranging from 17 % (Abdul-Al et al. 2010) to 59 % (Ward et al. 2010) and 64 % of cases (Shafizadeh et al. 2008). The tumor cells display canalicular membrane expression of pCEA (Ward et al. 2010). Interestingly, FL-HCC cells show a circumferential staining for pCEA, suggesting a loss of the normal apical-basolateral polarization of hepatocytes (own observations). The tumor cells may be positive for copper and copper-binding protein (Lefkowitch et al. 1983). The cells of FL-HCC typically and strongly express cytokeratin-7 in the cytoplasm (Van Eyken et al. 1990). Positivity for cytokeratin-7 has been confirmed in later studies (Gornicka et al. 2005; Klein et al. 2005; Abdul-Al et al. 2010; Fig. 10).

In one study, all cases of FL-HCC were positive for epithelial membrane antigen (EMA), and 36 % of FL-HCCs showed staining for cytokeratin-19, B72.3, and EpCAM (Ward

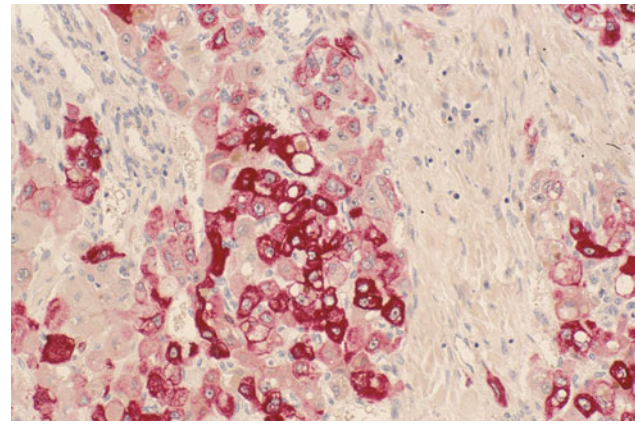

Fig. 10 Fibrolamellar hepatocellular carcinoma. Cells typically express cytokeratin-7 (CK7 immunostain)

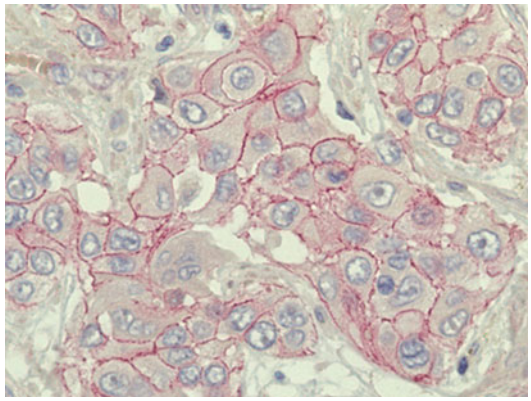

Fig. 11 Fibrolamellar hepatocellular carcinoma. The tumor cells show membranous reactivity for beta-catenin (beta-catenin immunostain)

et al. 2010). It has, however, been shown that FL-HCC is less often positive for CK19 than ordinary HCC (Abdul-Al et al. 2010). In ordinary HCC, expression of CK19 and EpCAM is associated with worse prognosis and the potential involvement of a bipotential progenitor cell (see the respective chapter). Cells of FL-HCC usually show a beta-catenin staining pattern similar to that of hepatocytes (Fig. 11).

Interestingly, the cells of FL-HCC are positive for CD68, a marker of lysosomal/endosomal membranes and typically positive in macrophages. The CD68 immunostaining, which involves almost all cases of FL-HCC, presents a distinctive granular, dot-like, or stippled pattern of the cytoplasm and had a sensitivity of 96 % and a specificity of 80 % (Ross et al. 2010). A part of FL-HCCs are immunoreactive for CD99 (Vasdev and Nayak 2003). Cells of FL-HCC produce several proteins that are also typical products of normal hepatocytes, including ferritin (Caballero et al. 1985) and alpha-1 antitrypsin, the latter sometimes accumulated in cytoplasmic globular inclusions or around such inclusions. FL-HCCs more often than ordinary HCCs express claudin-2 and claudin-5 (Patonai et al. 2011). FL-HCCs demonstrate hepatocyte growth factor receptor (c-met) levels similar to normal (Schoedel et al. 2003). In contrast to common HCC, FL-HCC has not been shown to express survivin (Kannangai et al. 2005). Similar to HCC, FL-HCC can express the CCK-B/gastrin receptor Caplin et al. 1999).

Immunohistochemistry of the Matrix Component

Immunohistochemically, the abundant extracellular matrix of FL-HCCs has been shown to contain large amounts of tenascin (Scoazec et al. 1996) and fibronectin (Jagirdar et al. 1985), whereas basement membrane proteins such as laminin seem to be less expressed. As FL-HCC cells more often express TGF-beta than HCC, it was suggested that fibrosclerosis and matrix protein production may be regulated by this fibrokine (Nerlich et al. 1992; Orsatti et al. 1997). The

tumor cells express a set of surface proteins that are important for cell-matrix interactions. The large epithelial cells are positive for alpha-1 integrin, E-cadherin, and the hepatocyte N-related cadherin, but lack beta-4 integrin (Scoazec et al. 1996). The tumor cells display a strong expression of CD44 (Washington et al. 1997), a widely distributed integral membrane protein and cell adhesion protein that has been implicated in cell-matrix contact, invasion, and metastatic spread. Most FL-HCCs revealed increased expression of active matrix metalloproteinase-2, in contrast to ordinary HCC (Schoedel et al. 2003). The sinusoid-like vascular channels of FL-HCC have diffusely CD34-positive endothelia (Abdul-Al et al. 2010).

Growth Features of FL-HCC

FL-HCCs typically grow with broad pushing borders. Invasion of adjacent parenchyma may be seen histologically, and portal tracts may be entrapped in the growing tumor front. FL-HCC has a very low mitotic activity, mitotic figures being normally structured in most cases. In a study of seven cases, the mitotic index was very low, i.e., 0–1 mitotic figure/10 high-power fields. The percentage of Ki-67 nuclear staining ranged from 1.0 to 29.7 %. There was no reactivity for S-phase kinase-associated protein (Skp) 2; all cases showed moderate to strong nuclear p16INK4 positivity (Dhingra et al. 2010).

Clear Cell Variant of Fibrolamellar Hepatocellular Carcinoma

A clear cell variant of FL-HCC has been described (Cheuk and Chan 2001). A 59-year-old female known to be a hepatitis B virus carrier was found to have a liver mass on routine checkup, visualized at CT as a solitary mass in the right liver lobe. Serum AFP was not elevated. The lesion was resected via right hepatectomy, and the patient was without of recurrence 13 months later. Grossly, the tumor was circumscribed, bosselated and formed a tumor measuring up to 50 mm in diameter. Histologically, the tumor consisted of oxyphilic cells and clear cells of about 50 % each, embedded in stroma consisting of strands of hyalinized collagen. Transitional forms between the two main cell types were seen. Pale bodies were found in part of the cells. Both the oxyphilic cells and the clear cells showed diffuse immunostaining for HepPar1, whereas antimitochondrial antibody stained the oxyphilic cells but weakened the clear cells. This variant has also been diagnosed by fine needle aspiration cytology (Kaplan and Hoda 2007.)

Glandular Variant of Fibrolamellar Hepatocellular Carcinoma

This probably rare and somewhat intriguing variant of FL-HCC is characterized by components of acinar or pseudoglandular structures, sometimes with mucin production (Goodman et al. 1985; Tanaka et al. 2005). The cells lining the gland-like spaces are structurally similar to other FL-HCC cells, but are usually smaller. Mucin is detectable within the neoplastic cells but also in the lumina of acinar profiles, and the mucinous substance is positive for mucicarmine and alkaline alcian blue (Goodman et al. 1985). The cells lining the pseudoglandular spaces immunohistochemically share features with cholangiocellular elements, i.e., positivity for biliary-type cytokeratins. This phenotype was also found in lymph node metastases of the tumor, a phenomenon which may exclude a collision tumor (Tanaka et al. 2005). This is the reason why such neoplasms were also termed, combined fibrolamellar carcinoma and cholangiocarcinoma, with biphenotypic antigen expression (Tanaka et al. 2005). This cholangiocyte-like differentiation is not associated with other histologic features of true cholangiocarcinoma; the biologic behavior of such combined tumors seems to be more in keeping with pure FL-HCC.

Combined Patterns

Combined tumors, albeit very rare, are of some theoretical interest because they may shed light on the cell of origin of FL-HCC. Exceptionally,

FL-HCC occurred in combination with conventional HCC (Hasegawa 1996; Okano et al. 1998; Seitz et al. 2002), the FL-HCC component being cytokeratin-7 positive, in contrast to the HCC component (Seitz et al. 2002; Zermani et al. 2005). In the tumor described by Hasegawa (1996), a common HCC element with trabecular structure existed at the periphery of the FL-HCC. In contrast, the tumor described by Seitz et al. (2002) showed HCC at the center of a large FL-HCC. In few cases, FL-HCC transformed into common HCC in recurrent lesions of the residual liver and in a remote metastasis (Yamamoto et al. 1999; Chang et al. 2003). FL-HCC has also been found to be associated synchronously with common HCC located in another part of the liver (Okada et al. 1993).

FL-HCC has been observed 5 years after hepatocellular adenoma in a 14-year-old girl (Terracciano et al. 2004). Nodular hyperplasia associated with or surrounding FL-HCC has been observed (Saul et al. 1987; Saxena et al. 1994). In a 14-year-old girl, a 9 cm subcapsular nodule was present in the right lobe of the liver, with a distinct zonation: ca central grayish white area of FL-HCC and peripheral fleshy, tan-colored rim of nodular hyperplastic liver parenchyma resembling FNH. It was suggested that the hyperplasia was a reaction to an abnormal arterialization of the tissue, the arteries originating from the central FL-HCC (Saxena et al. 1994). It has been assumed that FL-HCC may be the malignant counterpart of FNH (Vecchio et al. 1984), but there is no convincing evidence for this.

Biology of Disease

FL-HCC reveals a metastasizing pattern different from ordinary HCC. FL-HCC tends to metastasize within the abdominal cavity. This may lead to intriguing and misleading patterns, such as metastasis to the pancreatic head (Thirabanjasak et al. 2009) or the skeletal muscle (Kutluk et al. 2001). FL-HCC can metastasize to the ovaries (Benito et al. 2012) and has been shown to produce ovarian Krukenberg tumor as first tumor manifestation (Montero et al. 2007; Bilbao et al. 2008). FL-HCC is also a primary liver tumor that typically metastasizes to locoregional lymph nodes (Stipa et al. 2006; Tsilividis et al. 2010; Gras et al. 2012, Fig. 12), lymph node positivity representing a negative prognosticator and considered to be an indication for lymph node dissection (Yamamoto et al. 1995; Hiramatsu et al. 1999; Jaeck 2003).

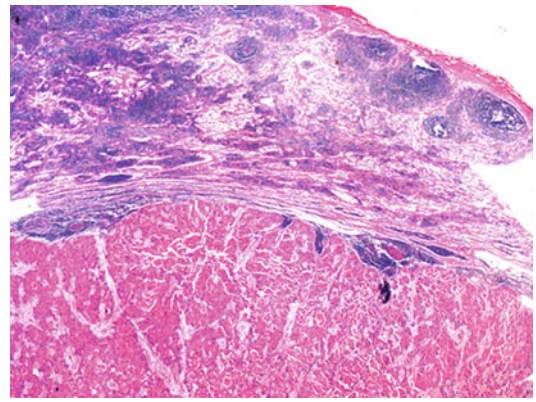

Fig. 12 Lymph node metastasis of fibrolamellar hepatocellular carcinoma. The typical tumor morphology, with strongly eosinophilic cells and fibrous bands, is recapitulated in metastatic disease (hematoxylin and eosin stain)

As ordinary HCC, FL-HCC can invade large vessels, including the inferior vena cava, and spread to the heart cavities and pulmonary arteries (Asrani and LaRusso 2012; Knudson et al. 2012).

Several studies have advocated that FL-HCC is less aggressive than conventional HCC (Berman et al. 1980; Craig et al. 1980; Lack et al. 1983; Wetzel et al. 1983; Nagorney et al. 1985; Hodgson 1987; Kaczynski et al. 1996; Pinna et al. 1997; Okuda 2002; El-Serag and Davila 2004; Meriggi and Forni 2007), and even in textbooks it is or was mentioned that FL-HCC is associated with a favorable prognosis (Everson and Trotter 2003; Sherlock and Dooley 2003; Ferrell 2004). There are single reports of long-term survival after surgery alone (Ishikawa et al. 2007), but in contrast to older suggestions, there is now evidence that the biology of FL-HCC in comparison with ordinary HCC is a complex issue, the presence or absence of differences in part being affected by artifacts of methodology (Njei 2014). For example, in patients with FL-HCC, the better outcome

in some patients is due to the absence of cirrhosis in these patients, and the presentation at a non-advanced stage, rather than its distinct clinicopathologic features (Stevens et al. 1995; Zografos et al. 1997). There is also evidence that tumor stage was in fact the most significant factor for prognosis in patients treated with resection and transplantation (Ringe et al. 1992; El-Gazzaz et al. 2000). The biology of FL-HCC shows, nevertheless, striking differences in comparison with conventional HCC, mainly what regards metastatic patterns and causes of death (Epstein et al. 1999). A study of the Pediatric Oncology Group (Pediatric Intergroup Hepatoma Protocol), analyzing 46 patients, showed that children with FL-HCC did not have a favorable prognosis and do not respond any differently to current therapeutic regimens than patients with common HCC (Katzenstein et al. 2003). In a study of 20 resected cases, the 5-year survival was 45 %, the overall mortality was 60 %, and mortality of FL-HCC was higher with metastatic disease at presentation. Age, gender, and tumor size did not correlate with survival (Kakar et al. 2005). In another retrospective investigation, however, age was a prognosticator, in that patients diagnosed before 23 of age had a worse outcome than those diagnosed after age 23 (Moreno-Luna et al. 2005). In a study on 41 patients, median tumor size in 28 patients treated with resection was 9 cm, 50 % of the patients had lymph node metastases, and nodal metastases were the only negative prognostic factor. Seventeen of these patients (61 %) underwent a second resection for recurrent disease. The 5-year survival of resected patients was 76 %, but 5-year recurrence-free survival was only 18 %, illustrating that this tumor has a characteristic tendency for recurrence (Stipa et al. 2006). In a series of ten patients, FL-HCC was treated with resection followed by close surveillance and aggressive management of relapse. Relapse occurred in all ten cases at a median of 2.2 years. With a combination of re-resection, systemic chemotherapy, and radiotherapy, the overall median survival was 9.3 years (Maniaci et al. 2009). FL-HCC is different from common HCC in its recurrence pattern after liver transplantation. Late recurrence (>1000 days) is typical for FL-HCC, and the tumors tend to be associated predominantly with extrahepatic or combined extra- and intrahepatic recurrence, while well-differentiated HCCs tended to recur within the liver (Schlitt et al. 1999). In the recent SIOPEL/Childhood Liver Tumour Strategy Group study on 24 patients with FL-HCC, long-term overall survival in FL-HCC and ordinary HCC was similar (Weeda et al. 2013). In contrast, the results of a nationwide survey using SEER data show that surgically treated patients with FL-HCC had better long-term outcomes than those with conventional HCC (Mayo et al. 2014). In the setting of a systematic review and meta-analysis of 368 FL-HCC patients, it turned out that overall there was a significant increase in 5-year survival for FL-HCC versus conventional HCC, but this difference was not detectable in the subgroup of non-cirrhotic patients (Njei et al. 2014).

Differential Diagnosis

There are conventional HCCs having a central scar and a scalloped tumor margin resembling FNH and FL-HCC. In one study, such tumors predominantly occurred in non-cirrhotic livers of patients in their 60s and were associated with a good surgical outcome (Yamamoto et al. 2006). There are other primary liver carcinomas with a marked stromal component, which may cause diagnostic problems (Malouf et al. 2009). Histologically, sclerosing hepatocellular carcinoma may mimic FL-HCC, but these tumors have smaller epithelial cells, the stroma is more cellular and not band-like, and the tumors occur in middle-aged persons, show a male predominance, and are associated with the typical HCC risk factors (Haratake and Horie 1989).

Pathogenesis

Cell Lineage(s) Involved

The cell lineage of FL-HCC is still not well known, despite the fact that the tumor cells resemble hepatocytes with oxyphilic features and that

the cells share with hepatocytes immunoreactivity for a hepatocyte marker, HepPar. Other findings that support a hepatocyte-like lineage in FL-HCC is the positivity for glypican-3, a canalicular staining pattern with polyclonal CEA/pCEA (see above), and the positivity for albumin mRNA by in situ hybridization (Ward et al. 2010). In contrast to normal hepatocytes, FL-HCC cells are usually positive for cytokeratin-7 and sometimes for cytokeratin-19 and for epithelial membrane antigen (EMA), normally expressed in cholangiocytes of the normal liver. These results have been interpreted to suggest that FL-HCCs show a dual differentiation, i.e., both hepatocellular and cholangiocellular (Ward et al. 2010). There is also immunohistochemical evidence for a stem cell-associated phenotype of FL-HCC. The tumor cells were positive for the stem cell markers CD133 and CD44, revealed reduced cell cycle progression, and displayed evidence of reduced differentiation (Zenali et al. 2010).

Cytogenetic Findings

FL-HCC generally reveals less ploidy and chromosomal aberrations than ordinary HCC and hence a greater genomic homogeneity (Lapis et al. 1990; Orsatti et al. 1994; Sirivatanauksorn et al. 2001; Ward and Waxman 2011). Specifically, 8p- and 17q+, which are typical for HCC, hardly occur in FL-HCC (Terraciano and Tornillo 2003). Also allele loss seems to be much less common that in conventional HCC (Ding et al. 1993). FL-HCCs with chromosomal alterations seem to behave more aggressively than tumors without cytogenetic abnormalities (Kakar et al. 2009). By the use of comparative genomic hybridization, chromosomal imbalances were identified in 6 out of 11 (55 %) of cases, and the mean number of aberrations per case was 3.9 for all cases and 7.2 in abnormal cases. The most common abnormalities were found in chromosomes 1, 7, 8 and 18, with gains in 1q and 8q and loss of 18q being the most common alterations (Kakar et al. 2009; review: Ward and Waxman 2011). As outlined in the next paragraph, 7p has a gene (AGR2) that is overexpressed in FL-HCC and affects cancer cell spread. Some of the tumors show complex chromosomal patterns, such as a nearly triploid karyotype (Hany et al. 1997). Genomic hybridization (CGH) studies demonstrated striking differences in recurrent cytogenetic aberrations between FL-HCC and common HCC (Wilkins et al. 2000). Loss of heterozygosity (LOH) on 6q at the mannose 6-phosphate/insulin-like growth factor II receptor locus has found in 33 % of FL-HCCs, in comparison with 69 % in common HCCs, suggesting that this gene may act as a tumor suppressor in HCC and FL-HCC (DeSouza et al. 1995). Previously (and in apparent contrast to conventional HCC), epigenetic instability manifesting as methylation of tumor suppressor promoters had been reported to be rare in FL-HCC (Vivekanandan and Torbenson 2008). In a later study, it was shown that FL-HCCs display frequent and distinct gene-specific hypermethylation in the absence of significant global hypomethylation. Frequent aberrant hypermethylation was found for the cyclin D2 and the RASSF1A genes as well as for the microRNA genes mir-9-1 and mir-9-2 (Tränkenschuh et al. 2010). The genomic features of FL-HCC loose homogeneity as a function of the tumor's spread, and recurrent metastatic tumors have complex karyotypes (Lowichik et al. 1996).

Molecular Findings

FL-HCC displays a distinct genomic landscape (Darcy et al. 2015b) and shows a unique genomic profile uncovering three robust molecular classes, i.e., a proliferation class, an inflammation class, and an unannotated class (Cornella et al. 2015). Recently, a recurrent DNAJB1-PRKACA chimeric transcript, arising as a result of a ~400 kb deletion on chromosome 19, was detected in FL-HCC. The chimeric RNA was predicted to code for a homolog of the molecular chaperone DNAJ, fused in frame with PRKACA, the catalytic domain of protein kinase A. The chimeric protein is expressed in tumor tissue and retains kinase activity (Honeyman et al. 2014; Xu et al. 2015).

FL-HCCs display various other molecular abnormalities. FL-HCC overexpresses epidermal growth factor receptor (EGFR), similar to conventional HCC (Buckley et al. 2008), probably due to polysomy 7 rather than gene amplification. Immunohistochemically, EGFR was strongly overexpressed on the cell membranes of more than 90 % of tumors tested (Buckley et al. 2006). FL-HCC exhibits overexpression of genes in the RAS, MAPK, PIK3, and xenobiotic degradation pathways (Kannangai et al. 2007) and reveals mTORC1 activation and FGFR1 overexpression (Riehle et al. 2015). FL-HCC cells express anterior gradient 2 (AGR2; Vivekanandan et al. 2009), a protein that is critical for normal embryonic development. AGR2 is located on chromosome 7p21.3 (Petek et al. 2000) and encodes the human homolog of a secreted protein identified in *Xenopus* (cement gland-specific gene), where it determines the formation of anterior structures during the generation of ectoderm. In the adult mammalian organism, AGR2 is mainly expressed in cells of the gastrointestinal tract. In the small intestine of mice, expression is found predominantly in Paneth, neuroendocrine, and goblet cells (Komiya et al. 1999; Wang et al. 2008). It has been shown that AGR2 encodes a protein disulfide isomerase (enzymes that aid protein folding and assembly), which is essential for the production of the intestinal mucin MUC2 (Park et al. 2009). A critical interacting protein of AGR2 is the ATP-binding protein, reptin (Maslon et al. 2010). AGR2 is expressed in several cancers, including pancreatic cancer, breast cancer, and lung cancer, where it affects cancer cell survival (via the p53 pathway), cancer cell motility, and cancer spread. Specifically, AGR2 promotes metastatic spread and its expression is associated with poor survival. This metastasis-promoting activity of AGR2 is repressed by ErbB3-binding protein 1 (Zhang et al. 2010). In FL-HCC, overexpression of AGR2 is associated with several polymorphisms, but no mutations (Vivekanandan et al. 2009). In contrast to ordinary HCC, where missense mutations and interstitial deletions of the beta-catenin gene and nuclear accumulation of beta-catenin are common, beta-catenin gene alterations were not yet detected in FL-HCCs (Terris et al. 1999), so that the Wnt-beta-catenin signaling pathway does not seem to be involved in the carcinogenesis of this tumor.

FL-HCC reveals alterations of mitochondrial structure and function. It is well known that ordinary HCCs show mitochondrial DNA mutations. In one molecular study, approximately 50 % of ordinary HCCs had lower levels of total mitochondrial DNA than paired nonneoplastic tissue, associated with deletions of the mitochondrial DNA control region. Despite their apparently increased numbers of mitochondria, primary FL-HCCs had lower levels of total mitochondrial DNA, while metastatic FL-HCCs had greatly increased mitochondrial DNA levels. Complete sequencing of the entire mitochondrial genome in FL-HCC identified several somatic mutations, but no consistent pattern of mutations was found (Vivekanandan et al. 2010).

HBV Infection

Ordinary HCC has an etiologic association with HBV in numerous cases. It was therefore of interest to test whether FL-HCC is also related to HBV infection, although this tumor is not associated with liver cirrhosis. The finding of integrated HBV DNA in certain instances of FL-HCC tissue may be consistent with an oncogenic role of HBV in at least a subset of the tumors (Davison et al. 1990; Dadke et al. 2002). This question has to be addressed in more detail with larger numbers of tumors.

Abstract

Hepatoblastoma (HB) is a rare malignant blastomatous liver tumor characterized by various combination of epithelial and mesenchymal cell lineages that recapitulate early phases of liver ontogenesis. HB is typically a pediatric liver neoplasm; most cases are diagnosed before the age of 5 years. Very rarely, HB develops in older children and adults. HB accounts for less than 5 % of pediatric malignancies. The tumor occurs more commonly in low birth weight children and is associated with several molecular and cytogenetic abnormalities, mutations in the Wnt/beta-catenin signaling pathway being frequent. Morphologically, HBs are divided into epithelial and mixed epithelial-mesenchymal types. Epithelial tumors are broken down into fetal, embryonal, macrotrabecular, and small cell undifferentiated subtypes, while mixed epithelial-mesenchymal HBs are grouped into those without or with teratoid features. A subset of small cell undifferentiated HB exhibits rhabdoid features associated with loss of INI1 expression, similar to malignant rhabdoid tumors. Although HBs are aggressive lesions with high recurrence rate and metastatic disease, modern therapies now produce excellent results. In order to improve treatment, molecular profiles are developed to refine risk stratification.

ICD-O Codes

Epithelial Variants	8970/3
Mixed Epithelial-Mesenchymal Variants	8970/3

Introduction

According to the 2010 WHO classification, hepatoblastoma is defined as a primary malignant blastomatous tumor of the liver characterized by various combinations of several epithelial and mesenchymal cell lineages. The epithelial lineages recapitulate early hepatic ontogenesis and include immature cells, embryonal and fetal hepatoblasts, and more mature hepatocyte-like cells (Zimmermann and Saxena 2010).

Epidemiology

Hepatoblastoma represents the most frequent epithelial liver tumor in infancy and childhood, comprising 50–60 % of all hepatic neoplasms in this age group and encompassing around 1 % of all pediatric malignancies (MacNab et al. 1952; Clatworthy et al. 1961, 1974; Hartley et al. 1990; Ross and Gurney 1998; Linely and Ross 2008; Spector and Birch 2012; Allan et al. 2013). Hepatoblastoma is a tumor of infants and small children . Most hepatoblastomas occur in children between 6 months and 3 years of age, around 90 % being diagnosed before the age of 5 years, but age at diagnosis ranges from prenatal stages to adulthood (Steiner 1938; Yamazaki et al. 2004; Admasse and Kebede 2007; Zheng et al. 2009). Only about 5 % of new hepatoblastoma cases are detected in children more than 4 years of age, and about 10 % of hepatoblastomas are diagnosed in the neonatal period (Florentin et al. 1956; Alagille 1961; Sallem et al. 2005; Cornert et al. 2007). Some hepatoblastomas are manifest at birth already, termed congenital hepatoblastoma (Stiller and Holzhausen 1983; Ammann et al. 1999; Worth et al. 1999; Shih et al. 2000a; Catanzarite et al. 2008). Few tumors are diagnosed prenatally (Shih et al. 2000b; Aviram et al. 2005; Ergin et al. 2008). Hepatoblastoma arising in the fetal period is one of the lesions inducing fetal nonimmune hydrops (Kazzi et al. 1989). In Western countries, the annual incidence rates range from 1 per 100,000 to 1 per 1,000,000 children under 15 years of age (Mann et al. 1990; Hughes and Michels 1992).

An increased incidence of hepatoblastoma has been observed between 1971 and 1983 at a Children's Tumor Registry in Manchester, United Kingdom, with an increase from 0.4 to 1.0 per million (Mann et al. 1990). Data on 849 children diagnosed with malignant hepatic tumors before the age of 15 years during 1978–1997 in Europe were extracted from the ACCIS (Automated Childhood Cancer Information System) database. Age-standardized incidence during 1988–1997 was 1.2 per million for hepatoblastoma and 0.2 per million for hepatocellular carcinoma.

Over 90 % of hepatoblastomas occurred before age 5 years (Stiller et al. 2006). In Germany, an annual incidence rate of 1 per 1,000,000 children under 15 years of age and of 6 per 1,000,000 children under 1 year of age was observed (Kaatsch 2002). In an epidemiological review based on the Surveillance, Epidemiology, and End Results (SEER) database, 918 primary hepatic malignancy deaths were reported for the United States among persons less than 20 years of age during the time period between 1979 and 1996. Between 1973 and 1997, 271 primary hepatic malignancy cases were reported to SEER among persons less than 20 years of age, of which 184 (67 %) and 83 (31 %) were hepatoblastoma and hepatocellular carcinoma, respectively (Darbari et al. 2003). A US trend in childhood cancer incidence analysis covering the time period 1992–2004 revealed an annual percent change of 4.3 % for hepatoblastoma (Linabery and Ross 2008). The main reason of an increase in hepatoblastoma incidence is thought to be the improved outcome of premature children, low and very low birth weight being a risk factor for hepatoblastoma (see below). For so far unknown reasons, hepatoblastoma occurs in males significantly more often than it does in females (Weinberg and Finegold 1983; Buckley et al. 1989).

Clinical Features

General Features

The pertinent clinical features have been reviewed in numerous publications. Main clinical signs and symptoms of hepatoblastoma in small children comprise abdominal distension with or without firmness, hepatomegaly, abdominal swelling, a palpable and/or rapidly growing abdominal mass, anorexia, weight loss, vomiting (sometimes projectile), and irritability or lethargy. Jaundice is found in a minority of patients (5 % or less).

In up to 90 % of patients, a marked elevation of serum alpha-fetoprotein (AFP) concentration is found (Alpert and Seeler 1970). Monitoring of serum AFP levels is used as an outcome predictor (Van Tornout et al. 1997). AFP has an important role in ontogenesis and is associated with several tumors, including hepatocellular carcinoma, hepatoblastoma, certain germ cell tumors, hepatoid carcinomas, and less often with other neoplasms (Abelev 1971). Caution must be taken in monitoring serum AFP levels in young infants since an "adult" level of AFP (<25 ng/mL) is not reached until about 6 months of age. Serum AFP levels roughly parallel the course of disease and drop following resection of the tumor (Ikeda et al. 1981) or chemotherapy (Pritchard et al. 1982; Kubota et al. 2004). Serial monitoring of serum AFP levels during treatment may identify favorable and poor responders to therapy (Koh et al. 2011). However, serum AFP is not increased in all patients with AFP. There are sporadic reports of AFP-negative hepatoblastoma (Goedeke et al. 2011). Low serum AFP has been observed in a very low birth weight infant (717 g) having a hepatoblastoma of the well-differentiated fetal-type AFP in serum amounting to 322 ng (mL (Tsuchida et al. 1999). A later study showed the analysis of 21 patients with low serum AFP (<100 ng/mL) at diagnosis, accrued onto SIOPEL trials. Eight patients had extrahepatic extension and eight had a multifocal tumor. 11 out of 15 available histologies were epithelial HB, including nine with a small cell undifferentiated subtype. Only nine patients achieved a

partial response and 16 died. The 2-year survival rate was 24 %. These findings demonstrate that hepatoblastomas with a low serum AFP concentration at diagnosis form a high-risk group with extensive disease at diagnosis and poor outcome (De Ioris et al. 2008). High-risk histologies including small cell undifferentiated hepatoblastoma and neoplasms with rhabdoid features are overrepresented in this group.

Hematological Abnormalities

Marked thrombocytosis (exceeding 50 × 10(4)/μL) is often found in hepatoblastoma and can be a diagnostic clue (Nickerson et al. 1980; Shafford and Pritchard 1993; Yamaguchi et al. 1996). There is evidence that thrombocytosis in hepatoblastoma results from the production of thrombopoietin within the tumor tissues (Nickerson et al. 1980; Komura et al. 1998). However, it was also shown that in a patient with hepatoblastoma-associated thrombocytosis, serum thrombopoietin levels were not high at diagnosis, whereas high levels were found after chemotherapy, and thrombopoietin was detected by use of PCR in both normal liver and tumor, with no measurable difference between them (Yamaguchi et al. 1996). A second mechanism of thrombocytosis in hepatoblastoma may be related to the production of interleukin-6 by the tumors. Hepatoblastomas produce IL-1beta and thus induced secretion of IL-6 by stromal cells (von Schweinitz et al. 1993). Stromal cells derived from liver, including myofibroblasts in culture, are capable to produce IL-6 (Tiggelman et al. 1995). Also in other malignancies associated with paraneoplastic thrombocytosis, IL-6 production has been shown to be involved, e.g., ovarian cancer and renal cell carcinoma (van Rossum et al. 2009; Stone et al. 2012).

Hormonal Abnormalities

A minority of hepatoblastomas have been shown to be associated with precocious puberty due to production of gonadotropins. Following the first report in 1931 (Behrendt 1931), more than 30 cases of precocious puberty associated with hepatoblastoma have been reported, and all patients were male. In at least a fraction of these cases, human chorionic gonadotropin secretion by the tumor has been observed to be the cause of precocious puberty (Hung et al. 1963; Root et al. 1968; Braunstein et al. 1972; McArthur et al. 1973; Nakagawara et al. 1985). In part of cases, both hCG and AFP were synchronously elevated in serum (Nakagawara et al. 1985; Eren et al. 2009). In a study of four patients (all male), histology was mixed fetal and embryonal in all cases (Nakagawara et al. 1985). A predominantly embryonal morphology was documented in another report (Heimann et al. 1987). Immunohistochemically, hCG was shown to be produced by both well-differentiated cells (Morinaga et al. 1983) and multinucleated tumor giant cells (Nakagawara et al. 1982; Watanabe et al. 1987). In one report, the hCG-positive giant cells were regarded as suspicious to be derivatives of choriocarcinoma (Watanabe et al. 1987). Precocious puberty associated with hepatoblastoma is not always caused by production of hCG. In one case, this endocrine disorder was caused by testosterone-producing hepatoblastoma (Galifer et al. 1985). In addition to gonadotropins and sex steroids, rare hepatoblastomas can produce other hormones, e.g., the ectopic ACTH syndrome (Rabl et al. 1988; Grunewald et al. 2010), or production of renin, sometimes associated with severe hypertension (Moritake et al. 2000; Tavasoli et al. 2013).

Complications

Hepatoblastomas may undergo spontaneous or traumatic rupture (Nissel 1928; Nitta et al. 2012; Saettini et al. 2013): Tumor rupture sometimes occurs during delivery in case of large lesions (Lai and Burjonrappa 2012). Hepatoblastoma may initially present as hemoperitoneum, owing to tumor rupture (Giacomoni et al. 1986), also in the rare adult hepatoblastoma (Baroni et al. 1984). Hepatoblastoma can be associated with sudden unexpected death in infancy (Pryce et al. 2010).

Imaging Features

The imaging features of hepatoblastomas that have been reviewed are not treated in this chapter (Dachman et al. 1987; Helmberger et al. 1999; Sato et al. 2000; Roebuck and Perilongo 2006; Lu and Greer 2007; McCarville and Roebuck 2012; Meyers et al. 2012).

Classification of Hepatoblastomas

Hepatoblastomas and related neoplasms exhibit a distinct variety of histopathological patterns. This phenomenon has led to a variety of classifications, which are still in a phase of reappraisal and further development. One early observation was that hepatoblastomas can consist of both epithelial and mesenchymal components, leading to a separation of wholly epithelial versus mixed epithelial and mesenchymal hepatoblastomas (MEMHB) (Ishak and Glunz 1967; Nikaidoh et al. 1970; Schiodt 1970; Gonzalez-Crussi and Manz 1972; Gonzalez-Crussi et al. 1982; Iwafuchi et al. 1981; Lack et al. 1982; Weinberg and Finegold 1986; Conran et al. 1992). About 60 % of hepatoblastomas are entirely epithelial at diagnosis, while the remaining cases are mostly MEMH, and a small minority consists of unusual subtypes, such as teratoid hepatoblastoma . Issues of histological classification of hepatoblastomas have been reviewed in detail (Rowland 2002). The classification of SIOPEL (Childhood Liver Tumour Study Group) trials is shown in Table 1.

Table 1 Histopathologic classification of hepatoblastomas as used in SIOPEL (Zimmermann 2003; Zimmermann and Lopez-Terrada 2011)

Wholly epithelial hepatoblastoma
Purely fetal
Mixed fetal embryonal/embryonal
Macrotrabecular
Small cell undifferentiated
Mixed epithelial and mesenchymal
Without teratoid features
With teratoid features
Hepatoblastoma, not otherwise specified (NOS)

Table 2 Hepatoblastoma family of tumors (Zimmermann 2005, modified)

Wholly epithelial hepatoblastomas
Fetal subtype (including "purely fetal HB")
Embryonal and mixed embryonal/fetal subtype
Macrotrabecular HB subtype 2 (MT-2)
Undifferentiated subtype (diffuse or focal)
Small cell undifferentiated HB (SCUD)
Intermediate cell undifferentiated HB (ICUD)
Large cell undifferentiated HB (LCUD)
Liver cell tumors with a mature-looking hepatocellular phenotype
Macrotrabecular HB subtype 1 (MT-1)
Transitional liver cell tumor (TLCT)
Stromal-epithelial and stromal tumors
Mixed epithelial and mesenchymal hepatoblastoma (MEMHB)
Stromal-epithelial tumors, including nested stromal-epithelial tumor
Pediatric hepatic stromal tumors (PHST)
Hepatoblastoma-like tumors with a bimodal differentiation
Cholangioblastic hepatoblastoma
So-called ductal plate tumors
Hepatoblastoma family tumors with organoid features
Hamartoma-like hepatoblastomas
Multilineage tumors
Teratoid hepatoblastoma
Primitive multilineage tumors with stem cell-like features

The histologic types and subtypes listed in this table are described in detail in a subsequent paragraph. The recognition of other and novel tumor phenotypes, together with the refinement of immunohistochemical and molecular methods, has led to the proposition of extended classifications. In particular, a *hepatoblastoma family of tumors* has been proposed in the sense of a working formulation (Zimmermann 2005), compiled in Table 2.

A novel classification was worked out in the setting of an International Pathology Symposium in March 2011, by 22 expert pathologists of COG, SIOPEL, GPOH, and JPLT as well as by pediatric oncologists and surgeons specialized in this field arriving at a consensus classification (the Los Angeles Classification; Lopez-Terrada et al. 2014; Table 3). The 2011 Conference was the first collaborative step to develop a classification leading to a

Table 3 Los Angeles hepatoblastoma classification (Lopez-Terrada et al. 2014; modified)

Epithelial hepatoblastomas
Fetal HB
Well differentiated: uniform (10–20 μm in diameter), round nuclei, cords with minimal mitotic activity (<2 mitotic figures per 10/400× microscopic fields); extramedullary hematopoiesis present
"Crowded" or mitotically active: more than 2 mitotic figures per 10/400× microscopic fields; conspicuous nucleoli, usually less glycogen
"Pleomorphic, or poorly differentiated": moderate anisonucleosis, high nucleus/cytoplasmic ratio, prominent nucleoli
"Anaplastic": marked nuclear enlargement and pleomorphism, nuclear hyperchromasia, abnormal mitotic figures
Embryonal HB
Tumor cells 10–15 μm in diameter, high nucleus/cytoplasmic ratio, angulated nuclei, primitive tubular structures, extramedullary hematopoiesis usually absent
Macrotrabecular
Epithelial HB (fetal or embryonal) growing in trabeculae of more than five cells thick (between the sinusoids)
Small cell undifferentiated
Tumor cells 5–10 μm in diameter, no distinct architectural pattern, minimal pale amphophilic cytoplasm, round to oval nuclei with fine chromatin structure and inconspicuous nucleoli, mitotic figures present; part of tumors lack nuclear INI1 expression
Cholangioblastic HB
Bile duct-like profiles are present, usually at the periphery of epithelial HB islands; this pattern may predominate
Mixed epithelial-mesenchymal hepatoblastomas
HB with stromal derivatives
Presence of spindle cells ("blastema"), osteoid, skeletal muscle, cartilage
Teratoid HB
Mixed HB plus primitive endodermal components, neural derivatives, melanocytes, glandular elements

common treatment stratification system incorporating tumor histopathology.

General Pathology Features

Introduction

As shown in the section on classification, pathology of hepatoblastoma family tumors has become complex after this malignancy had been separated from "hepatomas" in the old literature. Apart from the identification of types and subtypes based on in-depth analyses of case groups and later large series of tumors, in part by use of refined immunohistochemical methods, the definition of distinct histopathologic categories has been led by the attempt to identify risk stratifications in a therapeutic setting (reviews: Lopez-Terrada and Finegold 2007; Zimmermann and Saxena 2010, 2011; Lopez-Terrada and Zimmermann 2012).

Macroscopy

Hepatoblastoma is located more often to the right lobe of the liver (about 60 %), with only 15 % being located in the left lobe and 25–30 % of the tumors extending into both lobes (Exelby et al. 1975; Keeling 1971; Ke et al. 2005). In a study of 32 patients, the tumor was confined to the right liver lobe in 16 cases and to the left lobe in 3 cases, while in 13 cases tumor nodules were scattered throughout the liver (Keeling 1971). Hepatoblastomas can also present as large or giant masses involving the liver hilum (Dong et al. 2009). The tumors are usually large at diagnosis, often with a diameter of 10–12 cm. Among 35 cases, the size of hepatoblastoma ranged from 6 to 17 cm in greatest dimension (Ishak and Glunz 1967). Generally, hepatoblastomas reveal a lobulated or nodular cut surface, and part of the tumors bulge or project from the liver surface (Figs. 1 and 2).

The consistency is firm, soft, or soft and friable, about a third each (Ishak and Glunz 1967). Expanding lesions cause compression atrophy of the adjacent liver substance, sometimes with formation of a pseudocapsule, but true capsules have also been noted (Ishak and Glunz 1967). Epithelial hepatoblastomas tend to show a homogeneous cut surface, while mixed hepatoblastomas are more often variegated, epithelial components being present as tan or gray-to-yellow nodules and mesenchymal components as firm or fibrous gray zones, sometimes speckled with whitish material representing osteoid. In a minority of cases of well-differentiated hepatoblastoma, bile accumulation can cause greenish or even bile-stained nodules. Large venous vessels, sometimes

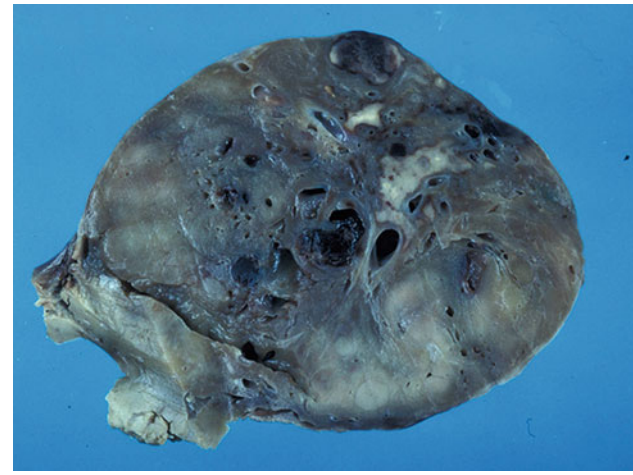

Fig. 1 Hepatoblastoma. Macroscopically, the large tumor shows an expanding growth pattern. Central parts exhibit extensive hemorrhage and whitish necroses (fixed specimen)

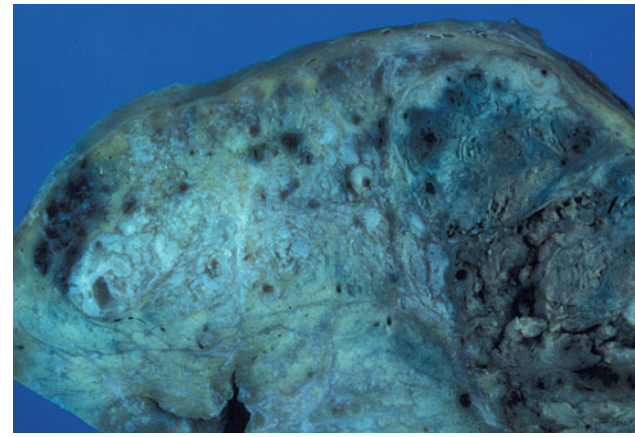

Fig. 2 Hepatoblastoma. The cut surface exhibits a complex mixture of partially necrotic nodular structures (fixed specimen)

thrombosed, may be present around the tumor, causing prominent vessels also at the capsular surface. A protocol for the examination of hepatoblastoma specimens has been developed (Finegold et al. 2007).

Histopathology: Distribution of Histologic Types and Subtypes

Among 105 hepatoblastomas classified on the basis of both their epithelial and mesenchymal components, 28 % were fetal, 17 % embryonal, 31 % mixed without teratoid features, 9 % mixed with teratoid features, 3 % macrotrabecular, 3 % SCUD, and 9 % hepatoblastoma not otherwise specified (NOS). When the tumors were classified on the basis of their epithelial component alone, the following distribution was found: 29 % of the tumors were fetal, 55 % embryonal, 3 % macrotrabecular, and 3 % small cell undifferentiated (Conran et al. 1992).

Hepatoblastoma, Wholly Epithelial Type: Fetal Hepatoblastomas (Fetal Subtype)

The morphology of fetal hepatoblastoma has been described in detail by Ishak and Glunz (1967). Fetal-type cells resemble, as their name indicates, cells of the prenatal fetal liver. They are polyhedral, uniform, and smaller than mature hepatocytes, with well-defined outlines. Two main cell types are recognized, i.e., a cell type with a granular and eosinophilic cytoplasm and a slightly

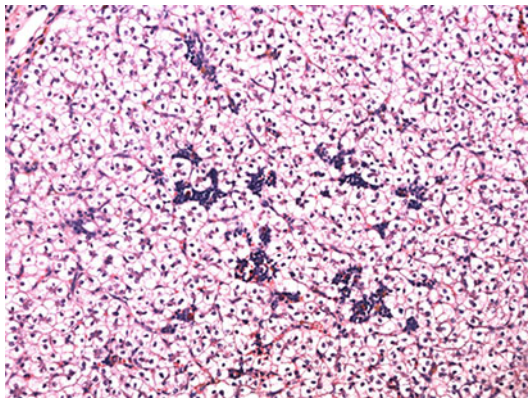

Fig. 3 Hepatoblastoma, fetal subtype. Tumor cells are medium sized, show a clear cytoplasm, and form slender cell plates. Several hematopoietic foci are present (hematoxylin and eosin stain)

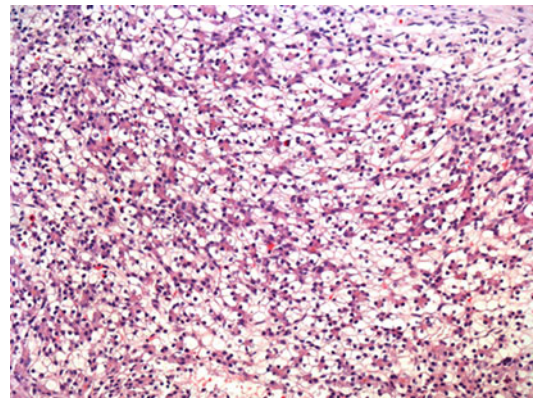

Fig. 4 Hepatoblastoma, fetal subtype. In addition to clear cells, neoplastic cells with a darker cytoplasm are noted (hematoxylin and eosin stain)

larger cell type with a clear and/or vacuolated cytoplasm. In frozen sections, it is shown that the clear cells contain oil red 0-positive fat droplets, and these cells also contain glycogen, with the glycogen particles being peripherally dispersed (Ishak and Glunz 1967). These two cell types often form clusters, causing the typical "dark and clear cell pattern" of fetal-type hepatoblastoma. Nuclei are usually centrally placed round or oval, with a fine chromatin structure and one nucleolus. The cells are mostly arranged in plates two cells thick, sometimes with bile canaliculi. These plates are lined by thin-walled channels resembling an immature sinusoidal network and are supported by a poorly developed reticulin web. Fetal-type cells are not always smaller than normal, nonneoplastic hepatocytes (Figs. 3, 4, 5, 6, 7, 8, 9, and 10).

Already in 1992, it was noted that, in a number of cases, the fetal-type cells appeared to be similar in size to the adjacent nonneoplastic hepatocytes rather than being smaller (Conran et al. 1992). Intervening thin-walled sinusoid-like vascular channels are lined by endothelial cells that show diffuse CD34 immunoreactivity. Fetal hepatoblastomas are often divided into irregular lobules with intervening collagenous septa containing the tumor vessels. The adventitia of these sometimes large and thick-walled vessels blends into the connective tissue of the septa. The septa may not represent tumor stroma, as

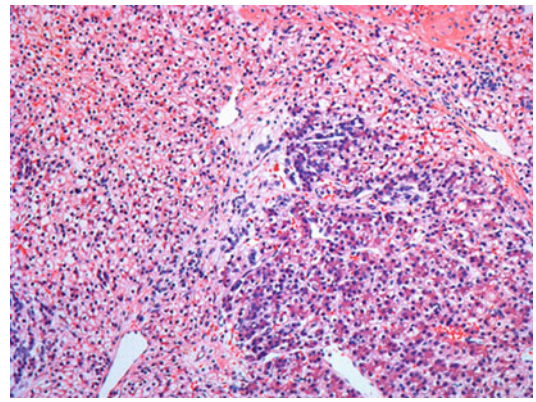

Fig. 5 Hepatoblastoma, fetal subtype. The left half of the figure shows a clear cell pattern, whereas an area with a higher cellularity is seen to the right (hematoxylin and eosin stain)

they often contain crowded preexistent bile ductules, suggesting the entrapment of portal tracts into these structures. The septa may thus be formed by the connective tissue pillars of the vascular tree feeding the tumor. The tumors may show a fibrous pseudocapsule, containing collagen and reticulin, and often this pseudocapsule may completely envelope the mass. Fetal hepatoblastomas typically contain foci of extramedullary hepatopoiesis, mainly of the erythroid lineage (Emura et al. 1985). In a systematic ultrastructural study of this phenomenon, it turned that hematopoiesis developed almost only in well-differentiated, fetal-type hepatoblastoma and that

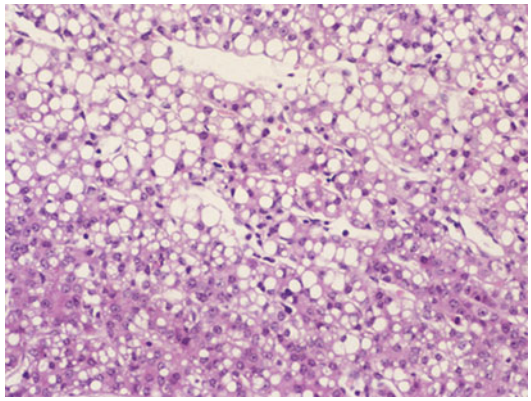

Fig. 6 Hepatoblastoma, fetal subtype, with marked, partly macrovesicular fatty change of neoplastic cells (hematoxylin and eosin stain)

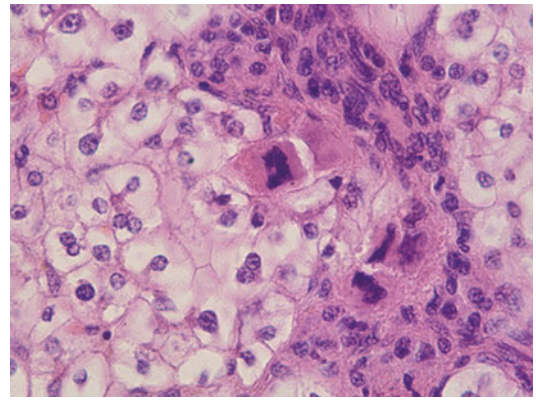

Fig. 8 Hepatoblastoma, fetal subtype. Extramedullary hepatopoiesis can also contain megakaryocytes in hepatoblastoma. There is a slight associated stromal reaction (hematoxylin and eosin stain)

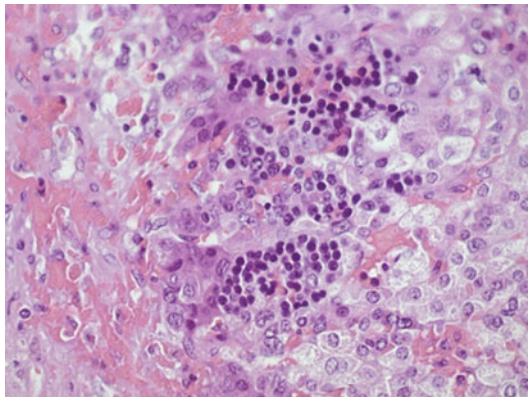

Fig. 7 Hepatoblastoma, fetal subtype. Hematopoietic cell nests (extramedullary hematopoiesis) are dominated by nucleated cells of the erythroid lineage (hematoxylin and eosin stain)

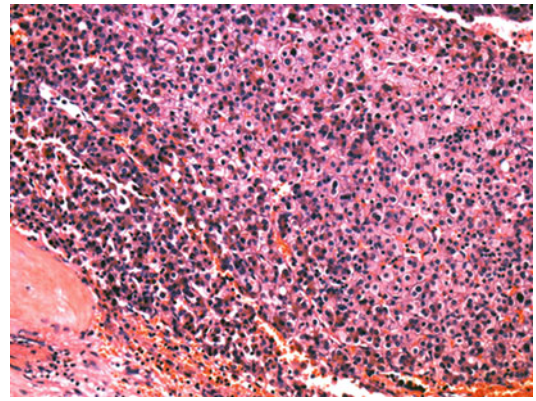

Fig. 9 Hepatoblastoma, fetal subtype. This tumor displays areas with higher proliferative activity and increased nuclear size, resulting in a "crowded pattern" (hematoxylin and eosin stain)

large immature erythroblasts were found among the tumor cells, whereas mature forms tended to gather in the subendothelial spaces or within the sinusoidal lumina. Desmosome-like attachment was often found between immature erythroblasts and tumor cells. Such hematopoietic nests were never found in lymph nodes, spleens, and nonneoplastic liver tissues obtained by surgery or autopsy of the patients (Emura et al. 1985).

Detailed analyses of fetal-type HB elucidated that this pattern can be broken down into three or four phenotypes with different biology of disease. The most common form of fetal HB is called *well-differentiated fetal HB* (*WDF*), *or pure fetal HB with low mitotic activity*. WDF is composed of the typical fetal cells having a diameter of 20–30 μm, arranged in cords one to two cells thick, either in sheets or slightly more cellular trabeculae. Nuclei of WDF have a finely stippled chromatin and inconspicuous nucleoli. Purely fetal HB has a very low mitotic activity, i.e., less than 2 mitotic figures per 10/400× microscopic fields. Based on PCNA immunohistochemistry, fetal hepatoblastomas exhibit a proliferation fraction that is clearly lower than that of embryonal-type cells (10.82 % vs. 59.85 %; Chopra et al. 2010).

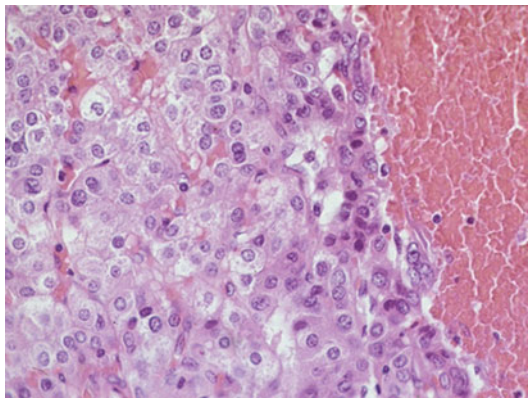

Fig. 10 Hepatoblastoma, fetal subtype. Tumor cells with increased nucleus-to-cytoplasm ratio and replicative activity at higher magnification (hematoxylin and eosin stain)

WDF is the variant that most commonly has hematopoietic foci. Tumors that have an exclusively WDF phenotype reveal a better outcome (Kasai and Watanabe 1970; Haas et al. 1989). All stage I WDF HB patients with tumors showing low or very low mitotic activity enrolled in COG protocols have been cured by surgery alone (Malogolowkin et al. 2011). However, the exact diagnosis of WDF requires the careful examination of pre-chemotherapy resection specimens and is, due to sampling problems, not feasible with small tumor biopsies or with post-chemotherapy specimens. A biopsy, which typically represents less than 3/100,000 of the entire tumor, will only rarely be representative for the lesion. In particular, post-chemotherapy resection specimens exhibit major regressive changes, and the mitotic activity of residual tumor cells cannot reliably be assessed (review: Lopez-Terrada et al. 2013).

A further variant of fetal-type HB is characterized by an elevated mitotic activity and is termed *mitotically active fetal HB or crowded fetal HB*. Already Conran et al. (1992) noted that there were isolated tumors with an elevated mitotic activity. This pattern has to be separated from "standard" WDF, because it has been shown to require chemotherapy. These neoplasms show more than two mitotic figures per 10 high-power fields at 400× magnification. Mitotically active fetal HBs show more cells with an amphophilic cytoplasm and an increased nucleus/cytoplasm ratio, resulting in a "hypernuclear" or "crowded" aspect. Mitotically active parts are often intermingled with typical WDF but may also represent a predominant pattern, and the crowded areas can be adjacent to embryonal-type HB parts, or even small cell undifferentiated parts. Within mitotically active fetal HB, the less mitotically active cells show a finely granular positivity for glypican-3. In regard to the biological impact of mitotically active component, it is currently unknown as to whether the amount of mitotically active parts, or their mere presence, is a decisive feature.

A third variant of fetal HB is characterized by increased nuclear atypia. This is called *pleomorphic* or *poorly differentiated fetal HB* and is more often encountered in post-chemotherapy specimens and in metastases following chemotherapy (review: Lopez-Terrada et al. 2013). The neoplastic cells still retain their typical fetal-type shape and fetal cytoplasmic features (more often with eosinophilic cytoplasm), but nuclei display an irregular shape, coarse chromatin, and large nucleoli. Some of the cells are difficult to distinguish from embryonal-type cells; therefore, the term "HB with a pleomorphic epithelial pattern" has been proposed (Lopez-Terrada et al. 2013). The tumors often show marked mitotic activity, but signs of anaplasia such as large cell size (three to four times the size of adjoining cells) are absent. As the pleomorphic pattern occurs in post-chemotherapy specimens, it is not yet clarified whether chemotherapy as such contributes, and to what extent, to nuclear pleomorphism.

Extramedullary hemopoiesis is a feature that is typical for the fetal subtype of hepatoblastoma (Stein 1952). It has also been reported in embryonal hepatoblastomas (Conran et al. 1992; Stein 1952), but seems to be rarer in this subtype. In the case reported by Stein (Stein 1952), multiple hematopoietic foci were found in metastases of hepatoblastoma, showing both fetal and embryonal morphologies. The embryonal liver is a source of stem cells and becomes the main site of hemopoiesis by 15 gestational weeks in humans and remains so until birth. The immature liver contains a specific stroma which supports homing, proliferation, and differentiation of hemopoietic progenitor cells. The mesenchymal elements

forming this stroma express both mesenchymal markers (vimentin, osteopontin, alpha-SMA, CD29, thrombospondin-1, calponin, Stro-1 antigens, and myocyte enhancer factor 2C) and epithelial markers (cytokeratins 7, 8, and 18, AFP, albumin, E-cadherin, and hepatocyte nuclear factor 3 alpha), suggesting epithelial-to-mesenchymal transition (Chagraoui et al. 2003; Zhang et al. 2005). These cells also express some hemopoiesis-related genes and have the ability to retain hemopoietic stem cells in an undifferentiated state in vitro during cytokine-stimulated proliferation (Zhang et al. 2005). The hemopoietic stem cells are resident in the bone marrow and are there associated with a distinct population of stromal cells which regulate proliferation and differentiation of hemopoietic precursors. In bone marrow, theses stem cells are largely quiescent and undergo only limited self-renewal. In contrast, stem cells located to the embryonal and fetal liver are more frequently cycling, owing to a specific interaction with hepatic stromal cells. These hemopoiesis-supporting fetal liver stromal cells induced a greater than tenfold enhanced proliferative capacity versus bone marrow stromal cells and revealed a higher expression of regulators of the Wnt signaling pathway (Martin and Bhatia 2005). Hemopoiesis in the embryonal and fetal liver seems to also be regulated by two components of basement membranes, nidogen-1 and nidogen-2, which are produced by hepatocytes, stellate cell precursors, endothelial cells, and hemopoietic cells themselves (Tomte et al. 2006). In hepatoblastomas, extramedullary hematopoiesis seems to be induced by fetal and embryonal tumor cells in cooperation with stromal cells by locally secreted cytokines (Von Schweinitz et al. 1995).

Hepatoblastoma, Wholly Epithelial Type: Embryonal and Mixed Embryonal/Fetal Subtype

Embryonal components are a common feature in HB. They are usually combined with a fetal-type pattern, but purely embryonal tumors also occur, albeit as rare lesions. The embryonal histology

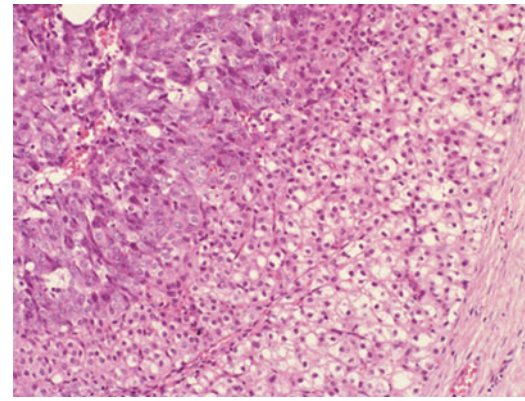

Fig. 11 Hepatoblastoma, fetal subtype. *(Right half)* with transition into larger, embryonal-type cells. *(Left half)* hematoxylin and eosin stain

resembles the morphology of the human liver at 6–8 weeks of gestation. The embryonal hepatoblasts reveal a scant and dark-looking, slightly granular cytoplasm usually lacking glycogen or lipid droplets. The nuclei are enlarged in comparison with fetal-type cells and contain a coarse chromatin and more conspicuous nucleoli. Embryonal cells are commonly arranged as solid nests or glandular/acinar structures, here and there with formation of pseudorosettes and/or papillary structures. In comparison with well-differentiated fetal HB, the mitotic activity is increased, a feature also demonstrable by use of PCNA immunohistochemistry (Rugge et al. 1998). Foci of extramedullary hematopoiesis are rarely present (Figs. 11, 12, 13, 14, and 15).

Hepatoblastoma, Wholly Epithelial Type: Macrotrabecular Subtype

Macrotrabecular HB (MT-HB) is defined as a distinct growth pattern of HB, characterized by the formation of trabeculae or plates which are 10–20 or more cells thick. Pictures of hepatoblastomas with a macrotrabecular growth patterns were published already in older articles (Neimann et al. 1963), and the tumors were defined in more detail by Gonzalez-Crussi et al. (1982), who documented the

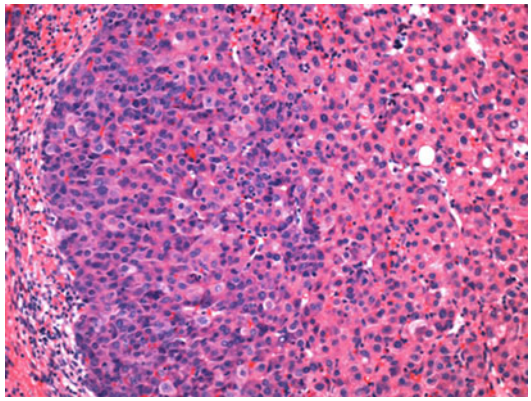

Fig. 12 Hepatoblastoma, mixed fetal and embryonal subtype, with immature embryonal cells to the left (hematoxylin and eosin stain)

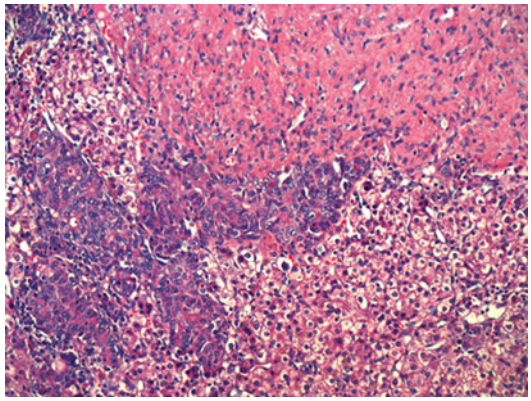

Fig. 13 Mixed fetal and embryonal hepatoblastoma with abortive acinar structures (hematoxylin and eosin stain)

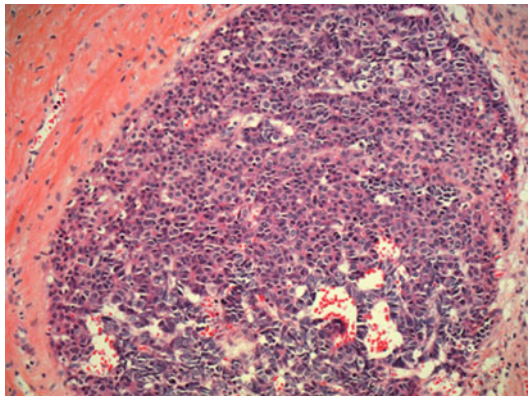

Fig. 14 Hepatoblastoma, embryonal subtype. Acinar structures are present in the *bottom* part (hematoxylin and eosin stain)

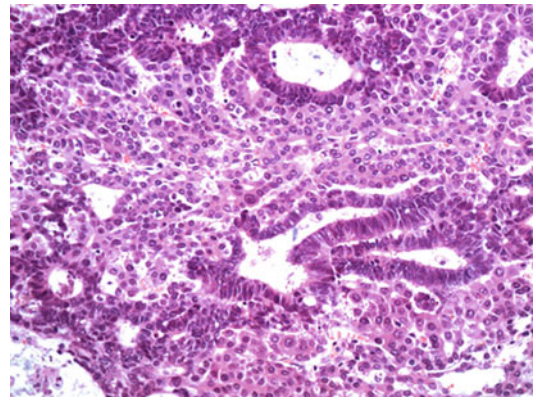

Fig. 15 Hepatoblastoma, mixed fetal and embryonal subtype. Atypical tubular structures with columnar cells are formed, similar to those found in teratoid hepatoblastoma (hematoxylin and eosin stain)

characteristic growth pattern with thick plates or trabeculae. Recent reevaluations of the morphology of MT-HB proposed to reduce the required plate thickness from 10 to 20 cells to 5 or more cells (Lopez-Terrada et al. 2014). Pure MT-HB is a rare variant, accounting for about 3 % of all HB, but MT components within other HB forms have been found in almost 20 % of tumors. Today, the term MT-HB should only be applied to neoplasms in which this pattern is a predominant feature. The macrotrabecular growth pattern in HB involves several types of neoplastic cells. Already Conran and coworkers (1992) specified that macrotrabecular hepatoblastoma contains either fetal- or embryonal-type cells or a third larger cell type with cytoplasm that is more abundant than in normal hepatocytes or fetal-type cells, or a combination of all three cell types. Most commonly, the thick plates are composed of a population of mixed fetal and embryonal cells. Less commonly, the plates consist of larger cells that resemble hepatocytes or cells of differentiated hepatocellular carcinoma. In tumors showing fetal and embryonal cells, these elements exhibit the same morphologic and proliferative features as those found in the respective tumors (see above). The variant with hepatocyte-like cells contains large cells with a granular and eosinophilic

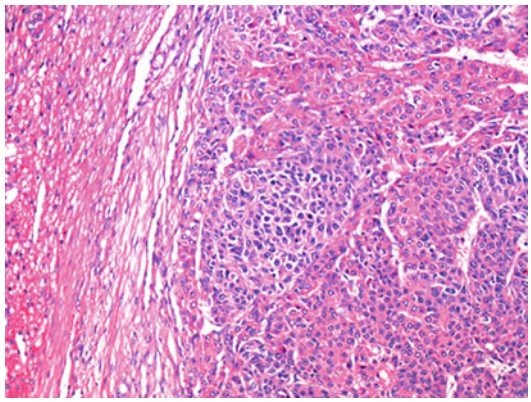

Fig. 16 Hepatoblastoma with a focal macrotrabecular pattern (hematoxylin and eosin stain)

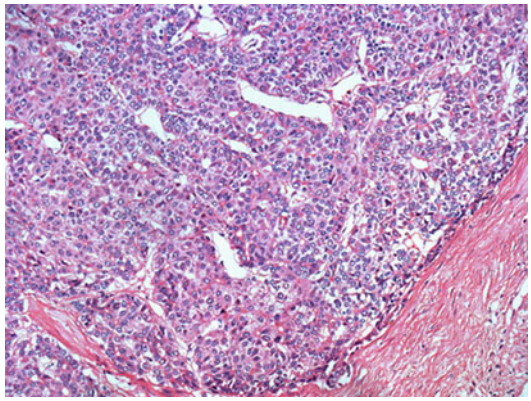

Fig. 17 Hepatoblastoma, macrotrabecular subtype. The large tumor cell plates consist of fetal- and embryonal-type cells (hematoxylin and eosin stain)

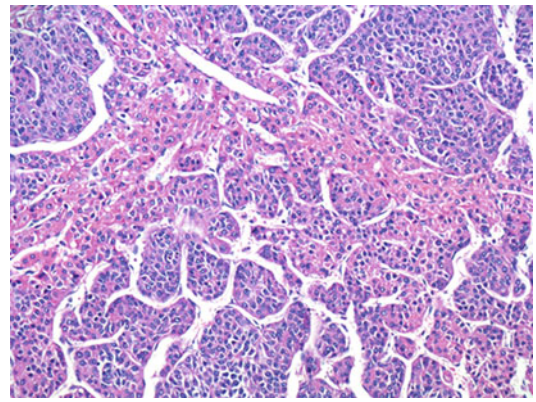

Fig. 18 Hepatoblastoma with macrotrabecular features (MT-1). The tumor cells forming large plates resemble those of hepatocellular carcinoma (hematoxylin and eosin stain)

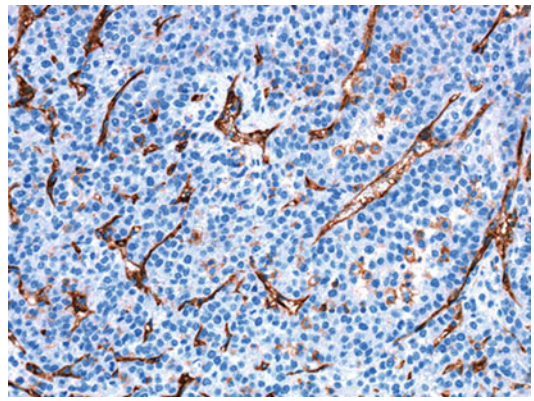

Fig. 19 Hepatoblastoma, macrotrabecular subtype. Immunostaining of intervening vascular channels for CD34 clearly uncovers the large cell plates (CD34 immunostain)

cytoplasm and vesicular nuclei with prominent nucleoli. Based on these two patterns, it was proposed to divide MT-HB into two variants, i. e., MT-1, characterized by HCC-like cells and expected to be a high-risk lesion, and MT-2, containing fetal and embryonal cells and expected to have standard risk (Zimmermann 2005). Histologically, MT-1 may be difficult to distinguish from HCC occurring in older children. The biology of disease of MT-HB is not yet known in detail. None of the three resected MT hepatoblastomas reported by Conran et al. (1992) survived (Figs. 16, 17, 18, and 19).

Hepatoblastoma, Wholly Epithelial Type: Small Cell Undifferentiated Subtype (SCUD)

Small cell undifferentiated hepatoblastoma (SCUD) is a very rare subtype of epithelial hepatoblastoma, with an estimated prevalence of 2–5 % of all hepatoblastomas. SCUD-HB can either occur as a very rare pure lesion (2 % or less of all HB) or make part of other types and subtypes of HB. In case SCUD components occur as focally expressed features in a tumor with an

otherwise different composition, the SCUD feature should be indicated in descriptive terms (HB, with focal SCUD component). In contrast to other subtypes of HB, patients with SCUD-HB reveal low or normal serum levels of AFP. Morphologically, SCUD makes part of the complex group of small blue cell tumors (Gonzalez-Crussi 1991; Sattler et al. 2000). This distinct subtype of hepatoblastoma was first described in 1970 using the term anaplastic hepatoblastoma (Kasai and Watanabe 1970) and was subsequently named undifferentiated small cell hepatoblastoma, in order to avoid confusion in regard to the term "anaplastic" which is used to designate a prognostically important cytological feature in nephroblastoma (Gonzalez-Crussi 1991). SCUD-HB is a high-risk lesion with an aggressive biology and poor outcome (Lack et al. 1982; Dehner and Manirel 1988). In a 1989 study that reported ten SCUD-HB cases, the estimated 24-month patient survival probability was 0 % (Haas et al. 1989). In patients with completely resected hepatoblastomas, the presence of a SCUD component may be a factor for unfavorable outcome, as 10 of 16 patients with this feature developed a disease recurrence (Haas et al. 2001). In a study of completely resected HB, a 38 % recurrence rate in tumors with a SCUD component was found (Ortega et al. 2000).

Macroscopically, SCUD hepatoblastomas tend to present as gray-to-white nodules with marked necrosis and hemorrhage, suggesting a tumor of high-grade malignancy. Invasion of large hepatic veins is a typical feature (Sattler et al. 2000).

Histologically, SCUD-HB is characterized by non-cohesive sheets of small round to ovoid cells resembling the cell of neuroblastoma or other small blue cell tumors. Typically, the cells are a little bit larger than lymphocytes, with a diameter of 7–8 μm. The cytoplasm is scant and amphophilic to basophilic, and nuclei show either a dense or a finely stippled chromatin, with usually small nucleoli (Figs. 20, 21, 22, 23, 24, 25, and 26).

Occasionally, SCUD-HBs contain spindled or stellate cells, usually in a mucoid matrix. The tumor cells, which show a highly invasive phenotype, are arranged as solid sheets, clusters, or nests

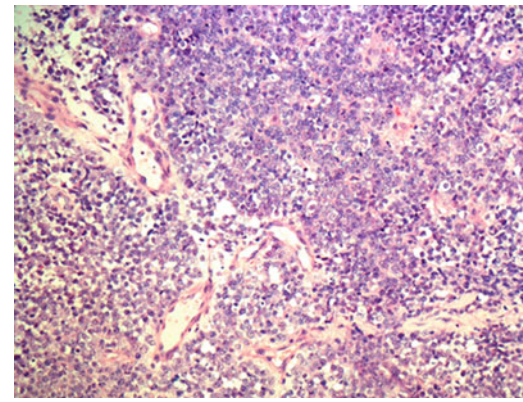

Fig. 20 Hepatoblastoma, small cell undifferentiated subtype. This "blue cellular tumor" consists of a solid growth of immature round cells with poorly developed cytoplasm (hematoxylin and eosin stain)

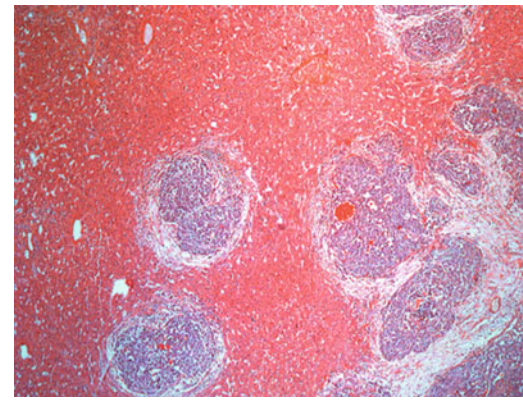

Fig. 21 Hepatoblastoma, small cell undifferentiated subtype. In this partly necrotic neoplasm, nests of immature tumor cells have survived around blood vessels (hematoxylin and eosin stain)

with an organoid pattern and show a variable mitotic rate, numerous apoptotic bodies, and often extensive necrosis. Sinusoid-like vascular channels are present, but they are usually less well developed than those in fetal or embryonal HBs. Based on histology and cytologic features alone, the diagnosis of SCD hepatoblastoma may be difficult, in particular difficult to distinguish from other anaplastic cellular tumors. Conran et al. (1992) stated that areas of other recognizable hepatoblastoma patterns must be present before a diagnosis of the small cell variant is made. Immunohistochemically, SCUD-HB cells are

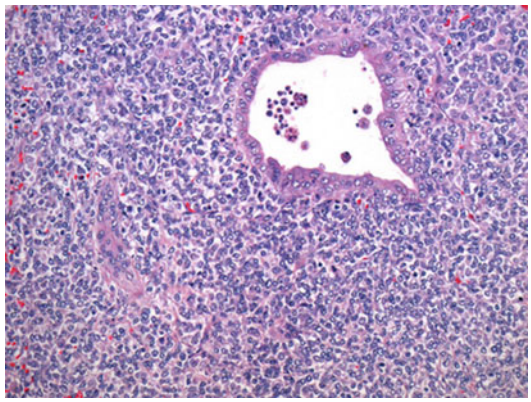

Fig. 22 Hepatoblastoma, small cell undifferentiated subtype. Damaged bile ducts are embedded in this hypercellular, highly invasive cancer (hematoxylin and eosin stain)

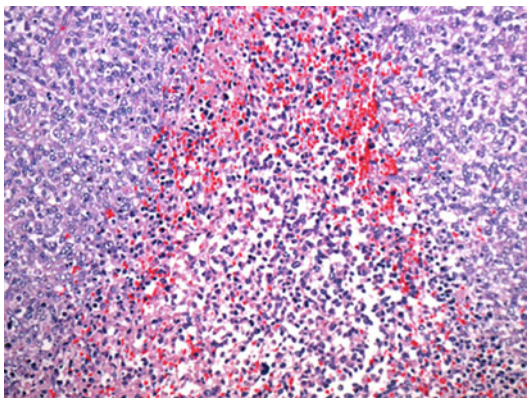

Fig. 23 Hepatoblastoma, small cell undifferentiated subtype, with focal necrosis, apoptosis, and numerous nuclear fragments (karyorrhexis; hematoxylin and eosin stain)

reactive for both cytokeratins (CK 8 and CK18) and vimentin, but not for AFP. Part of SCUD-HB cells are reactive for CD99, a phenotype that has been proposed as PNET-like small cell HB (Zimmermann 2005). Cytogenetically, SCUD-HBs are tumors with signs of genomic/chromosomal instability and various karyotypic abnormalities. In one patient, chromosomal analysis of cultured tumor cells revealed a translocation of most of the long arm of chromosome 22 to the distal long arm of chromosome 10 (Hansen et al. 1992).

SCUD-HB can occur in the form of several varieties, apart from the standard small cell

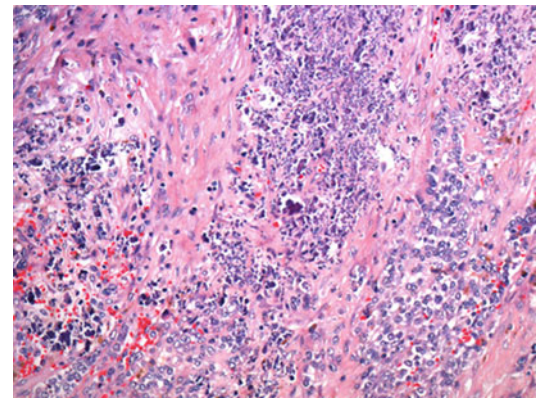

Fig. 24 Hepatoblastoma, small cell undifferentiated subtype, with postnecrotic, dystrophic calcifications (hematoxylin and eosin stain)

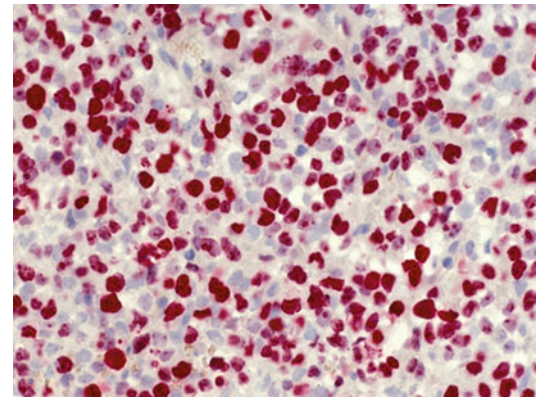

Fig. 25 Small cell undifferentiated hepatoblastomas have a very high proliferative activity (MIB1 immunostain)

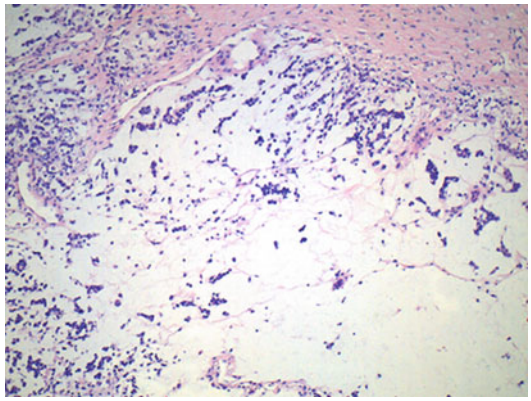

Fig. 27 Hepatoblastoma, mucoid/myxoid variant of small cell undifferentiated HB. Clusters of small neoplastic cells are embedded in a myxoid hypocellular matrix (hematoxylin and eosin stain)

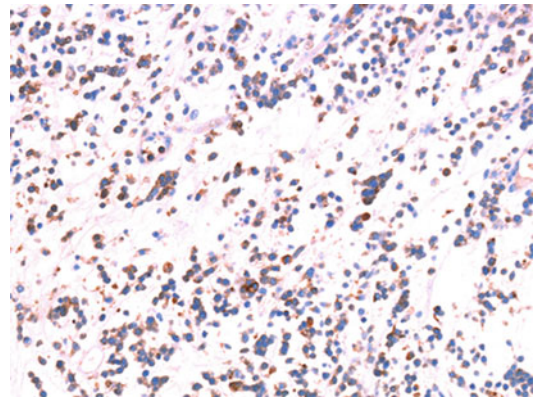

Fig. 29 Mucoid/myxoid variant of small cell undifferentiated HB. The scant cytoplasm of tumor cells shows expression of cytokeratins 8 and 18 (CAM5.2 immunostain)

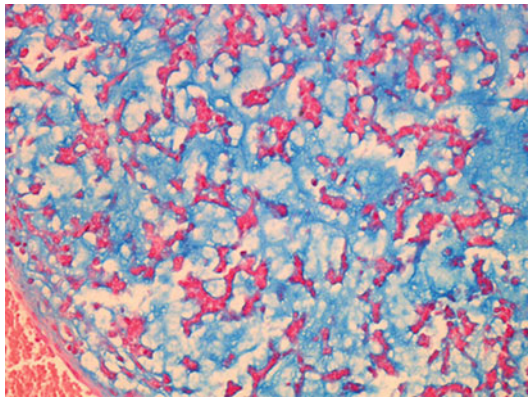

Fig. 28 Mucoid/myxoid variant of small cell undifferentiated HV. The myxoid matrix is rich in alcian blue-positive glycosaminoglycans (alkaline alcian blue stain)

morphology. One of the variants is *mucoid SCUD-HB*. Joshi and coworkers (Joshi et al. 1984) described a hepatoblastoma having, at gross examination, a soft to firm consistency; a cut surface that had a mucoid, glistening, grayish-white "cellular" appearance; and few small irregular cyst-like structures, 4–6 mm in diameters, containing mucoid material. The cells of the SCUD type were embedded in abundant amounts of ground substance rich in alcianophilic and PAS-negative acid mucopolysaccharides. Microcysts containing the same material were also in evidence (Figs. 27, 28, and 29).

Similar features were described in the metastasis of a SCUD hepatoblastoma, where SCUD cells were found in poorly cellular, highly myxoid stroma (Gonzalez-Crussi 1991). Some of the features of this variant of SCUD hepatoblastoma resemble yolk sac tumor. As the term SCUD implies, this subtype of HB is characterized by small cells. However, there are rare examples of undifferentiated HBs that are not, or not exclusively, composed of small cells. Within the SIOPEL pathology reviews, tumors with undifferentiated cells having an intermediate or large size were identified. In a working formulation, such neoplasms were denoted as *intermediate cell undifferentiated HB* (ICUD-HB) and *large cell undifferentiated HB* (LCUD-HB), respectively (Zimmermann 2005; Fig. 30). Large cell variants are known to occur in other blastomatous tumors, including medulloblastoma (Polydorides et al. 2008) and neuroblastoma (Tornoczky et al. 2004; Abramowsky et al. 2009).

Small Cell Undifferentiated Hepatoblastoma with Rhabdoid Features

Recently it has been shown that a subset of SCUD-HBs may present features characteristic of malignant rhabdoid tumors, in particular

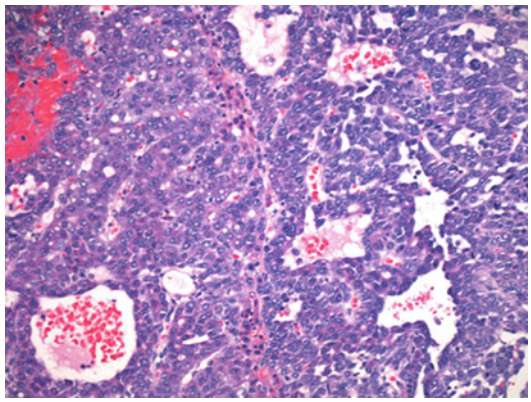

Fig. 30 Poorly/undifferentiated hepatoblastoma that consists of medium-sized cells ("intermediate cell undifferentiated hepatoblastoma"; ICUD; hematoxylin and eosin stain)

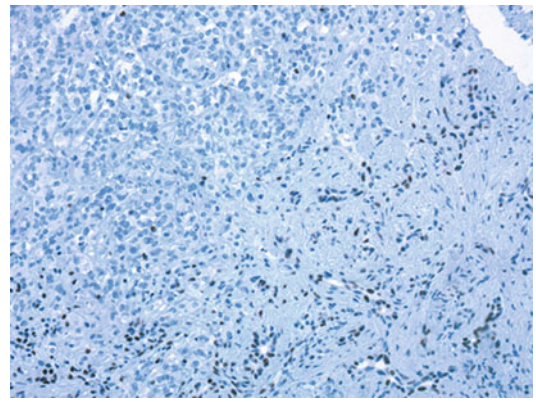

Fig. 32 Hepatoblastoma, small cell undifferentiated subtype with rhabdoid features. In contrast to nuclei of normal bile duct cells, vascular cells, and connective tissue cells, tumor cell nuclei are INI1-negative (INI1 immunostain)

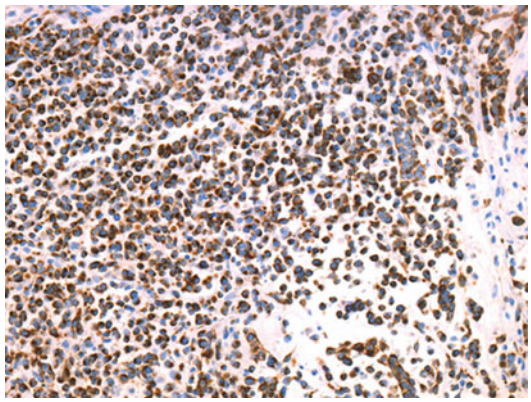

Fig. 31 Hepatoblastoma, small cell undifferentiated subtype with rhabdoid features. Similar to malignant rhabdoid tumors, these neoplasms show a *dot*-like cytoplasmic reactivity for vimentin (vimentin immunostain)

absence of nuclear INI1 expression (Wagner et al. 2007; Russo and Biegel 2009; Trobaugh-Lotrario et al. 2009). Lack of INI1/SMARCB1 expression by use of the BAF-47 antibody is typical for malignant rhabdoid tumors (RT) and has also been found in hepatic RT (Machado et al. 2010). These neoplasms seem to behave like malignant rhabdoid tumors rather than HB, and it will be important to distinguish INI1-negative SCUD-HB from INI1-positive SCUD-HB in order to stratify the lesions with respect to future treatment modalities. In addition, INI1-negative tumors should be submitted to molecular analyses for the detection of SMARCB1 mutations (Figs. 31 and 32).

Mixed Epithelial and Mesenchymal Hepatoblastoma (MEM-HB)

MEM-HB is a rather common variant of HB that may involve mechanisms of epithelial-mesenchymal transition. The tumors are mostly characterized by the presence of variable stromal components, such as fibroblastoid and osteoid tissue and other heterologous elements, intermingled with various lineages of epithelial cells (Figs. 33, 34, 35 and 36).

These features have an estimated prevalence of 20–50 % (Ishak and Glunz 1967). However, as in other types and subtypes of HB, such figures have to be interpreted with caution, mainly for pretreatment biopsies, as the incidences may be underestimated due to sampling errors. Furthermore, there is evidence that chemotherapy may favor the survival – and hence the prevalence – of mesenchymal components and particularly osteoid (Saxena et al. 1993; Heifetz et al. 1997). In addition to osteoid, HB-MEM may contain hyaline cartilage, usually immature looking, but cartilage is much more uncommon than osteoid.

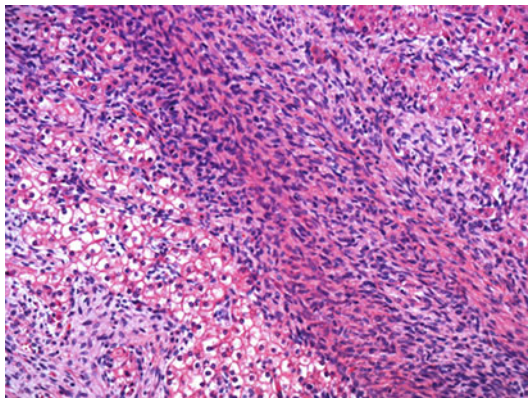

Fig. 33 Hepatoblastoma, mixed epithelial and mesenchymal type. Fetal-type cells are observed in the *left bottom* corner, while the *right half* is mainly occupied by densely packed tumor spindle cells (hematoxylin and eosin stain)

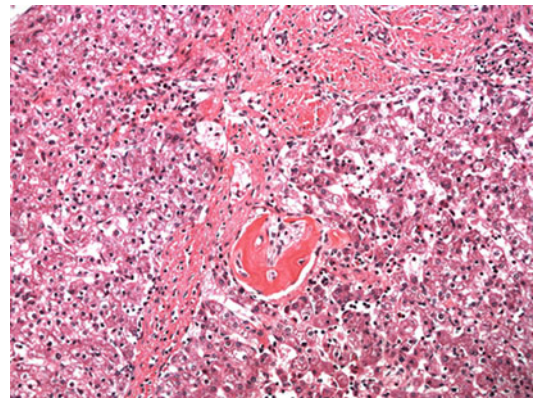

Fig. 35 Hepatoblastoma, mixed epithelial and mesenchymal type with formation of osteoid tissue (hematoxylin and eosin stain)

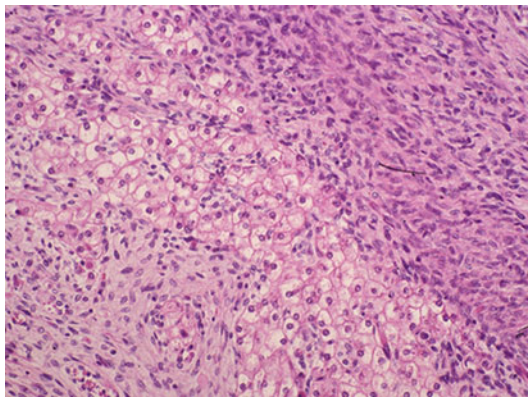

Fig. 34 In mixed epithelial and mesenchymal hepatoblastoma, some spindle cells (to the *right*) are eosinophilic and reveal a myoid phenotype (hematoxylin and eosin stain)

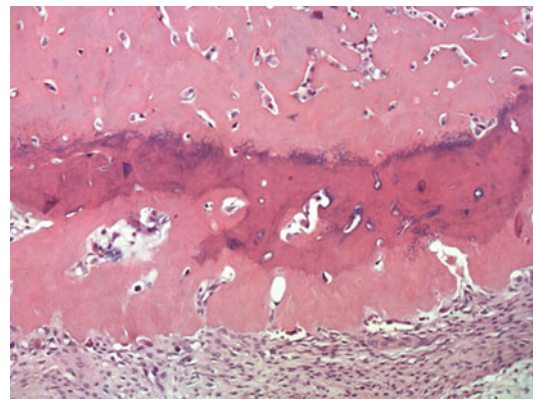

Fig. 36 Mixed epithelial and mesenchymal hepatoblastoma. In part of these neoplasms, osteoid formation is a dominant feature (hematoxylin and eosin stain)

Foci of hyaline tumor cartilage have probably been described for the first time by Grünberg in 1904 in a 2-year-old child, then a few times in the 10 years to come (Philipp 1908; Hippel 1910; Yamagiwa 1911; Idzumi 1912/1913), and later in 1928 in a mixed hepatoblastoma observed in a newborn female infant (Nissel 1928). In a 9-month-old male patient described by Philipp (1908), histology showed a mixed hepatoblastoma with foci of hyaline cartilage, but also epithelial structures composed of tall columnar cells, suspicious of teratoid hepatoblastoma. This feature has since been reported only a few times (Roth 1938; Pang 1961; Conran et al. 1992), reviewed by Pang (1961). In part of the cases, both cartilage and osteoid were present (Yamagiwa 1911; Idzumi 1912/1913; Nissel 1928; Leffers 1940/1941; Hünerwadel 1962; Fig. 37).

Striated muscle cells are observed in a minority of HB-MEM (Fig. 38). This feature has been documented in the older literature, first in a 6-year-old girl (Sheehan 1930), in 2.25-year-old boy (Williams (1953), and in 14-year-old boy (Pack and Miller 1956), illustrating that this phenomenon occurs in a wide age range. One case of mixed tumor occurring in 4-year-old girl and containing tumor cells with a typically striated

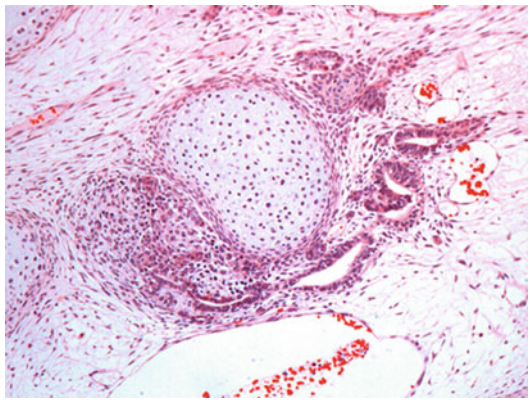

Fig. 37 Mixed epithelial and mesenchymal hepatoblastoma with formation of hyaline cartilage (*center*). This is a very uncommon feature of mixed hepatoblastomas (hematoxylin and eosin stain)

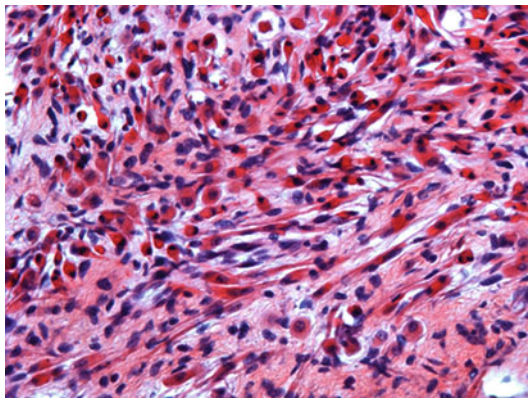

Fig. 38 Hepatoblastoma, mixed epithelial and mesenchymal type with immature cells of the striated muscle cell lineage (hematoxylin and eosin stain)

cytoplasm is intriguing insofar as the neoplasm also contained components indistinguishable from fibrosarcoma, a finding that is not known to occur in typical HB-MEM (Watanabe et al. 1975). Ultrastructurally, the osteoid foci showed fibroblast-like cells associated with collagen fiber formation (Silverman et al. 1975).

The first case of tumors now called mixed epithelial and mesenchymal hepatoblastoma (HB-MEM) was recorded in 1898, albeit erroneously described as a teratoma of the liver (Misick 1898). The right lobe of the liver of a boy who died at age 5 and a half weeks showed a large neoplasm containing large amounts of bony tissue requiring decalcification for histology. The tumor further consisted of embryonic liver cells, cysts, squamous epithelial pearls, immature mesenchyme, osteoblasts, and foci of hematopoiesis. This report is the first to document bone formation in a mixed hepatoblastoma, followed by a report in 1911 (Nakamura 1911). Mixed tumors in infancy and childhood, containing both epithelial cell lineages and immature mesenchyme with bony or cartilaginous differentiation, have subsequently been described and reviewed (Hippel 1910; Yamagiwa 1911; Idzumi 1912/1913; Nissel 1928; McRae 1935; Roth 1938; Webster 1938; Leffers 1940/1941; Milman and Grayzel 1951; Bigelow and Wright 1953; Allison and Willis 1956; Kattan et al. 1959; Wohlgemuth 1960). Nissel (1928) reviewed the German literature in 1928 and found 12 cases. Sheehan (1930) collected nine cases in 1930, two of which had not been listed in Nissel's series. Webster (1938) regarded the tumor he described as a hepatic analog of Wilms tumor. The case reported of Milman and Grayzel (1951) is often listed in the literature as an example of a mixed hepatoblastoma, but a careful study of their description fails to prove this. The patient described by Doris Milman and David Grayzel in 1951 was a 6-year-old boy admitted to the Jewish Hospital of Brooklyn. This child's illness had interestingly first been noted at the age of 20 months when it was observed that he was losing weight and that his abdomen was unusually large, and at the age of 26 months, he was found to have an enlarged liver. His abdomen continued to enlarge out of proportion to his skeletal growth, and he was later thought to have von Gierke's disease. Subsequent detailed investigations revealed a firm mass occupying the entire right side of the abdomen. Laparotomy showed a large globular tumor of 20 cm diameter arising from the under surface of the right liver lobe. Histology of a resection specimen displayed a lobulated tumor encapsulated by dense collagenous fibrous tissue. The description of the epithelial tumor cells indicates mixed fetal and embryonal hepatoblastoma associated with myxoid connective tissue, but no bona fide heterologous elements. Bigelow and Wright (1953)

reported a huge hepatic tumor from a 10-month-old female infant, showing hepatoid cells, squamous epithelial foci, and osteoid, but they classified this tumor in the category of carcinoma of the liver. The tumor type which we now term HB-MEM was again described in detail in 1956 (Allison and Willis 1956), by the use of the term ossifying embryonic mixed tumor. The epithelial component varied greatly in its differentiation, ranging from scattered groups of barely recognizable epithelial cells to well-formed masses of cuboidal cells arranged in trabeculae, without formation of lobules, and sometimes showing accumulation of fat. The less differentiated parts showed numerous mitoses and probably represent embryonal-type cells, while the better differentiated cells with fat were likely fetal-type cells. The mesenchymal component was characterized by abundant osteoid, without chondroid areas. Bone marrow was not observed by these authors and has in fact never been reported to occur in osseous tissue in hepatoblastoma. Kattan and coworkers (1959) reported on a primary hepatic carcinoma in infancy with calcified foci, probably representing tumor osteoid of a mixed hepatoblastoma. The case described by Roth (1938) is of special interest insofar as this female infant of 11 months also presented a unilateral overgrowth of the left side of the body and may thus have been the first report on hepatoblastoma associated with hemihypertrophy.

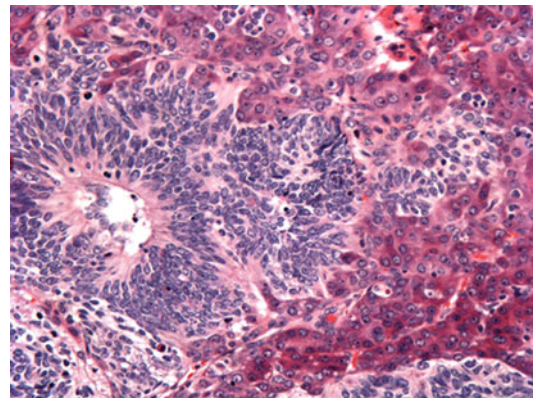

Fig. 39 Hepatoblastoma, mixed epithelial and mesenchymal type with teratoid features. Apart from hepatoid tumor cells (to the *top* and *right*), this neoplasm exhibits pseudostratified tubules reminiscent of early neural tube or ependymal structures (hematoxylin and eosin stain)

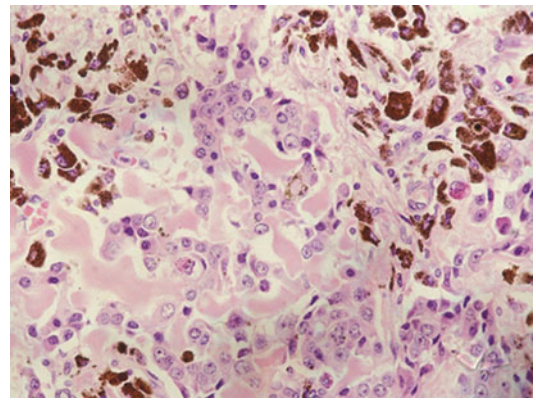

Fig. 40 Hepatoblastoma, mixed epithelial and mesenchymal type with teratoid features. This tumor contains numerous cells producing melanin (melanotic hepatoblastoma). In the center, epithelial tumor cells, osteoblast-like cells, and osteoid are seen (hematoxylin and eosin stain)

Teratoid Hepatoblastomas

In the group of hepatoblastomas currently classified as the mixed epithelial and mesenchymal type, a small subset is characterized by the presence of multiple lineages of differentiation, including neuroectodermal, rhabdomyoblastic, and endodermal cell lineages (Stranz 1913; Figs. 39, 40, and 41).

These lesions are termed teratoid hepatoblastomas (Misugi and Reiner 1965; Shabanov et al. 1981; Manivel et al.,1986; Lackner et al. 1990; Stocker 1994; Kim et al. 2001; Zhang et al. 2007; Buccoliero et al. 2008; Rabah 2012). Teratoid hepatoblastoma also occurs in adult patients (Zhang et al. 2007). Teratoid hepatoblastoma must not be confounded with a teratoma, which is a germ cell tumor.

One of the first descriptions (Wuester and Knauer 1961) referred to an 18-month-old male infant with a history of an enlarging tumor mass in the right upper abdomen of 10 weeks' duration. A roentgenogram showed a dense homogeneous opacity obscuring most of the abdomen. The mass was removed by a right lobectomy.

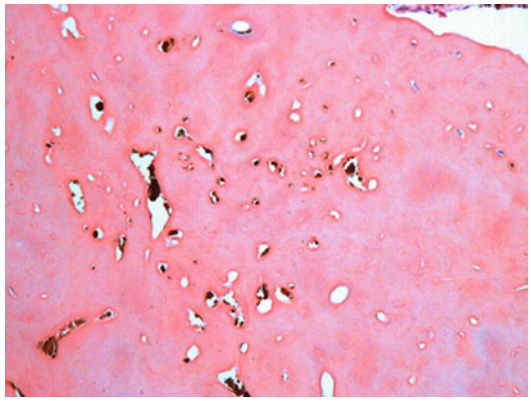

Fig. 41 Hepatoblastoma, mixed epithelial and mesenchymal type with teratoid features. The cavities of tumor osteoid harbor melanin-containing cells (hematoxylin and eosin stain)

Histologically, the tumor was composed of undifferentiated epithelial cells and of a mesenchyme with many embryonal rhabdomyoblasts with cross striation. Arthur P. Stout, who consulted this case, placed the tumor in the malignant teratoma class, but then preferred the term carcinosarcoma. The final histologic diagnosis was embryonal rhabdomyosarcohepatoma. A case originally diagnosed as malignant true teratoma of the liver (Misugi and Reiner 1965) has, based on the descriptions and figures in this paper, to be reclassified as teratoid hepatoblastoma. It is important to emphasize that these intriguing neoplasms should not be confounded with true teratomas, which are germ cell tumors. Part of teratoid hepatoblastomas contain cells producing melanin and typical melanin granules/melanosomes (Manivel et al. 1986; Kim et al. 2001). The tumors may contain melanin both in epithelial cells and mesenchymal cells, including those located within osteoid. Melanotic hepatoblastoma may contain large numbers of melanophages (macrophages/Kupffer cells containing phagocytosed melanin granules), ultrastructurally with melanosomes in the cytoplasm (Ruck and Kaiserling 1993). Melanotic components occur in other blastomatous tumors, including medulloblastoma (Polydorides et al. 2008). Teratoid tumors can contain rhabdomyoblastic elements (Shabanov et al. 1981), which may in some tumors even dominate the histologic pattern, similar to what is seen in some pediatric renal neoplasms. Teratoid hepatoblastomas sometimes show squamous differentiation (Rabah 2012), otherwise often seen following chemotherapy. Thyroid tumors may contain mucinous epithelia of bronchial or intestinal type, sometimes with formation of complex patterns involving mucin-producing and non-mucinous cells and formation of glandular structures. Similar to the GIT, CDX2 is a good marker for mucinous differentiation in teratoid hepatoblastomas (Fan and Lin 2013). The pathogenesis of teratoid hepatoblastomas is unknown. A stem cell origin has been suggested (Kim et al. 2001), but a formal proof of this hypothesis is lacking.

Unusual Variants of Hepatoblastoma

Unusual variants of HB are characterized by the presence of a highly diverse pattern of cell differentiation. These neoplasms have been termed "multilineage tumors" because they show cells apparently developing along several lines of differentiation, ranging from immature cells to more mature-looking, fetal, and/or embryonal cells and covering a broad array of ontogenetic pathways (Zimmermann 2011; Figs. 42 and 43).

Exceptionally, HB presents as a tumor with a fine papillary pattern (papillary HB; Zimmermann 2011; Fig. 44).

A rare subset of hepatoblastoma is characterized by a hypervascularized phenotype and the formation of multiple nodules, mimicking infantile hepatic hemangioendothelioma (hypervascular hepatoblastoma; Ingram et al. 2000; Lu and Greer 2007). These lesions demonstrate a delayed centripetal contrast medium fill in in MRI, a change that is more typical of hemangioendothelioma (Lu and Greer 2007).

Immature Stem-Like Cell Clusters in Hepatoblastomas

Clusters of "light cells" and of "primitive cells" occurring in HB have been published already in 1982 (Gonzalez-Crussi et al. 1982; Figs. 8 and 9

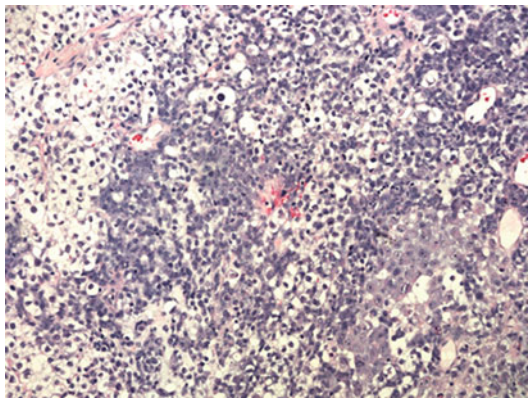

Fig. 42 Hepatoblastoma composed of several different epithelial lineages. Fetal-type cells are seen in the *left upper corner*. The center is dominated by small undifferentiated tumor cells, while large undifferentiated cells (large cell undifferentiated HB) are present in the *lower right corner* ("multilineage tumor"; hematoxylin and eosin stain)

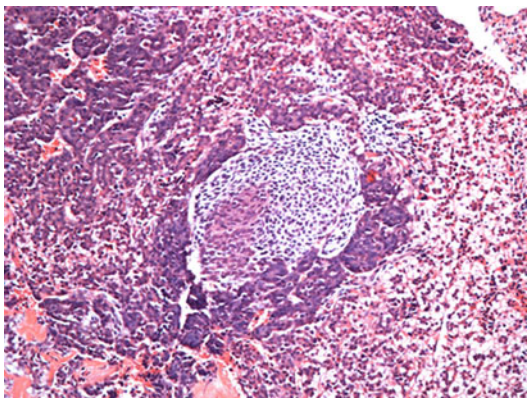

Fig. 43 Hepatoblastoma with a highly complex, "organoid" morphology, in part reflecting several phases of liver ontogenesis. The center shows a mesenchymal bud with an epithelial core (hematoxylin and eosin stain)

of this publication). We identified, both in fetal and mixed fetal-embryonal HB, nests of small and in part pale or clear cells with a roughly spherical shape (Zimmermann 2005; Zimmermann and Saxena 2010). These cells are clearly different from fetal and embryonal cells and have a poor development of cytoplasmic organelles, as estimated from a very weak immunostaining for a mitochondrial marker. Only few of these cells

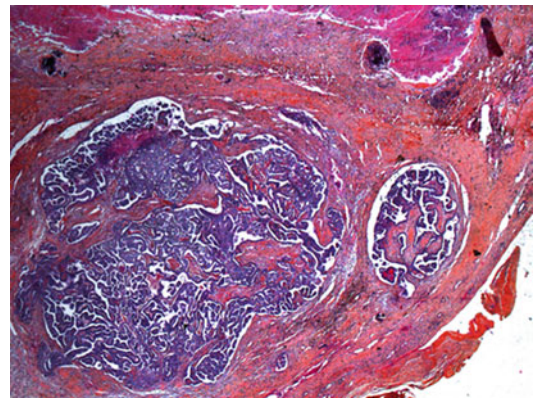

Fig. 44 Hepatoblastoma, papillary pattern. These very rare neoplasms reveal finely branching papillary structures resembling those of papillary thyroid carcinoma (hematoxylin and eosin stain)

show a Ki-67-reactive proliferative activity, whereas a thin rim of fetal or embryonal cells surrounding the nests exhibits a marked proliferative activity. In contrast to better differentiated adjoining cells, the cells in the nests display marked nuclear reactivity for beta-catenin. This distinct set of features might indicate that these are focal accumulations of tumor progenitor cells (Figs. 45, 46, 47, and 48).

Cytology Findings in Hepatoblastomas (Fine Needle Aspiration Cytology)

Hepatoblastoma can reliably be diagnosed by fine needle aspiration cytology (Cangiarella et al. 1994; Sola Perez et al. 1994; Us-Krasovec et al. 1996; Weir and Ali 2002; Iyer et al. 2005; Parikh et al. 2005; Philipose et al. 2006). It has been demonstrated that preparations of fine needle aspiration allow the distinction between poorly differentiated HB (including SCUD and embryonal subtypes) and differentiated HB (comprising fetal and macrotrabecular subtypes), while the separation of SCUD from embryonal HB is more complex and can be difficult to carry out (Sola Perez et al. 1994).

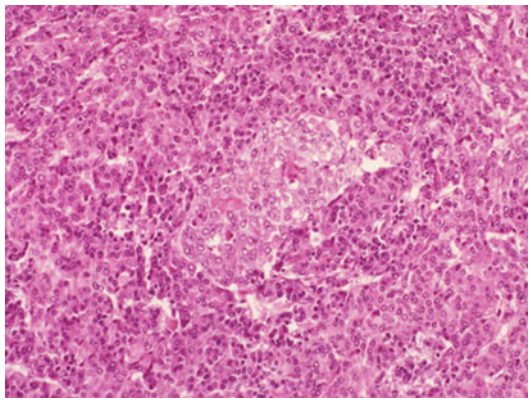

Fig. 45 Immature, progenitor cell-like cluster in hepatoblastoma. The cytoplasm of the cells is pale, and nuclear size is increased in comparison with fetal-type tumor cells (hematoxylin and eosin stain)

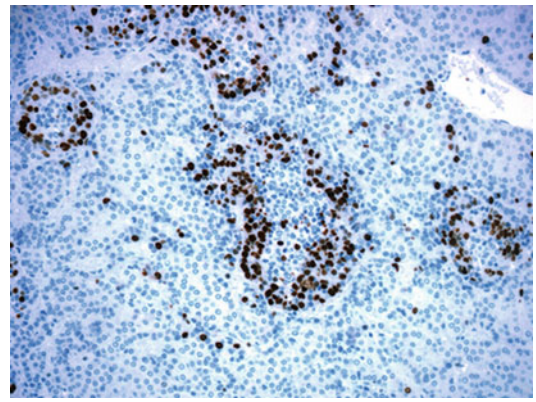

Fig. 47 Immature cell clusters in hepatoblastoma. The cells within the clusters reveal a low proliferative activity, whereas a tumor cell sheath encircling the clusters exhibits a very high proliferative activity (MIB1 immunostain)

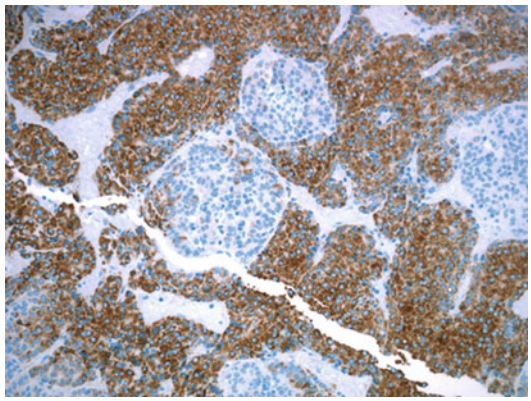

Fig. 46 Immature cell clusters in hepatoblastoma. In contrast to fetal-type cells, cluster cells are poor in mitochondria, reflecting their lower level of differentiation (mitochondrial antigen immunostain)

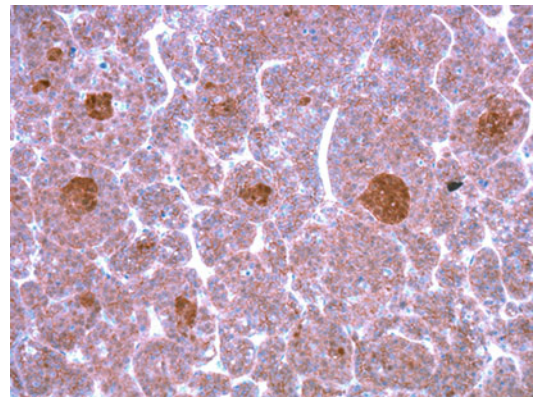

Fig. 48 Beta-catenin expression in immature cell clusters. The cells of the fetal hepatoblastoma background display membranous positivity, whereas cells in the spherical immature clusters show nuclear and cytoplasmic beta-catenin reactivity (beta-catenin immunostain)

Ultrastructural Features of Hepatoblastomas

Relatively few studies have investigated the electron microscopic features of hepatoblastomas (Ito and Johnson 1969; Silverman et al. 1975; Horie et al. 1979; Rosa and Grases 1980; Shabanov 1981, 1983; Stiller and Holzhausen 1983; Albenoza et al. 1987; Ruck and Kaiserling 1993; Veeramachaneni et al. 2003). Fetal cells display a rather well-developed cytoplasm containing numerous organelles, glycogen particles, and sometimes lipid droplets. In contrast to fetal cells, embryonal cells show a decreased number of cytoplasmic organelles, a poorly developed Golgi apparatus, and few or no visible glycogen particles (Ito and Johnson 1969; Stiller and Holzhausen 1983). Formation of biliary capillaries/canaliculi by tumor cells, with microvilli and typical junctional areas, has been described (Stiller and Holzhausen 1983; Ruck and Kaiserling 1993). Electron microscopically, the SCUD cells show a

cytoplasm with striking paucity of organelles (predominance of mitochondria; occasional RER profiles), absence of surface microvilli or canalicular domains, few lipid droplets and glycogen granules, sparse bundles of intermediate filaments, and primitive or few desmosomal cell junctions (Joshi et al. 1984; Gonzalez-Crussi 1991; Hansen et al. 1992; Ruck et al. 1996).

Immunohistochemistry of Hepatoblastomas

Cytokeratins

Immunohistochemically, the tumor cells variably express cytokeratins (mainly CK 8 and CK 18), vimentin, and sometimes CK 19 and CD34 (Fischer et al. 1987; O'Brien et al. 1989; Van Eyken et al. 1990; Pontisso et al. 1993; Sattler et al. 2000; Fig. 49).

In regard to expression of CK8, fetal-type cells with a granular cytoplasm are more strongly stained than pale/clear cells, and embryonal-type cells usually show a more variable and paranuclear staining. In contrast, CK18 reveals a more homogeneous and consistently marked staining for both fetal-type and embryonal-type cells (Van Eyken et al. 1990). A strong immunoreactivity for CK19 was found in embryonal-type cells (Van Eycken et al. 1990) and cholangioblastic hepatoblastomas (Zimmermann 2002). Embryonal cells situated in the center of macrotrabeculae in MTB hepatoblastomas can show CK19 reactivity (Van Eycken et al. 1990). In osteoid found in mixed epithelial and mesenchymal hepatoblastoma, epithelioid- or osteoblast-like cells in part express cytokeratins CK7, CK8, and CK19 (Van Eycken et al. 1990), suggesting mesenchymal-epithelial transition. CK 19 expression may occur in embryonal cells, but not or weakly in fetal-type cells (Cajaiba et al. 2006).

Hepatocyte Export Proteins

In a study of 19 cases, most of the differentiated hepatoblastomas were immunoreactive for cytokeratin and AFP and some for alpha-1-antitrypsin and ferritin (Abenoza et al. 1987; Cangiarella et al. 1994; Ramsay et al. 2008). Alpha-fetoprotein/AFP is detectable in epithelial cells of hepatoblastomas in a highly variable frequency, depending on tumor subtype and antibodies used (Norgaard-Pedersen et al. 1974; Abenoza et al. 1987; Fig. 50).

In an analysis of 12 needle core biopsies, AFP was positive in about half of the cases (Ramsay et al. 2008).

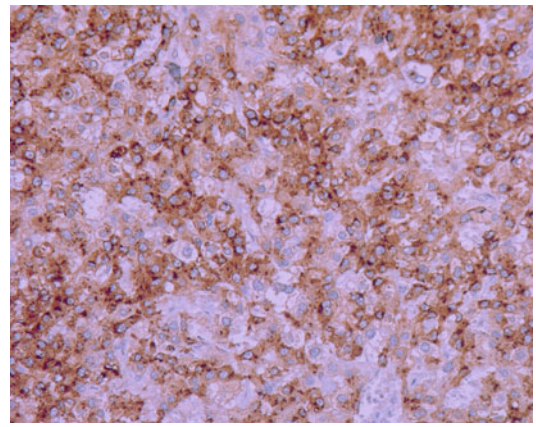

Fig. 49 Cytokeratin expression in epithelial hepatoblastoma (CAM5.2 immunostain)

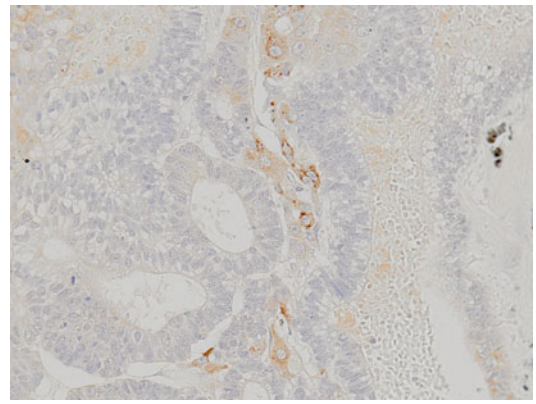

Fig. 50 Alpha-fetoprotein (*AFP*) reactivity in hepatoid cells of an epithelial hepatoblastoma (*center*; AFP immunostain)

Hep Par1

The differentiated epithelial cells of all hepatoblastomas seem to be positive for the marker, hepatocyte paraffin 1/Hep Par 1, with a granular intracytoplasmic pattern being less intense in embryonal cells than in fetal cells, probably reflecting the state of cell differentiation along the hepatocyte lineage (Fasano et al. 1998).

Glypican 3

An important marker for epithelial hepatoblastomas is glypican 3 (Toretsky et al. 2001; Chan et al. 2013), the product of one of the most overexpressed genes in hepatoblastoma by microarray analysis (Fig. 51).

In a study of 65 cases, cytoplasmic immunoreactivity for glypican 3 was found in all samples, with greater than 90 % of cases showing strong and diffuse positivity (Zynger et al. 2008). Expression of glypican 3 in hepatoblastoma cells depends on the activation of the Yes-associated protein, Yap, the effector of the Hippo kinase pathway (Li et al. 2012).

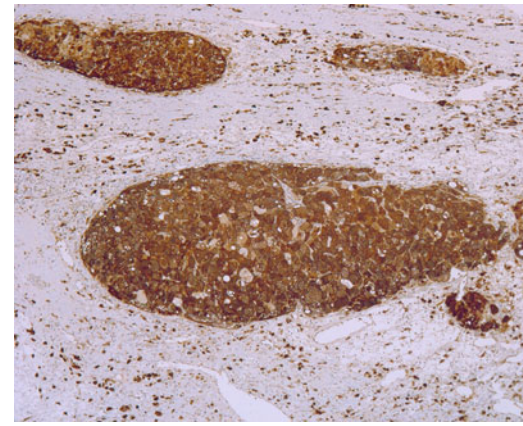

Fig. 51 Strong glypican-3 reactivity in epithelial hepatoblastoma (glypican-3 immunostain)

Beta-Catenin

HB cells often express beta-catenin in various patterns, depending on cell differentiation. Fetal-type cells display a membranous immunostaining, whereas less differentiated cells more often show a cytoplasmic and/or nuclear beta-catenin staining (Fig. 52).

A key target of beta-catenin is hepatic glutamine synthase/GS. GS can immunohistochemically be detected in neoplastic epithelial cells of the majority of hepatoblastomas (Fig. 53).

In hepatoblastomas carrying beta-catenin gene mutations, GS was only detected in tumor areas with epithelial differentiation, and particularly high expression of GS was found in hepatoblastoma cells directly neighboring a mesenchymal tumor area (Schmidt et al. 2011).

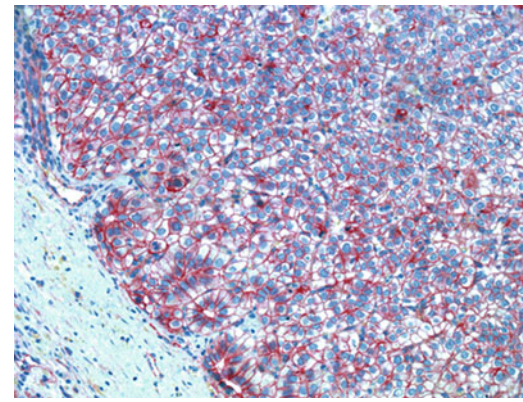

Fig. 52 Hepatoblastoma, fetal subtype. The tumor cells show marked beta-catenin reactivity with a membranous staining pattern (beta-catenin immunostain)

Markers of Progenitor Cells and Immature Cell Lineages

As hepatic progenitor cells are possible candidates as an origin of hepatoblastoma, HB cells were analyzed for the expression of stem cell markers. Significant fractions of hepatoblastomas express octamer-binding transcription factor 3/4 (Oct-3/4), epithelial cell adhesion molecule (EpCAM), and delta-like 1 homolog (DLK1) (Yun et al. 2013). Hepatoblastomas show an aberrant expression of the stem cell markers, CD44, CD90, and CD133 (Bahnassy et al. 2014). Cells of the embryonal subtype of HB are reactive for SALL4,

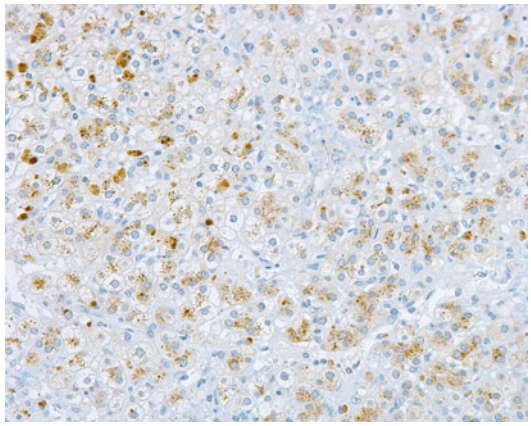

Fig. 53 Hepatoblastoma, fetal subtype. Part of neoplastic cells express glutamine synthetase in the cytoplasm (glutamine synthetase immunostain)

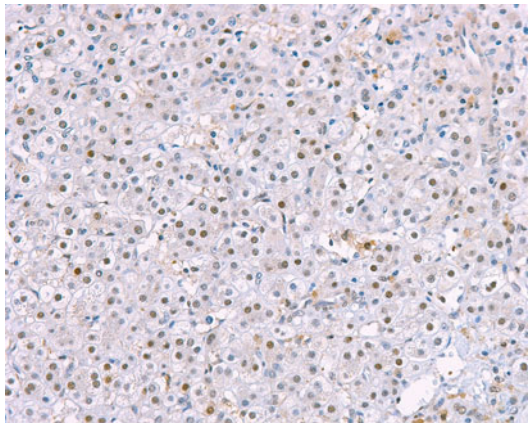

Fig. 54 Most hepatoblastomas show nuclear reactivity for INI1 (INI1 immunostain)

a marker of stem-like cells and germ cell tumors (Gnemmi et al. 2013). Apart from HB with rhabdoid features (see above), most HBs express INI1 in the nuclei (Fig. 54).

Other Markers

Cells of SCUD hepatoblastoma are positive for vimentin and may also show cytokeratin staining, as shown above (Abenoza et al. 1987). The canalicular domains found in fetal cells are reactive for polyclonal anti-carcinoembryonic (CEA) antigen (Fasano et al. 1998). Unusual antigens expressed in part of hepatoblastomas include CD99/MIC-2 and NCAM/CD56 (Ramsay etal. 2008) and common acute lymphoblastic leukemia antigen/CALLA (Von Schweinitz et al. 1996). Expression of CD99 is found in a subset of small cell undifferentiated hepatoblastomas (see above; Zimmermann 2005). Expression of claudins, members of a distinct family of transmembrane proteins, may be used to identify certain cell lineages in hepatoblastomas. Claudin1 and claudin2 are markedly expressed in fetal-type cells, but not in embryonal cells of hepatoblastomas, and the expression of these two claudins is inversely correlated with cell proliferation (Halasz et al. 2006). A further tight junction-associated protein, tricellulin, is also expressed in subsets of hepatoblastoma (Schlachter et al. 2014). Both fetal and embryonal tumor cells stained irregularly positive for intercellular adhesion molecule-1/ICAM-1 (Von Schweinitz et al. 1996). Primary hepatoblastomas express survivin, and survivin reactivity increased following chemotherapy, suggesting that this apoptosis inhibitor is involved in HB cell survival (Uehara et al. 2013).

Several novel markers expressed in HB cells have been reported. Delta-like protein, a transmembrane EGF-like homeotic protein encoded by the DLK1 gene, is expressed in a wide variety of embryonic tissues in the human organism and is a reliable marker for oval cells in the rat liver. Delta-like protein was found to be a sensitive marker for all types of hepatoblastoma (Dezsö et al. 2008). Dickkopf 3, a protein expressed in very early phases of hepatogenesis, is expressed in hepatoblastomas (Pei et al. 2009).

Hepatoblastomas express proteins of extracellular matrix, including laminin, fibronectin, and collagen types III, IV, and V (Ruck and Kaiserling 1992). In a subset of hepatoblastomas, immunohistochemical signs of neuroendocrine differentiation have been found, including reactivity for chromogranin A and/or neuron-specific enolase in fetal- and embryonal-type cells and in cells located within tumor osteoid. A fraction of embryonal cells also expressed serotonin or somatostatin (Ruck et al. 1990). Chromogranin A and

serotonin reactivity was also detected in a melanotic hepatoblastoma (Ruck and Kaiserling 1993).

Chemotherapy-Induced Alterations in Hepatoblastomas

Chemotherapy induces a wide array of secondary changes in HB and adjacent liver tissue (Figs. 55, 56, 57, 58, 59, 60, 61, 62 and 63).

Few studies have analyzed chemotherapy-induced alterations in hepatoblastomas (Forouhar et al. 1984; Saxena et al. 1993; Wang et al. 2010; Gupta et al. 2012). In contrast to other neoplasms, such as osteosarcomas and ES/PNETS (Raymond et al. 1987; review: Lowichik et al. 2000), a standardized prognostic factor grading system of chemotherapy effects has not yet been worked out for hepatoblastomas. In a study on 17 patients treated with preoperative chemotherapy compared with 11 patients not subjected to chemotherapy during the same 11-year period (Saxena et al. 1993), there was no correlation between the extant of necrosis and the number of chemotherapy courses. There also seemed to be no evidence of preferential ablation of a particular morphologic type of tumor. Interestingly, osteoid in case of mixed epithelial and mesenchymal hepatoblastomas was present in 36 % of untreated tumors, occupying less than 5 % of the surface area, while osteoid was present in 82 % of the cases treated with preoperative chemotherapy. It was suggested that an increase of osteoid and of the extent of mature mesenchymal tissues was induced by chemotherapy (Heifetz et al. 1997). It is, however, difficult to judge whether this reflects a true increase of osteoid (caused by a differential effect of therapy on osteoprogenitor cells) or whether this only reflects an apparent predominance of chemoresistant osteoid tissue owing to the shrinkage of other chemosensitive tumor components. In epithelial

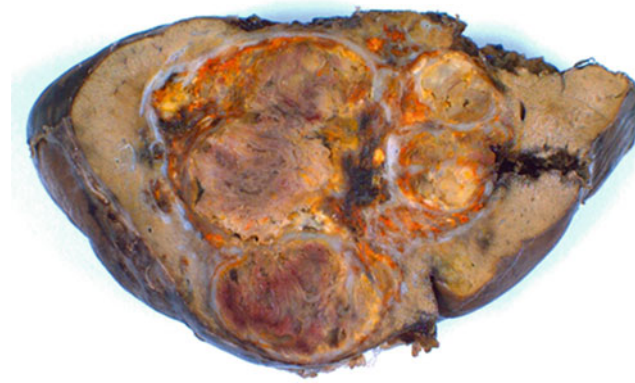

Fig. 55 Hepatoblastoma post-chemotherapy. The tumor presents as a conglomerate of necrotic nodules separated from adjacent liver by a fibrous, whitish pseudocapsule (fixed resection specimen)

Fig. 56 Hepatoblastoma after chemotherapy. There is an area of tumor shrinkage with scar tissue. The *yellowish* speckles seen on the *top* of the figure are foci of osteoid (fixed resection specimen)

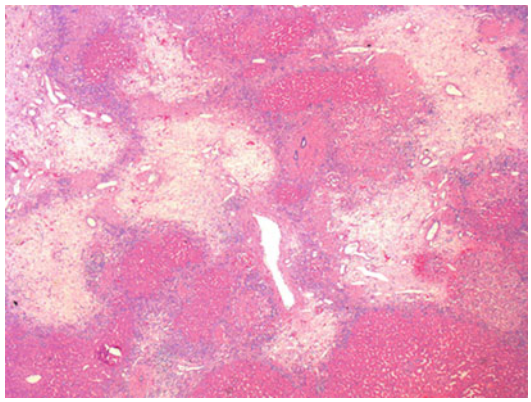

Fig. 57 Hepatoblastoma post-chemotherapy. Regressed tumor appears as pale shrunken areas intermingled with preserved hepatic parenchyma and portal tracts (hematoxylin and eosin stain)

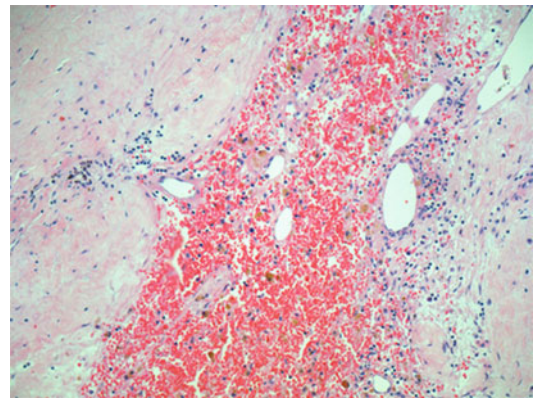

Fig. 59 Hepatoblastoma following chemotherapy. Necrotic tumor tissue may later be replaced by hypocellular connective tissue nodules (extreme *left* and *right*; hematoxylin and eosin stain)

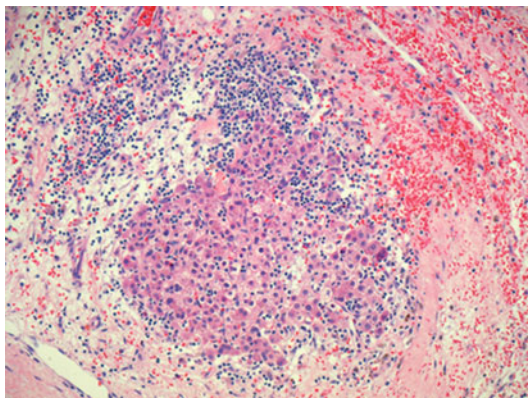

Fig. 58 Hepatoblastoma post-chemotherapy. A partly preserved focus of epithelial neoplastic tissue shows a lymphocytic infiltrate that probably represents an immune reaction (hematoxylin and eosin stain)

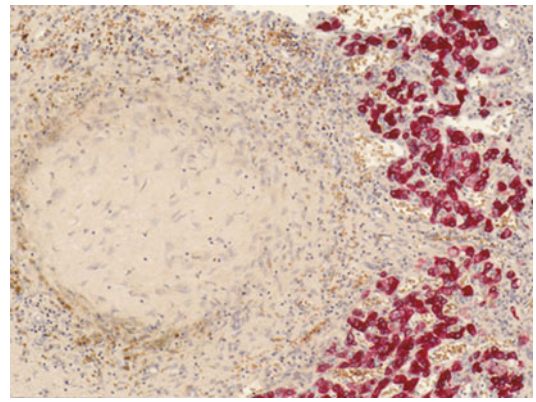

Fig. 60 Hepatoblastoma post-chemotherapy. In contrast to strong cytokeratin staining of intact normal hepatocytes (*right part*), the connective tissue sphere as a sclerosed tumor remnant is devoid of epithelial cells (CAM5.2 immunostain)

hepatoblastomas treated with chemotherapy, neoplastic epithelial cells may survive, however, with marked alterations (Table 4). The changes comprise fatty change of fetal-type cells, switch of fetal-type cells to a morphology resembling hepatocytes (so-called maturing hepatoblastoma), marked cellular and nuclear atypias mimicking high-grade cancer, and atrophy of tumor cells. A 15-year retrospective study of hepatoblastomas in 22 children who received neoadjuvant chemotherapy according to the COG protocol showed that, in addition to necrosis and fibroinflammatory changes, two thirds had areas of cytoarchitectural differentiation ("maturation") mimicking non-neoplastic liver, and a quarter revealed alterations mimicking hepatocellular carcinoma (Wang et al. 2010). In another study of 20 post-chemotherapy cases, tumor "maturation" and HCC-like changes of atypical epithelial components were also found as typical features, and the authors also observed peliotic-like foci and "glomeruloid clusters" (Gupta et al. 2012).

Surviving epithelial tumor components, mostly of the fetal type, are often difficult to be distinguished from normal hepatic parenchyma

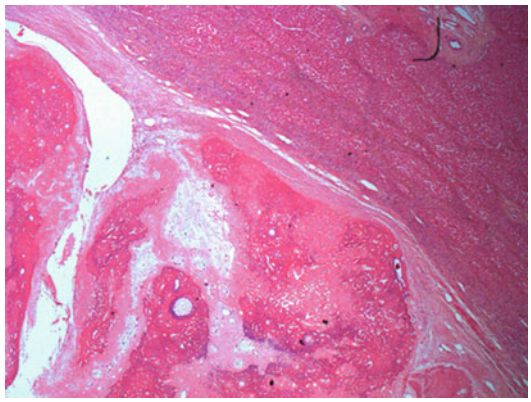

Fig. 61 Hepatoblastoma following chemotherapy. In treated mixed epithelial-mesenchymal hepatoblastomas with osteoid formation, remnant tumor may only consist of osteoid, which tends to resist chemotherapy (hematoxylin and eosin stain)

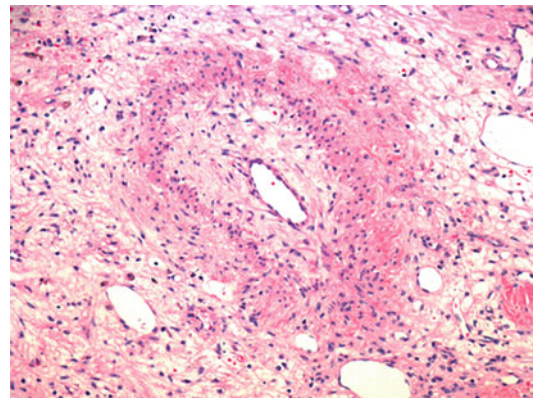

Fig. 63 Vascular changes in hepatoblastoma treated with chemotherapy. The tumor vessel in the center shows marked thickening of its intima and a damaged media (hematoxylin and eosin stain)

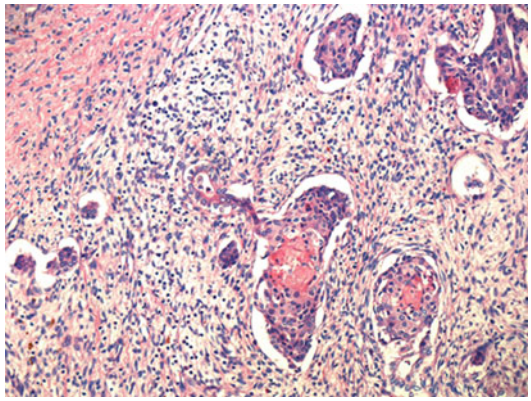

Fig. 62 Hepatoblastoma post-chemotherapy. In treated HB, nests and pearls of squamous epithelium are a common finding, sometimes associated with a foreign body reaction (hematoxylin and eosin stain)

entrapped within the regressing tumor, sometimes in the form of small nests or nodules of damaged hepatocytes. Immunohistochemical detection of nuclear beta-catenin reactivity in the cells of question may be helpful, as positivity favors the presence of tumor remnants (Wang et al. 2010). In one observation, a mature intestinal epithelium has been noted after chemotherapy using doxorubicin and cisplatin (Forouhar et al. 1984), but this might have been a teratoid hepatoblastoma before therapy already. Between the nodular scar-like lesions, collapsed tissue with blood-filled spaces resembling peliosis (Wang et al. 2010), inflammatory changes, accumulation of lipid-laden macrophages, hemosiderosis, and calcifications are found. Mesenchymal components have a tendency to persist more frequently than epithelial tumor cells (Fourouhar et al. 1984). They appear as hypocellular nodules or spheres ("regression spheres") that my contain central blood vessels and/or accumulations of hemosiderin and iron-positive macrophages. In post-chemotherapy resection specimens of hepatoblastoma, small foci of keratinizing squamous epithelium, forming "pearls," are often encountered. It has been proposed that this change is only seen in treated hepatoblastomas, but it also occurs in native tumors, albeit very rarely (McRae 1935; Leffers 1940/1941).

Changes of the Adjacent Normal Liver

Three foci of focal nodular hyperplasia (FNH) were found in the parenchyma surrounding a small cell undifferentiated hepatoblastoma of a 4-year-old boy with a history of stage IV neuroblastoma (Gutweiler et al. 2008). It is known that FNH can develop subsequent to treatment of other solid tumors in the pediatric age group (Icher-De Bouyn et al. 2003). On the other hand, FNH has been observed in association with other liver cell

Table 4 Morphologic alteration of hepatoblastomas following chemotherapy

Alterations of epithelial tumor cells
Necrosis
Fatty change
Swelling or ballooning
Cholestasis
Differentiation to a hepatocyte-like phenotype ("maturation")
Atrophy
Keratinizing squamous epithelium
Alterations of mesenchymal components
Nodular scar-like structures ("regression spheres")
Increase of tumor-associated osteoid in mixed hepatoblastomas
Fibrosis/scarring
Accumulation of lipid-laden macrophages
Hemosiderosis
Vascular sclerosis and obliteration
Other alterations
Inflammatory changes (lymphocytes, plasma cells)
Calcifications
Peliosis-like changes
Ductular proliferations

tumors, specifically hepatocellular carcinoma (Zhang et al. 2004; Langrehr et al. 2006). A perifocal hyperplasic reaction of hepatocytes may also be caused by tumor-induced alterations of local blood circulation. Portal vein invasion by diverse hepatic malignancies causes a derangement of portal venous blood flow, sometimes followed by peritumoral hyperplasia of hepatocytes (Arnason et al. 2013).

Differential Diagnosis

HB with hepatoid cells, i.e., non-fetal and non-embryonal cells, may be confounded with hepatocellular carcinoma, and undifferentiated small cell HB may mimic other small blue cell tumors. There are unusual situations where a malignant tumor different from hepatoblastoma can produce osteoid within the abdominal cavity, e.g., abdominal Ewing small cell sarcoma with the EWS/FLI1 fusion (Oshima et al. 2004).

Variants of the Hepatoblastoma Tumor Family

20

Contents

Abstract

A small subset of neoplasms of the hepatoblastoma tumor family is characterized by a morphology that resembles hepatocellular carcinoma (HCC) or holds a position intermediate between classical hepatoblastomas (HB) and HCC. Such tumors currently include anaplastic HB variants, HB with HCC-like features, and so-called transitional liver cell tumors.

Rare variants of HB exhibit ductule-like structures and are termed cholangioblastic hepatoblastomas. A related tumor that consists of immature hepatocyte nests surrounded by cholangiocyte structures resembling the embryonal ductal plate makes part of so-called ductal plate tumors.

HB and similar mixed tumors occur in adult patients. However, it is not yet certain whether all tumors described as "adult HB" are in fact true HB. Molecular studies will probably clarify this question.

Hepatoblastomas with "HCC-Like Features" and "Transitional Cell Tumors"

There is a complex group of rare hepatoblastoma-like tumors that contain, apart from HB cells (mostly of the fetal type), cells that are HCC-like or seem to hold a position intermediate between HB and HCC. HB with such pleomorphic features

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_20

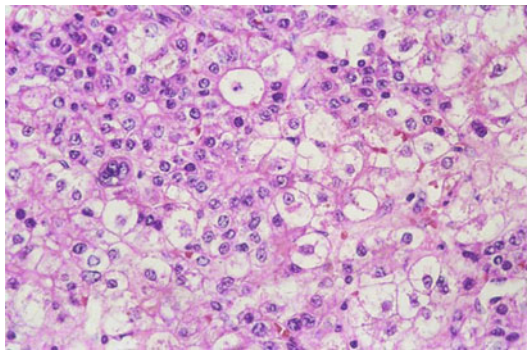

Fig. 1 HCC-like hepatoblastoma. Apart from clear cells resembling fetal-type cells, there are cells resembling hepatocellular carcinoma cells and polymorphous cells (hematoxylin and eosin stain)

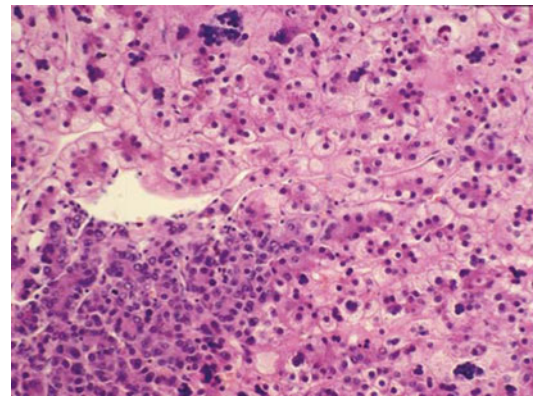

Fig. 2 HCC-like hepatoblastoma. Fetal-type cells (*right* and *upper* part of figure) are associated with less differentiated and highly atypical cells (*left lower corner*; hematoxylin and eosin stain)

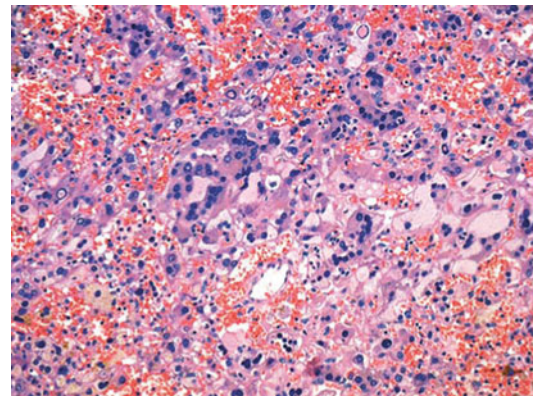

Fig. 3 HCC-like hepatoblastoma. This tumor exhibits pleomorphic cells and multinucleated giant cells (hematoxylin and eosin stain)

have been termed "HCC-like tumors" or "anaplastic tumors," but these terms seem to be obsolete, anaplasia having a different definition. Aggressive HB with HCC features or a HCC-like progeny exhibit a distinct genomic landscape characterized by CTNNB1 mutations, NFE2L2-KEAP1 pathway activation, loss of genomic stability, and TERT promoter mutations (Eichenmüller et al. 2014). Part of the tumors with HCC-like features has been observed in older children and adolescents. These lesions with a complex histology are characterized by an aggressive biology, very high serum AFP levels, and abnormal beta-catenin expression patterns and were termed "transitional liver cell tumors/TLCT" as a working formulation (Prokurat et al. 2002). This entire tumor group requires further definition and standardization (Figs. 1, 2, 3, 4, 5, and 6).

Bimodal Pediatric Liver Tumors: Cholangioblastic Hepatoblastoma (Hepatoblastoma with Cholangioblastic Features) and So-Called Ductal Plate Tumors

Cholangioblastic Hepatoblastoma

In a minority of hepatoblastoma family tumors, differentiation of neoplastic cells appears to develop along two lineages, i.e., hepatoblasts/hepatocytes and cholangiocytes, suggesting the involvement of an early bipotential progenitor cell not yet committed to either hepatocytes of cholangiocytes. In a case of mixed epithelial and mesenchymal hepatoblastoma, irregular gland-like spaces around which the cells assumed a columnar form, giving the appearance of immature bile ducts, were found in conjunction with fetal-type and embryonal cells (Allison and Willis 1956). This was probably the first description of the histologic features of cholangioblastic hepatoblastoma, a tumor characterized by the presence of immature, CK19-positive bile duct-like profiles in close association with hepatoblast islands either of the fetal or embryonal type (Zimmermann 2002, 2005; Figs. 7, 8, 9, and 10).

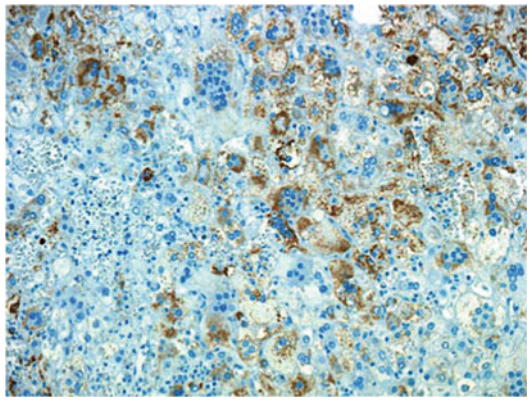

Fig. 4 HCC-like hepatoblastoma. The neoplasm shows focal reactivity for alpha-fetoprotein (AFP) in an irregular pattern (AFP immunostain)

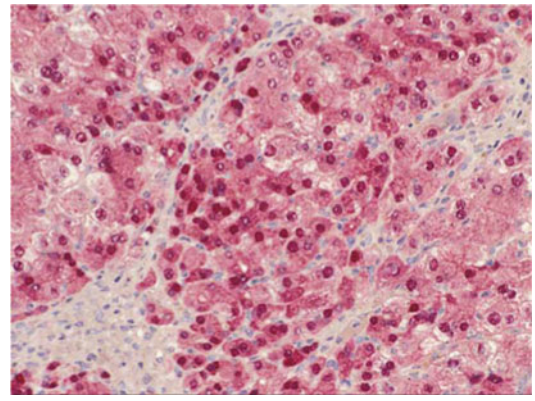

Fig. 6 HCC-like hepatoblastoma. Neoplastic cells display cytoplasmic and nuclear reactivity for beta-catenin (beta-catenin immunostain)

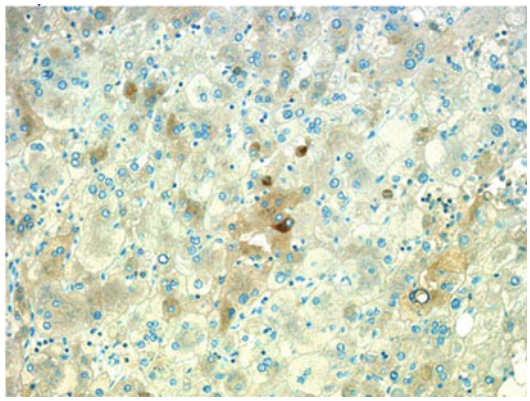

Fig. 5 HCC-like hepatoblastoma. Few tumor cells are reactive for glypican 3 (glypican 3 immunostain)

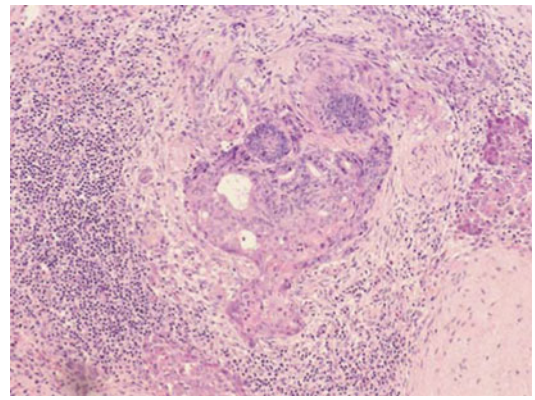

Fig. 7 Cholangioblastic hepatoblastoma. A central area of hepatoblastoma tissue shows focal formation of immature cholangiocellular acinar or tubular structures (hematoxylin and eosin stain)

Diagnosis of cholangioblastic hepatoblastoma requires the absence of ductular proliferations in the vicinity of the tumor. Stages of aberrant intrahepatic bile duct development in a mixed hepatoblastoma were reported (Libbrecht et al. 2003). An abundant cholangioblastic component was detected in a teratoid hepatoblastoma (Zhou et al. 2013).

Ductal Plate Tumors

Ductal plate tumors of the hepatobiliary tract are neoplasms that express structures resembling the embryonal ductal plate, a transient structure that acts as a pacemaker for the morphogenesis of intrahepatic bile ducts (Zimmermann 2002). Such a bimodal neoplasm of the liver was first observed in a young adult and was characterized by multiple small immature cell islands expressing hepatocyte lineage markers (so-called liverlets), consisting of small hepatoid cells arranged as a solid growth, surrounded by a CK19-positive double layer of cholangiocytes forming a rim in direct contact with the central hepatoid cell cluster. This double layer closely resembled the embryonal ductal plate (Gornicka et al. 2001; Figs. 11 and 12). Intrahepatic cholangiocarcinoma can also present with a

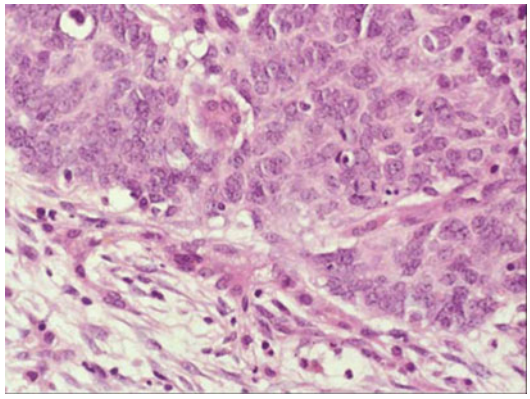

Fig. 8 Cholangioblastic hepatoblastoma. Embryonal-type cholangioblastoma is associated with few cholangiocellular nests forming abortive ductular structures (hematoxylin and eosin stain)

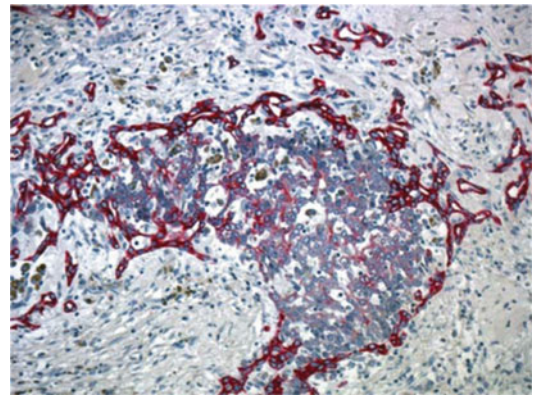

Fig. 10 Cholangioblastic hepatoblastoma. Within the tumor nodule and surrounding, there are numerous cytokeratin 19-positive elements (CK 19 immunostain)

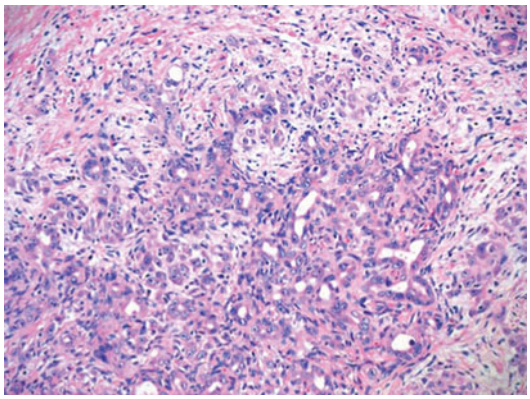

Fig. 9 Cholangioblastic hepatoblastoma. This neoplasm has produced numerous intertwining ductule-like profiles (hematoxylin and eosin stain)

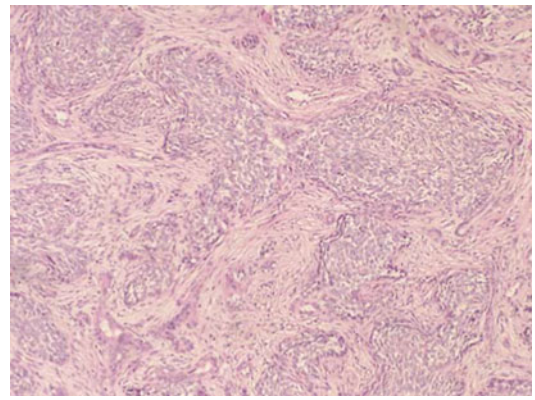

Fig. 11 Ductal plate tumor. Small nests or nodules of hepatoid cells ("liverlets") are surrounded by flattened biliary structures resembling the ductal plate (hematoxylin and eosin stain)

prominent ductal plate malformation pattern (Choe and Kim 2014).

Hepatoblastoma and Related or Similar Mixed Tumors in Adult Patients

True hepatoblastoma of the adult patient is an uncommon tumor, however, with a histology that is similar to or indistinguishable from hepatoblastoma occurring in infancy and childhood. It is not certain, whether all tumors described as "adult HB" are in fact true HB; this question is further discussed in a separate chapter.

On the other hand, the literature documents several examples of primary hepatic mixed neoplasms in adults that may more or less resemble components that we find in mixed hepatoblastomas of childhood. More than 40 cases of tumors have been reported that were either identified as hepatoblastomas of the adult or as mixed tumors that may share some features with hepatoblastoma.

et al. 1973; Meyer et al. 1974; Ludwig et al. 1975; Baird and McGovern 1976; Jameson and Chatkadakis 1978; Yoshida et al. 1979; Honan and Haqqani 1980; Popper 1980; Barbaryka and von Bouguoy 1981; Baroni et al. 1984; Kishimoto et al. 1984; Kawarada et al. 1985; Bhatnagar et al. 1987; Misra et al. 1988; Green and Silva 1989; Hartleb et al. 1989; Seabrook et al. 1989; Sugino et al. 1989; Oda et al. 1990; Altmann 1992; Mondragon et al. 1994; Harada et al. 1995; Inoue et al. 1995; Kacker et al. 1995; Bortolasi et al. 1996; Kuniyasu et al. 1996; Ahn et al. 1997; Inagaki et al. 2001; Kasper et al. 2005; Ke et al. 2005; Beppu et al. 2006; Remes-Troche et al. 2006; Krzewinski et al. 2007; Mukhopadhyay et al. 2007; Zhang et al. 2007; Fiaschetti et al. 2010; Nakamura et al. 2010; Wang and Liu 2012; Cienfuegos et al. 2013).

Hepatoblastoma and related tumors in the adult may occur even in old age (more than 80 years; Oda et al. 1990; Ahn et al. 1997). In a literature review of 21 cases, the age range covered 19–84 years, and 14 patients were more than 40 years old at diagnosis. In this series, there were 13 males and 8 females (Ahn et al. 1997). Hepatoblastomas in adults can cause marked elevation of serum AFP (Sugino et al. 1989) and are known to sometimes grow to impressive size. In the series of 21 cases of Ahn and coworkers (1997), 8 tumors weighed 3,000 or more grams, one mass having a weight of 8,500 g. Histologies and subtypes, as far as specified in the published reports, are the same as those encountered in childhood hepatoblastoma, although the mixed epithelial and mesenchymal type seems to prevail. In the 21 case reports by Ahn et al. (1997), 19 were of the mixed type and only 2 were wholly epithelial. Also teratoid hepatoblastoma has been noted in the adult age group (Zhang et al. 2007). Very rarely, neuroendocrine differentiation was observed in HB of adolescent or adult age (Fragulidis et al. 2013; Zhang et al. 2013).

Hepatoblastoma of the adult may present with sign of acute cholangitis, with cholestatic jaundice and intermittent low-grade fever caused by involved of the bile ducts (Kacker et al. 1995). The pathogenesis of adult hepatoblastoma is unknown, and it is also not clear whether, irrespective of the histology, adult hepatoblastomas are the same or other tumors as those in childhood. In one patient, the tumor was associated with oral contraceptive administration (Meyer et al. 1974). In a hypertriploid stemline derived from a hepatoblastoma of an adult patient, multiple numerical and structural chromosomal aberrations, including +2 and +20, were found (Parada et al. 1997).

A mixed hepatic tumor in an adult and listed as hepatoblastoma in several articles on adult hepatoblastoma was published in 1951 (Milman and Grayzel 1951). But it is likely that Barnett et al. (1958) described the first case of bona fide adult hepatoblastoma, a 35-year-old male patient who was admitted owing to severe epigastric pain and a weight loss of 35 lb during the preceding 3 months. The patient underwent exploratory laparotomy and died after a few weeks. At necropsy, a foul-smelling necrotic neoplasm of the liver occupied the upper abdomen and extended to the pelvis. The liver including the yellow-white, soft, and gelatinous tumor weighed 8,500 g. The tumor displayed a central cavity caused by necrosis and obstructed the portal vein and the inferior vena cava and surrounded the gallbladder and the extrahepatic biliary ducts. Histology revealed the pattern of mixed epithelial and mesenchymal hepatoblastoma, the epithelial cell population representing a mixed fetal and embryonal

subtype. The mesenchymal component contained several elongated cells with distinct cross striation. A further case was published twice in the same year by Bartok. In the old reports, terms other than hepatoblastoma have been employed, e.g., malignant mixed tumor, embryonic mixed tumor, and rhabdomyosarcohepatoma. The study of these reports leaves some doubt as to whether these lesions were in fact what we now define as hepatoblastomas or whether they rather belong to the category of mixed hepatic tumors sensu strictiori, discussed in a separate chapter. In fact, some features of mixed tumors in adults that have been discussed as being related to hepatoblastomas contain cell types that do not usually occur in pediatric hepatoblastomas, such as areas of adenocarcinoma (Carter 1969), hepatocellular carcinoma (Kerr 1966; Carter 1969; Goldman and Friedman 1969; Ludwig et al. 1975), chondrosarcoma (Carter 1969; Ludwig et al. 1975), and osteosarcoma (Carter 1969; Goldman and Friedman 1969). Therefore, the issue whether part of mixed tumors belong to the hepatoblastoma family of tumors remains controversial.

Combined Hepatoblastoma and Hepatocellular Carcinoma

Combined hepatoblastoma and hepatocellular carcinoma occurring as a synchronous lesion is very rare (de Potter et al. 1987; Cho et al. 2004; Ishimura et al. 2007; Mourad et al. 2007; Masuda et al. 2009; Canberk et al. 2013). In one patient, a sarcomatoid hepatocellular carcinoma showed foci of embryonal-type and small undifferentiated cells reminiscent of hepatoblastoma (Cho et al. 2004). Local relapse with hepatocellular carcinoma after treatment of hepatoblastoma has been observed (Gauthier et al. 1986). Late relapse of hepatocellular carcinoma in a child suffering from combined hepatoblastoma and hepatocellular carcinoma has been reported (Postovsky et al. 2001). In one patient, a combined hepatoblastoma and hepatocarcinoma developed 10 years after sibling donor bone marrow transplantation for severe aplastic anemia (Ishimura et al. 2007). Clear cell hepatocellular carcinoma arose in a patient 25 years after successful treatment of infantile hepatoblastoma (Basile et al. 2010). In a 54-year-old man with HCV-associated liver cirrhosis, a 3-cm-sized hepatic tumor was found to a mixed epithelial and mesenchymal hepatoblastoma with osteoid formation. Two years after the first operation, multicentric hepatocellular carcinoma developed (Masuda et al. 2009). On the other hand, HCC has been shown to relapse as hepatoblastoma, e.g., mixed hepatoblastoma after liver transplantation. This case was an adult patient transplanted for alcoholic liver cirrhosis complicated by multifocal hepatocellular carcinoma. One of the lesions (2 cm diameter) was histologically classified as mixed, trabecular and glandular, and moderately differentiated HCC, while the two other lesions (less than 1 cm diameter) were trabecular well-differentiated HCC. Three months after liver transplantation, a tumor recurred, associated with increased serum AFP (5,500 ng/ml), and a mixed hepatoblastoma had invaded the whole transplanted liver. Histology of the liver, which weighed 4,667 g, revealed a heterogeneous neoplasm. Some nodules contained an HCC-like growth associated with hepatoblastoma-like epithelial components and with tumor areas containing osteoid (Dumortier et al. 1999).

Stromal-Predominant Liver Tumors in the Pediatric Age Group

There are rare instances of pediatric liver tumors of the HB family that are characterized by large areas of stromal tissue, mostly fibroblasoid or immature mesenchymal/blastemal, lacking any epithelial components or only showing small nests of ill-defined epithelial cells. Such lesions may provisionally be termed “pediatric hepatic stromal tumors/PHST” as long as they are not further defined in regard to the cell lineages involved. These neoplasms may represent the hepatic counterpart of renal metanephric stromal tumors. Stromal-predominant tumors form well-circumscribed firm masses with an expanding growth pattern and perifocal liver atrophy.

Histologically, these neoplasms are characterized by a mesenchymal neoplastic tissue that consists of spindle and stellate cells embedded in a variably developed extracellular matrix. The spindle cells resemble fibroblasts or myofibroblasts but sometimes exhibit an immature phenotype. The spindled cells form fascicles or whorls. Myxoid areas may be present. Rarely, small clusters of non-hepatocyte epithelial cells are found, suggesting mesenchymal to epithelial transition.

Hepatoblastoma Associated with Other Hepatic Tumors and Tumor-like Lesions

Hepatoblastoma has been observed in combination with yolk sac tumor (Cross and Variend 1992). The authors described 6-month-old boy presenting with a large abdominal mass, caused by a liver tumor arising in the right liver lobe. At autopsy, the right lobe contained many confluent nodular and cystic masses. Histology revealed two components, the first being mixed epithelial and mesenchymal hepatoblastoma, with a fetal-embryonal epithelial lineage and osteoid formation, while the second component was yolk sac tumor with glandular structures, rounded papillary structures with central capillaries covered by cuboidal cells, and Schiller-Duval bodies. Both components were immunoreactive for AFP. Interestingly, yolk sac tumor of the liver has also been found together with hepatocellular carcinoma in an adult patient (Morinaga et al. 1996). Few observations revealed the combination of hepatoblastoma with true teratoma (Conrad et al. 1993; Moll et al. 2009). The patient described by Conrad et al. (1993) was a 17-month-old boy with a hepatic mass that was suggested to be teratoma based on imaging studies, but serum AFP was markedly elevated. The resected tumor comprised adjoining benign cystic teratoma and epithelial hepatoblastoma. In the case of Moll and coworkers (2009), a 3-year-old boy, the hepatic tumor resection specimen showed a tumor of up to 16 cm diameter that showed multiple cysts with a diameter of up to 1.5 cm. Histology showed tumor areas of very variable differentiation patterns intermixed with each other, i.e., not like in a collision tumor. Part of the tumor consisted of a fetal and embryonal hepatoblastoma, whereas other parts revealed neuroblastoma-like components, spindle cells with cross striation, cystic epithelial structures, and osteoid. Based on the published figures and the histologic description, this case rather represents a teratoid hepatoblastoma than a combination of hepatoblastoma and teratoma.

Hepatoblastomas: Biology of Disease and Prognostic Factors

21

Contents

Abstract

Biology of disease and prognosis in hepatoblastoma (HB) strongly depend on the initial stage of disease. At primary diagnosis, 40–60 % of HB either present as large or very large tumors, or involve both liver lobes, rendering the tumors unresectable. Therefore, downstaging of tumors by chemotherapy is a crucial approach. Tumor staging in HB has been standardized in great detail. Similar to hepatocellular carcinoma, HB has a strong tendency to invade the vascular system (macrovessel and microvessel invasion). Apart from stage, which is the most powerful prognosticator in HB, other prognostic factors include serum alpha-fetoprotein (AFP) levels, tumor histology, and molecular features. HB patients with low serum AFP concentrations form a high-risk group. Among various histologic types and subtypes, the fetal pattern is a favorable histology, whereas the small cell undifferentiated phenotype with or without rhabdoid features confers a high-risk biology. An increasing number of molecular abnormalities will be used in the future as risk stratificators.

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_21

Initial Tumor Extension, Invasion, Spread, and Metastasis

At primary diagnosis, 40–60 % of hepatoblastomas either present as large or very large tumors, or involve both liver lobes, causing the tumors unresectable. Preoperative chemotherapy results in downstaging in more than 80 % of patients, rendering the tumors resectable. Hepatoblastoma has a strong tendency to invade the vascular system, including portal and hepatic veins, the inferior vena cava, and smaller intrahepatic venous branches (macrovessel invasion and microvessel invasion; Wang et al. 2002). A main localization for distant metastases is the lung. Approximately 10–20 % of patients have lung metastases when first diagnosed. Lung metastases were already described in 1951 based on a postmortem examination of a 6-year-old boy with mixed hepatoblastoma (Milman and Grayzel 1951). Metastatic disease can also involve bronchopulmonary lymph nodes, and tumor can invade the pulmonary veins, tumor thrombi in pulmonary veins sometimes extending into the left atrium (Milman and Grayzel 1951). Hepatoblastoma metastases also involve the bony skeleton, brain, ovaries, and eye. Fetal or congenital hepatoblastoma may rarely cause extensive placental involvement, with diffuse tumor emboli in chorionic villus vessels (Robinson and Bolande 1985; Doss et al. 1998).

Biology of Disease and Modern Treatment

Previously, the prognosis of hepatoblastoma was very poor. Bodian (cited as a personal communication in Borman et al. 1961) had not had a survivor in all 13 cases in his experience. In a report of 1954, one patient lived 3 years after exploratory laparotomy (Debré et al. 1954), and another patient was reported to survive 10 years following excision (Tweedy 1956; personal communication to Borman et al. 1961). The first long-term survival of hepatoblastoma after hepatic lobectomy was reported in 1961. The patient was a 7-month-old girl having a globular tumor occupying nearly the whole of the left liver lobe. Based on the pathology description and the figure, the lesion probably represented mixed fetal and embryonal hepatoblastoma with numerous mitotic figures (Borman et al. 1961). Already in 1975 it had been reported that radiation and chemotherapy had a favorable effect in hepatoblastoma in which the tumor changed from inoperable to operable in three patients (Exelby et al. 1975). The 5-year survival of European patients with hepatoblastoma increased between 1978–1982 and 1993–1997 from 28 % to 66 % (Stiller et al. 2006) and has since further increased in an impressive manner. Based on modern surgical approaches, chemotherapies, and liver transplantation, numerous series of treatment results have been published.

Prognostic Factors

Stage

So far, tumor stage has been shown to be the most powerful prognosticator for the biology of hepatoblastomas. Features of hepatoblastoma predicting unresectability include multifocal tumors, high PRETEXT stage, involvement of large major liver blood vessels, and serum AFP

levels <100 ng/ml (Von Schweinitz et al. 1994; Fuchs et al. 2002; D'Antiga et al. 2007). The negative prognostic impact of hepatoblastomas presenting as tumor nodules throughout the liver has already been notes studied prior to systematic trials (Keeling 1971). It has in recent years been shown that hepatoblastoma staging has a central place as a predictor of outcome (Meyers 2007). The PRETEXT staging system, which has a moderate accuracy with a tendency to overstage patients, showed superior predictive value for survival and offers the opportunity to monitor the effects of preoperative therapy. In a study of 154 hepatoblastoma patients, 5-year overall survival and event-free survival were univariately associated with the PRETEXT stage and the presence of metastases. Additionally, tumor focality and enlargement of hilar lymph nodes at diagnosis were univariately associated with event-free survival (Brown et al. 2000). Following neoadjuvant chemotherapy, the extent of tumor necrosis independently predicted survival in patients with hepatoblastoma (Venkatramani et al. 2012). Congenital hepatoblastoma with its very early initiation and progression of disease does not appear to confer a worse prognosis (Trobaugh-Lotrario et al. 2013).

Serum Alpha-Fetoprotein/AFP

Hepatoblastoma patients with low serum alpha-fetoprotein (AFP) levels form a high-risk group (De Ioris et al. 2008). In a recent analysis of SIOPEL results covering 1995–2006 (541 patients with hepatoblastoma), reduced event-free survival correlated significantly with AFP <100 ng/ml, AFP => 1.2 × 10(6) ng/ml, metastatic disease, PRETEXT stage IV, multifocality, age >5 years, and borderline with small cell undifferentiated histology (Maibach et al. 2012).

Tumor Histology

Is tumor histology a risk stratificator? So far, the fetal phenotype was identified as a favorable histology (Haas et al. 1989; Conran et al. 1992), when compared with all other histologic pattern (Haas et al. 1989), and a small cell undifferentiated phenotype confers a high-risk biology (Dehner and Manivel 1988). Much less is known about the significance of other histomorphologies. In their analysis of the relationship between morphologic subtypes and prognosis, Dehner and Manivel (1988) had too few observations on MT-HB to be certain whether it is prognostically unfavorable or not. There is evidence that the proliferative activity of hepatoblastomas affects outcome. Fetal-type hepatoblastomas with a very low proliferative activity present the most favorable phenotype, while rapidly proliferating small cell undifferentiated hepatoblastoma is a highly aggressive tumor. Mitotic activity was associated with poor prognosis (Haas et al. 1989). Proliferative activity is assessable by the mitotic rate, the PCNA labeling index, the Ki-67/MIB-1 labeling index, and the expression of nucleolar organizing regions. The PCNA labeling index was found to be significantly higher in the embryonal than in the fetal phenotype (Rugge et al. 1998). The significant difference between fetal and embryonal cell proliferative activity assessed by immunohistochemistry was confirmed in a later study (Tsai et al. 2009). The Ki-67/MIB-1 labeling index varied from 0 % to 39.5 % in one study, with a mean value of 13.5 %. There was no significant correlation between this labeling index and age and sex, but with stage, in that the indices were lower in patients with stage I and stage II in comparison with higher stages (Ara et al. 1997). Overexpression of cyclin D1 and a high Ki-67 proliferation index was prognostically significant (Purcell et al. 2012).

Molecular Features

An increasing number of molecular abnormalities may be used in the future as prognosticators for hepatoblastoma. Expression of carcinoembryonic antigen-related cell adhesion molecule 1 has been found to be an adverse prognostic factor in hepatocellular carcinoma (Cruz et al. 2005), and loss of this molecule's expression predicts metachronous pulmonary metastasis and poor survival in

patients with hepatoblastoma (Tsukada et al. 2009). A high expression of the tight junction-associated protein, tricellulin, is associated with better survival in HB (Schlachter et al. 2014). Expression of a factor involved in epigenetic promoter hypermethylation, RAS association domain family protein 1/RASSF1A, indicates poor prognosis in hepatoblastoma (Honda et al. 2013). Prognosis of HBs can be estimated by use of distinct microRNA (miR) expression patterns. Specifically, high miR-21, low miR-222, and low miR-224 levels were associated with increased overall survival (Gyugos et al. 2014).

Hepatoblastoma Family of Tumors: Risk Factors and Pathogenic Pathways

22

Contents

Abstract

Hepatoblastoma (HB) is associated with several distinct risk factors, etiologies, and pathogenic pathways. A wide array of mainly congenital conditions is associated with HB, and part of these disorders are now classified as HB risk factors, including low and very low birth weight and Beckwith-Wiedemann syndrome. Low birth weight, and in particular a birth weight lower than 1,500 g, confers a disproportionate risk of HB. The pathogenesis of HB in low and very low birth weight is not yet known. HB shows recurrent patterns of chromosomal aberrations which are involved in carcinogenesis. Among molecular abnormalities involved in HB, deregulation of the Wnt/beta-catenin signaling pathway plays a central role. Somatic mutations in the beta-catenin gene are critically involved in the pathogenesis of sporadic HB. Other components of this important pathway may be altered in HB, including Axins and the adenomatous polyposis coli/APC protein. There is increasing evidence that deregulation of microRNAs and epigenetic mechanisms are effectors in HB pathogenesis.

Risk Factors and Associations of Hepatoblastomas

A wide array of mainly congenital conditions can be associated with hepatoblastoma (Table 1), and some of these are regarded as risk factors for this malignancy. Part of the conditions involve genes directly involved in cancerogenic pathways, while others increase the risk of neoplastic transformation through indirect pathways, such as increased regeneration of target cells or induction of cell injury, or DNA damage. An important risk factor for hepatoblastoma is low birth weight, discussed in a separate paragraph following the Table.

Hepatoblastoma and Low Birth Weight

Low birth weight (LBW; 1,500–2,500 g) and in particular very low birth weight (VLBW; <1,500 g) is associated with a disproportionate risk of hepatoblastoma. LBW infants amount to approximately 7 % of live births and VLBW infants to about 2 % in Europe and USA. Hepatoblastoma in infants of very low birth weight has increased in several countries.

Selected References Ikeda et al. 1997, 1998; Ross 1997; Feusner et al. 1998; Ribons and Slovis 1998; Tanimura et al. 1998; Maruyama et al. 1999, 2000; Tsuchida et al. 1999; Feusner and Plaschkes 2002; Jaing et al. 2002; Kisato et al. 2002; Oue et al. 2003; Kapfer et al. 2004; Latini et al. 2004; Reynolds et al. 2004; Spector et al. 2004, 2008, 2009; Ansell et al. 2005; McLaughlin et al. 2006; Slovis and Roebuck 2006; Pu et al. 2009; Heck et al. 2013; Turcotte et al. 2014.

In an investigation based on data of the Japan Children's Cancer Registry (543 children with hepatoblastomas), the relative risks of hepatoblastoma among children with birth weights of <1,000, 1,000–1,499, 1,500–1,999,

and 2,000–2,499 g were 15.64, 2.53, 2.71, and 1.21, respectively (Tanimura et al. 1998). In a UK national population-based case-control study, 3 of 24 children with hepatoblastoma weighed <1,500 g at birth, 2 of whom weighed <1,000 g (Ansell et al. 2005). Based on 58 hepatoblastoma cases diagnosed between 1985 and 2001 (New York State Cancer Registry), it was found that a birth weight less than 1,000 g was associated with a strongly increased risk of hepatoblastoma, with a relative risk of 56.9 (McLaughlin et al. 2006). In the largest case-control study, the odds ratio of hepatoblastoma in VLBW infants was 51 times higher than in those with normal birth weight (Reynolds et al. 2004). Overall, 20–40 % of hepatoblastoma patients were premature at birth, and it is estimated that at least 8 % were VLBW infants (review: Slovis and Roebuck 2006). In general, the increasing incidence of hepatoblastoma in children less than 4 years of age over the last 25 years corresponds roughly to the increased survival rate of infants with LWB and VLBW (Spector et al. 2004; Slovis and Roebuck 2006). In a case-control study comparing 12 hepatoblastoma cases and 75 birth weight-matched controls, it turned out that the gestational age of the hepatoblastoma cases tended to be lower than that of the controls and that all hepatoblastoma patients received oxygen therapy which had a longer duration than that of controls (Maruyama et al. 2000). One study showed that hepatoblastomas occurring in children with very low birth weight tend to be unfavorable, with a significant correlation between the gestational age and tumor stage (Ikeda et al. 1998). The pathogenesis of hepatoblastoma development in very low birth weight is not known. Tumors other than hepatoblastoma are also more common in very low birth weight infants, such as retinoblastoma and gliomas other than astrocytomas and ependymomas (Spector et al. 2009). The presence of erythropoietin receptor in some of the hepatoblastomas has been suggested to play a role (Trobaugh-Lotrario et al. 2007).

Pathogenic Pathways of Hepatoblastomas and Related Tumors

Cytogenetic Features

Karyotyping of hepatoblastomas has shown recurrent patterns of chromosomal aberrations. The most common alterations consist in trisomies, which may occur in conjunction with other structural anomalies and/or double-minute chromosomes.

Selected References Mascarello et al. 1990; Bardi et al. 1991; Fletcher et al. 1991; Swarts et al. 1996; Nagata et al. 1999, 2005; Ma et al. 2000; Parada et al. 2000; Yeh et al. 2000; Stejskalova et al. 2009; Terada et al. 2009; reviews: Tomlinson 2012; Tomlinson and Kappler 2012.

The most important recurring events include chromosome trisomies, unbalanced translocations with a breakpoint on the proximal short arm of chromosome 1, and reciprocal chromosomal arm 4 (Tomlinson 2012). Trisomies mainly involve chromosomes 2, 8, and 10. Gains in chromosomes 1q, 2 (or 2q), 8, 17q, and 20 and losses in chromosomes 4q and 11q were frequently identified (Steenman et al. 1999), and high-grade amplifications were detected at 7q34, 14q11.2, and 11q22.2 (Suzuki et al. 2008). Gains on chromosomes 1q and 2 have been recognized as a hallmark DNA copy number change in hepatoblastoma, with 2q24 as a critical chromosomal band. The rearrangement of 1q is usually in pericentromeric heterochromatin (Surace et al. 2002). In one study of 10 cases, trisomy 20 was the most commonly detected abnormality, followed by trisomies 2 and 8 (Surace et al. 2002). Furthermore, gains of 8q and 20 are associated with poor outcome (Weber et al. 2000). Hepatoblastoma can develop in trisomy 18 (Bove et al. 1996) and even multiple hepatoblastomas have been detected in a patient with trisomy 18 (Teraguchi et al. 1997). Rare events are translocations. Four cases of

hepatoblastoma with a derivative chromosome 4 from an unbalanced translocation between the long arms of chromosomes 1 and 4 were reported (Schneider et al. 1997). Translocation t(22;22)(q11;q13) was detected in small cell undifferentiated hepatoblastoma (Gunawan et al. 2002). In a fetal-type hepatoblastoma, del(3)(q11.2q13.2) was detected (Sandoval et al. 2002). Partial maternal isodisomy 7q was found in a 30-month-old girl with myelodysplasia and hepatoblastoma (Neas et al. 2006). Hepatoblastoma was found in an infant with paternal disomy 14 (Horii et al. 2012). Comparative genomic hybridization analysis revealed a high frequency of X-chromosome gains (Terracciano et al. 2003). In part of the cases, gains or losses of chromosomal parts have been allocated to distinct genes altered in hepatoblastoma. Gains immediately telomeric to the deleted locus del14q12 are associated with overexpression of FOXG1, suggested to contribute to the maintenance of an undifferentiated state in hepatoblastomas (Adesina et al. 2007).

DNA Ploidy

In early investigations, no correlation was found between DNA ploidy and the histologic type, although aneuploidy was detected in a significant proportion of cases (Conran et al. 1992). Today we know that hepatoblastomas reveal an abnormal nuclear DNA content which differs among the various histologic subtypes. Fetal-type cells are, like normal hepatocytes, diploid, while embryonal-type cells and anaplastic cells are aneuploidy.

Selected References Hata et al. 1991; Orozco-Florian et al. 1991; Conran et al. 1992; Schmidt et al. 1993; Kröber et al. 1995; Rugge et al. 1998; Chopra et al. 2010.

An investigation on 29 hepatoblastomas revealed a diploid phenotype in 79.9 % and an aneuploidy phenotype in 20.7 %. Patients with diploidy of their tumors were younger than the aneuploidy group and had a better prognosis, while aneuploidy tumors tended to occur in higher stages and had a worse prognosis (Schmidt et al. 1993). In one study, 8 out of 23 hepatoblastomas were aneuploid, and DNA aneuploidy was strongly associated with embryonal histological areas. DNA aneuploidy tumors showed a trend toward a more aggressive clinical behavior (Zerbini et al. 1998). In another study on 34 cases of hepatoblastoma, there was a significant association between histologic type, DNA content, and the percentage of cells in the S phase of the cell division cycle. Also this study revealed that aneuploidy and the highest proportions of S phase cells were significantly associated with embryonal-type histology (Rugge et al. 1998).

Role of Stem Cells

In the light of an apparent recapitulation of hepatogenic pathways in hepatoblastomas, and the finding of multilineage differentiation in mixed tumors, specifically in teratoid hepatoblastomas, a role of tumor stem/progenitor cells has been proposed (Ruck et al. 1995, 1996, 1997; Fiegel et al. 2004; Ward et al. 2010). Immunohistochemical features of oval cells with a biliary epithelium-type cytokeratin profile have been found in some hepatoblastomas (Ruck et al. 1997). In fetal-type hepatoblastoma, only few such cells were seen, and a moderate amount in embryonal-type tumors, while almost all cells in SCUD hepatoblastoma were of this cell type (Ruck et al. 1996). Stemlike cells resembling oval cells have been detected in atypical ducts of human hepatoblastomas. Furthermore, staining for stem cell marker Thy1 identified positive periductal clusters of cells resembling ganglionic groups, also expressing N-CAM/CD56 (Fiegel et al. 2004). Indirect evidence for a role of progenitor cells in hepatoblastoma is the finding of an overexpression of the hepatic progenitor cell marker, high mobility group AT-hook 2, and architectural nuclear factor (Lee et al. 2013). On the other hand, there are also findings that do not support the view that stem cells are involved in hepatoblastoma tumorigenesis. Small cells

occurring in hepatoblastoma lack an oval cell phenotype (Badve et al. 2003).

Familial Hepatoblastoma

Similar to hepatocellular carcinoma, there are rare reports on familial occurrence of hepatoblastoma (Fraumeni et al. 1969; Napoli and Campbell 1977; Surendran et al. 1989; Riikonen et al. 1990; de Chadarevian et al. 2002). In the first published report, two sisters of four sibs developed hepatoblastoma during infancy (Fraumeni et al. 1969).

Hepatoblastoma and Beckwith-Wiedemann Syndrome

Beckwith-Wiedemann syndrome (BWS; OMIM 130650; originally termed EMG, standing for **e**xomphalos/omphalocele, **m**acroglossia, and **g**igantism/macrosomia; Beckwith 1963; Wiedemann 1964) is a genetically heterogeneous overgrowth disorder. It represents the most common overgrowth disease, with a reported incidence of 1 in 13,700 live births (reviews: Cohen 2005; Smith et al. 2007; Choufani et al. 2010). Similar to two other overgrowth syndromes, i.e., hemihypertrophy/hemihyperplasia and Sotos syndrome, BWS is associated with a distinct spectrum of tumors. The tumor frequency in BWS is 7.5 %, higher than in hemihypertrophy (5.9 %) and Sotos syndrome (2.2 %). The malignant neoplasm developing in BWS comprises Wilms' tumor and other renal blastomatous tumors, adrenocortical carcinoma, pancreatoblastoma, glioblastoma, neuroblastoma, sarcomas, and lymphomas. In addition, BWS is complicated by the development of hepatoblastoma (Hamada et al. 2003; The and Ong 2007). Several benign tumors also occur, such as adrenal adenoma, fibrous hamartomas, cardiac hamartoma, myxoma, ganglioneuroma, hemangiomas, and hamartomas of the bladder (DeBaun and Tucker 1998). Congenital or infantile hepatoblastomas have been observed in BWS (Molina et al. 1981; Haas et al. 1986; Little et al. 1988; Orozco-Florian et al. 1991; Wilfong et al. 1992; Martelli et al. 1993; Tsai et al. 1996; Worth et al. 1999; Fukuzawa et al. 2003; Hamada et al. 2003; Kobrinsky et al. 2005; Mussa et al. 2011). Serial serum AFP screening can identify early hepatoblastoma in BWS (Clericuzio et al. 2003). Hepatoblastomas have also been found in isolated hemihypertrophy /hemihyperplasia, a disorder which may represent one end of the clinical spectrum of BWS (Hoyme et al. 1998; Dempsey-Robertson et al. 2012).

Around 85 % of cases with BWS are sporadic, and the remaining have an autosomal-dominant inheritance with preferential maternal transmission. BWS is caused by alterations of genes imprinted at 11p15, while chromosomal anomalies of 11p15 occur only in 1–2 % of BWS patients (mainly sporadic or inherited translocation of inversion of 11p15). About 20 % of BWS cases have uniparental disomy of chromosome 11, and such cases seem to result from mitotic recombination occurring in early embryogenesis. Among 52 cases with this disorder, all cases demonstrated mosaic paternal isodisomy, and IGF2 and H19 were included in the segment of uniparental disomy in all cases (Cooper et al. 2007). Apart from BWS, other imprinting disorders comprise Prader-Willi syndrome, Angelman syndrome, transient neonatal diabetes mellitus, uniparental disomy (14) syndromes (MatUPD14, PatUPD14), pseudohypoparathyroidism 1b, maternal hypomethylation syndrome, and Silver-Russell syndrome (reviews: Temple 2007; Amor and Halliday 2008; Eggermann 2009). Loss of maternal alleles on chromosome arm 11p, a region of imprinting in BWS, was found in hepatoblastoma (Albrecht et al. 1994). Imprinting takes place in a parent-of-origin fashion, expression being dependent on the silencing (imprinting) of maternal or paternal genes. The 11p15 region contains two clusters of imprinted genes in BWS, and the imprinting centers in these two clustered domains have differentially methylated regions. The first gene cluster is telomeric at 11p15 and contains two important genes, insulin-like growth factor-II (IGF2) and H19. The H19 gene encodes a non-coding mRNA that is strongly expressed during embryogenesis and which is maternally

expressed, and the neighboring IGF2 gene is transcribed from the paternal allele. These two genes are coexpressed in endoderm- and mesoderm-derived tissues during ontogenesis (review: Gabory et al. 2006). H19 seems to be a transregulator in the fine-tuning of the imprinted gene network (Gabory et al. 2009). The second cluster is centromeric at 11p15 and contains several genes, three of them being important for the pathogenesis of BWS (KCNQ1, KCNQ1OT1, and CDKN1C). Alterations in these different gene clusters are the reason why BWS represents a spectrum of disorders (Cooper et al. 2005). In regard to tumor development, the type of neoplasms observed in BWS cases with telomeric defects are different from those with defects limited to the centromeric domain (Weksberg et al. 2001).

IGF2 is maternally silenced (imprinted) and therefore paternally expressed. Failure of differential silencing or imprinting results in biallelic expression of IGF2, seen in part of BWS patients and in tumors that develop in them (Li et al. 1995; Rainier et al. 1995; Yun et al. 1998; review: Cohen 2005). In contrast, H19 is paternally silenced and thus maternally expressed. Approximately a fifth of BWS patients reveal paternal uniparental disomy with two paternally derived copies of 11p15 and no maternal copies, probably caused by postzygotic somatic recombination, but most of these patients in fact show somatic mosaicism. It is suggested that this explains the patients with isolated hemihypertrophy/hemihyperplasia who develop a BWS spectrum of tumors (review: Cohen 2005). Loss of imprinting at IGF2, in association with H19 silencing, has been described in hepatoblastoma (Rainier et al. 1995) and in a subgroup of BWS patients who have an increased risk for Wilms tumor. In one family showing this constellation, paternal inheritance of a cis-duplication at 11p15.5 spanning the BWS IC1 region and including H19, IGF2, INS, and TH was found, implicating IGF2 in overgrowth and Wilms tumor tumorigenesis (Algar et al. 2007). In another child without BWS, who later developed hepatoblastoma, focal congenital hyperinsulinism resulting from a paternally inherited recessively acting mutation of ABCC8 and pancreatic paternal uniparental disomy for 11p15 was found (Calton et al. 2013). There is strong evidence for an association of the overgrowth syndrome, Beckwith-Wiedemann syndrome, and the development of neoplasia, including hepatoblastoma (review: Tan and Amor 2006). Loss of IGF2 imprinting correlates with hypermethylation of the H19 differentially methylated region in hepatoblastoma (Honda et al. 2008). The expression of the H19 gene was inactivated by maternal allelic loss or hypermethylation in seven out of eight "sporadic" hepatoblastomas, and loss of imprinting of the IGF2 gene was linked to inactivation of the H19 gene in part of the tumors (Fukuzawa et al. 1999). Hepatoblastomas show monoallelic expression of H19 (Ross et al. 2000). In hepatoblastomas associated with chromosome 11p15.5, uniparental isodisomy beta-catenin mutation and/or nuclear beta-catenin immunoreactivity in tumor cells was found, but no reactivity for beta-catenin was detected in the tissue with hepatomegaly which contained uniparental disomy cells, suggesting that Wnt signal activation occurs later in tumorigenesis in BWS (Fukuzawa et al. 2003). The 11p15.5 chromosomal region also contains TSSC5 (tumor-suppressing subchromosomal transferable fragment cDNA; also known as ORCTL2/IMPT1/BWR1A/SLC22A1L). This gene encodes an efflux transporter-like protein with ten transmembrane domains. The expression of TSSC5 is regulated through paternal imprinting, and mutations of TSSC5 have been found in certain tumors. TSSC5 is regulated via an ubiquitin ligase, RING105, that can function in concert with the ubiquitin-conjugating enzyme UbcH6 (Yamada and Gorbsky 2006).

What are the functions of IGF2? The IGF axis is disturbed in hepatoblastomas. IGF2 stimulates hepatoblastoma cell proliferation in vitro and is expressed in an autocrine manner in hepatoblastomas (Akmal et al. 1995). These cells express the IGFI receptor, and inhibition of this receptor with picropodophyllin abolishes the proliferative response of the cells (Tomizawa and Saisho 2006). IGF2 induces rapid beta-catenin relocation to the nucleus during epithelial-

mesenchymal transition (Morali et al. 2001). The expression of the genes of ILGF-binding protein/ILGF-binding protein-related proteins is altered in hepatoblastoma (von Horn et al. 2001, 2002). Reactivation of the known competitor of the IGF axis, insulin-like growth factor-binding protein 3/IGFBP3 decreases the aggressive properties of hepatoblastoma cells (Regel et al. 2012).

IGF2 and the IGF2 Regulator PLAG1

Aggressive biology and poor outcome in hepatoblastoma are associated with amplification of chromosome 8q. A critical region in this area, 8q11.2-q13, contains the gene of the oncogene PLAG1, which is highly expressed in part of hepatoblastomas (Zatkova et al. 2004). PLAG1 (pleomorphic adenoma gene-like 1) is the main translocation target in pleomorphic adenomas of the salivary glands. Together with two other members, the tumor suppressor candidate PLAG-like1 (also called ZAC1 or LOT1, lost on transformation 1) and PLAG2, PLAG1 forms a subfamily of zinc-finger proteins involved in cell proliferation, tissue-specific gene regulation, and embryonic development. This C(2)H(2) family is characterized by transcription activation through binding to the bipartite consensus sequence GRGGC(N)(6–8)GGG. The three members share high homology with each other, particularly in their zinc-finger amino-terminal region, and exert different DNA binding capacities (Hensen et al. 2002). The proteins however differ in regard to their functional properties. PLAG1 is a proto-oncogene located on chromosome 8q12; is rearranged in several tumors, but mainly in pleomorphic salivary gland adenomas, lipoblastomas, hepatoblastoma, and AML; and is a transcriptional activator of IGF2. The LOT1 gene, assigned to human chromosome 6q24-25, is maternally imprinted, is regulated by epigenetic mechanisms, and encodes a growth suppressor protein that is altered in several tumors (via LOH) and in transient neonatal diabetes mellitus/TNDM (reviews: Abdollahi 2007; Van Dyck et al. 2007). PLAG1 is developmentally regulated and its activity is suppressed by SUMOylation via the small ubiquitin-related modifier (SUMO) modification pathway (Van Dyck et al. 2004). PLAG1 SUMOylation causes PLAG1-induced IGF2 expression, and it transactivates transcription from the embryonic IGF2 promoter P3 in hepatoblastomas (Zatkova et al. 2004). SUMOylation and acetylation play opposite roles in the transactivation of both PLAG1 and PLAG2 (Zheng and Yang 2005). The protein Tip6o associates with PLAG2 through its zinc-finger domain, acetylates PLAG2, and thus acts as promoter-specific coactivator of PLAG2 (Ning et al. 2008). PLAG1 is regulated by miRNAs 181a, 181b, 107, 424, and 492, and these miRNAs are epigenetically silenced in chronic lymphatic leukemia (CLL), causing PLAG1 overexpression in CLL cells (Pallasch et al. 2009; Patz et al. 2010). miRNA 492 has been shown to be processed from the keratin 19 gene and is upregulated in metastatic hepatoblastoma, suggesting that this microRNA and its targets, in particular PLAG1, may play a role in metastatic spread of this tumor (von Frowein et al. 2011). Expression of the PLAG2 target gene IGF2 is markedly diminished by inactivation of PC2 via silencing through PC2 siRNA (Wezensyk et al. 2010). PC2 (positive cofactor 2), a component of the ARC/Mediator complex, cooperates with PLAG2 and Pu.1 to enhance the activity of the known PLAG2 target promoter, NCF2. The Mediator complex is a polyprotein structure that forms the bridge between transcriptional activators and RNA polymerase II and is required for the regulated transcription of nearly all RNA polymerase II-dependent genes. It mainly consists of proteins of the MED protein family, including the key component MED1 (PBP or TRAP220), which interacts with nuclear receptors such as estrogen receptor and PPARg and other transcriptional activators, and is required for the generation of hepatic steatosis (Bai et al. 2011). MED1 directly interacts with the protein arginine and glutamate-rich 1 (ARGLU1), an interaction that is crucial for the regulation of estrogen receptor-mediated gene transcription (Zhang et al. 2011). Also MED28 (magicin), an interactor of merlin and playing a role in neurofibromatosis, is a Mediator complex component. The Mediator complex

also associates directly with heterochromatin at telomeres and influences the exact boundary between active and inactive chromatin, whereby the Mediator components Med5 and Med7 play significant roles in the interaction with regions near subtelomeric X-elements and in the balance between Sir2 and Sas2 proteins. By this mechanism, Mediator influences telomeric silencing and cellular lifespan (Zhu et al. 2011). The PLAG2 target NCF2 (neutrophil cytosolic factor 2) is the 67 kDa cytosolic subunit of the multiprotein NADPH oxidase complex found in neutrophils. NCF2 is mutated in chronic granulomatous disease (Köker 2010).

Growth Regulation and Deregulation in HB: Significance of the Wnt/Beta-Catenin Signaling Pathway

The Wnt/beta-catenin signaling pathway plays an important role in the biology of hepatoblastomas and other liver cell tumors (reviews: Laurent-Puig and Zucman-Rossi 2006; Jin et al. 2008; Armengol et al. 2011). The Wnt/beta-catenin signaling complex is a multiprotein signaling pathway, degradation of cytosolic beta-catenin by the APC/AXIN1 destruction complex being the key regulated step of this pathway. The signaling pathways contain, in addition to beta-catenin, Axins and the APC protein and several other regulatory proteins, including Amer1 (see below), glycogen synthase kinase, and kindlin 2, a focal adhesion protein which forms a transcriptional complex with beta-catenin and TCF4 to enhance Wnt signaling. Kindlin 2 strengthens the occupancy of beta-catenin on the Wnt target gene AXIN2 (Yu et al. 2012). During normal liver morphogenesis, beta-catenin is expressed in a stage-specific manner, with a peak of expression during embryogenesis and a drop in the prenatal period (Micsenyi et al. 2004). However, a complex interplay between Wnt/beta-catenin signaling and maintenance of a regulated cell cycle still works in the adult liver (Gougelet and Colnot 2012). In the normal liver, beta-catenin expression is centrally involved in liver ontogenesis, development of hepatoblasts, hepatocyte proliferation, and regeneration. Beta-catenin deletion in hepatoblasts disrupts hepatic morphogenesis (Tan et al. 2008). Hepatoblast growth and differentiation require calpain-mediated cleavage of beta-catenin, and the presence of the beta-catenin N terminus correlates with the differentiation status of hepatoblasts (Lade et al. 2012). Stabilized beta-catenin enhances hepatocyte proliferation, suppresses TNF-alpha/ActD-induced apoptosis, and causes weak anchorage-independent cell growth (Shang et al. 2004). In a murine model, liver-specific loss of beta-catenin resulted in delayed hepatocyte proliferation after partial hepatectomy (Sekine et al. 2007).

Somatic mutations of beta-catenin play an important role in the pathogenesis of sporadic hepatoblastoma. Mutations of the beta-catenin CTNNB1 gene, prodemonantly in the degradation box, have been observed in HBs.

Selected References Bläker et al. 1999; Jeng et al. 2000; Park et al. 2001; Takayasu et al. 2001; Udatsu et al. 2001; Taniguchi et al. 2002; Cairo et al. 2008; Curia et al. 2008; Takigawa and Brown 2008; Lopez-Terrada et al. 2009; Cairo et al. 2012; Jia et al. 2014.

Hepatoblastomas often show a mutated degradation targeting box of the beta-catenin genes, albeit with variable reported frequencies (48 %, Koch et al. 1999; 67 %, Wei et al. 2000; 19 %, Curia et al. 2008; reviews: Buendia 2002; Ranganathan et al. 2005; Armengol et al. 2011). In a recent study of 32 hepatoblastoma patients, 87 % carried CTNNB1 mutations within the ubiquitination domain (Lopez-Terrada et al. 2009). Activation of beta-catenin in hepatoblastomas is, however, not exclusively due to mutations inhibiting its degradation but also to HGF/c-Met-induced beta-catenin activation (Purcell et al. 2011). There is a relationship between abnormalities of Wnt/beta-catenin signaling and the histologic subtype of hepatoblastomas carrying the alterations. Large deletion of the CTNNB1 gene was seen only in pure fetal cases, also characterized by overexpression of cyclin D1 and GLUL/glutamine synthase, while small cell undifferentiated

(SCUD) hepatoblastoma did not express GLUL (Lopez-Terrada et al. 2009). The relationship between beta-catenin gene mutations and beta-catenin protein accumulation varies markedly. Whereas in one study, the rate of beta-catenin gene mutation was 19 %, and beta-catenin protein accumulation was found in 67 % of cases (Curia et al. 2008). In cases with beta-catenin accumulation, the protein is typically localized to the nuclei (Yamaoka et al. 2006). The nuclear localization of beta-catenin is controlled by Rac1 activation, whereby the role of Rac1 depends on phosphorylation of beta-catenin at Ser191 and Ser605, which is mediated by JNK2 kinase (Wu et al. 2008). Among Wnt signal genes downstream of beta-catenin, E-cadherin was expressed in all hepatoblastomas, while cyclin D1 expression was significantly detected in tumors with an advanced stage of disease (Yamaoka et al. 2006). Similarly, deletions and mutations of the beta-catenin gene were associated with overexpression of cyclin D1 and fibronectin and with poorly differentiated histology in another investigation (Takayasu et al. 2001). Mutations of the beta-catenin gene are associated with overexpression of cyclin D1 and fibronectin and poorly differentiated histology (Takayasu et al. 2001). In hepatoblastomas and hepatocellular carcinomas with beta-catenin gene mutations, overexpression of regenerating islet-derived 1 alpha (REG1A) and 3 alpha (REG3A) genes was found. Hepatoblastomas show an overexpression of the Wnt antagonists Nkd-1 and beta-TrCP, supporting an activation of the Wnt signaling pathway in these neoplasms (Koch et al. 2005).

What is the evidence that alterations in the beta-catenin pathway affect growth of hepatoblastomas? Nuclear translocation of beta-catenin during mesenchymal stem cell differentiation into hepatocytes is associated with a tumoral phenotype (Herencia et al. 2012). By use of hepatoblastoma and HCC cell lines, it has been found that RNA interference against beta-catenin inhibits the proliferation of these tumor cells (Sangkhathat et al. 2006). One effect of a deranged Wnt/beta-catenin signaling might involve a pathway that promotes the emergence of maintenance of a progenitor cell phenotype in liver cell tumors. In HCC, nuclear beta-catenin accumulation induced an early liver progenitor phenotype and altered biology of disease in the sense of tumor recurrence promotion (Zulehner et al. 2010).

Factors Associated with Beta-Catenin in the Wnt Signaling Pathway

AXIN1, in cooperation with APC protein, is the chief destruction complex for the degradation of cytosolic beta-catenin (Stamos and Weis 2013). This destruction complex consists of APC, Axin, CK1a, and glycogen synthase kinase 3 beta, to foster phosphorylation of beta-catenin by earmarking it for Lys-48-linked polyubiquitination and proteasomal degradation. In this reaction, APC is conjugated with Lys-63-linked ubiquitin chains by the action of HectD1, an E3 ubiquitin ligase that modifies APC with Lys-63 polyubiquitin (Tran et al. 2013). This function of Axin is counteracted through relocalization of the Axin protein to the Wnt receptor complex. Beta-catenin is not only phosphorylated inside the AXIN1 complex but also ubiquitinylated and degraded via the proteasome, all within an intact AXIN1 complex that is not disassembled (Li et al. 2012a). AXIN1 and AXIN2 turnover is regulated by its poly-ADP-ribosylation catalyzed by tankyrase, requiring a direct interaction of AXIN1 with tankyrase. Poly-ADP-ribosylation of Axins destabilizes Axins and promotes signaling (Morrone et al. 2012). In order to maintain low steady-state levels of Axin proteins, a positive regulator of Wnt signaling, the RNF146 RING-type ubiquitin E3 ligase, destabilizes tankyrases 1 and 2 and, in a reciprocal manner, tankyrase activity reduces RNF146 protein levels (Callow et al. 2011). Based on the position of Axin proteins in the Wnt signal cascade, it can be expected that the deficient AXIN1 function causes a similar effect as loss-of-function mutations of the beta-catenin gene, from what has been observed in hepatoblastoma (Miao et al. 2003). Conditional disruption of AXIN1 leads to liver tumorigenesis in mice (Feng et al. 2012). AXIN2 (conductin) is a direct target gene of Wnt signaling in

hepatoblastomas. In part of hepatoblastomas, mutations in the AXIN2 have been observed, representing an alternative mechanism leading to activation of Wnt signaling in these neoplasms (Koch et al. 2004).

The *APC protein* holds a strategical position in the Wnt/beta-catenin signaling pathway, in that it forms a complex with Axin to promote the entrance of beta-catenin into a proteasomal degradation pathway. The regulatory protein, Amer1/WTX, binds to APC and acts as an inhibitor of Wnt signaling by inducing beta-catenin degradation, in that it stabilizes Axin and counteracts Wnt-induced degradation of Axin, which requires membrane localization of Amer1 (Tanneberger et al. 2011). An association between familial adenomatous polyposis coli (FAP) and hepatoblastoma is well established.

Selected References Kingston et al. 1982, 1983; Garber et al. 1988; Phillips et al. 1989; Bernstein et al. 1992; Hughes and Michels 1992; Kurahashi et al. 1995; Giardiello et al. 1996; Oda et al. 1996; Cetta et al. 1997, 2003; Thomas et al. 2003; Aretz et al. 2006; Sanders and Furman 2006; Lazzareschi et al. 2009; Evers et al., 2012; Krawczuk-Rybak et al. 2012; Gupta et al. 2013; review: Moore et al. 2012.

The association is thought to relate to APC alterations, a protein making part of the Wnt/beta-catenin signaling pathway. The adenomatous polyposis coli (APC) gene encodes a protein having multiple domains, through which APC can bind to various proteins, including components of the Wnt pathway (beta-catenin and Axin). The incidence of FAP in hepatoblastoma patients is about 100 times that in the general population, but the reported incidence of APC germline mutations in children with sporadic hepatoblastoma varies considerably. In FAP families, APC gene mutation (in the 5′ end of the gene) was identified in all seven FAP kindreds in which an at-risk member developed hepatoblastoma, with male predominance (Giardiello et al. 1996). In a series of 93 patients with hepatoblastoma, 8 (8.6 %) reported family histories suggestive of FAP (Hirschman et al. 2005). In sporadic hepatoblastomas occurring in non-FAP families, LOH at the APC and/or MCC loci was observed in 57 % informative cases, and two cases showed double mutations (Oda et al. 1996). De Chadarevian and coworkers (2002) reported a FAP family in which one boy developed hepatoblastoma and his brother multiple adenomas and a well-differentiated hepatocellular carcinoma, but no APC gene mutation was found in this family. Rather, FAP occurred as a result of chromosomal rearrangement (inversion 5q21 to 5q31.3 9), involving the APC gene locus inherited from their father and grandfather. Hepatoblastoma has been observed in siblings sharing a gene mutation for FAP inherited from their father (Thomas et al. 2003). In one hepatoblastoma with a germline APC mutation studied among 13 sporadic infantile hepatic tumors, southern blot analysis at the APC locus revealed that the neoplasm had lost the opposite allele and was isodisomic at this locus, and RNA analysis indicated that the tumor contained only the small APC transcript, from which exon 4 was entirely absent (Kurahashi et al. 1995). In a multidisciplinary clinical study on 20 pediatric patients younger than age 10 years with FAP, none had developed hepatoblastoma during the observation period (Attard et al. 2008). Based on blood samples from 29 children (18 boys) with sporadic hepatoblastoma, no APC mutations were found (Harvey et al. 2008). No APC mutations were detected in a series of 21 paraffin-embedded hepatoblastoma cases (Curia et al. 2008). No hepatoblastoma was detected among 242 members from 57 unrelated FAP families having Singapore familial adenomatous polyposis, suggesting that Singapore FAP patients have some features distinct from Caucasian FAP (Cao et al. 2006). The findings accumulated so far raised the question whether children at risk for FAP should be screened for hepatoblastoma and children with hepatoblastoma for APC gene mutations. Among 1,166 German FAP families, seven unrelated cases of hepatoblastoma were identified, and in patients with apparently sporadic hepatoblastoma, germline mutations in the APC gene were identified in 10 % (Aretz et al. 2006). The relationship between APC protein alterations

and a second key component of the Wnt signaling pathway is complex. It has, e.g., been shown that hepatoblastoma from a FAP patient has nuclear beta-catenin accumulation in the absence of an APC gene mutation (Inukai et al. 2004). Hepatoblastoma has also been observed in the setting of Gardner syndrome (Krush et al. 1988). The human *Dickkopf-1* gene encodes a secreted protein acting as a potential inhibitor of the Wnt signaling pathway. Eighty one percent of hepatoblastomas revealed expression of Dickkopf-1, but none of normal pediatric or fetal liver tissues. It was suggested that overexpression of Dickkopf-1 in hepatoblastomas might be related to uncontrolled Wnt signaling and a negative feedback mechanism (Wirths et al. 2003).

Other Factors Potentially Involved in Growth and Progression of HB

Hepatocyte growth factor (HGF) was expressed in fibroblastoid mesenchymal cells of the tumor, while the receptor c-met was expressed by epithelial tumor cells (Von Schweinitz et al. 1998), suggesting a paracrine growth mechanism. Transcription factors and transcription co-activator CBP/P-300-interacting transactivator 1 (CITED1), a transcriptional coactivator, are expressed in embryonal and regenerating hepatocytes, but are undetectable in normal adult liver. In one study, CITED1 was abnormally expressed in 87.8 % of hepatoblastoma specimens, with a predominant expression in mixed embryonal/fetal tumors and less so in fetal tumors (Murphy et al. 2012). Transcription factor GATA-4, which is expressed in early fetal liver and is essential for hepatic organogenesis, is abundantly expressed in hepatoblastomas, but not in adult-type HCC (Soini et al. 2012). The homeobox transcription factor, Prox1, is required for normal hepatic ontogenesis and morphogenesis. Prox1 is expressed in early embryonic hepatoblasts and is still expressed in adult hepatocytes, but is absent from cholangiocytes (Dudas et al. 2004). It is expected that abnormal expression of Prox1 plays a role in hepatoblastoma biology.

Cyclin D1 is encoded by the CCND1 gene and is a major regulator of the cell cycle transition from G1 to S. Hepatoblastomas may show a CCND1 polymorphism (G to A) at codon 242, the boundary of exon 4 and intron 4, affecting the splicing such that exon 5 is not expressed in the A allele. This polymorphism is correlated with the age of onset of hepatoblastoma, in that the A/A genotype is associated with an earlier age of onset compared with the G/A or G/G genotype (Pakakasama et al. 2004). The p57(KIP2) gene is located to 11p15.5, is predominantly expressed from the maternal allele, and encodes a cyclin-dependent kinase inhibitor. LOH at the KIP2 locus occurred in 25 % of hepatoblastomas, but no gene mutations were found. KIP2 was upregulated in the majority of cases, associated with upregulation of IGF2 mRNA expression. All hepatoblastomas showed monoallelic KIP2 expression. Overexpression of KIP2 in hepatoblastomas with maternal loss of 11p15.5 suggests a reactivation of the paternal allele in these cases (Hartmann et al. 2000). The p16INK4A protein is involved in the regulation of the cell cycle. 66.6 % of methylation-positive hepatoblastomas showed a complete lack of p16 immunoreactivity. It has therefore been suggested that hypermethylation of p16 is a major mechanism of the transcriptional repression of p16 in hepatoblastomas (Shim et al. 2003). In hepatoblastomas, the genes CDKN2A (encoding p16) and CDKN2B 8 encoding p15) are not transcribed, while CDKN2C (encoding p18) was clearly detectable in hepatoblastoma tissue (Iolascon et al. 1998). The transcription factor, FOXG1, is implicated in the repression of TGF-beta-induced expression of p21cip1 and is overexpressed in hepatoblastoma (Adesina et al. 2007). In many aggressive neoplasms, Ki27/Kip1 shows a reduced expression. In hepatoblastomas it was shown that well-differentiated fetal-type tumors without mitotic activity were strongly p27 positive; embryonal-type tumor revealed a variable p27 expression pattern (low activity in highly proliferative areas), and SCD hepatoblastoma was negative (Brotto and Finegold 2002). The PI3K/AKT pathway is activated as a downstream signaling

pathway of multiple tyrosine kinases. An increased signaling activity of this pathway and activating mutations of PIK3CA, encoding a PIK3 catalytic subunit, have been detected in several childhood cancers. It has been shown that PIK3 signaling plays an essential role in growth control of hepatoblastomas (Hartmann et al. 2009). Overexpression of autophagy-associated genes, BECN1 and ATG5, in hepatoblastoma cells is associated with an increase of PIEK signaling, essential for cell survival (Chang et al. 2011).

The hedgehog signaling pathway, which plays a central role in stem cell biology, embryogenesis, and maintenance of tissue homeostasis, is altered in hepatoblastomas. Three hedgehog members, i.e., sonic hedgehog, Indian hedgehog, and desert hedgehog, bind to Patch1 or Patch2 receptors to release the smoothened signal transducer from patched-dependent suppression. Smoothened then activated STK36 serine/threonine kinase to stabilize glioma-associated oncogene homolog 1 (GLI1) members and to phosphorylate SUFI for nuclear accumulation of GLI1 (review: Katoh and Katoh 2006). Expression of hedgehog components showed an increase in hepatoblastoma compared with normal liver tissue (Li et al. 2010). In part of hepatoblastomas, the hedgehog target genes GLI1 and Patched 1 (PTCH1) are overexpressed, and the gene encoding the hedgehog interacting protein (HHIP) is transcriptionally silenced by CpG island promoter hypermethylation. Block of the hedgehog pathway inhibited hepatoblastoma growth (Eichenmüller et al. 2009). Immunochemistry revealed a strong nuclear expression of the downstream effector of the Hippo kinase pathway, Yes-associated protein (Yap). Yap overexpression was associated with marked induction of the three Yap target genes, glypican 3, CTGF, and survivin (Li et al. 2012b). The oncogene PLK1 was found to be expressed at very high levels in part of HB in comparison with normal liver, and this high expression was associated with a poorer outcome (Yamada et al. 2004). Well-differentiated hepatoblastoma cells showing low proliferative activity markedly express transforming growth factor-alpha (TGF-alpha), while proliferating embryonal cells reexhibit a low-level expression of TGF-alpha (Kiss et al. 1998). Expression of TGF-alpha has also been observed in hepatocellular carcinoma (Hsia et al. 1992; Schaff et al. 1998).

Deregulation of Apoptosis in Hepatoblastomas

In hepatoblastomas, the death receptor Fas and its ligand are coexpressed, and the tumors express the Fas-resistance pathway component FAP-1, whereas Bcl-2 is not detectable (Lee et al. 1999). As hepatoblastomas may overexpress p53 protein (mostly in the absence of p53 gene mutations), this feature may play a role in apoptosis of this tumor. Hepatoblastoma cells that primarily express p53 in the cytoplasm translocate p53 to the nucleus under oxidative stress, independent of the effects of the cytoplasmic p53 retention protein, Parc. This nuclear p53 translocation is associated with increased apoptosis (Yamamoto et al. 2007). Nuclear expression of p53 is essential for several functions of this protein. Parc protein, a Parkin-like ubiquitin ligase, is a cytoplasmic anchor protein that directly interacts with p53 in the cytoplasm to form a complex. In the absence of stress, inactivation of Parc induces nuclear translocation of endogenous p53 and activation of p53-dependent apoptosis (Nikolaev et al. 2003). p53 is a tumor suppressor protein that exerts antiproliferative and apoptotic effects in response to various forms of stress, such as oxidative stress, DNA damage, and abnormal proliferative signals. P53 is tightly regulated through posttranslational modifications. Endogenous p53 protein in the cytoplasm is bound to the anchor protein Parc, a Parkin-like ubiquitin ligase (Nikolaev et al. 2003). Abnormalities in the expression of the p53 oncogene in hepatoblastomas are found in the literature with markedly variable results. In four reports using immunohistochemistry (antibodies BP53-12, AB-6, and CM1), nuclear p53 protein reactivity was found in 14 % (Choi et al. 1993), 33 % (Ruck et al. 1994), 67 % (Kennedy et al. 1994), and 45 % (Zhang et al. 1998) of hepatoblastomas. Among

ten cases of hepatoblastoma, one case revealed overexpression of p53 protein, but direct DNA sequencing failed to show a p53 gene mutation (Chen et al. 1995). Direct sequencing revealed no p53 gene mutation among seven hepatoblastomas (Debuire et al. 1993). In a PCR study on 38 hepatoblastomas, TP53 mutations were found in an anaplastic hepatoblastoma cell line, but no aberration in the TP53 gene (exons 5–9) was found in tumor samples (Ohnishi et al. 1996). In the study of Kennedy and coworkers (1994; 67 % immunohistochemical reactivity), no p53 gene mutation was observed. By use of PCR-single-strand conformation polymorphism (PCR-SSCP), no p53 gene mutation was found in 11 hepatoblastomas (Kusafuka et al. 1997). In contrast, a p53 gene mutation (codon 249) was detected in one patient without exposure to aflatoxin B1 (Kar et al. 1993), and mutations were found by direct sequencing (exons 5–8) in 9 out of 10 hepatoblastomas (Oda et al. 1995), and were detected in 24 % of sporadic hepatoblastomas in a more recent investigation (Curia et al. 2008).

Factors Affecting Invasion, Spread, Metastasis, and Angiogenesis

Hepatoblastomas express adhesion molecules affecting interactions between tumor cells and extracellular matrix. Embryonal and SCUD-HB cells expressed CALLA and the hyaluronate receptor, CD44 (HCAM), while both fetal and embryonal areas stained irregularly positive for ICAM-1, the latter not being detectable in SCUD cells (von Schweinitz et al. 1996). Inhibitors of chymotrypsin-like seine proteases are known as serpins (**ser**ine **p**rotease **in**hibitors). Well-known examples in human pathobiology are antithrombin and the antitrypsins. Serpins undergo complex gene mutations giving rise to the serpinopathies, characterized by the formation of ordered polymers that are often retained within the rough endoplasmic reticulum of the cell of synthesis, a prominent example being the Z variant of alpha-1-antitrypsin deficiency (Irvin et al. 2011). In a study of 42 children with hepatoblastoma, SERPINB3 was positive at the transcriptional level in 79 % of cases. Immunohistochemically, SERPINB3 was mainly found in the embryonic, blastemal, small cell undifferentiated components of hepatoblastomas, but it was not detectable in normal hepatocytes. There was a significant correlation between SERINB3 expression and upregulation of Myc and PRETEXT tumor extension (Turato et al. 2012). Expression of VEGF in all malignant pediatric liver tumors was higher than that in adult HCC, but VEGF expression was higher in pediatric HCC than in hepatoblastomas (Sun et al. 2005).

Genomic and Epigenetic Features

Hepatocellular carcinomas (HCC) and hepatoblastomas have different patterns of gene expression. For example, insulin-like growth factor-II (IGF2), fibronectin, DLK1, TGF-beta1, MALAT1, and MIG6 are overexpressed in hepatoblastoma versus HCC (Luo et al. 2006). IGF2 and H19 are affected by copy-neutral loss of heterozygosity (uniparental disomy, UPD) at chromosome 11p15, an alteration found in part of hepatoblastomas (Suzuki et al. 2008). By use of gene expression profiling, gene signatures have been identified that reveal deregulated growth features and molecular heterogeneity of hepatoblastomas, in part in a histologic subtype-specific manner (Luo et al. 2006; Adesina et al. 2009; Shin et al. 2011; review: Chen et al. 2009). In recent study analyzing several molecular pathways as a function of hepatoblastoma morphology and subtypes, HES1 expression and HES1/AXIN2 used to measure Notch versus Wnt activation ratio were particularly elevated in pure fetal cases and were lowest in small cell undifferentiated (SCUD) hepatoblastoma. Hepatocyte nuclear factor 4alpha was elevated only in embryonal components, while the bipotential oval cell marker DLK1, AXIN2, and EGFR were elevated in all subtypes, suggesting a distinct pattern of molecular microheterogeneity (Lopez-Terrada et al. 2009). A high expression of telomerase is an independent prognostic factor in hepatoblastoma. The prognosis of the patients with high hTERT

mRNA expression was significantly worse than that of others (Hiyama et al. 2004). This effect was, in particular, observed in patients with tumors lacking beta-catenin mutations (Ueda et al. 2011).

In hepatoblastomas, upregulation of miR-214, miR-199a, miR-150, and miR-125a and a downregulation of miR-148a were found (Magrelli et al. 2009). By use of methylation-specific PCR, testing of the methylation profile of hepatoblastomas revealed a high tumor-specific DNA hypermethylation in the promoter region of five genes, i.e., APC, CDH1, MT1G, RASSF1A, and SOCS1, whereby MT1G hypermethylation may be useful as a prognostic indicator for hepatoblastoma (Sakamoto et al. 2010). Aberrant promoter methylation and silencing of the RASSF1A gene have been found in a previous study (Harada et al. 2002). The JAK-binding and JAK-inhibiting protein, SOCS1 (JAB1, SSI-1), is reduced in about half of hepatoblastomas, this silencing being accomplished via hypermethylation (Nagai et al. 2003). Aberrant methylation of the 5′CpG islands of the p16 gene was detected in 50 % of hepatoblastoma cases and found to be a major mechanism of the transcriptional repression of p16 in these tumors (Shim et al. 2003).

Nested Stromal-Epithelial Tumor of the Liver

23

Contents

Abstract

Nested stromal-epithelial tumor (NSET) is a rare and complex liver tumor characterized by multiple clustered nests of primitive-looking epithelial cells embedded in a spindle cell stroma, surrounded by a sheath of myofibroblastic cells, and associated with calcifications and ossification. The tumor occurs both in the pediatric age group and in adults and is not associated with preexisting liver disease. NSET may be associated with Cushing syndrome with production of ACTH due to ectopic synthesis of corticotropin-releasing hormone. NSET usually presents as a solitary liver neoplasm ranging in diameter from a few cm to 30 cm. A feature important for the elucidation of pathogenesis of NSET is the presence of nuclear beta-catenin expression in epithelial cells of the nests. This phenomenon is associated with mutations of the beta-catenin gene (exon 3) and expression of factors inducing epithelial-mesenchymal transition.

Introduction

Nested stromal-epithelial tumor (NSET; synonyms: ossifying stromal-epithelial tumor; ossifying malignant mixed epithelial and stromal tumor; desmoplastic nested spindle cell tumor of the liver; calcifying nested stromal-epithelial tumor/CNSET) is a rare non-hepatocytic, non-biliary tumor of the liver characterized by multiple,

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_23

clustered nests of primitive-looking epithelial cells embedded in a spindle cell stroma, surrounded by a sheath of myofibroblastic cells, and associated with calcifications and ossification. As at least part of the cells situated within the nests have features of immature hepatocytes, this neoplasm is treated in the setting of hepatocellular tumors.

Definition and Classification of the Entity

NSET was originally described as "ossifying stromal-epithelial tumor" of the liver in the 2001 third series AFIP fascicle (Ishak et al. 2001). A case published 1 year later under the term, "ossifying malignant mixed epithelial and stromal tumor of the liver" is on one of the three patients reported in 2001 (Heywood et al. 2002). However, the description of the tumor reported by these authors in several respects differs from what we nowadays understand to be NSET. The tumor was detected in a 28-year-old female patient without previous liver disease, except the presence of focal hepatic calcifications at age 4 which were noted on plain abdominal X-ray images acquired for unknown reasons. The calcification was attributed to a calcified hepatic hemangioma. The resected liver specimen contained a lobulated tumor with a maximum diameter of 14.5 cm. The histology part of the publication describes a malignant neoplasm consisting of a mixture of cytologically atypical spindle cells as a component of a myxoid stroma and epithelial areas with duct formation and mucin production, interpreted as infiltrating, desmoplastic adenocarcinoma. Extensive osteoid formation and scattered calcifications were present. There were numerous satellite lesions and portal and hepatic vein invasion. This description would not fit with NSET. However, the figures reproduced in the publication may be compatible with NSET. It remains unsettled whether this tumor is NSET or rather belongs into the category of so-called desmoplastic nested spindle cell tumor of the adult liver, treated in the following chapter.

In 2003, Hill et al. published a bona fide case of NSET with a histology similar to that described by Ishak and coworkers in 2000 (Hill et al. 2003). These authors observed tumors which they termed, "desmoplastic nested spindle cell tumor of the liver," in four previously healthy children. Since then, less than 30 more cases have been documented in the literature (Heerema-McKenney et al. 2005; Brodsky et al. 2008; Makhlouf et al. 2009; Meir et al. 2009; Rod et al. 2009; Grazi et al. 2010; Oviedo Ramirez et al. 2010; Hommann et al. 2011; More et al. 2011, Wang et al. 2011; Zimmermann and Lopez-Terrada 2011; Assmann et al. 2012; Geramidzadeh et al. 2012; Ghodke et al. 2012).

Epidemiology

Among the patients with NSET reported so far, age at presentation ranged from 2 years to more than 30 years, with a predominance of the female gender. NSET has rarely been observed in adult patients (Makhlouf et al. 2009; Grazi et al. 2010; Wang et al. 2011). NSET is not associated with preexisting liver disease. However, the neoplasm was observed in a patient having Beckwith-Wiedemann syndrome (Malowany et al. 2013).

Clinical Features

In the series of six patients reported by Heerema-McKenney et al. (2005), the patients were between 2 and 14 years of age at diagnosis, and all tumors presented as a solitary liver mass ranging from 4.0 to 30.0 cm in greatest diameter. In a subsequent series of nine patients, age at diagnosis ranged from 2 to 33 years, and four patients had a history of calcified liver nodules since childhood. The tumor size ranged from 5.5 to 20 cm (Makhlouf et al. 2009).

NSET may be associated with Cushing syndrome. Among six patients with NSET reported in 2005, two patients showed ectopic ACTH (adrenocorticotropic hormone) production associated with Cushing syndrome that abated after excision of the tumors. An association between NSET and

Cushing syndrome due to ectopic ACTH synthesis by the tumor was subsequently confirmed in other reports (Makhlouf et al. 2009; Rod et al. 2009; More et al. 2011; Geramidzadeh et al. 2012). Rod and coworkers (2009) described a 17-year-old female patient who had a large NSET with mild Cushingoid clinical features and intense biological hypercortisolism but moderate ACTH secretion. The epithelial component of the tumor co-expressed ACTH mildly, corticotropin-releasing hormone (CRH) strongly, and 11-beta-hydroxysteroid dehydrogenase at a level comparable with normal hepatocytes. The findings suggest that ectopic ACTH syndrome in these neoplasms may be caused by CRH production inducing ACTH synthesis. More et al. (2011) identified ectopic ACTH syndrome in one NSET patient among ten patients with this syndrome, seven other patients having well-differentiated neuroendocrine tumors (mostly bronchial carcinoid), one a poorly differentiated thymic carcinoma, and one an Ewing's sarcoma.

Pathology

Macroscopy

At gross examination, the tumors are medium-sized to sometimes large and circumscribed, lobular white to gray-white masses. The growth pattern is usually expanding, with signs of some perifocal atrophy of the liver substance. On cut surfaces, a granular aspect on a fibrous-looking background may be noted, owing to the presence of larger epithelioid nests. In the case of marked calcification and/or ossification, white speckles may be noted on the cut surface.

Histopathology

A characteristic feature of NSET is the presence of numerous small nests composed of epithelioid cells and spindle cells. At low magnification, these nests form discrete and well-demarcated foci scattered within a hypocellular and sometimes myxoid stroma, which itself exhibits a somewhat fuzzy border with respect to adjacent liver, but without clear-cut signs of invasive growth. These cellular nests are most often oval, but they may also show a more irregular shape, but even in these situations, maintaining smooth and rounded edges. The nests range in size from 0.1 to almost 1 cm. The largest nests were identified in tumors from adolescent females (Heerema-McKenney et al. 2005). The nests typically show a gradient of centrally placed epithelioid cells and more peripherally placed spindle cells. The epithelioid cells occur in the major variants, viz., eosinophilic cells (sometimes with hepatoid features), clear cells, and cells with a pale, ill-defined cytoplasm. The nuclei of the epithelioid cells are round to ovoid, with a finely stippled chromatin and small nucleoli. The transition to spindle cells is sometimes abrupt. Spindle cells are arranged in streams or parallelly oriented fascicles with a pale to slightly eosinophilic cytoplasm and larger oval nuclei with stippled chromatin, different from that of surrounding myofibroblasts. In few cases, psammoma bodies and/or osteoid foci are noted within the epithelioid nests (Figs. 1, 2, 3, 4, and 5).

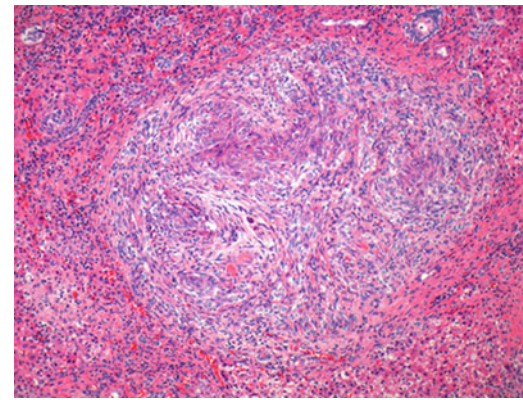

Fig. 1 NSET. A hypercellular tumor nodule consists of spindle cells arranged in haphazard manner (hematoxylin and eosin stain)

Large epithelioid nests may undergo cystic change, the cysts being lined by degenerating epithelioid cells. Such cysts may contain a lightly eosinophilic fluid (Heerema-McKenney et al. 2005). Mitotic activity in the nests is low (Hill et al. 2003). In the study of Heerema-McKenney et al. (2005), the majority of

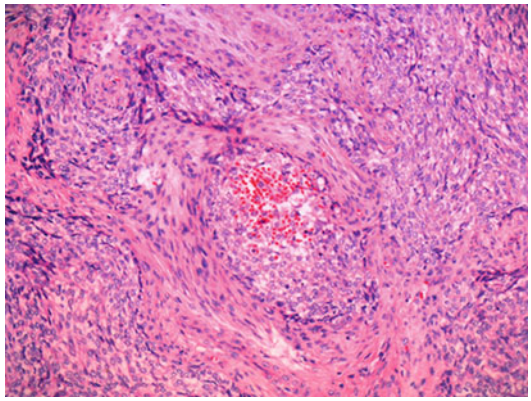

Fig. 2 NSET. The nodules show epithelial and spindle cells in interior parts and are surrounded by a sheath of eosinophilic, elongated spindle cells (hematoxylin and eosin stain)

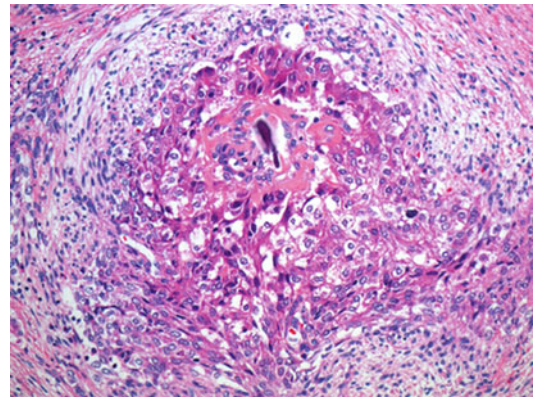

Fig. 4 NSET with osteoid formation in the center of a nodule (homogeneous eosinophilic structures). Note that a part of centrally located tumor cells have a hepatoid appearance (hematoxylin and eosin)

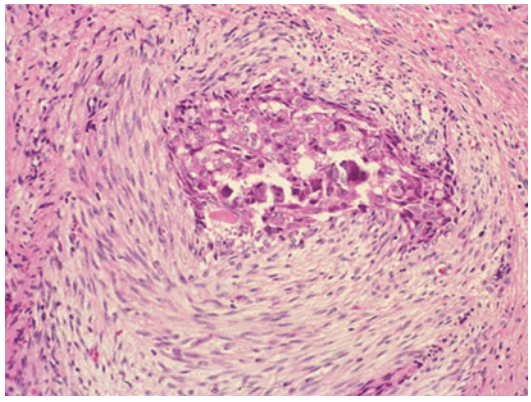

Fig. 3 NSET. The core of tumor nodules can contain calcifications (hematoxylin and eosin stain)

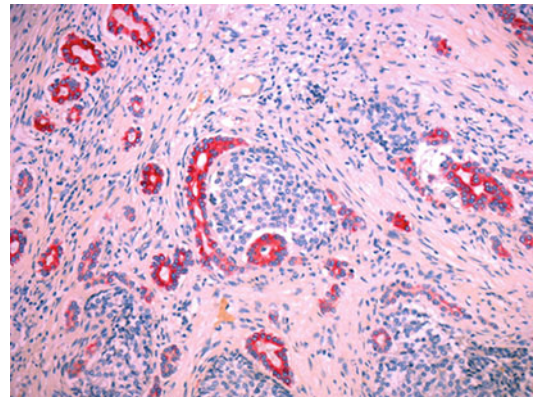

Fig. 5 NSET. The tumor nodules are associated with ductule-like cholangiocytic structures (cytokeratin 19 immunostain)

epithelioid nests had one or fewer mitotic figures per HPF, but there are cases having five or more mitotic figures per HPF. In some cases, confluence of nests was noted, with proliferative lesions entrapping stromal components and containing extensive necrosis with a foam cell reaction and some multinucleated giant cells (Heerema-McKenney et al. 2005). Tumors associated with ectopic ACTH syndrome were found to show a neuroendocrine-appearing trabecular architecture at the periphery of the tumors. In such areas, the surrounding stroma was attenuated (Heerema-McKenney et al. 2005). The nests are surrounded by a spindle cell sheath or collar of variable thickness, which is clearly demarcated from the stromal background of the tumor (Zimmermann and Lopez-Terrada 2011). The cells are morphologically typical myofibroblasts, with an amphophilic cytoplasm and elongated, tapered nuclei. The nuclei show a bland chromatin and tiny nucleoli. These cells are strongly reactive to alpha-SMA and are myofibroblasts. The myofibroblastic sheath can cause invaginations of the nests. Close to the nests and also outside the myofibroblastic sheath, one notes calcifications, sometimes of the psammomatous type, and osteoid with typical osteoblasts. In some nests, atrophy of the epithelioid and spindle cells seem to have occurred and only the calcifications

and the osteoid signal the former lesion. In some tumor, the osteoid tissue is maturing to lamellar bone and forms sickle-shaped structures surrounding the nests.

Ultrastructure

So far, only few information regarding the ultrastructure of NSET are available. In one case report, the nested tumor cells showed focally well-developed cell junctions, a basal lamina, and only few cytoplasmic organelles (Hill et al. 2003).

Immunohistochemistry

The cellular nests are variably immunoreactive for epithelial membrane antigen/EMA, pan-cytokeratin (AE1/AE3/LP34), S-100 protein, CD56, and CD57. Similar to spindle cells, epithelioid cells may be positive for WT-1 (amino terminus) (Hill et al. 2003; Heerema-McKenney et al. 2005; Makhlouf et al. 2009; Zimmermann and Lopez-Terrada 2011). Cell of the nests displays marked nuclear reactivity for beta-catenin, while other cells located in the tumor nodules are either negative or show membranous staining (Zimmermann 2005; Zimmermann and Lopez-Terrada 2011). The spindle cells of the cellular sheath surrounding the nests are markedly positive for alpha-SMA, representing myofibroblasts (Zimmermann and Lopez-Terrada 2011). The cells are negative for the hepatocyte marker, Hep Par 1 (Zimmermann and Lopez-Terrada 2011), negative for cytokeratins 7 and 20 (Makhlouf et al. 2009), and negative for AFP, polyclonal CEA, chromogranin A, synaptophysin, desmin, and inhibin (Heerema-McKenney et al. 2005). In cases with Cushing syndrome, the cells of the nests were immunoreactive for ACTH (Heerema-McKenney et al. 2005). The nuclei of spindle cells in the nests are strongly and diffusely positive for WT-1 (amino terminus). These cells are also reactive for vimentin, CD56, and neuron-specific enolase and focally for cytokeratin. The cells of the myofibroblastic collar are markedly positive for alpha-SMA and vimentin and focally positive for CD34 (Figs. 6, 7, 8, and 9).

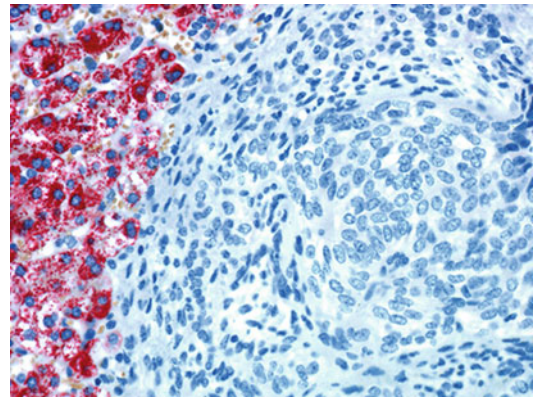

Fig. 7 NSET. In contrast to normal hepatocytes (to the *left*), nodule cells are not reactive for a hepatocyte marker (Hep Par 1 immunostain)

Differential Diagnosis

Hepatic tumors characterized by a mixture of spindled cells and epithelial/epithelioid cells as seen in NSET comprise other mixed tumors chiefly occurring in adults: synovial sarcoma of the liver, desmoplastic small round cell tumor (DSRCT), and epithelioid Schwann cell tumors. The histology of NSET, specifically its organoid structure, the distinctive nested arrangement of

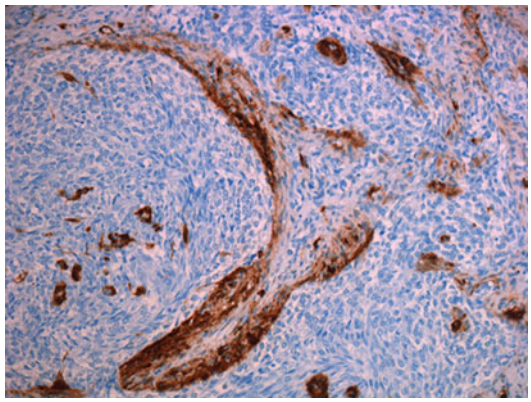

Fig. 8 NSET. The sheath of spindle cells surrounding the inner core of nodules is smooth muscle actin-positive and consists of myoid cells (alpha-SMA immunostain)

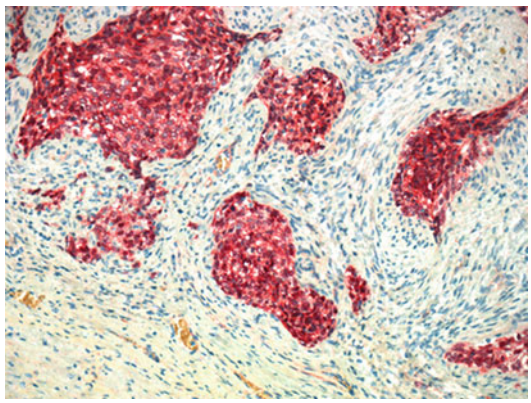

Fig. 9 NSET. Inner cells of tumor nodules are strongly reactive for beta-catenin, with both cytoplasmic and nuclear staining (beta-catenin immunostain)

the epithelioid cells, the myofibroblast sheath, and the osteoid formation together with psammomatous calcifications, is characteristic and will not be easily confounded with other bimorphic tumors.

Biology of Disease

NSETs often present as circumscribed tumors without evidence of local invasive growth or metastases at diagnosis. In an early study of four children with NSET, all patients were doing well after resection without recurrence after a follow-up ranging from 8 months to 7.5 years (Hill et al. 2003). However, a part of the NSET reveal a more aggressive course, with multifocal recurrence in the liver and extrahepatic metastasis (Heerema-McKinney et al. 2005; Brodsky et al. 2008; Makhlouf et al. 2009). Brodsky and coworkers reported a 17.5-year-old female with NSET causing Cushingoid features. After resection of the initial lesion, the tumor recurred in the form of multiple hepatic tumors 1 year later (Brodsky et al. 2008). In the series of nine patients reported by Makhlouf et al. (2009), two patients exhibited local recurrences successfully treated by radiofrequency ablation. In a 16-year-old girl with NSET, which was free of detectable metastases at diagnosis, liver transplantation was performed. At 28 months postoperatively, lung metastases were found and the patient died 37 months after transplantation from progressive pulmonary metastatic disease (Hommann et al 2011). So far, the biology of NSETs is best considered a low-grade malignancy (Makhlouf et al. 2009).

Pathogenesis

An interesting feature in the context of putative pathogenic pathways is the consistent finding of a marked nuclear immunoreactivity of nested cells for beta-catenin (Zimmermann 2005), a feature shared between NSET and many hepatoblastomas. It was later found that NSET can show mutations of the beta-catenin gene, characterized by large deletions in exon 3, resulting in an accumulation of beta-catenin in cytoplasm and nuclei of tumor cells (Assmann et al. 2012). In this investigation, the expression of the mesenchymal-epithelial transition factors Snail, Slug, Twist, c-met, vimentin, and beta-catenin was generally increased, whereas E-cadherin was decreased. It was suggested that NSET might be a variant of hepatoblastoma and showing impaired mesenchymal-epithelial transition (Assmann et al. 2012).

Abstract

Hepatocellular adenoma (HCA) is defined as benign liver neoplasm composed of hepatocytes. HCA is a rare hepatic neoplasm, accounting for 0.6 % of all liver tumors. In occidental countries, it chiefly occurs in young females, with an estimated incidence of 3–4 cases per 100,000. The female preponderance is considered to be related to ingestion of sex steroids/oral contraceptives. The standard histology of HCA is characterized by mature-looking hepatocytes that form slender plates. The reticulin pattern is normal. The cells are rich in glycogen and may undergo steatosis. HCA can contain peliosis-like blood-filled spaces and has a tendency for hemorrhage. HCAs are circumscribed but lack a capsule. There are distinct variant patterns associated with molecular abnormalities. Modern classifications of HCA are based on specific molecular features and distinguish hepatocyte nuclear factor 1alpha mutated, beta-catenin mutated, beta-catenin activated, inflammatory, and combined/mixed forms. HCA can undergo malignant transformation.

Introduction

According to the WHO classification of tumors, hepatocellular adenoma (HCA) is defined as a benign liver neoplasm composed of hepatocytes.

Liver cell adenoma has been described in the nineteenth century already (Jungmann 1861; Griesinger 1864; Rindfleisch 1864; Mahomed 1877; Simmonds 1884), and only relatively few reports are known from the first part of the twentieth century (Shaw 1923; Wilens 1938). The issues of HCA morphology, classification, and biology have been reviewed several times in recent years, together with the elucidation of a novel classification based on distinct molecular features.

Epidemiology

Hepatocellular Adenoma in Adults

HCA is a rather rare lesion, estimated to account for 0.6 % of all liver tumors (Edmondson 1958). In occidental countries, HCAs now chiefly occur in young females, with an estimated incidence of 3–4 cases per 100,000. In Asia, the incidence is lower. In a review of 50,000 autopsies at the Los Angeles County Hospital from 1918 to 1954, only two HCA were detected. However, oral contraceptives and other sex steroid administrations have increased the frequency of these tumors (see below). The male-to-female incidence ratio is 1:17 (Foster and Berman 1977; Theruvath et al. 2011), this impressive asymmetry most probably being caused by the effect of endo- or exogenous aromatic steroids on HCA tumorigenesis (see below). It is estimated that around 80 % of HCAs occur in users of oral contraceptives, but in the course of low-estrogen preparation use, the incidence in women may decrease. In recent decades, there was a trend toward an increase in HCAs reported in men in several countries (Ronald et al. 2004; Chang et al. 2013). Also in Japan, the former strong preponderance of women was not found (Sasaki and Nakanuma 2012).

Pediatric Hepatocellular Adenoma

HCA can occur in neonates, children, and adolescents (Chandra et al. 1984). Also multiple HCAs (adenomatosis) can occur in the pediatric age group. The neoplasms often develop as sporadic lesions, but can also emerge in association with administration of steroids or diverse inborn conditions, including familial adenomatous polyposis, glycogenosis, disorders of cortisol metabolism, and microvillus inclusion disease.

Classification

Modern classifications of HCA are chiefly based on molecular approaches that have shown that HCA is a heterogeneous entity. The current classification of HCAs lists several categories, i.e., hepatocyte nuclear factor 1alpha-mutated HCA (H-HCA; 35 % of cases), beta-catenin-mutated HCA (b-HCA; 10 % or less), inflammatory HCA (IHCA; 55 %), beta-catenin-activated inflammatory HCA (b-IHCA; 10 % of IHCA), mixed/combined, and unclassifiable HCA (Table 1). An additional complex spectrum of lesions is telangiectatic HCA, most of these cases having previously been classified as telangiectatic focal nodular hyperplasia. These lesions are now, at least in part, listed together with inflammatory adenomas.

Table 1 Current classification of hepatocellular adenoma (HCA)

Type of HCA	Molecular alterations
HNF-1alpha-mutated HCA (H-HCA)	HNF-1alpha (TCF1 gene); CYP1B1
Beta-catenin-mutated HCA (b-HCA)	Beta-catenin (CTNNB1 gene)
Inflammatory HCA (IHCA)	IL6ST (65 %), STAT3 (6 %), GNAS (5 %)
Beta-catenin-activated IHCA (b-IHCA)	Beta-catenin
Combined/mixed HCA	
Unclassifiable HCAs	

HNF1A-Inactivated HCA (H-HCA)

Roughly 40–50 % of HCAs show mutations of hepatocyte nuclear factor-1alpha/HNF-1alpha/HNF1A encoded by the TCF1 gene (H-HCA; Bluteau et al. 2002; Bacq et al. 2003; Zucman-Rossi et al. 2006; Laumonier et al. 2008a; Holter et al. 2011; Sakellariou et al. 2011; Iwen et al. 2013; review: Bioulac-Sage et al. 2007c). HNF1A is a transcription factor involved in hepatocyte differentiation and glucose homeostasis. HNF1A mutations are known to cause maturity-onset diabetes of the young (MODY) type 3. H-HCA shows biallelic inactivating mutations of HNF1A, whereby in 85 % both mutations are of somatic origin, while in 15 % one mutation is germline and the other somatic. Somatic and germline mutations of HNF-1alpha were also detected in familial liver adenomatosis (Bacq et al. 2003). Patients having germline HNF1A mutation are generally younger and often have a family history of liver adenomatosis. In particular, families with autosomal-dominant MODY type 3 diabetes caused by HNF1A mutations are prone to develop liver tumors, including HCA and HCC (Reznik et al. 2004; Willson et al. 2013). However, the spectrum of HNF1A somatic mutations in HCA differs from that in patients with MODY type 3 (Jeannot et al. 2010). In a subset of patients with H-HCA, heterozygous germline mutations of CYP1B1, causing reduced activity cytochrome p450, were identified (Jeannot et al. 2007). In rare cases, H-HCA may coexist with IHCA (Castain et al. 2014), and there are rare "mixed" genotype adenomas with both mutations of HNF-1alpha and beta-catenin (Fonseca et al. 2013). Pathogenetically, there is evidence that loss of HNF1A leads to aberrant expression of several genes with a potential significance for tumorigenesis, including growth factor receptors, cell cycle regulators, and factors affecting angiogenesis

(Pelletier et al. 2010). The pathologic phenotype of H-HCA is usually adenoma with marked steatosis, lack of inflammatory changes, and absence of atypia. Typically, H-HCA lacks immunoreactivity for liver fatty acid-binding protein (LFABP). Transformation to malignancy is less common than in b-HCA.

b-HCA

Less than 10 % of HCA show mutations in the beta-catenin gene (the CTNNB1 gene) including exon 3 deletions (Zucman-Rossi et al. 2006; Bioulac-Sage et al. 2007a; Chu and Moon 2013). These mutations are associated with marked expression of two beta-catenin target genes, glutamine synthetase and G-protein-coupled receptor 49/GPR49. b-HCA more often occurs in males, is less frequently steatotic, and more commonly exhibits acinar structures and nuclear atypia. In most Western cases, b-HCA is strongly associated with malignant transformation and may thus represent a borderline lesion. Immunohistochemically, b-HCA is characterized by nuclear reactivity for beta-catenin and strong and diffuse immunostaining for glutamine synthase.

IHCA

The majority of HCAs lack mutations in HNF1A or beta-catenin genes. This is heterogeneous group of adenomas that probably contains several entities and also includes lesions that have previously been termed telangiectatic HCA (see below). The principal member of the group is inflammatory HCA (IHCA), a neoplasm that was formerly classified, at least in part, as telangiectatic HCA and as the telangiectatic variant of focal nodular hyperplasia/FNH. IHCA is more common in women and can be associated with a systemic inflammatory syndrome, anemia, and amyloidosis and is more often encountered in patients with high alcohol consumption and obesity (Paradis et al. 2007; review: Bioulac-Sage et al. 2007a). In one series, 50 % of involved women had taken oral contraceptives (Fonseca et al. 2013). Typical IHCA are characterized by the presence of an inflammatory infiltrate, variable angiectases, and overexpression of acute inflammatory response genes (Bioulac-Sage et al. 2007a). In up to 65 % of IHCAs, recurrent somatic mutations in the interleukin-6/IL-6 signal transducer (IL6ST) locus, encoding the IL-6 effector gp130, are present. These mutants are associated with constitutive and IL-6-independent activation of the JAK1(Janus kinase1)/STAT signaling pathway (Rebouissou et al. 2009; Sommer et al. 2012; Poussin et al. 2013). In a minority of cases of IHCA, activating mutations involve STAT3 involved in the activation of the JAK/STAT pathway (Pilati et al. 2011) and GNAS/G protein alpha subunit (Nault et al. 2012), but in almost 25 % of cases, no genetic abnormality has been identified so far (review: Nault and Zucman-Rossi 2013). In an IHCA found in a patient with Castleman's disease, the tumor transformed into HCC and showed mutations for both gp130 and beta-catenin. High IL-6 secretion by the lymphoproliferative disorder may have played a role (Chun et al. 2012). In patients with multiple IHCA, part of the nodules can in addition show beta-catenin activation (b-IHCA), suggesting that beta-catenin mutations might be a late event in the tumorigenic pathway (review: Bioulac-Sage et al. 2013). The features of IHCA are outlined in more detail in a following paragraph.

Around 10 % of IHCA exhibit abnormal beta-catenin activation and are termed beta-catenin-activated IHCA (b-IHCA).

Coexistent IHCA and H-HCA

Recently, coexistence of inflammatory HCA and HNF1alpha-inactivated HCA was described. This coexistence was found in eight female and one male patients, with variable numbers of nodules and sizes of largest and smallest HCAs. This observation suggests coexistence of different genotypes with multiple adenomas potentially caused by a "benign tumorigenic field effect" (Castain et al. 2014).

Clinical Features of Hepatocellular Adenoma

The clinical, pathologic, and radiologic features of HCA have been described in detail (Kerlin et al. 1983). Pain and abdominal dullness are frequent symptoms (Cho et al. 2008). In the overview of Yoshidome and coworkers, analyzing 32 cases (Yoshidome et al. 1999), 63 % of the patients were female, abdominal pain was the leading symptom in 59 %, and 41 % had evidence of tumor hemorrhage. In a study on eight female patients with multiple HCA/adenomatosis (Ribeiro et al. 1998), abdominal pain was the presenting symptom in 87.5 %, higher than in patients with solitary HCA (42.1 %). Obesity and features of metabolic syndrome were frequently observed in patients with HCA (-Bunchornavakul et al. 2011).

HCA can cause paraneoplastic syndromes, including prurigo (Loze et al. 2000) and erythrocytosis (Marie-Cardine et al. 2001; Vik et al. 2009).

Major complications of HCA consist of infarction, intratumoral hemorrhage, and spontaneous rupture, resulting in hemoperitoneum (Leborgne et al. 1990; Chiappa et al. 1999; Adusumilli et al. 2002; Kumar et al. 2004; Deneve et al. 2009; Santambrogio et al. 2009; van Aalten et al. 2012; Bieze et al. 2014). In part of the cases, spontaneous rupture occurred after prolonged use of oral contraceptives (Pollak 1979; Meissner 1998; Chiappa et al. 1999) or of methyltestosterone (Bird et al. 1979). HCAs are also prone to rupture subsequent to sometimes minor blunt abdominal trauma (Suarez-Penaranda et al. 2001). HCAs can undergo hemorrhage without rupture (Boulafendis et al. 1985; Fink et al. 1985; Mueller et al. 1995; Croes et al. 1998; Bagia et al. 2000; Closset et al. 2000; Heeringa and Sardi 2001; Gunsar et al. 2002; Minami et al. 2002; Cotta-Pereira et al. 2013). Tumor bleeding was present in 62.5 % in adenomatosis (mostly in lesions larger than 4 cm) and in 26.3 % of the patients with solitary HCA. In another study, intralesional hemorrhage was found in 75 % of cases (Ji et al. 2000). In one study, risk factors for bleeding of HCA included a diameter of 35 mm or more, visualization of lesional arteries, location in the left lateral liver, and exophytic growth (Bieze et al. 2014). Infarctions and hemorrhages are relatively frequent events in HCA (Grazioli et al. 2001). Therefore, HCA may clinically present as acute surgical emergencies, and therefore resection of HCA larger than 5 cm diameter has been advocated to reduce the risk of such complications (Terkivatan et al. 2001). There is evidence that intralesional hemorrhage is associated with the onset of menstruation in women taking oral contraceptives (Edmondson et al. 1976).

The pertinent imaging features of HCA have been documented in numerous reports.

General Pathology of Hepatocellular Adenoma

Macroscopy

HCAs, which can be solitary or multiple lesions, are classically soft and spheroid or globular, well-demarcated tumors sometimes deforming the involved part of the liver. Many HCAs have, at the time point of diagnosis, a diameter of 10–15 cm and a mass of about 500 g, but much smaller lesions with diameter of few mm also occur (microadenomas), mainly in case of multiple lesions and adenomatosis (see below). In adenomatosis, hundreds of small to tiny lesions may be found. Solitary HCA can grow to impressive size, with diameters of up to 30 cm and a

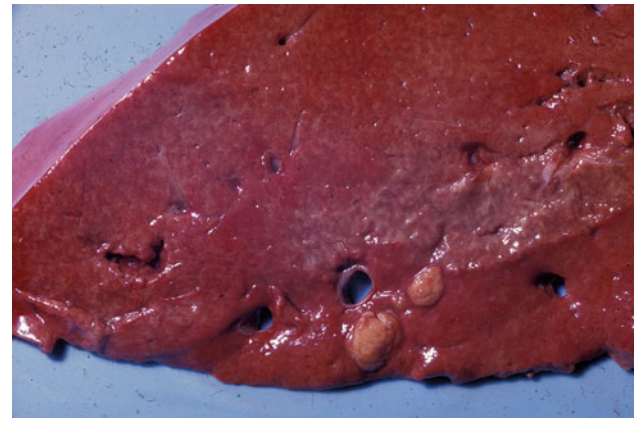

Fig. 1 Two small hepatocellular adenomas in a non-cirrhotic liver. In non-fixed specimens, the lesions appear as well-delineated *pale* to *yellow* and sometimes *tan* nodules

Fig. 2 In fixed resection specimens, hepatocellular adenomas present as *yellowish*, lobulated, and non-encapsulated tumor masses with an expanding growth pattern

weight of several kilograms ("giant liver cell adenoma"; Mueller et al. 1995; Nicastro et al. 1998). Giant HCA are associated with a particularly high incidence of rupture with intratumoral hemorrhage and may induce severe abdominal pain (Mueller et al. 1995; Reijnierse et al. 1997). HCA, in particular large tumors, can grow as exophytic or pedunculated masses (so-called hanging lesions; Ziegler and Glass 1966; Rafii 1971; Fléjou et al. 1985), and this phenomenon has also been detected in adenomatosis of the liver (Bader et al. 2001). HCA with beta-catenin activation may be larger than tumors of the other HCA types (Sasaki et al. 2011). On the cut surface, unchanged tumors exhibit a yellow to tan color; the tissue is soft or fleshy and may bulge from the surface. In part of the cases, marked accumulation of fat results in brightly yellow lesions (steatotic HCA). The tissue sometimes shows a nodular texture or a septate-like structure, but like in focal nodular hyperplasia, large blood vessels are often prominent within the tumor and on the surface (Figs. 1, 2, and 3).

Secondary Changes

HCA has a well-known tendency for intratumoral hemorrhage that may result in tumor rupture (Figs. 4, 5, 6, and 7). Necrosis and/or hemorrhage is frequently noted in tumors occurring subsequent to oral contraceptive therapy, and less often in other patients, fresh or old bleeding sometimes being an impressive change almost effacing the tumor tissue. In case of rupture, intratumoral hemorrhage is in direct continuation with the defect, which also contains fresh or coagulated blood, eventually resulting in a fistule-like alteration. HCA can undergo marked cystic change (Kobayashi et al. 1999), sometimes subsequent to necrosis and/or bleeding (Mays and Christopherson 1984). In rare cases, a giant multicystic tumor can develop (Katsuramaki et al. 2003). Calcifications and even bone formation with bone marrow have rarely been reported (Ranaldi et al. 1993). HCA are usually non-encapsulated tumors, although a thin pseudocapsule can occur, owing to the induction of matrix at the lesion's border (Craig et al. 1989).

Fig. 3 Large lipid-rich hepatocellular adenoma in a non-cirrhotic fatty liver

Fig. 4 Hepatocellular adenoma in a fixed resection specimen. More than a third of the tumor is occupied by rather fresh hemorrhage. The two *whitish* foci are necrotic tumor areas

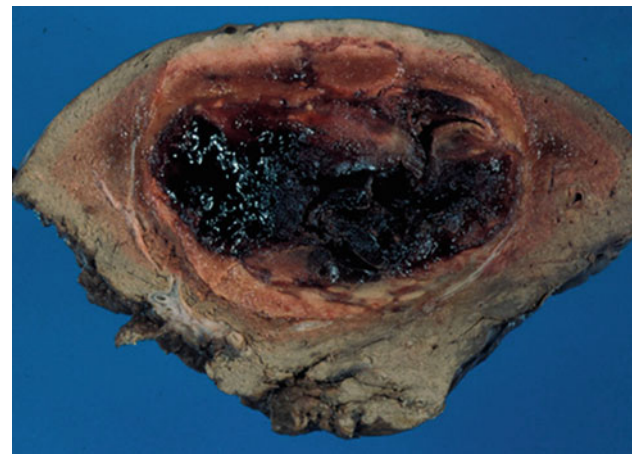

Fig. 5 Hepatocellular adenoma with massive hemorrhage ("tumor apoplexy"). Preserved tumor tissue is only present as a thin *yellow* rim at the periphery of the lesion

In rare cases, a thick capsule was found in large tumors (Ramakrishna et al. 1996). Remarkably, a fibrous capsule has been noted in all HCA occurring in five children (Wheeler et al. 1986), suggesting that there may be a difference in the response of the host organ between young and adult patients. Capsular features may be mimicked by the compression atrophy induced in adjacent liver substance. In case of (recurrent) bleeding at the periphery of the tumor, an inflammatory response followed by focal scarring can develop.

Fig. 6 Even small nodules of hepatocellular adenoma can develop hemorrhage, here in the form of tiny central speckles of bleeding

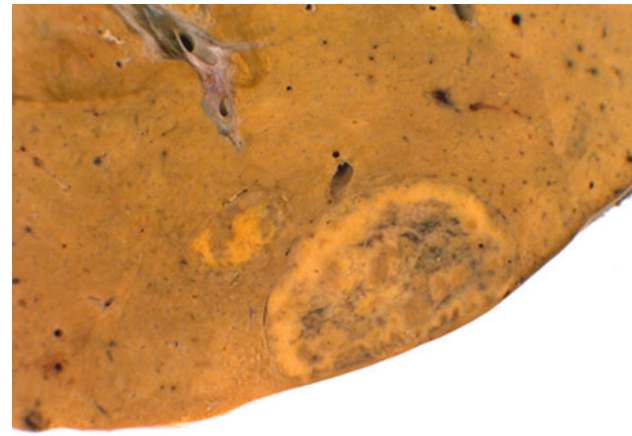

Fig. 7 Two peripherally located hepatocellular adenoma, one in a subcapsular position. Note the peripheral *yellow* tissue zone of the larger nodule, while numerous hemorrhages are present in the center

Histopathology

HCA consists of liver cell plates of normal or slightly increased width, and the hepatocytes are morphologically similar to normal parenchymal cells, albeit they are sometimes larger (Wegelin 1905; Fechner 1977; Ishak 1979; Bioulac-Sage et al. 2007b). The cells of HCA usually contain rather large amounts of glycogen. Deposition of neutral fat in tumor cells (steatosis) is rather common, and a part of HCAs exhibit marked fat accumulation (steatotic HCA), rendering the lesions macroscopically brightly yellow. A trabecular growth pattern mimicking normal liver cell plates predominates, but few tumors also display an acinar (or pseudoglandular) growth pattern. Nuclei are usually regular, nucleoli are not particularly prominent, and mitotic figures are mostly lacking (Figs. 8, 9, 10, 11, 12, 13, 14, and 15).

In a minority of HCA, nuclear atypias and increased mitoses are found. HCAs with acinar structures and nuclear atypia are difficult to distinguish from well-differentiated HCC by use of conventional diagnostic approaches. Uncommonly, the cells can display accumulation of hemosiderin, but not copper-associated protein, in contrast to fibrolamellar carcinoma, which is poor in glycogen and iron pigment, but usually shows copper-binding protein (Lefkowitch et al. 1983). In a minority of HCA, cells with steatosis also contain Mallory-Denk bodies, sometimes associated with steatohepatitis-like changes (Heffelfinger et al. 1987), a situation similar to alterations found in steatotic HCC. HCAs display a

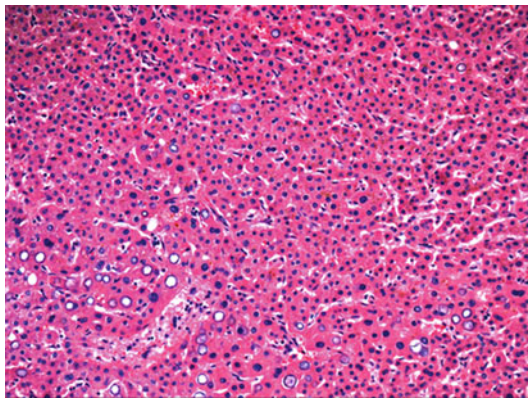

Fig. 8 Hepatocellular adenoma. Hepatocyte-like elements form slender cell plates that do not exceed a width of three cells. The microvascular system is sinusoidal. Part of neoplastic cells show nuclear vacuoles/invaginations (hematoxylin and eosin stain)

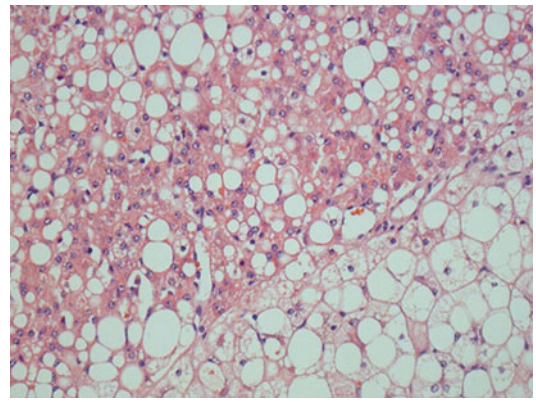

Fig. 10 Hepatocellular adenomas contain variable amounts of neutral fat/triglycerides, often in the form of macrovesicular steatosis. Tumor cells with a foamy cytoplasm may also develop (hematoxylin and eosin stain)

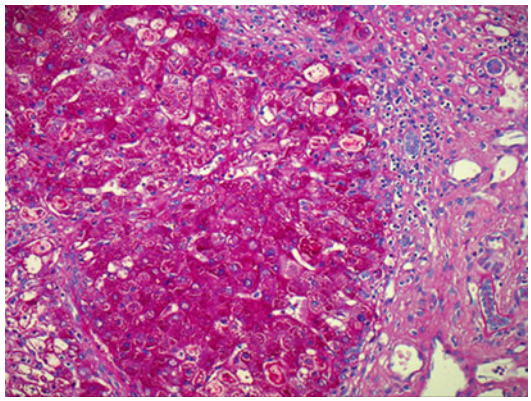

Fig. 9 In PAS stains, a high glycogen content of hepatocellular adenoma is in evidence (PAS stain)

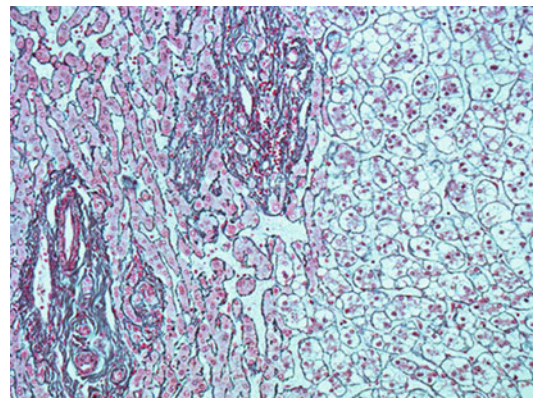

Fig. 11 In the reticulin stain, hepatocellular adenoma cell plates (*right half of figure*) are slender, but sometimes slightly thicker than normal hepatocyte plates seen in the *left half*. However, thin plates of normal hepatic tissue adjacent to tumor may in part be due to perifocal atrophy. Note that the sinusoidal channels of normal and tumor tissue are in continuation (*center*; Gomori silver stain)

reticulin pattern that is similar to that of normal liver, but clearly different from hepatocellular carcinoma (HCC), where the reticulin network is dramatically reduced. This difference manifests in fine-needle aspiration biopsies, where HCA cores are rigid, whereas HCC aspiration results in granular smears (Yang et al. 2004). However, reticulin loss can occur also in benign liver nodules in case of severe steatosis (Singhi et al. 2012).

HCA shows a characteristic vascular pattern. The parenchyma of the tumor is supplied by sometimes numerous thin-walled arteries that are not associated with portal tracts. The tumor discloses a sinusoidal vascular pattern conventionally similar to that in normal liver (Gouysse et al. 2004). The sinusoid-like channels may be dilated, and sometimes peliosis ensues. Immunohistochemically, the cells lining the channels are different from normal sinusoidal endothelium insofar as the cells in HCA are markedly reactive for CD34, similar to HCC, but in clear contrast to normal liver (Kong et al. 2000; Di

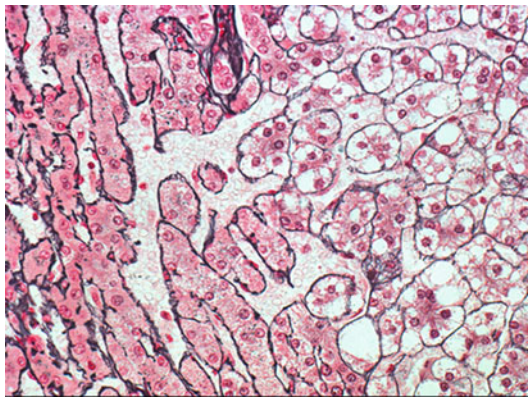

Fig. 12 At higher magnification, the distinct mode of vascular tumor feeding is characterized by a microvascular inlet structure that directs blood into the tumor periphery located to the right of the figure (Gomori silver stain)

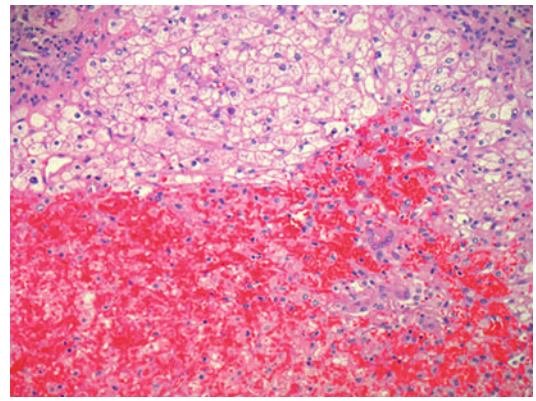

Fig. 14 Hepatocellular adenoma with fresh hemorrhage. Fragments of tumor within the hematoma are damaged and have lost the typical staining features (hematoxylin and eosin stain)

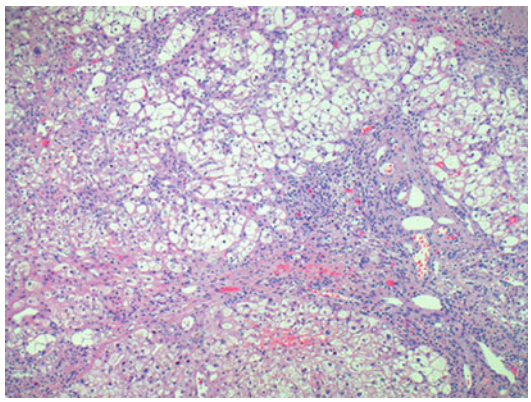

Fig. 13 Hepatocellular adenoma with inflammatory infiltrates, fibrosis, and focal clear cell change (hematoxylin and eosin stain)

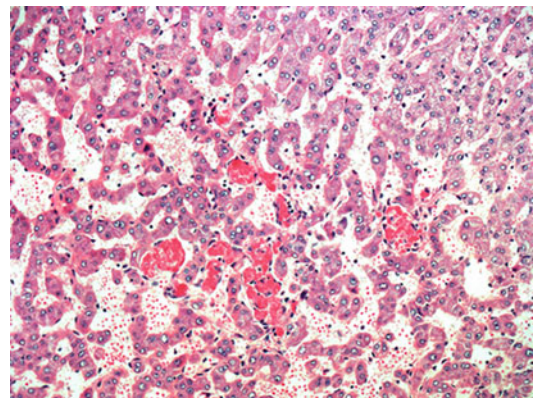

Fig. 15 Hepatocellular adenoma with ectatic sinusoids and fibrin-rich microthrombi with partial endothelialization (hematoxylin and eosin stain)

Carlo et al. 2002), suggesting an abnormal angiogenic response. In the acinus of the normal liver, CD34 expression is restricted to few sinusoidal endothelial cells in zone 1, i.e., close to the portal tracts, but CD34 is also expressed in endothelia of portal and hepatic veins (Theuerkauf et al. 2001). In some HCAs, these authors detected CD34 reactivity as reflecting a "lobular-like" vascular architecture, which is of interest insofar as HCA does not show a lobular internal pattern in routine sections. In addition, all HCAs had CD34-negative, CD105/endoglin-positive sinusoids which were oriented to draining veins, suggesting that these tumors have, in contrast to HCC, identifiable vascular inflow and outflow beds (Theuerkauf et al. 2001). The sinusoidal vascular channels of HCA contain Kupffer cells, in contrast to older views claiming that these tumors do not harbor such cells, although to variable amounts and with variable and sometimes reduced function (Goodman et al. 1987; Akatsu et al. 2004). Sometimes these hepatic macrophages are laden with PAS-positive material. In an immunohistochemical analysis of seven adenomas, lysozyme-reactive Kupffer cells were detected in each

lesion; three tumors had fewer Kupffer cells than the surrounding liver, three displayed about the same number, and one HCA showed more Kupffer cells (Goodman et al. 1987). In a retrospective review of 13 pathologically proven cases of HCA with technetium-99m sulfur colloid scintigrams, Kupffer cells were present in all 13 cases, and there were no histologic differences between tumors with colloid uptake and those without it (Lubbers et al. 1987). The presence of Kupffer cells indicates that the microenvironment for monocyte/macrophage homing into a vascular compartment in HCA is similar to that in the normal liver.

HCAs can undergo several common secondary changes. The most common alteration is hemorrhage, which may be focal and in some cases massive, almost effacing the tumor's tissue and rendering diagnosis difficult. In extreme situations, an HCA may present as a large hepatic hematoma, sometimes associated with rupture. Hemorrhage can be accompanied by edema, and in later phases, iron-loaded macrophages (siderophages) and granulation tissue followed by fibrosis (not real tumor stroma) can be found. Some HCAs show necrosis or even infarction, and part of these cases later show dystrophic calcification.

Less Common Histologic Features and Secondary Alterations

HCAs sometimes exhibit lipogranulomas, or intratumoral granulomas of unknown origin, and rarely numerous granulomas in both the tumor and the surrounding liver have been observed (Malatjalian and Graham 1982; Bieze et al. 2012). Granulomas have also been reported in liver adenomatosis, with granulomatous reactions in the tumors and/or the adjacent liver (Le Bail et al. 1992). The pathogenesis of epithelioid cell granulomas in HCA or in HCC, where they also may occur (Tomimatsu et al. 1982), is unknown. Other rare changes include the formation of intratumoral bone marrow tissue in tumors of children and adolescents (Wheeler et al. 1986; Anthony 1988), but also in adults (Ranaldi et al. 1993). The case of Ranaldi and coworkers involved a 65-year-old male patient with a large HCA showing hemorrhages, focal cystic change, and gross calcifications. Apart from the typical morphology of HCA, this tumor displayed multiple areas of trabecular bone, whose lumina were filled with adipose tissue and bone marrow, with a slight prevalence of erythroblasts. Extramedullary hematopoiesis is more frequently seen in other hepatic tumors, in particular hepatoblastomas. Interestingly, extramedullary hematopoiesis has also been noted in lesions classified as hepatic or hepatocellular adenoma of the placenta.

One very rare variant of HCA is characterized by the presence of adenoma cells embedded in an abundant matrix with myxoid features (myxoid HCA; Galassi et al. 1995). One report described a T1-hyperintense and T2-hypointense HCA with histologically proven iron overload of the tumor cells (siderotic liver cell adenoma; Cheng et al. 1995). Iron deposition occurs in other nodular hepatocyte lesions, including adenomatous hyperplasia and siderotic nodules in liver cirrhosis (Murakami et al. 1991).

Ultrastructure

HCAs exhibit alpha glycogen particles and lipid droplets in their cytoplasm. Typically, HCA cells have normal or reduced numbers of mitochondria (Garancis et al. 1969; Kay and Schatzki 1971; Sumner and Rosai 1981). Ultrastructurally, small blood vessels of HCAs have abnormal endothelial cells. These cells have an irregular thickness, most of them have few fenestrae. Instead of perivascular stellate cells, HCAs showed perivascular myofibroblast-like cells separated from endothelial cells by a basement membrane, corresponding to capillarization (Bioulac-Sage et al. 1986).

General Immunohistochemical Features

In this paragraph, general immunohistochemical features of HCAs are discussed, whereas specific immunophenotypical features of the novel HCA phenotypes are addressed in subsequent

paragraphs. Immunohistochemistry of HCAs is helpful to distinguish these lesions from FNH and HCC, also on needle biopsies (Ahmad et al. 2009; Bellamy et al. 2013; Bioulac-Sage et al. 2012a). HCA cells show cytokeratin 7 reactivity in patches, with gradual decrease in staining intensity as a function of hepatocyte differentiation (Iyer et al. 2008). But HCAs lack a cholangiocyte-related lineage and are therefore not, or only focally and weakly, reactive for cytokeratin 19 or NCAM (Iyer et al. 2008; Ahmad et al. 2009). In contrast to HCCs, HCA cells are not immunoreactive for glypican-3 (Wang et al. 2008; Lagana et al. 2013) or heat-shock protein-70/HSP-70 (Lagana et al. 2013), but are positive for HepPar-1 and arginase-1 (McKnight et al. 2012). Part of HCAs are reactive for glutamine synthetase (Lagana et al. 2013), but mostly those with beta-catenin mutation (see below). HCA cells show granular or globular cytoplasmic immunoreactivity for alpha-1-antitrypsin, but less frequently than HCC (Palmer et al. 1977). The cell surface adhesion molecule, cadherin, shows a more heterogeneous membranous expression in HCAs than in FNH or normal hepatocytes (Kozyraki et al. 1996). Expression of the adhesin, CD44, was detected in a minority of HCA (Washington et al. 1997). Carcinoembryonic antigen/CEA is usually not expressed in HCA (Koelma et al. 1986). In contrast to both, HCC and fibrolamellar carcinoma, HCAs show a significant level of immunoreaction to the basic (Ya) subunit of glutathione-S-transferase (Hayes et al. 1986). A part of HCAs express Golgi phosphoprotein 2/GOLPH2 (Riener et al. 2009). In contrast to HCCs, LCAs lack expression of matrix metalloproteinase-7 (Tretiakova et al. 2009). Lipid droplets in steatotic HCA stain for the lipid droplet-associated protein, perilipin, similar to lipid droplets in HCCs (Straub et al. 2010). In contrast to HCC, HCAs do not display p53 protein reactivity (Schaff et al. 1995) and are not reactive for the HCC marker, aldoketoreductase family 1B10/AKR1B10 (-Matkowskyi et al. 2014). With the exception of beta-catenin-activated HCA, adenoma cells show membranous beta-catenin expression, similar to normal hepatocytes (Fig. 16).

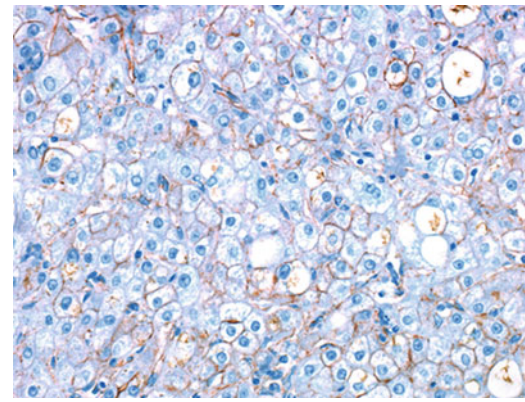

Fig. 16 Hepatocellular adenoma, beta-catenin expression. As with normal hepatocytes, beta-catenin reactivity is present as a membranous staining pattern (beta-catenin immunostain)

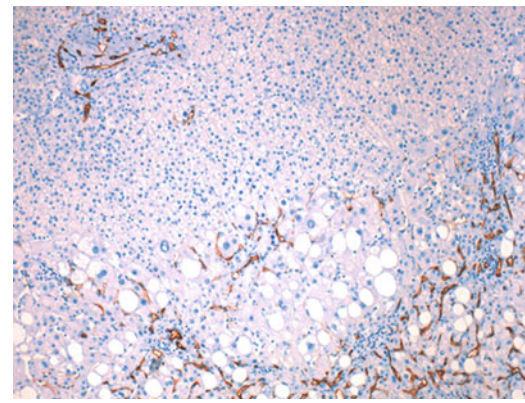

Fig. 17 Hepatocellular adenomas exhibit variable CD34 expression in their microvessels (CD34 immunostain)

HCAs can exhibit a diffuse endothelial staining for CD34 in microvessels (Ahmad et al. 2009; Fig. 17).

In contrast to neovessels in HCCs and high-grade dysplastic nodules, HCA vessels are not reactive for agrin (Tatrai et al. 2009). In comparison with normal hepatic tissue, HCAs showed an increase of angiopoietin-1 expression, possible associated with increased vascular remodeling to produce enlarged vessels and arterial sprouting (Gouw et al. 2010). Immunohistochemically, hepatic progenitor cells were identified in part of HCAs (Libbrecht et al. 2001).

Specific Pathology of HNF-1alpha-Mutated HCA (H-HCA)

H-HCA usually presents as a nodule with lobulated contours. A lobulated pattern is highly characteristic for this HCA variant, and this lobulated geometry is caused by coalescence of several adenomatous liver nodules. Nodule coalescence is supported by the occasional presence of normal or atrophic liver lobules trapped between HCA nodules. Small or tiny steatotic HCA nodules are characteristically found at some distance from the main lesion (Sempoux et al. 2014). Histologically, H-HCA present with a very homogeneous histologic aspect and often show the "classical" phenotype of adenoma, as described above, often with steatosis, but with no inflammatory changes, minor or absent sinusoidal congestion, and absence of nuclear atypia. Often, the steatotic nodule is sharply demarked from adjacent non-steatotic liver. Apart from steatotic hepatocytes, clear liver cells may also be present in variable numbers, but this feature is not a hallmark of H-HCA. H-HCAs more often show microadenomas, steatosis, and additional benign nodules (Bioulac-Sage et al. 2009). At low magnification, the tumors appear as nodular and clear lesions with a homogeneous histologic pattern. The growth pattern is trabecular, these rather thin plates composed of large hepatocytes steatosis, glycogen storage, and small dark nuclei. Tumor cell lipofuscinosis is often noted (Fonseca et al. 2013). Tumor bleeding is less frequently seen in this variant, but can be severe when it occurs (Bioulac-Sage et al. 2007a). The adjacent liver may show steatosis in a minority of cases.

An immunohistochemical and molecular analytic hallmark of H-HCA is the lacking expression of liver fatty acid-binding protein/LFABP, in contrast to normal adjacent liver showing marked expression. LFABP is a protein encoded by a gene that is positively regulated by HNF1A, whereby lack of LFABP is sometimes associated with more severe steatosis (Bioulac-Sage et al. 2007a; review: Bioulac-Sage et al. 2011). Steatosis in H-HCA may be related to lack of LFABP through deranged fatty acid trafficking. The tumor hepatocytes do not stain for SAA or CRP, and reactivity for glutamine synthetase/GS is lacking or is only seen at adenoma borders (Fonseca et al. 2013). GS reactivity may be present around veins or venules and in LFABP-expressing normal hepatocytes intermingled with adenoma cells at the adenoma-parenchyma transition.

Specific Pathology of Beta-Catenin-Activated HCA (b-HCA)

Beta-catenin-mutated HCAs (b-HCA) exhibit thicker liver cell plates, a more variable hepatocyte population, and more often show cytological/nuclear atypias with enlarged and irregular nuclei. The nodules may contain numerous vessels, a typical feature. The nuclear atypias may in part be related to cytogenetic alterations in b-HCA, including chromosome gains and losses. Significant steatosis is absent (Bioulac-Sage et al. 2007a, 2011; Chu and Moon 2013; Fonseca et al. 2013; Sempoux et al. 2014). In one patient, b-HCA had the features of pigmented adenoma with Dubin-Johnson-like pigment (Fonseca et al. 2013). The precise diagnosis of b-HCA is of particular importance, as this form of HCA is strongly associated with malignant transformation. Immunohistochemically, b-HCA is characterized by nuclear and cytoplasmic positivity for beta-catenin and patchy or marked and diffuse immunostaining for glutamine synthetase/GS (Bioulac-Sage et al. 2011, 2013). In a Korean study, glutamine synthetase (GS) staining was not always clearly diagnostic for beta-catenin-mutated HCA (Kim et al. 2013). Furthermore, diffuse GS overexpression was, in one patient, restricted to areas of peliosis in a beta-catenin-activated peliotic HCA (Berry et al. 2014).

Specific Pathology of Inflammatory HCA (IHCA)

The pathology of this group of HCAs is more complex, as this is a heterogeneous group of lesions that also contains telangiectatic HCA, a

mass previously interpreted as telangiectatic nodular hyperplasia. Many IHCAs are characterized by an adenoma showing inflammatory infiltrates and variable vascular anomalies, mainly dystrophic arteries, sinusoidal ectasias associated with congestion, peliosiform areas, and hemorrhage (Sempoux et al. 2014). Thick-walled arteries may be surrounded by inflammatory cells. Macroscopic and microscopic hemorrhage is more common in IHCA than in the other forms. Steatosis may occur in IHCA, mainly in patients with an elevated body mass index, and absent in tumors with high SAA (serum amyloid protein A) expression (Bioulac-Sage et al. 2007a; van Aalten et al. 2011). Steatotic cells may also be encountered in areas of sinusoidal ectasia (Sempoux et al. 2014). Very small nodules in a diameter range of few millimeters were observed in patients with multiple nodules, while in patients with a solitary IHCA, only rare nodules in the mm range were detectable (Bioulac-Sage et al. 2010). Livers harboring IHCAs show distinct alterations, both near the tumors and distant from them. Mild to moderate steatosis is found in a high frequency, as are sinusoidal dilatation, single arteries, and minute foci of CRP reactivity, the latter mainly in cases of multiple IHCA, indicating that these livers contain incipient IHCA foci (Han et al. 2012).

Immunohistochemically, infiltrate-containing structures containing CK7-positive ductular proliferations are found (Fonseca et al. 2013). The neoplastic hepatocytes often display reactivity for serum amyloid protein/SAA and C-reactive protein/CRP. CRP is more consistently expressed in tumor hepatocytes than SAA and is usually present as a diffuse and marked reactivity. SAA is expressed in tumor hepatocytes, but not in inflammatory cells. SAA overexpression in IHCA included all cases of tumors formerly classified as telangiectatic FNH (Lim et al. 2008), a strong argument that such lesions are in fact a variant of IHCA with telangiectatic features (Bioulac-Sage et al. 2007a). Expression of L-FABP is normal, and glutamine synthetase positivity is either absent or only seen at adenoma borders or around blood vessels, with few exceptions showing strong reactivity.

A minority of IHCAs are beta-catenin-activated tumors (b-IHCA). The nodules are characterized by sinusoidal dilatation, inflammatory infiltrates, and thick-walled dystrophic vessels. b-IHCAs show variable, either faint and heterogeneous, patchy, or strong and diffuse GS expression contrasting with the pericentral staining of normal liver parenchyma. In varying expression patterns, b-IHCA nuclei are reactive for beta-catenin, and cytoplasmic beta-catenin immunostaining may also be found (Sempoux et al. 2014).

Association of HCA with Other Synchronous Liver Alterations

In most instances, the liver harboring HCA does not show characteristic preexisting alterations, in particular no cirrhosis. In certain situations, the liver exhibits changes that are related to a disorder favoring HCA, e.g., glycogenosis. As inflammatory HCA is associated with obesity, mild to moderate hepatic steatosis was found in a high frequency in patients with this HCA type (Han et al. 2012).

HCA can simultaneously occur with focal nodular hyperplasia/FNH (Laurent et al. 2003; Dimitroulis et al. 2012). In a study from Bordeaux, HCA together with FNH was found in 5 out of 30 cases of multiple benign hepatocytic nodules. All five cases involved women on oral contraceptives. Possible causes of this association include local or systemic angiogenic anomalies induced by oral contraceptives, tumor-induced growth factors, or thrombosis and local arteriovenous shunting (Laurent et al. 2003). HCA can occur in a syndromic context, characterized by the synchronous occurrence of HCA, FNH, and hemangiomas of the liver (Di Carlo et al. 2003). A combination of HCA and FNH was also observed in association with spontaneous intrahepatic portosystemic shunt (Handra-Luca et al. 2006). HCA was observed in conjunction with nodular regenerative hyperplasia of the liver (Nguyen et al. 1986) and hepatic granulomas (Kazi et al. 2005).

Biology of Disease and Evolution

General Features

It is thought that HCAs grow rather slowly, an HCA of 10 cm diameter requiring an evolution time of 2–3 years. However, there are also information that HCA may progressively grow (Mariana et al. 1979), particularly in adenomatosis (Grazioli et al. 2000). A part of the HCAs are known to regress completely (at least radiologically), sometimes occurring in an apparently "spontaneous" fashion (Iijima et al. 2001). Regression may require as much as 8 years to be complete (Iijima et al. 2001). Conversely, rapid disappearance of even large HCA has been observed subsequent to contraceptive withdrawal (Kay 1977; Ramseur and Cooper 1978; Penkava and Rothenberg 1981; Steinbrecher et al. 1981; Bühler et al. 1982; Daldrup et al. 1995; Kawakatsu et al. 1997; Aseni et al. 2001), similar to steroid-induced FNH (Meunier et al. 1998), whereas in other situations, discontinuation of oral contraceptives resulted in no change of the tumor (Tajada et al. 2001). Regression of HCA following androgenic progestin therapy withdrawal was found (Svrcek et al. 2007), and regression was observed after discontinuation of danazol in patients with hereditary angioedema (Bork and Schneiders 2002).

Malignant Transformation of HCA

The first description of transition of HCA into HCC may be a thesis as of 1861 (Jungmann 1861). The malignant transformation of HCA to HCC (the adenoma-carcinoma sequence) is not a common phenomenon, but occurs more frequently in case of large and multiple tumors (Foster and Berman 1994; Nagorney 1996; Farges and Dokmak 2010) and is ten times more frequent in men than in women (Farges et al. 2011). A transformation process may start with focal cellular atypias in subsets of HCA (Fig. 18).

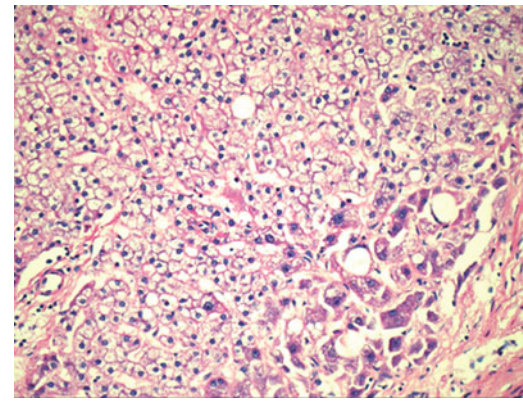

Fig. 18 Hepatocellular adenoma with focal cell and nuclear atypia (hematoxylin and eosin stain)

There is now evidence that certain molecular variants of HCA (see above), specifically, b-HCA, and obesity/overweight may represent a major risk of malignant transformation of HCA, possibly through the interleukin-6 pathway (Bioulac-Sage et al. 2012). In fact, presence of beta-catenin activation and absence of steatosis in HCAs seem to be indicators for increased malignancy risk (Van den Borght et al. 2007). In a genomic profiling study, integrative analysis of HCAs transformed to HCC showed beta-catenin mutation as an early alteration and TERT promoter mutations as a feature of the last step of an HCA-CC transition (Pilati et al. 2014). However, in H-HCA, where steatosis is rather common, transformation into HCC is not common (Zucman-Rossi et al. 2006). Also telangiectatic HCA can give rise to HCC (Gonzalez-Lara et al. 2013). Some of the observations described the development of HCC subsequent to the initial diagnosis of HCA (Grazioli et al. 2000). In a review of 39 HCAs, five patients subsequently developed HCC (Foster and Berman 1994). Among 58 patients who underwent surgery for HCA, 2 patients developed HCC 2 and 5 years after resection, respectively (Weimann et al. 1998). Dokmak and coworkers (2009) found eight cases of malignancy among 122 patients with HCA. Another report described HCC apparently having developed from HCA after 19 years (Janes et al. 1993). Based on a systematic literature search with a collection of

1,635 HCAs, the reported overall frequency of malignant transformation was 4.2 %. Only three cases of malignant alteration were found in a tumor smaller than 5 cm in diameter (Stoot et al. 2010). Recently, a potential derivation of non-cirrhotic hepatocellular carcinoma from HCA has been proposed (Liu et al. 2014). Well-differentiated HCCs in non-cirrhotic liver can contain areas that are similar to HCA. Among eleven cases of HCC arising in HCA in non-cirrhotic liver, atypical HCA-like areas were found in 64 %, and in more than half of these cases, the areas showed features of inflammatory HCA. It was suggested that HCA-like areas in such HCCs may represent an extremely well-differentiated variant of HCC (Kakar et al. 2014).

Selected References Davis et al. 1975; Boyd and Mark 1977; Gordon et al. 1986; Grigsby et al. 1987; Korula et al. 1991; Ferrell 1993; Herman et al. 1994; Perret et al. 1996; Scott et al. 1996; Ye et al. 1999; Closset et al. 2000; Choe and Yu 2002; Chuang et al. 2002; Ito et al. 2003; Burri et al. 2006; Micchelli et al. 2008; Dokmak et al. 2009; Baulieux et al. 2012; Seo et al. 2012; Kakar et al. 2014.

The pathogenic pathways involved in malignant transformation of HCA are incompletely known. In HCA developing in patients using oral contraceptives, liver cell dysplasia has been observed and suggested to be a premalignant change (Fink et al. 1985; Tao 1991; Closset et al. 2000; Hsu et al. 2003). The dysplastic changes appeared to arise after 9 years of oral contraceptive use (Tao 1991, 1992). As outlined above, B-HCA and b-IHCA are strongly associated with HCC transformation (reviews: Liau et al. 2013; Sempoux et al. 2013). A recent investigation showed recurrent somatic FRK mutations that induced constitutive kinase activity, STAT3 activation, and cell proliferation sensitive to Src inhibitors. In addition, uncommon recurrent mutations activating JAK1, gp130, and beta-catenin were detected. Integrative analysis of HCAs transformed to HCC exhibited beta-catenin mutations as an early change and TERT promoter mutations associated with the last step of the cancerogenic pathway (Pilati et al. 2014). A recent analysis demonstrated that HCCs that develop in non-cirrhotic livers have some clinical, morphological, or immunophenotypical associations currently described in HCAs (Liu et al. 2014).

Very rarely, HCA is followed by other hepatocellular tumors, e.g., fibrolamellar carcinoma (Terracciano et al. 2004). In a female patient with long history of oral contraceptive use, HCA was found within a large hepatic spindle cell carcinoma with positivity for keratins and alpha-1-antitrypsin (Grigsby et al. 1987).

Associations, Etiology, and Pathogenesis of Hepatocellular Adenoma

Sex Steroids

Apart from distinct mutations found in HCAs (see above), there are diverse factors, agents, and conditions that can trigger the initiation and progression of HCA, but in part of cases, the causes of HCA and LA are not yet fully clarified (Ribeiro et al. 1998; Yoshidome et al. 1999). Among probable nongenetic causes, sex steroids have aroused a major interest for long time periods. As both estrogen receptor-positive and estrogen receptor-negative tumors occurred in the same liver, it was concluded that estrogens may not play a decisive role in the pathogenesis of HCA/LA (Ribeiro et al. 1998; Torbenson et al. 2002). However, there is strong evidence that modified estrogens, in particular oral contraceptives, progestogens, and androgenic steroids, are involved in the pathogenesis of certain subsets of HCA.

Selected References for Estrogens Baum et al. 1973; Christopherson et al. 1975; Brander et al. 1976; Fechner 1977; Ishak 1979; Fléjou et al. 1985; Rabe et al. 1994; Perret et al. 1996; Tao 1992; Caballes and Caballes 1999; Crosnier et al. 2010.

The etiologic significance of steroids, and in particular sex steroids, for the development of HCA is underlined by the observation that HCA may

evolve or grow during, or at least being manifest in, pregnancy (gestational HCA; review: Cobey and Salem 2004). However, in the light of the slow growth of such lesions, it seems logical that large tumors detected during pregnancy were present before already (Monks et al. 1986; Rosel et al. 1990; Terkivatan et al. 2000). Interestingly, therapeutic abortion in a patient with a large HCA resulted in abrupt necrosis of the liver tumor, suggesting an effect of sudden estrogen deprivation (Stock et al. 1985). During pregnancy, the risk of rupture of HCA exists, associated with high maternal and fetal mortality (Bis and Waxman 1976; Rosel et al. 1990), requiring careful monitoring and, in case of large tumors (i.e., diameter 5 cm or more), eventual prophylactic resection (Terkivatan et al. 2000). Ninety-one of the cases reported in the older literature have been reviewed in 1976 (Bis and Waxman 1976), overall with a then-reported 59 % maternal and 62 % fetal mortality, in part due to delayed diagnosis and owing to associated disorders, such as preeclampsia. It has been suggested that high levels of sex steroids and an increased vascularity of the liver during pregnancy increase the risk of rupture.

Androgen administration, e.g., in patients with aplastic anemias and for the purpose of body building, is associated with the emergence of HCA.

Selected References Anthony 1975; Boyd and Mark 1977; Carrasco et al. 1984, 1985; McInerney et al. 1987; Leese et al. 1988; Pulpeiro et al. 1989; Gonzalez et al. 1994; Geders et al. 1995; Deodhar et al. 1996; Toso et al. 2003 Socas et al. 2005.

Few HCAs have been observed in patients receiving treatment with danazol, an attenuated androgen (Middleton et al. 1989; Watanabe and Kobayashi 1993), in one instance with formation of multiple HCAs (de Menis et al. 1999). In particular, HCA can develop subsequent to the treatment of hereditary angioedema with attenuated androgens such as danazol or stanozolol. Since 1999, four HCA patients having received long-term angioedema prophylaxis with danazol have been reported (Bork and Schneiders 2002).

Glycogenosis

HCA is now well known to occur in association with certain types of glycogen storage diseases (GSD; glycogenosis), most frequently in GSD type 1 (Mason and Andersen 1955; Nishio et al. 1981; Fink et al. 1985; Poe and Snover 1988; Fujiyama et al. 1990; Bianchi 1993; Labrune et al. 1997; Kelly and Poon 2001; Kudo 2001; Yoshikawa et al. 2001; Lee 2002; Rake et al. 2002; Lerut et al. 2003; Volmar et al. 2003; Di Rocco et al. 2008; Kishnani et al. 2009; Wang et al. 2011; Sakelliarou et al. 2012). In type I glycogenosis, HCA can occur in conjunction with HCC (Cassiman et al. 2010). HCA is much rarer in GSD type 3 (Labrune et al. 1997) and only exceptionally occurs in GSD type 4 (Alshak et al. 1994;). In GSD type 8, cirrhosis associated with a lesion tentatively interpreted to be adenomatous hyperplasia has been described (Shiomi et al. 1989). For GSD type 1, the first report of an associated HCA dates back to 1955 (Mason and Andersen 1955). Many of the cases observed in the following years have been reviewed (Bianchi 1993; Labrune et al. 1997; Lee 2002), and the radiologic features are known from several reports (Debaere et al. 1999). The range of prevalence in patients with GSD type 1 depends on the published series and amounts from 22 % to 75 %, indicating considerable selection bias; in fact, the true prevalence is still unknown. The retrospective European registry showed a 52 % prevalence of HCA in patients over 20 years of age (Moses 2002). The age at manifestation of HCA ranges from 3 to 54 years, even though more tumors are in evidence during or after puberty (Lee 2002) without gender preference (European GSD Registry; Rake et al. 2002). HCAs in GSD type 1 can be solitary tumors, but multiple lesions have also been reported (Howell et al. 1976; Coire et al. 1987; Endoh et al. 2001). Their biology seems to be similar to other HCA, i.e., they may bleed, recur after incomplete resection, or regress spontaneously (Iijima et al. 2001)

or upon dietary treatment (Parker et al. 1981). HCA developing in the setting of glycogenosis type I lacked HNF1A inactivation (Calderaro et al. 2013). Is HCA developing in GSD type 1 a precursor for HCC? Among the cases reported in the literature, at least ten have had associated HCC (Lee 2002), and in some situations, an evolution from HCA to HCC may have occurred (Limmer et al. 1988). The etiology and pathogenesis of HCA developing in GSD type 1 is unknown. HCAs do also occur in GSD type 3 and, rarely, in type 4, but these patients suffer from chronic fibrosing liver disease and eventually cirrhosis. It has been suggested that the hormonal imbalance of a high glucagon/insulin ratio characteristic of poorly controlled GSD patients may exert a permissive role in conjunction with specific growth factors in HCA formation, because strict diet can result in tumor regression (Bianchi 1993). However, patients with GSD types 6 and 9 have not been reported to develop liver tumors. Furthermore, the abnormal glycogen metabolism in liver tumor precursors occurring in rats does not mimic the situation of human HCA. It has also been proposed that the disordered fatty acid metabolism present in GSD may play a role in tumorigenesis, as, e.g., proposed for HCC (Ockner et al. 1993; Lee 2002), but further data are required to address this point in more detail. The clinical differential diagnosis of HCA evolving in glycogen storage disease includes focal nodular hyperplasia (FNH), which has been observed in these metabolic disorders (Suga et al. 2002), and HCC, which has been observed in GSD types 1, 3, 4, 6, and 9.

Abnormal Liver Circulation

Several reports documented an association between HCA and portosystemic shunt, a hepatic circulation disorder that may directly stimulate abnormal hepatocyte growth (Dhalluin-Venier et al. 2008; Pupulim et al. 2013). HCA was found in children with spontaneous intrahepatic portohepatic shunt (Kawakatsu et al. 1994). HCA also occurs in the setting of congenital absence of the portal vein, whereby the tumors showed HNF-1alpha inactivation (Tateishi et al. 2013). HCA and other nodular hepatocyte lesion occur in patients with idiopathic portal hypertension (Sugimoto et al. 2013).

Chromosomal and Molecular Genetic Alterations Other Than Those Discussed Above

Monoclonality of HCAs has been documented (Gong et al. 2006). So far, relatively few chromosomal and genetic changes have been detected in HCA, but they can in part distinguish HCA from HCC (Zucman-Rossi 2004; Chen et al. 2005). In contrast to HCC, no LOH or mutant sequences were observed for the p53 gene in HCA, and mutations of exon 3 of the beta-catenin gene were not found. In contrast to HCC, trisomies 1 and 8 are not found in HCA (Nasarek et al. 1995). HCA can molecularly be distinguished from well-differentiated hepatocellular carcinoma (HCC) by comparative genomic hybridization. In HCA, aberrations were detectable in a minority of cases, involving gains of chromosomes 7p, 17q, and 20, while most HCC had a complex array of chromosomal abnormalities involving numerous chromosomes (Wilkens et al. 2001). By use of microarray analysis, several genes were found downregulated in HCA in comparison with HCC (Yim et al. 2003).

Variants of Hepatocellular Adenoma 25

Contents

Abstract

Apart from its classical or typical form, hepatocellular adenoma (HCA) can present as one of several variants. HCA often occurs as solitary lesion, but some patients synchronously exhibit several or multiple tumors, a condition termed hepatocellular adenomatosis. Currently, adenomatosis is defined by the presence of more than ten adenomas in an otherwise normal parenchyma. Most of the former cases of telangiectatic focal nodular hyperplasia are now considered to be a variant of HCA (telangiectatic HCA) associated with systemic signs of inflammation. The majority of telangiectatic HCA exhibit inflammatory changes in the tumor. A further rare variant of HCA is pigmented HCA, solitary or multiple benign tumors having abundant Dubin-Johnson-like pigment granules in the cytoplasm.

Hepatocellular Adenomatosis

Hepatocellular adenoma (HCA) often manifests as solitary lesion. However, some patients exhibit several or multiple HCA. This distinctive clinicopathologic situation is termed liver adenomatosis (LA), thought to be an entity distinct from solitary HCA and first described under this term in 1985, based on a series of 13 cases and defined as a condition of ten or more HCA (Fléjou et al. 1985), and 1 year later by Okuda (1986). However, multiple or multicentric HCA have

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_25

been described already earlier, at least once under the term, hepatic adenomatosis. LA has been defined by the synchronous presence of more than three HCA in the same liver, the number of tumor nodules required for fulfilling the criteria however varies in the reports, ranging from just "more than three," "five or more" (Yoshidome et al. 1999), to "more than ten" (Fléjou et al. 1985; Shortell and Schwartz 1991; Chiche et al. 2000). Currently, LA is defined as the presence of more than ten adenomas in an otherwise normal parenchyma (Chiche et al. 2000). In one series, the diagnosis was made at a mean of 32 years (range, 13–75 years; Chiche et al. 2000). All cases reported between 1977 and 2008 have been reviewed (Yoshidome et al. 1999; Chiche et al. 2000; Veteläinen et al. 2008), amounting to 94 cases in 2008. In the review of Veteläinen and coworkers, 52 % of the female patients had a history of oral contraceptive use, and 18 % of patients had steatosis in the adjacent liver tissue. For further information, reference is made to numerous publications that have appeared on this issue (Marckwald 1896; Aleksic and Kosanovic 1956; Monges et al. 1963; Monaco et al. 1964; Mercadier et al. 1967; Caquet et al. 1976; Lui et al. 1980; Sinha and Prasad 1982; Chen and Bocian 1983). Since then, numerous cases have been reported, the age at presentation ranging from childhood to adolescents and adults.

Selected References Aleksic and Kosanovic 1956; Shortell and Schwartz 1991; Choi et al. 1991; Degos et al. 1994; Propst et al. 1995; Gokhale and Whitington 1996; Cristaldi et al. 1998; Grazioli et al. 2000; Rumi et al. 2000; Yunta et al. 2001; Balci et al. 2002; Musthafa et al. 2003; Barthelmes and Tait 2005; Lewin et al. 2006; Veteläinen et al. 2008; Bisceglia et al. 2009.

What is hepatocellular adenomatosis today? Recent investigations and modern classifications have shown that in all subtypes of HCA, and in all etiologic settings, the tumors can be solitary, multiple (<10 nodules), or multiple in the sense of adenomatosis (>10 nodules) (Frulio et al. 2014), suggesting that the term LA requires redefinition in the future.

Pathologically, the individual nodules occurring in adenomatosis are histologically of the type found in solitary HCA, with or without hemorrhage. The nodules may be associated with or surrounded by smaller nodules measuring 1–2 cm or less. These small nodules are either typical small HCAs or atypical nodules, the latter characterized by a polylobulated aspect with steatotic zones. Small atypical nodules may expand and join to form bigger nodules, followed by effacement of non-adenomatous components to end up with a typical HCA nodule (Lepreux et al. 2003b). The number of lesions detectable on imaging may be considerably less than that found in resection specimens (e.g., 10–50 per liver on imaging in a study on 15 patients, but many more in resections; Grazioli et al. 2000). Chiche and coworkers (2000) have divided LA into two forms with different presentations and evolution, i.e., a massive form and a multifocal form, the former being an aggressive form. The massive form, which predominates in the literature, can be unilobar, but more often, the entire liver is enlarged, associated with a hypervascularized nodular parenchyma. In contrast, the multifocal form is not associated with hepatomegaly, and only one or two nodules may eventually cause complications, this form therefore being less aggressive.

Telangiectatic FNH and Telangiectatic HCA: IHCA-Type Lesions

Previously, nodular liver lesions with a marked sinusoidal ectasia or even peliosis-like alterations were classified as telangiectatic focal nodular hyperplasia (TFNH) of the liver which was classified as a peculiar variant of FNH (Peterfy and Rosenthall 1990). The former TFNH was mainly regarded as a disorder of adult females (Gussick et al. 2005; Paradis 2007; Machida et al. 2008; Takayassu et al. 2009; Paradis 2010), with a mean age at diagnosis of 37 years (Paradis et al. 2004), but it also occurs in the pediatric or even perinatal age group, sometimes with spontaneous regression (Kim et al. 2003; Okamura et al. 2005;

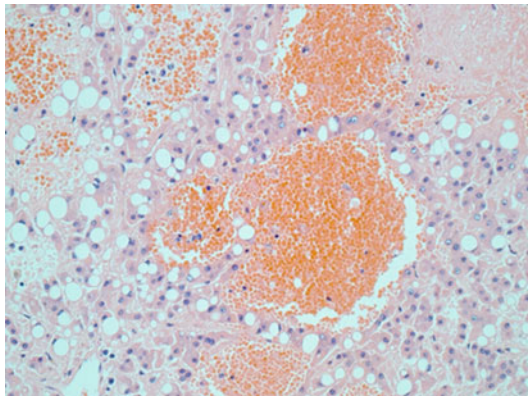

Fig. 1 Hepatocellular adenoma with peliosis-like and telangiectatic lesions (hematoxylin and eosin stain)

Hirakawa et al. 2009). Multiple foci were found in up to 62 % of patients (Attal et al. 2003; Fig. 1).

TFNH was described to show lack of central scar and radiating septa, medial muscular hypertrophy rather than intimal proliferation in target arteries, and direct drainage of abnormal blood vessels into adjacent sinusoids, while a direct sinusoidal drainage is not in evidence in typical FNH (Wanless et al. 1989; Nguyen et al. 1999; Attal et al. 2003).

Subsequently, telangiectatic nodular liver lesions were classified as a distinct variant of HCA, i.e., telangiectatic HCA (THCA). In fact, there are strong indications that the former TFNH is monoclonal and a true variant of HCA, specifically of the IHCA (inflammatory hepatocellular adenoma) type (adenoma with telangiectatic features; Paradis et al. 2004). In contrast with other types of HCA, THCA patients did not differ in the prevalence of oral contraceptive intake, but patients with THCA had longer periods of use than patients with other HCAs (Mounajied and Wu 2011). The histology is characterized by compact areas consisting of markedly vascularized portal tract-like structures, thickened arteries, and inflammatory infiltrated and ductular proliferations, these areas being surrounded by dilated sinusoids (Lepreux et al. 2003a). In one analysis, the mean diameter of nodules was 5 cm (range, 1–17 cm), and inflammatory changes were present in 91 %, steatosis in 53 %, vascular alterations in 59 %, and cellular atypias in 19 % (Paradis 2007). In a systematic study, no clinical difference was found between patients with TFNH and HCA. Hemorrhage, a typical feature of HCA, was found in 77 % of TFNH, which is unusual for "true" FNH. Patients with TFNH more often revealed multiple nodules, and there was evidence that TFNHs were monoclonal lesions (Bioulac-Sage et al. 2005). The telangiectatic lesions share with HCA a low mean value of the angiopoietin-1 and angiopoietin-2 mRNA ratio (2.1 in telangiectatic nodules, 2.6 in HCA, and 21.4 in FNH; Paradis et al. 2004). Telangiectatic HCA is associated with increased body mass index and systemic signs of inflammation (Paradis 2007). In rare situations, THCA presents as HCA variants also known for conventional HCA, e.g., pigmented HCA with nuclear beta-catenin reactivity and positivity for glutamine synthetase (Hechtman et al. 2011). Apart from associations known for other types of HCA, THCA was observed in primary sclerosing cholangitis (Maylee et al. 2012).

Notwithstanding the novel classification of telangiectatic nodular lesions, not all telangiectatic nodular lesions are HCA or IHCA, and a small subset of nodules may in fact still be FNHs or other hyperplastic nodular lesions with an abnormal vascularization pattern (Laumonier et al. 2010). THCA has histologically to be distinguished from nodular hyperplasic lesions with central telangiectatic fibrosis occurring in non-cirrhotic portal hypertension (Nakanuma et al. 1982).

Pigmented Liver Cell Adenoma

A mild lipofuscinosis occurs in some HCA, but other pigment depositions are exceptional. Few cases of pigmented HCA with deposition of Dubin-Johnson-like pigment have been reported (Bernard et al. 2000; Hasan et al. 2000; Ferko et al. 2003; Masuda et al. 2011; Koea and Kua 2012; Vij et al. 2012; Figs. 2 and 3). In one female patient, pigmented HCA was detected following long-term use of phenobarbital (Ferko et al. 2003). Multiple pigmented HCAs were observed in a male patient. The cut surfaces of these large and multinodular tumors had a few pale nodules of variable size standing out against

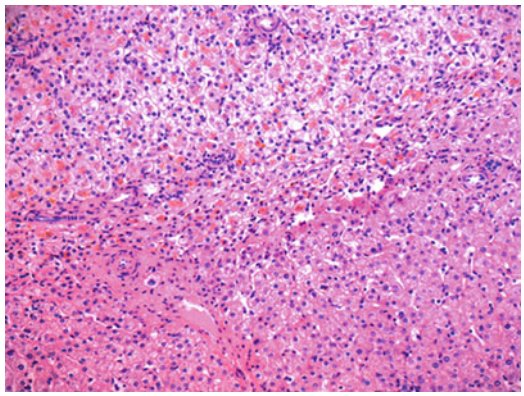

Fig. 2 Hepatocellular adenoma with accumulation of *yellow-brown,* Dubin-Johnson-like pigments (pigmented hepatocellular adenoma*, upper* half of figure; hematoxylin and eosin stain)

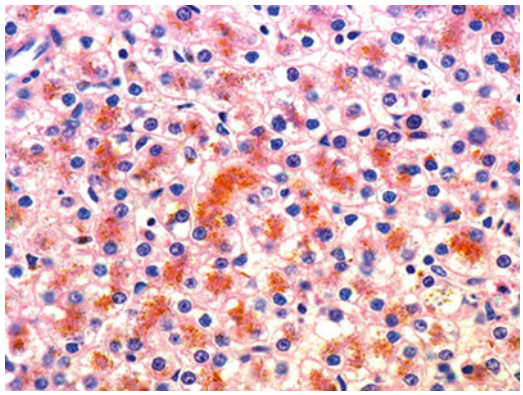

Fig. 3 Pigmented hepatocellular adenoma at higher magnification. Note the marked accumulation of Dubin-Johnson-like pigment granules in tumor cells, usually close to the canalicular pole of the cells (hematoxylin and eosin stain)

an overall strikingly dark gray or black color of the tumors. Histologically, most neoplastic cells are loaded with dark brown granules of Dubin-Johnson-like pigment, reactive in the Fontana-Masson stain and variably PAS-positive, whereas cells from the pale nodules were almost devoid of this pigment. Also ultrastructurally, the pigment granules strongly resemble those in Dubin-Johnson syndrome (Bernard et al. 2000). The accumulation of such a pigment in HCA in the absence of Dubin-Johnson syndrome is striking. In one case, the tumor showed a complete CD34-immunostaining pattern (Vij et al. 2012).

Dubin-Johnson syndrome is characterized by conjugated hyperbilirubinemia and by impaired secretion of anionic non-bile salt conjugates from hepatocytes into bile and is caused by the absence of multidrug-resistance protein 2 (MRP2; ABCC2), an ATP-dependent conjugate export pump at the canalicular membrane. Interestingly, a further case of "black" HCA (multiple tumors) showing a Dubin-Johnson-like pigment exhibited a decreased expression of cMOAT in the tumors in comparison with normal tissue, suggesting a partial defect of the MRP2 transporter in the neoplastic lesion (Bernard et al. 2000).

Ectopic Liver Cell Adenoma

Interestingly, a lesion morphologically similar to HCA occurs in the placenta (hepatic or hepatocellular adenoma of the placenta; Willis 1968; Chen et al. 1986; Fiutowski and Pawelski 1996; Vesoulis and Agamanolis 1998; Khalifa et al. 1998; Dargent et al. 2000). The case of Willis (1968) may rather represent hepatic heterotopia in the placenta. This is an extremely rare, solitary non-trophoblastic placental lesion of still disputed histogenesis. The tumor is incidentally found in woman between 20 and 30 years of age and is usually small, up to 1 cm. The histology is close to hepatic HCA, but fetal-type cells were reported to occur (Chen et al. 1986). It has been hypothesized that placental hepatocellular adenoma may take its origin from displaced yolk sac cells undergoing hepatocyte differentiation, a growing remnant of a fetus amorphous, a growing liver cell ectopia, or from a monodermal teratoma.

Hepatocellular Adenomatous Tumors of Doubtful Dignity

Atypical Hepatocellular Tumors Occurring in Fanconi Anemia

In some situations, HCA present with an unusual gross and/or microscopic presentation, being situated between bona fide HCA and highly differentiated HCC ("borderline lesions").

Interestingly, this has several times been documented and discussed for hepatocellular tumors developing in patients with Fanconi anemia (FA) and this may not only be related to not yet established dignity criteria in these partially older reports. Notwithstanding the fact that FA patients received corticosteroid and/or androgen therapy similar to other patients with different disorders, a disproportionally large number of liver tumor cases have been reported in FA (review: Schmidt et al. 1984). In part of these patients, a diagnosis of bona fide HCC can be confirmed by the histologic findings (Sarna et al. 1975; Cap et al. 1983; Abbondanzo et al. 1986; Moldvay et al. 1991). However, the data in the literature referring to hepatic tumors in FA do not always allow to clearly identify the type of liver lesions, because some masses were termed "hepatic tumors" (Farrell 1976; Shapiro et al. 1977; sometimes regressing subsequent to bone marrow transplantation with steroid weaning; Schmidt et al. 1984) and because some of the "hepatomas" reported may have had an unusual course (Sarna et al. 1975; Holder et al. 1975; Chandra et al. 1984). Is there a distinctive phenotype in hepatic neoplasms arising within the context of androgen therapy as such, or is the genotype of androgen- or corticosteroid-treated FA exerting a specific influence? In 1975, Anthony reviewed reports of 12 hepatocellular tumors associated with androgens, most of which had been originally reported as HCC (Anthony 1975). Employing strict histologic criteria, he accepted only two cases as having HCC, although other experienced pathologists have felt that some of the cases not accepted by Anthony were histologically malignant (Johnson 1975). Another group of experts had the opinion that of the cases reported since then, none would meet Anthony's criteria for malignancy, supported by the unusually benign course and even a tendency to regress after discontinuation of the therapy (Shapiro et al. 1977). Analysis of published reports raise doubts as to the appropriateness to call some of the lesions malignant: with the possible exception of the case described by Mokrohisky and coworkers (1977), death was not related to the presence of tumor, metastases not being observed, about half of the cases being incidentally detected at autopsy, and regression occurring in part of the tumors on discontinuation of androgen therapy (Johnson et al. 1972; Farrell 1976; Schmidt et al. 1984). In particular, the most appropriate terminology for the hepatocellular neoplasms associated with androgen therapy and/or arising in FA remains disputed. It has, therefore, been proposed to employ the term "hepatocellular neoplasm" for these unusual situations and to use HCA for clearly benign and HCC for clearly malignant lesions (Shapiro et al. 1977). Hence, it seems worthwhile to look at some of these published lesions in some more detail. The case of Holder and coworkers was described as a 4 cm tumor occurring in a non-cirrhotic liver, apparently "avascular" in a technetium scan; the lesion was described as "differentiated hepatoma," but a histologic description was not given (Holder et al. 1975). A tumor identified as "hepatoma" arising in a FA patient receiving androgen therapy was described as clinically and biologically "silent" (Meadows et al. 1974). In an 11-year-old boy with FA treated with androgens, corticosteroids, and transfusions, the liver showed peliosis and multiple tumors histologically representing well-differentiated hepatocellular carcinoma, a lesion being exceedingly rare in this age group (Moldvay et al. 1991). An informative case was described by Shapiro and coworkers (1977). This 13-year-old boy with FA treated with androgens and corticosteroids developed multiple liver nodules ranging in diameter from 0.5 to 4 cm, the larger nodules being hemorrhagic. The smaller nodules consisted of liver cell plates two cells thick, whereas the larger nodules were arranged in trabeculae and acini, the former not fulfilling the criteria of malignancy, while the latter were compatible with well-differentiated HCC. A striking feature was the marked cholestasis of the nodules. Among four patients with aplastic anemia (three with FA) having received oxymetholone (Chandra et al. 1984), all developed two to three unencapsulated, in part bulging nodules in their livers, the diameters ranging from 0.3 to 5 cm, histologically showing cells with enlarged nuclei, prominent nucleoli, scattered binucleate cells, and occasional

multinucleated cells, in the absence of mitotic activity or vascular invasion. Acinar formation was observed in two cases, and canalicular bile plugs were prominent in the nodules in all four. These changes were not detected in the non-androgen-related cases examined in parallel. Iron pigment was noted in the nodules, which is usually excluded from HCC. The authors concluded that these atypical lesions have an unknown malignant potential (Chandra et al. 1984). It therefore appears that in patients with androgen therapy, and in particular those with FA, a distinctive type of hepatocellular tumor may occur, whose biologic features require further investigation ("androgen hepatomas"; "Fanconi hepatomas").

Atypical Hepatocellular Adenoma-Like Neoplasms with Beta-Catenin Activation

A recently described tumor and termed atypical hepatocellular adenoma-like neoplasm with similarities to well-differentiated HCC is characterized by beta-catenin activation and cytogenetic features shared by well-differentiated HCC. In these neoplasms resembling HCA, beta-catenin mutations were more frequent (35 %), and transition into frank HCC was found in 1 out of 40 cases (Evason et al. 2013). It remains to be further studied whether such lesions are transitions between b-HCA and low-grade HCC.

Combined Hepatocellular-Cholangiocarcinoma

26

ICD-O code 8180/3

Contents

Abstract

Combined hepatocellular-cholangiocarcinoma (CHCC-C) is defined as a tumor that contains unequivocal, intimately mixed elements of both hepatocellular carcinoma and cholangiocarcinoma, resulting in a biphenotypic histologic picture. CHCC-C should not be confounded with collision tumors or rare hepatic mixed tumors. This is a rare liver malignancy of older individuals, probably accounting for less than 5 % of hepatic malignancies. The neoplasm develops in both non-cirrhotic and cirrhotic livers. Etiologic factors include hepatitis virus infections and alcoholic liver disease.

CHCC-C usually presents as a solitary tumor mass. Similar to hepatocellular carcinoma, the tumor tends to invade the portal vein system and bile ducts. Based on distinct histologic patterns, several types of CHCC-C are distinguished in the WHO classification, including a classical type and a type with stem cell features, the latter further subdivided into at least four subtypes. Rare variants of CHCC-C contain sarcomatoid components, or the HCC component is that of fibrolamellar hepatocellular carcinoma. CHCC-Cs are usually highly aggressive lesions with a high rate of metastatic spread.

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_26

Introduction

The WHO tumor classification (Theise et al. 2010) defines combined hepatocellular-cholangiocarcinoma (CHCC-C) as a tumor containing unequivocal, intimately mixed elements of both hepatocellular carcinoma (HCC) and cholangiocarcinoma (CC). This biphenotypic tumor should be distinguished from separate HCC and CC arising in the same liver: Such tumors may be separated or intermixed ("collision tumor").

Combined hepatocellular and cholangiocellular carcinomas are an uncommon type of primary liver cancer with a distinct clinicopathologic presentation. Carcinomas of the liver having features of both hepatocyte and cholangiocyte lineages have formerly been reported under various names, including mixed tumors (L'Esperance 1915; Ewing 1940), primary duplex liver carcinoma (Koster and Kasman 1952), intermediate-type carcinoma (Bonne 1937), carcinoma of dual origin (Gustafsen 1937/1938), and cholangiohepatoma (Warvi 1944). In 1940, the term, combined type – adenocarcinoma and hepatoma – was first employed in a New England Journal of Medicine case presentation (Cabot 1940). More recent and now more commonly used names comprise combined hepatocellular-cholangiocarcinoma, combined hepatocellular/cholangiocellular carcinoma, combined hepatocholangiocarcinoma, and hepatocholangiocarcinoma. CHCC-C was first described in a comprehensive way in 1949 by Allen and Lisa, who also presented a first classification scheme for these neoplasms, and was recently reviewed (Lee et al. 2013; Singh et al. 2013; O'Connor et al. 2014).

Epidemiology

CHCC-C is a rare lesion; the reported frequency among adults with primary liver malignancies varies, however, widely, from a rate of 2.4 % (Goodman et al. 1985) to 5.3 (Ng et al. 1998) and even 14.2 % (Allen and Lisa 1949). Among 302 explant specimens of patients transplanted for HCC, 10 (3.3 %) showed CHCC-C (Sapisochin et al. 2011). Based on the SEER population-based registry (1973–2004), the frequency is lower and amounts to 0.87 % of primary liver tumors (Wachtel et al. 2008). The first example of CHCC-C may have been reported in 1903 (Wells 1903), followed by a report in 1915 (L'Esperance 1915), the latter author using the term mixed tumor. Relatively few cases have been reported until 1950 (Goldzieher 1928; Tramontano and Fittipaldi 1930; Koster and Kasman 1932; Rasario 1934, 1937; Bonne 1937; Gustafsen 1937/38; Cabot 1940; Ewing 1940; Neumann 1944; Warvi 1944; Allen and Lisa 1949). In few early reports on HCC, the data were very suggestive that bile duct cells participated in the malignant process (Prescott 1895; Moon 1929; Larson 1937; Neumann 1944; reviewed by Allen and Lisa 1949).

The mean patient age at diagnosis was 61 years in one study (range, 41–79 years; Jarnagin et al. 2002) and 55 years in a study on 43 patients (Park et al. 2011a). CHCC-C shows a variable male preponderance. The gender distribution varies considerably among several investigations. Among 27 cases, there were 88.9 % males and 11.1 % females (Zhan et al. 2012). In another study on 27 patients, 52 % were men and 48 % women (Jarnagin et al. 2002). The figures of the latter study are intermediate between HCC (67 % men and 33 % women) and CC (30 % men and 70 % women). In an analysis of 465 patients with CHCC-C compared with HCC and cholangiocarcinoma, this neoplasm was more common in patients who were white, male, and older than 65 years (Garancini et al. 2014). CHCC-C develops in cirrhotic or non-cirrhotic livers (Shiraishi et al. 1998; Zhan et al. 2012), cirrhosis having been found in 4 % (Jarnagin et al. 2002), 37 % (Zhan et al. 2012), 39 % (Taguchi et al. 1996), 54.2 %(Koh et al. 2005), and 77.8 % (Ng et al. 1998) of cases. These variable prevalences may be related to marked variations in the presence of factors causing liver cirrhosis, mainly epidemiological differences in the frequency of HBV and HCV infections. In certain regions, CHCC-C is associated with HBV infection (Chu et al. 2014). Interestingly, the study of Taguchi et al. (1996) has shown that cirrhosis was

more frequent in those tumors that had more features in common with HCC than in the cumulated group of CHCC-C (55 % vs. 39 %). In a study on 25 cases of CHCC-C, there was no statistical difference in etiologic risk factors between CHCC-C and HCC patients in regard to the presence of liver cirrhosis, chronic alcohol abuse, presence of hepatitis B surface antigen, and presence of hepatitis C virus/HCV antibody (Chantajitr et al. 2006). In a Japanese group of patients, the anti-HCV-positive rate was high in CHCC-C as in HCC (Tomimatsu et al. 1993). In a more recent investigation, risk factors for CHCC-C development included HBV infection, heavy alcohol consumption, a family history of liver cancer, and diabetes mellitus (Zhou et al. 2014). What can we learn from these observations? It emerges that, similar to HCC, there seem to be marked etiologic differences between patients of different countries with CHCC-C. For example, patients from Hong Kong had a high prevalence of cirrhosis and chronic hepatitis (Ng et al. 1998), while Japanese patients with CHCC-C often have chronic HCV infection (Tomimatsu et al. 1993). It has been suggested that, in Western populations, viral infection of the liver and cirrhosis may represent risk conditions for CHCC-C (Portolani et al. 2008).

Clinical and Imaging Features

CHCC-C in principle presents as other primary malignancies of the liver, but has shown some differences in comparison with cholangiocarcinoma: CHCC-C has a lower incidence of fever, chills, and jaundice, but a higher incidence of fatigue and weakness (Lee et al. 2002). Raised serum AFP levels (above 300 ng/ml) were present in 61.5 % of 21 patients (Ng et al. 1998). Elevation of serum AFP was found less commonly than in HCC (in one study, 46.2 % of CHCC-C patients had high AFP vs. 60.3 % in HCC; Tang et al. 2006), and the serum AFP levels in CHCC-C were found to be lower than those found in HCC (Chantajitr et al. 2006). High levels of serum AFP, CEA, and CA19-9 are regarded as a typical combination in CHCC-C (Nakamura et al. 1996). CHCC-C is more frequently associated with liver cirrhosis than intrahepatic cholangiocarcinoma (Lee et al. 2006). CHCC-C has been found in association with cholangitis (Yarze et al. 2005) or hepatolithiasis (Deniz et al. 2011). CHCC-C can be associated with paraneoplastic syndromes, including tumoral hypercalcemia (Pérez Roldan et al. 1995; Maarouf et al. 2008) and dermatomyositis (Horie et al. 1989). In patients with tumor-associated hypercalcemia, secretion of PTH-rP was detected (Maarouf et al. 2008; Matsumoto et al. 2014).

At sonography, the tumors are typically round or ovoid hypoechoic masses with a central hyperechoic area (target appearance) in most patients (Choi et al. 1994; Zhou et al. 2007). CT has shown irregular or relatively well-delineated hypodense or isodense masses with variable contrast enhancement (Aoki et al. 1993; Choi et al. 1994; Omagari et al. 1995; Hanazaki et al. 1998; Toh et al. 2004; Nishie et al. 2005; Sanada et al. 2005; Phongkitkarun et al. 2007; Shin et al. 2007; Hwang et al. 2012; Shetty et al. 2014). Hypervascular tumors are a common feature (Uenishi et al. 2000), supported by characteristic angiographic findings (Choi et al. 1994). Tumors with a large HCC component were well enhanced in the early CT phase and changed to low attenuation areas in the late phase. Conversely, in lesions grossly resembling CCC, the majority of the masses were enhanced only at the peripheral portions in the early phase and changed to low attenuation areas or had only central portions enhanced in the late phase (Fukukura et al. 1997). The distinct arrangement of the two main tumor components can result in imaging features resembling focal nodular hyperplasia (Willekens et al. 2009). It was demonstrated that the presence of a significant component of intermediate cells can cause misdiagnosis of CHCC-C on enhanced CT (Nishie et al. 2005). Rarely, the tumors have shown cyst formation at imaging (Utsunomiya et al. 2000). At axial MR, tumors are hypointense on T1-weighted scans and hyperintense in T2-weighted images (Hashimoto et al. 1994; Zhou et al. 2007; Fowler et al. 2013). In PET, CHCC-C showed high F18 deoxyglucose uptake (Shiomi et al. 1999).

Although there are consistent imaging findings in patients with CHCC-C, preoperative diagnosis remains difficult without tumor biopsy, even together with serum AFP and CA 19-9 results, because too many of the features are shared with both HCCs and CCs (Panjala et al. 2010). Among 15 patients with CHCC-C, only 2 patients were reliably diagnosed by enhanced CT prior to operation, the other 13 patients being diagnosed by histopathology and immunohistochemistry after operation (Zuo et al. 2007).

Pathology

Macroscopy

In most cases, CHCC-C presents a solitary tumor mass (de Campos et al. 2012), with rubbery, often ill-defined, whitish-yellow masses, while the HCC component may be visualized as tan or greenish nodules (Sonobe et al. 1987; Sugihara et al. 1987). Similar to HCC, CHCC-Cs tend to invade large veins, in particular the portal vein. Growth into the common bile duct has also been observed (Saito et al. 2001).

Histopathology

CHCC-C, Classical Type

The most common and typical form of CHCC-C (CHCC-C, classical type according to the WHO classification) displays areas of HCC and areas of cholangiocarcinoma, the latter most often of the intrahepatic type with variable desmoplasia (Sugihara et al. 1987; Bedossa 2007; Theise et al. 2010; review: Yeh 2010; Figs. 1 and 2). The HCC component in cases where it can easily be identified varies markedly in regard to composition and grade. Classical trabecular areas composed of moderately to well-differentiated large and eosinophilic cells as seen in ordinary HCC occur, but sometimes the HCC component is of the poorly differentiated small cell type, classification as HCC certainly requiring immunohistochemistry (Kim et al. 2004a). The cholangiocarcinoma component can present with

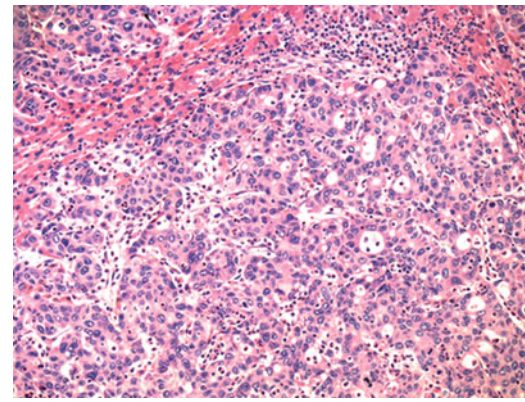

Fig. 1 Combined hepatocellular-cholangiocarcinoma. Apart from HCC-like cell plates, the neoplasm contains tubules and cribriform structures (hematoxylin and eosin stain)

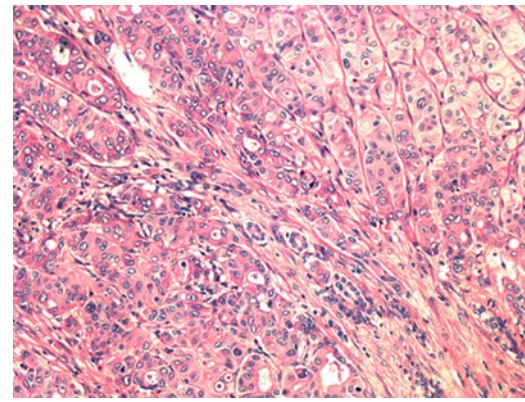

Fig. 2 In this combined hepatocellular-cholangiocarcinoma, the trabecular HCC component is readily discernible (*right upper* part). The *lower left* part of the figure shows tubular profiles (hematoxylin and eosin stain)

all the characteristic histologic features of intrahepatic CC and may show excessive mucin production (Wada et al. 1986; Morita et al. 2006) or undergo marked squamous cell differentiation/metaplasia (Tsuneyama et al. 2003). Sometimes, the mixed differentiation only reveals itself in metastases. For example, one tumor presented as HCC in the primary lesion, while intrahepatic metastases showed the typical features of CHCC-C (Morita et al. 2006).

CHCC-C often contains so-called transitional areas showing cells morphologically intermediate

between HCC and CC cells. Areas with an antler-like morphology were described, characterized by small or intermediate-sized cells being arranged in an antler-like anastomosing pattern (Tickoo et al. 2002; Park et al. 2011b). Areas of transition were found in at least 25 % of tumors in one analysis (Tickoo et al. 2002) and in all cases of another study, with strands/trabecules of small, uniform, and oval-shaped cells with scant cytoplasm and hyperchromatic nuclei, often embedded in a desmoplastic stroma (Zhang et al. 2008). The small cells found in transition areas look undifferentiated and share features with progenitor cells (Theise et al. 2003). In some tumors, the intermediate area is composed predominantly of spindle cells arranged in short fascicles (Park et al. 2011b).

Subtypes with Stem Cell Features

In a subset of CHCC-C, cells with progenitor cell features predominate. These CHCC-Cs with stem cell features include all three types of stem cell forms that have been described as components of CHCC-C (Theise et al. 2010; Akiba et al. 2013). The stemlike cells present in these malignancies are reactive for putative stem cell markers, including NCAM/CD56, CD133, EpCAM, CK19, and KIT, and in part express delta-like 1 homolog/DLK1 (Ikeda et al. 2013) and Yes-associated protein 1/YAP1 (Kim et al. 2013). There is evidence that CHCC-Cs with stem cell features and a stem cell component of more than 5 % have a poorer prognosis (Ikeda et al. 2013). At least four subtypes of CHCC-C with stem cell features have been described:

1. CHCC-C with stem cell features, typical subtype

   This subtype shows centrally placed clusters or nests of mature-looking hepatocytes (sometimes with clear cell change) with peripheral clusters of small cells with a high nucleus-to-cytoplasm ratio and hyperchromatic nuclei. These smaller cells are reactive for cytokeratins 7 and 19, NCAM1/CD56, KIT, and/or EpCAM, thus showing a progenitor cell phenotype. The progenitor-like cells may be embedded in a rich desmoplastic stroma. Typical subtype components were detectable in 16.1 % of CHCC-C (Sasaki et al. 2014).
2. CHCC-C with stem cell features, intermediate cell subtype

   This is a CHCC-C variant in which the predominant neoplastic cell population consists of cells with features intermediate between hepatocytes and cholangiocytes. This subtype is the most common one (Sasaki et al. 2014). Among 54 cases of CHCC-C from South Korea, 13 cases were of the intermediate type and demonstrated strands/trabecules of small, uniform, round-to-oval cells with scanty cytoplasm and hyperchromatic nuclei embedded within a thick desmoplastic stroma (so-called primary liver carcinoma of intermediate/hepatocyte-cholangiocyte phenotype; Kim et al. 2004a). The undifferentiated tumor cells are small and oval shaped with hyperchromatic nuclei and poor cytoplasm. Usually, these cells are embedded in an abundant desmoplastic stroma, where they form trabecules, solid nests, or strands. Well-developed glandular structures with mucin production are not present, but one may note few elongated and ill-defined gland-like profiles. Typically, the neoplastic cells co-express hepatocyte (Hep Par1 and AFP) and cholangiocyte (cytokeratin 19 and CEA) lineage markers, and KIT expression is common. The expression of CD133 and vimentin was found only in the intermediate cell subtype (Akiba et al. 2013). The cells, therefore, reflect an intermediate phenotype derived from a bipotential progenitor cell.
3. CHCC-C with stem cell features, cholangiocellular type

   This variant mainly consists of small cells with hyperchromatic oval nuclei, growing in the form of glandular structures and the "antler-like" pattern described above. Again, these primitive glandular cells are embedded in a desmoplastic stroma. The cells and their formations seem to mimic von Hering's canals or cholangioles. This is supported by their immunophenotype, characterized by positivity for cytokeratin 19, KIT, NCAM/Cd56, and

EpCAM. HCC-like and/or CC-like areas are often present at the periphery of the tumor nodules, where also a replacing pattern of growth is seen (Theise et al. 2010).

4. CHCC-C with stem cell features, ductal plate malformation type

   Intrahepatic cholangiocarcinoma with features of ductal plate malformation (DPM) has recently been described. A very rare variant of CHCC-C with stem cell features also shows DPM-like alterations. The index neoplasm was composed of well-differentiated HCC, well-differentiated cholangiocarcinoma, and intermediate tumor elements. Cholangiocarcinoma cells were present as tortuous, markedly irregular tubules with intraluminal cell projections, bridge formation, and intraluminal neoplastic biliary cells, features resembling ductal plate and DPM (Terada 2013).

Cytology

The presence of a dual cell population with features of malignancy in fine needle aspirates should raise the possibility of CHCC-C (Kilpatrick et al. 1993; Gibbons and de las Morenas 1997). However, the reliable diagnosis of CHCC-C on cytologic preparations alone is fraught with difficulty (Dusenbery 1997), particularly in the presence of so-called intermediate cells that have lost classic cytologic features of both HCC and CC (Wee and Nilsson 1999), so that additional methods, in particular immunocytochemistry, is strongly advocated.

Immunohistochemistry

The cells of the CC component are reactive for CK7 and CK19, as normal cholangiocytes (Goodman et al. 1985; Fisher et al. 1988; Hauben et al. 1996; Taguchi et al. 1996; Uenishi et al. 2002; Maeda et al. 2005), and for epithelial membrane antigen/EMA (Haratake and Hashimoto 1995; Tickoo et al. 2002). Positivities for CK7, CK19, and CK20 were 86.4 %, 90.9 %, and 18.2 %, respectively (Zhan et al. 2012). The hepatocyte-type population is reactive for cytokeratins 8 and 18 (Fisher et al. 1988) and for Hep Par1, but this marker is also expressed by a portion of the CC-type cells (Leong et al. 1998), in contrast to ordinary cholangiocarcinoma, where the tumor cells are usually not reactive for Hep Par1 (Kakar et al. 2003; Figs. 3, 4, and 5).

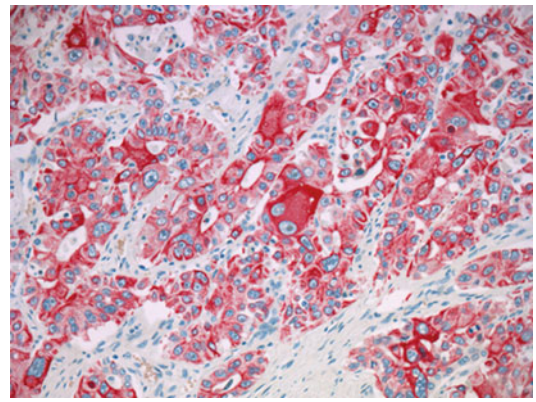

Fig. 3 Combined hepatocellular-cholangiocarcinomas exhibit heterogeneous immunostaining for cytokeratins 8 and 18, columnar cholangiocarcinoma cells often showing a more faint staining (CAM 5.2 immunostain)

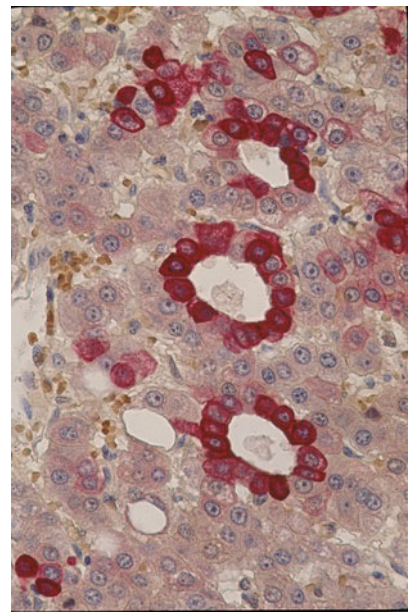

Fig. 4 Combined hepatocellular-cholangiocarcinoma with strong cytokeratin 19 expression of tubular, cholangiocellular structures (CK19 immunostain)

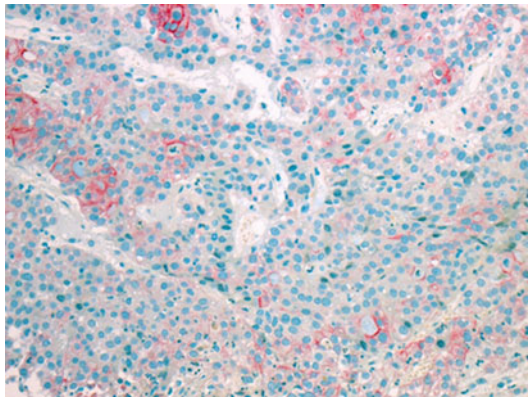

Fig. 5 In this combined hepatocellular-cholangiocarcinoma with predominance of HCC components, cytokeratin 19 is only focally expressed (CK19 immunostain)

The hepatoid cells in CHCC-C are reactive for glypican-3 (Shirakawa et al. 2009). It has been shown that cells that are morphologically intermediate between hepatocytes and cholangiocytes (cells of the transitional area) co-express CK19 and Hep Par1 (Tanaka et al. 2004). Simultaneous co-expression of Hep Par1 and CK7 or CK19 was demonstrated in 83.3 % of cases, and expression of c-kit was noted in 83.3 %, of which 70 % showed co-expression of OV-.6 (Zhang et al. 2008). Cells of the HCC component are reactive for AFP to variable degrees (Maeda et al. 2005). AFP reactivity was found in 55 % of tumors (Ng et al. 1998).

The CC components of CHCC-C rarely express the apomucins, MUC3 and MUC5AC, but they widely express MUC6 and MUC7, similar to certain subsets of cholangiocarcinomas (Sasaki et al. 1998). Immunoreactivity for E-cadherin and beta-catenin is present to variable degrees and may be used as prognosticator. E-cadherin and beta-catenin expressions are correlated with tumor differentiation and tumor progression in CHCC-C. Reduced expression of E-cadherin was significantly correlated with the tumor grade of HCC and CC components, intrahepatic metastases of HCC and CC components, and vascular invasion. There was a significant relationship between reduced expression of beta-catenin and the tumor grade of HCC components. The expression patterns of E-cadherin and beta-catenin of intrahepatic metastases were similar to those of the primary lesions in most cases (Asayama et al. 2002). CHCC-Cs express hepatocyte growth factor (HGF) and its receptor c-met. Immunoreactivity for HGF was significantly correlated with the differentiation degree of the CC components, being highest in well- and moderately differentiated and lowest in poorly differentiated components. No association was observed between expression of c-met or HGF and the presence of liver cirrhosis, vascular invasion, perineural invasion, lymphatic permeation, intrahepatic metastasis, or lymph node metastasis (Varnholt et al. 2002).

In Situ Hybridization (ISH)

ISH methods have been used as a diagnostic method in CHCC-C. Among 23 cases of CHCC-C, 96 % showed positive signals on ISH for albumin mRNA (Tickoo et al. 2002). Positivity for albumin mRNA and biliary markers confirms the biphenotypic differentiation in these tumors.

CHCC-C Combined with Other Tumors in the Liver

CHCC-C was found in combination with other liver tumors, e.g., hepatic angiosarcoma in a patient with thorotrastosis (Kojiro et al. 1982).

Classifications of CHCC-C

Macroscopically, the tumors have been classified according to variable criteria. Grossly, CHCC-C presents either as single nodular (SN) type or multinodular (MN) type (Sasaki et al. 2001). The nodular phase of CHCC-C can progress to a diffuse type of growth (Yoshida et al. 1985). Another group separated a more common HCC-predominant type from a CC-predominant type and from a separate-lesion type (Taguchi et al. 1996). Allen and Lisa (1949) proposed

Table 1 Allen-Lisa classification of CHCC-C (modified)

Type I
Separate tumors consisting of either hepatocyte-type cells or cholangiocyte-type cells
Comment:
Allen-Lisa Type I tumors seem to correspond to the collision tumors described by Goodman et al. (1985; see Table 2). This tumor type does no longer belong to CHCC-C *sensu strictiori* according to the WHO classification of tumors (Theise et al. 2010)
Type II
Contiguous tumors, each of different characters, that may mingle as they grow
Comment:
Allen-Lisa Type II tumors seem to correspond to the Type II tumors of Goodman et al. (1985; see Table 2)
Type III
Tumors that may display hepatocellular and cholangiocellular features intimately associated
Comment:
Allen-Lisa Type III tumors seem to correspond to a subset, but not all, of the tumors allocated to Type III of Goodman et al. (1985)

Table 2 Histopathological types of CHCC-C according to Goodman et al. (1985) (modified)

Type I
HCC and CC are clearly distinguished and are present as separate lesions at different sites within the same liver
Comment:
These are "collision tumors" or an apparently coincidental occurrence of HCC and CC within the same liver and may thus not represent bona fide CHCC-C. Therefore, they do not fulfill the WHO definition of classical CHCC-C
Type II
HCC and CC are contiguous, are present at adjacent sites, mingle with continued growth, and share transitional features
Comment:
These are "transitional tumors" showing a transition from HCC elements having a trabecular or solid pattern to components typical for CC having a tubular pattern and a fibrous stroma
Type III
HCC and CC are combined within the same tumor
Comment:
This is the intermediate type in which HCC elements and CC elements are almost indistinguishable, and the tumor cells are ovoid to round and show a solid growth and/or a cord-like pattern. The cells are considered to be intermediate in shape and structure between HCC and CC
In Goodman et al.'s original work (1985), part of these tumors contained a "fibrolamellar component" which resembles FLC, but which contains mucin-producing pseudoglands. It is this type which has led to considerable diagnostic and interpretational problems and hence to misunderstandings

three combinations of tumors of, as they called it, double nature, and this proposition entered in all future attempts at classifying CHCC-C. They distinguished (1) separate neoplastic masses comprised entirely of the liver cell type on the one hand and of the bile duct type on the other; (2) contiguous masses, each of different characters, which may mingle as they grow; and (3) individual masses that may display both features so intimately associated that they can be interpreted only as arising from the same site (Table 1). Later publications sometimes used Allen Types A, B, and C instead of Types I, II, and III.

Goodman et al. (1985) distinguished a collision type, apparently a coincidental occurrence of both HCC and CC in the same patient; a transitional type, with areas of intermediate differentiation and an identifiable transition between HCC and CC; and a fibrolamellar type which resembles the fibrolamellar variant of HCC but also contains mucin-producing pseudoglands (Table 2).

The separate (or separate-lesion) type seems to correspond to Goodman's collision type and is particularly rare (Hirohashi et al. 2002). It is defined by the synchronous presence of HCC and CC within the same liver as spatially separated lesions. To classify the separate-lesion type as CHCC-C is problematic because there is no evidence that the two tumors occurring in this situation have the same cellular origin. This is the reason why the WHO classification does not list this variant as a classical CHCC-C. In one series of lesions, Type I accounted for 17 %, Type II 66 %, and Type III 17 % (Taguchi et al. 1996).

An alternative classification was proposed by Wakasa et al. (2007). These authors distinguished: Type I, in which HCC and CC form nodules that can easily be distinguished from each other; Type II, in which both components are finely mixed, so that the two components are almost indistinguishable; and Type III, in which the tumors have

Table 3 Classification of CHCC-C according to the WHO tumor classification (2011)

CHCC-C, classical type
CHCC-C with stem cell features
Typical subtype
Intermediate cell subtype
Cholangiocellular subtype

lobular structures with HCC existing centrally and CC existing peripherally. The classification by the WHO is listed in Table 3.

Combined Hepatocellular and Cholangiocellular Carcinoma with Sarcomatoid Features

In a small subset of CHCC-Cs, sarcomatoid histologic features have been observed (Kimoto and Ugaki 1982; Nakajima et al. 1988; Nakasho et al. 1996, Papotti et al. 1997; Murata et al. 2001; Jeong et al. 2004; Kim et al. 2004b; Amano et al. 2005; Aishima et al. 2006; Boonsakan et al. 2007; Pua et al. 2009), similar to those known to occur in non-combined cholangiocarcinomas and hepatocarcinomas. These rare tumors have also been termed CHCC-C with sarcomatous transformation or with sarcomatous change. In one case, glandular areas of CHCC-C expressing mucins and AE1-reactive keratins showed transition toward a spindle cell sarcomatous growth in several areas of both the primary tumor and lymph node metastases. Based on S100 protein reactivity of the spindle cells, a Schwannoid cell differentiation was suggested (Papotti et al. 1997). Within the spindle cell areas, pleomorphic elements and osteogenesis have been observed (Nakajima et al. 1988), and the sarcomatous component can be dominated by vimentin-positive pleomorphic cells (Pua et al. 2009). The spindle cell component was immunoreactive for cytokeratins in one case (Jeong et al. 2004), suggesting mesenchymal-epithelial transition (MET) in these tumors. In one case, the tumor produced granulocyte colony-stimulating factor (Amano et al. 2005), a paraneoplastic phenomenon also known for HCC. Microsatellite loss of heterozygosity (LOH) at D8S555 was detected in both the carcinomatous and sarcomatous portions. 1-bp cytosine was deleted at codon 241 of exon 7 of the p53 gene in the combined portion, and p53 protein nuclear immunoreactivity was seen in sarcomatoid HCC and CC cells, suggesting that the combined tumor could be an offspring of the original HCC (Murata et al. 2001).

Combined Hepatocellular and Cholangiocellular Carcinoma

Cholangiocellular carcinoma is a very rare variant of intrahepatic biliary cancer and is thought to arise from cell systems of von Hering's canals or ductules, structures that contain a stem cell compartment. In a 71-year-old male, a tumor was observed that was a combination of HCC and a cholangiocellular carcinoma, the latter showing cells immunoreactive for CK7, CK20, and CAM5.2, but not for CK19 (Kanamoto et al. 2008). This very rare variant of CHCC-C should not be confounded with a subtype of CHCC-C with stem cell features as defined in the new WHO classification of tumors (Theise et al. 2010).

Combined Fibrolamellar Carcinoma and Cholangiocarcinoma

Fibrolamellar carcinoma (FLC) very rarely occurs in association with cholangiocarcinoma/CC (FL-CC; Goodman et al. 1985; Maeda et al. 1995; Ng et al. 1998; Tanaka et al. 2005a; Ward et al. 2010). Although Goodman et al. (1985) reported that 8/24 CHCC-C revealed features of FLC, it is questionable that all these tumors contained bona fide FLC, as this combination was found only very rarely thereafter. The involvement of a biliary-related cell lineage in these tumors is suggested based on the frequent immunoreactivity of FLC for the cholangiocyte marker cytokeratin CK7 (Van Eyken et al. 1990), but only very few FLCs show morphologic evidence of cholangiocytes. Histologically, FL-CC shows the large eosinophil cells typical for FLC, these cells being embedded in the characteristic

lamellar fibrous stroma (Tanaka et al. 2005a). Combined FLC and CC (FL-CC) was shown to express this phenotype also in its metastases (Tanaka et al. 2005a). In most reported cases, the presence of a cholangiocyte lineage was demonstrated by mucin-producing cells in FL-CC, with mucicarmine- and Alcian blue-positive mucin in the lumens (Ng et al. 1998; Tanaka et al. 2005a). As in ordinary FLC, the hepatoid cells of FL-CC show so-called pale bodies, which ultrastructurally consist of filamentous material packed densely into membrane-bound spherical structures (Tanaka et al. 2005a). Immunohistochemically, CEA was exclusively expressed in the cholangiocyte component of the primary hepatic tumor, while it was expressed in both CC and FLC cells in metastatic and recurrent tumors. Hep Par1 was also expressed in both components (Tanaka et al. 2005a).

Fibrolamellar Carcinoma with Mucin Production

This is a very rare tumor, characterized by a fibrolamellar carcinoma component that shows intracellular mucin, thought to represent an aberrant cholangiocellular differentiation in the sense of a variant CHCC-C (Rosa and Mohammadi 2014).

Differential Diagnosis

A differential diagnosis that may be difficult in the absence of appropriate immunohistochemistry is HCC with acinar/pseudoglandular structures (Kondo and Nakajima 1987). HCC and CCC can also develop from separate dysplastic nodules (Kwon et al. 2002) or may synchronously develop at different places within the liver (Li et al. 2012).

Biology of Disease

CHCC-C is a tumor that often exhibits a highly invasive phenotype with frequent venous permeation, direct invasion into adjacent liver substance and tumor satellite formation, and poor outcome (Ng et al. 1998; Hayashi et al. 2006; Kim et al. 2010; Park et al. 2011a; Ariizumi et al. 2012; Chi et al. 2012; Zhan et al. 2012; Lee et al. 2013; reviews: Zhou et al. 2007; Kassahun and Hauss 2008) and produces lymphonodal metastases and remote metastatic spread (Sonobe et al. 1987; Pérez Roldan et al. 1995). Similar to CC and HCC, CHCC-C is also known to cause gross portal vein invasion (Sonobe et al. 1987), but CHCC-C is more invasive to the portal vein than HCC (Yano et al. 2003). The characteristics of spread seem to be related to the gross growth patterns of the tumors. CHCC-C of the single nodular type shows a pattern of infiltration similar to HCC, while tumors of the multinodular type resembled intrahepatic cholangiocarcinoma (Sasaki et al. 2001). CHCC-C tends to locally recur, even following apparently complete resection. The most common site of recurrence was the remnant liver (Shin et al. 2007). The biology of CHCC-C disease is affected by several risk factors. Based on CT and MRI investigations, univariate log-rank analysis of imaging findings revealed that tumor necrosis, bile duct invasion, major vascular branch invasion, multiplicity, bilobar distribution, locoregional lymph node involvement, regional organ invasion, distant metastasis, and ascites had adverse influences on overall survival. Multivariate Cox proportional hazard analysis demonstrated that major vascular branch invasion, regional organ invasion, and nodal and distant metastases were independent prognostic factors that adversely affected overall survival rates (Lin et al. 2008).

Some authors had proposed that CHCC-C behaves like HCC, but in fact a biliary cell component is now thought to confer a poorer prognosis (Wu et al. 1996), and CHCC-C can undergo rapid progression (Saboo et al. 2011; Garancini et al. 2014; Kim et al. 2014) In a study on 25 patients, the overall median survival of CHCC-C patients was 38 weeks while that of HCC patients was 54 weeks (Chantajitr et al. 2006). In 29 Korean patients with CHCC-C who underwent liver resection or liver transplantation, disease-free survival rates at 6 months, 1 year, and 3 years were 51.1 %, 38.3 %, and

25.6 %, respectively. Univariate analysis revealed that the TNM stage was significantly associated with disease-free survival and that CA19-9 above 37 U/ml was predictive of low overall survival (Kim et al. 2009). Early TNM stage (I and II) compared with advanced stage (III and IV) correlated with higher overall survival on univariate analyses (Bhagat et al. 2006). Patients with localized tumors who were selected for cancer-directed surgery (CDS) were strongly associated with improved survival (Wang et al. 2010). On the other hand, a comparative analysis of stage I tumors showed that CHCC-C had shorter time to recurrence than HCC and CC and shorter overall survival than HCC (Lee et al. 2011). Among 21 patients with CHCC-C having undergone resection and compared with resected HCC and CC, the 5-year survival was lowest in patients with CHCC-C (24 %), but was not significantly different from that in patients with CC (33 %) or HCC (37 %) (Jarnagin et al. 2002). In a study on 43 patients, 32 underwent resection with curative intent. After resection, 27 patients (84.4 %) had tumor recurrence during the follow-up period of 18 months, and the median time to recurrence was 13 months. Overall median survival period was 34 months (Park et al. 2011a). The outcome following surgical treatment may be influenced by the histologic composition of the tumors, specifically by the proportion of hepatocellular versus cholangiocellular components. In one study, the mean survival period was significantly longer in the HCC-dominant group than in the CC-dominant group (Shin et al. 2007). Among 50 patients with CHCC-C treated with transcatheter arterial chemoembolization (TACE), 70 % were classified as responders. The median patient survival period was 12.3 months. Tumor size, tumor vascularity, Child-Pugh class, and portal vein invasion were independent factors associated with patient survival (Kim et al. 2010).

Genetic and Molecular Features

Genetically, the highest frequency of LOH in CHCC-C was seen on 4q and 17p, followed by 8p and 16q, but the patterns were distributed heterogeneously among the tumors studied (Fujii et al. 2000). Recurrent specific LOH was identified at 3p and 14q in more than 50 % of CC and CHCC-C, suggesting that CHCC-C is genetically closer to CC than HCC (Cazals-Hatem et al. 2004).

Pathogenic Pathways

Morphogenetic and pathogenic pathways involved in CHCC-C can be studied by use of in vitro models. CHCC-C cell lines were established and tested in the nude mouse model (Murakami et al. 1987). In human CHCC-C cell line, cells were shown to express functional characteristics of HCC, such as albumin synthesis, but cells growing on plastic dish were poorly differentiated and exhibited an overlap to CC cells. When grown within a Type I collagen gel matrix, cell morphology changed to a better differentiated HCC phenotype, while cells grown in the subcutis of nude mice revealed the phenotype of adenocarcinoma with mucin production (Yano et al. 1996). These findings suggest a marked plasticity of tumor cells constituting CHCC-C and imply the involvement of bipotential progenitor cells. In fact, it has been suggested that most CHCC-C arise from hepatic progenitor cells that retained their potential to differentiated into the hepatocyte and cholangiocyte lineages (Robrechts et al. 1998; Tanaka et al. 1998, 2005b; Kim et al. 2004a; Libbrecht 2006; Hunt and Varnholt 2008; Zhang et al. 2008). The precursor cell systems involved in the development of CHCC-C are, however, not known in detail. In one instance, a small CHCC-C was found to arise in a nodule of atypical adenomatous hyperplasia of the liver (Harada et al. 1993), suggesting a hepatocyte origin of these lesions. A hepatocyte origin of CHCC-C was also proposed based on the expression pattern of ABH and Lewis blood group antigens (Okada et al. 1987). Theise and coworkers (2003) identified undifferentiated cells with morphological and immunohistochemical features of hepatic progenitor cells in all cases of CHCC-C, and these findings were supported by a later study (Zhang et al. 2008). In a cohort of 80 patients with

CHCC-C, including 70 patients who underwent resection with curative intent, overall survival and disease-free survival were correlated with the proliferative activity of non-tumoral ductular reaction cells and the expression of progenitor cell markers. It turned out that proliferative ductular reaction related to hepatic progenitor cell activation was associated with recurrence of CHCC-C, in particular multifocal recurrence, suggesting a "field" effect of background progenitor activation (Cai et al. 2012). Mutational analyses of p53 and K-ras genes and allelotype studies of the Rb-1 produced evidence that both cellular components of CHCC-C (i.e., HCC cells and CC cells) might have arisen from the same cellular origin in some cases (Imai et al. 1996).

Contents

Abstract

Carcinoma of the extrahepatic bile ducts is defined as an adenocarcinoma arising in proximal, middle third, and distal (lower third) parts of extrahepatic ducts. As anatomically a division of the duct system into thirds is artificial, novel classifications distinguish perihilar/hilar cholangiocarcinomas from those of the mid-region and the distal part of the common bile duct. For the definition of perihilar cancers, the separation point between intrahepatic and extrahepatic tumors is defined by the level of second-order bile ducts. Bile ducts located to the hepatic plate of the hilum correspond to extrahepatic bile ducts. The growth patterns and associated clinical sequelae vary as a function of anatomical location. Perihilar/hilar tumor forms concentrically stenosing lesions (Klatskin tumors). Tumors in the mid-region more commonly present as tubular lesion with thickening of the duct wall, whereas distal tumor more often shows an exophytic growth pattern. Histologically, the neoplasms are adenocarcinomas of the cholangiocyte lineage, usually associated with abundant stroma (desmoplasia). The cancers have a strong tendency for perineural and intraneural invasion, extension along bile ducts, and lymphatic spread.

Introduction

In the 2010 WHO classification, carcinoma of the extrahepatic bile ducts is defined as malignant epithelial neoplasm usually with biliary, intestinal, foveolar, or squamous differentiation, arising in the extrahepatic bile ducts. Perihilar cholangiocarcinoma (PHC, hilar cholangiocarcinoma, Klatskin tumor, Altemeier-Klatskin tumor) is one of the three major forms of cancer of the extrahepatic bile ducts. Extrahepatic cholangiocarcinomas had previously been identified as a distinct entity. The concept of PHC had been refined and is now defined as a complex disease with several phenotypes. The meaning of the terms, hilar and perihilar, differs in several respects between surgeons and pathologists (see below; review: Castellano-Megias et al. 2013).

Schueppel is credited with being the first to describe carcinoma of the hepatic duct in 1878 (cited in David 1932), followed by observations in 1889 (Musser 1889) and 1908 (Scudder and Richardson 1908). A case of chronic jaundice and massive hepatomegaly due to cholangiocarcinoma commencing at the junction of the hepatic ducts was reported in 1905 (Parkes Weber and Michels 1905). A clinical communication referring to carcinoma at the junction (confluens ductuum) appeared in 1928 (Pliveric 1928). The distinct desmoplastic feature of the neoplasm has been described in 1957 under the term sclerosing carcinoma of bile ducts (Altemeier et al. 1957) and later by Klatskin (1965). However, descriptions of PHC are already found in the old literature. For example, professor Bernhard Naunyn from Königsberg (now Kaliningrad), who founded the Archiv für experimentelle Pathologie und Pharmakologie together with J. von Mikulicz-Radecki (later Naunyn-Schmiedeberg's Archives), reported in 1877 the autopsy findings of a female who had stenosing carcinoma at the confluence, extending into the left hepatic duct, what would now be called PHC type IIIb according to the modified Bismuth-Corlette classification (Howald 1890). A typically sclerosing cancer ("scirrhous neoplasm") situated in the confluence (Bismuth-Corlette type II) was reported in 1878 by Oscar von Schüppel (1878).

Definitions and Classification

Introduction

The definition of PHC or hilar cholangiocarcinoma is still subject to discussions (DeOliveira and Clavien 2012). Cholangiocarcinomas are currently classified into three broad groups: (1) intrahepatic, (2) perihilar, and

(3) distal carcinomas. Extrahepatic cholangiocarcinomas are or were divided into proximal (upper third), middle (middle third), and distal (lower third) subtypes (Tompkins et al. 1981). However, from anatomical and biological point of views, dividing the extrahepatic ducts into "thirds" is artificial and does not really reflect the oncologic situations of carcinomas in this region. Other systems divided extrahepatic cholangiocarcinomas into hilar/perihilar carcinoma, carcinomas of the lower mid-region (a rare group), and distal carcinomas (located to the terminal part of the common bile duct). As a subset of intrahepatic cholangiocarcinomas originate from large bile ducts and are therefore located close to the liver hilus, these neoplasms are also termed perihilar carcinomas. This term is however also employed for carcinomas of the extrahepatic ducts situated close to the hilus, including the confluens area, causing terminologic confusion.

What Is "Perihilar" vs. "Hilar" Cholangiocarcinoma?

The level between "mid-region" and "distal" is still not clearly defined, whereas the separation point between intrahepatic and extrahepatic cholangiocarcinomas is defined by the level of second-order bile ducts (De Oliveira and Clavien 2012). Bile ducts located to the hepatic plate system of the hilum correspond to extrahepatic bile ducts, with variable duct lengths for every segment (Masunari et al. 2008). Conventionally, the right and left hepatic ducts, their confluence, and their first to third branches are termed hilar and perihilar bile ducts, situated both intra- and extrahepatically. Large hilar/perihilar bile ducts situated proximal to the junction of second-order bile ducts are termed large intrahepatic bile ducts, as the visceral peritoneum is attached there. Conversely, the main hilar bifurcation involving right and left hepatic ducts is extrahepatic.

In tumor classifications based on surgical approaches, perihilar cholangiocarcinoma was defined as a cancer that requires resection of the hepatic duct bifurcation irrespective whether it has an intrahepatic component (Nakeeb et al. 1996; DeOliveira et al. 2007; DeOliveira and Clavien 2012). Certain authors identify perihilar carcinoma as a single entity that comprises all cancers involving the hepatic hilar area, irrespective of whether these lesions are extrahepatic or intrahepatic (extrahepatic hilar cholangiocarcinoma vs. intrahepatic hilar cholangiocarcinoma; Ebata et al. 2009). In the sixth edition of the "General Rules for Clinical and Pathological Studies on Cancer of the Biliary Tract", released in 2013, perihilar cholangiocarcinoma was proposed as an alternative to hilar cholangiocarcinoma, with perihilar cholangiocarcinoma defined as cholangiocarcinoma involving the perihilar bile ducts, despite the presence or absence of a significant liver mass component. This definition includes that both intrahepatic (hilus near) and extrahepatic perihilar tumors are grouped in the perihilar tumor category (review: Ebata et al. 2014). In recent studies, the classification of extrahepatic cholangiocarcinoma has been simplified and reduced to perihilar and distal cancers, the reasons being that carcinoma of the mid-region is very rare and their treatment is similar to that for Bismuth-Corlette type I PHC (review: Chung et al. 2008).

By tradition, the term PHC has been employed to denote all cholangiocarcinomas involving the hepatic confluence, but it had not been evaluated whether there is a biological difference between perihilar tumors with an intrahepatic versus an extrahepatic presentation. A recent study on 250 PHCs revealed that the two groups have comparable biological behavior, indicating that the concept of perihilar cholangiocarcinoma is valid (Ebata et al. 2009).

Pathology Classifications

Some authors divided PHC into several main growth patterns (Todoroki et al. 1980; Yamashita et al. 1992; Sakamoto et al. 1998; Table 1).

Both nodular and diffusely infiltrating subtypes are usually accompanied by a marked desmoplasia, resulting in ill-defined firm (sclerosed) lesions that represent the classical Klatskin tumor. Exophytic tumors have also been termed fungating lesions of burgeoning

Table 1 Classification of perihilar cholangiocarcinoma based on macroscopic pathology (growth patterns)

Intraluminally growing PHC

tumors (Solovei et al. 1993) and are more often associated with loss of heterozygosity at chromosome 5q (Hidaka et al. 2001). These tumors have a friable, cauliflower-like aspect. The exophytic variant of PHC has been divided into two subgroups depending on the main location of the tumor, i.e., a nodular, often hypervascular subtype located mainly inside the liver, and a less common, usually hypovascular periductal subtype having a tendency to spread along the portal vein (Yamashita et al. 1992).

Epidemiology

PHC accounts for 40–70 % of all cholangiocarcinomas, however with some differences between eastern and western countries. Of 294 patients with cholangiocarcinoma from a center in the USA, 6 % had intrahepatic, 67 % had perihilar, and 27 % had distal tumors (Nakeeb et al. 1996). Overall, carcinoma of the major extrahepatic ducts is a rather uncommon disease (Gerhards 2000; Shahib and El-Serag 2004; Khan et al. 2005; Welzel et al. 2006; Blechacz and Gores 2008; Rocha et al. 2010). It was detected in 0.0135 % of all autopsies or 0.11 % of all carcinomas in one investigation (Stewart et al. 1940) and in 0.26 % of 12,000 autopsies of another study (Neibling et al. 1949). Two other studies reported autopsy incidence of 0.4 % (Kirshbaum and Kozell 1941) and 0.073 % (McLaughlin 1933). In a study of 65 patients with extrahepatic cholangiocarcinoma, the ratio of men to women was 1:1.71; the average age of men at diagnosis was 64.5 years and that of women was 70 years. In this study, 27.7 % of the tumors were located to the confluence (Sons and Borchard 1987). In the USA, PHC has an estimated annual incidence of about 1,300. PHC is a cancer disease of older patients, more often male than female, but tumors developing in patients with inflammatory bowel disease (e.g., ulcerative colitis; Ross and Braasch 1973) and those with primary sclerosing cholangitis are younger at diagnosis of PHC (Qualman et al. 1984). The estimated frequencies of PHC and other forms of cholangiocarcinomas depend on the criteria of definition used (Welzel et al. 2006; Khan et al. 2012). For example, under the third ICD-O edition, Klatskin tumors are cross-referenced to either IHBD or EHBD, which may lead to misclassifications and skewing of cholangiocarcinoma registration. There is evidence that risk factors for PHC include choledocholithiasis, hepatolithiasis, cholecystolithiasis, and smoking (Cai et al. 2011; Suarez-Munoz et al. 2013; Lee et al. 2014). Few observations documented PHC occurring together with bile duct microhamartomas/von Meyenburg complexes (Eguchi et al. 2004). PHC was associated with fibrosing masses of the hilar region caused by *Schistosoma japonicum* (Andoh et al. 2004). Similar to other extrahepatic bile duct cancers, PHC can occur metachronously (Kwon et al. 2014).

Clinical Features

The clinical presentation of PHC is often nonspecific. The most common clinical features are abdominal discomfort or pain, anorexia, weight loss, and pruritus due to cholestasis. Most patients are diagnosed after they have presented with progressive, non-painful, and particularly non-colicky jaundice. Jaundice may be preceded by pruritus. Jaundice is, however, initially not experienced in patients with incomplete biliary obstruction, e.g., only obstruction of the right or left hepatic duct. Patients with unilateral hepatic duct obstruction will develop lobar atrophy or atrophy/hypertrophy complex before they are symptomatic. Patients with the less common papillary polypoid tumors may show intermittent jaundice caused by the floating tumor exerting a ball-valve effect or detached tumor fragments.

Bacterial cholangitis is initially a rare finding. Carcinoma markers for PHC include CA19-9 and CEA in serum, with levels that are associated with tumor stage (Juntermanns et al. 2010). PHC is associated with liver cirrhosis in part of patients, what can modify the presentation of the tumor (Abdelwahab et al. 2014).

Pathology

Macroscopy

PHC shows a characteristic gross pathology presentation (Bosma 1990; Figs. 1, 2, 3, 4, 5, 6, 7, 8, and 9). The examination of resection specimens for tissue sampling and documentation of findings has been standardized (Henson et al. 2000; Washington et al. 2010). PHC presents in the form of three major gross phenotypes, i.e., sclerosing, nodular, and papillary (polypoid). pT1 tumors often show an exophytically growing component, sometimes with a polypoid configuration and a friable, finely papillary-granular surface, resembling villous adenoma. Polypoid PHC can grow to relatively large size and may then appear as fungating lesions. The lesions have also been termed, burgeoning form of cancer (Solovei et al. 1993). The most commonly encountered sclerosing tumors are usually grayish white and present as firm annular lesions extending along the involved duct for up to 4 cm while thickening

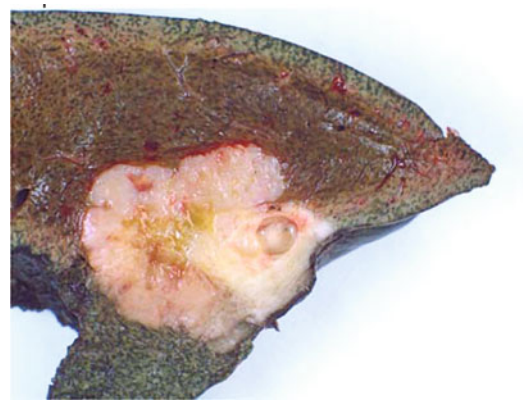

Fig. 8 Perihilar/hilar cholangiocarcinoma with polypoid intraductal growth

the duct wall up to 1 cm and showing extraductal extension in the form of a whitish fibrous tissue, sometimes with a stellate pattern (Weinbren and Mutum 1983; Beazley et al. 1984). Nodular tumors are characterized by a firm, irregular nodule often projecting into the duct. Typically, pT2 tumors are nodular lesions encasing the duct, leaving only a narrow or slit-like bile duct lumen on cross section. Sclerosing and nodular forms may occur as combined lesions (nodular-sclerosing PHC). In the course of invasion of perihilar structures, encasement of the portal vein or its branches and of bile ducts can develop (Hines and Pawlik 2010). This periductal and perivascular invasion, associated with marked desmoplasia, can result in a macroscopically impressive expansion of Glisson's triads, with formation of star-shaped whitish and firm structures. PHC may rarely undergo other secondary changes, including cystic change or calcification (Reuther and Horak 1997). Calcification of tumor is much less common than in intrahepatic peripheral cholangiocarcinoma, but may sometimes mimic a gallstone (Park et al. 2005).

Histopathology

The great majority of PHCs are adenocarcinomas with typical stroma formation (desmoplasia; Figs. 10, 11, 12, 13, 14, 15, and 16). The neoplastic cells are usually cuboidal to columnar, with a

Fig. 9 Secondary biliary cirrhosis due to stenosing hilar cholangiocarcinoma

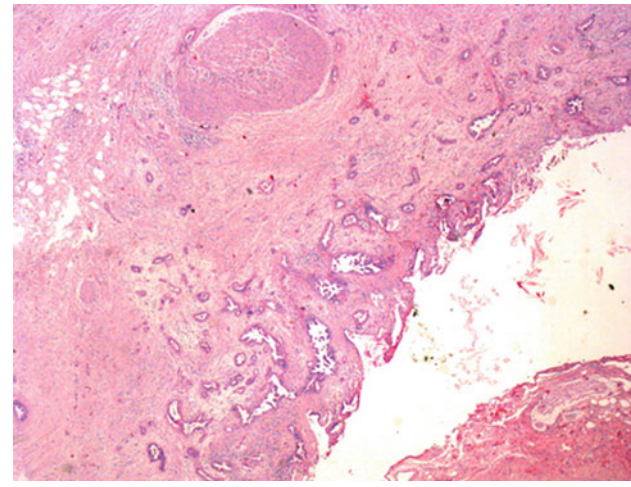

Fig. 10 Hilar cholangiocarcinoma. The adenocarcinoma has induced a marked transmural stromal reaction (desmoplasia, hematoxylin and eosin stain)

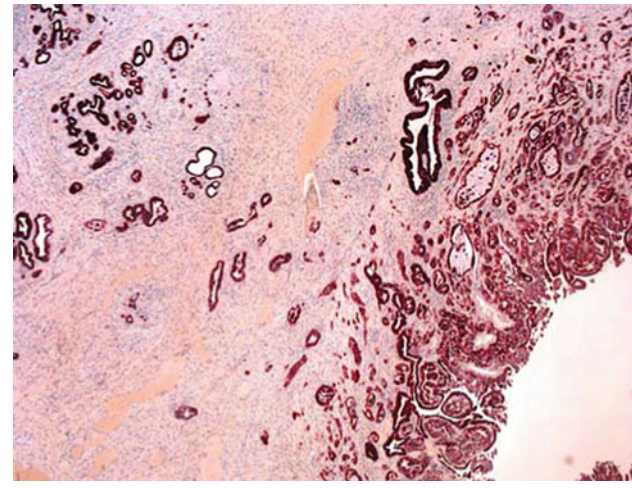

Fig. 11 Hilar cholangiocarcinoma, cytokeratin stain. Most of the tumor tissue involves the innermost layer of the ductal wall, but few cancer tubules have reached deeper parts as well. The *dark-brown* structures to the left are peribiliary glands (cytokeratin 7 immunostain)

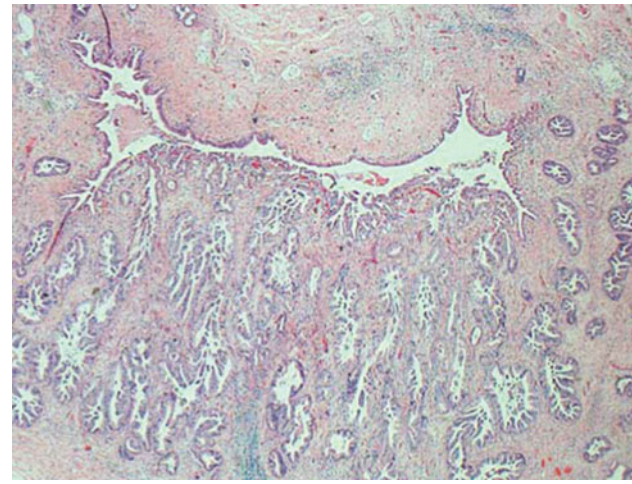

Fig. 12 Hilar cholangiocarcinoma with sectorial involvement of the bile duct. The tumor has caused severe duct stenosis, leaving a slit-like lumen (hematoxylin and eosin stain)

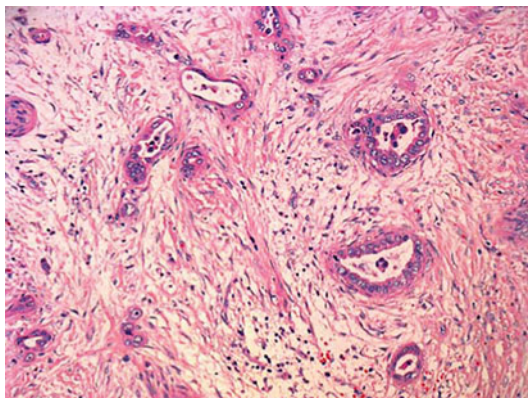

Fig. 13 Hilar cholangiocarcinoma with prominent desmoplasia. The stroma exhibits moderate cellularity and an abundant extracellular matrix (hematoxylin and eosin stain)

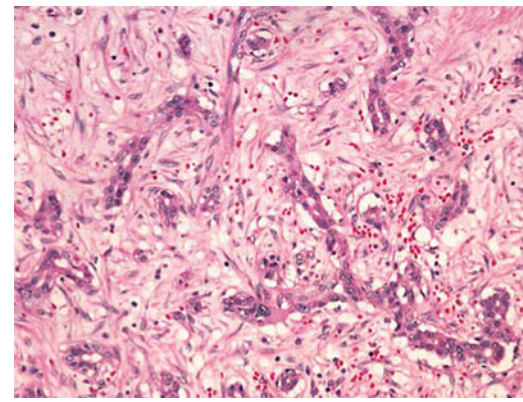

Fig. 14 The stroma of this perihilar cholangiocarcinoma shows high fibroblast cellularity. Stroma with numerous cancer-associated fibroblasts and other stromal cells is common in growing and invasive parts of carcinomas (hematoxylin and eosin stain)
