pale and sometimes clear cytoplasm. These cells form complete or incomplete tubular profiles that may fuse to form cribroid structures. Due to desmoplasia, neoplastic tubules are often markedly separated from each other. The density of tubules is often higher close to the involved duct and decreases as a function of distance from the duct. This phenomenon is best recognized in immunostains, e.g., CK7, CK19, or CAM5.2. Nuclei are ovoid or less commonly elongated, often with a chromatin that is more coarse than that of normal cholangiocytes and cells of peribiliary glands. Nucleoli are seen, but they are not very prominent. Depending on the differentiation grade, mitotic figures are found, in grade 3 lesions with abnormal mitoses. The stroma is cellular in the region of the invasion front but is often hypocellular in central parts of the tumor. Stromal cells have the features of fibroblasts or myofibroblasts. The extracellular matrix of the stroma is partly amphophilic due to the deposition of glycosaminoglycans. The vascularity of the stroma is highly variable. Uncommon variants of extrahepatic cholangiocarcinomas show marked mucin production, sometimes with mucin ball formation (Kenjo et al. 2000).

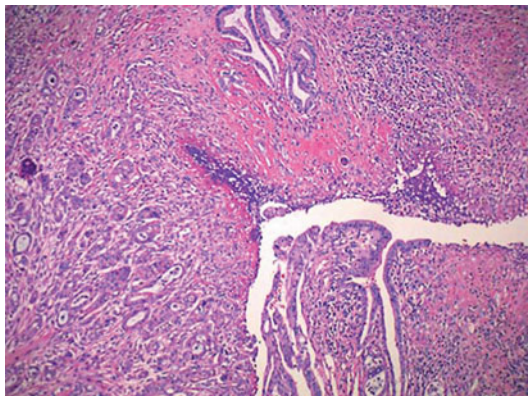

Fig. 15 Perihilar cholangiocarcinoma with severe duct ulceration reaching the level of perihilar glands (hematoxylin and eosin stain)

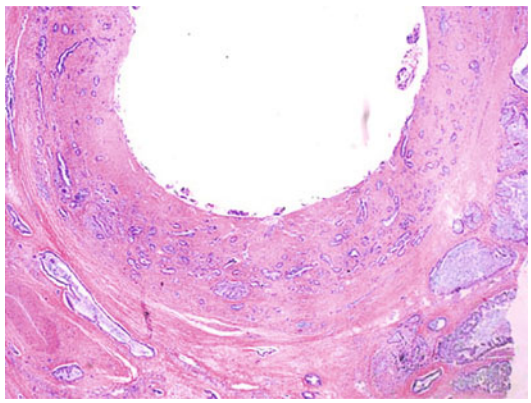

Fig. 16 Stented hilar cholangiocarcinoma, histology after removal of the stent. Note that the adenocarcinoma tubules reach the surface of the duct wall and that the stent has not induced gross tumor necrosis (hematoxylin and eosin stain)

For desmoplastic PHC, the general histopathologic features are very similar to stroma-rich variants of intrahepatic peripheral cholangiocarcinomas (Kuang and Wang 2010). There is also a striking resemblance to pancreatic duct adenocarcinomas, probably related to common embryogenetic pathways of the organ structures involved (Nakanuma and Sato 2014). Although rather slow-growing neoplasms, PHCs exhibit a highly invasive phenotype and infiltrate nerves, the perihilar tissues of the liver plate, the liver substance itself, and large liver vessels (both the portal vein and the hepatic artery). An important invasive feature is the tendency of PHC to invade and extend into second-order biliary radicles (see below).

Differentiation Patterns

The most common sclerosing, nodular, and mixed sclerosing-nodular carcinomas usually show a differentiation characterized by tubular and solid adenocarcinoma of the biliary type. The tumor cells are medium sized, cuboid, or columnar in shape, with a pale and sometimes mucinous cytoplasm, in the latter case with alcian blue-positive granules or droplets. The nuclei are usually larger than the nuclei of normal cholangiocytes, with a decontracted chromatin and small but well-recognizable nucleoli. The tubules and solid nests are embedded in a fibroblastoid-myofibroblastoid stroma of variable cellularity. Near the duct mucosal surface, the stroma is mixed with preexisting connective tissue of the duct wall, but the high cellularity and the homogeneous population of stromal cells are easily recognizable. Within the stroma, which participates in the growth and replacement of the duct wall, nonneoplastic small biliary glands can be found. In contrast to carcinoma cells, these glandular structures are composed of small cholangiocytes with small, regular, and dense nuclei. Papillary adenocarcinoma is a phenotype occurring in PHC, but it is less common than the classical nodular-sclerosing morphology (Weinbren and Mutum 1983; Yamaguchi et al. 1997; Albores-Saavedra et al. 2000; Hoang et al. 2002; Jarnagin et al. 2005). Invasive papillary carcinoma of the extrahepatic bile ducts amount to 4–5 % of carcinomas of this part of the biliary tract (Nomoto and Nakao 1996; Fatima et al. 2008). These variants are exophytically growing, soft tumors with a predominantly intraductal growth pattern, leading to expansion of the involved ductal segment. As in other exophytic carcinomas with a papillary pattern, invasive growth at the base is not a prominent feature and is, at least in some tumors, not easily detectable. The presence of a papillary component

is associated with more favorable outcome (Jarnagin et al. 2005). Less common variants of cellular differentiation, seen more often in intrahepatic cholangiocarcinomas and gallbladder carcinomas, comprise intestinal, foveolar, adenosquamous, or squamous lineages.

Histologic Variants of PHC

Apart from classical desmoplastic cholangiocarcinoma and papillary-exophytic variants, several other phenotypes occur, similar to the situation in intrahepatic cholangiocarcinoma (Table 2).

Few PHCs show the morphology of mucinous (colloid) carcinoma. In part of cases, this phenotype is the invasive part of papillary carcinomas (Albores-Saavedra et al. 2000). The mucin (colloid) accumulated in the duct wall or within stroma, sometimes with only few detectable carcinoma cells floating in the mucin lakes. These lakes can cause dissection of the duct wall and may induce a macrophage reaction with mucophages. Signet ring cell carcinoma is a very rare variant of extrahepatic bile duct carcinoma (Ogata et al. 2010). Very few PHCs show an intestinal differentiation with columnar cells that resemble those in colorectal carcinoma. An unusual variant of PHC exhibits a pancreatobiliary morphology. PHCs with a gastric foveolar differentiation are well-differentiated cancers composed of tubules with slender tall columnar cells with basally placed nuclei. Apart from foveolar-type tubules, irregular tubules with nuclear pseudostratification may occur (Albores-Saavedra et al. 1999). A very rare variant of PHC shows a pyloric gland-type morphology, with a very high differentiation level, glandular structures in a complex stellate pattern, pale to clear cells, and reactivity for MUC5AC and MUC6, but not MUC2. Notwithstanding their well-differentiated phenotype, these carcinomas are invasive and show perineural invasion (Albores-Saavedra et al. 2012). Similar to intrahepatic cholangiocarcinoma, few PHCs show a clear cell change, the neoplastic ells having a clear cytoplasm with PAS-positive granules. These cells are, in contrast to renal cell carcinoma, CK7 positive and are arranged in the form of solid nests, sheets, trabecules, or tubules (Vardaman and Albores-Saavedra 1995; Gu et al. 2010). Adenosquamous carcinoma is a well-recognized variant of hilar/perihilar carcinomas, characterized by complex mixtures of adenocarcinoma and squamous cells (CK5/6(+) p63(+)S100A2(+)) with or without keratinization. A poor outcome is paralleled with the proportion of squamous cell components (Lim et al. 2007; Hong et al. 2008). Squamous cell carcinoma of the perihilar area is very rare and less frequently found than adenosquamous carcinoma. Diagnosis requires complete lack of detectable glandular components. Perihilar squamous cell carcinoma is a highly aggressive neoplasm with poor outcome (Yamana et al. 2011). Among perihilar carcinomas with a squamous cell/keratinocyte component, mucoepidermoid carcinoma is the rarest lesion. One case was reported, with a tumor involving the common hepatic duct and extending into the proximal common bile duct (Koo et al. 1982).

Table 2 Histologic variants of perihilar cholangiocarcinoma

Mucinous (colloid) carcinoma
Signet ring cell carcinoma
Intestinal-type carcinoma
Pancreatobiliary-type carcinoma
Gastric foveolar-type carcinoma
Pyloric gland-type carcinoma
Clear cell carcinoma
Adenosquamous carcinoma
Squamous cell carcinoma
Mucoepidermoid carcinoma

Perineural and Intraneural Invasion

A characteristic feature of PHC is perineural and intraneural invasion (Figs. 17, 18, 19, 20, and 21). This mode of cancer spread has been described in 1905 (Ernst 1905) and has since been confirmed as a common invasion mode of this neoplasm

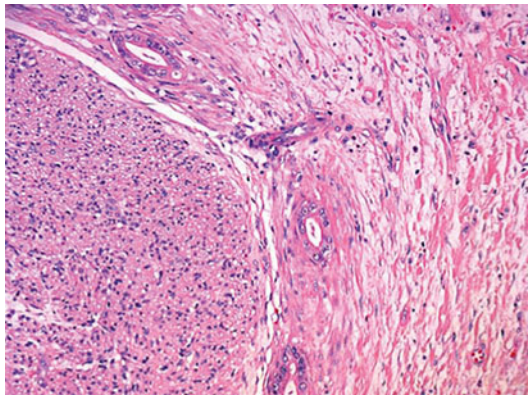

Fig. 17 Hilar cholangiocarcinoma. Invasion of the perineural sheath (hematoxylin and eosin stain)

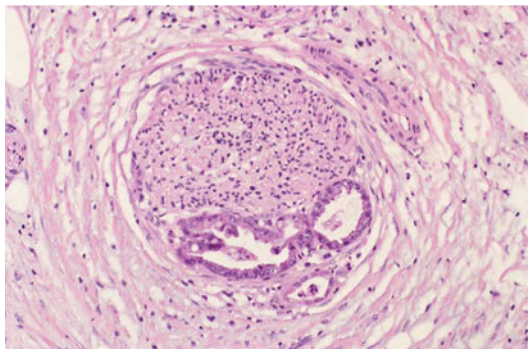

Fig. 18 Perihilar cholangiocarcinoma with perineural invasion. The carcinoma tubules are located at the entry site of the vasa nervorum (hematoxylin and eosin stain)

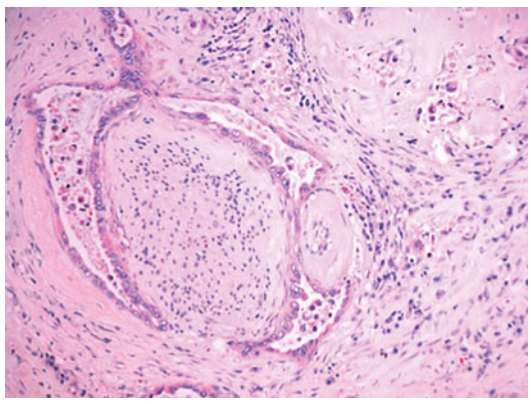

Fig. 19 Hilar cholangiocarcinoma, with circumferential perineural invasion. Involvement of the vascular "hilus" of the nerve is associated with fibrosclerosis of the vasa nervorum (hematoxylin and eosin stain)

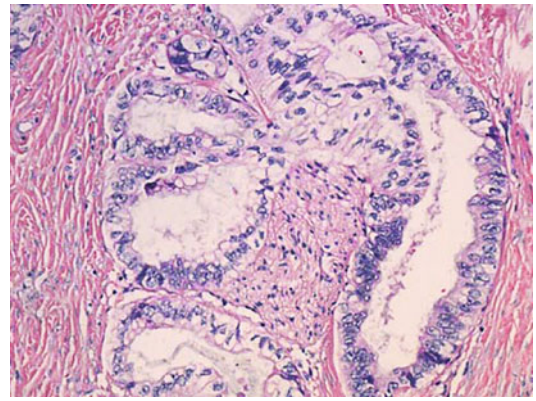

Fig. 20 Hilar/perihilar cholangiocarcinoma. Perineural invasion by a well-differentiated adenocarcinoma. The nerve is encircled by large tubules forming a cuff-like structure (hematoxylin and eosin stain)

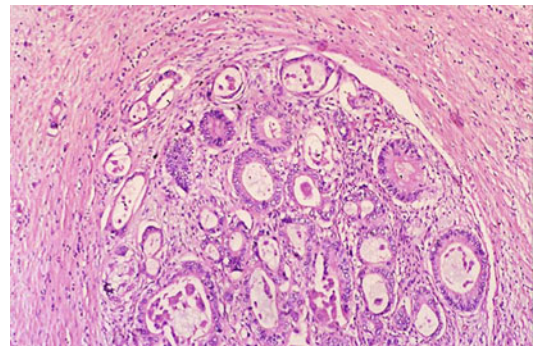

Fig. 21 Perihilar/hilar cholangiocarcinoma with intraneural and perineural invasion (hematoxylin and eosin stain)

(Davis et al. 1988). Perineural invasion is more common in PHC than in intrahepatic cholangiocarcinoma (Park et al. 2013). However, a relationship between site and incidence of perineural invasion in cholangiocarcinoma has not been found in another study (Bhuiya et al. 1992). Perineural invasion in PHC was detected in up to 75 % of cases (Yamaguchi et al. 1997). However, the incidence of perineural invasion varies among the different histologic types of cholangiocarcinoma. Perineural invasion was less frequently observed in papillary carcinomas (50 % positivity) than in well-differentiated (81.8 %), moderately differentiated (84.6 %), and poorly differentiated adenocarcinoma (100 %; Bhuiya

et al. 1992). Histologically, perineural invasion is visualized as carcinoma cells, either in rows or forming flat tubular or cribriform profiles, situated in a slit-like space between the neural fascicle and the peripheral border of the perineural sheath. These cell accumulations range in extension from small clusters to sickle-shaped infiltrates, to situations where the nerve is involved in its entire circumference. In some cases, perineural cancer cells surround – and possibly damage – the entry site of vasa nervorum.

Similar to ductal adenocarcinoma of the pancreas, molecules associated with nerve biology appear to be involved in cholangiocarcinoma perineural invasion, including nerve growth factor and its receptor, and neural cell adhesion molecule/NCAM (Shen et al. 2010). The pathogenesis of perineural invasion and factors promoting this invasion pattern have been studied in several carcinomas, particularly in pancreatic ductal carcinoma. Factors inducing, or associated with, perineural invasion include neurotransmitter substance P (Li et al. 2013), glial-derived neurotrophic factor (Liu et al. 2012), synuclein-gamma (Hibi et al. 2009), nerve growth factor and tyrosine kinase receptor A (Ma et al. 2008; Sakamoto et al. 2001), and activation of the STAT3 signaling pathway (Guo et al. 2013). The cellular source of these neurotrophic factors is not yet well known, but it was found that glial-derived neurotrophic factor is produced by endoneurial macrophages (Cavel et al. 2012).

Growth and Invasion Along the Bile Ducts

PHC tends to extend along structures of ducts and the hepatic plate to reach the liver substance. Extramucosal extent toward the hepatic side was detected in 77.8 % of cases and that toward the duodenal side in 44.4 %. The distance of extramucosal extent was longer on the hepatic side than on the duodenal side (Hayashi et al. 1994). Mucosal extension was predominantly found in nodular and exophytically growing tumors, while submucosal extension was predominant in infiltrating and nodular-infiltrating neoplasms. Submucosal extension usually consisted of direct or lymphatic invasion (Sakamoto et al. 1998).

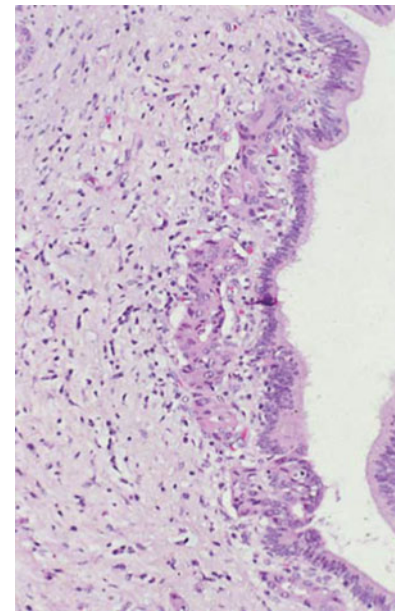

Fig. 22 Intramucosal (subepithelial) spread of cholangiocarcinoma in a bile duct (hematoxylin and eosin stain)

Part of PHC exhibits superficial mucosal spread (Sakamoto et al. 1998). This phenomenon, which is not the same as perineural spread, renders the estimation of tumor extension, and of resection radicality, difficult in some of the cases (Fig. 22).

Toyoda and Yoshida (1985) distinguished two types of PHC according to the type of infiltration. Type I included neoplasms, in which tumor cells were demonstrated in the mucosal or submucosal layer at a distance greater than 11 mm from the main tumor. Type II included neoplasms less than 11 mm distant. In regard to hepatic infiltration, vascular invasion, perineural invasion, and peritoneal invasion, type I was found to be more extended and aggressive. Among 117 cases of extrahepatic cholangiocarcinoma, 18 % were found to have extensive intramucosal spread, defined as spread $>$ or $=$ 20 mm from the main tumor (Nakanishi et al. 2008). In a study of 471 patients (351 perihilar and 120 distal cholangiocarcinomas), superficial spread, defined as noninvasive cancer extension of more than

20 mm, was detected in 14.6 %, with an average length of spread of 54 ± 19 mm. Interestingly, superficial spread was more often found in papillary and well-differentiated adenocarcinomas. Histologic indexes showing tumor aggressiveness, including lymphatic, venous, and perineural invasion, were lower in tumors with superficial spread, and staging levels were less advanced, suggesting this superficial spread is associated with less advanced and slower-growing tumors (Igami et al. 2009). There is evidence that PHC cells can spread via the peribiliary gland network, with formation of intraductal luminal spread and peribiliary invasion (Sato et al. 2013). In the liver, PHC cells have a tendency to spread between hepatocyte plates (Weinbren and Mutum 1983).

Ductal Recurrence of PHC

Following resection, PHC can recur at the level of the ductal stumps. Recurrence can start from remnant cancer cells in case of positive margins or can develop de novo from dysplastic cells that will evolve into carcinoma in situ and later invasive carcinoma. Theoretically, also carcinoma cells in perineural spaces may grow to the stump area and cause recurrence. At a molecular level, residual carcinoma in situ at ductal stumps was associated with nuclear expression of p53-binding protein 1/53BP1 which mediates the DNA damage response. This nuclear localization in neoplastic cells indicates 53BP1 inactivation and decreased apoptosis (Wakai et al. 2013).

Secondary Changes of PHC

Although desmoplastic stroma has a certain tendency to resist necrosis, extensive necrosis can occur in some PHC, specifically in those with rapid growth (Cha et al. 2013). PHC can undergo hemorrhage. Usually, bleeding presents as small focal extravasations, but massive bleeding can occur in few tumors. PHC may develop focal calcifications of the dystrophic type (Reuther and Horak 1997).

Locoregional Lymph Node Pathology

Cholangiocarcinoma of the extrahepatic ducts frequently metastasizes to locoregional lymph nodes (Ito et al. 2010). The frequency of nodal metastasis varies as a function of cancer localization. In one investigation, nodal metastases were present in 61 % of patients with distal bile duct carcinoma, 47 % with middle bile duct carcinoma, and 52 % with proximal bile duct carcinoma, and the number of involved nodes per node-positive patient was greater in patients with middle duct carcinoma than in those with proximal or distal cancers (Yoshida et al. 2003). In another study of 110 patients with PHC, 35.5 % had locoregional lymph node metastases, and 17.3 % had regional and para-aortic node metastases. The incidence of positive nodes was significantly higher in patients with pT3 disease than in those with stage pT2. Pericholedochal lymph nodes were the nodes most commonly involved (42.7 %), followed by periportal nodes (30.9 %), common hepatic nodes (27.3), and posterior pancreaticoduodenal nodes (14.5 %). In contrast, celiac and superior mesenteric nodes were rarely involved (Kitagawa et al. 2001). In a study of 320 patients with PHC, lymph node metastases were found in 45.6 % of patients (Aoba et al. 2013). Part of locoregional lymph nodes involved by carcinoma shows extracapsular involvement, in one study in up to 22 % of nodes (Noji et al. 2012). By use of immunohistochemistry, a higher proportion of nodal metastases are found in comparison with conventional histopathology. In a total of 954 lymph nodes from surgical specimens of 45 patients with histologically node-negative PHC, nodal micrometastases were detected immunohistochemically (CK8 and CK18) in 24.4 % of the 45 patients, being found in 13/954 (1.4 %) nodes examined. 84.6 % of micrometastases were found in the N2 regional node group rather than N1 (Tojima et al. 2003). As observed in other types of carcinoma, locoregional lymph nodes in PHC can show the development of epithelioid cell granulomas as a sign of a distinct type of cell-bound immune reactions, lesions sometimes mimicking sarcoidosis (Onitsuka et al. 2003). By measuring the size of

involved vs. noninvolved nodes, no cutoff point could be found for accurately predicting nodal involvement (Ruys et al. 2011).

Alterations of the Liver in Patients with PHC

Concomitant involvement of the right or left portal vein often causes hepatic lobar atrophy. Atrophy caused by ischemia has an important clinical implication for palling of surgery and considering biliary drainage in patients with unresectable cancer (review: Jarnagin and Winston 2005).

The biliary obstruction caused by stenosing PHC is followed by intrahepatic bile duct dilatation, cholangitis (sometimes purulent, with formation of multiple pyogenic abscesses), and biliary fibrosis. Cirrhotic remodeling is an exceptional finding, due to the short evolution phase available (Okuda et al. 1977), but secondary biliary cirrhosis or an atrophy/hypertrophy complex may develop in rare cases (Göke et al. 1989; Friesen et al. 2011). The liver tissue adjoining PHC usually shows various types of cellular infiltration or signs of inflammation. In case of infection, numerous neutrophils are observed in the region of the tumor and/or around dilated and inflamed bile ducts, sometimes with bile duct empyema or formation of multiple abscesses. The tissue directly surrounding the invasive carcinoma often shows a lymphocytic infiltrate, sometimes with formation of lymph follicles with or without germinal centers. Lymphocytes can also be found around nerves, both in nerves without cancer involvement and those with perineural or intraneural carcinoma invasion. Plasma cells occur along inflamed bile ducts, in particular in patients with signs of bacterial cholangitis. Infiltration of peritumoral but tumor-free parenchyma with IgG4-positive plasma cells has been observed in patients with PHC, suggesting that such plasma cells are of limited utility in distinguishing PHC from IgG4-associated sclerosing disease (Resheq et al. 2013).

Immunohistochemistry

Tumor cells of PHC typically express cholangiocyte lineage markers, i.e., cytokeratins 7 and 19, and epithelial membrane antigen/EMA. Immunohistochemically, MUC1 and S100 protein were significantly upregulated in PHC and mucin-producing intrahepatic cholangiocarcinomas in comparison with mixed intrahepatic cholangiocarcinomas and cholangiolocellular carcinoma (Mall et al. 2010; Komuta et al. 2012). The presence of MUC2, together with CDX2, expression in part of the tumors indicates that intestinal differentiation is present in certain subtypes of extrahepatic cholangiocarcinomas (Hong et al. 2005a). Many PHCs show nuclear expression of p53 (Fig. 23; Argani et al. 2001). Nearly all PHCs and extrahepatic cholangiocarcinomas are positive for S100 protein (Tsai et al. 2012). The proliferative activity of PHC cells can be assessed by means of PCNA and Ki-67 immunohistochemistry (Fig. 24). Extrahepatic cholangiocarcinomas showed significantly higher PCNA and Ki-67/MIB-1 indices than carcinoma in situ and nonneoplastic lesions (Lee 1996; Nishida et al. 1997). Normal cholangiocytes express E-cadherin and N-cadherin with a membranous staining pattern. However, cholangiocarcinomas differ in the patterns of cadherin expression from normal counterparts. While E-cadherin is

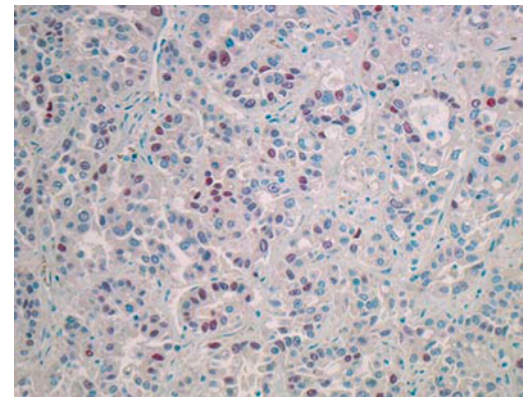

Fig. 23 Perihilar/hilar cholangiocarcinoma with nuclear expression of p53 protein (p53 immunostain)

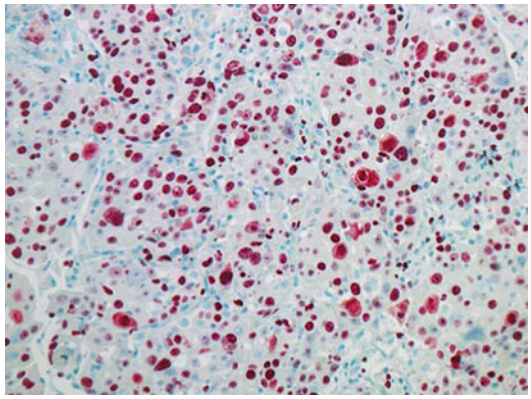

Fig. 24 Poorly differentiated cholangiocarcinoma. This tumor shows a high proliferation fraction (MIB-1 immunostain)

expressed in both intrahepatic cholangiocarcinomas and PHC, the expression of N-cadherin was significantly more frequent in peripheral than in hilar intrahepatic cholangiocarcinomas (Mosnier et al. 2009). P-cadherin and CD24 are expressed in cholangiocarcinomas with high frequency and are also expressed in precursor lesions (Riener et al. 2010). Invasive tumors abnormally express proteins that are components of intercellular junctions, including zonula occludens-1, occludin, and E-cadherin (Nemeth et al. 2009). A novel marker for carcinomas with a cholangiocyte linage is annexin A1/ANXA1 (Hongsrichan et al. 2013). Immunohistochemically, a subset of extrahepatic cholangiocarcinomas exhibit neuroendocrine differentiation, based on reactivities for synaptophysin and chromogranin A (Hong et al. 2005b).

Lymphangiosis Carcinomatosa of the Bile Ducts

Introduction

Lymphangiosis carcinomatosa is defined as the presence of clusters of carcinoma cells within the lumina of lymph vessels, sometimes with formation of tumor cell thrombi and dilatation of the vessels involved. In several tumor types, the presence of lymphangiosis carcinomatosa has been shown to be a negative prognosticator (Meyer et al. 2001) and should, therefore, be identified within a diagnostic and staging workup of a given tumor. However, the diagnosis required the reliable identification of lymph vessels, what may be difficult in H&E-stained preparations, as lymph vessels are difficult to distinguish from tissue slits or artifacts. This has changed with the introduction of lymphatic endothelial markers, in particular the D2-40 monoclonal antibody (Kahn and Marks 2002). This utility of this immunohistochemical approach has also been shown in human biliary tract cancers. It was, e.g., shown that perimuscular connective tissue of human gallbladder contained lymphatic vessels by D2-40 immunostaining (Nagahashi et al. 2007).

Clinical Features

The lymphatic vessels and lymph nodes in the gastrohepatic ligament are frequent sites of spread and metastasis from gastric carcinoma (Baker et al. 1987; Maruyama et al. 1989; Lyttkens et al. 1990). Lymphangiosis carcinomatosa of the bile duct caused by gastric carcinoma can produce obstructive jaundice (Lee et al. 1995; Gabata et al. 1998). In a retrospective cholangiographic study of 54 patients with advanced gastric carcinoma with obstructive jaundice, the causes of bile duct obstruction were lymph node metastases (93 %) in the hepatoduodenal ligament and direct invasion of the primary gastric tumor or recurrent tumor in 7 %. Fifteen percent were located at the level of the intrahepatic bile duct to the hilum, 46 % at the common hepatic duct, 32 % at the proximal half of the choledochus, and only 7 % at the distal choledochus. There was no evidence of lymphangiosis, but only part of the lesions (10/54) had been examined by exploratory laparotomy (Lee et al. 1995). Radiologically, lymphangiosis carcinomatosa causes concentric bile duct wall thickening (Gabata et al. 1998).

Lymph vessel involvement of the extrahepatic bile ducts is also detectable in patients with gallbladder carcinoma. Among 15 patients, submucosal lymph vessels of the extrahepatic bile duct, lined with D2-40-positive endothelial cells, were found to contain carcinoma cells in three patients (Chikamoto et al. 2009). As the lymphatic systems of the gallbladder are connected with the respective networks of the extrahepatic and intrahepatic bile ducts, and the liver, via the cystic duct network, gallbladder carcinoma can cause lymphangiosis carcinomatosa of the liver. However, this phenomenon is more often seen in cases where liver metastases have already developed (Itoh et al. 1988). Lymphangiosis carcinomatosa can cause progressive jaundice (Tada et al. 1996).

Pathology

Involvement of the biliary tract lymphatic system is detectable in diverse types and locations of lymphatics and can be associated with lymph node metastasis (Figs. 25, 26, 27, 28, and 29). Bile duct lymph vessels with or without lymphangiosis carcinomatosa are readily visualized through D2-40 immunostaining. Lymphangiosis carcinomatosa of the liver can cause a unique branching calcification (Matsumoto et al. 2004). The presence of lymphangiosis carcinomatosa in resection margins is a prognosticator, e.g., in non-small cell lung cancer (Passlick et al. 2001), but has not yet systematically been studied in biliary tract cancer.

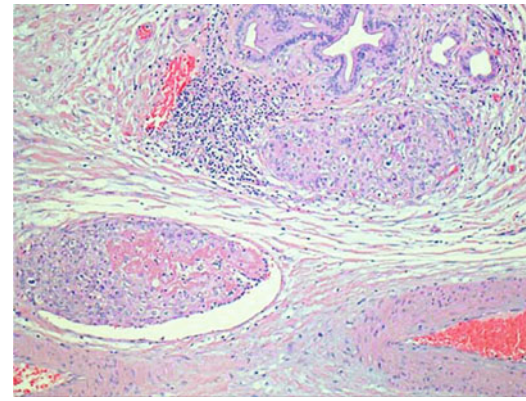

Fig. 26 Poorly differentiated cholangiocarcinoma, invasion of lymph vessels around peribiliary glands (*top*) and of a thin-walled dilated venule (*bottom*). The tumor cell plug in the venule contains thrombotic material (the so-called tumor thrombus, hematoxylin and eosin stain)

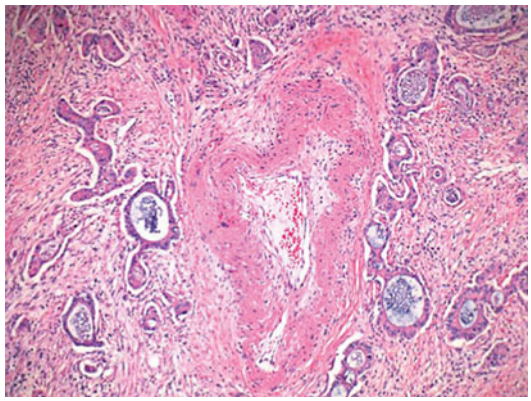

Fig. 25 Perihilar cholangiocarcinoma, invasion of perivascular lymphatic vessels. Due to lymphatic obstruction by the tumor cells, the blood vessel wall is damaged, with adventitional and intimal fibrosis (hematoxylin and eosin stain)

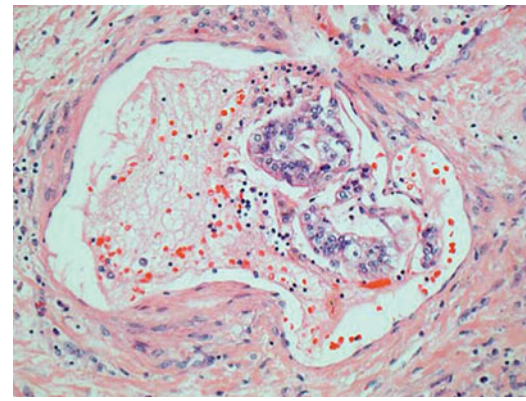

Fig. 27 Cholangio-carcinoma, invasion of a medium-sized, dilated lymph vessel (lymphangiosis carcinomatosa). The vessel lumen contains, in addition to tumor cells, a proteinaceous fluid with lymphocytes, i.e., lymph (hematoxylin and eosin stain)

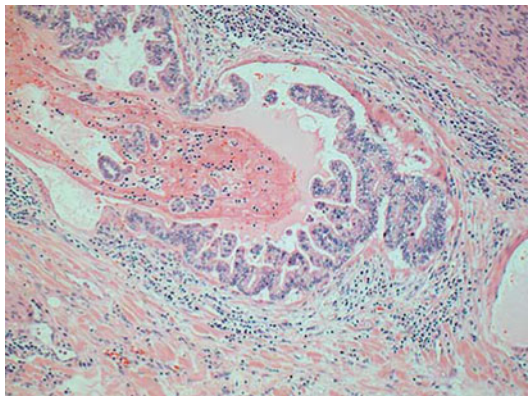

Fig. 28 Intralymphatic growth of cholangiocarcinoma, with formation of pseudopapillary structures (hematoxylin and eosin stain)

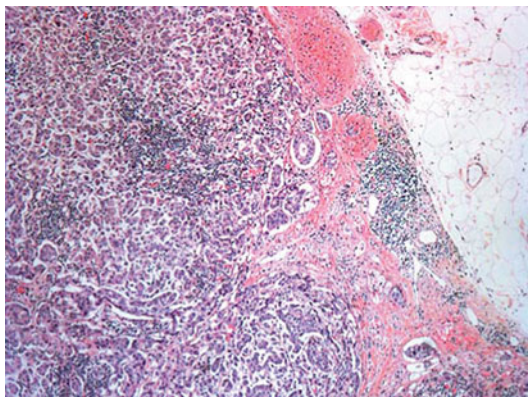

Fig. 29 Perihilar/hilar cholangiocarcinoma. Peripheral parts of a locoregional lymph node with metastasis (hematoxylin and eosin stain)

Determinants of Lymphatic Spread in Bile Duct Cancer

Determinants of lymphatic spread and lymph node metastasis include distinct modes of tumor cell motility, recognition of lymph vessel cells and lymph vessel-associated extracellular matrix components by cancer cells, differential adhesion of tumor cells (lymph vessel homing), lymphangiogenesis (see below), and changes in the adhesive properties of lymphatic endothelial cells in or near tumors. Invasion of local lymphatics and population of these vascular channels increases as a function of the depth of tumor infiltration into the duct wall (Takahashi 1996).

Neoplastic Lymphangiosis and Lymphangiogenesis

Both experimental tumor models and human clinicopathologic data indicate that growth of lymphatic vessels is induced by invasion of carcinoma cells (tumor-associated lymphangiogenesis, TALG; reviews: Achen and Stacker 2006, 2008). TALG mediates tumor cell dissemination and the formation of lymph node metastases in animal models of various neoplasms. Lymphangiogenic factors have been identified that promote formation of tumor lymphatics. They comprise VEGF-C and VEGF-D, which act via their cognate receptor tyrosine kinase VEGF receptor-3 (VEGFR-3) located to lymphatic endothelial cells (Von Marschall et al. 2005; Thelen et al. 2008a). Other growth factors inducing lymphangiogenesis are VEGF-A, platelet-derived growth factor-BB, and hepatocyte growth factor (review: Achen and Stacker 2008). In hilar cholangiocarcinoma, it was found that TALG correlates with lymph node metastases and prognosis (Thelen et al. 2008b,c; Thelen et al. 2010). In a study of 88 cases of intrahepatic cholangiocarcinoma, it was observed that poorly differentiated tumors showed a higher lymphatic vessel density in the tumor periphery and in the peritumoral area, and lymphatic invasion was significantly more prominent in the periphery than in the tumor center. Lymphatic invasion was correlated with VEGF-C expression, which was independent prognostic factor (Aishima et al. 2008). In extrahepatic bile duct carcinoma, the presence of carcinoma cells in lymph vessels significantly increased the hazard ratios of tumor recurrence and initial distant organ metastasis (Hasebe et al. 2005).

Differential Diagnosis

PHC has a broad differential diagnosis. It is estimated that about 5–15 % of specimens resected for presumed PHC prove not to be

Table 3 Differential diagnosis of perihilar carcinoma

Nonneoplastic conditions
Fibrosing inflammations of the hilar/perihilar region
Hepatolithiasis
Primary and secondary sclerosing cholangitis with dominant stricture
Various forms of chronic noninfectious or infectious cholangitis
Inflammatory pseudotumors
Amputation neuroma
IgG4-related sclerosing disease
Nodal sarcoidosis, tuberculosis, and other granulomatous disorders
Portal hypertensive biliopathy
Ischemic cholangiopathy
Retroperitoneal fibrosis
Sclerosing mesenteritis
Cysts and pseudocysts
Tissue ectopias/heterotopias
Cholelithiasis
Alveolar echinococcosis
Neoplastic conditions
Hilar/perihilar non-Hodgkin's lymphoma and Hodgkin's lymphoma
Various obstructing benign tumors of the bile ducts
Hepatic malignancies invading the hilar region
Intrabiliary (endoluminal) tumor thrombus (hepatocellular carcinoma and cholangiocarcinoma)
Bile duct metastasis
Perihilar myofibroblastic tumor

cholangiocarcinoma (Senthil Kumar and Marudanayagam 2012). A complex spectrum of neoplastic and nonneoplastic conditions can mimic PHC (Table 3).

For imaging diagnostic procedures, an important differential diagnosis of PHC is benign fibrosing disease at the hepatic confluence (Wetter et al. 1991; Verbeek et al. 1992; Medina-Franco et al. 2001; Koea et al. 2004; Corvera et al. 2005; Uhlmann et al. 2006; Dumitrascu et al. 2010; Juntermanns et al. 2011). Apart from fibrosing cholangiopathies, hepatolithiasis (Senda et al. 2011), follicular cholangitis (Lee et al. 2005; Fujita et al. 2010), autoimmune cholangiopathy (Shingina et al. 2011), primary sclerosing cholangitis (Kojima et al. 2004), tuberculosis (hepatic tuberculosis or tuberculosis of periductal lymph nodes; Arora et al. 2008; Hanafiah et al. 2013), amputation neuroma (Koike et al. 2000), IgG4-related sclerosing disease (Cheung and Lo 2008; Wakai et al. 2012), biliary inflammatory pseudotumor (Hammesfahr 1928; Worley et al. 2001; Gohy et al. 2007; Deng et al. 2010), heterotopic pancreatic tissue at the confluence (Heer et al. 2010), gastric mucosal heterotopia (Fukuda et al. 2013), biliary Erdheim-Chester disease (Gundling et al. 2007), and biliary sarcoidosis (Suzuki et al. 2011; Daniel Gonzalez et al. 2012) were found to mimic PHC. In a study of 171 patients with proximal biliary obstruction, 141 or 82.4 % had PHC. Alternative diagnoses other than PHC were encountered in 17.5 % of patients and included benign strictures (5.2 %) and other malignancies (12 %; Are et al. 2006). In rare instances, peripheral cholangiocarcinoma resulting in intrabiliary tumor thrombus resembled PHC (Lucidi et al. 2008). Non-carcinomatous tumors of the hilar region may mimic PHC, e.g., non-Hodgkin's lymphomas (André et al. 1996; Cristophides et al. 2009), neuroendocrine tumors (Chan et al. 2000), obstructing leiomyoma (Mandeville and Stawski 1991), neurilemmoma (Kamani et al. 2007), metastases (e.g., breast cancer; Coletta et al. 2014), or hilar inflammatory myofibroblastic tumor (Kim et al. 2011). Another lesion clinically and radiologically resembling PHC is mass-forming inflammatory periductal fibrosis of the hilar region (Hasegawa et al. 2000). In rare instances, obstructing bilateral stones in hepatic ducts or choledocholithiasis may mimic PHC (Läuffer et al. 1998; Dixit et al. 1999).

Abstract

Cholangiocarcinomas of the distal bile duct system are conventionally defined as neoplasms located between the cystic duct entry and the end of the common bile duct in the ampullary region (infrahilar cancers). Cancers arising in a segment just distal to the cystic duct entry are sometimes classified as tumors of the duct mid-region, due to their rather distinct growth pattern (middle duct cancer), but middle and distal cancers are put together into one category by other authors. Japanese authors identified two infrahilar tumor groups and denote middle carcinomas by the abbreviation Bm and distal carcinomas by Bi. Distal-most forms of cholangiocarcinoma may be difficult to distinguish from periampullary carcinomas. Infrahilar variants of extrahepatic cholangiocarcinoma account for 20–30 % of all bile duct carcinomas, but incidence rates vary considerably among different regions of the world, due to varying prevalence of etiologic factors such as stone disease and liver fluke infestation. Macroscopically, infrahilar cholangiocarcinomas display nodular stenosing masses, masses with a tubular configuration, ulcerated tumors, diffusely growing tumors, and exophytic growths, the latter predominating in distal-most lesions.

Introduction

Cholangiocarcinomas of the distal common bile duct (CDBDs) are conventionally defined as carcinomas located between the cystic duct entry and the end of the common duct in the ampullary region (Lad and Kooby 2014). CDBDs form, in addition to perihilar carcinoma, the second important group of extrahepatic bile duct carcinomas. Clinically, the distal-most forms of CDBD are sometimes difficult to distinguish from ampullary or periampullary carcinomas (Dickson and Behrman 2014). These generally uncommon neoplasms have first been described in 1840 (Durand-Fardel 1840; carcinoma of common bile duct) and then in 1878 (Schueppel 1878; cited by Renshaw 1922) and were then described in detail in the first half of the twentieth century (Scudder and Richardson 1908; Cheney 1914; Renshaw 1922; Wahl 1924; Shapiro and Lifvendahl 1931; Lee and Totten 1934; Dick 1939; Stewart et al. 1940). In the nineteenth century, part of investigators, such as Rokitansky, thought that extrahepatic ducts with cancer were involved by secondary growths from nearby organs (Rokitansky 1849). A classification of extrahepatic cholangiocarcinomas according to anatomic location, i.e., proximal, middle, and distal, was first proposed by Longmire (1976). As the limits along the duct are not always easy to define, and as tumors tend to infiltrate into neighboring or adjacent duct parts, other classifications have been proposed. Tumors have been divided into intrahepatic, hilar, and distal carcinomas (Nakeeb et al. 1996).

Classifications: CDBD-M Versus CDBD-D

Jarnagin et al. (2001) proposed a two-category system of proximal and distal bile duct carcinoma, however with middle duct cancer defined as a separate category. Middle and distal cancers are put together into one category by other authors (Nakeeb et al. 1996; Razumilava and Gores 2013). In the nomenclature of the Japanese Society of Biliary Surgery, abbreviations used to denote the two infrahilar/perihilar categories are Bm for middle carcinomas and Bi for distal carcinomas. As mid-duct and distal carcinomas differ in their macroscopic presentation, growth patterns, and features of locoregional metastasis, they should be distinguished. In the present chapter, extrahepatic cholangiocarcinoma of the distal part of the large bile duct (i.e., distal to hilar/perihilar tumors) is divided into carcinoma of the mid-region (CDBD-M) and carcinoma of the distal or distal-most part of the duct (CDBD-D). However, the exact limit between these two lesions remains to be defined in more detail. Based on different patterns of spread, the anatomy of bile duct blood vessels and of the duct-associated lymph vessel and node systems might serve as separation guidelines.

Epidemiology

In large autopsy studies, the incidence of bile duct tumors varies from 0.01 % to 0.2 %, and overall, malignancies of the distal extrahepatic bile duct constitute about 20–30 % of all bile duct carcinomas (Jarnagin and Shoup 2004; Ustundag and Bayraktar 2008; Mosconi et al. 2009). The general incidence rates of cholangiocarcinoma vary considerably among different regions of the world, as a function of variable risk factors such as stone disease or liver flukes. It is important to recognize that intrahepatic and extrahepatic cholangiocarcinomas have different epidemiological features and risk factors. In addition, incidence rates are not stable over time. For example, the age-adjusted incidence rate of extrahepatic cholangiocarcinoma in the USA declined by 14 % between 1975–1979 and 1995–1999 (review: Shaib and El-Serag 2004).

Data regarding the incidence of CDBD and their proportion among all cholangiocarcinomas vary considerably among diverse studies, in part dependent on the definitions of anatomical limits (Khan et al. 2008). Rolleston (cited by Springer 1925), in a study of 100 collected cases, found that one third of all extrahepatic bile duct carcinomas had arisen in the lower terminal portion of the choledochus, but it cannot be extracted from this work whether ampullary carcinomas also made part of this group. Of all carcinomas occurring in the periampullary region, CDBD-D accounted for 14 % (Zerbi et al. 1998). Among 37 cases of extrahepatic cholangiocarcinoma from the USA, 43.2 % were located at the middle third of the common bile duct, 37.8 % in the upper third, and 18.9 % in the distal-most third (Chao and Greager 1991). One analysis found 25 % of cholangiocarcinomas located to the distal part of the bile duct (Bahra et al. 2006). Among 564 consecutive patients from the USA with bile duct cancer, 8 % had intrahepatic, 50 % had perihilar, and 42 % had distal tumors (DeOliveira et al. 2007). Among 40 patients reported by Johnson et al. (2001), 80 % were located at the bifurcation, 12.5 % in the middle duct, and 7.5 % in the distal part. In a study of 207 patients undergoing pancreaticoduodenectomy, a reclassification based on the independent reevaluation of the histology resulted in an incidence of CDBD of 28 % (Pominasowska et al. 2012). The prevalence of CDBD may be underestimated based on difficulties of histologically distinguishing CDBD from ampullary carcinoma and pancreatic carcinoma invading the distal bile duct (Pomianoska et al. 2012). In contrast to gallbladder cancer, CDBD mostly occurs in males and is most common between the ages of 50 and 70. Rarely, this carcinoma develops in young adults or even adolescents (Agrawal et al. 2012). In part of patients with CDBD, the tumor was associated with choledocholithiasis (Su et al. 1996), a finding which has been suggested to play an etiologic role (Nishimura et al. 2005). In endemic areas, CDBD may be associated with liver flukes, e.g., clonorchiasis (Kim 2003). CDBD was found in association with anomalies of the pancreaticobiliary junction area (Nakao et al. 1997; Takayashiki et al. 2002) and rare bile duct abnormalities, such as bile duct duplication (Kosar et al. 2010).

Clinical and Imaging Features

Ewing noted that "epithelial tumors of the large bile ducts present much the same etiologic gross anatomic and microscopic features as carcinoma of the gallbladder, but their location favors early mechanical obstruction of important channels which promptly declares itself in severe jaundice and rapidly fatal course of the disease" (Ewing 1928). The most common presenting complaints in patients with CDBD are jaundice, followed by abdominal discomfort and pain, nausea and vomiting, and weight loss (Neibling et al. 1949; Martin and Page 1951; Kuwayti et al. 1957; Sako et al. 1957; Lippman et al. 1959; White 1959; Brown et al. 1961; Permen and McCollum 1963; Thomas 1970; Chao and Greager 1991; Patel 2006). Similar to ampullary carcinomas, CDBD-D cause marked biliary obstruction. Obstructive jaundice was present in 96 % of patients in one series, but was the first sign only in 78 % (Zerbi et al. 1998). Rarely, CDBD can present as cholangitis (Lee et al. 2010); in few cases, biliary stenosis had induced biliary

cirrhosis (Stutman and Bozian 1960; Gulsrud et al. 1979). Complications of CDBD include hemorrhage, abscess formation, and choledochoduodenal fistula (Lin et al. 2009). The preoperative imaging diagnosis of CDBD is performed by ultrasound, intraductal IS, CT, MRI, and endoscopic retrograde pancreaticocholangiography (Dancygier et al. 1988; Schulte et al. 1990; Alper et al. 2011; Ito et al. 2012). On CT images, the majority of CDBD patients reveal prestenotic dilatation of the bile ducts (Thorsen et al. 1984).

Pathology

The pathologic presentation of CDBD resembles that of other cholangiocarcinomas, with some remarkable differences. The pathology workup of specimens has been standardized, with formulation of a detailed protocol for examination (Washington et al. 2010).

Macroscopy

The macroscopic presentation of CDBD is characterized by nodular stenosing masses, masses with a tubular conformation, ulcerated tumors, diffusely growing cancers, or exophytic growths forming a papillary texture or polypoid tumors (Fig. 1).

Already in 1934, Lee and Totten had distinguished three macroscopic forms, namely, villous growths, which may distend and fill the ducts, nodular masses which tend to encroach upon and constrict the duct, and a diffuse growth along the duct which converts it into a firm tube. The tumors have been divided into polypoid, nodular, scirrhous constricting, and diffusely infiltrating types (WHO Classification; Albores-Saavedra et al. 2010), but there are considerable differences in macroscopic patterns between mid-region and distal tumors, and there are overlaps between the diverse phenotypes. The consistency varies considerably and ranges from soft masses to firm neoplasms in case of marked desmoplastic reaction, similar to sclerosing perihilar carcinoma. Infiltration of the duct wall results in thickening and induration of the duct. Tumors of the mid-region (CDBD-M) tend to be either tubular neoplasms that sometimes produce a filiform stenosis of 1 cm to 2 or 3 cm length or diffusely growing carcinomas with ill-defined borders. CDBD-D situated in the distal-most part of the common bile duct show a similar morphology or more often exhibit an exophytic growth mode, with fungating or polypoid masses with a papillary texture. In principle, CDBD-D tumors macroscopically often resemble ampullary carcinomas. In each location along the extrahepatic duct, the carcinoma can invade adjacent tissues, as there is no formal anatomical barrier. The tumor may be accompanied by

Fig. 1 Cholangiocarcinoma of the distal large bile duct. The duct mucosa is altered by granular and exophytically growing tumor tissue

enlarged and firm lymph nodes containing metastases. On cut surfaces of lymph nodes, small metastases are visualized as whitish nodules on the slightly tan-to-gray background of the lymph nodes, while large metastases may completely efface the lymph node architecture. Also, large perineural tumor deposits can be palpated or seen with the naked eye.

Histopathology

The histology of CDBD has already been described by Ziegler (1898), MacCallum (1919), Ewing (1919), Rolleston (1912), and Renshaw (1922). Based on the morphology of the carcinomatous epithelia, Rolleston (1912) proposed that most bile duct adenocarcinomas are derived from the biliary duct surface epithelium, which is in fact the leading cell lineage for adenocarcinoma NOS. Histologically, CDBD can present in various types and subtypes of adenocarcinoma and other carcinomas, as listed in the AJCC documents (Table 1).

A different classification of histologic types of CDBDs has been proposed in the protocol for the examination of specimens from patients with carcinoma of the distal extrahepatic bile ducts (Washington et al. 2010; Table 2).

Most CDBDs (at least 80 %) are adenocarcinomas, not otherwise specified/NOS, as defined in the 2010 fourth edition of the WHO Classification (Albores-Saavedra et al. 2010). Typical cholangiocarcinoma with a biliary cell lineage predominates in both CDBD-M and CDBD-D, and there is no difference in general differentiation between these two localizations. These adenocarcinomas often display a marked desmoplastic stromal reaction, thus resembling the sclerosing Klatskin tumors of the hilar/perihilar area. The epithelial cells of biliary-type adenocarcinomas are characterized by high columnar to cuboidal cells with a rather pale or even clear cytoplasm forming complete or incomplete tubular profiles embedded in a rich stroma (Laitio 1983; Davis et al. 1988). Cytoplasmic and/or luminal mucin is frequently present. This is the predominant pattern in well-differentiated carcinomas, whereas tumors with moderate or poor differentiation more often show solid parts or small nests or rows of cells in a desmoplastic stroma. In the latter situation, carcinoma cells tend to diffusely infiltrate the duct wall and the periductal connective tissue. The extensive and diffuse infiltration is impressively illustrated in immunohistochemical preparations, which may show many more dissipated tumor cells than anticipated in H&E-stained sections. A diffuse

Carcinoma, type cannot be determined

transmural growth pattern is typical for CDBD-M and results in the macroscopically tubular configuration of these mid-duct tumors, with short to long strictures. In contrast, desmoplastic CDBD-D more often tend to form nodular or mass lesions. A fraction of well-differentiated biliary-type adenocarcinomas may show focal intestinal differentiation and can contain goblet cells and neuroendocrine cells. Rarely, Paneth cells are noted.

As outlined below, adenocarcinoma can be accompanied by superficially spreading components or advanced dysplastic changes. These alterations may cause difficulties in the definition of clear margins, particularly in the setting of intraoperative frozen sections. Attempts to evaluate resection margins through frozen sections are also hampered in situations where a stent had placed prior to surgery. Stents can induce mucosal and tumor ulceration and necrosis of tumor tissue facing the stent, often associated with epithelial atypia caused by regeneration of cholangiocytes. These changes may be misinterpreted as dysplasia in frozen sections.

Histology of CDBD-M vs. CDBD-D

Overall, mid-region tumors form tubular invasive or nodular lesions, whereas distal carcinomas more often show an exophytic and papillary phenotype (Fig. 2). In an analysis of 96 extrahepatic cholangiocarcinomas, the histologic feature of lower third lesions was papillary in 26.7 %, 46.7 % of the tumors being well differentiated (Tompkins et al. 1981). However, if one lumps all extrahepatic bile duct carcinomas together, the papillary type is much rarer and does not exceed 5–6 % of all carcinomas, as this form very rarely occurs in the hilar/perihilar tumor group.

Perineural and Intraneural Invasion

Perineural invasion is a common feature of both CDBD-M and CDBD-D (Davis et al. 1988). Overall, perineural invasion was detected in 81.4 % of 75 resected bile duct cancers. In regard to tumor localization, incidences of perineural invasion were 80.7 %, 87.5 %, and 80 % for carcinomas of the hilar region, CDBD-M, and CDBD-D, respectively (Bhuiya et al. 1992). Perineural invasion is more frequently observed in nerves located in the deeper layers of involved bile ducts, but here a sampling effect may play a role, as larger nerves with easily detectable perineural invasion are more often found in the deep duct layer and in the duct's adventitia. In a first step, small deposits of carcinoma cells are found in the slit-like space of the perineurium, sometimes at entry sites of vasa nervorum. Later, as carcinoma undergoes further growth, sickle-shaped cancer deposits develop, which may sometimes encircle the entire nerve and cause

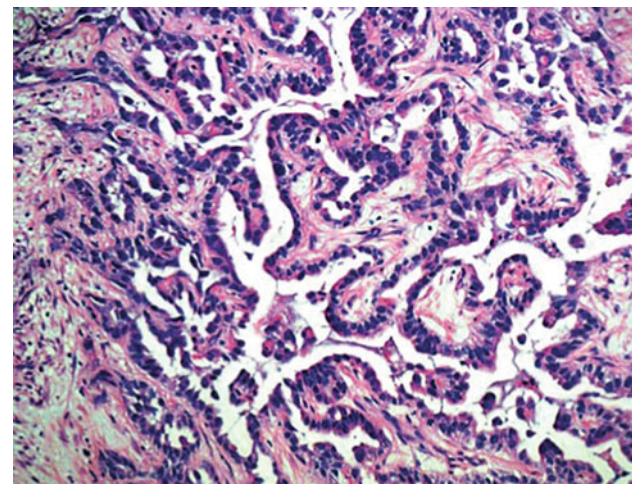

Fig. 2 Papillary cholangiocarcinoma of the distal extrahepatic bile duct. In distal parts of the extrahepatic biliary tract, papillary adenocarcinoma with an exophytic growth pattern is more common (hematoxylin and eosin stain)

neural atrophy. Tubular or cribriform structures may be found, with small necrotic foci and signs of tumor cell apoptosis. Apart from invasion of nerves in the immediate vicinity of tumor, also deep-seated neural plexus is involved. In one study, neural plexus invasion occurred in 20 % of patients, particularly involving the plexus in the hepatoduodenal ligament and around the pancreatic head (Kayahara et al. 1999). In order to estimate the extent of perineural invasion, a perineural invasion index (PNI) has been proposed, calculated as the ratio of the number of nerves invaded by tumor and total number of nerves with and without tumor invasion, determined in at least three places in each tumor (Bhuiya et al. 1992). PNI was graded as grade I (PNI = 0.00, no perineural invasion), grade II (PNI <0.70), and grade III (PNI => 0.70, severe perineural invasion). There seems to be a relationship between frequency and extent of perineural invasion and the histologic type. Perineural invasion was less often found in papillary adenocarcinoma than in other histologic types. The highest value (100 %) was found in poorly differentiated adenocarcinoma and in adenosquamous carcinoma (Bhuiya et al. 1992).

Grading

Grading of distal cholangiocarcinomas is performed as described in the chapter on hilar/perihilar carcinomas. In the CAP protocol for the workup for CDBD specimens (Washington et al. 2010), four histologic grades are distinguished (Table 3).

Table 3 Histologic grades for adenocarcinomas according to the CAP protocol (Washington et al. 2010)

GX: grade cannot be assessed
G1: well differentiated (greater than 95 % of tumor composed of glands)
G2: moderately differentiated (50–95 % of tumor composed of glands)
G3: poorly differentiated (less than 50 % of tumor composed of glands)
G4: undifferentiated

The grades are further defined as grade I being composed entirely of glands or having less than 5 % solid or cord-like growth patterns, grade II having more than 5 % but less than 50 % solid or cord-like growth patterns, and grade III having 50–100 % solid or cord-like growth patterns. About 75 % of all adenocarcinomas of the extrahepatic bile ducts are well to moderately differentiated. Among 96 cases of extrahepatic cholangiocarcinomas (including 49 % located to the upper third of the bile duct), 46 % were well differentiated, 25 % poorly differentiated, 20 % papillary, and 9 % sclerosing (Tompkins et al. 1981).

Immunohistochemistry

As other cholangiocarcinomas, CDBD tumor cells are reactive for the biliary cell lineage markers, CK7 and CK17, and for epithelial membrane antigen/EMA. Expression of carcinoembryonic antigen/CEA was found in most of the CDBD cells (Davis et al. 1988). Cholangiocarcinomas express IMP3 (Riener et al. 2009; Levy et al. 2010) and show nuclear and cytoplasmic reactivity for S100P (Levy et al. 2010).

Histologic Variants of Distal Cholangiocarcinoma

Adenocarcinoma, Intestinal Type

These carcinomas are characterized by tubular gland-like structures resembling those found in colorectal adenocarcinoma. A population of tall columnar cells predominates, and the pattern looks “basophilic” at low magnification. The epithelial cells are often arranged in a pseudostratified pattern, with nuclei in a basal position, but usually not in one single row, but rather arranged in several levels. Some of the nuclei move high up the epithelial lining, and nuclear debris and apoptotic bodies are found in the compartment of the tubuli. A less common variant of intestinal-type adenocarcinoma is characterized by a predominant population of

goblet cells, usually admixed with variable numbers of neuroendocrine cells. Intestinal-type adenocarcinoma of the distal bile duct can arise in zones of metaplastic biliary epithelium (Sano et al. 2003).

Adenocarcinoma, Gastric Foveolar Type

This variant is listed in the 2010 WHO classification of tumors of the digestive system. It is an unusual, well-differentiated adenocarcinoma composed of tall columnar cells with basally placed nuclei and abundant, mucin-containing cytoplasm. The tumors are composed of >95 % gastric foveolar-type epithelium, exhibit bland nuclei, and reveal a low mitotic index. The tumors can show perineural invasion and foci of less-differentiated adenocarcinoma (Albores-Saavedra et al. 1999). The cells are reactive for the MUC5AC mucin (Albores-Saavedara et al. 2010). The variant has been found in pure form in the extrahepatic bile duct system (Albores-Saavedra et al. 1999, 2000).

Adenocarcinoma, Pyloric Gland Type

Few cases of CDBD showing pyloric gland differentiation have been reported (Albores-Saavedra et al. 2012). The carcinomas revealed pyloric gland differentiation amounting to 80–1,000 %. Patients with this type of tumor were younger than those with adenocarcinoma NOS. Although the neoplasms were well differentiated, they displayed extensive perineural invasion. Histologically, the tumors showed small to medium-sized and cystically dilated glands arranged in a characteristic stellar pattern and embedded in desmoplastic stroma and composed of columnar cells with abundant mucin-containing cytoplasm. In part, MUC5AC and MUC6 were expressed in a pattern similar to that of pyloric gland adenomas of the gallbladder.

Mucinous Adenocarcinoma

Mucinous carcinomas (colloid carcinomas), characterized by extracellular accumulation of large amounts of mucin ("mucin lakes"), rarely occur in the extrahepatic bile duct and are less common in this site than, e.g., in the gallbladder. Among 170 cases of cholangiocarcinoma, 22 (12.9 %) were mucin-producing cholangiocarcinomas. Choledochoscopic findings included intraductal tumors in 40.9 % and infiltrative lesions with ductal stricture in 45.5 % (Chen et al. 1998). By convention, more than 50 % of the tumor contains extracellular mucin, which stains with PAS and alkaline alcian blue stains. One rare variant of mucinous bile duct carcinomas is characterized by marked neurotropism (neurotropic mucinous carcinoma). Macroscopically, the tumor is characterized by multiple transparent, mucinous nodules surrounding the main tumor and representing tumoral deposits following the ductal and periductal nerves. Histologically, peritumoral nerves are massively extended and spliced by large deposits of mucin with floating tumor cells.

Signet Ring Cell Carcinoma

Signet ring cell carcinoma, which as an entity is treated in a separate chapter, is a very rare primary tumor of the mid-duct and distal duct and is clearly rarer in this duct compartment than in the ampulla of Vater or the gallbladder. Signet ring cell carcinoma, as a poorly differentiated carcinoma, tends to grow in a disseminated pattern, diffusely infiltrating the duct wall, in association with variable desmoplasia and formation of a concentric duct stenosis. However, mass-forming lesions growing into the duct lumen are also known. As in gastric tumors, signet ring cells form small nests or files of round to void cells with a large mucin drop in the cytoplasm, displacing the sickle-shaped nucleus to the border of the cell. In contrast to other bile duct cancers, signet ring cell carcinoma tends to occur in a younger age group and is more often found in Asian countries. More cases situated in the CDBD-D (i.e., close to the ampulla) than in the CDBD-M

were described (Hiraki et al. 2007; Lee et al. 2010; Ogata et al. 2010; Matsumoto et al. 2011).

Papillary Carcinomas

Papillary adenocarcinoma of the extrahepatic bile ducts forms a distinct phenotype of cholangiocarcinoma that most commonly occurs in the distal half of the common bile duct and tends to show an exophytic/intraluminal growth pattern. Both invasive and apparently noninvasive variants are recognized. Frankly invasive papillary CDBD accounts for only 4–5 % of CDBD, and noninvasive and minimally invasive papillary carcinomas are even less common. Papillary carcinomas are often associated with adenomas or remnants of adenomas, which have been detected in up to 75 % of cases (Kozuka et al. 1984). Noninvasive and minimally invasive carcinomas are usually exophytically growing lesions with a polypoid shape. It has been shown that noninvasive and minimally invasive papillary carcinomas of the extrahepatic bile ducts, lesions different from biliary papillomatosis or intraductal papillary mucinous tumors, usually behave as in situ carcinomas and are associated with good to excellent prognosis, regardless of their cytological features or their immunohistochemical reactivity to p53 protein and proliferative activity assessed by MIB-1/Ki-67 (Albores-Saavedra et al. 2000; Fatima et al. 2008). Invasive papillary CDBD showed an equal gender distribution, and age at diagnosis ranged from 33 to 89 years (Hoang et al. 2002). Among 13 patients, five tumors were located in the distal portion, one in the mid portion, and six in the proximal portion of the common bile duct, and one tumor had arisen in the right hepatic duct (Hoang et al. 2002). In the invasive variant, infiltration of the bile duct wall, sometimes only the mucosal layer, is found, in polypoid tumor invasion commonly starting at the base of the tumor stalk (Nomoto and Nakao 1996). Depth of invasion is related to the growth pattern of tumors in that polypoid tumor rarely invades deeper than the fibromuscular layer, while flat or nodular carcinomas often infiltrate deeper than the fibromuscular layer (Kozuka et al. 1984). Of 174 invasive papillary carcinomas extracted from the SEER program, 71 tumors were confined to the ductal wall, and 61 had regional lymph node metastases. Even in the presence of locoregional lymph node metastases, invasive papillary carcinomas had a better outcome than adenocarcinoma NOS (Hoang et al. 2002).

Adenosquamous Cell Carcinoma and Squamous Cell Carcinoma

Relatively few cases of adenosquamous carcinoma of the extrahepatic bile ducts have been reported (Lantsberg et al. 1986; Hayashi et al. 1993; Hughes and Niemann 1996; Kimoto et al. 1996; Okabayashi et al. 2005; Lim et al. 2007; Kim et al. 2009; Aoki et al. 2012). Adenosquamous carcinomas of the bile duct are aggressive neoplasms, with a post-resection median survival in a Japanese cohort of 13 months (Okabayashi et al. 2005). This distinct tumor is discussed in more detail in a separate chapter. A very rare histologic variant of CDBD is squamous cell carcinoma (Burger et al. 1978; Gulsrud et al. 1979; La Greca et al. 2004; Sewkani et al. 2005). This type of biliary tract carcinoma has mostly been observed in the setting of hepatolithiasis, recurrent pyogenic cholangitis, and liver fluke disease. Squamous cell carcinoma of the common bile duct is much rarer than respective carcinomas in the gallbladder, intrahepatic bile ducts, or the ampulla of Vater. Squamous cell carcinoma found in the wall of the common bile duct is usually a metastasis from a primary tumor located elsewhere (Bass et al. 2010).

Mucoepidermoid Carcinoma

Mucoepidermoid carcinoma, histologically reflecting the phenotype of the respective salivary gland tumor, is a very exceptional bile duct tumor and has been observed in the distal-most (intrapancreatic) part of the common bile duct (Song et al. 2011; Moul et al. 2013). These

neoplasms are highly aggressive lesions that invade the underlying pancreas and peripancreatic tissue, sometimes with a pagetoid spread into the extrapancreatic common bile duct (Moul et al. 2013).

Lymphoepithelial Carcinoma

This type of carcinoma very rarely develops in the extrahepatic bile duct system and is treated in a separate chapter.

Poorly Differentiated Carcinoma, Undifferentiated Carcinoma, and Small Cell Carcinoma

Non-neuroendocrine high-grade undifferentiated carcinomas form cellular masses with poor desmoplasia (Nagai et al. 2002; Fujikawa et al. 2011). Typically, the tumors are composed of large cells with a high nuclear-to-cytoplasmic ratio, amphophilic cytoplasm, and nuclei with prominent nucleoli. Mitotic figures are frequent, as are apoptotic bodies and foci of necrosis. Part of undifferentiated carcinomas contain spindle cells and/or pleomorphic cells (Nagai et al. 2002). One variant of undifferentiated carcinoma of the distal duct is characterized by the presence of spindle cells and giant cells (undifferentiated spindle and giant cell carcinoma; Dowaki et al. 2003; Oikawa et al. 2007). Immunohistochemically, the neoplasms are reactive for AE1/AE3 and cytokeratins 8 and 18, but negative for chromogranin A, synaptophysin, and CD56 (Fujikawa et al. 2011). Due to their high cellularity and rapid growth, the tumors can form intraductal tumor thrombi (Fujikawa et al. 2011).

Carcinomas of the distal extrahepatic bile duct with a small cell morphology are almost always undifferentiated neuroendocrine carcinomas (Sabanathan et al. 1988; Van der Wal et al. 1990; Miyashita et al. 2001; Arakura et al. 2003; Kuraoka et al. 2003; Park et al. 2004; Kaiho et al. 2005; Viana Miguel et al. 2006; Hosonuma et al. 2008; Cho et al. 2009). In the protocol for the examination of specimens from patients with carcinoma of the distal extrahepatic bile ducts, the term small cell carcinoma has therefore been replaced by high-grade neuroendocrine carcinoma (Washington et al. 2010).

Mucosal Bile Duct Carcinoma with Superficial Spread

Distal adenocarcinoma may, similar to other cholangiocarcinomas, exhibit a mucosal localization with superficial spread/intraepithelial spread (IES) (Iwahashi et al. 1998; Sato et al. 2013), sometimes with extensive mucosal spread (Ogawa et al. 2010). IES has to be distinguished from BilIN-3 (Sato et al. 2013). Similar to carcinoma in situ/BilIN-3, IES lesions show flat or pseudopapillary pattern. The less frequent micropapillary pattern was found more often in BilIN-3 than in IES (Sato et al. 2013). In a study of 471 patients with cholangiocarcinoma (351 perihilar and 120 distal cancers), superficial spread was found in 14.6 %, and its length was 54 +/−19 mm. Superficial spread was detected more often in papillary and well-differentiated carcinomas, and lymphatic, venous, and perineural invasion were less frequent in carcinomas with superficial spread (Igami et al. 2009). It is difficult to judge whether this phenotype represents very early stage of cancer or whether some carcinomas have an inborn tendency to remain in a superficial layer of the duct for longer time periods. In one study, there was evidence that carcinomas with superficial spread might represent slower-growing and less advanced tumors with better survival (Igami et al. 2009).

Precursor Lesions of CDBD

Similar to intrahepatic cholangiocarcinoma, patients with CDBD may show various types of potential or established epithelial precursor lesions of the bile duct mucosa, either preceding invasive cancer or detectable synchronously with an already established carcinoma. This issue is further discussed in more detail in the ICC chapter. Low-grade or high-grade dysplasia was

observed in the distal bile duct, sometimes with a high frequency, in part associated with preexisting bile duct disease such as primary sclerosing cholangitis, stone disease, or liver fluke infestation (Davis et al. 1988; Haworth et al. 1989; lee et al. 1995). Primary sclerosing cholangitis is typically complicated by biliary dysplasia (Martins et al. 1994; Broomé et al. 1995; Fleming et al. 2001; Lewis et al. 2010). In an analysis covering 44 cases of extrahepatic cholangiocarcinomas, mild and in part multifocal dysplasia was detected in 91 % of cases and severe dysplasia in 45 % of cases (Laitio 1983). Adenocarcinoma in situ of the distal bile duct has been described (Yang et al. 2012). As outlined in the chapter on biliary precursor lesions, multistep carcinogenesis of cholangiocarcinoma is described by increasing grades of biliary intraepithelial neoplasia (BilIN), whereby BilIN-3 represents the stage of carcinoma in situ. BilIN-3 has to be distinguished from intraepithelial spread of carcinoma/IES, described in a later paragraph (Sato et al. 2013).

Biology of Disease

Outcome

Overall, the outcome of CDBD is better than that of ampullary carcinomas and carcinomas of the pancreatic head and similar to that of perihilar carcinoma, but worse than intrahepatic cholangiocarcinoma.

Selected references: Evander et al. 1980; Rodgers et al. 1981; Tompkins et al. 1981; Alexander et al. 1984; Anderson et al. 1985; Michelassi et al. 1989; Henson et al. 1992; Kayahara et al. 1992; Gozzetti and Principe 1995; Bortolasi et al. 2000; Heron et al. 2003; Albu et al. 2005; Bahra et al. 2008; Shimizu et al. 2008; Veillette and Castillo 2008; Lee et al. 2009; Ito et al. 2013.

In an investigation comparing 106 proximal and 98 distal resected extrahepatic cholangiocarcinomas, the estimated 5-year disease-specific survival (DSS) for all patients was 35 %, and tumor location (proximal vs. distal) was not associated with 5-year DSS (Allen et al. 2008). However, different results were found in other analyses, e.g., patients with distal bile duct cancer living longer than those with proximal cancers (Alden et al. 1995). The median survival for R0-resected patients with CDBD was 27 months, in comparison with 80 months for intrahepatic and 30 % for perihilar carcinomas (DeOliveira et al. 2007). In carcinomas of the distal-most part of the common bile duct, pancreaticoduodenectomy results in good 5-year survival rates (45 %; Shimizu et al. 2008).

Invasion and Spread

Perineural and neural plexus invasion is a common finding in CDBD (Bhuiya et al. 1992). Extrapancreatic neural plexuses were defined by the Japan Pancreas Society's Classification of Pancreatic Carcinoma (1966; Table 4).

Distant Metastases

Similar to other cholangiocarcinomas, CDBD produces distant metastases, sometimes late in the disease process and in a first round frequently to the liver and other visceral organs, including the stomach (Kim et al. 2009). Devic and Gallavardin (1901) already noted distant metastases in 20 % of patients. In an autopsy study on 65 patients, distant metastases were present in 75.4 % (Sons and Boerchard 1987). More patients with CDBD had liver metastases than patients with ampullary

Table 4 Classification of extrapancreatic neural plexuses (Japan Pancreas Society Classification of Pancreatic Carcinoma, 1996)

Celiac plexus (PL ce)
Superior mesenteric arterial plexus (PL sma)
Common hepatic arterial plexus (PL ch)
Plexus within the hepatoduodenal ligament (PL hdl)
Pancreatic head plexus I (PL ph I), which extends from the right celiac ganglion to the upper medial margin of the pancreas
Pancreatic head plexus II (PL ph II), which extends from the superior mesenteric artery to the medial margin of the uncinate process

adenocarcinoma (24 % vs. 10 %; Woo et al. 2007). Cholangiocarcinoma of the mid-common bile duct can produce umbilical metastasis, presenting as Sister Mary Joseph nodule (Agrawal et al. 2012). Extrahepatic cholangiocarcinomas can produce metastases to the ovary, sometimes with formation of Krukenberg tumors. Similar to other adenocarcinomas metastatic to the ovary, cholangiocarcinomas tend to undergo mucinous differentiation at the metastatic site and may even produce colloid carcinomas. In one study, mucinous epithelial differentiation was seen in 81 %, sometimes histologically resembling primary mucinous ovarian tumors (Young and Scully 1990; Young 2007; Khunamornpong et al. 2008).

Tumor Size

In inoperable distal tumors, tumor size was a significant variable associated with survival in univariate analysis (Kim et al. 2010). A threshold of 30 mm tumor diameter distinguished two survival profiles, tumors larger than 30 mm conferring about half the survival time in comparison with tumors smaller than 30 mm (Prat et al. 1998).

Perineural Invasion as a Risk Factor

Among 29 patients with CDBD-D, plexus invasion was detected in 27.6 %, mostly to the plexus pancreaticus capitalis (Kayahara et al. 1994). Overall, neural plexus invasion was more frequent in CDBD-D than in CDBD-M, and of eight patients with distal tumors, seven showed invasion of the superior pancreatic plexus (Kayahara et al. 1999). The presence of perineural invasion is a negative prognosticator (Murakami et al. 2007; Tan et al. 2013). Multivariate analysis indicated that perineural invasion was the only independent prognostic factor in one study (Shimizu et al. 2008).

Depth of Invasion

Among 147 patients with CDBD (49.7 % with T3 and 38.8 % with T4), most tumors had a depth invasion of 5 mm or more. Half of tumors had invaded to the duct 5–12 mm deep, and only 9.5 % had an invasion depth of less than 5 mm. It was found that depth of invasion was associated with worse outcome as tumor depth increased (Hong et al. 2009).

Pancreatic Invasion

Distal cholangiocarcinomas (CDBD-D) have a tendency to undergo invasive spread into the ampullary compartment and the pancreas. This mainly applies to those CDBD-D with a diffuse and/or sclerosing patterns and less so for papillary exophytic lesions. Pancreatic invasion was a significant prognostic factor in univariate analysis (Sakamoto et al. 2005). Among 20 patients with CDBD-D, ten showed pancreatic parenchymal invasion, and the frequency of lymph node metastasis in CDBD-D with pancreatic invasion was significantly greater than in CDBD-D without pancreatic invasion.

Vascular Invasion

Portal vein infiltration and lymph vessel invasion are strong predictors of outcome in patients with CDBD (Bahra et al. 2008).

Resection Margin

Univariate analyses revealed that a positive ductal and radial resection margin is a significant predictor of poor prognosis (Sakamoto et al. 2005; Murakami et al. 2007; Nomura et al. 2009; Lad and Kooby 2014). Multivariate analysis showed that negative resection margins are strong predictors for favorable prognosis (Bahra et al. 2008).

Lymph Node Metastasis

CDBDs (both CDBD-M and CDBD-D) have, similar to perihilar carcinomas, a tendency for locoregional lymph node metastasis (Kayahara

et al. 1993, 1999; Kiriyama et al. 2015). In a study of 42 patients, lymph node metastases were present in 60 % of patients, 42 % with pT2 tumors and 77 % with pT3 tumors. Also the total number of lymph node metastases was higher in pT3 lesions. All node-positive patients had involved nodes in the hepatoduodenal ligament or posterior pancreaticoduodenal region or both (Yoshida et al. 1999). In a previous study on 20 consecutive patients with carcinoma of the distal duct, lymph node metastases were detectable in 55 %, whereby posterior pancreaticoduodenal nodes were involved in 35 %, nodes around the hepatoduodenal ligament in 35 %, nodes around the common hepatic artery in 30 %, and para-aortic nodes in 25 %, in the latter mostly in the interaortocaval space (Yoshida et al. 1998a). In tumors with pancreatic invasion, metastases to nodes around the superior mesenteric artery (group 14) or around the aorta (group 16) were more frequent than in tumors without invasion of the pancreas (Yoshida et al. 1998b). In another study of 29 patients with CDBD-D, 68.9 % of patients had locoregional lymph node metastases and 37.9 % with involvement of the n3 group (Kayahara et al. 1994). In a systematic study of lymph flow in distal cholangiocarcinoma, lymph node numbers 12abp2 and 13a were important in lymphatic metastasis to superior mesenteric lymph node for distal bile duct cancer (Kayahara et al. 1993). A more recent study of 257 patients with extrahepatic bile duct adenocarcinoma found metastasis to regional lymph nodes in 34.6 %. The presence of nodal metastases was an independent prognostic factor of poor survival (Murakami et al. 2007; Ito et al. 2010). In a study comparing prognostic factors in patients with CDBD vs. ampullary carcinoma, only lymph node involvement was identified as a risk factor for recurrence of CDBD by multivariate analysis (Woo et al. 2007). Prognostically important lymph node factors were the number of involved nodes (Hong et al. 2005), common hepatic node metastasis, and para-aortic node metastasis (Nomura et al. 2009).

There is a difference in lymph node metastasis patterns between CDBD-M and CDBD-D lesions, however with variable findings in different investigations. Frequencies of nodal involvement were 57 % for CDBD-M and 71 % for CDBD-D. In a comparative study on 80 patients, the frequency of lymphnode spread of carcinomas in the proximal, middle, and distal parts of the large bile duct, excluding T1 tumors, was 48 %, 67 %, and 56 %, respectively. CDBD-D had a tendency to metastasize to nodes around the pancreatic head, while CDBD-M displayed a wide metastatic pattern, also including nodes around the mesenteric artery and the aorta (Kurosaki et al. 1996). The two topographic variants of CDBD also differ with respect to involvement of the resection margin, probably due to a difference in the growth pattern and differences in duct wall microcirculation. The tumor was present at the surgical margin in 50 % and 14 % of patients with mid-region carcinoma and distal carcinoma, respectively (Kayahara et al. 1999).

Histopathologic Type and Grade

The histologic grade is an important prognosticator affecting the prediction of overall survival (Kim et al. 2010). A papillary exophytic phenotype is associated with better outcome. In one study, papillary lesions were associated with a 50 % 22.3-month survival rate and a 31 % 5-year survival rate, as compared with a 50 % 9.8-month survival rate and an 8 % 5-year survival rate for well-differentiated non-papillary adenocarcinomas. The survival rates for poorly differentiated carcinomas were about the same as those of patients with well-differentiated tumors (Tompkins et al. 1981).

Other Prognostic Factors

A significant correlation was detected between a low proliferative activity as assessed through determination of the Ki-67/MIB-1 labeling index (less than 20 %) and survival (Rijken et al. 1998b). Low immunohistochemical expression of p53 (i.e., 0–30 %) is a favorable prognostic factor in patients with resectable CDBD (Rijken et al. 1999b), whereas overexpression of p53 in

CDBD was strongly associated with significantly reduced survival, independently of clinicopathologic prognostic factors (Cheng et al. 2007). p63 and p73 proteins were overexpressed in 26.3 % and 41.0 % of extrahepatic bile duct carcinomas. p63 expression was more frequent in tumors with vascular invasion and distal location, while p73 expression was more commonly found in carcinomas with deeper tumor invasion, and coexpression of both proteins was associated with a significantly worse overall survival (Hong et al. 2007). Epigenetic p16 hypermethylation may predict overall survival in curatively resected CDBD-M and CDBD-D (Park et al. 2013). Expression of the oncofetal protein insulin-like growth factor II mRNA-binding protein 3 (IMP3) was found in high-grade dysplasia of bile ducts, but not in low-grade dysplasia, and 58.3 % of bile duct carcinomas were strongly IMP3 positive. Cholangiocarcinoma IMP3 expression was associated with a higher proliferation rate and significantly reduced overall survival (Riener et al. 2009).

Differential Diagnosis

CDBD-M and CDBD-D can be mimicked by several neoplastic processes and reactive lesions that produce duct stenosis (Table 5).

Adenocarcinoma of the distal bile duct has to be distinguished from ampullary carcinoma and carcinoma of the pancreatic head infiltrating the distal-most part of the choledochus. Less common differential diagnoses include bile duct metastases of tumors outside the hepatobiliary tract and of hepatocellular carcinoma (Kim and Park 2012; Cha et al. 2013). Exophytically growing bile duct adenomas may radiologically be confounded with CDBD (Fletcher et al. 2004; Akaydin et al. 2009). Non-Hodgkin's lymphoma and Castleman's disease located to the duct wall have mimicked CDBD (Al-Salamah et al. 2005; Dote et al. 2009). Radiologically and histologically, adenomyoma may be confounded with well-differentiated cholangiocarcinoma (Läuffer et al. 1998; Ojima et al. 2000; Iwaki et al. 2008). Rare mesenchymal tumor of the common bile duct can simulate CDBD, including granular cell tumor, inflammatory myofibroblastic tumor, schwannoma, and leiomyoma (Jakobs et al. 2003; Goo et al. 2006; Martin Malagon et al. 2006; Tonsi et al. 2006). Neuroendocrine tumors primary to the common bile duct are rare lesions but can grow to relatively large size (Kim et al. 2006). Distal biliary stenosis due to bile duct stones can simulate CDBD (Plaza Santos et al. 2009). Heterotopic pancreas located to the bile duct wall can cause significant stenosis (Biswas et al. 2007). Tuberculosis of the common bile duct, pancreas, or periductal/peripancreatic lymph nodes can cause significant duct stenosis and obstructive jaundice (Chen et al. 1999; Colovic et al. 2008; Ray et al. 2012).

Table 5 Differential diagnosis of mid-duct and distal cholangiocarcinomas

Ampullary carcinoma
Carcinoma of the pancreatic head
Bile duct metastasis
Bile duct adenomas
Lymphomas of the bile duct
Adenomyoma of the bile duct
Mesenchymal tumors of the bile duct
Neuroendocrine tumors of the bile duct
Bile duct stones
Heterotopic pancreas
Tuberculosis of the common bile duct
Tuberculosis of the pancreas
Tuberculosis of periductal lymph nodes

Cytogenetic and Molecular Features

In CDBD, the most commonly lost chromosomal regions were, in decreasing order, 18q, 6q, 10p, 8p, 12q, 17p, 7q, 12p, and 22q. The most frequently gained regions were 8q, 20q, 12p, 17q, Xp, 2q, 6p, 7p, 11q, 13q, and 19q. These patterns resemble those found with pancreatic carcinoma (Rijken et al. 1999c). Flow cytometry and image cytometry investigations showed that 59 % of CDBDs were aneuploid (Rijken et al. 1999a). Among well-known oncogenes, K-ras codon 12 mutations are common in CDBD, but no prognostic values of these mutations could be

identified (Rijken et al. 1998a). In regard to molecular features, pertinent findings are summarized in the chapters on perihilar and intrahepatic cholangiocarcinomas.

Intrahepatic Cholangiocarcinomas (ICCs)

29

Contents

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_29

Abstract

Intrahepatic cholangiocarcinoma (ICC) is a cholangiocellular malignancy arising in any portion of the intrahepatic biliary tract. ICC can develop from small bile ducts and then occupies a peripheral compartment of the liver, but it also occurs in perihilar intrahepatic ducts and has to be distinguished from perihilar/hilar carcinoma of extrahepatic ducts. Overall, ICC is a rare neoplasm that accounts for less than 2 % of all malignant solid tumors. In relation to bile ducts involved, ICC is classified as a bile duct type (conventional type), further subdivided into a small bile duct type (peripheral type) and a large bile duct type (perihilar type), and a bile ductular type (bile ductular carcinoma or cholangiolocellular carcinoma). Several systems of pathomorphological classification of ICC have been proposed. The most commonly used system of the Japanese Liver Cancer Study Group distinguished mass-forming ICC, periductal-infiltrating ICC, and intraductal growth ICC. In the setting of the novel category of intraductal papillary neoplasm of the bile duct (IPN-B), treated in a separate chapter, most cases of intraductal growth ICC can now be considered to be invasive forms of IPN-B.

ICD-O Codes:

Intrahepatic cholangiocarcinoma 8160/3

Intraductal papillary neoplasm with:

Low-or intermediate-grade intraepithelial neoplasia 8503/0

High-grade intraepithelial neoplasia 8503/2

An associated invasive carcinoma 8503/3

Biliary intraepithelial neoplasia grade 3 (BilIN-3) 8148/2

Introduction

Intrahepatic cholangiocarcinoma (ICC) is a carcinoma with biliary epithelial differentiation that arises in any portion of the intrahepatic biliary tract (The Liver Cancer Study Group of Japan 1990; Chen 1999; Nakanuma et al. 2010). ICC can arise from cholangiocytes of segmental and areal bile ducts and their major branches to the smallest bile ducts and ductules, but different portions of the biliary system with their distinct cholangiocyte populations have an impact on the morphology of ICC. ICCs can originate from small bile ducts that are situated in the peripheral or mantle zone of the liver, but also from intrahepatic bile ducts that are close to the hilar area of the liver. ICCs originating from small intrahepatic ducts have been termed peripheral ICC, but this term should no longer be employed (Nakanuma et al. 2010). Perihilar ICC is defined as a tumor that arises from the large ducts that converge at the liver hilus. Such neoplasms may be difficult to distinguish from hilar cholangiocarcinoma or Klatskin tumor, which develops in the right or left hepatic duct or in the confluence region, particularly in situations of advanced stage. Careful anatomic preparation of resection specimens together with a consultation of CT and MR images is required to figure out which of the two tumor groups are involved.

Many ICCs harbor a population of mucin-producing cells and may originate from medium-sized to large ducts which normally have mucin-producing cylindrical cells. On the other extreme is cholangiolocellular carcinoma composed of non-mucin-producing and rather small cells, similar to those found in hepatic ductules. Between these two polar forms are various cancers that hold an intermediate position in regard to cell morphology and differentiation. The histologic phenotype of ICCs is also markedly influenced by the type of growth pattern of these carcinomas. Generally, mass-forming ICCs that grow within the liver substance predominantly show a tubular-to-solid morphology associated with desmoplasia, while ICCs growing within the lumina of bile ducts tend to produce papillary structures, a phenomenon also found in cancers of extrahepatic bile ducts. Finally, part of intrahepatic carcinomas exhibit a differentiation along a hepatocyte lineage, resulting in various types of combined cholangio-hepatocellular carcinomas.

Epidemiology

Cholangiocarcinoma as a whole is a rather uncommon malignancy that accounts for less than 2 % of all human malignant solid neoplasms, but is the second most frequent malignant intrahepatic primary liver tumor. It is estimated that about 5–15 % of primary liver cancers are ICCs (Craigh et al. 1989; Patel 2001; Okuda et al. 2002; Patel 2006; Cardinale et al. 2010), with certain geographical differences linked to the frequency of distinct risk factors, such as hepatolithiasis and liver flukes occurring in southeastern and eastern Asia. There are an estimated 2500 cases annually in the USA (a low-risk region), with 0.32–0.85 cases per 100,000 and a higher incidence in individuals of African descent. In comparison, 88 male cases per 100,000 were detected in one place in Thailand, a high-risk area due to a high frequency of liver fluke infestation. Several studies have shown that incidence and mortality of ICC are rising worldwide, whereas the incidence of extrahepatic cholangiocarcinoma (ECC) seems to decrease (Patel 2001; Khan et al. 2002, 2012; Shaib and El-Serag 2004; Shaib et al. 2005; Lazarides and Gores 2005; Singh and Patel 2006; Endo et al. 2008; Cardinale et al. 2010).

In the USA, the age-adjusted incidence rates of ICC increased by 165 % from 0.32 per 100,000 in 1975–1979 to 0.85 per 100,000 in 1995–1999 (Shaib and El-Serag 2004). This phenomenon may, at least in part, due to a potential role of chronic viral hepatitis, with or without liver cirrhosis, in the pathogenesis of ICC (Kobayashi et al. 2000; Khan et al. 2002; Hui et al. 2003; Shaib et al. 2005). In Europe, the mortality from ICC increased by around 9 % in both sexes from 1990 to 2008, reaching rates of 1.1/100,000 men and 0.75/100,000 women, the highest rates being in the UK, Germany, and France (Bertuccio et al. 2013). It was recently suggested that, in contrast to former views, cholangiocarcinoma is not uncommon in patients with hepatic cirrhosis (Lazarides and Gores 2005). When comparing 272 patients with ICC and 5829 patients with HCC, patients with ICC were more often elderly and had a lower proportion of asymptomatic tumors, less small tumors, or encapsulated tumors and a higher proportion of single tumors (Zhou et al. 2009). However, ICC also occurs in young patients, in part patients with preexisting congenital or acquired disorders of the biliary tract. Chinese ICC patients younger than 40 years had distinct features compared with older patients, including a low frequency of hepatolithiasis, a high positive rate of serum HBsAg and HBV-associated cirrhosis, a high frequency of elevated serum AFP, and often signs of hepatic inflammation (Zhou et al. 2010).

Clinical Features

At presentation, the most common symptoms and signs in patients with ICC comprise abdominal pain, malaise, weight loss, and hepatomegaly (Schlinkert et al. 1992; Kubo et al. 1995; Chu et al. 1997; Blechacz et al. 2011). In a series of 429 ICCs, upper abdominal discomfort or pain was recorded in 65 % of patients, but 12.1 % of patients were asymptomatic at diagnosis (Shen et al. 2009). Up to about 60 % of patients display elevated serum Ca 19-9, while CEA is detected in serum much less commonly. Some patients with ICC are seropositive for lectin-reactive alpha-fetoprotein/AFP. These patients showed a higher positivity rate for hepatitis viruses and more commonly chronic liver disease than those without

AFP positivity (Okuda et al. 2006). Most patients with ICC suffer from cholelithiasis, however, with varying prevalences in different geographical regions (Kaczynski et al. 1998). A complication of ICC is spontaneous tumor rupture, which may be followed by hemoperitoneum (Akatsu et al. 2005; Chong et al. 2006). In contrast to hepatocellular carcinoma, where spontaneous rupture is a rather common event, this complication is rarer in cholangiocarcinomas, probably due to a higher stroma content in cholangiocarcinoma increasing firmness and cohesion of tumor components. Rarely, ICC was associated with, or caused, Budd-Chiari syndrome (Kwon et al. 2007). Obstruction of local lymphatics in the course of carcinomatous lymphangiosis can result in lymph stasis and eventually chylous ascites (Yamamoto et al. 2004).

ICC can induce paraneoplastic syndromes. Few examples of ICC synthesizing granulocyte and granulocyte-macrophage colony-stimulating factor have been described (Kakinoki et al. 2000; Sasaki et al. 2003; Sohda et al. 2006; Takenaka et al. 2013). ICC producing granulocyte colony-stimulating factor can induce Sweet's syndrome (Shinojima et al. 2006). Another hormone that is sometimes secreted by cholangiocarcinomas is parathyroid hormone-related peptide, this production being associated with hypercalcemia (Audran et al. 1982; Davis et al. 1994; Yamada et al. 2000, 2009; Yen et al. 2004). ICC can produce more than one paraneoplastic factor at the same time, e.g., granulocyte colony-stimulating factor and parathyroid hormone-related peptide (Sohda et al. 2006). Paraneoplastic hypercalcemia induced by cholangiocarcinoma can be a lethal complication (Trikudanathan and Dasanu 2010). Very rarely, ICC was found to produce human chorionic gonadotropin/HCG (Izumi et al. 1986). Other paraneoplastic syndromes associated with cholangiocarcinoma include alopecia (Antoniou et al. 2012), disseminated porokeratosis (Torres et al. 2010), necrolytic migratory erythema (pseudoglucagonoma syndrome; Chiyomaru et al. 2010), paraneoplastic acrokeratosis of Bazex (Karabulut et al. 2006), and acanthosis nigricans (Ravnborg and Thomsen 1993).

Classifications of Intrahepatic Cholangiocarcinoma

Basic Classification: Perihilar Versus Peripheral Intrahepatic Cholangiocarcinomas

As outlined in more detail in the chapter on hilar/perihilar cholangiocarcinoma, classifications of cholangiocarcinomas are currently in a phase of redefinition, because past terminologies have led to some confusion. There is now strong evidence that both hilar carcinoma (Klatskin tumors) and ICC can involve bile ducts located in the "perihilar" region, rendering the distinction between ICCs situated close to the hilum and hilar carcinomas difficult in some cases. A current classification of ICC is based on the duct types involved. It basically distinguishes ICC derived from large (perihilar) and small (peripheral) bile ducts and tumors originating from bile ductules. Tumors developing from large perihilar ducts are termed large duct-type ICC or perihilar large duct type, and those originating from small peripheral ducts are called peripheral-type ICC or peripheral small duct type (Table 1; Nakanuma et al. 2008, 2010; Nakanuma 2012; Yeh et al. 2013; Aishima and Oda 2014).

Macroscopic Growth Patterns of Intrahepatic Cholangiocarcinoma

Several systems of pathomorphological classification of ICC have been proposed (Table 2; reviews: Yamaski 2003; Cardinale et al. 2013; Sanada et al. 2014). According to the classification approaches of the Liver Cancer Study Group of Japan, ICC was classified into three types based

Table 1 Basic classification of ICC in relation to bile ducts involved (Nakanuma et al. 2008, 2010; Aishima and Oda 2014)

Bile duct type (conventional type)
Small bile duct type (peripheral type)
Large bile duct type (perihilar type)
Bile ductular type (bile ductular carcinoma)

Hypervascular ICC

on the macroscopic appearance of cut surfaces of tumors, i.e., mass-forming ICC/MF-ICC, periductal-infiltrating ICC/PI-ICC, and intraductal growth ICC/IG-ICC (Liver Cancer Study Group of Japan 1997; review: Yamasaki 2003). The morphology of these three phenotypes is presented in more detail in a later paragraph.

MF-ICC produces an apparent mass lesion in the liver and often shows remnant hepatic recurrence. Some MF-ICCs occasionally show invasion of the biliary tract with segmental bile duct stenosis or an intraluminal growth resembling icteric-type HCC (Sano et al. 1996). PI-ICC causes obstruction or stricture of intrahepatic bile ducts/with spread along Glisson's sheath but without formation of large mass. This form of ICC is usually detected by ultrasonography due to the development of peripheral biliary dilatations. IG-ICC exhibits papillary projections into ductal lumina (Yamamoto et al. 1993). This classification has been discussed and further worked out in several studies (Sano et al. 1999; Lim 2003; Yamasaki 2003). Ohashi and coworkers divided ICCs into three categories, mass-forming ICC, periductal extension ICC, and spicula-forming ICC (Ohashi et al. 1994). Based on distinct invasion patterns, Aishima and coworkers (2007) divided ICC according to their origin from different levels of the bile duct system. The hilar type of ICC (H-ICC) is derived from large bile ducts close to the liver hilus, while the peripheral type of ICC (P-HCC) originates from smaller intrahepatic ducts situated in the mantle zone of the liver. In one study, H-ICC and P-HCC differed markedly in their behavior and in the biology of disease, H-ICC representing a high-risk group. The frequency of perineural invasion, lymph node metastasis, and extrahepatic recurrence was higher in H-ICC than in P-ICC, and prognosis was poorer in H-ICC. H-ICC showed large duct involvement within the tumor, and in cases of large tumor size, intraductal spread was present in the tumor periphery (Aishima et al. 2007). Nakanuma and coworkers (2008, 2010) have proposed a novel pathological classification (see below) that incorporates the new status of IG-ICC as intraductal neoplasm-type lesions. In another analysis, clinicopathological features were almost similar between patients with peripheral versus hilar ICC (Murakami et al. 2012).

Based on the vascularization pattern found at imaging, ICCs were divided into hypovascular (ordinary) versus hypervascular tumors (Yoshida et al. 1999). On gadolinium-enhanced MR images, hypervascular ICC showed complete or near-complete arterial enhancement and washout on delayed phases (Kim et al. 2012). In particular, ICCs in liver cirrhosis are hypervascular in comparison with those in normal livers (Xu et al. 2012). This classification is relevant insofar as the prognosis of hypervascular cholangiocarcinoma (h-CCC) is reportedly better than that of ordinary hypovascular CCC (o-CCC). h-CCCs show a high angiogenic activity and a high expression of stem cells and probably represent an early stage of tumor development (Sato et al. 2013a).

Molecular Classifications

The advent of molecular signatures that characterize distinct phenotypes of cholangiocarcinomas leads to refined stratification of these neoplasms and to molecular classifications. By the use of gene expression profiles, high-density single-nucleotide polymorphism arrays, and mutational analyses, two main biological classes of ICC have been identified (Sia et al. 2013). One class, the

inflammation class (38 % of ICC), was characterized by activation of inflammatory signaling pathways, overexpression of cytokines, and STST3 activation. The second class, the proliferation class (62 % of ICC), was characterized by activation of oncogenic signaling pathways (RAS, MAPK, and MET), DNA amplifications at 11q13.2, deletions at 14q22.1, mutations in KRAS and BRAF, and gene expression signatures previously associated with poor outcomes for patients with hepatocellular carcinoma. The proliferation class was associated with worse outcome (Sia et al. 2013).

General Macroscopic Features

ICCs present with three major characteristic macroscopic patterns which separate these tumors from other hepatic malignancies (Table 2; Figs. 1, 2, 3, 4, 5, 6, 7, 8, 9, and 10). These three forms (mass-forming, periductal-infiltrating, and intraductal growth ICCs) are discussed in more detail below. The striking differences between ICC and other primary liver tumors necessitate a specific approach when analyzing surgery and autopsy specimens. The examination of these tumors has been standardized in a protocol developed under the auspices of the College of American Pathologists (Washington et al. 2010). Specimen examinations to identify these features have been standardized (Washington et al. 2010).

ICC grows in one of several growth patterns that had led to macroscopic classifications of this tumor type by Japanese investigators. The Liver Cancer Study Group of Japan (1990) proposed a new classification based on the macroscopic appearance of ICC, i.e., the mass-forming (MF, mass-forming extraductal ICC) type, the periductal-infiltrating (PI) type, the intraductal growth (IG) type, and a mixed type having more than one of the three basic types, as already outlined above and discussed in more detail below. Macroscopically, the dominant mass-forming variant of ICC usually presents as a localized, more or less spherical tumor mass with a distinct border (Craigh et al. 1989), but more

Fig. 7 Intrahepatic cholangiocarcinoma, indeterminate type

complex forms also occur, including clusters of nodules or a wedge-shaped form (Wachsberg et al. 1996). At a molecular level, the three patterns of conventional or bile duct-type ICCs are similar to hilar cholangiocarcinoma (Liau et al. 2014). The three main growth patterns of ICC have an impact on tumor biology and the efficacy of hepatic resection (Guglielmi et al. 2009; Yeh et al. 2012). ICC of the various subtypes can undergo secondary changes, including cyst formation (Kokubo et al. 1990) or even multicystic change (Fujii et al. 2005).

In addition to these three major forms, few other macroscopic growth patterns have been recognized. ICC can present as minute nodular lesions defined as lesions with a diameter less than 3 cm in the greatest dimension. In a series of 50 ICCs, six tumors with this morphology were

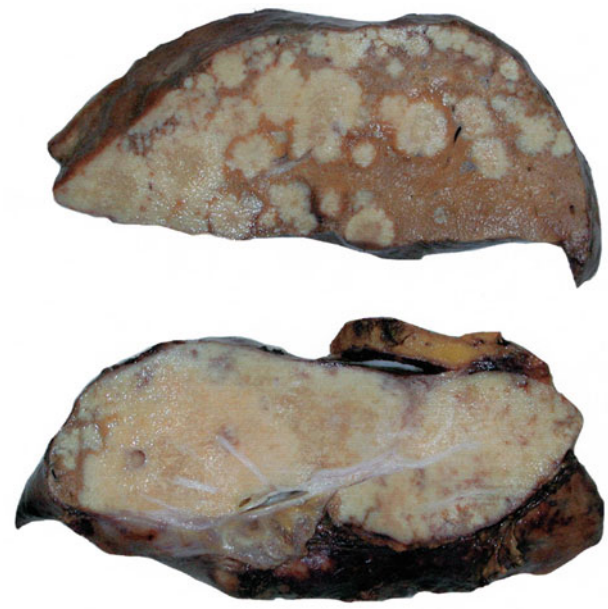

Fig. 8 Intrahepatic cholangiocarcinoma. The primary tumor (mass-forming type, *lower figure*) has led to numerous intrahepatic metastases (*upper figure*)

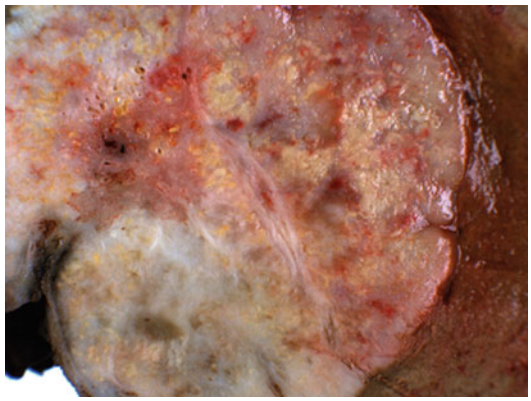

Fig. 9 Intrahepatic cholangiocarcinoma, mass-forming type, with numerous yellow necrotic foci and fresh hemorrhage

Fig. 10 Intrahepatic cholangiocarcinoma with extensive necrosis and formation of microcysts

detected, with a diameter ranging from 0.7 to 2.3 cm. The nodules were firm and had a gray to tan color and histologically showed desmoplasia. The average age of the patients was 57 years, with a male preponderance. Preoperatively, all these tumors except one were hypervascular on angiography or contrast-enhanced CT. Interestingly, these neoplasms are frequently associated with HCV infection and have a favorable biology of disease (Yamamoto et al. 1998). Very rarely, ICC can show a diffuse growth pattern, associated with extensive portal thrombi and acute hepatic failure (Uchida et al. 1998). Similar to hepatocellular carcinoma, ICC can present as an intrabile duct tumor, associated with obstructive jaundice and cholangitis. Macroscopically, a round tumor with a smooth surface was found to protrude into bile duct lumina, sometimes extending into the common bile duct (Sano et al. 1996; Yamamoto et al. 1997, 2009; Hai et al. 2005). It was shown that the intraductal growth (IG) type of ICC, and

also MF plus IG-ICC, had a better prognosis than other types of ICC (Yamamoto et al. 2009). The IG phenotype should not be confounded with intraductal growth ICC. In rare situations, invasion of the intrahepatic bile duct system is followed by detachment of tumor fragments, with free-floating tumor emboli causing intermittent obstructive jaundice (Capizzi et al. 1992).

Special Pathology of the Main ICC Types

Mass-Forming Intrahepatic Cholangiocarcinoma (MF-ICC)

MF tumors form the most frequently encountered type in a clinical setting and are grossly characterized as roughly spherical or potato-shaped masses with a distinct and sometimes slightly lobulated border. Irrespective of hilar invasion, MF lesions essentially show a macroscopically expansive growth pattern with formation of circumscribed masses without stellate extensions (Sano et al. 1999). MF-ICC can macroscopically closely mimic colorectal carcinoma metastasis, but look different from most hepatocellular carcinomas. Irrespective of their expanding growth pattern, MF-ICCs have marked tendency to invade adjacent structures. MF-ICC can grow along the surface of bile ducts and extend into the extrahepatic bile ducts (Regimbeau et al. 2003). Part of MF-ICCs show histologic bile duct invasion associated with segmental bile duct stenosis or an intraluminal growth resembling that of so-called icteric HCC (Kojiro et al. 1982; Sano et al. 1996). This invasion pattern was diagnosed in 26/41 patients with MF-ICC, and the presence of ductal invasion was correlated with an increased frequency of perineural invasion, lymphatic invasion, and a positive resection margin and lower survival rates, suggesting a more aggressive phenotype (Hirohashi et al. 2002a). Patients with this feature more often exhibited perineural invasion, lymphatic invasion, and a positive resection margin (Hirohashi et al. 2002a), suggesting a more aggressive phenotype among MF-ICC. There is a correlation between tumor size and spread, in that tumors with a diameter greater than 45 mm more often show invasion of portal and hepatic veins and more frequently exhibit invasion of lymphatics and perineural spaces (Sasaki et al. 2004). Some MF-ICCs develop intratumoral calcification (Kitade et al. 2005), but significant mineralizations are not a common feature of this tumor. Extraductal MF-ICCs were further subdivided into three categories. Type I lesions were those without biliary stricture; type II those with biliary stricture, but without jaundice; and type III those with biliary stricture with jaundice. Tumors without biliary stricture behaved more like hepatocellular carcinoma, while those with biliary stricture behaved more like hilar or extrahepatic cholangiocarcinomas (Yamanaka et al. 1995). Small ICCs of the MF subtype (diameter 3 cm or less) exhibit morphologic features different from larger lesions. In one series, small tumors did not show vascular or lymphatic invasion or perineural invasion, in resection specimens, and no patient had intrahepatic metastasis or lymph node metastasis (Kubo et al. 2004), suggesting that small and in particular peripheral MF lesions form a favorable risk group.

Periductal-Infiltrating (PI) Intrahepatic Cholangiocarcinoma (PI-ICC)

PI-ICC is a rare macroscopic type of cholangiocarcinoma with only a small mass or without any apparent mass that arises from the second order of intrahepatic bile ducts and shows a growth along dilated or narrowed bile ducts. Among 203 patients with ICC, only 7.9 % had PI-ICC (Uno et al. 2012). Radiologically, it manifests as an elongated, spiculated, or branching-like structure. Ultrasonographically, the tumors often present as a diffuse bile duct thickening with or without bile duct stenosis or obliteration, associated with dilatation of peripheral ducts, while CT and MR images display diffuse periductal thickening and increased enhancement associated with duct narrowing and prestenotic duct dilatations. This distinct growth pattern resembles that of many hilar/perihilar cholangiocarcinomas, with

the exception of a less prominent invasive phenotype. The PI type of ICC generally exhibits a diffuse invasion along the portal pedicle, but shows only minor or no invasion of the adjacent liver parenchyma (Sano et al. 1999; Uno et al. 2012). On resected specimens, a whitish ill-defined tumor is found that diffusely invades the tissues along the portal pedicles. A growth pattern mimicking PI-ICC results from intrahepatic periductal lymph vessel metastasis (lymphangiosis carcinomatosa) originating from extrahepatic cholangiocarcinoma (Tada et al. 1996). One variant of PI-ICC is a hilar type that usually causes obstructive jaundice. It presents as a diffuse low-density mass infiltrating the portal pedicle and causing unilateral or bilateral intrahepatic bile duct dilatation. These tumors can cause diffuse cancer invasion of the right or left hepatic artery and stenosis of the portal vein bifurcation (Sano et al. 1999). The prognosis of PI-ICC after surgery is better than that for MF-ICC without hilar invasion (Imai et al. 2010). In the study of Uno and coworkers (2012), the median survival was 7.7 years, with a 5-year survival rate of 62.1 %, and the overall outcome was better than that for MF plus PI-type ICC.

Intraductal Growth Intrahepatic Cholangiocarcinoma (IG-ICC): The Invasive Forms of Intraductal Papillary and Tubular Neoplasm of the Bile Duct (IPN-B and ITN-B)

The term intraductal growth ICC (IG-ICC; ICC of intraductal growth/IG type) was originally coined by the Liver Cancer Study Group of Japan and has been widely used until recently. IG-ICC encompasses a rare group of cancers that display intraductal exophytic growth, are associated with distinct precursor lesions, and can undergo a transition into invasive conventional ICC or mucinous carcinoma. There is a clear relationship between invasively growing intraductal cholangiocarcinomas and their non- or preinvasive partner lesion, intraductal papillary neoplasms of the bile duct (IPN-Bs), neoplasms discussed in a separate chapter. There is strong evidence that a majority of ICCs of intraductal growth (IG) type belong to neoplasms of an IPN-B lineage (Nakanuma et al. 2014).

Intraductal growth intrahepatic cholangiocarcinoma (formerly, intraductal variant of peripheral cholangiocarcinoma) is characterized by a cholangiocarcinoma that preferentially grows within intrahepatic bile ducts, often with a papillary or tubular growth pattern and variable invasion of adjacent liver tissue (Kim et al. 1989; Han and Lee 2004; Yeh et al. 2005; Nakanuma et al. 2008; Uno et al. 2012). In the original proposal of the Japanese classification of ICC, IG-ICC was designated as intraductal papillary ICC, a special type of ICC which developed a papillary projection into the duct lumen (Yamamoto et al. 1993). Intraductal variants of ICC had been reported previously (Kim et al. 1989). IG-ICC is also the invasive neoplasm that develops from intraductal papillary and tubular neoplasms of the bile duct (IPN-Bs and ITN-Bs). Among the three macroscopic subtypes of ICC, IG-ICC is the least common type, albeit with some differences between studies and countries. In a Japanese study of 64 patients with resected ICC, 28 were MF, 24 PI, and only 12 were IG-ICC (Sano et al. 1999). Among 98 Korean ICC cases, 42 were MF, 22 PI, 21 IG, and 13 mixed types (Suh et al. 2002). In a study of 16 patients, age at presentation ranged from 38 to 73 years (mean, 55.9 years), and 13 were men (Suh et al. 2000). The tumor occurs in the left and the right liver lobe with almost equal frequency. IG-ICC usually forms an ill-defined nodule, which is often smaller at presentation than those of other ICC subtypes. In an analysis of Suh and coworkers (2000), the average tumor diameter was 4.3 cm (range, 0.5–14 cm). Mucobilia is more frequent in this subtype than in MF and PI subtypes, as are anemia and elevated serum CEA levels (Yeh et al. 2005). IG-ICC is in most cases a neoplasm not associated with other neoplastic lesions, but has rarely been observed in conjunction with biliary papillomatosis (Güllüoglu et al. 2007). The tumors may cause, due to the intraductal exophytic growth, stenosis or obstruction of the involved intrahepatic duct. This is probably the

reason why a higher percentage of IG-ICC patients than non-IG-ICC patients presents physical signs at diagnosis and why these patients more often have signs of biliary tract infection, including bouts of fever, chills, and jaundice (Yeh et al. 2004). The imaging features of IG-ICC are characteristic (reviews: Suh et al. 2000). CT images show lobulated densities in the dilated bile ducts. In case of mucin secretion, dilatation of bile ducts is seen. Instead of a gross tumor mass, only cystic and tubular dilatation of the intrahepatic bile ducts may be noted (Lim et al. 2000). Cholangiography and ERCP reveal multiple filling defects in dilated intrahepatic bile ducts, sometimes mimicking gallstones.

In contrast to PI-ICC, which has a tendency to spread along Glisson's sheaths via lymphatic vessels (Sasaki et al. 1998b), ID-ICCs have a lower propensity for invasive growth, this probably being the main reason for the better outcome. ID-ICC less often produces lymph node metastases than any other ICCs (Suh et al. 2000; Isa et al. 2001). Among 16 patients with resected ID-ICC, not a single case showed lymph node metastases (Suh et al. 2000). Most studies demonstrate that, among ICCs, ID-ICC has the best prognosis (Suh et al. 2000; Tajima et al. 2004). In one study of five patients with resection, four were alive without recurrence, while one patient died 7 years and 7 months after surgery from a rapidly growing tumor in the liver remnant (Yamamoto et al. 1997). In a study of 98 ICCs, the 5-year cumulative survival rate was 23.3 % in the MF subtype, 0 % in the PI subtype, and 76.2 % in the ID subtype (Suh et al. 2002). In an analysis of the clinical features of 40 ID-ICCs (intraductal papillary type) having been treated by hepatectomy between 1977 and 2000, in comparison with 94 non-papillary-type ICC, both groups having similar age and sex distributions, the 5-year-survival rate was 24.7 % in the ID-ICC subtype versus 2.01 % in all other ICC types (Yeh et al. 2004). A papillary intraductal growth pattern was a positive prognosticator in a study of 373 peripheral ICCs (Jan et al. 2005). Even an intraductal papillary carcinoma component (IDPCC) in the tumor had a favorable effect on outcome, in that the presence of IDPCC, together with curative resection and the absence of perineural invasion, was a favorable independent prognostic factor in multivariate analysis (Tajima et al. 2004). Exophytic-papillary growth patterns generally seem to confer a favorable biology in cholangiocarcinomas. It has been shown, e.g., that a papillary phenotype confers improved survival after resection of hilar cholangiocarcinoma (Jarnagin et al. 2005).

The macroscopic features of IG-ICC have been described in detail (Yamamoto et al. 1994). Including the involved bile ducts, IG-ICCs form rather small and circumscribed masses with a mean diameter of 4.3 cm in one study (Suh et al. 2000), but tumors exceeding 10 cm in diameter may exceptionally occur. In some cases, aneurysmal dilatation of involved bile ducts occurs (Jin et al. 2002). In case of large lesions, massively dilated intrahepatic bile ducts are filled with coarse or fine papillary and sometimes granular masses of whitish tumor tissue. After cutting through the tumor and the discharge of viscid fluid, the papillary fronds typically separate from each other, leaving a friable tissue with numerous slits between the exophytic tumor parts. In the rare IG-ICC with marked gross invasion, the presentation is more complex and sometimes no longer characterized by an exophytic, papillary growth pattern. In a detailed analysis of five cases, the tumors showed intrabile duct growth and superficial mucosal spread in two patients. In two other patients, an apparent mass lesion accompanied the intraluminal component, while in the remaining patient, a polypoid tumor infiltrated the portal tract system of the left lateral segment, where it had arisen (Yamamoto et al. 1997).

General Histologic Features

Most ICCs are histologically mucin-producing adenocarcinomas with variable degrees of differentiation (90 % of cases; Nakajima et al. 1988; Sinawat and Hemsrichart 1991; reviews: Nakanuma et al. 2003; Esposito and Schirmacher 2008; Zimmermann 2001). ICCs have a biliary origin, but the cellular sources have not yet fully been clarified, as apart from cholangiocytes and

progenitor cells, also hepatocytes may be the source of ICC (Guest et al. 2014). Depending on the level of differentiation, the cellular features of ICC cells resemble cells lining small, medium-sized, or large bile ducts. The cytoplasm is often pale or slightly eosinophilic, sometimes vacuolated. In solid parts, distended intra- or intercellular lumina (so-called second glands) are found, sometimes blending into cribriform structures (Nakajima and Kondo 1989). Even in well-differentiated tumors, irregular nuclear configurations are very common (Figs. 11, 12, 13, and 14).

As already outlined above, Nakanuma and coworkers proposed a pathological classification of ICC based on a novel concept (Nakanuma et al. 2008, 2010). The system distinguishes a bile duct or conventional type, further broken down into perihilar or large duct and a peripheral or small duct type, a bile ductular type, an intraductal neoplasm type, and rare variants.

The conventional or duct type is the most common phenotype. This type is further divided in the small duct type or peripheral type and the large duct type or perihilar type. Macroscopically, duct-type ICC displays compressive growth and no fibrous capsule. The small duct type presents as the MF-ICC type and histologically appears as a tubular or, less commonly, micropapillary adenocarcinoma with desmoplastic stroma and

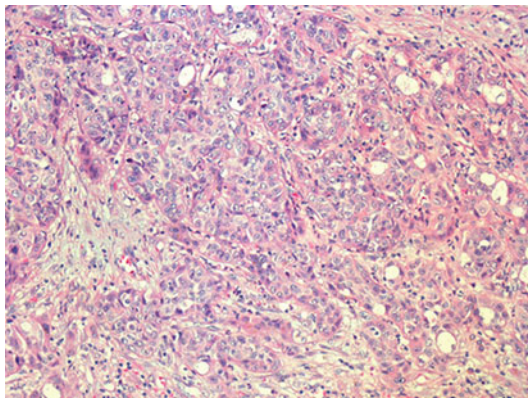

Fig. 11 Intrahepatic cholangiocarcinoma with poor desmoplasia (hematoxylin and eosin stain)

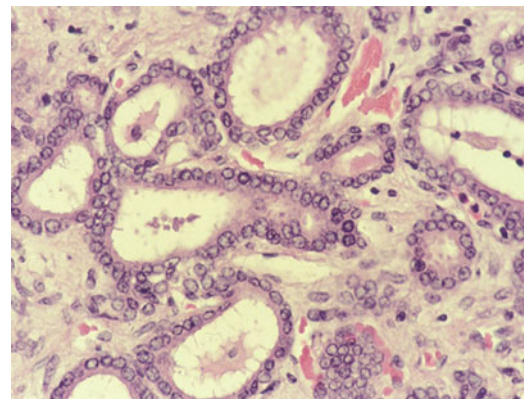

Fig. 13 Well-differentiated intrahepatic cholangiocarcinoma with formation of well-organized tubules and a homogeneous cell population (hematoxylin and eosin stain)

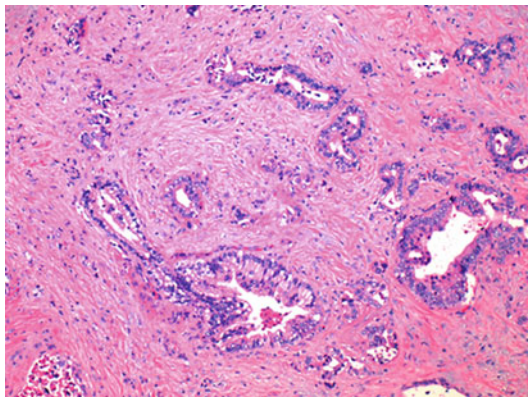

Fig. 12 Intrahepatic cholangiocarcinoma with marked stromal reaction (desmoplasia, hematoxylin and eosin stain)

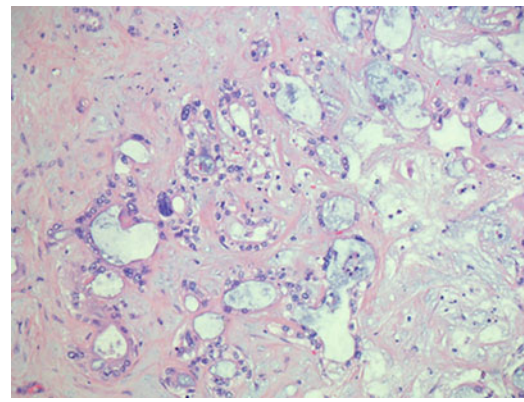

Fig. 14 Intrahepatic cholangiocarcinoma with mucin production and focal necrosis (hematoxylin and eosin stain)

inflammatory infiltrates and a compressive or replacing growth pattern. Most lesions are moderately differentiated and show central desmoplasia and/or necrosis. Immunohistochemically, the tumor cells, which are larger than normal cholangiocytes, are positive for cytokeratins 7, 8, 18, and 19, MUC1, MUC5AC, and MUC6, but not for NCAM (Nakanuma et al. 2008). The large duct or perihilar type presents macroscopically as PI-ICC or PI+MF-ICC types. The growth involves perihilar intrahepatic large bile ducts with formation of tubular, acinar, or micropapillary invasive tumor components and papillary or flat components growing within ducts. In addition, peribiliary glands can be involved (Nakanuma et al. 2010).

The bile ductular type usually presents as a MF-ICC with central scarring and a blurred margin blending into adjacent liver tissue. It consists of cells that are smaller than those in conventional ICC and mimicking those of ductules found in portal tracts. The tumor resembles collections of proliferated ductules (ductular proliferations), whereby small tubular profiles with slit-like lumina, acinar structures, or cord-like structures are present. Collagen bundles accompany the carcinoma cells. Bile ductular carcinoma exhibits a distinct replacing infiltrative growth of liver parenchyma. The invading tumor cells directly face parenchymal cells and appear to replace them. The cells are usually not alcian blue or PAS positive, except that some cells have discrete PAS-positive rim on their luminal face. Immunohistochemically, the tumor cells are reactive for cholangiocyte markers, NCAM, and often also vimentin. MUC1 is positive and MUC6 is focally present, but MUC2, MUC3, and MUC5AC are not detectable. The central desmoplasia histologically shows scar-like features and sometimes hyalinization. Within the fibrotic area, portal tract remnants may be found, together with trapped nodular or lobular parenchymal remnants (Nakanuma et al. 2008, 2010). A variant of ductular-type ICC mimics ductal plate malformations and presents as a carcinoma with an irregular configuration and branched, complex slit-like tubular spaces lined by cuboidal or columnar cells of high differentiation. A subset of ICCs show a combination of duct-type and ductule-type features (combined duct and ductular ICC), whereby the two components are present in amounts varying from one tumor to the other. These neoplasms exhibit ductular cholangiocarcinoma in the peripheral zone of the tumor and duct-type cholangiocarcinoma in central parts (Nakanuma et al. 2008).

The histology of IG-ICC is characterized by a papillary cholangiocarcinoma forming arborizing papillae that freely grow into the bile duct lumen, forming an exophytic mass. Thin papillary structures with a delicate vascular system are lined by a cuboid-to-columnar epithelium of the cholangiocellular type. The apical cytoplasm may contain PAS-positive and alkaline alcian blue-positive mucin. Depending on the grade, nuclei reveal variable degrees of atypia. One variant of IG-ICC is histologically characterized by mucosal spread, tubular and solid components with associated stroma growing within the mucosal lining of the intrahepatic bile duct (mucosal-spreading IG-ICC; Lim et al. 2000; Suh et al. 2000). In the vicinity of the neoplasm, variable degrees of epithelial dysplasia, immunoreactive for CA 19-9, can be observed in the bile duct mucosa (Ohta et al. 1991). A spatial association of dysplastic bile duct epithelium and IG-ICC is also found in ICC associated with hepatolithiasis, suggesting that biliary epithelium persistently exposed to biochemically altered bile may undergo a carcinogenic evolution (Ohta et al. 1991). The intraductal papillary neoplasm (IPN) type comprises the previous categories of biliary tract papilloma and papillomatosis and in part mimics intraductal papillary mucinous neoplasms (IPMNs) of the pancreas, and includes three subtypes, i.e., intraductal papillary neoplasms of the bile duct (IPN-Bs), intraductal tubular neoplasms of the bile duct (ITN-Bs), and a superficial spreading type. Typically, both IPN-B and ITN-B are associated with, or preceded by, a spectrum of precursor lesions that are discussed in more detail in the following paragraph. Intraductal neoplasm-type lesions can undergo transition into invasive cancers that show a conventional (bile duct-type) morphology or a mucinous morphology and correspond to IG-ICC (Nakanuma et al. 2010).

Electron microscopic examinations showed that cells of well-differentiated cholangiocarcinomas contain relatively numerous ribosomes, but few organelles, while organelles become more frequent in tumors of lesser differentiation. Some of the cells display groups of fine fibrils. Neoplastic cell lining tubules exhibit surface microvilli. The cells are often surrounded by a thin basement membrane, which is incomplete or fragmented in poorly differentiated tumors. Subsets of cells may show tonofilaments indicating squamous cell differentiation (Alpert et al. 1974; Stitnimankarn et al. 1978; Sriurauranata et al. 1996).

Alternative Histologic Classifications

Histologically, ICCs were categorized into classical and nonclassical (Table 3; Sempoux et al. 2011).

Classical ICCs (54.8 %) were characterized by tubular, glandular, or nested patterns of growth and were significantly associated with a tumor size of more than 5 cm diameter and the absence of underlying liver disease. The main properties of nonclassical ICC (45.2 %) included trabecular architecture, features of extrahepatic carcinomas, and features of carcinomas considered to arise from hepatic progenitor cells, i.e., combined hepatocellular/cholangiocarcinomas and cholangiolocellular carcinomas (ductular type of ICC). Nonclassical tumors were also smaller and often developed in chronic underlying liver disease, in particular HCV infection and/or significant hepatic fibrosis (Sempoux et al. 2011).

Table 3 Classification of ordinary intrahepatic cholangiocarcinomas/ICCs (excluding special variants, see below; Sempoux et al. 2011)

Classical ICCs
Nonclassical ICCs
Tumors with a trabecular architecture
Tumors with features of extrahepatic carcinomas
Combined hepatocellular/cholangiocarcinomas
Cholangiolocellular carcinomas (ductular type of ICC)

Table 4 Differentiation groups of intrahepatic cholangiocarcinomas (ICCs)

Null-type ICC
Gastric foveolar-type ICC
Pyloric gland-type ICC
Gastric combined-type ICC

Based on mucin/MUC expression patterns, ICCs were classified into several differentiation groups (Table 4).

They include null type, gastric foveolar type, pyloric gland type, and gastric combined type, whereby half of the gastric foveolar and gastric combined types were located to the hilar region (Aishima et al. 2006). Part of these variants are associated with a distinct tumor biology. For example, the gastric foveolar type with a gastric mucin phenotype (predominance of MUC5AC) is associated with an aggressive tumor behavior (Aishima et al. 2006). ICCs tend to invade into and spread between hepatocyte plates, infiltrate adjacent portal tracts, grow along bile ducts, and invade perineural spaces (Weinbren and Mutum 1983; Shen et al. 2010). There are certain differences between ICC arising in cirrhotic livers and those that developed in normal livers. ICCs in non-biliary chronic advanced liver disease are more frequent of the bile ductular, while intraductal papillary neoplasms of the bile duct/IPN-Bs are more frequent in the patient group without chronic advanced liver disease (Nakanuma et al. 2011). ICCs arising in liver cirrhosis are hypervascular in comparison with those developing in normal livers (Xu et al. 2012). Secondary histologic changes in ICC comprise, apart from necrosis, apoptosis, and hemorrhage, focal calcification. In a case of ICC with paraneoplastic production of parathyroid hormone-related peptide, marked psammoma body formation was found in the tumor (Yamada et al. 2000).

Histological Variants

In rare instances (around 10 % of cases), ICC is histologically associated with components different from ordinary adenocarcinoma (Nakajima et al. 1988; Table 5). These variants are treated in separate paragraphs.

Table 5 Rare variants of intrahepatic cholangiocarcinoma

Mucinous ICC (mucin-producing ICC)
Signet ring cell ICC
Papillary ICC
Micropapillary ICC (*sensu strictiori*)
Cribriform ICC
Perihilar cholangiocarcinoma-like ICC (S100P+)
ICC with tumor infiltrative lymphocytes and autoimmune hepatitis-like features
ICC with lymphoepithelioma-like components
Clear cell ICC
Oncocytic ICC
ICC with squamous cell or adenosquamous components
ICC with thyroid-like structures
ICC with cyst formation
Microcystic ICC
ICC with a ductal plate malformation pattern
AFP-producing ICC
ICC with sarcomatous change

Markedly mucin-producing cholangiocarcinoma (mucinous and colloid adenocarcinomas) is a special variant that is associated with a more favorable course (Chou and Chan 1976; Sasaki et al. 1995; Chow et al. 1997; Chen et al. 1998), but can rarely be a composite tumor together with small cell carcinoma (Ikegami et al. 2013). Mucinous cholangiocarcinoma is defined as an adenocarcinoma with abundant deposition of extracellular mucin, amounting to more than 50 % of the tumor mass. Mucinous and signet ring cell tumors are treated in separate chapters. One variant of ICC originating in intrahepatic large bile ducts and associated with hepatolithiasis is intestinal-type ICC. This rare tumor exhibits a predominantly intraductal papillary growth pattern and is primarily composed of absorptive columnar cells, associated with widespread Paneth cell, goblet cell, and neuroendocrine cell metaplasia. The tumor shows only minor local invasion (Bae et al. 2002). One variant of ICC is characterized by cells resembling, or derived of, cholangiocytes of small ducts or ductules (cholangiolocellular ICC), while another variant shows an infiltrating replacement growth pattern and a striking resemblance to reactive proliferating ductules (bile ductular carcinoma; Kozaka et al. 2007). These neoplasms are listed in the Nakanuma classification as a distinct type (Nakanuma et al. 2010). ICC can present as a neoplasm with thick-walled cysts that resemble liver abscesses (Kokubo et al. 1990; Lee et al. 1995) or presents with a microcystic pattern, the latter also occurring in mucinous ICC (Mizukami et al. 1999). A distinct subset of peripheral ICCs that are associated with intrahepatic lithiasis resemble perihilar cholangiocarcinomas; are S100P positive, similar to perihilar and extrahepatic cholangiocarcinomas; and probably originate from larger intrahepatic ducts (Tsai et al. 2012). S100P nuclear expression in peripheral-type ICC significantly correlated with vascular invasion, lymphatic invasion, and lymph node metastasis (Aishima et al. 2011). A lymphoepithelioma-like component was reported, in part associated with expression of EBV-encoded RNA (Chen et al. 2001; Xiao et al. 2012). Other rare ICCs show dense tumor-infiltrative lymphocytes and may have autoimmune hepatitis-like features (Izumi et al. 2010). ICC predominantly consisting of adenocarcinoma can contain a component of squamous cell carcinoma or adenosquamous carcinoma (Nakajima et al. 1988; Nakajima and Kondo 1990). Uncommon variants of ICC revealed oncocytic change (Fujii et al. 2005), clear cell change (Toriyama et al. 2010), or a phenotype resembling a thyroid follicular neoplasm (Fornelli et al. 2010), these features discussed in separate paragraphs. A rare variant of well-differentiated ICC presented as a single nodule and histologically showed numerous vague, small carcinomatous areas with desmoplasia and epithelial formations resembling a ductal plate malformation (Nakanuma et al. 2012). Very rarely, ICC is associated with elevated serum AFP and marked AFP immunoreactivity of ICC cells (AFP-producing ICC; Vij and Wang 2008).

Grading, Growth, and Differentiation

Grading of ICCs is usually performed by the use of grading systems applied to other adenocarcinomas, although definitive criteria have not been established (Washington et al. 2010; Table 6).

The histologic grade of ICC has a strong impact on the biology of disease and outcome (see below). The growth patterns of ICCs vary as a function of differentiation, well-differentiated neoplasms showing few mitoses, while poorly differentiated ICCs can show a high proliferation fraction. The PCNA labeling index was lowest in MF-ICC and was higher in periductal growth ICCs (Ohashi et al. 1994). Synthesis of proteins as an important factor of cell differentiation is reflected by argyrophilic nucleolar organizer regions (AgNORs). AgNOR is loop DNA encoded for ribosomal RNA production on the nucleoli controlling protein synthesis. In ICC, differentiation is reflected by the number of AgNORs per nucleus (Hayashi et al. 1995).

Table 6 Grading of ICCs of the conventional adenocarcinoma type

Grade X	Grade cannot be assessed
Grade 1	Well differentiated (more than 95 % of tumor composed of glands and less than 5 % solid or cord-like components)
Grade 2	Moderately differentiated (50–95 % of tumor composed of glands and more than 5 % but less than 50 % solid or cord-like components)
Grade 3	Poorly differentiated (5–49 % of tumor composed of glands and 50–100 % solid or cord-like components)
Grade 4	Undifferentiated (less than 5 % of tumor composed of glands)

Stroma Formation (Desmoplastic Stroma, Desmoplasia)

Similar to extrahepatic cholangiocarcinomas, ICCs are often characterized by marked stroma formation (desmoplasia), whereby stromagenesis is usually more prominent in MF and PD than in ID-ICC. Some ICCs display a marked desmoplasia that mimics that of hilar cholangiocarcinomas (sclerosing ICC; Altemeier et al. 1957). The stroma is a cellular tissue rich in myofibroblasts (MFBs), cancer-associated fibroblasts (CAFs), and extracellular matrix proteins and proteoglycans and is the tissue in which tumor vessels are embedded. ICC cells grow within this stroma, and cancer cells engage in a close and complex interaction with stromal cells. Stromal MFBs are involved in the progression of ICC and promote cancer cell proliferation, migration, invasiveness, apoptosis resistance, and epithelial-mesenchymal transition/EMT, EMT playing a critical role in the metastatic pathway (review: Sirica 2011).

There are subsets of ICC that exhibit a markedly sclerosing stromal reaction (Figs. 15, 16, and 17).

According to the degree of stroma formation, ICCs have been divided into scirrhous-type ICC (SICC) and non-scirrhous-type ICC (NSICC). The two groups differed with respect to various morphologic and biologic parameters. In SICC tumors, lymphatic invasion, perineural invasion, and proliferative activity were higher than in NSICC, and patients with SICC revealed a poorer prognosis than those with NSICC (Kajiyama

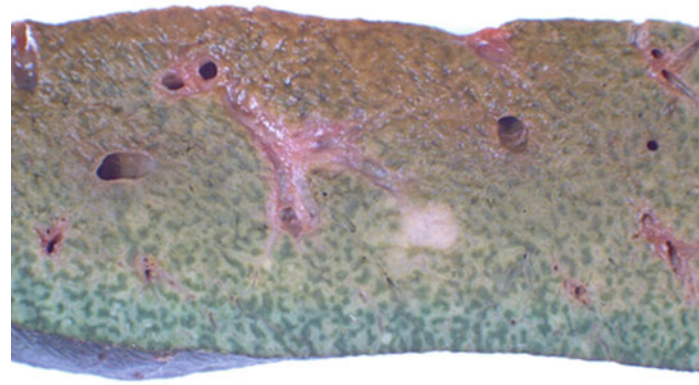

Fig. 15 Sclerosing intrahepatic cholangiocarcinoma. These tumors sometimes appear as small solitary lesions

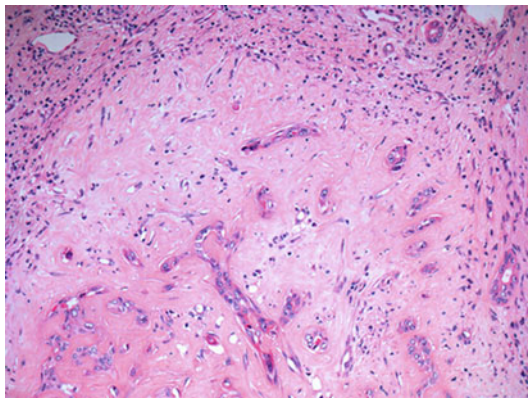

Fig. 16 Sclerosing intrahepatic cholangiocarcinoma. The tumor nodule is dominated by a sclerosed stroma with only few carcinoma tubules (hematoxylin and eosin stain)

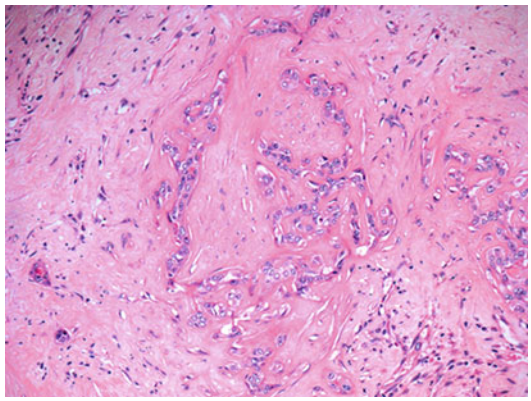

Fig. 17 Intrahepatic cholangiocarcinomas with marked fibrosclerosis and a poor contribution of small and monotonous carcinoma cells may mimic benign lesions such as adenofibroma (hematoxylin and eosin stain)

et al. 1999). Most ICCs show a fibromyxoid stroma rich in basement-membrane-type heparan sulfate proteoglycan (Sabit et al. 2001). The stroma of ICC was found to contain few S-100 protein-positive nerve fibers (Terada and Matsunaga 2001). Apart from fibroblastoid cells, alpha-SMA-positive MFBs are a predominant population, but their precursors, hepatic stellate cells, are also present in variable numbers, these cells being reactive for desmin, alpha-crystallin, and glial acidic fibrillary protein (Okabe et al. 2009). In stromal cell populations of ICC, alpha-SMA-reactive MFBs form two cell groups, i.e., peritumoral SMA-positive perisinusoidal cells and intratumoral SMA-positive stromal cells. There is evidence that SMA-positive peritumoral perisinusoidal cells are, in the course of tumor growth and invasion, incorporated into the stroma, where they then form the stromal MFBs. The number of both groups showed a positive correlation with the degree of tumor fibrosis (Terada et al. 1996a). The stroma of cholangiocarcinomas also harbors a population of CD10(+) fibroblasts, which are more involved in the progression of extrahepatic cholangiocarcinomas than that of ICC (Nishihara et al. 2009).

Stromal cells are biologically very active, engage in complex interactions with carcinoma cells, and are partners for mesenchymal cells derived from carcinoma cells in the setting of epithelial-to-mesenchymal transition (Sirica et al. 2011). Cholangiocarcinoma cells interact with stromal fibroblastoid cells via epithelial cell-derived neutrophil-activating peptide-78/CXCL5, a factor that causes accumulation of CD66(+) neutrophils in the tumor stroma (Okabe et al. 2012). Certain factors produced by stromal cells directly promote invasion. Periostin, produced by cholangiocarcinoma stromal cells, binds to carcinoma cells via integrin alpha5beta1, leading to activation of the invasion-promoting integrin/PI3K/AKT pathway (Utispan et al. 2012). In the stroma, hepatic stellate cells/HSCs or cells derived thereof interact with carcinoma cells. HSCs modify the behavior of carcinoma cells having contact with them or being exposed to their secreted products. On coculturing with HSC, ICC cells showed a marked increase in growth and invasive behavior (Okabe et al. 2009, 2011). Stromal-derived factor-1/SDF-1 produced by HSC induces cholangiocarcinoma cell migration via an interaction with CXCreceptor4 localized in carcinoma cells (Ohira et al. 2006; Gentilini et al. 2012). A direct interaction of cholangiocarcinoma cells with HSC promotes tube formation of human endothelial cells and accelerates the growth of the cancer cells (Okabe et al. 2011). A critical cell type of tumor stroma is the myofibroblast, a fibroblastoid cell that expresses alpha-smooth muscle actin and is

derived from the HSC lineage. In cholangiocarcinoma, stromal myofibroblasts promote proliferation of carcinoma cells through a pathway that drives epithelial cells into the S plus G2/M phases of the cell division cycle (Chuaysri et al. 2009). Fibroblastoid cells of cholangiocarcinomas produce periostin, which is a stromal factor that promotes an invasive phenotype (Utispan et al. 2010). Carcinoma-associated myofibroblasts also modulate ICC progression through their effects on apoptosis resistance and EMT, in part through aberrant hedgehog signaling between the two cells types involved (review: Sirica 2011).

Arterial vessels found within ICCs in part represent portal tracts that have been engulfed by the tumor. Aggressive invasion of tumors is manifest as decreased intratumoral arteries caused by portal tract destruction (Aishima et al. 2009). Extraductal mass-forming ICC can cause marked intrahepatic duct strictures/stenoses, whereby strictures confer a biology similar to that of perihilar or extrahepatic cholangiocarcinoma (Yamanaka et al. 1995).

Invasion and Spread

Intrahepatic Invasion and Spread

ICCs are highly invasive cancers that invade various hepatobiliary structures and tissues (Figs. 18, 19, 20, and 21). In regard to intrahepatic spreading, an analysis of 102 cases of ICC revealed expansion through sinusoidal spaces in 93 %, vascular invasion in 52 %, lymphatic involvement in 18 %, perineural invasion in 16 %, replacing growth in bile ducts in 12 %, and infiltration of portal connective tissue in 19 % (Nakajima et al. 1988).

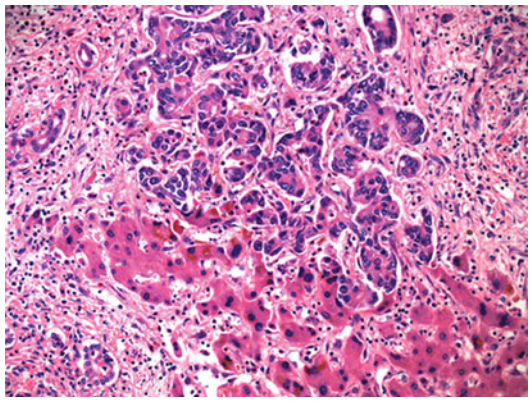

Fig. 21 Intrasinusoidal invasion of intrahepatic cholangiocarcinoma (hematoxylin and eosin stain)

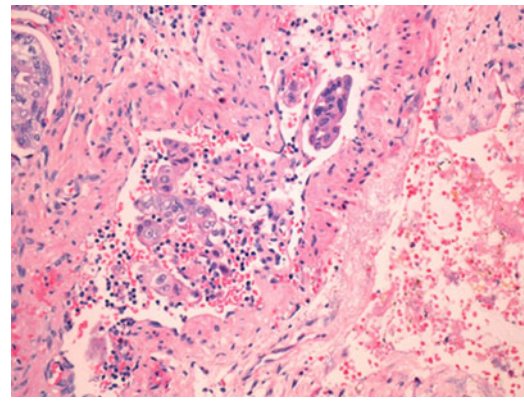

Fig. 22 Venous invasion of intrahepatic cholangiocarcinoma (hematoxylin and eosin stain)

Perineural Invasion

Perineural invasion is an important mode of spread for ICC, but is mainly observed in tumors located to areas where nerves are more common, i.e., close to the liver hilus. In a comparative investigation, the frequency of perineural invasion was higher in the hilar type of ICC than that in the peripheral type of ICC (Aishima et al. 2007). The recruitment of cholangiocarcinoma cells to the perineural compartment is accomplished by the actions of nerve growth factor and its receptors, neural cell adhesion molecule/NCAM, and matrix metalloproteinases (Shen et al. 2010).

Vascular Invasion

In contrast to hepatocellular carcinoma, gross invasion of the portal vein is less common, but portal tumor thrombi may be extensive and represent an unusual cause of hepatic failure or portal hypertension in patients with ICC (Terada et al. 1992; Soyer et al. 1998; Uchida et al. 1998; Kwon et al. 2000; Nakagohri et al. 2003; Uenishi et al. 2003). Obstructive portal vein invasion predominantly takes place when the portal vein branch is embedded within a large ICC mass. In addition to large intrahepatic veins, ICC also invades small venous vessels and venules (Fig. 22).

ICC may show a superficially spreading phenotype instead of an infiltrative growth pattern (Lim et al. 2000; Abe et al. 2005; Igami et al. 2009; Oshiro and Esaki 2011). ICC can be associated with extensive thrombosis of the inferior vena cava, causing Budd-Chiari syndrome (Law et al. 2005). The hepatic artery can also undergo direct invasion of ICC, followed by artery obstruction (Uenishi et al. 2003). A minority of ICC may show very unusual invasion patterns. In one case, well-differentiated mucin-producing ICC presented in the form of multiple irregularly shaped tumors in the liver. A mucinous fluid was found in the portal veins, the inner surface of which was lined with a single layer of tumor cells, reflecting an unusual mode of intravascular growth, while extravascular tissue invasion was hardly detectable (Minakawa et al. 2010).

Lymphatic Invasion and Lymph Node Metastasis

Similar to other forms of cholangiocarcinoma, ICC presents a high rate of lymphatic invasion and lymph node metastasis (Nozaki et al. 1998; Yamamoto et al. 1999; Okami et al. 2003; Nakagawa et al. 2005; Tamandl et al. 2009; Patel et al. 2011; review: Adachi and Eguchi 2014) (Fig. 23).

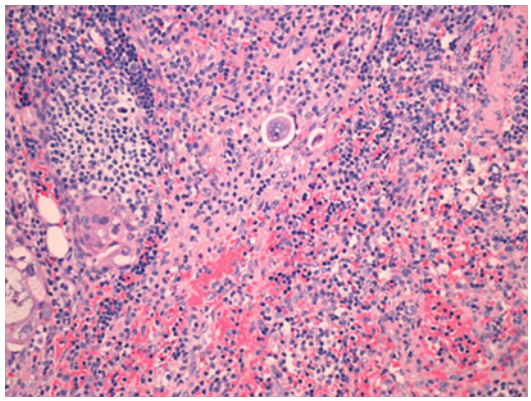

Fig. 23 Invasion of lymphatic vascular spaces by single cells of intrahepatic cholangiocarcinoma (hematoxylin and eosin stain)

Locoregional lymph node metastases were detected in up to 62 % of cases, with hilus-near cancers having slightly higher nodal metastasis rates than peripheral ones (Tsuji et al. 2001). Lymphatic spread in ICC is related to VEGF-C expression and D2-40-positive myofibroblasts, suggesting that a subset of myofibroblasts in stroma may contribute to lymphatic metastasis (Aishima et al. 2008) and is more often detectable in the tumor periphery and in peritumoral tissue than in the tumor center (Aishima et al. 2008). Lymph node dissection studies have shown that lymph node metastases in ICC were seldom limited to the locoregional nodes (Shimada et al. 2001). Involved nodes are located to the hepatoduodenal ligaments, along the hepatic and celiac arteries, around the abdominal aorta, on the posterior surface of the pancreatic head, along the left gastric artery, along the superior mesenteric artery, along the lesser curvature of the stomach, and around the cardia. The nodes of the hepatoduodenal ligament were the most common metastatic site, followed by nodes along the common hepatic artery, periaortic nodes, and nodes on the posterior surface of the pancreatic head (Tsuji et al. 2001). In another lymph node mapping analysis, nodal involvement was highest for nodes along the lesser gastric curvature (the left pathway), followed by nodes of the hepatoduodenal ligament (the right pathway; Okami et al. 2003). Lymph nodes in the hepatoduodenal ligament may be sentinel nodes for ICC lymphonodal metastases (Yamamoto et al. 1999; Chen et al. 2006). Metastases in nodes along the lesser gastric curvature and the left gastric artery were only observed in ICC that originated in the left liver lobe. The reported rate of perihepatic lymph node positivity for ICC was 27–62 % (Nozaki et al. 1998; Valverde et al. 1999; Yamamoto et al. 1999; Chen et al. 2006). In one study, metastatic nodes were divided into three groups, N1, N2, and N3, based on the classification proposed by the Liver Cancer Study Group of Japan. Among 23 patients with ICC, metastases were to N1 nodes in 10 patients, to N2 nodes in 9 patients, and to N3 nodes in 4 patients, and 19 patients had metastasis in nodes of the hepatoduodenal ligament, suggesting a sentinel node status (Yamamoto et al. 1999). However, the "true" incidence of perihepatic nodal metastases is not known, as micrometastases were not yet taken into account, but it was stated that the incidence of truly occult metastatic disease in perihepatic lymph nodes is low (Grobmyer et al. 2006). Rarely, ICC metastasizes to lymph nodes above the diaphragm, e.g., cervical lymph nodes (Hardeman et al. 2002; Imamura and Suzuki 2004).

Distant Metastasis

ICC has a complex metastasis pattern (Kim et al. 2003). Apart from intrahepatic metastases, metastatic spread involves the gastrointestinal tract (including the small intestine and colon; Izzo et al. 2010; Hayashi et al. 2011; Tokodai et al. 2012), pancreas (Labgaa et al. 2014), lung (Fukushima et al. 2011), skeleton including skull (Takahashi et al. 1994; Carlisle and Roberts 1999; Nishizawa et al. 2006; Kwon et al. 2007; Miyamoto et al. 2007; Fujimoto et al. 2013), soft tissue and muscle (Park et al. 2010), skin (Kondo et al. 2012), adrenal gland (Pandey et al. 2007), meninges (carcinomatous meningosis; Okamura et al. 2008), and brain (Mimatsu et al. 2011). Metastasis to the colon can cause intestinal obstruction (Tokodai et al. 2012). ICC may metastasize to the ovaries and mimic primary ovarian

cancer, but this is a rare metastatic pathway (Low et al. 2003; Khunamornpong et al. 2007; Corr et al. 2013). Ovarian ICC metastasis can result in Krukenberg tumor (Sharma et al. 1997).

Immune Reactions and Leukocyte Infiltration in Intrahepatic Cholangiocarcinoma

Lymphocytes that accumulate within and around ICC are of several types and reveal distinct distribution patterns. CD8(+) cytotoxic lymphocytes are most abundant at the invasion front of the tumor, whereas IL-17(+) and FOXP3(+) lymphocytes predominate in an intratumoral compartment (Gu et al. 2012). Similar to other carcinomas, ICCs harbor a distinct population of monocytes/macrophages, the tumor-associated macrophages/TAMs. TAMs located in the stroma play an important role in stromagenesis and in the regulation of tumor behavior. For example, TAMs are an important source of metalloproteinases and other proteinases, specifically MMP-9, in cholangiocarcinoma (Subimerb et al. 2010). In ICCs, the number of CD68(+) and CD163(+) macrophages is positively correlated with numbers of blood vessels and regulatory T cells. TAMs in ICC contribute to cancer progression via STAT3 activation (Hasita et al. 2010). Mast cells are detectable in the stromal tissue of ICC, and the density of these cells was higher in ICC than in hepatocellular carcinomas and higher than in portal tracts of normal liver (Terada and Matsunaga 2000). Mast cells may be involved in the generation of fibrosis in the stroma.

Immunohistochemistry

As neoplasms derived from cholangiocytes or progenitor cells that are primed to become bile duct cells, ICCs share at least part of the immunohistochemical reactivity patterns with normal biliary epithelial cells. Distinct immunohistochemical staining patterns will be helpful to improve stratification of these neoplasms (Iguchi et al. 2009).

Cytokeratins, Other Cholangiocyte Lineage Markers, and Markers of Cell Differentiation

Most ICCs reveal a characteristic marker profile, showing reactivity for CK7, CK8, CK17, CK18, CK19, and CD7 and lack of CDX2 (Maeda et al. 1996; Sasaki et al. 1999; Rullier et al. 2000; Shimonishi et al. 2000; reviews: Langer et al. 2006; Stroescu et al. 2006). Strong reactivity for CK7 in peritumoral ductular proliferations should not be confounded with cancer tubules (Fig. 24). In a comparative study, the most common cytokeratins positive in ICC were CK7, CK8, and CK19, and moderate and extensive expression of CK19 was found in almost all cases of well-differentiated ICC (Fig. 25), but expression decreased as a function of decreasing differentiation. CK20 is usually negative, but was occasionally detectable in poorly differentiated ICC, more frequent than in hilar cholangiocarcinoma (Shimonishi et al. 2000). Carcinoembryonic antigen/CEA is present in cells of invasive adenocarcinomas and in cells of carcinoma in situ, but is not detectable in hyperplastic lesions. In contrast, CA 19-9 is a typical marker of hyperplasia, reactivity being intermediate in dysplasia and low in invasive ICC (Terada and Nakanuma 1992). Practically all ICCs show marked membranous expression of epithelial membrane antigen/EMA, a marker which is

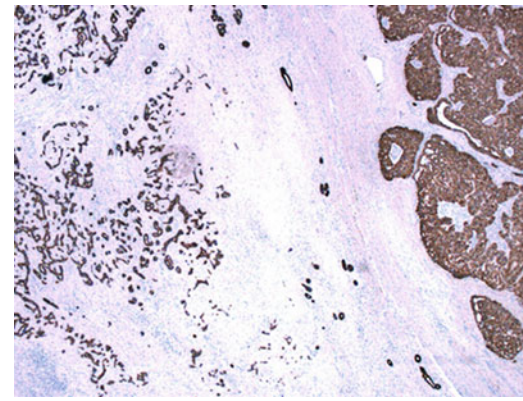

Fig. 24 Peritumoral ductular proliferations (*left half of figure*) in intrahepatic cholangiocarcinoma (cytokeratin 7 immunostain)

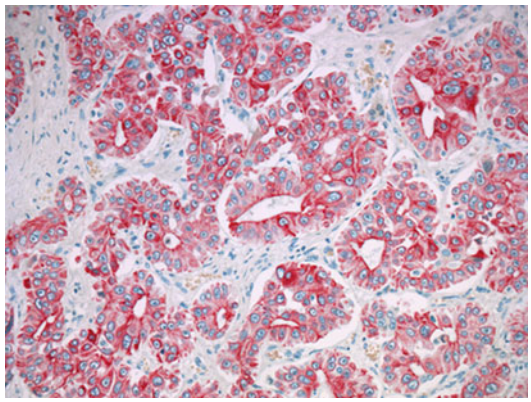

Fig. 25 Strong reactivity of intrahepatic cholangiocarcinoma cells for cytokeratin 19 (CK 19 immunostain)

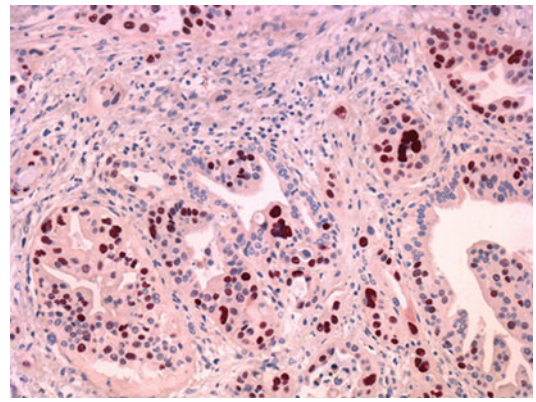

Fig. 26 Marked p53 protein reactivity of nuclei in intrahepatic cholangiocarcinoma (p53 immunostain)

important for distinction between ICC and pseudoglandular HCC (Bonetti et al. 1983). Two lineage markers of hepatocytes and hepatocellular carcinoma, HepPar-1 and arginase-1, were positive in a minority of cholangiocarcinomas (Leong et al. 1998; Radwan and Ahmed 2012). Most ICCs are reactive for fatty acid-binding protein 5 (Jeong et al. 2012). ICC cells do not, or only infrequently, express glypican-3 (Man et al. 2005), but may be positive for glutamine synthetase (Lagana et al. 2013). Human carcinoma antigen (HCA) is overexpressed in ICC and can be used a potential marker for ICC diagnosis (Zhou et al. 2011). The term HCA has been employed to collectively denote a group of mucin-type high molecular weight glycoproteins that are overexpressed in diverse epithelial cancers and are recognized by the monoclonal AE3 antibody (Thingstad et al. 1998; Palma et al. 2011). Peripheral ICCs express tubulin-betaIII more frequently than hilar carcinomas; this cytoskeletal protein serves as a helpful marker for ICC (Zen et al. 2014).

Stem Cell/Progenitor Cell Markers

Part of ICCs harbor population of tumor cells with progenitor cell or stem cell features. These cells may be reactive for NCAM and c-Kit (Xu et al. 2011), SALL4 (Oikawa et al. 2013), and/or CD44 and glioma-associated oncogene homologue 1/GLI1 (Nakanishi et al. 2013). CD133, a stem cell marker, shows distinct expression patterns in cholangiocarcinoma. CD133 reactivity is not restricted to stem cells, but also reflects the differentiation status of carcinoma cells. In cholangiocarcinoma, well-differentiated and moderately differentiated cancers were more often CD133 positive than poorly differentiated ones (Fan et al. 2011).

Oncogenes and Tumor Suppressors

A significant fraction of ICC shows nuclear immunoreactivity for p53 protein, positivity being detectable in up to 100 % of cases (Washington and Gottfried 1996; Batheja et al. 2000; Isa et al. 2002; Liu et al. 2006; Figs. 26 and 27). Positivity for p53 in ICC is, similar to other malignancies, associated with mutations in the TP53 gene in part of cases (Kiba et al. 1993; Liu et al. 2006), but epigenetic mechanisms that cause a stabilization of wild-type p53 also play a role (Furubo et al. 1999). There was no correlation between p53 reactivity and the gross appearance of ICC (Ohashi et al. 1995). Conversely, p53 reactivity is more frequent in well-differentiated ICC and less frequent in poorly differentiated ICC (Furubo et al. 1999). p73, a homologue of p53, was found in 41 % of cholangiocarcinomas, and p73 expression was not correlated with that of p53 (Tannapfel et al. 1999).

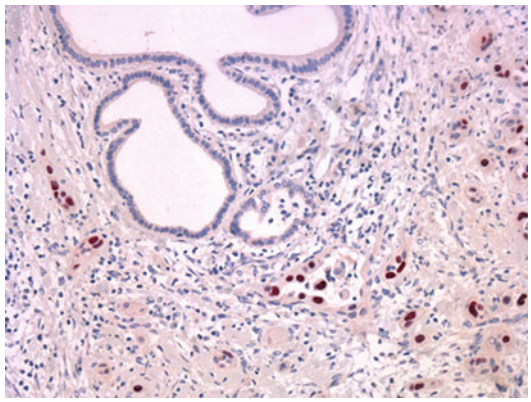

Fig. 27 p53 protein reactivity in intrahepatic cholangiocarcinoma cells within lymphatics surrounding peribiliary glands (p53 immunostain)

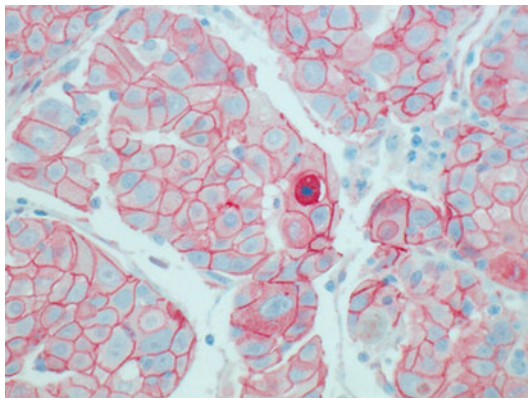

Fig. 28 Membranous expression of beta-catenin in intrahepatic cholangiocarcinoma. The *red* spherical structure with strong beta-catenin positivity is a tumor cell undergoing apoptosis (beta-catenin immunostain)

Ras p21 is expressed in part of ICC, but the expression is progressively lost with increasing dedifferentiation of tumor cells (Nonomura et al. 1987). The receptor for hepatocyte growth factor/HGF, MET, is not found in normal hepatic cells, but is present in conditions being a risk for cholangiocarcinogenesis, such as hepatolithiasis, where it is mainly seen in cells of hyperplastic septal and large bile ducts. MET overexpression was found in 58 % of ICC, being highest in well-differentiated tumors and lowest in poorly differentiated neoplasms (Terada et al. 1998). ICC cells show membranous expression of beta-catenin (Fig. 28).

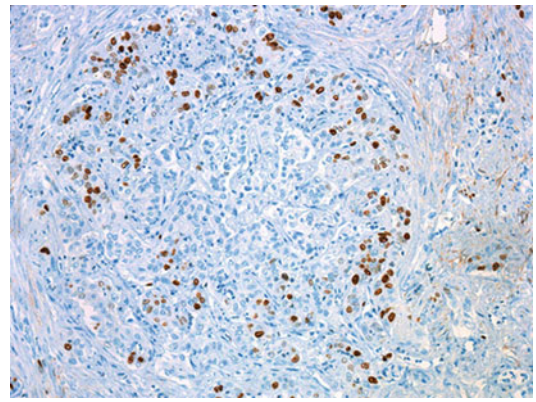

Fig. 29 High proliferative activity at the periphery of an intrahepatic cholangiocarcinoma nodule (MIB1 immunostain)

Proliferation and Apoptosis Markers

The proliferative activity of ICC cells can be assessed by PCNA and Ki-67 immunostaining (Minato and Nakanuma 1993; Settakorn et al. 2005; Fig. 29). The PCNA labeling index in poorly differentiated and moderately differentiated cholangiocarcinomas is higher than that of well-differentiated neoplasms (Minato and Nakanuma 1993). Estimation of the Ki-67 labeling may be used to classify ICC according to their growth features, as poorly differentiated tumors generally show higher Ki-67 indices (Wang et al. 2000), but the index has not been found to be a potent prognosticator (Kim et al. 1999). The Ki-67 index was correlated with overexpression of MDM2 protein, a protein which binds to and inactivates p53, and inhibits the p53-mediated transactivation processes (Horie et al. 2000).

Several factors operational in apoptosis are dysregulated in ICC. While normal cholangiocytes express Fas ligand/FasL, cholangiocarcinoma cells express both FasL and the Fas receptor and the FLICE inhibitor/I-FLICE, thus disabling Fas (Que et al. 1999). However, the percentage of Fas-expressing cells was significantly more often noted in extrahepatic tumors compared with ICC (Jhala et al. 2005). The reactivity for Bcl-2 in cholangiocarcinomas varies considerably from one investigation to another, ranging from non-detection (Okaro et al. 2001) or detection in occasional cases

(Terada and Nakanuma 1996) to reactivity in 100 % of cases (Skopelitou et al. 1996). Cytoplasmic positivity for Bcl-X(L) and Mcl-1 was found in 60–100 % of cholangiocarcinoma cells (Okaro et al. 2001). Part of cholangiocarcinoma cells express the receptor for tumor necrosis factor (TNF)-related apoptosis-inducing ligand (TRAIL/Apo2L) having the death domain, while another part of cholangiocarcinoma did not express the TRAIL decoy receptors lacking the death domain (Tanaka et al. 2000).

Mucin/MUC Status

Mucins expressed by various types of glandular epithelial cells are encoded by MUC genes, of which MUC1-4, 5AC, 5B, 6–8, 11–13, and 15–17 genes coding the backbone apomucin core protein have been found in humans. Several types of mucins are expressed in the intrahepatic bile duct systems and neoplasms derived thereof (Chou et al. 1976; Yamashita et al. 1993; Zen et al. 2006; reviews: Sasaki et al. 2007; Yeh et al. 2009; Yonezawa et al. 2010). Nondysplastic biliary epithelial cells in intrahepatic large bile ducts constantly express MUC3 apomucin, while expression of MUC3 and MUC5/6 apomucins was widespread in dysplastic biliary cells in hepatolithiasis (Sasaki et al. 1996). MUC1 was expressed in all three macroscopic subtypes of ICC, but MUC2 expression is rare and was expressed only in the ID-ICC subtype (Suh et al. 2002; Xu et al. 2009). Expression of MUC1 was detected immunohistochemically in 76 % of MF-ICC (Matsumura et al. 2002). In one study, MF-ICC showed significantly higher MUC1 expression rates than IP-HCC, while IP-ICC exhibited a more prominent MUC2 expression than MF-ICC (Higashi et al. 1999). Well-differentiated cholangiocarcinomas express MUC3 extensively in comparison with moderately or poorly differentiated tumors (Mall et al. 2010). Reactivity for MUC4, which is an intramembrane ligand for receptor kinase ErbB2 and involved in p27 regulation, was present in 37 % of MF-ICC and was a prognosticator (Shibahara et al. 2004). MUC5AC was found in 40 % and MUC6 in 21 % of ICC (Aishima et al. 2006). MUC6 apomucin was widely expressed in cholangiocarcinomas, irrespective of an association with liver cirrhosis, while MUC7 apomucin was frequently expressed in cholangiocarcinomas associated with cirrhosis (Sasaki et al. 1998a). Expression of MUC16 was found almost 50 % of MF-ICC (Higashi et al. 2012).

A group of proteins co-expressed with mucins are the trefoil factor family (TFF; TFF1, TFF2, and TFF3) peptides, which are mucin-associated molecules that are expressed in ICC and modify the behavior of cancer cells (Muenphom et al. 2006; Sasaki et al. 2007), acting via EGFR/MAPK activation (Kosriwong et al. 2011). TFF1 expression by intrahepatic cholangiocytes is increased in hepatolithiasis and is strongly upregulated in dysplastic bile duct epithelia and in noninvasive carcinoma, together with MUC5AC gastric-type mucin that colocalizes with TFF1. In contrast, TFF1 undergoes downregulation as soon as the carcinomas start an invasive growth pattern, probably accomplished by epigenetic methylation of the TFF1 promoter region (Sasaki et al. 2003).

Endocrine and Neuroendocrine Markers

Epithelial cells of bile ducts and cholangiocarcinomas, but not hepatocytes and hepatocellular carcinoma, express secretin receptors (Körner et al. 2006), secretin interacting with these receptors to induced bicarbonate-dependent, acid-independent bile flow.

Adhesion Molecules, Proteins of the Extracellular Matrix (ECM), and Proteins Involved in Invasion

ICC cells frequently exhibit N-cadherin at their surface membrane. Expression of N-cadherin together with CK7 resulted in a diagnostic

specificity of 98 % (Mosnier et al. 2009). Part of ICCs express the adhesion molecules, P-cadherin and CD24 (Su et al. 2006; Keeratichamroen et al. 2011), these expression patterns affecting the invasive phenotype. P-cadherin expression was found in up to 37 % of ICC and CD24 in 21 % of these neoplasms (Riener et al. 2010). About 50 % of ICCs express liver-intestine cadherin (LI-cadherin), a cadherin with seven cadherin repeats and a short cytoplasmic domain. Expression of LI-cadherin in ICC is associated with upregulation of placental growth factor (PIGF) and of metal-responsive transcription factor-1, via this mechanism promoting angiogenesis (Takamura et al. 2010). The alphaVbeta6 integrin is a highly specific immunohistochemical marker for cholangiocarcinoma (Patsenker et al. 2010), and expression of integrin alpha6 is associated with migratory and invasive phenotype in ICC (Ding et al. 2013). Laminin gamma 2 chain, an ECM protein critically involved in tumor cell migration and invasion, is expressed in ICC and is essentially localized in the stroma around cancer cells at the invasive front (Aishima et al. 2004). ICCs express the ECM proteins, laminin, tenascin, and collagen type IV in their stroma (Terada and Nakanuma 1994). Tenascin is typically expressed in actively invading parts of the tumor, specifically at the invasion front (Aishima et al. 2003). ICC cells express galectins, members of a family of beta-galactoside-binding lectins (Dechaphunkul et al. 2010). Galectin-3 is strongly expressed in the cytoplasm of well-differentiated ICC, but is reduced or absent in poorly differentiated ICC. In contrast, galectin-1 is predominantly expressed in ICC with high proliferative activity, is also expressed in tumor stroma, and may be involved in tumor progression (Shimonishi et al. 2001). Claudin-18, a tight junction protein, is aberrantly expressed in intraductal ICCs and intraductal neoplasms, expression associated with poor overall survival (Shinozaki et al. 2011). ICCs express matrix metalloproteinases (Terada et al. 1996b), and the majority of ICCs expressed maspin (Lok et al. 2014).

Other Markers

In larger bile ducts, S100P expression increases from reactive epithelial changes to low-grade BillN to high-grade BillN (Aishima et al. 2011), and S100P reactivity is generally useful as a diagnostic marker of cholangiocarcinomas (Levy et al. 2010) and the immunohistochemical expression of S100A2, involved in EMT. In one study, the relative expression level of S100P could determine cholangiocarcinoma at higher sensitivity than classical cytology (Hamada et al. 2011). S100P is also a potential prognostic marker in cholangiocarcinoma patients (Sato et al. 2013b). CD79a is a marker for hepatocellular carcinoma, but is not detectable in cholangiocarcinoma, thus representing a useful differential diagnostic marker (Li and Li 2013). In contrast to atypical cholangiocyte proliferations, invasive cholangiocarcinomas, including ICC, display loss of reactivity for SMAD4/DPC4 and share this feature with ductal pancreatic carcinomas (Tascilar et al. 2001; Chuang et al. 2004). Part of cholangiocarcinomas are reactive for salivary- and pancreatic-type amylase isoenzymes, reactivity being related to the differentiation grade, i.e., higher expression in well-differentiated tumors (Terada and Nakanuma 1993). Part of ICCs contain cytoplasmic hyaline inclusions that are p62(+) (Aishima et al. 2010).

Special Growth Patterns of Intrahepatic Cholangiocarcinoma

Peripheral ICC can present as a neoplasm with intraductal mucosa-spreading and mucin-producing morphology. Histologically, these neoplasms were characterized by a single layer of tall columnar cells with short intraluminal papillary projections lining the dilated bile ducts, the latter showing mucostasis. The process spreads diffusely and contiguously along intrahepatic bile ducts, with minimal invasion of the duct wall (Lim et al. 2000). It is suggested that such lesions form an overlap to the novel category of intraductal papillary mucinous neoplasms of the bile ducts, discussed in a separate chapter.

Intrahepatic Cholangiocarcinoma Synchronously Associated with Other Hepatobiliary Tumors

ICC can synchronously occur with hepatocellular carcinoma as spatially separated tumors (Kubo et al. 2004; Al Hamoudi et al. 2012). In one study, the incidence of double hepatic cancer was 0.25 % (Cao et al. 2013). Such patients may show evidence of hepatitis virus infection (Nagano et al. 2000; Jung et al. 2013), with HBV infection being found in up to 100 % of patients (Cao et al. 2013). Therefore, a common viral carcinogenic pathway involving hepatocyte and cholangiocyte lineage might be considered. In one Japanese patient, ICC was intricately admixed with fibrolamellar carcinoma (Tanaka et al. 2005). ICC was found in association with gallbladder papillary neoplasia and pancreaticobiliary malformation (Resende et al. 2012).

Differential Diagnosis

In rare instances, hepatic colorectal adenocarcinoma metastasis can undergo intrabile duct invasion and thus mimic cholangiocarcinoma (Kayashima et al. 2008). Other tumors or tumor-like lesions that may clinico-radiologically mimic ICC comprise inflammatory pseudotumors (Inaba et al. 2003; Ahn et al. 2012), ductocentric lymphomas, tuberculomas, and pyogenic liver abscesses. Histologically, inflammatory changes of intrahepatic bile may be associated with abnormal epithelial proliferations and cell atypia, not to be confounded with incipient cholangiocarcinoma (Fig. 30).

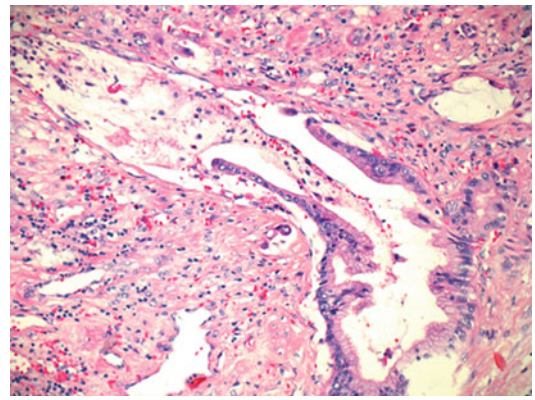

Fig. 30 Inflammatory changes of an eroded bile duct with cellular atypia and pseudopapillary structures (hematoxylin and eosin stain)

Biology of Disease

ICCs are aggressive malignancies of the liver that are still considered to be a fatal disease for many patients, because of a still low resectability (10–20 %) and frequent recurrences and spread following surgery. However, new treatment modalities have significantly improved outcome and survival in a selected subpopulation of patients (Berdah et al. 1996; Casavilla et al. 1997; El Rassi et al. 1999; Yamamoto et al. 2001; Hirohashi et al. 2002b; Morimoto et al. 2003; Fu et al. 2004; Endo et al. 2008; Yang and Yan 2008; Patel 2011; Yamamoto and Ariizumi 2011). In particular, unresected cholangiocarcinoma is a rapidly fatal process (Farley et al. 1995). The most obvious recurrence pattern following surgery was intrahepatic recurrence, in up to 60.9 % of patients (Miwa et al. 2006; Hyder et al. 2013). As other forms of cholangiocarcinoma, ICC tends to produce locoregional lymph node metastases, the presence of which is an important prognostic factor. In regard to outcome, there are certain differences between the main macroscopic subtypes of ICC, in that mass-forming (MF)-ICC with hilar invasion has a high load of local and hepatic recurrence, whereas the intraductal (ID) subtype and the periductal-infiltrating (PI) subtype without hilar invasion have a more favorable surgical outcome (Yedibela et al. 2009; Yamamoto and Ariizumi 2011). Even asymptomatic ICCs show perineural invasion and vascular or lymphatic involvement and are associated with poor prognosis. There are few reported instances of late recurrence of ICC (Kondo et al. 2012). In the course of pulmonary spread, pulmonary embolization followed by pulmonary hypertension may develop (Nakanishi et al. 2013).

Biology of Disease and Prognostic Factors of Cholangiocarcinomas

30

Contents

Abstract

Generally, cholangiocarcinomas are aggressive and invasive neoplasms with a high risk of local spread, tumor recurrence, and metastatic spread. To describe and predict the biology of disease, several prognostic factors have been identified for both intrahepatic and extrahepatic cholangiocarcinomas. In perihilar/hilar cholangiocarcinoma, preoperative stage is an important prognosticator for outcome. Negative histologic margins, concomitant partial hepatectomy, and well-differentiated histology are associated with improved outcome after resections. Perineural invasion is a strong predictor of an unfavorable course, and lymph node metastases constitute a major prognostic factor for survival after resection. Similar or the same prognostic factors have been identified for intrahepatic cholangiocarcinoma, but the gross growth pattern also plays a prognostic role in these neoplasms. Patterns with an infiltrative component, such as combined mass-forming and periductal-infiltrating types, confer increased risk for poorer survival. As in other tumors, molecular profiles and signatures are currently searched for in order to refine risk stratification.

Hilar/Perihilar Cholangiocarcinoma

Prognostic Factors: General Features

Hilar/perihilar cholangiocarcinoma (PHC) is an aggressive neoplasm with a distinct pattern in invasion, spread, and metastasis. In most instances, the prognosis of this cancer is still poor. At present, surgical resection based on precise preoperative staging is the optimal treatment options. A prognostication of outcome depends on a complex pattern of prognosticators having variable power to predict biology of disease (Murakami et al. 2007; Singal et al. 2010; Cho et al. 2012; Kaiser et al. 2013). Negative histologic margins, concomitant partial hepatectomy, and well-differentiated tumor histology were associated with improved outcome after all resections; however, in patients with R0 resection, concomitant partial hepatectomy was the only independent predictor of long-term survival. In a retrospective series of 49 patients with resected PHC, univariate analysis identified eight significant factors affecting mortality, i.e., total bilirubin, curative resection, histologic type, perineural invasion, liver invasion, depth of cancer invasion, positive proximal resection margin, and positive surgical margin (Su et al. 1996). In patients who underwent an R0 resection, concomitant partial hepatectomy, well-dedifferentiated histology, and negative lymph nodes were independent predictors of long-term survival (Matsuo et al. 2012).

Stage

Preoperative stage is an important prognosticator for outcome. Patients with advanced Bismuth-Corlette stage showed a tendence for reduced mean survival time, but the differences were not significant (Weber et al. 2007). A tumor size over 3 cm predicted poor short-term outcome after resection of PHC (Regimbeau et al. 2015).

Biliary Resection Margin

Positive resection margins are negative predictors of outcome in PHC (Ribero et al. 2011). Based on final histopathologic examinations, resection margins have been classified as wide margin (bile duct and specimen margins negative), narrow margin (bile duct margin negative but specimen margins positive), and positive margin (bile duct and specimen margins positive; Endo et al. 2008a). In a novel classification system of resection margins, four categories were defined, i.e., "insufficient" (insufficient for diagnosis due to distortion of specimen), "negative for malignancy" (no atypia suggestive of neoplasia), "undetermined lesion" (specimen showing either cellular or structural atypia), and "positive for malignancy" (Konishi et al. 2009). Involvement of ductal resection margins is a significant and independent risk factor for recurrence and poor prognosis (Burke et al. 1998; Wakai et al. 2005; Ramacciato et al. 2006; Tamada et al. 2006; Sasaki et al. 2007; Higuchi et al. 2010; Lee et al. 2012a). The adverse effect of a positive margin seems to depend on the part of the duct wall involved. In a Japanese investigation, margins positive for malignancy in intramural lesions of the proximal margin displayed poor prognosis, whereas positive for malignancy or undetermined in the epithelial surface of the proximal margin showed no difference in outcome compared with negative for malignancy (Konishi et al. 2009). The unfavorable effect of positive margins in resected PHC is modified by additional postoperative radiotherapy (Stein et al. 2005).

Intraoperative frozen section examination of bile duct margins is often employed to guide surgical resection in patients with PHC, but this method has some technical and interpretational difficulties that one has to consider (Okazaki et al. 2002). A positive ductal margin found in the setting of intraoperative histologic examination of the proximal ductal margin was related to clinical outcome, a finding favoring additional duct resection (Konishi et al. 2010). However, a study of 303 cases showed that additional-resection of >5 mm in the proximal duct is difficult after maximal or near-maximal duct resection, and such an additional resection did not improve survival, even when a negative margin could be achieved by this measure (Shingu et al. 2010). The results of frozen section analysis differ from those obtained with final histopathology. This is due to

greater thickness and, in part, lesser quality of frozen sections (damage of tissue) and to differences in experience. A retrospective comparative analysis of 101 cases of PHC has demonstrated the frozen section analysis of the proximal bile duct margin was misleading in 9 % of patients (Endo et al. 2008a). In a small investigation, frozen section and permanent diagnoses of the ductal margin in gallbladder and bile duct carcinomas were inconsistent in up to 25 % of patients, due to overdiagnosis of frozen sections or new recognition of cancer in permanent histology (Yamaguchi et al. 2005). The presence of extensive intramucosal spread in involved ducts, defined as spread > or = 20 mm from the main tumor, was not an indicator of a poor prognosis (Nakanishi et al. 2008). There is evidence that remnant carcinoma in situ may later evolve into invasive carcinoma and determine recurrence of disease (Nakanishi et al. 2010).

Invasive Features and Tumor Depth

Noninvasive and minimally invasive carcinomas of the extrahepatic ducts are associated with better long-term prognosis, and this is specifically the case for tumor with a papillary phenotype (Fatima et al. 2008). In a series of 106 resected PHC, median survival was associated with the invasion depth of the tumor (>= 5 mm vs. <5 mm). On multivariate analysis, tumor depth remained predictive of disease-specific death (de Jong et al. 2011a).

Perineural Invasion and Vascular Invasion

Perineural invasion is a common path for invasion and spread of cholangiocarcinomas. It is highly correlated with an invasive phenotype and is a predictor of postoperative recurrence and an unfavorable biology of disease (Bhuiya et al. 1992; Su et al. 1996; Shen et al. 2010; Patel et al. 2011). In order to correlate perineural invasion with other parameters, a perineural invasion index (PNI) was proposed, defined as the quotient between the number of nerve fascicles invaded by tumor and total number of nerve fascicles with and without tumor invasion (Bhuiya et al. 1992). Carcinoma cells can spread along the perineural sheaths for long distances and reach the neural plexuses. Neural plexus invasion can be detected by the use of CT imaging (Fukuda et al. 1998). The presence of lymphovascular invasion was associated with reduced overall survival (Ishiyama et al. 1998; Patel et al. 2011).

Nodal Status

Lymph node metastases constitute a major prognostic factor for survival after resection of PHC (Kitagawa et al. 2001; Murakami et al. 2007; Oshiro et al. 2011; Guglielmi et al. 2013). Among 62 resected patients, the median survival was 41.9 months in patients with N0 stage compared with 22.7 months in patients with N+. The 5-year survival for patients above and below the lymph node ratio of 025 was 0 % and 22.5 %, respectively (Guglielmi et al. 2011). In the analysis of Kitagawa et al. (2001), 3-year and 5-year survival rates for patients with PHC were 55.4 % and 30.5 % for patients with N0, 31.8 % and 14.7 % for patients with regional node metastases, and 12.3 % and 12.3 % for patients with paraaortic node metastases. In a recent study of 320 patients with PHC, lymph node metastasis was an independent and powerful prognostic factor. The survival rates were not significantly different between patients with locoregional node metastasis alone and those with distant lymph node metastasis, but the survival for patients with multiple node metastasis was significantly worse than that for patients with single metastasis (Aoba et al. 2013). The presence of positive paraaortic lymph nodes has an additional adverse effect on prognosis (Murakami et al. 2011). In one study, the presence of immunohistochemically detected lymph node micrometastases in otherwise histologically node-negative PHC had no survival impact (Tojima et al. 2003), but in a second analysis, the presence of immunohistochemically detected nodal micrometastases had an impact on outcome (Taniguchi et al. 2006).

Locoregional lymph node metastasis of extrahepatic cholangiocarcinoma is also a risk factor for remote/distant metastasis, e.g., bone metastasis (Katayose et al. 2012).

Distant Metastases

Apart from locoregional lymph node metastases, PHC tends to produce intrahepatic and intra-abdominal metastases (Nagorney and McPherson 1988; Carriaga and Henson 1995; Maaouni et al. 2006; Schmeding et al. 2006), whereas extra-abdominal metastases are less prominent findings. The most common extrahepatic metastatic sites are the lymph nodes, peritoneum, and lungs, while other sites such as the skin are rare (Lee et al. 2009). Similar to gastric carcinoma, PHC can sometimes form ovarian metastases with the phenotype of Krukenberg tumor (Sharma et al. 1997; Maaoui et al. 2006). Implantation metastases can occur following resection of PHC, whereby preoperative ERCP with biliary drainage was associated with a higher frequency of such metastases (ten Hoopen-Neumann et al. 1999). Regional or hepatic metastases may be expected in 30–50 % of cases. In contrast, distant metastases are not common and appear late in the course of disease, most often located to the lesser omentum and other sites of the abdominal cavity. Lymph node metastases are one of the most important prognostic factors in PHC (Noji et al. 2012). The presence of liver metastases has a significant adverse effect on prognosis (Arvanitakis et al. 2006).

Vascularity

PHC exhibit a high degree of vascularity, and this phenomenon affects biology of disease. PHC with a high microvessel density had a significantly higher incidence of lymph node metastases and local recurrence, and high microvessel density was a significant overall survival disadvantage as well as disease-free survival disadvantage, suggesting that neovascularization may be critically involved in PHC progression (Thelen et al. 2008; Nanashima et al. 2009). In PHC, microvessel density is correlated with the expression of trophoblast cell surface antigen 2 (TROP2), a factor that is associated with tumor progression and poor prognosis in a variety of cancers, and was an independent prognostic factor in human PHC (Ning et al. 2013). The presence of blood vessel cancer emboli within stroma significantly increased hazard's ratio of tumor recurrence, initial distant organ metastasis, and death (Hasebe et al. 2005). Tumor-associated lymphangiogenesis correlates with lymph node metastases and prognosis in PHC (Thelen et al. 2008; Thelen et al. 2010). Also factors regulating angiogenesis and lymphangiogenesis are expected to affect biology of disease. There was a trend toward higher VEGF A expression in highly vascularized extrahepatic cholangiocarcinomas (Möbius et al. 2007). In another investigation, there was however no correlation between VEGF, angiopoietin-1, angiopoietin-2, and thrombospondin-1 expression and tumor size, invasive features, intrahepatic metastasis, and survival (Tang et al. 2006). Expression of hepatoma-derived growth factor in PHC is associated with increased VEGF expression and poorer survival (Liu et al. 2011).

Growth and Differentiation of Cancer Cells

An elevated level of proliferative activity affects biology of disease of PHC. Expression of the proliferative marker Ki-67 increased with the stage and invasive features of PHC (Zhao et al. 2014). The PCNA index is a significant prognosticator for PHC (Nishida et al. 1997). The chemokine receptor 4/CXCR4 promotes proliferation in PHC, is induced in these neoplasms, and augments neural invasion (Tan et al. 2014). Among factors affecting growth and apoptosis, p53 protein has a central role. Among 45 extrahepatic duct carcinomas, including PHC, the median survival of patients with p53-negative tumors was 25.7 months, whereas survival of those with p53-positive tumors was 5.2 months (Diamantis et al. 1995). Inhibition of apoptosis promotes

growth and favors an aggressive course. In extrahepatic cholangiocarcinoma, expression of the apoptosis inhibitor Bcl-2 is increased in comparison with dysplasia (Li et al. 2003). Autophagy may promote invasion of cholangiocarcinoma, and expression of the autophagy-associated protein Ambra1 correlated with lymph node metastasis and poor survival (Nitta et al. 2014).

The presence of a papillary carcinoma component is an important determinant of survival after resection of PHC, papillary carcinomas being associated with significantly longer disease-specific survival (Hoang et al. 2002; Jarnagin et al. 2005; Sano et al. 2008). This is probably due to the less frequent invasion of papillary/exophytic tumors beyond the fibromuscular layer (Kozuka et al. 1984). In a review of 13 patients with papillary carcinoma of the extrahepatic ducts, six were localized to the proximal part of the duct system (Hoang et al. 2002). Production of various mucin types affects risk and biology of disease. MUC1 and MUC5AC expression in cholangiocarcinomas is closely related to dedifferentiation, invasive growth, and poorer survival, while expression of MUC6 is a marker of well-differentiated carcinomas (Park et al. 2009). The expression of MUC4 in PHC is an independent factor for poor prognosis and predicts outcome (Tamada et al. 2006). Mesothelin, which is expressed in various carcinomas as a function of differentiation, is also present in PHC. Its high-level expression was associated with an aggressive tumor phenotype (Kawamata et al. 2012). Among factors that affect differentiation, the nonopioid sigma-1 receptor (Sig1R) is associated with poor differentiation in PHC (Xu et al. 2014a).

DNA Ploidy of Carcinoma Cells

DNA ploidy has been shown to affect progression of PHC and other extrahepatic cholangiocarcinomas (Nishida et al. 1997). Among 60 consecutive patients with PHC, 29 or 48 % had diploid neoplasms, and 31 or 51 % were found to have aneuploid tumors. Survival of patients with diploid tumors was significantly longer than those with aneuploid tumors (Iachino et al. 1998). A similar distribution of ploidy was observed in a second study ($N = 58$), with 48 % diploid and 52 % aneuploid neoplasms, again with a worse outcome for patients with aneuploid tumors (Sato et al. 1994).

Factors Affecting Invasion and Spread

As in other carcinomas, the invasive properties of PHC cells strongly depend on the differential expression of adhesion molecules and histolytic enzymes. Factors interfering with cell adhesion affect invasive properties of cancer cells. The E-cadherin repressor, snail, is expressed in part of PHC, and snail expression can predict poor survival of PHC regardless of pathologic features and cancer cell proliferation (Kong et al. 2012). E-cadherin expression in PHC is regulated by the E-cadherin repressor slug. Slug is overexpressed in PHC, resulting in E-cadherin downregulation and increased invasion (Zhang et al. 2010b). Expression of the adhesion molecule L1 in extrahepatic cholangiocarcinomas is significantly associated with perineural invasion and is an independent prognosticator for poor overall survival (Li et al. 2009). The E/N-cadherin switch mediates carcinoma progression of PHC through TGF-beta-induced epithelial-to-mesenchymal transition (EMT). During EMT, epithelial cadherin (E-cadherin) is downregulated while neural cadherin (N-cadherin) is upregulated, referred to as the so-called cadherin switch (Araki et al. 2011). Expression of E-cadherin is lower in cholangiocarcinoma cells than in benign bile duct lesions (Li et al. 2008). In its regulation of invasive features in cholangiocarcinoma, E-cadherin expression is correlated with expression of protein kinase C-iota, which is positively related to tumor cell differentiation and invasion (Li et al. 2008). Expression of CD24 predicts distant metastasis in extrahepatic cholangiocarcinoma (Kim et al. 2013).

Expression of matrix metalloproteinases (MMPs) affects invasive features of many cancers. PHC cells upregulate matrix metalloproteinases required for tissue invasion. MMP-2 plays an important role in PHC invasion and

metastasis, while tissue inhibitor of metalloproteinase-2 (TIMP-2) was shown to strongly inhibit cancer invasion (Xiao et al. 2004). MMP-2 expression is present in extrahepatic cholangiocarcinomas and gallbladder cancers, including PHC (Xiao et al. 2004), but was not found in Klatskin tumors in another study (Kirimlioglu et al. 2009). Expression of MMP-2 was found at higher levels in tumors with perineural invasion (Sakai 2004). By the use of zymography and PCR, activity of MMP-2 and its active form were detected in 80 % and 57 % of intrahepatic cholangiocarcinomas (Jo Chae et al. 2004). MMP-7 was an unfavorable postoperative prognostic factor of cholangiocarcinoma arising from large bile ducts (Miwa et al. 2002; Itatsu et al. 2008). In PHC, expression of MMP-9 indicates poor prognosis (Sun et al. 2014). The expression of MMP-9 was found to be elevated in PHC in comparison with normal tissues, while a protein inhibiting MMP expression, RECK, was downregulated (Li et al. 2005). Levels of MMP-9 expression in PHC appear to be partially related to the presence of tumor-associated macrophages secreting this protease (Subimerb et al. 2010).

The mechanisms leading to perineural and intraneural invasion are only partially clarified. Expression of nerve growth factor-beta is associated with nerve infiltration in human PHC (Xu et al. 2010a). Other factors involved in extrahepatic cholangiocarcinomas promoting invasion, metastasis, and tumor progression in general comprise expression of c-erbB-2 proto-oncogene (Zheng and Zhu 2007); the CCN family member WISP1v (Tanaka et al. 2003); the differentiation regulator LAPTM4B-35 (Zhou et al. 2008), CD24 (Agrawal et al. 2007), CD44 (Kunlabut et al. 2012), KIT (Hong et al. 2007), fascin (Won et al. 2009; Mao et al. 2013), S100 protein (Sato et al. 2013), and HER3 (Lee et al. 2012b); downregulation of p21 (Kim et al. 2009), and decreased expression of focal adhesion kinase (Hayashi et al. 2010) and of WW domain-containing oxidoreductase (WWOX) (Wang et al. 2009). Expression of relatively few factors was associated with a favorable prognosis, e.g., caveolin-I overexpression (Murakami et al. 2003) and expression of the transcription factor ets-1 (Ito et al. 2000).

Intrahepatic Cholangiocarcinoma

General Features

There are numerous attempts to stratify ICC according to various prognostic factors. As with other hepatobiliary cancers, established prognosticators such as TNM stage, histologic grade, and invasion features play a predominant prognostic role. There are also aims to enter such prognosticators into scoring systems. For example, the independent predictors of outcome, serum alkaline phosphatase, CA 19-9 levels, tumor boundary type, tumor size, and number of intrahepatic tumors were incorporated into the Fudan score, which may provide a relatively accurate prognostic predictor for ICC patients regardless of the resection status (Jiang et al. 2011).

Tumor Stage

Advanced stage at the time point of diagnosis or surgery is a strong predictor of outcome. Stage IVa tumors and those with intra- or perihepatic metastases had a poor prognosis (Jiang et al. 2011). Large tumor size (diameter > than 4.5 cm or 5 cm) was a significant predictor of outcome in MF-ICC in part of studies (Endo et al. 2008b; Shirabe et al. 2010; Schiffman et al. 2014). In one investigation, patients with resected MF-ICC having tumor with a diameter >45 mm more often developed recurrence in the remnant liver, lymph nodes, and lung than patients with tumors <45 mm diameter (Sasaki et al. 2004). However, tumor size provided no prognostic information in another investigation (de Jong et al. 2011). Other stage-associated parameters that are prognosticators in MF-ICC include serosal invasion, PV1 or PV2, LI1 or LI2, and hepatic venous invasion (Shirabe et al. 2010). In MF-ICC, serosal invasion was not always identified as a prognosticator. In one study, serosal invasion exhibited no survival impact after hepatic resection for MF-ICC

(Uenishi et al. 2005). In a more recent study, it turned out that the AJCC/UICC staging system failed to stratify Japanese patients with MF-ICC. In a new staging approach, tumor size, tumor number, and vascular invasion were independently associated with survival after curative resection of MF-ICC, whereas serosal and periductal invasion were not, this new staging system better stratifying survival after curative resection (Uenishi et al. 2014).

In patients with the MF-ICC, lymphatic invasion was found to be the most important invasion pathway, and lymph node metastases is a good predictor for prognosis (Nozaki et al. 1998; Yamamoto et al. 1998; Inoue et al. 2000; Suzuki et al. 2002; Nakagawa et al. 2005; Guglielmi et al. 2009; Shimada et al. 2007a, 2009; Tamandl et al. 2009; Shirabe et al. 2010; Clark et al. 2011; de Jong et al. 2011b; Patel et al. 2011; Horino et al. 2012; Adachi and Eguchi 2014). In one study, patients with MF-ICC having two or more lymph node metastases failed to survive beyond 2 years post-surgery, while those with no or a single lymph node metastasis displayed survival rates of 80 % and 33 % at 5 years, respectively (Suzuki et al. 2002). In one European study, the lymph node ratio (LNR) had a high prognostic value, whereas the location of positive nodes did not (Guglielmi et al. 2013). Traditionally, para-aortic lymph node metastasis has been defined as distant metastasis, but recently been classified as resectable disease (Nakayama et al. 2013).

Macroscopic ICC Subtype and Local Growth Patterns

As already mentioned above, the three main growth patterns of ICC (MF, PI, and IG) affect biology of disease and outcome. The 5-year survival rate after surgery was significantly lower in patients with MF plus PI tumors than in patients with MF or IG subtype tumors (Yamamoto et al. 1998). The difference in outcome may in part be related to the more complex, infiltrative pattern of MF plus PI, characterized by a large mass lesion associated with a tumor that invasively follows the periductal tracts for longer distances, resulting in an ill-defined neoplasm. In fact, MF plus PI tumors more frequently exhibit positive resection margins and perineural invasion (Hirohashi et al. 2002). The incidence of lymph nodes with metastases was significantly higher in the patient group with MF plus PI than in those with IG (Yamamoto et al. 1998). In contrast, "pure" MF-ICC was associated with a longer survival than MF plus PI and PI (Inoue et al. 2000; Guglielmi et al. 2009). The presence of satellite nodules, i.e., a presentation with multiple tumor nodules indicating a more aggressive phenotype, had a significant effect on patient survival (Jan et al 1996; Casavilla et al. 1997; Harrison et al. 1998; Roayaie et al. 1998; Isaji et al. 1999; Okabayashi et al. 2001). The number of tumors including satellites was not related to the presence of vascular invasion in one study (Okabayashi et al. 2001), but a later investigation found that multiple intrahepatic tumors were a significant determinant of adverse postoperative prognosis (Marubashi et al. 2014).

Resection Margin

The histologic status of the resection margin is a critical prognostic factor. Patients with positive ductal margins generally have a poor prognosis (Guglielmi et al. 2009; Luo et al. 2014; Murakami et al. 2014). An unfavorable effect of a positive resection margin was found in both peripheral and perihilar forms of ICC (Yeh et al. 2014). A negative resection margin had a favorable impact on survival of patients with MF-ICC (Chou et al. 1995; Jan et al. 1996; Harrison et al. 1998; Madariaga et al. 1998; Isaji et al. 1999; Kim et al. 1999; Inoue et al. 2000; Isa et al. 2001; Uenishi et al. 2001; Tamandl et al. 2008; Yeh et al. 2013; Sonbare 2014). In peripheral ICC, a positive resection margin was more frequently found in higher-stage tumors, those with hepatolithiasis, and those with periductal infiltrative or mixed periductal infiltrative and mass-forming ICC (Yeh et al. 2014).

Grading and Distinct Differentiation Patterns

The tumor grade affects biology of disease, and in some studies, tumor grade was an independent factor predicting survival (Shirabe et al. 2010; Murakami et al. 2014). Remote organ metastases are more often found in the less-differentiated ICC group that in the well-differentiated group. The distinct ICC differentiation pattern characterized by papillary growth (PCC; papillary cholangiocarcinoma) is associated with a more favorable outcome, whereby PCC survival decreases with progression of the invasive component (Onoe et al. 2014).

MUC1 expression in MF-ICC was an independent risk factor affecting outcome (Matsumura et al. 2002). The pro-metastatic effect of MUC1 may be related to the findings that MUC1 as a transmembrane mucin is often overexpressed in metastatic cancers, its extracellular domain serving as a ligand for stromal and endothelial cell receptors (Horm and Schroeder 2013). Furthermore, MUC1 drives c-Met-dependent cancer cell migration (Horm et al. 2012). Expression of MUC4 and/or MUC16 in MF-ICC was an independent factor of poor prognosis (Shibahara et al. 2004; Higashi et al. 2012). Certain keratin/cytokeratin expression patterns in ICC are associated with tumor biology. In MF-ICC, reduced expression of keratin 903 was correlated with a favorable prognosis and an HCC-like pattern (Aishima et al. 2002). The subset of ICC expressing keratin 20 was associated with male gender, hilar location, intraductal papillary type, intestinal phenotype, and MUC2 expression. Patients with these neoplasm had a poorer outcome, suggesting an aggressive phenotype for keratin 20-positive ICC (Choi et al. 2012). Histone deacetylase (HDAC) is critically involved in chromatin remodeling and gene expression and regulates cell differentiation. In ICC, increased HDAC expression is closely associated with hypoxia-inducible factor activation and correlates with a worse survival rate (Morine et al. 2012). ICC with progenitor/stem cell features generally exhibit a more aggressive tumor biology. CD133, a stem cell marker, was observed in up to 8 % of ICC, and its presence tended to be related to higher incidences of intrahepatic metastasis and was independently related to worse prognosis (Shimada et al. 2010).

Invasion Patterns and Factors Regulating Invasion

Macroscopic vascular invasion is significantly related to survival in patients with ICC (Okabayashi et al. 2001; Guglielmi et al. 2009). Taking MF and PI tumors together results in a group of ICC with a more unfavorable prognosis even after radical surgery, as these neoplasms were more often associated with bile duct invasion, portal vein invasion, lymph node metastasis, and positive resection margin (Shimada et al. 2007b). Lymphovascular invasion is associated with reduced overall survival in ICC (Fisher et al. 2012). Perineural invasion of ICC is an important negative prognosticator (Shirai et al. 2008; Chen et al. 2012; Fisher et al. 2012) and is strongly associated with KRAS mutations in ICC (Chen et al. 2012).

Certain proteins involved in adhesion and in the construction of the extracellular matrix (ECM) and hence in invasion are differentially expressed in various growth patterns of ICC. Reduced cell surface content of E-cadherin in cholangiocarcinoma facilitates invasion through cell individualization and is associated with reduced survival (Mao et al. 2013). Expression of CD24, a sialoglycoprotein involved in cell adhesion, in cholangiocarcinomas is associated with disease progression and reduced patient survival (Su et al 2006; Keeratichamroen et al. 2011). The laminin gamma 2 chain, a C protein that plays an important role in cell migration and invasion, was more frequently expressed in PI and ID types of ICC than the MF type, and its expression was correlated with an aggressive phenotype (Aishima et al. 2004). Expression of human carcinoembryonic antigen-related cell adhesion molecule 6 (CEACAM6), a molecule involved in adhesion and invasion properties of various malignancies, is higher in ICC cells than in adjacent nonneoplastic liver tissue. ICC with

CEACAM6 expressed displayed higher rate of lymphatic invasion and were correlated with poorer disease-free survival (Ieta et al. 2006). Reduced expression of syndecan-1, a cell surface transmembrane heparan sulfate proteoglycan involved in functional aspects of the ECM, is found in ICC cases with lymph node metastasis and aggressive course (Harada et al. 2003). Expression of connective tissue growth factor/CTGF is a prognostic marker for ICC (Gardini et al. 2005).

Factors that affect structure and function of the cytoskeleton and cell motility also exert an important influence on the invasive behavior of ICC cells. Expression of cytoskeleton-associated protein 4 in ICC is related to the frequency of lymphatic metastasis (Li et al. 2013). A protein involved in the stimulation of tumor cell migration and metastasis is phosphatase of regenerating liver-3 (PRL-3). In contrast to normal cholangiocytes, which do not display PRL-3 immunostaining, this factor is expressed in ICC and is correlated with invasion and metastasis (Xu et al. 2010b). PRL-3 induces EGFR activation and its downstream signaling cascades, directly interferes with integrin beta1 and regulates its phosphorylation, promotes cell migration via Arf-activity-dependent stimulation of integrin alpha5 recycling, induces angiogenesis by increasing extracellular signal-regulated kinase phosphorylation, provokes a tyrosine phosphoproteome involving proteins that play a role in the induction of EMT, and induces several miRNAs involved in the metastasis cascade, including miR-21, miR17, and miRNA-19a.

Several types of matrix metalloproteinases (MMPs) are expressed by ICC cells and play a crucial role in tissue destruction in the course of invasion. Expression and secretion of MMP-2 (Zhang et al. 2010a), MMP-7 (Miwa et al. 2002), and MMP-9 (Tian et al. 2014) by cholangiocarcinomas are markers for an aggressive phenotype. Serum MMP-7 levels are useful as a predictive marker for fluke-related cholangiocarcinoma (Prakobwong et al. 2012), and expression of MMP-7 by ICC cells is associated with poor prognosis in patients with resected ICC (Hirashita et al. 2012). Other peptidases/proteinases that favor an invasive phenotype and an aggressive course in ICC patients include neutral endopeptidase and dipeptidyl peptidase IV (Zhu et al. 2014). Maspin, a member of the serpin family and suppressor of tumor growth, is expressed in a subset of ICC and represents a prognostic factor. The associated expression of maspin and Bax delayed ICC progression via increase of apoptosis and decrease of invasion (Romani et al. 2006). There are other factors that favor an invasive phenotype of cholangiocarcinomas. Aberrant expression of GATA6, a zinc-finger transcription factor either acting as a tumor promoter or tumor suppressor, was correlated with marked tumor invasion, lymph node and liver metastasis, and poor prognosis in cholangiocarcinoma patients (Tian et al. 2013). A protein that participates in mediating G2 arrest of the cell cycle in several cancers is stratifin (14-3-3 s). Cytoplasmic stratifin expression was found in 52.6 % of MF-ICC after hepatectomy, and this expression was significantly associated with elevated CEA levels (Yeh et al. 2010). Stratifin may affect the invasive properties of cancer cells, because it exerts an important influence on the biology of cell-to-cell adhesive junctions. Stratifin limits plakophilin-3 exchange with the desmosomal plaque, resulting in decreased desmosomal adhesion and increased cell migration (Roberts et al. 2013).

Stromal Features, Epithelial-Mesenchymal Transition (EMT), and Vascularization

Invasion and spread of ICC are markedly influenced by cell systems of the tumor stroma, in particular myofibroblasts and their precursor cells, the hepatic stellate cells. Patients with high alpha-SMA expression in cells of their ICC exhibited worse outcomes (Okabe et al. 2009). Myofibroblasts in cholangiocarcinoma stroma promote progression of the tumor through activation of the EGFR, and cholangiocarcinoma cells produce TGF-beta1 which in turn induces expression of heparin-binding epidermal growth factor (HB-EGF) on myofibroblasts (Clapéron

et al. 2013). Several proteins upregulated in ICC stroma affect biology of disease, including osteopontin, TGF-beta2, and laminin. Osteopontin, which is expressed in ICC stroma cells, is an independent predictor of poor prognosis in ICC (Sulpice et al. 2013). Stromal cell populations also exhibit stem cell signatures, including an overexpression of epithelial cell adhesion molecule (EpCAM). EpCAM expression as an indicator of stromal progenitor cells affects ICC progression and is associated with reduced overall and disease-free survival (Sulpice et al. 2014).

Invasive features of cholangiocarcinomas are related to the effects of epithelial-mesenchymal transition (EMT). Expression of EMT-related markers is associated with an aggressive course and poor prognosis (Ryu et al. 2012). Loss of the epithelial marker E-cadherin and acquisition of the mesenchymal markers vimentin and N-cadherin in ICC was associated with aggressive tumor behavior, increased progression, and a poor outcome (Gu and Choi 2012; Yao et al. 2012; Gu and Choi 2014). In particular, aberrant expression of vimentin in ICC correlated with dedifferentiation and poor survival (Korita et al. 2010). EMT which favors progression of ICC is strongly stimulated in these tumors by the factor Snail1 (Huang et al. 2014). Downregulation of E-cadherin in the setting of EMT in ICC is mediated by the transcription repressor, Slug (SNAI2; Snail2), which is not expressed in normal liver cells, but is highly expressed in ICC, this upregulation being associated with a higher rate of lymph node metastasis and poor survival (Zhang et al. 2010b). In ICC, expression of fibroblast growth factor receptor 4 (FGFR4) induces EMT, promotes an invasive phenotype, and correlates with poor prognosis (Xu et al. 2014b).

Angiogenesis and vascularization strongly influence invasive spread and metastasis of cancers and hence are prognosticators. In ICC, a lower microvessel count was associated with larger tumor size, PI-ICC, and advanced stage. The 5-year survival rate in the higher microvessel count group was significantly greater than that in the lower microvessel count group (Nanashima et al. 2009).

Growth Features, Factors Regulating Tumor Cell Growth, and Apoptosis

In MF-ICC, a shorter preoperative tumor doubling time (less than 70 days) estimated by imaging was associated with worse overall survival (De Rose et al. 2013). A low nuclear expression of p27Kip1 protein was correlated with vascular invasion and significantly lower survival (Taguchi et al. 2001). Vitamin D3 exerts an antiproliferative effect on cholangiocarcinoma cells, and overexpression of vitamin D receptor in cholangiocarcinoma was associated with an overall more favorable prognosis (Seubwai et al. 2007). Expression of epithelial and endothelial tyrosine kinase (Etk; bone marrow X kinase), a kinase regulating cell proliferation and apoptosis, in ICC cells was a predictor of poor prognosis (Guo et al. 2008). Overexpression of EGFR is associated with the degree of malignancy and with poor prognosis (Zhou et al. 2013). Expression of insulin-like growth factor II mRNA-binding protein 3, an oncofetal mRNA-binding protein, plays an important role in the regulation of cell growth and is expressed in a subset of ICC. This expression is associated with an invasive phenotype and a poorer overall survival (Chen et al. 2013). Hepatocyte growth factor and its receptor, MET, form a regulatory unit that affects several biological features of cancer cells, including growth regulation. Expression of the glucose transporter, GLUT-1, in ICC is associated with aggressive biology and lymph node metastasis (Kubo et al. 2014). A hydrophobic protein, CD151, forms a functional complex with MET and affects growth, invasion, and metastasis. In ICC, overexpression of CD151 is correlated with an invasive and metastatic phenotype (Huang et al. 2010).

Expression of TRAIL by cholangiocarcinoma cells does not result in carcinoma cell death, but promotes their tumorigenicity and favor metastatic spread. This effect is counteracted by second mitochondria-derived activators of caspase/Smacs, which enhance proapoptotic death receptor signaling by causing cellular degradation of inhibitor of apoptosis (IAP) proteins (Fingas et al. 2010). Survivin, a member of the inhibitors-of-apoptosis protein family, is an independent

prognostic factor for poor survival in ICC, and its expression is modulated by the Yes-associated protein (Bai et al. 2012).

Other ICC Markers of Potential Prognostic Significance

Elevation of serum gamma-glutamyltransferase was a predictor of an aggressive tumor behavior in ICC patients (Yin et al. 2013). The AKT1 signaling pathway, which is important for the regulation of protein synthesis and cell survival, revealed differential expression in ICC. Overexpression of phosphorylated AKT1was associated with a better survival in ICC patients, independent of PTEN expression (Lee et al. 2012c).

Abstract

Pathways leading from normal cholangiocytes and their progenitors to cholangiocarcinoma are complex and involve a wide array of genes and their products. For carcinomas of extrahepatic ducts in Western countries, the most common predisposing condition is probably primary sclerosing cholangitis. Congenital biliary cystic disease, in particular choledochal cysts and Caroli's disease, also plays an important role. In Southeast Asia and Japan, hepatolithiasis and liver fluke infestation are important factors. An established precursor of extrahepatic cholangiocarcinoma is biliary intraepithelial neoplasia (BillN), suggesting a dysplasia-carcinoma sequence. Precursor lesions found in bile ducts are also involved in the pathogenesis of intrahepatic cholangiocarcinoma. For this type of cancer, intraductal papillary neoplasms that later become invasive lesions play a significant role. For both intrahepatic and extrahepatic cholangiocarcinomas, molecular mechanisms involved in cholangiocarcinogenesis are currently identified.

Hilar/Perihilar Cholangiocarcinoma

Introduction

Most PHCs are sporadic cancers and are thought to arise from the superficial epithelial of proximal extrahepatic bile ducts and bile ducts close to the confluence. In addition, there is evidence that part of these neoplasms may originate from peribiliary glands (Terada et al. 1992). The pathways leading from normal cholangiocytes – and eventually their progenitors – to cholangiocarcinoma are complex and involve a wide array of genes and their products (reviews: Okuda et al. 2002; Wise et al. 2008; Hassid et al. 2009). Probably the most common predisposing condition of PHC in Western countries is primary sclerosing cholangitis (PSC). Occult cholangiocarcinoma has been found in up to 40 % of autopsy specimens of patients with PSC and up to 36 % of explanted livers in PSC. A second predisposing condition is congenital biliary cystic disease, in particular choledochal cysts and Caroli's disease. In certain parts of Southeast Asia and in Japan, hepatolithiasis is a well-known risk factor for cholangiocarcinoma. Liver flukes mainly occurring in Southeast Asia (*Opisthorchis viverrini*, *Clonorchis sinensis*) are also an important etiologic factor for cholangiocarcinoma.

Dysplasia-Carcinoma Sequence in Hilar/Perihilar Cholangiocarcinoma

Biliary intraepithelial neoplasia (BillN) is an established precursor lesion of PHC and other extrahepatic cholangiocarcinomas (Sato et al. 2014). Advanced dysplastic changes and carcinoma in situ can develop in the extrahepatic biliary tract, suggesting a dysplasia-carcinoma sequence (Komenaka et al. 2003). It was proposed that flat-type biliary intraepithelial neoplasia (BillN) and papillary-type intraductal papillary neoplasm of the bile duct (IPN-B) are precursor lesions of invasive perihilar intrahepatic cholangiocarcinoma (Nakanuma et al. 2009). The authors proposed three carcinogenetic pathways, i.e., BillN progressing to tubular adenocarcinoma and IPN-B progressing to tubular adenocarcinoma and colloid carcinoma. Carcinogenesis through BillN was characterized by MUC2/CK20 with MUC1 expression. p53 expression was upregulated at the invasive stage of BillN, but was low in noninvasive BillN (Nakanuma et al. 2009). It was proposed that BillN and IPN-B (IPNB) may represent lesions analogous to pancreatic intraepithelial neoplasia and intraductal papillary mucinous neoplasms, respectively (review: Bickenbach et al. 2009). Parts of sysplastic lesions of the extrahepatic biliary tract are associated with long-standing inflammatory bile duct disease, in particular primary sclerosing cholangitis (Katabi and Albores-Saavedra 2003). Dysplastic epithelia in extrahepatic bile ducts exhibit an immunophenotype that differs from normal cholangiocytes. While normal epithelia and low-grade dysplasia are negative for S100A4 protein and mesothelin, high-grade

dysplasia and carcinoma express these two factors at high rates (Zhao et al. 2007).

Cytogenetic and Molecular Features

Cholangiocarcinoma cells, but mainly those of intrahepatic carcinomas, overexpress the polycomb group protein Bmi1, a stemness gene involved in the maintenance of stem cells, malignant transformation, and malignancy grade in diverse neoplasms, and probably acting by repression of cellular senescence (Sasaki et al. 2009).

Tumor Suppressor Genes and Oncogenes

Similar to other cholangiocarcinomas, PHC show various types of abnormal expression of oncogenes and tumor suppressor genes (reviews: Rashid 2002; Enjoji et al. 2004). At least part of PHC shows mutations of the p53 gene, in part not associated with nuclear immunoreactivity for p53 protein (Jonas et al. 1998; Sturm et al. 1998; Della Torre et al. 2000; Chuang et al. 2004; Khan et al. 2005). There is a difference in the type of p53 gene mutations (except 175) between PHC occurring in European patients and with p53 mutation found in East Asian intrahepatic cholangiocarcinomas. In one study of European PHC, all p53 mutations occurred in exon 5 (Tullo et al. 2000). The expression of P53-binding protein 1 (53BP1), an early DNA damage response protein rapidly recruited to sites of DNA double-strand breaks, is an indicator for endogenous strand breaks in genomic instability. In PHC it was found that expression of 53BP1 is associated with local recurrence at ductal stumps following resection (Wakai et al. 2011, 2013). Part of PHCs show mutations in the K-ras oncogene (Sturm et al. 1998). In bile duct carcinogenesis, mutations of p16Ink4/CDKN2 rather than p15Ink4B appear to be important (Yoshida et al. 1995; Ueki et al. 2004). However, alterations of the p16Ink4 pathway were not found by other investigators (Della Torre et al. 2000). Part of cholangiocarcinomas, in particular those located in the common bile duct, display mutations of the candidate tumor suppressor gene, DPC4/Smad4, known to be inactivated in about half of ductal adenocarcinomas of the pancreas (Hahn et al. 1998; Suto et al. 2002). A relationship between choledochal cholangiocarcinomas and pancreatic carcinomas is underlined by the observation that DPC4 mutations occur more frequently in cholangiocarcinomas of the distal part of the common bile duct (Argani et al. 2001). Whereas K-ras mutations seem to be uncommon in periampullary cancers and cancers of the gallbladder, such mutations have been found in cholangiocarcinomas (Lee et al. 1995). In one study, the incidence of K-ras mutations in extrahepatic cholangiocarcinomas was 9.6 %, compared to a rate of 32.7 % for p53 gene (Suto et al. 2000).

Markers of Biliary Tract Development

PHCs share the expression of some ontogenically expressed factors with ductal carcinomas of the pancreas. Anterior gradient protein-2 and S100P are frequently expressed in PHC and pancreatic ductal adenocarcinoma, while PDX1 and HES1 were often expressed in ductal cancers of the pancreas, but less in PCH. Furthermore, PHC and pancreatic cancers reveal a similar expression of mucin types as well as certain transcription factors.

Factors Regulating the Cell Division Cycle

The expression of p27 decreased progressively from proximal to distal in cancers of the biliary tract, and the expression patterns of p27 and cyclin in PHC were more similar to that of gallbladder cancers than to intrahepatic peripheral cholangiocarcinomas (Jarnagin et al. 2006). Overexpression of ErbB-2 seems to be a rare phenomenon in extrahepatic cholangiocarcinomas and was detected in only 5.1 % of cases, similar to epidermal growth factor receptor (8.1 %), and both were associated with gene amplification (Nakazawa et al. 2005).

Factors Affecting Epithelial-Mesenchymal Transition (EMT) and Stromagenesis

EMT is a critical mechanism affecting cancer invasion and spread. In cholangiocarcinoma cells, EMT is induced by TGF-beta1/Snail activation, and this EMT induction is in turn associated with aggressive growth (Sato et al. 2010).

Epigenetic Mechanisms

There is increasing evidence that epigenetic mechanisms play a role in the pathogenesis of cholangiocarcinoma, specifically in intrahepatic tumors (Kohya et al. 2006; Tischoff et al. 2006). A significant proportion of cholangiocarcinomas showed promoter hypermethylation of tumor suppressor and tumor-related genes (Tozawa et al. 2004). Frequencies of promoter methylation were 70 % for p16/INK4a, 49 % for *O*-(6)-methylguanine-DNA methyltransferase (MGMT), 46 % for hMLH1, 41 % for E-cadherin, and 32 % for DAPK genes. Cholangiocarcinomas with MGMT methylation expressed multigene methylation more frequently than tumors without MGMT methylation, and reduced MGMT expression may increase the malignant potential of cholangiocarcinomas (Koga et al. 2005). Epigenetic silencing of DAP-kinase appears to be a significant prognostic factor in cholangiocarcinoma (Tozawa et al. 2004).

Intrahepatic Cholangiocarcinoma

Introduction

A growing list of risk factors has been recognized to be involved in cholangiocarcinomas (review: Bragazzi et al. 2012). Generally, risk factors for ICC can be divided into two major groups. The first, more common group of ICC represents a consequence of recurrent infestations of the biliary tract by liver flukes mainly occurring in East and Southeast Asia. The second group of ICC is a much rarer cancer induced by a wide array of etiologic factors and occurring worldwide (reviews: de Martel et al. 2010; Shin et al. 2010). Literature reviews and meta-analyses uncovered that, specifically in Western countries, liver cirrhosis, chronic HBV and HCV infection, alcohol abuse, diabetes mellitus, and obesity are major risk factors for ICC (Palmer and Patel 2012).

Precursor Lesions of Intrahepatic Cholangiocarcinoma

Typical precursor lesions of cholangiocarcinomas originating in larger bile ducts are termed biliary intraepithelial neoplasm (BillN), a distinct group of dysplastic processes that evolve into carcinoma in situ (Figs. 1, 2, and 3). BillN is generally confined to large and septal-sized bile ducts (Sato et al. 2013, 2014; Aishima et al. 2014). Precursor lesions, in particular biliary epithelial dysplasia, form a distinct precancerous change in extrahepatic bile ducts, but also develop in large intrahepatic bile ducts of patients with several risk factors of ICC. As BillNs are typically premalignant changes that occur in large ducts, they play a role in ICC located to perihilar intrahepatic ducts, i.e., in large-duct ICC. In contrast, precursor lesions of peripheral ICC are not yet well established. In a minority of peripheral ICC, bile duct adenoma, bile duct adenoma-like lesions, biliary adenofibroma, biliary microhamartomas (von Meyenburg complexes), and atypical bile duct lesions involving small bile ducts may be related to the development of this cancer (review: Nakanuma et al. 2014).

The histologic criteria for lesions previously termed intraepithelial atypical/proliferative biliary epithelial lesions have worked out by the study of stone-containing intrahepatic bile ducts of hepatolithiasis (Zen et al. 2005a). In livers with established ICC, dysplastic lesions occur both near and remote from ICC lesions (Shimonishi et al. 2000b). Precursors of invasive, perihilar, or peripheral intrahepatic cholangiocarcinoma (ICC) include flat-type biliary intraepithelial neoplasia (BillN) and papillary-type intraductal papillary neoplasm of bile duct (IPN-B). These two pathways have specifically been identified in ICC

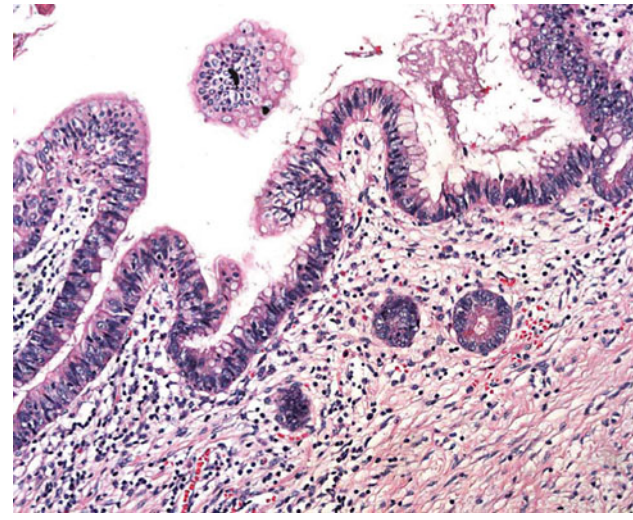

Fig. 1 BiIIN, low grade, in a bile duct (hematoxylin and eosin stain)

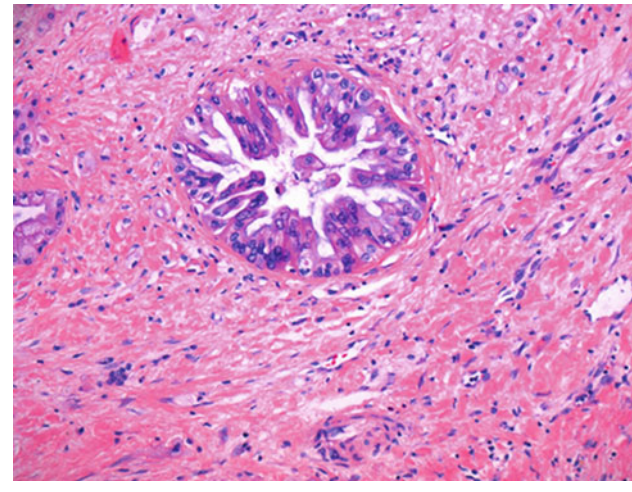

Fig. 2 BiIIN, moderate grade (hematoxylin and eosin stain)

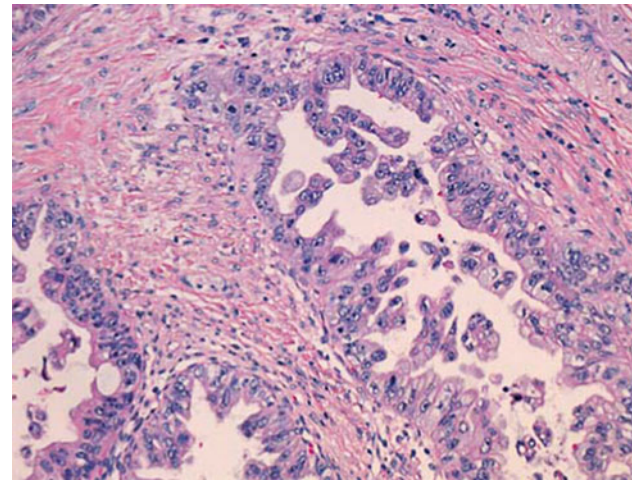

Fig. 3 BiIIN, high grade, in part with a papillary pattern (hematoxylin and eosin stain)

Table 1 Classification of flat-type biliary intraepithelial neoplasia (BillN; Zen et al. 2005b, 2007)

BilIN-1	Low-grade dysplasia of biliary epithelium, mild cellular-nuclear atypia suggestive of neoplasia
BillN-2	High-grade dysplasia of biliary epithelium, cellular-nuclear atypia evident but insufficient to represent overt malignancy
BillN-3	Carcinoma in situ, cellular-nuclear atypia representing overt malignancy

patients with hepatolithiasis, and a three-level grading system for BillN has been developed (Zen et al. 2005b, 2007; Table 1). For ICCs, three carcinogenic pathways have been proposed, viz., BillN progressing to tubular adenocarcinoma and IPN-B progressing to tubular adenocarcinoma or to colloid carcinoma.

In one analysis, carcinogenesis via BillN was characterized by MUC2-/CK7+/CK20- with increasing MUC1 expression, whereas IPN-B showed an intestinal phenotype with MUC2+/CK20+. Transition to invasive tubular adenocarcinoma was associated with increasing MUC1 expression and to that of colloid carcinomas with MUC1 loss (Zen et al. 2006). Other studies showed that progression from BillN involves an MUC1(+)MUC2(−)CK20(−)-associated pathway and upregulation of p53 in the switch to invasion (review: Nakanuma et al. 2009). In patients with hepatolithiasis, Sato and coworkers (2013) distinguished two forms of carcinoma in situ, i.e., (BillN-3), biliary intraepithelial neoplasia-3 and intraepithelial spread of carcinoma (IES). The two forms, which histologically mostly present as flat or pseudopapillary lesions, differ in their demarcation from the normal epithelial lining. BillN-3 is an atypia that gradually decreases toward the transition to the normal biliary epithelium, whereas in IES, the lesion displays an abrupt transition to normal epithelium. Both lesions were only found in livers with invasive ICC. BillN-3 and IES differ in their distribution within the intrahepatic bile ducts. Whereas BillN-3 was not present in septal and small ducts, IES was often found in such ducts (Sato et al. 2013).

The precursor lesions are associated with deranged expression of components of the Wnt signaling pathway. The membranous expression of beta-catenin decreased along with the progression of both BillN and IPN-B changes, and decreased E-cadherin expression was a marker for invasive ICC with BillN and IPN-B in comparison with noninvasive counterparts. BillNs 1–3 are not or only weakly associated with expression of the invasion markers MMP-7 amd MT1-MPP, while these two enzymes are expressed in invasive lesions (Itatsu et al. 2007). Expressions of p53, p21, and cyclin D1 were upregulated in both BillN and IPN-B, whereas Dpc4 was downregulated in these lesions. In bile ducts with BillN, expression of p21 is an early alteration, while expression of p53 is low in precursor lesions and undergoes a dramatic increase in invasive neoplastic lesions (Nakanishi et al. 2008).

Several types of chronic liver diseases have been analyzed for the expression patterns of BillN. Precursor lesions such as BillN are well-known for biliary cirrhosis (Aishima et al. 2011), specifically in patients with PSC, but can also develop in non-biliary cirrhosis, mainly alcohol- and HCV-induced cirrhosis (Torbenson et al. 2007; Rougemont et al. 2010). In cirrhosis, biliary neoplasia can show extensive intraductal spread (Aishima et al. 2008). In a series of explanted livers, those transplanted for alcoholic liver disease and alcoholic liver disease plus HCV cirrhosis had the highest prevalence of BillN, higher grades of BillN, and greater numbers of intrahepatic ducts with BillN as compared with HCV alone and non-cirrhotic livers, suggesting that alcohol and HCV infection may play a role in intrahepatic cholangiocarcinogenesis (Wu et al. 2009). In patients with end-stage PSC, livers with cholangiocarcinoma are more likely to have metaplastic duct changes, dysplasia/BillN of any grade, and high-grade dysplasia (Lewis et al. 2010). ICC has been observed in the setting of biliary papillomatosis (Cox et al. 2005).

Chronic Biliary Tract Inflammation and Bile Duct Cancer

ICC is found in association with cholangitis, cholelithiasis/hepatolithiasis, alcoholic liver disease, liver cirrhosis, chronic inflammatory bowel disease, and parasitoses (Ben-Menachem 2007;

Welzel et al. 2007; Khan et al. 2008; Zhou et al. 2008; Tyson and El-Serag 2011; Sibulesky et al. 2012). Established risk factors comprise primary sclerosing cholangitis, other inflammatory disorders of the biliary tree (including parasitoses), and choledochal cyst, but several other conditions are significantly associated with both ICC and ECC, such as biliary cirrhosis, cholelithiasis, alcoholic liver disease, nonalcoholic steatohepatitis with or without diabetes mellitus, hepatitis virus infection, nonspecific cirrhosis, smoking, and chronic pancreatitis (Shaib et al. 2005; Welzel et al. 2007). There is evidence that any process that results in increased epithelial cell turnover or hyperplasia of cholangiocytes can switch into a dysplasia-adenoma sequence increasing the risk of cholangiocarcinoma (Kurashina et al. 1988; Vianna et al. 1989; Pinho et al. 2012). Important effectors of inflammation-induced derangement of epithelial proliferation modes and subsequent carcinogenesis are certain cytokines. One of them is interleukin-6/IL-6 and its receptor. Most, if not all, inflammatory reactions taking place in bile ducts cause upregulation of IL-6 secretion, which in turn triggers several signal pathways, including PI3 kinase, JAK/STAT, and p38 MAP kinase, leading to increased cell proliferation and protection from apoptosis (review: Johnson et al. 2012). IL-6 also decreases cell senescence and increases telomerase activity in cholangiocarcinoma (Yamagiwa et al. 2006). The differential effects of IL-6 on diverse genes are in part mediated by the induction of epigenetic gene promoter methylation (Wehbe et al. 2006). In malignant human cholangiocytes, IL-6 epigenetically regulates microRNA-370, in the IL-6 overexpression reduced miR-370 expression, a gene target of which is the oncogene, mitogen-activated protein kinase kinase 8/MAP3K8 (Meng et al. 2008). On the other hand, the microRNA let-7a modulates the IL6-dependent STAT-3 survival signaling in cholangiocarcinoma cells (Meng et al. 2007).

Primary Sclerosing Cholangitis

Primary sclerosing cholangitis (PSC) is a well-recognized risk factor for cholangiocarcinoma, and is regarded as the most common predisposing factor for cholangiocarcinoma in the West, and patients with PSC develop cholangiocarcinoma at younger age, i.e., 30–50 years, in comparison with the general population (MacCarty et al. 1985; Martins et al. 1994; Knechtle et al. 1995; Chalasani et al. 2000; Maggs and Chapman 2008; Fevery and Verslype 2010). The prevalence of cholangiocarcinoma in patients with PSC ranges from 7 % to 13 % (review: Lazarides and Gores 2006), but there are reports giving a figure of 40 % (Shaib and El-Serag 2004). The cumulative annual risk of cholangiocarcinoma in patients with PSC is 1.5 % per year after the development of jaundice. In patients who concomitantly suffer from inflammatory bowel disease, the 10-year and 20-year risks for cholangiocarcinoma are 14 % and 31 %, respectively. The patient group with the highest risk for cholangiocarcinoma is that with large-duct PSC in contrast to small-duct PSC. However, in case small-duct disease progresses to large-duct disease, the risk for cholangiocarcinoma seems to increase (Björnsson et al. 2008). Apart from effects exerted by chronic inflammation and the associated deregulation of cytokine and growth factor secretion, there is evidence that genetic factors are involved in PSC-related carcinogenesis (Forsbring et al. 2009). In PSC, the biliary tract is prone to the development of various precursor lesions of cholangiocarcinoma, as discussed above, in particular various grades of dysplasia (Fleming et al. 2001). In a series of 100 consecutive liver explants of patients with PSC, mucinous metaplasia, pyloric metaplasia, and pancreatic acinar metaplasia were detected in 77 %, 73 %, and 10 %, respectively, and these rates did not differ between cancerous and noncancerous livers. In contrast, livers with ICC were more likely to have intestinal metaplasia, dysplasia of any grade, and high-grade dysplasia (Lewis et al. 2010). Two distinct pathways of cholangiocarcinogenesis in PSC have been proposed. Cholangiocarcinoma and biliary intraepithelial neoplasia were classified into intestinal and non-intestinal classical types, the former being slightly more common. Intestinal-type lesions revealed histological features resembling

intestinal dysplasia or adenocarcinoma and often exhibited an intraductal papillary proliferation and mucinous nodules. Patients with intestinal-type cholangiocarcinoma had a more favorable cancer-specific prognosis than those with classical-type cholangiocarcinoma (Zen et al. 2011).

Liver Fluke Disease

As specified in more detail in a separate chapter, liver flukes are well-known to be an important risk factor for the development of ICC (liver fluke-associated ICC; Flavell 1981; Kurathong et al. 1985; Choi et al. 1988; Riganti et al. 1989; Shirai et al. 1992; Haswell-Elkins et al. 1994; Elkins et al. 1996; reviews; Schwartz 1986; Watanapa and Watanapa 2002; Hughes et al. 2006; Ong et al. 2012). Liver fluke disease is not only a major challenge in endemic regions of Southeast and East Asia but also for numerous immigrants of these countries now living in other countries. It has been estimated in the 1970s that up to 26 % of Asian immigrants had active liver fluke infestation (Schwartz 1986). Cholangiocarcinogenesis induced by liver fluke infestation is a multistage process involving a pathway leading from inflammation to altered gene expression patterns in involved tissues (Pairojkul et al. 1991). The gene expression patterns of ICC differ between tumors associated with *O. viverrini* and nonparasite-associated ICC (Jinawath et al. 2006). More details are found in the chapter on parasitic diseases of the biliary tract.

Hepatolithiasis

Hepatolithiasis has been found to be associated with cholangiocarcinoma, mainly in East Asian countries, while this association is unusual in Western countries (Nakanuma et al. 1985; Lesurtel et al. 2002; Tabrizian et al. 2012). The presence of hepatolithiasis and the associated inflammatory changes centered on involved bile ducts can hinder diagnosis of ICC (Chen et al. 2000). The biology of ICC associated with hepatolithiasis is complex and probably modulated by associated inflammatory changes of and immune responses taking place in the bile ducts. The pathogenesis of ICC developing in hepatolithiasis is complex and includes an interplay of factors related to inflammation and altered expression of cancer-related genes (review: Kuroki et al. 2005). Bile ducts containing calculi regularly show cholangiocyte hyperplasia, but also an increased proliferative activity in peribiliary glands (Lee and Sheen 1999), probably induced by chronic inflammation. In hepatolithiasis, hyperplastic change can be followed by metaplastic and dysplastic changes which are the precursor lesions of cholangiocarcinoma and display a distinct gene expression signature (Terada and Nakanuma 1992; Lee et al. 2006). Similar to the liver with PSC, hepatolithiasis is associated with various metaplastic changes, including pyloric gland metaplasia, intestinal metaplasia, goblet cell metaplasia, and Paneth cell metaplasia (Kurumaya et al. 1990). A stepwise increase of the number of interphase AgNORs in bile duct cells was observed in the order, normal, hyperplasia, dysplasia, carcinoma in situ, and invasive carcinoma (Terada et al. 1992). The dysplastic areas were in part found in the vicinity of invasive carcinomas and were CA 19-9 immunoreactive (Ohta et al. 1991). In hepatolithiasis, epithelial proliferations start to express c-Erb-2 protein, which is then also expressed in cholangiocarcinomas (Terada et al. 1998a). The development of epithelial dysplasia in the livers with hepatolithiasis is associated with changes in the expression of factors known to be involved in dysplasia, e.g., loss of expression of the DPC4/SMAD4 gene (Lee et al. 2006), a gene that is inactivated in part of ICC (Argani et al. 2001) and is also inactivated in more than half of ductal pancreatic carcinomas. The features of ICC occurring in hepatolithiasis have been treated in numerous studies and reports.

Selected References Chen et al. 1984; Nakayama and Koga 1984; Ohta et al. 1984, 1988; Koga et al. 1985; Nishihara et al. 1986;

Nakanuma et al. 1988; Terada et al. 1989; Chu et al. 1997; Sato et al. 1998; Lee and Liu 2001; Lee et al. 2002a; Kim et al. 2003; Shoda et al. 2003; Hwang et al. 2004; Kawakami et al. 2007; Liu et al. 2011; Suzuki et al. 2012.

Hepatitis Viruses

HBV and HCV play an etiological role for ICC (Nakanuma et al. 2003; Liu et al. 2003; Hai et al. 2005; Lee et al. 2008; Zhou et al. 2008, 2009, 2011, 2012, 2014a; El-Serag et al. 2009; Li et al. 2012a; Matsumoto et al. 2014). As the development of ICC is related to liver cirrhosis, this is one pathway through which hepatitis viruses can promote cholangiocarcinogenesis. There is increasing evidence that there is an increased risk for developing ICC in patients with cirrhosis (Terada et al. 1994a; Sorensen et al. 1998; Kuper et al. 2001). In Western countries, ICC may be more common in patients without liver cirrhosis (Nkontchou et al. 2013). However, there is also increasing evidence that both HBV and HCV might play a direct role in the induction of intra- and extrahepatic cholangiocarcinomas (Yamamoto et al. 2004; Gatselis et al. 2007; Lee et al. 2009a; Zhou et al. 2010, 2012; Peng et al. 2011). Mainly in Japan and East Asia, ICC was found to be associated with a high prevalence of HCV infection (Tomimatsu et al. 1993; Yamamoto et al. 1998; Kobayashi et al. 2000). A strong association between HCV infection and ICC was found for minute nodular ICCs (Yamamoto et al. 1998). Viral hepatitis (B or C) was associated with a cholangiocellular differentiation pattern and N-cadherin expression (Yu et al. 2011). A recent meta-analysis showed a statistically significant increased risk of ICC incidence with HBV and HCV infection. Nucleic acids of both viral types can be detected in HCC cells. In one investigation, 27 % of ICC cases from the US contained HBV and/or HCV nucleic acids, suggesting a pathogenic role for these viruses in some ICC (Perumal et al. 2006). Bile duct dysplasia, a precursor lesion for ICC, was observed in the setting of chronic hepatitis C (Torbenson et al. 2007). The direct effects of HCV-associated viral proteins on cholangiocytes and in the pathway to cholangiocarcinoma cells are only partially known, but in part involve effects of core protein on cell proliferation (Chen et al. 2005) and mechanisms related to epithelial-mesenchymal transition (EMT) (Balsano et al. 2011). HCV core protein plays important roles in the development of ICC and induces EMT (Li et al. 2010). microRNA-124 is downregulated in HCV-induced ICC via epigenetic regulation, and this decreased expression promotes cell migration and invasion via upregulation of MMP9 (Zeng et al. 2012).

There is evidence that ICCs that develop in the setting of hepatitis virus infections differ from other ICCs. In a Japanese investigation, the proportion of patients who underwent curative resection was higher in the HCV-positive than in the HCV-negative group, and tumors were significantly smaller in the HCV-positive group (Hai et al. 2005). ICCs developing in HBV-infected patients are more often of the MF subtype and are associated with lower lymphatic invasion, a higher prevalence of capsule formation, and better survival (Wu et al. 2013). HBV infection has a favorable effect on outcome in ICC (Zhang et al. 2010; Zhou et al. 2011). HBV infection or HBV vaccination prior to resection, together with adjuvant chemotherapy, was independently associated with improved survival in patients with ICC (Liu et al. 2013).

Congenital Malformation Syndromes of the Biliary Tract

Caroli's disease (CD) is a rare condition that belongs to the group of congenital ductal plate malformations and that is characterized by segmental cystic dilatations of intrahepatic bile ducts (reviews: Taylor and Palmer 1998; Parada et al. 1999; Sgro et al. 2004; Yonem and Bayraktar 2007). Dilated bile ducts in CD often undergo chronic inflammation complicated by stone disease and eventually subsequent dysplastic alterations of the epithelium. Apart from dysplastic epithelial changes, carcinoma in situ was

observed in CD (Joly et al. 1990), suggesting a dysplasia-carcinoma in situ-invasive carcinoma sequence. In a relatively few patients, CD is complicated by invasive cholangiocarcinoma.

Selected References Phinney et al. 1981; Ludwig et al. 1982; Dayton et al. 1983; Ginaldi 1987; Takei et al. 1991; Balsells et al. 1993; Falco et al. 1993; Abdalla et al. 1999; Totkas and Hohenberger 2000; Takatsuki et al. 2001; Vlachogiannakos et al. 2004; Kasper et al. 2006; Mabrut et al. 2013.

Cholangiocarcinoma as a complication of CD was also noted in monolobar disease (Abdalla et al. 1999). The source of cholangiocarcinoma in CD is probably linked to continuous hyperregeneration caused by inflammation-induced cholangiocyte injury, followed by dysplastic changes, CD thus being a potentially premalignant condition (Dayton et al. 1983). Both in CD and congenital hepatic fibrosis, matrix proteins of basement membranes are degraded around bile ducts, mainly laminin and type IV collagen, probably mediated by proteases secreted by cholangiocytes, a mechanism that might contribute to cystic bile duct dilatation. This phenomenon was also observed in cholangiocarcinomas developing in the setting of CD (Yasoshima et al. 2009), suggesting that an unstable basement could favor the transition from carcinoma in situ into invasive carcinoma. ICC was found to arise in congenital hepatic fibrosis, an autosomal recessive ductal plate malformation disorder caused by mutations of fibrocystin/polyductin (Yamato et al. 1998). Very rarely, ICC develops in the setting of biliary cirrhosis caused by congenital biliary atresia (Kulkarni and Beatty 1977). Cholangiocarcinomas can also develop in bile duct cysts, whereby type I and type IV cysts showed higher cancer incidences, even after cyst resection (Soreide and Soreide 2007). ICC can arise after excision of type IV A choledochal cyst after a long delay, e.g., 28 years (Kumamoto et al. 2014). ICC was also found in association with developmental liver cysts (Azizah and Paradinas 1980; Imamura et al. 1984) or with polycystic kidney and liver disease (Landais et al. 1984).

Preexisting Hepatic Tumors and Tumor-like Lesions

ICC rarely develops from bile duct adenomas. In one case, there was a gradual dedifferentiation from a central adenoma-like lesion to an infiltrative ICC (Börnfors 1984). ICC can arise in bile duct adenoma with focal areas of bile duct microhamartoma (Hasebe et al. 1995). ICC was found in association with multiple bile duct microhamartomas (von Meyenburg complexes), a pathogenic link between the two lesions being suggested by a continuity between microhamartoma cells and those of ICC (Dekker et al. 1989; Röcken et al. 2000; Wisniewski et al. 2002; Orii et al. 2003; Neto et al. 2007; Droy et al. 2009; Xu et al. 2009). Hyperplastic and dysplastic alterations of peribiliary gland may be a potential source for ICC. Papillary and atypical hyperplasia of peribiliary glands, observed in less than 1 % of livers, may precede ICC. In one study, carcinomatous transformation and atypical hyperplasia coexisted, however in only 1 out of 799 livers (Terada and Nakanuma 1990).

Thorotrastosis

As outlined in more detail in another chapter, thorotrast exposure was significantly associated with the development of various liver malignancies, including cholangiocarcinoma (thorotrast-associated cholangiocarcinoma, TACC; Rota et al. 1971; Johnson and Babb 1975; Herzog et al. 1976; Rubel and Ishak 1982; Gras Borrell et al. 1985; Imai et al. 1988; Ito et al. 1988; Sasaki et al. 1989; Lee et al. 1996; Liu et al. 2002; Sahani et al. 2003; Zhu et al. 2004; review: Lipshutz et al. 2002). Thorotrast-induced cholangiocarcinomas are much more frequently intrahepatic than hilar tumors. In a study of 44 TACC, 91.7 % of the tumors were located in the middle-peripheral portion of the liver, while 77.8 % of cholangiocarcinomas not related to thorotrast were located in the hilar portion (Ito et al. 1988). Similar to other thorotrast-associated hepatic malignancies, TACC may be diagnosed after a long delay, in one case observed 40 years after

thorotrast administration (Sakai et al. 1984). There is some evidence that thorotrast-induced liver cancers are inclined to grow rapidly and to early produce intrahepatic metastases (Imai et al. 1988). In few cases, two thorotrast-associated hepatic tumors occurred synchronously, e.g., ICC+HCC, ICC+angiosarcoma, or ICC + hemangioendothelioma (Winberg and Ranchod 1979; Sakai et al. 1984).

Other Hepatobiliary Inflammatory Disorders

There is evidence that nonalcoholic steatohepatitis (NASH) with or without associated diabetes mellitus might be associated with ICC. In a US study on 181 patients who underwent resection for ICC, 31 or 17.1 % had underlying NASH (Reddy et al. 2013). In a study on 57 consecutive Caucasian patients with ICC in the absence of bile duct disease or cirrhosis, macrovesicular steatosis, steatohepatitis, and hepatic iron overload were prominent features, in part associated with high alcohol consumption, elevated BMI, and/or diabetes mellitus (Nkontchou et al. 2013).

Cancer Predisposition Syndromes

ICC was found in association with Muir-Torre syndrome (Vernez et al. 2007), a rare autosomal dominant syndrome with sebaceous skin lesions, basaliomas, spinaliomas, and hereditary nonpolyposis colorectal cancer.

Other and Rare Risk Factors

Cholangiocarcinoma has been observed after childhood radiotherapy for nephroblastoma/Wilms' tumor (Cunningham 1990).

Pathogenic Pathways of Intrahepatic Cholangiocarcinoma

Pathogenic pathways involved in ICC are, also due to the various known etiologies, complex and in many ways different from those of extrahepatic cholangiocarcinomas (reviews: Nakanuma et al. 2003; Berthiaume and Wands 2004; Blechacz and Gores 2008; Khan et al. 2008; Wise et al. 2008; Fava 2010; Kumar et al. 2011; Nault and Zucman-Rossi 2011; Wadsworth et al. 2011; Fava and Lorenzini 2012; Leyva-Illades et al. 2012; Rizvi and Gores 2013; Sia et al. 2013).

Cellular Origin of ICC

It is usually held that ICC originates from cholangiocytes of intrahepatic bile ducts. However, novel findings have shed a different light onto this question, suggesting a more complex cellular origin (Cardinale et al. 2012; Carpino et al. 2012; Komuta et al. 2012). Also based on the observation that there is a relation between hepatitis virus infection, in particular HCV infection, and ICC, it has been suggested that the hepatocyte lineage might be involved in ICC carcinogenetic pathways. Biliary lineage cells giving rise to ICC may in fact derive from hepatocytes via a Notch-mediated cell conversion (Sekiya and Suzuki 2012). In subsets of ICC, cells with hepatobiliary progenitor cell features were identified. Part of ICC are reactive for stem cell factor and its receptor, c-Kit (Mansuroglu et al. 2009). The expression of hepatic progenitor cells markers, NCAM and c-Kit, was higher in ICC with chronic advanced liver disease (Xu et al. 2011a). Part of cholangiocarcinoma cells co-expressed stem cell factor and its receptor, c.Kit, but these proteins were also detectable in tumor-associated macrophages and in stromal myofibroblastic cells. In the tumor, upregulation of stem cell factor was stronger than that of c-Kit (Mansuroglu et al. 2009). There are subsets of cholangiocarcinomas expressing the stem cell marker, CD133. A strong expression of CD133 was associated with nodal metastasis, a positive resection margin, and increased invasion (Leelawat et al. 2011). SALL4, a stem cell biomarker in liver cancers, is strongly expressed in part of cholangiocarcinomas, this expression indicating a more aggressive phenotype (Oikawa et al. 2012). ICC contains cells that express

CD44 and glioma-associated oncogene homologue-1 (GLI1), and ICC with such stemlike cells had a poor prognosis (Nanashima et al. 2013).

Gene Mutations in Intrahepatic Cholangiocarcinoma: LOH, Oncogenes, Tumor Suppressor Genes, and Genes Involved in Invasion

The chromosomal and molecular pathology of cholangiocarcinomas has been investigated and resulted in the recognition of distinct molecular profiling patterns.

Selected References Cong et al. 2001; Momoi et al. 2001; Okuda et al. 2002; Kumar et al. 2011; Andersen et al. 2012; Andersen and Thorgeirsson 2012; Fava and Lorenzini 2012; Andersen and Thorgeirsson 2013; Subrungruanga et al. 2013; Voss et al. 2013; Patel 2014; Rizvi and Gores 2014.

Cholangiocarcinomas as a whole show a high frequency of loss of heterozygosity (LOH) involving several chromosomal loci. Particularly, allelic loss plays an important role in microsatellite alterations at chromosome 1p36, a locus that is thought to play a special role in fluke-associated ICC (Limpaiboon et al. 2006). Fifty percent of cases with MF + PI types were frequently detected by LOH at D8S258 compared to cases of the MF or ID growth type (Kawaki et al. 2000). Deregulated gene functions in ICC are in part related to distinct chromosomal abnormalities found in these neoplasms, in particular losses of heterozygosity (LOHs) involving chromosomal loci 3p13-p21, 4q, 5q35-qter, 6q, 8p22, 9q, 16q, 17p13, and 18q and gains of 5p, 7p, 13q, and 20q (Kang et al. 2000; Koo et al. 2001; Momoi et al. 2001). MF-ICC showed higher frequencies of LOH (Momoi et al. 2001). 17p13 involves p53. Genome-wide analyses of gene expression will lead to the identification of distinct gene expression signatures in cholangiocarcinoma (Obama et al. 2005a; Wang et al. 2006; Miller et al. 2009; Seol et al. 2011). In one investigation, 52 genes were identified that were commonly upregulated and 421 genes that were downregulated in ICC (Obama et al. 2005a).

K-RAS (KRAS) mutations are rather common in ICC and in experimental models of this tumor and are now considered to play a central pathogenic role and have been found in 22–48 % of these cancers (Tada et al. 1992; Ohashi et al. 1994, 1995; Boberg et al. 2000; Tannapfel et al. 2000; Isa et al. 2002; Xu et al. 2011b; O'Dell et al. 2012; reviews: Rashid 2002; Chen et al. 2012; Hsu et al. 2013). The prevalence of KRAS mutations depends on the underlying risk factor for ICC. KRAS mutations, in conjunction with TP53 mutations, are frequently observed in cholangiocarcinomas that develop in the setting of primary sclerosing cholangitis (Ahrendt et al. 2000; Boberg et al. 2000). In contrast, KRAS mutations are less common in ICC developing in thorotrastosis in comparison with non-thorotrast-associated ICC, while p53 mutations are more frequent (Kamikawa et al. 1999). Generally, genetic alterations in thorotrast-related ICC are more similar to those in other cholangiocarcinomas than those in hepatocellular carcinoma (Liu et al. 2004). In addition to ICC, KRAS mutations also occur in potential precursor lesions of invasive bile duct cancer, i.e., biliary intraepithelial neoplasia-2 (BilIN-2) and BilIN3 (Hsu et al. 2013). The presence of KRAS mutations is more often noted in the PI-ICC subtype (Ohashi et al. 1995) and is strongly associated with perineural invasion and represents an independent prognostic factor of ICC after hepatectomy (Chen et al. 2012). Overall, the presence of KRAS and GNAS mutations in ICC was associated with poor overall survival (Jang et al. 2014). The RAF/MEK/ERK (mitogen-activated protein kinase-MAPK) signal transduction pathway is an important mediator of cell proliferation and survival and is modified in several malignancies. The B-RAF (BRAF) gene, an isoform of human RAF, is activated by oncogenic Ras. Mutations in the BRAF gene have been identified in cholangiocarcinoma, but not in hepatocellular carcinoma (Tannapfel et al. 2003). In contrast to KRAS mutations, BRAF mutations are less frequent in cholangiocarcinomas (Xu et al. 2011a; Robertson

et al. 2013). BRAF V600E-specific mutations seem to be restricted to ICC, while no extrahepatic cholangiocarcinomas showed BRAF mutations (Goeppert et al. 2014). As already specified above, ICC regularly displays alterations of p53 protein expression, in part caused by mutations in the TP53 gene, in part by epigenetic mechanisms (Petmitr et al. 1998; Kang et al. 1999; reviews: Khan et al. 2005, 2006; O'Dell et al. 2012). P53 mutations causing p53 inactivation are common events in cholangiocarcinomas (Terada et al. 1994b; review: Khan et al. 2005). In one investigation, mutations in TP53 were detected in 37 % of ICC (Tannapfel et al. 2002).

The INK4a-ARF locus on chromosome 9p21 encodes two cell cycle-regulatory proteins, p16 (INK4a) and p14(ARF), acting through the Rb-CDK4 and p53 pathways. A minority of ICC revealed homozygous deletion of the INK4a-ARF locus, but specific mutations were not detected (Tannapfel et al. 2002). Runt-related transcription factor 3 (RUNX3) is a tumor suppressor gene on chromosome 1p36. The gene product, RUNX3 protein, is involved in TGFbeta-SMAD signaling. Downregulation of RUNX3 was found in liver fluke-associated ICC, caused by DNA copy number loss at 1p36.1 and promoter hypermethylation (Dachrut et al. 2009). Deleted in malignant brain tumor-1 (DMBT-1) is more frequently expressed in biliary epithelia in hepatolithiasis, but is markedly decreased in invasive ICC due to homozygous deletion of the DMBT-1 gene, a late event in ICC pathogenesis (Sasaki et al. 2003). The fragile histidine triad (FHIT) gene, a putative tumor suppressor gene on chromosome 3p14.2, is lost in part of ICC via LOH (Koch et al. 2003), but reduced expression of FHIT is also accomplished by promoter methylation (Foja et al. 2005). In some ICC, mutations in genes encoding factors required for invasion were identified. Mutations of exons 7, 8, and 9 of the E-cadherin gene were found, correlated with downregulated E-cadherin protein expression, reduced cell adhesiveness, and high histological grade (Endo et al. 2001). Isocitrate dehydrogenase 1 and 2 genes are mutated in a subset of ICC, and these mutations are more commonly encountered in ICC than in extrahepatic cholangiocarcinoma (Kipp et al. 2012; Wang et al. 2013). Sporadic ICCs display complex changes of the FGFR and EGFR pathways (Borad et al. 2014). ICCs show alterations of fibroblast growth factor receptor 2 (EGFR2), while amplifications of ERBB2 nd ROS1 are rare events (Graham et al. 2014). More than 40 % of ICCs contained somatic mutations of the protein tyrosine phosphatase, PTPN3, and activating mutations and high expression levels of PTPN3 were associated with tumor recurrence (Gao et al. 2014).

Deregulation of microRNA in Intrahepatic Cholangiocarcinoma

Differential expression patterns of microRNAs (miRNAs) play an important role of the expression of gene involved in cholangiocarcinogenesis (Stutes et al. 2007; Chen et al. 2009; Plieskatt et al. 2014). A cluster of more than 30 miRNAs is distinguished between ICC and normal hepatic tissues (Chen et al. 2009; Karakatsanis et al. 2013). One of the miRNAs that is consistently expressed in cholangiocarcinoma is miRNA-21, which regulated the expression of PTEN and PDCD4 (Liu et al. 2012). Inhibitors of miR-21 increased protein levels of programmed cell death 4 (PDCD4) and tissue inhibitor of metalloproteinases 3 (TIMP3) (Selaru et al. 2009). miRNA-370 is underexpressed in a large cohort of human cholangiocarcinomas, induced by silencing of the paternal allele through genomic imprinting and time-dependent silencing of the maternal allele of miRNA-370 by interleukin-6 (An et al. 2012). A further miRNA that is downregulated in cholangiocarcinoma is miRNA-494, regulating the G1/S checkpoint, an effect counteracting miRNA-494-induced growth retardation (Olaru et al. 2011). In cholangiocarcinomas, miRNA-26a promotes tumor cell growth by activating beta-catenin and thus the Wnt signaling pathway, glycogen synthase kinase-3beta being a direct target of miRNA-26a (Zhang et al. 2012). In ICC, miRNA-31 has RAS p21 GTPase activating protein 1 (RASA1) as its direct target. Downregulation of RASA1 by miRNA-31 promoted cell proliferation and inhibited apoptosis,

in part by upregulation of the activity of the RAS-MAPK signaling pathway (Hu et al. 2013; Sun et al. 2013). miR-124 is epigenetically regulated by HCV core protein and promotes migration and invasion of ICC cells by targeting SMAD3 and the downstream target genes, c-Myc and MMP9 (Zeng et al. 2012). Downregulation of miR-214 contributes to ICC spread and metastasis through targeting of Twist, a protein involved in EMT (Li et al. 2012b). The pre-miRNA-886/nc886, a novel type of noncoding RNA, inhibits activation of protein kinase R which has a pro-apoptotic activity though eukaryotic initiation factor 2alpha phosphorylation. This mechanism is important on host defense against viral infections. In cholangiocarcinoma cells, nc886 is downregulated, causing disinhibition/activation of protein kinase R and the pro-survival nuclear factor-kappaB pathway (Kunkeaw et al. 2013). miRNA-421 is an oncogenic miRNA/oncomir in cholangiocarcinomas. A decrease of miRNA-421 expression was correlated with induction of G0/G1 cell cycle arrest, while increased miRNA-421 expression downregulated farnesoid X receptor expression, a tumor suppressor for several cancers (Zhong et al. 2012). miRNA-204 was frequently downregulated in ICC, and the low-level expression of this miRNA was associated with lymph node metastasis. miRNA-204 inhibits EMT by targeting slug in ICC cells, and lack of miRNA-204 therefore favors an EMT-mediated invasive phenotype (Qiu et al. 2013). A further miRNA that affects EMT in ICC is miRNA-214. miRNA-214 levels are decreased in metastatic ICC, associated with increased Twist levels and promotion of pro-metastatic EMT (Li et al. 2012).

Growth Factors and Growth Inhibitors in Intrahepatic Cholangiocarcinoma

In cholangiocarcinomas, several factors regulating cell proliferation and differentiation exhibit altered expression patterns, including the p16INK4a-ARF pathway (Kang et al. 2002; Tannapfel et al. 2002; Karamitopoulou et al. 2008; Sasaki et al. 2008), p27(KIP1) pathway (Taguchi et al. 2001; Hashimoto et al. 2009), p38 kinase system (Dai et al. 2012), and cyclin kinase subunit-2 (Shen et al. 2013). The expression of cell cycle-regulatory proteins varies as a function of the tumors' localization within the biliary tract (Jarnagin et al. 2006). Overexpression and gene amplification of cyclin D1 are frequent in ICC and contribute to increased proliferation carcinogenesis (Ito et al. 2000a; Sugimachi et al. 2001a; Shen et al. 2013). Overexpression of cyclin D1 leads to the escape of ICC from the growth inhibitory effect of TGFbeta-1 (Zen et al. 2005a). ICC cells express receptors for insulin-like growth factor 1 and estrogens, which cooperate in the modulation of both cell proliferation and apoptosis (Alvaro et al. 2006). Loss of expression of DPC4 (deleted for pancreas cancer, locus 4)/SMAD4, a factor involved in several carcinogenic pathways and functioning as a tumor suppressor (Hann et al. 1996), is observed in both extrahepatic and intrahepatic bile duct cancers and is detectable in tumor cells by immunohistochemistry (Tascilar et al. 2001). In carcinomas of the common bile duct, loss of this factor was detected in 15% (Hahn et al. 1998), while loss of expression was found in 15–54.2 % of ICC (Argani et al. 2001; Kang et al. 2002; Chuang et al. 2004). In one analysis, loss of DPC4/SMAD4 was associated with frequent 18q allelic loss and with the pTNM stage (Kang et al. 2002), and another study demonstrated an association of DPC4/SMAD4 loss with dysplasia and ICC emerging in hepatolithiasis (Lee et al. 2006). Loss of DPC4 also characterizes a subset of tumors now classified as biliary intraductal papillary mucinous neoplasms (Sclabas et al. 2012). Loss of DPC4/SMAD4 in cholangiocarcinomas can act through several pathways, and it frequently affects the TGFbeta signaling pathway. DPC4/SMAD4 is required for TGFbeta-induced epithelial-to-mesenchymal transition in cancer cells (Deckers et al. 2006). Loss of DPC4/SMAD4 can operate through upregulation of the TGFbeta pathway known to promote carcinogenesis. In cholangiocarcinoma cell lines, TGFbeta-1 is produced, which stimulates TGFbeta-1 production and function in an autocrine manner and which accelerates the expression of interleukin-6, this interaction contributing to cell growth promotion (Shimizu et al. 2006). A TGF-beta-independent

tumor suppressor action of DPC4/SMAD4 involves its function to induce resistance to serum-deprivation-induced cell death through a PAK1-PUMA pathway (Lee et al. 2011). DPC4/SMAD4 downregulates an invasion-promoting matricellular protein, SPARC (Volmer et al. 2004), and loss of DPC4 will therefore promote the pro-invasive action of SPARC. DPC4 also mediates tumor suppression through suppression of angiogenesis, having a function as an angiogenic switch via the angiogenic mediators, vascular endothelial growth factor, and thrombospondin-1 as key target genes (Schwarte-Waldhoff et al. 2000). Based on these mechanisms, inactivation of SMAD4 is a prognostic factor in ICC (Yan et al. 2013). The DPC4 suppression mechanism in cancer itself involves somatic inactivating SMAD4 gene mutations, but also suppression via microRNA 421 (Hao et al. 2011). The growth factor receptors, EGFR, HGFR, and IGFR1, are expressed in cholangiocarcinoma cell lines (Xu et al. 2010) and in ICC (Yoshikawa et al. 2008; Zhou et al. 2013). The epidermal growth factor receptor (EGFR) was strongly expressed in 47 % of human cholangiocarcinomas (Jan et al. 2004). The c-erbB-2 proto-oncogene encoding a transmembrane protein highly homologous to the EGFR and an important factor in carcinogenesis, including cholangiocarcinoma (Roskoski 2004; Sirica 2008; Hynes and MacDonald 2009), is expressed in up to 70 % of cholangiocarcinomas, but was not correlated with proliferative activity or p53 protein expression (Terada et al. 1998b; Aishima et al. 2002a; Endo et al. 2002; Sirica et al. 2002; Zheng and Zhu 2007). In contrast, overexpression of c-erbB-2 in ECC varied markedly among several reports, being detectable in only 5.1 % in one analysis (Nakazawa et al. 2005) and 80 % in another (Zheng and Zhu 2007). RAD51AP1 (RAD51 associating protein-1), which interacts with RAD51, a molecule involved in DNA repair, is a proliferation-promoting factor that is upregulated in and induces growth in ICC (Obama et al. 2008). The Wilms' tumor 1-associated protein (WTAP), a nuclear protein that regulates cell proliferation and apoptosis, is upregulated in cholangiocarcinomas and regulates the motility of the cancer cells (Jo et al. 2013). Factors that initiate DNA synthesis are altered in ICC. PSF2 (partner of SLD five 2), a member of the GIBS multiprotein complex involved in initiation of DNA replication, is upregulated in ICC (Obama et al. 2005b). Loss of cilia (deciliation) in cholangiocytes is associated with an increased proliferation rate and induction of anchorage-independent growth, through a MAPK and hedgehog activation pathway. Deciliation in cholangiocarcinoma cells is induced by histone deacetylase 6 and promotes an increased growth phenotype (Gradilone et al. 2013). Progranulin, a growth factor overexpressed in several caners, is also upregulated in cholangiocarcinoma cells, driven by the action of IL-6 (Frampton et al. 2012). The polycomb protein Mbi1 is overexpressed in cholangiocarcinomas and promotes cell proliferation and represses cell senescence (Sasaki et al. 2009).

Defects and Abnormalities in the Cell Division Machinery

Dysregulation of mitosis is a common phenomenon in cancer. In ICC, several proteins operational in mitosis show a nuclear overexpression, including Aurora-A, Aurora-B, survivin, and p53 protein, and simultaneous overexpression of Aurora-A and Aurora-B was correlated with that of p53 (Shen et al. 2009). More than half of cholangiocarcinoma showed centrosome abnormalities mainly centrosome hyperamplification, which can result in multipolar division spindles, unbalanced chromosome segregation, and aneuploidy (Kuo et al. 2000).

Cell Death Mechanisms and Autophagic Pathways

As in other malignancies, deregulation of cell death and in particular apoptosis plays an important role in pathways leading to cholangiocarcinoma. Mutations in TP53, a common alteration in ECC and ICC, affect transcription of the pro-apoptotic Fas gene, causing a lack in cellular Fas expression and a blunted cell death response. The number and ratios of Fas-expressing cells are higher in ECC

than in ICC, and Fas expression decreased from dysplastic epithelium to cholangiocarcinoma, suggesting that reduced Fas expression is an early event in cholangiocarcinogenesis (Jhala et al. 2005). Whereas Fas expression counteracts cell growth and induces apoptosis in cultured cholangiocarcinoma cells (Pickens et al. 1999), Fas expression in cholangiocarcinomas decreases in cases with poor differentiation and high proliferative activity, and both expressions of Fas and Fas ligand thus reflect distinct biological features rather than the status of apoptosis in these tumors (Ito et al. 2000b). Human cholangiocarcinoma cells exhibit reciprocal co-expression of Fas and Fas ligand (Fas-L) (Que et al. 1999), regulated by NF-kappaB which inhibits Fas expression and increases FasL expression through binding to the promoters of the respective genes (Shimonishi et al. 2000a; Pan et al. 2007). Upregulation of Fas ligand in ICC is found in early-stage disease, while it is downregulated in progressed stages (Shimonishi et al. 2000a). Cholangiocarcinomas can express several factors counteracting apoptosis and promoting increased cell survival. Variable proportions of cholangiocarcinomas express Bcl-2 protein (Charlotte et al. 1994). Expression of this antiapoptotic protein is important, as Bcl-2 interacts with Bax to regulate apoptosis in biliary epithelial cells (Stähelin et al. 1999). Bcl-2 expression in cholangiocarcinomas is less common than that of p53 (Terada and Nakanuma 1996; Arora et al. 1999), When present, Bcl-2 expression is more frequent than in normal cholangiocytes (Harnois et al. 1997), and more frequently observed in well- or moderately differentiated cholangiocarcinomas (Ito et al. 2000c), but the tumors display a greater expression of Bcl-2 mRNA than that of the Bcl-2 protein (Fiorentino et al. 1999). Overexpression of IL-6 in cholangiocarcinoma cells enhances cell survival (Meng et al. 2006). Resistance to apoptosis in cholangiocarcinoma cells is accomplished through enhanced myeloid cell leukemia 1 (Mcl-1) expression induced by interleukin-6/IL-6-mediated signal transducers and activators of transcription 3 (STAT-3) phosphorylation. IL-6 contributes to Mcl-1 upregulation and TRAIL resistance through an Akt-signaling pathway (Kobayashi et al. 2005). Mcl-1 itself mediates resistance to the action of TRAIL (tumor necrosis factor-related apoptosis-inducing ligand) by blocking the mitochondrial pathway of cell death (Taniai et al. 2004). Epigenetic silencing of cytokine signaling 3 (SOCS) is responsible for sustained IL-6/STAT-3 signaling in the tumor cells (Isomoto et al. 2007). Another mechanism to protect Fas-expressing cholangiocarcinoma cells from cell death involves cyclooxygenase-2 (COX-2), an enzyme that produces prostanoids and is expressed in cholangiocarcinomas. COX-2 counteracts Fas-mediated apoptosis through prostaglandin E2-induced expression of the TRAIL antagonist, Mcl-1 (Nzeako et al. 2002). Expression of Yes-associated protein in ICC modulates a member of the inhibitors-of-apoptosis family, survivin. Survivin expression is an independent prognostic factor for poor survival in ICC (Bai et al. 2012). Autophagy serves to recycle damaged organelles and long-lived proteins in normal cells and cancer cells. One of the key regulators of autophagy is Beclin-1. Interestingly, beclin-1 is expressed in a subset of ICC, a feature associated with a metastatic phenotype (Dong et al. 2011).

Regulation of Cell Differentiation

ICC cells containing increased amounts of IL-6 are usually well-differentiated neoplasms, while poorly differentiated cholangiocarcinomas exhibit a downregulation of IL-6, suggesting that IL-6 expression is inversely related to cell proliferation and positively related to differentiation (Sugiwara et al. 1998).

Epithelial-Mesenchymal Transition (EMT) in Intrahepatic Cholangiocarcinoma

EMT is an important process in which epithelial cells lose epithelial cell features and assume properties that characterize mesenchymal cells. EMT is a mechanism that is critically involved in carcinoma-stroma interactions and cancer invasion and spread. During progression, many carcinoma

cells acquire a gene expression signature that more and more resembles that of mesenchymal cells, observations that change our views regarding the properties of metastasizing carcinoma cells. EMT is activated by numerous gene products, including growth factors and cytokines. In ICC, tumor necrosis factor-alpha (TNF-alpha) stimulates the EMT regulator Snail (Techasen et al. 2012). EMT induced by TGFbeta/Snail activation increased invasive growth of cholangiocarcinoma cells (Sato et al. 2010), while EMTs induced by Notch1 expression affect the migration capability of cholangiocarcinoma cells (Zhou et al. 2013). Smad7, a factor involved in EMT, is markedly overexpressed in cholangiocarcinoma in comparison with normal liver, and this expression pattern was associated with perineural invasion and lymph node metastasis (Huang et al. 2012). Proteins selectively upregulated in the course of EMT also include vimentin, which characterized mesenchymal cells, fascin, and E-cadherin. In the setting of EMT mechanisms in cholangiocarcinoma, fascin and vimentin are overexpressed, while E-cadherin is downregulated. The expression of fascin and vimentin indicated dedifferentiation and an invasive phenotype (Iguchi et al. 2009; Mao et al. 2013). In the course of EMT in cholangiocarcinoma, downregulation of the ANXA8 gene product by the EGF-FOXO4 signaling axis is involved in cell scattering (cell individualization) and metastatic spread (Lee et al. 2009b). Angiotensin II enhances EMT through an interaction between activated stellate cells and the stromal cell-derived factor-1 (CXCR4) axis (Okamoto et al. 2012). EMT in ICC is also regulated by microRNAs. Inactivation of miR-200c resulted in induction of EMT, whereas inactivation of miR-200c led to a reduction of EMT including reduced cell migration and invasion of ICC cells (Oishi et al. 2012).

Mechanisms of Invasion

The initiation of an invasion cascade requires individualization of cancer cells through tight junction decay mechanisms and a novel world of cell-cell and cell-matrix interactions via differential expression of adhesion molecules. Part of ICC cells display aberrant expression of the tight junction protein, claudin-18, normally restricted to the stomach and lung, but claudin-18 expression in ICC is less common than in other biliary tract cancers and biliary intraepithelial neoplasias. Among ICCs, claudin-18-positive cases showed higher frequencies of the PI subtype, perineural invasion and lymphonodal metastasis (Shinozaki et al. 2011). Several adhesion molecules that affect early steps of invasion and spread are variously expressed in ICC. CD24, an adhesion molecule which controls morphogenetic processes, induces invasion of cholangiocarcinoma cells by upregulating CXCR4 and increasing the phosphorylation of ERK1/2 (Leelawat et al. 2013). E-cadherin, an important adhesion molecule in the biliary tract, is downregulated in ICCs, in part caused by altered expression of beta-catenin which has a role in E-cadherin cell surface expression (Sugimachi et al. 2001b). Integrins hold a central position in mediating adhesion and intercellular recognition pathways and are therefore involved in cancer cell invasion. The integrin alpha6 subunit, part of the integrin alpha6beta1 and alpha6beta4 complexes, is overexpressed in human ICC, associated with a migratory and invasive phenotype (Ding et al. 2013). A protein expressed by cholangiocarcinoma stromal cells, periostin, activates alpha5beta1 integrin through a PI3K/AKT-dependent signaling pathway (Utispan et al. 2012). A secreted adhesive glycoprotein is osteopontin, which is overexpressed or downregulated in ICC (Hass et al. 2008). Its downregulation in ICC causes reduced cell adhesion and invasive phenotype with perineural and lymphatic invasion (Terashi et al. 2004).

Relatively few informations are available regarding the most important factors that regulate cancer cell motility in ICC. Expression of the cell adhesion molecules P-cadherin and CD24 in cholangiocarcinomas is a mechanism that increased motility in these neoplasms (Riener et al. 2010). Basic fibroblast growth factor induced cholangiocarcinoma cell migration via activation of the MEK1/2 pathway (Narong and Leelawat 2011). Nuclear expression of the

calcium-binding protein, S100A4, a protein also involved in EMT and the metastasis cascade (Sherbet and Lakshmi 1998; Helfman et al. 2005), promotes motility and invasiveness of tumor cells in cholangiocarcinoma (Fabris et al. 2011). The regulation of ICC cell motility also involves an interaction between the receptor CXCR4, produced by ICC cells, and its ligand, stromal-derived factor-1, and TNFalpha released from stromal cells. In this interactome, TNFalpha enhances CXCR4 expression on cancer cells (Ohira et al. 2008). Extracellular matrix protein-1 (ECM1) is significantly overexpressed in part of cholangiocarcinomas and is a factor contributing to tumor cell migration and invasion (Xiong et al. 2012).

An invasive phenotype also depends on a tumor cell-stromal cell cross talk. TGFbeta1 secreted by tumor cells acts on stromal cells where it reduces the expression of stromal-derived factor 1 involved in invasion (Ohira et al. 2006). Bone morphogenetic protein (BMP) signaling plays a role in carcinoma cell spread and invasion. The activity of BMPs in the extracellular space of carcinomas is regulated by the Twisted gastrulation (TWSG1) protein, which is expressed in cholangiocarcinoma (Johnston et al. 2012). Migration and invasion of cholangiocarcinoma is promoted by expression of the small nuclear protein, nuclear protein-1 (NUPR1), a protein that is responsive to various stress stimuli (Kim et al. 2012). Expressions of ErbB family receptor tyrosine kinases (see above) are expressed in part of ICC and play a role not only in cell proliferation but also in cell migration and invasion (Spencer et al. 2000).

Invasion of carcinoma cells into adjacent normal tissues strongly depends on the expression of diverse types of enzymes that degrade proteins and glycosaminoglycans of the extracellular matrix (ECM) or are involved in fibrinolysis. The most prominent proteases in cholangiocarcinoma are matrix metalloproteinases (MMPs) MMP-2, MMP-7, and MMP-9, and their tissue inhibitors, IMP-1 and TIMP-2 (Terada et al. 1996; Jo Chae et al. 2004; Hirashita et al. 2012). The upregulation of MMP-9 in cholangiocarcinoma is induced by the cytokine, tumor necrosis factor-alpha (TNFalpha; Tanimura et al. 2005), a mechanism regulated by overexpression of fascin (Onodera et al. 2009). TNFalpha induces the activation of cyclooxygenase-2 (COX-2), the subsequent production of prostaglandin E2 (PGE2) upregulating MMP-9 expression through binding to the PGE2 receptor (Wu 2005; Itatsu et al. 2009). COX-2-derived PGE2 also promotes cholangiocarcinoma cell growth and invasion through EP1 receptor-mediated activation of EGFR and AKT (Han and Wu 2005). In ICC cells, expression of MMP-2 is induced by overexpression of a factor involved in spread and metastasis of cancer cells, calpain small subunit 1 (Capn4) (Zhang et al. 2013). Enhanced expression of MMPs in cholangiocarcinoma is also correlated with downregulation of reversion-inducing cysteine-rich protein with Kazal motifs (RECK), suggesting that RECK functions as a metastasis suppressor in cholangiocarcinoma (Namwat et al. 2011). In cholangiocarcinoma, MMP-9 is stabilized by lipocalin 2 (neutrophil gelatinase-associated lipocalin, NGAL), which forms a complex with MMP-9 (Nuntagowat et al. 2010). Expression of urokinase plasminogen activator (uPA) in cholangiocarcinomas is associated with lymphatic invasion and metastasis (Thummarati et al. 2012).

The Tumor Microenvironment

The neoplastic transformation of cholangiocytes and/or their progenitor cells/stem cells to cholangiocarcinoma strongly depends on the generation of a distinct microenvironment that provides the developing, expanding, and spreading tumor with stromal cells, immunomodulatory cells, blood vessels, and access to lymph vessels (review: Leyva-Illades et al. 2012). The invasive phenotype of malignancies, including ICC, depends on angiogenesis that prepares a terrain for further growth and spread of cancer cells and is required for stroma formation and EMT. Establishment of a tumor-type microvascular system through tumor-induced angiogenesis is an important prerequisite for invasion and spread of cancer cells. In progressing cholangiocarcinoma,

angiogenesis is induced by various types of growth factors, in particular vascular endothelial growth factors (VEGFs) and fibroblast growth factors (FGFs). The expression of VEGF in cholangiocarcinomas is itself subject to regulators, e.g., endothelin, which decreases tumor growth via inhibition of VEGF expression (Fava et al. 2009). Apart from VEGF, angiopoietin-2 acts as a proangiogenic factor in cholangiocarcinomas, while thrombospondin-1 may play an inhibitory role in CC angiogenesis (Tang et al. 2006). Enhanced expression of thrombospondin-1 in cholangiocarcinoma is associated with tumor hypovascularity (Kawahara et al. 1998). Apart from "classical" angiogenic factors such as VEGFs, a further proangiogenic pathway operational in ICC is the Slit2/roundabout1 (Robo1) signaling pathway, which however also affects tumor cell proliferation and migration in these malignancies (Mano et al. 2013). Robo1 is a transmembrane receptor of the immunoglobulin family, and Slit2 is one of its ligands (Wang et al. 2013). In cancer cells, Robo1 is cleaved by metalloproteinases and gamma-secretase and migrates to the nucleus. Slit molecules belong to the repellent factor protein family that functions as morphogenetic proteins in foregut separation, as repulsive factors in growing axons of the nervous system, but also affects activated migration of certain cancer cells. Robo1 and Robo4 modulate endothelial cell motility and migration and via this effect promote angiogenesis (Legg et al. 2008). In ICC, factors regulating angiogenesis are altered in their expression, and part of these expression patterns are correlated with prognosis, e.g., expression of thrombospondin-1 (Aishima et al. 2002b). Also lymphangiogenesis has a central place in invasive pathways and the spread of tumor cells. Vascular endothelial growth factor-C (VEGF-C) is a critical lymphangiogenetic factor. 41.7 % of ICC showed a strong expression of VEGF-C, associated with a more aggressive phenotype, lymph node metastasis, and poor prognosis (Park et al. 2006). Certain factors present in the tumor microenvironment exert an influence on stromal leukocytes which in turn affect invasion patterns. The CXC-type chemokine family member CXCL5 is overexpressed in ICC, promotes metastasis, and recruits neutrophils in the stroma. Neutrophils in turn contribute to tumor metastasis (Zhou et al. 2014b).

Epigenetic Mechanisms

Several genes considered to play a role in the pathogenesis of ICC are subject to epigenetic alterations through gene promoter methylation (Lee et al. 2002b; Yang et al. 2005; Tischoff et al. 2006; Stutes et al. 2007; Sandhu et al. 2008; Isomoto 2009). Epigenetic inactivation of the p16 (INK4A) gene is a frequent event in cholangiocarcinoma (Tannapfel et al. 2000). Epigenetic hypermethylation of the p16 (INK4A) promoter is induced by overexpression of the polycomb protein EZH2 in cholangiocarcinoma (Sasaki et al. 2008). Other genes subject to methylation in ICC comprise RASSF1A, p15INK4b, APC, E-cadherin, p14(ARF), p73 and DAPK (Yang et al. 2005), and integrinalpha4 (Uhm et al. 2010).

Contents

Abstract

Bile duct cancers similar to those of adult patients also develop in the pediatric age group, but pediatric cholangiocarcinoma is a very rare condition in infants and children. The neoplasms become slightly more common in adolescents. Pediatric cholangiocarcinoma is usually associated with congenital hepatobiliary disorders, including congenital biliary dilatation and choledochal cysts, congenital pancreaticobiliary maljunction, and congenital biliary atresia. Cholangiocarcinoma can also develop in individuals who suffered from primary sclerosing cholangitis in childhood and in adolescents following pediatric-onset inflammatory bowel disease.

Introduction

Pediatric cholangiocarcinoma (PA-CC) is one of the rarest primary cancers of the biliary tract in infants and children. The tumor becomes slightly more common in adolescents and young adults, significantly associated with primary sclerosing cholangitis in this age group (Klein et al. 2005; Björnsson and Angulo 2007). In children, both PA-CCs of the extra- and intrahepatic bile ducts have been described. Probably the first example of intrahepatic PA-CC was reported in 1922 (Dansie and Eng 1922). PA-CC either develops without obvious predisposition or identifiable cause or arises in the setting of congenital or acquired hepatobiliary disorders.

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_32

Pediatric Cholangiocarcinoma Not Associated with Hepatobiliary Disorders

Less than five cases of this unusual tumor have been reported (Dansie and Eng 1922; Imai et al. 1995; Andiran et al. 1997), but pathology reviews in the setting of trials of pediatric liver tumors have identified several cases that have not been published (own observations). In one patient, CC was diagnosed 12 years after pediatric liver transplantation (Channabasappa et al. 2010).

Pediatric Cholangiocarcinoma Associated with Congenital Hepatobiliary Disorders

Congenital Biliary Dilatation and Choledochal Cysts

Congenital biliary dilatation (CBD) is probably the most frequent cause of cholangiocarcinoma developing in childhood and young adult age (Iwai et al. 1990; Kuriyama et al. 1997; Tanaka et al. 2006; Nakamura et al. 2008; Saikusa et al. 2009; Ono et al. 2010). In adults, CBD is highly associated with hepatobiliary malignancies (Dexter 1957; Young et al. 1992; Tsuchida et al. 2003; Ono et al. 2008), and CBD-associated chronic mucosal lesions appear to be a strong driving force for the development of CC in young individuals. In a review of 11 cases, seven were male and five female, with an age range at diagnosis of 11–19 years (Tanaka et al. 2006). PA-CC was also found in a 3-year-old Japanese boy with Todani type 1a congenital biliary dilatation. The histology revealed well-differentiated tubular adenocarcinoma with lymphovascular invasion (Saikusa et al. 2009). A second very young patient was an 11-year-old Japanese boy with Todani type IV-A congenital biliary dilatation. The tumor was situated in the dilated choledochal duct, and dilatation was associated with pancreaticobiliary maljunction. Nodal metastasis was found in one of the mesenteric lymph nodes, and vascular invasion was detected in the region of the primary tumor (Tanaka et al. 2006). A 14-year-old girl died of recurrent PA-CC of the common bile duct 2 years after the initial resection of a choledochal cyst (Ono et al. 2010). The pathogenesis of CBD-associated cholangiocarcinoma is not fully established, but it was shown that bile from choledochal cysts exerts a proliferative activity on human cholangiocarcinoma cells through a COX-2 and PGE(2) pathway (Wu et al. 2003).

Congenital Pancreaticobiliary Maljunction

Congenital pancreaticobiliary maljunction (CPBM) or anomalous pancreaticobiliary ductal union is a disorder causing pancreaticobiliary reflux. CPBM is associated with an increased risk of cholangiocarcinoma in adults and children (Kobayashi et al. 1999; Ono et al. 2011). It has been suggested that reflowing pancreatic juice admixed with bile can exert a pro-proliferative effect on biliary epithelia, e.g., documented in the gallbladder mucosa (Ono et al. 1999; Tanno et al. 1999). Cholangiocarcinoma may develop early in patients with CPBM, mainly in those with associated cystic bile duct dilatation, e.g., at 13 years (Ueda et al. 2000) or 15 years of age (Nakamura et al. 2008).

Congenital Biliary Atresia

An 11-year-old girl was diagnosed with PA-CC in association with secondary biliary cirrhosis due to congenital biliary atresia (Kulkarni and Beatty 1977). Among 157 patients with biliary atresia who had been followed-up after Kasai's operation, 13 developed liver tumors, including one cholangiocarcinoma (Yoon et al. 2014).

Congenital Metabolic Disorders

Intrahepatic PA-CC developed in two girls with progressive familial intrahepatic cholestasis

caused by mutations of the bile salt export pump ABCB11. It was proposed that bile composition shifts or bile acid damage of cells might be significant factors for biliary carcinogenesis in this disorder (Scheimann et al. 2007).

Pediatric Cholangiocarcinoma Associated with Acquired Hepatobiliary Disorders

Primary sclerosing cholangitis (PSC) is a well-known risk factor for the development of cholangiocarcinoma, and carcinogenesis proceeds along a dysplasia-carcinoma sequence in at least part of adult patients (Ahrendt et al. 1999). In a study from Utah, PA-CC was detected in follow-up in 6.9 % of children with primary sclerosing cholangitis (Deneau et al. 2013). Rarely, cholangiocarcinoma already arises in young individuals, e.g., at age 15–18 years (Deneau et al. 2011; Lai et al. 2012; Liu et al. 2014). Cholangiocarcinoma was also found in small duct sclerosing cholangitis (Lai et al. 2012). PA-CC in adolescents was also observed following pediatric-onset inflammatory bowel disease (Peneau et al. 2013).

Pathology

PA-CC histologically shows patterns that are known for adult-type cholangiocarcinomas (Figs. 1, 2, and 3), an observation that has however been reported only few times. Dansie and Eng (1922) described a 10-week-old male infant with a primary liver malignancy. At autopsy, the liver was mottled with purplish areas, and these areas varied from a mere spot to about 0.25 in. in diameter. Histologically, the tumor is rich in stroma, with an epithelial tumor cell population forming retiform strands which had infiltrated the parenchyma. Some of the strands showed an open center, and the cells resembled bile duct cells. An own observation revealed a classical desmoplastic cholangiocarcinoma with the typical hypocellular, desmoplastic/sclerosing stroma, and atypical glands composed of neoplastic, CK-9-positive cholangiocytes.

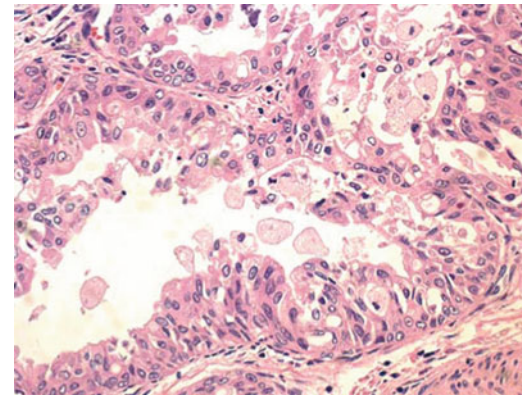

Fig. 1 Pediatric cholangiocarcinoma. Enlarged tubular structures are lined with atypical columnar cells with signs of tumor cell shedding (hematoxylin and eosin stain)

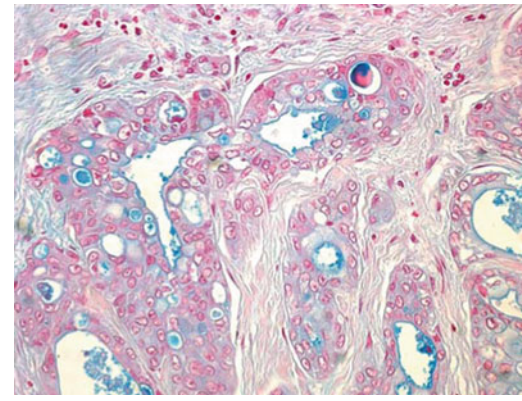

Fig. 2 Pediatric cholangiocarcinoma. This tumor exhibits marked mucin production, mostly with intracellular mucin accumulation (alkaline Alcian blue stain)

Alpha-Fetoprotein (AFP)-Producing Pediatric Cholangiocarcinoma

AFP-producing cholangiocarcinoma is a very rare variant of cholangiocarcinoma in adult patients, characterized by aberrant synthesis and secretion of AFP by biliary carcinoma cells. The tumors are usually of the desmoplastic variant. We observed

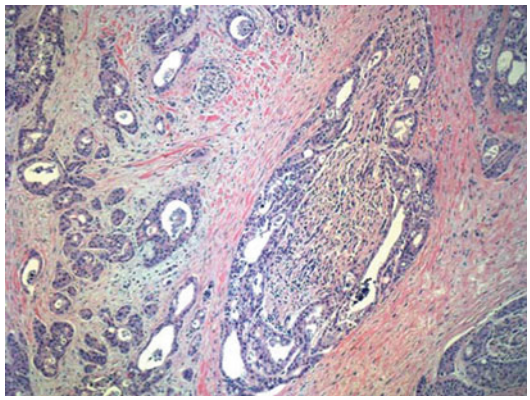

Fig. 3 Pediatric cholangiocarcinoma with perineural invasion (hematoxylin and eosin stain)

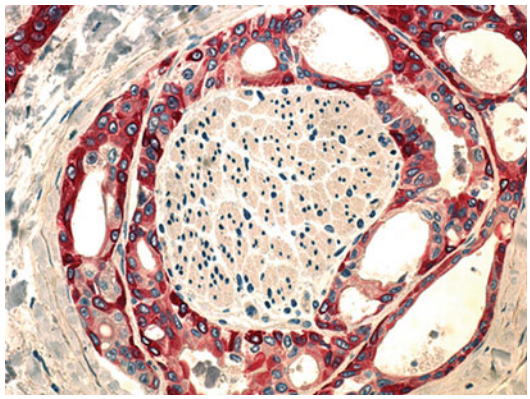

Fig. 4 Pediatric cholangiocarcinoma, alpha-fetoprotein (AFP)-expressing variant. AFP-reactive cancer cells have invaded a perineural space (AFP immunostain)

one small child with such an unusual tumor (Fig. 4).

Pediatric Biliary Papillomatosis

Biliary papillomatosis is a rare condition of the biliary tract in adults, known to transform into cholangiocarcinoma in part of the patients (see the respective chapter). Exceptionally, multiple biliary papillomatosis occurs in children (Bines et al. 1992). Papilloma of the ampulla of Vater was observed in an infant (Shabot et al. 1975).

Intraductal Neoplasms of the Biliary Tract

33

Contents

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_33

Abstract

Intraductal papillary neoplasm of the bile duct (IPN-B) is a rare epithelial bile duct tumor characterized by a predominantly papillary growth pattern, a phase of intraluminal noninvasive growth, and a later high risk of transition into invasive cholangiocarcinoma. A recently proposed more general term is intraductal neoplasm of the bile duct (IN-B), because not all of these neoplasms are papillary lesions. IPN-B is now regarded as the biliary counterpart of intraductal mucinous papillary neoplasm of the pancreas. Histologically, the majority of IPN-Bs exhibit a papillary or tubulopapillary morphology, but a rarer variant is characterized by a tubular morphology. A mucinous phenotype, which is regularly found in pancreatic intraductal neoplasms, is not a constant finding in IPN-B. IPN-B lesions undergo dysplastic changes, divided into four groups, i.e., low-grade dysplasia, high-grade dysplasia, carcinoma in situ, and IPN-B associated with invasive carcinoma. In analogy to pancreatic lesions, IPN-B is subclassified into branch duct type, main duct type, and mixed type. Distinct epithelial changes developing in peribiliary glands are considered as precursor lesions of IPN-B.

ICD-O codes

IPN with low- or intermediate-grade intraepithelial neoplasia	8503/0
IPN with high-grade intraepithelial neoplasia	8503/2
IPN with associated invasive carcinoma	8503/3

Introduction

Intraductal neoplasm of the bile duct (IPN-B) is a group of neoplasms presenting with a complex spectrum ranging from preneoplastic lesions to noninvasive and invasive carcinomas, whereby the invasive phenotype of the papillary form of intraductal neoplasm in many or most cases appears to correspond to the previous intraductal growth intrahepatic cholangiocarcinoma (IG-ICC) (see the chapter of intrahepatic cholangiocarcinoma).

Intraductal neoplasm of the bile duct (IPN-B) is a rare epithelial bile duct tumor characterized by a predominantly papillary growth pattern, intraluminally growing in a first phase of evolution, but a high risk of transition into invasive carcinoma. IPN-B in part mimics intraductal mucinous papillary neoplasm (IPMN) of the pancreas and has previously been described under several terms (mucin-hypersecreting bile duct tumor or mucin-secreting bile duct adenoma, intraductal papillary neoplasm (IPN), intraductal papillary mucinous neoplasm of the bile duct (IPMN-B)). A distinct clinicopathologic pattern of intrahepatic mucin-producing cholangiocarcinomas, characterized by a cystic or ductectatic presentation, has been described by Okamoto and coworkers (Sakamoto et al. 1999). Intraductal neoplasms of the bile ducts are now accepted to be the biliary counterpart of the long-known pancreatic intraductal neoplasms (Klöppel and Kosmahl 2006). Both types of neoplasms share a predominantly exophytic macroscopic growth pattern with a tendency to fill the involved ducts, histologically a papillary or tubulopapillary growth pattern, and the development of dysplastic changes that can result in invasive carcinoma (Aishima et al. 2014). However, one rare variant is characterized by a tubular morphology rather than a papillary growth pattern (review: Nakanuma et al. 2010a).

Selected References Kim et al. 2000; Chen et al. 2001; Chung et al. 2001; Nakanuma et al. 2002, 2010a; Oshikiri et al. 2002; Shibahara et al. 2004; Yeh et al. 2004; Aoki et al. 2005; Zen et al. 2006a, 2011; Yamashita et al. 2007; Ji et al. 2008; Crippa and Falconi 2012; Lapsia 2012; Rocha et al. 2012; Xu et al. 2012; Yang et al. 2012; Klöppel et al. 2013; Minagawa et al. 2013; Wan et al. 2013; and Ohtsuka et al. 2014.

Definitions and Classifications

According to the recent WHO classification, these tumors are termed intraductal papillary neoplasms of the bile duct (IPN-B). The concept of IPN-B was first proposed by Chen et al. (2001) and Nakanuma et al. (2002). IPN-B includes the

previous categories of biliary papilloma and papillomatosis and other forms of intraductal neoplasms with a papillary or tubular phenotype and is characterized by dilated intrahepatic bile ducts containing a noninvasive papillary, villous, tubulopapillary, or tubular biliary neoplasm.

A recently proposed, more general term is intraductal neoplasm of the bile duct (IN-B). IN-B is usually found in the intrahepatic bile ducts, but similar lesions also occur in the hilar/perihilar and extrahepatic bile ducts. IN-B is further subdivided into the most common papillary form (intraductal papillary neoplasm of the bile duct, sensu stricto IPN-B), intraductal tubular neoplasm of the bile duct (ITN-B), and a rare form characterized by extensive spread along the luminal surface of intrahepatic bile ducts (superficial spreading type of IN-B; Nakanuma et al. 2010a). For reasons of comparison of literature data, the term IPN-B will be employed in this chapter throughout.

As the mucinous phenotype regularly found in pancreatic intraductal neoplasms (IPMN) is not a constant feature in the biliary tract counterpart, papillary biliary lesions are more often termed IPN with an added "B" for biliary tract or "L" for liver (IPN-B and IPN-L, respectively), whereby IPN-B is more commonly used now. As specified above, a term covering all variants of intraductal lesions has also been proposed, i.e., intraductal neoplasm of the bile duct (IN-B). IPN-B usually shows intraductal intraepithelial spread involving large to small bile ducts. The cell types of hepatobiliary tract IPN present with four main cell lineages, namely, a pancreatobiliary type, an intestinal type, an oncocytic type, and a gastric type (Shibahara et al. 2004; Nakanuma 2010). Furthermore, both types of intraductal neoplasms give rise to morphologically similar invasive carcinomas, i.e., ductal adenocarcinoma in the pancreas and intrahepatic cholangiocarcinoma of the intraductal growth type (ID-ICC) in the liver. The dysplastic changes developing in IPN have been divided into four groups, i.e., IPN with low-grade dysplasia (group 1), IPN with high-grade dysplasia (group 2), IPN lined with carcinoma in situ and no or only microinvasion (group 3), and IPN associated with distinct invasive carcinoma (group 4).

Table 1 Classification of intraductal neoplasms of intrahepatic bile ducts

Intraductal papillary neoplasm of the bile duct (IPN-B)
IPN-B with low- or intermediate-grade intraepithelial neoplasia
IPN-B with high-grade intraepithelial neoplasia
IPN-B associated with mucosa-confined carcinoma
IPN-B associated with invasive carcinoma (intraductal growth intrahepatic cholangiocarcinoma, ID-ICC)
Intraductal tubular neoplasm of the bile duct (ITN-B)
Intraductal neoplasm of the bile duct, superficial spreading type
Variant forms

In analogy to pancreatic lesions, IPN-Bs have been subclassified into branch duct type, main duct type, and mixed type (Lim et al. 2011a; Nakanishi et al. 2011; Fujita et al. 2013; Kato et al. 2013). In all reported cases, cystic or papillary lesions were present in peribiliary glands. Lim and coworkers (2011b) reported that certain types of cystic IPN-Bs that originate from peribiliary glands are considered to be a counterpart of the branch duct type of pancreatic IPMN. More recently, cystic and micropapillary epithelial changes of peribiliary glands have been studied in detail and proposed to represent a precursor lesion of IPN-B, including the branch duct type (Sato et al. 2014). The subclassification into duct types may have an impact on the biology of disease, as IPN of the branch duct type had no malignant component, had limited wall invasion, and were not associated with lymph node metastasis, while all patients with main duct and mixed duct types IPN-B had a malignant component (Kato et al. 2013).

A proposal of a classification is shown in Table 1.

Intraductal Papillary Neoplasm of the Bile Ducts: Relationship to Cholangiocarcinoma with Intraductal Growth

IPN-B as an emerging tumor category may be confounded by what is or was termed intraductal growth type of intrahepatic cholangiocarcinoma

(IG-ICC) or biliary tract carcinoma of papillary growth (BTC-PG). In fact, IPN-B with a marked invasive component may show a marked overlap with intraductal growth cholangiocarcinoma. It has been proposed that among the intraductal growth type of intrahepatic cholangiocarcinoma and papillary carcinoma of extrahepatic bile ducts, cases with a clearly intraductal component consisting of papillary fronds with fine vascular cores are exclusively included in IPN-B (Ohtsuka et al. 2014). There is evidence that the two lesion groups are related, in that IPN-B is a precursor lesion of invasive intraductal carcinomas. A recent clinicopathologic study has shown that in fact a majority of IG-ICC and BTC-PG could be regarded as an IPN-B lineage (Nakanuma et al. 2014a,b).

Epidemiology

Probably due to improved diagnostic techniques and increased awareness, the frequency of diagnosis for pancreatic IPN has increased during the last years (Klibansky et al. 2012; Zen et al. 2014). Whether this will turn out to also be the case for biliary tract IPN (IPN-B) remains to be demonstrated. Overall, IPN-B is mainly observed in Far Eastern areas, including Japan, Korea, and Taiwan, and regions with an elevated incidence of hepatolithiasis and liver fluke infestations, specifically clonorchiasis (Nakanuma et al. 1988; Wan et al. 2013). IPN-B is mainly diagnosed in individuals of 50–70 years of age, with a male-to-female ratio that varies somewhat from one area to another. While in Japan the two sexes are equally affected, patients from Korea and Western countries are twice as often males than females, whereas the inverse exists in Taiwan. IPN-B is more common than mucinous cystic neoplasms of the liver (MCN-L) of the hepatobiliary tract. In a retrospective Asian comparative pathology study, the ratio between IPN-B and MCN-L was 5.7:1 (Zen et al. 2014). The tumor has also been observed in the setting of *Clonorchis sinensis* infestation (Jang et al. 2008) and of primary sclerosing cholangitis (Hachiya et al. 2014). Other and rare associations, such as gallbladder agenesis (Kim et al. 2012b), are likely to be coincidental.

IN-B with or without associated invasive carcinoma can occur in conjunction with other neoplastic disease, mainly including synchronous intraductal papillary tumors of the pancreas (Joo et al. 2000; Ishida et al. 2002; Zalinski et al. 2007; Valente et al. 2012), metachronous intracystic papillary tumor of the gallbladder (Sato et al. 2013), mucinous cystic neoplasm of the liver (Budzynska et al. 2014), and rarely other neoplasms, such as hepatocellular carcinoma (Xu et al. 2011) and adenoneuroendocrine carcinoma (Onishi et al. 2013).

General Clinical and Imaging Features

As IPN causes significant bile duct disease due to luminal obstruction, many patients are symptomatic at presentation, but asymptomatic disease is also reported, and incidental detection in up to 20 % of patients is known (Hayashi et al. 2008; Paik et al. 2008). In few patients, IPN only manifests as dilatation of lobar or segmental bile ducts (Lim et al. 2008). Intraluminal tumor growth, excessive mucin discharge into the ducts, and tumor tissue sludge can cause biliary obstruction and cholestatic jaundice (Verma et al. 2009). The abundance of mucin secretion and hence the frequency of mucin-related sequelae depend on the histologic type of IPN, mucin hypersecretion being more common in patients with intestinal or gastric-type lesions than pancreatobiliary or oncocytic-type lesions (Kim et al. 2012a).

Radiologically, there may few to multiple tumors along the bile ducts which are dilated due to obstruction by tumor tissue, secreted mucin, and/or sludged tumor debris. Debris and mucin plugs may be confounded with bile duct stones (Lim et al. 2002, 2008; Carrafiello et al. 2008; Nanashima et al. 2008a; Lim and Jang 2010; Wan et al. 2013; Yoon et al. 2013; Bal et al. 2014). In one study, bile duct dilatation was found in 92 % of patients (Paik et al. 2008). Cystic lesions contain enhancing or non-enhancing solid parts (Martin et al. 2002),

and on CT images, the mass can present as hypodense lesions in comparison with the surrounding tissue during the basal phase and with a light peripheral enhanced rim in the arterial phase, increasing in the portal venous phase, while in late phase, the lesions displayed a punctate aspect due to the presence of intratumoral hypervascular spots (Carrafiello et al. 2008; Ogawa et al. 2012). On CT images, cystic variants of IPN-B can be distinguished from mucinous cystic tumors mainly by the presence of mural nodules and dilatation of the bile ducts distal to the cystic tumor (Lim et al. 2007). ERCP is useful in diagnosis and localization of IPN-B (Pavone et al. 1997; Somogyi et al. 2003). Carcinoma arising from IPN-B can produce a circumscribed mass appeared as an impacted stone on ERCP (Ustundag et al. 2006). Cholangiographically, several patterns of IPN-B mainly seen in East Asian patients have been described, based on the presence of hepatolithiasis and associated strictures, mucobilia, and localization of neoplasias (Yeh et al. 2006). Biliary IPN is detectable on fluorodeoxyglucose positron emission tomography (Inoue et al. 2009; Dong et al. 2012) and by direct cholangioscopy (Somogyi et al. 2003; Tsuyuguchi et al. 2010; Lim et al. 2011; Zou et al. 2011; D'souza et al. 2013).

Pathology of Intraductal Papillary Neoplasm of the Bile Ducts (IPN-Bs)

Introduction

IPN-B is the most common form of IN-B and is the first intraductal papillary lesion mimicking the pancreatic counterpart that has been described. Clinicopathologically, IPN-B is classified into several subtypes (Table 2).

The papillomatosis or papilloma type covers a majority of those lesions that have previously been classified as biliary papillomatosis and solitary bile duct papilloma. It appears, however, not yet settled whether all cases of "biliary papillomatosis" described in the older literature completely fit into the novel concept of IPN-B, as there are certain morphologic differences in part of the cases. This issue is therefore addressed in a later paragraph. The intraductal growing type of IPN-B is the "standard variant" and is described in more detail below. The mucin-producing type (M-IPN-B) is less common and often closely mimics its mucinous counterpart of the pancreas. Similar to the pancreas, the mucinous type of IPN-B can produce copious amounts of mucin that is secreted into the bile duct lumen and causes mucobilia and bile duct obstruction, bile duct dilatation, and eventually discharge of mucin through the orificium of the common bile duct. The cystic type is a distinct phenotype of biliary cystic tumor with a bile duct communication, in contrast to hepatobiliary mucinous cystic neoplasms that do not communicate with the biliary system.

Macroscopy

Macroscopically, IPN-B is characterized by intraductal growths of soft, friable tissue with granular surface caused by the tips of multiple papillary structures (Figs. 1, 2, and 3). The presentation of the lesions was described as polypoid, cast-like intraductal growth, and cyst forming (Nanashima et al. 2008a; Kim et al. 2011). The lesions occur as solitary or multiple tumors of grayish, tan, or yellowish color. Markedly papillary growths are whitish, red, or tan, depending on the presence and amounts of hemorrhage and/or necrosis. These masses may fill the ducts and cause dilated ducts that are fusiform or cystic, in an unilocular or multilocular pattern. IPN-Bs develop in one or multiple intrahepatic ducts, in the hilar duct area, and/or in the extrahepatic bile

Fig. 1 IPN-B. The dilated bile duct is filled with an exophytically growing tumor. Dilated bile duct segment contain mucus

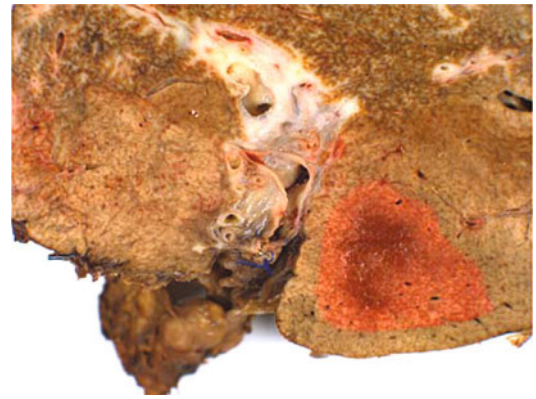

Fig. 3 Small intraductal papillary tumor of an intrahepatic bile duct (*upper third* of figure)

ducts. Tumors can occur in both intra- and extrahepatic ducts in a synchronous or metachronous manner. The slit-like spaces in the papillary growth mostly contain a bile-stained or clear watery fluid, but in about a third of the cases, mucin secretion by the tumors results in a viscid intraductal fluid or even in mucobilia (the mucin-producing type; M-IPN-B). M-IPN-B has to be distinguished from mucinous cystic neoplasms of the liver (Kubota et al. 2014). Part of IPN-Bs are characterized by marked cystic dilatation of the involved ducts, causing macrocystic lesions (cyst-forming IPN-B or cystic type; Lim et al. 2011b, Mano et al. 2011; Shimoda et al. 2013). The cysts are multilocular or unilocular and appear as aneurysm-like dilatations of the bile ducts which, when crowded, leave the impression of a multicystic hepatic tumor. Part of the patients showed diverticulum-like cystic tumors with or without communication, and cystic tumors laterally attached to bile ducts occur (Lim et al. 2011b). Very rarely, the cystic IPN-B manifests as an unilocular cyst with minor papillary components, mimicking a simple hepatic cyst or a hepatic hemorrhagic cyst (Kakisaka et al. 2013). Cyst-forming IPN-B typically occurs at the level of intrahepatic bile ducts but may also develop in the hilar region (Makino et al. 2010). Such lesions may be confounded with mucinous cystic neoplasms of the liver, but in contrast to the latter, cystic forms of IPN show bile duct communication (Zen et al. 2006b; Li et al. 2009).

Histopathology

Histologically, IPN-B is characterized by papillary growths that form in part large tumors with long papillae that are anchored to the mucosa by a vascular interface and which grow into the lumen. Most of the lesions consist of simple papillae that arborize but do have cellular bridges. However, a subset of neoplasms possess complex fused papillary structures that form cribriform lesions. This pattern is associated with a worse biology and was proposed to be called mucosa-confined cholangiocarcinoma (Jung et al. 2012). In IPN-B, two main histopathologic categories have been distinguished, i.e., a columnar type composed of pseudostratified columnar intestinal-type cells and elongated nuclei and a cuboidal type composed of pancreatobiliary and/or oncocytic elements (Shibahara et al. 2004). Further studies confirmed that the papillary structures and tubulopapillary profiles consist of one of four epithelial lineages or combinations thereof, i.e., a pancreatobiliary type, an intestinal type, an oncocytic type, and a gastric type (Table 3; Figs. 4, 5, 6, 7, 8, 9, and 10).

Intestinal and Pancreatobiliary Types

Intestinal and pancreatobiliary types were the most prevalent in all locations of IPN-B, while gastric-type cells prevailed in lesions located to the intrahepatic ducts (Choi et al. 2010; Kubota et al. 2014). In a study of 119 cases of IPN-B, 51 were of the pancreatobiliary type, 33 of the intestinal type, 23 of the oncocytic type, and only 12 of the gastric type (Kubota et al. 2014). Intestinal-type cells are usually columnar elements that cover papillary fibrovascular cores, with basally placed nuclei in low-grade dysplastic lesions and nuclear pseudostratification in high-grade dysplastic lesions. The cells may contain variable amounts of mucin, mainly in the apical part of the cells. IPN-Bs with significant mucin production are very similar to pancreatic IPN (Ohtsuka et al. 2011). Pancreatobiliary-type neoplastic cells are mostly cuboidal to columnar elements with a slightly basophilic, amphophilic, or, rarely, clear cytoplasm. Part of the cells may contain mucin vacuoles (PAS and Alcian Blue positive) or basal mucin deposits or retronuclear/subnuclear mucin vacuoles, but clearly less pronounced than in the gastric type. In some tumor

cells, a large paranuclear eosinophilic structure representing a hypertrophic Golgi area is seen. Nuclei are basally placed in low-grade dysplasia, while in higher grades of dysplasia, they are irregularly arranged within the epithelial lining, also being positioned in the apical part of the epithelium. In the course of increasing dysplasia, nuclear morphology shifts from ovoid ort elongated nuclei with a coarse chromatin to more and more enlarged vesicular nuclei with prominent nucleoli. There seems to be a relationship between the presence of these two most important histologies and underlying bile duct disease. In Korean patients, a pancreatobiliary cellular phenotype was predominant in patients with *Clonorchis sinensis* infestation, while an intestinal phenotype was more often detected in patients without liver fluke disease (Jang et al. 2008).

Gastric Type

Pancreatic IPMN of gastric-type differentiation has been described, with a cell lineage characterized by mucin-rich columnar cells resembling those of gastric foveolae (Ban et al. 2006; Kim et al. 2012a). A similar cell type is observed in a minority of IPN-B, where a cell population

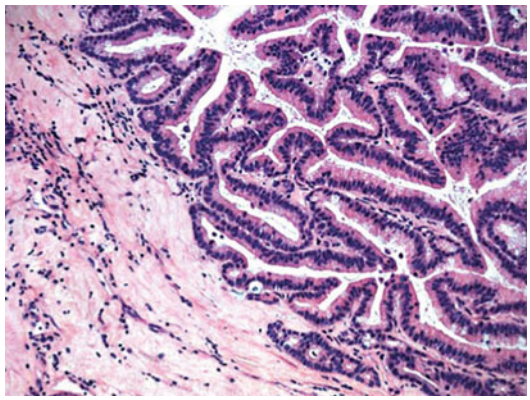

Fig. 10 Well-differentiated IPN-B. The finely branching papillae are lined with a columnar epithelium with basally placed nuclei (hematoxylin and eosin stain)

dysplastic columnar cells resembling pyloric glands was found (Tajiri et al. 2012). Apart from intracellular mucin accumulation, part of IPN-B secrete mucin, sometimes in large quantities. Mucin is more often and more strongly secreted by tumors with an intestinal or gastric phenotype than with a pancreatobiliary or oncocytic phenotype (Kim et al. 2012a). On the other hand, IPN-B with macroscopically visible mucin secretion showed striking similarities to INP of the pancreas (Ohtsuka et al. 2011).

Oncocytic Type (Intraductal Oncocytic Papillary Neoplasm (IOPN))

IPN-Bs with oncocytic cells form a rare subgroup, particularly those entirely composed of oncocytes (intraductal oncocytic papillary neoplasms (IOPN); Martin et al. 2002; Spector et al. 2004; Terada and Taniguchi 2004; Rouzbahman et al. 2007; Tabibian et al. 2008; Lee et al. 2009; Nakanishi et al. 2009; Tanaka et al. 2009; Cocieru et al. 2010; Liszka et al. 2010; Kato et al. 2012; Jurczyk et al. 2013; Watanabe et al. 2013). Apart from intrahepatic ducts, IOPN rarely also occurs in the extrahepatic ducts/common bile duct, in a part with a high-grade morphology (Rouzbahman et al. 2007; Terada 2012). The oncocytic variant of IPN-B often forms large hepatic cysts with papillary projections, cyst diameters reaching more than 20 cm in some patients (Martin et al. 2002; Tanaka et al. 2009; Watanabe et al. 2013). IOPN often forms lesions with finely arborizing papillary formations and/or cribriform structures composed of medium-sized to large granular and strongly eosinophilic cells containing numerous mitochondria. The cells stain with an antimitochondrial antibody (Tanaka et al. 2009) and show a mucin core profile similar to the counterparts in the pancreas, i.e., positivity for MUC3, MUC4, MUC5AC, MUC5B, and MUC6 (Rouzbahman et al. 2007). IOPN may be admixed with various types of non-oncocytic cells (Tanaka et al. 2009). The situation as regards origin of cell lineages is complex, as oncocytic populations can occur together with pancreatobiliary or gastric foveolar-type cell populations within the same lesion (Liszka et al. 2010), suggesting the involvement of a common cellular ancestor. IOPN frequently shows microscopically minimal invasion (Tanaka et al. 2009), but it can also transform into a frankly invasive carcinomatous neoplasm which has been termed intraductal oncocytic papillary carcinoma (Cocieru et al. 2010). Oncocytic biliary cystadenocarcinoma was considered to be a form of oncocytic IPN-B (Sudo et al. 2001). In one study, oncocytes of IPN-B produced gastric-type mucins (MUC5AC and MUC6) and showed immunoreactivity for claudin-18 and Hep Par 1 (Tanaka et al. 2009).

Immunohistochemistry

The epithelial cells of IPN are reactive for CK7 (Fig. 11; Matsubara et al. 2012) and, in case of the intestinal-type cell lineage, CK 20 (Kloek et al. 2011). The expression of mucin genes seems to play a significant role in IPN and carcinomas derived thereof, as in other types of intrahepatic cholangiocarcinomas and their precursor lesions (Sasaki et al. 1995, 1998). IPN of the intestinal type expressed MUC2 and CK20 ("intestinal metaplasia"; Sasaki et al. 1996; Shimonishi et al. 2002; Yaman et al. 2009; Nakanuma et al. 2010b), and progression to invasive carcinoma was accompanied by an increasing MUC1 expression (Zen et al. 2006c). Expression

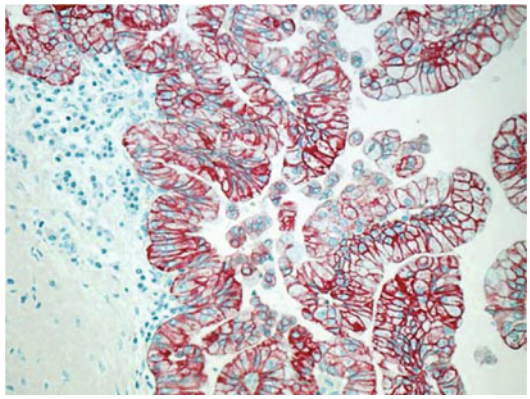

Fig. 11 Expression pattern of cytokeratin 7 in IPN-B (CK 7 immunostain)

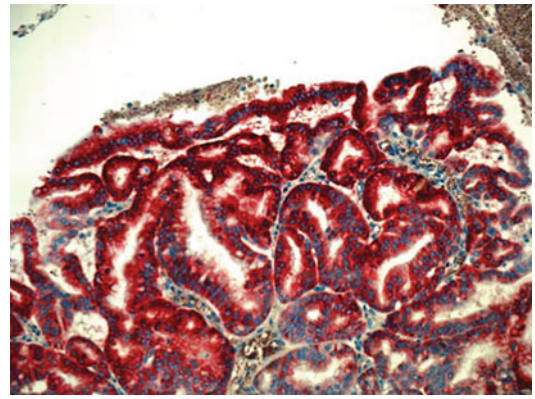

Fig. 12 IPN-B with expression of MUC5AC (MUC5AC immunostain)

of the gastrointestinal markers, CK20 und MUC2, is more frequently expressed in IPN than that in non-papillary biliary tract neoplasms, while the cholangiocyte marker, CK7, is decreased in IPN (Shimonishi et al. 2002). Specifically, IPN cells express MUC5AC widely and MUC2 focally, and this expression pattern is associated with aberrant expression of the homeodomain protein CDX2 (Ishikawa et al. 2004a; Yeh et al. 2005; Nakanuma et al. 2010b). CDX2 protein is, in the target cells of IPN, immunohistochemically either expressed in the nuclei or in the cytoplasm, in a mutually exclusive pattern (Ishikawa et al. 2004a). It has been suggested that aberrant expression of MUC5AC starts in cholangiocytes at an early stage of the carcinogenic pathway occurring in hepatolithiasis, which is found in low-grade INP, followed by expression of MUC2 along with the progression of IPN-L to mucinous ICC (Sasaki et al. 1995, 1996; Shimonishi et al. 2002), this assumption being supported by the observation of MUC2-positive neoplastic cells being situated within areas with MUC5AC expression, coexpression of both MUC2 and MUC5AC probably representing a feature typical for established mucinous ICC (Ishikawa et al. 2004a). The MUC2 phenotype of IPN is reflected by its pancreatic counterpart: whereas MUC2 is rarely expressed in pancreatic ductal carcinoma, it is highly expressed in IPM with mucinous carcinoma, and there seems to be a progression of MUC2 expression from IPM with simple hyperplasia and pyloric gland adenomas to those with associated dysplasia (Terris et al. 2002; Nakamura et al. 2002; Adsay et al. 2003).

In regard to MUC and cytokeratin (CK) expression, the patterns of the four histologic subtypes (pancreatobiliary, intestinal, gastric, and oncocytic) may be summarized as follows: MUC5AC is expressed by all four types (Fig. 12). Pancreatobiliary lineage is MUC1(+)/MUC2(−), intestinal is MUC1(−)/MUC2(+), gastric is MUC1(−)/MUC2(−), and oncocytic is MUC1(focal+)/MUC2(focal+). All four lesions are CK7(+) and CK20(+).

Nuclear expression of p53 protein is present in about a third of IPN but increases as a function of progression along the dysplasia-carcinoma pathway (Shimonishi et al. 2002) and is considered to play a significant role in carcinogenesis of IPN (Nakanishi et al. 2008). In low-grade IPN, p53 expression is less frequent and of low-level, while it reached a higher plateau in high-grade lesions, similar to invasive carcinoma (Nakanishi et al. 2008). IPN cells (in particular the pancreatobiliary-type cells) show membrane immunostaining for beta-catenin, which decreases in the course of progressive increase in the grade of dysplasia (Itatsu et al. 2007). Expression of SOX9, a transcription factor important for developmental pathways, in cells of IPN is low in comparison with normal cholangiocytes (Kuroki et al. 2013). Similar to IPN of the pancreas, the majority of IPN expresses claudin-18, while expression of this protein is less frequent in intrahepatic cholangiocarcinoma (Shinozaki et al. 2011).

Grading of IPN-B

Noninvasive IPN-B can show cellular and nuclear atypia, which are classified as low-grade, intermediate-grade, and high-grade dysplasia (Zen et al. 2006a, b; Nakanishi et al. 2008; Kubota et al. 2014; Figs. 13, 14, 15, 16, and 17). IPN-B can show a relative high proportion of lesions with advanced atypia and high grade. Among 119 Japanese cases of IPN-B, 53 cases were low or intermediate grade and 23 were high grade, while 43 lesions showed invasive growth (Kubota et al. 2014). There is evidence that IPN-B has a higher proportion of tumors with high grade than IPN of the pancreas (Zen et al. 2014).

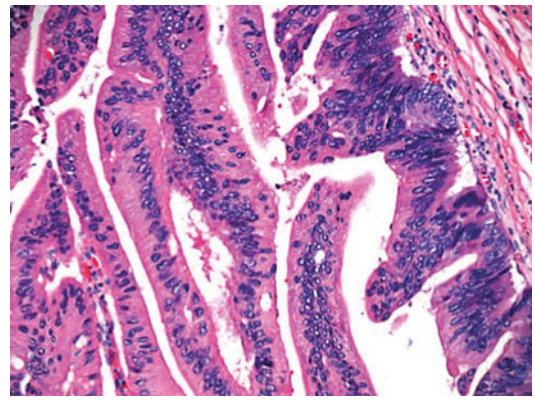

Fig. 14 IPN-B with moderate dysplasia (hematoxylin and eosin stain)

Transition of IPN-B into Invasive Carcinoma of the Bile Duct

In part of the cases, microinvasion or frank invasion of the bile duct wall is found (IPN-B with associated invasive carcinoma; Fig. 18). The transition of microinvasion into deeper invasion is associated with formation (induction) of a tumor stroma (desmoplasia), similar to that found in other intrahepatic cholangiocarcinoma. Adenocarcinoma arising from IPN-B is in most cases cholangiocarcinoma of the intraductal growth type (IG-ICC). Carcinoma arising in IPN-B consisting of pancreatobiliary-type cells is usually a "classical" cholangiocarcinoma, while

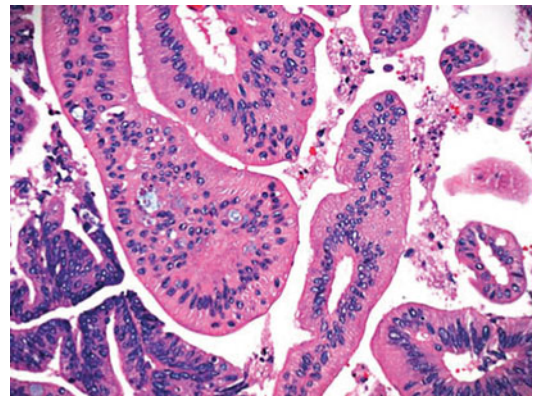

Fig. 15 IPN-B with focal oxyphilic cell change and low-grade to moderate dysplasia (hematoxylin and eosin stain)

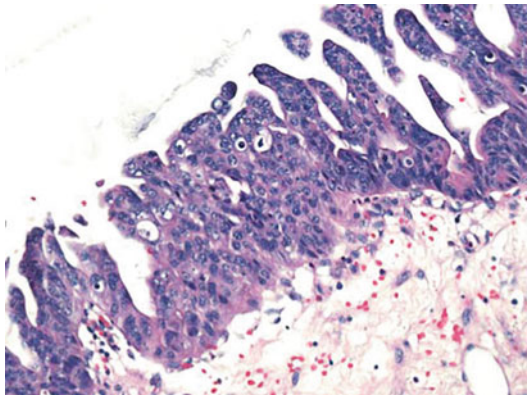

Fig. 17 IPN-B with high-grade dysplasia and carcinoma in situ (hematoxylin and eosin stain)

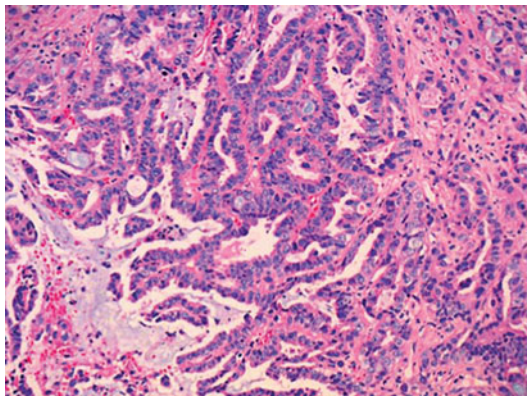

Fig. 18 High-grade IPN-B with transition into invasive adenocarcinoma (hematoxylin and eosin stain)

carcinomas arising in intestinal-type IPN-B often show a colloid adenocarcinoma phenotype (Kang et al. 2012), and carcinomas derived from gastric-type IPN-B are mucin-rich adenocarcinomas (Choi et al. 2010).

Intraductal Tubular Neoplasm of the Bile Ducts (ITN-B)

Most intraductal tumors of the biliary tract reveal a papillary growth pattern. Exceptionally, different growth patterns may develop, including intraductal tubular neoplasms that have been observed in the common bile duct but also develop in intrahepatic ducts. These tubular neoplasms may form several subgroups, as both the histomorphology and immunohistochemical phenotype differed among the cases reported so far. There are lesions that show an almost exclusively tubular phenotype (Sato et al. 2010), while others present a tubulopapillary morphology with high-grade dysplasia (intraductal tubulopapillary neoplasm, ITPN-B; Park et al. 2010). Intraductal tubulopapillary neoplasm of the bile duct was suggested to take its origin from peribiliary cysts (Zen et al. 2012). Mucin secretion is usually absent, but there are variants with marked mucin production. ITN-B displays the characteristic spectrum of precursor lesions, although within the same tumor.

Sato and coworkers (2010) reported a rare case of intraductal tubular neoplasm (ITN) arising in the distal common bile duct of an elderly woman. Macroscopically, the tumor presented as polypoid mass of up to 10 mm in diameter. Histologically, the neoplasm was composed of an admixture of tubular glands resembling pyloric gland adenoma with minimal atypia or low-grade tubular adenoma and glands resembling intestinal-type tubular adenoma or high-grade tubular adenoma. Papillary structures were absent. There were small foci of carcinoma in situ of intestinal type. The low-grade tubular component expressed MUC5AC and MUC6 and was negative for MUC2 and CD20, while the high-grade intestinal-type tubular adenoma and the carcinoma in situ lesions expressed MUC2 and CD20. Later, Katabi and coworkers (2012) reported ten cases of biliary intraductal neoplasms with a predominantly tubular architecture. Three male and seven female patients (38–78 years) had obstructive jaundice or abdominal pain. The neoplasms ranged in size from 0.6 to 8.0 cm. Eight lesions were intrahepatic, one lesion extrahepatic, and one in the common bile duct. Histologically, the neoplasms showed intraductal back-to-back tubular glands and solid sheets with minimal papillary components. The tumor cells were cuboidal to columnar with mild to moderate cytological atypia. Six cases showed intraductal necrosis. In seven cases, an extraductal invasive carcinoma was present. In contrast to the case reported by Sato et al. (2010), the tumors were

immunohistochemically negative for MUC2 and MUC5AC, but expressed MUC1 and MUC6. Four patients with invasive carcinoma experienced metastases, in three patients quite late.

Intraductal Neoplasm of the Bile Duct, Superficial Spreading Type

In principle, this is a variant of intrahepatic cholangiocarcinoma (ICC) which presents an extensive spread along the luminal (mucosal) surface of intrahepatic bile ducts, without or with only minor invasion of the duct walls or the adjacent liver substance. The involved bile duct mucosa is flat, without nodular lesions (Nakanuma et al. 2010a). In one patient, CT showed cystic and tubular dilatation of intrahepatic ducts without grossly visible tumor mass. Histologically, a neoplasm spread diffusely and contiguously along the intrahepatic ducts, with minimal duct invasion. The duct surface was lined by a single layer of columnar tumor cells with short intraluminal papillary projections (Lim et al. 2000).

Variants of IPN

Recently, a distinct category of IPN lesions has been identified, characterized by the presence of complex fused or cribriform papillae instead of simple papillae, and associated with worse prognosis. This group of neoplasms has been proposed to be termed mucosa-confined cholangiocarcinoma (Jung et al. 2012).

Biology of Disease

IPN-Bs are a group of neoplastic lesions that, similar to those in the pancreas, have a complex biology and are high-risk lesions for later invasive carcinoma. Intrahepatic tumors can extend distally and may then protrude into the large extrahepatic ducts (Uchiyama et al. 2007). The lesions can also extend superficially from the intrahepatic to the extrahepatic bile ducts, sometimes in the form of carcinoma in situ that continually extends along the mucosa, or replaced the normal mucosal surface epithelium (Nanashima et al. 2006). Rarely, IPN-B can produce fistulation, e.g., into the common bile duct (Barnardo et al. 2007). Even low-grade IPN-B lesions can, albeit rarely, lead to severe complications apart from transition into frank carcinoma. One patient with low-grade IPN developed, 6 years after surgical treatment of the primary tumor, pseudomyxoma peritonei, suggested to be caused by spillage of tumor cells in the course of the intervention (Jhuang and Hsieh 2012). A case of needle tract seeding of IPN-B after percutaneous biopsy has been reported (Takahashi et al. 2014).

Part of IPN-B can undergo transition into an invasive cancer, mainly resulting in intraductal growth cholangiocarcinoma/IG-ICC rather than mass-forming intrahepatic cholangiocarcinoma (Fukatsu et al. 2006; Nanashima et al. 2008b; Bickenbach et al. 2009; Takanami et al. 2011; Matsubara et al. 2012). This transition into cancer varies among diverse investigations, but overall 40–80 % of IPN-Bs contain a component of invasive carcinoma of various types (Yeh et al. 2005; Ohtsuka et al. 2011; Rocha et al. 2012; review: Wan et al. 2013). Apart from conventional adenocarcinoma, also colloid carcinoma and papillary cholangiocarcinoma can develop (Onoe et al. 2014). The frequency of invasive carcinoma in the pancreatobiliary type of IPN-B was significantly higher than those in intestinal and gastric types (Takasu et al. 2010; Kim et al. 2012a). In cases of IPN-B associated with invasive carcinoma, vascular invasion and lymph node metastases may be less common than in other forms of cholangiocarcinoma (Nanashima et al. 2008). There was no difference in regard to depth of invasion and lymph node metastasis between lesions located to intrahepatic ducts, hilar area, or large extrahepatic ducts (Choi et al. 2010). The prognosis of IPN-B in the absence of invasive carcinoma is better in comparison with conventional intrahepatic cholangiocarcinoma (Chen et al. 1998; Nakanuma et al. 2002; Kubota et al. 2014). In a series of 25 patients, the median survival time of resected patients was 59.8 %, and the 1-, 2-, and 4-year survival rates were 90.5 %,

84.0 %, and 84.0 %, respectively, and all patients with low-grade IPN remained alive (Paik et al. 2008). The poorer prognosis of IPN-B in comparison with the pancreatic counterpart is probably related to a higher proportion of IPN-B tumors with high grade and a more advanced stage of an associated invasive cancer (Zen et al. 2014).

The influence on outcome exerted by the diverse types of invasive carcinoma originating from IPN-B is not fully known, but there was a tendency for patients with invasive carcinomas derived from intestinal-type IPN-B to have a better prognosis than those whose invasive carcinomas were derived from IPN with a pancreatobiliary type (Takasu et al. 2010; Bronsert et al. 2013). In a recent study, gastric-type IPN-Bs were associated with a better 10-year survival rate than both pancreatobiliary- and intestinal-type lesions (Kubota et al. 2014). There is evidence that carcinomas that express the pan-epithelial membrane-associated mucin, MUC1, but do not express MUC2, display an aggressive behavior with poor outcome, while noninvasive IPN with MUC2, but not MUC1, expression shows a favorable course (Yonezawa et al. 2010; Sasaki et al. 2013). Interestingly, distinct differentiation and growth pattern of noninvasive IPN exert an influence on the biology of disease. IPN-B with complex fused or cribriform papillae showed a worse prognosis than IPN with simple papillae (Jung et al. 2012; see above). Multiplicity of IPN-B had a negative impact on prognosis (Kang et al. 2013).

IPN-Bs are proliferative lesions, and cell proliferation is also a prerequisite for those lesions that undergo invasion. Expression of molecules involved in cell cycle regulation is often upregulated in IPN-B. Cyclin D1 and c-Myc, target molecules of Wnt/beta-catenin signaling, are frequently upregulated in IPN-B (Itatsu et al. 2007). Whereas enzymes involved in invasion and spread, including matrix metalloproteinase-7 and membrane type 1-matrix metalloproteinase, are not or only very weakly expressed in noninvasive IPN-B, enzyme activity significantly increases in invasive lesions (Itatsu et al. 2007). IPN-Bs with a stepwise progression to invasive carcinoma involve common molecular pathways associated with alterations in K-Ras and TP53 regulation and loss of p16 (Schlitter et al. 2014).

Differential Diagnosis

IPN-B with an important cystic component may be difficult to distinguish from mucinous cystic neoplasms (Li et al. 2009). In contrast to mucinous cystic neoplasms (MCN) of the hepatobiliary tract, cystic variants of IPN do never show a subepithelial ovarian-like stroma, an important differential diagnostic element. In addition, IPN-Bs are in communication with the bile duct system, while MCN are not or only exceptionally so, and the female preponderance typical for MCN does not apply for IPN-B. Mucin-producing intraductal tumors can extend from the main pancreatic duct into the distal bile duct system. A mucin-filled bile duct was found as a complication of pancreatic IPN (Patel et al. 2005), and pancreatic IPN can in rare instances penetrate into the common bile duct (Goto et al. 2012). In rare cases, colorectal carcinoma metastases to the liver showed an intraductal papillary growth pattern mimicking IPN-N (Nanashima et al. 2011).

Biliary Papillomatosis: A Long-Known Condition Now Classified as Preinvasive Papillary Forms of Intraductal Neoplasm of the Bile Ducts

Introduction

Biliary papillomatosis (BP) was previously classified a rare neoplastic entity of the intra- and extrahepatic biliary tract, characterized by the development of multiple papillary cholangiocellular and frequently recurring lesions on a focal, multifocal, or diffuse distribution within bile ducts, associated with significant risk of malignant transformation. Most, if not all, cases of BP are now considered to represent the

preinvasive papillary variant of intraductal neoplasm of the bile ducts (IPN-Bs).

This unique lesion has first been reported in 1894 (Chappet 1894) and was described in more detail in 1959, based on a choledochal lesion (Caroli et al. 1959). Numerous observations were published in the following years (Boerner 1960; Eiss et al. 1960; James and Gardner 1974; Madden and Smith 1974; Padfield 1988; and Yeung et al. 2003). BP was regarded a disease of multicentricity due to generalized biliary tract field changes (Tireli and Uslu 1992; Holtkamp and Reis 1994; Nakanuma et al. 2002; Yeung et al. 2003; Braeye and Vanheste 2010). BP has a tendency to spread superficially along the bile duct mucosa, finally resulting in diffuse papillomatosis (Terada et al. 1991), but invasive growth and transformation into carcinoma are well-established complications of BP. BP occurs in the pediatric age group and is as rare as pediatric cholangiocarcinoma (Bines et al. 1992). Apart from extrahepatic ducts, BP also arises in the intrahepatic large bile ducts, and the neoplastic and nonneoplastic parts of the intrahepatic biliary tree exhibit segmental and saccular dilatation. The extrahepatic biliary tract is involved either in combination with intrahepatic BP or as a lesion restricted to the common bile duct (Sagar et al. 1993; Centorrino et al. 1998; Sotiropoulos et al. 2003). In a study of 33 patients, concomitant intrahepatic and extrahepatic disease was observed in 42 % (Yeung et al. 2003). BP may involve the cystic duct and extend into the gallbladder. BP may be restricted to the distal biliary tract (Sotiropoulos et al. 2003). BP can arise in congenital choledochal cysts (Ohta et al. 1993; Iwasaki et al. 2002; Negi et al. 2009; Sen et al. 2012) but may also form cystic cavities lined by papillary growths in the absence of a congenital cystic bile duct disorder (Aoki et al. 2005). There are rare observations of BP occurring in conjunction with other liver disorders, including recurrent pyogenic cholangitis (Cheng et al. 1999) and autoimmune hepatitis (Kageyama et al. 2003).

Originally, BP was classified as either a mucin-hypersecreting type (mucinous biliary papillomatosis (MBP); review: Padfield et al. 1988) or a non-mucin-producing type (NMBP), because both these disease types have similar macroscopic and microscopic findings but may have a different pathogenesis and outcome. In one study, NMBP was twice as frequent as MBP (Lee et al. 2004).

Pathology

Macroscopy

Resected tumors are described as grayish tan to yellow, friable, papillary, or granular masses that fill dilated bile duct portions. MBP and NMBP showed no gross differences, except for mucin in the ductal lumen in the case of MBP (Lee et al. 2004).

Histopathology

The histopathologic presentation of BP is the same as that described for IPN-B (see above). The lesions shows a villous, papillo-tubular, papillary, or papillo-villous growth pattern (James and Gardner 1974; Lee et al. 2004).

The villous pattern is characterized by sharp arrow head-like formations. Many of the lesions resemble low-grade tubulovillous or villous colorectal adenomas. The growths possess a usually thin fibrovascular stalk which often contains a mild degree of lymphocytic infiltration. In NMBP, the predominant epithelial cell type has either a biliary epithelial (cholangiocyte) phenotype or a pyloric gland-like phenotype. The biliary phenotype is characterized by a tall single to multilayered epithelium with a variable cytoplasmic staining, while the pyloric gland-like phenotype resembles pseudopyloric gland metaplasia of the gallbladder as seen in chronic cholecystitis, i.e., with a clear and abundant cytoplasm and flattened nuclei on the basal layer. Goblet cell metaplasia and colon-like metaplasia are often seen, and goblet cell metaplasia tends to predominate in MBP (Lee et al. 2004). Rarely, Paneth cell metaplasia may occur. The apical cell parts show a prominent zone of PAS-positive mucinous material, and almost all cells exhibit an Alcian Blue-positive

mucin rim in the luminal border and sometimes in the supranuclear cytoplasm.

Etiology, Pathogenic Pathways, and Molecular Features of Intraductal Neoplasms

The etiology of IPN-B has not yet been fully clarified. In Far Eastern countries, hepatolithiasis and clonorchiasis are major risk factors (review: Wan et al. 2013). In one study from Taiwan, nearly 87 % of patients with IPN-B suffered from hepatolithiasis (Yeh et al. 2005). Both hepatolithiasis and liver fluke infestation are associated with, or directly cause, chronic inflammation of the bile duct mucosa, followed by cholangiocyte proliferation and long-standing hyper regeneration. This phenomenon increases the risk of mutational events, selection of pro-growth mutations, generation of dysplastic changes, and finally neoplastic transformation (an inflammation-hyperplasia-dysplasia-neoplasia pathway). It is estimated that the time lag between active hepatolithiasis and the development of IPN-B is the region of 6–8 years, while in situ carcinoma requires 1–2 years to become an invasive lesion (summarized in Wan et al. 2013).

Distinct types of genomic and molecular alterations have been detected in intraductal papillary mucinous neoplasms of the pancreas, which are known for a longer time period than their hepatobiliary tract counterparts. Based on the similarity between these neoplasms and IPN-B with respect to histogenesis and morphology (Ohtsuka et al. 2011), it may be anticipated that biliary tract IPN expresses similar changes, all the more so as pancreatic and IPN-B can occur simultaneously (Ishida et al. 2002). Similar to its pancreatic counterpart, IPN-B lacks expression of the stem cell marker, CD133 (Ohtsubo et al. 2012). High-level microsatellite instability was present in 11.8 % of IPN-B, while low-level instability was present in 35.3 % in IPN-B, with a difference in the pattern of allelic shifts between the noninvasive and invasive components (Abraham et al. 2002).

Certain gene mutations known to play a role in hepatobiliary carcinogenic pathways were observed in IPN-B. In IPN-B associated with invasive carcinoma, the same K-ras mutations were present in both the intraductal and invasive components. Activating mutations in codon 12 of the K-ras gene were detectable in 29–32 % of IPN-B, whereas mutations in the beta-catenin gene were not found (Abraham et al. 2003; Tsai et al. 2013; Schlitter et al. 2014). However, there are also differences in the molecular signature between pancreatic and biliary IPN. For example, GNAS codon 201 mutations that are found in approximately two thirds of IPMNs of the pancreas are less common in IPN-B, but amount to up to 46.2 % of cases (Matthaei et al. 2012; Sasaki et al. 2013a; Tsai et al. 2013). GNAS, the gene of which is located on chromosome 20q, is the alpha subunit of a stimulatory G protein which activates a cyclic 3′-5′-cyclic AMP-mediated intracellular signaling cascade regulating cell proliferation. Overexpression of TP53 and loss of p16 were detected in low-grade IPN-B, whereas loss of SMAD4 was found in late phases of tumor development (Schlitter et al. 2014). In comparison with normal cholangiocytes, IPN-B showed decreased expression of the transcription factor, SOX9, which also plays a role in the development of pancreatic IPMNs (Kuroki et al. 2013).

Recently, IPN-Bs have been studied with respect to CDX2. IPN-Bs, mainly those occurring in the Far East, frequently express MUC2 and MUC5AC associated with aberrant expression of the homeodomain protein CDX2 (Ishikawa et al. 2004a). CDX2 is a caudal-related homeobox gene encoding an intestine-specific transcription factor, and expression is detectable in the nuclei of goblet cell-type intestinal epithelial cells (Yamamoto et al. 2003; Werling et al. 2003). Expression of this gene in cells examined in vitro affects intestinal cell differentiation and the transcription of intestine-specific genes (Qualtrough et al. 2002; Hinoi et al. 2002; Werling et al. 2003). This role as a differentiation switch is exemplified for gastric mucosa, where ectopic expression of CDX2 induces, or is associated with, intestinal metaplasia, while normal gastric mucosa does not express the gene (Silberg et al. 2002; Mutoh et al. 2002; Bai et al. 2002; Almeida et al. 2003). Furthermore, ectopic CDX2

expression characterizes the distinctive phenotype of intestinal-type cells developing in Barrett's esophagus (Eda et al. 2003). Based on transgenic mice, it has been suggested that expression of CDX2 is linked to the expression of MUC2 and alkaline phosphatase in the CDX2-expressing target cells (Silberg et al. 2002). This has been confirmed by the finding of a CDX2 interaction with the MUC2 promoter, thus activating MUC2 transcription (Yamamoto et al. 2003). Factors regulating the cell division cycle may be altered in the expression and activity in IPN-B. Inactivation of p16INK4a, mainly through promoter hypermethylation, is an early event in the transition from IPN-B to invasive carcinoma in patients with hepatolithiasis (Ishikawa et al. 2004b).

Cholangiocarcinomas Arising in Cystic Lesions of the Hepatobiliary Tract and in Pancreaticobiliary Maljunction

34

Contents

Abstract

There is a well-known association between cholangiocarcinomas and several types of cystic lesions of the hepatobiliary tract and pancreaticobiliary maljunction. Specifically, biliary tract cysts and inflammatory changes occurring in them result in significant risk for cholangiocarcinogenesis. These cysts include cystic dilatation of the common bile duct, diverticulum of the extrahepatic duct, choledochocele, multiple extrahepatic biliary cysts, and Caroli's disease. Among complications of choledochal cysts, malignant transformation is in fact the most concerning. Carcinomas develop either in the cyst wall itself or in undilated parts of intrahepatic or extrahepatic ducts. Histologically, cyst-associated cancers are mostly classical cholangiocarcinomas, but squamous cell carcinomas and other malignancies may also occur. A second group of biliary tract conditions that are associated with increased carcinoma risk are various forms of pancreaticobiliary maljunction.

Cancers Arising in Choledochal Cysts

Introduction

Choledochal cysts are uncommon congenital or acquired cystic dilatations of the extrahepatic or intrahepatic bile ducts. These distinct lesions were

Table 1 Todani classification of biliary tree cysts (modified)

Type	Morphologic features
I	Cystic dilatation of the common bile duct
	I A: saccular, involving the entire extrahepatic bile duct
	I B: saccular, involving a limited segment of the extrahepatic duct
	I C: fusiform, involving all or most of the extrahepatic duct
II	True diverticulum of the extrahepatic bile duct
III	Choledochocele (cystic change limited to the intraduodenal portion of the distal common bile duct)
IV	Multiple extrahepatic biliary cysts
	IV A: associated intrahepatic cysts
	IV B: extrahepatic cysts only
V	Caroli's disease

first described by Vater and Ezler in 1723. In 1852, Douglas described the clinical features of choledochal cyst based on a jaundiced female adolescent patient who showed a palpable abdominal mass (reviews: Yamaguchi 1980; Lipsett et al. 1994; Gigot et al. 1996; Soreide et al. 2004; Visser et al. 2004; Wiseman et al. 2005).

The cysts were first classified in 1959 (Alenso-Lej et al. 1959), based on the clinical and anatomic findings of 96 cases. The authors divided choledochal cysts into three types. This classification system was later refined by Todani and coworkers. The Todani classification of these lesions is based on five main types (Todani et al. 1977, 2003; Table 1).

Type I cysts are the most common (80–90 %) and are characterized by saccular or fusiform dilatation of the entire common bile duct and common hepatic duct or of parts/segments of each. As seen in the Table, the cyst morphology and the extent of involvement are used to subdivide type I cysts into three subtypes. Type II cysts present as mostly isolated protrusions projecting from the common duct wall. The diverticular morphology ranges from rather flat or sessile to pedunculated lesions showing a stalk. In Type IV A, the most common configuration is that of a large extrahepatic solitary cyst associated with multiple smaller cysts of the intrahepatic bile ducts. Type IV B show multiple dilatations involving exclusively the extrahepatic bile duct system. Type V, identical to Caroli's disease, shows dilatations of the intrahepatic biliary radicles that mostly involve both liver lobes. Unilobar/monolobar disease may also occur and usually involves the left liver lobe.

Epidemiology

Among complications of choledochal cysts, malignant transformation is the most concerning. This is an age-related phenomenon occurring in 10–14 % of adults with choledochal cysts. All studies have shown that cholangiocarcinoma and other carcinomas complicating choledochal cysts occur more often in adults than in children.

et al. 1991; Pisano et al. 1991; Holzinger et al. 1996; Han and Choi 1996; Stalder et al. 1996; Todani and Toki 1996; Ishibashi et al. 1997; Kale and Kuzu 1997; Lenriot et al. 1998; Yoshikane et al. 1998; Okamura et al. 2000; Patel et al. 2001; de Vries et al. 2002; Jan et al. 2002; Atkinson et al. 2003; Tseng et al. 2003; Tsuchida et al. 2003b; Zheng et al. 2004.

Carcinomas and other malignancies develop either in the cyst wall itself or in remnant tissues or undilated parts of the intrahepatic or extrahepatic bile duct system. The tumors are either detected at primary operations or secondary operations (review: Kagawa et al. 1978), but several cases were found at autopsy only, without previous operation (Armanino 1946; Dexter 1957; George and Maingot 1962; Jones and Shreeve 1970; Nasu et al. 1971; Gallagher et al. 1972).

Gallbladder carcinoma or cholangiocarcinoma was noted in 9.7 % of 42 patients (Lipsett et al. 1994). Among 42 patients with various types of choledochal cysts, cholangiocarcinoma was found in six patients, four of whom had previously undergone internal drainage procedures (de Vries et al. 2002). In a follow-up study of 72 adult patients who presented with choledochal cysts, the incidence of cholangiocarcinoma with non-cyst excision or non-operated congenital choledochal cysts was 10.8 % (Zheng et al. 2004). Intrahepatic cholangiocarcinoma can develop in patients subsequent to choledochal cyst resection, sometimes after a period exceeding 30 years (Fukuuchi 1967; Gallagher et al. 1972; Shields 1977; Chaudhuri et al. 1982; Yoshikawa et al. 1986; Scudamore et al. 1994; Kobayashi et al. 1999; Watanabe et al. 1999; Goto et al. 2001; Suzuki et al. 2004; Ono et al. 2008; Shimamura et al. 2009). In a review of nine cases of cholangiocarcinoma developing subsequent to resection of a choledochal cyst, the time period between cyst resection and diagnosis of carcinoma ranged from 2 to 34 years, in five cases exceeding 10 years and in four cases exceeding 20 years (Shimamura et al. 2009). Cholangiocarcinoma has been found in an adult patient aged 26 years after an infantile choledochal cyst resected at the age of 5 months (Ono et al. 2008).

Choledochal Cyst-Associated Adenocarcinoma

The types of cancer that have been reported in these lesions or the draining intrahepatic bile ducts mainly comprised classical cholangiocarcinoma and less commonly squamous cell carcinoma. In one of the first reports, from 1944, the tumor arising in a stone-containing choledochal cyst itself was squamous carcinoma (Irwin and Morison 1944). In a study reviewing 40 cases, adenocarcinoma was found in 31 cases, undifferentiated carcinoma in seven cases, and squamous cell carcinoma in two cases (Kagawa et al. 1978). Carcinoma can develop at the anastomotic site of hepaticojejunostomy (Yamamoto et al. 1996). It is known that late bile duct cancer is a complication of biliary-enteric anastomosis as such, i.e., not only after resection of choledochal cyst (Strong 1999). Among 204 patients with adult choledochal cyst disease in whom cysts were resected, de novo malignancy at the cyst remnant occurred in two patients (1 %; Cho et al. 2011). A part of congenital choledochal cysts are associated with pancreaticobiliary maljunction. In a study of 1433 Japanese patients with choledochal cysts, 151 patients had maljunction (Yamaguchi 1980). There is evidence that maljunction increases the risk of biliary tract carcinogenesis in choledochal cyst disease (Kobayashi et al. 1999; Song et al. 1999; Sugiyama et al. 1999; Matsumoto et al. 2003; Tashiro et al. 2003). Extrahepatic cholangiocarcinoma has been found in patients having choledochal cyst associated with pancreaticobiliary maljunction (Baumann et al. 1987; Sameshima et al. 1987; Okamura et al. 2000). Among 52 patients with choledochal cyst, pancreaticobiliary maljunction was associated with choledochal cyst in 64 % of the cases, but maljunction was only found in Todani types I

and IV. Carcinoma developed only in the maljunction group (32 %; Song et al. 1999).

Early Choledochal Cyst-Associated Carcinoma

Early carcinoma can sometimes be detected in choledochal cysts. In one case, a resected cyst showed a white plain area of thickness 3 and 8 mm in diameter, histologically characterized by well-differentiated tubular adenocarcinoma (Kraus et al. 2003). There are few published observations referring to precursor lesions of cholangiocarcinoma found in choledochal cysts. Adenomatous hyperplasia was detected in a simple excision specimen of cysts, followed by cholangiocarcinoma 2 years later (Coyle and Bradley 1992). Development of cholangiocarcinoma from an adenoma in choledochal cyst has also been described. In one patient, the resected cyst was lined with a shaggy papillary pink mucosa histologically representing a predominantly villous adenoma, at one place with a transition to cholangiocarcinoma (Franko et al. 2006). In rarer situations, early cancer or invasive adenocarcinoma has been observed in the dilated intrahepatic ducts associated with choledochal cysts (Tajiri et al. 1997; Kawamoto et al. 1998). It is currently thought that chronic inflammatory damage of epithelium and erosion/ulceration followed by persistent regeneration is the main pathogenic pathway for cancerogenesis in these cysts. Cholangiocarcinoma may also develop after surgical treatment of choledochal cysts (Tsuchida et al. 2003b), possibly caused by ascending cholangitis. In one patient with treated Todani type Ia congenital biliary dilatation, intrahepatic cholangiocarcinoma developed 10 years after Roux-en-Y hepaticoduodenostomy (Goto et al. 2001).

Choledochal Cyst-Associated Squamous Cell Carcinoma

Few cases of squamous cell carcinoma have been reported (Todani et al. 1977; Harris et al. 2002; Jan et al. 2002; Price et al. 2008). These carcinomas may develop from squamous metaplasia within cysts. Metaplasia can undergo dysplasia, thus initiating a dysplasia-carcinoma sequence.

Biliary Papillomatosis/Intraductal Papillary Neoplasms

Choledochal cyst can be complicated by the development of biliary papillomatosis followed by adenocarcinoma (Negi et al. 2009). A patient with congenital choledochal cyst associated with intrahepatic gallstones developed biliary papillomatosis with point mutation of the K-ras gene (Ohita et al. 1993).

Cyst-Associated Sarcomas

Very rarely, choledochal cysts are complicated by development of sarcomas, e.g., pleomorphic rhabdomyosarcoma (Tufail et al. 2006). On the other hand, embryonal rhabdomyosarcoma of the common bile duct may radiologically mimic choledochal cyst in childhood (Tireli et al. 2005).

Carcinoma Arising in Caroli's Disease

Caroli's disease is a congenital disorder of the hepatobiliary tract characterized by usually nonobstructive fusiform or saccular dilatations of larger intrahepatic bile ducts (review: Yonem and Bayraktar 2007). Probably owing to progressive damage and regeneration of epithelia, there is an increased risk of cholangiocarcinoma (Leroy et al. 1980; Balsells et al. 1993; Falco et al. 1993; Abdalla et al. 1999; Totkas and Hohenberger 2000; Wang 2002; Vlachogiannakos et al. 2004; Kasper et al. 2006). Cholangiocarcinoma was observed in a female patient with Caroli's disease accompanied by hepatolithiasis and choledochlithiasis (Takei et al. 1991). Carcinoma in situ of dilated bile duct segments was detected in Caroli's disease (Joly et al. 1990).

Carcinoma Arising in Ciliated Foregut Cyst

Ciliated foregut cyst is a rare congenital cystic lesion of the liver derived from the embryonic foregut. The term was coined in 1984 to describe an hepatic cyst sharing common histologic features with both esophageal and bronchial/bronchogenic cysts (Wheeler and Edmondosn 1984). The cysts are thought to originate from evagination of a foregut component into the liver anlage. This type of cyst is usually located in the left liver lobe, with a strong predilection for segment IV, but it has also been observed in the right liver lobe, the gallbladder, the pancreas, and the retroperitoneal space. The cyst is lined by a single layer of ciliated cuboidal to prismatic cells. A little more than 100 cases have been reported, with less than 20 cases diagnosed in children (review: Fujita et al. 2011). Carcinomas can develop in ciliated foregut cysts. Almost all cases were squamous cell carcinomas (Vick et al. 1999; de Lajarte-Thirouard et al. 2002; Furlanetto and De Tos 2002; Zhang et al. 2009). This type of carcinoma may develop on the basis of squamous metaplasia known to occur in foregut cysts of the liver. In most instances, metaplasia was found in cysts that also had squamous cell carcinoma (Vick et al. 1999; de Lajarte-Thirouard et al. 2002; Furlanetto and Dei Tos 2002). In one case without associated carcinoma, the cyst was lined mainly by a regular squamous epithelium without keratinization. The squamous epithelial cells expressed cytokeratin 5/6 and cytokeratin 19, while the superficial squamous cells expressed cytokeratin 7. Focally, a ciliated pseudostratified columnar epithelium with some goblet cells was found. This ciliated epithelium expressed cytokeratins 7 and 19 (Ben Mena et al. 2006).

Cancer Arising in Nonparasitic Simple Liver Cysts

Cholangiocarcinoma can develop in simple developmental liver cysts (Ackerholm et al. 1981). Typically, the involved cysts show hemorrhage and/or inflammatory changes and have been found to be filled with chocolate-colored fluid. Squamous cell carcinoma was also demonstrated in simple nonparasitic cysts (Richmond 1956; Greenwood and Orr 1972; Bloustein and Silverberg 1976; Bloustein 1977; Lynch et al. 1988; Nieweg et al. 1992; Pliskin et al. 1992; Banbury et al. 1994; Weimann et al. 1996; Monteagudo et al. 1998; Hsieh et al. 2005). Symptoms and signs described in this type of tumor include pain and loss of weight. Jaundice and a palpable mass in the epigastrium have sometimes been found. At least a part of the tumors described in the literature were large lesions within remnants of a cyst. The carcinoma often grows into the tissue encircling the cyst, making resection difficult. The tumor tends to metastasize to the locoregional lymph nodes, while remote metastases have less often been found. Large squamous cell carcinoma tends to undergo necrosis and form central cysts, but the presence of innocuous epithelium in the cystic parts of the mass excludes the possibility that the cyst had arisen from necrosis of a preexistent primary or metastatic solid tumor. Biliary carcinosarcoma was also found in a simple liver cyst (Terada et al. 1994).

Carcinoma in Autosomal Dominant Polycystic Disease

Intrahepatic cholangiocarcinoma rarely develops in autosomal dominant polycystic kidney disease (ADPKD) with liver involvement (Imamura et al. 1984; Kataoka et al. 1985; Carone et al. 1994; Sasaki et al. 2002; Matsuoka et al. 2005). In one autopsy case (Sasaki et al. 2002), a 69-year-old man with known ADPKD, the liver was mildly enlarged, and many cysts up to 3 cm in diameter were mainly distributed along the biliary tree at the liver hilus and to a lesser degree in the hepatic parenchyma. A yellowish-white firm tumor (6 cm) was present in the right hepatic hilus, extending into the right lobe of the liver and involving several of the cystic lesions. Histologically, the mass was

composed of a well to moderately differentiated, desmoplastic tubular adenocarcinoma with vascular, lymphatic, and perineural invasion. In addition, there was well-differentiated papillary adenocarcinoma spreading in the lumen of several cysts embedded in and adjacent to the main carcinoma.

Cystadenocarcinoma Originating from Hepatic Cysts

Cystadenocarcinoma without mesenchymal stroma can develop in association with benign hepatic cysts (Azizah and Paradinas 1980). In one case, this lesion was associated with progressive morphologic changes assessed by follow-up imaging during 10 years (Akiyoshi et al. 2003).

Cholangiocarcinoma in Disorders of the Pancreaticobiliary Ductal Union

Introduction

Anomalous pancreaticobiliary ductal union (APBDU; synonym: pancreaticobiliary maljunction) is a congenital anomaly more commonly encountered in Asian than Western countries and significantly more common in females. The common feature of this condition is a pancreaticobiliary ductal union located proximal to the sphincter of Oddi, an anomaly first reported in 1969 (Babbitt 1969). APBDU is, therefore, characterized by union of the pancreatic and bile ducts located outside the duodenal wall, forming a very long common channel (usually >15 mm; average length in one study, 24.7 mm, Tanaka et al. 1998). Normally, the two ducts open into the duodenum either separately or via a common channel. The length of the common channel in normal subjects ranges from 1 to 12 mm, with a mean of 4.5 mm (Misra et al. 1989; Misra and Dwivedi 1990). The mode of union has been classified into two groups. The biliary-pancreatic (B-P) type junction has a common bile duct joining the main pancreatic duct; the pancreaticobiliary (P-B) type junction is the reverse of this (Kimura et al. 1985). APBDU may also be classified into dilated and non-dilated types in regard to the morphology of the common bile duct, the dilated type being more frequent. In a study of 1627 patients with APBDU enrolled and analyzed by the Japanese Study Group on Pancreaticobiliary Maljunction, 1239 patients had the dilated type, and 388 had the non-dilated type. Individuals with latter type were significantly older than those of the former (47 years vs. 24 years, respectively). APBDU is associated with various pancreaticobiliary diseases, including pancreatitis and biliary cancer (Kato et al 1983; Kamisawa et al. 2002, 2003, 2006, 2009b, 2010b; Matsumoto et al. 2002; Kimura et al. 2005; Miyazaki et al. 2008; Funabiki et al. 2009; Kimura 2009). The occurrence rate of cancer in the biliary tract was 10.6 % in the dilated type and 37.9 % in the non-dilated type (Tashiro et al. 2003).

APBDU is associated with a narrow portion of the terminal choledochus, and this narrow distal segment represents the functional region of the sphincter of Oddi (Kune 1964, 1970). Hence, the presence of APBDU is determined by two parameters, the length of the common channel and the length of the narrow segment (review: Nomura et al. 2002). Among patients with APBDU, biliary dilatation (>10 mm) was more frequent in those with the narrow choledochal portion (Nomura et al. 2005). A distinct entity is dilatation of the intrahepatic bile duct system associated with anomalous junction of the cystic duct, in the absence of APBDU (Ohama and Ishikawa 2006). APBDU is likely to be caused by disturbance in the morphogenesis of the connections of the pancreatic and biliary duct system that occurs very early during gestation when the common bile duct joins with the ventral pancreatic duct system (Matsumoto et al. 2001). Familial occurrence of APBDU has been described (Miyazaki et al. 1989). The long common channel causes two-way fluid regurgitation, with bile flowing into the pancreatic duct and pancreatic juice flowing into the bile duct, because the sphincter now cannot functionally affect the channel (Kamisawa and Okamoto 2006; Kamisawa

et al. 2009a). There is a relation between pancreaticobiliary reflux and the length of the common channel. The minimum length of a common channel that could induce a markedly elevated amylase level in bile was determined as 5 mm. Based on this observation, high confluence of pancreaticobiliary ducts (HCPBD) was defined as cases with a common channel > or = 5 mm, in which the communication between the pancreatic and bile ducts was occluded with the sphincter contraction (Kamisawa et al. 2010a). In the majority of cases, APBDU is associated with a normal intrapancreatic duct morphology, but in a minority, there is dorsal pancreatic duct dominance. In this situation, most pancreatic juice in the upper dorsal pancreatic duct is drained into the duodenum through the minor duodenal papilla, and reflux of pancreatic juice to the biliary tract may be reduced, resulting in reduced damage (Kamisawa et al. 2005).

How frequent is APBDU? Among 680 individuals with clearly visualized pancreaticobiliary radiograms during ERCP, 8.7 % had APBDU (Wang et al. 1998). In a nationwide Korean cooperative prospective study of 10,243 patients undergoing ERCP, the frequency of APBDU and choledochal cyst was 4.1 % and 0.32 %, respectively (Kim et al. 2002). In a prospective study of 354 ERCP cases, a common channel was detected in 131 cases (37 %). Among these, 11 had APBDU and 13 a high confluence of pancreaticobiliary ducts (Kamisawa et al. 2007). A strong association of APBDU with congenital duct dilatation or choledochal cyst has been confirmed in several studies (Kimura et al. 1977; Ono et al. 1982; Todani et al. 1984; Okada et al. 1990), the incidence ranging from 64 % (Song et al. 1999) to 93.8 % (Wang et al. 1998). In one study, APBDU was found only in type I and type IV choledochal cysts according to Todani's classification (Song et al. 1999). In congenital dilatation of the common bile duct associated with APBDU, epithelial hyperplasia accompanied by round cell infiltration and increased thickness of the duct wall with fibrosis was observed histologically in the resected bile duct in all patients (Oguchi et al. 1988).

Cholangiocarcinoma of the Extrahepatic Bile Ducts in APBDU

Cholangiocarcinoma involving the extrahepatic bile duct in APBDU is less often reported than gallbladder carcinoma, and the incidence varies considerably in the different reports (Kato et al. 1983; Suda et al. 1983; Strijk et al. 1984; Ohta et al. 1990; Tsai 2001; Nakamura et al. 2008; Saji et al. 2010). In an autopsy study of 72 cases of biliary tract carcinoma APBDU was found in 8/34 cases of common bile duct carcinoma and in 4/24 gallbladder carcinomas (Suda et al. 1983). Cholangiocarcinoma in APBDU associated with congenital biliary dilatation can already develop in childhood (Tanaka et al. 2006; Saikusa et al. 2009). In one study, 9/27 (33.3 %) patients with APBDU had common bile duct cancer, but only 1/47 (2.1 %) had hilar carcinoma (Wang et al. 1998). In another study, a long common channel was an infrequent finding in patients with cholangiocarcinoma. The mean length of the common channel in patients with cholangiocarcinoma was 6.43 mm, which was comparable to the length of the common channel in normal subjects (Sharma 1994). In a nationwide survey in Japan, a close relationship was shown between biliary tract carcinogenesis and APBDU, according to the type of maljunction (dilated vs. non-dilated types) and age distribution. APBDU patients with cystic dilatation of the bile duct had a high risk of bile duct cancer, even in those who were young (aged less than 20 years), and the incidence of gallbladder cancer increased markedly in patients older than 40 years. In contrast, the incidence of gallbladder carcinoma gradually increased in APBDU patients having the undilated type (Hasumi et al. 2000; Miyazaki et al. 2008). In a study of 38 patients with APBDU, the incidence of malignancy was 17.8 % in the dilated type (two patients with cholangiocarcinoma and three with gallbladder carcinoma) and 90 % in the non-dilated type (all with gallbladder carcinoma) (Tanaka et al. 1998). The predominance of gallbladder carcinomas over cholangiocarcinomas in non-dilated APBDU was shown in a previous study (Tanaka et al. 1993). The importance of the bile dilation status was

confirmed in another study. Ninety-eight cases of APBDU were divided into five groups according to the maximum diameter of the extrahepatic bile duct. Gallbladder carcinoma developed in 55 % of patients whose maximum diameter of the extrahepatic duct was < or = 30 mm, but no gallbladder carcinoma occurred in patients with APBDU whose duct diameter was > or = 31 mm. Bile duct carcinoma occurred in 12 % of patients whose duct diameter was > or = 21 mm, but no bile duct carcinoma occurred in those with a duct diameter of < or = 20 mm (Kamisawa et al. 2006).

Carcinoma of the Gallbladder in APBDU

APBDU confers a significant risk for gallbladder cancer. There is a clear predominance of female patients (Kamisawa et al. 2008). Even a long common channel (≥8 mm) in the absence of APBDU is associated with a higher frequency of gallbladder carcinoma (review: Misra and Dwivedi 1990). Among 106 Japanese patients with biliary tract cancer (58 patients with gallbladder carcinoma and 48 patients with cholangiocarcinoma), 10 patients (9.4 %) had APBDU (Sandoh et al. 1997). In a Chinese cohort of patients, the frequency of APBDU was significantly higher in patients with gallbladder carcinoma (Hu et al. 2003). Among 14 patients with APBDU, five patients developed gallbladder carcinoma, associated with a more frequent development of gallbladder mucosal metaplasia (Jung et al. 2004).

Selected References Kato et al. 1983; Kimura et al. 1985; Nagata et al. 1985; Yamauchi et al. 1987; Miyazaki et al. 1989; Sautereau et al. 1989; Ohta et al. 1990; Mori et al. 1993, 1999; Tanaka et al. 1993; Sandoh et al. 1997; Chang et al. 1998; Tanno et al. 1998a; Yoshida et al. 1999; Hasumi et al. 2000; Jung et al. 2004; Adham et al. 2005; Minami et al. 2008; Oshiro et al. 2008; Lahmar et al. 2010.

APBDU may be associated with hyperplastic polyp of the gallbladder (Okada et al. 2009), with adenomyomatosis of the gallbladder (more often in the presence of the undilated type of APBDU; Chang et al. 1998; Tanno et al. 1998b), and with multiseptate gallbladder (Yamamoto et al. 2005).

Pathogenesis of Cancer in APBDU

APBDU is associated with hyperplastic, metaplastic, and dysplastic alterations in the extrahepatic biliary tract and the gallbladder (review: Tsuchida and Itoi 2010). Children with APBSU showed epithelial hyperplasia of the gallbladder mucosa in up to 60 % (Tanno et al. 1999). In adults, 63 % of patients with APBDU has gallbladder epithelial hyperplasia, and this hyperplasia was significantly more frequent in the undilated type of APBDU. 2/9 high-grade hyperplasias revealed codon 12 K-Ras mutations (Tanno et al. 1998a). APBDU is associated with papillary epithelial hyperplasia in both the extrahepatic bile ducts and the gallbladder, which is a precursor lesion for cancer (Seki et al. 2005). In a study of 45 children with APBDU (median age: 2.9 years), the most common histological finding was villus-type mucosal hyperplasia (57.1 %) (Ono et al. 2010). Diffuse papillary hyperplasia of the gallbladder mucosa in APBDU exhibits senescent features such as expression of p16 (INK4A) and low cell proliferative activity and is induced by lysolecithin, a lipid the level of which is elevated in gallbladder bile in APBDU (Yamaguchi et al. 2009). An effect of APBDU on carcinogenesis is shown in choledochal cysts, where carcinomas develop more frequently when the cysts are associated with APBDU (Song et al. 1999). Mutation of K-Ras (codon 12) seems to be involved in APBDU-associated biliary tract cancers (reviews: Matsubara et al. 1995; Matsumoto et al. 2003; Tsuchida et al. 2003a). In a series of 20 adult patients with APBDU, point mutations of K-Ras were detected in 80 % of the cancerous cases and 58 % of the hyperplastic and metaplastic lesions (Matsubara et al. 1996). Among 35 pediatric patients with APBDU, PCR analysis of cholangiocyte DNA revealed that K-Ras mutations were detected in five children, four of whom showed epithelial hyperplasia or metaplasia. In a 12-year-old girl,

adenocarcinoma had developed in a choledochal cyst, and here both K-Ras and DPC-4 (Smad-4) mutations were found, suggesting a multistep cancerogenic process with K-Ras mutations occurring as an early event (Shimotake et al. 2003). Mutations of K-Ras and p53 genes were also found in noncancerous biliary epithelia of adult patients with APBDU (Matsubara et al. 2002). Even in the presence of a relatively long common channel (high confluence) alone without fulfilled criteria of APBDU, overexpression of p53 and K-Ras was found in epithelial of the gallbladder (Kamisawa et al. 2004). In gallbladder mucosal cells of patients with APBDU, Bcl-2 expression and activation of telomerase are early events involved in carcinogenesis (Ichikawa et al. 2004).

There is evidence that the COX-2 pathway is involved in APBDU-induced carcinogenesis. Generally, COX-2 expression is strongly related to cancer progression or development by means of its anti-apoptotic effect, promotion of angiogenesis, and/or decrease of cell-to-cell adhesive activity. Bile from APBDU can significantly promote the proliferation of human cholangiocarcinoma cells. This response is associated with marked upregulation of COX-2 transcripts, and the proliferative reaction can be abolished by a COX-2 inhibitor (Wu et al. 2003). Immunohistochemically, overexpression of COX-2 in biliary tract tissues of patients with APBDU was found in 20 % of regenerative epithelium, 11.1 % of hyperplasia without atypia, 86.4 % of hyperplasia with mild atypia, and 75 % each of dysplasia and carcinoma. COX-2 expression was associated with expression of VEGF (Tsuchida et al. 2003c). In a second immunohistochemical study, COX-2 expression in noncancerous biliary tract tissue of patients with APBDU and biliary cancer was 20 % vs. 7.1 % in patients without APBDU (Watanabe et al. 2004).

The reflux phenomena associated with APBDU may cause bacterial colonization of the biliary tract. One microorganism considered to be a causative factor for biliary cancer is *Helicobacter bilis*. By the use of PCR analysis of bile juice and biliary tissue samples, it has been shown that *Helicobacter bilis* colonization of the biliary system is very common in patients with APBDU (Kosaka et al. 2010).

APBDU causes regurgitation of pancreatic juice into the biliary tract and into choledochal cysts. In choledochal cysts associated with APBDU, fatty acid calcium stones (Kaneko et al. 2008) and protein plugs develop. One component secreted by pancreatic acinar cells is lithostathine, which is an important component of protein plugs. Lithostathine is the major nonenzymatic protein of pancreatic secretions and has several synonyms, including pancreatic stone protein, protein-X, pancreatic thread protein, and P19, and is now termed Reg protein (review: De Reggi and Gharib 2001). The Reg I gene makes a part of the Reg protein gene family and encodes a 166-amino acid glycosylated protein with a 22-amino acid signal peptide (review: Okamoto 1999). The Reg I gene product has been identified as a regenerative/proliferative factor for pancreatic islet cells, but it is also active in other cell systems and in cancer cells and affects liver regeneration (Wang et al. 2009). It is upregulated in blood after trauma, and here it binds to and activates neutrophils (Keel et al. 2009).

In choledochal cysts associated with APBDU, protein plugs are an important or dominant cause of symptoms, and the plugs consist mostly of lithostathine. Activated trypsin from pancreatic juice is present together with lithostathine in bile of APBDU patients (Ochiai et al. 2004), and trypsin cleaves soluble lithostathine into insoluble forms that aggregate to form plugs (Kaneko et al. 2007). Lithostathine-containing protein plugs in choledochal cysts/APBDU are dissolved by acidic and basic solutions (Kaneko et al. 2009).

Bile Duct Carcinomas with Marked Extracellular or Intracellular Mucin Accumulation: Mucinous and Signet Ring Cell Carcinomas

35

Contents

Abstract

Uncommon variants of cholangiocarcinoma, both of intrahepatic and extrahepatic ducts, are characterized by marked production of mucin. Depending on secretion or storage of mucins, two major groups of mucin-rich carcinomas are distinguished, i.e., mucinous cholangiocarcinoma or signet ring cell carcinoma. Mucinous cholangiocarcinoma (colloid carcinoma) is a rare cancer that may develop as a complication of hepatolithiasis. A part of these neoplasms also occur in the setting of intraductal papillary neoplasms of bile ducts. Most mucinous cholangiocarcinomas are intrahepatic neoplasms, but very rare forms also occur in extrahepatic ducts and cystic duct. Due to massive extracellular mucin accumulation, mucinous cholangiocarcinomas can show rapid mass increase. In contrast to mucinous cancers, the rare signet ring cell carcinomas of bile duct do not secrete mucin, but store it within cells, resulting in intracellular mucin deposits with peripheral displacement of the nucleus. Signet ring cell carcinomas show a diffuse growth pattern and are highly invasive lesions.

Mucinous Cholangiocarcinoma (Colloid Carcinoma of the Biliary Tract)

Introduction

Mucinous cholangiocarcinoma (mucinous carcinoma; colloid carcinoma) is a very rare primary liver malignancy (Chou and Chan 1976; Sugihara and Kojiro 1987; Nakajima et al. 1988; Motoo et al. 1993; Sakamoto et al. 1995; Sasaki et al. 1995; Chow et al. 1997; Mizukami et al. 1999; Kenjo et al. 2000; Nakagohri et al. 2003). The prevalence varies considerably in the literature, probably also depending on the histologic diagnostic criteria used. Among 102 consecutively studied cases of intrahepatic cholangiocarcinoma, there was only one case of mucinous cholangiocarcinoma (Nakajima et al. 1988). A study of 61 cases of intrahepatic cholangiocarcinoma from Thailand listed 13.66 % of mucinous cholangiocarcinoma (Sinawat and Hemsrichart 1991). Mucinous carcinoma may develop as a complication of hepatolithiasis (Chow et al. 1997). At least a part of these neoplasms seem to develop at the invasive parts of intraductal papillary neoplasms of the bile ducts (review: Nakanuma et al. 2010).

Clinical and Imaging Features

Most of the mucinous hepatic cholangiocarcinomas develop within the liver, but other primary sites also occur, including the extrahepatic bile duct (Sakamoto et al. 1995; Yamanaka 1996; Mizukami et al. 1999; Kenjo et al. 2000), the cystic duct (Oku et al. 2006), and the ampulla of Vater (Malik et al. 1992; Seidel et al. 2002; Wolfson 2002; Inagaki et al. 2007). Due to massive mucin production, mucinous cholangiocarcinomas may rapidly grow (Motoo et al. 1993). Intrahepatic mucinous cholangiocarcinoma may be associated with portal vein thrombosis (Nakagohri et al. 2003).

Ultrasonographically, mucinous cholangiocarcinomas are high-echoic tumors with less echogenic portions (Motoo et al. 1993). CT scans showed low-density lesions characterized by the features of large mucinous lakes throughout the tumor (Hayashi et al. 1996; Lee et al. 2001). MRI has shown low intensity on T1-weighted images and high intensity on T2-weighted images (Motoo et al. 1993). Some tumors are microcystic (Sonobe et al. 1995) or have a multicystic appearance and show a periportal collar in imaging (Mizukami et al. 1999). A part of the tumors may show calcifications at imaging (Hayashi et al. 1996; review: Nagakura et al. 1999).

Macroscopic Pathology

Grossly, the tumors are bulky and often circumscribed lesions with a sometimes expanding growth mode. Typically, colloid carcinomas exhibit a glassy or transparent aspect caused by the massive accumulation of mucin in the interstitial space. When cutting through a fresh, unfixed specimen, the copious mucin forms viscous threads between the knife and the cut surface. Large tumors may contain whitish to yellow foci of calcification in the center. The glassy aspect of the tumor is also in evidence in metastatic lesions.

Histopathology

Mucinous adenocarcinoma is histologically characterized by medium-sized to large tumor cells containing abundant mucin. A large part of this mucin is, in contrast to signet ring cells, secreted into the extracellular space, where it forms large masses of PAS-, mucicarmin-, and Alcian blue-positive mucin, producing an expanding mass (Figs. 1 and 2). The tumor cells float in these mucin lakes, which may show a lobulated architecture. The floating cells are either present as single cells and small cell groups or form incomplete or, less commonly, complete tubular profiles. In situations of massive extracellular mucin deposition, it may be difficult to detect viable cancer cells. Sparse neoplastic cells are detectable by use of cytokeratin immunohistochemistry. A part of the tumors show a multicystic appearance

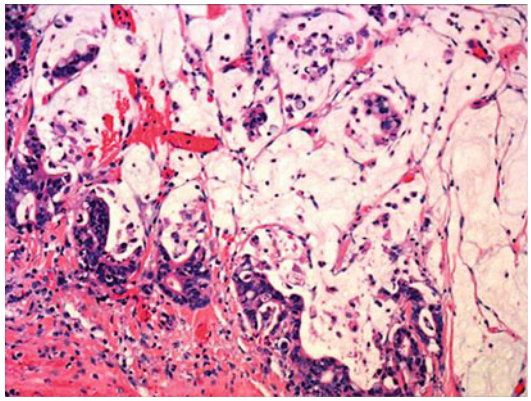

Fig. 1 Mucinous cholangiocarcinoma. Abundant extracellular mucin contains nests of carcinoma cells (hematoxylin and eosin stain)

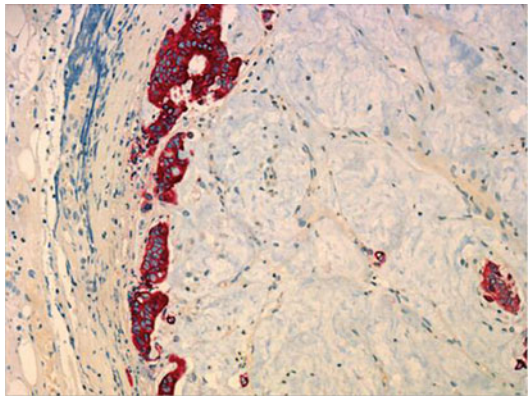

Fig. 2 Mucinous cholangiocarcinoma. Most of the tumor mass consists of extracellular mucin (cytokeratin 7 immunostain)

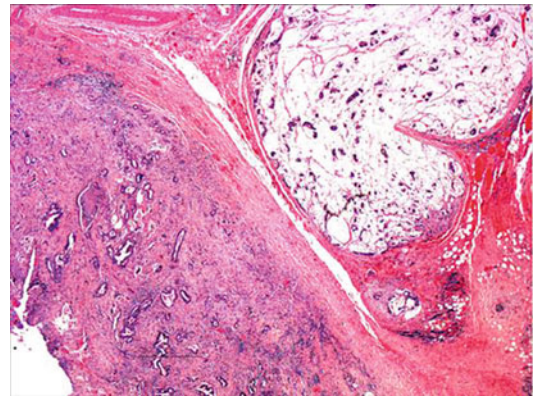

Fig. 3 Perihilar cholangiocarcinoma with mucinous component. The adenocarcinoma in the bile duct wall (*lower left corner*) reveals a classical cholangiocarcinoma morphology, while a mucinous component with abundant extracellular mucin has developed in a tumor part with intraneural invasion (*right upper corner*; hematoxylin and eosin stain)

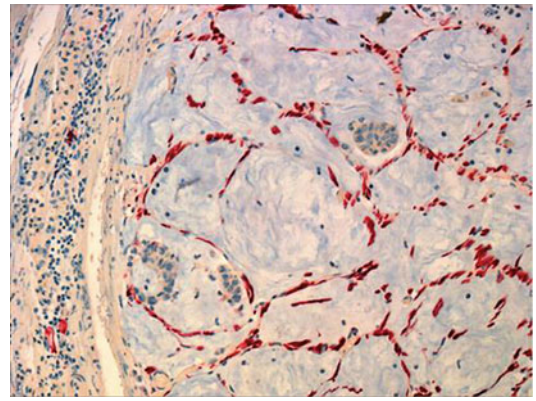

Fig. 4 Mucinous cholangiocarcinoma with intraneural invasion. Clusters of carcinoma cells are suspended in mucin masses. S100 protein-positive nerve elements (Schwann cells) are dissociated by the mucin lakes (S100 protein immunostain)

(Mizukami et al. 1999) or display microcystic features (Sonobe et al. 1995). Mucinous cholangiocarcinoma usually does not secrete mucin into the bile duct lumina (Motoo et al. 1993). A rare subset of mucinous cholangiocarcinoma tends to produce massive peri- and intraneural invasion with formation of colloid-like nodules along regional nerves (neurotropic mucinous carcinoma; Figs. 3 and 4). Mucinous cholangiocarcinoma can show mineral deposits (calcification /mineralization) visualized as basophilic structures, usually within the mucinous lakes. Among nine cases of focally calcified cholangiocarcinomas reported in the literature, six were of the mucinous type (Nagakura et al. 1999). Some of the neoplasms are mixed in regard to mucin storage, i.e., with formation of signet cells (Sasaki et al. 1995). In the vicinity of the tumor, extracellular mucin can induce several tissue reactions. The mucin can cause tissue dissection, with formation of clefts or mucin-filled pseudocysts. Mucin is in part pinocytosed by tumor-associated macrophages (mucophages), which sometimes form mucin granulomas. Activation of macrophages and lymphocytes by

abnormal mucin can result in the secretion of chemokines and fibrokines, ending up with a fibrotic reaction around mucin depositions.

Mucinous cholangiocarcinoma display a characteristic pattern of MUC gene expression. In particular, mature MUC1 mucin and core protein of MUC1 mucin are expressed (Sasaki et al. 1995). The tumors show variable positivity for carcinoembryonic antigen (CEA); Lewis Y, T, and Tn antigens; Lewis X antigen; sialyl-Lewis X antigen; sialyl-Tn antigen; and carbohydrate antigen 19-9 (Sasaki et al. 1995). Electron microscopy revealed mucin-containing vacuoles in the cytoplasm of carcinoma cells (Motoo et al. 1993).

Combined Tumors

Colloid carcinoma can develop from preexisting intraductal papillary mucinous neoplasm of the liver (Bu-Ghanim et al. 2004). Mucinous cholangiocarcinoma has been found in combination with hepatocellular carcinoma (Wada et al. 1986; Morita et al. 2006).

Associated Conditions

Mucin-producing intrahepatic cholangiocarcinoma was observed in conjunction with several disease states, including primary sclerosing cholangitis (Yokomuro et al. 2007), hepatolithiasis with pyogenic cholangitis (Chow et al. 1997), and clonorchiasis (Shim et al. 2004). This type of carcinoma was also found in a patient with Muir-Torre syndrome caused by MSH2 gene mutation (Vernez et al. 2007).

Differential Diagnosis

Metastases of mucinous colorectal cancers may mimic mucinous intrahepatic cholangiocarcinoma (Aoki et al. 1990; Tokai et al. 2006). Recurrence of mucinous neoplasms of the appendix has been observed at the porta hepatis (Sugarbaker and Bijelic 2008).

Biology of Disease

In other organs, mucinous carcinomas exhibit variable evolutions. In the colon they have been shown to progress more rapidly and are associated with a poorer prognosis than non-mucinous cancers (Nozoe et al. 2000; Goi et al. 2006), while gastric mucinous adenocarcinomas either revealed a worse overall survival rate (albeit correlated with more advanced stage at diagnosis) (Wu et al. 1998) or did not differ in outcome in comparison with non-mucinous gastric carcinomas (Yasuda et al. 2001; Hidaka et al. 2008). In contrast, mucinous carcinoma of the breast has a favorable outcome (Di Saverio et al. 2008). Biliary mucinous/colloid carcinomas metastasize to the locoregional lymph nodes (Gotoh et al. 1999) and, similar to gastric mucinous carcinomas, to the ovaries, causing Krukenberg tumors (Andrieu et al. 1972; Sharma et al. 1997; Khunamornpong et al. 2007, 2008; Young 2007). Generally, carcinomas of the gallbladder and the bile ducts often metastasize to the ovaries. In one of the main studies on Krukenberg tumors, 10 % of the tumors had originated from the gallbladder or, in one case, from a bile duct (Schlagenhaufer 1902).

Microcystic (Multicystic) Mucinous Cholangiocarcinoma

Introduction

Microcystic or multicystic mucinous cholangiocarcinoma is a distinct variant of peripheral mucinous cholangiocarcinoma characterized by marked mucin production and a striking microcystic appearance (Sonobe et al. 1995). Mucinous carcinoma with considerable mucin production is a rare variety of cholangiocarcinoma first described in 1987 (Sugihara and Kojiro 1987). This distinct phenotype has an incidence of 0.8 % in autopsied cholangiocarcinoma cases and shows a rapid progression with poor prognosis (Nakajima et al. 1988; Motoo et al. 1993; Sasaki et al. 1995).

Clinical and Imaging Features

Ultrasonography of the liver reveals multiple, small cystic lesions with varying echogenicity. These lesions are also in evidence in CT images and may be associated with a slight dilatation of the intrahepatic bile ducts (Mizukami et al. 1999).

Pathology

Resection specimens show multiple irregularly shaped cystic lesions which contain a gelatinous, viscous mucus, sometimes causing a honeycomb-like appearance. The cysts have a diameter of 0.2–0.4 cm (Sonobe et al. 1995). The internal surface of the microcysts is lined with one or more layers of neoplastic cells, sometimes with a papillary growth pattern. The carcinoma cells are seen to invade both the portal tracts and the liver parenchyma. Interestingly, the invasive carcinoma component tends to show tubular structures associated with a stromal reaction (Sonobe et al. 1995; Mizukami et al. 1999). The cysts contain copious mucus. Some of the cysts may rupture, causing variably sized mucus lakes with accumulation of detached and mostly non-vital cancer cells and macrophages (mucophages).

Intrahepatic Multicystic Mucinous Cholangiocarcinoma with Oncocytic Change

In this rare variant of intrahepatic cholangiocarcinoma, the carcinomatous epithelia may rarely undergo oncocytic change, cells being markedly immunoreactive for mitochondrial antigen, in the absence of an ovarian-like stroma (Fuji et al. 2005).

Signet Ring Cell Carcinoma of the Biliary Tract

ICD-O Code 8490/3

Introduction

Signet ring cell carcinoma (SRCC) is known to develop in several organs, but it occurs most frequently in the stomach, accounting for 15–30 % of all gastric cancers (Kim et al. 1994; Adachi et al. 2000), while the colon is less often involved (about 1 % of all colorectal cancers; Anthony et al. 1996; Nissan et al. 1999). SRCC occurring in the biliary tract including the ampullary region is a rare type of neoplasm, which represents a variant of adenocarcinoma characterized by the presence of greater than 50 % signet ring cells (Fig. 5).

Signet Ring Cell Carcinoma of the Extrahepatic Bile Ducts

SRCC has been observed in the lower common bile duct (Hiraki et al. 2007; Lee et al. 2010; Ogata et al. 2010; Matsumoto et al. 2011). The 55-year-old man described by Lee and coworkers (2010) presented with jaundice and pruritus, and CT and PET suggested the presence of a distal common bile duct cancer. A pylorus-preserving Whipple's operation was performed, with postoperative chemoradiotherapy because of positive proximal margins. The patient survived with no evidence of recurrence for 2 years. Ogata et al. (2010) described a 42-year-

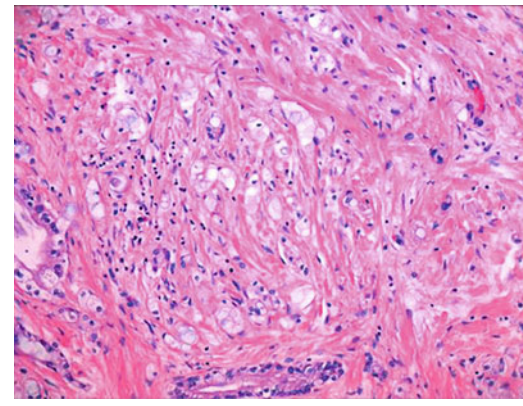

Fig. 5 Sigillocellular cholangiocarcinoma (hematoxylin and eosin stain)

old woman with obstructive jaundice and a stricture of the common bile duct in the absence of gallstones. Based on the diagnosis of malignancy, a pylorus-preserving pancreatoduodenectomy was performed. The resection specimen revealed a common bile duct with a thick whitish wall and a narrow lumen. Histology showed signet ring cell carcinoma, the tumor cells being CK7-positive and their nuclei p53 protein positive. In a 72-year-old male patient reported by Matsumoto and coworkers (2011), the tumor had taken its origin from the lower part of the common bile duct, showed intraluminal growth, and contained cystic components.

Signet Ring Cell Carcinoma of the Intrahepatic Bile Ducts

Very few data are found regarding intrahepatic cholangiocarcinomas with a signet ring cell component (Saito and Nakanuma 1995; Nakanuma et al. 2010).

Signet Ring Cell Carcinoma of the Ampullary Region

SRCC of the ampullary region is uncommon but somewhat more frequent than SRCC in the biliary tract proper. This neoplasm may sometimes be difficult to distinguish from SRCC located to the distal-most part of the common bile duct, due to the diffuse, ill-defined invasive growth pattern. The tumor mainly occurs in older subjects, but has also been observed in a young adult (Purohit et al. 2005). In a review of 14 reported cases, eight involved men and six women. The median age at diagnosis was 57 years (range: 32–83 years), i.e., similar to that of colorectal SRCC, but about 15 years older than patients with gastric SRCC (Akatsu et al. 2007). In a more recent case review of 30 reported patients, 16 were male and 9 female, with an age at presentation ranging from 32 to 83 years and with most tumors having a diameter smaller than 2 cm (Acharya et al. 2013). In a review of 14 cases, the median tumor diameter was 1.8 cm, with a range of 0.8–2.5 cm (Akatsu et al. 2007). The tumors usually present as nodular, firm, and ulcerated lesions. As the neoplasms are associated with marked stromal reactions and tend to show diffuse growth in deeper parts of the ampulla, SRCCs are markedly stenosing lesions that often cause obstructive jaundice and, sometimes, acute pancreatitis (Tas et al. 2011). In some patients, a diffuse infiltration encircling the ampullary duct and extending into the parenchyma of the adjacent pancreatic head was found (Acharya et al. 2013). Specifically, ampullary SRCC may extend into the wall of the distal common bile duct and cause its stenosis. Stenosis of the ampullary duct by SRCC may induce acute pancreatitis (Tas et al. 2011). Immunohistochemically, SRCCs of the ampullary region have been divided into pancreaticobiliary type (CK7+, CK20−, CDX2−, and MUC2−) and an intestinal type (CK7−, CD20+, CDX-2+, and MUC2+), the pancreatobiliary type having a more aggressive course associated with poorer outcome (Gheza et al. 2011). Expression of MUC2 and CDX-2 was previously found in ampullary cancers with signet ring cell components (Chu et al. 2005).

As in other locations, SRCC can result in widespread, disseminated carcinomatosis (Nabeshima et al. 2003), including metastases to CNS and meninges (Paplomata and Wilfong 2011). Ampullary SRCC was associated with ampullary adenocarcinoma in one patient (Maekawa et al. 2011). Although SRCC generally predicts a poor prognosis elsewhere in the gastrointestinal tract, the course of ampullary SRCC may sometimes be more favorable. Ampullary SRCC was found as tumor coexisting with ordinary adenocarcinoma of the ampulla (Maekawa et al. 2011). Periampullary SRCC can occur as a collision tumor together with high-grade neuroendocrine carcinoma (Kurana et al. 2011).

et al. 2007; Gao et al. 2009; Ishibashi et al. 2009; Garcia et al. 2011; Tas et al. 2011; Terada 2012; Acharya et al. 2013; Talebi et al. 2014.

Signet Ring Cell Carcinoma of the Gallbladder

SRCC of the gallbladder is a rare but well-established entity (Nishida et al. 1997; Yamauchi et al. 2000; Krunic et al. 2007; Karabulut et al. 2008; Khoo and Nurul 2008; Czysczon and Alatassi 2010; Mondal 2010; Pavic et al. 2010) and will be further treated in the chapter of gallbladder tumors.

Pathology

As in the stomach, signet ring cell carcinomas of the bile duct system show a diffuse invasive growth pattern associated with marked desmoplasia, causing stenosis of the involved duct. The cells are usually medium sized and show a prominent, mucin droplet or glycoprotein body that displaces the flattened and sickle-shaped nucleus to the margin of the cell, resulting in a structure resembling a signet ring. Frequently, the mucin droplet dominates the cell mass, leaving only a thin rim of cytoplasm. In HE preparations, the mucin droplet is amphophilic or slightly basophilic, either homogeneous or with a finely spongy structure. Due to the compact nucleus and the sparse cytoplasm, signet ring cells may be missed, particularly when they are embedded in a stroma with a leukocytic infiltration rich in macrophages. Macrophages that have pinocytosed mucin (mucophages) can strikingly resemble signet ring cells, calling for mucin stains and immunohistochemistry to avoid misinterpretations.

Differential Diagnosis

Differential diagnostically, the distinction between ampullary and duodenal (periampullary) SRCC may be difficult, specifically in the presence of large tumors, where the center of the neoplastic process is not easily identifiable. In addition, duodenal SRCC was found in synchronous conjunction with intestinal-type ampullary carcinoma (Aurello et al. 2011). Sometimes one may observe benign signet ring cell aggregates in the gallbladder mucosa, visualized as loose, cytokeratin-positive cell aggregates overlying ulcerated mucosal surfaces, without signs of invasive growth (Michal et al. 1998).

Nonneoplastic Signet Ring Cells in the Hepatobiliary Tract

Nonneoplastic signet ring cells (NNSRCs) may cause considerable differential diagnostic problems, mainly in the assessment of resection margins in the setting of intraoperative frozen sections. Apart from the typical signet ring cell carcinomas best known from the stomach, signet ring cells have been in many tissues and cell systems (review: Wang et al. 2003). Typical situations include acute inflammations, such as acute erosive gastritis (Dimet et al. 2004), pseudomembranous colitis (Schiffman 1996; Damiani and Campidelli 2002; Abdulkader et al. 2003), and ischemic enteritis (Galli 2000; Biedrzycki et al. 2005). Macrophages can undergo a change that is hardly distinguishable from neoplastic signet ring cells. The best example is signet ring cell sinus histiocytosis of lymph nodes (mucicarminophilic histiocytosis), an alteration that may easily be confounded with cancer metastasis without performing immunohistochemistry (Gould et al. 1989; Frost et al. 1992; Guerrero-Medrano et al. 1997; Groisman et al. 1998; Pathi et al. 2009). This type of lymph node pathology is mimicked by mucicarminophilic histiocytosis caused by polyvinylpyrrolidone (Kuo and Hsueh 1984). A part of these situations share acute mucosal and epithelial damage associated with inflammatory reactions, probably causing dropout of damaged mucin-rich cells/goblet cells. In fact, NNSRCs in enteritis are found as dissociated cells within the lumina of damaged dilated crypts, and immunohistochemistry showed that the cells had a striking localization to the lower aspect of the altered

mucosa, in the absence of the cells within the mucosal connective tissue (Biedrzycki et al. 2005). That acute cell damage may cause a signet ring cell-like change supported by the observation that thermic damage can induce such a cytological change, e.g., signet ring cells found in prostatic tissue of transurethral prostatectomy specimens (Alguacil-Garcia 1986), and signet ring cell change of stromal fibroblasts after thermocauterization of the uterine cervix (McKenna and McCluggage 2008).

NNSRCs have been observed in the ulcerated gallbladder mucosa (Michal et al. 1998; Suri et al. 2001; Ragazzi et al. 2009). In these situations, there were focal collections of these cells both on the mucosal surface and within the lumina of glands. The cells were positive for Mayer's mucicarmine and were immunoreactive for keratin AE1/AE3. Typically, NNSRCs are, in contrast to their neoplastic counterpart, not embedded in a desmoplastic stroma. These cells, which were admixed with macrophages and other inflammatory cells, were interpreted to be damaged normal goblet cells (Ragazzi et al. 2009).

DOI 10.1007/978-3-319-26956-6_36

Abstract

Apart from classical cholangiocarcinoma with a desmoplastic adenocarcinoma morphology, several variants of these neoplasms are recognized. A part of these tumors differ from cholangiocarcinoma by the cell lineages involved, including intestinal, gastric foveolar, pyloric gland types, and carcinomas with Paneth cell metaplasia. One rare variant of bile duct carcinoma derives from cells of small ducts or ductules (cholangiolocellular carcinoma). Uncommon cholangiocarcinomas exhibit distinct growth patterns or cell arrangements, such as cribriform carcinoma, micropapillary carcinoma, and cholangiocarcinoma with a thyroid follicular neoplasm-like pattern. An unusual variant of cholangiocarcinoma displays a ductal plate malformation pattern. Very rare forms of cholangiocarcinoma show production of alpha-fetoprotein (AFP), with intracellular accumulation of AFP. This neoplasm has also been observed in children.

Cholangiocarcinoma: Intestinal, Gastric Foveolar, and Pyloric Gland Types

Introduction

A subset of cholangiocarcinomas of the extrahepatic and intrahepatic biliary tract is characterized by a glandular cell lineage deviating from the cholangiocellular phenotype. The mechanisms causing this phenotypic diversity have not been clarified, but pathways of metaplasia/transdifferentiation, stem cell effects, and the role of distinct cell systems present in the bile ducts but not yet characterized have been discussed.

Intestinal-Type Cholangiocarcinoma

Intestinal-type adenocarcinoma is well defined for the gallbladder (Albores-Saavedra et al. 1986b) but is less well known in the biliary tract. It has been described as a new entity in 2002 (Bae et al. 2002). These authors reported an intestinal-type cholangiocarcinoma in a large intrahepatic bile duct, associated with hepatolithiasis. The striking resemblance to colorectal carcinoma may pose differential diagnostic problems, but the imaging features will help in the decision process. Intestinal cellular features may be focally expressed in intrahepatic cholangiocarcinoma (Nakanuma et al. 2003). Distal bile duct carcinoma with an intestinal phenotype has been suggested to have arisen in a hyperplastic mucosa showing metaplastic biliary epithelium of the intestinal type (Sano et al. 2003).

In the original description, the tumor showed mainly an intraductal papillary growth primarily composed of absorptive columnar cells, and Paneth cell metaplasia was widespread, and goblet cells and neuroendocrine cells were also observed (Bae et al. 2002). Otherwise the histology of this variant is characterized by tubular structures and papillary formations consisting of columnar cells of the intestinal/colonic type and by pseudostratification of the elongated atypical nuclei, with or without interspersed goblet cells or Paneth cells. On cytology aspirates, intestinal-type cholangiocarcinoma mimics colorectal adenocarcinoma, columnar cells having cigar-shaped nuclei with marked atypia, crowding, and pseudostratification, on a background with signs of necrosis (Chaudhary et al. 2005). The bile duct mucosa adjacent to the tumor may show intestinal metaplasia and dysplastic changes in these areas (Bae et al. 2002).

Intraductal papillary neoplasia of the liver (IPNL) often presents gastrointestinal metaplasia with aberrant expression of MUC2 and MUC5AC and oversecretion of mucin into the ductal lumen. Aberrant expression of CDX2, a homeodomain protein involved in the regulation of intestinal development and differentiation, is closely related to the overexpression of MU2 in IPNL associated with hepatolithiasis (Ishikawa et al. 2004).

Pyloric Gland-Type Cholangiocarcinoma

A pyloric gland component seems to a rather common change in intrahepatic cholangiocarcinomas. In one study, albeit defining the

tumors also through MUC typing, 11/100 intrahepatic cholangiocarcinomas were of the pyloric gland type (Aishima et al. 2006).

Gastric Foveolar-Type Cholangiocarcinoma

Gastric foveolar-type cholangiocarcinoma is a rare variant of well-differentiated adenocarcinoma that has been found in the extrahepatic bile ducts (Albores-Saavedra et al. 1999). The tumors were composed predominantly (>95 %) of gastric foveolar-type epithelium. The resemblance to gastric epithelium in this variant of cholangiocarcinoma has caused confusion with adenocarcinomas of the gallbladder (Albores-Saavedra et al. 1999). This variant of cholangiocarcinoma has subsequently been observed. Among 100 intrahepatic cholangiocarcinomas, a gastric foveolar type was found in 36 of the tumors, i.e., with a very high frequency, but the tumor subtyping was also based on the expression pattern MUC gene products. According to the expression frequency of MUCs (MUC2, MUC5AC, and MUC6), the tumors were classified into the following groups: null type, gastric foveolar type, pyloric gland type, and gastric combined type (Aishima et al. 2006). The tumors originally described in 1999 (Albores-Saavedra et al. 1999) were morphologically defined and were located in the extrahepatic bile ducts. Half of intrahepatic cholangiocarcinomas with a gastric foveolar phenotype were located in the hilar region of the liver. The gastric foveolar type was associated with a higher incidence of lymph node metastases and was more often associated with an aggressive course and worse survival (Aishima et al. 2006).

Histologically, the neoplastic glands are lined by a single layer of rather tall columnar cells rich in mucin. These reveal basal nuclei with minor structural anomalies, small nucleoli, and a low mitotic activity. Focally, a micropapillary or polypoid to lobular growth patterns may be noted (Albores-Saavedra et al. 1999). Foci of less differentiated adenocarcinoma and perineural invasion were reported for the first two cases. The neoplastic cells and extracellular mucin were PAS and Alcian Blue positive (Albores-Saavedra et al. 1999). Aspirate smears of this variant of cholangiocarcinoma show cuboidal-to-columnar epithelial cells with relatively bland nuclear features, low nuclear-cytoplasmic ratios, and an abundant, mucin-producing cytoplasm (PAS, mucicarmine, and alkaline Alcian Blue positive), this morphology resembling gastric foveolar-type epithelium (Chaudhary et al. 2005). Focal expression of a gastric foveolar-type neoplastic epithelium has been observed in intraductal papillary cholangiocarcinoma associated with von Meyenburg complexes (Neto et al. 2007). Similar to normal gastric foveolar epithelium, the tumor cells are reactive for cytokeratins 8 and 20 and for cathepsin D, as reported for normal foveolar cells (Albores-Saavedra et al. 1999).

Pyloric/Pseudopyloric Gland (Antral) Metaplasia of the Biliary Tract

Pyloric gland metaplasia (antral metaplasia) is well known to occur in the gallbladder, the pancreas, and the colon, in the organ usually in the context of inflammatory bowel disease. In the gallbladder, this type of metaplasia is sometimes extensive and complex (Laitio 1975, 1976) and may represent a component of metaplasia-dysplasia-carcinoma sequence (Azadeh and Parai 1980; Hirai 1980; Lewis et al. 2007). Gallbladder adenomas consisting of pyloric-type cells can develop pyloric gland-type adenoma, co-expressing gastric and biliary phenotypes (Nagata et al. 2007), and gallbladder adenocarcinomas can undergo a differentiation toward gastric foveolar cells (Kushima et al. 1996). Cells of pyloric gland metaplasia are reactive for lysozyme, class III mucin (Tsutsumi et al. 1984).

In contrast, less is still known regarding pyloric metaplasia in bile ducts. Gastric/pyloric metaplasia resembling the morphologic features of pyloric glands may be observed within and near pathologically altered large intrahepatic bile ducts, together with the expression of gastric epithelial-type mucins, i.e., MUC5AC and MUC6 (Sasaki et al. 1998; Hoang et al. 2001; Nakanuma

et al. 2003). Among 42 pancreaticoduodenectomy specimens (32 with neoplastic lesions and 10 with inflammatory changes of the extrahepatic bile ducts), 40 % of the neoplastic specimens and 70 % of the inflammatory specimens had metaplastic changes in the extrahepatic bile ducts, and pyloric gland metaplasia was the most common change (80 % of the metaplasias). Only 5 % of the metaplasias were of the intestinal type, 10 % were mixed pyloric and intestinal metaplasia, and 5 % had a component of squamous metaplasia. None of the normal bile ducts obtained from ten autopsies had metaplastic changes (Hoang et al. 2001). The predominance of pyloric gland metaplasia in the bile duct system was also documented in other studies (Tsuru 1984; Kurumaya et al. 1990). In an investigation of 22 cases of hepatolithiasis, intrahepatic bile ducts had pyloric gland metaplasia in all cases, and the rate of intestinal metaplasia was (23 %), i.e., much higher than in bile ducts having cholangiocarcinoma or inflammation not related to lithiasis (Kurumaya et al. 1990). The biologic behavior of cells in pyloric gland metaplasia, apart from being a potentially precancerous lesion, is only partly known. In the gallbladder, pyloric gland metaplasia is usually confined to the lamina propria of the mucosa, but the so-called florid variant extends to the muscular wall and serosa, mimicking cancer invasion (Albores-Saavedra et al. 1993). Intriguing are observations that florid pyloric gland metaplasia, albeit benign, may show perineural and intraneural invasion, e.g., in the gallbladder (Albores-Saavedra and Henson 1999).

Intestinal Metaplasia

In the gallbladder, intestinal metaplasia has been studied in detail (Järvi and Laurén 1967). The extent of metaplasia differs as a function of the presence of endocrine cells: in the absence of endocrine cells, intestinal metaplasia was restricted to isolated or small clusters of mature goblet cells. While gallbladders with endocrine cells showed, in addition, gland-like structures resembling colonic crypts and Paneth cells (Albores-Saavedra et al. 1986a), colonic-type epithelial metaplasia is found in hyperplastic and dysplastic biliary epithelia (Shimonishi et al. 2002), sometimes associated with goblet cell change and formation of Paneth cells in peribiliary glands. Goblet cells in intestinal metaplasia stain for antigen 17NM (Hughes et al. 2006), 17NM being an antigen expressed in the mucus vacuole of colonic goblet cells and detectable by a monoclonal antibody (Hughes et al. 1986).

For intestinal metaplasia in the biliary tract, less information is available (Järvi and Laurén 1967), but it is considered as a precancerous state (Iguchi et al. 1982). In a retrospective study, up to 20 % of cases of bile duct cancer and gallbladder cancer displayed intestinal metaplasia in the surrounding mucosa, with Paneth cells, enterochromaffin cells, and goblet cells (Kozuka et al. 1984). In a study comparing bile duct mucosa in autopsy cases and surgical specimens with and without cholangiocarcinoma, pyloric gland metaplasia was generally more often seen than intestinal metaplasia characterized by goblet cells, although bile ducts with cholangiocarcinoma revealed a higher yield of goblet cells than bile ducts with benign obstruction (Tsuru 1984). Among 22 cases with hepatolithiasis, intestinal metaplasia with goblet cells and Paneth cells amounted to 23 %, while all cases had pyloric gland metaplasia (Kurumaya et al. 1990).

Paneth Cell Carcinoma of the Biliary Tract

Paneth Cells in Neoplasia

Contribution of Paneth cells has been described in several tumor types and tumor localizations, including the duodenum, small intestine, colon, appendix, and stomach (Gibbs 1969; Miyajima and Takeguchi 1976; Shousa 1979; Heitz and Wegmann 1980; Lundqvist and Wilander 1983; London et al. 1988; Wada et al. 1992; Serio and Zampatti 2000). Paneth cells participate in the adenoma-carcinoma sequence in that precursor lesions in the colon may show Paneth cell

metaplasia (Wada 2009). A Paneth cell differentiation may take place in tubular adenomas of the colon (in minute adenomas in up to 32.5 % of cases; Wada et al. 1992) and in some benign neoplasms, e.g., adenomyoma of the ileum (Takahashi et al. 2006). The biliary tract is rarely involved, and Paneth cell tumors mainly develop in the ampulla of Vater. Widespread Paneth cell metaplasia was observed in an intrahepatic intestinal-type cholangiocarcinoma with intraluminal spread, associated with hepatolithiasis (Bae et al. 2002).

Paneth Cell Tumors of the Ampulla of Vater

Variable contributions of Paneth cells have been noted in few malignant tumors of the ampulla of Vater (Ferrell and Beckstead 1991; Kimura et al. 1994; Mora et al. 2004). The case reported by Mora et al. (2004) was that of 64-year-old man who presented with obstructive jaundice. Cholangiography revealed an ampullary stricture and biopsy showed adenocarcinoma. The resected specimen of the ampulla showed a yellow-tan mass within the mucosa measuring up to 2.3 cm. Histology displayed a moderately to poorly differentiated carcinoma. The neoplastic cells formed rudimentary, misshapen, gland-like structures, whereas other areas showed haphazardly arranged cells. Most of cells had a rich cytoplasm with coarse and brightly eosinophilic granules which immunohistochemically expressed lysozyme. Lysozyme was also detected in the tumor reported by Ferrell and Beckstead (1991). It is currently unknown whether neoplastic Paneth cells recapitulate the capability of normal Paneth cells to create a niche for (neoplastic) stem cells.

Paneth Cell Tumors of the Gallbladder

Intestinal-type adenocarcinoma of the gallbladder can contain few Paneth cells (Albores-Saavedra et al. 1986b), but extensive Paneth cell metaplasia has been observed in gallbladder adenocarcinoma only very rarely (Sakaki et al. 2000).

Paneth Cells Are Highly Specialized Intestinal Cells Involved in Innate Immunity

Paneth cells are specialized cells found at the bottom of crypts of the entire intestine and proximal colon, including the appendix. They contain specific granules which contain lysozyme, defensins, and IgA (Geller and Thung 1983). In the intestinal crypts, mature Paneth cells constitute the niche for Lgr5 stem cells. Genetic removal of Paneth cells in vivo results in the concomitant loss of Lgr5 stem cells, but this Paneth cell requirement can be substituted by a pulse of exogenous Wnt (Sato et al. 2011). The differentiation pathways of specific crypt cell derivatives are regulated by an intricate factor system, mainly involving notch/gamma-secretase inhibitors which block crypt cell proliferation and induce secretory cell differentiation. The atonal homolog 1 (Atoh1) transcription factor is required for all effects of the notch/gamma-secretase inhibitor (Kazanjian et al. 2010). The goblet cell lineage, characterized by the expression of goblet cell genes AGR2, MUC2, RETLNB, and SPINK4, is induced by the epithelial ETS transcription factor, SAM pointed domain ETS factor (SPDEF) (Noah et al. 2010). In the Paneth cell differentiation pathway, APC/beta-catenin/Tcf signaling plays a role (Joo et al. 2009), and Paneth cell maturation depends on E-cadherin which is required for the intestinal epithelial lining by providing mechanical integrity (Schneider et al. 2010).

Paneth cells have a central role in intestinal antimicrobial defense and innate mucosal immunity (Quellette 2010). Paneth cells produce alpha-defensin peptides (mainly the human alpha-defensins [HDs] HD-5 and HD-6) which modulate the complex composition of the intestinal microflora. Defensins are small cysteine-rich cationic proteins which exist in both invertebrates and vertebrates, are produced by leukocytes or Paneth cells, and are active against bacteria, fungi, and enveloped and non-enveloped viruses. Alpha-defensins (synonym: cryptdins) are a group of antimicrobial peptides encoded by the genes DEFA1 (neutrophil defensin 1), DEFA1B (defensin alpha 1),

DEFA3 (neutrophil defensin 3), DEFA4 (corticostatin, neutrophil defensin 4), DEFA5 (Paneth cell specific, defensin 5), and DEFA6 (Paneth cell specific, defensin 6). Beta-defensins are the most widely distributed defensins and are secreted by leukocytes and epithelial cells of many kinds. They comprise DEFB1 (beta-defensin 1), DEFB2 (beta-defensin 2), and DEFB103A (beta-defensin 103), DEFB107B (beta-defensin 107), DEFB110 (beta-defensin 110), and DEFB136 (beta-defensin 136). q-defensins are rare, have been identified in leukocytes of rhesus macaque and olive baboons, and are vestigial in humans and other primates (DEFT1P). It follows that two alpha-defensin species are produced by Paneth cells, i.e., defensins 5 and 6 (Defensin database, Singapore; Quellette 2005; Mastroianni and Quellette 2009). Ligation of Toll-like receptor 9 (TLR9), e.g., by the action of *Toxoplasma gondii*, leads to Paneth cell degranulation and release of defensins (Buzoni-Gatel 2010; Foureau et al. 2010). In Crohn's disease, alpha-defensins 5 and 6 are specifically reduced, and ileal extracts from Crohn's disease patients are comprised in clearing bacteria, and enteroadherent *Escherichia coli* colonize the mucosa ("Paneth's disease"). The mechanisms for defective antimicrobial Paneth cell function in Crohn's disease are complex and include an association with a NOD2 loss of function mutation, a disturbance of the Wnt pathway transcription factor TCF7L2 (TCF4), the autophagy factor ATG16L1, the endosomal stress protein XBP1, the Toll-like receptor TLR9, the calcium-mediated potassium channel KCNN4, as well as mutations or inactivation of HD5 (Wehkamp et al. 2007; Wehkamp and Stange 2010). Defensin-4 (cryptdin-4) has the most potent microbicidal activity and predominantly affects noncommensal bacteria (Masuda et al. 2011). Human defensin-5 is one of the major antimicrobial peptides secreted by Paneth cells in the human small intestine. As the other defensins, defensin-5 is produced and stored as a propeptide in Paneth cell granules, secreted in response to stimulation by cholinergic reagents or bacterial components. The activation process involves trypsin (Ishikawa et al. 2009). Human defensin-5 is expressed in Paneth-type gastric cancer cells (Inada et al. 2005).

Cholangiolocellular Carcinoma and Bile Ductular Carcinoma

Carcinomas of Small Bile Ducts

A small subset of cholangiocarcinomas have features of, or eventually arise from, bile ductules. These tumors are termed cholangiolocellular carcinoma or bile ductular carcinoma (Steiner and Higginson 1959; Mukerjee and Maheshwari 1964; Shiota et al. 2001; Sasaki et al. 2003; Kim et al. 2004). Two variants of these unusual tumors have been described.

Cholangiolocellular Carcinoma

Cholangiolocellular carcinoma (CLC) is a rare subtype of cholangiocarcinoma that has been described in 1959 (Steiner and Higginson 1959). CLC is characterized by a neoplastic proliferation of small cholangiocytes of a type normally found in ductules, the cholangioles. Since 1959, relatively few cases have been reported.

CLC accounts for about 1 % of all primary liver cancers. Steiner and Higginson described the tumor as being characterized by small epithelial profiles resembling cholangioles or the canals of Hering and ductular reaction-like anastomosing glands in abundant fibrous stroma.

Selected References Mukerjee and Maheshwari 1964; Sugihara et al. 1987; Yamamoto et al. 1996; Fukukura et al. 2000; Takeuchi et al. 2005; Okuda et al. 2005; Matsuda et al. 2006; Kanamoto et al. 2008; Joshita et al. 2009; Motosugi et al. 2009; Asayama et al. 2010; Sempoux et al. 2011; Iwahashi et al. 2013; Maeda et al. 2013.

The term cholangiolocellular carcinoma was first employed by Steiner at the Kampala Conference on liver cancer in 1956 (Steiner 1957).

In their publication of 1959, Steiner and Higginson noted that "in theory, a tumor should exist that corresponds to every type of normal cell in the body in which division can occur. On this basis one gap has persisted in carcinomas of the liver; no tumor has been described that corresponds to the epithelium of the cholangioles or canals of Hering (end of quotation)" (Steiner and Higginson 1959). In 1959, Steiner and Higginson described a series of 11 liver carcinomas that seemed to meet the criteria for designation as cholangiolocellular carcinoma. An analysis of the previous literature showed that this lesion is unusual. It did not occur in a series of 100 liver cancers reported from Los Angeles by Edmondson and Steiner (1954), and one case was found among a total of 40 in Chicago (Steiner 1957). In a total of 863 liver cancers in Trans-Saharan native Africans studied by Steiner in 1957, in nine different case collections, there were ten additional examples of this tumor (cited in Steiner and Higginson 1959). In their review of 1959, these authors refer to potential other previous cases in the literature, mainly based on published figures of liver cancers. For example, Fig. 5 in a 1911 book on liver cancer may show this tumor (Goldzieher and von Bökay 1911), and in Ninard's book on liver tumors, Fig. 175 illustrates a tumor that may represent cholangiolocellular carcinoma (Ninard 1950). In the case review of 1959, the overall frequency was, therefore, 11 cholangiolocellular carcinomas among 1030 primary liver cancers of all types or about 1 %. The sex ratio was four cases in women and seven in men, which is similar to that seen in cholangiocarcinoma. The range in age was from 22 to 64 years, with an average age of 49.5 years. In a more recent study, two cases were identified among 708 consecutively resected cases of primary liver cancer or 0.56 %, with an average patient age at presentation of 66 years, i.e., much higher than in Steiner and Higginson's study (Shiota et al. 2001).

CLC may represent a progenitor/stem cell-derived neoplasm. CLC seems to have "junctional potentialities" because part of CLC had HCC-like features (Steiner and Higginson 1959). This was the first observation suggesting that this neoplasm might be related to a stem cell process. CLC has been proposed to originate from cells of cholangioles or canals of Hering, structures that harbor progenitor cells (Roskams et al. 2004). More recent findings in fact suggest a derivation from hepatic progenitor cells, with immunoreactivity of CLC cells for keratins 7 and 19, prominin-1, OCT4, and c-Kit (Komuta et al. 2008). An immunohistochemical study revealed positivity of CLC cells for the stem cell markers CD133, EpCAM, and CD44 (Iwahashi et al. 2013). That the pathogenesis of CLC is strongly linked to stem/progenitor cells is supported by the findings that this neoplasm can contain hepatocellular carcinoma (HCC) and/or cholangiocarcinoma components, suggesting the involvement of a bipotential progenitor cell (Kanamoto et al. 2008). Out of 30 cases, 19 showed papillary and/or glandular formations with mucin production, representing areas of cholangiocarcinoma, and all cases exhibited HCC-like areas, mainly at tumor boundaries (Komuta et al. 2008).

Among 30 patients, a single tumor was observed in 25 (83.3 %), whereas multiple (2–8) tumors considered as intrahepatic metastases were found in five patients (16.7 %). Coexistence of HCC was detected in three patients. Maximum tumor diameter ranged from 0.8 to 11 cm (mean, 4.9 cm) (Komuta et al. 2008). CLC may be associated with seropositivity for AFP-L3 alone, with low AFP serum concentration (Okuda et al. 2005). The clinical behavior of CLC has not been clarified in detail, but may be similar to intrahepatic cholangiocarcinoma (Maeda et al. 2013). In the study of Komuta et al. (2008), tumors with a diameter greater than 4 cm showed a higher recurrence rate compared to smaller CLC cases. Rapidly progressing CLC has been reported (Takeuchi et al. 2005). On dynamic CT or MRI, the tumors presented hypervascular masses with delayed washout, the lesions showing peripheral enhancement with concentric delayed filling (Fukukura et al. 2000; Asayama et al. 2010). On arterial phase images, tumors appeared as masses exhibiting early and complete enhancement or predominantly peripheral enhancement. Retention of contrast media in the masses was detected

in half of the lesions (Motosugi et al. 2009). Persistent enhancement in the late phase by contrast-enhanced CT has been described (Joshita et al. 2009). It seems that early enhancement with persistent delayed enhancement is a characteristic feature of this rare tumor.

Macroscopic Pathology

Macroscopically, tumors were described as whitish in color, solid, lobulated, not encapsulated, and with irregular margins (Komuta et al. 2008). The liver with cholangiolocellular carcinoma usually shows numerous small nodules up to several cm in diameter in part of the liver or in the entire organ. The lesions develop mostly in a non-cirrhotic liver. The nodules may show some confluence, and one nodule may be larger and dominant. The nodules are firm and creamy in color. The average weight of the tumor-bearing livers was, in the review of 11 cases (Steiner an Higginson 1959), 2916 g, an average which is about 500 g less than that for hepatocellular carcinoma in African natives, but about 500 g more than that for a series of cholangiocarcinoma (Steiner, unpublished data; cited in Steiner and Higginson 1959). Metastases were present in seven of the ten patients upon whom an autopsy had been performed, and the primary metastatic sites were the portal lymph nodes and the lungs.

Histopathology

The tumor is chiefly (90 %) composed of small monotonous and/or antler-like anastomosing glands resembling abnormal ductular reactions and forming moniliform structures (Fig. 1). Typically, the neoplastic cells are arranged in cords that usually appear solid but may show miniature lumina or form small ductules resembling ductular profiles. In these areas, the tumor cells are cuboidal and clearly smaller than normal hepatocytes. Unlike the cells of ordinary cholangiocarcinoma, the cells of cholangiolocellular carcinoma are often slightly eosinophilic. They

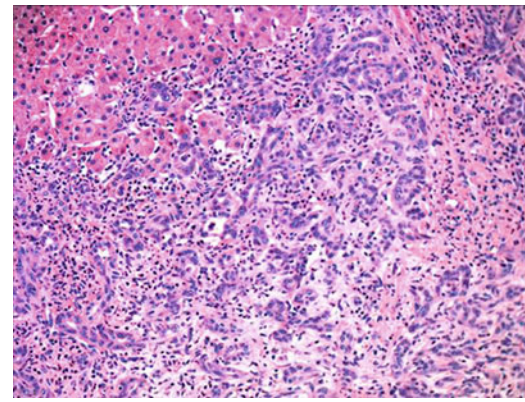

Fig. 1 Cholangiolocellular carcinoma (hematoxylin and eosin stain)

have a scanty cytoplasm and small round nuclei with distinct nucleoli, the nuclei being slightly atypical in comparison with cells of normal ductules. In addition, papillary and clear cell glandular formations resembling ordinary cholangiocarcinoma are seen. Where an apical domain facing a lumen is present, the apical membrane is positive in Mallory's phosphotungstic acid stain. Cholangiolocellular carcinoma, similar to ordinary cholangiocarcinoma, is a markedly desmoplastic lesion. Desmoplasia has been documented in studies (Goldzieher and von Bökay 1911; Steiner and Higginson 1959; Shiota et al. 2001). This stroma may appear pale owing to a high content in interstitial glycosaminoglycans and exhibits a variable cellularity. In grossly firm and larger tumor nodules, the central parts tend to be densely fibrous, with only scarce cancer cells. Necrosis may also be found in these central regions.

At the tumor border, solid or trabecular components mimicking HCC are found. In a series of six cases, two cases contained HCC-like areas in addition to the cholangiolocellular component (Shiota et al. 2001). In another study, all cases showed HCC-like areas, mainly at the tumor boundary (Komuta et al. 2008). Based on morphology, a putative transition of hepatocytes into cholangiolar cells in such tumors had already been proposed in 1911 (Goldzieher and von Bökay 1911). Here, the cells are mildly atypical and have an abundant eosinophilic cytoplasm. The HCC-like

cells seem to replace the normal adjacent liver cell plates, with only scanty stroma. These three patterns reveal transitional zones with each other (Komuta et al. 2008). The association of CLC with HCC in the same lesion (Sugihara et al. 1987) or with ordinary cholangiocarcinoma and a component representing HCC (Kanamoto et al. 2008) has been described. CLC has also been observed in combination with HCC located elsewhere in the liver (Matsuda et al. 2006). The main part of CLC usually shows an abundant stroma with edema, hyalinization, and focal lymphocytic infiltrations.

The tumor cells of the predominant, pure CLC component are strongly positive for CK7 and CK19 (Shiota et al. 2001). pCEA showed an intraluminal staining pattern in all cases, but CD10 and Hep Par 1 are negative in these areas. 86.7 % of the cases showed immunoreactivity for NCAM, and in the CLC area, the tumor cells displayed a diffuse apical MDR1 expression and basolateral MRP1, MRP3, and BCRP expression (Komuta et al. 2008). At the tumor boundary, most cases show HCC-like trabecular areas with canalicular expression of CD10/polyclonal CEA and submembranous CK7 expression, a pattern resembling that of intermediate hepatocytes. In these HCC-like areas, small cells with scanty cytoplasm show strong cytoplasmic CK7 and CK19 reactivity, cells representing HPC (Komuta et al. 2008). As already outlined above, a part of tumor cells express several stem cell markers (Iwahashi et al. 2013). In contrast to bile duct adenomas and ductular reactions, CLC cells are reactive for the polycomb group protein, EZH2 (Sasaki et al. 2014).

CLC has to be distinguished from bile duct adenoma and circumscribed forms of benign ductular proliferations (Sempoux et al. 2011).

Bile Ductular Variant of Peripheral Intrahepatic Cholangiocarcinoma

Bile ductular intrahepatic cholangiocarcinoma (BD-IHC; "bile ductular carcinoma") is an uncommon subgroup of peripheral intrahepatic cholangiocarcinoma with an infiltrating growth pattern and a resemblance to ductular proliferations (Kozaka et al. 2007). These neoplasms are similar to the cholangiolocellular carcinomas described above, but in contrast to those, they form a subgroup of *peripheral* cholangiocarcinomas.

In one study, all peripheral CCs with a ductular phenotype comprised whitish nodules with a blurred margin against the surrounding liver. The adjacent liver did not seem to be compressed (Kozaka et al. 2007). In one systematic study, 15/24 peripheral cholangiocarcinomas exhibited the features of BD-IHC, with structures resembling reactive proliferating ductules (RBD) at both the peripheral and central parts of the nodules in 8/24 (the RBD/RBD phenotype) and with RBD-like structures at the periphery and ordinary CC in the center in 7/24 (the RBD/OAC phenotype) (Kozaka et al. 2007). At the periphery, RBD/RBD-type carcinoma cells were directly apposed to the adjacent hepatocytes, and a distinct infiltrating replacement growth pattern was in evidence. The central areas of RBD type showed variable dense fibrosis (desmoplasia) and even scarring, and ghostlike outlines of portal tracts or a nodular fibrous framework were found. Within the latter, cord-like carcinoma cell with pericellular fibrosis was identifiable, reflecting the replacement of hepatocellular cords of preexisting hepatic lobules or regenerative nodules by carcinoma cells. No fibrous capsules were encountered. In contrast to normal and mature small bile ducts and bile ductules, but similar to proliferating ductules, 75 % of RBD/RBD and 71.4 % of RBD/OAC showed a positive immunohistochemical reaction of the cancer cells for NCAM. Cytokeratins 7, 8, 18, and 19 were variably expressed in carcinoma cells of all cases.

Bile duct hamartomas may mimic liver metastases of BD-IHC (Nagano et al. 2006).

Pathogenesis

The presence of CK7-/CK19-positive hepatic progenitor cells (HPCs) in the tumor, cells that are also positive for prominin-1 (CD133), c-kit receptor, octamer-4 transcription factor, and leukemia

inhibitory factor, suggests a progenitor cell origin of CLC (Komuta et al. 2008). This is supported by the expression of stem cell markers EpCAM, CD133, and CD44 in these tumors (Iwahashi et al. 2013). HPCs normally exist in the smallest and peripheral-most branches of the biliary tree, the ductules, and the canals of Hering (review: Roskams et al. 2004). HPCs represent bipotential liver-specific adult stem cells that are activated when fully differentiated hepatocytes or cholangiocytes are injured or lost. HPC activation is histologically characterized by the presence of increased numbers of HPC and intermediate hepatocytes in the portal tracts in the lobular zone 1 adjacent to portal tracts, associated with an increase of periductular extracellular matrix and fibroblastoid cells (the periductular sheath). Cells of CLC may have undergone a cholangiocyte lineage switch that requires activation of notch (review: Roskams et al. 2010).

Cribriform Carcinoma of the Biliary Tract

Cribriform carcinoma of the biliary tract is a distinct variant of cholangiocarcinoma. The histology reveals a striking resemblance to infiltrating cribriform carcinoma of the breast, which is a well-established entity (Venable et al. 1990; Fig. 2). These breast tumors showed a positivity for sex steroid receptors in 69 % of cases (Venable et al. 1990). In the gastrointestinal tract, cribriform carcinoma has also been described in the pancreas (Kimura et al. 2001) and the gallbladder (Albores-Saavedra et al. 2008).

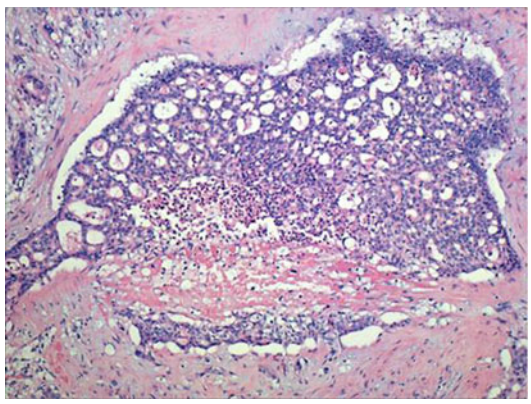

Fig. 2 Cribriform carcinoma of the bile duct (hematoxylin and eosin stain)

Micropapillary Cholangiocarcinoma (Bile Duct Adenocarcinoma with Micropapillary Components; Biliary Invasive Micropapillary Carcinoma, BD-IMPC)

Introduction

Invasive micropapillary carcinoma (IMPC) is a distinct variety of adenocarcinoma with an aggressive biology and a propensity to invade lymph vessels (lymphotropism) and to produce lymph node metastases (reviews: Nassar 2004; Yoshizawa et al. 2014). Histologically, the hallmark is a distinctive cleft formation around the neoplastic cell clusters which is presumably caused by the detachment of the epithelial cells from the stroma. It has been described in several organs, although the lesion is best known as a distinct, aggressive entity of breast cancer (Luna-Moré et al. 1994; Nassar et al. 2001; Zekioglu et al. 2004). The neoplasm has been observed in the major salivary glands (Nagao et al. 2004), lung (Amin et al. 2002), stomach (Kondo et al. 2008), biliary tract (see below), pancreas (Kitagawa et al. 2007), colon (Kuroda et al. 2007), and urinary bladder (Amin et al. 1994). In many of these tumors, the IMPC growth pattern was generally a focal component in otherwise typical invasive ductal carcinomas or other adenocarcinomas (Nassar et al. 2001).

Biliary Invasive Micropapillary Carcinoma (BD-IMPC)

Few examples of IMPC of the biliary tract have been reported (Kondo 2009; Yoshizawa et al. 2014). A tumor detected in the common bile duct was measuring 11 mm on cut surface and was histologically composed of conventional adenocarcinoma with severe neutrophil

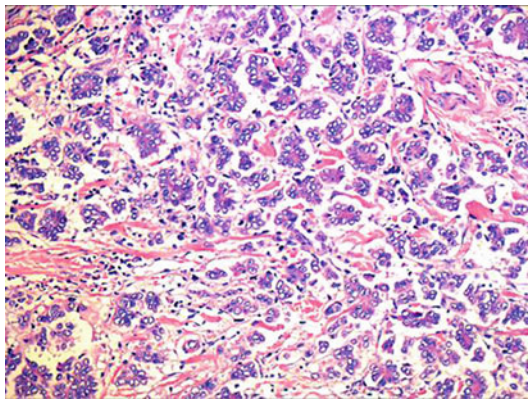

Fig. 3 Invasive micropapillary carcinoma of the bile duct. The small micropapillary structures are surrounded by a clear space (hematoxylin and eosin stain)

infiltration and a small focus (2 mm) of micropapillary carcinoma. The tumor showed marked lymphatic invasion. Resected regional lymph nodes revealed micrometastasis of a few cancer cells in a micropapillary pattern only in one lymph node (Kondo 2009). Yoshizawa and coworkers (2014) identified 13 tumors with an IMPC component among 93 consecutive cases of extrahepatic bile duct cancers. The presence of an IMPC component was significantly correlated with lymph node metastasis, lymphatic invasion, poor disease-free survival, and prognosis. IMPC also develops in the ampullary/periampullary region, with marked lymphotropism, and is associated with neutrophil infiltration, both within cancer epithelia and the stroma (Khayyata et al. 2005).

Histologically, the small-to-medium-sized cells form clusters or micropapillary structures that seem to float within clear spaces resembling lymphatic channels (Fig. 3). However, there is no immunoreactivity supporting the view that we deal with vascular channels (review: Nassar 2004). The clefts are an artifact and are not seen in frozen sections. The periphery of these clear spaces is formed by the contact border of the adjacent extracellular matrix of the stroma. The cell clusters consist of cells with an eosinophilic, finely granular-to-dense cytoplasm, contain nuclei with only moderate atypia, and display a variable mitotic activity. The tumor cells characteristically show a reverse polarity, termed an "inside-out" growth pattern. The clusters are devoid of fibrovascular cores and often show tubular profiles in their center. The stroma forms thin strands delineating the clear spaces, leading to a "spongy" appearance of the stroma. Immunohistochemically, the cells are characterized by MUC1 staining predominantly in the stroma-facing surface of the cell clusters in all cases (Nassar et al. 2004; Khayyata et al. 2005). E-cadherin expression was cytoplasmic rather than membranous, and the tumor stains for galectin-3 (Khayyata et al. 2005).

IMPC of the Gallbladder

In a study of 90 consecutive cases of gallbladder carcinoma, 20 cases had foci of IMPC, which ranged from 5 % to 10 % of the primary tumor tissue. Tumors with IMPC had marked lymphatic invasion, and for those 20 cases, 17 (85 %) also included lymph node metastasis, which was more frequent than in conventional carcinoma (32.8 %). This illustrates that lymphotropism is also a feature of gallbladder IMPC (Hara et al. 2010).

Differential Diagnosis

In light of the specific histology, only metastases may pose differential diagnostic problems. Bile duct wall metastasis from IMPC of the urinary bladder has been observed (Hong et al. 2002).

Pathogenesis

The highly characteristic feature of IMPC, i.e., the pericellular cleft formation, has not been clarified. It has, however, been suggested that the tumor cells may have undergone a reversal of their polarity or orientation ("inside-out growth") in regard to the adjacent matrix, based on the fact that EMA shows an inverse immunostaining and the glycoprotein MUC1 is largely limited to the basal surface of the cells and not, as usual, to the apical

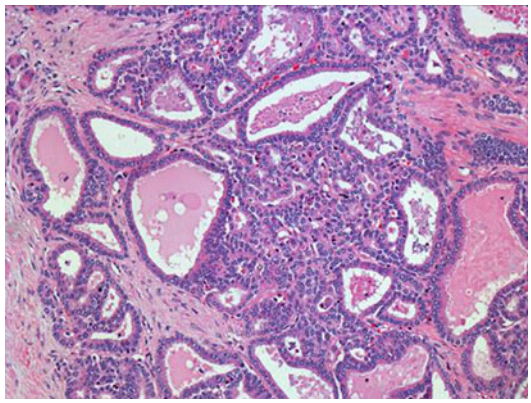

Fig. 4 Thyroid-like intrahepatic cholangiocarcinoma. This tumor shows numerous follicle-like structures mimicking follicular thyroid carcinoma (hematoxylin and eosin stain)

surface (Nassar et al. 2004). Cytoplasmic immunostaining for E-cadherin in IMPC (Khayyata et al. 2005) may also indicate loss or derangement of cell polarity.

Thyroid Follicular Neoplasm-Like Cholangiocarcinoma

In very rare instances, intrahepatic cholangiocarcinoma can present as a well-differentiated neoplasm with a prominent follicular architecture that resembles follicular carcinoma of the thyroid (Fig. 4). The follicular structures contain a colloid-like eosinophilic, homogeneous material with so-called resorption vacuoles, lined by uniform cuboidal cells. In contrast to follicular thyroid carcinomas, these tumor cells are negative for thyroglobulin and thyroid transcription factor-1 (Fornelli et al. 2010).

AFP-Producing Cholangiocarcinoma

Introduction

Alpha-fetoprotein (AFP) is a glycoprotein that is normally produced by fetal and regenerating hepatocytes, certain gastrointestinal cells, and yolk sac cells (Gitlin et al. 1972). Serum AFP is widely used as a tumor marker for diagnosis and follow-up of hepatocellular carcinoma, hepatoblastoma, and certain germ cell tumors. However, other tumors may rarely produce AFP at high serum levels, including hepatoid adenocarcinomas of the hepatobiliary tract (Abdullah et al. 2010), mixed hepatocellular and cholangiocellular carcinomas (Sasaki et al. 2001), renal cell carcinomas (Morimoto et al. 1988), collecting duct carcinoma of the kidney (Blandamura et al. 2005), certain gastric carcinomas (Adachi et al. 2003), distinct lung carcinomas (Saka et al. 1988; Yoshino et al. 1996), rare colorectal carcinomas (Nakajima et al. 1985; Hocking et al. 1995), acinar cell carcinomas of the pancreas (Itoh et al. 1992; Mueller et al. 2005), pancreatoblastoma (Iseki et al. 1986), and bile duct carcinomas.

AFP-Producing Cholangiocarcinoma

Elevated serum AFP has been detected in a minority of intrahepatic cholangiocarcinomas showing a histology typical for this tumor, i.e., without any evidence of a hepatocytic lineage. Elevation of serum AFP to levels higher than 20 ng/ml is found in approximately 20 % of intrahepatic cholangiocarcinoma patients (Liver Cancer Study Group of Japan 1990), but only very few patients with this type of tumor show an elevation of serum AFP to levels higher than 1000 ng/ml. The group with high levels mainly consists of typical intrahepatic cholangiocellular adenocarcinomas (Tanigawa et al. 1987; Nonomura et al. 1989; Omori et al. 2004; Ishikawa et al. 2007; Vij and Wang 2008; Zhou et al. 2008; Ishii et al. 2010). Among 131 patients who underwent surgical resection for pathologically confirmed intrahepatic cholangiocarcinoma, 32 showed serum AFP of more than 20 ng/ml, and among these AFP-positive cases, liver cirrhosis and positivity for HBsAg were more frequent than in the group with normal serum AFP (Zhou et al. 2008). A retrospective study of 429 intrahepatic cholangiocarcinomas diagnosed in China showed 90 patients with serum AFP >20 ng/ml (21.3 %; Shen et al. 2009). Production

of AFP was found to be more common in poorly differentiated cholangiocarcinomas (Nonomura et al. 1989). In AFP-producing cholangiocarcinomas, a part of the tumor cells are immunoreactive for AFP (Ishikawa et al. 2007).

Some intrahepatic cholangiocarcinomas are associated with elevated lectin-reactive AFP, but have low AFP levels (Okuda et al. 2005, 2006). In one 57-year-old female patient with Budd-Chiari syndrome, hepatocellular carcinoma was resected, and AFP returned to normal after surgery. However, *Lens culinaris* agglutinin-reactive AFP (AFP-L3) later increased, and ultrasonography showed a nodule 2 cm in diameter located in the left liver lobe, which was resected and exhibited the histology of tubular cholangiocellular adenocarcinoma with focal AFP immunostaining (Yamamoto et al. 2005). AFP production (up to 2265 ng/ml) has been observed in patients with a clear cell carcinoma arising from the extrahepatic bile duct (Kure et al. 2000; Miyazawa et al. 2006).

A subset of gallbladder carcinomas can produce AFP, mainly poorly differentiated variants (Haruta et al. 1987; Sugaya et al. 1989; Brown and Roberts. 1992; Ng and Ng 1995; Cocquyt et al. 1996; St. Laurent et al. 1999).

Pathogenesis

The pathogenesis of AFP production by cholangiocarcinomas has not been clarified. The fact that the tumor cells expressed CK14 and CD133 in one case suggested the contribution of a liver stem cell (Ishikawa et al. 2007). In one study, AFP enhancer/promoter-driven EGFP gene was transfected into human cholangiocarcinoma cell lines, and one of the lines expressed both AFP and EGFP. Clonal analyses revealed that one EGFP-positive cell generated both EGFP-positive and EGFP-negative cell fractions. However, one EGFP-negative cell never produced EGFP-positive cells. The AFP-producing cells were therefore suggested to be cancer stem cells (Ishii et al. 2010). Derepression of the AFP gene caused by genomic instability of the tumor may be an alternative hypothesis.

Cholangiocarcinoma with Ductal Plate Malformation Pattern

A small subset of intrahepatic cholangiocarcinomas is characterized by the presence of a "ductal plate malformation" pattern. In one case, the neoplasm was composed of numerous small carcinomatous areas with desmoplastic reaction, and neoplastic glandular structures exhibited a dilated lumen lined with a single layer of cuboidal to low columnar cells, resembling ductal plate malformation. The cells were reactive for cytokeratin 19, EMA, and epithelial cell adhesion molecule (Nakanuma et al. 2012; Choe and Kim 2014). A part of the features resemble those of ductal plate tumor, a neoplasm originally identified in a young adult (review: Zimmermann 2002).

Inflammatory Cholangiocarcinoma

A very rare variant of intrahepatic cholangiocarcinoma is characterized by high densities of tumor-infiltrating lymphocytes (TILs), similar to certain hepatocellular carcinomas. This alteration can be associated with autoimmune hepatitis-like features of the tumor-bearing liver (Izumi et al. 2010).

Abstract

Similar to clear cell hepatocellular carcinoma, rare variants of cholangiocarcinoma are characterized by clear cells that resemble cells of metastasizing renal cell carcinomas. Clear cell cholangiocarcinoma with a glandular or acinar pattern develops in extrahepatic bile ducts and in the gallbladder, but very rare forms have also been observed within the liver, whereby intrahepatic clear cell cholangiocarcinomas were usually small and peripheral lesions. These neoplasms exhibit a stromal reaction (desmoplasia) similar to that of classical cholangiocarcinomas. A very rare subset of clear cell cholangiocarcinoma shows a papillary component (clear cell papillary carcinoma of the liver).

Clear Cell Carcinoma of the Extrahepatic Bile Ducts

According to the histologic classifications for tumors of the gallbladder and biliary system from the World Health Organization, clear cell carcinomas of the biliary system are a special tumor type resembling metastatic renal cell carcinoma (Albores-Saavedra et al. 1991). Few single reports of this distinct lesions appeared in the literature (Paraf 1996; Gu et al. 2010). Vardaman and Albores-Saavedra reported the clinical and histologic characteristics of ten clear cell carcinomas of the gallbladder and extrahepatic bile ducts

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_37

detected in 7 of 550 patients with carcinoma of the gallbladder (1.3 %) and in 3 of 168 patients with carcinoma of extrahepatic bile ducts (1.8 %; Vardaman and Albores-Saavedra 1995).

Intrahepatic Clear Cell Cholangiocarcinoma

Several reports have document clear cell intrahepatic cholangiocarcinoma as a distinct entity (Nakajima et al. 1988; Logani and Adsay 1998; Haas et al. 2007; Fig. 1). In a large study, a clear cell component was identified in as many as 6 of 102 (5.9 %) intrahepatic cholangiocarcinomas (Nakajima et al. 1988). In one case, cholangiocarcinoma of the cystic duct exhibited clear cell change in lymph node metastases (Tajiri et al. 2006). The clear cell variant of peripheral intrahepatic cholangiocarcinoma has been reported very few times only (Adamek et al. 1998; Falta et al. 1999) and presents as rather small and nodular peripheral lesions. On one report, this unusual tumor was detected in a 50-year-old diabetic male who underwent open cholecystectomy for acute gangrenous cholecystitis. A mass measuring 1.5 cm was identified peripherally in the right lobe of the liver. Grossly, the lesion had a white appearance and a firm character. Histology showed a carcinoma consisting of clear cells growing in an acinar pattern and in form of nests embedded in a stromal matrix, with tumor cells seemingly emerging directly from bile ducts. The neoplastic cells were PAS-positive and this staining reaction was diastase resistant, indicating accumulation of mucin. Immunohistochemical staining showed reactivity for cytokeratins 7 and 8 and for epithelial membrane antigen (EMA), but not for CK20, and staining for CEA did not reveal the presence of a canalicular domain (Falta et al. 1999). The immunohistochemical differentiation from clear cell hepatocellular carcinoma has been specified (Adamek et al. 1998; Haas et al. 2007). The tumor cells have been shown to be positive for CK7, CK8, CK18, variably CK19, and CD56 (Haas et al. 2007). Electron microscopically, the neoplastic cells showed optical empty vacuoles, presumably representing lipid droplets. Only scanty glycogen granules were detected (Haas et al. 2007).

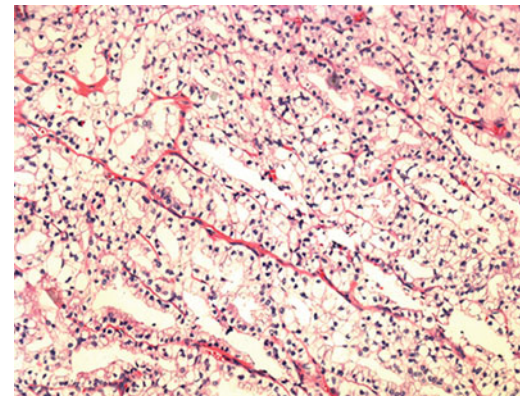

Fig. 1 Clear cell carcinoma of the bile duct (hematoxylin and eosin stain)

The immunostaining for CD56 is of both diagnostic and theoretical interest. In the liver, CD56 is associated with regeneration of damaged bile duct epithelium and is expressed in proliferated bile ductules and transiently during early developmental stages of the ductal plate. CD56 is expressed in bile duct adenomas, but only rarely in intrahepatic and extrahepatic cholangiocarcinomas (Gütgemann et al. 2006).

Clear Cell Papillary Carcinoma of the Liver (Clear Cell Papillary Cholangiocarcinoma)

A subset of clear cell cholangiocarcinomas show a papillary component. Only very few patients with this unique neoplasm have been reported in the literature.

One of these lesions was found in a 72-year-old patient with a liver mass not associated with elevated serum AFP (Tihan et al. 1998). Abdominal ultrasound revealed a 13 cm mass replacing the left lobe of the liver. Cut sections of the resection specimen disclosed a rubbery, tan-pink, solid 15 cm mass within the parenchyma, with lobulated borders that were sharply outlined. The center of the mass contained firm, yellow-gray, necrotic appearing components. On histologic

examination, the invasively growing neoplasm had a lobulated appearance with relatively cellular nests separated by stromal bands. There was a biphasic architecture, papillary and micropapillary areas (about 60 % of the lesion) projecting into small cystic spaces alternating with small glands and solid nests of cells. In the center, geographic necrosis was present. The cells had a clear cytoplasm and were cuboidal to columnar with ragged luminal borders. The cells forming glandular profiles and solid areas also had a clear cytoplasm. The mitotic rate was low. The cells stained focally positive with mucicarmine and showed diastase-sensitive PAS positivity. Immunohistochemically, the cells were reactive for cytokeratins 7, 8, and 19, but not for cytokeratin 20. EMA showed focal strong positivity. Ultrastructurally, the neoplastic cells were joined by scattered desmosomes and cell junctions. The cytoplasm contained numerous lipid droplets and clusters of beta-type glycogen particles. No bile canaliculi were noted. It was concluded that this tumor represents a distinct variant of peripheral cholangiocarcinoma (Tihan et al. 1998). A second example of this lesion had been observed in a 64-year-old female who underwent a partial hepatectomy for a liver mass measuring 12 cm in maximum diameter. Histologically, the tumor showed the pattern of clear cell cholangiocarcinoma, sometimes reminiscent of the histology of renal cell carcinoma, again with focal expression of a papillary phenotype (Logani and Adsay 1998). A similar case was reported more recently (Khera et al. 2014).

Alpha-Fetoprotein-Producing Clear Cell Carcinoma of Bile Ducts

This is a rare and unusual tumor, although some elevation of serum AFP may be observed in as much as 20 % of carcinomas of the intrahepatic bile ducts (Okuda and The Liver Cancer Study Group of Japan 1980). It has been reported as a clear cell cholangiocarcinoma located either to extrahepatic bile ducts (one case in the series of Vardaman and Albores-Saavedra 1995; Kure et al. 2000) or to the hilar/perihilar region (Miyazawa et al. 2006), associated with a significantly elevated serum AFP. In the patient reported by Miyazawa and coworkers, pathologic examination of a resected perihilar tumor (6 × 4 cm size) revealed a fragile composition with papillary-shaped structures growing into the duct lumen and forming frond-like growths, but glandular and solid profiles were also noted. The neoplastic cells were negative for the mucicarmine stain, but were immunoreactive for AFP (Miyazawa et al. 2006). AFP-positive carcinoma, albeit not of the clear cell type, has also been observed in the gallbladder (Haruta et al. 1987).

Differential Diagnosis

The differential diagnosis mainly includes clear cell tumors of a non-cholangiocytic lineage arising in the bile ducts or the gallbladder (with secondary involvement of bile ducts or liver). They mainly comprise clear cell carcinoma of the gallbladder (Bittinger et al. 1995; Paraf 1996; Piana et al. 2002; Vaillo et al. 2004), which also exists as a papillary variant (Sartelet et al. 2004), clear cell carcinoid tumors of the gallbladder and biliary tract (Sinkre et al. 2001; Konishi et al. 2003; Todoroki et al. 2007), which are in part associated with von Hippel-Lindau disease (Sinkre et al. 2001). Very small nodular clear cell cholangiocarcinomas may be confounded with clear cell type bile duct adenoma (Albores-Saavedra et al. 2001). Clear cell tumors metastatic to the liver mainly include renal cell carcinomas with a clear cell phenotype. The differentiation of primary vs. metastatic clear cell tumors in the liver is facilitated by cytokeratin immunohistochemistry and, for clear cell HCC, by in situ hybridization for albumin messenger RNA (Oliveira et al. 2000).

Bile Duct Tumors with Oncocytic Features

38

Contents

Abstract

Several bile duct tumors are characterized by the presence of oncocytes (bile duct tumors with oncocytic features). Oncocytes show an abundant, eosinophilic, and finely granular cytoplasm due to increased numbers of mitochondria. Similar to the exocrine pancreas, variants of intraductal papillary neoplasm of bile ducts (IPNB) are characterized by oncocytic neoplastic cells. Intraductal oncocytic papillary neoplasms of the bile ducts are rare neoplasms, but a focal or partial oncocytic change of IPNB may occur more frequently than anticipated. The cell lineage involved is not yet well elucidated, but oncocytic cells in these neoplasms can produce mucins. Few examples of intrahepatic cholangiocarcinoma with oncocytic change have been described. Rarely, biliary cystadenocarcinoma (malignant biliary mucinous cystic neoplasm) can show oncocytic features. An oncocytic variant of bile duct adenoma (peribiliary gland hamartoma) is known.

Introduction

Oncocytes were first described by Hamperl in 1931 as epithelial cells, which show abundant, eosinophilic, and finely granular cytoplasm by light microscopy due to an increased number of mitochondria. The cells are called oncocytes because of the "swollen" appearance they have

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_38

as a result of the striking accumulation of mitochondria. Oncocytic tumors represent a unique set of lesions with distinctive granular cytoplasmic eosinophilia of the neoplastic cells (reviews: Chang and Harawi 1992; Tallini 1998). Biliary tract tumors with oncocytic features are rare lesions. Part of these neoplasms have their phenotypic parallels in oncocytic intraductal tumors of the pancreas (Albores-Saavedra et al. 2005).

Intraductal Oncocytic Papillary Neoplasm of the Intrahepatic Bile Ducts

Intraductal oncocytic papillary neoplasms (IOPNs) were first described in the pancreas to differentiate a subset of pancreatic neoplasms from the intraductal papillary mucinous neoplasms (IPMNs) (Adsay et al. 1996) and were later identified among cases of intraductal papillary neoplasms of bile duct (IPNB). Three cases were reported in 2002, and all three presented with well-defined intrahepatic cystic masses ranging in size from 7.2 to 21.1 cm. The most prominent cells of the lining epithelium were columnar with oncocytic features showing abundant granular eosinophilic cytoplasm and a centrally placed nucleus (Martin et al. 2002). A further case was that of a 63-year-old male Japanese patient suffering from abdominal pain and jaundice. Imaging revealed a unilocular cystic neoplasm of 14 cm diameter in the left liver lobe. The tumor communicated with the left segmental intrahepatic bile duct, which contained mucus produced by the tumor. Histologically, the neoplasm consisted of papillary growth of atypical epithelial cells with oncocytic change. Atypical goblet cells were also present. Bile duct near the tumor exhibited dysplastic epithelial change. The tumor cell was immunoreactive for cytokeratins 7, 18, and 19 and for mitochondrial antigen (Terada and Taniguchi 2004). Other single cases have been reported (Spector et al. 2004; Ji et al. 2008; Lee et al. 2009; Cocieru et al. 2010; Liszka et al. 2010; Kakisaka et al. 2013; Watanabe et al. 2013). The prevalence of oncocytic features in intraductal papillary neoplasms may be higher than anticipated from case reports. Among 126 Japanese cases of IPNBs, 19 were oncocytic types (Nakanuma et al. 2014). In a collective of 119 mucin-producing intraductal papillary neoplasms of intrahepatic bile duct (M-IPNB), 23 were of the oncocytic type (Kubota et al. 2014). The biological significance of oncocytic features has not yet been sufficiently clarified. The lesion may be associated with a dysplastic and carcinogenic pathway. In one case, IOPN was associated with adenocarcinoma in situ apparently derived from IOPN (Watanabe et al. 2013). In an analysis of four cases of extrahepatic biliary tract IOPN, two of the lesions showed invasive growth, the invading cells having oncocytic features as well. None of the cases showed aberrant expression of Wnt signaling proteins (beta-catenin, E-cadherin, APC protein), although cyclin D1 was markedly overexpressed in all. Three of four cases showed the following mucin profile: MUC3, MUC4, MUC5A, MUC5B, and MUC6-positive (Rouzbahman et al. 2007). In a further series of six cases, four appeared grossly to be cystic neoplasms with papillary projections located in the liver and the other two were papillary neoplasms of the dilated hilar bile duct that ranged from 1.5 to 16 cm in size. The majority of the neoplastic cells had typical oncocytic features with marked positivity for mitochondrial antigen. Four neoplasms were mixed with minor components of non-oncocytic cells. The oncocytic cells as well as the non-oncocytic cells produced gastric-type mucin (MUC5AC and MUC6) and showed claudin-18 and Hep Par 1 positivity (Tanaka et al. 2009). The positivity for Hep Par 1, also known for IOPNs of the pancreas, was interpreted as a consequence of mitochondriosis, because Hep Par 1 binds predominantly to carbamoyl phosphate synthase 1, typically located in the mitochondria. What is the biological behavior of hepatobiliary IOPNs? Among 19 cases reviewed in 2009 (Tanaka et al. 2009), the mean age at diagnosis was 62 years, with a male to female ratio of 10:8. The mean diameter of the lesions was 5.9 cm, smaller than intraductal papillary neoplasms of

the bile ducts without oncocytic change (IPNB) (7.5 cm). Fifteen percent of the lesions were adenoma or borderline, 59 % noninvasive carcinoma, and 26 % invasive carcinoma. The mean overall survival was 20 months, shorter than that of IPNB (28 months). In contrast to IPNs, IOPNs lack K-Ras gene mutations (Liszka et al. 2010).

Intraductal Oncocytic Papillary Neoplasm of the Extrahepatic Bile Duct

IDPN with oncocytic features/IOPNs of the extrahepatic bile duct are very rare tumors. Among six cases of IDPN of the common bile duct, one tumor was composed of malignant oncocytes and was therefore regarded as intraductal oncocytic papillary carcinoma (Terada 2012).

Biliary tract IOPN has been described to derive from a peribiliary gland of a hepatic duct. In this situation, macroscopic examination of the surgically resected specimen revealed a reddish papillary tumor in the left hepatic duct just proximal to the bifurcation of the hepatic ducts. The biliary mucosa around the tumor was flat and focally reddish. The tumor itself displayed a polypoid appearance on the cut surface and originated from a cystic space in the bile duct wall. Histologically, the cystic space at the bottom of the tumor corresponded to a dilated peribiliary gland, covered by carcinoma in situ. There was a direct connection between the papillary oncocytic tumor and carcinoma in situ in the cystically altered peribiliary gland (Nakanishi et al. 2009).

Intrahepatic Cholangiocarcinoma with Oncocytic Change

Few examples of intrahepatic cholangiocarcinoma with oncocytic features of the neoplastic cells have been reported (Fujii et al. 2005; Güllüoglu et al. 2007). Focal oncocytic change has been noted in an intraductal growth-type mucin-producing peripheral cholangiocarcinoma associated with biliary papillomatosis (Güllüoglu et al. 2007).

Intrahepatic Cholangiocarcinoma with Multicystic Mucinous Appearance and Oncocytic Change

Extensive oncocytic change has been found in the multicystic and mucinous variant of intrahepatic cholangiocarcinoma, a distinct subtype of intrahepatic cholangiocarcinoma different from cystic carcinomas. The oncocytic variant of this tumor (Fujii et al. 2005) had macroscopically a spongy or honeycomb appearance. In this tumor, the numerous mucin-containing microcysts were lined by micropapillary adenocarcinoma cells with oncocytic features, reactive for mitochondrial antigen. This example illustrates that also oncocytic carcinomas may produce and secrete mucin.

Oncocytic Biliary Cystadenocarcinoma

Biliary cystadenocarcinoma with oncocytic change was first reported in 1992 (Wolf et al. 1992). This first patient was a 56-year-old male. The resected tumor was a well-demarcated cyst filled with numerous branching papillary fronds. The tumor cells had oncocytic features, and the mitochondriosis was proven by electron microscopy. Few further cases were described between 2001 and 2004. In the patient of Sudo et al. (2001), the tumor was observed in 71-year-old male who showed multicystic lesions in the left hepatic lobe. At autopsy, the tumor was found to be composed of adjoining multiple cystic lesions and a solid lesion with infiltration of the hepatic hilus. Histologically, the cysts were lined by a papillary epithelium with an oncocytic cytoplasm. The subepithelial matrix of the cysts did not reveal ovarian-like mesenchymal stroma. The solid component represents mucinous carcinoma with acidophilic and granular cells. It was suggested that this variant of cystadenocarcinoma is a form of intraductal oncocytic papillary neoplasm of the liver (Sudo et al. 2001). The neoplastic epithelia are immunoreactive for cytokeratin 7. Absence of mesenchymal stroma in oncocytic hepatobiliary cystadenocarcinoma was confirmed in later reports (Bardin et al. 2004).

Bile Duct Adenoma with Oncocytic Features

Oncocytic bile duct adenoma is a very uncommon variant of benign epithelial bile duct tumor (Arena et al. 2006). The lesion described by these authors was found incidentally at autopsy in a 57-year-old female patient. Macroscopically, the lesion was 3 mm in diameter, located to the right liver lobe. Histology revealed small to medium tubular structures with secondary cystic dilatation of some affected bile ducts. The epithelium of the tubules consisted of large granular eosinophilic cells with central small nuclei. No mitotic activity was noted. Immunohistochemically, the cells were positive for CEA, EMA, and cytokeratin 7, but negative for Hep Par 1.

Oncocytic Metaplasia of Biliary Epithelia

Oncocytic metaplasia of interlobular bile duct epithelia was observed in a patient with hepatic graft versus host reaction after bone marrow transplantation (Bligh et al. 1995).

Mucinous Cystic Neoplasms (MCN) and Related Cystic Neoplasms of the Hepatobiliary Tract

39

Contents

Abstract

Mucinous cystic neoplasms (MCNs) of the liver and biliary tract are cyst-forming epithelial neoplasms with cyst lines by a mucin-producing epithelium, frequently associated with a subepithelial cellular ovarian-like stroma. Noninvasive MCNs were previously termed mucinous hepatobiliary cystadenoma with mesenchymal stroma, whereas the invasive form was termed hepatobiliary cystadenocarcinoma. MCN are mostly located within the liver and present as solitary or multiloculated large cystic masses, but very rare microcystic variants have been reported. The neoplasms usually show an expanding growth pattern and can undergo secondary changes, including hemorrhage. Histologically, the cystic spaces are lined by a single layer of mucin-producing columnar cells, sometimes with papillary projections. The underlying stroma is hypercellular and forms a characteristic, ovarian-like tissue, with nuclear expression of estrogen receptors and/or progesterone receptors. The stromal cells are reactive for inhibin-alpha. Signs of malignant transformation are similar to those in other organs where a dysplasia-carcinoma sequence occurs, eventually resulting in invasive carcinoma.

ICD-O codes

MCN with low- or intermediate-grade intraepithelial neoplasia	8470/0
MCN with high-grade intraepithelial neoplasia	8470/2
MCN with an associated invasive carcinoma	8470/3

Introduction

According to the definition of the WHO classification (Tsui et al. 2010), mucinous cystic neoplasms (MCNs) of the liver and biliary tract are cyst-forming epithelial neoplasms with cysts lined by a cuboidal to columnar, variably mucin-producing epithelium resembling cholangiocytes, often, but not always, associated with an underlying subepithelial cellular ovarian-like stroma. MCNs are typically intrahepatic tumors, but MCNs also occur in the extrahepatic bile ducts and the gallbladder. With few exceptions, MCNs do not communicate with the bile duct system, in contrast to intraductal papillary neoplasms of the bile ducts. MCNs predominantly occur in women, but variants without an ovarian-like stroma also develop in males. MCN are principally subdivided into noninvasive and invasive (carcinomatous) forms. In noninvasive forms, the neoplasms are categorized based on the highest degree of atypia into MCN with low-grade dysplasia, MCN with intermediate-grade dysplasia, and MCN with high-grade dysplasia. In invasive forms, the invasive part originating from the dysplastic cyst lining has a morphology that is very similar to cholangiocarcinoma.

Formerly, noninvasive MCNs have been termed mucinous hepatobiliary cystadenoma with mesenchymal stroma (CMS; hepatobiliary cystadenoma with ovarian-like stroma), and invasive MCNs were named hepatobiliary cystadenocarcinoma (Table 1). For practical reasons, the term, cystadenocarcinoma instead of MCN associated with invasive carcinoma, is maintained in the present chapter.

Table 1 Comparison of current (WHO 2010) and previous nomenclatures of cystic epithelial neoplasms of the hepatobiliary tract

Previous nomenclature	Current nomenclature
Hepatobiliary cystadenoma	Mucinous cystic neoplasm (MCN)
	Low-grade dysplasia
	Intermediate-grade dysplasia
	High-grade dysplasia
Hepatobiliary cystadenocarcinoma	MCN with associated invasive carcinoma

Mucinous Cystic Neoplasm of the Liver (Hepatobiliary Cystadenoma)

Introduction

Biliary cystadenoma, or now termed MCN, was first described in 1889 under the term cystadenoma of the bile duct (Siegmund 1889). The first report of resection for biliary cystadenoma was made by Keen in 1892 (Keen 1892), followed about 10 years later by a second report (Bishop 1901). In the following years, these lesions were reported under a wide spectrum of terms, including multilocular cystadenoma (Bevan 1919), cystic adenoma of bile ducts (Evans 1921), bile duct cystadenoma (Snedecor 1967), biliary cystadenoma (Short et al. 1971), cystadenoma of the liver (Martin et al. 1973), and cystic hamartoma of the bile duct (Ansari et al. 1976). The lesion was comprehensively described in 1958, coining the tumors cystadenoma with mesenchymal stroma/CMS (Edmondson 1958; Wheeler and Edmondson 1985). The definition of CMS has undergone some changes as a function of time and the description of more and more lesions. In their 1985 publication, Wheeler and Edmondson specify that "The original suggestion that the term "cystadenoma" be confined to multilocular cystic tumors lined by mucin secreting columnar epithelium overlying a dense cellular (mesenchymal)

stroma (Edmondson 1958) has proved to be inadequate as review of the literature reveals that a number of the reported cystadenoma cases lack at least the cellular (mesenchymal) stroma." Recently, hepatic, pancreatic, splenic, and mesenteric mucinous cystic neoplasms (MCNs) have been proposed to be lumped together as extraovarian MCNs (Shiono et al. 2006).

Epidemiology

CMS amounts to about 4.5 % of intrahepatic biliary cystic lesions (Geist 1954) and occurs predominantly in adults and among these in middle-aged women (more than 85 %; mean age of 50 years). Relatively few reports of noninvasive MCN document the occurrence of CMS in males (Kazama et al. 2005). However, invasive forms, i.e., MCN associated with invasive carcinoma (the former cystadenocarcinoma), seem to occur in females and males with equal frequency. MCN associated with invasive carcinoma is diagnosed in an older patient age group (mean: 59 years as compared with 45 years for noninvasive MCN). A part of published MCN with invasive features, specifically those involving the extrahepatic bile duct system and occurring in males, would now be classified as intraductal papillary neoplasms (IPNs) of the bile ducts with marked cystic changes (see the respective chapter). MCNs of the liver and bile ducts are usually lesions not associated with other hepatobiliary pathologies, but MCN can occur in association with mucinous cystic tumor of the pancreas (Brachet et al. 2007). MCN is very uncommon in the pediatric age group, observed in children of 8 months to 4 years of age.

Selected References Alexander 1925; Claggett and Hawkins 1946; Warren and Polk 1958; Beasley et al. 1986; Williams et al. 1990; Wood et al. 1998; Senyüz et al. 2004; Tran et al. 2013. In regard to MCN in adults, several reports have appeared, in part with literature reviews (Daivella 1950; Courtois-Suffit and Chaleux, 1960; Williams 1961; Corrin 1962; Mondini 1962; Koban 1964; Snedecor 1967; Kosaka et al. 1968; Monnin 1969; Short et al. 1971; Martin et al. 1973; Merchant 1973; Forde et al. 1974; Marsh et al. 1974; Ishak et al. 1977; Cahill et al. 1982; Kokal et al. 1983; Nagorney et al. 1984; Organ and Petrek 1984; Wheeler and Edmondson 1985; Marcial et al. 1986; Okamura et al. 1987; Akwari et al. 1990; Adam and Nonas 1995; Busoni et al. 1996; Gadzijev et al. 1996; Tsiftsis et al. 1997; Kim et al. 1998; Hwang et al. 2000; Dixon et al. 2001; Florman and Slakey 2001; Owono et al. 2001; Barabino et al. 2004; Park et al. 2004; Sima et al., 2004; Thomas et al. 2005; Vogt et al. 2005; Yamashita et al. 2005; Beuran et al. 2006; Carson et al. 2006; Manouras et al. 2006; Teoh et al. 2006; Zhou et al. 2007; Fukunaga et al. 2008; Yu et al. 2008a; Qu et al. 2009; Yi et al. 2009; Bogert et al. 2010; Erdogan et al. 2010; Yu et al. 2010; Gad et al. 2011; Hennessey and Traynor 2011; Cecka et al. 2011; Doepker et al. 2011; Kim et al. 2011; Meng et al. 2011; Romagnoli et al. 2011; Sang et al. 2011; Yoon et al. 2011; Ahanatha Pillai et al. 2012; Ratti et al. 2012; Sendt et al. 2012; Fei et al. 2013; Martel et al. 2013; Soares et al. 2014.

Clinical and Imaging Features

Most of the lesions develop within the liver (more than 80 %; intrahepatic cystadenoma). Among the intrahepatic cystadenomas, 50 % occupy the right lobe, 35 % occupy the left lobe, and 15 % are bilateral lesions. Extrahepatic MCNs located to the hepatic ducts or common bile duct have also been observed, amounting to less than 10 % of all cases (Rogers 1946; Burhans and Myers 1971; Ansari et al. 1976; Ishak et al. 1977; Udoff et al. 1979; Thomsen et al. 1984; Byrne et al. 1989; Coulter and Baxter 1989; Nagorney et al. 1984; Hodgson and Bayjoo 1991; Davies et al. 1995; Kimura et al. 1998; Park et al. 2004; Shima et al. 2004; Hedayat et al. 2005; Mohan et al. 2006; Trummer et al. 2006; Seidel

et al. 2007). Extrahepatic cystadenomas have the following duct distribution: right hepatic duct, 14.3 %; left hepatic duct, 28.6 %; common hepatic duct, 32.1 %, common bile duct, 21.4 %; and cystic duct, 3.6 % (Davies et al. 1995). Among 19 patients with extrahepatic cystadenoma, 18 were female (Davies et al. 1995). Extrahepatic MCN may grow in an exophytic manner, producing a pedunculated mass (Sankar et al. 2009). MCNs located to the extrahepatic bile ducts have been hypothesized to arise from ectopic embryonic tissue destined to form the adult gallbladder. Chronic biliary obstruction caused by MCN of the common bile duct caused secondary biliary cirrhosis (Thomsen et al. 1984).

In the majority of cases, MCN are asymptomatic or oligosymptomatic, sometimes presenting with nonspecific abdominal discomfort or dull pain, mostly in the right upper quadrant, thought to be due to a mass effect (in 55 % of 53 patients reviewed; Akwari et al. 1990; Ahanatha et al. 2012). Diffuse abdominal discomfort was noted in 16 %, and 59 % complained of an abdominal mass that was freely movable with respiration and confirmed by physical examination in the right upper quadrant or epigastrium (review: Akwari et al. 1990). Acute pain may arise in intracystic hemorrhage or cyst infection, the latter also causing fever and eventually septicemia. Intermittent or constant and in part obstructive jaundice may occur in up to 39 % of patients (Akwari et al. 1990; Gadzijev et al. 1995; Nunes et al. 2006; Gonzalez et al. 2009; Li Petri et al. 2010; Saravanan et al. 2010; Harmouch et al. 2011; Soochan et al. 2012), associated with extrahepatic lesions or tumor-induced cholangitis (Ansari et al. 1976; Beretta et al. 1986; Buetow et al. 1995; Davies et al. 1995; Taketomi et al. 1998; Preetha et al. 2004; Erdogan et al. 2006; Siriwardana and Pathirana 2009; Ray et al. 2010). In a series of 19 extrahepatic cystadenomas compiled by Davies et al. (1995), jaundice was noted in 17 patients. Jaundice may be more commonly expected in cystadenocarcinoma (Kanamori et al. 1985). In a review of 35 analyzable patients compiled from the literature, the mean duration of symptoms before final treatment was 2.2 years and varied from 5 days to 17 years (Akwari et al. 1990). The detection of a cystic hepatic lesion associated with elevated serum CA 19-9 is highly suggestive of MCN and of good diagnostic help (Thomas et al. 1992; Horsmans et al. 1996; Lee et al. 1996; Mantke et al. 2001; Li et al. 2013), the CA 19-9 levels decreasing to normal after complete surgical resection (Kim et al. 1998). The cyst fluid of cystadenomas also shows elevated concentrations of CA 19-9 (Horsmans et al. 1996; Lee et al. 1996), and CA 19-9 is produced by the tumor epithelia where it can be demonstrated immunohistochemically (Thomas et al. 1992).

MCR may undergo complications such as "spontaneous" rupture (Chang et al. 1995; Lempinen et al. 2005; Elfadili et al. 2010; Sun et al. 2010), intracystic bleeding (Naganuma et al. 2006), infection, intermittent obstruction of the inferior vena cava (Catto et al. 1999), pleural effusion (Yu et al. 2012), and malignant transformation (see below). In an MCN with intracystic hemorrhage, contrast-enhanced sonography (CEUS) showed microbubbles oozing from the cyst wall into the cystic cavity after intravenous contrast injection (Naganuma et al. 2006). Exceptionally, MCN may cause bile duct obstruction via ingrowth of tumor into the extrahepatic duct system, sometimes with a tumor embolus-like lesion (Van Steenbergen et al. 1984; Beretta et al. 1986; Sielezneff et al. 1992; Sutton et al. 2000; Siriwardana and Pathirana 2009; Yi et al. 2009; Abe et al. 2012). In one patient, the dilated extrahepatic bile duct was filled with fluidlike matter at imaging, shown to be part of a cystic tumor originating from the intrahepatic duct of segment 4 and protruding into the duct lumen (Yi et al. 2009).

Ultrasonography examinations show fluid-filled hypoechoic masses with echogenic septations (Forrest et al. 1980; Choi et al. 1989; Palacios et al. 1990; Xu et al. 2012). In abdominal X-ray images, displacement of the duodenum, stomach, or colon by a large hepatic mass has been found. In CT images, a well-demarcated hypoattenuating cystic mass is the characteristic finding, without evidence of enhancement within the lesion or wall structures. Septations were seen in almost all tumors studied, usually with no or

less nodularity than in cystadenocarcinoma (Choi et al. 1989; Korobkin et al. 1989; Palacios et al. 1990; Buetow et al. 1995; Seidel et al. 2007; Pojchamarnwiputh et al. 2008; Nakagawa et al. 2011; Facy et al. 2012; Qian et al. 2013). At MRI, T2-weighted images showed all lesions to be hyperintense, while T1-weighted images showed either hypointense or isointense lesions (Lewin et al. 2006). ERCP and percutaneous transhepatic cholangiography showed obstruction or compression of the biliary tree (review: Akwari et al. 1990).

Most MCNs are macrocystic and multilocular (the macrocystic variant).

The microcystic variants are less common. The diameter of the cysts does not exceed 1 cm, and CT scans with contrast show multiple small cysts delineated by enhanced thin walls. MRI shows a typical fluid-containing lesion with low signal on SE T1-weighted images and high signal on SE T2-weighted images. After intravenous administration of gadolinium-DTPA, SE T1-weighted images demonstrate enhancement of the cyst walls, giving the lesion of honeycomb pattern (Meyer et al. 1997). MCN may cause mucobilia, suggesting a communication between the cystic space of the tumor and the lumina of the biliary tract. A subset of MCNs deviate from these more common patterns. MCN may consist of a large principal mass associated with a smaller daughter cyst (Verbeeck and Hoebeke 1997). Unilocular extrahepatic MCN may grow to very large size (giant cystadenomas; Busoni et al. 1996; Hwang et al. 2000; Kazama et al. 2005) and mimic choledochal cyst at sonography and CT examination (Park et al. 2004) or may produce a phenotype resembling cystic lymphangioma (Hwang et al. 2000) or parasitic hydatid cyst (Kapoor et al. 1997; De Backer et al. 2000; Raza et al. 2009). In case of a solitary MCN with mucin secretion, the lesion may mimic a simple hepatic cyst at imaging (Stoupis et al. 1994; Matsumoto et al. 1997). Exceptionally, gallstone formation has been seen within cysts of MCN (Lei et al. 1994). A subset of biliary MCNs can protrude and grow into the bile duct system (Gadzijev et al. 1998). MCN has been observed in conjunction with unilateral mucinous cystadenoma of the ovary (Skopelitou and Hadjiyannakis 1996). Radiologically, MCN may be difficult to distinguish from simple hepatic cysts, requiring a combined diagnostic approach. Comparing with simple cysts, symptoms, left-lobe cyst, thick wall, septation, mural nodule, bile duct dilatation, and increase in serum alkaline phosphatase were significantly frequent in biliary cystic tumors.

Pathology

Macroscopy

Macroscopically, the lesions are either solitary or multiloculated, are globular in shape, and show a diameter ranging from few cm to 30 cm or even more (Figs. 1 and 2). The cysts are usually not communicating with the bile duct systems, with few exceptions (Marrone et al. 2011; Billington et al. 2012). Multiloculated lesions prevail in most studies (review: Akwari et al. 1990). In these patterns, a large cyst (the macrocystic variant) may contain numerous smaller cysts, mainly at the periphery or within septated trabecular structures. These smaller cysts commonly bulge outward (Ishak et al. 1977). Very rare variants of MCN exclusively consist of small cysts (microcystic variant; Meyer et al. 1997). The tumors show an expanding growth pattern and may bulge from the liver surface. On cutting, a watery to slightly viscous fluid of various color is

Fig. 1 Solitary mucinous cystic neoplasm (MCN) of the liver with incompletely segmented chambers. The cavities contain a mucinous, viscous fluid (fixed resection specimen)

Fig. 2 Multiloculated mucinous cystic neoplasm of the liver. Usually, the larger cavities are located to central parts of the tumor (fixed resected specimen)

seen, which may become coagulated after formalin fixation, leaving a cloudy gel-like substance, depending on protein concentration. The color of the cyst fluid depends on admixtures of blood or blood products, presence of granulocytes in infected cysts, and eventually bile, but most often the fluid looks either like water or is whitish turbid. In sediment of the fluid, cholesterol crystals were found (Ishak et al. 1977). In case of cyst hemorrhage, a thick dark red to brown-red mass, frankly coagulated red-blue blood may be seen. These blood masses may coalesce to balls or spheres with a rough, spiny surface. After removal of the fluid, a smooth and often glistening inner surface of the cyst is seen, with a network of fine vasculature and occasional trabeculations. The aspect may closely resemble or be grossly indistinguishable from simple nonparasitic cysts. The walls of the larger cysts vary in thickness from a few millimeters to 2 cm or more (Gourley et al. 1992). CMS may show mural nodules similar to those found in ovarian mucinous cystadenoma (Joseph et al. 1993).

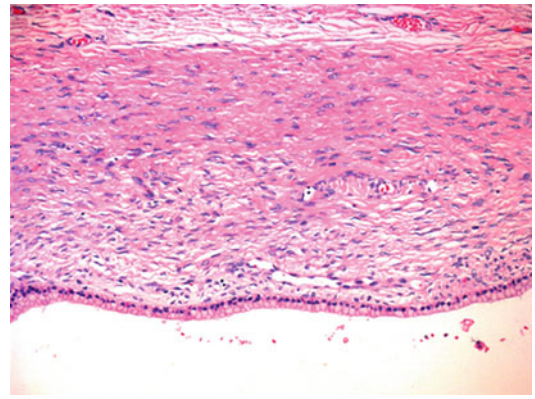

Fig. 3 Hepatobiliary mucinous cystic neoplasm. The cystic space is lined by a mucin-producing neoplastic epithelium. There is a subepithelial band of hypercellular ovarian-like mesenchymal stroma (hematoxylin and eosin stain). Adjacent liver may show perifocal pressure atrophy, ductular proliferations, and sometimes biliary microhamartomas in the portal tracts (Wheeler and Edmondson 1985; Tomiaka et al. 1986)

Histopathology

Histologically, the wall of MCN consists of three layers: an inner single epithelial lining of cuboidal to columnar cells, a moderately to densely cellular stroma composed of spindle cells (see below), and a dense layer of hypovascular collagenous connective tissue which may even undergo hyaline change. The cuboidal to columnar epithelial cells are similar to those seen in interlobular bile ducts, but the nuclei may be somewhat larger. The columnar cells may show basal nuclei and PAS- and Alcian Blue-positive mucin accumulated in the middle and apical parts of the cell, sometimes with signs of mucin secretion (Figs. 3, 4, 5, and 6). The morphology of the columnar epithelial cells has been described as being similar to that of the developing gallbladder (Subramony et al. 1993). The presence of detectable mucin varies considerably among the CMA, ranging from tumors resembling mucinous ovarian tumors to lesions where mucin is detectable in a minority of the cells only. In the latter situation, MCN may be confounded with simple hepatic cysts, particularly in cases where the subepithelial band is hypocellular or otherwise poorly developed. Mucin-rich cells are often more easily found in

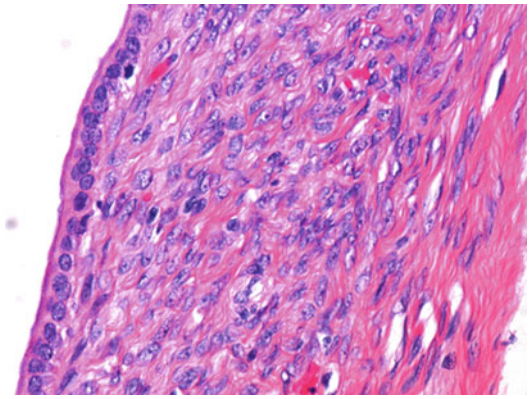

Fig. 4 Mucinous cystic neoplasm of the liver. The cells of ovarian-like mesenchymal stroma differ from conventional fibroblasts seen in the collagenous connective tissue at the right end of the figure (hematoxylin and eosin stain)

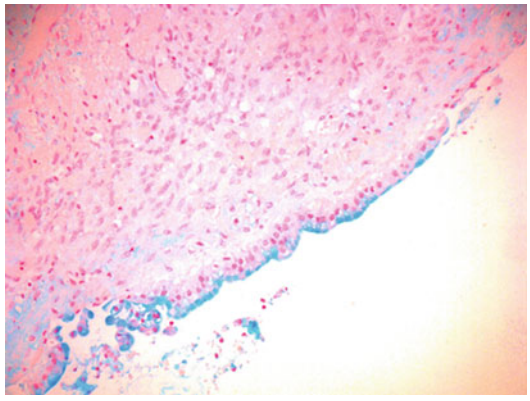

Fig. 5 Mucinous cystic neoplasm of the liver. Mucin production by epithelium lining the cystic spaces predominates in apical portions of the neoplastic cells (alkaline Alcian Blue stain)

small tumors, whereas large lesions display atrophy of the tumor epithelium with poor or lacking mucin storage. Copious sampling from different parts of the cyst walls should be performed, mainly from regions without scarring or calcifications. Some regions of cyst walls may show polypoid or papillary structures or papillary projections covered by mucin-containing cells. The bases ("crypts") of these papillary formations are seen in the form of tubular or ectatic glands (Gourley et al. 1992), sometimes difficult to distinguish from microinvasion in lesions with malignant transformation. The cells in these

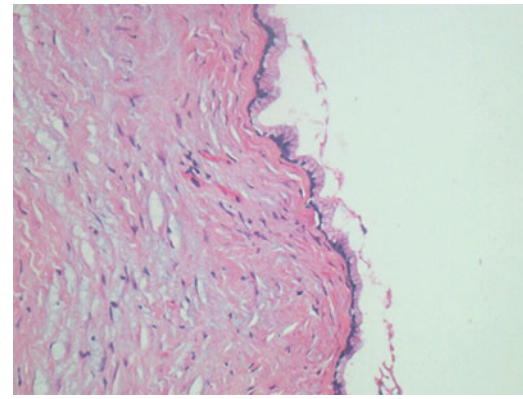

Fig. 6 Mucinous cystic neoplasm of the liver with absence of ovarian-like mesenchymal stroma (hematoxylin and eosin stain)

glandular structures contain immature forms like in primitive crypt-like glands, goblet cells, Paneth cell-like elements with eosinophilic supranuclear cytoplasmic granules, and endocrine cell-like cells (Gourley et al. 1992). Mainly in larger cysts, atrophy of the inner wall components may be associated with ulceration, followed by granulation tissue formation and accumulation of macrophages (in part pigmented, with PAS-positive lipofuscin) in the cyst wall (Ishak et al. 1977). The cyst walls may contain numerous cholesterol clefts with or without formation of cholesterol granulomas. In the microcystic variant, eosinophilic differentiation of the cyst epithelium has been noted, without underlying cellular stroma (Meyer et al. 1997). Whether this phenotype reflect mucinous or serous cystadenoma is difficult to judge from the pathology description.

A large percentage of MCNs show a characteristic zone of hypercellular stroma beneath the epithelia lining, termed mesenchymal stroma or ovarian-like stroma (synonym: ovarian-type stroma), because this stromal lamella closely resembles ovarian cortex stroma (Wheeler and Edmondson 1985). This stroma is not present in cystadenomas occurring in male patients. The stroma consists of densely packed small-to medium-sized spindle cells sometimes forming whorls and shows a characteristic vascular network. Scattered lymphocytes and monocytes/macrophages may be noted within the stroma.

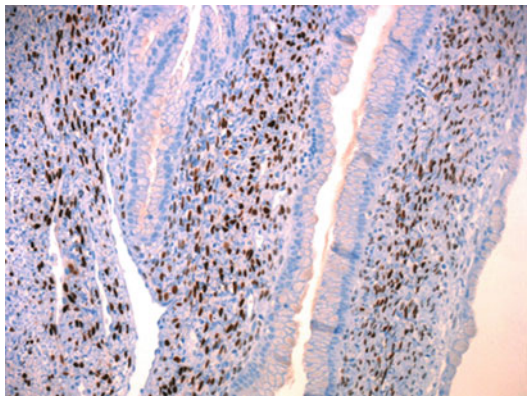

Fig. 7 Mucinous cystic neoplasm of the liver. Marked nuclear expression of estrogen receptor (*dark brown* reaction product; estrogen receptor immunostain)

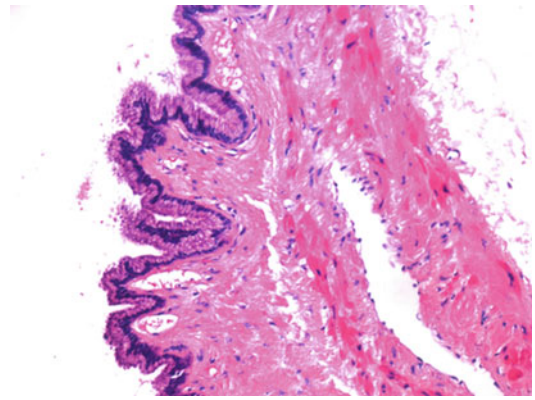

Fig. 8 Mucinous cystic neoplasm of the liver with low-grade dysplasia (hematoxylin and eosin)

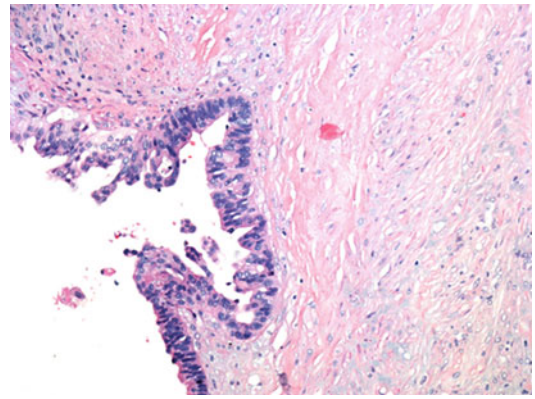

Fig. 9 Mucinous cystic neoplasm of the liver with moderate- to high-grade dysplasia (hematoxylin and eosin stain)

Usually, the stroma reaches very close to the epithelial lining, whereas the transition to the peripheral collagenous zone is less sharp. In pancreatic mucinous cystic tumors, stromal luteinization was detected in 32.4 % of the cases (Izumo et al. 2003), but this phenomenon is not seen in hepatic MCN. The stromal cells are reactive for vimentin and, in part, for alpha-smooth muscle actin (SMA; Abdul-al et al. 2007). Typically, the mesenchymal stroma shows nuclear expression of both estrogen and progesterone receptors (Fig. 7; Scott et al. 1995; Grayson et al. 1996; Weihing et al. 1997; Pedram-Canihac et al. 2000; Daniels et al. 2006; Abdul-Al et al. 2007). The immunohistochemical detection of these receptors in stromal cell nuclei perfectly works on formalin-fixed tissue (Scott et al. 1995). The stromal cells are also reactive for inhibin-alpha, also detectable in mucinous tumors of the pancreas (Riddeer et al. 1998; Izumo et al. 2003; Yeh et al 2004; Abdul-Al et al. 2007). A comparative study showed that the stroma of hepatic MCN had greater estrogen and progesterone receptor staining and more consistent inhibin-alpha staining than pancreatic mucinous tumors (Lam et al. 2008).

Signs of incipient malignant transformation are similar to those defined in great detail for lesions characterized by an adenoma-carcinoma sequence, chiefly in the colon. In cystadenomas, early changes are focal anaplasias consisting of glandular crowding, stratification of enlarged hyperchromatic nuclei, loss of cytoplasmic mucin, and up to 20 mitotic figures per 10 HPFs (Gourley et al. 1992). This alteration pattern may represent low-grade to moderate-grade dysplasia. High-grade dysplasia in MCN is characterized by "blue areas" at low magnification, seen both in flat epithelial lining and in papillary formations (Figs. 8, 9, 10, and 11). At high magnification, changes seen in adenocarcinoma in situ

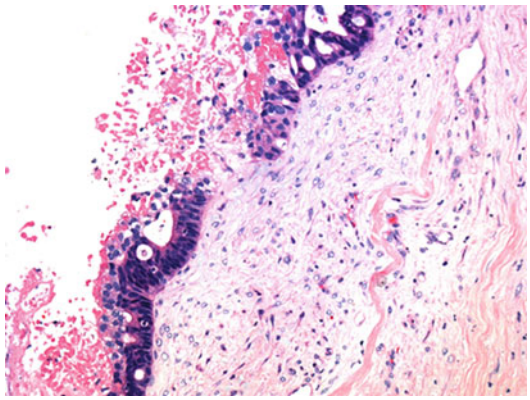

Fig. 10 Mucinous cystic neoplasm of the liver with high-grade dysplasia and focal erosion (hematoxylin and eosin stain)

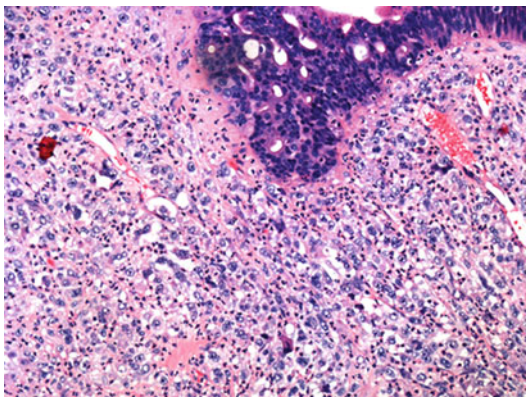

Fig. 11 Mucinous cystic neoplasm of the liver with high-grade dysplasia-carcinoma in situ and transition into poorly differentiated invasive carcinoma (hematoxylin and eosin stain)

are noted. In this situation, numerous samples and sections may be required to find or exclude focal microinvasion, usually with cribriform structures or at least fused glands and an incipient stromal reaction being loose in contrast to the compact ovarian-like stroma. In fact, microinvasive lesions with stromal reaction may form a characteristic gap in the preexisting band of mesenchymal stroma. Diagnosis of MCN may be obtained through fine needle aspiration and cytologic examination (Logrono et al. 2002).

Immunohistochemistry of Epithelial Components

The epithelia of mucinous MCN express cytokeratins 7 and 19, epithelial membrane antigen (EMA), CA 19-9, and sometimes carcinoembryonic antigen (Tomiaka et al. 1986; Gourley et al. 1992; Thomas et al. 1992; Maruyama et al. 2003). In cystadenocarcinomas, CA 19-9 may be expressed in a focal pattern (Horsmans et al. 1997). The epithelial lining has been found to express hepatocyte growth factor and its receptor, c-Met (Lam et al. 2008). Paneth cell-like cells, mainly found in glands, are reactive for lysozyme (Gourley et al. 1992). About 50 % of hepatobiliary MCN and cystadenocarcinomas contain neuroendocrine cells immunoreactive for chromogranin A and several hormones, including serotonin, gastrin, and somatostatin (Gourley et al. 1992). These cells tend to be located beneath and among the columnar epithelial cells. Based on the close spatial relationship between endocrine cells of cystic tumors and the endocrine cells found in peribiliary glands, it has been suggested that MCN may originate from these glands (Terada et al. 1997).

Variants of MCN

Neoplasms with an Oncocytic Lineage

A minority of MCN exhibit aberrant differentiation patterns of the epithelial lining. In 1992, an intrahepatic cystadenocarcinoma with oncocytic differentiation was reported. The neoplasm showed a prominent papillary growth pattern, and the tumor cells were characterized an abundant granular, intensively eosinophilic cytoplasm on light microscopy examination and large numbers of densely packed mitochondria by electron microscopy (Wolf et al. 1992). A second case, diagnosed in a 43-year-old woman, was reported in 2004 (Bardin et al. 2004). This tumor lacked an ovarian-like subepithelial stroma. It was proposed that these neoplasms should be classified as a form

of intraductal papillary neoplasm (IPN) with oncocytic differentiation (Sudo et al. 2001), similar to those occurring in the pancreas.

Neoplasms Without Ovarian-Like Stroma

As discussed above, the majority of MCNs exhibit a subepithelial cellular ovarian-like stroma. There are, however, neoplasms that lack such a stroma, mainly in MCNs occurring in male patients (Kishida et al. 2014).

Malignant Transformation of MCN (MCN with an Associated Invasive Carcinoma)

The spontaneous biologic behavior of hepatobiliary MCN is difficult to judge, because most lesions grow slowly, and only a fraction shows malignant behavior in early phases of evolution. However, traditional treatment of cysts such as aspiration, drainage, and marsupialization results in near universal recurrence and occasional malignant transformation, clearly showing that even benign-looking cystadenomas require a therapeutic approach that is different from simple hepatic nonparasitic cysts, preferably complete resection (Thomas et al. 2005; Delis et al. 2008; Limongelli et al. 2009). Among benign-looking CMS, up to 25 % recurred after primary surgery (Akwari et al. 1990). Transformation from MCN to cystadenocarcinoma has been described several times (Thompson and Wolff 1965; Woods 1981; Wheller and Edmondson 1985; O'Shea et al. 1987; Coulter and Baxter 1989; Lei and Howard 1992; Matsuoka et al. 1997; Del Poggio et al. 2000; Peyrègne et al. 2001) and may be a multistep process involving increasing degrees of dysplasia and carcinoma in situ. In the study of Wheeler and Edmondson (1985), malignant transformation was noted in 4 out of 17 patients. In a review of 53 patients, malignancy seemingly arose from MCN epithelium in seven cases (Akwari et al. 1990). Sarcomatous change of the mesenchymal stroma has been reported (Akwari et al. 1990).

Differential Diagnosis

In MCN located to bile ducts, the most important differential diagnosis is intraductal papillary neoplasm (IPN). Both neoplasms form mucin-containing cysts lined by a cuboidal to columnar epithelium. A diagnosis of IPN is favored by the presence of a communication to the bile duct system and the absence of an ovarian-like stroma. A further differential diagnosis is intrahepatic cholangiocarcinomas (ICCs) with cystic components. At least part of these neoplasms originate from preexisting IPN and, similarly to the latter, lack a subepithelial ovarian-like stroma with sex steroid receptor expression. MCNs are rarely mimicked by multicystic lesions of peribiliary glands, which have been suggested to be site or origin of MCN. Hepatobiliary MCN was found to develop in conjunction with multiple liver cysts (Hara et al. 2001), rendering the detection of the adenoma component difficult. Expanding intrahepatic cholangiocarcinoma may rarely show cyst formation and thus mimic MCN (Horie et al. 1987; Kokubo et al. 1990; Lee et al. 1995). Marked cystic change in adult mesenchymal hamartoma of the liver mimicked bile duct cystadenoma (Yamamoto et al. 1994). Hemorrhagic hepatic cysts sometimes mimic biliary MCN, because the coagulated blood at the cyst walls shows, at ultrasound, CT, and MRI, mural nodules on irregularly thickened walls, high-density straps inside the cyst, and flame-like prominences on the wall (Zhang et al. 2009). Intracystic hemorrhage of a simple liver cyst has also mimicked biliary cystadenocarcinoma (Kitajima et al. 2003). MCN may develop in the retroperitoneal space and mimic a primary retroperitoneal cystic process of different nature (Isse et al. 2004). MCN rarely presents under the clinical picture of hydatid disease (Geramizadeh et al. 2010; Kumar et al. 2011), and may mimic biliary smooth muscle neoplasms (Wong et al. 2001).

Hepatobiliary Mucinous Cystadenocarcinoma with or Without Mesenchymal Stroma (MCN Associated with Invasive Carcinoma)

Introduction

Hepatobiliary cystadenocarcinoma is a rare lesion which has first been described in 1943 (Willis 1943). For practical diagnostic reasons, three main types of cystadenocarcinoma may be distinguished, i.e., mucinous cystadenocarcinoma (developing from CMS in at least part of the cases), the much rarer serous hepatobiliary cystadenocarcinoma (see below), and a group of diverse hepatic tumors showing the macroscopic and histopathologic patterns of biliary cystadenocarcinoma, but revealing neither a mucinous nor a typically serous phenotype (hepatobiliary cystadenocarcinoma not otherwise specified, NOS). Expectedly, the latter group is mainly seen with tumors of low-grade differentiation.

The malignant variant of mucinous cystadenoma is a rare lesion and estimated to have an incidence of one per ten million individuals. Older patients, in their sixth decade of life, are more likely to present with malignant tumors. However, the true incidence of cystadenocarcinoma and of malignant transformation of preexisting cystadenoma is not known, in part caused by the lack of reproducible criteria for diagnosing malignancy, varying considerable in the published reports. Cystadenocarcinoma was found to be connected to the hepatic duct, characterized by a cystadenoma with a mural nodule showing in situ papillary adenocarcinoma (Sato et al. 2003). Biliary cystadenocarcinoma has been observed to arise in a congenital cyst (Devine and Ucci 1985), to be associated with hepatolithiasis (Tseng et al. 2004), and to develop in the setting of congenital fibropolycystic disease of the liver (Theise et al. 1993). Cystadenocarcinoma can invade adjacent tissues and organs, e.g., spread into extrahepatic bile ducts (Matsumoto et al. 2001), and lead to complications, such as invasion of the hepatic veins (Facy et al. 2012), inferior vena cava obstruction (Arkadopoulos et al. 2013), or perforation of bile ducts (Harima et al. 1984; Bacher et al. 1999), sometimes mimicking invasive hydatid disease (Bacher et al. 1999). Cystadenocarcinoma perforating into bile ducts can give rise to mucobilia and mucus-induced biliary obstruction (Chamberlain and Blumgart 2000). Similar to intrahepatic cholangiocarcinomas, cystadenocarcinoma can give rise to extrahepatic metastases, including the skeleton (Berijan et al. 1981).

Pathology

Grossly, the cystadenocarcinomas are usually multiloculated tumors, with a morphology mostly similar to that of noninvasive MCN (Ishak et al. 1977).

Histologically, papillary adenocarcinoma with finely arborizing micropapillary structures with fibrovascular axes prevails. The malignant epithelial lining is generally multilayered and shows high-grade dysplastic changes, with marked anisocytosis and anisonucleosis, loss of polarity and loss of most of the mucin, and microinvasive or frankly invasive growth. Vascular invasion may be observed (Ishak et al. 1977). The cells are columnar, polygonal, or round and commonly with a finely granular eosinophilic cytoplasm with

variable numbers of small vacuoles containing remnant mucin. Most tumor cells possess one nucleus, but occasional multinucleated cells are present (Ishak et al. 1977). Mitotic figures, a part of them with visible anomalies, are often seen. The locules lined by nonmalignant epithelium resemble those seen in cystadenomas (Ishak et al. 1977). In some cases, the diagnosis of carcinoma seems to have been based on abnormal growth patterns, e.g., the intracystic growth of markedly arborizing papillary formations (Kubota et al. 2003). Similar to MCN without invasive features, cystadenocarcinoma can show a subepithelial cellular stroma, but cases without ovarian-like stroma are also known (Ishibashi et al. 2007).

Mucinous Cystic Neoplasm and Cystadenocarcinoma of the Gallbladder

Cystadenoma of the gallbladder has occasionally been reported (Bishop 1901; Kordenat 1930; Sambaugh 1933), and also cystadenocarcinoma of the gallbladder is very rare (Ishak et al. 1977; Nakagawa et al. 1990; Spector et al. 2003; Terada et al. 2003; Rooney et al. 2005; Waldmann et al. 2006; Sistla et al. 2009). Cystadenocarcinoma of the gallbladder was observed in an 88-year-old man and presented as multilocular cystic tumor of the fundus, up to 3.5 cm in size, containing a seromucous fluid and associated with hemobilia, but not protruding into the gallbladder lumen. Histologically, the tumor consisted of mucin-rich columnar cells compatible with cystadenoma, but at some places, papillotubular structures and invasive growth were found, indicating malignant transformation (Terada et al. 2003). In one patient, a 50-year-old female patient, the tumor clinically presented with an abscess in the gallbladder fossa (Sistla et al. 2009).

Serous Hepatobiliary Cystadenoma and Cystadenocarcinoma

Very few cases of hepatobiliary serous cystic neoplasms (SCN; serous hepatobiliary cystadenoma and serous cystadenocarcinoma, non-mucinous cystic tumor) have been reported, sometimes without specification of the serous features (Fig. 12; Devaney et al. 1994; Anthony 1995; Suh et al. 1997; Akiyoshi et al. 2003; Ishibashi et al. 2007; Tani et al. 2008; Yu et al. 2009). In principle, these very unusual lesions resemble their counterpart in the pancreas. The neoplasms are probably almost always malignant lesions that occur on both sexes. At imaging, the cystic masses may exceed 20 cm in diameter (Yu et al. 2009) and are associated with elevated serum CA 19-9 and CA125 (Yu et al. 2009). In the lack of a clearly identifiable serous phenotype, the tumors are, on descriptive terms, cystadenocarcinomas without mesenchymal stroma. These tumors are usually not associated with a preexisting hepatobiliary cystadenoma with mesenchymal stroma and occur both in women and men. These lesions are thought to be more aggressive, but there are rare examples with normal CA 19-9 levels and a prolonged course (Horsmans et al. 1997). As in many of these tumors, it will be impossible to clearly identify the epithelial cell lineage involved (mainly in poorly differentiated neoplasms); we propose, as a working formulation, to denote the tumors as hepatobiliary cystadenocarcinoma, not otherwise specified (NOS). The pathogenesis of non-mucinous cystadenocarcinoma is unknown. In one patient,

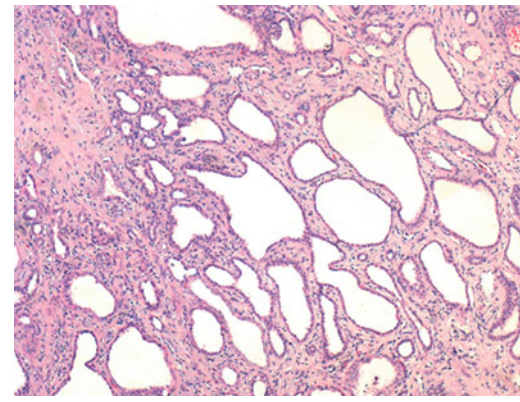

Fig. 12 Multilocular serous cystic neoplasm of the liver. The cystic spaces are lined with a flat, serous (non-mucinous) epithelium. This very rare tumor resembles its pancreatic counterpart, serous cystadenoma (hematoxylin and eosin stain)

progression from a benign cystic lesion to cystadenocarcinoma without mesenchymal stroma has been suggested (Akiyoshi et al. 2003).

Differential diagnostically, serous cystadenocarcinoma of the pancreas (malignant serous cystic neoplasm) is known to metastasize to the liver (Eriguchi et al. 1998; Strobel et al. 2003; Franko et al. 2008). But even benign-looking pancreatic serous cystadenoma (serous cystic neoplasm) may show an aggressive behavior and give rise to hepatic metastases (Wu et al. 1999), thus representing highly differentiated serous cystadenocarcinoma. Serous cystadenocarcinoma of the ovary (Lee et al. 2002) and of the retroperitoneal space (Kaku et al. 2004) can metastasize to the liver and may mimic primary serous neoplasms of the liver in a biopsy.

Hepatic Cystadenocarcinosarcoma

Primary hepatic cystadenocarcinosarcoma is a very unusual lesion that has been described in 2008, based on a case observed in 42-year-old woman presenting with a 4-month history of a mass in the upper abdomen (Yu et al. 2008b). It is a carcinosarcoma that is distinguished from its solid counterparts by the presence of a large, multilocular cystic mass with a large mural nodule, internal septa, and solid portions. On CT images, the enhancing tumor resembled hepatobiliary cystadenoma and cystadenocarcinoma.

Pathogenic Pathways

The similarities between pancreatic and hepatobiliary mucinous cystic tumors in regard to gender, morphology, stromal reactions, and sex steroid receptor expression suggested a common pathway for their development (Zamboni et al. 1999). Several hypotheses have been proposed to explain the pathogenesis of CMS and related lesions. The epithelia of cystadenomas resemble those of the developing gallbladder, also in regard to their ultrastructural features, and the fetal gallbladder also shows a subepithelial stromal band positive for alpha-smooth muscle actin (Subramony et al. 1993). Based on 11-year-long follow-up of a hepatic cystic lesion, it has been suggested that CMS may develop from a preexisting simple hepatic cyst (Fukunaga et al. 2008).

The origin and biologic features of ovarian-type stromal cells are still unknown. The development of a sex steroid-responsive Müllerian stroma outside the ovaries is known not only for mucinous tumors of the pancreas and the liver but was also observed in non-mucinous tumors such as cystic nephroma (multilocular renal cyst; Steele et al. 1994) and the normal or inflamed biliary tract (Alvaro et al. 2002, 2006). Involvement of a mesenchymal progenitor cell may be suggested owing to the emergence of other cell lineages in the this unique stroma, e.g., neoplastic osteoclast-like, CD68-positive giant cells (pancreatic giant cell tumor within mucinous cystadenocarcinoma; Bergman et al. 1995). Subsets of mesenchymal stem cells are estrogen-responsive, express estrogen receptor (Wang et al. 2006), and estrogen can exert an osteogenic effect in these cells (Hong et al. 2006). Whether the cell lineage forming the typical mesenchymal stroma of CMS have an origin similar to that of gonadal stromal cells is unknown. However, it is of interest to note that both gonadal stromal cells and stromal cells in hepatic and pancreatic mucinous tumors produce inhibin-alpha, a member of a pleiotropic effector family, inhibiting gonadotropin release (apart from gonadotropin-inhibitory hormone, GnIH; review: Tsutsui 2009) and being a tumor suppressor in mice (Ball et al. 2004).

DOI 10.1007/978-3-319-26956-6_40

Abstract

The extrahepatic and intrahepatic biliary tree develops several types of benign epithelial neoplasms and hamartomas. Rarely, papillary and tubulopapillary adenomas, sometimes with a villous configuration, occur in the extrahepatic ducts. These lesions can present as solitary neoplasms, but also develop in the form of numerous lesions involving large parts of the biliary. The latter condition was previously termed biliary papillomatosis. Its relation to multiple intraductal papillary neoplasms of the bile duct (IPN-B) has to be further clarified. Small benign epithelial nodules often located in peripheral parts of the liver were termed bile duct adenoma and are now classified as peribiliary gland hamartomas. The most common variant consists of cholangiocyte-like cells. Rare variants include clear cell, oncocytic and signet-ring cell hamartomas, and a variant with endocrine features. A variant with a marked stromal component is called biliary adenofibroma. A rather common hamartoma of the liver is biliary microhamartoma (von Meyenburg complex). The hamartomas consist of a microcystic network of biliary spaces that may contain bile. These lesions occur as solitary changes or as numerous lesions that can involve both liver lobes synchronously.

Papillary Adenoma and Tubulopapillary Adenoma (Villous and Tubulovillous Adenoma) of the Bile Ducts

ICD-O codes

ICD-O Papillary adenoma	8260/0
ICD-O Tubulopapillary adenoma	8263/0

Introduction

Historically, part of biliary tract adenomas with a papillary or tubulopapillary growth pattern have been referred to as villous adenomas. This term was chosen to denote lesions with a striking gross

morphology, characterized by a growth with an arborizing structure and having a velvety surface that somewhat resembles intestinal villi. In principle, villous adenomas may be regarded as excessive forms of papillary adenomas. As numerous examples of this potentially premalignant neoplasm have been reported under the name villous adenoma instead of papillary adenoma, the main features of this lesion are summarized in this paragraph. Localized or solitary papillary (villous) adenoma in contrast to diffuse biliary papillomatosis was described as a distinct entity by Caroli and coworkers in 1959, who also defined a third papillary lesion, adenoma of the ampulla (Caroli et al. 1959). In this report, Caroli et al. also described the mucin-hypersecreting variant of bile duct adenoma.

Epidemiology

Papillary adenomas can develop at any site in the gastrointestinal tract, but they are most often encountered in the colon and rectum, less commonly in the small intestine, and very rarely in the biliary tract. Marshall (1932) reported the 20-year experience at the Mayo Clinic with bile duct tumors. In over 20,000 operations on the biliary tract, 49 cases of carcinoma were found, but only four cases of benign tumors were encountered, none of which was papillary. The first case of villous/papillary bile duct adenoma was probably reported in 1946. The patient had a recurrent "papillary adenoma" of the common hepatic duct with progressive extension into the left hepatic duct producing cholangitis, liver abscesses, and eventual death (Rogers 1946). A report of 1950 summarized a collected series of 30 well-documented tumors of the extrahepatic biliary system, and the most common type was papillary, but nine-tenths of these were located to the ampulla (Chu 1950). In 1962, 16 cases of polypoid or papillary bile duct tumors were reviewed, and among these, 14 were solitary neoplasms of the distal common bile duct in the region of the ampulla (Cattell et al. 1962). Most papillary biliary adenomas develop in ampullary region, followed by the common bile duct and the hepatic ducts. The tumor rarely also occurs in the intrapancreatic distal bile duct, cystic duct, cystic duct remnants, and choledochoceles.

Clinical and Imaging Features

Whereas adenomas of the gallbladder often remain asymptomatic, papillary adenomas of the extrahepatic biliary tree usually present clinical signs and symptoms, albeit after a rather long evolution. As other benign bile duct tumors (Burhans and Myers 1971), these lesions are thought to remain "dormant" for long time periods (up to 14 years) and may first cause vague symptoms due to local pressure effects (Harshfield et al. 1990). Clinical findings reported for lesions in the common bile duct comprise jaundice without fever (biliary obstruction with obstructive jaundice, Mendel 1987; Saxe et al. 1988; Jennings et al. 1990; Buckley and Salimi 1993; Chae et al. 1999; Skelly et al. 1999; Fletcher et al. 2004; Akaydin et al. 2009; Sotona et al. 2010), right-upper-quadrant abdominal pain, nausea, vomiting, and sometimes weight loss. Tumors located to the common bile duct generally mimic the signs and symptoms of an ampullary obstructing tumor. Most distally

located lesions may cause acute pancreatitis (Mancheron et al. 1988). Adenoma of the major duodenal papilla can undergo intraductal extension into the lower common bile duct (Uchiyama et al. 2008).

Diverse imaging modalities, including ultrasonography, CT, MRI, MRCP, and ERCP, have been employed in identifying these tumors with variable and overall limited success. Ultrasonography reveals an echogenic exophytic lesion associated with prestenotic bile duct dilatation. Fairly well-defined expansive solid intraductal masses without posterior acoustic shadow are rather characteristic, but may also be seen in sludge, blood clots, non-shadowing stones, and other tumors (Xu and Chen 2008). ERCP reveals a filling defect with a polypoid configuration (Mancheron et al. 1988).

Pathology

Papillary adenomas can be divided into non-mucin-secreting adenoma and mucin-secreting adenoma. Macroscopically, non-secreting adenomas are more often large lesions that have a stalk and float within the duct lumen. Specifically, large villous adenomas of the ampulla of Vater may be pedunculated lesions (Katsinelos et al. 2004). Histologically, the main feature is a growth with collections of long papillary structures with a fibrovascular core and a lining of columnar with basally place elongated nuclei. Non-mucin-secreting villous adenomas can show variable degrees of dysplasia, similar to their colorectal counterparts. High-grade dysplasia may be encountered (O'Shea et al. 2002; Goh et al. 2003), rendering the distinction from adenocarcinoma in situ difficult. Part of the adenomas contain glandular or tubular structures in addition to papillary components and are termed tubulopapillary or tubulovillous adenomas. Part of villous adenomas of the extrahepatic bile ducts are mucin-(hyper) secreting lesions (Styne et al. 1986; Doberauer et al. 1997). These tumors were first described in 1959 (Caroli et al. 1959) and may in fact represent solitary variants of intraductal papillary mucinous tumor (IPMT) (Oshikiri et al. 2002). When located in the most distal part of the common bile duct, such lesions present with a dilated orifice of Vater's papilla with mucus exiting (the fishmouth sign) and a filling defect in the bile duct (Katsinelos et al. 2006).

Bile Duct Adenomas in Familial Adenomatous Polyposis

Solitary adenomas of the extrahepatic bile ducts have been observed in few patients with adenomatous polyposis of the colon (APC). The lesions were found in the distal common bile duct (Järvinen et al. 1983). In one patient, there was diffuse polyposis involving the hepatic and common ducts (Järvinen et al. 1983). APC can also be associated with cholangiocarcinoma of the extrahepatic ducts (Spigelman et al. 1991).

Biology of Disease

Villous adenomas may undergo an adenoma-carcinoma sequence, with stepwise increase of dysplastic changes (Heidecke et al. 2002) and transition into adenocarcinoma/cholangiocarcinoma (Mendel 1987; Ariche et al. 2002; Genc et al. 2007; Aparajita et al. 2008; Kim et al. 2008). Carcinoma in situ arising in a tubulovillous adenoma of the distal common bile duct was described (Kim et al. 2008). Transition into adenocarcinoma has also been observed in villous adenoma arising in a choledochal cyst (Lee et al. 2009).

Pyloric Gland Adenoma of the Bile Ducts

Introduction

Pyloric gland adenoma is a rarely described tumor of the gastric mucosa characterized by a nodular or polypoid growth of glands resembling pyloric glands. The lesion has, however, also been detected in the gallbladder, the main pancreatic duct, the esophagus, and the bile ducts (Kushima

et al. 1996; Bakotic et al. 1999; Vieth et al. 2003; Nakayama et al. 2005). This type of adenoma has been observed in heterotopic gastric mucosa located to the duodenum (Kushima et al. 1999) or the rectum (Vieth et al. 2005). The gastric neoplasm was first described in 1976 (Elster 1976) but misinterpreted as adenoma-like hyperplasia of mucoid glands. Lesions in the stomach have a predilection in the gastric corpus, and here they are often found in patients suffering from autoimmune gastritis, but it has been suggested that many of these lesions are underdiagnosed (Vieth et al. 2003). Pyloric gland adenomas of the stomach seem to be precancerous lesions, since 30 % reveal a transition to a gastric-type carcinoma (Schmitz and Stolte 1997; Vieth et al. 2003; Kushima et al. 2006). Pyloric gland adenomas have a distinct immunophenotype. Typically, they are strongly positive for mucin 6 (deep mucoid gastric glands), and the lesions express this mucin over the whole lesion up to the surface often only with a small layer of the columnar epithelium expressing apomucin 5AC (Vieth et al. 2006).

Histopathology

Among 90 patients with pyloric gland adenomas, three had bile duct adenomas of this type (Vieth et al. 2003). The morphology is characterized by closely packed pyloric-type glands. The glands are lined by cuboidal or columnar, mucus-secreting cells with basal, round nuclei lacking atypia. The cytoplasm is pale eosinophilic. Few of the glands may form ectatic foveolae.

Immunohistochemically, the cells of pyloric gland adenomas are positive for mucin 6, with paradoxical concanavalin A staining being specific for the mucin of pyloric gland cells, mucous neck cells, and Brunner gland cells. Lesions located to the gallbladder have been shown to be reactive for MUC5A (38 %), MUC6 (100 %), human gastric mucin (HGM, 50 %), M-GGMC-1 (pyloric gland-type mucin, 93 %), and, for the biliary marker, CD10 (34 %), suggesting that these adenomas show a differentiation toward pyloric glands, but accompanied by a biliary phenotype (Nagata et al. 2007).

Pathogenesis

In contrast to the gallbladder, where pyloric gland metaplasia is well recognized, less is known in regard to glandular epithelium metaplastic changes in the large bile ducts (Hoang et al. 2001). In the latter study of 42 pancreaticoduodenectomy specimens and ten autopsy cases serving for comparison, 20/42 total resected cases (48 %) had metaplastic duct changes, and pyloric gland metaplasia was the most common type (16/20, 80 %), whereas intestinal metaplasia was seen in 5 %. Conversely, none of the autopsy cases had ductal metaplasia (Hoang et al. 2001). In an investigation focusing at intrahepatic bile ducts in hepatolithiasis, pyloric/pseudo-pyloric metaplasia was found in all cases (Kurumaya et al. 1990). Pyloric gland metaplasia, which may rarely give rise to bile duct pyloric gland-type adenoma, has been observed in association with anomalous arrangement of the pancreaticobiliary ductal system (pancreaticobiliary maljunction; Noda et al. 2007). Patients with such an anomaly also exhibit an increased proliferative activity of large bile duct epithelia (Fujii et al. 1999).

Bile Duct Adenoma (Peribiliary Gland Hamartoma, Intrahepatic Bile Duct Adenoma) and Its Variants

ICD-O Code 8160/0

Introduction

Bile duct adenoma (BDA, synonyms: peribiliary gland hamartoma, intrahepatic cholangiocellular adenoma) is a benign neoplasm derived from cholangiocytes. Recently, it has been proposed to call these lesions peribiliary gland hamartoma, based on a possibly or probable origin of the lesions from cells of peribiliary glands (Bhathal et al. 1996; Hughes et al. 2010). In regard to their location, BDAs are classified as either *intrahepatic BDA* or *extrahepatic BDA*. This paragraph refers to the intrahepatic variant, while the extrahepatic variant is discussed in the chapter on tumors of the larger bile ducts.

Epidemiology

BDAs are rare hepatic tumors and are mostly incidental lesions. They are usually solitary tumors, but may occur as multiple tumors (bile duct adenomatosis; Levin et al. 1974). In a study of 16 patients, the lesions were multiple in two (Govindarajan and Peters 1984). Rarely, BDA is combined with other liver tumors, e.g., FNH, hemangioma and angiomyolipoma (Langner et al. 2001). Because of their rarity and apparently innocuous nature, reports of BDA are rather scarce. Among 50,000 autopsies, only four cases of BDA were reported (Edmondson 1958). Gold and coworkers have reported ten cases of BDA in a review of 45 cases of benign hepatic tumors (Gold et al. 1978). In a study on 11 BDAs, the female-male ratio was 7:4, and the mean age at presentation was 57 years ± 15 SD (Guzman et al. 1977). BDA behaves in a benign way; no recurrent lesions have been observed after their resection (Anderson et al. 1992).

Selected references: Wagner 1861; Ribbert 1904; Luddecke and Yoon 1958; Gold et al. 1978; Guzman et al. 1977; Cho et al. 1978; Edmondson 1958; Govindarajan and Peters 1984; Foucar 1985; Karhunen 1986; Ishak 1988; Allaire et al. 1988; Skelly et al. 1999; Ibrarullah and Sreenivasa 2003; Kim et al. 2010; Fernandez Fernandez et al. 2015; and Chen et al. 2014.

Clinical and Imaging Findings

Due to their small size and benign biology, BDAs are in most instances asymptomatic lesions and are detected incidentally. In CT, even the typically small masses show distinct delayed or prolonged enhancement (Tajima et al. 1999). Angiographically, BDAs present as circumscript hypervascular masses with early nodular enhancement (Tajima et al. 1999; Kim et al. 2010). The nodules are enhanced in the arterial phase and hypo-enhanced in the portal venous and late phases, findings that may suggest malignancy in some cases (Ignee et al. 2009), in particular hepatic metastatic disease (Takumi et al. 2013). In MRI, the lesion was described as a well-defined mass that appears hyperintense on T2-weighted images and hypointense on T1-weighted images (Semelka et al. 1999; Boraschi et al. 2007), but other cases appeared hypointense on both T1- and T2-weighted images (Maeda et al. 2006). Prolonged ring enhancement is a typical feature (Semelka et al. 1999).

Pathology

Macroscopy

BDAs are usually subcapsular lesions and are visualized in the form of spheroid, frequently flattened nodules of gray to white color. BDAs are well circumscribed and typically nonencapsulated. They range in size from 1 mm to more than 20 mm. In a study of 152 cases, the mean diameter was 5.8 mm (Allaire et al. 1988). Exceptionally, BDA can grow to very large size, in one case with a diameter of 9.2 cm (Koga et al. 2012). Very rarely, BDA has been observed deeper within the liver substance (Otani et al. 2006).

Histopathology

The nodules consist of usually densely packed and irregular, branching bile duct-like structures, the cells of which look normal or then show only minor nuclear anomalies (Figs. 1, 2, and 3). In addition to profiles with a lumen, there are also epithelial formations that look solid and have no lumen. In contrast to biliary microhamartoma, the duct-like profiles are not cystically dilated, do not form arborizing structures, and do not contain bile (Govindarajan and Peters 1984). The cells of the ductules or tubules are cuboidal and typical for the normal cells seen in the smallest bile ducts or ductules. However, the nuclei of BDA cells may be somewhat lighter than in normal duct and ductule cells. There are varying amounts of intervening stroma which can contain sparse lymphocytic infiltrates, the latter sometimes more pronounced at the margins of the lesions (Allaire

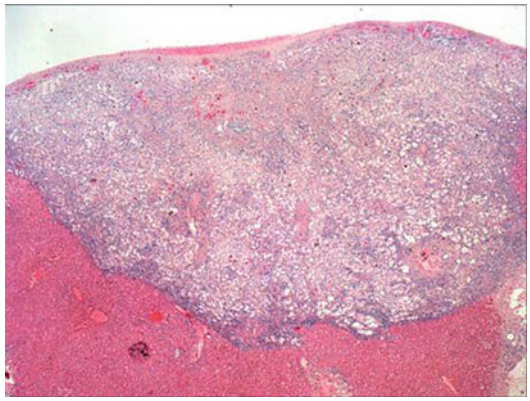

Fig. 1 Peribiliary gland hamartoma (bile duct adenoma). A subcapsular, well-delineated nodule consists of numerous small cholangiocyte tubules or ductules (hematoxylin and eosin stain)

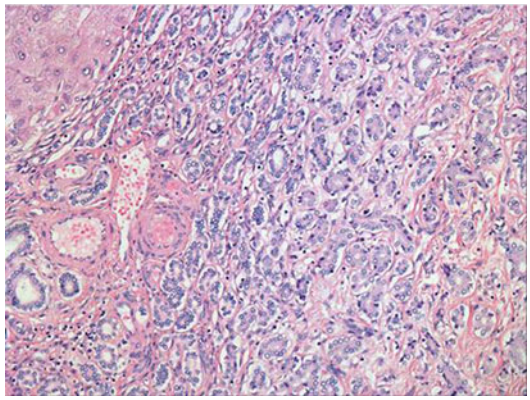

Fig. 2 Peribiliary gland hamartoma (bile duct adenoma). There is a dense collection of homogeneous cholangiocyte tubules without atypia. A portal tract with an interlobular bile duct is seen to the extreme left of the figure (hematoxylin and eosin stain)

et al. 1988). The interface to adjacent liver substance is smooth at low magnification, but shows a finely jagged border at higher magnification, caused by interdigitation of ducts and stroma with parenchyma. This spectrum of changes may render it difficult to distinguish BDA from well-differentiated cholangiocarcinoma, particularly in intraoperative frozen sections (Albores-Saavedra et al. 2001). BDA may undergo secondary changes, such as calcification (Maeda et al. 2006) and hyalinization.

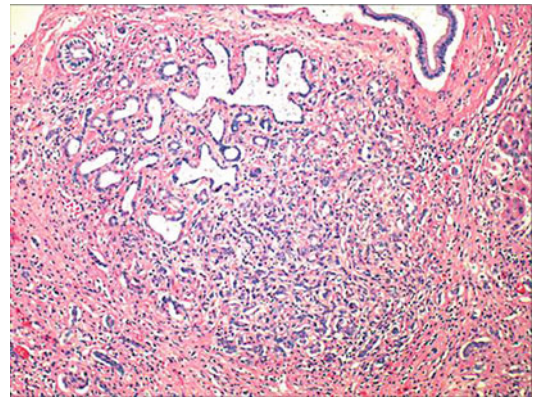

Fig. 3 Peribiliary gland hamartoma (bile duct adenoma) combined with biliary microhamartoma (hematoxylin and eosin stain)

Immunohistochemical Phenotype of BDA

The immunophenotype of BDA epithelial cells is similar to that of normal ductules and interlobular bile ducts (Allaire et al. 1988; Lai et al. 1989; Van Eyken et al. 1991). Expectedly, the cells are markedly reactive for cytokeratins 7 and 19, however, with some variation in staining from one tubular profile to the other (Fig. 4). Part of BDAs also express epithelial membrane antigen (EMA), with a luminal- and cytoplasmic-type staining pattern, whereby the luminal type resembles a ductular reaction and the cytoplasmic-type interlobular bile ducts (Aishima et al. 2014). BDAs have been found to express five foregut antigens, i.e., MUC6 (94 %), MUC5AC (90 %), TFF2 (80 %), D10 (67 %), and 1F6 (61 %); 40 % of BDAs expressed all of these five markers. The findings suggest that BDA displays the same phenotype as pyloric gland metaplasia and that the lesions might represent a localized biliary healing response equivalent to the function of a peribiliary gland or pyloric gland metaplasia in the foregut (Hughes et al. 2010). On the other hand, BDA and peribiliary glands both express two foregut antigens, i.e., D10 and 1F6, and are characterized by the secretion of acid mucin. Peribiliary gland cells invariably expressed D10, 1F6, MUC6, and TFF2, while expression of MUC5AC was only

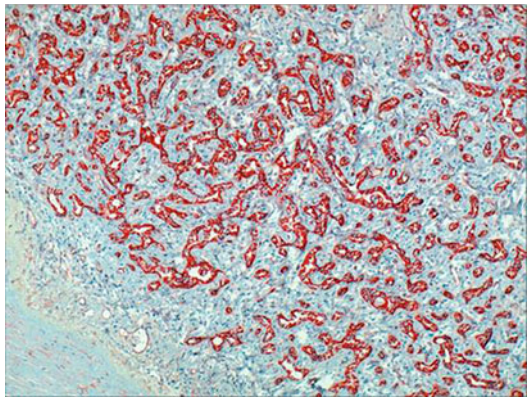

Fig. 4 Peribiliary gland hamartoma (bile duct adenoma) with strong and diffuse expression of cytokeratin 19 (CK 19 immunostain)

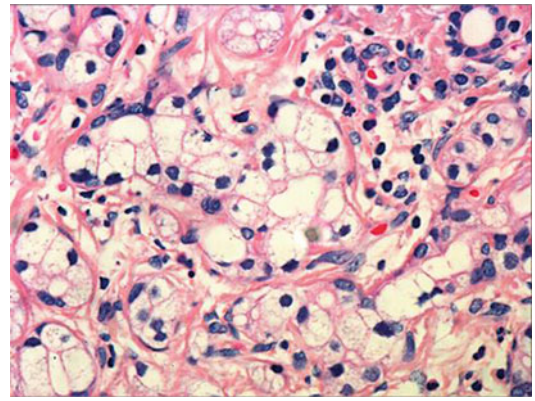

Fig. 5 Peribiliary gland hamartoma (bile duct adenoma), clear cell type. The large cells have a clear or slightly vacuolated cytoplasm. Many of the small nuclei are excentrically placed (hematoxylin and eosin stain)

found in inflamed, but not in normal, peribiliary glands. Most BDAs express MUC6, MUC5AC, and TFF2, while about two thirds of these lesions are reactive for D10 and 1F6, suggesting a relationship between BDA and peribiliary glands (Hughes et al. 2010). More than 80 % of BDAs expressed the senescence marker p16(INK4a), much more frequently than cholangiocarcinoma (Sasaki et al. 2014). The majority of BDAs were found to be reactive for CD56, whereas von Meyenburg complexes expressed CD56 only very focally in less than 5 % of lesional cells, and only very few cholangiocarcinomas were positive in part the carcinomas with a clear cell morphology (Gütgemann et al. 2006). BDAs have been found to have an exceedingly low proliferation activity as based on Ki-67 immunostaining (Tan et al. 2004). In contrast to the malignant counterpart, cholangiocarcinoma, BDA cells are not immunoreactive for the glucose transporter protein 1 (Glut-1; Zimmerman et al. 2002). In contrast to cholangiolocarcinoma, BDA is not reactive for the polycomb protein EZH2 (Sasaki et al. 2014).

BDA, Clear Cell Type

In 2001, three examples of an unusual variant of BDA were reported (Albores-Saavedra et al. 2001). All three tumors were incidental findings occurring in two males and one female (age range, 25–64 years). The lesions measured from 0.8 to 1.1 cm and represented atypical BDA histologically characterized by clear cells that closely resembled metastatic renal cell carcinoma (Figs. 5 and 6). The neoplasm was, therefore, termed atypical BDA, clear cell type (Albores-Saavedra et al. 2001). As described in the original report, this variant of BDA is immunoreactive for CK 7, epithelial membrane antigen (EMA), CEA, and p53 protein (Albores-Saavedra et al. 2001). CK19 reactivity is also observed (Fig. 6). This rare tumor has since been observed by other investigators (Wu et al. 2014).

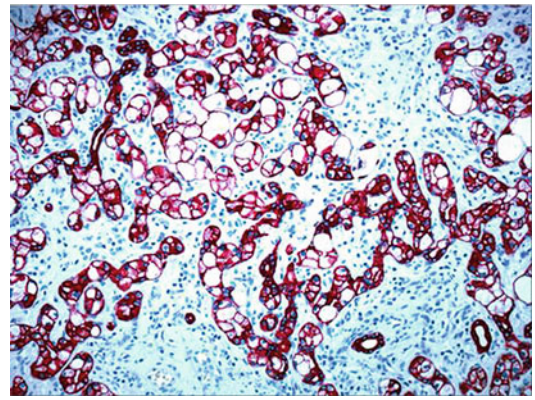

Fig. 6 Clear cell variant of peribiliary gland hamartoma (bile duct adenoma), cytokeratin 19 expression (CK19 immunostain)

BDA, Oncocytic Type

Rarely, the epithelial cells of BDA undergo oncocytic change (oncocytic BDA, BDA with oncocytic features; Figs. 7 and 8; Arena et al. 2006; Hastir et al. 2013; Johannesen et al. 2014). In one case, the tubular epithelium of the nodular lesion was composed of a homogeneous population of cells with abundant, granular, and eosinophilic cytoplasm. The nuclei were small to medium in size and centrally located, and nucleoli were not detectable. Occasional binucleated cells were noted. A lymphocytic infiltration was present in the stroma (Arena et al. 2006).

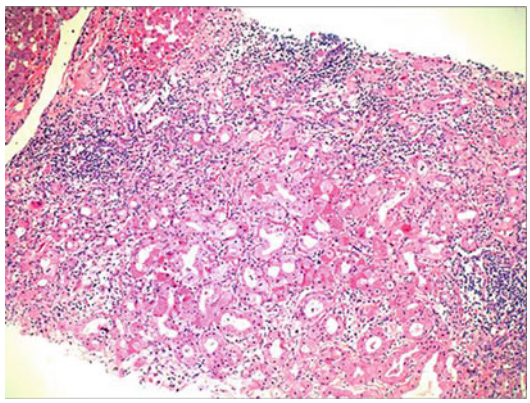

Fig. 7 Peribiliary gland hamartoma (bile duct adenoma), oncocytic variant (needle biopsy, hematoxylin and eosin stain)

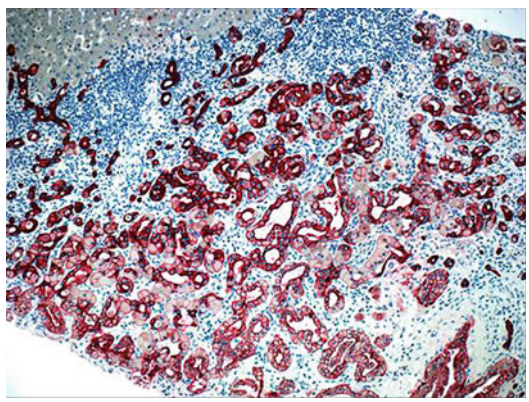

Fig. 8 Peribiliary gland hamartoma (bile duct adenoma) with focal oncocytic features. In this cytokeratin 19 stain, oncocytic elements show reduced and only membranous staining in comparison with non-oncocytic cells (CK 19 immunostain)

BDA, Signet-Ring Cell Type

This variant of BDA is characterized by the presence of PAS-positive diastase-resistant intracytoplasmic globules conferring a signet-ring appearance to the cells. In one case, similar globules were found in the biliary epithelium in the peritumoral portal tracts and in periportal hepatocytes. All these inclusions were strongly positive for alpha-1-antitrypsin, and the patient had the heterozygous M (Malton) genotype (Gambarotti et al. 2008).

BDA with an Endocrine Component

A subset of BDA contains, in addition to the typical small caliber ducts/ductules, periductular nests and clusters of endocrine cells (O'Hara et al. 1992). It was shown that these cell nests decorate with several endocrine markers, including NSE, chromogranin, synaptophysin, and Leu-7, and these (neuro-) endocrine proliferations morphologically resemble pulmonary tumorlets (O'Hara et al. 1992).

Bile Duct Adenoma: A Lesion Associated with Malignancy?

In one case, a BDA was found to have atypical ductular profiles, with cells showing hyperchromatic large nuclei. At the periphery of the lesion, the ductules revealed an invasive behavior. The findings were interpreted to be cholangiocarcinoma arising in BDA (Hasebe et al. 1995). One patient with biopsy-diagnosed BDA described in 1978 (Gold et al. 1978) was followed up. Fifteen years after the lesion was first documented, the female patient died of her tumor. At autopsy, the 8,600 g liver was extensively replaced by a bile duct neoplasm, and there were metastases in the lungs and in lymph nodes. In

most areas, the histologic appearance of the tumor at autopsy showed the same bland appearance demonstrated earlier in the disease course. This situation made it difficult to decide whether to classify this neoplasm as a very unusual cholangiocarcinoma or a BDA (as originally diagnosed) with malignant transformation (Foucar 1985). However, it was argued in a letter that this lesion might not have been bona fide BDA (Govindarajan 1985). Another patient with multiple BDAs was reported to have developed an asymptomatic cholangiocarcinoma, identified at autopsy 10 years after the diagnosis of the BDAs (Bornfors 1984).

Differential Diagnosis

Histologically, BDA of the common, "ordinary" type may be confounded with biliary microhamartoma (von Meyenburg complex) or small, peripheral well-differentiated intrahepatic cholangiocarcinoma.

Pathogenic Pathways

The etiology and pathogenesis of BDA are not clear. Different from liver cell adenoma, BDAs do not exhibit a relationship to oral contraceptive intake (Guzman et al. 1977). There is one case report describing the synchronous occurrence of BDA ("cholangioma") and cholangiocarcinoma several decades after thorotrast administration (Sachs and Encke 1991).

Bile Duct Adenofibroma

Introduction

Biliary adenofibroma (BAF) is a very rare benign neoplasm of bile duct origin with an indolent behavior (Tsui et al. 1993), histologically somewhat resembling biliary hamartoma. Since 1993, less than ten cases have been reported (Parada et al. 1997; Garduno-Lopez et al. 2001; Haberal et al. 2001; Akin and Coskun 2002; Varnholt et al. 2003; Gurrera et al. 2010). The variegated histologic presentation in regard to the amount of stroma present may render it difficult, and sometimes arbitrary, to distinguish BAF from bile duct adenoma with marked stromal reaction or from hepatobiliary cystadenoma with mesenchymal stroma. Cytogenetically, monosomy 22 has been detected in one case of biliary adenofibroma (Parada et al. 1997).

Pathology

In the index patient (Tsui et al. 1993), a wedge resection from the right liver lobe contained a circumscribed, nonencapsulated tumor that abutted on the hepatic capsule, causing a smooth protuberance. The spherical mass had a diameter of 7 cm and a spongy cut surface with multiple, closely apposed, thin-walled, round-to-oval cysts ranging from 1 to 5 mm. The cystic structures were assembled into lobular aggregates by slender septa. The remainder of the tumor consisted of a compact stromal mass. Histologically, tubules (in part branched), glandular profiles, and cysts were embedded in an abundant fibrous vascularized stroma and were lined by flattened to cuboidal cells of biliary type (Figs. 9 and 10). Microcysts can show polypoid projections into their locules or reveal an apocrine-like epithelial configuration. Few tubules contain debris or bile concretions. The poorly vascularized stroma was fibroblastic and highly collagenous, albeit with only focal sclerosis. A modest, patchy inflammatory cell infiltrate is present in the stroma, consisting predominantly of lymphocytes.

Immunohistochemically, the tubular profiles share a cytokeratin expression phenotype with that of interlobular or larger intrahepatic bile ducts, i.e., reactivity for CK7 and CK19 and EMA (Gurrera et al. 2010), suggesting that BAF is derived from this biliary duct system

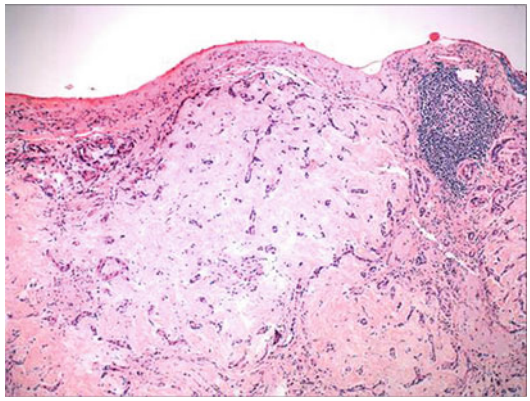

Fig. 9 Adenofibroma of the bile duct. The hypocellular subcapsular fibrous nodule contains only a few bile ductule-like profiles. Note that accompanying lymph follicle with a germinal center (hematoxylin and eosin stain)

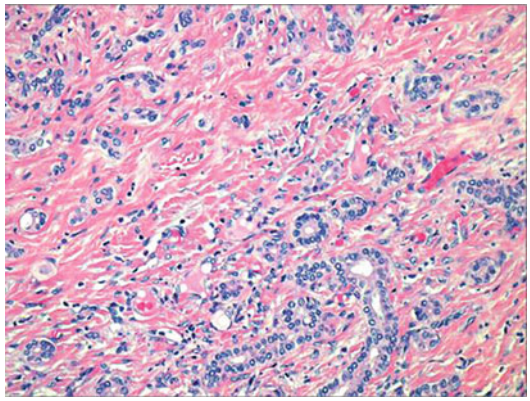

Fig. 10 Adenofibroma of the bile duct. Bile ductule-like profiles are embedded in a collagenous matrix (hematoxylin and eosin stain)

(Tsui et al. 1993; Varnholt et al. 2003). The stromal cells are strongly and diffusely positive for alpha-smooth muscle actin, suggesting their myofibroblastic nature (Gurrera et al. 2010).

Malignant Evolution of Biliary Adenofibroma

In rare instances, BAF may recur, and very few reports have described malignant transformation of such lesions (Haberal et al. 2001; Akin and Coskun 2002). In one case, diagnostically confirmed by biopsy, the lesion grew to a size of 20 cm, with central necrosis and hepatic and pulmonary metastases (Akin and Coskun 2002).

Variants of Biliary Adenofibroma

Apart from classical adenofibroma, lesions resembling this rare growth occur and may pose differential diagnostic difficulties. Kai and coworkers (2012) described a tumor of 7-cm diameter presenting as a multicystic mass. The cystic part of the tumor was composed of locules lined by biliary epithelium with variable atypia, papillary growth, and apocrine snouts. The solid part revealed a tubulocystic proliferation of tumor cells embedded in a dense and partly hyalinized stroma. The lesion was classified as a multicystic biliary tumor with adenofibroma features.

Multicystic Adenofibroma-Like Tumor of the Bile Duct

Introduction

This type of multicystic tumor was observed in an 40-year-old Japanese man, whereby abdominal CT revealed a well-circumscribed multicystic mass measuring approximately 7 × 6 cm (Kai et al. 2012).

Histologically, the tumor was composed of a cystic and a solid lesion. The multicystic part exhibited locules lined by cholangiocyte-like cells with various cytological atypia. The stroma was fibrous and the neoplastic cells showed marked apocrine snouts. Part of the tumor showed a papillary growth with more pronounced cytological atypia. The solid component displayed a tubulocystic proliferation of neoplastic cells, again with prominent apocrine snouts, embedded in dense and partially hyalinized fibrous stroma. This solid part resembled biliary adenofibroma (Kai et al. 2012).

Bile Duct Hamartoma (Biliary Microhamartoma)

Introduction

Bile duct hamartoma (BDH, synonyms: biliary hamartoma, biliary microhamartoma, von Meyenburg complex, biliary cholangiomatosis, minute bile duct adenomas, fibroadenomata, intracapsular aberrant bile ducts) is, according to WHO, defined as a benign lesions consisting of a collection of bile ducts set in a fibrous stroma which is frequently hyalinized. The term now used to designate this lesion has a spectrum of earlier synonyms, as exemplified in the title of the chapter. BDH and its relation to other benign hepatic biliary tumors have recently been reviewed (Tsui 1998). BDHs are clearly nonneoplastic nodules, and their pathogenesis, although not yet fully clarified, seems to be related to a disordered construction of the ductal plate. The recognition of this type of lesion goes back to von Meyenburg, who in 1918 described groups or clusters of small bile ducts in lover lobules separate from portal tracts and interpreted these as being vestigial intrahepatic bile ducts that had formed normally in the embryo, but failed to involute after birth to then undergo cystic dilatation (Von Meyenburg 1918). Hanns (with two n's) von Meyenburg (1887–1971) made his medical thesis in Zurich in 1912; worked under the surgeon, Ernst Ferdinand Sauerbruch; became full professor of pathology at Lausanne in 1921; and then followed a call to the pathology chair at Zurich in 1925 (Uehlinger 1972). The lesions having his eponym were described in an article on polycystic liver disease in 1918.

What is a hamartoma? The term, hamartoma, was introduced in 1904 (Albrecht 1904) to designate a tumor-like malformation. A hamartoma is basically a malformative lesion resembling a tumor and having many features of a tumor, without being neoplastic. It is a focal, often circumscribed overgrowth in improper proportions of tissues normally present in that part of the body. Eugen Albrecht (1872–1908), who created the entities hamartoma and choristoma, was a German pathologist appointed to succeed Weigert as director of the Senckenberg Institute of Pathology. He is the founder of the Frankfurter Zeitschrift für Pathologie (1907). Pulmonary tuberculosis caused his untimely death at the age of only 36 years (Ober 1978). In his 1904 article, Albrecht wrote: "One has to distinguish a novel class of tumors distinct from neoplasms. For these I wish to introduce two new terms:(1) Choristoma (from Greek: 'to separate'), i.e. tumor-like formations located in abnormal places but true parts of these organs : normal tissues abnormally placed; (2) Hamartoma (from Greek: 'to err'), i.e. tumor-like formations in which we can demonstrate abnormal mixture of normal components of the organ in which they occur either by amount, structure, degree of maturity or all three together. . .We can assume that the formation of these above growths took place by abnormal mixing or fundamental disturbance in the course of development" (Ober 1978). It is seen that this was a modern concept of abnormal tissue development, and bile duct hamartoma is in fact an excellent example for the original description as to what a hamartoma is.

Epidemiology

In a series of 1697 consecutive liver needle biopsies, a total of six patients or 0.35 % were confirmed by histology to have BDH (Lin et al. 2013). In autopsy investigation, the incidence of these lesions is somewhat higher. In a large series of autopsies, BDHs were found in 0.69 % (Chung 1979). In another study of 2,843 autopsies, 157 cases having BDH or cysts in the liver were identified. The prevalence of BDH increased with age, an increase found in both sexes, and similar trends were seen if solitary BDH or multiple BDHs were considered separately. BDHs were found in 5.6 % of adults and 0.9 % of children, and macroscopic hepatic cysts were detected in 16.9 % of livers that also had BDH; of livers with hepatic cysts, 73.5 % also had BDH, and among

adults with APKD, BDHs were observed in 97 % (Redston and Wanless 1996). Based on these observations, these authors allocated BDH to three types, namely, type I (BDH with APKD), type II (BDH with liver cysts and without APKD), and type III (BDH without APKD or liver cysts). Overall, the data support a pathogenetic association of BDH and cystic liver disease, but the authors also concluded that, as APKD could account for only 11 % of the patients with BDH, such lesions occurring in the absence of APKD are a manifestation of a different disease. In regard to the incidence in biopsies, 12/2,000 (0.6 %) needle biopsies showed a total of 15 BDHs (as two biopsies contained two and three BDH, respectively; Thommesen 1978).

Patterns of Presentation: Solitary vs. Multiple Lesions

BDH can present as a solitary mass (Shin 2011), sometimes mimicking a liver neoplasm. The presence of multiple BDH lesions (multiple biliary hamartomatosis), usually with a diameter of about 5–8 mm, is a rather frequent finding which has repeatedly been described, sometimes as an incidental finding, but lesions mimicking hepatic metastatic disease, small liver abscesses, or dilated intrahepatic ducts in other instances. In cases where numerous small lesions were observed, the term "diffuse miliary benign fibrocholangioma" had been used by Caroli and coworkers (1974).

Clinical and Imaging Features

Many, if not most, BDHs are incidental findings. The lesions are seen in hepatic imaging performed for other reasons and/or are seen during laparoscopy or upper abdominal surgery. In a minority of cases, diffuse abdominal pain and discomfort or signs reminiscent of cholangitis were observed (Sinakos et al. 2011). Larger lesions can cause nonspecific upper-quadrant discomfort, and multiple BDHs may induce portal hypertension (Yoshida et al. 2009).

BDHs have a rather characteristic presentation in US, CT, and MRI imaging (Eisenberg et al. 1986; Vogel et al. 1986; Cooke and Cooke 1987; Arenson et al. 1988; Evans et al. 1989; Tan et al. 1989; Niizawa et al. 1991; Martinoli et al. 1992; Slone et al. 1993; Brunner et al. 1994; Bravo and Laing 1994; Sada and Ramakrishna 1994; Gallego et al. 1995; Cheung et al. 1997; Wohlgemuth et al. 1998; Luo et al. 1998; Maher et al. 1999; Chen et al. 2000; Chen and Goldstein 2002; Mortelé et al. 2002; Mendez-Sanchez et al. 2003; Martins Machado et al. 2003; Neri et al. 2004; Zheng et al. 2005). It has, however, been emphasized that definitive diagnosis could only be obtained by the use of histologic examination (Principe et al. 1997). In US, scattered hypoechoic or hyperechoic lesions (with or without posterior acoustic reverberation) are noted. Lesions studied so far in more detail were hypoechoic in two reports (Eisenberg et al. 1986; Martinoli et al. 1992), hyperechoic in one report (Tan et al. 1989) and mixed hypo- and hyperechoic in a further report (Slone et al. 1993). Multiple lesions may be more readily detectable in US than solitary lesions (Vogel et al. 1986; Markhardt et al. 2006). Contrast-enhanced sonography has been found to detect very small BDHs, but the findings may be confounded with malignancy (Hohmann et al. 2009). CT reveals well-outlined hypodense areas or nodules that fail to take up contrast medium (Eisenberg et al. 1986; Cooke and Cooke 1987; Arenson et al. 1988; Tan et al. 1989; Salo et al. 1992; Ryu et al. 2010), with the exception of one case in which enhancement with IV

contrast material was reported (Martinoli et al. 1992). In a study of 18 patients who covered a broad spectrum of lesions, ranging from one or two BDHs to innumerable lesions, all cases were hypodense on contrast-enhanced CT scans and hypoechoic on sonograms (Lev-Toaff et al. 1995). Multicystic forms may occur (Ryu et al. 2010), with dilatation of the duct-like structures. The small lesions (typically <1.5 cm) usually have a high signal intensity on heavily T2-weighted images and coronal MR cholangiography, corresponding to low signal intensity on T1-weighted images (Bruegel et al. 2005; Tohmé-Noun et al. 2008; Dilli et al. 2012; Gong et al. 2012; Lung et al. 2013). Gadolinium enhancement may be useful for better resolution of the lesions (Semelka et al. 1999). Multiple lesions may mimic diffuse hepatic metastases (Guiu et al. 2009; Madhusudhan and Das 2009). The angiographic appearance of BDH was characterized by abnormal vascularity, consisting of grape-like clusters of small rings, which could be confused with other benign and malignant conditions demonstrable by angiography (McLoughlin and Phillips 1975). It has been suggested that lesions seen on CT images may represent either solitary lesions or aggregates of multiple BDHs, and there was no correlation between the presentation on imaging and the morphotype of the lesions (Lev-Toaff et al. 1995).

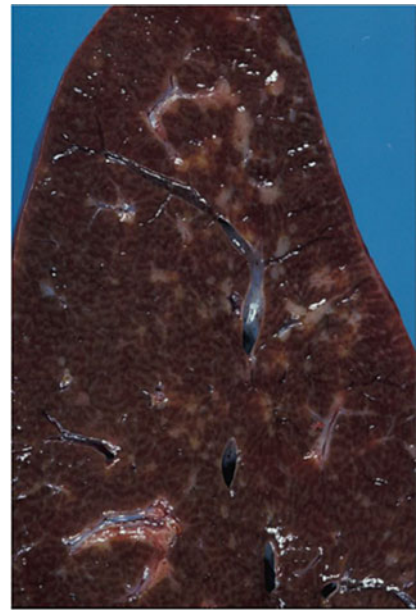

Fig. 11 This liver with signs of chronic congestion exhibits numerous whitish parenchymal lesions representing multiple biliary microhamartomas

Pathology

Macroscopy

BDHs are usually small or very small lesions, however, clearly detectable with the naked eye. They are small, rather well-defined spheroid nodules that are usually creamy white in unfixed specimens, sometimes with bulging after sectioning, and whitish-gray after fixation (Fig. 11). Lesions located to the subcapsular space may show a flat dimple or may exhibit umbilication, particularly in larger nodules. A gross resemblance to small metastases or granulomas is sometime striking, also during laparoscopy (Ioannidis et al. 2012), whereas microabscesses are distinguishable owing to their yellow rather than white color. Typically, BDFs do not leave fluid on the knife upon sectioning. In a study of 18 cases where both pathologic and radiologic informations were available, the lesions varied in size from ≤1 to 1.5 cm in diameter. In six patients, the lesions were less than 1 mm in diameter; in eight they were 1–5 mm; in two, 6–10 mm; and in two, 1–1.5 cm (Lev-Toaff et al. 1995). One report described nodules ranging in size from 0.7 to 3.0 cm (Martinoli et al. 1992). In larger peripheral BDH, the liver capsule may be retracted. Rarely, BDHs present as dark or even "black" nodules on a smooth liver surface, owing to the accumulation of thickened bile within the ductular lumina (Ohta and Ushio 1984). Rare variants of BDH show clusters of macroscopically visible cysts measuring up to 1.2 cm in diameter (macrocystic BDH; Kobayashi et al. 2005).

In regard to the distribution within the organ, many lesions seem to be located to the periphery or even the subcapsular compartment of the liver, visible at laparoscopy (Henning et al. 1982), but this may be biased by sampling and visibility from outside the organ. It has in fact been suggested

that the distribution of BDH is consistently uniform throughout the liver (Slone et al. 1993).

Histopathology

The main histologic features of BDH are characteristic and allow the morphologic diagnosis in needle biopsies (Figs. 12 and 13; Thommesen 1978; Bhusnurmath et al. 1980). They comprise an apparently frequent peripheral and, even more typically, subcapsular and less frequently deeper distribution (the latter particularly in cases of polycystic disease; see below), but this may not be true because deeper lesions may be missed owing to sampling reasons: a close relation to portal tracts in deep-seated lesions, nonencapsulated but relatively well-circumscribed boundaries, a complex network of dilated small duct-like profiles embedded in a sometimes fibrotic stroma that may be hyalinized, visible communications between the profiles and adjacent small bile ducts (Chung 1970), and variable amounts of mainly lymphocytic infiltrations in the matrix (mostly of low density). The lumina of the duct-like structures look ramified and are tubular or cleft shaped, with varying degrees of dilatation. The epithelium lining the duct-like profiles is cubic to low columnar, and there is, similar to normal bile ducts, only slight variation in the height of the epithelial cells within a single lesion, but the epithelium characteristically higher in small BDH than in larger lesions (Thommesen 1978). In most cases, a close spatial relationship to portal tracts is seen.

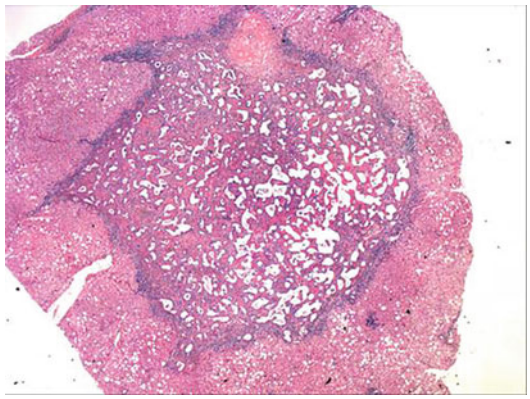

Fig. 12 Biliary microhamartoma (von Meyenburg complex). The well-delineated lesion consists of numerous microcystically dilated ductular profiles. Lymphocytic infiltration is present at the level of the lesion interface (hematoxylin and eosin stain)

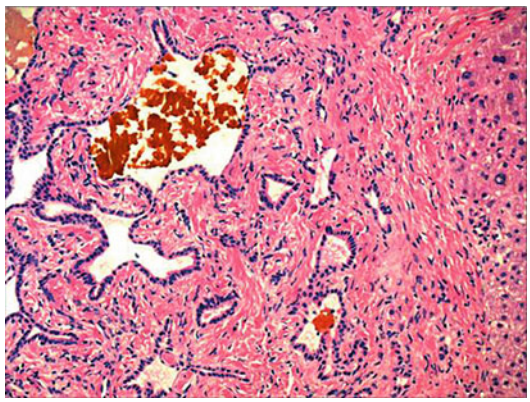

Fig. 13 Biliary microhamartoma (von Meyenburg complex). Irregular and communicating cystic spaces with a normal-looking cholangiocyte lining are embedded in a fibrous matrix. The spaces can contain bile (hematoxylin and eosin stain)

In a biopsy series, all BDHs were located interlobularly in close relation to portal tracts, and the connective tissue of the BDH always merged directly with the connective tissue of the adjacent portal tracts (Thommesen 1978). In serial sections, a communication between all the lumina in each BDH was in fact proven (Thommesen 1978; Ohta and Ushio 1984). The lumina of the cystically dilated ducts of BDH are either empty or contain an amorphous or thready material, or pale to dark, inspissated bile, and sometimes even bile plugs or bile-containing concrements (Thommesen 1978; Röcken et al. 2000). Rarely, intraluminal dystrophic calcifications were found, also visualized as punctiform calcified lesions on CT images (Gil-Bello et al. 2012). The partly hyalinized connective tissue contains only a few visible blood vessels without sclerosis of the walls. At the periphery of the lesions, biliary ductules may be found, sometimes interdigitating with adjacent hepatic parenchyma (Thommesen 1978). At least one report described the presence of nerves within the lesions (autopsy case; Honda et al. 1986). BDH can rarely occur together with a lesion representing to morphology of bile duct

adenoma (Hasebe et al. 1995). Based on the morphology of the biliary channels seen within BDH, the lesions have been attributed to class 1 (solid lesions with narrow bile channels), class 2 (intermediate, the most frequent one), and class 3 (predominantly cystic lesions with prominent dilated bile channels; Lev-Toaff et al. 1995). In one case, BDH was associated or complicated with microscopic polyangiitis (Sato et al. 2013).

The fact that BDH can contain bile supports the view that these lesions are in continuation with structures physiologically transporting bile. Already von Meyenburg found a communication between all the lumina of the single lesions, but did not examine connections to adjacent bile ducts (Von Meyenburg 1918). Later authors found areas of direct transition from liver cell plates to the epithelium of some BDH (Melnick 1955; Chung 1970). The spatial relationship between the ductular profiles of BDH and the resident intrahepatic bile ducts has been studied by the use of histological reconstruction (Ohta and Ushio 1984). These authors observed spicular branches from the BDH penetrated into the liver parenchyma to form what appeared to be canalicular junctions with liver cell plates, and the tubular branches of the hamartoma were in direct contact with ordinary small, terminal bile ducts of neighboring portal tracts. From this observation the authors suggested that BDH is an equivalent of a functioning bile duct (Ohta and Ushio,1984). The finding of such communications has been confirmed in a later microanatomical study of samples from polycystic disease (Grimm et al. 1990).

Immunohistochemistry

Immunohistochemically, the cells of the duct-like profiles are, expectedly, reactive for the biliary-type cytokeratins, CK7 and CK-19 (Pontisso et al. 1993). BDHs also express MUC1 apomucin, but less or not mature MUC1 mucin, suggesting an immature phenotype of the biliary epithelium involved (Sasaki and Nakanuma 1996). Only a minority of BDHs are immunoreactive for CD20 (10 %), and they are negative for mCEA, p63, and p53 protein (Hornick et al. 2005). In contrast to cholangiocarcinoma that reveals immunostaining for glucose transporter protein 1 (Glut-1) in 50 % of cases, no Glut-1 staining was found in BDH, similar to bile duct adenomas that also fail to be reactive (Zimmerman et al. 2002). In contrast to malignant epithelial tumors of the liver, including cholangiocarcinomas, BDH cells are not reactive for enhancer of zeste homologue 2/EZH2 (Hajosi-Kalcakosz et al. 2012).

Is BDH a Precancerous Lesion?

Several observations have documented an association of BDH with hepatic malignancy, specifically intrahepatic cholangiocarcinoma and perihilar cholangiocarcinoma with features that are not different from cholangiocarcinoma in general (Lindgren et al. 1961; Homer et al. 1968; Börnfors 1984; Honda et al. 1986; Dekker et al. 1989; Burns et al. 1990; Hasebe et al. 1995; Yaziji et al. 1997; Kim et al. 1999; Blanc et al. 2000; Jain et al. 2000; Röcken et al. 2000; Wisniewski et al. 2002; Orii et al. 2003; Eguchi et al. 2004; Song et al. 2008; Droy et al. 2009; Xu et al. 2009; Takahashi et al. 2010). This is of interest in the light of the generally increased incidence of biliary malignancies in developmental disorders of the bile duct system, including polycystic liver disease, Caroli's disease, choledochal cyst, abnormal biliopancreatic junction syndrome, and ductal plate malformations (Willis 1943; Daroca et al. 1975; Bloustein 1977; Flanigan 1977; Tsuchiya et al. 1977; Kagawa et al. 1978; Scott et al. 1980; Landais et al. 1984; Baumann et al. 1987; Yamato et al. 1998; Totkas and Hohenberger 2000). It seems that cholangiocarcinoma was more frequently observed in situations where multiple BDHs are present (Homer et al. 1968; Börnfors 1984; Honda et al. 1986; Dekker et al. 1989; Burns et al. 1990; Yaziji et al. 1997; Röcken et al. 2000). Furthermore, at least three observations document the association of cholangiocarcinoma or hepatocellular carcinoma and BDH in the setting of hemochromatosis (Yaziji et al. 1997; Blanc et al. 2000; Wisniewski et al. 2002).

Few reports described an association of BDHs with hepatocellular carcinoma (Heinke et al. 2008; Jain et al. 2010). It is currently unknown whether this is an incidental association or whether the association reflects a pathogenic link between the two lesions. A unique case of an adenocarcinoid, positive for chromogranin A and gastrin, arisen in an area of a large biliary hamartoma has been reported (Papadogiannakis et al. 1996). What are the arguments for an eventual hamartoma-carcinoma sequence? Histologically, a gradual transition from BDH to hyperplastic or adenomatous lesions, carcinoma in situ, and cholangiocarcinoma have been suggested as evidence for a "neoplastic transformation" of BDH (reviews of the literature: Röcken et al. 2000; Jain et al. 2000), suggesting a hamartoma-dysplasia-carcinoma sequence. In fact, dysplastic features of biliary epithelia in BDH associated with cholangiocarcinoma were reported by several publications (Homer et al. 1968; Burns et al. 1990; Hasebe et al. 1995; Yaziji et al. 1997). In an autopsy case, the stroma surrounding BDHs showed infiltrating carcinoma, characterized by nests of pleomorphic cells which often formed rudimentary ductal structures, and areas of transition between seemingly benign and clearly malignant epithelium were found occasionally (Honda et al. 1986).

Differential Diagnosis

The histologic differential diagnosis of BDH includes bile duct adenoma and adenofibroma. Moreover, BDH might be confounded with situations of ductular proliferation/reaction occurring in several disorders, including biliary obstruction and hepatic remodeling. Bile ductular hyperplasia may also occur as an isolated phenomenon in patients with persistently abnormal liver function tests (idiopathic isolated ductular hyperplasia; Sonzogni et al. 2004). Abnormal bile duct profiles developing in congenital liver fibrosis may mimic BDSH, but are easily identified owing to the characteristic concentric arrangement of ductal plate derivatives. Microcystic lesions histologically similar to BDH have been observed subsequent to hepatic ischemia (including liver infarcts) and ischemic bile duct damage ("ischemic cholangitis") caused by arteritis, in particular polyarteritis nodosa (Popovsky et al. 1979; Doppman et al. 1979; Amir et al. 1984; Chang et al. 2003) and, very rarely, temporal arteritis (Rousselet et al. 1989). That ischemic bile duct injury can induce cystic alterations of small bile ducts has also been documented by experimental small vessel hepatic artery occlusion in an animal model (Doppman et al. 1979). Multiple BDHs can mimic diffuse hepatic metastases (Nagano et al. 2006; Salles et al. 2007; Fuks et al. 2009; Singhal et al. 2010). Histologically, specifically in biopsies, BDH may be confounded with metastases of tubular adenocarcinomas, in particular ductal carcinoma of the pancreas. In cases of doubt, immunohistochemistry may help in the differential diagnosis. It has been found that p53 protein, TAG-72, mCEA, and mesothelin had the highest specificity for pancreatic adenocarcinoma, with mCEA having the highest sensitivity (92 %). No significant differences were observed in the degree of CK7, CK8/CK18, CK19, or pCEA expression between metastatic adenocarcinoma and BDH (Hornick et al. 2005). Rarely, BDH has mimicked other cystic hepatic tumors, e.g., biliary cystadenocarcinoma (Karahan et al. 2007).

Pathogenetic Considerations

Based on the morphologic presentation, there seems to be some analogy of BDH and remodeling of the primitive human biliary system (Desmet 1998; Sergi et al. 2000; Awasthi et al. 2004).

Association of BDH with Adult Polycystic Liver Disease

An association between adult polycystic disease and BDH has been noted since long (Melnick 1955; Naim et al. 1987) and has more recently studied in detail (Grimm et al. 1990; Redston and Wanless 1996; Lalosevic et al. 2005). In polycystic livers, the frequently multiple BDHs are

grossly visualized as small whitish nodules in the septal-like structures situated between the cysts, and histologically a close spatial relationship between the hamartomas and the cyst walls is seen. It seems that BDHs in polycystic liver disease (PLD) are related to the evolution of disease. The relationship between BDH and adult PLD was studied in a series of ten autopsy cases. BDHs were found in every case and were the most abundant in livers with cyst size of 1 cm or less and were rare in cases with the largest cysts, suggesting that BDHs prevail in early phases of PLD and that they might transform into cysts (Karhunen 1986). Another study also described that the density of BDH and the stage of PLD in ADPKD were strongly correlated and that 41.4 % of the hepatic cysts were connected to BDH (Ramos et al. 1990), suggesting that hepatic cysts in ADPKD might result from cystic change of BDH. In contrast, BDHs were not communicating with the biliary tract lumen in autopsy specimens of congenital biliary dilatation in ADPKD in another study (Terada and Nakanuma 1988). Peribiliary glands have been shown to be cystically dilated in ADPKD (Kida et al. 1992). Hepatic peribiliary cysts (also called hepatic hilar cysts) were first reported in 1984 (Nakanuma et al. 1984) and were speculated to derive from cystic dilatations of intrahepatic peribiliary glands (review of the literature: Terada et al. 2003).

Association of BDH with Caroli's Disease or Caroli's Syndrome

BDHs have been observed in conjunction with Caroli's syndrome (Aguilera et al. 2004), the so-called "complex" type with congenital hepatic fibrosis (Nakanuma et al. 1982; Davies et al. 1986; Sung et al. 1992). Portal tract-associated lesions similar to BDH have also been noted in an experimental model of this disorder, i.e., the polycystic kidney rat (PCK rat; Lager et al. 2001; Sanzen et al. 2001). In the PCK rat, biliary dysgenesis is associated with an activation of the MAPK/extracellular signal-regulated protein kinase 5 (ERK5) (MEK5/ERK5) cascade that seems to play a pivotal role in the maldevelopment of the bile duct cell lineages (Sato et al. 2005).

Association of BDH with Congenital Liver Fibrosis

BDH may develop in association with congenital liver fibrosis (CLF, synonym: biliary fibroangioadenomatosis), a ductal plate malformation caused by mutations of the fibrocystin gene (see below). CLF was first published in 1954 under the term fibrocystic disease of the liver (Grumbach et al. 1954). The association of CLF with renal dysplasia and renal cystic disease was already noted by these authors and confirmed 4 years later (Leger et al. 1958). The clinical features have been reviewed.

Other Associations

BDHs have been observed in ectopic livers (Watanabe et al. 1989).

Hamartomatous collections of small bile ducts were detected in congenital disorder of glycosylation Ib (CDG Ib; Damen et al. 2004). CDG Ib is caused by deficiency of phosphomannose isomerase (E.C. 5.3.1.8; de Koning et al. 1998; Schollen et al. 2000). Interestingly, patients with CDG Ib also exhibit a distinct type of hepatic fibrosis in addition to protein-losing enteropathy (Oren and Houwen 1999), characterized by mild portal tract fibrosis and an excess of bile duct structures in ductal plate configuration (de Koning et al. 2000), further supporting a link between ductal plate malformations and the pathogenesis of BDH.

Hamartomatous Lesions Probably Related to Biliary Hamartomas

Introduction

Apart from the common hamartomas, i.e., biliary microhamartoma and peribiliary hamartoma/bile duct adenoma, several other, rare hamartomatous lesions of the hepatobiliary tract have been described.

Intrahepatic Multicystic Biliary Hamartoma of the Liver

This is a very rare type of nodular hamartoma which has first been found around the falciform ligament close to the hepatic capsule in the form of protruding lesions. Histologically, these nodular lesions consisted of ductal structures, periductal glands, and fibrous connective tissue. Similar to myoid multicystic hamartoma, these small nodules also contained myoid spindle cells. Bile-like material was observed within some of the ductal profiles. Two cases were associated with a xanthogranulomatous inflammation (Zen et al. 2006). Few further cases have subsequently been reported (Kai et al. 2008; Ryu et al. 2010; Song et al. 2013). The lesions were situated near the liver surface, and imaging showed that the nodules are often intermingled with normal liver parenchyma within the peripheral portion of the lesions (Ryu et al. 2010). In one patient, a 55-year-old man, the liver showed a localized nodular lesion of 5-cm diameter, displaying a multicystic honeycomb appearance. Histologically, the nodule consisted of ductal structures, periductal glands, vascularized connective tissue, and a ductocentric xanthogranulomatous inflammation (Kai et al. 2008).

Myoid Hamartoma

Myoid hamartoma is a hepatic mesenchymal hamartoma containing numerous biliary ductules (Gornicka et al. 2004). The index case showed, in a liver resection specimen, an unencapsulated solid hilar tumor measuring up to 5 cm in diameter. Histologically, it predominantly consisted of eosinophilic spindled or fusiform cells with blunt-ended nuclei, the cells intermingled with cholangiocyte ductules. Immunohistochemically, most of the spindle cells were reactive for smooth muscle actin (alphaSMA), whereas only few cells were positive for CD34 and desmin. The proliferation fraction (Ki-67) was less than 5 %.

The cellular origin of myoid hamartoma of the liver is unknown. It has been shown that hepatic ductules are surrounded by a myoid cell layer (Badaruddin et al. 1976). More recent knowledge refers to myoid cells and myofibroblasts located to the portal tracts (mainly in a periductular sheath), representing the differentiated offspring of hepatic stellate cells situated in a compartment outside the perisinusoidal space, i.e., in an extralittoral compartment (Tang et al. 1994; Tuchweber et al. 1996; Zimmermann et al. 1999; Kinnman and Housset 2002; Ramadori and Saile 2004). These portal myofibroblasts seem to affect the development of intrahepatic bile ducts (Libbrecht et al. 2002). There is evidence to indicate that bile ducts may stimulate chemoattraction of stellate cells mediated by platelet-derived growth factor (PDGF; Kinnman et al. 2000). PDGF-BB apparently produced by cholangiocytes (Grappone et al. 1999; Kinnman et al. 2000). But peribiliary fibrogenic cells can also undergo a myofibroblastic conversion distinct from hepatic stellate cells and stimulated by PDGF (Kinnman et al. 2003). Whether the pathogenesis of myoid hamartoma is related to an abnormal interaction between proliferating small bile ducts and their associated myoid cells is unknown, but it has been observed that another hepatic hamartoma, mesenchymal hamartoma, contains a stromal component consisting of myofibroblasts (Cook et al. 2002).

Myoid Multicystic Hamartoma of the Liver

Rare hamartomatous lesions of the liver are characterized by conglomerates of cysts associated with other tissue components normally occurring in the liver. In one instance, such a lesion observed in an adolescent patient was huge, measuring up to 21 cm, and presented as a smooth multicystic tumor showing cysts up to 6 cm in diameter, but sometimes also with duct-like features. The cyst linings consisted of two types of epithelium, i.e., a mucinous component with cuboidal to columnar cells and an intestinal-type epithelium with goblet cells, Paneth cells and neuroendocrine cells. The cyst walls contained small bundles of smooth muscle as well as groups of small duct-like profiles resembling peribiliary glands, also associated

with smooth muscle (Azar et al. 2003). Part of this cystic lesions resembled congenital solitary nonparasitic cysts (CSNPC) of the liver.

Giant Biliary Hamartomas and Other Hepatobiliary Hamartomas with a Contribution of Bile Ducts

Rarely, liver hamartomas with a predominant bile duct component are unusually large. In one reported case, the lesion was associated with an adenocarcinoid and presented as a well-demarcated area measuring up to 7 cm, with increased consistency and gray-yellow cut surface with multiple cystic dilated spaces and a 1.5-cm tumor-like lesion in the periphery (Papadogiannakis et al. 1996). Histologically, the larger area showed an admixture of bile ducts (mostly cystically dilated) and vascular channels, while the tumor-like lesion consisted of an adenocarcinoid.

Cystic Hamartoma of Bile Ducts

These are hamartomatous lesions arising in large extrahepatic bile ducts at or near the porta hepatis (Dowdy et al. 1962; Toledo-Pereyra et al. 1973; Ansari et al. 1976). In one adult patient, the mass produced intermittent obstructive jaundice and was found to cause a smooth, oblong filling defect in the left hepatic bile duct. Laparotomy revealed a soft, cystic mass measuring 2 cm on the anteromedial wall of the duct. Microscopic examination of the resected specimen displayed cystic spaces lined by a flat or cuboid-to-columnar epithelium, the walls consisting of connective tissue, bundles of smooth muscle, and ductular profiles (Ansari et al. 1976).

Hepatic Nodular Hamartoma with Signs of Ductal Plate Malformation

Terada (2011) described a complex hamartomatous liver lesion observed in 83-year-old man. This patient was found to have a low-echoic and low-density hepatic tumor measuring 7.2 × 5.6 cm. Histologically, the complex mass consisted of liver cysts, ductal plate malformation lesions, peribiliary glands, hepatocytes, portal tracts, and mesenchymal tissue. The cysts were lined by a layer of cuboidal, biliary-type (CK7- and CK-19-positive) epithelia with multiple papillary protrusions. This lesion may represent a hamartomatous growth of several components of hepatic ontogenesis, associated with ductal plate malformation. In fact, ductal plate malformation can occur as a circumscribed lesion limited to restricted areas of the liver, e.g., described as monolobar ductal plate malformation (Terada and Moriki 2010).

Hamartomas of the Hepatic Pedicle

Cystic hamartomatous lesions associated with the hepatic pedicle have very rarely been observed (Bugnon et al. 1987; Alamowitch 1988). In one young adult patient, US and CT showed a partitioned, polylobulated fluid mass which appeared to be connected to the liver. The removed, polycystic mass (20 g, up to 5-cm diameter) was found to originate from the hepatic pedicle, close to the cystic duct. The cysts contained a clear fluid, and the compact wall disclosed several small cavities. Histologically the cyst walls were composed of a fibrovascular tissue with some smooth muscle bundles, adipose tissue, and nerves. The epithelial lining was not specified, but the wall contained glandular structures (Bugnon et al. 1987). In a second patient, a spherical cystic mass measuring 5 cm in diameter was found at US in the region of the pancreatic head, more precisely situated between the gallbladder and the inferior caval vein. At resection, this cyst was attached to the hepatic pedicle. Histologically, the incomplete lining consisted of a mucoid epithelium, and the wall of the cyst contained smooth muscle (Alamowitch 1988). Whether the interpretation of the author that this lesion represents a hamartoma is correct has to be left open, because an intestinal-type duplication may also be taken into account.

Complex Hamartomas with a Marked Ductular Component: Mixed Hamartomas and Solid Hamartoma of the Liver (Solid Hepatic Hamartoma)

Mixed hamartomas of the liver are rare lesions with a histology probably situated between biliary hamartomas and focal nodular hyperplasia (FNH). An impressive case, detected in a 3-month-old child, was described in 1978. A large midline mass, palpable inferior to the liver edge for about 8 cm, extended into the right-upper quadrant. Laparotomy revealed a large and pedunculated, solid pale red-brown nodular mass arising from the caudate lobe, but involving both liver lobes. The resection specimen showed a multinodular tumor with firm to rubbery consistency. The nodules, up to 1 cm in diameter, had white centers and were surrounded by thin septa, similar to the pattern seen in FNH. In contrast to typical FNH, the nodules were histologically subdivided into numerous small PSE, and most of the nodules have a portal tract in the center (not as in FNH), with radiating smaller branches that tended to subdivide the nodules. Abnormal blood vessels typical for FNH were in evidence (Rhodes et al. 1978). Is this type of mixed hamartoma just an early report of FNH? The main difference between this lesion and classical FNH is the unique organoid pattern of the hepatic lesion with pseudolobulation of the nodules, with a large bile duct-containing area occupying the centers, and a peripheral rim of hepatocytic nests or lobular fragments. This hamartoid pattern is not seen in typical FNH. In a small infant, a mixed hamartoma measured 7.5 cm and weighed 179 g. It consisted of loose fibrous stroma intermingled with spindle and polygonal cells and ductular structures (Toda et al. 1990). This pattern seems to mimic mesenchymal hamartoma, which is discussed in another chapter.

Under the term solid hamartoma, an unusual lesion observed in the left liver lobe of an infant was described. It presented as a well-defined, solid nodular lesion with irregularly shaped yellow islands of parenchyma and white-gray fibrous nodules, histologically composed of a mosaic of parenchyma, fibrous stroma, prominent ductular proliferations, and vascular proliferation, resulting in a fibroadenomatous pattern (Sonobe et al. 1988). Hamartomatous nodules with ductular proliferation somewhat resembling FNH have been seen in patients with developmental disorders of the biliary tract, including Alagille's syndrome (Nishikawa et al. 1987; Tuset et al. 1995) and biliary atresia (Ohtomo et al. 1991).

Tumors and Tumor-like Lesions of Peribiliary Glands

41

Contents

Abstract

Peribiliary glands are tubular-alveolar glands with serous and mucinous acini embedded in a fibromuscular bed of ductal walls. These glands can develop several types of lesions that may mimic tumors. The glands may undergo hyperplastic changes, most commonly emerging in the setting of chronic bile duct inflammation, with or without associated bile duct cancer. Hyperplasia may be multifocal and less frequently diffuse, involving intrahepatic and extrahepatic glands. Marked hyperplasia of peribiliary glands, in part associated with dysplasia, is observed in patients with hepatolithiasis and those with liver fluke infestation. Peribiliary glands can give rise to rare cystic and papillary neoplasms and to invasive carcinomas. They play a role in hepatic cancer spread, due to their close spatial relationship with bile duct walls and sharing of a vascular plexus. The glands can also undergo tumor-like cystic changes.

Introduction

Peribiliary glands, bile duct-associated glandular structures important for biliary epithelial homeostasis and bile composition, were not studied in detail in the older hepatobiliary pathology literature but have now gained more attention, mainly by the work of Japanese authors (Nakanuma et al. 1994a, b). Peribiliary glands show a broad

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_41

spectrum of hyperplastic, dysplastic, hamartomatous, neoplastic, and cystic changes and participate in biliary tract carcinogenesis (review: Cardinale et al. 2014).

Normal Morphology and Function of Peribiliary Glands

Peribiliary glands (glands of the biliary tree) are tubular-alveolar glands with serous and mucinous acini. The small glands are deeply embedded in a fibromuscular bed of the duct walls. Peribiliary glands are divided into intramural mucous glands and extramural seromucous glands, and both types are continuous with the lining epithelium of bile ducts (Terada et al. 1987; Terada and Nakanuma 1988; Nakanuma et al. 1994a, 1997). Intramural glands consist of irregularly distributed simple tubular glands with much mucin, while extramural glands show seromucinous acini (sometimes admixed with pancreatic exocrine acini), excretory units, and a conducting system. Analysis of biliary casts and SEM investigations showed that treelike projections from large bile ducts at the bifurcation frequently anastomosed each other and represented extramural peribiliary glands, while pouch-like projections corresponded to intramural glands (Ishida et al. 1989). In intrahepatic bile ducts, peribiliary glands start at the level of septal bile ducts, while interlobular bile ducts lack these glands. Usually, peribiliary glands are more common and dense at the level of large area and segmental intrahepatic ducts. In the extrahepatic biliary tract, peribiliary glands are found along the entire duct system and are also present in the terminal common, pancreatobiliary segment. Generally, peribiliary glands predominate in areas of branching points, i.e., the perihilar region, periampullary area, and cystic duct entrance (Cardinale et al. 2011). Peribiliary glands also occur in transverse fissures and are, in this anatomical locations, the "aberrant biliary structures" of former investigations (El Gharbawy et al. 2011). The gallbladder has no peribiliary glands. Epithelial cells of peribiliary glands consistently express two foregut antigens termed D10 and 1F6 (Hughes et al. 2006, 2010). In normal livers, the pancreatic duodenal homeobox factor 1/PDX1 is frequently expressed in peribiliary glands, but HES1/hairy and enhancer of spli1, which is often expressed in bile duct lining epithelia, is only focally expressed in glands. The glands normally also express SOX9 and EpCAM (Igarashi et al. 2013). Extrahepatic and intrahepatic peribiliary glands express alpha-amylase isoenzymes, trypsin, and pancreatic lipase, immunoreactivity being located to the Golgi area (Terada and Nakanuma 1991, 1993a, b; Terada et al. 1993). Morphological and immunohistochemical investigations showed that intrahepatic peribiliary glands arise from periportal immature hepatocytes at the hepatic hilum, with a stable cytokeratin phenotype during development, and that differentiation of peribiliary glands into mucus-producing acini occurs 3 months after birth (Terada and Nakanuma 1993c).

Peribiliary glands of larger bile ducts are a niche of stem/progenitor cells that can contribute to biliary epithelial replacement and regeneration (Cardinale et al. 2011; Carpino et al. 2012; Sutton et al. 2012). Such progenitor cells have the phenotypic features of endodermal stem cells and express endodermal transcription factors in the nuclei, including SOX9, SOX17, FOXA2, PX1, HES1, NGN3, and PROX1, and show stem cell surface markers, such as EpCAM, NCAM, CD133, and CXCR4 (Cardinale et al. 2011). Cells with the phenotype of biliary stem/progenitor cells are located at the bottom of peribiliary glands near the fibromuscular layer. These progenitors form a heterogeneous population, variably expressing SOX9/17, PDX1, SOX17, EpCAM, NCAM, CXCR4, Lgr5, and OCT4, whereby the most proximal/primitive group was PDX1(+)/SOX17(+)/EpCAM(+/−) (Carpino et al. 2012). In injured extrahepatic bile duct specimen showing epithelial cell loss, large numbers of Ki-67(+) cells were observed in peribiliary glands, which also contained few c-Kit-positive cells, suggesting that peribiliary glands might contribute to biliary regeneration as a source of progenitor cells (Sutton et al. 2012). In the absence of peribiliary glands in the gallbladder, progenitor cells are situated in mucosal crypts in this organ (Carpino et al. 2014). It has been

proposed that these progenitor cell populations play a role in the pathogenesis of cholangiocarcinoma (review: Cardinale et al. 2014).

There is direct and indirect evidence that peribiliary glands play a role in regeneration and repair of bile duct epithelia and the pathogenesis of bile duct inflammation and fibrotic changes. Injury of peribiliary glands, in particular deep-seated glands, together with damage of vascular plexus was associated with the occurrence of biliary strictures after transplantation (op den Dries et al. 2014).

Hyperplastic Changes of Peribiliary Glands

Most cases of peribiliary gland hyperplasia were observed in the setting of chronic bile duct inflammation, with or without associated bile duct cancer. Hyperplasia may be multifocal and less frequently diffuse and involves intrahepatic and extrahepatic glands. It consistently develops in hepatolithiasis (Terada and Nakanuma 1988; Nakanuma et al. 1988) and more variably in other conditions, such as bile duct infection and infestation, and following submassive liver necrosis (Nakanuma et al. 1994b). Marked peribiliary gland hyperplasia, in part associated with dysplasia (see below), was often found in intrahepatic bile ducts of patients with hepatolithiasis (Lee and Sheen 1999). In livers without hepatolithiasis, hyperplastic changes are generally less frequent. In a systematic study of 1000 consecutive autopsy liver specimens, hyperplasia of intramural glands was observed rather evenly in normal livers and in livers with various hepatobiliary diseases. The prevalence of hyperplasia of extramural mucous acini was high in cirrhosis, submassive hepatic necrosis, cholangitis, systemic infection, and extrahepatic biliary obstruction (Terada and Nakanuma 1992). A marked hyperplasia of peribiliary glands was observed in patients with liver fluke-associated cholangiocarcinoma, the hyperplastic cells being D10-positive (Hughes et al. 2006). There is a weak correlation between gland-type involvement and underlying hepatobiliary disease. Hyperplasia of extramural glands is more common in cirrhosis, submassive hepatic necrosis, cholangitis, systemic infection/sepsis, and biliary obstruction, while hyperplasia of intramural glands prevails in intrahepatic cholangitis with or without associated hepatolithiasis. Dumas and coworkers (1998) described a rare case of diffuse, severe, macroscopically recognizable hyperplasia of peribiliary glands of intrahepatic and extrahepatic ducts. This condition was detected in a patient with massive hepatic necrosis, and the cause of hyperplasia could not be elucidated. Through increased production and secretion of seromucinous substance discharged in duct lumens, peribiliary gland hyperplasia can induce mucin-related biliary disease. Histologically, multifocal hyperplasia shows both an increased number of glands and signs of epithelial hyperplasia. Differential diagnostically, hyperplasia of peribiliary glands may histologically be confounded with well-differentiated cholangiocarcinoma.

Cystic and Papillary Neoplasms Derived from Peribiliary Glands

A rare variant of cystic and papillary tumor derives from peribiliary glands, thought to derive from stem/progenitor cells located in these glands (Nakanuma and Sato 2012). Similarly, intraductal papillary neoplasm may arise from peribiliary glands, these tumors being composed of papillary and glandular components, and the tumor cells being similar to gastric foveolar and pyloric gland epithelia (Nakanishi et al. 2011). There is one report referring to two patients with intraductal tubulopapillary neoplasm of intrahepatic bile ducts. These neoplasms were associated with multiple peribiliary cysts located to the hilar region. As these cysts were partly lined by carcinoma cells that were continuous with the papillotubular neoplasms, it was suggested that this form of intraductal neoplasm might originate from peribiliary gland cysts (Zen et al. 2012). Based on radiologic findings showing diverticulum-like cystic lesions, part of cyst-forming intraductal papillary neoplasms of bile ducts were suggested to arise from peribiliary

glands (Lim et al. 2011). Intraductal oncocytic papillary neoplasm originating from peribiliary glands was described (Nakanishi et al. 2009). In this case, the oncocytic tumor originated from a cystic space in the bile duct wall, histologically identified as a cystically dilated peribiliary gland. This space contained carcinoma in situ.

Invasive Carcinomas Originating from Peribiliary Glands

Invasive "classical" cholangiocarcinoma arising from peribiliary glands is probably a rare neoplasm. Hilar cholangiocarcinoma (Klatskin tumor) originating from peribiliary gland has been reported (Terada et al. 1992a). Usuda and coworkers (2009) described carcinoma of Vater's ampulla arising from peribiliary gland.

Peribiliary Glands as a Potential Source of Cholangiocarcinomas

It has been suggested that peribiliary glands may have a tumorigenic role or contribute to the development of biliary tract cancers in a complex manner. In patients with hepatolithiasis and associated chronic cholangitis, so-called chronic proliferative cholangitis and atypical glandular proliferations can occur, the latter associated with dysplastic changes. These proliferative changes are now known to involve, or originate from, peribiliary glands. In a systemic investigation of 799 autopsy livers, papillary hyperplasia of peribiliary glands as a form of atypical hyperplasia was found in 0.8 %, papillary hyperplasia and atypical hyperplasia coexisted in 0.5 % (Terada and Nakanuma 1990a). Both hyperplastic and dysplastic alterations of peribiliary glands exhibit elevated PCNA levels, but dysplastic cells had a higher PCNA labeling index than hyperplastic cells. Also cells in extramural glands displayed a higher proliferative activity than those in intramural glands, suggesting that high turnover in dysplastic cells and extramural glands may have a higher neoplastic potential (Lee and Sheen 1999). Peribiliary glands can harbor cystic and cystic-micropapillary changes that might represent tumor precursor lesions. In an autopsy study of 938 livers, cystic-micropapillary and cystic lesions were detected in 1 % and 4 % of cases, respectively (Sato et al. 2014). MUC5AC expression was more frequent in the cystic-micropapillary group than in cystic lesions. The mean Ki-67 labeling index was higher in the former than in the latter, and cystic-micropapillary lesions expressed cyclin D1 and S100P, reflecting a pattern similar to that of the branch-type intraductal papillary mucinous neoplasm of pancreas. In the rare cystic-micropapillary lesion group, atypia of micropapillary epithelia was usually mild, but was associated with invasive adenocarcinoma in one case. Overall, the findings suggested that cystic-papillary lesions have neoplastic lesions and a status of biliary cancer precursors. It has been proposed that mucin-producing cholangiocarcinoma might derive from biliary stem/progenitor cells located in peribiliary glands (Cardinale et al. 2012).

Peribiliary Glands: Their Role in Hepatic Cancer Spread

Due to their close spatial relationship with bile duct walls, sharing of a vascular plexus with that of ducts and a distinct periglandular matrix, peribiliary glands might play a role in spread of biliary tract cancers. Hilar well-differentiated cholangiocarcinoma can extensively involve the peribiliary gland networks, with or without association with in situ-like spread of carcinoma cells in bile duct lumen (Sato et al. 2013).

Peribiliary Gland Hamartoma (Bile Duct Adenoma)

The former bile duct adenoma is now most often designated as peribiliary gland hamartoma (Bhathal et al. 1996). Both so-called biliary adenomas and peribiliary glands are characterized by the expression of two foregut antigens, known as D10 and 1F6, and secretion of mucin. Both cell systems often express MUC6, MUC5AC being

expressed in "adenoma," but not normal (quiescent) peribiliary glands, which becomes MUC5AC(+) when inflamed (Hughes et al. 2010). As, however, most of the literature employed the term "adenoma," this lesion is treated in a separate paragraph in more detail.

Hepatobiliary Hamartomas Containing Elements of Peribiliary Glands

Zen and coworkers (2006) described three cases of unusual hamartomatous nodules of the liver, located close to the capsule of the left lobe and protruding from the liver. The nodules consisted of ductal structures, periductal glands, and vascularized fibrous connective tissue and were associated in part of cases with xanthogranulomatous inflammation. A hepatobiliary nodular hamartoma involving peribiliary gland elements was described by Terada (2011). An 83-year-old man showed a hepatic tumor measuring up to 7.2 cm suggesting intrahepatic cholangiocarcinoma. Histologically the mass consisted of liver cysts, ductal plate malformations (resembling the fetal ductal plate), peribiliary glands, hepatocytes, portal tracts, and mesenchymal tissue. The cysts were lined by a layer of cuboidal cells with multiple papillary protrusions.

Monolobar Ductal Plate Malformation Disease

Under this term, Terada and Moriki (2010) described an interesting combination of Caroli's disease, peribiliary cysts, peribiliary gland proliferation, ductal plate malformations, hepatolithiasis, and portal phlebosclerosis. This combination of alterations was found in a 73-year-old man with multiple segmental dilatations of left intrahepatic bile ducts. The left liver lobe was atrophic and partly fibrotic. In some respects, the changes resembled monolobar Caroli's disease with ductal plate malformation, but a striking feature was the involvement of peribiliary glands.

Intrahepatic Peribiliary Gland Cysts

Multiple hilar cysts of the liver derived from peribiliary glands occur and have first been described in 1984 by Nakanuma and coworkers, who detected them in the hilar peribiliary connective tissue in livers with portal hypertension and/or portal vein thrombosis (Nakanuma et al. 1984). Since their first description, numerous reports have documented peribiliary gland cysts/PBGC, although this entity is still not well known in clinical practice (Nakanuma 2001). The lesions were described under various terms, including multiple cysts at the hepatic hilum, hepatic cysts of periductal gland origin, mucinous hamartoma of the biliary system, peribiliary cysts, multiple hilar cysts, and Nakanuma disease. The cysts are usually multiple, mostly develop around large intrahepatic bile ducts, and range in diameter from few millimeters to more than 3 cm, albeit most cysts are smaller than 1 cm. Cysts also develop in peribiliary glands of extrahepatic ducts, but this seems to be a less common pathology.

Selected References Wanless et al. 1987; Chin et al. 1988; Terada and Nakanuma 1990; Baron et al. 1994; Itai et al. 1994; Nakanuma et al. 1994b; Terayama et al. 1995; Fujioka et al. 1997; Colina et al. 1998; Kudo 2001; Motoo et al. 2001; Nakanuma 2001; Okada et al. 2001; Seguchi et al. 2004; Miura et al. 2006; Kai et al. 2008; Nakayama 2010; Da Ines et al. 2011; Montoriol et al. 2012; Seo et al. 2012.

Intrahepatic PBGC are lesions with varying reported frequencies. In a systematic study of 1000 autopsy livers, a cystic change was noted in 20.2 %, often associated with necroinflammatory changes, portal hypertension, or obstruction (Terada and Nakamura 1990b). In contrast, they were detected in only 0.26 % of autopsied patients with chronic fibrosing liver disease or cirrhosis (cited in Fujioka et al. 1997). These cysts correspond to cystic dilatation of peribiliary glands and are arranged along intrahepatic bile ducts both in large portal tracts

and in the hilar area (Itai et al. 1994). PBGC most often occur in patients with fibrosing liver disease or liver cirrhosis, in particular alcoholic cirrhosis or alcoholic hepatitis (Nakayama 2010; Seo et al. 2012), but have also been found in association with severe liver disease, hepatolithiasis, portal vein thrombosis, adult-type polycystic disease (Kida et al. 1992), and liver malignancy. Many cases of PBGC are probably asymptomatic, but part of cases can exert external compression of bile ducts and, in case of bilateral intrahepatic duct involvement, eventually induce biliary obstruction (Wanless et al. 1987; Stevens et al. 1996; Seguchi et al. 2004; Yokomichi et al. 2006; Kai et al. 2008; Fujiwara et al. 2009; Pang et al. 2010). PBGC can be complicated by cholangitis and sepsis (Otani et al. 2006). Peribiliary gland cysts are visualized by ultrasound, showing hilar multicystic echo complexes around portal venous branches near the hilum (Terada et al. 1992b). Clinico-radiologically, PBGC can mimic Caroli's disease (Fusai et al. 2005). On contrast-enhanced CT images, PBGC are clusters of relatively small and usually multiple cystic lesions that are found along the larger portal veins up to the third- or fourth-order branch, while on cholangiographic contrast-enhanced CT scans, the cystic areas were located adjacent to or surrounding bile ducts (Itai et al. 1994; Hoshiba et al. 1996; Terayama et al. 1995; Tohma et al. 2009). On MR images, cysts appeared as tubular structures or of high intensity on T2-weighted images, sometimes mimicking dilated bile ducts or as clusters of cysts (Baron et al. 1994; Motoo et al. 2001; Montoriol et al. 2012). There is radiological evidence that both number and size of PBGC can increase with time (Ahmadi et al. 1997; Kudo 2001; Motoo et al. 2001).

Pathogenetically, several mechanisms have been suggested (Nakanuma 2004). It has been proposed that chronic inflammatory alterations may damage and destroy the peribiliary glandular conduits (Terada et al. 1990), resulting in stasis and prestenotic dilatation. In fact, peribiliary cysts have been observed in the setting of cholesterol hepatolithiasis associated with a foreign-body reaction (Terada et al. 2003) and in primary sclerosing cholangitis, where cystic lesions were considered to reflect peribiliary gland dilatation (Terasaki et al. 1997). Alcohol-related liver disease is associated with the development of PBGC, including alcoholic liver cirrhosis (Fujioka et al. 1997; Seo et al. 2012). In one study based on clinical and autopsy cases, the frequency of these cysts was correlated with the degree of alcohol-related hepatic fibrosis (Matsubara et al. 2014). PBGC have been observed in the setting of cholesterol hepatolithiasis (Terada et al. 2003), suggesting that biliary stone disease may be involved in PBGC pathogenesis. Hilar peribiliary cysts have been observed as a rare posttransplant biliary tract complication, often presenting as cystically dilated peribiliary glands with multilocular, sometimes multiple cavities ranging up to 2 cm in diameter (Colina et al. 1998). Cystic dilatation of peribiliary glands was frequently observed in the setting of adult polycystic liver disease and less frequently in patients with solitary nonparasitic liver cysts (Kida et al. 1992).

Macroscopically, PBGC appear as few to numerous small cysts within large portal tracts or the hilar area (Seguchi et al. 2004), ranging in diameter from 2 mm to more than 3 cm (Ahmadi et al. 1997; Colina et al. 1998) and containing a serous or, less commonly, mucinous fluid. This accumulation is linked to the capability of peribiliary glands to produce and secrete neutral and acid mucins into the gland lumen (Nakanuma et al. 1994a). The surface of the cysts is glistening and the cyst walls are semitranslucent and thin (Fujioka et al. 1997). On cut surfaces of autopsy liver or liver resection specimens, the cysts are typically arranged along large intrahepatic bile ducts close to the hilar region.

Histologically, the cysts are lined by a single layer of flattened or cuboidal epithelial cells without cellular or nuclear atypia, and cysts may be associated with atrophic remnants of peribiliary glands that still show acinar structures in part of cases (Fig. 1; Seguchi et al. 2004). In some patients, numerous dilated peribiliary glands may accompany macroscopically

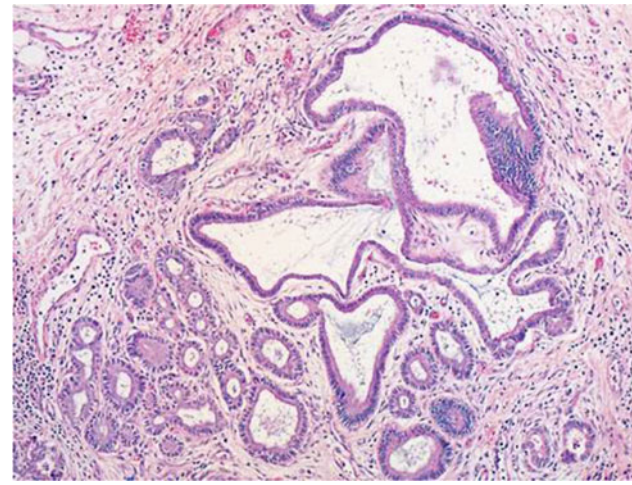

Fig. 1 Peribiliary gland cysts (hematoxylin and eosin stain)

recognizable cysts (Fujioka et al. 1997). Part of the lining cells have PAS-and/or Alcian blue-positive material in the apical portion of the cytoplasm. The mucinous material within cysts is partly stained with both PAS and Alcian blue, but the cysts did not contain bile (Fujioka et al. 1997). The cysts lack goblet cells and Paneth cells. The epithelial cyst cells are immunoreactive for cytokeratin 19 (Fujioka et al. 1997). The cyst walls consist of connective tissue, with absence of smooth muscle cells and elastic fibers. Some of the cysts are associated with inflammatory changes.

Peribiliary Gland Cysts of Extrahepatic Bile Ducts

In contrast to PBGC developing in intrahepatic ducts, peribiliary cysts arising in extrahepatic ducts are rare lesions. In some patients, a solitary large PBGC was detectable either in the hilar area, the hepatic ducts, or the common bile duct (Lee et al. 1999; Johnson et al. 2007; Ikenaga et al. 2009). PBGC of the common bile duct can cause obstruction and refractory obstructive jaundice (Johnson et al. 2007; Ikenaga et al. 2009; Takahashi et al. 2009). Intrahepatic PBGC can occur together with such cysts located to the cystic duct (Miyake et al. 2001).

DOI 10.1007/978-3-319-26956-6_42

Abstract

Several types of bile duct cancer are characterized by a squamous cell lineage. Squamous cell carcinomas with keratinization can occur in both extrahepatic and intrahepatic bile ducts. These tumors may present as lesions entirely composed of cancerous keratinocytes or occur in conjunction with other cellular components, such as adenocarcinoma. Overall, these are rare neoplasms that account for less than 2 % of biliary malignancies. Most of squamous cell carcinomas originate from bile ducts, but the site of origin may be difficult to determine in intrahepatic tumors. There is evidence that squamous cell carcinoma can develop in the liver substance without detectable association with bile ducts. These neoplasms can also develop in various types of hepatic cysts, in particular choledochal cysts. Adenosquamous carcinoma is a rare malignancy containing both squamous and glandular elements. In the liver, it develops either as a variant of cholangiocarcinoma or as a neoplasm not proven to be related to bile ducts. A further and very uncommon hepatobiliary carcinoma that possesses a squamous cell lineage is mucoepidermoid carcinoma.

Squamous Cell Carcinoma of the Hepatobiliary Tract

ICD-O code 8070/3

Introduction

Squamous cell carcinoma of the biliary tract is rare, accounting for less than 2 % of biliary malignancies. This biliary neoplasm was first described in 1930 (Cabot 1930). Squamous cell carcinoma can develop in the intrahepatic or extrahepatic bile ducts. It may present as a tumor entirely composed of keratinocytes or may occur in conjunction with other cellular components, such as adenocarcinoma or neuroendocrine neoplasms. Clinically, the tumors show the growth pattern of mass lesions and therefore cause duct stenosis with all sequelae known from classical cholangiocarcinoma. As squamous cell carcinomas of the biliary tract are rapidly growing, highly invasive, and aggressive lesions, they are clinically characterized by large tumor size and high stage at diagnosis, aggressive modes of intrahepatic spreading, and frequent metastasis (Nakajima and Kondo 1990).

Squamous Cell Carcinoma of the Extrahepatic Bile Ducts

Extrahepatic duct squamous cell carcinomas develop in the hepatic duct (Hagemann 1964; Abbas et al. 2008) or common bile duct (Cabot 1930; Neibling et al. 1949; Sako et al. 1957; Shani et al. 1974; Andersson et al. 1977; Burger et al. 1978; Gulsrud et al. 1979; Nakajima et al. 1988; Funakawa et al. 1996; Gatof et al. 2004; La Greca et al. 2004; Sewkani et al. 2005; Sanada et al. 2010). Very few cases of squamous cell carcinoma of the hilar area are found in the literature (Aranha et al. 1980; Nakajima and Kondo 1990). There is only one report describing squamous cell carcinoma of the cystic duct. This tumor developed in a patient with occupational asbestos, and asbestos bodies were detected within the tumor (Szendroi et al. 1983).

Squamous Cell Carcinoma of the Intrahepatic Bile Ducts

Several reports have document pure or mixed squamous cell carcinoma apparently developing in intrahepatic bile ducts, although the site of origin may be difficult to determine (Aranha et al. 1980; Song et al. 1984; Nakajima and Kondo 1990; Roediger and Dymock 1991; Saito and Nakanuma 1995; Shinagawa et al. 1996; Tsuneyama et al. 2003; La Greca et al. 2004). For cases that are not clearly related to the intrahepatic bile duct system, the term squamous cell carcinoma of the liver is used. Most squamous cell tumors occurring in intrahepatic bile ducts are mixed lesions, consisting of squamous cell carcinoma with focal adenocarcinoma,

adenosquamous carcinoma, adenocarcinoma with focal squamous differentiation, and anaplastic carcinoma with either squamous, adenoid, or combined squamous-adenoid differentiation (Nakajima and Kondo 1990). In one reported case, squamous cell carcinoma was in close association with a cholangiocarcinoma and hepatocellular carcinoma (Tsuneyama et al. 2003). Squamous cell carcinoma of bile ducts was found in association with hepatolithiasis (Song et al. 1984).

As in other organs, the tumor is histologically characterized by a stratified epithelium consisting of keratinocytes in various phases of differentiation. Hepatobiliary squamous cell carcinomas may show marked keratinization (Nakajima and Kondo 1990; Tsuneyama et al. 2003).

Primary Squamous Carcinoma of the Liver

Introduction

Primary hepatic squamous cell carcinoma (SCC-L) is defined as a squamous cell carcinoma apparently arising in the liver substance without detectable association with the biliary tract or congenital or acquired cysts. In part of the reports relating to SCC-L, it is difficult to judge from which tissue structure the tumor had arisen, and an origin from intrahepatic ducts may be difficult to exclude. However, in few instances the hepatic origin of this rare tumor has been verified by autopsy. Younger females and the left liver lobe seem to be more frequently involved. There is an association of this tumor type with hepatolithiasis (Song et al. 1984), a disorder also complicated by cholangiocarcinoma (Chen et al. 1984).

Selected References (Imai 1934a,b; Geddes 1970; Song et al. 1984; Gresham and Rue 1985; Pawelczak et al. 1987; Mandai et al. 1989; Clements et al. 1990; Koyama et al. 1990; Banbury et al. 1994; Quijano Orvananos et al. 1994; Shinagawa et al. 1996; Doctor et al. 1998; Yoshida et al. 1998; Saito et al. 2002; Kaji et al. 2003; Klug et al. 2003; Bondini et al. 2005; Lee et al. 2006; Shchegolev et al. 2006; Yuki et al. 2006; Naik et al. 2009).

There is evidence that many of SCC-Ls might have arisen from hepatic epidermoid cysts (Lombardo et al. 1995; Caratozzolo et al. 2001); congenital cysts (Pliskin et al. 1992; Steffani et al. 2003; Hsieh et al. 2005), including the ciliated hepatic foregut cyst (Vick et al. 1999b; Furlanetto and Dei Tos 2002); or solitary nonparasitic cysts (Edmondson 1958; Greenwood and Orr 1972; Bloustein and Silverberg 1976; Bloustein 1977; Kasai et al. 1977; Beppu et al. 1978; Gresham and Rue 1985; Lynch et al. 1988; Nieweg et al. 1992; Banbury et al. 1994; Weimann et al. 1996; Chou et al. 1997; Charles and Gupta 2001; Yagi et al. 2004).

Clinical and Imaging Features

Clinically, these tumors may present as right upper abdominal fullness and/or pain, hepatomegaly, weight loss, and intermittent fever (Roediger and Dymock 1991; Caratozzolo et al. 2001). A literature review had shown that abdominal pain is the chief symptom of primary SCC-L (Yuki et al. 2006). SCC-L has been found in association with liver cirrhosis (Yuki et al. 2006). In some patients, the tumor was associated with hypercalcemia (Arase et al. 1988), and more recently, it surfaced that part of these tumors produce, as a paraneoplastic phenomenon and similar to squamous carcinomas located elsewhere (Welsh and Powers 1993; Jais et al. 1997; Crespo et al. 1999), parathyroid hormone-related peptide/protein (PTHrP) (Asanuma et al. 2002; Saito et al. 2002), this peptide being immunohistochemically detectable in the neoplastic cells (Saito et al. 2002). In one patient, PTHrP production was associated with increased serum levels of IL-6, thought to result from induced osteoblasts (Asanuma et al. 2002). Similar to adenosquamous carcinoma (see below), primary SCC-L has been shown to rarely produce granulocyte colony-stimulating factor (Koyama et al. 1990). The diagnosis may be suspected in bile cytology specimens from PTCD (Shinagawa et al. 1996). The prognosis of this type of hepatic cancer is extremely poor, no patient having survived longer

than 6 months after diagnosis, as far as can be judged from the literature (Bloustein and Silverberg 1976; Clements et al. 1990; Yagi et al. 2004; Lee et al. 2006). In case the squamous cell carcinoma arises in a hepatic cyst, an unusual color of the cyst fluid upon puncture (blood-stained or brown fluid), cyst infection, and rapid cyst recurrence subsequent to conservative treatment should raise suspicion of malignancy.

Pathology

Macroscopy

SCC-Ls are usually large or very large tumors with either an expanding or grossly invasive growth pattern, and even in case where the tumor took its origin from a preexistent hepatic cyst, most of the cystic space may be replaced or occupied by the cancer masses. In one case, a unilocular hepatic cyst was buried within a large tumor mass, but the carcinoma also exhibited an intracystically growing, exophytic component, forming an impressive intraluminal fungating mass (Pliskin et al. 1992).

Histopathology

Histologically, the phenotype found in other such tumors is observed, i.e., medium-sized to large keratinocytes forming strands in a variably developed stroma (Figs. 1, 2, 3, and 4). Marked keratinization of the neoplastic cells can develop (Chou et al. 1997), sometimes with decay of the keratinocyte masses and formation of a central cystic lesion. In such a situation, the tumor may be clinically confounded with a hepatic abscess (Doctor et al. 1998). On the other hand, part of the tumors lacked keratinization (Shchegolev et al. 2006).

Interestingly, tumors with a basaloid component have also been detected as primary hepatic lesions (basaloid-squamous carcinoma, BSC; Bastiaan de Boer 2000). The entity of BSC was first described in 1986 based on a group of ten unusual cancers involving the mucosa and underlying tissue of the

tongue, hypopharynx, and larynx and originally was termed basaloid-squamous carcinoma (Wain et al. 1986). BSC is a highly aggressive neoplasm, histologically characterized by an intimate association of a basaloid pattern with squamous cell carcinoma, the basaloid part consisting of small crowded cells with hyperchromatic nuclei, scant cytoplasm, small cystic spaces, foci of tumor necrosis, and prominent hyalinosis. The only case reported for the liver was in a 46-year-old female and presented as a huge, i.e., 27 cm-sized, centrally necrotic tumor in the right liver lobe (Bastiaan de Boer 2000).

Differential Diagnosis

Apart from squamous cell carcinoma arising from bile ducts, the principal differential diagnosis is metastasis of extrahepatic squamous cell carcinomas, which have numerous primary sites. However, esophageal SCC is a predominant primary lesion producing hepatic metastases (Maclean et al. 1962; Sumi et al. 2000; Nakajima et al. 2001; Ikeda et al. 2003; Pouessel et al. 2005; Pawlik et al. 2007; Morris et al. 2011; Sanal et al. 2011). Hepatic metastases of SCC can present as hepatic cysts (Morris et al. 2011). Squamous cell carcinoma arising in adjacent organs can directly invade the liver, e.g., squamous cell carcinoma of the esophagus (Akagi et al. 2011).

Pathogenesis

Squamous cell metaplasia with varying degrees of dysplasia has been reported in conjunction with squamous cell carcinoma of the bile duct (Song et al. 1984; Shinagawa et al. 1996; Abbas et al. 2008), but metaplasia was not detected in one study (Nakajima and Kondo 1990). Squamous metaplasia also occurs in the gallbladder (Hanada et al. 1986; Daud et al. 2007), where squamous cell carcinoma is a rather common entity, again suggesting that a metaplasia-dysplasia-carcinoma sequence may be involved. A progression from adenocarcinoma to squamous cell carcinoma has been observed in a cholangiocellular carcinoma nude mouse strain (Iemura et al. 1992).

Squamous Cell Carcinoma in Hepatic Cysts

Introduction

Several types of hepatic cysts with an epithelial lining can undergo metaplastic changes, including squamous metaplasia. This alteration may be the starting point of a dysplasia-carcinoma sequence, ending up with squamous cell carcinoma. Most observations of cystogenic squamous cell carcinoma relate to simple nonparasitic liver cysts, which are the most frequent hepatic cystic lesions.

Squamous Cell Carcinoma in Simple Nonparasitic Hepatic Cysts

Solitary nonparasitic (simple) hepatic cysts are relatively common developmental disorders of the biliary cell system, probably related to ductal plate malformations and related lesions (Flagg and Robinson 1967). Squamous cell carcinoma arising from a nonparasitic cyst is a rare entity with an unfavorable prognosis. It is assumed that this type of cancer develops in an epithelial cyst lining having undergone squamous metaplasia. However, squamous cell carcinoma of the liver has also been found to arise adjacent to a nonparasitic cyst (Iimuro et al. 2011). Squamous

cell carcinoma may develop in simple hepatic cysts after a long delay, in one patient after a 15-year follow-up (Yagi et al. 2004). In a review of ten cases, age range was 30–78 years, with a marked male predominance. Of the seven patients of whom follow-up was available, the survival ranged from 13 days to 16 months, six patients not surviving longer than 6 months (Weimann et al. 1996).

Selected References (Greenwood and Orr 1972; Bloustein and Silverberg 1976; Sanz Esponera et al. 1979; Gresham and Rue 1985; Lynch et al. 1988; Nieweg et al. 1992; Pliskin et al. 1992; Banbury et al. 1994; Weimann et al. 1996; Chou et al. 1997; Monteagudo et al. 1998; Steffani et al. 2003; Yagi et al. 2004; Hsieh et al. 2005; Iimuro et al. 2011).

Malignancy in a simple cyst may be suspected when the cyst fluid is hemorrhagic and the cyst recurs several times after conservative treatment. However, it is also known that repeated episodes of spontaneous intracystic hemorrhage may occur in the absence of malignancy (Chang et al. 2000). In one patient, the tumor was found in the context of cyst recurrence after six attempts of conservative treatment with sonography-guided drainage over a period of more than 1 year, leading to surgical cyst deroofing (Weimann et al. 1996).

Squamous Cell Carcinoma in Polycystic Liver Disease

Carcinomas developing in the cystic spaces of adult-type polycystic liver disease are very uncommon. The few cases reported so far included papillary adenocarcinoma (Rehulova and Dite 1981), cholangiocellular carcinoma (Inamura et al. 1984; Landais et al. 1984), and poorly differentiated adenocarcinoma (Kataoka et al. 1985).

Squamous Cell Carcinoma in Ciliated Foregut Cyst

Ciliated foregut cyst is a rare benign cystic lesion of the liver that arises from the embryonic foregut, like the bronchogenic cysts (Wheeler and Edmondson 1984). Most ciliated foregut cysts occur in the left liver lobe, particularly in segment IV (Jakowski et al. 2004; Sharma et al. 2008), but they also develop in the right liver lobe, the gallbladder, the pancreas, and the retroperitoneal space (Kaijya et al. 1997; Munshi et al. 1998; Chatelain et al. 2000). The mean age at diagnosis is 50 years, and there is a slight male predilection (Vick et al. 1999a). It is usually a solitary uniocular asymptomatic lesion, but it rarely causes portal hypertension by hepatic vein compression or jaundice by bile duct compression. Histologically, the cyst lining is a pseudostratified ciliated columnar epithelium.

There are relatively few reports on squamous cell carcinoma arising in ciliated hepatic foregut cysts (Vick et al. 1999b; Caratozzolo et al. 2001; De Lajarte-Thirouard et al. 2002; Furlanetto and Dei Tos 2002; Zhang et al. 2009). Ciliated foregut cysts rarely show squamous metaplasia, in contrast to bronchogenic cysts, but rare cysts may undergo extensive squamous epithelial metaplasia almost hiding the preexistent ciliated epithelium (Ben Mena et al. 2006). Squamous metaplasia may be the field change promoting malignant transformation. In fact, four cases of this type of cyst with squamous metaplasia were always associated with squamous cell carcinoma (Vick et al. 1999b; Caratozzolo et al. 2001; De Lajarte-Thirouard et al. 2002; Furlanetto and Dei Tos 2002). In the case of Caratozzolo and coworkers (2001), the zone of invasive squamous cell carcinoma was separated from the ciliated columnar epithelium by a zone of squamous metaplasia.

Squamous Cell Carcinoma in Hepatic Epidermoid Cyst

Development of dysplasia, carcinoma in situ, and squamous cell carcinoma is well established in epidermoid cysts occurring in several organs. Squamous cell carcinoma has been identified in epidermoid cysts of the liver (Lombardo et al. 1995; Ödemis et al. 2006). In the case reported by Ödemis and coworkers (2006), the cyst was situated in segment VIII and was lined

by a markedly keratinizing stratified squamous epithelium without endodermal or neuroectodermal components, blending into an invasively growing squamous cell carcinoma.

Squamous Cell Carcinoma in Cystic Hepatic Teratoma

There is a single case report describing the development of squamous cell carcinoma in a cystic teratoma of the liver (Imai 1934a, b).

Squamous Cell Carcinoma in Choledochal Cysts

Choledochal cysts are rare congenital or acquired cystic dilatations of the intrahepatic or extrahepatic bile ducts. The estimated incidence is around 1 in 100,000–150,000 persons (Lipsett et al. 1994). These cystic dilatations, when untreated, cause bile stasis, inflammation, and scarring, conditions that may lead to epithelial damage, dysplasia, and eventually cancer. Pathology of resected choledochal cysts has shown denudation, erosion or even ulceration of the cyst mucosa, acute and chronic inflammation, fibrosis (Swisher et al. 1994), and disruption of elastic fibers in the cyst wall (Jordan et al. 2004).

Malignant transformation in choledochal cysts is an age-related phenomenon that occurs in 10–14 % of adults with this disorder. Most commonly reported malignancies include adenocarcinomas of the cholangiocarcinoma type, but other carcinomas also develop in choledochal cysts (Voyles et al. 1983; Fieber and Nance 1997; Bismuth and Krissat 1999; Jan et al. 2002). Squamous cell carcinoma in choledochal cysts has been reported several times (Todani et al. 1977; Harris et al. 2002; Jan et al. 2002; Price et al. 2008). Primary adenosquamous carcinoma has also been reported in a congenital choledochal cyst (Terada 2009).

Squamous cell carcinoma may be manifest after a long time period. In one patient, the cancer was detected more than 30 years after cyst excision (Harris et al. 2002). In another patient, a poorly differentiated squamous cell carcinoma was found in the residual posterior wall of a cyst 22 years after cystojejunostomy and Roux-en-Y hepaticojejunostomy (Jan et al. 2002). In a third patient, the tumor was observed to arise from the posterior wall of a drained cyst 2 years after choledochocystoduodenostomy (Todani et al. 1977). Carcinoma may develop in the remaining intrapancreatic biliary tract years after the primary excision of a choledochal cyst (Fujisaki et al. 1999). Squamous cell carcinoma in these cystic dilatations is sometimes associated with multiple intracystic calculi (Price et al. 2008), which may play a pathogenic role for the generation of metaplastic and dysplastic changes. Pathogenetically, the tumor is possibly related to squamous cell metaplasia of the epithelial cyst lining. Squamous cell carcinoma has also been observed in conjunction with hepatolithiasis (Song et al. 1984).

Differential Diagnosis

Primary squamous cell carcinoma of the liver may undergo necrosis and thus present as a cyst or a liver abscess (Doctor et al. 1998). Squamous cell carcinoma has an unexplained tendency to develop cystic changes in its metastases, including those located to the liver (Marcy et al. 2004; Nair and Pai 2005; Morris et al. 2011). Liver metastases of squamous cell carcinoma, e.g., originating in the female genital tract, can mimic polycystic liver disease (Estermann et al. 1996; Alsolaiman et al. 2002).

Adenosquamous Carcinoma of the Hepatobiliary Tract

ICD-O code 8560/3

Introduction

Adenosquamous carcinoma (ASC; adenoacanthoma (AA)) is defined as a cancer containing both squamous and glandular elements

in the same lesion, with each component comprising at least 10 % of the entire tumor (WHO). ASCs occur in numerous organs and tissues; in the liver, they develop either as variants of cholangiocarcinomas (CCs) or as primary tumors not proven to be related to intrahepatic bile ducts, the latter probably representing a minority of the cases. ASC is one of the best-known cholangiocarcinoma variants, with numerous reports describing this distinct lesion.

Selected References (Urushizaki et al. 1973; Barr and Hancock 1975; Muto et al. 1982; Kubo et al. 1983; Moore et al. 1984; Lantsberg et al. 1996; Ohyanagi et al. 1986; Tomioka et al. 1987; Hu et al. 1988; Mandai et al. 1989; Nakajima and Kondo 1990; Suga et al. 1990; Hamaya et al. 1991; Horiuchi et al. 1991; Baba et al. 1992; Hayashi et al. 1993; Higuchi et al. 1993; Kitakado et al. 1993; Ahn et al. 1994; Hamamoto et al. 1994; Sasaki et al. 1994; Hayshi and Onitsuka 1995; Hughes and Niemann 1996; Kimoto et al. 1996; Ochiai et al. 1996; Yamamoto et al. 1996; Isa et al. 1997; Maeda et al. 1997; Nakazawa et al. 1997; Takahashi et al. 1997; Okamura et al. 2000; Yavuz et al. 2000; Kwon et al. 2001; Sato et al. 2001; Zhang et al. 2001; Ono et al. 2002; Suzuki et al. 2002; Ueno et al. 2002; Yeh et al. 2002, 2003; Tsuneyama et al. 2003; Nakai et al. 2004; Demir et al. 2005; Gu et al. 2005; Kobayashi et al. 2005; Okabayashi et al. 2005; Shin et al. 2006; Song et al. 2006; Lim et al. 2007; Yokota et al. 2007; Hong et al. 2008; Kim et al. 2009).

Classification: Hepatic Versus Biliary Tract Adenosquamous Carcinoma

Most ASCs develop in the intrahepatic or extrahepatic bile duct system (ASC-BD). ASC can develop along the entire biliary tract, including the gallbladder.

Selected References (Kusakina and Nigmatulina 1980; Muto et al. 1982; Stamatiadis et al. 1989; Kojima et al. 1994; Nishihara et al. 1994; Nishihara et al. 1995; Wagreich et al. 1998; Ercolani et al. 1999; Saito et al. 1999; Kondo et al. 2002; Oohashi et al. 2002; Akcali et al. 2005; Fujita et al. 2005b; Mingoli et al. 2005; Chan et al. 2007; Lada et al. 2007).

Primary ASC of the liver (ASC-L) sensu strictiori develops as a mass-forming lesion and seems, with respect to the growth pattern and probably origin, to occur in two variants, i.e., one related to intrahepatic CC and the other without a clear-cut relation to preexisting bile duct cancer. In several reports, it is claimed that the first observation was published in 1971 (Pianzola and Drut 1971), but these authors in fact described a hepatic mucoepidermoid carcinoma, and the ADC of the liver/bile duct was probably reported in 1973 under the term "adenoacanthoma" (Urushizaki et al. 1973).

Epidemiology

Overall, this type of carcinoma is rare, the incidence among cholangiocarcinomas being 2–3 %. The reported data markedly depend on definitions employed to denote a tumor as adenosquamous carcinoma. One study analyzed a set of 177 histologically defined cases of intrahepatic cholangiocarcinomas observed from 1975 to 1988 in Japan. Of these, 11 cases (1 surgical and 10 autopsy cases) showed a feature of squamous carcinoma (Nakajima and Kondo 1990). The authors had further broken down the cases with respect to the other histologic components present. Adenosquamous carcinoma was accepted in case the tumor contained equal amounts of squamous and glandular elements. Of the 11 cases of cholangiocarcinoma with squamous cell features, 3/11 were classified as bona fide adenosquamous carcinoma, 3/11 as squamous cell carcinoma with focal adenocarcinoma, 3/11 as adenocarcinoma with focal squamous cell carcinoma, 1/11 as anaplastic carcinoma with adenocarcinoma and squamous cell carcinoma, and 1/11 as anaplastic carcinoma with squamous cell carcinoma. 3/11 patients showed gallstones. In this series, there was no instance of a pure form of squamous cell carcinoma. In a study of 228 surgically treated cholangiocarcinoma patients,

12 (5.3 %) had adenosquamous carcinomas (Yeh et al. 2002). A male predominance is observed in the reported cases, as is a prominent relationship to hepatolithiasis.

Clinical and Imaging Presentation

Clinically, the tumor causes abdominal pain, and the majority of the masses are associated with obstructive jaundice (Kim et al. 2009). The tumor may clinically present as liver abscess (Kwon et al. 2001) and has been shown to produce biliary fistula (Ohyanagi et al. 1986) or extrahepatic growth with formation of a tumor-colon fistula (Shin et al. 2006). The tumor has been found to develop in association with congenital choledochal dilatation and pancreaticobiliary maljunction (Okamura et al. 2000; Terada 2009). In one patient, primary adenosquamous carcinoma of the liver was associated with an elevated level of serum squamous cell carcinoma-related antigen (Yamamoto et al. 1996).

Imaging features are shared with other carcinomas developing in the extrahepatic biliary tract (Yokota et al. 2007; Kim et al. 2009). In CT scans, the lesion was diagnosed as bile duct cancer of the periductal infiltrative type seen as a segmentally thickened ductal wall encircling the lumen, with delayed enhancement. Rarely, intraductal polypoid lesions occur. The highly invasive phenotype is manifest as periductal fat infiltration, seen as a fatty strand in the periductal soft tissue on CT scan. Hyperattenuation of the lesion on portal venous phase was commonly shown (Kim et al. 2009).

Pathology

Macroscopy

ASCs developing in bile ducts (ASC-BD) form large and invasive masses that cause duct obstruction. The neoplasms are usually nodular lesions with ill-defined margins. Similarly, most ASC-Ls are mass-forming and sometimes large lesions, and their diameter may exceed 15 cm. Rarely, the tumors grossly present as a focally cystic tumor (Barr and Hancock 1975). Growth is either expanding or macroscopically invasive, sometimes associated with peritumoral satellites or intrahepatic metastases. Owing to desmoplasia, the tumors exhibit a form consistency, but the center may be friable due to extensive necrosis. Rare variants of ASC-L present as multinodular or multicystic lesions with spongiform changes (Park et al. 2012). ASC-L can also mimic a liver abscess (Yeung et al. 2012).

Histopathology

In the majority of cases, a moderately to well-differentiated (G1 and G2) biliary-type adenocarcinoma prevails, commonly with easily recognizable gland-like structures and focally abundant mucin production as seen in alkaline Alcian blue preparations (Fig. 5). Papillary components may be found. Admixed with areas of adenocarcinoma and sometimes occurring as separate sheets of neoplastic cells are foci of squamous cell carcinoma, with varying differentiation of the neoplastic keratinocytes. These foci are characterized by cell groupings with a pavement-like appearance. Individual cell keratinization is common, and squamous pearl formation has been reported, albeit rarely.

In comparison with purely adenoid-/glandular-type intrahepatic cholangiocarcinoma, cholangiocarcinoma with a squamous cell component was

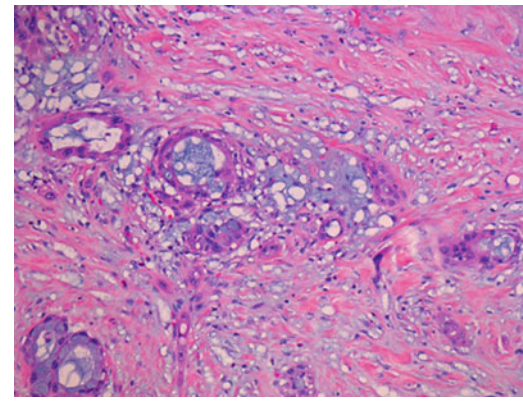

Fig. 5 Adenosquamous carcinoma of the biliary tract. There are only small squamous cell nests (hematoxylin and eosin stain)

found to show a higher incidence in sinusoidal invasion, vascular involvement, permeation in the portal tract connective tissue, perineural or intraneural invasion, and lymphatic involvement, but replacing growth along the bile duct epithelium was not detected in tumors with a squamous component, in contrast to other cholangiocarcinomas, where this was noted in 15.8 % (Nakajima and Kondo 1990). In general, a similar histologic pattern (i.e., the concurrent presence of glandular and squamous components) was observed at various metastatic sites (Nakajima and Kondo 1990). An acantholytic pattern may occur in the squamous component, a feature that has previously been described for adenosquamous carcinoma of the pancreas (Alwaheeb and Chetty 2005).

Immunohistochemistry

Immunohistochemically, the adenocarcinoma components are reactive for both cytokeratin 7 and 19. In admixed regions, cytokeratin 7 and 19 expression tends to be more marked in the central parts, where adenoid components with tubulo-glandular formations prevail. The squamous cell carcinoma components were positive for cytokeratin 7 in all cases but positive for cytokeratin 19 in only about two thirds of the cases. In contrast to squamous cell carcinomas, adenosquamous carcinomas in the liver were positive for CJ 903 only in about a third. Adenosquamous carcinomas frequently express cytokeratins 8 and 18 (Maeda et al. 1997). An interesting immunohistochemical pattern is seen when testing for the expression of high-molecular-weight cytokeratins. In admixed regions, cells with squamoid features located more to the periphery of the cancer cell formations tend to be more strongly stained, thus suggesting a transition between squamous cells of varying grades of differentiation and glandular components. CYFRA 21-1 is a tumor marker which is useful in evaluating carcinomas with a squamous cell component (Yen et al. 1998).

Combined Tumors

Adenosquamous carcinoma of the liver has been observed in combination with hepatocellular carcinoma (Zhang et al. 2001; Tsuneyama et al. 2003). Also synchronous hepatic ASC and hepatocellular carcinoma have been described (Shimizu et al. 2013). In a middle-aged female patient with recurrent fever and a clinical diagnosis of hepatic abscess, adenosquamous carcinoma was found to have arisen in biliary cystadenocarcinoma (Moore et al. 1984). Adenosquamous carcinoma has also been observed to arise in mucinous cystic tumor of the pancreas (Campman et al. 1997).

Differential Diagnosis

Apart from hepatic metastases of adenosquamous carcinoma (which tend to produce cystic liver masses; Mizuguchi et al. 1997; Hyodo et al. 1999), adenosquamous carcinoma of the gallbladder may invade the hilar structures and/or the liver. This type of carcinoma has been reported to arise in the gallbladder several times (Nishihara et al. 1994; Saito et al. 1999; Kondo et al. 2002; Akcali et al. 2005; Mingoli et al. 2005; Noske and Pahl 2006; Chan et al. 2007).

Biology of Disease

In regard to the biological behavior, adenosquamous carcinomas usually have a poorer prognosis than common adenocarcinomas in other organs, such as the stomach, pancreas, or gallbladder (Mori et al. 1986; Nishihara et al. 1994). In a set of eight patients (age range: 49–69 years), time to death after diagnosis ranged from 3 to 8 months (Maeda et al. 1997). In a study of 11 cases of intrahepatic cholangiocarcinomas with a squamous component identified among 117 intrahepatic cholangiocarcinomas (three of them adenosquamous carcinomas sensu strictiori), this tumor type was prone to develop in a rather advanced stage of the disease, as

indicated by short survival time, large tumor size, aggressive modes of intrahepatic spreading, and frequent metastasis. Intrahepatic metastases were seen in 100 % versus 67.1 % and lymph node metastases in 81.8 % versus 68.3 %, in tumors with a squamous component versus those who had not, respectively. Conversely, in an analysis of 12 patients with adenosquamous cholangiocarcinoma, there was no significant difference in overall survival between adenosquamous carcinoma and other cholangiocarcinomas (Yeh et al. 2002).

Pathogenesis of Hepatic Adenosquamous Carcinoma

The potential of cholangiocarcinoma to undergo differentiation along a squamous cell lineage is illustrated by cholangiocarcinoma cell lines propagated in vitro or in nude mice (Iemura et al. 1992; Momosaki et al. 1995). In cultured adenocarcinoma cells, transfection of human papillomavirus DNA can induce squamous metaplasia (Kinjo et al. 2003). Adenosquamous carcinomas are aggressive lesions and seem to undergo genomic instability, also suggested by desilencing of genes, e.g., with production of parathyroid-related peptide/protein (Hyodo et al. 1999; Inoue et al. 2004), sometimes with paraneoplastic hypercalcemia (Fujita et al. 2005a). Squamous cell carcinoma antigen (SSCA), previously termed TA-4, is encoded by two highly homologous genes, SCCA1 and SCCA2. An elevated level of SCCA has only once been documented in hepatic adenosquamous carcinoma (Yamamoto et al. 1996). In some squamous carcinomas, the ratio of increased expression of SCCA1 and SCCA2 was correlated with aggressive behavior and poor prognosis (Hsu et al. 2007).

Mucoepidermoid Carcinoma of the Hepatobiliary Tract

ICD-O code 8430/3

Introduction

Mucoepidermoid carcinoma (MEC; previous terminology: "mucoepidermoid tumor") is defined as a malignant neoplasm comprising mucus-secreting cells, epidermoid cells/keratinocytes, and intermediate cells in variable combinations; forming cysts and solid islands, MECs chiefly occur in major and minor salivary glands, oral cavity, larynx, thyroid, bronchopulmonary system, esophagus, skin, and breast. Less common localizations include several visceral organs, e.g., the pancreas and the hepatobiliary tract. MEC is the commonest malignant salivary gland neoplasm in adults, adolescents, and children. Patients with low-grade salivary gland MEC now show a favorable outcome, with more than 90 % of patients surviving for more than 5 years after diagnosis, while high-grade MEC is associated with poor prognosis (Friedrich et al. 2007).

Hepatobiliary Mucoepidermoid Carcinoma

The first report on hepatic MEC dates back to 1971 (Pianzola and Drut 1971). Since then, less than 25 other observations of this rare tumor have been published. An origin from the biliary tract (both intrahepatic and extrahepatic) has been suggested from both spatial relationships and ultrastructural features supporting a cholangiocyte-derived cell lineage (Di Palma et al. 1992), and the tumor has in fact been regarded to be a variant of cholangiocarcinoma (Kim et al. 1984). In few cases, an origin from bile ducts has explicitly been specified, e.g., the common bile duct (Koo et al. 1982; Shuangshoti and Shuangshoti 2000; Song et al. 2011; Moul et al. 2013). In one patient, the tumor involved the common hepatic duct, cystic duct, gallbladder, and proximal common bile duct (Koo et al. 1982). Shuangshoti and Shuangshoti found, in their review, 11 patients reported in the English literature, including their own case; among these, nine tumors were intrahepatic, two were extrahepatic and arose in the common bile ducts, three were in

the right lobe, and six were in the left liver lobe. There were six males and five females, 44–78 years old, with a mean age of 60 years. In a more recent review of 17 cases, the range for age at diagnosis was 35–81 years; ten patients were male and seven were female (Arakawa et al. 2008).

Selected References (Ho 1980; Koo et al. 1982; Katsuda et al. 1984; Kim et al. 1984, 1994; Lambrianides et al. 1986; Hayashi et al. 1987; Sasaki et al. 1991, 1995; Di Palma et al. 1992; Minami et al. 1992; Shuangshoti and Shuangshoti 2000; Kang et al. 2003; Choi et al. 2004; Arakawa et al. 2008; Song et al. 2011; Nishiyama et al. 2012; Moul et al. 2013).

It is not known whether there are distinct underlying hepatic or biliary alterations that predispose for MEC. Koo and coworkers (1982) suggested that hepatobiliary MEC may be related to *Clonorchis sinensis* infestation with or without associated chronic bacterial cholangitis, because three of five reported patients had clonorchiasis and two showed evidence of recurrent bacterial pyogenic cholangitis. In few patients, MEC was suggested to arise from preexisting congenital cysts (Katsuda et al. 1984; Hayashi et al. 1987; Choi et al. 2004). The first of these cases relates to an autopsy case of a 78-year-old male who showed a massive tumor of up to 11 cm in size in the left lobe of the liver associated with multiple sero-mucinous cysts. These cysts were lined with a single layer of cuboidal or columnar cells and were apparently not in communication with bile ducts. Part of these cyst-lining cells were in continuity with carcinoma cells (Katsuda et al. 1984). Hepatobiliary MEC has been observed in synchronous association with hepatocellular carcinoma (Minami et al. 1992; Kang et al. 2003). In one patient, hepatobiliary MEC was associated with thorotrastosis (Lambrianides et al. 1986).

Clinical Features

Among 17 reviewed patients, 8 patients presented with abdominal pain and only 2 with jaundice. Seven tumors were located to the right liver lobe and ten to the left liver lobe (Arakawa et al. 2008). The size of the tumors ranged from 1.5 to 18 cm in the greatest dimension (average: 8.4 cm). As other hepatic tumors with a squamous cell component, MEC can present as a cystic lesion or may mimic a liver abscess (Choi et al. 2004). Similar to SCC-L and ASC-L, MEC is an aggressive tumor with a very poor prognosis, invading the portal vein and frequently metastasizing to locoregional lymph nodes and to the lung; ten patients died within 11 months regardless of the treatments (Shuangshoti and Shuangshoti 2000). Of 14 patients compiled in a recent review, 9 patients died within 6 months of admission or surgery; 6 patients who had undergone surgery lived for at least 45 days, and 1 of them was alive 1 year after surgery; 6 patients received only conservative treatment, and 4 of these died between 2 weeks and 3 months, 1 being lost to follow-up (Kang et al. 2003). In the review of 17 patients compiled by Arakawa et al. (2008), locoregional lymph node metastases were found in 7 patients, while intrahepatic metastases were observed in only 2 patients. Fifteen patients died after a survival period ranging from 14 days to 3 years; one patient was alive after 1 year, and in one patient, no follow-up information was available (Arakawa et al. 2008).

Pathology

Macroscopically, MECs of the liver are medium-sized to large and firm tumors exhibiting an expanding growth pattern and forming polycyclic masses of gray to whitish color, sometimes with extended central necrosis (Arakawa et al. 2008), or formation of cystic spaces. In the distal common bile duct, the tumors cause stenosing lesions that may infiltrate the duct wall and extend into the ampullary and pancreatic region (Moul et al. 2013).

Histologically, this neoplasm is dominated by irregularly arranged, mucin-filled cysts and solid tumor nests composed of mucous, epidermoid (squamous; keratinocytic), and nondescript intermediate cells in variable combinations. The

association between squamous cell and mucin-producing cells is usually intimate. The mucin-containing components are PAS and alkaline Alcian Blue positive. Within the squamous parts, individual keratinization may occur. MEC of the hepatobiliary tract may contain oxyphilic cells (Katsuda et al. 1984), a feature which has been described in respective carcinomas arising from salivary glands (oncocytic mucoepidermoid carcinoma; Jahan-Parwar et al. 1999; Jing et al. 2012). There is marked desmoplasia, with production of sclerotic stroma. In particular at the tumor's periphery, an inflammatory reaction (probably an immune response) is encountered. In case mucin is extruded from the cells, a foreign body-type reaction to mucin is elicited, contributing to the deposition of extracellular matrix. Necrotic keratinized squamous cells can induce keratin granulomas, although keratin formation is usually sparse or even lacking. Although the tumors reveal expanding features at gross examination, microscopy usually shows irregular invasive borders, with infiltration of adjacent liver substance, including invasion of hepatic sinusoids. Angioinvasion and invasion of perineural spaces in Glisson's sheaths or at the porta hepatis may be observed.

The mucin-producing cells of hepatic MEC were immunoreactive for cytokeratin 7, but variably for CK 20, many cases being CK20 negative (Choi et al. 2004; Moul et al. 2013). Part of the cells were MUC1 positive, while luminal cells also expressed MUC5 (Moul et al. 2013). Epidermoid cell nuclei of the tumor have been shown to be p63 positive (Choi et al. 2004).

Differential Diagnosis

The differential diagnosis of primary MEC of the liver includes primary hepatic adenosquamous carcinoma and extrahepatic MEC metastatic to the liver (Chen et al. 1995; Gruttadauria et al. 2000; Sato et al. 2002; Herd et al. 2012). In MEC metastasizing to the liver, a cytokine-induced leukemoid reaction has been observed. Immunohistochemistry of the metastatic tumor revealed staining for IL-1 alpha and IL-6, and elevation of cytokine levels in the fluid of necrotic tumor included IL-1 alpha, IL-6, granulocyte-macrophage colony-stimulating factor, and granulocyte colony-stimulating factor by ELISA testing (Chen et al. 1995).

Pathogenesis

It has been suggested that MECs of the liver take their origin from bile duct cells, therefore being variants of intrahepatic CCC (Di Palma et al. 1992; Shuangshoti and Shuangshoti 2000). MEC has also been found to have arisen in a preexistent hepatic cyst (Hayashi et al. 1987). In one patient, hepatic MEC was associated with thorotrastosis, known to be complicated by the emergence of CC and HCC (Lambrianides et al. 1986). Rarely, MEC of the liver has been observed together with HCC (apparent double primaries) at two different places within the liver (Minami et al. 1992; Kang et al. 2003).

Subsets of MEC of the salivary glands, lung, thyroid, breast, and skin exhibit a characteristic translocation, t(11;19)(q21-22; p13), resulting in a chimeric gene linking WAMTP1/Mect1 /Torc1/CRTC1 to exons 2–5 of the Mastermind-like (MAML) gene (Tonon et al. 2003; reviews: Seethala et al. 2010; Chenevert et al. 2011). Specifically, this translocation fuses 42 residues from AMTP1/Mect1 (mucoepidermoid carcinoma translocated-1)/Torc1, a cyclic AMP (cAMP)-responsive element binding protein (CREB)-dependent transcriptional coactivator (CRTC1; CREB regulated transcription coactivator), with 982 residues from MAML2, a Notch receptor coactivator (see below), leading to altered Notch signaling as a pathogenic mechanism for tumorigenesis. Molecular classification of MEC in relation to this translocation has a clinical impact, in that the translocation negatively affects tumor cell growth (Komiya et al. 2006) and that fusion-positive patients had a significantly lower risk of local recurrence, metastases, or tumor-related death compared to fusion-negative patients (Behboudi et al. 2006; Okabe et al. 2006).

Hepatobiliary Tumors with Acinar Cell and Adenoid Cystic Cell Lineages

43

Contents

Abstract

Acinar cell carcinoma, a well-known pancreatic neoplasm, very rarely occurs as a primary tumor in the hepatobiliary tract. In contrast to their pancreatic counterparts, hepatic acinar cell carcinomas are usually heterogeneous tumors that contain well-differentiated acinar cells, endocrine-like cells, and less differentiated elements. Acinar carcinomas of the liver can form large solitary masses with an expanding growth pattern. In at least part of cases, production of trypsin, amylase, or lipase can be detected. The tumors can also develop from heterotopic pancreatic tissues and can invade the distal bile duct system from a primary tumor located in the pancreas. Adenoid cystic carcinoma, a tumor well known from salivary glands, can very rarely develop as a primary lesion in the hepatobiliary tract.

Acinar Cell Carcinoma of the Hepatobiliary Tract

ICD-O Code 8550/3

Introduction

Acinar cell carcinoma, usually a pancreatic neoplasm, very rarely occurs as a primary tumor in the hepatobiliary tract. Acinar cell carcinoma of the pancreas is also a rare tumor that accounts for

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_43

only about 1–2 % of exocrine pancreas tumors in adults. Acinar cell tumors of the pancreas can present with three subtypes, i.e., classical acinar cell carcinoma, acinar cell cystadenocarcinoma, and mixed acinar-endocrine carcinoma. Endocrine components can also occur in hepatic acinar cell carcinomas.

Primary Acinar Cell Carcinoma of the Liver and Bile Ducts

Few cases of primary hepatic acinar cell carcinoma have been reported (Hervieu et al. 2008; Agaimy et al. 2011; Terris et al. 2011; Wildgruber et al. 2013; Fig. 1). In one patient, a 35-year-old woman, imaging studies showed a hypervascular mass, and serum alpha-fetoprotein (AFP) was elevated at 6000 IU/mL. Histologically, the neoplasm displayed a heterogeneous composition and consisted of well-differentiated acinar structures with granular, trypsin-positive cells and of endocrine-like cells in less differentiated areas. Immunoreactive AFP was present in about 30 % of cells, and some cells were positive for chromogranin A and synaptophysin (Hervieu et al. 2008). Agaimy and coworkers (2011) reported a primary hepatic acinar carcinoma that had arisen in non-cirrhotic livers of two males and two females with a mean age at presentation of 65 years (range, 49–72 years). The liver tumors were large, well-circumscribed masses with a mean diameter of 12 cm and lobulated or multinodular cut surface. Histologically, the neoplasms revealed a predominantly microacinar pattern, with occasional trabecular, solid, and microcystic parts, and variable cellular atypia and mitotic activity. Immunohistochemically, the cancer cells were reactive for CK18 and at least one acinar cell marker (trypsin, amylase, or lipase). Two neoplasms were focally reactive for synaptophysin and chromogranin A. During a mean follow-up of 22 months, no metastases occurred, but one patient developed local recurrence (Agaimy et al. 2011). In a patient described by Terris and coworkers (2011), the acinar cell carcinoma was located at the liver hilum.

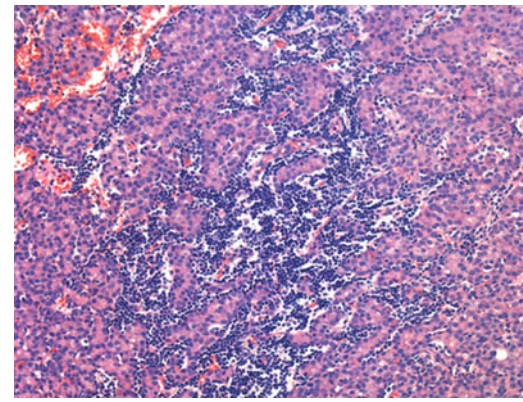

Fig. 1 Acinar cell carcinoma of the liver with focal lymphocytic infiltration (hematoxylin and eosin stain)

Acinar Cell Carcinoma Probably Derived from Heterotopic or Metaplastic Pancreatic Foci

There are few examples of intra-abdominal acinar cell carcinomas found in the absence of a primary pancreatic tumor, e.g., located in pancreatic lymph nodes or the colon. The neoplasms exhibited a predominantly acinar cell differentiation intermingled with a ductal component, with intracellular or extracellular mucin production by at least 25 % of tumor cells, and one case showed endocrine differentiation. An origin from heterotopic or metaplastic pancreatic foci was postulated (Terris et al. 2011). Also primary intrahepatic acinar cell carcinoma might take its origin from hepatic ectopic/heterotopic exocrine pancreatic tissue, which is known to occur in diverse sites of the liver and the biliary tract. In fact, adenocarcinoma arising from intrahepatic heterotopic pancreas was reported (Yan et al. 2012).

On the other hand, there is evidence from animal experiments and in vitro cell cultures that hepatocytes can transdifferentiate into pancreatic acinar cells and vice versa (Kanoh et al. 2011; Yi et al. 2012). In humans, pancreatic trypsinogen/trypsin and cathepsin can be expressed in cells of cholangiocarcinomas and hepatocellular carcinomas (Terada et al. 1995), while solid adenoma of the pancreas can present as an exclusively hepatocellular tumor (Cuilliere et al. 2002). Also pancreatic islet cells appear to have the potential to

transdifferentiate into albumin-producing neoplastic hepatocytes (Nozawa and Pour 2005), suggesting that two major derivatives of the ventral foregut endoderm, pancreas and liver, retain their capacity to switch into each other. Signaling signatures defining hepatic and pancreatic progenitor cell lineage divergence can be reprogrammed to convert adult hepatic cells into pancreatic cells (Rodriguez-Seguel et al. 2013). A further pathway potentially involved in the generation of acinar cell carcinomas in the hepatobiliary tract refers to the role of intrahepatic/intrabiliary plutipotential stem cells. The biliary tree is a rich reservoir of multipotent stem cells. In particular, peribiliary glands contain multipotent stem cells which self-replicate and can differentiate into hepatocytes, cholangiocytes, or pancreatic islet cells. Similar cells are found in the gallbladder (Cardinale et al. 2012). Embryonic stem cells are capable to differentiate into pancreatic cells (Lee and Chung 2011).

Secondary Involvement of the Bile Duct System by Acinar Cell Carcinoma of the Pancreas

Acinar cell carcinoma located in the pancreatic head can show an intraductal polypoid growth and extend into the intrapancreatic part of the common bile duct, with formation of intraluminal casts (Yamaguchi et al. 2006; Nagata et al. 2012). Hepatic metastasis of acinar cell carcinoma can invade intrahepatic bile ducts and form a bile duct tumor thrombus that may mimic a primary biliary manifestation (Kiitaka et al. 2012).

Differential Diagnosis

Acinar cell carcinoma of the liver has been distinguished from hepatic metastases of acinar cell carcinoma originating in the pancreas. Pancreatic acinar cell carcinoma is well known to produce solitary or multiple liver metastases (Tatli et al. 2005; Kim et al. 2011; Nishimizu et al. 2011; Bhosale et al. 2013). In a study of 30 patients, liver metastases were detected in 40 %, and the metastases typically were well circumscribed, hypoattenuating to the hepatic parenchyma on all the phases of contrast enhancement, and had a lobulated margin (Bhosale et al. 2013). The hepatic metastatic lesions may grow to giant size (Nishimizu et al. 2011). Also mixed acinar-neuroendocrine carcinoma of the pancreas metastasizes to the liver (Lee et al. 2013). Metastatic pancreatic acinar cell carcinoma may result in a confusing situation, as part of these tumors can produce alpha-fetoprotein (Nojima et al. 1992; Lin et al. 2007; Lin 2012).

Adenoid Cystic Carcinoma of the Hepatobiliary Tract

Introduction

Adenoid cystic carcinoma (ACC; cylindroma) is a malignant epithelial tumor showing a characteristic cribriform growth pattern. Tumors of the salivary glands are currently classified by the WHO not only according to morphological features but also in accordance to biologic behavior, prognosis, and treatment results. High-grade tumors with a more aggressive course comprise ACC, high-grade mucoepidermoid carcinoma, salivary duct carcinoma, squamous cell carcinoma, carcinoma ex-pleomorphic adenoma, adenocarcinoma NOS, and undifferentiated carcinoma. Salivary gland adenoid cystic carcinoma (SACC), which can metastasize to the liver, is a relatively frequent type of salivary gland malignancy characterized by relatively slow growth, multiple local recurrences, a distinct propensity for perineural invasion (Shimamoto et al. 2012), and a prolonged clinical course often with delayed development of distant metastases (SEER review of 3026 patients: Ellington et al. 2012). In most series, ACC accounts for 10–15 % of all parotid gland malignancies, and parotid SACC is reported to metastasize in 24 % of cases (Bradley 2001). The organs involved by metastasis of SACC in decreasing order of frequency are the lung, bone, brain, and liver (Spiro et al. 1974).

Primary Adenoid Cystic Carcinoma of the Hepatobiliary Tract

There is a single reported case of adenoid cystic carcinoma primary to the liver (Ziarkiewicz-Wroblewska et al. 2001). The hepatic tumor was detected incidentally during pregnancy in an asymptomatic 21-year-old female patient. No focal lesions in other organs were found in imaging examinations. A huge tumor of 30 cm diameter was found during surgery, encompassing almost the whole left and right lobes of the liver.

The tumor described by Ziarkiewicz-Wroblewska et al. (2001) showed all morphological features of salivary gland-type ACC (SACC). The epithelial cells are often arranged in a cribriform (sieve-like) pattern with neatly punched out spaces resembling a cookie cutter, but nests or cords representing solid components are also noted. The cells show a scanty and slightly eosinophilic cytoplasm and round to ovoid nuclei of regular shape. The cells surround circular areas or cyst-like spaces that are not true glandular lumina but are circular profiles or spherules/nodules in continuity with the ECM of stroma and consisting of basement membrane material. In a basal position, one notes small cells of the myoepithelial lineage. As shown in the single case of primary hepatic ACC, the tumor cells express glandular-type cytokeratins and share some phenotypes with biliary tract epithelia (Ziarkiewicz-Wroblewska et al. 2001).

Hepatic Metastasis of Adenoid Cystic Carcinoma

The main differential diagnosis is adenoid cystic carcinoma metastatic to the liver (Akhavan et al. 2013; Garg et al. 2014). In rare case, liver metastasis is the first clinical manifestation of adenoid cystic carcinoma (Spolverato et al. 2014). The likelihood of developing distant metastases of salivary gland tumors is associated with high-grade tumors, such as adenoid cystic carcinoma, salivary duct carcinoma, and high-grade mucoepidermoid carcinoma, local or neck recurrence, the presence of locoregional nodal metastasis, and tumors located in the submandibular gland, posterior tongue, and pharyngeal tumors. In contrast to the lung, SACC rarely metastasizes to the liver. In one series of cases, out of 46 patients with metastases of ACC, only one had liver metastasis, in conjunction with pulmonary and bone metastases (Sung et al. 2003). For hepatic metastases, the primary tumor is often located in the salivary glands (Garg et al. 2014), other primary locations comprising the lacrimal gland, external auditory canal, breast, Bartholin's gland, and other even more uncommon primary sites (Deshpande and Kelkar 2009; Shahabi et al. 2009; Balducci et al. 2011; Scuderi et al. 2011). Hepatic metastasis of ACC is generally seen as a part of disseminated tumor disease, isolated liver metastasis in ACC being very rare (Spiro 1997; Balducci et al. 2011). In few instances, hepatic metastasis of SACC was diagnosed by cytodiagnosis based on fine needle aspiration (Plafker and Nosher 1983; Thomas et al. 1991; Deshpande and Kelkar 2009). Liver metastasis can occur after a long delay, e.g., 10 years after resection of a salivary gland primary tumor (Qureshi et al. 2005), and may be the initial clinical manifestation of SACC (Deshpande and Kelkar 2009).

Pathogenesis

Part of ACC displays a chromosomal rearrangement characterized by a recurrent and specific t(6;9)(q22–23;p23–24) translocation causing MYB-NFIB chimeric fusion, with translocation of NFIB sequences to proximal or distal sites of the MYB gene (review: Bhaijee et al. 2011).

Rare Malignant and Semimalignant Epithelial Neoplasms of the Biliary Tract

44

Contents

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_44

Abstract

The hepatobiliary tract is the site of an intriguing group of malignancies occurring in several other organs, extrapulmonary small cell carcinoma. In contrast to its bronchopulmonary counterpart, extrapulmonary small cell carcinomas occur with similar rates in female and male patients. With the exception of the gallbladder, the biliary tract is very rarely involved. Small cell carcinomas of the hepatobiliary tract belong to several categories, i.e., neuroendocrine type, mixed type, non-neuroendocrine type, and not otherwise specified types. Small cell carcinomas are highly aggressive neoplasms. Diagnosis and classification require immunohistochemical and molecular methods. Poorly differentiated or undifferentiated carcinomas of the bile ducts also include spindle cell carcinoma and carcinomas with rhabdoid features. Unusual neoplasms primary to the bile ducts also comprise hepatoid carcinoma and solid pseudopapillary tumor, a neoplasm better known from the pancreas.

Small Cell Carcinomas of the Hepatobiliary Tract

Introduction

Extrapulmonary small cell carcinoma is a distinct category of high-grade malignancies distinct from bronchopulmonary small cell carcinoma. In the United States, the estimated incidence is between 0.1 % and 0.4 % of all cancers (Levenson et al. 1981; Richardson and Weiland 1982; Remick and Ruckdeschel 1992; Walenkamp et al. 2009). In a study from South East England, covering the years 1970–2004, the incidence of extrapulmonary SCC was much lower than for SCC of the lung, similar in males and females, with incidence rates of 0.45 per 100,000 in males and 0.37 in females (Wong et al. 2009). The pathology of extrapulmonary SCC has been reviewed (Frazier et al. 2007). Poorly differentiated or undifferentiated small cell carcinomas also arise in the gastrointestinal tract, including the hepatobiliary tract.

Epidemiology

In the entire gastrointestinal tract, 0.1–1 % of all malignancies are small cell carcinomas, with the esophagus being the most common primary site (Galanis et al. 1997; Fenoglio-Preiser 2001; Brenner et al. 2004a; Brenner et al. 2007; Lee et al. 2007). With the exception of the gallbladder, the biliary tract is very rarely involved by this malignancy. Among 544 reviewed gastrointestinal cases, 46 were located to the gallbladder (8.4 %), 6 in the ampulla (1.1 %), 3 in the common bile duct (0.5 %), and 7 in the liver (1.3 %) (Brenner et al. 2004b). In a study of 52 patients with extrapulmonary SCC, 33 (62.3 %) were detected in the esophagus, 5 in the cervix, 4 in the larynx, 3 in the pharynx, 2 in the upper sinus, 2 in the rectum and sublingual gland, 1 in the thyroid gland, 1 in the pleura, and 1 in the liver (Yuan et al. 2006).

Classification

Primary small cell carcinomas (PSCC) of the hepatobiliary tract can come in five basically different forms, i.e., (1) PSCC of the neuroendocrine type, (2) PSCC of mixed type, (3) PSCC of non-neuroendocrine type, (4) PSCC of hepatoid type, and (5) PSCC of unknown type (PSCC, not otherwise specified (NOS)) (Table 1). Part of PSCC described in the older literature are usually PSCC-NOS, owing to the lack of immunohistochemical examinations.

Table 1 Types of primary small cell carcinomas (PSCC) of the hepatobiliary tract

PSCC of the neuroendocrine type
PSCC of mixed type
PSCC of non-neuroendocrine type
PSCC of hepatoid type
PSCC, not otherwise specified

Small Cell Carcinoma of the Liver and Bile Ducts

Introduction

Small cell carcinoma can develop as a very rare primary or apparently primary malignancy within the liver substance, without proven connection to intrahepatic bile ducts. PSCC of the liver forms a heterogeneous group of lesions, as part of the cases in the old literature were reported without immunohistochemical and/or ultrastructural examinations and are therefore difficult to classify. Based on what we know today, most of the reported cases probably were undifferentiated neuroendocrine tumors. As bronchopulmonary small cell carcinoma can be small even in the metastasizing phase of disease, some small cell carcinomas purported to be liver tumors may in fact have been a metastasis of a missed lung primary.

Clinical and Imaging Features

Similar to other aggressive primary liver malignancies, PSCC present with hepatomegaly, upper abdominal discomfort or pain, fever, and jaundice in part of the patients (Sengoz et al. 2003; Yuan et al. 2006; Otten et al. 2013). Serum AFP is, in most patients, not elevated, with the exception of the very uncommon PSCC with AFP secretion (Walshauser et al. 2013). Imaging reveals solitary or multiple, sometimes lobulated masses, predominantly in the right liver lobe. On CT scans, invasion of the portal vein and the hepatic artery had been detected (Jo et al. 2013).

Hepatic PSCC of the Neuroendocrine Type

Extrapulmonary PSCC shares many features with bronchopulmonary small cell undifferentiated carcinoma (Remick et al. 1987; Vrouvas and Ash 1995). This includes the cytological and histological appearance, an aggressive behavior, and the frequent short-lasting response to either chemotherapy or radiotherapy. Very few PSCC of the neuroendocrine type have been reported.

Selected References Nakasuka et al. (1998), Kim et al. (2004, 2006a, b), Ryu et al. (2005), Choi et al. (2007), Balta et al. (2008), Iwasa et al. (2010), Kaman et al. (2010), and Jo et al. (2013).

In one patient, neuroendocrine PSCC was associated with adenoid cystic carcinoma of a salivary gland (Premkumar et al. 2013). In a review of the few published cases (Choi et al. 2007), most patients were elderly to old males, and tumor diameters ranged from 6.7 to 12 cm. It is assumed that these neoplasms arise from the neuroendocrine cell system of the liver. The neoplasms usually present as large and solitary, highly invasive and advanced-stage lesions at diagnosis, although multiple synchronous hepatic tumors have also been reported (Nakasuka et al. 1998). In part of the reported cases, immunohistochemistry clearly proved the neuroendocrine features of these neoplasms (Kim et al. 2004; Ryu et al. 2005; Choi et al. 2007).

Hepatic PSCC, Mixed Types

In some rare PSCC of the liver, a second carcinomatous component was found in addition to the small cell neuroendocrine lineage. In one patient, PSCC had arisen from combined hepatocellular and cholangiocarcinoma (Khaw et al. 2011). Very rare cases of hepatocellular carcinomas can contain a small cell tumor component with neuroendocrine features, the HCC component expressing hepatocyte markers and AFP, and the SCC component reactive for chromogranin A and synaptophysin (Yamaguchi et al. 2004; Garcia et al. 2006; Yang et al. 2009). Composite small cell and mucinous adenocarcinoma can also originate from intrahepatic bile ducts (see below; Ikegami et al. 2013).

Combined SCC and adenocarcinomas have been observed in the stomach (Jang et al. 2007) and the colon (Scherwitz et al. 2002) and found to have metastasized to the liver. Malignant neoplasms with such a mixed phenotypes involving at least two different cell lineages may originate from progenitor cells having two cell fating strategies.

PSCC, Non-neuroendocrine Type or with Unknown Neuroendocrine Features

In few examples of PSCC primary to the liver, the neuroendocrine status was negative or not known, although the cytologic and histopathologic features were those of bronchopulmonary small cell or oat cell carcinoma (Sengoz et al. 2003; Morikawa et al. 2008; Ochsenreither et al. 2009; Groeschl et al. 2013).

Small Cell Hepatoid Carcinoma of the Liver

This is a still ill-defined category of primary liver tumors characterized by a small cell neoplasm arising in non-cirrhotic livers, composed of broad nests of small epithelial cells with little supporting tissue. The tumor cells were immunohistochemically positive for low molecular weight keratins and alpha-fetoprotein and erratically for neuroendocrine markers. Such neoplasms were suggested to be a variant of hepatocellular carcinoma (Zanconati et al. 1996).

Small Cell Carcinoma of the Bile Ducts

Relatively few cases of small cell carcinoma primary to the common bile duct have been published. These neoplasms clinically present as other malignancies developing in this anatomical compartment, i.e., with abdominal pain and obstructive jaundice. Probably caused by massive necrosis, the tumor may cause hemobilia (Cho et al. 2009). On CT, an intraluminal mass is detectable (Park et al. 2004; Okamura et al. 2009), and MRI has shown a tumor mass surrounding the common bile duct wall, with ERCP showing a smooth narrowing of the bile duct (Arakura et al. 2008). In one case, the tumor was associated with clonorchiasis (Thomas et al. 2005). Identical p53 gene mutation has been identified in small cell carcinoma of the bile duct and malignant proliferating trichilemmal tumor in the same patient (Nakai et al. 2008). Histology and immunohistochemistry are the same as with small cell gallbladder carcinomas (Kuraoka et al. 2003). Mucinous adenocarcinoma of intrahepatic bile ducts can rarely be combined with small carcinoma, the tumors showing CK 19-positive and chromogranin A-positive cell populations (Ikegami et al. 2013). Small cell carcinoma of the bile ducts exhibits an aggressive biology (Jeon et al. 2006), the longest reported survival after multidisciplinary management being 23 months (Okamura et al. 2009).

(2003), Park et al. (2004), Kaiho et al. (2005), Thomas et al. (2005), Jeon et al. (2006), Viana Miguel et al. (2006), Nakai et al. (2008), Cho et al. (2009), Okamura et al. (2009), and Groeschl et al. (2013).

Differential Diagnosis

The main differential diagnosis of hepatobiliary PSCC is metastasis of bronchopulmonary small cell undifferentiated carcinoma (Vaideeswar et al. 2012; Sato et al. 2013), followed by metastasis of extrapulmonary SCCs (mainly the esophagus, the pancreas, and the lower digestive tube; Akiyama et al. 2011; Al-Jiffry and Al-Malki 2013), several types of other anaplastic neuroendocrine and PNET tumors (O'Byrne et al. 1994), and other small cell undifferentiated neoplasms (Khalbuss et al. 2005). Another small cell tumor

of poor differentiation metastasizing to the liver is Merkel cell carcinoma (Bottles et al. 1984; Gollub et al. 1996).

Undifferentiated Carcinomas of the Bile Ducts

There are bile duct carcinomas with a low to very low level of cell differentiation. This is a typical feature of lymphoepithelial carcinomas, treated in a separate chapter. In addition, a very small fraction of intrahepatic cholangiocarcinomas show an undifferentiated phenotype. These neoplasms consist of medium-sized to large cells showing a solid growth pattern in the absence of any glandular structures. In the light of these morphologic features, diagnosis of cholangiocarcinoma is difficult, apart from a close spatial relation to intrahepatic ducts. A derivation from cholangiocytes is suggested by the positivity for cytokeratin 7 and CAM5.2 (Fujikawa et al. 2011).

Spindle Cell-Type Carcinoma of Bile Ducts

Apart from carcinosarcomas with a spindle cell component, rare variants of cholangiocarcinoma partially or entirely consist of spindle cells, which are only attributable to an epithelial cell lineage after performing immunohistochemistry. These lesions are of theoretical interest insofar as they may represent examples of epithelial-mesenchymal transition.

Spindle cell carcinoma also develops in the region of the hepatic hilus and may then mimic classical Klatskin tumor. In one 59-year-old patient, the tumor had led to complete obliteration of the left hepatic duct and stenosis of the bile duct from the superior to the right hepatic duct. Histologically, the tumor was a mixture of tubular adenocarcinoma and spindle cell carcinoma, the spindle cells being immunoreactive for CAM5.2 and AE1/AE3 (Nakanishi et al. 2007). Generally, spindle cell carcinoma developing in other organs co-expresses epithelial and mesenchymal markers, positivity for epithelial markers being somewhat more often expressed than vimentin (Lewis et al. 2005).

The differential diagnosis of hepatobiliary spindle cell carcinoma mainly includes sarcomatous cholangiocarcinomas (Imazu et al. 1995; Matsuo et al. 1999) and other malignant sarcomatoid liver tumors (Eriguchi et al. 2001; Matsui et al. 2010), which may also contain spindle cell components. Very rarely, primary liver carcinomas entirely consist of spindle cells (Grigsby et al. 1987).

Primary Hepatoid Carcinoma of the Bile Ducts

Introduction

Hepatoid carcinomas have a distinct and unique immunophenotype, characterized by reactivity for cytokeratins 7, 8, 18, 19, and 20, alpha-fetoprotein (AFP), and p-CEA (Terracciano et al. 2003). The immunoreactivity for AFP is variable, ranging from the absence of staining to massive staining, illustrating that not all carcinomas with a hepatoid morphology are producing AFP (Nagai et al. 1993). Many hepatoid carcinomas of the gastrointestinal tract show, similar to hepatocellular carcinomas, reactivity for hepatocyte paraffin 1 (Hep Par 1) antibody, underscoring the fact that Hep Par 1 expression is not unique to primary hepatocellular neoplasms (Maitra et al. 2001). Hepatoid carcinomas are reactive for glypican-3, a cell surface heparin sulfate proteoglycan expressed specifically in the fetal liver and malignant neoplasms of the hepatocyte lineage (Hishinuma et al. 2006).

Histologically, hepatoid carcinomas consist of large polygonal cells that are arranged in trabecular fashion or solid nests separated by narrow fibrous stroma bands and sinusoid-like vascular channels. The differential diagnosis between manifestations of hepatocellular carcinoma and hepatoid carcinoma is often difficult, owing to the almost identical histology and part of the

immunohistochemical findings. Co-expression of antigens not found in a liver cell lineage may be helpful, e.g., in the stomach, where hepatoid carcinoma expresses the fetal gut differentiation stem cell marker, SALL4, lacking in HCCs and hepatoblastomas (Ushiku et al. 2010). Hepatoid adenocarcinoma of the stomach expresses the palate, lung, and nasal epithelium carcinoma-associated protein (PLUNC) gene, and PLUNC immunostaining differentiates hepatoid carcinomas from ordinary adenocarcinomas (Sentani et al. 2008).

Hepatoid Carcinoma of the Bile Ducts

Hepatoid carcinoma is an exceptional neoplasm of the biliary tract. Hepatoid carcinoma was observed in the common hepatic duct where it mimicked Klatskin tumor, causing bile duct stenosis and obstructive jaundice (Abdullah et al. 2010).

Hepatoid Carcinoma of the Gallbladder

Few cases of hepatoid carcinoma of the gallbladder have been reported (Nakashima et al. 2000; Maitra et al. 2001; Sakamoto et al. 2004, 2005; Gakiopoulou et al. 2007; Koswara et al. 2007; van den Bos et al. 2007; Kao et al. 2009). The tumors may be associated with elevated serum AFP (van den Bos et al. 2007). They show the same histologic features as those in other locations, but may show cholangiocarcinoma-like components, which also immunostain for AFP (Koswara et al. 2007).

Solid Pseudopapillary Tumor (Papillary Cystic Tumor) of the Liver/ Bile Duct

Introduction

Solid pseudopapillary tumor (SPPT; papillary cystic tumor; Frantz tumor) is a rare pancreatic tumor clinico-radiologically belonging to the cystic tumor group (Adams et al. 2008; Lee et al. 2008; Chakhachiro and Zaatari 2009). The neoplasm typically occurs in females and only rarely in males: an analysis of 1014 patients reported in the literature revealed only 137 (13.5 %) males (Lin and Stabile 2010). SPPT is usually an expandingly growing mass lesion, but a solid, infiltrating variety also exists (Matsunou et al. 1990). The biology of disease is that of benign or low-grade malignant behavior, metastases (mostly to the liver) being uncommon (Gonzalez-Campora et al 1995; Nagri et al. 2007). Males had a twofold higher incidence of metastases and a threefold higher death rate, and SPPT therefore has an atypically aggressive biology in males (Lin and Stabile 2010). The cell of origin is not known, but suspected to be a pancreatic stem cell.

Solid Pseudopapillary Tumor Primary to the Liver

A case of a primary tumor of the liver with pathologic features strikingly similar to pancreatic SPPT has been observed in a 41-year-old female patient (Kim et al. 1990). In this patient, two large, solid and cystic tumors with extensive hemorrhage and necrosis were detected in the right and left liver lobes, measuring 30 cm and 5.5 cm, respectively, in diameter. The pancreas was free of tumor.

Morphologic and Biologic Features of Solid Pseudopapillary Tumor

Histologically, SPPTs are characterized by loosely cohesive, relatively uniform polygonal cells with a slightly eosinophilic or pale cytoplasm, sometimes with vacuolization. The nuclei exhibit grooving and have a finely stippled chromatin. These cells surround delicate capillary-sized blood vessels. As an artifact, cell layers around vessels may separate from each other, hence resulting in a pseudopapillary pattern (Santini et al. 2006; Fig. 1).

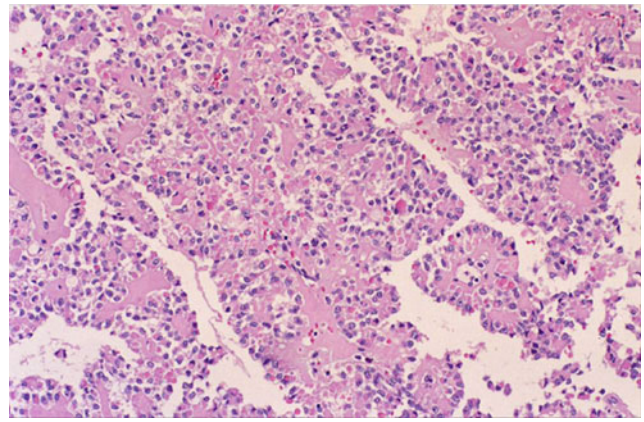

Fig. 1 Solid pseudopapillary tumor (papillary cystic tumor) of the liver (hematoxylin and eosin stain)

There are few very rare histologic variants of SPPT, including clear cell SPPT (Hav et al. 2009), pigmented SPPT (Daum et al. 2005), a spindle cell variant (El-Bahrawy et al. 2010), and ossifying SPPT (Kim et al. 2005). Immunohistochemically, the tumor is complex and polyphenotypic, positive marker including vimentin, CD10, CD56, alpha-1-antichymotrypsin, neuron-specific enolase, synaptophysin, estrogen receptor beta, and progesterone receptor (Pettinato et al. 1992; Morales et al. 2003; Santini et al. 2006; Serra and Chetty 2008). SPPT shows a peculiar claudin expression profile and the highly specific pattern of claudins 5 and 7 differentiates SPPT from other pancreatic tumors (Comper et al. 2009).

SPPTs of the pancreas almost always harbor mutations of the beta-catenin gene, with nuclear accumulation of beta-catenin being present in 95 % of the cases (Abraham et al. 2002; El-Bahrawy et al 2008; Kang et al 2009; reviews: Antonello et al. 2008; Serra and Chetty 2008). Nuclear expression of beta-catenin and loss of E-cadherin are important diagnostic features of SPPT (Kim et al. 2008; Burford et al. 2009). Nuclear relocalization of beta-catenin in SPPT is associated with loss of E-cadherin and decrease or loss of p120, a protein which regulates E-cadherin and is responsible for its degradation (Audard et al. 2008; Chetty et al. 2008). In the pathogenesis of SPPT, the Notch signaling pathway is also involved (Cavard et al. 2009).

Tumors with Rhabdoid Features of the Biliary Tract

Introduction

Malignant tumors containing variable amounts of rhabdoid cells commonly exhibit a more aggressive biology. Therefore, the identification of rhabdoid features is an important diagnostic element. The nomenclature of these lesions is not yet standardized. Several terms have been employed to denote the presence of rhabdoid cells in neoplasm, including rhabdoid features, rhabdoid phenotype, rhabdoid differentiation, rhabdoid transformation, rhabdoid areas, and rhabdoid as an adjective preceding the name of the tumor (such as rhabdoid adenocarcinoma). Carcinomas and adenocarcinomas with rhabdoid features occur in most organs and tissue derived from the foregut. They comprise the thyroid (including follicular carcinoma), the lung, the esophagus, the stomach, the pancreas (including neuroendocrine carcinoma), the small intestine, and the colon. In the liver, tumors with rhabdoid features chiefly comprise a distinct lesion mostly occurring in the pediatric age group, i.e., malignant extrarenal rhabdoid tumor.

Intrahepatic Cholangiocarcinoma with Rhabdoid Features

Intrahepatic CC with rhabdoid features (synonyms: intrahepatic CC with rhabdoid

transformation; rhabdoid cholangiocarcinoma) is a very rare malignant neoplasm of the intrahepatic biliary tree, characterized by a variable component of cells with a rhabdoid phenotype (Honda et al. 1996; Lim et al. 2004; Sugano et al. 2013). The patient reported by Honda and coworkers, a 61-year-old female, showed multiple liver masses at imaging. Histologically, these tumors exhibited both sarcomatous and ordinary tubular adenocarcinomas, the sarcomatous areas being occupied by rhabdoid cells expressing both vimentin and cytokeratin (Honda et al. 1996). In the case of Lim and coworkers (a 41-year-old female), a left hepatic lobectomy showed a huge mass (up to 17 cm) with extensive necrosis and an infiltrative border. The viable tumor, found only in the peripheral portion of the mass, was reddish yellow to tan and hemorrhagic. Histologically, the entire tumor was composed of loosely cohesive, round to polygonal cells with abundant eosinophilic, glassy cytoplasm. The vesicular nuclei were eccentrically placed. Close to the nuclei, the cytoplasmic body typical for rhabdoid cells was noted. Some of the cells had mucin-containing vacuoles. Immunohistochemically, the cells expressed both vimentin and epithelial markers (Lim et al. 2004). Differential diagnostically, peritoneal spread of adenocarcinomas with rhabdoid features should be distinguished from malignant peritoneal mesothelioma containing rhabdoid cells (Matsukuma et al. 1996).

Primary Rhabdoid Tumor of the Gallbladder

In a 46-year-old male patient, the gallbladder showed a slight thickening in the body wall, measuring 1 cm. The lesion was located on the peritoneal side, i.e., away from the liver bed. Sections from this area revealed collections of loosely arranged plump cells with the features of rhabdoid cells, which showed the typical eccentric, paranuclear positivity for vimentin (Suri et al. 2003). A second case of gallbladder carcinoma with a rhabdoid component, but associated with sarcomatoid features, was reported in a 61-year-old female patient. This tumor of 4.5 cm size was located in the neck portion of the gallbladder (Kim et al. 2003).

Pathogenesis

At least in part of rhabdoid tumors and tumors with rhabdoid features, genetic alterations of the INI1 gene are well established (see ▶ Chap. 78, "Malignant Rhabdoid Tumors and Tumors with Rhabdoid Features"). In mucinous carcinoma with rhabdoid features, INI1/SMARCB1 missense mutations (codon 116) have been identified (Cho et al. 2006).

Epithelial Tumors of the Liver of Uncertain Lineage

45

Contents

Abstract

The hepatobiliary tract is the primary site of a small group of tumors that are, in regard to their origin, characterized by uncertain cell lineages. Adrenal rest tumor is an unusual lesion thought to take its origin from an adrenal rest, probably deriving from aberrant adrenal primordia or extraadrenal cells. This neoplasm is typically a gonadal tumor but very rarely also develops in the liver. The neoplasms are circumscribed lesion that typically develop close to the liver capsule and histologically resemble adrenocortical cells. A second group of hepatic tumors of uncertain pathogenesis are progenitor cell tumors, lesions that include undifferentiated liver tumor with stem cell-like features, and progenitor cell neoplasms with an intermediate cellular phenotype.

Adrenal Rest Tumor

Introduction

Adrenal rest tumor (ART) denotes a tumorous or multinodular lesion thought to take its origin from an adrenal rest, which probably derives from an aberrant adrenal primordium or from extraadrenal cells secondarily committed to become adrenocortical cells (Barwick et al. 2005). ART occurs at several sites, including the retroperitoneal space (including the perirenal region), testis, ovary, broad ligament, spinal nerves, and liver, but

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_45

excluding the limbs. ARTs are very well recognized to occur in the testis (testicular adrenal rest tumor; TART) of patients with congenital adrenal hyperplasia, caused by 21-hydroxylase deficiency in more than 90 % of the patients (Cakir et al. 2012; Delfino et al. 2012; Aycan et al. 2013). TART are usually bilateral lesions and are mostly localized to the rete testis rather than the testicular parenchyma. The aberrant adrenocortical cells within the testicular compartment are stimulated by pro-opiomelanocortin in periods of suboptimal hormonal control inducing hypertrophy and hyperplasia (Claahsen-van der Grinten et al. 2009).

Adrenal Rest Tumor of the Liver: An Intriguing Entity

Hepatic ART (HART; obsolete synonyms, primary "hypernephroma" of the liver; hypernephroid tumors of the liver; primary hypernephroid cancer of the liver) is a rare finding and is, similar to ART located elsewhere, thought to derive from misplaced adrenocortical cells within the capsule, or under the capsule, of the liver. Based on a resemblance of the tumor cells with those of renal cell carcinoma, the term "hypernephroma of the liver" has been employed in some of the early reports. The designations, "primary adrenal carcinoma of the liver" (Powell et al. 1908) or "primary liver tumor of probable adrenocortical origin," (Cirio 1922) have also been used. The identification and definition of the lesion require the presence of normally located extrahepatic and perirenal normal adrenal glands to exclude AHA or AHF (Craig et al. 1989), and the detection of steroid hormone synthesis/production is one essential component for the diagnosis.

Is HART a bona fide neoplastic process? Hamperl (1970) started his detailed review article on hepatic ART with the question: "Do adrenal rest tumors of the liver really exist?" In particular for small subcapsular lesions, this question is difficult to answer, because a distinction between reactive growth of ectopic adrenocortical-like cells and neoplasia may not be possible by the use of morphologic analysis. Schmorl (1891) had described adrenal rests in the liver similar to those found in the kidney, and these observations were confirmed by Beer (1904) and Weller (1925), who found adrenal rests in 4 % and 0.34 %, respectively, of their cases (cited from Hamperl 1970). Conversely, large tumors are thought to be neoplastic and may even represent carcinomas; in fact, malignant transformation of ART has been reported (Craig et al. 1989; Goren et al. 1991), but more cases have to be collected in order to arrive at a more precise description of the lesions' biology.

Epidemiological, Clinical, and Imaging Features

Hepatic ART (HART) is a very uncommon neoplasm. Among 26 cases compiled by Hamperl (1970), age at diagnosis ranged from 14 months to 70 years. The male to female ratio was 15:11. HART has been observed in infants and children (Mason and Speese 1933; Zverev 1963). The clinical presentation of hepatic adrenal rest tumors is variegated.

One of the early reports described a boy aged 17 months who was admitted with the chief complaint of severe upper abdominal pain having developed suddenly and high fever. The abdomen was distended, and palpation revealed a hard,

irregular, tender mass in the left hypochondrium. At laparotomy, a vascular, orange-sized and encapsulated, firm tumor was discovered attached to the under surface of the right liver lobe (today we would call this a pediculated tumor). Histology showed a neoplasm containing cells resembling those of the inner zone of the adrenal zona glomerulosa. In addition, there were acinar-like areas lined by cuboidal cells or lacking any epithelial lining. The majority of these acini were filled with a hyaline, colloid-like material. Five years later, the child presented multiple bony metastases attributed to hypernephroid renal carcinoma (Mason and Speese 1933). This example highlights the difficulties in diagnosis. Was this HART later followed by hypernephroma or was the liver tumor an early metastatic manifestation of a then still small renal cell carcinoma? However, this patient later also developed signs of an androgen-producing tumor, with coarse face, precocious enlargement of the genitals and development of pubic hair, and a small sella, suggesting HART.

In fact, HART are either nonfunctional (Tajima et al. 2001) or functional and then may cause Cushing's syndrome amenable to successful therapy with ketoconazole, blocking tumoral steroidogenesis (Contreras et al. 1985). Most HART are nonfunctioning and benign. A combination of virilization and a mild degree of Cushing's syndrome has also been reported, associated with elevated androgen levels, loss of cortisol circadian rhythm, and marked increase in urinary 17-ketogenic and 17-ketosteroids; in this young female patient with a hepatic ART, both the adrenals and the ovaries were atrophic (Wallace et al. 1981). Virilism combined with Cushing's syndrome owing to HART has also been observed in a small child (Wilkins and Ravitch 1952).

Most of the tumors were localized in the right liver lobe and often on its under surface. The ultrasonography reveals a solid mass showing heterogeneous echogenicity. At imaging, hepatic ART have been described to have CT features of a hypodense mass containing components of both fat density and soft tissue density with early fill-in and early fill out (Shin 2010). The masses appear to be isointense on T1-weighted, hypointense on T2-weighted, and hyperintense on superparamagnetic iron oxide-enhanced MR imaging (Baba et al. 2008) and showing homogeneous hypervascularity in angiography (Tajima et al. 2001). HART appear to be nourished by branches of the hepatic artery (Pollice 1973; Wallace et al. 1981; Contreras et al. 1985; Arai et al. 2000).

Pathology

Macroscopy

At gross examination, HART are usually located close to the liver capsule and present as solid and well circumscribed or even encapsulated, yellowish or yellowish-brown to glossy masses with an expanding growth pattern. On the fresh cut surface, the tumors tend to bulge, with retraction of the adjacent liver substance. The surface looks geographic, sometimes with gyrifications or a puzzle-like arrangement of the tissue. HART are mostly rather small or minute lesions, 5–7 mm, but larger tumors have also been reported (Arai et al. 2000; Baba et al. 2008) and huge multinodular masses even resulting in hepatomegaly (Wallace et al. 1981). However, HART are mostly incidental findings if there are no signs of steroidogenic activity. Central hemorrhagic necrosis is observed in some case, and marked calcification has been noted (Pollice 1973; Craig et al. 1989).

Histopathology

Histologically, the cells of HART resemble adrenocortical cells that form a mass with a thin capsule, which is usually incomplete. Frequently, so-called pale cells or clear cells ("hypernephroid cells"), being PAS-negative, predominate, while eosinophilic, sometimes large and polygonal cells, are more frequent toward the center of the lesion (Arai et al. 2000). In frozen sections, most of the cells are sudanophilic owing to their high lipid content. The cells may contain birefringent lipid droplets of rather uniform size. The tumor

cells are arranged in the form of alveolar or fascicular structures (Arai et al. 2000; Baba et al. 2008), in some way mimicking the architecture of the adrenal cortex, with intervening thin-walled vascular channels and fibrous strands. Some of the vacuolated cells resemble those of the adrenocortical zona fasciculata. Nuclei are small or of intermediate size and ovoid, with tiny or lacking nucleoli and only minor atypia, and mitotic figures are usually not found. Small foci with increased cellular pleomorphism can occasionally be found, predominantly with pale or clear cells.

Immunohistochemistry

Immunohistochemically, the tumor cells did not stain for cytokeratin, epithelial membrane antigen, vimentin, S-100 protein, AFP, or chromogranin, but staining for adrenal 4-binding protein (Ad4BP) and six types of steroidogenic enzymes has been reported (Arai et al. 2000).

Electron Microscopy

Ultrastructurally, lipid droplets and mitochondria with tubulo-vesicular cristae have been identified, features regarded as typical for steroid-producing cells (Arai et al. 2000). HART consistently lack adrenomedullary tissue. There are usually no signs of invasive growth; rather the HART cells interdigitate with liver tissue at sites of incomplete encapsulation, sometimes with apparent infiltration of parenchymal sinusoids (Craig et al. 1989), and preexistent hepatocytes and/or bile duct profiles can be entrapped within HART tissue.

Differential Diagnosis

The most important differential diagnosis is other hepatic tumors with a clear cytoplasm. They include clear cell hepatocellular carcinoma, clear cell perivascular epithelioid tumors (PEComas; including clear cell epithelioid angiomyolipoma and so-called sugar tumors), and metastases of a diverse spectrum of extrahepatic primary tumors with a clear cell population. Adrenal rest tumor can rarely develop in the immediate vicinity of the liver, e.g., in the retroperitoneal space (Akishima-Fukasawa et al. 2011).

Etiology and Pathogenesis

The etiology and pathogenesis of ART and HART have not been elucidated. One hypothesis claims that HART originate from misplaced adrenocortical cells. Schmorl was the first to deport on misplaced adrenal tissue within the light liver lobe. He found this phenomenon four times among 510 necropsies (Schmorl 1891). Bothe (1926) reported on a 16 mm human embryo where he noted the juxtaposition of adrenal anlage cells with the primitive cell masses of the liver, kidney, and gonads. For extrahepatic ART, and in particular for gonadal ART, a relationship with congenital adrenal disorders is well established. Male patients with congenital adrenal hyperplasia caused by steroid enzyme defects (e.g., 11-hydroxylase deficiency) can develop testicular tumors with the features of ART, these lesions being more frequently manifest in adolescents and adults (Clark et al. 1990; Oberman et al. 1993; Stikkelbroeck et al. 2001; Proto et al. 2001). We are not aware of any case of HART being related to congenital adrenal disorders. In situations not related to congenital adrenal disease, a histogenic pathway originating from misplaced adrenal progenitor cells or metaplastic coelomic cells has been suggested (Adashi et al. 1980). A similar pathogenesis may be discussed for ART arising in the liver, i.e., priming of preexistent coelomogenic cells to enter an adrenocortical cell lineage. What is the evidence that ART cells in fact belong to such a lineage? Immunohistochemically, reactivity for the adrenal 4-binding protein (Ad4BP) and a number of enzymes involved in the synthesis of adrenocortical steroids have been detected (Arai et al. 2000; Baba et al. 2008). The presence of the 11-hydroxylase B1 in adrenal rest tumors is of special importance, because this enzyme is a marker for the adrenal zona fasciculata/reticularis (the enzyme form B2 is exclusively expressed in the zona glomerulosa). Similar to ART occurring

in other sites and specifically in the testis, it may be assumed that adrenal rest cells may fail to undergo regression and may be stimulated for growth and differentiation into tumor-like lesions.

Progenitor Cell Tumors of the Liver

Introduction

Both hepatocellular carcinoma and various types of cholangiocarcinoma can contain cell lineages with progenitor/stem cell-like features. This issue has been addressed in the respective chapters referring to these neoplasms. In addition, there are primary hepatic neoplasms that seem to predominantly consist of progenitor cells. Such tumors are denoted by the use of several not yet standardized names, including stem cell tumors of the liver, progenitor cell tumors, or tumors with progenitor cell-like features.

Undifferentiated Liver Tumors with Stem Cell-Like Features

It may be anticipated that distinct subsets of undifferentiated or poorly differentiated liver neoplasms showing features of "small cell blue tumors" contain variants composed of primitive progenitor cells primed or not primed for a known liver cell lineage. Chu and coworkers reported a hepatic tumor in an adult male that was composed of solidly packed small, round and uniform, undifferentiated cells with an immunophenotype c-kit+, EpCAM+, E-cadherin+, keratin 7, keratin 19, and AFP. C-kit mutations were not detected. It was concluded that this neoplasm consisted of a primitive lineage with stem cell features (Chu et al. 2014).

Progenitor Cell Tumors with an Intermediate Cellular Phenotype

In case stem/progenitor cells driving a hepatic neoplasm are primed to become bipotential cells, tumors with a phenotype intermediate between hepatocyte and cholangiocyte lineages might be expected. Such an interesting lesion was observed in a 57-year-old female. The aggressive neoplasm exhibited a trabecular growth pattern and was composed of uniform small cells that were immunoreactive for both hepatocytes (cytokeratins 8 and 18) and bile duct cells (cytokeratins 7 and 19). Also parathyroid hormone-related peptide, a cholangiocarcinoma marker, was expressed. It was suggested that this neoplasm with an intermediate phenotype represents an immature progenitor cell tumor (Robrechts et al. 1998). Tumors with such an intermediate phenotype, in part characterized by small round to oval cells with scanty cytoplasm and a desmoplastic stroma, were described in subsequent studies, and part of these lesions expressed c-kit (Theise et al. 2003; Kim et al. 2004). A further liver tumor showing bidirectional differentiation proposed to be related to bipotential progenitor cells was observed in a patient with citrin deficiency (Soeda et al. 2008).

Progenitor Cell Tumors of the Liver: Distinction from Hepatocellular Carcinomas and Cholangiocarcinomas with Stem Cell-Like Features

As outlined elsewhere, part of hepatocellular carcinomas (HCCs) and cholangiocarcinomas (CCs) contain neoplastic cells with features shared by normal hepatobiliary stem or progenitor cells (Lee et al. 2006, 2014; Komuta et al. 2008; Yamashita et al. 2009; Kim et al. 2011; Cheuk-lam Lo and Ng 2013; Iwahashi et al. 2013; Kim and Park 2014; Oishi et al. 2014; Xu et al. 2014). Also combined hepatocellular-cholangiocarcinoma displays subtypes with stem cell features (Sasaki et al. 2014). It is proposed that such neoplasms should not be termed progenitor cell tumors as long as the majority of the neoplastic cells are typical for either HCC or CC. In fact, progenitor-like cells can form a minor component in otherwise "classical" HCCs or CCs. It was found that about 8.3 % of resected HCCs expressed the stem cell marker neural cell adhesion molecule/NCAM (Tsuchiya et al. 2011). Stem-like cells contributing to HCC

or CC may represent a constitutive component of the neoplasms, or may be selected from another cell pool by the distinct microenvironment of the cancers. It has been demonstrated that inflammatory cytokines present in an inflammatory environment can promote the retrodifferentiation of tumor-derived hepatocyte-like cells to progenitor cells (Dubois-Pot-Schneider et al. 2014). Loss of p53 expression facilitates the dedifferentiation of mature hepatocytes into nestin-positive progenitor-like cells, a further mechanism for cellular plasticity in hepatic neoplasms (Tschaharganeh et al. 2014).

Epithelial Tumors Originating from Epithelial Inclusions in Locoregional Lymph Nodes of the Liver

Introduction

Lymph nodes sometimes contain benign epithelial glandular or cystic inclusions that may be misinterpreted as metastatic disease. The most common situations include breast epithelia in axillary lymph nodes (Zynger et al. 2009), thyroid follicles in cervical lymph nodes (folliculosis; Meyer and Steinberg 1969), genital epithelia in pelvic nodes (endosalpingiosis and endocervicosis;), and various glandular structures in pulmonary/mediastinal nodes (Lewis et al. 2011). Benign epithelial nodal inclusions may be remote from the orthotopic normal epithelium. For example, endosalpingiosis can occur in axillary lymph nodes (Carney et al. 2014).

Epithelial Inclusions in the Liver and Pancreas Associated and Abdominal Lymph Nodes

Epithelial inclusions can occur in lymph nodes at the liver hilus (Arcidiacono 1952). Hilar lymph node inclusions may give rise to malignancies, e. g., serous papillary adenocarcinoma (Terada 2012). Peripancreatic lymph nodes may contain squamous cell nests glandular cystic inclusions (Zheng et al. 2012) and very rarely cystic lymphoepithelial lesions (Sako et al. 1999). Simple benign glandular inclusions also occur in retroperitoneal lymph nodes (Horn and Bilek 1996), and abdominal lymph nodes may contain squamous cell nests together with mucin-containing cells (Arai et al. 1992). A non-Müllerian benign epithelial choristoma was incidentally detected in a celiac lymph node (Carr et al. 1987).

Mixed Epithelial-Mesenchymal Tumors of the Hepatobiliary Tract (Tumors with Epithelial-Mesenchymal Transition)

Hepatobiliary Carcinosarcomas and Related Neoplasms

46

Contents

Abstract

In the hepatobiliary tract, several types of malignancies characterized by a complex mixture of epithelial and mesenchymal components can develop. Previously, most of these lesions were classified as either carcinosarcomas or mixed tumors, but novel findings suggest that these neoplasms in fact reflect aspects of epithelial-mesenchymal transition or mesenchymal-epithelial transition. Carcinosarcomas are usually adenocarcinomas admixed with heterologous components, which can include most known types of neoplastic mesenchymal tissues. Rarely, hepatocellular carcinoma occurs with sarcoma as a combined neoplasm. Carcinosarcomas are difficult to distinguish from an ill-defined group of tumors termed sarcomatoid carcinoma of the liver. These are most commonly hepatocellular carcinomas and cholangiocarcinomas that contain sarcoma-like spindle cell components.

Carcinosarcomas of the Liver

ICD-O Code 8980/3

Introduction

Carcinosarcomas are defined as malignant neoplasms in which epithelial and mesenchymal neoplastic cell lineages synchronously occur together

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_46

within the same tumor (Wick and Swanson 1993). For the liver, the WHO Classification defines carcinosarcomas as tumor containing both carcinomatous (either hepatocellular or cholangiocellular) and sarcomatous elements, including malignant mixed tumors in this category. Carcinosarcoma of the liver (CSL) has formerly been defined as hepatocellular carcinoma combined with differentiated sarcomatous elements (Ishak et al. 2001), i.e., excluding cholangiocarcinoma. An alternative term sometimes used is sarcomatoid carcinoma (Nishie et al. 2003), but such tumors are treated in another paragraph, because the lesions do not fit the requirements for a diagnosis of CSL.

Craig and coworkers had suggested that the term, carcinosarcoma of the liver, should be reserved for primary hepatic tumors with both hepatocellular carcinoma (HCC) and non-spindle cell sarcoma, such as osteosarcoma, chondrosarcaoma, angiosarcoma or malignant schwannoma (Craig et al. 1989). Also in the 2001 edition of the AFIP's tumor atlas, Ishak and coworkers emphasized that carcinosarcoma of the liver should be defined as hepatic tumors with both HCC and a non-spindle cell sarcomas such as osteosarcoma, chondrosarcoma, or rhabdomyosarcoma (Ishak et al. 2001). The reason for this restriction may be that a spindle cell component, or a transformation into spindle cells, is sometimes seen in HCC in the absence of other components that would result in a diagnosis of CSL. The restriction of carcinosarcoma to those containing HCC as the epithelial component is problematic, as there are rare instances of hepatic adenocarcinomas/cholangiocarcinomas associated with sarcomas (Nomura et al. 2000; Kwon et al. 2007; Zhao et al. 2010).

Epidemiology and Clinical Features

CSL are rare malignant neoplasms with a very poor prognosis. So far, little or nothing is known about the epidemiology, risk factors, the significance of preexisting liver disease, and pathogenic factors. The majority of cases have been reported from Japan, but it is difficult to judge whether this reflects a geographic prevalence or an effect of more frequent reporting. The risk factors for these neoplasms are not known, but have been suggested to be similar to those for HCC. In a review of 11 cases, the tumors were found in patients with an age range of 46–84 years; 5/11 report finding liver cirrhosis and one reports precirrhotic fibrosis (She and Szakacs 2005). Thus, chronic fibrosing hepatopathy associated with remodeling of the liver may play a pathogenic role in part of the cases. The biology of disease of CSL is highly aggressive, and all of the 11 patients reviewed in 2005 had shown a fatal outcome, the longest survival being 9 months after diagnosis (She and Szakacs 2005).

Less than 70 cases of these highly interesting lesions (excluding those termed, sarcomatoid carcinoma) have been reported so far.

Selected References (Epshtein 1957; Bialik 1964; Kerr 1966; Isoda et al. 1976; Bogdanskaia 1979; Jinnouchi et al. 1989; Iareshko et al. 1992; Leger-Ravet et al. 1996; Fayyazi et al. 1998; Nomura et al. 2000; Eriguchi et al. 2001; Ishak et al. 2001; Nishie et al. 2003; Freeman et al. 2004; Jelovsek et al. 2004; Morise et al. 2004; Wang et al. 2004; She and Szakacs 2005; Garcez-Silva et al. 2006; Huang et al. 2009; Park et al. 2009; Shu et al. 2010; Sun and Zhong 2010; Yamamoto et al. 2010; Aparicio et al. 2011).

Pathology

Based on the absence of a generally accepted definition, the tumors discussed in this paragraph are regarded as CSL, irrespective whether the epithelial component is of the HCC type or the adenocarcinoma type, although it has to be emphasized that one definition restricted the use of the term CSL, to those tumors having an HCC component (Craig et al. 1989).

Macroscopy

At gross examination, this variant of CSL either presents in the form of large, usually greyish-

Fig. 1 Carcinosarcoma of the liver with large central necrosis

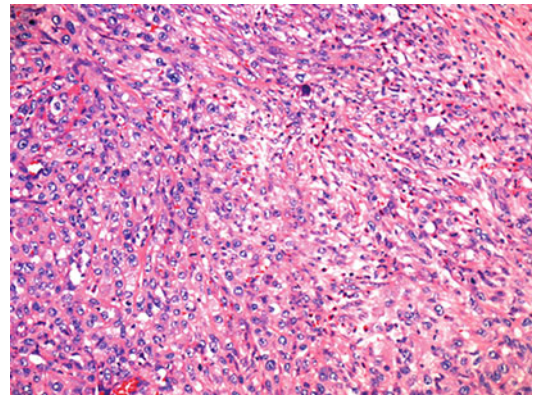

Fig. 2 Carcinosarcoma of the liver. This poorly differentiated neoplasm shows a complex mixture of immature epithelial cell nests and tumor spindle cells (hematoxylin and eosin stain)

white liver masses with hemorrhage and necrosis, or as multinodular lesions (Fig. 1). In case the heterologous component consists of osteoid matrix, the cut surface may be gritty. Satellite nodules may be in evidence (Morise et al. 2004). Some of the lesions have shown cystic changes (Wang et al. 2004), probably due to colliquation of necroses.

Histopathology of Epithelial Components

Adenoid structures have been observed in the epithelial part of the tumors, and have sometimes been designated, adenocarcinoma (Nomura et al. 2000; Freeman et al. 2004; Wang et al. 2004; Zhao et al. 2010; Yamamoto et al. 2014). Combined hepatocellular/cholangiocarcinoma and sarcoma has been described (Nakasho et al. 1996; Papotti et al. 1997). From the descriptions, it is sometimes difficult to judge what this epithelial component in fact represents (adenoid features of HCC vs. biliary-type adenocarcinoma). In few reports, the adenoid component was clearly interpreted as cholangiocarcinoma (Nomura et al. 2000; Kwon et al. 2007). In a fraction of the cases, the HCC component has been described as such (Saphir and Vass 1938; Jaffe 1924; Isoda et al. 1976; Uno et al. 1977; Dolorme 1978; Shin et al. 1981; Kimoto and Ugaki 1982; Kishimoto et al. 1984; Sonoda et al. 1984; Kubosawa et al. 1988; Jinnouchi et al. 1989; Craig et al. 1989; Ishiwata et al. 1990; Oda et al. 1994; Leger-Ravet et al. 1996; Akasofu et al. 1999; Tsuji et al. 2001; Figs. 2 and 3).

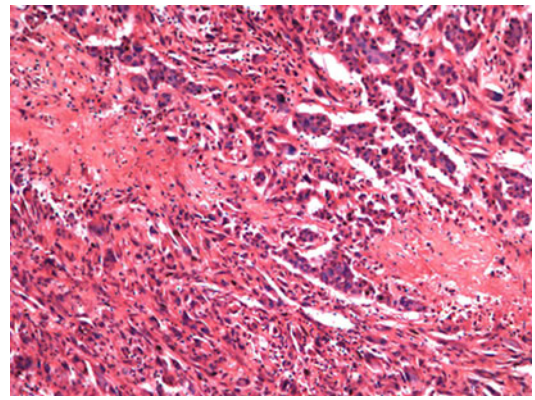

Fig. 3 Carcinosarcoma of the liver. The epithelial component with a solid growth pattern is found to the top and right of the figure, whereas a mesenchymal component is seen to the bottom and left lower corner (hematoxylin and eosin stain)

Immunohistochemistry has been performed in several of the tumors reported in the literature. Expectedly, the HCC components showed reactivities usual for this tumor, while the different sarcomatous components expressed the markers of the respective mesenchymal lineages

(Ooi et al. 1987; Oda et al. 1994; Nakasho et al. 1996; Ikebe et al. 1998; Nomura et al. 2000; Eriguchi et al. 2001; Tsuji et al. 2001; Freeman et al. 2004; Morise et al. 2004; Wang et al. 2004; Lin et al. 2013).

Histopathology of Mesenchymal Components

The heterologous components observed in reported cases are listed in the Table. It is of interest to note that most cases of HCC-type CSL with osteosarcoma components also have a coexisting spindle cell sarcomatous lesion, but these two components are separated in Table 1. Furthermore, tumors with a spindle cell component are only included as CSL if this component was looking like a sarcoma, excluding cases now identified as sarcomatoid HCC.

Spindle Cell Components

Part of CSL show a combination of HCC and bona fide spindle cell sarcoma, the latter sometimes identified as fibrosarcoma. In the case of Nakano et al. (1974), the HCC component was described as anaplastic. A CSL with a fibrosarcomatous component developing in a 35-year-old female patient was associated with oral contraceptive use (Ladaga et al. 1979). In this tumor, epithelial and spindle cells were in part intermingled, and fibrosarcoma showed entrapped small bile ducts. In a study of 14 autopsy cases, HCCs with sarcomatous change were characterized by negative or low serum AFP levels and a high incidence of extrahepatic metastases. Grossly, the tumors were of infiltrative, mixed expanding and infiltrative, and pedunculated types. Histologically, the sarcomatous component was prominent and consisted of vimentin-, but also cytokeratin-positive spindle cells and giant cells, whereas the epithelial component revealed an HCC phenotype (Kakizoe et al. 1987). There are, however, also neoplasms where the spindle cells fail to express cytokeratins, but strongly express vimentin (Figs. 4 and 5).

Table 1 Heterologous components in carcinosarcoma of the liver

Spindle cell sarcoma
Chondrosarcoma
Osteosarcoma
Rhabdomyosarcoma
Leiomyosarcoma
Angiosarcoma
Malignant mesenchymoma
Malignant fibrous histiocytoma
Several mesenchymal and other components

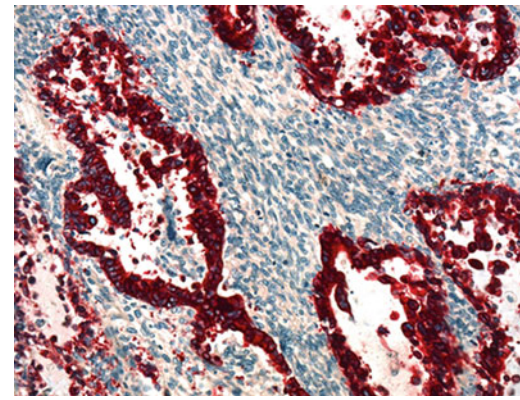

Fig. 4 Carcinosarcoma of the liver, cytokeratin expression pattern. The carcinoma component forming tubules is strongly positive, while intervening tumor spindle cells are not cytokeratin-reactive (CAM5.2 immunostain)

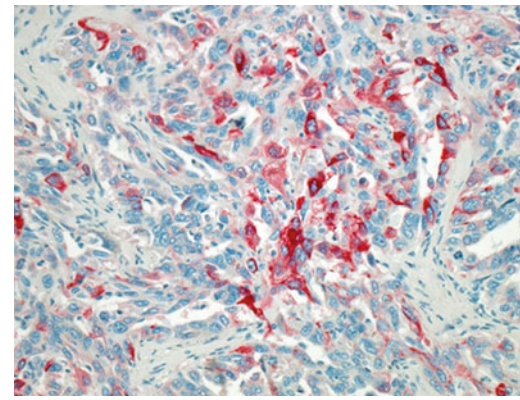

Fig. 5 Vimentin expression in hepatic carcinosarcoma. Vimentin-reactive mesenchymal tumor cells are intermingled with epithelial/carcinomatous cells (vimentin immunostain)

As cytokeratin positivity is seen in spindle cells of spindle cell-type HCCs, it is difficult to judge whether all the reported CSL with spindle cells were in fact true CSL. Overall it has to be emphasized that only rare tumors showing a fibrosarcomatous component with cytokeratin-negative spindle cells may qualify for CSL. Most authors exclude HCC with bland spindle cell components from true CSL, and classify these tumors as spindle cell HCC, discussed in a separate chapter.

Selected References (Nakano et al. 1974; Ladaga et al. 1979; Kimoto and Ugaki 1982; Miyazaki et al. 1983; Kakizoe et al. 1987; Kojiro et al. 1989; Haratake and Horie 1991; Nakasho et al. 1996; Komada et al. 1997; Papotti et al. 1997; Tsuji et al. 2001; Kim et al. 2004; Morise et al. 2004; Wang et al. 2004; Sumiyoshi et al. 2007; Park et al. 2009; Aparicio et al. 2011; Wang et al. 2012).

Chondroid Components

Chondroid or chondrosarcomatous tissue is known to occur in mixed hepatoblastomas of the pediatric age group, but it also occurs as the single histologic feature of primary hepatic sarcomas (primary chondrosarcoma of the liver; HCS) or as a component of CSL. True carcinosarcomas with chondroid/chondrosarcomatous components are now a well-recognized entity (Imholz and Noltenius 1977; Kishimoto et al. 1984; Ooi et al. 1987; Leger-Ravet et al. 1996; Fayyazi et al. 1998; Ikebe et al. 1998; Fu et al. 2000). For CSL showing a chondroid or chondrosarcomatous component, several terms have been employed to denote such lesions, including chondrosarcoma (Kishimoto et al. 1984; Sonoda et al. 1984), chondrosarcoma with hepatoma (Ojima et al. 1964), sarcomatoid HCC with chondroid variant (Fu et al. 2000), HCC with chondrosarcomatous variation (Ooi et al. 1987; Ikebe et al. 1998). This variant of CSL may grow to large or very large tumors which produce intrahepatic metastases. At gross examination, the presentation is similar to that of HCC. Histologically, the epithelial HCC component is intermingled with neoplastic mesenchymal tissue, disclosing spindle-shaped cells (sometimes in a storiform pattern) and foci of matrix-rich chondrosarcoma. The chondroid parts may be separated from the remaining tumor tissue by a thin fibrous band, but a complex interdigitation of the different lineages occurs as well, and transitional features of poorly differentiated HCC and sarcomatous tissue may be present, epithelial and mesenchymal cells being situated face to face (Ikebe et al. 1998).

The chondrosarcomatous component is sometimes only recognized within immature mesenchymal areas otherwise consisting of spindle cells (Sonoda et al. 1984; Ikebe et al. 1998). In the tumor described by Ikebe and others, the mesenchymal component was characterized by a diffuse proliferation of spindle-shaped, atypical cells that showed focal transition to a poorly differentiated HCC. These cells were partially arranged in a storiform pattern. Within these areas, clearly malignant cells were embedded in a hyaline chondroid matrix, this lesion fulfilling the morphologic criteria of chondrosarcoma (Ikebe et al. 1998). In another observation, the sarcomatous part of the tumor contained multinodular chondroid foci, with chondroid cells embedded in a hyaline chondroid matrix. Cellularity of this area was low, and there was no marked pleomorphism of the chondroid cells, but here was an apparent transition from the sarcomatoid component (pleomorphic spindle cells) to the chondroid component. Interestingly, the chondroid cells were not only immunoreactive for vimentin and S100 protein, but also for AFP, and the authors thus concluded that the chondroid component was a metaplastic growth of sarcomatoid HCC (Fu et al. 2000). In one patient, chondrosarcoma in CSL was associated with osteosarcoma (Leger-Ravet et al. 1996). Expectedly, the chondroid cells are reactive for vimentin, and a strong and selective immunostaining for S100 protein has been observed in cells embedded in the chondroid matrix (Ikebe et al. 1998). In cases where the chondroid component is associated with poorly differentiated spindle cells, the latter may express

cytokeratins and AFP, suggesting a spindle cell HCC component (Fayyazi et al. 1998). In addition to HCC, adenocarcinoma of the liver can also contain a chondrosarcomatous component (Volkov et al. 1979; Nomura et al. 2000). In this situation, carcinosarcoma is defined as a tumor with both adenocarcinoma and non-spindle cell sarcoma (so-called adenosarcoma).

Osseous Components

Primary malignant bony neoplasms (primary hepatic osteosarcoma) are exceedingly unusual lesions (Liony et al. 1990; Kitayama et al. 1995; Govender and Rughubar 1998; Boldt et al. 1999). Similarly, CLS combining HCC with osteoid and malignant bone formation have rarely been described (Kerr 1966; Ladaga et al. 1979; Blanding 1986; Maeda et al. 1986; Nakajima et al. 1988; Leger-Ravet et al. 1996; Ishak et al. 2001; Morise et al. 2004; Kwon et al. 2007; Goto et al. 2010; Yamamoto et al. 2010). The osteosarcomatous component may develop together with a chondrosarcomatous differentiation (Leger-Ravet et al. 1996; Kwon et al. 2007; Goto et al. 2010), or represent the only detectable heterologous component. The latter situation has been described for a CSL both with an HCC component (Kerr 1966; Yamamoto et al. 2010), or with a cholangiocellular epithelial lineage (Celikbilek et al. 2011).

In the first reported case of "osteosarcohepatoma" (Kerr 1966), a 56-year-old man with liver cirrhosis showed, at autopsy, a large and friable, hemorrhagic and extensively necrotic tumor mass arising from the right liver lobe. Histology showed ordinary HCC blending into an immature mesenchymal component containing multiple foci of osteoid tissue, in the absence of chondroid tissue. In the autopsy case reported by Nakajima and coworkers, the HCC component of this CSL was combined with cholangiocarcinoma (Nakajima et al. 1988). In part of these neoplasms, the exact identification of the nature of epithelia remains difficult without immunohistochemistry. A large hepatic tumor (8 cm diameter) reported by Kwon et al. (2007) mainly consisted of a sarcomatous component with a diffuse proliferation of spindle cells. In this area, chondrosarcomatous change was found, with a hyaline chondroid matrix and foci of osteoid. Clusters of epithelial cells, in part arranged as tubules, were found in the sarcoma, these cells being reactive for cytokeratins 7 and 19, and for EMA, but not for a hepatocyte marker, compatible with poorly differentiated cholangiocarcinoma.

Are the osteoid and osteoid-associated bone-forming cells found in bone-forming CSL malignant changes or a reactive alteration? In mixed epithelial and mesenchymal hepatoblastomas, where osteoid formation is frequently encountered (Allison and Willis 1956; Pang 1961), the osteoid is regarded as a manifestation of the neoplastic lineage per se, although the osteoblast-like cells embedded in the osteoid matrix are unusual elements, because they markedly express cytokeratins. Interestingly, cytokeratin reactivity of malignant neoplastic cells has also been detected in a variant of osteosarcoma of adults, osteosarcoma with epithelioid features (Hasegawa et al. 1993). In CSL, this question has not been addressed in similar detail. An earlier observation of such a CSL used the term, HCC associated with *ossification*, and not osteosarcoma (Maeda et al. 1986). In this autopsy report, the authors described trabecules of partially mineralized osteoid within the tumor, and this osteoid seemed to develop into well-formed bony trabecules. These structures were surrounded by relatively small malignant cells, and the morphologic features of some of the cells located inside the osteoid matrix suggested the production of malignant osteoid by malignant cells (Maeda et al. 1986). In the report of Nakajima et al. the respective figure illustrates that highly atypical cells surrounding osteoid scatter into this matrix, and resulting picture looks like osteosarcoma indeed (Nakajima et al. 1988). In cases where foci of osteoid are situated within an area of immature-looking spindle cell mesenchyme (Kwon et al. 2007), a role of mesenchymal tumor stem cells having the capability to be primed for osteoprogenitor cells may be anticipated.

Rhabdomyoid/ Rhabdomyosarcomatous Components

Hepatobiliary rhabdomyosarcoma is a well-known, although rare, entity in the pediatric age group. The exceptional cases of primary rhabdomyosarcoma in the adult liver, which do not have a connection with the biliary tract, are less well recognized, but several cases have been reported. They can occur as pure hepatic rhabdomyosarcomas (HRMS; Watanabe et al. 1983; Shibata et al. 1987; Scheiden et al. 1988; McArdle et al. 1989; Cote and Urmacher 1990; Hayakawa et al. 1990; Zornig et al. 1992; Burrig and Knauer 1994; Hiyama 1995; Tominaga et al. 1995; Meyer-Pannwitt et al. 1996; McRae and Lee 2005). Even less commonly, rhabdomyosarcoma makes part of carcinosarcoma of the liver.

A typical case of this unusual combination is the autopsy observation of Goldman and Friedman (1969). This lesion, termed "rhabdomyosarcohepatoma" by the authors, comprised two divergent patterns, one rhabdomyosarcoma of the embryonal type, the other hepatoma. The former consisted of sheets of rhabdomyoblasts which occasionally assumed an alveolar configuration. The cells were characterized by scant to moderately abundant brightly eosinophilic "myogenic" cytoplasm which often was elongated and tapered. Cross-striations were infrequent but unequivocal. The epithelial component was composed of nests, columns, and trabecules of cells typified by well-defined granular amphophilic cytoplasm, resembling the morphology of HCC. The two components at some places showed intimate intermingling.

Selected References Goldman and Friedman 1969; Mori et al. 1979; Hatanaka et al. 1983; Kawarada et al. 1985; Morimoto et al. 1986; Kubosawa et al. 1988; Hayakawa et al. 1990; Akasofu et al. 1999; Aito and Seki 2006; Lao et al. 2007; Lai et al. 2011; Wang et al. 2012.

CSL with rhabdomyosarcomatous components occurs in two main patterns. In the first pattern, rhabdomyosarcoma cells are intermingled with carcinoma cells or other neoplastic mesenchymal elements. In the tumor described by Kawarada et al. (1985), tumor cells with cross-striation were associated with poorly differentiated cartilage and osteoid tissues. The epithelial elements may be difficult to identify. A tumor showing rhabdomyoblastic features was classified to be CSL due to its marked reactivity for AFP (Mori et al. 1979). In the second pattern HCC and rhabdomyosarcoma are clearly separated within the tumor. In one of the other reported CSL cases, the lesion was therefore suggested to represent a collision tumor (Morimoto et al. 1986). In the case of Akasofu et al. (1999), autopsy of a 55-year-old man revealed a massive tumor measuring up to 19 cm in diameter occupied almost the entire right liver lobe. Several satellite nodules were present in both liver lobes. Most of the neoplasm consisted of small undifferentiated cells admixed with desmin-positive rhabdomyoblasts showing cross-striation. Within this large sarcomatous tumor, a 2 cm-sized nodule of HCC was detected. Also in the large CSL described by Aito and Seki (2006), a nodule of HCC was found within a desmin-and SMA-positive spindle cell sarcoma. The tumor produced granulocyte colony-stimulating factor. The epithelial and mesenchymal components may show different metastasizing features. The encapsulated liver tumor reported by Kubosawa and coworkers (1988) was an HCC situated within a rhabdomyosarcoma. Metastasis of the HCC component was only seen in the left adrenal gland, whereas intrahepatic metastatic foci as well as tumor thrombi occluding the portal vein branches were composed exclusively of rhabdomyosarcoma.

Histologically, rhabdomyosarcomatous CSL usually show a mixture of poorly differentiated or undifferentiated small and short spindle-shaped cells, and rhabdomyoblast-like cells with plum eosinophilic cytoplasm, the latter sometimes with cross-striation seen in either H&E-stained preparations or by use of the phosphotungstic acid stain (Kubosawa et al. 1988). Ultrastructrally, rhabdomyoblast-like cells occurring in these tumors exhibit thick myosin filaments assembled in parallel fashion, and a hexagonal arrangement of thick and thin (actin) filaments (Kubosawa et al. 1988). The neoplastic mesenchymal cells

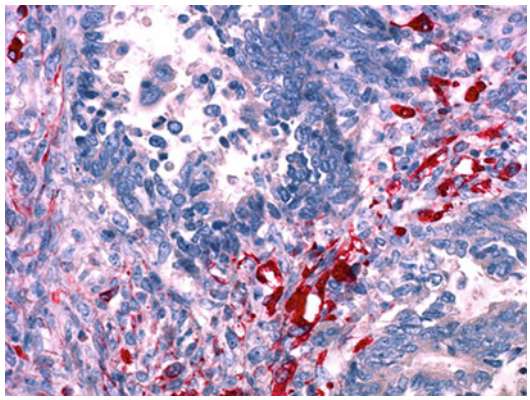

Fig. 6 This hepatic carcinosarcoma exhibits focal rhabdomyosarcomatous differentiation with desmin-reactive tumor cells (desmin immunostain)

may be embedded in a myxoid matrix. The neoplastic rhabdomyoblasts have been shown to be reactive for desmin (Fig. 6), myoglobin, and HHF 35 (on the cross-striations), and negative for hepatocyte-type cytokeratin (Akasofu et al. 1999). The poorly differentiated small cells may be positive for both, cytokeratins and desmin (Akasofu et al. 1999), suggesting that these cells may represent an immature and only partially primed neoplastic progenitor cell.

Angiosarcomatoid Components

Only very few reports describe the combination of HCC with a hepatic hemangioendothelial sarcoma/angiosarcoma (Imholz and Noltenius 1977; Dolorme 1978; Kimoto and Ugaki 1982). One observation found an association of angiosarcoma of the liver and HCC in a vinyl chloride worker (Dolorme 1978). This 51-year-old male patient had been in contact with vinyl chloride for 23 years and died with signs of liver failure. Autopsy revealed a liver of 3000 g weight, showing a tumor mass of 15 cm in the right lobe. One part of this tumor showed HCC of the trabecular type but of high grade, with numerous mitotic figures. A second component of the neoplasm consisted of typical angiosarcoma. The latter was also found in a lymph node metastasis of the process (Dolorme 1978). A similar combination has been observed in an experimental model of vinyl chloride carcinogenicity (Maltoni and Lefemine 1974). In a further adult patient without history of thorotrast exposure and a CT diagnosis of HCC, autopsy revealed a tumor of 15 cm size in the right lobe of a cirrhotic liver. The report notes marked adhesion of the right liver to the right adrenal gland and kidney, and a resemblance of the tumor to a Grawitz tumor. Histologically, this neoplasm showed two main morphologic patterns, i.e., liver parenchymal and mesenchymal/sarcomatous. The first component fulfilled the criteria of trabecular-type HCC combined with mixed cholangio–hepatocellular carcinoma. The second component presented as fibrosarcoma and angiosarcoma (hemangioendothelioma), the latter thought to have been derived from sinusoidal endothelial cells. The spindle cell part also contained multinucleated giant cells. Then metastases were exclusively sarcomatous (Kimoto and Ugaki 1982).

Other Mesenchymal Components

CSL can containing spindle cells components corresponding to the former malignant fibrous histiocytoma (Wang et al. 2012).

Combined Hepatocellular Carcinoma and Osteoclast-Like Giant Cell Tumor

A single case of this tumor was observed in a 74-year-old woman. The neoplasm consisted of ordinary HCC and a giant cell tumor composed of monocytoid cells and CD68-positive osteoclast-like giant cells. The boundary between the two components showed transitional features (Tanahashi et al. 2009).

Multilineage Carcinosarcoma

Composite hepatic malignancies showing more than the usual histologic components discussed above may be termed, multilineage carcinosarcomas. In the light of the highly diverse

differentiations found in such rare tumors, a pathogenetic role of pluripotent tumor stem cells may be considered. In a patient reported by She and Szakacs (2005), a highly complex liver neoplasm consisted of HCC, fibrolamellar carcinoma, neuroendocrine carcinoma, spindle cell sarcoma, leiomyosarcoma, rhabdomyosarcoma, and osteosarcoma.

Fibrolamellar Carcinoma with Heterologous Components

Only one published observation reports on the concurrence of fibrolamellar-type carcinoma with adenocarcinoma, a poorly differentiated spindle cell component, leiomyosarcoma, desmin-reactive rhabdomyosarcoma, and osteosarcoma (She and Szakacs 2005).

Combined (Composite) Hepatic Carcinomas and Sarcomas

In rare situations, hepatic carcinoma and sarcoma occur in the form of combined lesions, but not forming single tumors with both components present in the same lesion as in carcinosarcoma (coexistence of two different neoplasms in the same organ). Most patients with this type of neoplasms were elderly males with liver cirrhosis (Saltykow 1909; Jaffe 1924; Edmondson 1958; Ojima et al. 1964; Ishizu et al. 1974; Nagamine et al. 1978; Shin et al. 1981; Takaoka et al. 1983; Sonoda et al. 1984). Among ten cases compiled by Sonoda et al. (1984), the carcinoma was HCC in nine and cholangiocarcinoma in one, whereas the sarcomas were stated as spindle cell tumor or fibrosarcoma in eight, rhabdomyosarcoma in one, and chondrosarcoma in one patient.

Differential Diagnosis

Gastrointestinal extrahepatic carcinosarcomas can metastasize to the liver (Shen et al. 2010). There are instances where HCCs exhibit a massively developed and in part myxoid stroma that may suggest a sarcomatoid lesion. This alteration has been reported for clear cell HCC, where and abundant myxoid stroma was also found in metastatic nodules at necropsy (Fukuda et al. 1992). Rarely, HCC can show an osseous stroma (osseous stromal metaplasia; Leger et al. 1980), extensive stromal calcification (Moenandar 1974), parenchymal calcification (Itai et al. 1979; Kunstilger et al. 1980; Scatarige et al. 1983; Muramatsu et al. 1985; Chin et al. 1986; Teefey et al. 1987; Friedman 1988), which may also be in evidence subsequent to hepatic desarterialization (Bengmark 1989), or so-called ring/rim calcification (Mitchell et al. 1994; Fukuya et al. 1999).

Cytogenetic and Molecular Features

Relatively few informations regarding cytogenetic features are available. As the tumors seem have marked genomic instability, complex karyotypes have been identified, without a specific alteration (Schaefer et al. 2012).

Sarcomatoid Carcinoma of the Liver

Introduction

Sarcomatoid carcinoma of the liver (SCL) forms a group of neoplasms different from carcinosarcoma of the liver. SCL have not yet been sufficiently defined. This also shows up in a host of synonymous terms that have been employed to denote such tumors, including hepatic carcinomas with sarcomatoid features; spindle cell hepatocellular carcinoma. sarcomatous hepatocellular carcinoma; hepatocellular carcinoma with sarcomatous lesions; hepatocellular carcinoma with sarcomatous appearance; hepatocellular carcinoma with sarcomatous transformation; hepatocellular carcinoma with sarcomatous change; hepatocellular carcinoma with sarcomatous proliferation, and hepatic sarcomatoid tumor. As a working formulation, the term, SCL, denotes liver tumors, mostly hepatocellular carcinomas and more rarely cholangiocarcinomas or mixed

hepatocellular/cholangiocellular carcinomas, which show a characteristic morphologic transition between HCC cells and sarcomatoid cells.

Selected References (Isomura et al. 1979; Schmid et al. 1979; Miyazaki et al. 1983; Tsujimoto et al. 1984; Andreola et al. 1987; Kakizoe et al. 1987; Chan and Leung 1988; Ishii et al. 1988; Nakajima et al. 1988; Kojiro et al. 1989; Ishiwata et al. 1990; Haratake and Horie 1991; Matsuoka et al. 1992; Oda et al. 1994; Honda et al. 1996; Maeda et al. 1996; Komada et al. 1997; Mirejovsky and Mirejovsky 1997; Papotti et al. 1997; Han et al. 1998; Morishita et al. 1998; Yamanaka et al. 2000; Eriguchi et al. 2001; Tsuji et al. 2001; Nishie et al. 2003; Kishino et al. 2004; Sato et al. 2006; Matsui et al. 2010).

Epidemiology

The incidence and prevalence of SCL are not known for Western countries, but SCL has been detected in one study in 12.6 % of autopsied cases in Japan (Ishii et al. 1988), and in another study of 579 autopsy cases of HCC in 9.4 % (Kojiro et al. 1989). However, the incidence of HCC with spindle cell features or spindle cell components sometimes suggesting sarcoma may increasingly be reported, in part associated with the more frequent use of transarterial chemoembolization and local ablation therapy. It has been suggested that a spindle cell change may be induced by ischemic and/or necrotic lesions caused by such therapies (Morise et al. 2004). A sarcomatous appearance was found in 20 out of 335 autopsy cases of HCC (5.9 %) during the 12 years from 1969 to 1980, and in 35 out of 244 autopsy cases of HCC (14.3 %) during the 6 years before 1989, when effective anticancer therapies, such as one-shot injection of anticancer agents into the hepatic artery and transcatheter arterial embolization (TAE) have become popular. Among these various anticancer therapies, a sarcomatous component was most frequent (27.6 %) in cases with repeated TAE (Kojiro et al. 1989).

Clinical Features

SCL develop in older adult patients and exhibit an aggressive course and show poor prognosis, often with wide-spread metastatic disease (Tsujimoto et al. 1984; Kakizoe et al. 1987; Honda et al. 1996; Maeda et al. 1996; Eriguchi et al. 2001). In particular, lymphatic and peritoneal metastasis occurs almost twice as frequently as it does in HCC without sarcomatous components (Kojiro et al. 1989; Honda et al. 1996). Among six patients, lymphadenopathy was found in 100 % and intrahepatic metastasis in 83 % (Honda et al. 1996). SCL also have a greater tendency to invade the portal vein (Maeda et al. 1996). Among other prognostic parameters tested in 513 cases of HCC, a sarcomatous component was more frequent in a tumor group showing massive early recurrence after liver resection in comparison with a group showing later recurrence (63 % vs. 3 %, Yamanaka et al. 2000).

Pathology

Macroscopically, infiltrative, mixed expanding and infiltrative, and pedunculated growth patterns were found (Kakizoe et al. 1987), i.e., gross pattern similar to those known for ordinary HCC.

Histologically, the sarcomatoid component usually consists of malignant-looking round, stellate or spindle cells in close association with the HCC cells. A round cell sarcoma component may be prominent (Sato et al. 2006). Transitional forms between the morphologically epithelial cells and mesenchymal-looking cells have been described and are a histologic hallmark of these neoplasms (Miyazaki et al. 1983; Tsujimoto et al. 1984; Andreola et al. 1987; Nakajima et al. 1988). Some of the tumors contain pleomorphic cells or multinucleated giant cells. Extreme variations of SCL exclusively consist of spindle cells, however showing expression of epithelial markers (Eriguchi et al. 2001). Very rarely, the epithelial component of a sarcomatoid tumor is combined hepatocellular-cholangiocarcinoma (Jeong et al. 2004).

Immunohistochemically, the HCC component shows the usual features of epithelial cells forming this tumor (Oda et al. 1994). In contrast, the spindle cells have been shown to be reactive for vimentin, alpha-SMA, and sometimes desmin (Kakizoe et al. 1987; Chan and Leung 1988; Ishiwata et al. 1990; Oda et al. 1994; Maeda et al. 1996; Mirejovsky and Mirejovsky 1997; Han et al. 1998; Eriguchi et al. 2001; Tsuji et al. 2001). Some of these cells may also be keratin (CK 8)-positive (Ishiwata et al. 1990; Haratake and Horie 1991; Tsuji et al. 2001), but lack expression of AFP or alpha-1-antitrypsin (Haratake and Horie 1991), supporting their transitional status. Ultrastructurally, desmosomes were restricted to the epithelial component (Andreola et al. 1987), and one study suggested the an epithelial nature of the spindle cells (Chan and Leung 1988).

Unusual Combined Hepatocellular Carcinomas

There are few examples of hepatocellular carcinomas (HCC) that are, in contrast to mixed hepatocellular and cholangiocarcinoma, combined with other cellular components, resulting in complex phenotypes. The tumors include HCC and high-grade neuroendocrine carcinoma (Garcia et al. 2006), HCC and yolk sac tumor (Morinaga et al. 1996), HCC and malignant lymphoma (Shikuwa et al. 1996), HCC and hepatic sarcoma (Shin et al. 1981), and HCC mixed with fibrolamellar carcinoma (Okano et al. 1998; Seitz et al. 2002). In some of these tumors, a common oncogenic developmental pathway may be present (e.g., in the case of fibrolamellar carcinoma), whereas in others, the combination may have occurred by change.

Giant Cell Tumors of the Hepatobiliary Tract

47

Contents

Abstract

Few primary hepatobiliary tumors are characterized by multinucleated giant cells that are different from the giant cells observed in less-well-differentiated hepatocellular carcinomas and pleomorphic hepatic carcinomas. A distinct example is hepatocellular carcinoma (HCC) with osteoclast-like giant cells, a counterpart of a well-defined pancreatic tumor. These lesions usually present as large, solitary, and expanding neoplasms occurring in the sixth to seventh decades with nearly equal gender ratio. Histologically, HCC cells of variable differentiation are admixed with large cells that contain numerous and uniformly shaped nuclei, strikingly resembling osteoclasts and the giant cells of osteoclastoma of the bone. In contrast to HCC, the giant cells are positive for the macrophage markers, CD68. Osteoclast-like giant cell tumors behave in a more favorable manner than HCCs, with a predilection for local spread and slower metastasis formation. Tumors of this type rarely also develop in large bile ducts and gallbladder.

Hepatocellular Carcinoma with Osteoclast-Like Giant Cells

Introduction

Hepatocellular carcinoma with osteoclast-like giant cells (HCC-OGC; hepatic giant cell carcinoma) is a very rare entity characterized by the

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_47

presence of multinucleated giant cells of the osteoclast-like type in a background of liver cell carcinoma. A similar tumor occurs in the pancreas, being more common than its hepatic counterpart. The first description of HCC-OGC dates from 1980 (Munoz et al. 1980) and referred to an 87-year-old man with macronodular liver cirrhosis and a histology characterized by abundant osteoclast-like giant cells. The authors interpreted the neoplasm to be of reticuloendothelial (Kupffer cell) origin. Relatively few cases have since been reported (Kuwano et al. 1984; Andreola et al. 1985; Horie et al. 1987; Chetty et al. 1990; Hood et al. 1990; Rosai 1990; McCluggage and Toner 1993; Westra et al. 1998; Ikeda et al. 2003; Ahaouche et al. 2005; Rudloff et al. 2005; Bauditz et al. 2006; Schildhaus and Dombrowski 2006; Matsumoto et al. 2012; Zhang et al. 2012; Rastogi et al. 2013).

Clinical and Imaging Features

HCC-OGC usually present in the sixth to seventh decades, with a nearly equal gender ratio. The clinical presentation is nonspecific and has been reported as abdominal pain and a sometimes rapidly enlarging liver mass.

Macroscopic Pathology

The tumors are usually large, solitary, and expanding lesions. They form roundish masses with a pushing border and a grayish red to whitish cut surface (Fig. 1).

Histopathology

The neoplasm consists of two clearly different cell lineages. One component is characterized by hepatocellular carcinoma of various grades, usually growing in a trabecular pattern. These HCC components are admixed with striking non-epithelial multinuclear giant cells resembling osteoclasts (Fig. 2). The giant cells usually display 10–20 uniformly shaped and small nuclei and lack cellular or nuclear atypia, hence closely resembling osteoclastomas of the bone. The tumor cells may rarely contain prominent intracytoplasmic hyaline bodies (Rastogi et al. 2013). Some tumors contain small mononuclear cells with cytological atypias and an increased mitotic count (Bauditz et al. 2006). Instead of a clear-cut HCC component, epithelial cells corresponding to mucin-producing adenocarcinoma or cells undergoing squamous metaplasia have also been noted (Bauditz et al. 2006).

Electron microscopically, both mononuclear and multinucleated giant cells showed features of mesenchymal and epithelial cells (Hood et al. 1990).

The HCC-like epithelial cells are reactive for cytokeratins 8 and 18 (Fig. 3), whereas the osteoclast-like giant cells are immunoreactive for

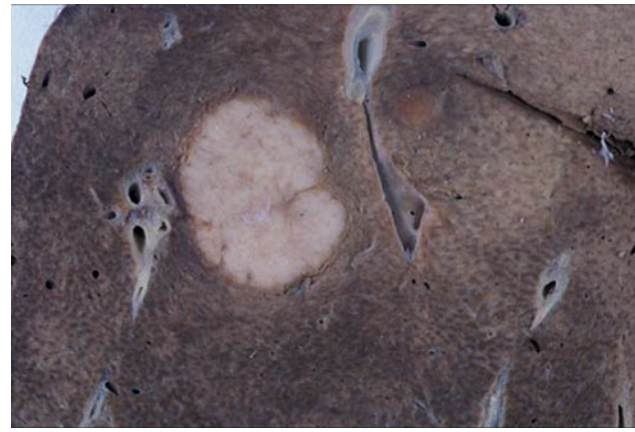

Fig. 1 Giant cell tumor of the liver. The neoplasm presents as a well-delineated mass with an expanding growth pattern

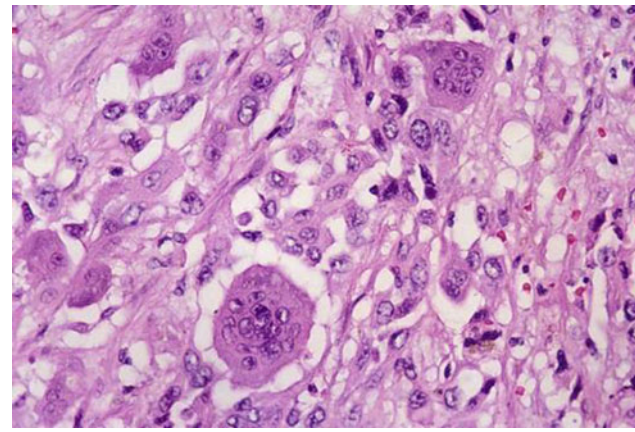

Fig. 2 Hepatic giant cell tumor with osteoclast-like giant cells (Hematoxylin and eosin stain)

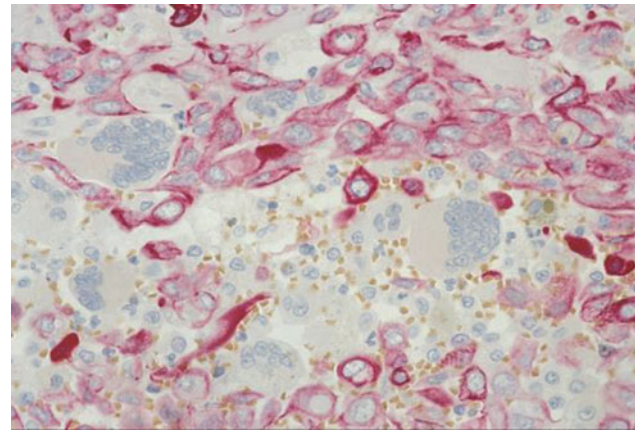

Fig. 3 Hepatic giant cell tumor. In contrast to the osteoclast-like giant cells, mononuclear neoplastic cells are cytokeratin-reactive (CAM5.2 immunostain)

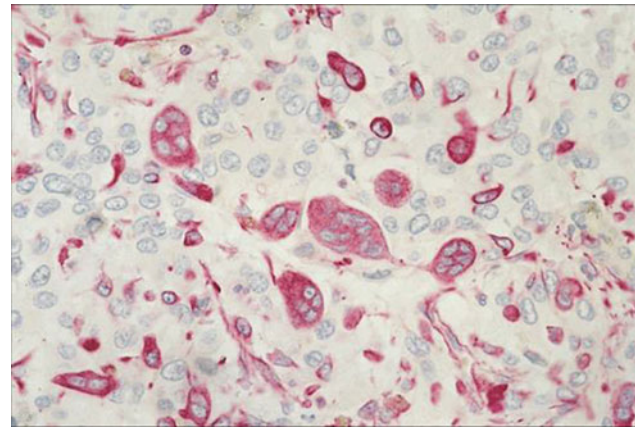

Fig. 4 Hepatic giant cell tumor. Multinucleated, osteoclast-like giant cells are CD68-reactive, nonneoplastic cells derived from fused macrophages (CD68 immunostain)

CD68 (Fig. 4), vimentin (Ikeda et al. 2003; Bauditz et al. 2006), CD163, CD51, CD54, and matrix metalloproteinase-9 (Ikeda et al. 2003). The giant cells are also positive for alpha-1 antitrypsin and anti-chymotrypsin (Hood et al. 1990). The hepatocellular lineage of the non-giant cells is also supported by the expression of albumin (Ikeda et al. 2003).

Differential Diagnosis

HCC-OGC has to be distinguished from other non-osteoclast-like giant or pleomorphic variants of HCC (Korkolis et al. 2009) and Edmondson-Steiner grade 3 HCCs which exhibit multinuclear tumor cells, albeit not of the osteoclast-like type. Pleomorphic and giant cells in HCCs express epithelial markers, and not CD68. This is also the case for the rare syncytial giant cell HCC occurring in the pediatric age group (Atra et al. 2007). Epithelioid angiomyolipoma of the liver can rarely manifest as a giant cell tumor (Alatassi and Sahoo 2009). Osteoclastomas originating from other organs and tissues may metastasize to the liver, e.g., those originating in the pancreas (Cho et al. 2005), although osteoclast giant cell tumors of the bone usually metastasize to the lung in case of metastatic spread, which occurs in a minority of cases (Cai et al. 2007; Gupta et al. 2008). However, these tumors do not contain epithelial components, but consist of osteoclast-like cells and a spindle-cell component. Osteoclast-rich giant cell tumor of the gastrointestinal tract resembling clear cell sarcoma of soft parts metastasized to the liver (Zambrano et al. 2003). Another giant cell tumor metastasizing to the liver is epithelioid hemangioendothelioma with osteoclast-like giant cells (Tsuji et al. 2002). Reactive giant cells derived from fused macrophages develop after spontaneous or induced tumor necrosis, e.g., after microwave coagulation therapy of HCC (Yamashiki et al. 2003). Histologically, it is important to clearly identify osteoclast-like giant cells with their distinct nuclear morphology and arrangement of the nuclei within the cell body, clearly different from other tumor giant cells. In cases of doubt, immunohistochemistry to detect or exclude an epithelial differentiation of neoplastic cells is mandatory.

Biology of Disease

Pure osteoclast-like giant cell tumors usually behave in a more favorable manner than HCCs, with a predilection for local spread and slower metastasis formation, mostly not to locoregional lymph nodes. However, and similar to its pancreatic counterpart, HCC-OGC may show an aggressive course with multiple metastases, e.g., to the bone and soft tissues (Rastogi et al. 2013). In one case, widespread intra-abdominal and pulmonary metastases developed within 3 months of hemihepatectomy (Rudloff et al. 2005). On the other hand, long-term survival has been achieved with a combination of surgical resection, radiofrequency ablation, and chemotherapy (Bauditz et al. 2006).

Molecular Features

K-ras mutations have been detected in these neoplasms, and in each analyzed case, the same K-ras mutation was present both in the epithelial component and in the mononuclear cells, but the authors suggested that the finding of K-ras mutations in the osteoclast-like giant cells may reflect their propensity to phagocytose tumor cells (Westra et al. 1998). In situ hybridization revealed the expression of receptor activator of nuclear factor-kappaB (RANK) in the giant cells and receptor activator of nuclear factor-kappaB ligand (RANKL) in the hepatoid tumor cells, suggesting an osteoclastogenesis by hepatocyte-derived cells (Ikeda et al. 2003).

Sarcomatoid Giant Cell Tumor with Osteoclast-Like Giant Cells

These rare liver tumors are characterized by the morphologic features of a giant cell tumor of the osteoclast-like type in the absence of features of HCC (Horie et al. 1987; Sasaki et al. 1997). In the case reported by Horie and coworkers, electron microscopy offered no definitive evidence whether the neoplasm arose from epithelial cells or non-epithelial cells. These neoplasms may originate from cells undergoing mesenchymal-epithelial transition, as part of the mononuclear cells have been shown to be reactive not only for mesenchymal markers but also for cytokeratins 7, 8, and 19 (Sasaki et al. 1997).

Combined Hepatic HCC-OGC

Tanahashi et al. (2009) reported a case of simultaneous hepatocellular carcinoma and osteoclast-like giant cell tumor in a single hepatic tumor. Histologically, this neoplasm consisted of two distinct components: mononuclear and multinuclear giant cells of the osteoclast type and a conventional hepatocellular carcinoma. The giant cells were reactive for vimentin and CD68, but negative for cytokeratins, whereas the HCC cells were reactive for cytokeratin-8 and AFP. The boundary between the two components showed transitional features.

Carcinomas with Osteoclast-Like Giant Cells of the Biliary Tract

Few examples of these rare neoplasms have been reported (Albores-Saavedra et al. 2006; Fan et al. 2010; Griglione et al. 2010). Three male patients (mean age, 55 years) described by Albores-Saavedra et al. (2006) presented with biliary obstruction. Two tumors were located to the common bile duct and one tumor to the cystic duct. Histologically, the tumors were similar to giant cell tumors of the bone, with a mixture of non-atypical mononuclear cells and multinucleated osteoclast-like giant cells. The former were CD163 positive, while the latter were positive for CD68 and HAM 56. Apart from neoplasms located to the extrahepatic biliary tract, intrahepatic sarcomatoid cholangiocarcinoma with osteoclast-like giant cells has also been observed (Fan et al. 2010).

Carcinomas with Osteoclast-Like Giant Cells of the Gallbladder

Giant cell carcinomas with osteoclast-like giant cells rarely develop in the gallbladder (Grosso and Gonzalez 1992; Ito et al. 1992; Akatsu et al. 2006; Albores-Saavedra et al. 2006). As in HCC-OGC, the osteoclast-like cells are of macrophage/histiocyte origin (Akatsu et al. 2006). The epithelial component is usually of the glandular adenocarcinoma type (Ito et al. 1992), but adenosquamous carcinoma has also been noted (Grosso and Gonzalez 1992; Akatsu et al. 2006). Long-term survival without recurrence was found (Akatsu et al. 2006).

Mixed Tumors of the Liver and Related Neoplasms

48

Contents

Abstract

Malignant mixed tumors of the hepatobiliary tract form a not well-defined and heterogeneous group of malignancies that share complex mixed patterns of several neoplastic cell lineages. As more refined classification parameters become available, more and more of these neoplasms are now allocated to better defined entities. Malignant mixed tumors of liver and bile ducts traditionally include nonhepatocytic malignant mixed tumors of the adult (neoplasms that histologically differ from carcinosarcoma), Müllerian adenosarcoma, hepatocytic tumors with atypical mesenchymal reactions, and a group of ossifying and stromal tumors of the liver. A further group of mixed tumors consists of mixed epithelial and mesenchymal hepatoblastomas or hepatoblastoma-like tumors in adults.

Malignant Mixed Tumors of the Liver in Adults

Malignant mixed tumors of the liver form a not well-defined, heterogeneous group of primary hepatic malignancies. In the literature, these lesions are either described as nonhepatocytic malignant mixed tumors (the most characteristic group) or as tumors that contain hepatoid cells. The latter are, based on published descriptions, often very difficult to distinguish from

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_48

carcinosarcomas, and part of the neoplasms would now be classified as adult mixed hepatoblastomas.

Malignant mixed tumor of the liver (MMTL) in adults is rarely reported in the literature. A first review of cases described up to the first 4th of the 20th in the German literature century listed only 12 patients (Nissel 1928), and Sheehan in 1930 collected nine cases, two of which had not been included in Nissel's series (Sheehan 1930). The patients' age at presentation ranged from 20 to 80 years, with an equal gender distribution. In most cases, the clinical history has been one of progressive jaundice and hepatomegaly. The majority of lesions has been solitary and located to the right liver lobe. In contrast to children, MMTL rarely metastasized outside the liver in adult patients (Walter 1896; Bramwell 1897; Marx 1904; Dominici and Merle 1909; Nissel 1928; Milman and Grayzel 1951; Barnett et al. 1958; Alexander 1961; Ojima et al. 1964; Blanding 1968). The literature data present a highly variable spectrum of histologies, and a consistent picture cannot be extracted so far. In what follows, a brief survey of the pertinent morphologies is presented.

Walter (1896) reported on a multiple tumor of the cirrhotic liver of a man of 76 years in which tumor tissue strongly reminiscent of liver parenchyma was intimately mixed with a spindle cell sarcoma. The young adult patient reported by Bramwell in 1897 had a single encapsulated tumor in the right lobe, composed of spindle cells and adenomatous formations, and interpreted by the author to be an angiosarcoma (Bramwell 1897). Another patient (male, 56 years old) exhibited, again in a cirrhotic liver, a tumor in which epithelial and sarcomatous components were spatially separated, indicating a collision tumor (Dominici and Merle 1909). The male patient described by Saltykow (1914) had a single tumor nodule in a cirrhotic liver composed of epithelial tissue resembling liver parenchyma, alveolar structures, spindle cells, cartilage, osteoid, and bone, but the lack of adequate illustrations does not permit to exactly judge this situation. The 35-year-old male patient described by Barnett and coworkers in 1958 revealed, at autopsy, a huge necrotic neoplasm of the liver (organ weight: 8500 g) with extrahepatic growth. Grossly, the tumor was yellow-white, soft, and gelatinous. Microscopically, the lesion was composed of embryonic-looking tissue elements. The main components were elongated cells in stream-like pattern, rather small epithelial cells in nests embedded in a scanty stroma, cords of epithelial cells in an immature stroma, and striated myocytes (Barnett et al. 1958). The 68-year-old female patient described by Alexander (1961) showed, at necropsy, that the right lobe of the liver was enlarged and almost entirely replaced by a rounded mass of growth 15 cm in diameter. The center of the tumor was necrotic; the periphery consisted partly of soft white tissue and partly of firmer tissue which appeared to contain thin seams of cartilage. The remainder of the liver was normal. Histological examination revealed a mixed neoplasm consisting of variably sized, poorly differentiated epithelial cells forming strands and nests, interspersed with scattered pleomorphic cells and multinucleated giant cells. In addition, some epithelia formed acinar and tubular structures lined by cuboidal cells. The second component consisted of an immature-looking, loose cellular mesenchyme and islands of primitive cartilage. This constellation might suggest mixed hepatoblastoma of the adult, but some findings, based on the figures of the report and the tumor description, may not support such a diagnosis. Specifically, pleomorphic and multinuclear giant cells do not usually occur in hepatoblastoma without previous chemotherapy. In the patient described by Blanding (1968), autopsy revealed an enlarged liver (3000 g) grossly irregular due to multiple tumor nodules, predominantly in the right lobe. These nodules measured up to 8 cm in diameter and exhibited a variegated tan-to-yellow bulging cut surface with scattered areas of necrosis and hemorrhage. Histology showed the neoplasm to consist of adenoid epithelial structures supported by loose, edematous, and in part myxoid mesenchymal tissue with interspersed islands of squamous epithelial cells and small foci of poorly differentiated cartilage, chondroid, and osteoid tissues. The epithelial component was not blastomatous,

the tumor thus not representing adult-type mixed hepatoblastoma, although squamous islands are well recognized in hepatoblastoma. Very few further examples have been reported since these older reports (Shono et al. 2008).

Adenosarcoma of the Liver

Müllerian adenosarcoma is an uncommon biphasic, mixed mesodermal tumor (a variant of Müllerian mixed tumor) characterized by a benign-looking epithelial or glandular component and a low-grade sarcomatous mesenchymal/stromal component (Clement and Scully 1990; Gallardo and Prat 2009; D'Angelo and Prat 2011). This neoplasm mainly arises in endometrial tissue and hence can develop in ectopic foci of endometriosis. Immunohistochemically, the sarcomatous cells are reactive for estrogen and progesterone receptors (Amant et al. 2004a), supporting the origin from steroid-responsive cells of the genital tract, and for CD10 (Amant et al. 2004b).

Malignant neoplasms are known to develop in endometriosis. In a review of 205 cases, extragonal sites of endometriosis accounted for 20 % of the endometriosis-associated malignancies (Heaps et al. 1990). In a further analysis, adenosarcomas accounted for 12 % of the lesions (Clement and Scully 1990). However, adenosarcoma can develop in tissues other than endometrium (Clement and Scully 1978), including the ovary (Litta et al. 2004), the vagina (Toyoshima et al. 2004), the testis (Fleshman et al. 2005), the peritoneal surface (Kanngurn et al. 2005), and the pelvic area (Roman et al. 1993). In adenosarcoma, the mesenchymal component of the process can predominate and lead to a heterologous sarcoma with the sarcomatous part increasing and overgrowing with each recurrence of the tumor (Tackin et al. 2006). Stromal overgrowth associated with the formation of fetal-type cartilage has also been observed in primary peritoneal adenosarcoma (Kanngurn et al. 2005). The pluripotentiality of the neoplastic mesenchymal cells is illustrated by the rare finding of a rhabdomyosarcomatous lineage in the stromal component of adenosarcoma (Mikami et al. 2004).

The only well-recognized situation where true primary adenosarcoma has been observed in the liver is in the context of the rare hepatic endometriosis (N'Senda et al. 2000; Jelovsek et al. 2004). In one 54-year-old patient who had had a hysterectomy 6 years previously, CT demonstrated a huge heterogeneous hypodense mass with cystic changes in the liver. The hepatectomy specimen revealed adenosarcoma with a benign-looking epithelial component and a malignant mesenchymal component associated with hepatic endometriosis (N'Senda et al. 2000). In another postmenopausal patient, liver endometriosis was first treated with leuprolide. After treatment failure, the mass was resected and showed to contain focal areas of adenosarcoma (Jelovsek et al. 2004).

Hepatocytic Tumors with Marked and Atypical Mesenchymal Reactions

There are instances where HCCs exhibit a massively developed and myxoid stroma that may suggest a sarcomatoid reaction. This alteration has been reported for clear cell hepatocellular carcinoma, where the abundant myxoid stroma was also found in metastatic nodules at necropsy (Fukuda et al. 1992).

Nonhepatocytic Malignant Mixed Tumor (NHMMT) of the Liver

NHMMT is a term proposed to denote primary hepatic malignancies which consist of adenocarcinoma-like components associated with a spindle cell component (Kawarada et al. 1985). In a case reported by Kawarada et al. (1985), the large and pedunculated liver tumor consisted of epithelial and mesenchymal elements. The mesenchymal cells were spindle shaped and proliferated over the entire tumor, in which the variegated epithelial islands were scattered, sometimes forming structures with mucin secretion. There was squamous

differentiation of the epithelial component with keratinization. In another tumor, the neoplastic tissue contained benign-looking nonhepatocytic, in part tubular epithelia, and a mesenchymal component with foci of osteoid and numerous osteoclast-like giant cells (Shono et al. 2008).

Ossifying Malignant Mixed Epithelial and Stromal Tumor of the Liver

This lesion was found in an adult patient and was characterized by three distinct neoplastic phenotypes: malignant spindle cells, adenocarcinoma, and extensive osteoid formation. Following resection, the patient was alive 8 years postoperatively (Heywood et al. 2002).

Hepatoblastoma-Like Tumors in Adults

Adult-Type Hepatoblastoma

The probably first case of bona fide adult-type hepatoblastoma has been cited in 1951, referring to an old reference of Marx of 1904 (Milman and Gryzel 1951). Several cases have since been reported, but it is sometimes difficult to judge from these observations whether the tumors were true hepatoblastomas or rather other mixed hepatic tumors as described in the previous paragraph.

Selected References (Bartok 1958; Barnett et al. 1958; Alexander 1961; Ojima et al. 1964; Kerr 1966; Blanding 1968; Carter 1969; Goldman and Friedman 1969; Meyer et al. 1974; Ludwig et al. 1975; Baird and McGovern 1976; Jameson and Chatkadakis 1978; Yoshida et al. 1979; Honan and Haqqani 1980; Popper 1980; Barbaryka and von Bouquoy 1981; Genova and Rimi 1982; Kishimoto et al. 1984; Mildeova and Bednar 1984; Kawarada et al. 1985; Bhatnagar et al. 1987; Diaz-Faes et al. 1987; Misra and Mansharamani 1988; Green and Silva 1989; Seabrook et al. 1989; Sugino et al. 1989; Oda et al. 1990; Slugen et al. 1990; Altmann 1992; Mondragon Sanchez et al. 1994; Harada et al. 1995; Inoue et al. 1995; Kacker et al. 1995; Bortolasi et al. 1996; Kuniyasu et al. 1996; Ahn et al. 1997; Parada et al. 1997; Reddy et al. 1997; Diotallevi et al. 1999; Inagaki et al. 2001; Vicente et al. 2001; Yamazaki et al. 2004; Kasper et al. 2005; Ke et al. 2005; Shchegolev et al. 2005; Beppu et al. 2006; Remes-Troche et al. 2006; Krzewinski et al. 2007; Mukhopadhyay et al. 2007; Zhang et al. 2007, 2013; Zheng et al. 2009; Fiaschetti et al. 2010; Nakamura et al. 2010; Di Benedetto et al. 2011; Rougemeont et al. 2012; Wang and Liu 2012; Al-Jiffry 2013).

In a recent literature review of 40 patients, the median age at presentation was 41.5 years, with 21 males and 19 females. Liver cirrhosis was only confirmed in seven patients. Prognosis was worse than in the pediatric age group, with a median survival time for 27 patients with available follow-up of 4 months and a 1-year survival rate of 29.6 %. However, part of the reports date from a time period when modern chemotherapy and surgery schemes were not yet available (Wang and Liu 2012). Similar to pediatric cases, part of these tumors in adults were of the mixed epithelial and mesenchymal type (Barnett et al. 1958; Baird and McGovern 1976; Honan and Haqqani 1980; Popper 1980; Barbaryka and Bouquoy 1981; Diaz-Faes et al. 1987; Oda et al. 1990; Altmann 1992). The term, mixed hepatoblastoma, goes back to Willis (1960). However, the literature of mixed hepatoblastomas in adults is controversial and somewhat confusing, owing to the various terms that have been used in the older literature, including mixed malignant tumors, which have been discussed above, and embryonic mixed tumor, rhabdomyosarcohepatoma, and carcinosteochondrosarcoma. It has been suggested that some authors may have hesitated to employ the designation, "blastoma," for tumors occurring in the adult liver, although the histologic presentation is the same or at least very similar in children and adults (Honan and Haqqani 1980). The diagnosis of mixed hepatoblastoma of the adult patient requires that the epithelial component shows clear features of fetal and/or embryonal hepatoblastoma

and, based on published figures and descriptions, at least a fraction of the reported cases seem to fulfill this criterion. The heterologous components in adult-type mixed hepatoblastoma include fibrosarcomatoid (Carter 1969), chondrosarcomatoid (Carter 1969; Ludwig et al. 1975), osteoid/osteosarcomatoid (Ludwig et al. 1975; Honan and Haqqani 1980), and rhabdomyoblastic (Goldman and Friedman 1969) morphologies. Similar to tumors occurring in children, adult-type hepatoblastoma may show unusual epithelial differentiation, such as marked neuroendocrine differentiation (Zhang et al. 2013). Teratoid hepatoblastoma also occurs in adult patients (Zhang et al. 2007).

Adult-Type Hepatoblastoma Combined with Hepatocellular Carcinoma

There are several reported cases of adult-type hepatoblastoma or mixed liver tumors sharing features with hepatoblastoma containing foci of hepatocellular carcinoma (Kerr 1966; Carter 1969; Goldman and Friedman 1969; Ludwig et al. 1975; Yoshida et al. 1979; Serezhin and Paikova 1984; Harada et al. 1995; Ahn et al. 1997; Ishimura et al. 2007; Canberk et al. 2013). It may be surmised that a transformed hepatoid cell lineage can differentiate along several carcinogenic pathways, with one lineage failing to switch from a hepatoblast phenotype to a hepatocyte lineage. A relationship between hepatocellular carcinoma and hepatoblastoma has also been recognized in children. In one patient suffering from combined hepatoblastoma and hepatocellular carcinoma, late recurrence of disease after 5 years was characterized by the HCC component only (Postovsky et al. 2001).

Adult-Type Mixed Hepatic Tumors with Hepatoblastoma-Like Features

There is a small group of interesting primary hepatocellular tumors which contain hepatoblastoma-like components. A sarcomatoid hepatocellular carcinoma with hepatoblastoma-like features has been described in a 66-year-old male patient with chronic HCV infection (Cho et al. 2004). This mixed epithelial and mesenchymal tumor of the liver showed an epithelial component composed of poorly differentiated hepatocellular carcinoma and more primitive-looking components, which were embryonal and small cell undifferentiated components of hepatoblastoma-like areas. The small cell undifferentiated cells surrounded HCC and the embryonal component of hepatoblastoma-like areas and revealed a transition to areas of rhabdomyosarcoma. A small portion of chondrosarcoma was also noted.

Metachronous Hepatocellular Carcinoma Following Hepatoblastoma

Few reports described the emergence of various types of metachronous hepatocellular carcinoma following hepatoblastoma that had been treated in infancy and childhood (Masuda et al. 2009; Basile et al. 2010). In one patient, clear cell hepatocellular carcinoma arose 25 years after the successful treatment of infantile hepatoblastoma (Basile et al. 2010). We observed a similar case.

Metachronous Hepatoblastoma Following Hepatocellular Carcinoma

This is a very unusual situation described only once so far. An adult patient was transplanted for alcoholic liver cirrhosis complicated by multifocal hepatocellular carcinoma. Recurrence of the tumor was in the form of mixed hepatoblastoma invading the entire transplanted liver, suggesting a filiation between hepatocellular carcinoma and hepatoblastoma in adults (Dumortier et al. 1999).

Multilineage Tumors

Very rarely, primary epithelial liver tumors reveal a differentiating along several lineages, including epithelial, mesenchymal, and neuroectodermal

lineages. One such tumor consisted of mixed hepatoblastoma, hepatocellular carcinoma, cholangiocarcinoma, and neuroectodermal tumor/apudoma (Serezhin and Paikova 1984). The involvement of pluripotent stem/progenitor cells may be considered to play a pathogenic role.

Vascular Tumors of the Hepatobiliary Tract

Cavernous and Small Vessel Hemangiomas of the Hepatobiliary Tract

49

Contents

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_49

Abstract

Among primary vascular tumors of the liver, cavernous hemangiomas are the most common lesions. Autopsy data document an incidence of up to more than 7 %. There is a female preponderance. These tumors, which consist of dilated vascular channels with an endothelial lining and a fibrous intervascular tissue, occur as solitary or multiple lesions in livers that usually do not show preexistent disease, although the tumors can occur in conjunction with other hepatic changes, such as focal nodular hyperplasia. Macroscopically, cavernous hemangiomas are dark red to bluish, well-delineated tumors that may show a spongy aspect. Many hemangiomas are small lesions, but large tumor also occurs (giant hemangiomas). Large hemangiomas are sometimes synchronously accompanied by several or numerous small lesions. Cavernous hemangiomas show complex feeding vessels that are visualized by modern imaging techniques. The tumors may undergo secondary changes, including thrombosis, inflammation, necrosis, hemorrhage, calcifications, and fibrosis. Cavernous hepatic hemangiomas can undergo spontaneous regression. A second group of hepatic hemangiomas is characterized by dense collections of small vessels (small vessel hemangiomas and capillary hemangiomas).

Cavernous Hemangioma of the Liver

ICD-O code 9121/0

Introduction

Cavernous hemangioma of the liver (synonym: cavernoma) is a relatively common primary hepatic angiomatous tumor morphologically characterized by a circumscribed, tumor-forming growth of often dilated vascular channels (cavities, caverns) forming a spongy-like and blood-rich mass (reviews: Hamilton and Holmes 1950; O'Donoghue and Nicosia 1950; Ochsner and Halpert 1958; Olmsted and Stocker 1975; Starzl et al. 1980; Reading et al. 1988; Hobbs 1990; Hanazaki et al. 1999; Herman et al. 2005; Bioulac-Sage et al. 2008; Etemadi et al. 2011). Hepatic cavernomas were first described in German by Virchow in 1852 (review: Kuske 1938). In the English literature, hepatic hemangioma has first been reported by Frerichs (1861). The author did not consider this tumor be of clinical importance ("The pathologic and clinical significance of the cavernous tumor is very slight"). In 1942, already 66 cases in which an operation had been performed could be reviewed; among these 66 cases, 56 had been resected (Shumacker 1942).

Epidemiology

In regard to frequency, there are considerable differences between autopsy data and clinico-radiological informations. Autopsy series reported an incidence of 0.4–7.3 % (Ochsner and Halpert 1958; Ishak and Robin 1975). In larger series, mean or median age at presentation varies considerably, e.g., 35 years (Lise et al. 1992) and 49 years (Tait et al. 1992), respectively. In Shumacker's review of 66 cases (1942), the average age at diagnosis was 44 years. Most authors report a marked preponderance of female patients: in Shumacker's review 4.5:1 (1942), other reviews showing 5:1 (Henson et al. 1956), and 10:1 in symptomatic patients. Diameters of giant liver hemangiomas reported are 8.5 cm (median; Lise et al. 1992), 11 cm (median; Brouwers et al. 1997), 13.9 cm (mean; Hanazaki et al. 1999), and 19 cm (mean; Vishnevsky et al. 1991). Most of the tumors are sporadic, but familial hemangioma of the liver has been reported (Moser et al. 1998; Admiraal et al. 2004; Diez Redondo et al. 2004a). Apart from the influence of steroid hormones (see below), relatively few factors have been identified to induce cavernous hemangiomas. Systemic lupus erythematodes is associated with a fivefold increased odds of liver hemangiomas (Berzigotti et al. 2011).

Clinical Features

Clinically, small, but even giant, hepatic hemangiomas frequently exhibit a static nature and may remain symptomless ("asymptomatic" hemangioma; Tait et al. 1992). Lesions smaller than 4 cm rarely become manifest. Other tumors, mainly giant hemangiomas (larger than 4 cm), may produce symptoms ("symptomatic" hemangioma), including abdominal discomfort or pain, digestive difficulties, the sensation of an abdominal mass, or distention. In a Japanese review of symptomatic cases, 24 % of patients had abdominal pain, and 20 % had sense of fullness (Kato et al. 1975). In a series from the Mayo Clinic, 41 % of 49 patients with hemangiomas larger than 4 cm were symptomatic (Trastek et al. 1983). Large cavernous hemangiomas can cause complications, including portal hypertension (Takahashi et al. 1997), bile duct stenosis (Issahar-Zadeh et al. 1997; Cortes-Blanco and Martinez-Lazaro 2000), Budd-Chiari syndrome (Hanazaki et al. 2001; Kim et al. 2005), cavernous transformation of the portal vein (Tuncer et al. 2002), and hemobilia (Mikami et al. 1998), and a minority of these lesions present with alarming systemic symptoms and signs, including the Kasabach-Merritt phenomenon (see below), fever of unknown origin (FUO; Lee et al. 1994), polymyalgia rheumatica (Kadry et al. 2000), and a febrile inflammatory syndrome, sometimes with weight loss, pain, accelerated erythrocyte sedimentation rate, anemia, and thrombocytosis (Pateron et al. 1991; Taillandier et al. 1995; Pol et al. 1998; Poupardin et al. 2002). In particular, large lesions (giant hemangioma) have been found in association with fever and an inflammatory syndrome (Taillandier et al. 1995). The pathogenesis of this inflammatory syndrome is not clarified, as hemangiomas that have been histologically analyzed in this situation lacked inflammatory changes (Pol et al. 1998). Spontaneous rupture (Dessoff 1967; Scribano et al. 1996; Cappellani et al. 2000; Chan et al. 2010) or traumatic rupture can occur but is an uncommon event (review: Ribeiro et al. 2010). Large pedunculated hemangiomas may undergo torsion and cause an acute abdomen suggesting acute appendicitis (Ersoz et al. 2010). Very rarely, and similar to infantile hepatic hemangioendothelioma, adult hepatic cavernous hemangiomas may be associated with highly elevated serum AFP, thought to be caused by AFP secretion by the tumor (Han et al. 2010). Large hemangiomas can compress bile ducts and cause obstructive jaundice (Losanoff and Millis 2008). Polycythemia associated with elevated serum erythropoietin levels was found in a patient with hepatic hemangioma (Lanne et al. 2010). In one patient with giant hepatic hemangioma, elevated plasma TGF-beta1 levels were observed, thought to be involved in an altered immune status and decreasing after resection (Ito et al. 1997).

In large hepatic hemangiomas, particularly in giant hemangiomas with a large vascular surface, a distinct coagulopathy with thrombocytopenia, termed Kasabach-Merritt phenomenon (KMP; eponym: Kasabach-Merritt syndrome), can exceptionally occur (Kasabach and Merritt 1940; Vogel et al. 2002; Ontachi et al. 2005; Aslan et al. 2009; Concejero et al. 2009; Tani et al. 2010). It has to be emphasized that KMP is rarely associated with classical hemangioma but rather with kaposiform hemangioendothelioma and tufted hemangioma with evidence of lymphatic malformation (Enjolras and Mulliken 1997). Based on a review of 74 cases, a median age at presentation of 7 weeks was found (Shim 1986). The use of KMP should be restricted to cases caused by hemangioma and not refer to a chronic consumptive coagulopathy occurring throughout the life of patients with vascular malformations (Enjolras and Mulliken 1997). In KMP, profound and sometimes life-threatening thrombocytopenia is the primary hematologic manifestation and is followed by consumption of coagulation factors. Thrombosis occurring in the vascular spaces of a hemangioma is associated with an increase in the tumor's mass and with inflammatory changes. The pathogenic mechanisms involved in KMP have not yet been clarified. At least for non-visceral vascular tumors, it has been observed that KMP was seldom associated with classic hemangioma but rather in lesions exhibiting a lymphatic component, in particular kaposiform hemangioendothelioma and tufted

angioma (Enjolras and Mulliken 1997). However, relatively few reports document KMP in hepatic and usually giant hemangiomas with an apparently capillary or cavernous phenotype, occurring in adults (Margarit et al. 1986; About et al. 1994; Akiyoshi et al. 2000; Hochwald and Blumgart 2000; Billio et al. 2001) and sometimes requiring liver transplantation (Longeville et al. 1997). KMP can also occur in diffuse neonatal hemangiomatosis (see below) which involves the liver (Lopriore and Markhorst 1999). Hepatic giant cavernous hemangioma can be associated with microangiopathic hemolytic anemia/MAHA (Prematilleke 1972), hypofibrinogenemia (Behar et al. 1963), and consumption coagulopathy (Prematilleke 1972, Watanabe et al. 1978; Banton et al. 2005), which is arrested by resection of the tumor (Shimizu et al. 1990).

Imaging Features

Differentiation of hepatic hemangiomas from other tumors is possible by sonography, CT, and MR (Olmsted and Stocker 1975; McArdle 1978; Freeny et al. 1979; Itai et al. 1980; Gandolfi et al. 1983; Chin 1984; Tung et al. 1994; Soyer et al. 1997; Yamashita et al. 1997; Yu et al. 1998; Vilgrain et al. 2000; Brancatelli et al. 2001; Coumbaras et al. 2002; Danet et al. 2003; Mastropasqua et al. 2004; Caseira-Alves et al. 2007; Choi et al. 2009). The ultrasonographic presentation is that of a hyperechoic homogeneous mass for small lesions (less than 3 cm diameter), while larger tumors hyperechoic and heterogeneous. Typical for hemangiomas is a posterior enhancement of a hyperechoic mass. In gray-scale and color Doppler sonography, the tumors manifest as rather homogeneous or slightly heterogeneous, solid masses showing a similar or slightly lower echogenicity than the surrounding liver substance. The Doppler presentation depends on the vascularization mode and the presence of shunts, but feeding arteries and draining veins with high velocity and low pulsatility flow in comparison with intrahepatic vessels are noted. In some cavernous hemangiomas, atypical peripheral rim activity on hepatic blood pool imaging was noted (Özdemir and Friedman 2003). Such a typical presentation may, however, lack in fetal and infantile tumors (see below). On CT images, cavernous hemangioma reveals a low-density area in the parenchyma. After contrast medium, scans show early peripheral opacification followed by variable degrees of filling in of the central parts (Johnson et al. 1981). Well-defined, dense and continuously spreading enhancement on single level dynamic CT is a characteristic sign of hepatic cavernous hemangioma (Itai et al. 1989). Particularly in case of multiple hemangiomas, it may be difficult to distinguish such lesions from hepatic metastases. In a study comparing 91 patients with cavernous hemangioma and 47 patients with hepatic metastases, 76 % of hemangiomas had globular enhancement on CT images, compared to 10 % of metastases. 72 % of cavernous hemangiomas had enhancement isodense with the aorta, and 96 % of metastases were hypodense, and 76 % of hemangiomas had peripheral enhanced compared to 38 % of metastases (Leslie et al. 1995). MR can distinguish hemangioma from hepatic malignancies with a 90 % sensitivity, 92 % specificity, and an overall accuracy of 90 % (Stark et al. 1985). On MR images, an inverse relationship between the number of endothelial cells in histologic specimens and the mean T2 value of the tumor was found (Tung et al. 1994). In an analysis of 115 patients, it turned out that MR is the best method to reliably arrive at diagnosis. The diagnosis of hemangioma was established by ultrasonography in 57 % of patients, by CT scan in 73 %, and by MR in 84 % (Yoon et al. 2003).

In a comparative radiological study, Vilgrain et al. (2000) have proposed several categories of hepatic hemangiomas based on imaging presentation, including typical hemangiomas, large heterogeneous hemangiomas (giant hemangiomas if >4 cm), rapidly filling hemangiomas (16 % of all hemangiomas but seen in 42 % of hemangiomas smaller than 1 cm), hyalinized hemangioma (rare lesions that represent the end stage of tumor involution), cystic or multilocular hemangioma, hemangioma with fluid-fluid level, hemangioma with arterioportal shunt, and hemangioma with capsular retraction.

Relatively few mass lesions are confounded with hemangioma at imaging, including telangiectatic focal nodular hyperplasia (Sasaki et al. 2001). Hepatic angiosarcoma may mimic cavernous hemangioma of the liver on dynamic CT (Itai and Teraoka 1989). On the other hand, hepatic hemangioma may mimic primary liver cancer (Zheng et al. 2004), cholangiocarcinoma (Sood et al. 2009), or metastatic disease (Sood et al. 1996).

Pathology

Macroscopically, about 80 % of cavernous hemangiomas are solitary lesions, and 20 % are multiple. In a minority of patients numerous lesions form a diffuse growth pattern (Pierini and Zanniello 1964; Hercberg et al. 1982). The right liver lobe is more often involved; in a study of 50 cases, the right liver lobe was affected in 39, the left lobe in 5, and both lobes in 6 cases (Petri et al. 1993). There is a tendency for cavernous hemangiomas, in particular the smaller ones, to be situated underneath the liver capsule, macroscopically visualized as either flat, umbilicated, or fungating blue-red to almost black masses. Virchow (1863) wrote that the tumors prevail at the lower liver margin and close to the suspensory ligament. Most of the small lesions are spherical, the part touching the capsule being flattened. Cavernous hemangioma of the liver displays several gross and microscopic growth patterns (Table 1; Figs. 1, 2, 3, 4, 5, and 6).

Table 1 Growth patterns of cavernous hemangioma of the liver

Fig. 2 Pedunculated cavernous hemangioma of the liver (cut surface)

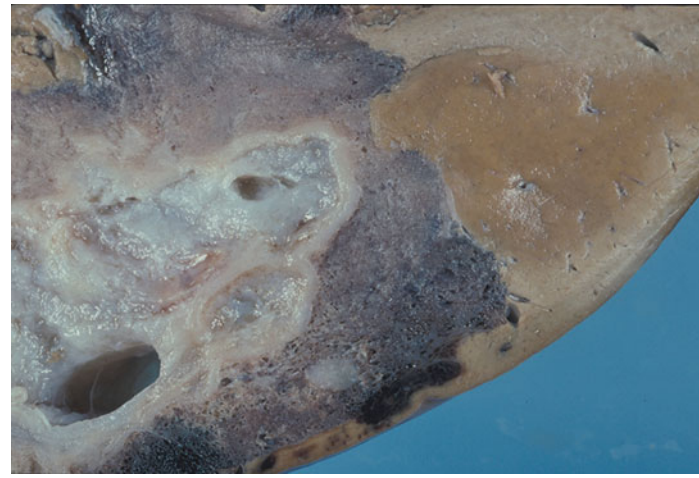

Fig. 3 Cavernous hemangioma of the liver. The tumor is well-delimitated from the adjacent liver tissue but has grown around a large Glisson's tract (fixed specimen, cut surface)

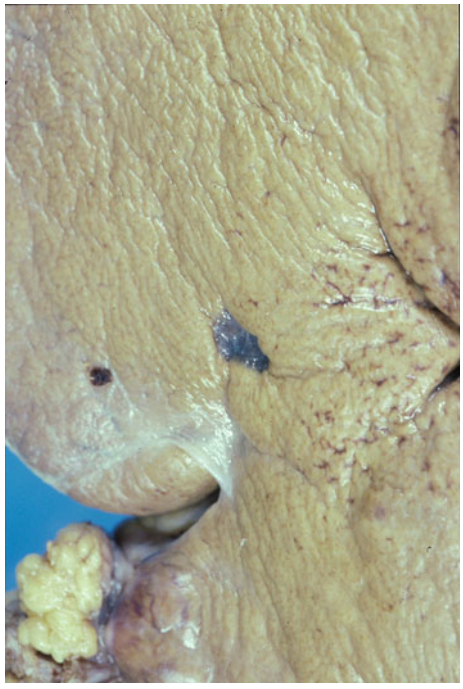

Fig. 4 Very small hepatic hemangioma, visible as a *tiny red* and sunken area

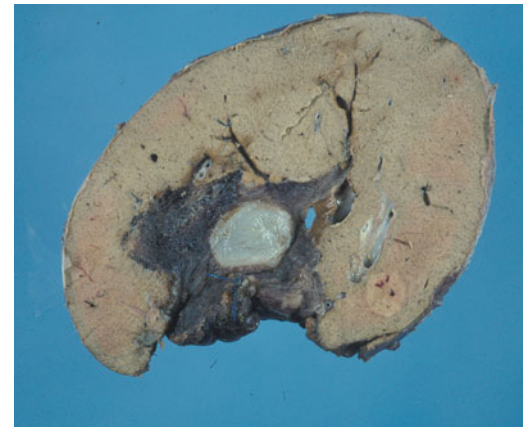

Fig. 5 Hepatic cavernous hemangioma with central regression. Note the *gray-white* focuses in a vascular spongy mass (fixed specimen, cut surface)

et al. 1996), or large tumors accompanied by smaller lesions elsewhere in the organ are known, sometimes producing what has been termed massive hepatic hemangiomatosis, a situation which may require liver transplantation (Keegan et al. 2001). Furthermore, large lesions may grow outside the organ's contour to form polypoid masses (pedunculated giant hemangioma; Bhatnagar et al. 1987; Parikh and Iyer 1990; Kumarakrishnan et al. 1997; Maekawa et al. 1997; Tsai et al. 1999; Liang et al. 2002; Kudara et al 2004; Masui et al. 2005; Moon et al. 2011). Similar to certain malignant tumors, hepatic hemangiomas may induce capsular retraction visualized in CT and MR (Yang et al. 2001; Lee et al. 2001; Blachar et al. 2009). Hemangiomas may rarely produce cystic spaces, sometimes with formation of giant cysts (Hanazaki et al. 2001) or the presentation as a multilocular cystic mass (Yonemoto et al. 1966; Hihara

Fig. 6 Hepatic hemangioma with marked regressive changes in the center of the tumor (fixed specimen, cut surface)

et al. 1990; Hussain et al. 1992; Cha et al. 2008). In large tumors with cystic change, multicystic loculi were mainly found at the periphery of the tumor, the cysts being lined by a single layer of endothelial cells, while the center of the tumor was occupied by necrosis of serous fluid or thrombi (Cha et al. 2008). Therefore, peripheral cystic change may be a secondary alteration following marked regression of central tumor parts.

Giant Cavernous Hemangioma of the Liver

Giant cavernous hemangioma of the liver has been defined as a lesion exceeding 4 cm in diameter. In the literature, such large lesions have also been termed enormous angioma, massive hemangioma, or gigantic hemangioma of the liver.

Selected References M'Weeney 1912; Shumacker 1942; Wilson and Tyson 1952; Polikarpova 1955; Sewell and Weiss 1961; Ecker and Doane 1969; Adam et al. 1970; Ang and Tanoue 1972; Grinberg 1975; Wald et al. 1976; Spoor et al. 1977; Taitelbaum et al. 1982; Sharma et al. 1991; Taillandier et al. 1995; Diez Redondo et al. 2004b.

Old reports document, in fact, "enormous" lesions. Pfannenstiel, the inventor of the obstetric surgery technique still having his name (the Pfannenstiel laparotomy), in lectures held in 1897 and 1898 at the "medicinal section of the Silesian Society for patriotic culture," reported on the successful extirpation of a giant hepatic hemangioma that weighed, after flowoff of much of the blood, five pounds, estimated to have the mass doubled before surgery (Pfannenstiel 1898). In a study of 22 patients, 12 were females and 10 males, and the ages at diagnosis ranged from 4 months to 77 years, with an average age of 51 years. Eighteen of 22 patients were symptomatic (epigastric and right upper quadrant pain, abdominal discomfort, diffuse abdominal distention, diffuse peritoneal irritation as a result of rupture). Tumor diameters ranged from 6 to 45 cm (Adam et al. 1970; Koszka et al. 2010) As giant hemangiomas can show large vascular spaces, thrombosis followed by phleboliths can develop (Holtz et al. 1977).

Giant liver hemangiomas exhibit distinct growth pattern, which may have an impact on resectability, in particular with respect to the sometimes relative ease to remove even very large lesions. Liver resection has been shown to be indicated for giant liver hemangiomas with abdominal discomfort, especially for lesions greater than 20 cm in size (Jiang et al. 2011). Outcome is related to the operative approach used for resection (Lerner et al. 2004). In a retrospective study on the tumor borders of ten giant hemangiomas, Zimmermann and Baer (1996) identified four distinct interface patterns (Table 2): fibrous interface (pattern A), interdigitating interface (pattern B), compression interface (pattern C), and irregular/spongy interface (pattern D). In five tumors, a single interface pattern (pattern A)

was detected, whereas the remaining tumors showed a mixed interface type, but seven lesions were exclusively or partially separated from the liver substance by a fibrous, pseudocapsule-like interface (Zimmermann and Baer 1996). In another study of 19 hepatic cavernous hemangiomas, irregular interface instead of a well-defined fibrous pseudocapsule was found in 84 % (Kim et al. 2006a). A fibrous interface in giant hemangiomas may favor a rather easy resection or enucleation even in case of very large lesions (Baer et al. 1992).

Histopathology

The typical histology is that of a dense collection of blood-filled spaces representing abnormal, often markedly dilated vascular channels (vascular cavities; Figs. 7 and 8). In serial sections, these cavities are round, elliptical, or polygonal, and the caverns communicate with each other, with partial or complete loss of septa. The number of tandem chambers does not seem to exceed three chambers in sequence. There are, however, also communications in the shape of bifurcated vascular channels or tubes situated within the connective tissue, lacking a media and an elastic interna (Kuske 1938). These dilated "caverns" have given the lesion its name. The spaces are lined by a usually flat and monolayered endothelial lining with pale cytoplasm and elongated, dense and small nuclei. Between the spaces are thin fibrous septa containing the stromal cells of hemangioma and, in few cases, round cell infiltrated. The stromal cell population consists of fibroblastoid cells, myofibroblasts, and rare smooth muscle cells. A part of septa can contain small bile ducts, considered to be remnant structures trapped within the growing hemangioma (Kuske 1938). Although the vascular lumina of cavernous hemangiomas resemble thin-walled abnormal postcapillary venules, these channels seem to be derived from vessels of the arterial port. Scanning electron microscopic studies have shown that the vascular channels of hemangioma often form a labyrinth of caves 50–150 μm in diameter, the caves being separated by septa 20–40 μm in width. The inner endothelial surface of the cavities resembled that of the hepatic artery and clearly differed from that of portal vein or hepatic vein. Specifically, endothelial cells were spindle shaped and arranged in parallel, what is found in arterial vessels (Yamamoto et al. 1983). The vascular spaces usually contain fluid blood.

Table 2 Types of tumor boundaries in giant hepatic hemangioma (Zimmermann and Baer 1996)

Pattern A: Fibrous interface
Pattern B: Interdigitating interface
Pattern C: Compression interface
Pattern D: Irregular/spongy interface

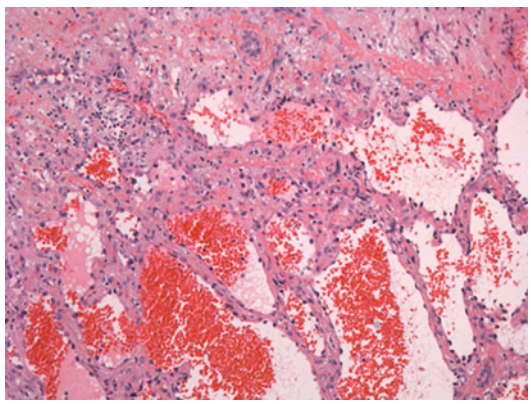

Fig. 7 Cavernous hemangioma of the liver. A spongy network of dilated vascular spaces with a flat endothelial lining characterized this tumor (hematoxylin and eosin stain)

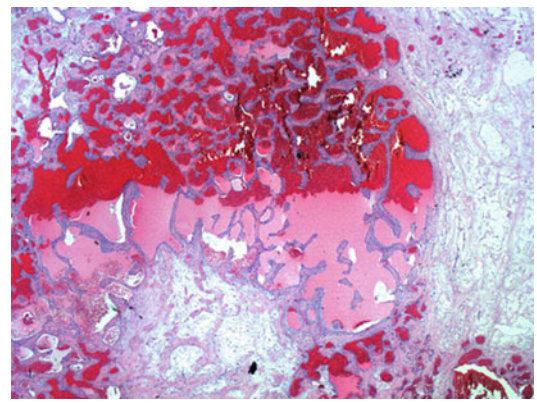

Fig. 8 Hepatic cavernous hemangioma with blood sedimentation after storage of a resection specimen (hematoxylin and eosin stain)

In resection specimens stored in fixative, blood sedimentation takes place in the vascular spaces, later seen as a sickle-shaped erythrocyte-rich structure in stained sections. In part of hemangiomas, mostly in large tumors, thrombosis can occur (see below), followed by organization by granulation tissue and fibrosis. Both the preserved hemangioma and thrombosed areas can be diagnosed by needle biopsy (Caturelli et al. 1986; Cronan et al. 1988; Tung and Cronan 1993), but this procedure bears risks and will not be required in most cases, owing to the advanced imaging techniques now available. The extracellular matrix of cavernous hemangiomas contains collagen and basement membrane proteins. Few elastic fibers have been observed (Kim et al. 2006a).

The boundary of hepatic hemangiomas is either smooth, with an interposed layer of fibrous tissue (sometimes a pseudocapsule) and compression and atrophy of adjacent liver substance, or irregular, with a "corona" of vascular channels interdigitating with liver parenchyma in a complex manner. In the latter situation, abnormal, malformed, and often dilated vascular channels are found outside the hemangioma proper. It is not clear whether these channels belong to the vascular system supporting the tumor and whether they represent vessels of a growing tumor.

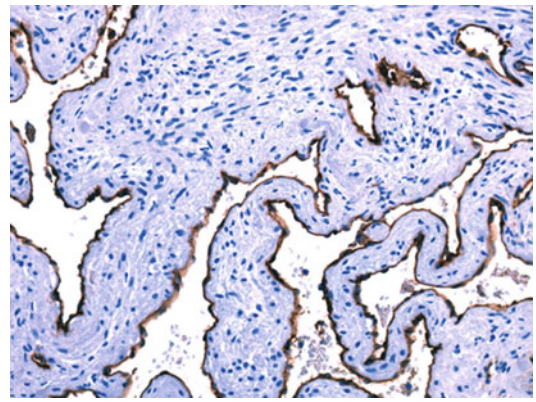

Fig. 9 Hepatic hemangioma, flat endothelial lining of the vascular spaces (CD34 immunostain)

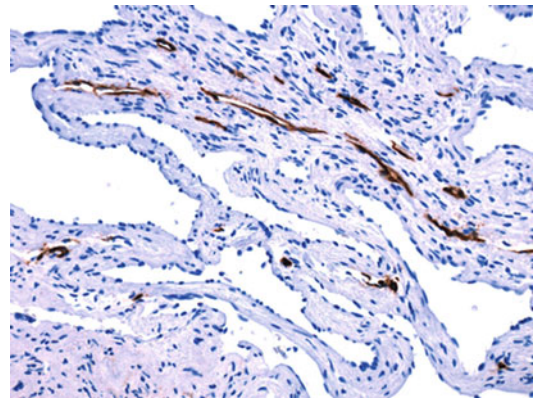

Fig. 10 The fibrous septa separating vascular spaces in hepatic hemangioma can contain lymph vessels (D2-40 immunostain)

Ultrastructure

Endothelial cells contained pinocytotic vesicles, scattered ribosomes, rough endoplasmic reticulum, and Golgi apparatus. A distinct basement membrane was present beneath the endothelial cells. In addition to endothelial cells, hemangiomas also contained stromal cells, forming a population of fibroblast-like cells, myofibroblasts, and smooth muscle cells (Kojimahara 1986).

Immunohistochemistry

The endothelial cells of cavernous hemangiomas are variably immunoreactive for CD31, CD34 (Fig. 9), and factor VII-associated antigen. Cavernous hemangiomas only exceptionally contained lesional cells immunoreactive for simple epithelial keratins (Miettinen and Fetsch 2000). Most of the lesions express decorin, in contrast to angiosarcomas and Kaposi's sarcoma (Salomäki et al. 2008). The endothelium of the hemangiomas does not express the hyaluronan receptor for endocytosis, suggesting that these tumors demonstrate vascular but not sinusoidal differentiation (Duff et al. 2002). Estrogen and progesterone receptors were not detected in these tumors (Kim et al. 2006). Prox1 expression is generally absent in cavernous hemangiomas, in contrast to venous hemangiomas and lymphangiomas (Miettinen and Wang 2012). Lymph vessels may be present in septa separating vascular channels (Fig. 10).

Hemangiomas Located Outside the Normal Hepatic Parenchyma

Giant cavernous hemangioma has been found to arise from the Glisson's capsule (Guibert and Candon 1957) and from accessory lobe of the liver (Avdei and Vas'kovsij 1975). Hemangioma-like lesions develop in portal biliopathy (cavernous transformation of the portal vein, portal vein cavernoma). This issue is further discussed in another chapter.

Vascular Supply of Cavernous Hemangiomas of the Liver

The first who systematically studied the vascular supply of hepatic cavernous hemangiomas was Virchow, who performed injections with staining substances of the entire liver and found that the tumor was connected both with the hepatic artery and the portal vein (reviewed in Virchow 1863; Fig. 11). Ribbert injected staining material directly into a cavernoma and found that vessels in the interstitial were stained, but the capillaries in the vicinity of the hemangioma, suggesting that hepatic cavernous hemangioma has a vascular system of its own, are not connected with the hepatic capillary network (Ribbert 1898). However, analyses of tumor borders reveal that the microvascular system of cavernous hemangiomas is in direct continuation with adjacent parenchymal microvessels (Fig. 12). In serial sections of a cavernous hepatic hemangioma, Kuske found one single artery directly entering a cavity, proving arteries as direct feeding vessels of hemangioma (Kuske 1938). In histological sections, medium-sized to large blood vessels are seen in the vicinity of hemangiomas. In larger tumors, these vessels may be found up to 2 cm beyond the confines of the hepatic tumor (so-called hemangioma-like vessels; Kim et al. 2006). The vascular supply of hemangiomas has been studied by serial selective hepatic arteriography (Li et al. 2003). This technique has uncovered that the tumors are supplied by one to numerous arterial branches. In the portal phase of portography, contrast medium failed to enter the tumors, and the intrahepatic portal venous branches were pushed aside by the tumor. In this study, no arterioportal fistula was detected within the tumor (Li et al. 2003). However, hepatic cavernous hemangioma with shunt formations is now a recently recognized entity. Arterioportal shunts have been described more commonly (Kim et al. 2001, 2006; Tanaka et al. 2002; Han and Kim 2004), but the less common combined arterioportal and portosystemic shunts are well documented (Hekimoglu and Ustundag 2010).

Secondary Changes of Hepatic Cavernous Hemangioma

Thrombosis

Dilated vascular spaces in cavernous hemangiomas may undergo thrombosis due to blood stasis, mainly in large or giant hemangiomas (Figs. 13, 14, 15, and 16). With time, and similar to other thrombi, granulation tissue sprouts into the thrombotic material and organizes it and in the end leaving a scar tissue with collapse and obliteration of the involved cavity/cavern. In rare instances, thrombi in hemangiomas undergo colliquation and puriform change (abscess formation) or develop into phleboliths (angiomatous phleboliths). Thrombosis of cavities in cavernous hemangioma may be complicated by pulmonary embolism (Dennis 1980).

Infection and Inflammation

Bacteria circulating in peripheral blood can be trapped within the vascular spaces of hepatic hemangioma, particularly in thrombi, and cause infected hemangioma, sometimes with formation of a central large abscess (Figs. 17 and 18; Pinkernelle et al. 2007). However, abscesses in

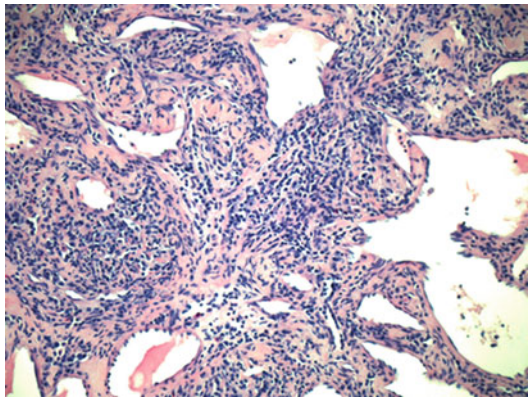

Fig. 18 Inflamed (inflammatory) hepatic hemangioma. The fibrous septa are densely infiltrated with leukocytes (mainly lymphocytes; hematoxylin and eosin stain)

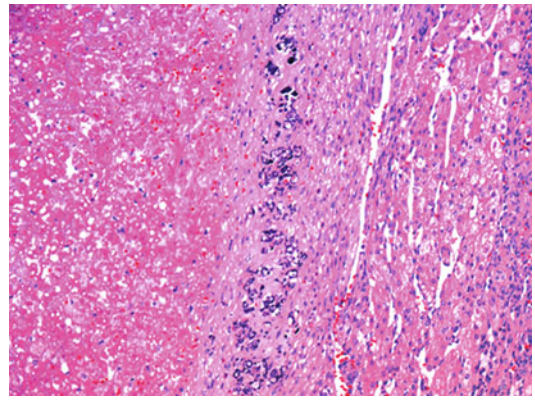

Fig. 20 Hepatic hemangioma with necrosis (*left*) and dystrophic calcifications (*middle*; hematoxylin and eosin stain)

cavernous hemangioma have also found in the absence of obvious bacterial infection (Berliner et al. 1983). As briefly outlined above, hepatic cavernous hemangiomas are sometimes associated with a clinical inflammatory syndrome, but these cases do not necessarily show inflammation of the hemangioma itself (Pol et al. 1998).

Intratumoral Hemorrhage

Intratumoral hemorrhage was seen in giant hepatic hemangioma (Fig. 19; Feldman and Regev 2007). The pathogenesis of hemorrhage in the absence of trauma is not known but may be related to thrombosis and thrombosis-associated damage of the vascular walls.

Calcification

Hepatic hemangiomas, particularly large (giant) lesions and those with thrombosis and necrosis, can undergo extensive calcification (Fig. 20), which is visualized on sonographic, CT, and MR images (Plachta 1962, 1965; Bhatt et al. 1970; Scatarige et al. 1983; Mitsudo et al. 1995; Stoupis et al. 1998; Toshikuni

et al. 2006). In giant hemangiomas, calcifications are large and coarse, usually found in central parts of the tumors where fibrosis has developed (Stoupis et al. 1998).

Marked Cellular Fibrosis in Organizing Lesions

Following thrombosis, fibromatosis-like lesions may develop within the cavernous spaces of hemangiomas (Morita et al. 1970).

Spontaneous Regression

A minority of cavernous hemangiomas undergo slow regression, possibly following thrombosis, organization, and fibrosis. The end result of this process has been termed hyalinized hemangioma (Vilgrain et al. 2000) and may resemble sclerosed hemangioma (Miyaki et al. 2011), which is however thought to be a different lesion and therefore treated in a separate chapter. Exceptionally, cavernous hemangiomas reveal spontaneous rapid regression (Chiu et al. 2005).

Deformation by Hepatic Remodeling

Subcapsular hemangioma can be distorted by liver cirrhosis (de caralt et al. 1999), due to the space-occupying effect of regenerative nodules and the marked rearrangement of hepatic vasculature in cirrhosis.

Atrophic and Hyperplastic Changes in the Adjacent Liver

Hepatic hemangiomas can induce both atrophy and hyperplastic changes in the surrounding liver parenchyma. Localized peritumoral nodular hepatocyte proliferations have been described. In one study, the angiomatous hepatic nodules had dark, congested centers surrounded by a pale yellow to tan periphery. The nodules were well circumscribed and partially encapsulated. The centers consisted of cavernous hemangiomas, while the peripheral nodular area consisted of hepatocyte nodules similar to those of focal nodular hyperplasia (Ndimbie et al. 1990). True FNH has been observed in association with hepatic hemangioma (Mathieu et al. 1989).

Peliosis Hepatis

In rare instances, hepatic hemangioma is synchronously associated with peliosis of the liver (Herrera et al. 1981). The pathogenesis is unclear, but an abnormal circulation in the vicinity of the tumor, with shunting channels and sinusoidal flow overload, may play a role.

Colonizing by Malignant Tumor Cells

Metastases of extrahepatic malignancies may localize to hepatic hemangiomas, which offer an extended vascular system potentially trapping circulating tumor cells. Colonization of hemangioma by metastasizing colorectal cancer cells has been reported (Faccini et al. 2005). Cavernous hemangioma of the liver can be infiltrated in the setting of leukemias, e.g., chronic lymphocytic leukemia (Fig. 21).

Combination with Other Liver Lesions

Cavernous hemangioma of the liver is sometimes associated with other synchronous liver lesions, e.g., hepatic tuberculosis (Astrukov and Baev 1990), focal nodular hyperplasia/FNH (Mathieu et al. 1989; Vilgrain et al. 2003), and combinations of liver adenoma and FNH (Di Carlo et al. 2003; Kondo 2003). Patients with FNH are more likely to have an associated hepatic hemangioma (Vilgrain et al. 2003). In two elderly men, multiple hepatic hemangiomas were synchronously associated with focal regenerative nodules (Ndimbie et al. 1990).

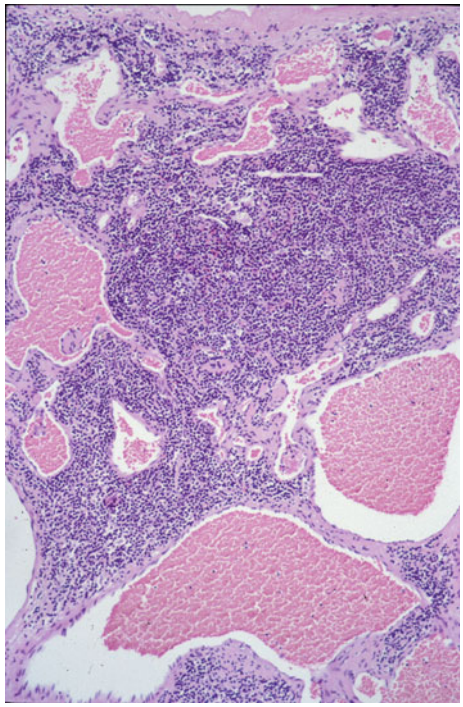

Fig. 21 Hepatic cavernous hemangioma with massive infiltration in chronic lymphocytic leukemia (hematoxylin and eosin stain)

Hemangiomas of the Bile Ducts

Hemangiomatous lesions of the large bile ducts are exceptional findings. Juvenile hepatic hilar hemangioma is a rare cause of extrahepatic biliary tract obstruction (Szavay et al. 2013). A case of angioleiomyoma of the common bile duct was reported (Pönkä et al. 1983). The differential diagnosis of true angiomatous tumors of bile ducts includes intramural collaterals ("varices") in portal vein thrombosis (Denys et al. 1998) and intramural portal cavernoma (Novellas et al. 2004).

Biology of Disease

Many hepatic cavernous hemangiomas seem to arrest their growth after they have reached a certain size (Gandolfi et al. 1991), but other will undergo a slow progressive growth, interrupted by phases of growth arrest (Conter and Longmire 1988; Nghiem et al. 1997). Ultrasonographically, no change over time has been found for many hepatic hemangiomas. Forty-seven patients with 68 hemangiomas were rescanned 1–6 years after the initial study. Eighty-two percent showed an identical appearance on follow-up study. Only 12 lesions (18 %) had an appreciably changed sonographic appearance: three lesions could no longer be found, seven were less obvious, one was larger, and one was smaller (Gibney et al. 1987). Similar results have been obtained in other investigations (Mungovan et al. 1994; Okano et al. 2001). In the study of Nghiem and coworkers (1997), four cavernous hepatic hemangiomas were shown to have doubled to tripled in diameter on follow-up imaging studies done between 34 months and 10.5 years after the initial diagnosis. The mechanisms driving this evolution are not well known. In a study of 180 hepatic hemangiomas, the diameter increased over time in 7.7 % of cases. The tumor volume doubling time of these lesions ranged from 17.3 to 178.1 months (Yeh et al. 2007). Liver hemangiomas may undergo rapid growth following interferon treatment for hepatitis C (Strzelczyk et al. 2004). The growth of hepatic cavernous hemangiomas seems to be influenced by endogenous or exogenous female sex steroids, although significant enlargement occurs only in a minority of cases (Morley et al. 1974; Conter and Longmire 1988; Glinkova et al. 2004; Ozakyol and Kebapci 2006; van Malenstein et al. 2011). Enlargement of hepatic cavernomas has been observed in pregnancy (Koskela 1965; Saegusa et al. 1995; Au and Liu 2005) and in puberty (Baker et al. 1985). On the other hand, a case-control study could not demonstrate an association of liver hemangiomas with menstrual, reproductive, and oral contraception use history (Gemer et al. 2004).

Malignant Transformation of Hepatic Cavernous Hemangioma

The question whether hepatic cavernous hemangioma may transform into malignancy has not been solved. Two reports described hepatic

cavernous hemangioma surrounded by angiosarcoma, suggesting eventual malignant transformation of the former (probably the same patient reported twice; Drouot et al. 1990; Tohme et al. 1991).

Cavernous Hemangiomas of the Liver in Fetuses and Infants

Large or giant liver hemangiomas can present during the fetal stage (Imai et al. 1995; Dreyfus et al. 1996; Gembruch et al. 2002), may show calcifications (Dreyfus et al. 1996), and may result in the Kasabach-Merritt phenomenon (Gembruch et al. 2002), but usually hepatic angiomas in this group are small, i.e., frequently in the range of 3 mm to about 1 cm (Sepulveda et al. 1993), and exhibit different imaging and Doppler features, showing strongly hyperechogenic patterns similar to regressing hemangiomas and only a low flow perfusion (Sepulveda et al. 1993). In newborns and infants, solitary or multiple liver hemangiomas are well known as well (Beal et al. 1974; Somppi et al. 1974; Malamou-Mitsi et al. 1996). They occur more frequently in girls and show clinical manifestations differing as a function of gross tumor morphology and age at presentation. Solitary and large infantile tumors are usually present at birth and may show the clinical triad of hepatomegaly, congestive heart failure, and anemia (triad in a larger series: 3/16 patients; Boon et al. 1996). Conversely, multiple tumors manifest at 1–16 weeks of age and may present with the same triad plus multiple cutaneous lesions (triad in 19/23 patients, Boon et al. 1996; Enjolras and Mulliken 1997). In the series of Boon et al. (1996), no patient showed the Kasabach-Merritt phenomenon (see below). Infantile hepatic hemangiomas have recently been classified into five types on the basis of angiographic findings, i.e., classic appearance with stagnation of contrast and without shunting (type 1), high-flow nodules without direct shunts (type 2), lesions with arteriovenous shunts (type 3), with portovenous shunts (type 4), and with both arteriovenous and portovenous shunts (type 5), indicating the heterogeneity of these tumors with respect to hemodynamic features (Kassarjian et al. 2002). In infants and children, hepatic hemangiomas have a tendency to regress, similar to cutaneous lesions (Berman and Lim 1978; Cohen and Myers 1986). Rupture is a very rare complication of hepatic hemangioma in the pediatric age group. It has been observed as an intrapartum complication (Krasuski et al. 2001).

Etiology and Pathogenesis

Endothelial Cells and Other Cells in Cavernous Hemangioma

Hemangiomas of the liver chiefly consist of endothelial cells, but they also contain mesenchymal cells and cells associated with the vascular channels. Whether the fibroblastoid cells interspersed between the endothelial channels are members of a neoplastic lineage or are nonneoplastic bystander cells is not yet known. Endothelial cells of hepatic cavernous hemangiomas are different in several respects from other endothelia. Morphologically, they are often spindle shaped, and their arrangement on the vascular surface resembles that of arteries, with formation of parallel streams. Endothelial cells derived from cavernous hemangioma showed overexpression of alphavbeta3 (Zhang et al. 2006) and of Derlin-1, a rhomboid pseudoprotease involved in retrotranslocation of misfolded proteins which inhibits ER expansion in endothelial cells (Hu et al. 2006; Greenblatt et al. 2011).

In other organs, hemangiomas have also been shown to be formed by cells expressing high levels of alphavbeta3 integrins and lacking acetylated LDL uptake (Aurrand-Lions et al. 2004). Cultured endothelial cells from human hepatic cavernous hemangiomas released more vascular endothelial growth factor A, produced significantly more pro-matrix metalloproteinase 2 and activated matrix metalloproteinase 2, and exhibited higher procoagulant and fibrinolytic activities compared with liver sinusoidal endothelial cells (Zhang et al. 2006).

Cytokines, Chemokines, and Growth Factors

Interleukin-17, which pays a role in angiogenesis, is significantly upregulated in the tissues of hepatic hemangiomas and was proposed to mediate hemangioma angiogenesis in a IL-6-STAT3-dependent manner (Wang et al. 2012).

Sclerosed Angioma and Sclerosed Cavernous Hemangioma of the Liver

Introduction

Sclerosed hemangioma of the liver (synonyms: hyalinized hemangioma, hemangioma with fibrosclerotic changes, thrombosed hemangioma) is a variant of mostly cavernous hemangioma of the liver characterized by a significant increase of cellular or hyalinized fibrous tissue obliterating the vascular channels. The first report of hepatic sclerosed hemangioma was documented in 1983, based on five patients with an unusual lesion in the liver which had a hyalinized fibrotic capsule with a completely necrotic core, i.e., a type of solitary necrotic nodule resulting from regression of hemangioma (Shepherd and Lee 1983). A similar case of post-hemangioma necrotic nodule was reported 2 years later (Berry 1985). An alternative term for sclerosed hemangioma, as used by Goldman (1987), is sclerosing hemangioma (Yamashita et al. 2000), formally describing two phases of an ongoing process of fibrous tissue development.

Most hepatic cavernous hemangiomas remain stable on follow-up imaging (Gibney et al. 1987; Gandolfi et al. 1991; Okano et al. 2001), with relatively few tumors showing enlargement over time (Mungovan et al. 1994; Nghiem et al. 1997), but there is a fraction of these tumors which may develop thrombosis (Dennis 1980; Berliner et al. 1983; Ros et al. 1987) and/or undergo inflammation followed by a fibroblastic reaction, i.e., sclerosed hemangioma (Goldman 1987). Sclerosis is, similar to situations in other organs and tissues, a late stage of fibrosis with predominance of extracellular matrix over fibroblastoid cells, and hyalinosis is an even later phase of this process, characterized by marked hypocellularity and hyaline change of the collagenous matrix. Based on the cellular and matrix composition, the lesions are classified as sclerosing hemangioma, sclerosed hemangioma, and hyalinized hemangioma.

Epidemiology

Sclerosed hemangioma of the liver is a rare lesion. Of 675 hemangiomas accessioned from 1970 to 1999, only 20 cases of sclerosed hemangiomas were identified from the files of the Armed Forces Institute of Pathology (AFIP) (Makhlouf and Ishak 2002). In a review of 11 cases, age at diagnosis ranged from 41 to 72 years; seven patients were female and one was male, and in two cases, the data were not available (Mori et al. 2008).

Clinical and Imaging Features

Most patients with sclerosed hepatic hemangiomas are asymptomatic, the lesions being detected in the course of abdominal imaging performed due to other reasons. The imaging appearance of sclerosed hemangioma is that of so-called atypical hemangioma of the liver. The features of these lesions have been presented in detail and reviewed (Vilgrain et al. 2000; Jang et al. 2003; Mori et al. 2008; Jin 2010). Typical alteration in atypical hepatic hemangioma includes the bright-dot sign, atypical low signal on T2-weighted MR images, a heterogeneous appearance with central scar, the presence of calcification, central cystic degeneration, and fluid-fluid levels. The lesions may be associated with arterial-portal shunt, capsular retraction, and surrounding nodular hyperplasia of parenchyma. Suggestive features of sclerosed hemangioma comprise geographic outline of hypodense masses, capsular retraction, decrease in size over time, and loss of previously seen regions of enhancement, presence of transient hepatic attenuation difference (THAD), rim enhancement, and nodular regions of intense enhancement as seen in ordinary hemangiomas (Shim et al. 1995; Vilgrain

et al. 2000; Yamashita et al. 2000; Aibe et al. 2001; Doyle et al. 2007; Mori et al. 2008). Rim enhancement has been described in part of the reports (Takayasu et al. 1986; Haratake et al. 1992; Yamashita et al. 2000). At imaging, the size of sclerosed hemangiomas varies considerably. In one study of ten cases, the diameter of the lesions ranged from 1.4 to 7.7 cm (mean, 3.7 cm) (Doyle et al. 2007). MR reveals a mass with low signal intensity in T1-weighted images and high signal intensity and focal low signal in T2-weighted images (Mori et al. 2008; Park et al. 2009). Sclerosed hepatic hemangioma may show a high apparent diffusion coefficient (ADC), presenting as a heterogeneously hyperintense mass in fat-suppressed T2-weighted images (Hida et al. 2010). Based on the imaging features, sclerosed hepatic hemangioma may be confounded with other tumors, particularly intrahepatic cholangiocarcinoma (Park et al. 2009), hepatocellular carcinoma (Mathieu et al. 1994; Cheng et al. 1995; Lee et al. 2005), and hepatic metastasis (Yamashita et al. 2000). The presence of a ring-like enhancement in enhanced CT in up to 60 % of the cases may be confusing, because this ring is a typical sign of adenocarcinomas in the liver, similar to the hypoechoic ring in some cavernous hemangiomas resembling malignant tumor (Choi et al. 2009).

Pathology

Macroscopy

Sclerosed hemangiomas are sharply delineated, firm masses with a whitish cut surface. In a study of 18 cavernous hepatic hemangiomas with fibrosclerotic changes, all sclerosed hemangiomas and the majority of sclerosing hemangiomas were solitary, sclerosing lesions were larger than sclerosed lesions (mean 6 $\pm$ 4.73 cm vs. 3 $\pm$ 2.2 cm diameter), and sclerosing tumors occurred much more frequently in the right lobe than sclerosed tumors (Makhlouf and Ishak 2002). The peripheral contour is often irregular, with spikes probably representing obliterated feeding vessels with perivascular fibrosis. The cut surface is usually homogeneous, but by use of a magnification glass, one may note a granular structure caused by scarred foci of granulation tissue adjacent to collapsed and obliterated tumor vessels. Brown-to-red areas correspond to old hemorrhage or regions of thrombosis with accumulation of iron pigment. Mainly in larger tumors, central necrosis with or without calcification and central cavities containing clear, turbid, or hemorrhagic fluid may occur. Gross and sometimes sickle-shaped calcifications of whitish or cream-white color may be seen in the fibrous capsule of the lesions. In the hyalinized end stage of the lesions, the tumors are hard, and the cut surface has a homogeneous, porcelain-like aspect, resisting the penetration even of a sharp-tipped probe.

Histopathology

Histologically, three major patterns of sclerosis can be distinguished (Table 3; Fig. 22).

Table 3 Histological patterns of sclerosed hepatic hemangioma

Pattern 1: Central regression with or without cyst, peripheral fibrosis
Pattern 2: Internal fibrosclerosis with or without thrombosed vessels
Pattern 3: Complete fibrosclerosis
Pattern 4: Hyalinosis

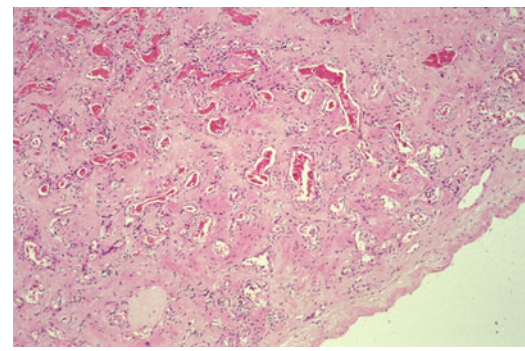

Fig. 22 Sclerosed hepatic hemangioma. Abnormal vascular channels are separated from each other by a fibrosclerosed connective tissue (hematoxylin and eosin stain)

Pattern 1 is characterized by fibrous tissue surrounding a core of regressed and eventually necrotic hemangioma, with or without a central cyst; pattern 2 shows internal fibrosclerosis in a geographic pattern, with or without thrombosed vessels and granulation tissue; pattern 3 is complete fibrosclerosis; and pattern 4 is hyalinosis. The peripheral rim of fibrous tissue in pattern 1 corresponds to a halo surrounding a central isoechoic mass in sonography (Takayasu et al. 1986). These patterns, together with the structure of the vascular channels, can be integrated into three major types of presentation, viz., sclerosing, sclerosed, and hyalinized hemangiomas.

Sclerosing cavernous hemangiomas are "active" lesions which are composed of thin-walled and often dilated vessels with a single layer of endothelial cells, probably representing a vascular growth phase with signs of proliferation. The fibrotic component varies from scanty (fibrillar) to abundant (sclerotic and eventually hyaline), with the patterns 2, 3, or 4. The vascular spaces may contain thrombi, with or without signs of organization by granulation tissue. Interestingly, the sclerosed matrix contains elastic fibers (mild to moderate) in most of the cases (Makhlouf and Ishak 2002). Close to 30 % of these lesions show mineralizations/calcifications, sometimes with formation of psammomatous bodies, and the majority of the tumors display hemorrhages and hemosiderin deposits.

Sclerosed cavernous hemangiomas are "silent" or "burnt-out" lesions which are characterized by abundant collagen and elastin deposition with the patterns 3 and 4, with extensive collapse, atrophy, and obliteration of the vascular bed and with hyalinization being complete in about 25 % of the cases (Makhlouf and Ishak 2002). Numerous thick-walled blood vessels are present in most of these lesions. The sclerotic tissue may contain mast cells, as seen in other hemangiomas (Hagiwara et al. 1999; Makhlouf and Ishak 2002; Tan et al. 2004; Sun et al. 2007). In a systematic study of 18 cases of sclerosing and sclerosed hepatic hemangiomas, the density of mast cells was higher in sclerosing lesions than in sclerosed lesions. The number of mast cells was significantly correlated with vascular proliferation and inversely related to the degree of fibrosis (Makhlouf and Ishak 2002). One variant of hepatic hemangioma with sclerosing changes is characterized by a peculiar type of pericapillary smooth muscle cell proliferation (Choi et al. 2008). This lesion is further discussed in a separate paragraph.

Immunohistochemistry

The basement membranes of the vascular channels are reactive for type IV collagen, beta chain of laminin, and perlecan, as in other hemangiomas (Tan et al. 2000). Type IV collagen and laminin were more uniformly positive in sclerosing ("active") hemangiomas than in sclerosed hemangiomas, and endothelial markers (FVIII-related antigen, CD 31 abd CD34) were more diffusely positive in sclerosing hemangiomas than in sclerosed hemangiomas, reflecting vascular proliferation and active matrix remodeling in sclerosing tumors, the latter representing lesions in an earlier phase of evolution.

Hyalinized Hemangioma of the Liver

Fibrosclerosis may end up with hyaline change of the tumor's connective tissue (Haratake et al. 1992, 1995; Cheng et al. 1995; Hosokawa et al. 2005). Such lesions have been termed hyalinized hemangioma of the liver. Hyalinized hemangioma of the liver may represent a highly hypocellular variant or end stage of sclerosed hepatic hemangioma. Haratake and coworkers (1992) specified the morphology of these lesions in detail. They diagnosed a hepatic tumor measuring 2.6 × 1.8 cm in a 64-year-old woman, located in segment 8. On CT images, the lesion was of low density and was circularly enhanced with contrast medium. A late post-contrast scan showed that this ring enhancement pattern remained unchanged. The resection specimen revealed a circumscribed and firm, evenly whitish tumor. Histologically, the tumor was composed of a dense collagenous tissue with marked hyalinization and scattered small blood vessels, sclerosed vessels being in evidence in the

tumor's center. Around these sclerotic vessels, numerous concentric elastic fibers were noted. This histologic pattern resembled somewhat to part of cases described as solitary necrotic nodules.

Differential Diagnosis

On CT images, sclerosed hepatic hemangiomas may be confounded with stroma-rich liver metastases of gastrointestinal tract adenocarcinomas (Yamada et al. 2012).

Pathogenesis

One mechanism that may operate in sclerosis of hepatic hemangiomas is thrombosis of vascular spaces followed by organization by a granulation tissue, which in turn will transform into connective tissue. The pathogenic role of secondary involutive changes is supported by the observation of a significant "spontaneous" regression of a cavernous hepatic hemangioma to a sclerosed hemangioma over 12 years (Miyaki et al. 2011).

Liver Hemangiomas with a Myoid Component

Leiomyomatous Hemangioma of the Liver

This is a very rare lesion which had first been described based on 74-year-old male patient who had died of cardiac arrest. Autopsy revealed a normal-sized liver with several white, solid tumors on the cut surface of both lobes. The nodules ranged in diameter from 0.3 to 0.6 cm and had a firm texture. Histologically, the tumors were well circumscribed and consisted of interlacing bundles of spindle-shaped cells with a smooth muscle cell phenotype. Some of the tumors appeared to arise from smooth muscle of veins, and the lesions were associated with cavernous hepatic hemangioma (Key and Rao 1986).

Sclerosing Liver Hemangioma with Pericapillary Smooth Muscle Proliferation

As discussed in the respective chapter, sclerosis of liver hemangiomas is a rare event (Makhlouf and Ishak 2002), and there are only a few reports on imaging findings of this lesion which may mimic metastasis or hepatocellular carcinoma.

Sclerosing hepatic hemangioma may develop a myoid component. In a 63-year-old man, CT and MRI revealed a 14 cm-sized ill-demarcated hypoattenuating mass arising from the right liver lobe, containing multifocal low-attenuation areas and multiple small calcifications. On dynamic CT, an enlarged and tortuous right hepatic artery, prominent intratumoral vessels, and multifocal patchy enhancement were seen during the arterial phase. The right lobectomy specimen showed an ill-demarcated, solid, and myxoid mass of 15.5 cm diameter with multiple blood-containing areas and a yellowish portion 0f 4.5 cm size. Histology showed sclerosing and hyalinized hemangioma, with the yellowish focus being a fully hyalinized area. Interestingly, the vascular channels showed a marked, SMA-positive perivascular smooth muscle proliferation, in the form of bundles and nodules of myocytes surrounding the hemangioma vessels (Choi et al. 2008).

Small Vessel Hepatic Hemangioma of the Capillary Type (Capillary Hemangioma of the Liver)

ICD-O code 9131/0

Capillary Hemangioma of the Liver in Adults

Capillary hepatic hemangioma and mixed capillary-cavernous hemangioma of the liver are very uncommon primary tumors of the liver in adults (Fig. 23; Ascari and Lusvarghi 1963; Astrukov and Baev 1990; Matsuo and Uchida 1990; Kojima et al. 2000; Noda et al. 2005;

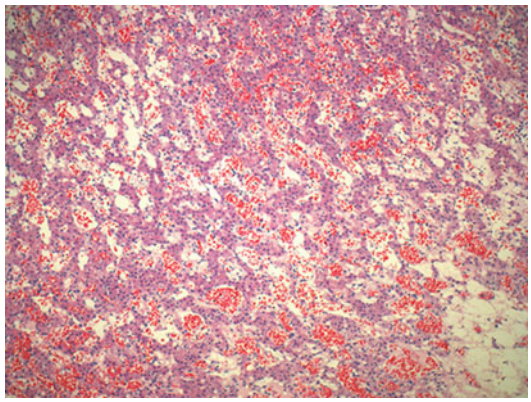

Fig. 23 Capillary hemangioma of the liver (hematoxylin and eosin stain)

Jhuang et al. 2011; Unal et al. 2011), and its entity has been discussed in the context of other hemangiomas (Scialpi et al. 2010).

In a 55-year-old male patient with a hepatic tumor, ultrasonography revealed a hypoechoic mass with a peripheral hypoechoic ring, the latter being characteristic of hepatocellular carcinoma. CT showed an enhancement pattern different from that of hepatocarcinoma or cavernous hemangioma. The resection specimen displayed a tumor measuring 22 × 20 mm, of reddish-brown color, with a clear boundary and solid components usually not encountered in cavernous hemangioma. Histology showed capillary hemangioma characterized by a proliferation of capillary-type blood vessels with a small diameter of 20 μm (Noda et al. 2005). In two other reported cases of hepatic capillary hemangioma in adults, the ultrasonographic patterns were either mosaic, hyperechoic (Kojima et al. 2000), or mixed (Matsuo and Uchida 1990). Capillary hepatic hemangioma was diagnosed in a 71-year-old female patient, in whom abdominal sonography revealed a 2 cm nodular lesion and fatty liver. CT showed a hypervascular tumor. It was decided to observe lesion which increased in size to 3 cm within 2 years. Resection showed a capillary hemangioma associated with steatohepatitis (Jhuang et al. 2011). The clinical presentation of hepatic capillary hemangiomas, which are sometimes compact and almost solid masses with almost slit-like or even collapsed vascular spaces ("compressed sponges"), may mimic that of hepatocellular carcinoma. In one patient, liver transplantation was performed for such a hemangioma, revealing atypical imaging features and resembling hepatocarcinoma (Unal et al. 2011).

Capillary Hemangioma of the Liver in Infancy and Childhood

In the pediatric age group, capillary hemangioma of the liver was reported to be a manifestation of diffuse neonatal hemangiomatosis (Satoh et al. 1994) or to accompany Kasabach-Merritt syndrome (Akiyoshi et al. 2000). In Rubinstein-Taybi syndrome, large areas of cutaneous capillary hemangioma may be associated with hepatic hemangioma (Sahiner et al. 2009). It has been shown that extracutaneous infantile hemangioma, including tumors in the liver, is GLUT1 positive (Drut and Drut 2004). In fact, GLUT1 endothelial reactivity distinguishes hepatic infantile hemangioma from congenital hepatic vascular malformation with associated capillary proliferation (Mo et al. 2004).

Differential Diagnosis

Hepatic hemangiomas, also those with a contribution of small vessels, may be difficult to distinguish from hepatocellular carcinoma at sonography and imaging. If initial US examinations of a cirrhotic liver depicts a hepatic hemangioma, confirmatory findings of imaging studies are necessary since 50 % of hemangiomas found in one study were hyperechogenic HCCs (Caturelli et al. 2001). Hepatic infantile hemangioma is GLUT1 positive and therefore distinguished from GLUT1-negative hepatic vascular malformation with capillary proliferation (HVMCP).

Lobular Capillary Hemangioma of the Hepatobiliary Tract

Introduction

Lobular capillary hemangioma (LCH; current synonym: pyogenic granuloma) is a common, usually solitary benign vascular tumor, mainly occurring in the skin or mucous membranes. This lesion group was first described by in 1897 under the French term "botryomycose" (botryomycosis; Poncet and Dor 1897), the word meaning "grape-like fungus." Later, numerous synonyms have been created, most of them no longer in use (telangiectatic granuloma, botryomycoma, botryomycosis, pyogenic granuloma, granuloma pediculatum, eruptive angioma, proliferating angioma). The original view was that the lesion now termed LCH was a reactive growth or rather overgrowth of granulation tissue in the context of disordered wound healing, i.e., an outgrowth of fibrovascular tissue through an epidermal or mucosal gap failing to be reepithelialized on time. Deletion (21)(q21.2q22.12) was the sole clonal cytogenetic abnormality found in LCH of the nasal cavity (Truss et al. 2006).

In the skin, superficial lesions are much more frequent than subcutaneous lesions (reviews: Patrice et al. 1991; Lin and Janniger 2004; Jafarzadeh et al. 2006; Fortna and Junkins-Hopkins 2007; Salum et al. 2008; Godfraind et al. 2013). LCHs of the skin are equally prevalent in male and female patients. The peak incidence of LCH of the skin was found in the second decade of life, and the most common cutaneous sites were the trunk, upper extremities, and head, and the mucosal lesions were common on the lips, gingiva, and tongue (Harris et al. 2000). LCH may enlarge gradually or can evolve rapidly over a few weeks. They are known to recur (recurrent pyogenic granulomas; Eng and Hong 1993). Now regarded as a neoplastic process, the etiology of LCH is unknown. Hormonal factors may play a role, as oral LCHs are known to occur more frequently during pregnancy (so-called granuloma gravidarum or pregnancy tumor; epulis gravidarum; Sills et al. 1996; Demir et al. 2004; Rader et al. 2008). However, LCH cells do not express estrogen or progesterone receptors (Nichols et al. 1992). LCH can present rarely in a disseminated form, usually associated with other disorders. These disseminated LCH may develop suddenly in adults (Gönül et al. 2005). Involvement of visceral organs is rare but has been observed in the esophagus (Van Eeden et al. 2004), the stomach (Kusakabe et al. 2005), the duodenum (Park et al. 2009), the small intestine (Yao et al. 1995; Van Eeden et al. 2004; Kuga et al. 2009; sometimes causing obstruction and intussusception; Stojsic et al. 2008), and the colon (Carmen Gonzalez-Vela et al. 2005). LCH may occur as an intravenous lesion (intravenous pyogenic granuloma; Ghekiere et al. 2005) or develop in arteriovenous malformations (Hung et al. 2004).

Macroscopically, LCHs arising from skin or mucous membranes are flat to polypoid vegetations of meat-red to dark bluish-red color, easily bruising owing to the fragility of the capillary vessels. The typical aspect has led to the term "proud flesh" (Caro luxurians in Latin; exuberant flesh), describing the view that tissue overgrowth had ensued. Histologically, the tumorous lesion shows a lobular structure and consists of proliferating capillary-type vessels associated with small feeding arteries, dilated vascular channels with or without perivascular hemorrhage, and a fibroblastic or myofibroblastic stroma rich in glycosaminoglycans, containing macrophages and sometimes numerous neutrophils, the latter mostly in case of infection of superficial lesions (Fig. 24). The tissue may home hematogenic progenitor cells leading to extramedullary hematopoiesis (Vega Harring et al. 2004). Immunohistochemically, endothelial cells of LCH are reactive for factor VIII-associated antigen, CD31, and CD34 but, in contrast to other hemangiomas, not for glucose transporter-1 (GLUT-1) protein (Stojsic et al. 2008; Browning et al. 2009).

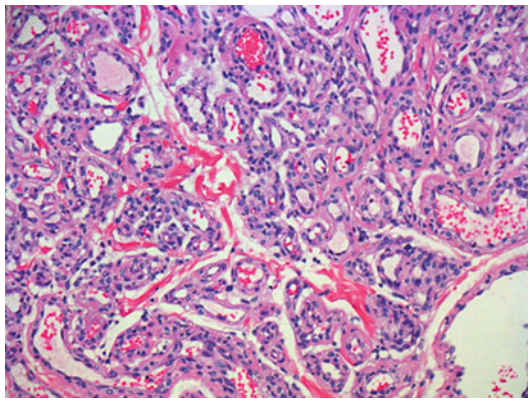

Fig. 24 Lobular hemangioma of the liver (hematoxylin and eosin stain)

Lobular Capillary Hemangioma of the Liver

Hepatic lobular hemangioma was described in 35-year-old female patient presenting with a large asymptomatic hepatic mass discovered during abdominal ultrasound for evaluation of gross hematuria (Abaalkhail et al. 2009). Sonography revealed a distinct 4.6 cm mass in the right liver lobe, with significant intralesional vascular flow on Doppler evaluation. On CT scans, the mass measured 5 cm in diameter, and MRI revealed a vascular lesion with a central scar. A later MRI showed unusual signal intensity in T2-weighted imaging and exhibited prominent vascularity within the lesion.

The resection specimen showed a well-circumscribed tan-brown tumor measuring 4 cm in diameter, having a 0.3 cm central scar on the cut surface. Histologically, the mass was composed of a lobular proliferation of vascular channels, lined by plump, CD31-, and CD34-positive endothelial cells without any atypia and without mitotic activity. In certain areas, the channels were compressed, imparting a solid appearance. Multiple thick-walled veins were present at the periphery and within the center of the mass. There was a focal extramedullary hematopoiesis.

Lobular Capillary Hemangioma of the Biliary Tract

A 69-year-old female patient with a history of cholecystectomy and side-to-side choledochoduodenostomy and recurrent attacks of cholangitis presented with right upper quadrant pain. Endoscopy of the distal common bile duct revealed a semipedunculated, smooth polypoid lesion 5 mm in diameter, hyperemic, and dark red. The lesion was removed by snare polypectomy and showed the histology of ulcerated pyogenic granuloma with a dense network of CD31-positive capillary vessels (Lee et al. 2007).

Anastomosing Hemangioma of the Liver

Introduction

Anastomosing hemangioma (ASH) is a rare variant of capillary hemangioma predominantly found in the genitourinary tract of adult patients, specifically the kidney, but other organs are also involved, including the adrenal gland, ovary, and gastrointestinal tract (Montgomery and Epstein 2009; Kryvenko et al. 2011; Ross et al. 2012; Lin et al. 2013; Wetherell et al. 2013; Zhao et al. 2013). ASH is characterized by a distinct anastomosing sinusoidal network of capillary-sized vessels, strikingly reminiscent of the splenic red pulp, sometimes mimicking angiosarcoma. Within the vascular channels, endothelial cells often exhibit hobnail morphology, but most of the cells look bland, with immunoreactivity for CD31 and CD34. Mitoses are absent or rare. A part of the tumor cells contain eosinophilic intracytoplasmic globules. Between the endothelial-lined channels, non-endothelial supporting cells are found. The growth pattern is typically lobulated, with intervening hypocellular and even hyaline areas. Extramedullary hematopoiesis was observed in part of the tumors (Kryvenko et al. 2011). Macroscopically, the lesions were described as well-demarcated,

spongy nodules of mahogany brown color (Kryvenko et al. 2011). ASH can present as an intravenous hemangioma with closely packed, fenestrated vascular channels. The course is benign, although some tumors can extend into adjacent connective or adipose tissue.

Anastomosing Hemangioma of the Liver

ASH is rarely observed in the gastrointestinal tract, including the liver (Lin et al. 2013). Similar to their genitourinary counterparts, the tumors were of gray-brown spongy appearance. Histologically, the lesions had a loosely lobular architecture and consisted of a pulp-like vascular tissue with the typically anastomosing pattern of capillary-sized sinusoidal blood vessels with intervening supporting cells. Endothelial cells, in part of the hobnail type, were positive for CD31 and CD34. Two thirds of the lesions revealed vascular thrombi. There were no recurrences or metastases.

Abstract

Apart from the common cavernous and small-vessel hemangiomas of the liver, there is a group of other but rare benign vascular tumors in the pediatric and adult liver. Multiple hepatic hemangiomas with a cavernous histology and different from infantile hepatic hemangioma/hemangioendothelioma exist in the pediatric age group and are termed congenital, neonatal, and infantile hemangiomatosis. These lesions can be accompanied with extrahepatic hemangiomas, e.g., those of the skin. One variant is characterized by a diffuse hemangiomatosis involving several organ systems. Diffuse hepatic hemangiomatosis also occurs in adult patients as a rare condition, whereby liver lobes are densely involved by vascular nodules of variable size. The disorder may be associated with splenic hemangiomatosis. Hepatic angiomatosis also develops in the setting of Osler's disease. An unusual form of hepatic vascular tumor is intravascular papillary endothelial hyperplasia, a reactive lesion usually occurring in the skin and subcutis of adult patients. Hepatic hemangiomas can rarely be associated with proliferation of smooth muscle cells (angioleiomyoma). A further, very rare hepatic vascular tumor is hemangioblastoma, which occurs as a sporadic lesion or develops in the setting of von Hippel-Lindau disease.

Congenital, Neonatal, and Infantile Hepatic Hemangiomatosis

Introduction

Apart from neonatal and infantile hepatic angiomatous tumors classified as hemangioendotheliomas (type 1 lesions), discussed in a special chapter, there are situations where cavernous vascular malformations (hemangiomas) of the skin are associated with similar lesions in the liver. This combination may be present at birth (congenital or neonatal hepatic hemangiomatosis), manifest postnatally, or later in infancy (infantile hemangiomatosis).

Congenital Hemangiomas Associated with Hepatic Vascular Tumors: Benign Neonatal Hemangiomatosis

A part of infantile hepatic hemangiomas develop in the context of congenital hemangiomas of the skin and other organs and in the setting of hemangiomatosis. A neonate with multiple hemangiomatosis can be categorized into two main clinical entities: (1) benign neonatal hemangiomatosis (BNH; Stern et al. 1981) and (2) diffuse or disseminated neonatal hemangiomatosis (DNH). Multiple cutaneous infantile hemangiomas (hemangiomatosis) are reported to arise in 10–25 % of infants with cutaneous hemangiomas (Achauer et al. 1997). Multiple hemangiomas of the skin in infants, in particular more than five lesions, are a marker of possible internal hemangiomatosis, with the liver being an important site (concurrent cutaneous and hepatic hemangiomas; Robinson and Hambleton 1977; Berman and Lim 1978; Metry et al. 2004). Among 47 patients with segmental hemangiomas of the skin, 79 % of the patients had their skin hemangiomas on the face, and 43 % showed liver hemangiomas, followed by the gastrointestinal tract (34 %) and the brain (34 %). Forty percent of the patients in this study fulfilled the criteria of PHACE syndrome (posterior fossa brain malformations, hemangiomas, arterial anomalies, coarctation of the aorta, cardiac defects, and eye abnormalities) (Metry et al. 2001, 2004). Multiple congenital hemangiomas of the skin in a neonate have been found to be associated with hepatic angiosarcoma (Nord et al. 2006).

Diffuse Neonatal Hemangiomatosis

In some of the patients with congenital hemangiomas, the development of the lesions follows a diffuse pattern (diffuse congenital/neonatal hemangiomatosis). Diffuse/disseminated neonatal hemangiomatosis (DNH) is a rare neonatal condition in which cutaneous and visceral hemangiomas coexist. The disorder is also termed multiple miliary neonatal hemangiomatosis (review: Enjolras and Mulliken 1998). DNH

hemangiomas are either present at birth or develop during the first week of life and are twice as frequent in girls in comparison with boys (Holden and Alexander 1970; Golitz et al. 1986; Ho et al. 2000; Schulze et al. 2006; Wananukul et al. 2006; Gouedard et al. 2007; Al-Kaabi et al. 2009; Glick et al. 2012). The first sign of DNH is the appearance of cutaneous hemangiomas, which may become more numerous and extensive. In addition to multiple hemangiomas of the skin, other possibly involved organs include the liver and, less commonly, pleura, lungs, intestines, central nervous system, and eyes. Involvement is limited to the skin and liver in part of the patients. If left untreated, DNH is often fatal at an early age, carrying an estimated 60–95 % mortality, although novel treatments have improved prognosis.

DNH reveals liver angiomas with variable frequencies (Pavlenishvili and Nemsadze 1978; Young et al. 1981; Montgomery et al. 1990; Hurvitz et al. 2000; Gottschling et al. 2006). Hepatic hemangiomas arising in the setting of DNH may grow to large size (e.g., 4 cm diameter; Gottschling et al. 2006). Hepatic hemangiomas in DNH may be associated with cardiac insufficiency caused by blood shunting through the tumor's vascular channels (Hurvitz et al. 2000; Gottschling et al. 2006). DNH with or without liver involvement may be associated with placental chorioangioma (Witters et al. 2003; Bakaris et al. 2004).

Previously, the mean age at death was 11 weeks (Stratte et al. 1996). In a retrospective analysis of the literature, it turned out that the mortality rate was 77.4 % in untreated patients and 27 % in treated patients, important risk factors for adverse outcome being congestive heart failure, coagulopathy, and the involvement of five or more organs (Lopriore and Markhorst 1999). Complications of DNH include high-output cardiac failure, marked thrombocytopenia with hemorrhage, consumption coagulopathy, and hepatic failure. In adult long-term survivors of DNH, visceral hemangiomas in the absence of cutaneous hemangiomas have been observed (Ohnishi et al. 2002). In some of these adults, DNH is visualized on CT images as multiple calcifications in the liver, spleen bowel wall, and adrenals (Latifi and Siegel 1992), representing dystrophic calcification of regressed hemangiomatous lesions. Rarely, DNH develops in congenital overgrowth syndromes, e.g., Simpson-Golabi-Behmel syndrome (Poetke et al. 2002).

The previous concept of DNH may require revision, specifically in regard to the exact types of vascular tumors involved. A recent evidence-based review of case reports of DNH was based on the hypothesis that many cases reported as DNH did in fact not have infantile hemangiomas and also other forms of neonatal vascular diseases. Between the years 1950 and 2009, 73 cases were selected from the literature and categorized into three groups: infantile or probable (P) infantile hemangioma (IH/P-IH), multifocal lymphangioendotheliomatosis with thrombocytopenia (MLT/P-MLT), and multifocal vascular lesions, not otherwise specified. Of these 73 cases, 43 had IH/P-IH, 17 had MLT/P-MLT, and 13 had multifocal vascular lesion NOS. Five percent of patients in the IH/P-IH group died, in contrast to a death rate of 65 % in the MNLT/P-MLT group (Glick et al. 2012).

Hepatic Hemangiomatosis of Infancy

There are published observations of infantile hemangioma, i.e., postneonatal hemangiomatosis characterized by the combination of cutaneous hemangiomas and visceral/hepatic hemangiomas, i.e., cavernomas and not hemangioendotheliomas (Robinson and Hambleton 1977; Rotman et al. 1980; Larcher et al. 1981; Vorse et al. 1983; Platokouki et al. 1998; Mendiratta et al. 2008). Hepatic hemangiomas may be combined with other visceral hemangiomas, in particular splenic lesions (Platokouki et al. 1998). Similar to the neonatal situations, large and/or multiple lesions can cause cardiac failure (Vorse et al. 1983).

Pathogenic Pathways

The concomitant development of angiomatous lesions in the skin and visceral organs is striking and suggests an abnormal multifocal angiogenic

mechanism leading to the emergence of multiple circumscribed angiomatous malformations. The cause of this angiogenic response is not known, and we also do not know why such characteristic multifocal patterns arise and why certain organs and not others are involved. As some of the lesions can later undergo involution, a complex derangement of vascular growth versus vascular remodeling and regression through apoptosis may be operational. The transient growth of angiomatous lesions, in part modulated by external factors, in some way mimics the emergence of a definitive vascular network but with a highly abnormal growth overshoot.

Diffuse Hepatic Hemangiomatosis of Adults

Introduction

Diffuse hepatic hemangiomatosis of adults is a very rare condition with so far not well-known etiology and natural history. The disorder is mostly known from infants and is much less common in adults. It is defined as the presence of numerous synchronous hemangiomas, mostly of the cavernous type, in one liver lobe, right and left lobe, or the entire liver, in the absence of extrahepatic hemangiomas. The difference between "numerous" hemangiomas (diffuse hemangiomatosis) and "multiple" hemangiomas has not been clearly worked out. For the diagnosis of diffuse hemangiomatosis, the distribution pattern of the lesions is crucial, i.e., involvement of large parts of the liver or the entire liver. The prevalence of diffuse hemangiomatosis of the liver is not well known. Among 26 patients with hepatic hemangiomas, six were diffuse lesions (Dickie et al. 2009). Sometimes, accompanying hemangiomatosis of the spleen is present (diffuse hepatosplenic hemangiomatosis; Tarazov et al. 1990; Langner et al. 2001). Most patients are women (Popa et al. 1984; Langsteger et al. 1990; Lehmann et al. 1999; Moon et al. 2000; Guzman-Valdivia Gomez et al. 2006; Kim et al. 2008).

Clinical and Imaging Features

The clinical presentation of hepatic hemangiomatosis is usually nonspecific and related to multiple mass effects and hepatomegaly. Some of the patients experience moderate to intense abdominal pain. Patients with diffuse liver hemangiomas sometimes produce significant tumor-associated shunts, followed by heart failure (Jayanthi et al. 2000). Diffuse hepatic hemangiomatosis with its enormous coagulative vascular surface with altered endothelial features can cause thrombocytopenia (Jayanthi et al. 2000). Extensive hemangiomatosis can cause sinusoidal compression/congestion, thereby causing a sinusoidal blockage and eventually portal hypertension with esophagogastric varices. The hemangiomas may behave in a stable way, with minor or absent change with time, but progressive forms extending from liver lobe to the other are known (Lehmann et al. 1999). Diffuse hepatic hemangiomatosis can be associated with secondary polycythemia (Popa et al. 1984). The cause of progressive growth is not established, but enhanced growth of hepatic hemangiomatosis was observed in two adults following postmenopausal estrogen replacement therapy (Ozakyol and Kebapci 2006). One patient with secondary polycythemia has been described (Popa et al. 1984).

Diffuse hepatic hemangiomatosis has characteristic imaging features on US, CT, and MR images (Crespo Uriguen et al. 1988; Feurle 1990; Langsteger et al. 1990; Frangides et al. 1995; Lehmann et al. 1999; Moon et al. 2000; Vilgrain et al. 2000; Mihalche and Dumitrache 2004; Guzman-Valdivia Gomez et al. 2006; Blondet et al. 2007). Ultrasonography shows small to large, hypoechoic masses with ill-defined margins to the adjacent liver substance, but confluent hyperechoic masses are also in evidence (Vilgrain et al. 2000). Contrast enhancement with a centripetal filling pattern of the entire tumors on the delayed phase of dynamic CT and inhomogeneous diffuse uptake of the entire tumor on delayed blood-pool images on

99mTc-labeled red blood cell scans are characteristic features (Kim et al. 2008). As the tumorous lesions have prominent flow, hepatic artery branches as the feeding vessels are dilated (Moon et al. 2000). On MR images, most tumors showed a low signal intensity on T1-weighted images and a high signal intensity on T2-weighted images. Areas with macroscopic cystic change have foci of lower intensity than the remainder of tumor on T1-weighted images and higher intensity than the remainder of tumor on T2-weighted images (Moon et al. 2000).

Pathology

In most cases, the liver lobes are densely involved by hemangiomatous nodules of variable diameters (Fig. 1), resulting in distinct patterns summarized in Table 1. In part of patients, the entire liver is packed with typical, well-delineated angiomatous tumors, with thin and partly atrophic parenchymal bridges between the nodules (massive panhepatic hemangiomatosis, MPHH). In regard to the distribution of lesions, a diffuse pattern, in which numerous tumors are present as isolated, more or less evenly distributed hemangiomas, and nodular pattern consisting of multiple coalescent nodules measuring <5 mm in diameter have been distinguished (Jhaveri et al. 2011). Individual tumors may exceed 4 cm in diameter and therefore qualify for giant hemangiomas. In fact, hemangiomatosis can be associated with giant hepatic hemangiomas in a significant proportion of cases (Adam et al. 1970; Jhaveri et al. 2011). In a series of 22 patients with giant hepatic hemangioma, associated diffuse hemangiomatosis involving the right and left liver lobes was found in four patients (Adam et al. 1970). At laparoscopy, multiple to numerous medium-sized to large blue-black spongy masses are seen, sometimes bulging from the liver surface (Guzman-Valdivia Gomez et al. 2006). Pedunculated lesions also occur (Blondet et al. 2007). The number and size of hemangiomas may be such as to grossly mimic massive diffuse hepatic metastatic disease.

Most tumors show the typical histology of cavernous hemangiomas, with large, endothelium-lined channels prevailing in the core region of the tumors and smaller vascular channels at the periphery of the nodules, where also feeding vessels are found, and regressive changes in the center (fibrosis, thrombosis, granulation tissue). As in isolated giant liver hemangiomas, large tumors may show extended central fibrosclerosis or even hyalinosis and sometimes fresh or old infarctoid necrosis. The adjacent liver substance reveals perifocal parenchymal atrophy or fatty change of hepatocytes and may contain dilated veins or intermediate vessels, sometimes rather remote from the tumor nodules (Lehmann et al. 1999).

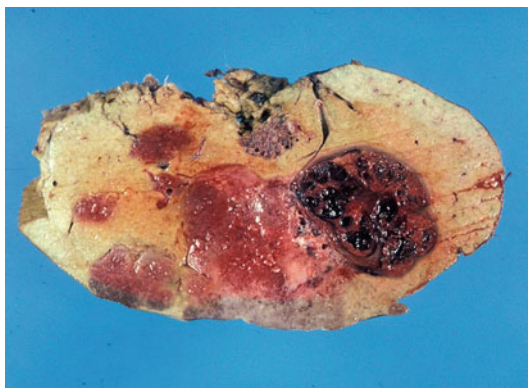

Fig. 1 Hepatic hemangiomatosis of the adult. The liver contains several well-delineated foci of hemangioma, in part with fresh thrombosis

Table 1 Proposed classification of macroscopic patterns of diffuse hepatic hemangiomatosis of adults

General patterns
Diffuse hepatic small-nodular hemangiomatosis
Diffuse hepatic hemangiomatosis associated with giant hemangiomas
Diffuse hepatic hemangiomatosis with pedunculated lesions
Massive panhepatic hemangiomatosis (MPHH)
Diffuse versus nodular patterns (Jhaveri et al. 2011)
Diffuse pattern (more or less even distribution of isolated tumors)
Nodular pattern (multiple coalescent small nodules)

Diffuse Hemangiomatosis of the Liver and Spleen (Diffuse Hepatosplenic Hemangiomatosis)

In part of the patients with diffuse hemangiomatosis, the liver and spleen are synchronously involved (Tarazov et al. 1990, 1991; Langner et al. 2001). This entity may be associated with progressive liver failure, thrombocytopenia, and coagulopathy (Langner et al. 2001).

Focal and Diffuse Hemangiomatosis Associated with Giant Hepatic Hemangioma

Circumscribed or focal, or even diffuse, hemangiomatosis with the development of multiple small nodules may be noted in association with large cavernous hepatic hemangiomas (so-called giant hemangiomas; Melis 1954; Jhaveri et al. 2011). Among 42 cases of giant hepatic hemangioma, associated hepatic hemangiomatosis was detected in 18 patients (44 %). Twelve patients had a diffuse pattern of hemangiomatosis (67 %), and six patients showed a nodular pattern consisting of multiple coalescent nodules measuring <5 mm (33 %). There was no association between the size of the giant hemangioma and extent of hemangiomatosis (Jhaveri et al. 2011). The pathogenesis of this alteration has not been clarified. Theoretically, small and satellite-like hemangiomas in the vicinity of a large lesion may emerge due to the abnormal blood circulation surrounding the large lesion, or may reflect a field effect, i.e., emergence of multiple angiomas within an abnormal vascular bed, with one and large predominant lesion.

Hepatic Hemangiomas in Systemic Adult Hemangiomatosis (Polysomatic Hemangiomatosis)

Systemic hemangiomatosis (diffuse hemangiomatosis, hemangiomatosis diffusa) is a very rare condition characterized by the occurrence of cavernous hemangiomas in multiple organ systems, including the skin, bone, central nervous system, and visceral organs. The process has either been interpreted to be neoplastic or to represent a hamartoma-like malformation, but the involvement of numerous tissue and organ types together with continuous growth in at least part of the patients favors a highly abnormal angiogenic and probably neoplastic process. The disease is sporadic, without evidence of a familial trait (Fischer and Roeckl 1961; Tsukagoshi et al. 1998; Erdogan et al. 2003). Visceral manifestations can involve several intra-abdominal organs, e.g., the spleen, liver, intestine, peritoneum, and lymph nodes, in one and the same patient (Maeda et al. 1981; Ribback et al. 2011). Some cases have revealed an aggressive course with poor prognosis, owing to continuous growth of the lesions (Böhm et al. 1980).

Liver involvement in the form of cavernous hemangiomas has been observed (Bargon and Yu 1968; Gordin et al. 1975; Maeda et al. 1981; Erdogan et al. 2003; Edlow et al. 2006). Liver involvement can be associated with angiomatous lesions of the intestine, spleen, and lymph nodes (Maeda et al. 1981). The angiomatous lesions developing in the liver may be extensive and cystic, resulting in a "honeycomb-like" liver (Tsukagoshi et al. 1998).

Hepatic Hemangiomas Combined with Skeletal Hemangiomatosis

Diffuse skeletal hemangiomatosis (disappearing bone disease) is a very uncommon disorder, which is characterized by osteolytic angiomatous lesions causing vanishing bone in part of the patients (syndrome of phantom bone or disappearing bone). An aggressive form of the disease that shows regional involvement and massive osteolysis, frequently involving the shoulder and hip areas, is called Gorham's disease. In the marrow cavities of involved bones, numerous thin-walled and partly dilated vascular channels are present, with signs of bone substance lysis in

the vicinity (Bezold 1951; Gorham et al. 1954; Ishida et al. 1994; Wallis et al. 1994, Clayer 2002).

The disorder is sometimes associated with visceral and in particular hepatic hemangiomas (Bargon and Yu 1968; Waldron and Zeller 1969; Kane and Newman 1973; van den Bosch et al. 1975; Rolain et al. 1978; Körster and Jansen 1981; Kiriyama et al. 2001). In an old female patient described by Kane and Newman (1973), marked hepatomegaly was found, tender to palpation. A large left lobe presented as an epigastric mass with a systolic bruit. A liver scan showed an enlarged pattern with increased uptake in the left lobe. Transfemoral visceral angiography demonstrated numerous diffuse capillary-sized hemangiomatous vessels accounting for hepatomegaly and bruit. There was rapid shunting to the hepatic veins and inferior vena cava and retrograde filling of the portal vein, coronary vein, and gastric and mesenteric collateral veins.

Hepatic Hemangioma in Cystic Angiomatosis of the Bone

Cystic angiomatosis of the bone (CAB, diffuse cystic angiomatosis of the bone; Gorham's vanishing bone disease; Gorham's massive osteolysis; Gorham-Stout syndrome; phantom bone disease; idiopathic massive osteolysis) is a rare, multicentric disease characterized by involvement of blood and lymph vessel systems, producing diffuse cystic lesions in the skeleton, predominantly affecting the trunk bones (review: Möller et al. 1999).

This intriguing disorder has been described in 1914 (Shennan 1914; "histologically nonmalignant angioma, with numerous metastases"), and the term CAB was coined in 1953 (Jacobs and Kimmelstiel 1953). In most cases, CAB will show a widespread distribution in the skeleton, but very rare localized forms have also be encountered, e.g., in the cranio-cervical region (Pavanello et al. 2007). Familial CAB has been observed in one family over four generations (Reid et al. 1989) and four siblings showing congenital generalized lipodystrophy accompanied by CAB (Brunzell et al. 1968). In its presentation, CAB is similar to diffuse angiomatosis of the bone, but the relationship between these two disorders has not yet been clarified. Histologically, CAB shows a contribution of lymph vessels, a feature usually lacking in diffuse angiomatosis of the bone. CAB causes osteolytic lesions with internal septation of the bone and a honeycomb appearance of the skeletal system (Jacobs and Kimmelstiel 1953; Ritchie and Zeier 1956; Boyle 1972; Shivaram et al. 2007; Pulido-Zamudia 2001; Malik et al. 2008).

CAB may be associated with chylothorax (Deveci et al. 2011) and with visceral hemangiomas, including hepatic hemangiomas and splenic angiomas/angiomatosis (Fernandez Jimenez et al. 2000; Vanhoenacker et al. 2003). In two patients found in the literature, only splenomegaly was noted (Shennan 1914). Lymphangioma of the spleen has been described in CAB (Boyle 1972), further supporting the involvement of the lymph vessel system and a systemic lymphangial disorder in CAB.

Hepatic Hemangiomas in Segmental Infantile Hemangioma and Reticular Infantile Hemangioma

Introduction

An uncommon form of cutaneous infantile hemangioma is characterized by a flat, blotchy lesion, which, in the past, has been called "port-wine stain-like". When occurring in the face, this variant is called "segmental" and is known to be an indicator for posterior fossa brain malformations, hemangiomas, arterial anomalies, coarctation of the aorta, cardiac defects, and eye malformations (the PHACE association; Frieden et al. 1996; Haggstrom et al. 2010). Later, this variant of cutaneous hemangioma has been renamed, reticular infantile hemangioma, to denote this distinctive macular, network-like lesion (Mulliken et al. 2007).

Liver Involvement in Segmental Hemangioma

A total of 47 cases of solitary segmental hemangiomas of the skin in association with visceral hemangiomatosis has been reviewed. Among these cases, the liver was the most common internal organ involved by hemangiomas (43 % of the cases; Metry et al. 2004).

Liver Involvement in Reticular Hemangioma

In this hemangioma, liver manifestations may be present. In one male infant with reticular cutaneous hemangioma associated with arteriovenous shunting in the pelvis and lower extremity, the liver showed multiple nodular enhancing lesions on T2-weighted MRI, consistent with multiple hemangiomas (Mulliken et al. 2007).

Intravascular Papillary Endothelial Hyperplasia (IPEH) of the Liver

Introduction

Intravascular papillary endothelial hyperplasia (IPEH; synonyms: Masson's pseudoangiosarcoma; Masson lesion; Masson's tumor) was described by Masson in 1923 under the term, hémangioendothéliome végétant intravasculaire (vegetant intravascular hemangioendothelioma, Masson 1923; review: Steffen 2003). In 1932, the lesion was described again by use of a different terminology (thrombopoietic proliferating endovasculitis; Henschen 1932). IPEH is now regarded as a benign, nonneoplastic vascular lesion originating from an organizing vascular thrombus or, less frequently, from a hematoma, with unusual reactive proliferation of endothelial cells (Clearkin and Enzinger 1976; Hashimoto et al. 1983). Variants of PEH developing in an extravascular compartment and specifically in hematomas are termed extravascular papillary endothelial hyperplasia (EPEH; Pins et al. 1993; Sezgin et al. 2005).

The lesion typically occurs in adults, but pediatric cases have also been reported. IPEH has a propensity to occur in the skin and subcutis, but other locations are also well documented, including the breast and mammary subcutaneous tissue, oral cavity, hypopharynx and larynx, parotid gland, lung, intestinal tract, spleen, tendon sheaths, kidney, urinary bladder, renal vein, other large vessels and their aneurysms, adrenal, retroperitoneal space, bone, central nervous system, and liver (Hong et al. 2004; Kan et al. 2004). In the skin, IPEH may present as multiple recurrent dark to almost black papular lesions involving the entire body, resembling cutaneous metastases of malignant melanoma. IPEH is commonly a slow-growing lesion, but phases of rapid enlargement of the process may be caused by repeated bleeding into the lesion, and hemorrhage from IPEH may be massive (Jung et al. 2005; Rizza et al. 2009).

IPEH of the Hepatobiliary System

IPEH can involve the gastrointestinal tract (Meadows et al. 2010). Very rarely, IPEH has been detected in the liver (Hong et al. 2004; Kan et al. 2004). A 69-year-old female showed, on abdominal CT scan, a 10 × 7 cm-sized, lobulated heterogeneous contrast-enhancing soft tissue mass involving the entire left liver lobe (Hong et al. 2004). In the arterial phase of CT, the mass had a focal nodular enhancement around its peripheral portion, whereas in the delayed phase, there was a persistent low-density noncontrast-enhancing portion in the tumor center. Angiography exhibited some tumor-supplying arteries originating from the left hepatic artery. The mass seen during operation was limited to the left liver lobe, of 10 × 7 cm size, and was a nonhomogeneous multinodular mass including focal necrosis. No major vessel invasion was observed. Histology of the resection specimen showed IPEH. The 65-year-old male patient described by Kan and coworkers (Kan et al. 2004) had a cystic, focally calcified mass of several cm diameter located within a dilated left ventricular cavity. This mass appeared to float

between the ventricle and mitral valve area. Multiple hyperechoic hepatic nodules were also identified on an abdominal sonograph. Histology of the resected lesion showed IPEH, and similar alterations were found in liver biopsies. The liver nodules had the same papillary structures within the liver parenchyma but had spared the portal tracts.

Pathology

Based in the pattern of lesion development, IPEH is pathologically classified in three subtypes: a pure form, the most common, in which the lesion arises in dilated blood vessels; a mixed form in which IPEH arises in preexisting vascular alterations (hemangioma, aneurysm, arteriovenous malformation, and pyogenic granuloma), and an extravascular form, the latter called EPEH.

Histologically, two different papillary structures are observed: one defined as inflammatory papilla constantly associated with thrombotic material and the other defined as fibrous papilla in the absence of a visible thrombus (Eusebi et al. 1980). IPEH may mimic Kaposi's sarcoma (Reed et al. 1984; Torres and Rodriguez 1984). Immunohistochemically, the endothelial structures are reactive for CD34, and the spindle cells are positive for vimentin and, in part, smooth muscle actin (Soares et al. 2008). Reactivity of endothelial cells for factor VIII-associated antigen was only observed in advanced or "mature" lesions, similar to what happens in organizing thrombi (Albrecht and Kahn 1990).

Pathogenesis

There is clear evidence that IPEH arises from an exuberant organizing reaction within a thrombus (organizing thrombus theory; Del Rio et al. 1992). Similar lesions are sometimes found within hematomas, i.e., outside vascular spaces (EPEH; see above; Pins et al. 1993; Aulicino et al. 1995; Sezgin et al. 2005).

Hepatic Angioleiomyoma

Introduction

Angioleiomyoma (angiomyoma, vascular leiomyoma) is a benign soft tissue tumor that usually develops in the subcutaneous tissue of the lower extremities. These circumscribed nodules consist of intertwined thick-walled, abnormal vessel structures formed by proliferating smooth muscle cells and narrow or slit-like vascular channels (reviews: Hachisuga et al. 1984; Ramesh et al. 2004).

Clinical and Imaging Findings

Angioleiomyoma commonly presents as a painful mass in about 60 % of the cases. Tumors located in the extremities, and specifically in the hand, typical display swelling with physical activity of the involved part (Hachisuga et al. 1984; Ramesh et al. 2004). Pain of the nodule (tuberculum dolorosum) is thought to be caused by local ischemia due to contraction of the tumor vessels. In an analysis of 229 cases, the lesions were detected in high incidence in the fourth to sixth decade, with a clear predilection for females (Katenkamp et al. 1988).

Cytogenetic Findings

Relatively few data are available concerning karyotypic aberrations in angioleiomyomas, including t(X;10)(q22;q23.2) (Sonobe et al. 1996), del (6)(p21p23), del(21)(q21)[12] (Heim et al. 1986), t(X;11)(p11.4;p15) (Hennig et al. 1999)), and t(4;5)(p12;q33), der(13;15)(q10;q10) (Welborn et al. 2010), and del(6)(q13q23), add(8)(q24),del (19)(q10) (Welborn et al. 2010). Comparative genomic hybridization was employed to study relative DNA copy number changes in 33 angioleiomyomas. In about a third of the cases, DNA copy number changes involved one or two chromosomes with losses of chromosome 22 being the most common (Nishio et al. 2004).

Angioleiomyoma of the Hepatobiliary Tract

Angioleiomyoma of the liver has been described in 60-year-old woman with mild upper right quadrant pain for 1 month. Plain spiral CT scans showed a solitary, well-demarcated liver lesion of 4 cm diameter in liver segment VIII. CT with contrast revealed slight homogeneous enhancement (60 HU) of the tumor in relation to the surrounding normal liver substance. Tumor biopsy showed typical angioleiomyoma, with medium-sized blood vessels with thickened walls. The vessel wall cells were in concentric order with intervening radiant emission of spindle and epithelioid cells in intervascular bundles. The patient had an eventful course (Beissert et al. 2002). Angioleiomyoma has been observed in the gallbladder, sometimes causing hemobilia and acute colicky pain (Aschl et al. 1999; Segura-Sampedro et al. 2012).

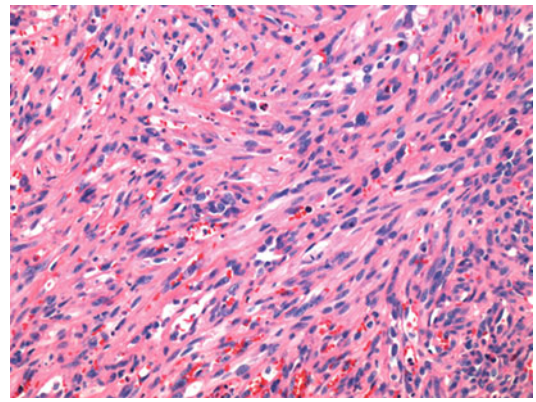

Fig. 2 Hepatic angioleiomyoma. Slit-like vascular spaces with intervening smooth muscle cells (hematoxylin and eosin stain)

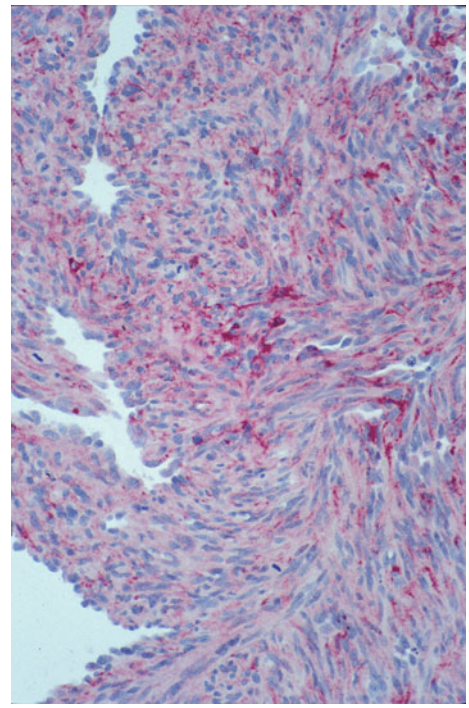

Fig. 3 Hepatic angioleiomyoma. Numerous neoplastic spindle cells are reactive for smooth muscle actin (alpha-SMA immunostain)

Pathology

Histologically, four variants have been described, i.e., solid/capillary forms (18 %), venous forms (38 %), mixed/combined forms (43 %), and cavernous forms (<1 %) (Hachisuga et al. 1984; Katenkamp et al. 1988; Figs. 2 and 3). Mixed and cavernous forms seem to be more frequent in male patients (Katenkamp et al. 1988). Most of the cells forming the nodule are strongly reactive for alpha smooth muscle actin. Immunohistochemically, the tumor itself does not contain CD34-positive stromal cells, but bundles of such cells are present at the tumor border and in the adventitial tissue of the surrounding normal vessels (Nakayama et al. 2002). Subcutaneous smooth muscle tumors stain for p16 (Longano et al. 2010).

Hemangioblastoma

ICD-O code 9161/1

Introduction

Hemangioblastoma (synonym, capillary hemangioblastoma) is a distinct benign vascular tumor of uncertain histogenesis characterized by

a network of vascular channels admixed with often lipid-laden macrophages (the stromal cells). Most hemangioblastoma develops in the central nervous system, particularly in the area of the cerebellum and less often in the lateral ventricle, corpus callosum, spinal cord, retina, optic nerve, pituitary gland, pineal gland, and meninges. Up to 2.5 % of all intracranial tumors are hemangioblastomas. Hemangioblastomas occur as sporadic lesions or arise in the setting of von Hippel-Lindau disease. A distinct pathway is involved in angioblastomas developing in von Hippel-Lindau (VHL) disease. In this disorder, angioblastomas typically emerge in the retina and the central nervous system, but they may also occur in other parts of the body. Organs and tissue involved with sporadic hemangioblastoma outside the CNS include the kidney, adrenal gland, and retroperitoneum. In the lung, a novel hemangioblastoma-like clear cell stromal tumor was found that may have a relation to the hemangioblastoma-associated stromal cells (Falconieri et al. 2013). Few hemangioblastomas have been shown to contain complex differentiation patterns, e.g., rhabdoid features (Yin et al. 2012). Hemangioblastomas occurring in the setting of VHL contain mast cells that seem to be tumor-derived (Merrill et al. 2013).

Primary Hepatic Angioblastoma

Hemangioblastoma can very rarely develop in the liver, even as multifocal hyperechogenic lesions (Rojiani et al. 1991; McGrath et al. 1992; Hayasaka et al. 1999). These hypervascular and arterialized masses have been reported to show the same histologic pattern as the respective CNS tumors, i.e., a complex mixture of vascular structures and stromal cells mainly representing lipid-laden foamy macrophage-like cells (Rojiani et al. 1991; Hayasaka et al. 1999). This morphologic presentation is clearly different from typical hepatic hemangioma, which may rarely occur in VHL (Zeitlin 1942). A part of the hepatic hemangioblastomas were developed in the setting of VHL (Hayasaka et al. 1999). In one patient with VHL, multiple hepatic and pulmonary hemangioblastomas were demonstrated (McGrath et al. 1992).

Other Hepatic Lesions Associated with von Hippel-Lindau Disease

Patients with VHL can develop ordinary hepatic hemangiomas (Yavas et al. 2013) and hepatic cysts (Lee et al. 2010) as a part of the VHL-associated multiple cyst syndrome.

Differential Diagnosis

The very rare hepatic hemangioblastomas may histologically be confounded with other hepatic angiomatous lesions having small vascular channels, such as capillary or lobular hemangiomas.

Pathogenic Pathways

Hemangioblastomas composed of a probably still immature endothelial lineage and stromal cells seem to represent a mimicker of an early mesodermal phase of angiogenesis. The potential involvement of an early mesodermal switch is supported by the reactivity of these tumors for the mesodermal transcription factor, brachyury/Bra (Barresi et al. 2012). The typical stromal cells of hemangioblastoma are thought to be committed stem cells, because they express both CD133 and Oct4, and are suggested to produce the distinct CD133-positive endothelium of these tumors (Welten et al. 2012). It has also been proposed that the tumors might derive from neoplastic transformation of neural stem cells in a specific niche (Ma et al. 2011) or from embryologic multipotent cells (Park et al. 2007). In the cerebella of patients with VHL, developmentally arrested structural elements (arrest of angioblastic lineage) were detected (Vortmeyer et al. 2003). These structures are composed of poorly differentiated cells expressing hypoxia-inducible factor (HIF)2alpha, but not HIF1alpha or brachyury. These elements were mainly found

in the molecular layer of the dorsum cerebelli, structures proposed to be developmentally arrested hemangioblast progenitor cells (Shively et al. 2011).

The cell systems involved in the pathogenesis of hemangioblastoma are subject to the complex metabolic alterations associated with von Hippel-Lindau disease (VHL), an autosomal-dominant disorder (OMIM 193300). Patients with VHL suffer from familial and sporadic hemangioblastomas, clear cell carcinoma of the kidney, pheochromocytoma, distinct neuroendocrine tumors, epididymal papillary cystadenomas, microcystic adenomas of the pancreas, endolymphatic sac tumors, cysts in several organs (mainly pancreas), and inherited forms of erythrocytosis (review: Maher et al. 2011). VHL is caused by germ line mutations of the VHL tumor suppressor gene and of the gene product, pVHL (review: Kortmeyer et al. 2013).

pVHL, which is localized to the cytoplasm of normal and neoplastic cells (Corless et al. 1997). has a central role in the regulation of oxygen sensing via the hypoxia-inducible factor (HIF) signaling cascade. HIFs are heterodimeric oxygen-sensing transcription factors that are crucially involved in the cellular adaptation to low oxygen environments. The extensive transcriptional program regulated by HIFs involves the induction of genes that control angiogenesis, cell proliferation and apoptosis, and mechanisms involved in metastasis. HIFs are heterodimers consisting of HIF-alpha and HIF-beta subunits. HIF-2alpha-dependent gene expression, such as ANGPLT4 and erythropoietin, are regulated by PARP-1/poly(ADP-ribose) polymerase-1 in the hypoxic response (Gonzalez-Flores et al. 2014). VHL acts as a master regulator of HIF activity by recognizing the substrate-recognition component of an E3 ubiquitin ligase complex that ubiquitinylates the hydroxylated catalytic alpha subunit of HIF for oxygen-dependent degradation (review: Haase 2009). Three cellular oxygen sensors mark the HIFs for pVHL-mediated degradations, i.e., the prolyl hydroxlyases PHD1, PHD2, and PHD3 (Pientka et al. 2012; Jaakkola and Rantanen 2013; Myllyharju and Koivunen 2013). The stability of HIF1alpha is increased by interaction of the transitionally controlled tumor protein/TCTP and degradation of pVHL. In hypoxic tumor tissues, VEGF expression is positively regulated by histone deacetylase 1/HDAC1 and negatively regulated by the pVHL via HIF1alpha (Reynoso-Roldan et al. 2012). HIF2alpha is regulated, in its action as a proangiogenic factor, by the orphan nuclear receptor TLX (Zeng et al. 2012). The role of HIFs as proliferation-stimulating factors depend on their role as an mTORC1 activator (Elorza et al. 2012).

pVHL binds to two subunits of the transcription elongation complex elongin, causing a decreased activity of this complex, suggesting that pVHL functions as a negative regulator of transcription elongation. There is evidence that regulated accumulation of HIF caused by failure of pVHL-mediated HIF degradation is an important factor in oncogenic pathways operating in VHL, e.g., in clear cell renal carcinoma. A second proposed oncogenic mechanism related to HIF involves E-cadherin, an adhesion molecule playing a significant role in cancerogenesis. pVHL promotes an E2-box-dependent E-cadherin transcription by HIF-mediated regulation of the transcription repressors SIP1 and snail (Evans et al. 2007). pVHL is also involved in the control of genomic stability. In response to DNA double-strand breaks, the suppressor of cytokine signaling 1 (SOCS1) promotes nuclear redistribution and K63 ubiquitinylation of pVHL. Loss of pVHL function in VHL compromises its K63 ubiquitinylation and attenuates the DNA-damage response, causing persistence of DNA double-strand breaks and promoting genomic instability and tumorigenesis (Metcalf et al. 2013). A further important role of pVHL, proposed to be involved in tumorigenesis, is related to cilial function. Primary cilium formation in renal cells requires the action of pVHL (Lutz and Burk 2006), and defective function of pVHL in VHL may thus promote renal and other cysts by failure of ciliogenesis (Rankin et al. 2006). This effect of pVHL on ciliogenesis depends of the phosphorylating factor, Nek1 (Patil et al. 2013). The high frequency of renal carcinomas in VHL may also be connected with a cilial connection of pVHL. It was found that human renal carcinomas have a lower frequency of cilia than the

neighboring parenchymal tissue (Basten et al. 2013). Mice with targeted inactivation of the VHL gene developed hepatic cavernous hemangiomas (Haase et al. 2001), while in another murine model, VHL and PTEN conditional deletions caused multiple cavernous liver lesions in a coordinated manner (Chen et al. 2010). The probability of developing familial or recurrent sporadic hemangioblastoma in patients with mutated VHL is higher in the presence of a vitronectin M381T polymorphism (Huang et al. 2009).

Liver Involvement in Splenic Littoral Cell Tumors

Introduction

Littoral cell vascular tumors of the spleen form a unique group of vascular neoplasms are derived from cells of the red pulp, with a variable biology of disease. Littoral cell angioma, the most common form within the group, was first described in 1991 (Falk et al. 1991). Since then, other variants have been defined. The neoplastic cell is regarded as the transformed offspring of splenic littoral cells or venous sinus-lining cells (Rosso et al. 1995, 1996; Johnson et al. 2007; Kranzfelder et al. 2012; Larsen et al. 2013). The tumors can be divided into splenic littoral cell angioma (SLCA), splenic littoral cell hemangioendothelioma (SLCH), and littoral cell angiosarcoma (SLCAS) (He et al. 2014).

SLCA is regarded as benign and usually occurs in adults without gender predilection. The solitary or multiple nodules can cause significant asymptomatic or symptomatic splenomegaly. Multiple nodules are found in 85 % of cases. SLCA can occur with concomitant visceral malignancies, such as colorectal cancer, pancreatic carcinoma, renal cell carcinoma, urologic cancer, ovarian cancer, and lung carcinomas, and was also observed in association with melanoma and lymphoma. SLCH shows a protracted course (Ben-Izhak et al. 2001) and can behave in a low-grade malignant manner. SLCAS exists as low- and high-grade malignancy lesions (Rosso and Paulli 2004). Histologically, littoral cell vascular tumors are composed of a network of ectatic blood-filled channels lined by plump, bland, or atypical cells that may form intraluminal papillary fronds and show erythrophagocytosis. There seems to be a transition from littoral cell angioma to low-grade malignant forms (Fernandez et al. 2006). Immunohistochemically, the littoral tumor cells are reactive for CD31, CD68, CD21, and CD163 but negative for CD34 . This unique cell therefore expresses both endothelial and macrophage/histiocyte markers (Fernandez et al. 2006; Larsen et al. 2013). Littoral cells or splenic venous sinus-lining cells highly express the formin homology domain protein 1, the red blood cell Duffy antigen receptor for chemokines, CD8 a/a, and SIRPa (CD172a).

Liver Involvement in Littoral Cell Hemangioendothelioma and Littoral Cell Angiosarcoma

Both SLCH and SLCAS can metastasize to the liver (Fernandez et al. 2006; Wang et al. 2013; He et al. 2014). In SLCH, two forms have been shown to metastasize to the liver, a more common typical hemangioendothelioma with nuclear atypia and necrosis, and an uncommon variant with bland, plump cells (Fernandez et al. 2006). Most cases of SLCAS metastasizing to the liver form metastatic nodular masses, but diffuse spread to the liver is also known. Specifically, low-grade SLCAS can spread to the liver with a diffusely infiltrating pattern (Larsen et al. 2013). SLCH and SLCAS metastasizing to the liver show the same histology and immunohistochemical phenotype as the primary splenic tumors.

Hepatic Hemangioendothelioma with Epithelioid Morphology and Eosinophilia

Introduction

Vascular tumors are characterized by an epithelioid phenotype of endothelial cells from a complex group of neoplasms with a broad spectrum of

biologic behavior, ranging from benign to potentially malignant and frankly malignant (the family of epithelioid vascular tumors; Tsang and Chan 1993). The most common epithelioid vascular tumor of the liver is epithelioid hemangioendothelioma (HEHE), but there are few lesions with an epithelioid phenotype that deviate from the features of HEHE. Hepatic hemangioendothelioma with epithelioid morphology and eosinophilia is a very rare example of such unusual vascular liver tumors.

Clinical Features

As described in the original report (Kimura et al. 2006), a 33-year-old man was found to have hepatosplenomegaly, an itchy eczematous rash scattered on the trunk and the extremities, marked peripheral blood eosinophilia, markedly elevated IgE serum levels, and an increased serum IL-5. A bone marrow biopsy showed a hypercellular hemopoietic tissue with increased eosinopoiesis but without signs of malignancy. No chromosomal anomalies were detected in marrow cells. Liver biopsy revealed an eosinophil infiltrated and a vascular proliferation characterized by well-formed blood vessels lined with plump endothelial cells (positive for CD31 and factor VIII-associated antigen but not for CD34) with eosinophilic cytoplasm and a large vesicular nucleus. Steroid therapy improved the skin lesions and hydroxyurea normalized eosinophilia, but 1 year after diagnosis, liver failure ensued causing death.

Pathology

Autopsy revealed massive hepatomegaly (4,160 g) and ill-defined multiple spongy lesions scattered throughout the liver. In addition, nodular gray to white areas, 2–6 cm in diameter, were observed in this organ.

Microscopically, the lesions were composed of vascular proliferations with epithelioid endothelial cells as already seen in the liver biopsy. A part of these endothelial cells had a vacuolated cytoplasm. Dilated vascular channels and solid areas with few vascular spaces were noted.

The histologic phenotype somewhat resembles other vascular proliferations with an inflammatory response, encompassing such entities as angiolymphoid hyperplasia with eosinophilia (ALHE), inflammatory angiomatous nodules, atypical pyogenic granuloma, histiocytoid hemangioma, and Kimura's disease.

Hepatic Epithelioid Hemangioendothelioma

51

Contents

Abstract

Hepatic epithelioid hemangioendothelioma (HEHE) is a rare vascular neoplasm which is the hepatic counterpart of lesions that develop in various tissues and organs. This tumor consists of a distinct vascular cell type that resembles epithelial cells, but not belonging to an epithelial cell lineage, hence the term epithelioid. HEHE occurs in all age groups, but is more common in individuals older than 40 years. Macroscopically, HEHE presents as solitary to multiple firm to rubbery nodules with infiltrative borders. Multiplicity was observed in more than 80 %. Histologically, the lesion consists of three cell types, i.e., epithelioid, dendritic, and intermediate cells. The common eosinophilic epithelioid cells form strands embedded in stroma. Formation of signet ring-like cells with intracytoplasmic lumina or vacuoles is a typical feature. Dendritic cells show a spindled or stellate morphology and intracytoplasmic lumina as well. Immunohistochemically, the cells are reactive for CD31, CD34, and vimentin and sometimes also cytokeratins. HEHE generally behaves as a low-grade malignant tumor with a slow progression phenotype, but may follow a more aggressive course in older subjects, with metastases and fatal outcome.

Introduction

Epithelioid hemangioendothelioma (EHE) was first described as a distinct entity in 1982, based on 41 soft tissue lesions, as a vascular tumor with unpredictable biology (Weiss and Enzinger 1982), estimated to be of intermediate malignancy. EHE can occur as a solitary tumor in diverse organs or can rarely also present with multiorgan involvement (Weiss et al. 1986; Celikel et al. 2007). The primary liver manifestation of EHE, hepatic epithelioid hemangioendothelioma (HEHE), is an uncommon vascular tumor. This neoplasm consists of a distinct vascular cell type occurring in three morphotypes, and not an epithelial cell, hence the term epithelioid. Owing to the lack of any conclusive marker profiles, the diagnosis of HEHE is difficult and therefore requires histologic and immunohistochemical confirmation by use of a biopsy.

Selected References (Ishak et al. 1984; Kawabe et al. 1987; Noguchi et al. 1987; Ruebner and Eggleston 1987; Cobden et al. 1988; Darras et al. 1988; Kelleher et al. 1989; Bancel et al. 1993; Hidaka et al. 1995; Läuffer et al. 1996; Pokharna et al. 1997; Makhlouf et al. 1999; Uchimura et al. 2001; d'Annibale et al. 2002, with a literature update; Woddall et al. 2008; Lutgendorf et al. 2009).

Epidemiology

HEHE has been reported to occur predominantly in females in contrast to tumors arising in soft tissues (61 % vs. 39 %; Makhlouf et al. 1999), but this has not been confirmed for Japanese patients (Uchimura et al. 2001). The mean age at presentation varies between about 46 years and 60 years, depending on the series. In a collection of 137 patients, only relatively few patients are 20 or less than 20 years old at presentation (Makhlouf et al. 1999; Da Ines et al. 2010; Zhang et al. 2010). In a study of 12 pediatric patients, age at diagnosis ranged from fetal to 5 years, with nine females versus three males (Zhang et al. 2010). HEHE may very rarely be associated with malformations, e.g., congenital hemihypertrophy (Miller et al. 1999).

Clinical and Imaging Features

Apart from asymptomatic patients (42 % in a series of 137 patients; Makhlouf et al. 1999), HEHE may present with abdominal pain, jaundice, and ascites (Makhlouf et al. 1999; Ben-Haim et al. 1999). In rare circumstances, HEHE may be complicated by Budd-Chiari syndrome (Clements et al. 1986; Hayashi et al. 1999; Ozturk et al. 2009) or by hepatic vein invasion with a VOD-like presentation (Fukayama et al. 1984; Eckstein and Ravich 1986). On the other hand, invasion of outflow tract veins by HEHE can mimic Budd-Chiari syndrome (Walsh et al. 1998). The angioinvasive phenotype, characterized by spreads through medium-sized to large vein (Fukayama et al. 1984), can cause ischemia followed by hepatic necrosis and fever of unknown origin (De Man et al. 1994). Necrosis and hemorrhage can result in rupture of the tumor (Lau et al. 1989). Exceptionally, HEHE was found to cause Kasabach-Merritt syndrome (Imanishi et al. 2002; Frider et al. 2005). HEHE may occur in combination with EHE located elsewhere, e.g., the lung and mediastinum (Maamouri et al. 2008). In rare instances, HEHE was found in association with multiple focal nodular hyperplasia and cavernous hemangiomas of the liver (Bralet et al. 1999; Wanless 2000) or with nodular regenerative hyperplasia (Malamut et al. 2001).

HEHE generally behaves as a low-grade malignant tumor with a slow progression phenotype (Mosoia et al. 2008), but the neoplasm appears to be resistant to chemotherapy, and it may have an unfavorable outcome in older patients (Wang et al. 2012) and even follow a fatal course due to metastasizing (Ekfors et al. 1986; Bellmunt et al. 1989; Lee et al. 1989; Buccellato et al. 1990; Uchimura et al. 2001); Kayler et al. 2002; Aalaei and Jakate 2005; (Kassam and Mandel 2008; Komatsu et al. 2010;

Kim and Kim 2011), malignancy rarely also occurring in children (Taege et al. 1999). Part of patients with extensive liver disease are subjected to liver transplantation (Marino et al. 1988; Gelin et al. 1989; Kelleher et al. 1989; Van de Stadt et al. 1989; Bancel et al. 1993; Nudo et al. 2008; Tonglet et al. 2009), also in children (Guiteau et al. 2010; Otte and Zimmerman 2010). In a recent retrospective study on 11 patients, 7 patients had extrahepatic lesions, detected at preoperative imaging or discovered at exploration, two resections of apparently localized lesions were followed by rapid and aggressive recurrence, and of five patients undergoing liver transplantation, two died of tumor recurrence (Ben-Haim et al. 1999). In a minority of cases, extrahepatic metastases developed without intrahepatic recurrence after resection (Jeong et al. 2008). Few cases of HEHE present as a primarily malignant neoplasm (Sugahara et al. 1974; Dean et al. 1985; Dietze et al. 1989; review: Mehrabi et al. 2006).

Radiologically, about 20 % of the lesions exhibit focal calcifications, sometimes even resulting in subtotal liver calcification (Boruchowicz et al. 1993; den Bakker et al. 1998), and are nodular lesions at early stages, to then sometimes change into a diffuse growth pattern (Furui et al. 1989). Multiple nodules of HEHE may closely mimic metastatic hepatic disease (Kubota et al. 2012). On enhanced CT, the lesions showed peripheral enhancement only, whereas MRI exhibited low tumor signal on T1-weighted images and moderately high signal on T2-weighted images, and color Doppler ultrasound revealed a moderate vascularity at the periphery of nodules as well as central neovascularity (Darras et al. 1988; Radin et al. 1988; Terg et al. 1988; Miller et al. 1992; Van Beers et al. 1992; Pokharna et al. 1997; Shen et al. 1999; Kehagias et al. 2000; Nagase et al. 2000; Uchimura et al. 2001; Lyburn et al. 2003; Dighe et al. 2004; Mermuys et al. 2004; Matsushita et al. 2005; Askri et al. 2009; Ji et al. 2010; Lin and Ji 2010; Thin et al. 2010; Amin et al. 2011; Bruegel et al. 2011; Chen et al. 2011; Liu et al. 2011; Lupinacci et al. 2012; Mistry et al. 2012). On MRI images, the nodules may show multilayered target appearance with prominent peripheral rim with high signal intensity on T1-weighted images and very low signal intensity on T2-weighted images, corresponding to thrombosed or tumor-filled vascular channels (bright-dark sign; (Economopoulos et al. 2008). By use of MRI employing RES-specific contrast agent, a "bright-bright" sign is found (Paolantonio et al. 2009). PET revealed intense FDG uptake by these tumors (Nguyen 2004; Lin and Agoff 2007; Suga et al. 2009; Dong et al. 2013).

Pathology

Macroscopy

Macroscopically, HEHE was reported to usually present as pale and firm to rubbery lesions with infiltrative borders, single tumors having a mean diameter of 5.6 cm, and multiple lesions ranging from 0.2 to 14 cm (Fig. 1; (Makhlouf et al. 1999). In the latter series of 137 patients, multiplicity was detected in 82 % of cases, and such lesions may involve the entire liver. The cut surface is often heterogeneous, with red-brown flecks, abnormal vessels, and central fibrosis/scarring or infarction. Multiple and large tumors have also been observed in pediatric HEHE. In a study of 12 pediatric patients, the size of solitary lesions ranged from 5 to 13.8 cm, and solitary tumors presented as well-circumscribed, red-brown tumors with a

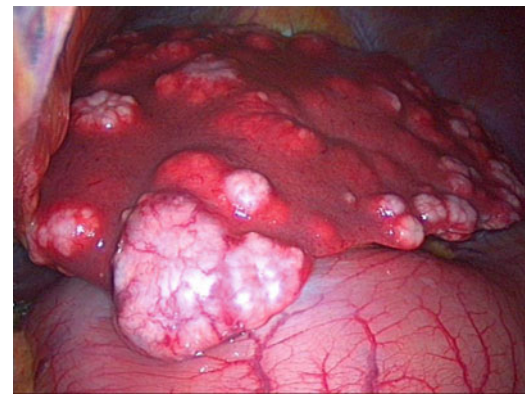

Fig. 1 Hepatic epithelioid hemangioendothelioma with exophytically growing, umbilicated nodules

smooth and glittering appearance and a capsule with abundant blood vessels (Zhang et al. 2010). Superficial/subcapsular tumors may show umbilication. In cases with multiple tumors, the liver capsule becomes highly irregular. In such cases, tumor size may be smaller, in the region of 1–2 cm, sometimes with coalescence of nodules.

Histopathology

Histologically, the neoplastic cell exhibits epithelioid, dendritic, or intermediate features, i.e., consists of three main cell types (Ishak et al. 1984; Dietze et al. 1989; Fedeli et al. 1991; Furuta et al. 1992; Jurczyk et al. 2014). The eosinophilic epithelioid cells occur in all cases and may show signet ring cell-like features representing intracytoplasmic lumina sometimes containing erythrocytes ("vacuoles"; Elias and Ryan 2003; Figs. 2, 3, 4, and 5). Dendritic cells reveal a spindle or stellate morphology with interdigitating processes; they can contain intracytoplasmic lumina as well and were observed to predominate in 16 % of HEHE (Makhlouf et al. 1999). The detection of mitotic figures varies markedly; in a large series, no mitoses were observed in 58 % (Makhlouf et al. 1999). The third cell type, the intermediate cell, is seen in nearly all cases. Typically, HEHE produces a stroma which may either be scanty or abundant, in the latter case with myxohyaline and sclerotic features which may be pronounced in the center of the tumor. The stroma may obliterate the hepatocyte plates, and in early lesions, the stromal reaction is particularly prominent in acinar zone 3 or the central parts of the lobules, i.e., preferring the outflow tract. HEHE exhibits a distinct growth pattern within the liver. The epithelioid cells invade the sinusoids, thereby resulting in hepatocyte plate atrophy, and veins (terminal, hepatic and portal veins), frequently producing polypoid or tufted intravenous structures (Makhlouf et al. 1999). There are variants of HEHE with a deviant histopathologic presentation, e.g., solid and vasoformative growth similar to hemangioendothelioma of bone, involvement of bone and the testis in addition to the liver, and marked peripheral eosinophilia (Kimura et al. 2006).

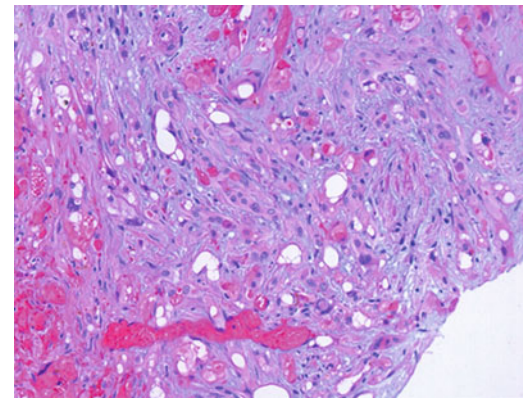

Fig. 2 Hepatic epithelioid hemangioendothelioma. Strands of tumor cells are embedded in a fibrous matrix and show large vacuoles (hematoxylin and eosin stain)

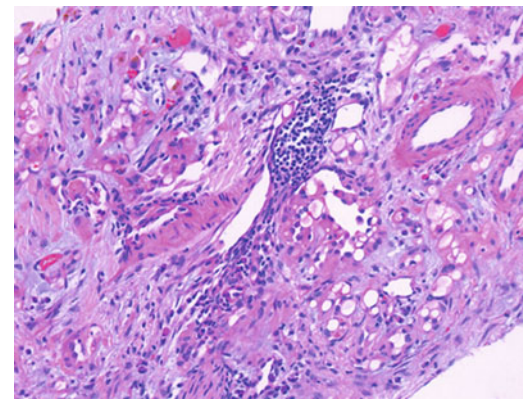

Fig. 3 Hepatic epithelioid hemangioendothelioma. Part of tumor cells with vacuoles project into vascular spaces (*right to the center* of figure; hematoxylin and eosin stain)

Immunohistochemistry

The origin of the neoplastic cell of HEHE is difficult to define, because the cells exhibit a complex marker profile (Makhlouf et al. 1999), with immunoreactivity for factor VIII-associated antigen (FVIII-AA; Ishak et al. 1984; Walsh et al. 1998; Hayashi et al. 1999; Miller et al. 1999; Uchimura et al. 2001), CD31 (Fig. 6; Makhlouf et al. 1999), CD34 (Walsh et al. 1998;

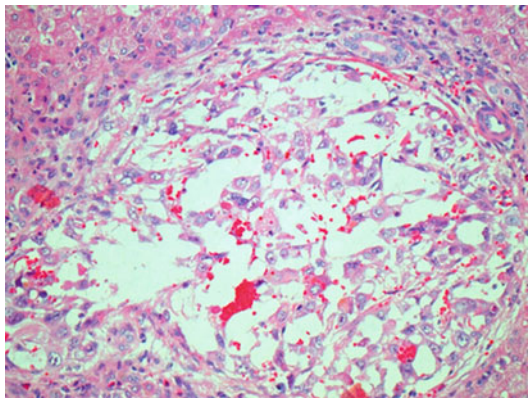

Fig. 4 Hepatic epithelioid hemangioendothelioma. Larger tumor focus with dissociation of cells, vacuole formations, and erythrophagocytosis (hematoxylin and eosin stain)

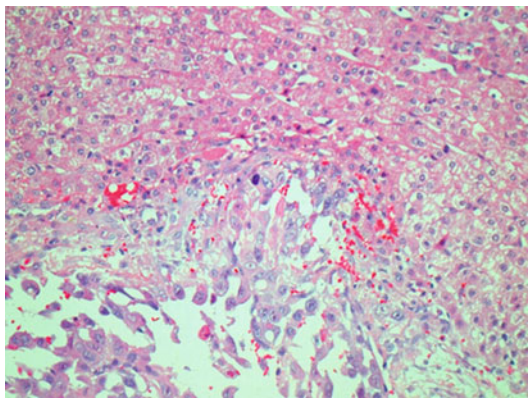

Fig. 5 Hepatic epithelioid hemangioendothelioma. In this tumor with pseudopapillary projections, the epithelioid aspect of tumor cells is clearly in evidence (hematoxylin and eosin stain)

Hayashi et al. 1999; Miller et al. 1999), vimentin (Hayashi et al. 1999), and UEA-1 (Hayashi et al. 1999). CD34 reactivity has been proposed to be more sensitive than FVIII-AA for recognition of disease (Demetris et al. 1997). In addition, cytokeratins have been observed in HEHE (Gray et al. 1990; in 14 %; Makhlouf et al. 1999) what has also been found in other EHEs (K7, K8, and K18, most frequently K18; Miettinen and Fetsch 2000). EHEs, including HEHE, show reactivity for claudin-5 (Miettinen et al. 2011), for

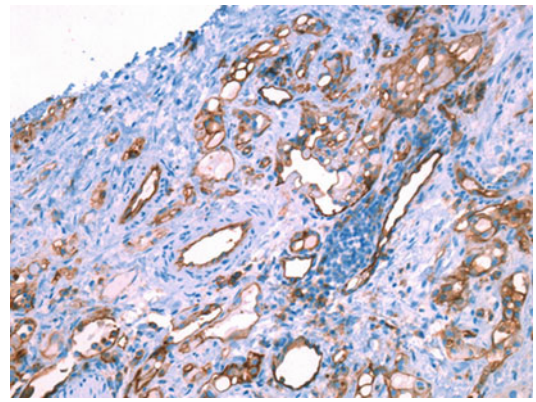

Fig. 6 Hepatic epithelioid hemangioendothelioma. The vacuolated tumor cells are reactive for CD31 (CD31 immunostain)

podoplanin (Fujii et al. 2008), and for CD10, the latter having a sensitivity of 78 % and a specificity of 70 % for EHE (Weinreb et al. 2009). HEHE regularly expresses VEGF, but only occasionally fms-related tyrosine kinase1/Flt-1 (Emamaullee et al. 2010).

Ultrastructure

Most of the tumor cells reveal features suggestive of an endothelial cell lineage, including presence of Weibel-Palade bodies and signs of vasoformative growth, characterized by formation of both intra-and extracellular vascular channels ("vacuoles"). Part of the cells share a phenotype with pericytes (Scoazec et al. 1989).

Cytogenetic and Molecular Features

EHE was found to have a recurrent WWTR1-CAMTA1 gene fusion, associated with t(1;3)(p36.3;q25), as consistent abnormality (Errani et al. 2011, 2012). CAMTA1 is a member of a calmodulin-binding transcription activator family of proteins, potentially involved in Ca2+ signaling-dependent cell cycle regulation. WWTR1 (synonym: TAZ) is a transcriptional co-activator with PDZ-binding motif, acting as a

downstream effector of the Hippo pathway controlling cell proliferation and apoptosis. Analysis of the WWTR1-CAMTA1 breakpoints revealed that multifocal EHEs are monoclonal lesions (Errani et al. 2012).

Pathogenesis

The observation of cytokeratin expression, albeit not found in all studies and also thought to be the result of antibody cross-reactivity (Makhlouf et al. 1999), is not a proof for an epithelial phenotype, because endothelia can express cytokeratins (Ramani et al. 1990; Miettinen and Fetsch 2000). Therefore, HEHEs seem to represent endothelium-derived tumors, but an alternative view has also been suggested, i.e., an origin from a "reticuloendothelial" cell differentiating along endothelial and dendritic cell pathways (Demetris et al. 1997). The endothelial phenotype of HEHE cells is further underlined by the ultrastructural observation of Weibel-Palade bodies in the tumor cells (Scoazec et al. 1989; Hayashi et al. 1999), but EM studies have, in addition, uncovered a cell type exhibiting the features resembling those of pericytes (Scoazec et al. 1989), suggesting that HEHE may differentiate along a complex mixture of cell lineages, mimicking successive steps of vascular morphogenesis.

So far, informations about the genetic background, biochemical properties, or the expression of angiogenic factors of/in EHE are very limited. In two EHE, cytogenetic studies have uncovered translocation t(1;3)(p36.3;q25) as a nonrandom aberration, but this has not been confirmed with other tumors so far (Mendlick et al. 2001). In a pulmonary EHE, expression of glucocorticoid receptor and 11-beta-hydroxysteroid dehydrogenase has been observed (Kumazawa et al. 2002). Immunohistochemically, VEGF and VEGF receptor flk-1 reactivity has been detected in a pediatric malignant HEHE, suggesting the regulation of tumor growth by this signaling pathway (Taege et al. 1999).

Infantile Hepatic Hemangioma/ Hemangioendothelioma

52

Contents

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_52

Abstract

Infantile hepatic hemangioma (IHE; previously termed infantile hepatic hemangioendothelioma) is a vascular liver tumor presenting as solitary or multiple lesions and diagnosed almost exclusively in infants and children before 6 months of age. Apart from focal involvement of the liver, a diffuse phenotype is also recognized. IHE usually manifests as hepatomegaly, but part of patients show cardiovascular failure due to intratumoral shunting, coagulopathy, jaundice, respiratory distress, and a distinct form of consumptive hypothyroidism. IHE can be associated with angiomatous lesions in other organs, including chorangioma of the placenta. Macroscopically, IHE manifests as solitary or multiple, well-circumscribed, and spherical vascular tumors. Histology is characterized by a network of densely arranged and thin vascular channels with an endothelial lining. Calcifications and other regressive changes can develop. Part of patients show a histology with variable cellular atypias, previously termed type 2 lesions. There is an overlap between such lesions and a distinct form of infantile hepatic angiosarcoma.

Introduction

Infantile hepatic hemangioma (IHE) (synonym: infantile hepatic hemangioendothelioma, IHHE) is a vascular liver tumor that presents with solitary or multiple lesions, presents almost exclusively in children before 6 months of age, and has a slight female preponderance. The term hemangioendothelioma was first coined in 1912, based on a tumor observed in a cirrhotic liver (Kothny 1912). Multiple hepatic hemangioendotheliomas were first reported in 1911 (Bondy 1911) and in 1913 (Veeder and Austin 1913). These authors described a 10-week-old female infant who died with increasing abdominal distention and progressive weakness (heart failure), and autopsy revealed multiple hepatic nodules consisting of vascular spaces with interposed fibrosed hepatic tissue. Foote (1919) reported a further case and reviewed the literature on congenital hemangioendothelioma of the liver. He proposed that these lesions be called hemangioendotheliosarcoma, because they originated from a rapid and seemingly unrestrained proliferation of hepatic vascular endothelia. The ten patients reviewed by Foote (1919) showed a fatal termination of disease before they were 6 months of age. Numerous cases have since been reported, using different terms to denote the lesions.

Hemangioendothelioma Versus Hemangioma: Novel Issues of Definition and Classification of Hepatic Hemangiomas in Infants and Children

The terminology of IHE has gone through an entire spectrum of names, having resulted in some confusion, as in several reports the exact

nature of the vascular tumor can only be reconstructed with difficulty. Terms to denote the lesions comprise hemangioma, capillary hemangioma, cavernous hemangioma, cellular hemangioma, hemangiomatosis, arteriovenous malformation, and hemangioendothelioma. At least part of the tumors have, e.g., been called hemangiomatosis (Braun et al. 1975) or juvenile hemangioendothelioma of the liver (Blumenfeld et al. 1969). It has to be emphasized that the term hemangioendothelioma was not used for hepatic lesions in the same sense as for those located in other organs, e.g., the skin, where the term cellular hemangioma has been proposed to be preferable at a certain time (Gonzales-Crussi and Reyes-Mugica 1991). IHE shared biological and morphologic features with cutaneous infantile or juvenile hemangioma, and frequently cutaneous and hepatic lesions coexist in the same patient. Infantile hemangioma of the skin, which may be associated with hepatic hemangioendotheliomas, is the most common vascular tumor. It is an endothelial cellular proliferation, stimulated after birth (tenth day), and then usually undergoes a slow involution. Congenital hemangioma of the skin is a lesion different from infantile hemangioma, because it develops prenatally and is fully developed at birth. The outcome follows two pathways, i.e., non-involuting congenital hemangioma (NICH), which requires surgery, and rapidly involuting congenital hemangioma (RICH). As also infantile hepatic hemangiomas can undergo involution, it is tempting to assume that the cutaneous and visceral forms of infantile hemangiomas are closely linked entities. To date, the widely used term, IHHE, has therefore been replaced by the term, infantile hepatic hemangioma (IHE; Christison-Lagay et al. 2007), and this new nomenclature will be employed in the present chapter. Recently, other classification schemes have been proposed. IHE was classified as single focus, multiple foci, and diffuse phenotypes (Christison-Lagay et al. 2007; Dickie et al. 2009; Dong et al. 2009; Table 1). According to Christison-Lagay et al. (2007), focal lesions are well-defined, solitary, and spherical tumors that are hypointense relative to the liver on T1-weighted sequences and hyperintense on T2-weighted sequences. The lesions can show central necrosis and hemorrhage. Most focal lesions are asymptomatic and are rarely accompanied by cutaneous hemangiomas. Many focal tumors are detected antenatally on routine prenatal ultrasonography. The lesions variably demonstrate the presence of high-flow shunts, and some of the lesions are associated with minor anemia or thrombocytopenia. Multifocal lesions present as homogeneously enhancing spherical tumors by MRI, and flow voids present in or adjacent to the nodules may indicate the presence of arteriovenous shunts. Multifocal IHE is associated with cutaneous hemangiomas. Some of the lesions are asymptomatic, while others cause high-output heart failure and/or coagulopathy. The lesions may undergo the typical course of involution, as cutaneous hemangiomas. Diffuse lesions are those which exhibit extensive hepatic involvement and near-total replacement of parenchyma with innumerable centripetally enhancing lesions. Most of the infants with the diffuse form have severe clinical manifestations with massive hepatomegaly with compression effects, but the diffuse form is usually not associated with cardiac failure. The patients may develop hypothyroidism (see below). Based on patients studied in a hemangioma registry (cases entering the registry between 1995 and 2010; www.liverhemangioma.org), tumor was studied according to this three-level classification. Of 119 tumors, 33 were focal, 68 were multifocal, and 18 were diffuse lesions. The focal type had a balanced sex distribution, whereas multifocal and diffuse types were more common in women (66.2 % and 70.0 %, respectively) (Kulungowski et al. 2012).

Table 1 Classification of infantile hepatic hemangiomas and related lesions

Christison-Lagay et al. classification (2007)	
	Synonym
Focal	Solitary
Multifocal	Multinodular
Diffuse	Disseminated
Mo et al. classification (2004)	
Hepatic infantile hemangioma (HIH), GLUT1 positive	
Hepatic vascular malformation with capillary proliferation (HVMCP), GLUT1 negative	

IHEs have also been classified according to their angiographic phenotype. Based on angiograms obtained in 15 infants with a diagnosis of hepatic hemangioma, Kassarjian and coworkers (2002) distinguished five types of these vascular tumors. Type 1 was defined as the classic appearance with early filling of abnormal vascular channels, stagnation of contrast medium, and no evidence of a direct shunt; type 2 showed high-flow nodules without direct shunts; type 3 was characterized by direct arteriovenous shunts, type 4 by direct portovenous shunts, and type 5 by both direct arteriovenous and portovenous shunts.

A further classification of these hepatic lesions relates to tumors sensu strictiori versus congenital vascular malformations, an issue that has previously been discussed (Boon et al. 1996; Prokurat et al. 2002). A refined version of this distinction or classification was proposed by Mo et al. (2004). They distinguished multifocal hepatic lesions with features of IHE (termed, by the authors, hepatic infantile hemangioma (HIH)) from solitary angiomatous hepatic lesions (termed hepatic vascular malformation with capillary proliferation (HVMCP)). Apart from the clearly different macroscopic presentation and growth pattern, IHI differed from HVMCP that IHI was GLUT1 positive and HVMCP not, suggesting that the two groups represent two fundamentally different hepatic vascular lesions in infants and young children.

Epidemiology

IHE accounts for about 12–20 % of all childhood hepatic tumors and is the most common symptomatic liver tumor during the first 6 months of life. Altogether, 85 % of patients with IHHE are diagnosed before the age of 2 months, and the tumor is rarely diagnosed beyond the age of 3 years. The tumor may develop during the fetal period and may be manifest as a congenital neoplasm (Schiavon et al. 1982; de Bievre et al. 1994; Sheu et al. 1994; Dreyfus et al. 1996; Morris et al. 1999; Gembruch et al. 2002; Morimura et al. 2003; Pott Bartsch et al. 2003; Ritter et al. 2003; Walsh et al. 2004; Chou et al. 2005; Govender et al. 2006; De Paoli et al. 2007; Schmitz et al. 2009; Franchi-Abella et al. 2012).

In a review of 30 patients, 20 were female (McLean et al. 1972). Prenatal sonographic appearances of (early) lesions (Gonen et al. 1989; Abuhamad et al. 1993; Sepulveda et al. 1993; Chuileannain et al. 1999; Meirowitz et al. 2000; Chou et al. 2005; Schmitz et al. 2009) and features in fetal MRI (Dong et al. 2010) have been reported. Such studies are of particular interest because they have described the dynamic evolution of the complex vascularization of IHE, including feeding arteries with altering flow patterns and characteristics of the continuously changing umbilical-placental circulation (Abuhamad et al. 1993; Meirowitz et al. 2000). IHE can result in fetal hydrops (Skopec and Lakatua 1989; Gonen et al. 1989). In one investigation, hepatic hemangioma was detected prenatally in 30 % of patients with the focal type (Kulungowski et al. 2012). Even though most IHEs occur, as the term implies, in the infantile period, the majority being manifest in the first 6 months, rare instances of such tumors in adolescence (18 years; Selby et al. 1994) and adult patients are known (Diment et al. 2001). The tumor has also been observed in heterotopic intrathoracic liver (Shah et al. 1987).

Clinical Features

General Features

The majority of focal/solitary IHEs are asymptomatic, most symptoms and signs therefore being associated with multifocal or diffuse lesions (Christon-Lagay et al. 2007). The dominant clinical features of multifocal IHE comprise hepatomegaly (83 %); an enlarging upper abdominal mass (66 %); sequelae of the shunting vascular mass, such as cardiovascular failure and coagulopathy; and jaundice. In case of multiple or diffuse lesions, hepatomegaly can be massive (Cohen and Myers 1986; De Paoli et al. 2007). In a study of 19 patients surveyed by the Japanese Infantile Hepatic Hemangioma Study Group, abdominal distention (47.4 %), high-output

cardiac failure (47.4 %), coagulopathy (42.1 %), and respiratory distress (31.6 %) were the major presentations (Kuroda et al. 2011). Solitary lesions exert symptoms and signs in relation to their size and the shunting volume (McGahon et al. 1964; Mortele et al. 2002). In regard to frequency, mass effects and shunt effects are followed by less common manifestations such as vomiting (Bay et al. 2005), splenomegaly, jaundice, ascites, gastrointestinal bleeding, anemia, feeding difficulties, and hepatic bruit (Pellerin et al. 1971; Smith et al. 1978). Vomiting, in particular projectile vomiting, is a rather uncommon sign of IHE (Bay et al. 2005). Obstructive jaundice has been observed in IHE located to the hepatic hilar region (Hase et al. 1995).

Selected References Fox and Cella 1951; Crocker and Cleland 1957; Sommacal 1957; Dachman et al. 1983; Hanchard et al. 1983; Holcomb et al. 1988; Becker and Heitler 1989; Cornelius et al. 1989; Samuel and Spitz 1995; Woltering et al. 1997; Amonkar et al. 1999; Daller et al. 1999; Robben et al. 1999; Lu et al. 2002; Kasahara et al. 2003; Walsh et al. 2004; Riley et al. 2006; Dickie et al. 2009; Moon et al. 2009; Van der Meijs et al. 2009; Zenzen et al. 2009; Marsciani et al. 2010

Cardiac and Circulatory Complications

Multifocal, but usually not focal or diffuse, IHE can result in congestive heart failure (due to arteriovenous shunting), and cardiac failure may even be the initial manifestation, suggesting congenital heart disease (38.5–58 % of the patients) (Levick and Rubic 1953; Cleland 1959; Bredon and Baker 1969; Leonidas et al. 1973; Braun et al. 1975; Slovis et al. 1975; Rocchini et al.1976; Prabhu and Purandare 1977; Rotman et al. 1980; Vorse et al. 1983; Zavota et al. 1984; Burrows et al. 1985; Becker and Heitler 1989; Stanley et al. 1989; Davenport et al. 1995; Pethe et al. 1995; Iyer et al. 1996; Lu et al. 2002; Chen et al. 2003; Sidwell et al. 2004; Jothilakshmi et al. 2006). The relative incidences of these manifestations vary considerably among different reports. In the series reported by Chen et al. (2003), 50 % had abdominal distention, 38.8 % congestive heart failure, 38.8 % abdominal mass, 30 % jaundice, and 23 % skin hemangiomas. In another report, the most common presenting features among 16 patients were high-output cardiac failure (69 %), consumptive coagulopathy (75 %), and anemia (75 %) (Samuel and Spitz 1995). In a recent study on 13 patients (median age, 14 days), congestive heart failure and abdominal mass were predictive of 5-month mortality rates, and patients who underwent resection surgery, with or without OLT, had a lower 5-month mortality rate and a greater 2-year survival rate than those who underwent hepatic artery ligation or embolization (Daller et al. 1999). The severe cardiac complications of IHE can clinically present as acute asystole (Malvy et al. 1978) and may cause sudden unexpected death (Dempers et al. 2011). The arteriovenous shunting depends on the formation of feeding vessels that are perfused by blood from the hepatic artery. High-output failure of infants with IHE can dramatically be controlled by hepatic artery ligation (de Lorimier et al. 1967; Rake et al. 1970; Mattioli et al. 1974; Laird et al. 1976; Malvy et al. 1978; Moazam et al. 1983). Cardiac decompensation and circulatory failure can already occur in patients with fetal IHE. Among 16 fetuses with focal IHE, four had associated cardiomegaly and five had cardiac failure. Eight of the nine fetuses with cardiac disorders were symptomatic at birth. Prenatal cardiac abnormality, enlargement of more than one hepatic vein, and large volume of the hepatic lesion were associated with symptomatic disease (Franchi-Abella et al. 2012).

Coagulopathy

Coagulopathy is a complication of multifocal IHE and is caused by consumption mechanisms and activation of the coagulation cascade within the large vascular network (Nöller and Freundt 1958; Haferland 1961; Linderkamp et al. 1976; Hase et al. 1995; Jayanthi et al. 2000). This complication may already develop in fetal hepatic hemangioendothelioma (Gembruch et al. 2002). Similar to

other highly vascularized tumors, IHE may, therefore, induce the Kasabach-Merritt phenomenon or syndrome (Kasabach and Merritt 1940; Sevinir and Özkan 2007). Skopec and Lakatua 1989). Large tumors may cause obstructive jaundice (Linderkamp et al. 1976). IHE may undergo a rapid course ending up with coagulopathy, liver insufficiency, and cardiac failure (Grabhorn et al. 2009; van der Meijs et al. 2009).

Other Complications

Further complications mainly include tumor rupture and/or hepatic rupture, followed by hematoperitoneum and hemorrhagic shock. Sudden death may ensue (Caussade et al. 1954; Karbel' et al. 1990; Lunetta et al. 2004).

Consumptive Hypothyroidism

Interestingly, IHE can cause disorders of thyroid hormone function, specifically hypothyroidism caused by iodothyronine deiodinases, a disorder termed consumptive hypothyroidism. This complication almost exclusively occurs in the diffuse form of IHE. Hypothyroidism occurring in patients with IHE is caused by increased thyroxine catabolism by the tumor and was first reported in 2000 (Huang et al. 2000). To normalize the serum TSH levels in IHE patients, unusually high doses of intravenous liothyronine and LT4 are required. In the autopsy case of Huang et al. (2000), samples revealed that the IHE tissue had high D3 iodothyronine deiodinase, showing that IHE can produce type 3 iodothyronine deiodinase which converts T4 and T3 to inactive metabolites, i.e., reverse T3 and 3,3′-diiodothyronine, respectively (review: Huang 2005). Several other cases of IHE-induced consumptive hypothyroidism have been reported (Mason et al. 2001; Konrad et al. 2003; Güven et al. 2005; Ho et al. 2005; Kalpatthi et al. 2006; Cho et al. 2008; Mouat et al. 2008; Cetinkaya et al. 2010; Peters et al. 2010; Jassam et al. 2011; Imteyaz et al. 2012). In patients with regression of hepatic IHE associated with consumptive hypothyroidism, the hormonal disorder also regresses (Konrad et al. 2003), as it does following liver transplantation for IHE (Lee et al. 2006; Balazs et al. 2007). Consumptive hypothyroidism can occur in recurrent IHE after steroid therapy, caused by increased type 3 iodothyronine deiodinase activity (Bessho et al. 2010). There is a relationship between the incidence of hypothyroidism and the growth pattern of IHE. In a study of 121 patients, hypothyroidism was documented in all patients with diffuse hepatic hemangioma and 21.4 % in patients with multifocal hepatic hemangioma, but not in patients with focal hepatic hemangioma (Kulungowski et al. 2012). Consumptive hypothyroidism caused by increased deiodinase activity has also been found in adults with hepatic vascular tumors (Huang et al. 2002; Howard et al. 2011). The disorder has also been noted in non-angiomatous tumors, e.g., malignant solitary fibrous tumor, as a manifestation of a paraneoplastic syndrome (Ruppe et al. 2005). In one infant, both increased activity of the tumor for type 3 iodothyronine deiodinase and an increased production of a TSH-like hormone were detected (Ho et al. 2005).

Production of Thyrotropin

Ayling et al. (2001) reported on seven with IHE showing increased thyrotropin levels. The serum thyroxine level was decreased in 4 and increased in 2. Immunohistochemistry of the tumors exhibited positive staining of tumor tissue, but of normal liver tissue, for thyrotropin, suggesting the synthesis and secretion of a thyrotropin-like factor by some IHE.

Elevation of Serum AFP Levels

IHE can be associated with elevated serum AFP (sometimes several thousand ng/ml) leading to the suspicion of hepatoblastoma, but probably not related to the tumor as such (Urbach et al. 1987; Han et al. 1998; Herman and Siegel 2001; Lu et al. 2002; Zenge et al. 2002; Sari et al. 2006;

Moon et al. 2009; Kim et al. 2010; Seok and Kim 2010). Among 16 patients with IHE, two patients with bilobar disease showed elevated levels of serum AFP at presentation (Moon et al. 2009). In an immunohistochemical study, it was demonstrated that, in two cases of IHE, hepatocytes near or entrapped within the tumors were the source of AFP (Kim et al. 2010). An elevated serum AFP has also been reported to occur in the mother in case of a fetal IHE (Meirowitz et al. 2000; Mhanni et al. 2000), and maternal AFP may be the first manifestation of the developing tumor (Meirowitz et al. 2000).

Associations

Extrahepatic Hemangioendotheliomas

Hepatic IHE can occur in conjunction with splenic IHE (hepatosplenic IHE; Kumar et al. 2000; Ng et al. 2003; Wang et al. 2009). Association of IHE with a paraspinal hemangioendothelioma was described (Wood et al. 1977).

Skin Angiomas

IHE is known to come together with other angiomatous lesions, particularly hemangiomas of the skin, the latter apparently being detectable in up to 50 % of the patients (Sween and Weinberg 1950; Prabhu and Purandare 1977; Robinson and Hambleton 1977; Berman and Lim 1978; Dehner 1987; Douri 2005; Mendiratta et al. 2008; Dickie et al. 2009; Horii et al. 2010; Tan et al. 2011; Yeh et al. 2011). In a series of 91 patients, skin hemangiomas were noted in 11 % (Selby et al. 1994). The incidence of accompanying cutaneous hemangiomas is correlated with the type of growth pattern of IHE. Of 121 patients studied within a hemangioma registry, cutaneous hemangiomas accompanied 77.4 % of multifocal hepatic hemangioma, 53.3 % of diffuse hepatic hemangioma, and 15.3 % of focal hepatic hemangioma (Kulungowski et al. 2012). There is a relationship between the number of cutaneous hemangiomas and the probability of associated hepatic hemangiomas. A multicenter prospective study of children with cutaneous infantile hemangiomas conducted at pediatric dermatology clinics at Hemangioma Investigator Group sites in the United States, Canada, and Spain between 2005 and 2008 revealed that 24 of 151 infants (16 %) with five or more cutaneous infantile hemangiomas had hepatic hemangiomas identified by abdominal ultrasound, versus none of the infants with fewer than five (Horii et al. 2011).

Placental Lesions

The tumor has been observed together with chorangioma (Meirowitz et al. 2000), with placental tumor manifestations (Marton et al. 1997), or with anomalous dilated and tortuous vessels on the placental surface (Kanai et al. 1998), suggesting a generalized anomaly of vascular morphogenesis. IHE was found in association with congenital circumscribed choroidal hemangioma/chorangioma (Shturman-Ellstein et al. 1978; Shaikh et al. 2001). IHE is also commonly associated with non-tumoral placental pathologies. In a group of 13 infants who developed IHE, gross lesions with disturbance of the uteroplacental circulation were found in all placentas from children who developed IHE, including retroplacental hematoma in two infants, extensive ischemic infarction in seven, and large dilated vascular communications, severe vasculitis, chorioamnionitis, and funiculitis in four. It was suggested that such abnormalities may cause fetal hypoxic stress followed by release of vascular endothelial growth factors and placental growth factor, potentially playing a role in hepatic vasoproliferation (Lopez Gutiérrez et al. 2007).

Non-angiomatous Tumors

A very rare association is IHE combined with hepatic mesenchymal hamartoma (Bejarano et al. 2003; Hsiao et al. 2007; Behr et al. 2012), sometimes causing elevated serum AFP levels (Hsiao et al. 2007). In a 6-month-old child, continuously shrinking IHE after interventional

therapy was followed by focal nodular hyperplasia (FNH) at the site of the former IHE (Turowski et al. 2009). Similar to other situations, FNH may have been induced by the focal circulatory disorder connected with the shunting vascular tumor. Multicentric IHE was found in association with a large brain hemangioma (Bar-Sever et al. 1994).

Other Associations

A vertical association of IHE with biliary atresia has been suggested (Sharp et al. 2008). In one patient, IHE was associated with congenital hemihypertrophy (Wood et al. 1977). IHE has been found in association with congenital absence of the pericardium and congenital diaphragmatic hernia (Terbruegge et al. 2005) and with agenesis of the corpus callosum with interhemispheric cyst and trisomy 21 (Murphy et al. 2006).

Imaging Features

IHE has characteristic sonographic features, characterized by complex heterogeneous masses that usually reveal hypoechoic components. Calcifications may be seen, and Doppler evaluation may uncover shunting (Abuhamad et al. 1993; Kardorff et al. 2001; Zenge et al. 2002; Ng et al. 2003; Kassarjian et al. 2004; Breysem et al. 2008). Sonographically, the lesions may initially present as a roundish solitary lesion predominantly consisting of markedly perfused and tortuous cavities, whereas multifocal type 2 lesions may present as solid tumors. Fetal IHE can be suspected and monitored by sonography (Meirowitz et al. 2000). Sonography is also useful for the monitoring of the treatment response (Warmann et al. 2003). Non-contrast CT images show several or multiple hypoattenuating masses or nodules of lower density than the surrounding liver, while postcontrast images reveal intense enhancement of the lesions. Many IHEs show a characteristic dense peripheral nodular enhancement. The typical enhancement patterns are similar to those seen in adult hemangiomas (Presedo et al. 1996; Robben et al. 1999; Herman and Siegel 2000; Parmar et al. 2001; Kaniklides et al. 2000; Ng et al. 2003; Kassarjian et al. 2004; Singh et al. 2008; Feng et al. 2010). In a large series of patients, contrast-enhanced CT showed a peripheral rim (51.6 %), uniform (48.4 %), fibrillary (33.3 %), and nodular (28.8 %) contrast enhancement in the hepatic arterial phase. Homogeneous (100 %), rim (98.2 %), and mixed enhancement patterns were noted in tumors <1.0 cm, >2.0 cm, and 1.0–2.0 cm in diameter, respectively, in the hepatic arterial phase (Feng et al. 2010). Rarely, ringlike calcifications on CT and MRI have been found (Mavili et al. 2006). MRI with or without gadolinium enhancement reveals mostly hypointense masses in T1-weighted images, with an isointense and sometimes irregular border, and hyperintense masses in T2-weighted images. In case of tumor necrosis, contrast material is absent in the tumor center (Chung et al. 1996; Presedo et al. 1996; Mortele et al. 2002; Kassarjian et al. 2004; Halefoglu 2007; Feng et al. 2010). Angiography findings of IHE are rather complex and characterized by early filling of abnormal vascular channels with or without extensive shunts (Jackson et al. 1977; Mortensson and Pettersson 1979; Burke et al. 1986; Kassarjian et al. 2002). As complex and heterogeneous tumors, IHEs show considerable variations in the vascular supply (Burrows 1991; Park et al. 1996). In particular, part of the tumors reveal portal vein-hepatic vein fistulas and extensive systemic arterial supply with formation of a complex collateral circulation (Burrows 1991; McHugh and Burrows 1992). The diagnosis and evolution of IHE can be confirmed and followed by technetium-99 m-labeled red blood cell scans (Kristidis et al. 1991; Hertleb et al. 1994), and dynamic and static hepatic scintigraphy will demonstrate the vascularity and size of the liver masses and provide distinction from other tumors (Cruveiller et al. 1965; review: Stanley et al. 1977).

Regression/Involution of IHE

Part of infantile hemangiomas, particularly those in the skin, show a distinct sequence of

developmental stages, characterized as a proliferation or growth phase, followed by an involuting phase, and complete involution itself. Early growth of infantile hemangiomas seems to be influenced by endothelial progenitor cells (Yu et al. 2004). Involution depends on finely tuned apoptosis of endothelial cells (Razon et al. 1998). As their cutaneous counterpart, IHE can undergo involution, but this phenomenon is mainly seen in the multifocal form of IHE. Similar to its cutaneous counterpart, IHE may undergo rapid involution (RICH; Sakamoto et al. 2011; Roebuck et al. 2012), sometimes associated with hepatic failure (Zenzen et al. 2009). It is not yet known whether involuting IHE displays the same or similar features in the involution pattern in comparison with hemangiomas of the skin. The histologic appearance of RICH differs from that of non-involuting tumors (NICH) and common hemangiomas, but there are important overlaps. RICH was composed of small to large lobules of capillaries with moderately plump endothelial cells, the lobules being surrounded by fibrous tissue. Involuting zones are visualized as centrolobular atrophy, fibrosis, and draining channels, associated with hemosiderosis and/or calcifications. The endothelia in RICH were not GLUT1 positive (Berenguer et al. 2003). Involuting lesions differ from hepatic vascular malformations in that they express GLUT1 and, by activation of apoptotic pathways, are associated with expression of the Wilms tumor 1 gene/WT1 (Lawley et al. 2005).

Pathology

Macroscopy

Macroscopically, three growth patterns can be distinguished, i.e., solitary (focal; single focus), multifocal (multinodular), and diffuse phenotypes (Figs. 1 and 2). In multifocal tumors, the lesions may be scattered throughout the liver or may be clustered within one lobe (Dehner and Ishak 1971), resulting in a gross pattern resembling metastatic liver disease. In most cases, the tumor nodules are lighter in color than the surrounding liver tissue, and in cut sections the lesions usually

Fig. 1 Infantile hepatic hemangioma. The liver exhibits numerous tumor nodules with central hemorrhage (unfixed necropsy specimen)

Fig. 2 Infantile hepatic hemangioma. Numerous, in part confluent tumor nodules in both liver lobes (fixed necropsy specimen)

reveal a dark-red center surrounded by a lighter-colored ring (Foote 1919; McLean et al. 1972). In cases with a high content of blood in the lesions, the liver surface is covered with purple to bluish-red nodules varying in size from a marble to a ping-pong ball. When the remaining liver shows fatty change, these nodules stand on a dull yellow background of liver substance (Goodale 1930). The subcapsular nodules are flat or umbilicated and are usually soft on palpation. In the diffuse form of IHE, almost the entire liver is densely occupied by nodules of IHE which may touch each other and which leave only a small amount of functioning parenchyma. The nodules are usually well circumscribed, not encapsulated, relatively soft and spongy, or discretely firm, with a reddish-brown or gray to white cut surface

(Dachman et al. 1983; Lunetta et al. 2004). Solitary (focal) lesions tend to be more solid and gray, whereas multifocal lesions tend to be soft and yellowish red, with small hemorrhages. In one study, the tumor nodules ranged from 0.2 to 15 cm in diameter, and there was no significant difference in size between solitary and multifocal forms (Dehner and Ishak 1971). The tumors tend to grow by compression rather than invasion. Pedunculated lesions are uncommon. Central parts of large masses may show evidence of infarction, hemorrhage, necrosis, fibrosis, and/or focal dystrophic calcification.

There is evidence that the gross growth pattern is related to a specific cell lineage or differentiation pathway involved. GLUT1-positive tumors were shown to form multiple white-tan nodules showing central regressive changes in some cases (Mo et al. 2004). These were the tumors representing the classical IHEs or, as proposed by the authors, infantile hepatic hemangiomas (IHIs). Patients with GLUT1-negative lesions usually had a single large mass with a mean diameter of 8 cm, typically with a central infarcted and hemorrhagic area. These lesions were termed hepatic vascular malformation with capillary proliferation/HVMCP (Mo et al. 2004).

Histopathology

As already specified above, Dehner and Ishak (1971) subdivided this tumor histologically into types 1 and 2. The histopathology of the former type I lesions has been described in detail (Figs. 3, 4, 5, and 6; Touloukian 1970; Dehner and Ishak 1971; Dehner 1978). These nodules show irregularly dilated and usually rather small, compressed vascular channels lined by a single layer or, less commonly, several layers of flat endothelial cells with only minor structural anomalies. The channels are outlined by a reticulin fiber sheath. In highly vascular areas, the extracellular space is not well developed and contains only few fibroblastoid cells and very few lymphoid cells. Part of the tumors contain areas with more stromal elements, sometimes with myxoid features resembling mesenchymal hamartoma (Dehner and Ishak 1971). Areas of central fibrosis are seen in part of the tumors, mainly in solitary/focal lesions. Some cases show a cavernous differentiation or arteriovenous structures, probably representing shunts. In the study of Dehner and Ishak (1971), ten out of 17 type I lesions had cavernous hemangiomatous foci. Rarely, extramedullary hemopoiesis was detected (Orzechowski 1928; Sigameni et al. 2010). Solitary IHE can undergo extensive cystic necrosis (Herman and Siegel 2001). The tumors often contain clusters of biliary ductules and may contain entrapped, cytokeratin 7-positive small bile ducts (Bhattacharyya et al. 2007).

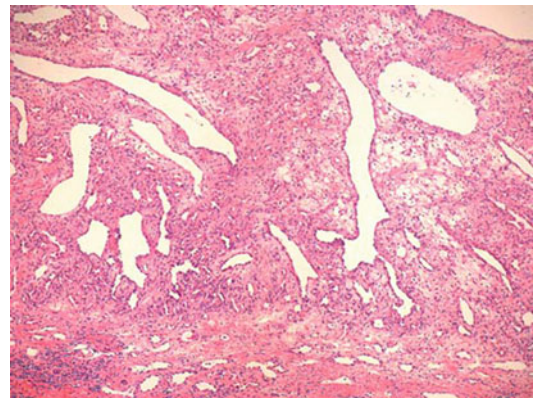

Fig. 3 Infantile hepatic hemangioma, type 1. *Solid* areas with small vascular spaces alternate with cavernous spaces. The interface to the adjacent liver is at the bottom of the figure (hematoxylin and eosin stain)

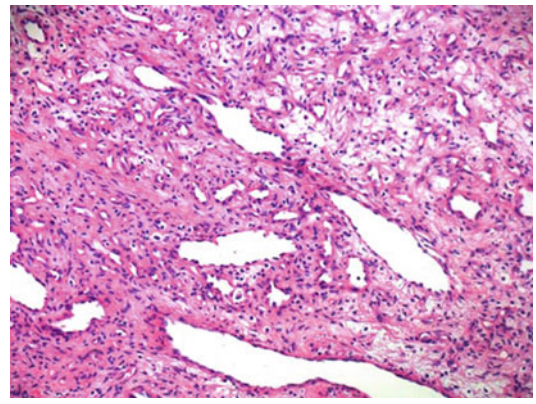

Fig. 4 Infantile hepatic hemangioma. The small and also the larger vascular channels are lined with flat endothelial cells. The intervascular tissue has a fibrous or myxoid aspect (hematoxylin and eosin stain)

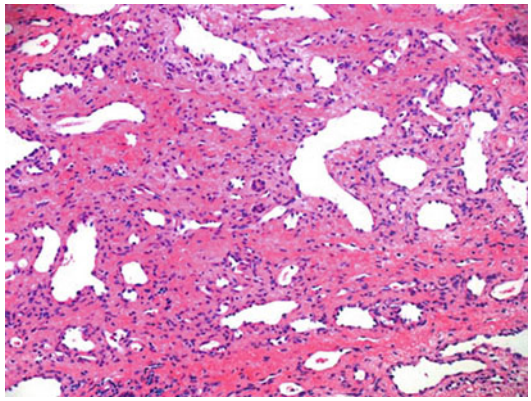

Fig. 5 Infantile hepatic hemangioma, type 1. Older lesions may undergo fibrosclerotic change. Note the portal tract with small bile ducts in the center. Infantile hepatic hemangiomas can integrate preexisting structures of the liver (hematoxylin and eosin stain)

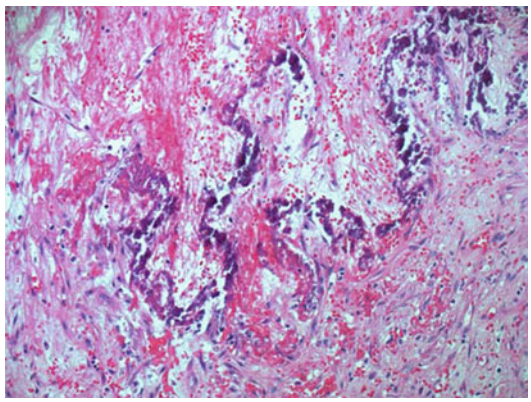

Fig. 6 Infantile hepatic hemangioma, type 1. In this tumor, regressive changes are associated with calcifications (hematoxylin and eosin stain)

Hepatic infantile hemangiomas (IHIs) as defined by Mo et al. (2004) and being GLUT1-positive multiple lesions are histologically characterized by closely packed small capillary-sized vessels with interspersed pericytes and collagen fibers, resembling cutaneous infantile hemangioma and corresponding to type 1 IHE according to Dehner and Ishak's classification. The second group of lesions defined by Mo et al. (2004) is the solitary large masses that are GLUT1 negative and called hepatic vascular malformation with capillary proliferation (HVMCP). These lesions show a central zone of hemorrhage and necrosis/infarction and a peripheral zone with congested and dilated thin-walled vessels lined by flattened epithelium, associated with vascular thrombi and calcifications. This zone is surrounded by a rim of myxoid stroma containing numerous capillary-type blood vessels, with an indistinct demarcation between the lesion and adjacent liver (Mo et al. 2004).

The former type 2 lesions show a very vascular and in part hypercellular neoplasm composed of atypical, anastomosing vascular channels admixed with necrosis and hemorrhage (Andries and Kaump 1944; Dehner and Ishak 1971). That such lesions differ in biology and histology from the more common type 1 lesions was first worked out by Andries and Kaump in 1944. These authors underlined the absence of encapsulation and an infiltrative growth with whorls of spindle-shaped cells. The irregularly shaped lumina are lined by atypical, flattened polygonal endothelial cells, sometimes with hobnail-like formations, similar to those noted in angiosarcomas. Polygonal cells may form multilayered structures and show cytoplasmic microlumina. Part of the vascular spaces display papillary intraluminal projections covered with one of the several layers of enlarged endothelial cells. Mainly in areas with necrosis, structures resembling Schiller-Duval bodies of yolk sac tumors may be observed (Ganguly and Mukherjee 2010). Mitotic activity is brisk, sometimes with atypical and tetrapolar mitotic figures. The vascular spaces contain erythrocytes, at some places with pooling of blood in cavernous or peliosis-like spaces. Erythrophagocytosis by the abnormal endothelial cells is found. The same or a similar histology was found in lymph node metastases or remote metastases of the hepatic tumors (Ganguly and Mukherjee 2010). The nodules may contain foci of extramedullary erythropoiesis. Ductular biliary profiles and hepatocytes are intermingled with vascular channels in the majority of cases.

Cytology

Fine needle aspiration cytology smears revealed clusters of and isolated cuboidal, round cells with benign-looking features (Kumar et al. 2010).

Spindle-shaped cells with scant cytoplasm and wavy, kinked, and indented nuclear outlines were also found (Sigamani et al. 2010).

Ultrastructure

Electron microscopically, type 1 IHE showed large numbers of vascular channels of varying sizes lined by abnormal endothelial cells. An incomplete basement membrane separated endothelial cells from extracellular matrix, in the absence of pericytes. The interstitium contained fibroblastoid cells, microfibrils, and collagen fibers (Feldman et al. 1978). No pericytes were observed in another study (Selby et al. 1994). However, another EM investigation of type 1 IHE had uncovered a high density of pericytes in the walls of vascular channels, and these cells may play a role in vessel contractility and the establishment of shunting (Zerbini et al. 1991). In type 2 I.E. electron microscopy revealed that tumor endothelial cells appeared less differentiated and more disorganized than in type 1 tumors. Marked thickening and duplication of basement membranes were noted (Chan et al. 1986).

Immunohistochemistry

Immunohistochemically, endothelial cells of the abnormal vascular channels are reactive to von Willebrand factor, CD31, CD34 (Fig. 7), Ulex europaeus I lectin, an endothelial cell marker (EC), and vimentin and are lined by a continuous basement membrane (Yasunaga et al. 1989; Selby et al. 1994; Cerar et al. 1996; Amonkar et al. 1999; Lunetta et al. 2004; Riley et al. 2006; Ganguly and Mukherjee 2010; Zhang et al. 2010). Subendothelial cells, enveloped with basement membrane, express smooth muscle actin, but not desmin, and appear to represent a pericyte phenotype (Cerar et al. 1996), also detectable by use of EM (Zerbini et al. 1991). Focal IHEs are not reactive for GLUT1, an erythrocyte-type glucose transporter protein (North et al. 2000), whereas

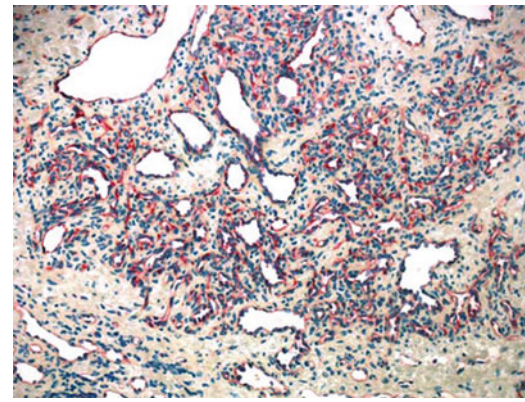

Fig. 7 Infantile hepatic hemangioma, type 1. The endothelial lining is CD34 positive (CD34 immunostain)

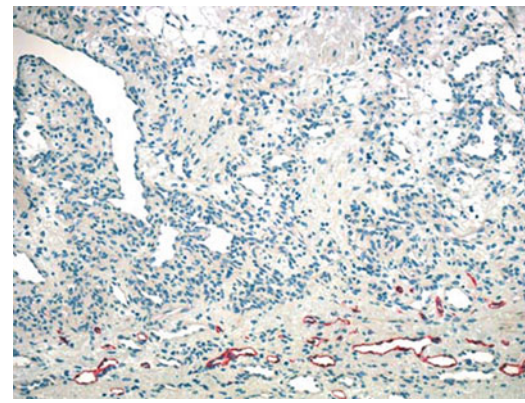

Fig. 8 Infantile hepatic hemangioma, type 1. Lymph vessels are detectable in liver tissue adjacent to the tumor (*bottom*), while the neoplasm itself does not contain lymphatics (D2-40 immunostain)

the endothelial cells of multifocal lesions and diffuse lesions are typically GLUT1 positive, like typical cutaneous hemangiomas of this age group (Drut and Drut 2004; Hernandez et al. 2005; Christison-Lagay et al. 2007). Reactivity for GLUT1 distinguishes IHE from other types of hepatic angiomatous tumors, in particular congenital hepatic vascular malformations (Mo et al. 2004). In contrast to cutaneous hemangiomas, nuclei of IHE are not reactive for p57KIP2 (Drut and Drut 2005). D2-40-reactive lymph vessels are not present within the tumors (Fig. 8).

Differential Diagnosis

IHE must be distinguished from other hepatic vascular tumors occurring in the pediatric age group, in particular angiosarcoma, cavernous hemangioma, capillary hemangioma, and epithelioid hemangioendothelioma. Angiosarcoma of the adult type occurs in the pediatric liver and shows the characteristic histology of highly atypical and sometimes large or pleomorphic endothelial cells that often reveal the hobnail phenomenon and line markedly abnormal and often slit-like spaces. Bizarre and giant cells with massively abnormal mitotic figures are a typical feature, as are solid sarcomatous foci with spindle cells. Cavernous hemangioma of the liver is much less common in infants and children than IHE and is histologically characterized by widely dilated, thin-walled vascular channels lined with flat endothelial cells and by an intervening stroma that may contain lymphoid cells. Capillary hepatic hemangioma is a very rare tumor in infants and children, but its histology may be very close to that of type 1 I.E. However, in contrast to IHE, capillary hemangioma of the liver is usually a small and solitary tumor. Epithelioid hemangioendothelioma is an intermediate-grade invasively growing vascular tumor with medium-sized to large cells forming strands and clusters within a stroma and displaying vacuole-like intracellular lumina. In case mutlifocal IHE is associated with splenic or retroperitoneal hemangioma, neuroblastoma with liver metastases may be suspected on clinical and radiological grounds (Wang et al. 2009).

Biology of Disease: Type 2 IHE as a Low-Grade Angiosarcoma

Two histologic types (type 1 and type 2; Dehner and Ishak 1971; see below) have been recognized, their identification possibly being of importance insofar as IHE1 eventually regresses, and type 2 IHE has been proposed to show a more aggressive phenotype and has been reported to undergo malignant change, i.e., to angiosarcoma or related lesions (Orzechowski 1928; Andries and Kaump 1944; Schwartz 1945; Kauffman and Stout 1961; Kirchner et al. 1981; Noronha and Gonzales-Crussi 1984; Strate et al. 1984; Dehner 1987; Selby et al. 1992; Nazir and Pervez 2006; Ganguly and Mukherjee 2010). One of the first reported cases referred to a 2.5-month-old girl, who was markedly icteric and had a hepatic hemangioendothelioma which had metastasized to the lung and the skin (Orzewchowski 1928). Type 2 IHE may show a fulminant course with extrahepatic extension affecting intestine, lung, skin, and soft tissues, hence being clinically confounded with neuroblastoma (Garcia-Rodriguez et al. 2010). However, the histologic distinction between these two lesions may be difficult, and the prediction of the ultimate course is not easy and often not possible (Dehner an Ishak 1971; Awan et al. 1996; Prokurat et al. 2002), all the more so because the patterns may coexist in the same lesion (Noronha and Gonzalez-Crussi 1984). Even in the case of a benign-looking histology (type 1), multifocality, rapid growth, poor treatment response, and of course metastatic disease indicate malignancy characteristic for at least part of the tumors classified as type 2 (Zurcher et al. 1982). On the other hand, part of the cases, and probably those with a type 1 histology, may show spontaneous regression within 12–18 months (Araujo et al. 2008). Although type 2 IHE thus appears to be associated with a poorer outcome in part of cases, some series have not substantiated this observation (Selby et al. 1994; Cerar et al. 1996). In the large series (91 patients) of Selby et al. (1994), 87 % were first seen before the age of 6 months; the 6-month-survival rate, based on 71 patients, was 70 %, all deaths occurring during the initial presentation/hospitalization of infants, with the exception of two patients who died 3 months and 7 months after diagnosis. Significant factors predicting death 6 months after diagnosis included the presence of congestive heart failure, jaundice, multiple tumor nodules, and absence of cavernous differentiation (Selby et al. 1994). The issue of type 2 lesions as angiosarcoma is further discussed in the chapter of pediatric hepatic angiosarcoma.

Variants of Hemangioendotheliomas of the Hepatobiliary Tract

53

Contents

Abstract

Apart from epithelioid hepatic hemangioendothelioma and infantile hepatic hemangioendothelioma/hepatic infantile hemangioma, there are few other endotheliomas that can manifest as primary neoplasms of the liver. Kaposiform hemangioendothelioma is a rare, locally aggressive, vascular spindle-cell tumor that resembles Kaposi's sarcoma. This neoplasm most commonly develops in the skin and the retroperitoneal space of infants and children, but is also observed in the hepatobiliary tract in rare instances. Kaposiform hemangioendothelioma is a well-known cause of Kasabach-Merritt syndrome. Histologically, the neoplasm is characterized by nodules or lobules of rather bland-looking spindle cells which encircle slit-like, CD31- and CD34-positive vascular channels. A further hemangioendotheliomatous neoplasm that develops in the liver as a primary tumor is polymorphous hemangioendothelioma.

Kaposiform Hemangioendothelioma

Introduction

Kaposiform hemangioendothelioma (KFE) is a rare, locally aggressive (borderline), vascular spindle-cell tumor with resemblance to Kaposi's sarcoma, first described in 1993 (Zukerberg et al. 1993). Before the definition as KFH, the

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_53

lesion has anecdotically been described under various names, such as hemangioendothelioma, congenital hemangioendothelioma, Kaposi's-like infantile hemangioendothelioma, and hemangioma with Kaposi's sarcoma-like features (Niedt et al. 1989). The neoplasm seems to be closely related to tufted angioma (TA), and both KFE and TA are now considered neoplasms of intermediate malignancy because of infiltrative growth, local aggressiveness, and variable prognosis. Tumors exhibiting features that are transitional between KFE and TA have been described even in the same specimen of some patients (Brasanac et al. 2003), and a dynamic transformation between both tumors has been reported (Chu et al. 2003), suggesting that KFE and TA may reflect different stages in the evolution of a single entity (Arai et al. 2006). Most commonly, KFE develops in the skin and in the retroperitoneal space of infants and children. The development of KFE in adolescents or in adults is rare (Mentzel et al. 1997; review: Fernandez et al. 2009).

Epidemiology

In a study of 163 patients from North America, the prevalence of KFE in Massachusetts was 0.91 case per 100,000 children (Croteau et al. 2013). Most of KFH present during early childhood (first year of life), and the lesion is more common in males. In the Boston study, KFE manifested in infancy in 93 % of cases, with 60 % as neonate (Croteau et al. 2012). Cases in adults are rare (Mentzel et al. 1997) and may in part have been diagnosed as TA.

Clinical Manifestations and Imaging Features

Apart from the classical sites, i.e., skin and retroperitoneal space, KFH can also occur in visceral locations. Multifocal and particularly internal lesions may, depending on their extension, cause severe complications. Retroperitoneal extensions or manifestations occur in 18 % of the patients. Owing to its distinct angioarchitecture and vascular composition, KFH has a tendency to bleed and to sometimes cause life-threatening hemorrhage. In contrast to infantile and juvenile hemangiomas, KFH shows no tendency to spontaneously regress and involute. Untreated KFH is associated with a rather high mortality rate (up to 30 %), mainly caused by locally invasive effects, large and irresectable visceral manifestations, massive hemorrhage, and KMS (review: Fernandez et al. 2009).

KFH is a well-known cause of Kasabach-Merritt syndrome/KMS (synonym: Kasabach-Merritt phenomenon) (Zukerberg et al. 1993; Walker et al. 2002; Hauer et al. 2007; Drucker et al. 2009; Fahrtash et al. 2010; Veening et al. 2010; Garcia-Monaco et al. 2012), mainly in case of large retroperitoneal lesions. In fact, KMS is closely associated with KFH and TA and not with common infantile hemangioma (Enjolras et al. 1997; Sarkar et al. 1997). KMS was described in 1940 (Kasabach and Merritt 1940) and is characterized by a complex vascular tumor coagulopathy with profound thrombocytopenia (<20,000) and consumptive coagulopathy and hypofibrinogenemia with fibrin degradation products (reviews: Maguiness and Guenther 2002; Rodriguez et al. 2009). KMS in KFH usually develops in the first months of life. The pathogenesis of KMS has not been clarified and is complex, because KMS is not related to the lesion mass or the clinical extent since many large and very large juvenile hemangiomas, vascular malformations with a large internal vessel surface, and disseminated Kaposi's sarcoma never lead to this complication. There is some evidence that KMS preferentially evolves in vascular tumors and tumor-like lesions that have a lymphatic contribution. KMS was found in advanced Kaposi's sarcoma, multifocal lymphangioendotheliomatosis, and TA (Alvarez-Mendoza et al. 2000). KFH was observed to develop on the background of a capillary-lymphatic vascular malformation, followed by Kasabach-Merritt syndrome. KFH may be associated with lymphangiomatosis, characterized by the presence of either diffusely infiltrating lymphangiomas or as lymphangioma involving multiple sites (Zukerberg et al. 1993; Vetter-Kauczok et al. 2008). This association is usually seen in children and only exceptionally in adults (Mentzel et al. 1997).

KFH Involvement of the Hepatobiliary Tract

The liver can be involved by KFH in situations of multifocal tumors, whereby sometimes one dominant extrahepatic lesion is found (Nakaya et al. 2014). KFH has been observed in the choledochus of a 5-month-old male infant with cholestatic jaundice. CT revealed a vascular tumor in the hepatic portal region causing biliary obstruction. The tumor was successfully resected followed by hepatoportoenterostomy (Terui et al. 2010). KFH occurs in the kidney and can invade the inferior vena cava to reach the retrohepatic space (Indolfi et al. 2010).

Pathology

Histologically, KFH is characterized by nodules, solid sheets, or lobules of morphologically rather bland-looking spindle cells, ranging in size from small to large, that are grouped to fascicles and which encircle slit-like capillary channels at the periphery of nodules and lobules. Small areas with densely packed spindle cells may be noted. Dense spindle-cell areas are mainly noted at the periphery of vascular lobules, where the spindle cells stream into the vascular compartment. Central portions of the lobules (the so-called glomeruloid islands), in contrast to the cellular periphery, are composed of hemovascular channels with surrounding clusters of small or epithelioid-looking SMA-positive cells (possibly pericyte-like cells; Lyons et al. 2004). The vascular spaces may look empty, but also contain red blood cells and sometimes microthrombi. Extravasation of erythrocytes and focal hemosiderosis are found.

Immunohistochemically, the endothelial cells of the vascular channels are in part reactive for CD31 and CD34. Staining of these two endothelial markers is diffuse across the vascular lobules, including the circumferential spindle cells at the periphery and the small vascular channels in the center. The endothelial cells of KFH are GLUT1 negative (North et al. 2000; Lyons et al. 2004). More than 90 % of KFH are positive for D2-40 (podoplanin), a marker of lymphatic endothelium (Debelenko et al. 2005; Galambos and Nodit 2005; Arai et al. 2006). D2-40 stains the neoplastic spindle cells and lymphatic channels adjacent to vascular lobules. The staining is typically concentrated at the peripheral part of vascular lobules where D2-40 highlights spindle cells that stream between the lobules and circumscribe the glomeruloid cores. This results in "dark" rings encircling "pale" centers of the vascular lobules. D2-40 staining was observed in 20–70 % of the cellular component of the lesions and 70–90 % of the large spindled cells (Debelenko et al. 2005). Similar to Kaposi's sarcoma and Dabska-type hemangioendotheliomas which have features of lymphatic differentiation, KFH is positive for vascular endothelial growth factor receptor-3 (VEGFR-3), a lymphatic endothelial marker (Folpe et al. 2000; Saito et al. 2009). Part of the cells of KFH express the lymphatic endothelial nuclear transcription factor, Prox1, with a distinct pattern; the mainly peripherally located spindle cells are positive for Prox1, podoplanin, CD31, and CD34, and also the endothelial cells in the glomeruloid foci are Prox1 positive (Le Huu et al. 2010; Miettinen and Wang 2012). It has been proposed that both VEGFR-3 and Prox1 might be superior to D2-40 in identifying endothelial cells of a lymphatic lineage (Castro and Galambos 2009). Prox1 has been found to promote invasion of KFH cells in an experimental murine model (Dadras et al. 2008). In contrast to Kaposi's sarcoma, human herpesvirus 8 was not detected in KFH (Cheuk et al. 2004; Lyons et al. 2004; Robin et al. 2004; Deraedt et al. 2006).

Polymorphous Hemangioendothelioma

Introduction

Polymorphous hemangioendothelioma (PHE) was originally described as a distinctive vasoproliferative lesion developing in lymph nodes, characterized by solid, primitive vascular, and angiomatous patterns and relatively bland cytologic features (Chan et al. 1992). These

authors reported a series of 39 patients with primary vascular tumors of lymph nodes other than Kaposi's sarcoma and identified three cases with the novel phenotype of PHE. The term polymorphous was chosen to emphasize the great variability of histological patterns present in this tumor. PHE is a neoplasm of borderline malignant potential and has both nodal and extranodal manifestations (Rehring et al. 1999; Tadros et al. 2003; Moreno-Ramirez et al. 2004; Falleti et al. 2009). PHE is histologically characterized by a complex mixture of intermingled solid, spindled, retiform, epithelioid, and angiomatous components. The tumor cells are immunoreactive for CD31, CD34, and factor VIII-associated antigen (Nascimento et al. 1997).

Polymorphous Hemangioendothelioma of the Liver

PHE may occur as primary hepatic neoplasm (Cobianchi et al. 2009). A large hepatic mass was detected in 47-year-old female patient suffering from abdominal pain and anemia. Sonography and MRI of the abdomen revealed a large heterogeneous mass ($9 \times 7 \times 7$ cm) in the left lateral hepatic segments (segments II, III, and partially IV). The hepatic resection specimen was almost completely replaced by a nodular, hemorrhagic mass with an expanding growth pattern without encapsulation. Cut sections showed a variegated color from red to yellowish. On histology the tumor displayed a thin inflammatory pseudocapsule and a composite pattern, consisting of angiomatous, retiform, and solid areas. The angiomatous areas showed clefts, branching channels, and dilated vascular spaces lined by plump cuboidal and often hobnailed cells. Pseudopapillary structures were noted, and there were areas mimicking the pattern seen in retiform hemangioendothelioma. The solid areas consisted of oval to spindle cells with vacuolated nuclei and an indistinct, slightly eosinophilic cytoplasm, these cells being arranged in a trabecular to vaguely fascicular pattern. The intervening stroma was sclerotic to fibrocellular to edematous. Only occasional mitotic figures were found. Areas of tumor necrosis were observed. Immunohistochemically, cells of the angiomatous and spindled areas were positive for vimentin, CD31, and factor VIII-associated antigen, but not CD34. The growth fraction (Ki-67) was less than 1 %.

Angiosarcoma of the Liver

54

ICD-O code 9120/3

Contents

Abstract

Angiosarcoma is a high-grade (grade 3) sarcoma that consists of a proliferation of atypical endothelial cells. Angiosarcoma develops in various organs and tissues and is the most important hepatic sarcoma, albeit it amounts to only 2 % of all primary hepatic malignancies. There is a male predominance, probably linked to risk factors related to chemical industries. The peak incidence of hepatic angiosarcoma is in the sixth to seventh decades of life, but the tumor also occurs in the pediatric age group. Seventy percent of hepatic angiosarcomas are sporadic lesions, and 30 % are associated with agents known to play a role in this neoplasm, particularly vinyl chloride monomer, pesticides, arsenicals, androgenic steroids, external ionizing radiation, and formerly thorotrast. Macroscopically, angiosarcoma presents in various growth patterns, ranging from massive tumors to diffuse micronodular lesions. Histopathology resembles that of angiosarcomas in other locations. Two main cell types prevail, i.e., highly abnormal endothelial cells lining abortive vascular spaces and interstitial spindle cells. Polymorphous elements and giant cells may occur, and part of tumor cells exhibit erythrophagocytosis. Hepatic angiosarcoma is a very aggressive, metastasizing neoplasm associated with poor outcome.

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_54

Introduction

Angiosarcoma is defined as highly malignant (grade 3) soft tissue sarcoma composed of atypical endothelial cells with complex genetic and genomic changes. Hepatic angiosarcoma is a rare primary malignancy of the liver that usually affects adults, but rarely also affects the pediatric liver. Hepatic angiosarcoma has been described in the older literature under various names, including hemangiosarcoma, hemangioendothelial sarcoma, malignant endothelioma, and retothel sarcoma (Nazari 1906). The first reported case of hepatic angiosarcoma was probably that of von Frerichs (von Frerichs 1861). The term, primary angiosarcoma of the liver, has already been employed in 1890, based on two observations (Arnold 1890). After the definition of hepatic angiosarcoma, a series of detailed descriptions of this tumor have been published, sometimes under the alternative and now obsolete terms, hemangioendothelial sarcoma, hemangioendotheliosarcoma, angioendothelioma, reticuloendothelioma, angioblastic reticuloendothelioma, sarcome angioplastique, and Kupffer cell sarcoma (Arnold 1890; Peyser 1893; Israil 1894; Bramwell and Leith 1896; D'Urso 1896; Pepere 1900; De Haan 1903; Marx 1904a, b; Jores 1908; Kothny 1912; Fischer 1913; Hachfeld 1914; Kahle 1919; Schlesinger 1920; Blumberg 1926; Puhr 1931; Matturi and Rossi 1963; Rakov et al. 1963). Important aspects of hepatic angiosarcoma have been reviewed (Alrenga 1975; Locker et al. 1979; Buetow et al. 1994). Hepatic angiosarcoma is sometimes listed in the group of malignant vascular tumors (MVT) of the liver, also including hemangioendothelioma and its epithelioid variant, and tumors formerly classified as hemangiopericytoma (Groeschl et al. 2014).

Epidemiology

Angiosarcomas account for only 2 % of all primary hepatic malignant neoplasms, but are the most common primary hepatic sarcoma. This high-grade hepatic sarcoma has an estimated incidence of 0.14–0.25 per million (Mani and van Thiel 2001). There is male predominance (male/female ratio of 3:1), probably related to the direct link with industrial chemical exposure; however, the male predominance persists even in idiopathic hepatic angiosarcoma at a rate of 4:1 (Baxter 1981). In an autopsy study from Japan, the male/female ratio in patients with thorotrast-induced hepatic angiosarcoma was 27:2, because most of the male patients were ex-servicemen who had received thorium dioxide injections during radiologic examinations for war-related wounds (Kojiro et al. 1985). The peak incidence is in the sixth and seventh decades of life, although true hepatic angiosarcoma also occurs in the pediatric age group (Geramizadeh et al. 2011; Wang and Wei 2013). Among 161 angiosarcomas reviewed from the files of the French Sarcoma Group from 1980 to 2004, 7 tumors were primary hepatic angiosarcomas (4 %; Fayette et al. 2007). Among 11,939 patients diagnosed with primary hepatic tumors from 1985 to 2007 at 2 South Korean centers, 5 patients were diagnosed with primary hepatic angiosarcoma (Kim et al. 2009).

About 70 % of hepatic angiosarcomas are sporadic, i.e,. without recognizable cause (Fiechtner and Reyes 1976), and the remaining 30 % are associated with agents known to induce this type of tumor, in particular vinyl chloride monomer, pesticides, arsenical compounds, use of androgenic steroids, hepatic iron overload, external radiation, and, formerly, thorotrast (Falk et al. 1979a, 1981a; Baxter 1981; Buetow et al. 1994; Timaran et al. 2000; Mani and Van Thiel 2001; Budd 2002; Koyama et al. 2002; Molina and Hernandez 2003; Bonaccorsi-Riani and Lerut 2010; Huang et al. 2011). A minority of hepatic angiosarcomas have been found in association with liver cirrhosis (Kothny 1912; Kahle 1919). Very rarely, hepatic angiosarcoma develops in pre-existing liver tumors, such as adult mesenchymal hamartoma (Kulkarni et al. 2010).

Clinical and Imaging Presentation

The clinical features of hepatic angiosarcoma are nonspecific and include abdominal pain, hepatomegaly, abdominal distension, weakness,

weight loss, ascites, and eventually jaundice with or without fever.

Selected References Giacomelli 1950; Fontaine et al. 1954; Miller et al. 1964; Barjon et al. 1965; Yamagiwa et al. 1967; Ansari and Weigent 1971; Sugahara et al. 1974; Alrenga 1975; Locker et al. 1979; Wang et al. 1983; Roester et al. 1985; Lelbach 1996; Molina and Hernandez 2003; Kim et al. 2009; Zhou et al. 2010; Chi et al. 2011; Duan and Li 2012; Poggi Machuca et al. 2012; Yang et al. 2012.

In one series of 103 patients, jaundice or ascites (usually hemorrhagic) were found on presentation in 24 % and 28 %, respectively, of the patients (Locker et al. 1979). In rare situations, hepatic angiosarcoma was detected incidentally, during routine imaging procedures (Kajihara et al. 2013). Owing to the rapid growth, necrosis, and/or bleeding, hepatic angiosarcomas are known to undergo "spontaneous" rupture (Ho et al. 2004; Chien et al. 2012). Disseminated intravascular coagulopathy may ensue (Tordjman et al. 1995), and up to one fourth of the patients may present with sometimes severe intra-abdominal bleeding. Massive tumor involvement of the liver may cause liver failure in up to 31 % and portal hypertension (Locker et al. 1979; Rojter et al. 1995; Akdogan et al. 2002; Bhati et al. 2008), but signs of significant liver disease were not detected in other studies (Makk et al. 1976; El Zayadi et al. 1986; Dannaher et al. 1981). Massive tumor burden can create extensive arteriovenous shunting followed by congestive heart failure (Harrison et al. 2001). Due to invasive growth and formation in tumor thrombus, angiosarcoma can induce portal vein thrombosis (Pimentel Cauduro et al. 2002).

Complications

A severe complication of hepatic angiosarcoma is rupture of large hemorrhagic tumors, causing rupture of the liver and often massive intra-abdominal bleeding (Mahony et al. 1982; Azodo et al. 1993; Burke and Opeskin 2000; Horger 2003; Ho et al. 2004; Ikeda et al. 2006; Leowardi et al. 2006). Rupture is promoted by the high density of abnormal vascular structures and the extensive necrosis of these neoplasms. Acute intra-abdominal hemorrhage is a well-known complication and may occur in up to one fourth of the patients (Locker et al. 1979; Tordjman et al. 1995; Lelbach 1996; Stambo and Guiney 2007). Some hepatic angiosarcomas may primarily manifest as recurrent hemoperitoneum (Lee et al. 2008). Other, less common complications include consumption coagulopathy and microangiopathic hemolytic anemia (Michot et al. 1987), congestive heart failure (Harrison et al. 2001), and fulminant liver failure due to diffuse tumor infiltration (Montell Garcia et al. 2012; Olson et al. 2014). Hepatic angiosarcoma is a very rare cause of Kasabach-Merritt syndrome (Alliot et al. 2001; Gonzalez Rodriguez et al. 2012). Hepatic angiosarcoma can rarely be associated with veno-occlusive disease and mimick sinusoidal obstruction syndrome. This change probably represents secondary alterations due to injury to the hepatic sinusoids by the invasive/angioinvasive malignant neoplasm (Wiland et al. 2012).

Imaging

Most patients with hepatic angiosarcoma present with hepatic mass lesions identified on imaging examinations (Vasile et al. 1983; Ross and Rasmussen 1989; Fajadet et al. 1990; Ohtomo et al. 1992; Rademaker et al. 2000). Contrast-enhanced ultrasound of hepatic mesenchymal malignancies reveal as peripheral nodular enhancement, chaotic central vascularization, and absence of contrast enhancement in the late phase (Trojan et al. 2010). On contrast-enhanced CT images, hepatic angiosarcomas present as nonspecific hypoattenuating masses with heterogeneous enhancement, lesions that cannot easily be distinguished from other invasive malignant primary or metastatic liver tumors (Silverman et al. 1983; Fajadet et al. 1990; White et al. 1993; Buetow et al. 1994;

Ohmoto et al. 2000; Koyama et al. 2002; Yu et al. 2003; Chiu et al. 2005; Kim et al. 2006; Maeda et al. 2007; Yu et al. 2008; Park et al. 2009; Wang et al. 2012). Small tumors (e.g., 15 cmm) may be difficult to differentiate from hemangioma (Okano et al. 2012). Diffuse forms of angiosarcoma, a heterogeneous appearance on contrast-enhanced CT, have been described (Vasile et al. 1983; Rademaker et al. 2000). Some reports state that angiosarcomas with a large dominant mass can mimick hepatic hemangioma (Vasile et al. 1983; Itai and Teraoka 1989; Yamanaka et al. 2002). Hepatic angiosarcoma may not be difficult to distinguish from hepatic hemangioma on CT (Peterson et al. 2000), but in more complex cases, it has been shown that early central enhancement and arterioportal shunting on dynamic CT might be helpful for distinguishing hepatic angiosarcoma with a solid growth pattern from benign vascular neoplasms (Ohmoto et al. 2000). In general, early central enhancement, numerous hepatic lesions, and arterioportal shunting suggest angiosarcoma rather than hemangioma. Hepatic angiosarcoma with a portal venous supply may mimick hemangiomatosis of the liver (Kitami et al. 2003). In some cases, the tumors have been undetectable with US or CT (Locker et al. 1979; Silverman et al. 1983; Kanel et al. 1987), sometimes owing to predominantly intrasinusoidal growth (Thomas et al. 1975). Angiography of liver illustrates the rich and complex vascularization of the neoplasms. In some case, the tumors were shown to be supplied by both the hepatic artery and portal vein (Hoshi et al. 2006).

Association with Other Liver Tumors

Exceptionally, hepatic angiosarcomas develop in conjunction with other liver tumors, e.g., adult mesenchymal hamartoma (Li et al. 2007; Kulkarni et al. 2010). It has also been suggested that angiosarcoma of the liver may emerge from pre-existing other vascular tumors, e.g., epithelioid hemangioendothelioma (Cioffi-Pretti et al. 2009).

Pathology

Macroscopy

Hepatic angiosarcoma presents in the form of several growth patterns (Ito et al. 1988; Table 1).

Angiosarcoma can present as a large circumscribed or ill-defined tumor that involves large parts of liver lobes or almost the entire liver (massive form; Fig. 1). These neoplasms often show a central necrosis and multiple hemorrhages, while the periphery of the tumor displays a dark-red spongy texture. The massive lesions may contain isolated remnants of liver substance and often show invaded or thrombosed entrapped veins. Large tumors can be accompanied by satellite nodules that develop through intravascular metastatic spread. The multinodular form is characterized by small- to medium-sized, isolated or

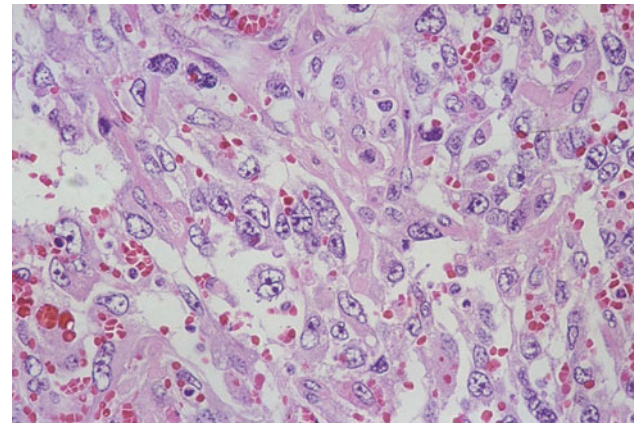

Fig. 2 Primary hepatic angiosarcoma. Abnormal and in part slit-like vascular spaces are lined by highly atypical endothelial cells with large nuclei (hematoxylin and eosin stain)

coalescent spongy hemorrhagic nodules that may involve large parts of the organ or almost the entire liver. These lesions can be identified during laparoscopy (Yasunaka et al. 2012). Less frequently, the liver is diffusely occupied by small to tiny hemorrhagic tumor foci, a presentation resembling peliosis hepatis or diffuse hemangiomatosis (the diffuse micronodular pattern). In these cases, the cut surface of the liver is speckled with small dark-red spots, sometimes on a yellowish steatotic parenchyma (Rojter et al. 1995). Massive tumors can be associated with areas of multinodular growth (mixed forms). Less commonly, the initial presentation is that of a small solitary nodule that may be confounded with small hemangioma (Heo et al. 2007). Rarely, the initial presentation is that of a large, circumscribed angiomatous, large tumor that macroscopically closely mimics giant hepatic hemangioma (Kirschstein et al. 2000). Part of the tumors form cystic structures (Ludwig and Hoffman 1975). In some tumors, the center of the lesion is occupied by a large hemorrhagic cyst filled with liquid or clotted blood, while the tumor periphery shows a rim of hemorrhagic tissue, associated with small dark-red satellite lesions.

Histopathology

Diagnosis by needle biopsy of the tumor is possible, but this diagnostic procedure may be treacherous, nondiagnostic, and even dangerous, as at least one lethal complication following image-guided percutaneous liver biopsy has been reported (Drinkovic and Brkljacic 1996). The histopathology resembles in many aspects that known from soft tissue angiosarcomas (Ludwig and Hoffman 1975; Thomas and Popper 1975; Kojiro et al. 1985; Ito et al. 1988; Saleh and Tao 1998). Generally, angiosarcomas reveal four main histologic patterns, i.e., vasoformative, spindled, epithelioid, and mixed (Figs. 2, 3, 4, 5, 6, 7, 8,

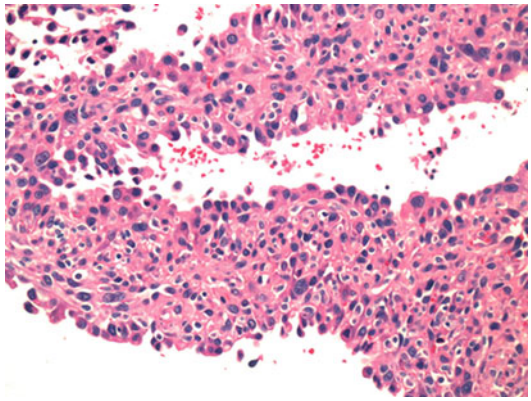

Fig. 4 Primary hepatic angiosarcoma with so-called hobnail cells protruding into the lumen of vascular spaces (hematoxylin and eosin stain)

and 9). In hepatic angiosarcomas, the tumor mainly consists of two cellular components, i.e., spindle cells and highly abnormal endothelial cells that line irregular vascular spaces, the vasoformative pattern. The spindle-shaped cells somewhat resemble fibroblasts or myofibroblasts, and these cells contain elongate nuclei with one or two nucleoli. The endothelial cells vary much in their shape, ranging from flat cells with enlarged, hyperchromatic nuclei, enlarged protruding cells forming the hobnail pattern, to highly polymorphous cells or multinucleated tumor giant cells. The large and atypical endothelial cells may show

erythrophagocytosis, later associated with hemosiderosis of tumor tissue. According to Kojiro and coworkers (1985), two main growth patterns of hepatic angiosarcoma can be distinguished. The first, the sinusoidal or intrasinusoidal growth pattern (Thomas et al. 1975; Kojiro et al. 1985), is characterized by a proliferation of single or multilayered tumor cells along sinusoid-like vascular channels with variable degrees of vascular dilatations and atrophy of the intervening liver cell plates. The tumor cells may completely fill the vascular channels, including small- and medium-sized branches of the portal venous system. The second pattern, the solid pattern, is characterized by solid tumor nests consisting mostly of spindle-shaped cells and fewer polyhedral cells, with a poorly developed vascular network. The solid areas tend to undergo extensive necrosis. In both growth patterns, secondary changes may occur, including extramedullary hemopoiesis, fibrosis, and hyalinosis. The liver tissue surrounding the tumor nodules exhibits atrophy, fatty change, hepatocyte apoptosis, focal and sometimes peliosis like sinusoidal dilatations, fibrosis, and ductular proliferations (Scherer et al. 1996).

Immunohistochemistry

Angiosarcoma cells are immunoreactive for the endothelial cell lineage markers, FVIII-associated antigen, CD31, and CD34 (Figs. 10 and 11; Saleh and Tao 1998). Strong expression of vascular endothelial growth factor A and C as well as p-AKT, p-4EBP11, and elF4E was detected in human angiosarcomas (Lahat et al. 2010). Angiosarcomas are reactive for claudin-5, mostly with a diffuse cytoplasmic staining (Miettinen et al. 2011). The stromal tissue surrounding angiosarcoma expresses decorin, while the tumor itself is negative (Salomäki et al. 2008). Part of angiosarcomas may show immunoreactivity for the neuroendocrine markers synaptophysin and/or chromogranin A, a potential diagnostic pitfall (Tessier Cloutier et al. 2014). The highly

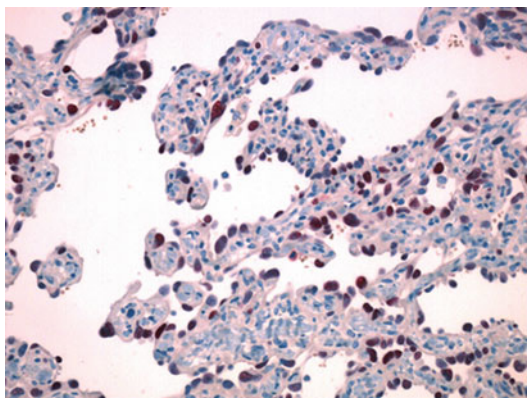

Fig. 13 Nuclear reactivity for p53 protein in hepatic angiosarcoma (p53 immunostain)

invasive phenotype of angiosarcoma in the liver is impressively visualized in cytokeratin stains depicting the invaded hepatocyte population (Fig. 12). Hepatic angiosarcoma, similar to angiosarcomas in other locations, can express p53 protein in the nuclei (Fig. 13). As a grade 3 sarcoma, hepatic angiosarcoma exhibits a high to very high proliferative activity (Fig. 14).

Pathology of Thorotrast-Induced Hepatic Angiosarcoma

Thorotrast-induced hepatic angiosarcoma is, in the whole, very similar to angiosarcomas induced by other agents (Umezu 1984; Kojiro et al. 1982, 1985; Ito et al. 1988). Based on 29 autopsy cases, Kojiro and coworkers (1985) studied the macroscopy and histopathology of thorotrast-induced hepatic angiosarcoma in detail. These authors divided the macroscopic growth patterns into four types, i.e., diffuse micronodular, multinodular, massive, and mixed multinodular and massive, diffuse micronodular and multinodular types being the most common. In the diffuse micronodular type, ill-defined hemorrhagic macular and/or micronodular lesions were scattered throughout the liver. In the multinodular type, fingertip- to walnut-sized hemorrhagic nodules are found. In the massive type, a confluent hemorragic mass measuring more than 10 cm in diameter is detected. In the mixed multinodular and massive type, varying-sized hemorrhagic nodules coexist with a large confluent hemorrhagic mass (Kojiro et al. 1985). Thorotrast deposition is already visualized in H&E-stained sections, in the form of a grayish-white particulate matter that may form clusters with fibrotic areas containing macrophages. The material is also located within the macrophages themselves (thorotrast phagocytosis).

Autoradiography, using the technique of overlayering tissue sections with photoemulsion (Yamamoto et al. 2010), shows the typical high-LET particle tracts radiating from thorotrast grains situated in tissues. These tracts form starlike

profiles, and the length of the tracts nicely shows how many cells are in the damaging reach of the alpha-type ionizing radiation.

Angiosarcoma as a Component of Mixed Hepatic Tumors

Very rarely, angiosarcoma has been observed as a component of mixed malignant liver tumors or atypical "carcinosarcomas." L'Esperance (1915) described the case of a 27-year-old female patient who had died of acute abdominal hemorrhage. Autopsy revealed an immensely enlarged liver measuring 30 cm across both lobes and weighing 6 kg. The organ was studded with numerous nodules measuring up to 6 cm, in part hemorrhagic, and projecting above the surface of the liver. Other nodules were necrotic rather than hemorrhagic, and still others were bile stained. Similar tumor tissue was found in the enlarged hilar lymph nodes. Histology showed a mixture of angiosarcoma ("perithelioma"), hemangioma, and hepatocellular carcinoma.

Differential Diagnosis

An important differential diagnosis is hepatic metastasis of soft tissue, skin, and skeletal angiosarcoma (Meis-Kindblom and Kindblom 1998; Tateishi et al. 2003; Yamashita et al. 2012; Blackmon et al. 2014), but also primary visceral angiosarcomas are known to often metastasize to the liver (Chami et al. 1994; Brown et al. 2004; Yoshida et al. 2009; Ni et al. 2013), in particular those arising in the spleen (Kishikawa et al. 1977; Ferreira et al. 2012; Duan et al. 2013; Kamocki et al. 2013). Involvement of the liver by the rare primary angiosarcoma of the gallbladder was reported (Odashiro et al. 2005). Angioblastic meningioma/hemangiopericytoma, which tends to metastasize to the liver, may be confounded with angiosarcoma (Petito and Porro 1971). In rare instances, hepatocellular carcinoma exhibits an angiosarcoma-like morphology, but the tumor cells lack expression of CD31 and CD34 (Suzuki et al. 2010). Squamous cell carcinomas are also known to sometimes develop a pseudoangiosarcomatous pattern (Conde-Taboada et al. 2005). Anastomosing hemangioma of the liver, further discussed in another paragraph, can histologically mimic angiosarcoma (Lin et al. 2013).

Biology of Disease

Hepatic angiosarcoma is a highly aggressive grade 3 sarcoma that massively invades the liver substance and adjacent tissue, and which widely metastasizes, also to unusual sites such as the spleen, small intestine, or stomach (Casado Martin et al. 1994; Vennarecci et al. 1997; Kim et al. 2005; Ahmad et al. 2008). The tumor has generally a poor outcome, this histology being worse than any other primary hepatic sarcoma (Matthaei et al. 2009), although long-term survivors have been reported after resection, but mainly in case of solitary lesions (Louagie et al. 1984; Timaran et al. 2000; Özden et al. 2003; Arima-Iwasa et al. 2007; Zhou et al. 2010). In a meta-analysis covering 25 articles published from January 2000 to December 2012, the median survival time was 5 months. Local excision alone or combination with adjuvant chemotherapy was the optical choice, with a median survival time of 17 months (Zheng et al. 2014). Palliative chemotherapy in metastasizing hepatic angiosarcoma is potentially useful to improve survival (Kim et al. 2009). Most cases of hepatic angiosarcoma are discovered at an advanced stage, and less than 20 % of patients have received surgery with liver resection. The results of liver transplantation for angiosarcoma are disastrous with a universal tumor recurrence within 6 months (Maluf et al. 2005; Castaldo and Wright Pinson 2007; Bonaccorsi-Riani and Lerut 2010), and in fact, hepatic angiosarcoma is now an absolute contraindication to liver transplantation (Orlando et al. 2013). So far, there is no standardized treatment for hepatic angiosarcoma, but surgery still seems to be the treatment of choice for selected patients. When the lesion is still confined to one lobe of the liver without extrahepatic disease, hepatic resection has in fact proven to be beneficial (preoperative interventional embolization of

the tumor-supplying vessels reduces the risk of pre- and intraoperative hemorrhage (Matthaei et al. 2007). Up to 40 % of patients with hepatic angiosarcoma have liver fibrosis or liver cirrhosis, but the causal relationship between this tumor and fibrosing liver disease is still unknown.

Etiology and Pathogenesis of Hepatic Angiosarcoma

Main causative agents of hepatic angiosarcoma comprise vinyl chloride monomer, thortrast, arsenical salts, aromatic steroids, and a range of other chemical agents. A retrospective epidemiologic study of deaths from hepatic angiosarcoma in the USA revealed that, during 1964–1974, there were 168 such cases, of which 22 % were associated with vinyl chloride, thorotrast, or arsenical salts (Falk et al. 1979a).

Vinyl Chloride

Vinyl chloride (VC) monomer is used for the manufacture of polyvinyl chloride, an important plastic resin for the production of tubes and pipes and for construction and siding. In 1974, VC had been shown to be a human carcinogen, first demonstrated by Professor Cesare Maltoni (Mehlman 2002), inducing angiosarcoma of the liver (Block 1974; Creech and Johnson 1974; Lee and Harry 1974; Maltoni 1974; Wallnöfer and Zinnagl 1977; reviews: Lewis 1999; Bosetti et al. 2003; Bolt 2005; Sherman 2009). The carcinogenic role of VC was also demonstrated on the basis of experimental evidence in rodents. In the light of this carcinogenicity, the exposure levels were drastically reduced arriving at a level of $\leq$1 ppm (review: Dogliotti 2006). Since 1974, numerous reports from several countries have confirmed the role of VC as a hepatic carcinogen (Delorme and Makk 1975; Heath et al. 1975; Lilis et al. 1975; Thomas and Popper 1975; Thomas et al. 1975; Baxter 1976; Makk et al. 1976; Waxweiler et al. 1976; Brady et al. 1977; Delorme 1978; Delorme and Theriault 1978; Popper et al. 1978; Roche et al. 1978; Spirtas and Kamenski 1978; Dannaher et al. 1981; Vianna et al. 1981; Louagie et al. 1984; Falk 1987; Brugnami et al. 1988; Paliard et al. 1991; Riordan et al. 1991; Lee et al. 1996; Lelbach 1996; Elliot and Kleinschmidt 1997; Hozo et al. 2000; Lewis and Rempala 2003; Di Lorenzo et al. 2012). VC also palys a role in causing non-tumorous liver lesions, such as steatohepatitis (toxicant-associated steatohepatitis, TASH; Cave et al. 2010). Among 7,000 men who were at some time between 1940 and 1974 exposed to VC monomer in the manufacture of polyvinyl chloride, four cases of liver cancer were found, of these two were hepatic angiosarcomas (Fox and Collier 1977). VC-associated cases of angiosarcoma have been tabulated in the hepatic angiosarcoma register of the Association of Plastic Manufacturers in Europe (Forman et al. 1985). Among 61 patients with angiosarcoma of the liver registered in England and Wales (1979–1986) and in Scotland (1975–1987), ten cases were found among VC workers (Elliott and Kleinschmidt 1997). During the follow-up of 12,700 male workers in the VC industry in four European countries, a total of 53 deaths from primary liver cancer and 18 incident cases of liver cancer were identified, including 37 angiosarcomas, 10 hepatocellular carcinomas, and 24 liver cancers of other and unknown histology (Ward et al. 2001). Two pooled analyses of worker cohorts from 56 VC plants in North America and Europe included over 22,000 workers; overall, a total of 1,778 cancer deaths were observed, with 71 confirmed angiosarcomas and a standardized mortality ratio of 0.97 (Bosetti et al. 2003). Hepatic angiosarcoma has not only been noted in workers exposed to VC monomer gas in the course of polyvinyl chloride manufacture but also in other situations, such as polyvinyl chloride autoclave cleaning (Riordan et al. 1991), or among hairdressers and barbers using hair spray containing VC propellant (Infante et al. 2009). Vinyl chloride-induced hepatic angiosarcoma may later be followed by peliosis hepatis (Paliard et al. 1991). Vinyl chloride-induced hepatic angiosarcoma was found in association with hepatocellular carcinoma (Delorme 1978).

The toxicity of VC and pathogenic mechanisms have been studied in animal experimentation (Holmberg et al. 1976; Winell et al. 1976;

Suzuki 1983; Maltoni and Cotti 1988; review: Williamson 1976). In mice and rats treated with vinyl chloride, hepatic angiosarcoma developed (Radike et al. 1977; Gehring et al. 1979; Hong et al. 1980; Spit et al. 1981; Suzuki 1981; Saito et al. 1997). In one experimental study, one mouse has shown hepatic angiosarcoma 56 weeks after exposure to 600 ppm vinyl chloride for 4 weeks. Ultrastructurally, two neoplastic cell types, a mesenchymal and a well-differentiated endothelial cell type, were identified, and a pericyte-like cell was also present (Suzuki 1981). The molecular mechanisms of carcinogenesis by VC have been reviewed (Dogliotti 2006). VC is rapidly metabolized to generate reactive metabolites reacting with proteins, DNA, and RNA. In particular, cholorethylene oxide and its derivatives, chloroacetaldehyde and chloroethanol, react with nucleic acids, the reaction being most rapid with chloroethyleneoxide (Malaveille et al. 1975). Chloroethylene oxide, which is the most relevant toxic product of VC, is produced by the action of cytochrome P450 isoenzyme CYP2E1 (El Ghissassi et al. 1998) and is degraded by epoxide hydrolase and glutathione-S-transferase. A major type of modified nucleic acid base is 7-(2-oxoethyl)-guanine, which constitutes 98 % of total adducts but which is not mutagenic. In contrast, the less copiously produced etheno-adducts are mutagenic/miscoding agents, particularly 1,N6-ethenoguanine, 3,N4-ethenocytosine, N2,3-ethenoguanine, and 1,N2,ethenoguanine (review: Barbin 2000). Mutagenic etheno-adducts are recognized and eliminated from DNA by the action of DNA glycosylases which are the key enzymes in this repair pathway (review: Gros et al. 2003). These enzymes remove the etheno-adducts from DNA by hydrolizing the N-glycosidic bond between the altered base and deoxyribose, thus leaving an abasic site in the DNA. A second repair mechanism involves the DNA helicase encoded by the XPD gene, which shows polymorphisms that are thought to play a role in differential susceptibility for VC-induced DNA damage (Zhu et al. 2005). Etheno-adducts alter genes involved in growth regulation and also the genes for DNA polymerases (Guengerich et al. 1999). Non-repaired mutagenic etheno-adducts have been shown to cause Ras gene mutations (Marion et al. 1991; Marion and Boivin-Angele 1999; Boivin-Angele et al. 2000). In particular, G>A transitions were observed at codon 13 in part of the tumor cases (Marion et al. 1991; Weihrauch et al. 2002). The adducts also cause p53 gene mutations, all A>T transitions (Hollstein et al. 1994). VC-induced hepatic angiosarcomas have shown p53 mutations at A/T base pairs (Hollstein et al. 1994; Smith et al. 1998).

Arsenic

Chronic arsenic exposure (chronic arsenosis) leads to several disorders of the liver, including cirrhosis, hepatoportal sclerosis, hepatocellular carcinoma, and angiosarcoma (Cowlishaw et al. 1979; Calmus and Poupon 1982). Inorganic arsenic is a well-known human carcinogen inducing skin cancer and tumors of several inner organs, such as the lung, urinary bladder, and liver (Jackson and Grainge 1975). The liver is a distinct target of arsenic carcinogenesis (review: Liu and Waalkes 2008). Hepatic angiosarcoma has numerous times been associated with arsenic salt exposure, either through treatments or by contact and intake in the environment. Also brief arsenic therapy (e.g., with Fowler's solution, potassium arsenite) has been observed to be followed by the development of this tumor (Roth 1957; Regelson et al. 1968; Lander et al. 1975; Popper et al. 1978; Falk et al. 1981b; Roat et al. 1982; Kasper et al. 1984; Kadas et al. 1985; Salgado et al. 1995; Dueñas et al. 1998; Tsai et al. 1998; Ho et al. 2004). Hepatic angiosarcoma and other arsenic-induced pathologies have been registered in the International Tissue and Tumor Repository for Chronic Arsenosis (ITTRCA; Centeno et al. 2002). The delay between arsenic ingestion and diagnosis of hepatic angiosarcoma may exceed 30 years (Roat et al. 1982).

Arsenic is in the nitrogen group of the periodic system and is a transitional or metalloid element. Pure metallic arsenic is rarely found in nature. Elemental arsenic has zero oxidation state, but

arsenic can occur in trivalent or pentavalent states. In more detail, arsenic occurs in five different valence states, i.e., +V (arsenate), +III (arsenite), +I (arsonium metal), 0 (arsenic), and –III (arsine). Arsenic readily reacts with diverse metals, oxygen, sulfur, carbon, and hydrogen. The three most important inorganic forms are red arsenic (realgar, As4S4), yellow arsenic (orpiment or opperment, As2S3), and white arsenic (arsenic trioxide, As2O3). The most toxic arsenicals (the arsenites) are those which contain trivalent arsenic, in particular the very poisonous arsenic trioxide, derived from arsenious acid (H2As2O3). But the most toxic arsenical is the volatile hydride, arsine (AsH3). Organic arsenicals (mostly several forms of methylated arsenic compounds) contain trivalent or pentavalent arsenic linked to a carbon atom by a covalent bond.

Arsenic is widely present in soil, water, air, and components of the biomass. It is estimated that the natural global emission of arsenic and of arsenic-containing components amounts to 8,000 tons per year, and emissions from man-made sources 23,600 tons per year, one major source being arsenic-containing pesticides such as dimethylarsinic acid (DMA) (review: Huang et al. 2004). Arsenic (from Greek, arsenikon, meaning "potent") in various galenic forms has been employed as a drug for more than 2,000 years (review: Jolliffe 1993). In the eighteenth century, Fowler's solution (1 % potassium arsenite) was used for the relief of various ailments, including Sydenham's chorea (Fowler 1994), and remained popular for over 150 years. This arsenic solution was introduced by Thomas Fowler in 1786 as a flavored solution to mainly treat headaches, remittent fevers, anemia, and rheumatism. As reviewed in the interesting article by Jolliffe (1993), Fowler with the apothecary Hughes had identified arsenic as the major constitutent of the "ague drops" patented by Thomas Wilson, a London chemist, in 1781. By the early 1900s, Ehrlich's experiments showed that arsphenamine was active in syphilis, and arsenicals remained the most important antiluietic treatment for almost 40 years. Until recently, arsenicals have been ingested for the treatment of sleeping sickness. Today, arsenic trioxide is used for the treatment of acute promyelocytic leukemia (PML). Besides exposure to arsenic-containing medical drugs, nonoccupational exposure to arsenic can take place through ingestion of contaminated food and water. One well-known example of waterborne intoxication is contamination of well water with arsenic leached from underground sediments in large areas of India and Bangladesh, with hundreds of thousands of people having developed precancerous skin lesion due to arsenic ingestion (NRC 1999). Inhalational exposure to arsenic occurs in industrial settings such as lead, copper and zinc smelting, from fossil fuel combustion in power plants, in the semiconductor industry, and in pesticide production.

What Is the Biochemistry of Arsenic in Normal Prokaryotic and Eukaryotic Cells?

The oxidation status of arsenic markedly affects the toxicity of arsenic (review: Huang et al. 2004). Arsenite is taken up by mammalian cells by passive diffusion, whereas arsenate competes with phosphate for cellular uptake. Arsenite strongly interacts with thiol group-containing molecules (thiols and dithiols) and thus affects enzyme activities by binding to cysteinyl residues. Conversely, arsenate in its structure resembling that of phosphate interferes with oxidative phosphorylation via formation of unstable arsenate esters, causing ATP deficiency. Arsenate is rapidly reduced to arsenite in blood via reaction with glutathione. In the cytosol of hepatocytes, arsenite undergoes methylation by the action of arsenic methyltransferase (encoded by the As3mt gene) to monomethylarsonic acid (MMA) and then to dimethylarsinic acid (DMA). The methyl donor is S-adenosyl-L-methionine. MDA and DMA are more cytotoxic and more genotoxic than the parent arsenic oxides. Arsenic is rapidly excreted in urine as a mixture of arsenate, arsenite, MMA, and DMA, DMA being the major component accounting for 60–80 % of total arsenic. Arsenate is excreted more rapidly than arsenite, this being a main reason for the greater toxicity and carcinogenicity of arsenite. In prokaryotes and

eukaryotes, resistance to arsenical compounds is mediated by several members of the Acr3 family of cell membrane As and Sb antiporters/permeases that facilitate efflux of trivalent arsenic and antimony, dependent on the electrochemical potential gradient of protons generated by plasma membrane H(+)-translocating P-type ATPase/ArsA ATPase (Maciaszczyk et al. 2011). In prokaryotes, the trivalent metalloids, As(III) and Sb (III), are transferred to the ArsA ATPase, the catalytic subunit of the arsenic efflux pump, by the ArsD metallochaperone (Yang et al. 2011). The ars operon encoded by *E. coli* plasmid R773 has arsD and arsA genes, where ArsA is the arsenic ATPase unit of the pump and ArdD the gene for the As(III) metallochaperone (Abdul Ajees et al. 2011).

What Are the Carcinogenic Pathways of Arsenic ?

Arsenic is an atypical carcinogen, because it is neither an initiator nor a promoter (Barrett et al. 1989; review: Huang et al. 2004). Arsenic exerts direct effects on chromosomes, the genome, and the replication machinery. Unlike other carcinogens, arsenic fails to cause point mutations, but instead causes large multilocus deletion mutations leading to cell death. Arsenic exposure induces chromosome aberrations, aneuploidy and formation of micronuclei (similar to ionizing radiation), DNA-protein cross-linking, and sister chromatid exchange. Arsenite inhibits DNA ligase and hence DNA repair. Arsenic, even at low doses, affects the expression of several cellular pathways in part shared by toxic effects of cadium (Benton et al. 2011; review; Huang et al. 2004). Oxidative stress, altered DNA repair, and altered DNA methylation patterns seem to play a major role in arsenic-mediated carcinogenesis (Kitchin 2001; Huang et al. 2004; Kitchin and Conolly 2010). Arsenic induces the production of reactive oxygen species (ROS) during its metabolism in cells, countreracted by cellular superoxide dismutase. Arsenic also increases the production of hydrogen peroxide in the extracellular space. Cells deficient in catalase are hypersentitive to arsenic cytotoxicity, supporting the pathogenic role of ROS. ROS themselves are known to play a role in the initiation and promotion processes of carcinogenesis and to be involved in signaling of the cell transformation response . Induction of p-ERK and cell proliferation by arsenite is mediated by oxidative stress, since antioxidants can inhibit arsenite-induced cell transformation (Li et al. 2011). Arsenic alters gene expression via activation of signal transduction pathways. Arsenite is a potent stimulator of c-fos and c-jun expression and AP-1 transactivational activity. Induction of AP-1 is mediated by activation of protein kinase C and MAPKs family members. Both arsenate and arsenite induce the activation of the transcription factor, NFkappaB, in an ERK-dependent pathway (review: Huang et al. 2004). Arsenic is found to target and degrade a class of proteins with high levels of cysteine residues and vicinal thiol groups, such as zinc finger proteins, promyelocytic leukemia protein (PML), and PML-retinoic acid receptor alpha (PML-RARalpha) fusion protein. Arsenite interacts selectively with zinc finger proteins containing C3H1 or C4 motifs (Zhou et al. 2011), and arsenic directly binds the C3HC4 zinc finger motif in the RBCC domain of PML and PML-RAR (retinoic acid receptor) alpha, induces their homodimerization and multimerization, and enhances their interaction with the SUMO E2 conjugase Ubc9, thus facilitating proteasomal degradation (Zhang et al. 2010; Chen et al. 2011). Wild-type p53 protein accumulates in cells treated with arsenic, while mutant p53 protein is a target of arsenic trioxide in that its degradation is promoted by arsenicals (Yan et al. 2011). Arsenic affects apoptotic pathways. Apoptosis induced by arsenic oxide in PML cells depends on the presence of the expression of PML-RARalpha, not the PLZF-RARalpha fusion protein. Redistribution of PML nuclear bodies upon As2O3 treatment is accompanied by recruitment of PIC-1/SUMO-1 into PML nuclear bodies, and this modified PML-RARalpha is involved in the induction of apoptosis (Sternsdorf et al. 1999). Arsenic oxide (As(2)O(3) targets the stem cell marker, CD133/

prominin-1, to gallbladder carcinoma cells and via this mechanism induces apoptosis (Ai et al. 2011).

Thorotrast (Thorium Dioxide)

Thorotrast and Umbrathor are thorium-containing roentgenographic contrast media that had been introduced into market in 1929. Thorotrast is a 25 % colloidal solution of thorium 232 dioxide. Thorium nuclide 232 is slighty unstable and decays through the emission of alpha particles which exert high-LET ionizing radation. Thorotrast was widely used until 1955. It was intensively employed owing to its excellent contrast characteristics and almost inexistent acute toxicity and had wide indications for cerebral angiography, cholangiography, and urographic techniques. It is estimated that up to ten million persons received thorotrast for a wide variety of examinations. About 10 years after its introduction, reports of thorotrast-related cancers started to appear, but thorotrast was still used until the mid-1950s. The most common liver tumors induced by this high-LET radiation source are cholangiocarcinomas, hepatocellular carcinoma, angiosarcoma, and squamous cell carcinoma (review: Lipshutz et al. 2002) . Thorium 232 is a radioactive isotope that naturally emits alpha and beta particles and gamma rays. Around 90 % of the emitted ionizing radiation is in the form of alpha particles. Thorium 232 has a half-life of 14 billion years. After injection, the particulate matter contained in thorotrast is taken up by cells of phagocytic system (mainly macrophages) and other cells and is stored in the body for life, particularly in the spleen, the liver (the Kupffer cell system) and the bone marrow. For more details, see the chapter on liver involvement in pneumokonioses and other dust-induced disorders.

The first report of hepatic angiosarcoma related to thorotrast dates from 1947 (MacMahon et al. 1947). Since then, numerous reports have documented the causal relationship between thorotrast exposure and the emergence of hepatic angiosarcoma (Da Horta 1956; Batzenschlager et al. 1961; Vellenga 1962; Rakov et al. 1963; Hohenstatt 1965; Leitner 1965; Underwood and Huck 1978; Falk et al. 1979a; Telles et al. 1979; Winberg and Ranchod 1979; Baxter et al. 1980; Hiraoka et al. 1981; Manning et al. 1983; Silverman et al. 1983; Mohr et al. 1984; Umezu 1984; Bruguera et al. 1985; Kojiro et al. 1985; Abe and Wakasa 1987; Azodo et al. 1993; Ishikawa et al. 2001; Arteche et al. 2007; Van Kampen et al. 2007). Thorotrast-induced hepatic angiosarcoma is well known to occur after delays of many years after exposure (Underwood and Huck 1978; Abe and Wakasa 1987). In one study of 29 cases examined by autopsy, the tumors were diagnosed after a latent period after thorium dioxide injection ranging from 27 to 49 years, with a mean of 36.2 years (Kojiro et al. 1985). Hepatic angiosarcoma induced by thorotrast was produced experimentally in rats, which however also developed hepatic Kupffer cell sarcomas (Wesch et al. 1984). In the German Thorotrast study, covering 2,326 patients that had been compared with 1890 nonexposed controls, the latent period of all liver cancers ranged from 16 years to more than 50 years; in comparison, the first cases of acute myeloid leukemia were seen 5 years after thorotrast injection. Two thirds of the 454 hepatic cancers observed in the thorotrast group were classified as carcinomas (predominantly cholangiocarcinomas), and one third as angiosarcomas (Van Kaick et al. 1999).

Other Etiopathogenetic Relations

Diverse aromatic sex steroids are considered to play an etiologic role in hepatic angiosarcoma. They include androgenic-anabolic steroids (Daneshmend and Bradfield 1979; Falk et al. 1979b; Nordsten 1985), oral contraceptives (Monroe et al. 1993; Shi et al. 1981), and diethylstilbestrol (Hoch-Ligeti 1978). Among 131 deaths from hepatic angiosarcoma not induced by VC, thorotrast, or arsenic, observed between 1964 and 1974 in the USA, 4 (3.1 %) were associated with the use of androgenic-anabolic steroids (Falk et al. 1979). Other chemical substances that were

associated with the development of hepatic angiosarcoma include cyclophosphamide (Rosenthal et al. 2000), urethane (Cadranel et al. 1993), and pesticides (El Zayadi et al. 1986). There is a rare correlation between hemochromatosis and hepatic angiosarcoma (Sussman et al. 1974; Timaran et al. 2000; Mani and Van Thiel 2001; Özden et al. 2003; Stambo and Guiney 2007).

Pathogenic Pathways

Whereas etiologic factors playing a significant role in the development of hepatic angiosarcoma are well recognized (see above), pathogenic mechanisms are only starting to be better understood. In what follows, a selection of pathways probably important in pathogenesis is briefly summarized.

Angiosarcomas exhibit recurrent mutations of PTPRB and PLCG1, factors intimately linked to angiogenesis (Behjati et al. 2014). PTPRB is protein tyrosine phosphatase, receptor type B that regulates various cellular processes, including regulation of growth. PLCG1 is a signal transducer of tyrosine kinases and phospholipase centrally involved in inositol phosphate signaling. Sporadic and thorotrast-induced hepatic angiosarcomas show frequent and multiple point mutations in the K-ras-2 gene (Przygodski et al. 1997). Mutations of K-ras-2 have also been detected in hepatic angiosarcoma caused by vinyl chloride exposure (Weihrauch et al. 2002). P53 gene mutations are well-known and frequent events in angiosarcomas caused by vinyl chloride monomer and alpha-particle radiation (Hollstein et al. 1994; Andersson et al. 1995; Wada et al. 1999). In the absence of such etiologic factors, the status of p53 gene mutations is less clear, as the published results vary considerably regarding the frequency of p53 mutations, either found to be uncommon in extrahepatic angiosarcomas (Inohara 1994; Naka et al. 1997) or rather common (Zietz et al. 1998). Whereas TP53 mutations are, e.g., frequent in leiomyosarcoma and undifferentiated pleomorphic sarcoma, these aberrations are rarely involved in the pathogenesis of angiosarcoma (Italiano et al. 2012). Few cases of p53 mutations have been reported for hepatic angiosarcomas not related to vinyl chloride or thorotrast (Soini et al. 1995). P53 mutations in primary hepatic angiosarcomas have also been detected in tumors not associated with vinyl chloride exposure (Soini et al. 1995).

Pediatric Hepatic Angiosarcomas 55

Contents

Abstract

Distinct variants of hepatic angiosarcoma occur in the pediatric age group. Overall, these are very rare neoplasms. Infantile type of hepatic angiosarcoma, at least part of which was previously classified as type 2 of infantile hepatic hemangioendothelioma, is a rapidly growing neoplasm that commonly involves both liver lobes and causes marked hepatomegaly. The tumor may be associated with respiratory distress but does not induce congestive heart failure. The histology is different from adult-type hepatic angiosarcoma and characterized by a complex network of anastomosing and sometimes slit-like vascular channels lined by plump, often spindle-shaped endothelial cells with atypical nuclei. Whorls of sarcomatoid cells and kaposiform spindle cells are observed. Irregular budding and branching structures are a typical feature. Infantile hepatic angiosarcoma can metastasize, mainly to the lungs, and is associated with rapid progression. Very rarely, pediatric hepatic angiosarcoma displays the morphology of adult-type angiosarcoma. These neoplasms develop in children older than 3 years of age and are sporadic lesions.

Pediatric Hepatic Angiosarcoma, Infantile Type

Introduction

As discussed in the respective chapter, infantile hepatic hemangioendotheliomas of type 1 are vascular tumors that characteristically appear in infancy and, subsequently, involute, thus displaying a relatively benign behavior. Rarely, such lesions behave in an aggressive way and in such a setting have metastatic potential, hence showing the features of angiosarcomas. Less than 50 of such malignancies have been reported in the literature so far. Most of such tumors have previously been classified as infantile hepatic hemangioendothelioma type 2 (Dehner and Ishak 1971). In brief, Dehner and Ishak defined the type 1 as a pattern predicting a benign course, the histology closely resembling that of hemangioendotheliomas developing at other site, mainly characterized by irregularly arranged and dilated vascular channels lined by a single layer of cytologically bland-looking endothelial cells. In contrast, type 2 is associated with an aggressive course, including metastatic disease, and exhibits irregularly budding and branching vascular structures with larger and atypical endothelial cells. The latter variant of hepatic hemangioendothelioma is now generally interpreted to be an angiosarcoma, also based on the aggressive clinical course (Ishak et al. 2001). Dehner and Ishak (1971) already emphasized that the histologic pattern as such is not an absolute predictor of the clinical behavior. This difficulty is further enhanced by the fact that benign-looking (type 1) hepatic hemangioendotheliomas may with time transform into lesions histologically representing low-grade angiosarcomas, an evolution discussed in more detail below. In the present context, this type of low-grade hepatic angiosarcoma occurring in infancy and early childhood is termed infantile-type hepatic angiosarcoma (pediatric hepatic angiosarcoma of infantile type). Much rarer are hepatic angiosarcomas that histologically reflect the features of hepatic angiosarcomas of adult patients. These adult-type pediatric hepatic angiosarcomas are treated in a separate chapter.

Epidemiology

Since the reports of de Haan (1903) and Dehner and Ishak (1971), relatively few cases of infantile-type hepatic angiosarcoma have been described (Chabalko and Fraumeni 1975; Falk et al. 1981; Kirchner et al. 1981; Moazam et al. 1982; Noronha and Gonzalez-Crussi 1984; Strate et al. 1984; Alt et al. 1985; Selby et al. 1992; Awan et al. 1996; Dimashkieh et al. 2004; Premalata et al. 2005; Nazir and Pervez 2006; Ackermann et al. 2011; Geramizadeh et al. 2011).

Pediatric hepatic angiosarcoma is among the most uncommon types of childhood hepatic vascular tumors. In the series of Dehner and Ishak (1971), the age at diagnosis ranged from 13 days to 4 years, and 87 % of the tumors were diagnosed before the patients reached the age of 6 months. Patients with angiosarcoma are older at diagnosis than those with type 1 hepatic hemangioendothelioma (Chabalko and Fraumeni 1975; Selby et al. 1992; Dimashkieh et al. 2004). In a series of ten cases, the range of age at diagnosis was 18 months to 7 years, with a mean of 3.7 years (Selby et al. 1992), and in a series of four cases, the mean age at diagnosis was 38 months (Awan et al. 1996). Among 41 cases reported in the literature, about half of the patients were older than 2 years at diagnosis (Dimashkieh et al. 2004). In contrast to adult hepatic angiosarcoma, pediatric hepatic angiosarcoma affects females more than males, with an overall female to male ratio of about 2:1.

Clinical and Imaging Features

Similar to type 1 hepatic hemangioendothelioma (see the respective chapter), infantile-type hepatic angiosarcoma usually presents as hepatomegaly, which is in fact the most frequent physical finding. The abdominal enlargement caused by tumor-induced hepatomegaly may develop rapidly, and involvement of both liver lobes is common from the outset. Hepatomegaly may be accompanied by abdominal pain, vomiting, fever, jaundice, respiratory distress, and anemia. In contrast to

type 1 hemangioendothelioma, patients with angiosarcoma do not show congestive heart failure (Selby et al. 1992), and consumption coagulopathy has not been noted. Metastases, especially in the lungs, are a common early occurrence.

It has been suggested that this type of neoplasm may arise via malignant transformation of type 1 infantile hepatic hemangioendothelioma, based on observations that angiosarcoma became histologically evident on repeat biopsy, in liver resection specimens, or on autopsy, requiring ample biopsy in patients where the clinical course is suspicious of malignancy (Dehner and Ishak 1971; Falk et al. 1981; Kirchner et al. 1981; Strate et al. 1984; Alt et al. 1985; Awan et al. 1996). Patient 15 (2 months of age) listed in the publication of Dehner and Ishak (1971) showed a mixture of type 1 and type 2 lesions, but the biology of tumor disease is unknown as the patient died during cardiac surgery for patent ductus arteriosus. Falk and coworkers (1981) described three infantile hepatic vascular tumors that were histologically benign on the initial biopsy, but subsequently (i.e., within 2–20 months) transformed into an aggressive-looking histology associated with a malignant clinical course. All three malignant tumors consisted of remnants of type 1 hemangioendothelioma, foci of low-grade angiosarcoma, and multiple nodular areas composed of loose mesenchymal tissue with scattered malignant cells and embedded small bile ducts. The 6-month-old infant described by Kirchner et al. (1981) had multiple hepatic hemangioendothelioma that regressed after steroid therapy, but recurred at 4 years of age as a neoplasm with an angiosarcoma histology. In the case reported by Strate et al. (1984), a 3-month-old male infant presented with multiple hepatic nodules interpreted, also based on a biopsy, as benign hemangioendothelioma. After an unsuccessful steroid therapy of several weeks duration, the liver gradually decreased in site during a 6-month period, and the child was well at 2.5 years of age, with a normal liver radionuclide scan, but reappeared at 5 years with painful hepatomegaly and hepatic filling defects. Following progressive abdominal distention, anemia, and fever, the patient died. Autopsy revealed a markedly enlarged liver (2,620 g) with ruptured and in part cystic, hemorrhagic tumor masses histologically showing angiosarcoma with a prominent spindle cell component.

Abdominal CT displays low-attenuating vascular lesions forming masses of variable diameters, typically around 2–4 cm (Awan et al. 1996). There are no clear features to differentiate pediatric angiosarcoma from type 1 hemangioendothelioma (Awan et al. 1996). Doppler flow studies showed an increase in hepatic arterial blood flow and sometimes reverse flow in portal venous branches secondary to tumor infiltration (Awan et al. 1996).

Pathology

Macroscopy

Similar to type 1 lesions, infantile-type pediatric hepatic angiosarcoma presents as either solitary or multiple nodular masses without predilection for the right or the left liver lobe. The tumors are more or less well delineated, sometimes with infiltrating borders, but are unencapsulated. The cut surface is gray to red or tan, sometimes with hemorrhage, friable necrotic areas, or cystic alterations. In part of the cases, most tumor revealed cysts filled with a hemorrhagic fluid (de Haan 1903). In contrast to solitary nodules, which tend to be more solid, multiple nodules are more often soft and hemorrhagic or hyperemic.

Histopathology

The histology of infantile-type pediatric hepatic angiosarcoma is different from that of adult-type angiosarcoma. In the infantile type, most cases representing the former infantile hepatic hemangioendothelioma type 2, histology displays a complex network of irregular and in part anastomosing vascular channels, some of them slit-like, lined by plump, often spindle-shaped, endothelial cells with eosinophilic cytoplasm and

large, oval, and vesicular nuclei with prominent nucleoli. In contrast to adult-type angiosarcoma, hypercellular whorls of sarcomatoid cells or kaposiform spindle cell areas can be found (Dimashkieh et al. 2004). In cells lining vascular spaces, the nuclei appear pushed to the side. A typical feature, already described for type 2 hemangioendothelioma (Dehner and Ishak 1971), is the presence of "irregular budding and branching structures, in part giving the impression of lying free within tortuous vascular spaces." The budding structures sometimes form endoluminal polypoid formations covered by several layers of highly atypical endothelial cells. Sometimes, very few endothelial cells surround an erythrocyte-containing space, resulting in the appearance of capillary-like vessels lined by tumor cells (Falk et al. 1981). In some areas, anaplastic endothelial cells seem to line preexisting sinusoidal vessels with interposed atrophic liver cell plates (so-called trabecular angiosarcoma; Falk et al. 1981). Angiosarcoma tissue can invade subterminal veins and tributaries of the hepatic veins. Within larger vascular spaces, angiosarcoma typically forms filiform, fibrous stalks covered by neoplastic endothelial cells (Falk et al. 1981). There are areas where the vascular spaces are poorly developed or look collapsed. Such areas are often occupied by a solid growth of spindle cells with entrapped atrophic hepatic parenchymal cells and small bile duct and ductules, this pattern somewhat resembling Kaposi's sarcoma or kaposiform hemangioendothelioma of soft tissues (Ishak et al. 2001). In these areas, mitotic figures may be more frequent than in the clearly vascular components. At the periphery of the tumor nodules, arterioles with muscle cells and small feeding arteries may be in evidence. Sometimes, such feeding vessels are abundant and traverse the connective tissue sheath of the tumor nodules. Cavernous vascular spaces may occur, but are less prominent than in type 1 lesions, although they were detected in five out of six cases in one study (Dehner and Ishak 1971). The tumor may also show hypercellular whorls of sarcomatoid cells or glomeruloid foci. Pleomorphic cells or multinucleated giant cells are usually sparse, in contrast to adult-type angiosarcoma. Intracellular eosinophilic, PAS-positive globules are present in most cases and may be abundant, specifically within kaposiform spindle cells (Selby et al. 1982; Dvorak 1993). These globules are not immunoreactive for alpha-1 antitrypsin. Part of the tumors show foci of extramedullary hematopoiesis (five out of six patients; Dehner and Ishak 1971). The tumors usually show necrosis and hemorrhage, sometimes prominent. Granulation tissue and fibrosis may develop around necrotic components of the tumor. In this connective tissue, thick collagen bundles may develop, and the adjacent liver substance can show perifocal atrophy, ductular proliferations, and cholestasis. In one case, electron microscopy revealed plump cells lining vascular spaces showing multiple free ribosomal helices together with a well-developed smooth endoplasmic reticulum and small mitochondria. The tumor cells often contained myelin figures, membrane-bound inclusions (lysosomes), and lipid droplets. Typical Weibel-Palade bodies were not detected (Noronha and Gonzalez-Crussi 1984).

Immunohistochemistry

The endothelial cells lining the vascular channels are reactive for CD31, CD34, and factor VIII-associated antigen (Selby et al. 1992; Dimashkieh et al. 2004). Also part of the (kaposiform) spindle cells is positive for CD31 and CD34 (Dimashkieh et al. 2004). The proliferative activity assessed in MIB1 immunostains ranged from 0.4 % to 6 % (Dimashkieh et al. 2004).

Hepatic Angiosarcoma Associated with Other Angiomatous Tumors

It is well known that cutaneous hemangiomas can be associated with internal vascular tumors. Specifically, the presence of more than five cutaneous lesions seems to be a marker of possible internal hemangiomatosis, with the liver being the most often involved site. Hepatic angiosarcoma (type 2 hemangioendothelioma) was found in conjunction with multiple cutaneous infantile

hemangiomas in neonates, infants, and children up to 4 years of age (Dehner and Ishak 1971; Chabalko and Fraumeni 1975; Falk et al. 1981; Kirchner et al. 1981; Alt et al. 1985; Selby et al. 1992; Awan et al. 1996; Walsh et al. 2004; Nord et al. 2006). Infantile-type hepatic angiosarcoma has also been observed associated with other visceral vascular tumors, e.g., jejunal angiosarcoma (Ganguly and Mukherjee 2010).

Biology of Disease

Infantile-type hepatic angiosarcoma has a very poor prognosis, with an average survival of 16 months (Dimashkieh et al. 2004). The often multicentric tumor grows rapidly and is usually unresectable. Metastases occur early in the course of disease, especially metastases to the lung (Kaufmann and Stout 1961; Falk et al. 1981; Selby et al. 1992; Awan et al. 1996).

Etiopathogenic Pathways

In one case of infantile-type hepatic angiosarcoma, exposure to arsenic was found, and etiologic factor known to play a role in hepatic angiosarcomas of adult patients (Falk et al. 1981), but in the other reported cases, there was no clear association with environmental cancerogens.

Adult-Type Pediatric Hepatic Angiosarcoma

Introduction

As in adults, angiosarcoma in children is one of the rarest soft tissue tumors, representing fewer than 1 % of soft tissue sarcomas, and visceral forms of this tumor are even much less common. Adult-type pediatric hepatic angiosarcoma is a highly aggressive tumor that is histologically different from infantile-type hepatic angiosarcoma (type 2 infantile hepatic hemangioendothelioma; see above), in that it does not occur in conjunction with hepatic hemangioendothelioma and its histology closely resembles that of hepatic angiosarcoma of adult patients.

Epidemiology and Presentation

Relatively few adult-type angiosarcomas have been reported (Nielsen 1951; Davis 1961; Sugahara et al. 1974; Adam et al. 1975; Falk et al. 1981; Selby et al. 1992; Hernandez et al. 1999; Premalata et al. 2005; Gunawardena et al. 1997; Bien et al. 2009; Deyrup et al. 2009; Geramizadeh et al. 2011; van den Brand et al. 2011). Hepatic angiosarcomas not associated with infantile hepatic hemangioma/hemangioendothelioma are diagnosed in children of an older age group than infantile hemangioma, i.e., with a mean age of 3.7 years at diagnosis (Selby et al. 1992).

Sugahara et al. (1974) described a large liver angiosarcoma in a 15-year-old male; this tumor was particularly large, the right hepatic lobectomy specimen weighing 3,550 g. A primary hepatic tumor observed in a 3-year-old girl (Adam et al. 1975) was associated with cachexia, ascites, abdominal wall edema, venous congestion, and bilateral pleural metastases, the malignancy rapidly leading to death. At autopsy, the right liver lobe was replaced by a huge, in part yellowish gray, in part hemorrhagic tumor with the histology of angiosarcoma. The case of Gunawardena et al. (1997) was a 3-year- and 11-month-old female with a large nodular and firm liver tumor which histologically consisted of a grade 3 pleomorphic cell angiosarcoma. The patient reported by Hernandez and coworkers (1999) was a 3-year-old boy presenting with a large hepatic tumor and pulmonary nodules representing metastases. CT of the liver showed a tumor mass that was centrally liquefied with a hemorrhagic component. An exophytic component of the tumor protruded through the diaphragm at the level of the right cardiophrenic angle. Biopsy of the tumor revealed angiosarcoma characterized by haphazard slit-like spaces lined by highly atypical endothelial cells. Among ten children with angiosarcoma studied by the Polish Pediatric Rare Tumors Study, one

2.5-year-old male child had hepatic angiosarcoma (stage T2N1M0), and this patient died with regional relapse after R1 liver resection (Bien et al. 2009). In a study of 15 high-grade angiosarcomas in the soft tissues and viscera of children, tumors arose in both sexes (8 males, 7 females), and the age at diagnosis ranged from 3 months to 19 years (median, 11 years). Only two tumors were located in the liver. Eight cases showed an epithelioid morphology and seven cases were primarily spindled. One case was positive for podoplanin (Deyrup et al. 2009). Hepatic pediatric angiosarcoma has been observed in association with the ICF syndrome (immunodeficiency, centromeric region instability, facial anomalies; a disorder caused by defective DNA methylation; van den Brand et al. 2011). In contrast to hepatic angiosarcoma in adult patients, the role of cancerogenic environmental factors is less prominent in pediatric angiosarcoma. In one patient, exposure to elevated levels of arsenic in the environment may have played an important role (Falk et al. 1981).

Pathology

The tumors present large nodular masses with invasive borders. On cut surfaces, the neoplastic tissue is gray to white, sometimes with necroses, hemorrhages, and cyst formation (Hernandez et al. 1999).

Histologically, the neoplasm reported by Sugahara et al. (1974) revealed a mixture of pleomorphic angiosarcoma with marked nuclear atypia and mitotic activity and areas consisting of spindle cells, blood lakes with lining endothelial cells, and irregular capillary-like channels. Erythrophagocytosis was in evidence. The hepatic tumor described by Gunawardena et al. (1997) consisted of CD34-positive pleomorphic tumor cells with an eosinophilic cytoplasm, large nuclei, and numerous mitotic figures, including abnormal ones. A solid growth prevailed, but small dilated channels lined by plump cells were also noted. The tumor cells contained numerous eosinophilic, PAS-positive globules that stained for alapha-1 antitrypsin. In the systematic study of Deyrup et al. (2009), two histologic patterns were observed either individually or in combination: (1) a racemose vasculature dissecting through adjacent normal tissue and (2) solid sheets and nests of cells (Deyrup et al. 2009). Most tumors display at least focal vasoformative areas, characterized by the formation of vascular channels lined by endothelial cells with hyperchromatic nuclei. Solid areas show dense tissue consisting of elongated spindle cells forming fascicles and whorls, with a variable admixture of epithelioid cells. In one study, an epithelioid component was detected in 53 % of the tumors (Deyrup et al. 2009). A hobnail morphology was seldom seen and was not associated with podoplanin expression (Deyrup et al. 2009). The mitotic activity is usually high to very high, with up to more than 60 mitotic figures per 10 HPFs.

The neoplastic cells are immunoreactive for the endothelial cell lineage markers, CD31, CD34, and FVIII-associated antigen. Positivity for podoplanin is an exceptional finding (Deyrup et al. 2009).

Differential Diagnosis

The main differential diagnosis is low-grade hepatic angiosarcoma occurring in conjunction with infantile hepatic hemangioma/hemangioendothelioma. In these tumors, the histology is different from adult-type angiosarcoma in that hypercellular whorls and "kaposiform" spindle cells prevail.

Hepatic Kaposi's Sarcoma

56

ICD-O code 9140/3

Contents

Abstract

Kaposi's sarcoma (KS) is a malignant tumor composed of spindle cells and slit-like, frequently abortive vascular structures. KS mainly occurs in the skin and several internal organs and exists in the form of four main types, i.e., classical, endemic, immunosuppression-associated, and epidemic or AIDS-associated KS. KS is associated with herpesvirus or herpesvirus type 8 infection. KS primary to the liver almost always develops in the setting of AIDS. Lesions restricted to the liver are very uncommon, most patients also showing KS lesions elsewhere, but hepatic KS is a well-known tumor that was already documented in Kaposi's own patients. The liver neoplasms are usually multiple and are visualized as red-brown and hemorrhagic nodules that may reach more than 5 cm in diameter. The histologic picture is dominated by spindle cells that are reactive for the endothelial markers CD31 and CD34, but are also positive for D2-40. In fact, KS cells seem to originate from a lymphatic endothelial cell lineage. Apart from KS apparently developing in the liver, this organ is also involved by metastatic KS.

DOI 10.1007/978-3-319-26956-6_56

Introduction

Kaposi's sarcoma (KS) is a malignant neoplasm composed of spindle cells and angioid slit-like vascular structures. KS can present with cutaneous lesions with or without internal tumors, but primary deep organ KS in the absence of cutaneous involvement also occurs. KS has a strong etiologic relationship with a human gammaherpesvirus, KSHV, or human herpesvirus 8 (HHV8) (Fig. 1).

Kaposi described the lesion in 1872 (Kaposi 1872). Moriz Kohn Kaposi (1837–1902) was an internationally respected dermatologist and is also credited with the first description of xeroderma pigmentosum. In regard to the pigmented sarcoma he described, he emphasized that this new disease was incurable and rapidly lethal. Among the five patients he described, three were dead within 12–16 months of presentation. As his autopsy findings showed also visceral involvement, Kaposi said that " [one] must postulate, for this scourge, that there is a generalized disease (dyscrasia) pre-existing from the beginning" (Breimer 1994; Zantinga and Coppes 1996; reviews: Orfanos et al. 1995; Antman and Chang 2000; Szajerka and Jablecki 2007). KS was first regarded as a hyperplastic process with features of reversibility (Brooks 1986), but is now established to be a neoplastic process.

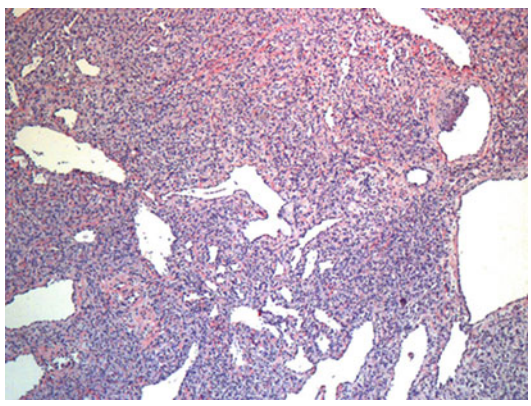

Fig. 1 Kaposi's sarcoma of the liver. A highly cellular neoplasm consisting of spindle cells and polygonal cells contains relatively few vascular spaces hematoxylin and eosin stain

Based on distinct clinical settings and manifestations, KS can be separated into several forms (Table 1).

Being previously a rare and little studied condition, the AIDS epidemic drew much attention to this complex tumor. The disease is caused by a transmissible agent, Kaposi's sarcoma-associated herpesvirus (KSHV) or human herpesvirus type 8 (HHV8) (Chang et al. 1994; Schalling et al. 1995; Moore et al. 1996), a member of the gamma-herpesviridae.

Epidemiology

KS occurs in four forms, i.e., classic, endemic (African), posttransplant, and epidemic (AIDS-related) forms. Classic KS is rare and occurs predominantly in Mediterranean and Middle Eastern men. Among 438 classic KS patients studied in the USA, the tumor was more common in men with a mean age of 74 years; the lesions presented predominantly in the lower extremities, in the nodular stage, and KSHV was detected in the majority of patients. Classic KS is a rather indolent disease and rarely accounts, as such, for patient demise, but a second, non-classic KS malignancy was present in 42 %, 73 % with a

Table 1 Classification of Kaposi's sarcoma (KS)

Classic KS
The originally described disease affecting elderly men in Mediterranean populations of Eastern European descent. Clinical course relatively indolent
Endemic KS
Endemic KS occurs in two types, i.e., African cutaneous KS and African lymphadenopathic KS. Endemic KS affects young African persons, mainly from sub-Saharan Africa. This disease is a cutaneous disorder not related to HIV infection, with a more aggressive course
Immunosuppression-associated KS
This form of KS was increasing in frequency in the era of solid organ transplantation, mainly before the advent of calcineurin inhibitors. It is related to KSHV infection, either of the recipient or the graft
AIDS-associated KS or epidemic KS
This is the most aggressive form of KS that is 300 times more common in AIDS patients than in solid organ transplant recipients. It is caused by sexually transmitted KSHV

higher incidence over the general population (Hiatt et al. 2008). In AIDS-associated KS, there was also a male predominance, and a more aggressive behavior, with higher rates of visceral and disseminated disease (Hiatt et al. 2008).

The epidemic form is associated with immunosuppression-induced KSHV infection (reviews: Beral et al. 1990; Beral 1991). Sexual contacts are the most important mode of transmission of the agent, although transmission by blood and perinatally may also occur. KS became an epidemic among male homosexuals and foreshadowed the AIDS epidemic. HIV-induced immunosuppression allows KS to manifest itself in individuals who are normally asymptomatic carriers of KSHV, and this is the main reason why the combined infection with HIV and KSHV promotes the frequent development of KS in AIDS. KS is often the first manifestation of AIDS. KS rarely occurs in heterosexuals from Europe or North America, but occurs frequently among heterosexuals from Africa, because the prevalence of KSHV among the population is much higher in Africa (Beral. 1991). Up to 1998, nearly 5,000 cases of morphologically confirmed classic KS have been reported in Europe, the Mediterranean Basin, and the Americas (review: Iscovich et al. 2000). In the era of highly active antiretroviral therapy (HAART), the incidence of AIDS-KS has considerably declined, probably due to enhanced immune reconstitution and anti-KSHV-specific immune responses (review: Hengge et al. 2002). KSHV is also associated with a recently described disorder, KSHV inflammatory cytokine syndrome (KICS), characterized by systemic illness as a result of systemic, lytic KSHV infection (Tamburro et al. 2012).

By 1989, 15 % of all reported AIDS cases in the USA had KS as the primary AIDS-defining illness (Beral et al. 1990). Subsequent to the introduction of highly effective antiretroviral therapy, the incidence of AIDS-KS has declined, but the prevalence of KS remains high in untreated HIV patients, particularly in sub-Saharan Africa. Cases of KS in antiretrovirally treated HIV patients may be linked to the development of the immune reconstitution inflammatory syndrome (Bower et al. 2005; Leidner and Aboulafia 2005; Hofman and Nelson 2006). KS is the most common gastrointestinal malignancy in AIDS, seen in about 40 % of patients, and is often asymptomatic. KS may involve the stomach, the small and large bowels, and rarely the appendix (review: Arora and Goldberg 2010).

KS is a well-known complication after organ transplantation (Serraino et al. 2005; review: Lebbé et al. 2008); its incidence ranges between 2 % and 5.5 %, according to different centers worldwide. Among 1,721 Italian solid organ transplant recipients, the risk for KS was about 100 times greater compared to the general population, especially during the first 2 years after transplantation. Age older than 30 years at transplantation and a more aggressive immunosuppressive regimen were both independent risk factors for the disease (Tessari et al. 2006). KS has been observed to develop subsequent to liver transplantation (Aseni et al. 2001; review: Di Benedetto et al. 2008), also in the liver graft itself (Colina et al. 1996; Mazza et al. 1996).

Primary and Secondary Hepatic Kaposi's Sarcoma

Introduction

KS of the liver almost always evolves in the context of AIDS, and lesions restricted to the liver are very rare, most patients in fact having KS lesions elsewhere (Hasan et al. 1989; Kumar et al. 1989; Gonzalez-Lopez et al. 1996; Ikezaki et al. 2011). Liver involvement by KS, seen at autopsy, was already noted among the first five patients described by Kaposi (1872). However, there are relatively few reports documenting primary hepatic KS (Defalque et al. 1988; Luburich et al. 1990; Towers et al. 1991; Valls et al. 1991; Gottesman et al. 1993; Tanaka et al. 1995). In a patient with AIDS, ultrasonography (US) revealed several small (5–10 mm) hyperechoic nodules and dense periportal bands. Autopsy showed primary hepatic KS (Luburich et al. 1990). In the AIDS patient reported by Tanaka et al. (1995), hepatic KS was detected by US and CT, US showing multiple hyperechoic tumors

along the portal vein and CT showing low density and delayed enhancement by contrast material. Hepatic KS was confirmed in the setting of an autopsy. As the hepatic KS lesions are very hypervascular, tumor biopsy can cause massive bleeding (Gottesman et al. 1993). Primary hepatic KS occurs in the pediatric age group (Moore et al. 2008). Multiple hepatosplenic KS has been reported in an HIV-infected child (Hsieh et al. 2007).

Pathology

Tumors are usually multiple and present as red-brown, spongiform, and hemorrhagic nodules, ranging in diameter from few millimeters to more than 7 cm. Lesions with infiltrating borders occur.

The four clinical forms of KS display very similar histopathological features, with the proliferation of spindle cells considered as the KS tumor cells, associated with inflammation and neo-angiogenesis. This distinct pattern, which is also in evidence in early lesions and precursor lesions of KS, has led to a model of KS's histogenesis, including both a spindle cell and a frankly endothelial cell lineage (Russell-Jones and Wilson-Jones 1988). The KS spindle cells seem to originate from a lymphatic endothelial cell lineage (review: Gessain and Duprez 2005). KSHV is expressed in these spindle cells at all stages of the disease, with latency gene expression clearly predominating, while cells expressing markers of lytic infection form a minority. Spindle cell areas contain large numbers of slit-like spaces which lack endothelial lining but are stuffed with erythrocytes (Dorfman 1984; Holzhausen et al. 1988; Ioachim et al. 1995). Areas rich in red cells may contain hemosiderin granules. The angiomatoid areas show a capillary-like meshwork or sinusoidal patterns lined by atypical endothelial cells. In the liver tissue surrounding KS lesions, peliotic foci may develop. Ultrastructurally, part of the endothelial cells shows Weibel-Palade bodies (Holzhausen et al. 1988; Orenstein 2008), and the spindle cells show erythrophagocytosis (Orenstein 2008).

KS tumor cells are immunoreactive for the endothelial markers, CD31 and CD34 (Miettinen et al. 1994; Russell Jones et al. 1995), CD31 staining being present in endothelial cells but not spindle cells (DeYoung et al. 1995). KS endothelia are reactive for ICAM-1, thrombomodulin, and tissue factor (Zhang et al. 1994) and for CD40 (Pammer et al. 1996). The tumor cells are podoplanin/D2-40 antibody-positive (Weninger et al. 1999; Kahn et al. 2002; Fukunaga 2005; Kalof and Cooper 2009) and are reactive for another lymphatic endothelial marker, hyaluronan receptor/LYVE-1 (Xu et al. 2004). The endothelioid cells also express VEGFR3, all these findings suggesting a lymphatic endothelial cell lineage (Jussila et al. 1998; Weninger et al. 1999; Folpe et al. 2000). KS of the GIT may morphologically mimic GIST, and like GIST, a fraction of GIT-KS are reactive for CD117 (Parfitt et al. 2008).

Metastatic Hepatic Kaposi's Sarcoma and Disseminated Kaposi's Sarcoma

Liver involvement in disseminated KS is well known and also occurs in AIDS-related KS (Dhrif et al. 2007). Subsequent to cutaneous KS, hepatosplenic manifestations are well-known complications, but mainly based on autopsy findings (Gonzalez-Lopez et al. 1996). Whether these hepatosplenic manifestations represent metastatic disease or de novo disease has not been formally clarified.

Glomus Tumor and Glomangiopericytic Tumors of the Liver

57

ICD-O code 8711/0

Contents

Abstract

Glomus tumor is a distinct neoplasm derived from pericyte-like cells normally present in neuromyoarterial structures with the morphology of specialized arteriovenous anastomosis in the skin. These cells normally form glomus bodies involved in thermoregulation and control of hemodynamic features. Glomus tumors are usually benign neoplasms that usually occur in the skin in the vasculature of inner organs and exceptionally in the liver. A distinct neoplasm originating from perivascular myoid cells is termed myopericytoma, glomangiopericytoma, and myofibroma. Most of these unusual neoplasms develop in soft tissues and the skin of children and mid-adult individuals. The tumors very rarely occur in the hepatobiliary tract and the periampullary region, sometimes associated with Epstein-Barr virus infection.

Glomus Tumor

Introduction

Glomus tumors derived from a distinct pericyte-like cell type normally present in a distinct neuromyoarterial structure with the morphology of a specialized arteriovenous anastomosis and involve in the regulation of hemodynamic mechanisms, in particular thermal regulation (glomus body or glomus organ; organ of Hoyer and

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_57

Grosser). Glomus bodies chiefly occur in the subungual dermis and in the lateral areas of the digits, in the palm, and in the precoccygeal soft tissue (glomus coccygeum), but may also occur in the vascular system of internal organs. Normally, the glomus body has an afferent arteriole branching into two or four preglomic arterioles, which blend into a distinct segment with an irregular lumen and harboring the AV anastomosis proper, the canal of Suquet and Hoyer, which then drains into collecting veins. Glomangiomas derived from these specialized organs of skin soft tissue are also termed glomuvenous malformations (Boon et al. 2004; Solovan et al. 2012). Syndromatic, hereditary multiple glomuvenous malformations (familial glomangiomas) are caused by mutations of glomulin, a protein that inhibits cullin-RING ligases (Brouillard et al. 2005; Hristova et al. 2012; Tron et al. 2012). The term glomus tumor was formerly employed to denote tumors arising from sensor cells of glomera such as the glomus jugulare, but these neoplasms are now termed paraganglioma. Glomus tumors or glomangiomas are neoplasms with a usually benign course, albeit malignant variants also occur (Folpe et al. 2001). Visceral glomus tumors have been observed in the lung, small intestine, colon, kidney, and liver.

Glomus Tumor/Glomangioma of the Liver

Primary hepatic glomus tumors (glomangiomas) are very rare neoplasms (Gassel et al. 2002; Kenn et al. 2002; Jaiswal et al. 2004; Amoueian et al. 2011; Geramizadeh et al. 2011; Kihara et al. 2014). The clinical presentation is nonspecific, with upper abdominal discomfort or pain due to a mass effect. The size of hepatic glomus tumors at presentation varies considerably. In one patient, glomangioma of the liver presented as a 4.5-cm subcapsular tumor in a 61-year-old male patient (Gassel et al. 2002). In an another case, a 50-year-old woman showed a large, hypervascular, and cystic lesion of 15 cm diameter, suggesting the presence of hepatic vascular tumor (Geramizadeh et al. 2011). In other patients, the tumor appeared as a cystic hepatic mass (Amoueian et al. 2011; Kihara et al. 2014).

Histologically, hepatic glomus tumors are composed of small uniform round to oval cells, separated by thin fibrovascular stromal components. The cytoplasm is slightly eosinophilic, with indistinct borders, and nuclei show an open chromatin. Immunohistochemically, the tumor cells are reactive for vimentin, CD34, and smooth muscle actin (Amoueian et al. 2011; Geramizadeh et al. 2011). In one case, tumor cells were focally positive for calponin (Jaiswal et al. 2004).

Differential Diagnosis

A rare differential diagnosis is liver metastases of malignant glomus tumor (Dasaev and Stepanov 1985; Brathwaite and Poppiti 1996).

Hepatic Myopericytoma, Glomangiopericytoma, and Myofibroma

Introduction

Myopericytoma (MPC) is term proposed to describe a group of neoplasms that originate from perivascular myoid cells. These tumors show a range of histologic growth patterns and mainly occur in the soft tissues (Folpe AL 2002; Dray et al. 2006; Mentzel et al. 2006; Fisher 2013). In 1998, Granter and coworkers formally used the term MPC and defined a spectrum of tumors showing perivascular myoid differentiation, comprising myofibromatosis in adults, myofibroma (MF), glomangiopericytoma (GPC), and myopericytoma (Granter et al. 1998). The entities have been endorsed by the WHO classification, where myopericytoma and myofibroma are listed as separate entities and glomangiopericytoma as a subtype of myopericytoma (Folpe AL 2002). The cell lineages involved in this tumor group share features of both smooth muscle cells and glomus cells, but the cell of

origin of these lineages and their eventual relation to the perivascular epithelioid cell (PEC) are still unknown.

Clinical and Imaging Features

MPC occurs mainly in childhood and to mid-adult years, with a male predominance (Folpe AL 2002; Dray et al. 2006). The vast majority of the tumors arise in the soft tissues and the skin (Mentzel et al. 2006), but few intracranial cases have been observed (Rousseau et al. 2005), and there are patients who presented with solitary or multiple pulmonary nodules (Cao et al. 2009; Lau et al. 2009; Song et al. 2012), tumor of the heart (Orlandi et al. 2004), myopericytoma of the kidney (Lau et al. 2010; Dhingra et al. 2012), and parotid gland (Kuczkowski et al. 2010). The MPC group of tumors is usually benign lesions, but malignant variants of MPC have been reported (McMenamin and Fletcher 2002). Part of the MPCs have been shown to develop in conjunction with EBV infection in patients with AIDS (Calderaro et al. 2008; Lau et al. 2009).

MPC, GMP, and MF of the Hepatobiliary Tract

Calderaro and coworkers described multifocal MPC occurring in a 34-year-old male patient with AIDS and EBV infection, the tumor being located intracranially, in the spine, and in the liver. Tumor cells were positive for EBV by the use of EBER (Calderaro et al. 2008). In a second patient, a 42-year-old man with HIV infection, the neoplastic process started in the orolaryngeal mucosa, followed by tumor manifestations in the frontal lobe of the brain and in the liver. Again, the tumor was EBV positive (Lau et al. 2009). Periampullary EBV-associated myopericytoma was reported in a patient with AIDS who presented with obstructive jaundice. Based on the presence of cellular pleomorphism and increased mitotic activity, a malignant variant was favored (Ramdial et al. 2011).

General Histopathology

Myopericytoma

MPC is characterized by plump spindle cells, some with a myofibroblast appearance, arranged in sheets and fascicles and focally arranged around blood vessels in a concentric pattern, resulting in a hemangiopericytoma-like vascular pattern. The perivascular cells may have a glomoid appearance. The mitotic count is low (<1 per 10 high power fields). Some of the spindle cells exhibit features resembling smooth muscle cells, albeit with less cytoplasmic eosinophilia. Part of the tumors show hyalinization and hyalinized nodules protruding into vascular spaces similar to the pattern seen in myofibromatosis (Dray et al. 2006). Immunohistochemically, the cells are positive for vimentin, smooth muscle actin, and, in a patchy pattern, for desmin, but usually not for vimentin (Dray et al. 2006). The tumor cells are not reactive for HMB45, S-100 protein, CD99, or CD34.

Glomangiopericytoma

Glomangiopericytoma is a rare tumor that almost only occurs in the sinonasal region, mid-facial structures, and the pterygopalatine fossa (sinonasal glomangiopericytoma, sinonasal-type hemangiopericytoma; Thompson 2004). It is histologically characterized by pericytes and myoid cells surrounding a dense network of capillary-type vascular channels (Arpaci et al. 2012).

Myofibroma

The histology of myofibroma reveals an overlap with that of myopericytoma, but a biphasic zonation pattern composed of fascicles of spindle-shaped cells with abundant eosinophilic cytoplasm that resemble smooth muscle cells in the peripheral zones of the lesion prevails. In the central areas, one notes clusters of more primitive-looking, round to polygonal, or small spindle cells with less and amphophilic cytoplasm and some nuclear pleomorphism. These cells were typically arranged in a hemangiopericytoma-like vascular pattern. Hyalinized areas with nodular

intravascular bulging are present. The immunohistochemical phenotype is similar to that of MPC, but desmin staining is less prominent.

Tumor-Like Vascular Malformations 58

Contents

Abstract

Vascular malformations represent a broad and complex spectrum of in part congenital and tumor-like conditions that occur either as systemic disorders or organ-specific pathologies. Hemodynamically, vascular malformations are classified as slow flow, high flow, and mixed malformations. The slow-flow disorders, Klippel-Trenaunay syndrome, Sturge-Weber syndrome, and unilateral nevoid telangiectatic syndrome, rarely involve the liver, where they manifest as abnormal vessels, mainly venous abnormalities, angiectases, and angioma-like lesions, sometimes associated with focal nodular hyperplasia or related changes. A distinct group of disorders is congenital and acquired venovenous malformations of the liver and patent ductus venosus, resulting in portosystemic shunts and associated parenchymal changes.

Introduction

Several vascular lesions are currently classified as malformations, although a generally accepted classification has still to be awaited, owing to the lack of criteria, the use of eponymic terms, and the problems arising when defining what a malformation is (Breugem et al. 2001). Of importance is that a distinction has to be made between blood vessel tumors/neoplasms and vascular malformations (Mulliken and Glowacki 1982; Mulliken 1997), although the latter may clinically

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_58

produce a tumor-like tissue. However, the growth of vascular malformations is commensurate with the growth of the patient (Cohen 2000), what is clearly not the case with neoplasms. The biologic classification of vascular malformations is based on the observation that they may predominantly involve a single type of channel anomaly (arterial, capillary, lymphatic, venous) or that they come as complex/combined lesions (Mulliken 1993; Cohen 2000). The Mulliken classification, which relates to clinical presentation and cellular features of the lesions, has been accepted by the International Society for the Study of Vascular Anomalies (ISSVA; Enjolras and Mulliken 1997; Cohen 2000). In regard to hemodynamic features and consequences, vascular malformations and vasomalformative syndromes are classified into slow-flow or high-flow disorders (review: Garzon et al. 2007). Slow-flow or high-flow disorders with known structural involvement of the liver are listed in Table 1.

Molecular Features

Recent progress relating to the identification of molecular mechanisms operational in vascular morphogenesis had its impact on the understanding of vascular malformations, and this will also modify our view of those lesions developing in the liver (reviews: Timur et al. 2005; Wang 2005; Dompmartin et al. 2010; Frigerio et al. 2012; Table 2). Here, we briefly discuss those malformations which can be accepted as such, hepatic lesions evolving in the setting of hereditary hemorrhagic telangiectasia being addressed in a separate chapter.

Table 1 Slow-flow and high-flow vascular malformations and mixed malformations, with liver involvement

Slow-flow disorders
Klippel-Trenaunay syndrome
Sturge-Weber syndrome
Congenital portosystemic venous shunts
Unilateral nevoid telangiectatic syndrome
Adams-Oliver syndrome
Rubinstein-Taybi syndrome
Proteus syndrome
High-flow disorders
Capillary malformation-arteriovenous malformation syndrome
Parkes Weber syndrome
Malformation syndromes with venous, lymphatic, or mixed features
Blue rubber bleb nevus syndrome
Maffucci syndrome
Gorham-Stout syndrome

Extracranial Non-syndromatic Vascular Malformations

Vascular malformations located to the liver are much less common than hemangiomas and may manifest at an early age (Boon et al. 1996; Burrows et al. 2001). Arteriovenous malformations (AVM) sometimes result in congestive heart failure already in the newborn. AVM observed in later childhood are usually seen in the context of hereditary hemorrhagic telangiectasia (HHT), which is discussed in more detail below. The spectrum of lesions is relatively broad and ranges from arterioportal fistulas to complex and shunting anomalies of portal and hepatic veins, to portomesenteric venous malformations, and to pure venous and venolymphatic malformations. Most of the intrahepatic arterioportal fistulas

Table 2 Molecular features of vascular malformations and associated syndromes

Malformation	Molecule/gene involved
Klippel-Trenaunay syndrome	AGGF1
Capillary malformation syndrome	RASA1
Rhodoid nevus	RASA1
Sporadic Sturge-Weber syndrome	RASA1
Cutaneous/mucosal venous malformations	TIE2
Hereditary hemorrhagic telangiectasia	ENG, ACVRLK1, MADH4
CADASIL	Notch3
Cerebral cavernous malformations	KRIT1, MGC4607, PDCD10
Coats' disease	NDP
Proteus syndrome	PTEN

(arterioportal fistula syndrome) are sporadic (Lu et al. 1996; Vauthey et al. 1997), but they are also known to occur in HHT and Ehlers-Danlos syndromes. The fistulas can result in portal hypertension (Billing and Jamieson 1997), in heart failure, and in intestinal ischemia (Vauthey et al. 1997). A congenital presentation was detected in only 13 % in a series of 76 patients (Vauthey et al. 1997). Most congenital arterioportal fistulas present with a large intrahepatic varix, sometimes with multiple connecting arteries (Burrows et al. 2001). Owing to shunt-induced shearing stress, intimal damage of the venous part with subsequent portal vein thrombosis may ensue (Maeda et al. 1997). At imaging, the lesions may be confused with hepatic hemangiomas, which can show arterioportal shunting (Kim et al. 2001). Portovenous shunting is known to occur in infantile hepatic hemangiomas and in galactosemia (Ono et al. 1998), but may also manifest as isolated portovenous fistulas. It can develop in Osler-Weber-Rendu disease (Matsuo et al. 2001). Pure venous hepatic anomalies are mostly observed in the blue rubber bleb nevus syndrome, which is discussed below.

Klippel-Trenaunay Syndrome (KTS)

KTS (synonym: angioosteohypertrophy syndrome; OMIM 149000; Vollmar 1974), a rare so-called mesodermal phakomatosis, has been defined to consist of combined vascular malformations of capillary, venous, and lymphatic vessels and varicosities of unusual distribution observed during infancy and childhood and has an early onset (in particular the lateral venous anomaly) and limb enlargement (Klippel and Trenaunay 1900; in the original article not spelt with an é; Servelle 1985; Jacob et al. 1998; Cohen 2000, 2002; Breugem et al. 2001).

Although several reports bring KTS together with Parkes Weber syndrome (frequently written as Parkes-Weber syndrome, which is not correct: Frederick Parkes Weber, 1863–1962, is written without a hyphen) and even combine the eponyms within the designation of a syndrome (e.g., Klippel-Trenaunay-Weber syndrome), it had been emphasized that KTS and Parkes Weber syndrome are two different entities, the latter being a high-flow malformation and always manifesting arteriovenous fistulas (not present in KTS) and lacking the lymph vessel involvement typical for KTS. There is no bona fide overlap between KTS and Sturge-Weber syndrome (Cohen 2000; Jay 2000), although features of Sturge-Weber syndrome can occur in combination with KTS and phakomatosis pigmentovascularis (Chhajed et al. 2010; Finklea et al. 2010). The study of such combination within a familial setting has led to the view that KTS and SWS might represent different manifestations of the same affliction (Pereira de Godoy and Fett-Conte 2010). KTS occurs sporadically or as a hereditary disorder linked to a locus on chromosome 8q22.3 (Lindenauer 1965; Cohen 2002), and males and females are equally affected. In KTS associated with a genetic defect, variants of the angiogenic factor AGGF1 gene have been found (Tian et al. 2004; Hu et al. 2008). Experimentally, AGGF1 is involved in establishing venous identity in zebra fish embryos, overexpression of AGGF1 leads to increased angiogenesis and increased lumen diameter of veins via an AKT pathway, whereas knockdown of AGGF1 resulted in defective vasculogenesis and angiogenesis, with a loss of venous identity (Chen et al. 2013). The expression of AGGF1 is regulated GATA1 (Fan et al. 2009).

Hepatic manifestations of Klippel-Trenaunay syndrome reported so far are sparse and, in part, difficult to judge because it is not always clear whether the patients in fact suffered from KTS. Silent hepatic manifestations of KTS may present as multiple low-attenuation areas in the liver at imaging, representing abnormal vascular structures (Fig. 1; Jafri et al. 1983). A patient with KTS developed multiple focal nodular hyperplasia/FNH (Bathgate et al. 1999), lesions known to be caused by a hepatic circulation disorder. Other alterations comprise venous anomalies, with large abdominal veins draining from the dome of the liver into the hepatic veins (Haber et al. 1995). Such anomalies may result in portal hypertension (Grundfest-Broniatowski et al. 1982). Visceral hemangiomas in KTS have been reported,

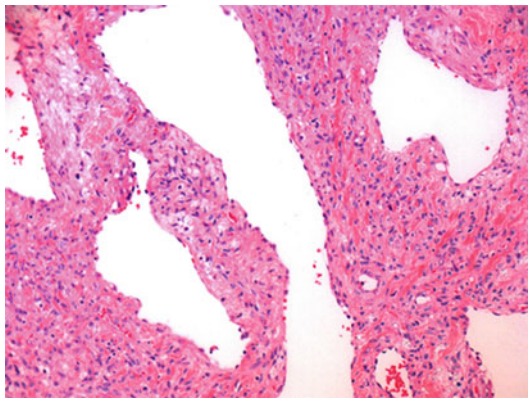

Fig. 1 Thick-walled dilated vascular anastomoses seen in hepatic manifestations of Klippel-Trenaunay syndrome (hematoxylin and eosin stain)

including the liver (Alpay et al. 1996). In patients with KTS, focal nodular hyperplasia of the liver has been observed (Haber et al. 1995; Bathgate et al. 1999). Similar to other circulation disorders of the liver, this change may develop in response to an altered intrahepatic blood distribution owing to vascular anomalies.

Sturge-Weber Syndrome

Sturge-Weber syndrome (SWS, encephalofacial angiomatosis, craniofacial angiomatosis, OMIM 185300) is characterized by an intracranial vascular abnormality, leptomeningeal angiomatosis, usually involving the occipital and posterior parietal lobes, associated with facial cutaneous vascular malformations (port-wine stains), seizures, and glaucoma. Leptomeningeal angiomatosis can cause a derangement of superficial cortical perfusion, with laminar cortical necrosis and calcifications (Baselga 2004; Manivannan et al. 2012). A variant of SWS is Shapiro Shulman syndrome, characterized by cutaneous vascular nevi, abnormal intracranial venous drainage, and hydrocephalus (Prats Viñas et al. 2011). Sporadic SWS showed a RASA1 mutation (Zhou et al. 2011). There are few reports of manifestations of SWS outside the classical manifestation sites. In very rare instances, SWS is associated with hepatic angiomas, sometimes extensively (Billson and Gillam 1984). A persistent hepatic venous plexus has been found in a patient with SWS (Gajinov et al. 2008), characterized by three additional vessels arising from the inferior vena cava, circulating between liver segments, forming a common trunk in the suprahepatic region that flowed into the right atrium.

Unilateral Nevoid Telangiectatic (Telangiectasia) Syndrome (UNTS)

UNTS was first described in 1899 and is chiefly characterized by a dermatomal distribution of telangiectases developing mostly in the upper and middle dermis. The disorder may be congenital, but in other instances, it is related, e.g., to high estrogen levels, UNTS occurring in pregnancy, during puberty, and in chronic liver disease (Uhlin and McCarty 1983; Wilken 1984). Rarely, visceral manifestations in UNTS have been described, one patient exhibiting gastric involvement with hemorrhages (Anderton and Smith 1975). Liver involvement seems to occur in the form of multiple dilated vascular channels associated with portal fibrosis, suggesting that UNTS may produce an abnormal hepatic vascular morphogenesis (Capron et al. 1981).

Congenital and Acquired Venovenous Malformations of the Liver

Congenital extrahepatic portosystemic shunt (CEPS) was first described by John Abernethy in 1793 (Abernethy 1793). This is the reason why extrahepatic portosystemic shunts are also termed Abernethy malformations (reviews: Gallego et al. 2004; Stringer 2008). Morgan and Superina (1994) classified extrahepatic portosystemic shunts into two types (Table 3). The more common CEPS type I is the side-to-end anastomosis or congenital absence of the portal vein, resulting in complete diversion of portal blood into the vena cava inferior. The malformations are further subdivided into those in which the superior mesenteric and splenic veins end up separately at the systemic veins and those in which these two

Table 3 Classification of venovenous malformations of the liver

***Extrahepatic portosystemic shunts* (*Morgan-Superina classification and Abernethy classification*)**
Abernethy type I
Abernethy type II
***Intrahepatic portosystemic shunts* (*Park* et al. *classification*)**
Type 1
Single large channel connects the right portal vein to the IVC
Type 2
Localized peripheral shunt in which one or more communications exist in a single hepatic segment
Type 3
Portosystemic shunt through a venous aneurysm
Type 4
Multiple communications between peripheral portal and hepatic veins in several segments
Persistent ductus venosus
***Absent ductus venosus* (*agenesis of ductus venosus*)**

venous systems join to form a common trunk that ends up at the inferior vena cava, the iliac veins, or the right atrium. Type I is usually observed in girls and is often associated with other malformations, including cardiac abnormalities, malrotation, and polysplenia. CEPS type II or side-to-side anastomosis with portal vein supply partially conserved has no gender predilection and no associated malformations (Witters et al. 2008). Pathogenetically, it has been suggested that congenital absence of the portal vein is attributed to an excessive involution of the peri-intestinal vitelline venous loop or to failure of vitelline veins to generate anastomoses with umbilical veins or hepatic sinusoids. Both forms of extrahepatic CEPS have a number of hepatic associations, the most common being nodular hyperplastic lesions of parenchyma (Yonemitsu et al. 2000; Murray et al. 2003), clear-cut nodular regenerative hyperplasia (Peker et al. 2009), and liver cell adenomas (Kawakatsu et al. 1994). The patients can show liver calcifications (Avila et al. 2006).

Congenital intrahepatic portosystemic shunts are defined as abnormal intrahepatic connections between branches of the portal vein and the hepatic veins (Jabra and Taylor 1991; Kakitsubata et al. 1996; Caiulo et al. 2001; Senocak et al. 2008; Bernard et al. 2012). These intrahepatic shunts have been classified into four morphologic types by Park and coworkers (1990), as summarized in Table 3.

Acquired (spontaneous) intrahepatic portosystemic venous shunts (SIPSVS) are relatively rare lesions of unknown etiology that are characterized by communications between portal and hepatic veins, mostly occur in cirrhotic livers, and can undergo aneurysmatical change. Patients may suffer from shunt-induced hepatic encephalopathy and/or glucoregulation problems (Villar et al. 2000; Yamagami et al. 2000; Oguz et al. 2003; Pocha and Mallakkal 2004; Filik and Boyacioglu 2006). Intrahepatic portosystemic shunts can be associated with focal liver lesions, e.g., multiple hemangioma-like lesions (Matsumoto et al. 1990). Focal nodular hyperplasia (FNH) of the liver has also been found in the setting of intrahepatic porto-portal communication, characterized by the absence of the horizontal segment of the left portal vein with portal supply between the anterior segmental branch of the right portal vein and the umbilical portion of the left portal vein (Mignon et al. 1996).

Irrespective of the cause and the anatomical differences, any portosystemic shunt can result in atrophic-hyperplastic changes (atrophy-hypertrophy complex/AHC of the liver) of the liver, often with formation of nodular lesions. Hyperplastic liver nodules were found following portal systemic shunt surgery (Guérin et al. 2009). Experimentally, portocaval anastomosis in the rat caused hyperplastic liver nodules (Weinbren and Washington 1976), these nodules in rats developing in the background of an atrophic liver (Dubuisson et al. 1985).

Patent Ductus Venosus as a Cause of Intrahepatic Portosystemic Shunt

The ductus venosus (DV; Ductus venosus Arantii; discovered by Giulio Cesare Aranzio, Bologna, 1530–1589) is a transitory vascular channel that shunts approximately half of the blood flow of the fetal umbilical vein directly into the inferior vena cava and oxygenated blood

from the placenta, thus bypassing the liver. The DV naturally closes during the first week of life in the majority of full-term neonates. In an ultrasonographic study of 50 healthy neonates, the DV was closed in 94 % of the infants before day 3, whereas the DV was closed in only 12 % at the same time, in 76 % before day 7, and in all infants before day 18 (Fugelseth et al. 1997). The DV shows a delayed closure in preterm infants, with no significant correlation to the closure of the ductus arteriosus or the condition of the infant (Fugelseth et al. 1998). After closure of DV, a fibrous strand called ligamentum venosum remains, usually attached to the left branch of the portal vein, and it may be continuous with the ligamentum teres hepatis. Patent (persistent) ductus venosus (PDV) is a very rare condition characterized by persistence of a large shunt connecting the portal vein with hepatic veins (Zientarski 1976; Nagano et al. 1999). Congenital intrahepatic portosystemic shunt due to PDV can cause progressive liver dysfunction with hepatic steatosis (Uchino et al. 1996). In adult patients with persistent DV, partial nodular transformation of the liver was found (Wanless et al. 1985), probably a hyperplastic reaction similar to that observed in other shunt situations.

Absence of the Ductus Venosus as a Cause of Portosystemic Venous Shunts

Agenesis of the DV is a rare condition that causes extra- or intrahepatic venous shunts and is often associated with hydrops and cardiac and extracardiac anomalies (Krutsay 1959; Contratti et al. 2001; Langman et al. 2001; Berg et al. 2006; Acherman et al. 2007). The absence of DV may be a feature of Down syndrome (Pipitone et al. 2003). Among 23 fetuses studied by Doppler techniques, 19 fetuses with agenesis of DV showed that the umbilical vein connected to the portal sinus, while the remaining four fetuses had extrahepatic umbilical venous drainage (Berg et al. 2006). Three main patterns of abnormal venous circulation were found, i.e., (1) umbilical vein bypassing the liver and connecting directly to right atrium (46 %); (2) umbilical vein bypassing the liver and connecting to the inferior vena cava, mostly through one of the iliac veins (25 %); and (3) umbilical vein connecting to the portal circulation without giving rise to a ductus venosus (21 %; Contratti et al. 2001). In the extrahepatic shunt variant, the development of the portal venous system depends on the size of the shunt. If the shunt is narrow, the portal system will develop normally. In contrast, a wide shunt is associated with hypoplasia or the absence of the portal system, hepatic dysfunction, tricuspid regurgitation, and poor outcome (Shen et al. 2011). The abnormal venous flow in DV agenesis is sometimes associated with hepatic vascular wall changes, including proliferation of the hepatic arterioles with reduction of portal venules (Langman et al. 2001).

Adams-Oliver Syndrome

Adams-Oliver syndrome (OMIM 100300) is a rare genetic disorder assigned to chromosome locus 3q13.33 and characterized by congenital absence of skin/aplasia cutis congenita (in particular scalp vertex defects), transverse limb defects, congenital cardiac malformations, and cutis marmorata telangiectatica congenita. It is suggested that the disorder results from an early ontogenetic vascular abnormality. There is an association between the syndrome and portal hypertension due to hepatoportal sclerosis and extrahepatic portal vein obstruction, associated with nodular regenerative hyperplasia (Girard et al. 2005; Silva et al. 2012).

Proteus Syndrome

Proteus syndrome (OMIM 176920) is a highly variable, severe malformative overgrowth disorder characterized by disproportionate overgrowth of body parts (the phenotype of the “elephant man”), connective tissue nevi, epidermal nevi, exostoses and hyperostoses, visceral hamartomas

and lipomas, and vascular malformations. Proteus syndrome is caused by a mosaic somatic activating mutation in AKT1 (Lindhurst et al. 2011). Proteus syndrome patients can show hepatomegaly (Ahmetoglu et al. 2003), probably caused by hemolymphangiomas occupying the liver and other visceral organs (Eberhard 1994).

Blue Rubber Bleb Nevus Syndrome (BRBNS)

BRBNS (OMIM 112200; synonym : Bean's syndrome), described in 1860 (Gascoyen 1860) and defined in 1958 (Bean 1958), is a rare disease characterized by distinct venous malformations in the skin, in the gastrointestinal tract, and less frequently elsewhere (Kisu et al. 1986; Moodley and Ramdial 1993; Fernandes et al. 1999; Giordano et al. 2004; Deng et al. 2008; Ng et al. 2009; Das et al. 2013). It occurs as a sporadic or autosomal-dominant disorder, with a responsible locus situated on chromosome 9p (Boon et al. 1994), where the gene for Tie2 kinase is located. The lesions mostly appear at birth or in early childhood, with a tendency to increase in number and size with age. The BRBNS skin lesions are blue and soft nodules histologically consisting of dysplastic venous channels with a flattened endothelium and lacking smooth muscle cells (Robinowitz and Esterly 1995). The cells of the small vascular channels express c-kit (Mogler et al. 2010). Angioma-like and in part polypoid lesions with a similar histology (Ertem et al. 2001) predominate in the intestinal tract, resulting in occult or overt hemorrhage, e. g., originating from ampullary lesions (Badran et al. 2007). Other visceral organs include the parotid gland, the urinary bladder, and the liver. Hepatic venous malformations in BRBNS have been suspected (Hashimoto et al. 1989), suggested based on multiple small poolings in angiography (Kisu et al. 1986), or found on CT images (Giordano et al. 2004; Deng et al. 2008; Krishnappa and Padmini 2010), but systematic studies on the morphology of liver manifestations are not yet available, with the exception that the venous malformations may contain phleboliths.

Maffucci Syndrome

Maffucci syndrome (OMIM 166000) is a rare condition typically including enchondromas at various sites, the presence of cutaneous and visceral vascular malformations/angiomas, and a tendency to develop spindle cell hemangioendothelioma (review: Superti-Furga et al. 2012). Both Ollier disease (multiple enchondromatosis) and Maffucci syndrome are caused by somatic mosaic mutations of isocitrate dehydrogenases 1 (IDH1) and 2 (IDH2) (Amary et al. 2011). In a pediatric patient with this syndrome, a hepatic hemangioma with a diameter of 11 cm was detected (Pezzilli et al. 2009).

Gorham-Stout Syndrome

Gorham-Stout syndrome (Gorham's disease, vanishing bone disease, massive osteolysis with lymphangioma and/or hemangioma, invasive lymphhemangiomatosis) is a rare vasomalformative disorder characterized by multiple destructive and progressive bone defects thought to be caused by invasive systemic lymphangiomas/hemangiomas. The syndrome can be associated with visceral hemangiomas, including hepatic hemangiomas (Takahashi et al. 2005).

Other Syndromatic Vascular Malformations Involving the Liver

An overlap syndrome characterized by multiple anomalous venous channels, persistent primitive hepatic venous plexus, interrupted inferior vena cava, and renal lymphangiomatosis has been described (Watson et al. 2012). Hepatic vascular malformations have been found in a patient with Simpson-Golabi-Behmel syndrome. A 1-year-old

boy showed a hypervascular lesion in the right posterior liver. The resection specimen showed an unencapsulated lesion measuring up to 1.7 cm in diameter, composed of multiple variably sized vessels with intervening fibrous stroma, consistent with a hemangiomatous vascular malformation (Cureton et al. 2007). A large hepatic cavernous vascular malformation was diagnosed in a patient with nevus vascularis mixtus (cutaneous vascular twin nevi) associated with intracranial vascular malformation of the Dyke-Davidoff-Masson/homolateral hypertrophy of skull and sinuses type (Ruggieri et al. 2012). Focal nodular hyperplasia (FNH) of the liver was observed in children with hemihypertrophy and multiple cutaneous vascular malformations (Everson et al. 1976; Al-Attar et al. 2004). Hepatic vascular lesions characterized by clusters of dilated endothelial channels and vascularized cysts are found in Mulibrey nanism, the lesions having a diameter of 5 mm to 7 cm and associated with hepatomegaly. Part of the lesions are histologically hemangiomas or peliotic foci and are associated with abnormal sinusoidal patterns and central veins with unusually thick walls (Karlberg et al. 2009). Mulibrey nanism (muscle-liver-brain-eye nanism, OMIM 253250) is a monogenic disorder caused by recessive mutations in the TRIM37 gene encoding the peroxisomal Trim37 protein with E3 RING ubiquitin ligase activity. Patients with the syndrome reveal prenatal-onset growth failure, fibrous dysplasia of long bones, J-shaped sella, cutaneous nevi flammei, perimyocardial cardiopathy, and severe insulin resistance with metabolic syndrome as young adults.

Hepatic Angiomas, Angioma-Like Lesions, and Telangiectases in Osler's Disease

Osler's disease (Rendu-Osler-Weber disease, hereditary hemorrhagic telangiectasia, HHT) is an autosomal dominant vascular dysplasia characterized by telangiectasias and arteriovenous anastomoses in several organs and tissues, including visceral organs. Arteriovenous malformations, a hallmark of HHT, occur predominantly in the lungs (50 %), liver (30–70 %), and brain (10 %) (review: Govani and Shvlin 2009). In HHT, arterial aneurysms occur with high prevalence.

So far, five types of HHT have been identified. The mutated gene in type 1 Osler's disease/HHT (OMIM 187300) is assigned to chromosome 9q34.11 and involves endoglin (HHT1), while HHT2 is caused by mutations of ALK1, both abnormalities affecting the TGF-beta signaling pathway which is crucial in angiogenesis (review: Fernandez et al. 2006). Specifically, endoglin as a transmembrane auxiliary receptor for TGF-beta expressed in proliferating endothelial cells plays a central role in endoglin-mediated vascular remodeling linked to TGF-beta signaling pathways (Lebrin and Mummery 2008; ten Dijke et al. 2008). HHT2 (OMIM 600376; chromosome 12q11-q14) is caused by mutations of Alk-1/activin receptor-like kinase involved in TGF-beta signaling. HHT3 and HHT4 (OMIM 601101 and 610655, respectively) are assigned to chromosomes 5q31 and 7p14, respectively, but the defects are not yet specified. The fifth type is termed JPHT or juvenile polyposis/hereditary hemorrhagic telangiectasia syndrome. JPHT (OMIM 175050, chromosome 18q21.1) is caused by mutations of the MADH4 gene encoding Smad4, a component of the TGF receptor signaling pathway. A vascular anomaly syndrome with phenotypic overlap with HHT is associated with BMP (bone morphogenetic protein 9) mutations (Wooderchak-Donahue et al. 2013).

Hepatic involvement in HHT occurs in 8–31 % of cases and is characterized by small telangiectases, discrete blood vessel dysplasias, and vascular anastomoses, including portovenous, arteriovenous, and arterioportal anastomoses causing complex shunts. These anomalies may result in high-output cardiac failure, biliary tract ischemia, and portal hypertension (Buscarini et al. 1994, 2006; Garcia-Tsao 2007; Khalid and Garcia-Tsao 2008; Coremans et al. 2015). Part of large anastomoses may mimic vascular tumors and other hepatic neoplasms. In Osler's disease, multiple telangiectatic lesions may develop in the liver

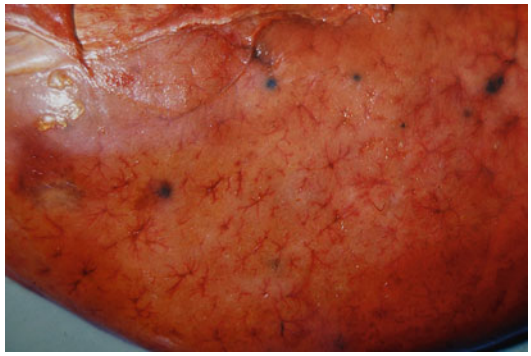

Fig. 2 Small hepatic hemangiomas and spider-shaped or stellate subcapsular telangiectasias in Osler's disease (non-fixed necropsy specimen)

(Fig. 2). Exceptionally, hepatic hemangiomatosis with formation of calcified lesions develops in the setting of Osler's disease (Selmaier et al. 1993) liver involvement.

Bacillary Angiomatosis and Peliosis Hepatis

59

Contents

Abstract

Bacillary angiomatosis is a reactive vascular disorder associated with *Bartonella* (*B.*) infection, specifically *B. henselae* and suspectedly *B. clarridgeiae*. The lesions are characterized by hemangioma-like endothelial proliferations. In the liver, bacillary angiomatosis (bacillary peliosis) may be associated with *Bartonella*-induced granulomatous hepatitis. Foci of hepatic bacillary angiomatosis can mimic neoplastic processes, because the lesions may exceed few centimeters in diameter. In contrast to neoplastic lesions, bacillary peliosis regresses upon antibiotic therapy. Some of the lesions contain stainable *Bartonella* organisms. Pathogenetically, *Bartonella* modulate vascular morphogenesis and induce endothelial cell migration and proliferation. Peliosis hepatis, another reactive vascular process which radiologically resembles liver tumors, is characterized by focal or diffuse cystic blood-filled spaces mainly localized in parenchyma. Peliotic lesions show a loss of endothelial lining and an effacement of the perisinusoidal reticulin network. Peliosis hepatis can be induced by a wide array of factors, including infections and drugs.

Bacillary Angiomatosis

Introduction

Bartonella organisms are Gram-negative, oxidase-negative, fastidious bacteria belonging to the a2 subclass of Proteobacteria, which are usually transmitted by numerous arthropod vectors, employ mammalian host reservoirs, and reveal a distinct natural history (Jacomo et al. 2002). *Bartonella* ssp. evoke persistent infections in several wild and domestic animals producing a substantial reservoir in nature being the source of inadvertent human infections (Breitschwerdt and Kordick 2000). By studying vascular, hemangioma-like proliferations in patients with AIDS, clusters of bacteria exhibiting the structure of Gram-negative, Warthin-Starry-positive rods and thus showing the staining profile of Bartonella have been detected (LeBoit et al. 1988). These lesions had an epithelioid appearance and regressed after antibiotic therapy in several patients. The histomorphologic features of what was then termed bacillary or epithelioid angiomatosis were described in detail (Walford et al. 1990).

The genus, *Bartonella*, has been extended by the inclusion of the genera *Rochalimaea* and *Grahamella*. Members of the genus *Bartonella* are involved in a broad array of human diseases, including Carrion's disease, trench fever, cat-scratch disease, bacillary angiomatosis-peliosis, endocarditis, and bacteremia. At least 14 species with several strains are currently recognized, and 7 out these are implicated to play a role in human infections. Phylogenetic data based on the analysis of 16S rDNA, 16S–23S rRNA intergenic spacers, citrate synthase, and 60 kDa heat shock proteins have first resulted in the identification of six significant evolutionary clusters (Houpikian and Raoult 2001), and by comparison of groEL sequences, a reliable classification of species and subspecies has recently been proposed (Zeaiter et al. 2002b). Cat-scratch disease and the associated vascular lesions are caused by *Bartonella* (B.) *henselae* and, suspectedly, by *B. clarridgeiae* (Kordick et al. 1997). *B. henselae* manifests in the form of several genotypes, however not exhibiting different epidemiological or clinical characteristics (Zeaiter et al. 2002a). Starting from a still enigmatic niche, *Bartonella* spp. typically parasite erythrocytes of mammalian hosts in a distinct seeding rhythm and by use of a type IV secretion system (Baron et al. 2002; Seubert et al. 2002; Dehio 2004; Devio 2005; Raoult 2007) encoded by *Bartonella* virB operon genes (Schmiederer et al. 2001) and thus produce long-lasting hemotropic infections. *Bartonella* organisms evoke a distinct immune response in hosts, involving both humoral and cellular reactions and having an impact on the manifestations of several disease phenotypes (Karem et al. 1999; Karem 2000; Bonatti et al. 2006).

Hepatobiliary Manifestations

The main liver lesions induced by *Bartonella* include granulomatous hepatitis and a variant of peliosis. Granulomas, also well-known from other organs in bartonellosis, may grow to considerable size (more than 3 cm; (Murano et al. 2001; Florin et al. 2008), i.e., lesions which may be confounded with tumors at imaging. With respect to peliosis of the liver, nomenclature of such lesions in bartonellosis is somewhat ambiguous, the range of terms employed including *Bartonella*-positive peliosis hepatis, bacillary peliosis, and parenchymal bacillary peliosis, all terms apparently denoting the same type of lesion. In what follows, the term bacillary peliosis will be used throughout (Alkan and Orenstein 1991; Carucci and Halvorsen 2006). In a study of liver tissue from eight HIV-infected patients, peliotic lesions showed clumps of a granular purple material that on Warthin-Starry staining and electron microscopy proved to be bacilli, morphologically identical to those found in skin lesions of bacillary angiomatosis. It was found that this bacillary peliosis responded to antibiotic therapy (Perkocha et al. 1990). Later, *Rochalimaea henselae* (now *Bartonella henselae*) was identified in both bacillary peliosis and bacillary angiomatosis by use of immunocytochemistry and lipid chemical and molecular biology methods (Reed et al. 1992;

Slater et al. 1992; Welch et al. 1992). At electron microscopy, the organisms were observed in sinusoidal endothelial cells, but also extracellularly (Leong et al. 1992). In an epidemiological study of *Bartonella* infections employing molecular techniques, it has been demonstrated that bacillary peliosis was associated exclusively with *B. henselae* (Koehler et al. 1997).

Some of the mechanisms involved in the pathogenesis of *Bartonella*-induced vascular changes have been studied. Generally, *Bartonella* appear to cause or to modulate vascular morphogenesis including endothelial cell migration and proliferation (Conley et al. 1994; Schmid et al. 2004; Scheidegger et al. 2009), but *B. henselae* can attach and invade several cell systems, including erythrocytes and epithelial cells apart from endothelial cells. Vascular colonization in vitro by *B. henselae* requires a close contact between the leading lamella of endothelial cells resulting in a bacterial aggregate which is afterward internalized via the so-called invasome. This actin-dependent invasion process, which is operational for clinical isolates of *B. henselae* but not for a mutant, by-passes the ordinary phagosomal pathway (Devio et al. 1997; Devio 2001). The contact between the organisms and endothelial cells seems to depend on outer membrane proteins (OMPs) of *B. henselae*. Out of nine members of OMPs characterized so far, the 43 kD variant (Omp43) has been shown to be the major adhesin for human umbilical vein endothelial cells (Burgess and Anderson 1998). The cloned Omp43 gene has an ORF of 1,206 nucleotides coding for a protein of 402 amino acids, and this Omp43 gene product is predicted to exist as a 16 stranded beta barrel protein similar to the Omp2b *Brucella abortus* porin, even though it is not yet known whether Omp43 protein also functions as a porin in *B. henselae* (Burgess et al. 2000). Adhesion of piliated *B. henselae* strains to human endothelial cells results in a protracted upregulation of E-selectin and ICAM-1, ICAM-1 upregulation being dependent on a heat-stable component (Maeno et al. 2002) and mediated by the activation of NF-kappaB, and this mechanism is dependent on OMPs, but not on lipopolysaccharides (Fuhrmann et al. 2001). Endothelial cell reaction to *B. henselae* is complex insofar as the proliferation response of these cells does not depend on a direct contact with the germ, and a proliferative response also ensues upon exposure to non-piliated bacterial strains unable to attach to endothelia (Maeno et al. 1999), suggesting that a humoral signal is involved. Upon interaction of *B. henselae* with viable host endothelia, bacterial rRNA synthesis and replication are rapidly induced, suggesting a specific interaction (Kempf et al. 2000). It has recently been shown that *B. henselae* induces host cell production of the angiogenic factor, vascular endothelial growth factor (VEGF), resulting in the proliferation of endothelial cells (Kempf et al. 2001).

Is there, in immunocompromised hosts, a coinfection-based relationship between *Bartonella*-induced angiomatoid lesions and Kaposi sarcoma (KS)? In fact, epithelioid angiomatosis can develop together with KS in patients with AIDS (Schwartzman et al. 1990). However, it has been reported that KS-associated herpes virus DNA is, expectedly, absent in bacillary angiomatosis-peliosis lesions (Relman et al. 1999), suggesting that the two lesion patterns emerge independently.

Peliosis and Lipopeliosis Hepatis

Introduction

Peliosis hepatis is defined as the presence of focal or diffuse cystic blood-filled spaces in the liver, chiefly localized to the parenchyma. Peliosis hepatis was first mentioned in the literature in 1861 as “blood cysts of the liver” (Wagner 1861) and was for a long time judged to just represent some sort of a strange liver lesion. In a report of 1900, the condition was termed cavernous degeneration of the liver (Fabris 1900). Hedrén coined the designation telangiectasia hepatis disseminata (Hédren 1909). The term peliosis appears in 1916 (Schönlank 1916). But it took a long time until peliosis was consistently employed to denote the changes. In particular, the concept that peliosis is characterized by hepatic hemorrhage appeared for decades after peliosis was defined, e.g., using

terms such as "miliary hepatic hemorrhages" (Senf 1939). The term peliosis (from Greek, pelios) originally denotes a macroscopic change meaning purple or dusky. This distinct gross feature, i.e., reddish-purple areas, is particularly detectable on the liver surface at laparoscopy (Solis-Herruzo et al. 1983). Peliosis chiefly occurs in the liver but, e.g., also in spleen, lymph nodes, lung, parathyroids, and pancreatic islet cell adenomas.

Epidemiology

Numerous cases of hepatic peliosis have been described in the literature since the appearance of the initial defining reports (Burger and Marcuse 1952; Hamilton and Lubitz 1952; Kent and Thompson 1961; Taxy 1978; Trites 1957; Winkler and Poulsen 1975; Yanoff and Rawson 1964; Yap et al. 1993; Young 1953; Zak 1950). The condition mainly develops in adults, but pediatric cases have also been reported (Bank et al. 1978; Nuernberger and Ramos 1975; Pautard et al. 1986; Samyn et al. 2004; Usatin and Wigger 1976), and it has even been observed in a neonate (Kawamoto and Wakabayashi 1980).

Clinical and Imaging Features

Most cases of peliosis hepatic are asymptomatic, and patients usually suffer from underlying disease associated with peliosis. Rarely, hepatic peliosis causes portal hypertension and contributes to progressive hepatic insufficiency and to fatal complications including intrahepatic or peritoneal hemorrhage (Toth et al. 2002). It leads to hemorrhagic hepatic necrosis in some patients, can result in life-threatening or fatal hepatic rupture, and sometimes initially presents as acute hepatic failure and intraperitoneal hemorrhage. In children, space-occupying peliosis was found to cause inferior vena cava compression Hiorns et al. 2005.

Selected References: Chawla et al. 1980; Okuda et al. 1981; Smathers et al. 1984; Adam et al. 1991; Berzigotti et al. 2006; Fidelman et al. 2002; Hayward et al. 1991; Jacquemin et al. 1999; Karger et al. 2005; Marechal et al. 2005; Oriordan et al. 2000; Vignaux et al. 1999; Wang et al. 2001; Toth et al. 2002; Kim et al. 2007b; Khadikar et al. 2008; Buelow et al. 2012; Choi et al. 2009.

Peliosis hepatis can be diagnosed at liver imaging, based on characteristic features of focal to diffuse vascular lesions (Battal et al. 2010; Iannaccone et al. 2006; Jamadar et al. 1994; Kleinig et al. 2003; Nougaret et al. 2009; Saatci et al. 1995; Steinke et al. 2003; Tsukamoto et al. 1984; Yekeler et al. 2004). The peliotic lesions may reach several cm in diameter and can therefore, on sonography and CT images, mimic hepatic tumors (Ferrozzi et al. 2001; Vreswijvel et al. 2003; Atila et al. 2007; Han and Kim 2007a; Savastano et al. 2005; Kim et al. 2007a; Bexten et al. 2012).

Peliosis Hepatis Can Mimic Liver Tumors

Large foci of peliosis can simulate a hemorrhagic hepatic cancer on CT images (Dai and Zhong 2013; (Huang and Wang 2013). In case of multiple lesions, peliosis hepatis can resemble metastatic liver tumor (Liu et al. 2014; Tateishi et al. 1998; Wannesson et al. 2009; Xiong et al. 2012). In rare instances, peliosis-associated hemorrhage presents, on CT and MR, as a pseudotumoral lesion (Ferrozzi et al. 2001).

Pathology

Macroscopy

Macroscopically, major and minor forms of hepatic peliosis are distinguished. Macroscopic (major) peliosis is in evidence as sharply delineated, dark cavities of frequently spherical shape seen both from the liver's capsular surface and, as confluent and clustered, spongy cystic lesions, on the cut surface, sometimes grossly resembling a cavernous hemangioma. The lesions vary in

size from less than 1 mm to several cm in diameter and are usually multiple, single lesions being rare. Microscopic (minor) peliosis hepatis is characterized by smaller lesions detectable at histologic examination.

Histopathology

In contrast to sinusoidal dilatation or evacuation of liver cell plates owing to hepatocyte drop out, the histologic definition of peliosis requires the observation of a breakdown of the perisinusoidal reticulin fiber network and, at least in early lesions, the loss of an endothelial lining of the cavities, even though re-endothelization may occur in later stages (Tsokos and Erbersdobler 2005; Wold and Ludwig 1981; Tzirogiannis et al. 2006). Peliotic cavities are usually poor in Kupffer cells or may even lack them. In liver tissue adjacent to peliotic lesions, sinusoids may show dilatation (Zafrani et al. 1984a; Wold and Ludwig 1981), and perifocal hepatocytes may exhibit cholestatic change. Peliosis hepatic can result in intrahepatic calcifications (Muradali et al. 1996). Peliotic cavities have been classified into phlebectatic and parenchymal variants (Yanoff and Rawson 1964), which may coexist in the same liver (Wakabayashi et al. 1984). In the former variant, vascular spaces with regular contour and uniform size have been described, mainly in zone 3, and communicating with central/terminal veins. These spaces were lined by fibrin and layered blood elements, with an incomplete endothelial or fibrous wall. The latter variant was characterized by irregularly shaped blood-filled channels in a diffuse distribution, without endothelial lining, no communication with central veins, and no thrombi (Yanoff and Rawson 1964). Several reports have later employed this classification (McGiven 1970; Naeim et al. 1973). However, others were unable to confirm this distinction (Bagheri and Boyer 1974; Taxy 1978; Wold and Ludwig 1981). Wold and Ludwig (1981) studied five autopsy cases of incidentally detected hepatic peliosis, including scanning electron microscopy, and observed that all cases presented a mixture of the patterns previously proposed, thus rendering the classification into two variants not useful.

Ultrastructure

Ultrastructurally, sinusoidal endothelial cells show signs of damage (swelling, blebs, clear cell change) or regeneration, large areas of communication between the sinusoidal and the perisinusoidal space, and the formation of multicellular endothelial layers (Zafrani et al. 1984a).

Immunohistochemistry

In dilated sinusoids and cavities, expression of the cell adhesion molecules, ICAM-1, LFA-1, and VLA-4 was found, involving endothelial cells, Kupffer cells, and hepatocytes, suggesting a complex interaction of these cell types in peliosis (Gulubova 2005). Within the lesion, deposition of collagen types II and IV, tenascin, and alpha-SMA was found, suggesting activation of myofibroblasts as a secondary event (Gulubova 2002).

Peliosis in Tumors or in the Vicinity of Liver Tumors

Peliosis-like alterations also occur in liver cell adenomas, adult-type hepatocellular carcinoma, fibrolamellar carcinoma, and angiomyolipoma (Akatsu et al. 2004), but it is not known whether the ectatic vessels observed under these circumstances are bona fide peliosis or a lesion morphologically mimicking it. Peliosis can also evolve together with other tumors in the liver, including angiosarcoma (Cadranel et al. 1993; Scherer et al. 1996), where peliotic cysts are lined by atypical or malignant endothelial cells. Hepatic peliosis has been observed in association with hepatocellular carcinoma/HCC (Herrera et al. 1981). Rarely, HCC itself undergoes prominent peliotic change. In this situation, HCC contains multiple blood-filled cystic spaces and dilated sinusoid-like vascular channels (pelioid-type HCC; (Ikeda et al. 2011; Ji et al. 2001).

Causes and Associations

Peliosis hepatis has been observed in numerous conditions and associations (Table 1).

It is of interest to note that all 32 cases reported in the literature between the first descriptions in 1861 (Wagner 1861) and 1947 (Weber 1947) were found in patients with tuberculosis (Schrohe 1899; Swetschnikow 1910; Hedrén 1909; (Geisler 1931; Grätzer 1928; Lunghetti 1914; Meusburger 1934; Mittasch 1920; Peltason 1921). Peliosis hepatic can occur as a congenital lesion (Bracero et al. 1995; Kawamoto and Wakabayashi 1980), e.g., in association with congenital portal vein aneurysm (Mungan et al. 2009), and is sometimes observed in infants (Cragg et al. 1984), in one report as a focal lesion thought to be related to asphyxial death (Selby and Stocker 1995). In children, peliosis hepatis has been repeatedly found in X-linked myotubular myopathy (Terlizzi et al. 2013). Is there a relationship between the phenotype of peliosis hepatis and its etiology? There appears to be a tendency for macroscopic peliosis to occur more frequently as complication of anabolic, estrogenic, or glucocorticoids, in certain chronic infections (tuberculosis and leprosy), in vasculitis, in leukemia, and in AIDS, whereas microscopic forms are more frequently seen in kidney- or liver-transplanted patients and in malignancies. Why this seems to be so is currently unknown. In some situations, no association had been identified, leading to the term idiopathic peliosis hepatis (Brochard et al. 1981; Hyodo et al. 2004).

Differential Diagnosis

Peliosis hepatis should not be confounded with simple congestive sinusoidal dilatation and with red blood cell extravasation (the so-called red blood cell-trabecular lesion; RBCTL), even though transfer of erythrocytes into the perisinusoidal space may occur in peliosis as well. RBCTL is morphologically characterized by accumulation of red blood cells in the space of Disse, frequently associated with hepatocyte plate atrophy and/or hepatocyte dropout. It is seen in hepatic venous outflow disorders (e.g., acute Budd-Chiari syndrome), liver graft harvesting injury, acute liver graft failure, left-sided heart failure without hypotension, and myeloproliferative disorders, adjacent to liver masses, and as a side effect of drugs.

Pathogenesis

The pathogenesis of peliosis hepatis has not yet been fully clarified. It has been proposed that lesions may form through cystic expansion of sinusoids or the space of Disse, in some way representing an extreme variant of sinusoidal dilatation. Whether this is so or whether peliosis is something more complex than dilatation remains to be clarified. Endothelial cell damage with cell loss and formation of gaps even enabling erythrocytes to pass into the perisinusoidal space may play an important role (Zafrani et al. 1984a). Of particular pathogenic interest is the fact that a whole spectrum of aromatic steroids and derivatives or analogs thereof can result in peliosis. Periportal sinusoidal dilatation has also been reported in pregnancy (Fisher and Neiman 1984; Perarnau and Bacq 2008). In an electron microscopic study of liver tissue with sinusoidal dilatation of patients under oral contraceptives, proliferation and an enhanced activity of sinusoidal endothelial cells were observed, but blood cell extravasation was lacking, this constellation being different from peliosis induced by androgenic steroids (Balasz 1988). This may indicate that a complex interplay between damage with gap formation and a proliferative/regenerative response may be involved, probably modulated by factors produced by adjacent hepatocytes, Kupffer cells, hepatic stellate cells, Pit cells, and intrasinusoidal leukocytes. In the rat liver, activation of Kupffer cells results in the generation and release of superoxide anion which can induce sinusoidal endothelial cell injury (SEC) (Hasegawa et al. 2001). Under several circumstances, neutrophils can accumulate in the sinusoids and produce variable degrees of SEC (Gong et al. 2002). Leakiness of sinusoids via induction of gaps as large as to allow the transit of nucleated cells can result from cell loss induced by cytostatic drugs such as cyclophosphamide (Malhi et al. 2002).

In some situations, peliosis appears to result from sinusoidal wall injury induced by neoplastic cells; this has been proposed for hairy cell leukemia (Zafrani et al. 1987). Hairy cells express nonretractable cell surface projections, in part organized by an actin-binding, leukocyte-specific phosphoprotein, pp52/LSP1 (Miyoshi et al. 2001), and resulting in intravascular cell convolutes contacting endothelial surfaces. The homing of these abnormal leukemic cells into sinusoids and their interaction with endothelial cells is

mediated by the expression of vascular adhesion molecule-1 (VCAM-1) receptors on these endothelia, whereas hyaluronan triggers the homing of hairy cells to portal tracts in the liver, but not to sinusoids, where hyaluronan expression is lacking (Aziz et al. 2000). The endothelium-damaging mechanisms are not clarified so far. Hairy cells express the interleukin (IL)-3 receptor a chain (CD123) in a characteristic pattern (Munoz et al. 2001) and produce tartrate-resistant acid phosphatase (TRAP; (Lamp and Drexler 2000). Local activity of TRAP results in the production of reactive oxygen species (ROS) which may directly damage contacting endothelial cells of the sinusoids. On the other hand, hairy cell leukemia can be associated with vasculitis (Hasler et al. 1995), eventually mediated by autoantibodies to hairy cells cross-reacting with endothelial cells (Gabriel et al. 1986), and this mechanism may be operational in hepatic peliosis. In lymphoproliferative disorders with immunoglobulin chain production, sinusoidal damage may be related to the deposition of light chains, e.g., in Waldenström's disease (Voinchet et al. 1988). Regenerative overshoot of endothelial cells may play a role in the abnormal configuration of these vascular channels in peliosis.

Are there animal models of hepatic peliosis? Aged male Long-Evans Cinnamon (LEC) rats (an animal model of Wilson's disease) develop severe lesions of peliosis hepatis, together with hepatic dysplastic/neoplastic lesions (Onaya et al. 2000). In a conditional H-RAS/V12G transgenic mouse tumor (melanoma) model with engineered VEGF tumor expression, it was found that mice harboring VEGF-expressing tumors developed a fatal liver syndrome resembling peliosis hepatis, and the severity of liver lesions was correlated with serum levels of VEGF. These interesting observations suggest that one of the main angiogenic factors, VEGF, may play a significant role in the pathogenesis of peliosis

Lipopeliosis of the Liver

The term lipopeliosis was originally coined to denote a novel form of preservation injury in a grafted liver of a 51-year-old man and superficially resembling peliosis hepatis, however with accumulation of fat within the peliotic cavities instead of blood (Ferrell et al. 1992), and later described in more detail based on five grafted livers (Cha et al. 1994). This change occurred as early as 3 days after grafting and may be associated with poor allograft function. Histologically, in four of five patients originally reported by Cha and coworkers (Cha et al. 1994), grafts exhibited in zero-time biopsies a mild or moderate fatty change. All five first post-OLT liver biopsies obtained between days 3 and 8 after grafting showed a striking dilatation of the sinusoidal spaces, shown by immunohistochemistry to represent sinusoids. Oil red O stains confirmed that these spaces were filled with fat. Lipopeliosis can be cleared within 25 days via elimination of fat by the action of the hepatic macrophage/Kupffer cell system (Cha et al. 1994). Pathogenetically, it was suggested that injured, fat-laden hepatocytes may discharge their accumulated neutral fat into the sinusoidal space; therefore, lipopeliosis may not only occur after grafting of fatty livers but also in other situations of steatosis with subsequent liver cell damage. In fact, neutral fat may leave the compartment of a steatotic liver to enter, in droplet form, the bloodstream, as exemplified by the occurrence of fat embolism in case of massive steatosis of the liver in pregnancy (Jones 1993) or in acute hepatic necrosis with steatosis (Schulz et al. 1996). However, this view as to pathogenic mechanisms involved may need revision, based on the recent observation that, in transplanted steatotic livers, large fat globules accumulate mainly outside sinusoids, thus requiring an alternate hypothesis as to how fat then may get access to the circulation (Bioulac-Sage et al. 2002). The authors propose that fat, discharged from damaged or necrotic hepatocytes, may accumulate in the extrasinusoidal space, hence mimicking dilated sinusoids, be surrounded by hepatic macrophages, and to then be cleared by macrophages. Therefore, the term lipopeliosis, previously criticized (Yokoo 1995), may in fact seem inappropriate and is replaced by pseudopeliotic steatosis (Bioulac-Sage et al. 2002).
