The Ki-67 protein (also known as MKI67) is a cellular marker for cell proliferation (Gerdes et al. 1983). During interphase, Ki-67 protein is present in the nuclear matrix and is located to the nucleolus, whereas it is relocated to chromosomal surfaces during mitosis. In the cell division cycle, Ki-67 is present in all cycle phases (G1, S, G2, M), but it is not detectable in the G0 phase (Scholzen and Gerdes 2000). The protein is required for the assembly of the perichromosomal layer and is a cell cycle-regulated, protein phosphatase-1 binding protein that is involved in phospho-regulation of the nucleolar protein, nucleophosmin, and other proteins that are necessary for the construction of the mitotic chromosome periphery (Booth et al. 2014). The perichromosomal layer (synonyms: perichromosomal sheath, chromosomal coat, chromosome surface domain) is a distinct specialized chromosome domain involved in synthesis of messenger RNA, ribosome assembly, repair of DNA double-strand breaks, telomere maintenance, and apoptosis regulation (Van Hooser et al. 2005). Ki-67 contributes to the recruitment of protein phosphatase 1gamma to the perichromosomal layer of anaphase chromosomes (Takagi et al. 2014) and contributes to chromatin compaction (Kametaka et al. 2002). A Ki-67 antigen-related perichromosomal protein implicated in higher-order chromatin structure is chmadrin (Takagi et al. 1999). In proliferating and quiescent cells, the Ki-67 protein is associated with ribosomal RNA and regulates its transcription (Bullwinkel et al. 2006). The original Ki-67 antibody and the monoclonal antibody MIB-1 are directed against different epitopes of the same antigen and detect the Ki-67 antigen in normal and neoplastic replicating cells, also in HCCs and cholangiocarcinomas (Gerdes et al. 1983; Ng 1998).

Ki-67 Labeling in Hepatocellular Carcinoma

The Ki-67/MIB-1 proliferation index in HCC varies considerably and ranged from 15 % to 50 % (Grigioni et al. 1989). The number of MIB-1-positive cells in HCC correlates with the total mean number of nucleolar organizer regions (AgNORs) (Nagao et al. 1995). Similar to PCNA, Ki-67 expression is correlated with HCC grade (Ng et al. 1995; Kalogeraki et al. 2002; Witjes et al. 2013). Even well-differentiated HCCs display higher MIB1 indices than dysplastic nodules/adenomatous hyperplasia (Than et al. 1995), and there is a gradual increase of Ki-67 labeling from regenerative nodules to HCCs (Quaglia et al. 2006). The MIB-1 LI was elevated in HCCs and was found to be significantly higher in poorly differentiated tumors than in well-differentiated ones and was also higher in nonencapsulated tumors, but was not correlated with invasiveness (Ng et al. 1995), in contrast to PCNA labeling (see above). High Ki-67 labeling in HCCs is correlated with overexpression of an important regulator of cell cycle, centromere protein A (CENP-A) (Li et al. 2011). Elevated Ki-67 indices reflect more aggressive disease and poor prognosis (Colleoni et al. 1995). The regulation of Ki-67 in HCC cells is not yet well understood. A regulator of HCC growth and invasion, myocyte enhancer factor 2C, interacts with Ki-67 (Bai et al. 2014).

Ki-67 Labeling in Cholangiocarcinomas

Generally, cholangiocarcinomas show higher Ki-67 labeling indexes than well- to moderately differentiated HCCs. Specifically sarcomatoid components in cholangiocarcinomas exhibit a high proliferative activity that may exceed 40 % (Settakorn et al. 2005; Aishima et al. 2006; Iguchi et al. 2009). Also in combined hepatocellular-cholangiocarcinomas, the Ki-67 LI is lower in the HCC component than in the cholangiocarcinoma component (Wakasa et al. 2007). In extrahepatic cholangiocarcinomas, MIB-1 and/or AgNOR levels were associated with more aggressive disease, lymph node metastases, and poorer survival (Yamada et al. 1995; Shrestha et al. 1998; Suto et al. 1998; Murakami et al. 2003). In hilar cholangiocarcinoma, Ki-67 expression increased with stage of disease and invasion of cancer cells (Zhao et al. 2014). In patients with distal cholangiocarcinoma, a significant correlation was found between a low MIB-1 index and survival (Rijken et al. 1998). In intrahepatic cholangiocarcinomas, the Ki-67 LO correlated with overexpression of MDM2, an oncoprotein that binds to Tp53 and inhibits p53-mediated transactivation (Horie et al. 2000). The Ki-67/MIB-1 labeling index was a powerful prognostic factor in ampullary carcinoma (Shyr et al. 1999), and elevated Ki-67 levels may serve to distinguish ampullary adenomas from carcinomas (Kubota et al. 2013).

Assessment of Proliferative Activity in Liver Cancer: Additional Parameters

S-phase cells of HCCs can be assessed by in situ hybridization for histone 3 mRNA. Histone 3 accumulates in the cytoplasm during S phase and then decreases as cells approach G2. The histone H3 labeling index is elevated in HCCs and correlates with other proliferation markers, including PCNA and Ki-67/MIB1 (Nagao et al. 1996). The MIB1 LI is correlated with the number of nucleolar organizing regions (AgNORs) (Nagao et al. 1995). PRO2000/ANCCA is a candidate gene located within a region of chromosome 8q in HCC, and its expression was found in a high proportion of HCCs, more in poorly differentiated ones, and correlated with the Ki-67 index. Its expression was correlated with number of tumor nodules, TNM stage, portal vein invasion, and recurrence, suggesting a role as prognosticator (Yang et al. 2014a).

Initiation of Cell Cycle and Replication Control in Liver Cancer

Control of DNA Replication Initiation in Normal and Liver Cancer Cells

It is very important that only one DNA replicative round occurs per cell division cycle to avoid aneuploidy and genomic instability, alterations that often occur in cancers, including liver cancers. This control step, DNA licensing, is executed by the nuclear protein, geminin. Geminin is a substrate of the anaphase-promoting complex (APC/C). From the S phase of the cycle to the end of mitosis, geminin inhibits the replication factor Cdt1, which promotes assembly of the prereplication license complex, thus preventing the assembly of this complex. In G1, the APC/C mediates degradation of geminin via ubiquitination. By this machinery, the geminin-Cdt1 system guarantees a mono-round replication. This platform is linked to proteins that load helicase onto DNA, the MCM (minichromosome) maintenance helicases (see below). In the prereplication license complex, Cdt1 cooperates with the cell cycle protein Cdc6 to promote loading of MCMs onto the chromatin-bound origin recognition complex (ORC) via chromatin unfolding, to initiate DNA replication. In contrast, geminin prevents loading of MCM onto ORC by binding to Cdt1 and modulating its activity and stability. Geminin availability is itself regulated by its partner molecules, the Idas, whereby heterodimeric geminin-Ida complexes inhibit geminin function (reviews: Caillat and Perrakis 2012; Caillat et al. 2013). A central step in DNA replication initiation is the loading of replicative helicase at DNA replication origins to form a replicative fork. The loading causes each replication origin to be unwound and assembles functional bidirectional replisomes just once in each cell cycle. This step must be tightly regulated, as its failure will result in DNA damage and genomic instability, as in many cancers. The principal helicase loader is the MCM2-7 ATPase system, forming a hexameric ring. This ring forms the core of the DNA helicase and is first loaded at replication origins in an inactive form. ORC, Cdc6, and Cdt1 assemble two MCM2-7 hexamers into one double hexamer around dsDNA. This ring loading occurs through a DNA entry gate comprised of the MCM2 and MCM5 subunits. The helicase is activated by formation of a holo-helicase complex containing MCM2-7, Cdc45, and GINS proteins (Boos et al. 2012; Kang et al. 2014; Samel et al. 2014).

Geminin shows distinct expression patterns in HCC (Quaglia et al. 2006). Specifically, geminin is frequently amplified in these cancers and functionally linked with cyclin-dependent kinase 13 (Cdc13) (Kim et al. 2012). Although geminin is a negative regulator of DNA replication, its expression in HCCs reflects growth patterns, in that geminin-negative tumors represent resting tumors, while geminin-positive tumors are slowly growing or expanding lesions (Quaglia et al. 2006). Overexpression of MCM2 in HCCs characterizes tumors with poor differentiation (Sun et al. 2010), while MCM-negative tumors are resting lesions (Quaglia et al. 2006).

G1/S Transition Checkpoint and Mitosis Checkpoint Controls in Cancer Cells

The entry of cycling cells into cell cycle and cell division is controlled by checkpoint proteins acting at the G1/S transition. This checkpoint control, together with replication initiation control discussed above, is one of the major mechanisms to regulate cell cycle entry and progression. The most important factors controlling this checkpoint are several forms of checkpoint kinases and associated regulatory proteins. Checkpoint kinase 1 (CHK1) is an enzyme that is essential for preventing mitosis in response to DNA damage and functions as a mitogen-dependent protein kinase that suppresses p21 and p57, but not p27, activation (Ullah et al. 2011). Following checkpoint recovery upon completion of DNA repair

after DNA damage, Greatwall and Polo-like kinase 1 coordinate to promote checkpoint recovery (Peng et al. 2011). Polo-like kinase 1 (Plk1) is a member of the serine/threonine kinases as it represents the mammalian counterpart of *Drosophila* polo. Plk1 has a central role in the biogenesis of the mitotic spindle and chromosome segregation and in DNA damage repair (van Vugt and Medema 2005). Plk1 is recruited to centrosomes, kinetochores, and the spindle midzone and is critically involved in the initiation and progression of cytokinesis (Petronczki et al. 2008; Burkard et al. 2009). Plk1 is expressed in the nuclei of proliferating cells, but immunoreactivity disappears in the course of cell differentiation (Yuan et al. 1997).

After G1/S checkpoint control, control of mitosis entry is a second major regulatory machinery. Control of mitosis entry critically involves cyclin-dependent kinase 1, a mitotic driver enzyme involved in the ordered phosphorylation of numerous proteins required for cell division. The phosphorylated status of these proteins is maintained all through mitosis, but has to be abolished at mitotic exit through phosphatic dephosphorylation to become ready for a next cycle round. This is accomplished by protein phosphatase 2A (PP2A), which in turn is negatively regulated by the kinase Greatwall that phosphorylates the protein ARPP-19 and converts it into a potent phosphatase 2A inhibitor (Haccard and Jessus 2011; Wang et al. 2014a). Greatwall kinase is a serine/threonine kinase of the AGC family that is essential for the promotion of correct mitosis timing, having Endos as a substrate (Burgess et al. 2010; Rangone et al. 2011; Vigneron et al. 2011). PP2A-mediated dephosphorylation of Akt to repress mTORC1 signaling is enhanced by REDD1 regulated in DNA damage and development 1 (Dennis et al. 2014). An intracellular inhibitor of protein phosphatase 2A is cancerous inhibitor of PP2A (CIP2A), a target of bortezomib, which regulates cell proliferation via the Akt-mTOR signaling pathway (De et al. 2014; Lei et al. 2014). Inhibition of CIP2A by erlotinib reactivates PPA2 (Yu et al. 2014a). PP2A and CIP2A play a role in carcinogenic pathways. PP2A promotes hepatic carcinogenesis in a mouse model through inhibition of p53 (Duong et al. 2014). The hepatocarcinogenic HCV virus induces upregulation of PP2A associated with dysregulation of histone modifications (Duong et al. 2010). CIP2A is highly expressed in HCC and predicts poor prognosis (He et al. 2012; Huang et al. 2012).

Role of Cell Ploidy in Normal and Cancer Cells: Protection from Replicative Overshoot

Polyploidy, a situation characterized by an increase in the number of chromosomes sets, is a widely distributed phenomenon in nature, but is not a common feature in higher vertebrate cells. In humans, polyploidy usually results from a diploid-polyploid conversion whereby additional sets of chromosomes originate from the same individual (autopolyploidy). In the adult liver, progressive polyploidization takes place physiologically in the postnatal period. Tetraploid binucleated hepatocytes emerge upon stimulation with insulin signaling via PI3K/Akt signaling pathways, and hepatocyte polyploidization generally reflects terminal differentiation and senescence, associated with increased autofluorescence, accumulation of lipofuscin, loss of replicative capacity and regenerative power, and an increased apoptotic rate (reviews: Sigal et al. 1999; Gupta 2000; Gentric et al. 2012a, b; Gentric and Desdouets 2014). The generation of polyploid hepatocytes is a complex process that occurs not only physiologically but also in situations of so-called replicative stress responses. The latter can ensue under excessive proliferation stimuli leading to cell restriction and/or apoptosis. This is an important counterregulation mechanism that protects tissues and organs from replicative overshoot, but is thought to be bypassed in cancer. A repressor of replicative stress responses is the COP9 signalosome, a regulator of cullin-ring ligases, important members of ubiquitin ligases. Inactivation of this signalosome in the liver results in the activation of S- and G2-phase checkpoints, irreversible cell cycle arrest, polyploidization, and cell death (Panattoni et al. 2014). Polyploid cells

in primary HCC exhibit a reduced proliferative activity (Gerlyng et al. 1992).

Growth Regulation in Hepatobiliary Cancer: Involvement of Growth Factors

173

Contents

Abstract

Cell proliferation in the regenerating liver and in liver neoplasms requires a complex system of growth factors that promote or inhibit proliferative growth. In hepatocellular carcinoma (HCC), protumorigenic growth factor signaling is frequently deregulated. Growth factors that are involved in liver cancer and specifically in HCC are those that also operate in normal liver regeneration, with some exceptions. The most important growth factors active in expansion and progression of HCC include hepatocyte growth factor (HGF) and its receptor Met, insulin-like growth factors, transforming growth factors alpha and beta, and epidermal growth factor. HGF and Met have been implicated in human hepatocarcinogenesis. HGF is up-regulated in part of HCCs, and amplification of Met characterizes subsets of HCC, whereby Met activation does not only affect growth, but also invasion and spread, suggesting that abnormal growth factor and growth factor receptor expression in cancers exerts complex effects on tumor biology.

Introduction

Liver regeneration and neoplasms of the hepatocyte lineages require a complex system of growth factors that promote or inhibit cell growth (reviews: Fausto 1991; Breuhahn et al. 2006; Breuhahn and Schirmacher 2010; Zender et al. 2010). In

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_173

hepatocellular carcinomas, protumorigenic growth factor signaling is frequently deregulated, whereby both diverse growth factors and/or their receptors may be upregulated. Growth factors that are involved in liver cancers are those that also operate in normal liver regeneration, with some exceptions. The most important growth factors active in liver cancer include hepatocyte growth factor, insulin-like growth factors, transforming growth factors alpha and beta, and epidermal growth factor. These growth factors and their receptors are or will be interesting targets for molecular therapies. In addition to these major factors, numerous other factors known to play a role in liver regeneration are identified in liver cancers, but their roles are less well understood.

Hepatocyte Growth Factor

Hepatocyte growth factor (HGF; scatter factor) is a multifunctional protein that is expressed in several organs and tissues and is, therefore, not specific for hepatocyte growth regulation. In the liver it is synthesized and secreted by non-hepatocyte cells, including hepatic stellate cells and their differentiated offspring. HGF interacts with its c-Met receptor which is itself regulated by a factor, modulating several tyrosine kinase receptors, decorin. HGF induces growth stimulation in various cell types, including hepatocytes in primary culture, but also growth inhibition in certain tumor cell lines. The opposing effects of HGF are caused by differences in downstream target signaling of the HGF receptor, c-Met. HGF induces redistribution of p21(CIP1) and p27(KIP1) via ERK-dependent p16(INK4a) upregulation, leading to cell cycle arrest at G1 (Han et al. 2005).

HGF and c-Met have been implicated in human hepatocarcinogenesis, and HGF is expressed in part of HCCs (Huitzil et al. 2008; Ang et al. 2013). In HCC, HGF is secreted by cancer-associated fibroblasts/CAFs and alphaSMA-reactive myofibroblasts and increases the proliferative activity of HCC cells (Jia et al. 2013). The HGF receptor c-Met is implicated in proliferation, invasion, and spread of numerous malignancies. Cancer cells having c-Met gene amplification can activate alternative signaling pathways to escape c-Met inhibition (Wang et al. 2009). In HCC, abnormal expression patterns of c-Met are detectable (Ueki et al. 1997; Huitzil et al. 2008; Ang et al. 2013; Kondo et al. 2013). Overexpression of c-Met in HCC defines tumor subtypes with increased vascular invasion and elevated microvessel density/angiogenesis (Kaposi-Novak et al. 2006), poor to moderate differentiation and increased proliferation (Suzuki et al. 1994), and shorter 5-year survival (Ueki et al. 1997).

Insulin-Like Growth Factors, Epidermal Growth Factor, and Neuregulins

Insulin-Like Growth Factors and Their Receptors

Insulin-like growth factors (IGFs) are polypeptides with sequence homology to insulin. IGFs exhibit strong proproliferative and antiapoptotic properties and consist of two major IGF family members, IGF-1 and IGF-2. These two ligands bind to membrane-bound receptors, IGFR1 and the mannose-6-phosphate receptor/IGFR2, respectively. The kinase activity of IGFR1 is triggered by clustering of syndecan-1, thus coupling IGFR1 function to inside-out integrin activation (Beauvais and Rapraeger 2010). IGFR2 plays an important role in trafficking IGFs to lysosomes. Both IGFs also bind to the insulin receptor isoform A. The bioavailability and function of IGFs within the so-called IGF axis is modulated by six secreted IGF-binding proteins (IGFBP1-6). Receptor binding results in the phosphorylation of several intracellular targets, in the activation of PI3K and Akt/protein kinase C, and finally in the activation of several genes involved in growth regulation (cyclin B, Myc, Fos, p27kip1).

IGFs have an important role in the promotion of cell growth and are commonly deregulated in many cancers, including HCC (Rashad et al. 2014; Liu et al. 2015). IGF-2 is highly expressed in fetal tissues but is downregulated in the normal adult liver via four epigenetically controlled promoters. IGF-2 is upregulated in a significant proportion of HCCs and their precursor lesions via reactivation of a fetal-type promoter

patterns and promotes growth in an autocrine manner. The expression pattern of IGF-2 in HCCs is modulated via IGFR2, which is downregulated in a major subset of these tumors (review: Breuhahn et al. 2006).

Expression of IGF-1 in HCCs follows more complex pathways, with both upregulation and downregulation occurring in phase-dependent manners (Ikeda et al. 2013; Yan et al. 2013). Development of HCC is accompanied by a significant reduction in serum IGF-1 levels, regulated by microRNA-190b (Hung et al. 2014). In contrast, IGF-1 may be elevated in HCC tumor tissue itself but is low in adjacent liver tissue. IGF-1 upregulation in HCC was associated with poorer median survival (Chun et al. 2014). Expression of IGFR1 beta was detectable in more than 50 % of HCC, but less than 10 % of normal liver samples, and in HCC was associated with poor differentiation (Liu et al. 2011).

HCCs express IGF-binding proteins/IGFBPs in complex patterns. The liver is the major source of at least two IGFBPs, IGFBP-1 and IGFBP-3, proteins that usually serve to attenuate the effects of IGFs at the receptor levels, thereby limiting the pro-growth effects of IGFs. In HCCs, the expression of IGFBPs 1, 3, and 4 is significantly downregulated, what results in failure of IGF inhibition and growth stimulation (Gong et al. 2000). HCCs also revealed upregulation of insulin-like growth factor 2-binding protein 1/IGF2BP1, a protein which enhances expression of c-Myc and Ki-67 proteins and potently regulates cell proliferation (Gutschner et al. 2014). HCCs also express insulin-like growth factor-2 mRNA-binding protein 3/IMP3, an oncofetal protein expressed in various cancers (Wachter et al. 2012).

Epidermal Growth Factor and Its Receptors

Epidermal growth factor receptor (EGFR, ErbB-1, HER1 in humans) belongs to the ErbB subfamily of transmembrane tyrosine kinase receptors, the other members being HER2/c-neu (ErbB-2), HER3 (ErbB-3), and Her4 (ErbB-4). EGFR can bind eight ligands in humans (TGF-alpha, EGF, heparin-binding EGF, amphiregulin, betacellulin, epiregulin, epigen, and crypto (review: Breuhahn et al. 2006). Upon ligand binding, EGFR dimerizes to form a homodimer which achieves intracellular protein tyrosine kinase activity. Active kinase autophosphorylates several receptor tyrosine residues leading to downstream activation of signaling pathways, mainly MAPK, Akt, and JNK pathways, causing DNA synthesis and cell proliferation. Receptor monomer dimerization occurs following ligand binding, but also the cytoplasmic protein plakophilin-2 enhances ligand-dependent and independent EGFR dimerization. EGFRs are internalized via endocytosis, mediated by Rab GTPases, a process deregulated in cancer cells (Grandal and Madshus 2008).

Members of the epidermal growth factor/EGF family are upregulated in subsets of HCCs and play an important role in growth regulation of these neoplasms (Higashiyama et al. 2008; Berasain et al. 2009; Nalesnik and Michalopoulos 2012). A single nucleotide polymorphism 61*G in the EGF gene has been identified in part of HCCs (Yuan et al. 2013). Individuals with the G/G EGF genotype had a higher adjusted risk for HCC than those with genotype A/A, and higher serum levels of EGF were seen among subjects with at least one G allele (Abu Dayyeh et al. 2011). In subsets of HCC, phosphorylated ErbB-3/HER3 and its ligands, the neuregulins, are upregulated, forming an autocrine loop affecting growth and invasion (Hsieh et al. 2011).

In many HCCs, the EGF receptor system (EGFR) plays a role as a signaling platform where different growth signals can converge (Berasain et al. 2009, 2011). EGFR is frequently overexpressed in HCCs, associated with extra EGFR gene copies and gains of chromosome 7 (Harada et al. 1999; Moon et al. 2006; Buckley et al. 2008). Inhibition of EGFR attenuates hepatocarcinogenesis, suggesting that the EGF-EGFR signaling system is critically involved in the development of liver cancer (Fuchs et al. 2014). High expression of EGFR is a marker of poorly differentiated HCCs, and EGFR polymorphisms in HCC are associated with prognosis (Wang et al. 2014). The homologue of EGFR, the c-erbB-2 oncogene, is

expressed in a minority of HCCs and is absent in cholangiocarcinoma (Collier et al. 1992). The mechanisms of growth-promoting effects of EGF/EHGR in HCCs are not fully clarified. EGFR transactivation in HCC cells is induced by TNF-alpha which triggers amphiregulin shedding from tumor cells, whereby amphiregulin is necessary for TNF-alpha activation of ERK1/2 and Akt signaling (Berasain et al. 2012). EGF can induce the expression of cytokeratin 19 in HCC cells, an alteration which is associated with increased growth capability (Yoneda et al. 2011).

Apart from its action on HCC cells, EGFR also affects the tumor microenvironment and the biology of tumor-associated cells located in stroma. The EGF-EGFR signaling system is involved in the generation of an inflammatory microenvironment in HCCs (Huang et al. 2014) and stimulates macrophages to produce interleukin-6, which in turn triggers the proliferation of HCC cells (Lanaya et al. 2014). EGFR expressed in tumor vessel endothelia promotes tumor angiogenesis, and tumors with EGFR expression show a higher microvessel density than those without expression (Moon et al. 2006).

Amphiregulin

Amphiregulin is a member of the EGF family and a ligand of EGFR. Amphiregulin is produced as a large precursor that is proteolytically cleaved and shed from cell surfaces by metalloproteinases. A protease involved in amphiregulin shedding is ADAM17, an enzyme upregulated in liver regeneration and HCCs (Berasain et al. 2012). Amphiregulin expression is not found in the normal liver but is upregulated during liver regeneration and in liver cirrhosis. It has functions in regulating immunity, inflammation, and tissue repair in normal and cancerous tissues (Zaiss et al. 2015). Amphiregulin is involved in HCC cell proliferation, is overexpressed in HCC tissues, and plays a role in hepatocarcinogenesis (Berasain et al. 2007). Amphiregulin gene expression is regulated by beta-catenin signaling in human HCC cells, and its upregulation participates in the induction of cyclin D1 and cell proliferation elicited by FGF19 (Latasa et al. 2012).

Transforming Growth Factor-Alpha

Two structurally related growth factors, transforming growth factor-alpha (TGF-alpha) and epidermal growth factor (EGF), act through a common cell surface receptor, the epidermal growth factor receptor (EGFR). Members of the TGF-alpha/EGF family occur as transmembrane-anchored factors that can be released through ectodomain shedding mediated by ADAM17. TGF-alpha is a potent mitogenic protein. In normal liver, TGF-alpha is expressed in cholangiocytes, but only occasionally and weakly in hepatocytes, and not in Kupffer cells. In part of HCCs, expression of TGF-alpha is deregulated, however, to variable degrees in published studies. TGF-alpha was found in the cytoplasm of HCC cells, and levels of mRNA were significantly elevated in part of cases (Harada et al. 1999; Yeh et al. 2007; Pannain et al. 2012). It was expressed at a high level from 31.9 % to more than 80 % of human HCC, preferentially in tumors growing in cirrhotic liver (Hsia et al. 1992; Pannain et al. 2012). TGF-alpha seems to mainly act in early stages of hepatocarcinogenesis and correlates with tumor proliferation and differentiation (Kira et al. 1997). TGF-alpha can show complex expression pattern in HCC, depending on the distribution of lineages with different levels of cell differentiation. Zones with high differentiation usually show prominent TGF-alpha expression, while poorly differentiated foci revealed lower levels of expression (Morimitsu et al. 1995; Zhang et al. 2004).

Transforming Growth Factor-Beta Superfamily Members

Transforming Growth Factor-Beta

Transforming growth factor-beta (TGF-beta) acts as a potent inhibitor of hepatocyte proliferation and is a critical termination signal of liver regeneration. It also mediates p53-dependent apoptosis in HCC cells (Wang et al. 2006). In its regulation of cell cycle progression and cell differentiation, TGF-beta operates through Smad protein

signaling. In their intranuclear action, Smads are negatively regulated by two nuclear proto-oncogenes, Ski and SnoN, which directly interact with Smad2, Smad3, and Smad4 and repress their capability to activate TGF-beta target genes.

TGF-beta is often overexpressed in HCC, and HCC cells show TGF-beta receptor-dependent growth inhibition in response to TGF-beta (Yamazaki et al. 2011). Based on RNA analysis, marked overexpression of TGF-beta1, TGF-beta2, and TGF-beta3 was found in HCCs. All three TGF-beta isoforms were also detected in HCC by immunohistochemistry (Abou-Shady et al. 1999). TGF-beta receptors are expressed in HCCs in various manners, but generally TGF-betaRs are expressed at low levels. Part of the tumors show decreased TGF-betaRII protein expression (Musch et al. 2005). HCC also shows diverse alterations in Smad signaling. In HCC cell lineages, Smad5 levels are either maintained or upregulated by an increase in gene dosage via a copy number gain, reflected by aberration in the long arm of chromosome 5 in part of HCCs (Zimonjic et al. 2003).

TGF-beta mediates a complex crosstalk between HCC cells and tumor microenvironment in HCC (Gupta et al. 2014). A distortion of TGF-beta signaling in HCC cells accelerates the malignant potential of the cells by enhancing stroma-induced cell growth (Sugano et al. 2003), suggesting that cancer cell-stroma interactions and epithelial-mesenchymal transition/EMT play an important role in TGF-beta-induced tumor progression. TGF-beta-induced hepatocyte EMT is modulated by microRNA-181a, overexpressed in cirrhosis and HCC (Brockhausen et al. 2014).

Bone Morphogenetic Proteins

Bone morphogenetic proteins/BMPs, TGF-beta superfamily members, play a role in the regulation of proliferation and differentiation of normal and cancer cells. BMP9, which triggers Smad 1, Smad 5, and Smad 8 phosphorylation and upregulates inhibitor of DNA binding 1/Id1 expression, is a proliferative and survival factor in HCC (Herrera et al. 2013). The activin/follistatin system, members of the TGF-beta superfamily, is also involved in hepatocarcinogenesis and regulation of HCC cell growth (Deli et al. 2008). Activins are disulphide-linked homo- or heterodimers formed from four different beta subunits termed beta(A), beta(B), beta(C), and beta(E). Activin A (beta(A) beta(A)) is a potent regulator of cell proliferation, apoptosis, and architecture of the liver, involved in the termination process of regeneration. The activity of activin A is counteracted by follistatin. Follistatin was overexpressed, while both activin subunits beta(A) and beta(E) were downregulated in the majority of human HCCs (Grusch et al. 2006).

Other Growth Regulatory Factors Promoting Cell Proliferation in Liver Cancers

Augmenter of Liver Regeneration

Augmenter of liver regeneration (ALR; encoded by the GFER gene; hepatic stimulatory substance; hepatopoietin) is a pleiotropic effector of growth for several cell systems, although it was originally identified as a liver cell growth factor involved in hepatocyte regeneration. In the liver, ALR is only expressed in hepatocytes and is a survival factor for these cells in that it protects them against apoptosis (Ilowski et al. 2011). ALR induces hepatocyte proliferation in an EGF receptor-independent manner (Ilowski et al. 2010). ALR is upregulated in subsets of human HCCs and stimulates autonomous growth of cancer cells (Thasler et al. 2005; Tang et al. 2009; Yu et al. 2010). These neoplasms in part show stable cytoplasmic expression of the 15 kDa isoform of ALR, whereby ALR expression is associated with reduced angioinvasion and less metastases (Dayoub et al. 2011).

Fibroblast Growth Factors

Fibroblast growth factors (FGFs), members of a large family of growth factors, and their receptors

are deregulated in many cancers, including HCCs and cholangiocarcinomas (Sandhu et al. 2014). In HCC, FGFs are often aberrantly expressed in conjunction with the reregulation of other growth factors, mainly HGF and TGF-beta (Gupta et al. 2014). In recent studies, more than 80 % of HCCs revealed overexpression of at least one FGF and/or FGFR. The main FGF family members upregulated in HCCs were FGF8, FGF17, and FGF18, all these three FGFs involved in autocrine and paracrine growth and survival signaling (Gauglhofer et al. 2011). Also the FGF19-FGFR4 signaling pathway is involved in development and growth of HCC (Lin and Desnoyers 2012). The isoform B of fibroblast growth factor receptor 2/FGFR2-IIIb is highly expressed in hepatocytes and acts in growth regulation. Lack of FGFR2-IIIb expression in HCCs is associated with more aggressive biology and reduced proliferative activity (Amann et al. 2010). Upregulation of FGF17 and FGF18 stimulates the growth of HCC-derived myofibroblasts, while FGF8, FGF17, and FGF18 induce the proliferation of endothelial cells, illustrating that the FGF system of growth factors also affects the growth of stromal and vascular cells of liver cancers (Gauglhofer et al. 2011).

In addition to FGFs, HCCs can also express FGF receptors/FGFRs. Human HCCs can present FGFR3, whereby higher expression levels are found in tumors of high grade (Qiu et al. 2005). A subset of HCCs expresses FGFR4, expression being associated with stage and TGF-beta1 expression. It surfaced that deregulated expression of FGFR4 is a key driver of an aggressive and rapidly growing phenotype of HCC (Ho et al. 2009; Chen et al. 2013b; Gauglhofer et al. 2014). FGFR4 signaling in HCC cells suppressed by its co-receptor Klotho-beta, a factor upregulated in subsets of HCC (Poh et al. 2012). Expression of FGFR2 in HCCs drives poor differentiation and an aggressive tumor phenotype (Harimoto et al. 2010). 13.6 % of intrahepatic cholangiocarcinomas showed a fusion of FGFR2 tyrosine kinase involving AHCYL1 and BICC1 as fusion partners. Expression of these fusion proteins promotes enhanced proliferation and transforming ability (Arai et al. 2014).

Krüppel-Like Factors

Krüppel-like factor 6 (KLF6) is an oncogene and ubiquitously expressed zinc finger transcription factor that is deregulated in numerous cancers. KLF6 is frequently inactivated in HCC, with LOH of the KLF6 gene found in up to 39 % of primary HCC. Downregulation of KLF6 is an early event in the course of hepatocarcinogenesis (Kremer-Tal et al. 2007). While wild-type KLF6 inhibits cell proliferation, mutant KLF6 in cancer cells can promote proliferation (Kremer-Tal et al. 2004, 2007). In HCC there is a correlation between activated Ras signaling and increased KLF6 alternative splicing. In cultured HCC cells, Ras signaling increases the expression of KLF6 SV1, thereby enhancing proliferation (Yea et al. 2008).

Antagonists of Proliferation in Liver Cancers

Glypican-3, which can enhance the pro-growth action of several growth factors, can itself inhibit HCC growth through induction of apoptosis (Pan et al. 2013). HCRP1/hepatocellular carcinoma-related protein 1, assigned to chromosome 8p21, encodes a growth inhibitory protein and is downregulated in HCC (Xu et al. 2003). Depletion of Aurora A kinase in HCC cells leads to upregulation of FoxO1 to induce cell cycle arrest (Lee et al. 2013). Overexpression of signal transducer and activator of transcription 1/STAT1 significantly reduced the proliferative activity of HCC cells and augments apoptosis (Chen et al. 2013a). Nogos (neurite outgrowth inhibitor proteins) form a family of three major members. Nogo-B is elevated in and plays a role for liver cirrhosis. Nogo-C is an inhibitor of cell proliferation and is extremely downregulated in HCC, associated with large tumor size and worse prognosis (Liu et al. 2014).

Substances Stimulating Liver Cancer Growth Produced by Platelets and Cells of the Tumor Microenvironment

Proliferation Stimulators Derived from Platelets

Platelets traffic to the microcirculation of liver cancers and may interact with tumor endothelia, where they can undergo viscous metamorphosis and aggregation, followed by the release of thrombocyte granule factors. Platelet aggregation associated with vascular thrombosis is a common event in liver cancer and is triggered by invading tumor cells. Endothelia of sinusoids and sinusoid-like vascular channels bind platelets in an integrin-dependent manner leading to platelet recruitment (Lalor et al. 2013). Subsequent to endothelial cell binding, platelets can induce hepatocyte proliferation (Takahashi et al. 2013) and endothelial cell apoptosis and therefore participate in regeneration and tumor-associated microvascular remodeling (Lisman and Porte 2010; Goubran et al. 2014).

Upon activation, platelets can release numerous factors from their dense and alpha granules. Through tumor cell-induced aggregation and formation of direct tumor cell-platelet contacts, cancer can induce thrombocyte activation and thus promote growth factor release. Platelet factors stimulate hepatocyte proliferation through induction of HGF and insulin-like growth factor 1/IGF-1 (Matsuo et al. 2008). Signal transducer and activator of transcription 3/STAT3 activation by IL-6 derived from SECs and Kupffer cells promotes regeneration upon contact with platelets (Murata et al. 2014). One source of this pathway, the Kupffer cells, fails in liver cancer, as HCCs do not contain Kupffer cells in any significant amount. However, platelets can stimulate liver cell proliferation even in the absence of Kupffer cells and secretion of TNF-alpha, due to their induction of HGF and IGF-1.

As platelets express P-selectin, they exert an influence on cancer cell homing to stroma and premetastatic niches (Coupland and Parish 2014) and tumor-stromal cell interactions which promote cell growth. Platelets can influence tumor growth also by induction of recruitment of growth-promoting immunomodulatory cells into stroma (Sitia 2014). Platelets can affect growth of cancer cells by release of platelet microparticles (PMPs; the former "platelet dust"). PMPs are fragments or microvesicles shed from the plasma membrane of thrombocytes undergoing activation, stress, or apoptosis. Via their cargo, PMPs can act in platelet-cancer loops that affect numerous functions of cancer cells, including growth and apoptosis (Goubran et al. 2015; Burnouf et al. 2014). The fragments measure 0.1–1.0 μm and represent the majority of circulating microparticles. Their cargo, which includes procoagulant phosphatidylserine, growth factors, and signal substances, modulates inflammatory responses in tumor microenvironment and cancer cell growth and invasion. Platelets can also have an effect on cancer cell growth by favoring tumor cell survival. Thrombocytes, via their close interaction with both endothelia and tumor cells, can protect cancer cells from shear-induced damage (Egan et al. 2014). Also the survival of nonneoplastic cells located to cancers is influenced by platelets. Phagocytosis of platelets by endothelial cells enhances the survival of these cells via inhibition of apoptosis by platelet constituents (Jiang et al. 2015). This mechanism may have an effect on the release of caspase-3-containing microparticles released by detached and apoptotic endothelial cells (Abid Hussein et al. 2005), whereby endothelial cells undergoing apoptosis become proadhesive for nonactivated platelets (Bombeli et al. 1999). Platelets diminish apoptosis in another cellular component of tumor microenvironment, i.e., monocytes. In monocytes that phagocytose platelets, apoptosis is inhibited by induced downregulation of caspase-3 and caspase-9 and upregulation of heat shock protein 70 (Lang et al. 2002). Neutrophils, which play a role in cancer cell invasion and growth, engage in complex interactions with platelets. Polarized neutrophils reveal a protruding domain that serves a scanning device for activated platelets via selectin

ligand PSGL-1. This interaction causes receptor redistribution and exerts a proinflammatory action (Sreeramkumar et al. 2014).

Proliferation Stimulators Derived from Cells of the Tumor Microenvironment/ Stroma

As outlined in detail in the chapters referring to primary liver cancer, hepatic metastases, and tumor stroma, the microenvironment or stroma of liver malignancies contains a complex set of mesenchymal cells that provide a niche for tumor progression and spread but also directly influence tumor cell growth. The stromal cell types capable to promote proliferation of HCC cells include hepatic stellate cells/HSCs, myofibroblasts/ MFBs, cancer-associated fibroblasts/CAFs, and tumor-associated macrophages/TAMs. HSCs interact with HCC cells in a complex manner, in that HCC cells determine the fate and growth of HSCs, and HSCs exert an influence on HCC proliferation, utility, and invasion (Amann et al. 2009; Carloni et al. 2014). HSCs can indirectly promote HCC growth via secretion of VEGFs which induce tumor angiogenesis (Lin et al. 2015). The activation of proangiogenic genes in HSCs is in turn stimulated by HCC cells, illustrating the intricate mutual influence tumor cells and stromal cells exert on each other (Sancho-Bru et al. 2010). HCCs specifically modulate the generation and function of HSCs located to their microenvironment. HCC cells under hypoxic conditions secrete platelet-derived growth factor-BB which in turn activates HSC proliferation, migration, and expression of VEGFA (Lu et al. 2015). HCC cells can secrete angiogenin which activates stromal HSCs and through this pathway tumor progression (Barcena et al. 2015). MFBs possess multifactorial proteomes and secretomes that can modulate HCC cell behavior (Slany et al. 2013). MFBs are a major source for hepatocyte growth factor/HGF in HCCs (Neaud et al. 1999; Guirouilh et al. 2001). HCCs themselves stimulate secretion of HGF by MFBs via a posttranscriptional mechanism (Guirouilh et al. 2000). MFBs can also promote tumor cell growth via affecting the extracellular matrix scaffold and its associated proteins. Neuropilin-1 produced by MFBs provides communications between these cells and soluble fibronectin which in turn promotes integrin-dependent fibronectin fibril assembly and thus a growth-promoting matrix (Yaqoob et al. 2012). Similar to HSCs, HCC cells can regulate the production and differentiation of MFBs and therefore generate cells which in turn modulate the cancer cells that gave rise to their production. For example, HCCs can secrete lysophostatidic acid which promotes the differentiation of peritumoral fibroblasts into MFBs (Mazzocca et al. 2011). A third group of stromal spindle cells, CAFs, are capable to secrete HGF and hence stimulate HCC cell proliferation (Jia et al. 2013). CAFs also upregulate CCL2, CCL26, interleukin-6, and LOXL2 genes related to proliferation of HCC cells (Lin et al. 2012).

Cyclins: Key Switches for Cell Cycle Entry and Progression

Introduction

The entry into the progression through and the exit from cell cycle is a multistep process that its regulated by numerous factors, both in normal and neoplastic cells (reviews: Ford and Pardee 1999; John et al. 2001; Vermeulen et al. 2003; Murray 2004; Fung and Poon 2005). Cyclins regulate the cell division cycle in a cycle phase-specific manner and are key switches for G1/S entry and entry into mitosis. Their expression changes in a cyclical fashion along the cell cycle, hence their name. However, not all cyclins known today show this oscillating pattern. Cyclins that show phase-specific expression fluctuations activate cyclin-dependent kinases/CDKs by formation of specific cyclin-CDK complexes that are the drivers of cell cycle entry and progression through phosphorylation of numerous substrates. In addition to CDK-interacting cyclins, there are several orphan cyclins which have no known CDK partner. In order to activate CDKs in a tightly controlled fashion, cyclins are synthesized in a transcriptionally regulated manner and eliminated via proteasomal degradation at defined set points (Udvardy 1996). This cycle of synthesis and destruction forms the substrate of the master clock which determinates the orderly function of the cell division cycle, a process fundamentally deregulated in cancer cells (Johnson and Walker 1999; Stacey 2010; Bloom and Cross 2007).

Types and Functions of Cyclins

The numerous known cyclins are members of several families (families A to L, O, T, and Y). Several cyclin types consist of subtypes. The cyclins most important for cell cycle regulation form two main groups, summarized in Table 1.

G1/S cyclins rise in G1 and fall in early S phase. In the G1/S transition and in S, cyclin-CDK complexes start to induce DNA synthesis, the hallmark of S phase. In G2, M cyclin concentrations start to increase, and their complexing of CDKs is the mechanism for M entry (the G2/M transition).

Table 1 Major cyclins centrally involved in cell cycle regulation

G1/S cyclins (*control of G1 to S transition*)	
Cyclin A and the cyclin A-CDK2 complex	Active in S phase
Cyclin D and the cyclin D-CDK4 complex	G1/S transition
Cyclin D and the cyclin D-CDK6 complex	G1/S transition
Cyclin E and the cyclin E-CDK2 complex	G1/S transition
G2/M cyclins (*control of G2 to M transition*)	
Cyclin A and the cyclin A-CDK1 complex	G2/M transition
Cyclin B and the cyclin B-CDK1 complex	G2/M transition

Cyclin A

Cyclin A exists in two forms, cyclin A1 and cyclin A2, the genes being located on chromosomes 13q12.3–q13 and 4q27, respectively. Cyclin A can activate two different CDKs and functions in both S and M phases of cell cycle (Pines and Hunter 1992). It starts to accumulate during S, whereby its phase-specific synthesis is controlled at the transcription level involving several transcription factors, specifically E2F regulated by Rb protein, and is rapidly destroyed before metaphase via ubiquitination and proteasomal degradation. With its cyclin box, cyclin A interacts with a distinct domain of its two CDK partners, CDK1 (p34) and CDK2, termed PSTAIRE to form cyclin-CDK complexes. The cyclin A-CDK2 complex is required for passage into S, while the cyclin A-CDK1 complex is required for entry into M phase of the cell cycle. In the course of G1/S transition, newly synthesized cyclin A associates in the nucleus with CDK2, replacing cyclin E which was active before S as an initiator of the DNA pre-replication complex, rendering chromatin ready for DNA synthesis. At a distinct level, the novel cyclin A-CDK2 complex terminates the

assembly of the initiating cyclin E-CDK2 complex and then initiates DNA synthesis. During the cycle, cyclin A has a second important function. Via Cdc6, it ensures that DNA is replicated only one per cell cycle through inhibition of additional replication complex formation. In late G2, cyclin A associates with CDK1, a complex required for the activation of the cyclin B-CDK1 complex which is necessary for G2/M transition. Afterward, cyclins A and B are degraded and therefore switched off, until a new synthesis round will take place. Cyclins A and B possess a destruction box, and cyclins D and E have a PEST sequence, domains that are required for ubiquitin-mediated cyclin proteolysis in proteasomes at the end of the controlled cycle phase (Hershko 1999). The synthesis-degradation cycle found for cyclin A is exemplary for the timely expression of cyclins along the cell division cycle and illustrated as to how a cyclin switch can be put into on or off positions. In addition to its action on CDKs, cyclin A can promote microtubule detachment from kinetochores in prometaphase and is therefore directly involved in control of faithful chromosome segregation, protecting from microtubule-kinetochore binding errors.

Cyclin B

As outlined in the preceding paragraph, cyclin B is a mitotic cyclin involved, together with its partner CDK1, in the regulation of G2/M transition. Cyclin B exists in three forms (cyclins B1, B2, and B3), allocated to chromosomes 5q12, 15q21.3, and Xp11, respectively. The three B-type cyclins differ in their subcellular localization. Both B1 and B2 can associate with CDK1. Through tightly controlled synthesis, activity of the cyclin B-CDK1 complex (also termed mitosis-promoting factor, MPF) rises during the S phase of the cycle until M and is then abruptly degraded (Hershko 1999; Parry and O'Farrell 2001). In contrast to cyclins A and B, CDK1 is constitutively expressed all through the cycle (see below). The cyclin B-CDK1 complex activates its activating phosphatase, Cdc25, and inhibits its inhibiting kinase, Wee1. This process is associated with inhibiting of the phosphatase that counteracts the complex (Domingo-Sananes et al. 2011). The cyclin B1-CDK1 complex phosphorylates a microtubule-bundling protein, PRC1, which plays a critical role in the biogenesis of mitotic spindles and the spindle midzone. PRC1 phosphorylation by the cyclin 1 kinase complex is promoted by the mitotic kinase TOPK (Abe et al. 2007). There is recent evidence that cyclin B3 is a mitotic cyclin promoting metaphase-anaphase transition and being a late-destroyed cyclin subject to degradation by the APC/C-Cdc20 complex late in metaphase (Yuan and O'Farrell 2015). The cyclin B-CDK2 complex closely interacts with microtubule-associated serine-threonine kinase-like protein or MAST-L, the human orthologue of Greatwall kinase (Voets and Wolthuis 2010). This kinase promotes mitotic entry and maintenance of mitosis by inhibiting the protein phosphatase 2A/PP2A, a phosphatase which dephosphorylates cyclin B-CDK2 substrates (Burgess et al. 2010; Gharbi-Ayachi et al. 2010; Glover 2012; Lorca and Castro 2013; Wang et al. 2014a). MAST-L promotes cyclin B1 destruction by enforcing Cdc20-independent binding of cyclin B1 to the cyclosome (Voets and Wolthuis 2015).

Cyclin C

Cyclin C, encoded by the CCNC gene cyclin D1 (encoded by the gene CCDC on chromosome 6q16.2), is a cell cycle protein that regulates transition from G1 to S. Cyclin C interacts with CDK8, and this complex phosphorylates the C-terminal domain of the large subunit of RNA polymerase II, whereby this activity peaks in the G1 phase as a preparation for entry into S. The cyclin C-CDK8 complex is also present in some mammalian mediator-like protein complexes which repress activated transcription. Activated CDK8 phosphorylates cyclin H, repressing the ability of transcription initiation factor IIH to activate transcription.

Cyclin D

Cyclin D exists in three forms (cyclins D1, D2, and D3) and is a G1/S cyclin that is synthesized during G1 and promotes G1/S transition. The genes of the three D-type cyclins are localized on chromosomes 11q13, 12p13, and 6p21, respectively. Cyclins D are synthesized in response to growth factors and are regulated by downstream mitogen receptors through Ras/MAP kinase and Wnt/beta-catenin signaling. The MAP kinase ERK activates the transcription factors Myc and AP-1, causing transcription of the cyclin D, CDK4, and CDK6 genes to form complexes driving G1/S transition. Cyclin D can interact with four CDKs, i.e., CDK2, CDK4, CDK5, and CDK6. The cyclin D-CDK4/CDK6 complex that forms in late G1 phosphorylates and thus inhibits the Rb protein (see below), leading to induction of several proteins required for S phase, including cyclin E. Cyclin D1 has functions that are independent of CDK-mediated cell cycle progression. It regulates transcription factors, coactivators, and corepressors involved in chromatin remodeling. The expression of cyclin D and its complexes are also regulated by p21 and p27 (Kip1) proteins (see below). For their function, cyclin D1-cyclin-dependent kinase 2 complexes require the scaffold protein p21 for their assembly, activation, and substrate specificity (Jahn et al. 2013). Stabilized nuclear localization of cyclin D1 is mediated by c-Fos overexpression (Güller et al. 2008). After S, cyclin D-CDK complexes are rapidly inactivated by CDK-inhibiting proteins, above all INK4 family proteins (p14, p15, p16, and p18).

Cyclin E

Cyclin E is a G1/S transition cyclin that binds to CDK2. It exists in two forms, cyclin E1 and cyclin E2, the genes located to chromosomes 19q12 and 8q22.1, respectively. The cyclin E-CDK2 complex plays a central role in the regulation of G1 and the G1/S transition. The complex inhibits Rb protein through its phosphorylation and thus promotes progression through G1 via release of the transcription factor E2F from its binding to Rb. The cyclin E complex can also phosphorylate the cell cycle inhibiting TGF-beta pathway mediator Smad3, inhibiting its function and thus facilitating cell cycle progression. The cyclin E-CDK2 complex is involved in the centrosome cycle via phosphorylating nucleophosmin, which then detaches from unduplicated centrosomes and triggering centrosome duplication.

Cyclin F and Other Cyclins

There are several other cyclins that may affect cell cycle progression in an indirect way. Cyclin F (CCNF gene on chromosome 16p13.3) interacts with CP110, a protein that is essential for centrosome duplication. Cyclin F and CP110 associate on the centriole during G2, followed by CP110 proteolytic degradation after ubiquitination by the SCF/cyclin F ubiquitin ligase complex. Cyclin G, assigned to chromosome 5q34, is a cyclin that is induced by p53 upon DNA damage. It differs from other cyclins in that it lacks a protein-destabilizing/PEST sequence, but depends on its proteasome-mediated degradation on a cyclin box (Piscopo and Hinds 2008). Cyclin G is one of the earliest p53 target genes, and cyclin G-mediated p53 regulation is dependent upon ataxia-telangiectasia-mutated/ATM protein, which activates p53 in response to DNA damage (Ohtsuka et al. 2004). A partner of cyclin G is cyclin G-associated kinase/GAK, an enzyme that peaks in G1. Cyclin H (the CCNH gene assigned to 5q14.3) is a cyclin that is regulated by the cyclin C-CDK8 complex and interacts with the transcription factor IIH. Cyclin H forms a complex with CDK7 which stabilizes a protein that promotes epithelial-mesenchymal transition/EMT in cancer, C-terminal binding protein 2/CtBP2 (Wang et al. 2013). Cyclin I forms a complex with CDK5, this complex activating MEK/ERK pathways and resulting in increased Bcl-2 and Bcl-X(L) expression and enhanced survival of postmitotic cells (Brinkkoetter et al. 2009, 2010). The subcellular distribution and in particular the nuclear accumulation of CDK5, an

atypical CDK, are determined by cyclin I (Hagmann et al. 2015). Cyclin K (CCNK on chromosome 14q32.2) has a dual role in regulating the expression of CDKs and modulating RNA polymerase II activity.

Cyclin Deregulation in Liver Cancer

Cyclins play an important role in growth regulation of cells of the hepatocyte lineage, both normal and neoplastic. Cyclin deregulation is involved in atypical hepatocyte regeneration and hepatocarcinogenesis (Kitamura et al. 1998). In these pathogenic pathways, the various cyclins occupy distinct roles. In HCC, various patterns of cyclin deregulation have been detected, part of them exerting an influence on cancer growth and invasion (Masaki et al. 2003).

Cyclin A was upregulated in about half of HCCs (Zhou et al. 2003; Bahnassy et al. 2011). Cyclin D1 is subject to a common polymorphism (G870A) in exon 4 of the CCDN1 gene. This polymorphism may increase the risk of HCC (Hu et al. 2014). Cyclin D1 is upregulated in up to two thirds of HCCs (Bahnassy et al. 2011), but was downregulated in part of HCCs (Lu et al. 2013). HBx protein stabilizes cyclin D1 and increases its nuclear accumulation (Chen et al. 2015). Cyclin D1 upregulation is associated with increased levels of macrophage inhibitory factor/MIF in HCCs (Huang et al. 2014). Part of cyclin D1 expression depends on etiological factors, such as hepatitis virus infections. HBx protein promotes hepatic stem cell proliferation via upregulation of cyclin D1 mediated by MEK/ERK and PI3K/Akt signaling pathways (Wang et al. 2014b). In HCCs, cyclin D3 is significantly upregulated. This is associated with decreased expression of microRNA-138 which targets cyclin D3 (Huang et al. 2015). Stabilization of cyclin D1 in nuclei induces proliferation of hepatocytes (Güller et al. 2008). Cyclin D1 is a mediator of c-Met- and beta-catenin-induced hepatocarcinogenesis (Patil et al. 2009). Cyclin E facilitates dysplastic hepatocytes to bypass the G1/S checkpoint in the course of hepatocarcinogenesis (Pok et al. 2013). In established HCCs, cyclin E was overexpressed in up to about 50 %, and this expression pattern was correlated with differentiation, invasion, and metastasis (Zhou et al. 2003; Bahnassy et al. 2011). The pro-growth effect of cyclin E is associated with expression of HOXA7 (Li et al. 2015a). Cyclin F, capable to generate the Skp1-Cul1-F-box protein ubiquitin ligase complex, controls centrosome duplication and prevents genomic instability. Cyclin F oscillates in the course of the cell cycle with a pattern similar to that of cyclin A. In HCC, this cyclin is significantly decreased, downregulation being associated with growth, low differentiation, and tumor multiplicity (Fu et al. 2013). In most HCCs, cyclin G1 is downregulated in comparison with normal hepatic tissue (Cui et al. 2013). However, expression of cyclin G1 expands liver tumor-initiating cells by Sox induction through Akt/mTOR signaling (Wen et al. 2013). In HCC cells, cyclin G1 suppresses p53 activity by Notch3 (Giovannini et al. 2014). Cyclin G1 can mediate epithelial-mesenchymal transition/EMT through PI3K/Akt signaling, a process that affects tumor cell growth and invasion (Wen et al. 2012). In HCCs, expression of cyclin G1 is regulated by microRNA-122a which directly targets this cyclin (Gramantieri et al. 2007b; Fornari et al. 2009). Cyclin J (CCNJ) is downregulated in HCC through epigenetic promoter hypermethylation in the majority of cases, associated with enhanced growth and aggressive tumor biology (Takano et al. 2015).

Regulation of Cyclins in Liver Cancer by microRNAs

The function of cyclins in liver cancer is also regulated by microRNAs, which by this pathway exert an influence on cancer cell growth (see below). Downregulating to cyclin D3 (CCND3) by microRNA-503 inhibits the G1/S transition of cell cycle in HCC cells (Xiao et al. 2013). Cyclin D3 is also targeted by microRNA-138 which induces cell cycle arrest in HCC (Wang et al. 2012). MicroRNA-520 b targets cyclin D1

and via this effect inhibits growth of HCC cells. In clinical HCC tissues, microRNA-520b expression is markedly reduced (Zhang et al. 2012). CCNE1, an important mediator of G1/S transition and tumor suppressor, is targeted by microRNA-7 in HCCs (Zhang et al. 2014a).

Cyclin-Dependent Kinases

Introduction

Cyclin-dependent kinases (CDKs) are a family of protein kinases that interact with diverse cyclins and hold a central role in cell cycle regulation (reviews: Morgan 1997; Ekholm and Reed 2000; Vermeulen et al. 2003; Malumbres and Barbacid 2005; Suryadinata et al. 2010). CDKs phosphorylate substrates at serine and threonine residues and are therefore by definition serine-threonine kinases. For having full kinase activity, CDKs have to bind distinct cyclins.

Types of Cyclin-Dependent Kinases and Their Function as Cell Cycle Regulators

So far, more than ten CDKs have been identified, but only a fraction of them play crucial roles in cell cycle regulation (Table 2). It has been emphasized that certain CDKs can interact with more than one type of cyclin.

In contrast to cyclins, whose expression oscillates along the cell cycle in a characteristic manner, CDKs are constitutively expressed during the entire cell cycle, and their kinase activity pattern is determined by the phase-specific expression of their cyclin-binding partners. Apart from their activation through the binding cyclins, CDK activity is also regulated by phosphorylation on serine, threonine, or tyrosine residues produced by distinct CDK kinases. For example, CDK1 is activated through phosphorylation via the cyclin H-CDK7 complex/CAK. Most of these phosphorylations of CDKs augment their binding capacity for cyclins. CDKs are also activated by a distinct group of activators that interact with specific CDKs. For the CDK5 activator p35, LZAP is a binding protein that can act as a tumor suppressor in various neoplasms. Conversely, a group of proteins is active in inhibiting CDKs. The two main families of CDK inhibitor proteins are the INK4 family and the Cip/Kip family (see below). CDKs are also subject to inhibition by various other CDK inhibitors/CDKNs. CDKN1B affects the G1/S transition, while CDKN3 belongs to the protein phosphatase family. CDKs are dephosphorylated by CDK-associated protein phosphatase (KAP), a dual-specificity phosphatase that mainly dephosphorylates CDK2 and inhibits cell cycle progression (Hannon et al. 1994). KAP dephosphorylates CDK2 on threonine 160 in a cyclin-dependent manner.

Table 2 Major cyclin-dependent kinases (CDKs) and their binding cyclins

CDK	Cyclins	Activity in cell cycle phase
CDK4	Cyclins D1–D3	G1 and G1/S transition
CDK6	Cyclins D1–D3	G1 and G1/S transition
CDK2	Cyclin E	G1/S transition
CDK2	Cyclin A	S
CDK1	Cyclin A	G2/M transition
CDK1	Cyclin B	M

Deregulation of Cyclin-Dependent Kinases and Their Regulators in Liver Cancer

Similar to cyclins, several CDKs are subject to deregulation in liver cancers. Overexpression of CDK1 and CDK2 in cancer is generally associated with high aggressiveness and poor prognosis and is correlated with poor differentiation in HCCs (Shen et al. 2010). HCCs show enhanced expression of CDK4, mostly associated with downregulation of cyclin D1 (Lu et al. 2013). CDK4-/CDK6-dependent cell cycle progression in HCC cells is inhibited by p16 (INK4a) in an Rb protein-independent manner (Rivadeneira et al. 2010). Usually involved in the biology of neuronal cells, CDK5 also plays a role in cancer progression. Expression and activity of CDK5 were increased in HCC tissue and were associated with proliferative activity. In these cells, the enzyme is most

active in cells in G2/M phase of cycle. CDK5 regulates DNA damage response by phosphorylating ataxia-telangiectasia-mutated (ATM) kinase (Ehrlich et al. 2015). CDK10 is a Cdc2-related kinase that is important for the progression from G2 to M phases of the cell cycle. In HCCs, expression of CDK10 is markedly reduced in comparison with normal surrounding liver tissue, closely linked to tumor progression (Zhong et al. 2012). A Cdc2-related protein kinase is PFTK1, which is frequently upregulated in HCC. It interacts with cyclin Y to activate noncanonical Wnt signaling in HCC (Sun et al. 2014). Subsets of HCCs show upregulation of KAP, the CDK-associated protein phosphatase (Lin et al. 2013). The function of CDKs is inhibited by CDKN1/p57, implicated in various cancers. In HCC cells, expression of CDKN1 induces tumor cell senescence via the activity of the Notch target gene Hes1 (Giovannini et al. 2012).

A binding protein for the CDK5 activator p35, LZAP, is significantly decreased in HCC, associated with enhanced growth of the tumors (Zhao et al. 2011). Subsets of HCC exhibit aberrant transcripts of the CDK phosphatase KAP (Yeh et al. 2000). HCCs display downregulation of the CDK inhibitor CDKNB1 via direct targeting by microRNA-452, causing dramatically increased proliferation via induction of G1/S transition (Zheng et al. 2014). The CDK phosphatase-type inhibitor, CDKN3, is upregulated in HCC and promotes tumor cell proliferation by stimulating G1/S transition (Xing et al. 2012).

Retinoblastoma (Rb) Protein as an Inhibitor of Cell Cycle Pathways

Introduction

As outlined in the preceding paragraphs, entry into and progression through the cell division cycle is a tightly controlled process that is closely linked to cell production demands and which possesses several brakes to avoid cell production overshoots. A distinct array of proteins act as switches operating as "on" or "off" signals for cell cycling (Matsuda et al. 2013a). Phosphorylation is a common mechanism to maneuver the position of these switches.

Retinoblastoma Protein

Retinoblastoma protein (Rb, gene locus Rb1 on chromosome 13q14.2) is a tumor suppressor protein that is deregulated in numerous cancers. The main function of Rb is to prevent excessive cell proliferation by the inhibition of cell cycle progression until a cell is programmed to undergo division. At that time point, Rb is phosphorylated by a kinase to pRb, which is inactive and therefore releases cell cycle progression. For its function, active Rb binds to and inhibits a transcription factor of the E2F family, E2F1. In a complex with the dimerization partner DP, non-inhibited E2F1 releases a cell into S phase, while an inhibited complex keeps the cell waiting in G1. E2F1 and other E2F members are maximally expressed in late G1 and are present in association with E2F-regulated promoters during the G1/S transition. Rb protein is the switch that decides upon the activity of the E2F complex. The Rb switch in turn depends in its activity on cyclin-dependent kinases (see above) which phosphorylate it and thus cancel its action on E2F. Rb protein itself can interact with a host of proteins (review: Giacinti and Giordano 2006).

Deregulation of Rb Protein in Liver Cancers

Inactivation of Rb is a frequent event in HCCs and is an important mechanism for unlimited cell cycling in these neoplasms (Mayhew et al. 2007; Machida et al. 2009; Ahn et al. 2014). However, mutations of the Rb gene as a cause of Rb silencing is a relatively uncommon event in HCC. In contrast, Rb exhibits imprint abnormalities in a high proportion of primary HCCs, loss of imprinting being a major mechanism for Rb inactivation (Anwar et al. 2014). There is a significant correlation between loss of Rb and Rb gene methylation, emphasizing the significance of epigenetic mechanisms (Edamoto et al. 2003; Zhang

et al. 2014a). Loss of E2F inhibition in HCC due to Rb inactivation leads to activation of E2F target pathways. The E2F1 target, stathmin1, is frequently upregulated in HCCs with low AFP levels and promotes polyploidy and invasion in these cancers (Hsieh et al. 2010; Chen et al. 2013a). Ef2 promotes transcription of the Notch signaling pathway, which in turn serves as a negative feedback mechanism to slow down HCC growth (Viatour et al. 2011). HCCs with positive immunoreactivity for Rb protein showed a higher rate of intrahepatic metastasis (Naka et al. 1998). Apart from Rb, its target E2F also shows deregulation in various cancers, including HCC (Zhan et al. 2014).

Rb protein interacts with proteins that are deregulated in liver cancer. One group consists of retinoblastoma-binding proteins. The histone demethylase Rb-binding protein 2/RBP2 is overexpressed in HCC and negatively regulated by microRNA-212 (Liang et al. 2013). Rb is regulated by the expression of distinct microRNAs (Li et al. 2015b). MicroRNA-645, which is expressed in subsets of HCCs, downregulates Rb and by this effect enhances proliferative activity of tumor cells (Hernandez et al. 2013). Conversely, microRNA-26a/b activates pRb and in cooperation with cyclin E1 and CDK6 inhibits the G1/S transition (Zhu et al. 2012). In addition to its direct effects on cell cycle regulation, Rb protein affects other cell functions that may indirectly contribute to deregulated proliferation. For example, the Rb expression mode has striking effects on responses to genotoxic hepatocarcinogens (Reed et al. 2009, 2010, 2014). Rb potentiates the innate immune response in hepatocytes, while loss of Rb function in hepatocarcinogenesis alters the local innate immune status and favors tumor development (Hutcheson et al. 2014).

CDK Inhibitors and Their Deregulation in Liver Cancer

Introduction

The activity of CDKs is counteracted by a group of several CDK inhibitors which can either bind and inhibit CDKs directly or bind cyclin-CDK complexes. Two families of CDK inhibitors exist, the INK4 family and the Cip/Kip family (Table 3).

Table 3 Cyclin-dependent kinase inhibitors

INK4 family	*Members*	*Function*
	p15 (INK4b)	Inhibition of G1-associated CDKs
	p16 (INK4a)	(CDK4, CDK6)
	p18 (INK4c)	
	p19 (INK4d)	
Cip/Kip family		
	p21 (Cip1)	Inhibition of G1 cyclin-CDK
	p27 (Kip1)	Complexes and cyclin B-CDK1
	p57 (Kip2)	

p15 (INK4b, CDKN2B)

p15 (INK4b, CDK inhibitor 2B, CDKN2B, MTS2) is an INK4 family member CDK inhibitor that blocks the cell cycle at the G1/S transition via inhibition of CDK4 and CDK6 complexes. The gene is located to chromosome 9p21.3, where it lies adjacent to the p16 gene. p15 is frequently deregulated in various cancers, including HCC, via deletion of 9p (Liew et al. 1999; Shao et al. 2000). Downregulation of p15 causes promotion of growth, while ectopic expression of p15 is associated with inhibition of cell proliferation (Qin et al. 2004). Homozygous deletions of p15 exons were detected in part of HCCs, but are less frequent than those of p16 (Jin et al. 2000). In HCCs, p15 expression is also silenced by hypermethylation of its gene, found in up to 49 % of HCC cases (Roncalli et al. 2002; Pang et al. 2003; Yang et al. 2003; Qin et al. 2004; Fukai et al. 2005; Ko et al. 2008; Dong and Wang 2014; Zekri et al. 2014b; Zhang et al. 2014a). A p15 promoter hypermethylation status was associated with elevated serum AFP levels in HCC (Zhang et al. 2007). Expression of p15 in

HCCs is regulated by mitogen-activated protein kinase ERK5. Downregulation of ERK5 is associated with increased expression of p15 and p27 and leads to decreased cell proliferation, whereas enhanced ERK5 expression in HCC is associated with increased proliferation (Rovida et al. 2014). p15 induction is mediated by TGF-beta-induced complex of Smad2, Smad3, Smad4, and Sp1 (Feng et al. 2000). Downregulation of p15 by both genetic and epigenetic mechanisms was also found in cholangiocarcinomas (Chinnasri et al. 2009).

p16 (INK4a, CDKN2A, MTS1)

The 9p21.3 chromosomal INK4alpha/ARF locus encodes the proteins p14 (ARF) and p16 (INK4alpha), both functioning to mediate cell cycle arrest via the p53 and Rb protein pathways, respectively. p14 (ARF) shares exon 2 with p16 in a different reading frame. It is an upstream regulator of the Rb-CDK4 pathway and binds to MDM2 causing a stabilization of functional p53 (Horie et al. 2000). Part of HCCs showed inactivation of p14 (ARF) in up to 20 % of cases (Tannapfel et al. 2001; Peng et al. 2002). Inactivation of p14 (ARF) was frequently associated with the concomitant inactivation of p16 (INK4a), but inactivating hypermethylation of p14 occurred independently of that of p16 (Tannapfel et al. 2001). p14 (ARF) inactivation occurred more often in HCV-associated HCC. Inactivation is either caused by homozygous deletion (Peng et al. 2002) or epigenetic hypermethylation (Herath et al. 2002). Overexpression of p14 (ARF) may be a less common alteration in HCC than changes of other cycle regulators. It was mainly observed in poorly differentiated neoplasms in Japan (Ito et al. 2004). p16 protein is a G1-specific cell cycle inhibitor that prevents the association of cyclin-dependent kinase 4/CDK4 and CDK6 with cyclin D1. In HCCs, the p16/cyclin D1/Rb protein pathway is disrupted in the majority of cases, in up to 66 % of cases (Chaubert et al. 1997; Jin et al. 2000; Azechi et al. 2001; Tannapfel et al. 2001; Matsuda and Ichida 2006; Matsuda et al. 2008, 2013a; Dong and Wang 2014). Inactivation of p16 in HCC was found more often in advanced stage tumors (Hui et al. 1996). p16 downregulation is caused by allelic loss of chromosome 9 in subsets of HCC (Liew et al. 1999). Part of HCCs show aberrant p16 (INK4a) transcription caused by hypermethylated promoters, epigenetic silencing resulting in significant downregulation of p16 (Roncalli et al. 2002; Zhang et al. 2002; Qin et al. 2004; Fukai et al. 2005; Matsuda 2008; Shiraz et al. 2011; Zang et al. 2011; Matsuda et al. 2013a; Dong and Wang 2014; Mah and Lee 2014; Zekri et al. 2014a). Silencing of p16 in HCC via methylation was associated with poor prognosis in recurrent early-stage tumors (Ko et al. 2008). In patients with HBV-associated liver cirrhosis and HCC, there was a gradual transition from normal to cirrhotic to cancerous tissue with respect to p16 promoter hypermethylation, suggesting that this epigenetic change is an early event associated with hepatitis virus infection (Li et al. 2004; Wang et al. 2012; Zhang et al. 2014a). There is evidence that hepatitis C virus core protein can induce downregulation of p16 by promoter methylation (Park et al. 2011). p16 downregulation promotes cancer cell growth, while experimental activation of p16 inhibited proliferation of HCC cells (Huang et al. 2003). Loss of p16 protein in HCCs is closely related to the functional inactivation of p27 and contributes to p27 sequestration by cyclin D1-cyclin-dependent kinase 4 complexes (Matsuda et al. 2003). Inactivation is associated with overexpression of inhibitors of differentiation and DNA-binding-1/Id-1, which opposes Ets-mediated activation of p16 (Lee et al. 2003). On the other hand, Id-1 is downregulated by HGF through ERK-dependent and ERK-independent signaling pathways, resulting in increased expression of p16 (INK4a) in HCC cells (Ushio et al. 2009). These aberrant proteins regulate pRb phosphorylation by binding with cyclin-dependent kinase (CDK) 4 (Cho et al. 2003). Apart from its effects on tumor growth, p16 stimulates Cdc42 GTPase-dependent migration of HCC cells (Chen et al. 2013b). Deregulation of p16 also plays a

role in the induction of metastasis of HCC cells (Chen et al. 2007).

p16 (INK4a) is extensively expressed in a minority of bile duct cancers, but is present in most bile duct adenomas and ductular proliferations (Sasaki et al. 2014). p16 is downregulated in a significant fraction of cholangiocarcinomas (Tannapfel et al. 2000b; Ito et al. 2001a; Kang et al. 2002; Tannapfel et al. 2002; Karamitopoulou et al. 2008; Gonda et al. 2012; Ruys et al. 2014). In extrahepatic and intrahepatic cholangiocarcinomas, the p16 promoter was hypermethylated and epigenetically silenced in 50–76 % (Lee et al. 2002; Tannapfel et al. 2002; Yang et al. 2005; Chinnasri et al. 2009). In addition to epigenetic inactivation, a minority of cholangiocarcinomas exhibited recurrent homozygous deletions and mutations of the p16 (INK4a) locus (Tannapfel et al. 2002; Maehura et al. 2014). Functional promoter mutations of the p16 gene were detected in primary sclerosing cholangitis/PSC and PSC-associated cholangiocarcinoma (Ahrendt et al. 1999; Taniai et al. 2002; DeHaan et al. 2007). Loss of p16 is observable in intraepithelial neoplasia of bile ducts, whereby the decrease of expression becomes more prominent in a stepwise manner with increasing grade of BillN (Sasaki et al. 2008; Schlitter et al. 2014). Inactivation of p16 is a frequent event in intraductal papillary neoplasms, e.g., those arising in hepatolithiasis (Ishikawa et al. 2004). The expression of p16 in cholangiocarcinoma and precursor lesions is regulated in the catalytic subunit of the polycomb repressive complex 2, enhancer of zeste homologue 2/EZH2, a driving force for an accelerated cell cycle (Nakagawa et al. 2013). Another malignant hepatic neoplasm with abnormalities of the p16 pathway is angiosarcoma (Weihrauch et al. 2002).

p18 (INK4c, CDKN2C)

p18 (INK4c, CDKN2C) is encoded by a gene on chromosome 1p32.3 and is an inhibitor that strongly interacts with CDK6 and weakly with CDK4, but not with other CDKs. By inhibiting cyclin D-CDK4/CDK6 complexes, p18 blocks the cell cycle at the level of the G1/S transition. Immunohistochemically, a frequent loss of p18 was detected in HCCs, especially in poorly differentiated neoplasms. In p18-positive HCCs, p18 interacted with CDK4 rather than with CDK6 (Morishita et al. 2004). The pathogenesis of p18 decrease in HCC is not fully clarified. In contrast to other CDKNs, the p18 gene is not epigenetically methylated (Roncalli et al. 2002). The expression levels of p18 in HCCs are negatively regulated by lncRNA highly upregulated in liver cancer (HULC), which is dramatically upregulated in HCC and is inducible by hepatitis B virus X protein. High HULC levels are associated with decrease of p18 expression (Du et al. 2012). In collaboration with p53, p18 can suppress hepatocarcinogenesis in murine models (Damo et al. 2005).

p19 (INK4d, CDKN2D)

p19 (INK4d, CDKN2D) inhibits G1-associated cyclin-CDK complexes, in particular those which contain CDK4 and CDK6. The gene is located to chromosome 19p13.2. Overexpression of p19 rapidly induces arrest in G1 phase. This inhibitor shows frequent loss of expression in HCC, although the exact role of p19 in cell cycle regulation of these cancers is not well elucidated. Downregulation of p19 in HCC is associated with increased growth, poor differentiation, and aggressive biology (Morishita et al. 2011). p19 controls oncogenic function of STAT3 (signal transducer and activator of transcription 3) in HCC cells (Schneller et al. 2011). In addition to its effects on cell proliferation, p19 also modulates the invasive behavior of HCC cells. Experimental knockdown of p19 in HCC cell lines promotes cell invasion, while reintroduction of p19 restores the migratory capacity (Chen et al. 2008).

p21 (Cip1, CDKN1A)

The cyclin-dependent kinase (CDK) inhibitor p21 (Cip1, CDKN1A, wild-type p53-activated fragment1, Waf1) is assigned to chromosome 6p21.2

and plays an important role in response to DNA damage. Its overexpression results in cell cycle arrest. p21 is upregulated following ionizing radiation in a p53-dependent manner. It also inhibits the function of PCNA. p21 (Cip1) associates with cyclin D1, cyclin E, and CDK2 and is a very potent and tight-binding inhibitor of CDK. The inhibitor mediates p53 suppression on tumor cell growth. p21 expression is transcriptionally suppressed by histone deacetylase 2/HDAC2 through the Sp1-binding site enriched proximal region of the p21 promoter (Noh et al. 2011).

In the normal liver, tightly regulated p21 is required for sustained regeneration, while deregulated p21 provides a mechanism promoting liver cancer development (Goldenberg and Eferl 2014; Marhenke et al. 2014). p21 has been implicated as tumor suppressor and is deregulated in most HCC cases by immunohistochemical assessment (Zhang et al. 2009), in part associated with epigenetic p21 variants (Liu et al. 2013). Also precursor lesions of HCC, specifically small cell dysplasia, display downregulation of p21 (Park 2014). p21 gene polymorphisms individually or in combination with p27 polymorphisms increase the risk for HCC (Liu et al. 2013). In contrast to p53, p21 may serve as an early-event molecular carcinogen in HCC (Abdou et al. 2016; Ehedego et al. 2015). Targeted activation of p21 expression is a potent mechanism for inhibiting HCC cell growth (Kosaka et al. 2012). In HCCs, expression of p21 was correlated with a high PCNA LI and favorable risk, but not with p53 expression (Kao et al. 2007), while HCCs with p21 downregulation had advanced stage disease (Naka et al. 1998). MicroRNA-423 promotes cell growth in HCCs and regulates the G1/S transition by targeting p21 (Lin et al. 2011). MicroRNA-105 and microRNA-218, which are suppressed in HCCs, target the PI3K/Akt signaling pathway resulting in upregulation of p21 (Shen et al. 2014; Xiao et al. 2014). In subsets of HCC, p21 is upregulated, mainly in poorly differentiated tumor, but rather in late stages of tumor progression (Park et al. 2003).

The deregulated function of p21 in liver cancer is connected with a complex network of factors affecting cell proliferation. In HCCs, downregulation of p21 is induced by Notch3 signaling (Giovannini et al. 2013). In these neoplasms, overexpression of upregulator of cell proliferation (URGCP/URG4) increases cellular entry into G1/S transition associated with downregulation of p21 (Xie et al. 2012). Overexpression of URGCP/URG4 in the presence of the HBV X protein may function as a hepatocarcinogenic oncogene (Dodurga et al. 2012). The redistribution of p21 activity in HCCs is promoted by hepatocyte growth factor through ERK-dependent p16 upregulation, leading to cell cycle arrest at G1 (Han et al. 2005). Upregulation of p21 (Cip1) in hepatoma cells mediated by ERK-dependent and ERK-independent signaling affects HGF-induced inhibition of cell proliferation (Shirako et al. 2008).

Bile duct cancers and gallbladder cancers also show deregulation of p21 expression (Ito et al. 2000, 2001; Kim et al. 2009). In cholangiocarcinoma, absence of p21 expression predicted poor outcome, also in patients with no lymph node metastases and partly in patients with biologically less aggressive phenotypes (Kim et al. 2009). In cholangiocarcinomas, p21 is a downstream target of ligands of peroxisome proliferator-activated receptor gamma (PPARgamma), which by this pathway suppresses cancer cell growth (Han et al. 2003).

p27 (Kip1, CDKN1B)

Cyclin-dependent kinase inhibitor p27 (Kip1, CDKN1B) is a CDK inhibitor that plays a key role in controlling cell cycle by negatively regulating the progression through the G1 phase of the cycle and entry into S phase, causing G1 arrest. p27 blocks the kinase activities of CDK2-cyclin A and CDK2-cyclin E complexes (Borrellio et al. 2011; Wander et al. 2011). The protein is frequently expressed in cell differentiation, but is often downregulated in cancer cells. The expression of p27 (Kip1) is regulated by the far upstream element (FUSE), FUSE binding protein1 (FBP1; Matsushita et al. 2013), which activates translation of p27 (Kip1) mRNA via its internal ribosomal entry site (Zheng and Miskimins 2011).

Cytoplasmic mislocalization of p27 (Kip1), contributing to epithelial tumorigenesis, is induced by constitutive overactivation of the Ras signaling pathway, via oncogenic N-Ras-mediated activation of the Ral-GEF pathway (Tazat et al. 2013). p27 (Kip1) induces the accumulation of the repressor complexes of E2F, inhibits expression of the E2F-regulated genes, and inhibits expression of cyclin A and cyclin E (Shiyanov et al. 1997). p27 is degraded to permit cycle progression, degradation being mediated by ubiquitin-dependent targeting of p27 by SCF-Skp2, the F-box protein of the Skp1-Cullin-F-box protein (SCF) E3 ubiquitin ligase complex (Binné et al. 2007). Skp2 itself is involved in liver tumor development in cooperation with N-Ras and Akt (Delogu et al. 2015). Skp2-mediated degradation of p27 regulates the progression of cycling cells into mitosis via downregulation of CDK2 activity (Nakayama et al. 2004; Pagano 2004). The expression levels of Skp2 are regulated by Notch1 signaling that induces Skp2 transcription (Sarmento et al. 2005) and by the phosphorylation of the ezrin-radixin-moesin-binding phosphoprotein 50/EBP50 by Akt (Song et al. 2015). p27 is also regulated by Skp2-mediated ubiquitination induced by the cell cycle regulator Cks1 (S-phase kinase-associated protein 2), which is also involved in hepatocarcinogenesis (Lee et al. 2011; Qi et al. 2015). Cks1 itself is suppressed by the dual-specificity phosphatase 1/DUSP1 (Calvisi et al. 2008; Hao et al. 2015). Ubiquitination of p27 by the Skp-Cul1-F-box complex is regulated by the kinesin family member, KIP14, which is upregulated in HCCs (Xu et al. 2014), and by EGF, which upregulates Skp2/Cks1 (Kim et al. 2014). In addition, there exists an early phase, Skp2-independent ubiquitination pathway for p27 degradation (Hara et al. 2001; Kotoshiba et al. 2014).

p27 (Kip1) expression in HCCs is complex, variable, and linked to tumor stage. It was significantly decreased in part of HCCs, but was expressed in others, sometimes at high levels (Hui et al. 1998; Tannapfel et al. 2000a; Qin and Ng 2001; Armengol et al. 2003; Matsuda et al. 2003, 2013b; McAllister et al. 2003; Claudio et al. 2004; Lei et al. 2005; Shehata et al. 2006; Matsuda 2008; He et al. 2011). In HCCs, p27 expression is related to hepatocarcinogenic pathways (Bassullu et al. 2012) and predicts recurrence (Ito et al. 1999) and was inversely correlated with the expression of c-Jun activation domain-binding protein1/JAB1, associated with a shift of p27 and JAB1 from cytoplasm to nucleus (Chen et al. 2010; Qin et al. 2010; Yachida et al. 2010). In early stages of hepatocarcinogenesis, p27 may be overexpressed (Yachida et al. 2008), but p27 underexpression was also frequent in early stages of HCC and is an independent predictor of recurrence in these lesions (Armengol et al. 2003). Downregulation of p27 in HCCs is linked to expression of microRNA-221 (Fornari et al. 2008), whereby microRNA-221 expression is correlated with higher stage and aggressive biology (Fu et al. 2011). In HCCs with high p27 expression, this mode was associated with epigenetic downregulation of p16 and poor prognosis (Matsuda et al. 2003). In HCCs expressing p27 (Kip1), the proliferation index was significantly lower than in those lacking p27 (Kip1) expression (Jing et al. 2005). Hepatocyte growth factor/HGF induces the redistribution of p21 (Cip11) and p27 (Kip1) in HCC via upregulation of ERK-dependent p16 (INK4a), causing cell arrest at G1 (Han et al. 2005). In some HCCs, p27 gene mutations were found and suggested to affect HCC cancer risk (Chen et al. 2000; Liu et al. 2013). Downregulation of p27 by microRNA-222 overexpression in HCC promotes cancer cell proliferation (Yang et al. 2014a). Kinesin family member 14/KIF14 is involved as an oncogene in HCC. Silencing of KIF14 interferes with cell cycle progression by blocking p27 (Kip1) ubiquitination pathway in HCC cells (Xu et al. 2014). In HCCs, p27 (Kip1) also promotes migration and invasive capacity of tumor cells (Wang et al. 2008). Nuclear expression of Skp2, a mediator of ubiquitination-associated degradation of p27, promotes cycling in HCC and predicts poor prognosis (Shin et al. 2012; Zhang et al. 2012). In HCC cells, degradation of p27 is mediated by the ubiquitin ligase Pirh2, which is overexpressed in these neoplasms (Hattori et al. 2007; Huang

et al. 2011) and via this mechanism promotes tumor cell growth by overcoming the G1 arrest. Pirh2 overexpression is not specific for HCCs, but was also observed in other cancers (Shimada et al. 2009).

Downregulation of p27 also plays a role in aberrant cell cycle progression in cholangiocarcinomas. In these neoplasms, low or absent p27 expression predicts an aggressive biology and poor survival (Fiorentino et al. 2001; Taguchi et al. 2001; Hashimoto et al. 2009; Ruys et al. 2014). In cholangiocarcinomas, p27 expression decreased progressively from proximal to distal in the biliary tree and correlated with location-related differences in outcome (Jarnagin et al. 2006). Downregulation of p27 in cholangiocarcinoma is induced by activation and increased expression of the ubiquitination mediator, Skp2 (see above; Luo et al. 2015). On the other hand, TGF-beta can exert an antitumor effect in cancers via upregulation of p27 (Lee et al. 2013).

p57 (Kip2, CDKN1C)

p57 (Kip2) or CDK inhibitor 1C (CDKN1C, KIP2) is a member of the KIP (kinase inhibitory protein) family of CDKNs and a potential tumor suppressor gene. It is encoded by an imprinted gene located at chromosome 11p15.4, whereby the paternally inherited allele is transcriptionally repressed and methylated. It negatively regulates the cell cycle by inhibiting G1 cyclin-CDK complexes and the cyclin B-CDK1 complex, but it also modulates certain functions of the cytoskeleton (review: Pateras et al. 2009). p57 is the only CDKN that is induced by TGF-beta, a mechanism which is important for the termination phase of liver regeneration (see above). p57 is targeted by microRNA-221 whose overexpression accelerates hepatocyte proliferation in liver regeneration, and p57 (Kip2) is downregulated by Akt in the setting of HER2/Neu oncogenic pathways (Zhao et al. 2013b).

p57 expression is deregulated in various cancers, including liver cancer. Immunohistochemistry and molecular studies documented a frequent loss of p57 (Kip2) expression in HCCs (Guo et al. 2011; Hu et al. 2013a), particularly in moderately and poorly differentiated neoplasms, associated with higher PCNA labeling and poor survival (Ito et al. 2001b; Nan et al. 2005; Hu et al. 2013). HCCs with positivity for p57 (Kip2) and a low PCNA LI had a significantly better prognosis (Nakai et al. 2002). The mechanisms of p57 downregulation in HCCs are only partially known. Gene deletions or point mutations in the p57 gene are no frequent events in HCC (Bonilla et al. 1998). Downregulation of Notch1 and Notch3 in HCC cell lines resulted in a decrease of the Notch target gene Hes1, which in turn transcriptionally represses p57 (Giovannini et al. 2012). In human HCCs, p57 expression is negatively controlled by microRNA-221, which directly targets CDKN1C and is upregulated in the majority of HCCs, this increase favoring a growth phenotype (Fonari et al. 2008).

In extrahepatic cholangiocarcinoma and intrahepatic cholangiocarcinoma, p57 expression is downregulated in comparison with normal cholangiocytes, and a decreased p57 labeling index is related to increased proliferative activity and tumor progression (Ito et al. 2002).

Mitotic Cell Cycle Progression

Introduction: Anaphase-Promoting Complex (Cyclosome), Spindle Assembly Checkpoint, and Associated Protein Networks

In the control of segregation of sister chromatids during mitosis, the multiprotein anaphase-promoting complex (APC/C) or cyclosome has a central place. In association with its activating protein, Cdc20, APC/C is critically involved in the destruction of securin, leading to the activation of separase, a protease that cleaves the kleisin subunit of the cohesin complex, to abolish cohesion between sister chromatids (reviews: Sczaniecka and Hardwick 2008; Meadows and Millar 2015). Overall, exit from mitosis and the separation of sister chromatids require inactivation of cyclin B1-CDK1 kinase activity, APC/C, and inhibition of the anaphase inhibitor Pds1.

Orderly progression through M and exit from M are tightly regulated by APC/C, a large multiprotein cullin-RING E3 ubiquitin ligase having two activating subunits, Cdc20 (cell division cycle 20) and Cdh1 (reviews: Barford 2011; Chang and Barford 2014; Chang et al. 2014). Cdc20 activates APC/C from the onset of M through the metaphase-anaphase transition, whereas Cdh1 activates the cyclosome from anaphase through G1. Cdh1 also activates APC/C to inhibit the anaphase inhibitor securin. The APC/C complex recognizes its substrates by the aid of Cdc20, which can interact with a recognition motif in cyclins, BubR1, Bub1, and Acm1 (Di Fiore et al. 2015). Exit from mitosis involves accumulation of cyclin kinase inhibitors as well as cyclin proteolysis mediated by APC/C, both processes depending on CDK14 phosphatase, whose release from the nucleolus during anaphase leads to dephosphorylation and activation of an APC/C-activating subunit. The active CDK14 phosphatase hold a central position in reversing the activity of mitosis-associated cyclins and in exit from mitosis (review: Queralt and Uhlmann 2008). Release of CDK14 phosphatase depends on APC/C bound to Cdc20 that mediates proteolysis of Pds1 and the S-phase cyclin 5 (Shirayama et al. 1999; Irniger 2002). The APC/C-Cdc20 complex has a crucial role in cyclin destruction at the end of mitosis (Sudakin et al. 1995; Irniger 2002) and is subject to regulation by Rb protein. Excess transcription factor E2F1 due to Rb protein inactivation recruits Cdc20 and the APC/C-Cdc20 complex (Nath et al. 2015). An inhibitor of APC/cyclosome, early mitotic inhibitor-1 (Emi1), is an important cell cycle regulator that promotes S-phase and M-phase entry. In order to prevent premature degradation/inhibition of securin, the nuclear transport factors Nup98 and Rae1 associate with APC/C(Cdh1)-securin complexes. Nup98 and Rae1 escape from these complexes in late metaphase, as soon as all kinetochores are attached to spindle microtubules, leading to prompt ubiquitination of securin by APC/C (review: Baker et al. 2007).

Genomic stability and premature chromosome segregation are ensured by the function of the spindle assembly checkpoint (SAC). The SAC prevents the APC/C from recognizing cyclin B and securin by promoting the incorporation of Cdc20 into a complex termed mitotic checkpoint complex (Izawa and Pines 2015). During mitosis, the activity of the cyclosome is inhibited by products of the BUB and MAD genes, which form the mitotic checkpoint which is a fail-safe unit to ensure accurate chromosome segregation during mitosis, avoiding that unaligned chromosomes prematurely enter anaphase. The mitotic checkpoint complex consists of BubR1, Bub3, Mad2, and Cdc20 (Lara-Gonzalez et al. 2011) and is a complex that is subject to a "wait anaphase" signal provided by unattached kinetochores. It is assumed that a single unattached kinetochore can amplify the "wait anaphase" signal through a kinase cascade consisting of hBubR1, hBub1, and Mps1. The components of the mitotic checkpoint interact with the APC/C complex through a Cdc20-binding box in the BubR1 protein, providing a means to form BubR1-Ccd20 interactions to control APC/C activity (Diaz-Martinez et al. 2015). The APC/C complex also directly affects the mitotic checkpoints, in that one APC/C subunit, APC15, releases mitotic checkpoints and makes it responsive to kinetochore attachment (Mansfeld et al. 2011).

Control of mitosis progression is affected by NIMA-related kinases, of which the Nek (never in mitosis gene A-related kinases) family of cell cycle kinases plays a significant role. Specifically, Nek2, Nek6, Nek7, and Nek9 regulate mitotic events and associated processes, including centriole functions related to microtubule organization and cilia formation (O'Regan et al. 2007), whereas Nek1, Nek10, and Nek11 are implicated in DNA damage response (Fry et al. 2012). Nek6 and Nek7 kinases are required for mitotic spindle biogenesis, whereby both Neks localize to spindle poles, while only Nek6 also localizes to spindle microtubules in metaphase and anaphase and to the midbody during cytokinesis (O'Regan and Fry 2009). In the spindle generation process, the Nek7-associated protein Nek7-interactor RGS2 localizes to the spindle in a Nek7-dependent manner and contributes to spindle morphology and mitotic spindle pole integrity (de Souza et al. 2015). The activation of Nek6 and Nek7

depends on a kinase cascade mediated by the NIMA kinase system, Nercc1/Nek9 activated in mitosis (Belham et al. 2003).

Deregulated Cyclosome and Nek Functions in Liver Cancer

The APC/C interacting protein, Cdc20, is upregulated in HCC tissues in more than two thirds of cases. This increased expression is associated with increased Ki-67 labeling and TNM stage (Li et al. 2014a). The APC/C complex is inhibited by early mitotic inhibitor-1 (Emi1). Emi1 is highly expressed in HCCs, expression being correlated with stage and poor outcome. Emi1 expression in HCC goes in parallel with upregulation of the Emi1 substrates, cyclins A and B, and Skp2, while p27 (Kip1) is downregulated (Zhao et al. 2013a). Nek6 required for mitotic cell cycle progression is overexpressed in clinical HCC samples and HCC cell lines, and ectopic overexpression of Nek6 promotes cell proliferation. This Nek regulates the transcription of cyclin B via Cdc2 activation, inducing the accumulation of G0/G1 cells (Zhang et al. 2014b).

Complex Signaling Pathways Linking Cancer Growth with Other Features of Neoplastic Cells

Wnt/Beta-Catenin Signaling

Introduction

The Wingless/Wnt signaling pathway holds a central position in ontogenesis and oncogenesis. It works through a multiprotein-signaling cascade and activates several targets, in particular factors of the TCF/LEF HMG domain family. Activation of Wnt signaling results in cytoplasmic accumulation of beta-catenin (Armadillo in *Drosophila*), followed by nuclear translocation and interaction with TCFs to generate a transcriptional complex. In the absence of Wnt signaling, the negative regulator GSK3beta (glycogen synthase kinase 3) is activated, causing proteasomal degradation of cytoplasmic beta-catenin and lack of nuclear beta-catenin. In deficiency of nuclear beta-catenin, TCFs mediate target gene enhancement by the corepressor Groucho (review: Barker et al. 2000). Beta-catenin exerts a regulating influence on the growth of normal and neoplastic cells. However, as Wnt/beta-catenin signaling affects, apart from growth control, several other functions that are important for cancer cell biology, including cell differentiation, cell motility and adhesion, apoptosis, and invasion, this signaling pathway is briefly discussed separately.

Wnt/Beta-Catenin Signaling in Normal Liver Growth

Beta-catenin is critically involved in physiological liver growth (Monga 2014). In the normal liver, beta-catenin overexpression induced in mice provides a growth advantage during liver regeneration (Nejak-Bowen et al. 2010), and inhibition of beta-catenin in hepatoma cells inhibits growth and promotes apoptosis (Liyan et al. 2011), underlining the role of Wnt/beta-catenin in hepatocyte growth regulation. Factors involved in hepatocyte growth regulation, i.e., TGF-alpha and cyclin D1, are direct targets of beta-catenin signaling (Torre et al. 2011).

Wnt/Beta-Catenin Signaling in Liver Cancer

Oncogenic activation of the complex beta-catenin/Wnt signaling pathway is a frequent event in HCC, and activating mutations of beta-catenin markedly affect tumor growth regulation (Lee et al. 2006, 2014; Ding et al. 2014; Li et al. 2014b; Lu et al. 2014; Vilarinho et al. 2014; Wands and Kim 2014; review: Buendia 2002). Beta-catenin mutations that stabilize beta-catenin were found in 13–31 % of HCC (Edamoto et al. 2003) and promote hepatocyte proliferation and inhibit TNFalpha-induced apoptosis (Shang et al. 2004). HCC- and hepatoblastoma-associated beta-catenin mutations often involved the degradation box of the beta-catenin gene, resulting in failure of

proteasomal degradation of cytoplasmic beta-catenin and persistent nuclear expression, where the protein is detectable by immunohistochemistry. In HCC cells, Wnt/beta-catenin signaling regulates the cell cycle via expression of cyclin A and cyclin E (Wang et al. 2009b). SUMO-specific protease 2/SENP2, which plays an important role in the control of HCC cell growth, modulates the stability of beta-catenin in these tumors by SUMOylation (Shen et al. 2012). The stability of beta-catenin is also promoted by its interaction with SOX10, a tumor promoter that is upregulated in HCCs (Zhou et al. 2014). The Wnt/beta-catenin signaling pathway can also affect growth of HCCs via its regulation of angiogenic factor expression (Qu et al. 2014). In HCCs, a distinct pathway involved in the modification of beta-catenin degradation depends on the ubiquitin-like protein FAT10 (Yuan et al. 2014). A factor that counteracts Wnt/beta-catenin signaling in HCC is SOX17, an antagonist of canonical Wnt signaling which is downregulated in HCC (Yang et al. 2014b). In normal hepatocytes and HCC cells, secreted frizzled-related proteins/SFRPs function as negative regulators of Wnt signaling. In HCC, hypermethylation of SFRP1, SFRP2, and SFRP5 is frequent, causing SFRP downregulation in these neoplasms and inhibition of SFRP-mediated suppression of proliferation (Shih et al. 2007). One of the co-receptors of the Wnt/beta-catenin pathway is low-density lipoprotein receptor-related protein-6/LRP6, which forms a signaling complex with Wnt ligand and frizzled receptor to activate downstream signaling. Upregulation of LRP6 promotes hepatocarcinogenesis via hyperactivation of Wnt/beta signaling (Tung et al. 2012). For its activity, LRP6 requires caveolar endocytosis modulated by Wnt3a and Dickkopf1/Dkk1 (Yamamoto et al. 2008) and by the Rab GTPase RAB8B (Demir et al. 2013).

Notch Signaling in Liver Cancer

Notch receptor signaling is a highly conserved mechanism that plays a role in cell fating and control of cell growth. Mammals have four different Notch receptors, termed Notch1, Notch2, Notch3, and Notch4. Notch receptors are activated by contact with cells that bear Notch ligands at their surface. Notch ligands are transmembrane proteins that are members of the Delta/Serrate/LAG-2 (DSL) family. In mammals and humans, the ligands are known as Delta-like and Jagged/Jag. Notch signaling, counteracted by Numb signaling, plays an important role in several functions and diseases of the liver (Morel et al. 2013). During hepatic ontogenesis, Notch signaling is critically involved in the morphogenesis of the ductal plate and tubulogenesis (Strazzabosco and Fabris 2012; Geisler and Strazzabosco 2014).

Notch is involved in carcinogenic pathways and progression of numerous malignancies. Activated Notch signaling in mice livers induces the formation of HCC-like tumors (Villanueva et al. 2012). However, the effects of Notch expression vary considerably as a function of the cell system studied, having oncogenic or tumor-suppressive functions. In hepatocytes and HCC cells, Notch signaling is activated by the ligand Jag-1 which is upregulated by the transcriptional regulator YAP/Yes-associated protein (Tschaharganeh et al. 2013). Notch modulates the fate and behavior of hepatic progenitor cells (Bogaerts et al. 2014), and its expression pattern in cultured HCC cell lines is modulated by HBV X protein, in that HBx upregulated the expression of Notch1, Jagged-1, and Hes1 at the transcriptional level by binding to the Notch1 intracellular domain (Wang et al. 2012) . It was shown that Notch1 overexpression acting on various cell cycle regulators inhibited proliferation of HCC cells by inducing G0/G1 cell cycle arrest (Qi et al. 2003). On the other hand, there is evidence for a prooncogenic function of Notch in HCC. In comparison with cirrhotic tissue, HCCs can show aberrant nuclear expression of Notch1 and Notch3 (Gao et al. 2008; Giovannini et al. 2009; Wang et al. 2009a). Notch1 activation increased the proliferative activity in human HCC cell lines (Gao et al. 2012), while Notch1 signaling inhibited growth in another human HCC cell system through induction of cell cycle (G0/G1) arrest and apoptosis (Qi et al. 2003). In HCC cells,

cytoplasmic expression of Notch1, cytoplasmic expression of Notch3, coexistent nuclear expression of Notch3, and cytoplasmic Notch4 overexpression were observed, whereby Notch1 and Notch4 expression were markers for poor prognosis (Ahn et al. 2013). Expression of Notch3 decreased the invasive capacity of HCC by regulating MMP expression in one study (Zhou et al. 2013). On the other hand, an aberrant expression of Notch3 was associated with bigger tumor size, tumor multiplicity, and metastatic spread and predicts poor survival for HCCs (Hu et al. 2013b). In HCCs, Notch3 is a regulator of cell self-renewal by interacting with the beta-catenin signaling pathway (Zhang et al. 2015). Notch4 was downregulated in 80 % of HCC, but in Notch4-positive HCCs, this receptor was frequently expressed in endothelial cells (Gramantieri et al. 2007a). Notch signaling is the pathway by which the RUNX3 transcription factor suppresses HCC. RUNX3 directly interacts with the intracellular Notch1 domain and thus suppresses Notch signaling (Gao et al. 2010). Numb overexpression itself in HCC promotes cell proliferation (Wu et al. 2014).

Hippo Signaling Pathway in Liver Cancer

Hippo denotes a distinct kinase involved in a complex signaling pathway. The Hippo pathway consists of a core kinase cascade in which Hippo or MST1/MST2 in mammals phosphorylates the protein kinase Warts/LATS1/LATS2 to become active. LATS1 and LATS2 are nuclear DBF-2-related kinases that phosphorylate and inactivate Yes-associated protein/YAP (Yorkie in *Drosophila*), a transcriptional coactivator binding to TEAD-type transcription factors in its active, unphosphorylated form to activate expression of targets promoting cell proliferation and preventing apoptosis. Hippo signaling is critically involved in the control of organ size by regulating cell proliferation versus apoptotic rates. The Hippo-WW45/adaptor for Hippo kinase pathway controls liver size by controlling liver cell fate and restraining hepatic oval cell proliferation (Lee et al. 2010; Yimlamai et al. 2014). This signaling pathway also plays a role in the development of cancer, including HCC (reviews: Liu et al. 2012; Jie et al. 2013).

Carcinogenesis, including hepatocarcinogenesis, is modulated by two important downstream effectors of the Hippo kinase pathway, i.e., Yes-associated protein/YAP and PDZ-binding motif/TAZ. Increased expression of YAP was observed in HCC cells, with marked nuclear YAP immunoreactivity being present in most tissues. This expression pattern was associated with prominent induction of glypican-3, connective tissue growth factor/CTGF, and survivin, three YAP target genes, and downregulated expression of LATS kinase, the main upstream regulator of YAP (Li et al. 2012). Via YAP, the Hippo pathway is linked to Notch signaling, as YAP upregulated the Jagged-1 ligand and activates Notch (Tschaharganeh et al. 2013). A direct target of YAP and TAZ is the epidermal growth factor family member, amphiregulin. YAP, TAZ, and amphiregulin were expressed in the majority of HCCs, YAP expression being a prognostic factor (Han et al. 2014).

Hedgehog Signaling Pathways in Liver Cancer

The Hedgehog signaling pathway plays a central role in development (segment polarity), adult stem cell biology, and regulation of growth homeostasis in the adult organism. In *Drosophila*, Hedgehog is the ligand and an intracellular signaling molecule, while mammals possess three Hedgehog homologues termed DHH, IHH, and SHH/sonic Hedgehog, of which SHH is most intensively studied homologue. The SHH ligand, which is produced by cleavage from a precursor and has a cholesterol moiety at the carboxyl end serving as a trafficking and secretion signal, binds on target cells to the Patched-1 receptor/PTCH1, a molecule homologous to the Niemann-Pick disease protein NPC1. In the absence of SHH ligand binding, PTCH1 inhibits a downstream effector termed Smoothened/SMO via removing oxysterols from SMO

through a sterol sensor/sterol pump contained in PTCH1. Full complementation of SMO with sterols allows it to remain within cell membranes. All three mammalian Hedgehog homologues also bind to a second receptor, PTCH2. The effectors of this signaling pathway are the Gli proteins (glioma-associated oncogene homologue), DNA-binding zinc finger domain proteins. Gli transcription factors (Gli1, Gli2, and Gli3) inhibit transcription of SHH targets via binding to Gli-responsive genes. Transcriptional control by Gli proteins is in part tissue specific, with certain Gli proteins preferentially expressed in distinct tissues. Gli1 plays an important role in DNA folding in chromosomes via recruitment of histone deacetylase complexes. An important negative regulator of SHH signaling is the Rab family GTPase, Rab23, which is involved in the regulation of certain development steps during ontogenesis.

The SHH signaling cascade promotes cell proliferation, specifically the growth of progenitor cells located to various tissues, and is involved in hepatic homeostasis (Omenetti et al. 2011) and hepatitis C virus replication (Choi et al. 2011). SHH also regulates viability and turnover of hepatic stellate cells, in part modulated by glypican-3 (Magistri et al. 2014). The pathway is deregulated in several cancers, including liver cancer (review: Zheng et al. 2013). As SHH drives the growth and development of endodermal progenitors to become liver cells, a regression of neoplastic liver cells to immature precursor-like cells may anticipate deranged SHH signaling. HCC cell lineages in culture express Hedgehog signaling components and show overexpression of SMO, which may act as an oncogene and drive hepatocarcinogenesis (Sicklick et al. 2006). Activation of the Hedgehog signaling pathway is a frequent event in HCC, whereby expression of SHH, PTCH1, and Gli1 was observed at high rates (2006). HCC overexpressing components of the Hedgehog signaling pathway show increased proliferation and invasiveness (Cheng et al. 2009). In HCC cells, Gli1 activation and Gli1 nuclear localization are stimulated by the HBV X protein (HBx) (Kim et al. 2011). The negative SHH regulator Rab23 is overexpressed in subsets of HCC and HCC cell lines (Sun et al. 2012).

Regulation of Cell Proliferation in Liver Cancer by MicroRNAs/OncomiRs

Introduction

MicroRNAs (miRs) form a large class of noncoding RNAs that typically consist of only about 22 nucleotides. They act as endogenous suppressors of gene expression through binding to the 3′-untranslated region of target mRNAs. This suppression results in mRNA degradation and hence translation repression. As microRNAs affect numerous mRNAs involved in cell proliferation, differentiation, apoptosis, and invasion, they play significant roles in cancer pathogenesis. Among the more than 1,000 species of microRNAs, an increasing number are altered in their expression in liver cancers (Callegari et al. 2013; Gailhouste et al. 2013; Khare et al. 2013; Xiong et al. 2013; Hung et al. 2014; Saito et al. 2014). They can affect both proliferation and suppression of proliferation in liver cancers (Table 1). In their pro-proliferative and antiproliferative actions, microRNAs employ a wide array of factors, the expression of which they regulate. There is increasing evidence that, similar to signal substances and growth factors, microRNAs can be transported from their sources to tumor cells via microvesicles/exosomes, a system forming an intricate signaling platform within tumors that may be amenable to future treatment strategies.

MicroRNAs as Promoters of Cell Proliferation in Liver Cancer

MicroRNA-21 is an oncomiR that promotes HCC proliferation by targeting several factors, including PTEN, PDCD4, and RECK. Hepatitis B virus X protein induces cell proliferation through microRNA-21 targeting programmed cell death protein 4/PDCD4 and PTEN (Damania et al. 2014). Proliferation and invasion of HCC cells are promoted by microRNA-24, which is upregulated in HCC and targets the sex-determining region Y (SRY)-box 7/Sox7, a putative tumor suppressor (Ma et al. 2014). Human cholangiocarcinoma shows increased levels of microRNA-26a, associated with elevated proliferative activity via targeting glycogen synthase kinase-3beta and subsequent (Zhanget al. 2012). In intrahepatic cholangiocarcinoma, microRNA-31 was significantly upregulated, associated with increased proliferation due to suppression of RASA1 signaling (Hu et al. 2013). MicroRNA-93 promotes proliferation in HCC and activates the c-Met/PI3K/Akt signaling pathway by targeting PTEN and CDKN1A (Ohta et al. 2015). Both microRNA-96 and microRNA-182 promote cell proliferation in HCC and are upregulated in this tumor. The microRNAs act through targeting ephrin 5A, which is a tumor suppressor in HCC (Wang et al. 2015). MicroRNA-199a-3p, underexpressed in HCC, promotes cell proliferation via targeting caveolin-2 (Shatseva et al. 2011). MicroRNA-222 overexpression augments cell proliferation in HCC via downregulation of the cycle inhibitor p27 at a posttranslational level (Yang et al. 2014a). In human HCC, microRNA-221 promotes cell proliferation by targeting CDKN1B/p27 and CDKN1C/p57 (Fornari et al. 2008). MicroRNA-224 functions as a proliferation-stimulating oncomiR in HCC cells by activating Akt signaling (Ma et al. 2012). MicroRNA-331-3p is one of the most markedly overexpressed microRNAs in HCC, highly associated with metastases. It promotes proliferation of HCC by targeting PHLPP PH domain and leucine-rich repeat protein phosphatase, an enzyme which dephosphorylates Akt (Chang et al. 2014). Expression of microRNA-362-3p in HCC results in enhanced proliferation via direct targeting of Tob2, a member of the Tob family of antiproliferative, cell cycle-regulating proteins that interact with the CCR4-NOT transcription complex (Shen et al. 2015). Through downregulation of pre-mRNA processing factor 4 homolog B/PRPF4B, microRNA-371-5p facilitates G1/S transition in HCC cells (Liu et al. 2013b). Expression of microRNA-421 in cholangiocarcinoma promotes proliferation and acts as an oncomiR via downregulation of FXR/farnesyl X receptor (Zhong et al. 2012). Certain HCC showed overexpression of microRNA-452, associated with dramatic enhancement of cell proliferation via induction of G1-S transition. This MiR directly targets cyclin-dependent kinase inhibitor 1B/CDKN1B (Zheng et al. 2014). Expression of microRNA-675 in HCC tissue confers cell cycle activation and a proliferation phenotype linked to downregulation of Rb and Twist1 (Hernandez et al. 2013). HCCs show overexpression of microRNA-1269, which promotes cell proliferation through directly suppressing FOXO1 associated with deregulation of p21, cyclin D1, phosphorylated Rb, and Ki-67 expression (Yang et al. 2014b).

MicroRNAs as Suppressors of Cell Proliferation in Liver Cancer

Through targeting of endothelin-1, microRNA-1 inhibits proliferation of HCC cells (Li et al. 2012). Overexpression of microRNA-7 in HCC cells induces G1/S arrest via targeting cullin 5/CUL5 (Ma et al. 2013). The same MiR also targets CCNE1, a tumor suppressor which blocks the G1/S transition (Zhang et al. 2014a). Tumor-specific expression of microRNA-26a suppresses HCC cell growth via modulation of estrogen receptor signaling (Chen et al. 2011). Expression of microRNA-29a in HCC cells suppresses cell proliferation via inhibition of Akt/mTOR

phosphorylation downstream of SPARC (Zhu et al. 2012). Cell cycle arrest at G1 in HCC is induced by microRNA-99a via a mechanism involving cyclin D1 (Li et al. 2011). Hepatitis B virus can downregulate microRNA-101-3p. This leads to blunting of the antiproliferative effect of this microRNA via targeting the Rab5a pathway (Sheng et al. 2014). MicroRNA-122 suppresses cell proliferation and induces apoptosis by targeting beta-catenin. It is, however, downregulated in most HCCs (Xu et al. 2012). MicroRNA-124 is downregulated. It suppresses cell proliferation by targeting phosphoinositide-3-kinase catalytic subunit alpha/PIK3CA (Lang and Ling 2012). By targeting Sox2 (sex-determining region Y-box 2), microRNA-126 inhibits cell proliferation and induces apoptosis in HCC cells (Zhao et al. 2015). Suppression of HCC cell growth by microRNA-127 is caused by a G2/M block mediated by downregulation of Sept7, a septin protein involved in cytokinesis and microtubule turnover (Zhou et al. 2014b). FoxD3-regulated microRNA-137 suppresses growth and metastasis in HCC by targeting Akt2 (Liu et al. 2014a). MicroRNA-138 is downregulated in cholangiocarcinoma, associated with enhanced proliferation and invasion via upregulation of the RhoC/p-ERK/MMP-2/MMP-9 pathway (Wang et al. 2013a). In HCCs, microRNA-138 was downregulated in 77.8 % of cases, and this miR induces cell cycle arrest by targeting cyclin D3 (Wang et al. 2012c). Tumor growth and metastasis of HCC is suppressed by microRNA-140-5p via its targeting of transforming growth factor-beta receptor 1 and fibroblast growth factor 9 (Yang et al. 2013). Proliferation and metastasis of HCC is suppressed by microRNA-144 by targeting the E2F transcription factor 3, whereby this inhibitory microRNA is markedly reduced in HCC (Cao et al. 2014). In HCC, the levels of microRNA-145 are markedly decreased, inversely associated with abundance of insulin receptor substrate 1/IRS1, a key mediator of insulin-like growth factor/IGF signaling. IRS1 is a direct target of miR-145, which inhibits HCC cell proliferation via compromising downstream Akt/FOXO1 signaling (Wang et al. 2014). MicroRNA-145 also inhibits cell proliferation in HCC by directly targeting ADAM17 (a disintegrin and metalloproteinase 17) (Liu et al. 2014b). In human HCCs, microRNA-148b is significantly downregulated. This alteration is associated with increased growth, because microRNA-148b suppresses HCC cell proliferation by targeting the Wnt/beta-catenin pathway (Zhang et al. 2015). HCC shows a downregulation of microRNA-152, an miR that suppresses cell growth and inhibits invasion via targeting of Wnt-1, DNMT1, ERK1/ERK2, Akt, and TFRS6B (Dang et al. 2014). MicroRNA-185 decreases cell proliferation in HCC cells via targeting of the DNMT1/PTEN/Akt signaling pathway, but is downregulated in HCC (Qadir et al. 2014). MicroRNA-193b is downregulated in most HCCs, while its expression suppresses proliferation by inducing cell cycle arrest through regulation of CCND1 and ETS1 (Xu et al. 2010a). Targeting multiple cell cycle regulators is the mechanism of suppressed proliferation in HCC by microRNA-195 (Furuta et al. 2013). Suppression of several mitogenic factors is the effect exerted by microRNA-198 in HCC cells (Elfimova et al. 2013). In HCCs, low expression levels of microRNA-199a are associated with malignant potential and poor prognosis. This MiR regulates cell proliferation by targeting the frizzled type 7 receptor/FZD7 (Song et al. 2014). MicroRNA-202 suppresses HCC cell proliferation through downregulation of low-density lipoprotein receptor-related protein 6/LRP6 (Zhang et al. 2014b). Targeting of survivin is the mechanism by which microRNA-203 inhibits proliferation of HCC cells (Wei et al. 2013a). MicroRNA-206 is downregulated in HCC and suppresses cell proliferation by an unknown mechanism (Yunqiao et al. 2014). Through suppression of beta-catenin signaling via targeting of the beta-catenin mRNA, microRNA-214 inhibits cell growth in HCC (Wang et al. 2012a). A block in the G1/S transition is induced in HCC cells by microRNA-219-5p which decreases the expression levels of glypican-3 (Huang et al. 2012). Targeting of EGFR is the mechanism whereby microRNA-302b suppresses cell proliferation in human HCC cells (Wang et al. 2013b). MicroRNA-302c can inhibit growth of HCC by

suppressing endothelial-mesenchymal transition of endothelial cells (Zhu et al. 2014). MicroRNA-342-3p is a suppressor of HCC cell proliferation via its suppressive action of the NF-kappaB pathway (Zhao and Zhang 2015). MicroRNA-376a targets PIK3R1 (p85alpha) and via this pathway suppresses proliferation (Zheng et al. 2012). MicroRNA-363 suppresses the proliferation of HCC cells via downregulation of S1PR1/sphingosine-1-phosphate receptor 1 (Zhou et al. 2014a). MicroRNA-424 is downregulated in HVV and suppresses cell proliferation and migration by targeting of c-Myb (Yu et al. 2014). MicroRNA-429 directly targets Notch1 and via this mechanism represses cell proliferation and induces apoptosis (Gao and Liu 2014). The expression of microRNA-451 is markedly suppressed in HCC cells, what promotes proliferation, because miR-451 is a suppressor of proliferation via downregulation of cyclin D1 and c-Myc through inhibition of NF-kappaB pathway initiated by direct targeting of the IKBKB 3′-untranslated region (Li et al. 2013). MicroRNA-494 is a major modulator of cell cycle progression from G2 to M phases. In cholangiocarcinoma cells, it induces cycle arrest at the G2/M transition via targeting pituitary tumor-transforming gene1 and topoisomerase IIalpha (Yamanaka et al. 2012). This microRNA is downregulated in cholangiocarcinoma (Olaru et al. 2011). MicroRNA-503 is often downregulated in HCC. It suppresses the proliferative activity of HCC cells by G1-phase arrest, mediated by downregulation of cyclin D3 and suppression of the Rb/E2F signaling pathway (Xiao et al. 2013). Proliferation of HCC cells is suppressed via expression of microRNA-506 through targeting YAP/Yes-associated protein mRNA 3′UTR (Wang et al. 2014). MicroRNA-511 inhibits growth and metastasis of human HCC by targeting phosphoinositide-3-kinase regulatory subunit 3/PIK3R3 (Cao et al. 2015). MicroRNA-517a and microRNA-517c inhibit cell proliferation by blocking G2/M transition via targeting Pyk2, a focal adhesion kinase-related protein tyrosine kinase (Liu et al. 2013a). Targeting MEKK2 (mitogen-activated protein kinase kinase kinase 2) and cyclin D1 and a decrease of Rb protein phosphorylation are the mechanisms by which microRNA-520b inhibits growth of HCC cells (Zhang et al. 2012a). Human HCCs show a downregulation of microRNA-610, associated with enhanced cell proliferation. This MiR decreases Wnt/beta-catenin signaling through suppression of lipoprotein receptor-related protein 6/LRP6 and transducin beta-like protein1/TBL1X (Zeng et al. 2014). MicroRNA-612 has inhibitory effects on cell proliferation, migration, invasion, and metastasis of HCC and suppresses the stemness of liver cancer through Wnt/beta-catenin signaling (Tang et al. 2014). MicroRNA-744 is often downregulated in HCC tissues, whereby this MiR acts as a tumor suppressor by targeting c-Myc (Lin et al. 2014a).

Effects of Hepatitis B- and Hepatitis C Virus-Associated Proteins on Growth and Proliferation of Liver Cancers

Hepatitis B Virus

Hepatitis B virus (HBV) plays a major role in hepatocarcinogenic pathways worldwide (Rivière et al. 2014). The genome of HBV encodes several proteins that can affect cell cycle regulation in normal hepatocytes, regenerating liver cells, and liver cancer cells.

A central role the regulation of HCC cell proliferation is played by the HBV X protein (HB X protein; reviews: Madden and Slagle 2001; Gearhart and Bouchard 2010; Kew 2011; Gong et al. 2013; Lin et al. 2014b). HB X protein directly stimulates cell proliferation by promoting the reinitiation of DNA replication by regulating the expression of the replication licensing factor CDC6 (Pandey and Kumar 2012). Ectopic expression of HB X protein in HCC cells stabilizes cyclin D1, mainly in S phase, and increases cyclin D1 nuclear accumulation via ERK-mediated inactivation of GSK-3beta (Chen et al. 2015a). HB X protein can upregulate the expression of Notch1, jagged-1, and Hes-1 in HCC, leading to enhanced proliferation (Wang et al. 2012b). One mechanism in this pathway is characterized by HB X protein-induced reduction of Notch1 cleavage (Xu et al. 2010b).

In HCC cells, HB X protein interacts with and activates the endoplasmic reticulum stress-associated protein, cAMP-responsive, element-binding protein H/CREBH, resulting in expression of AP-1 target genes and cell proliferation (Cho et al. 2015). HB X protein regulates the expression of a cell contact protein, LIM and SH3 protein1/LASP-1, a focal adhesion protein, which is overexpressed in HCC and mediates cell proliferation (Tang et al. 2012).

HBV and its proteins are associated with complex patterns of microRNA expression in HCCs (review: Xie et al. 2014). Several pathways modulating microRNA expression in HBV-associated HCCs are mediated by HB X protein (Wang et al. 2010). HB X protein-induced upregulation of microRNA-221 results in proliferation of HBV-related HCC cells by targeting estrogen receptor-alpha, which functions as a tumor promoter (Chen et al. 2015b). The protein downregulates the expression of microRNA-16, abolishing the proliferation-suppressing function of this microRNA in HCC cells (Wu et al. 2011). On the other hand, Hb X enhances the expression of a microRNA that increases proliferation in HCC, microRNA-148a (Yuan et al. 2012). HB X protein is capable to modulate growth of HCC cells by affecting apoptosis. It induces microRNA-21 in these cells, followed by targeting programmed cell death protein 4/PDCD4 (Damania et al. 2014). HB X protein downregulates microRNA-338, a microRNA which inhibits cell proliferation by targeting cyclin D1 (Fu et al. 2012). It also downregulates microRNA-216b in HCC, associated with increased growth and invasion (Liu et al. 2015). MicroRNA-132 hypermethylation in HBV-associated HCCs is promoted by HB X protein, leading to downregulation of this microRNA (Wei et al. 2013b). Downregulation of microRNA-15b by HB X protein enhances HCC cell proliferation through fucosyltransferase 2-induced Globo H expression, Globo H being a cancer-associated carbohydrate antigen highly expressed in various cancers (Wu et al. 2014). MicroRNA-101 is downregulated by HB X protein and induces aberrant DNA methylation by targeting DNA methyltransferase (Wei et al. 2013c). HB X protein can also affect liver tumor cell growth by modulating the function of stromal cells. It activates hepatic stellate cells through upregulation of TGF-beta1, associated with pro-growth effects of these cells (Chen et al. 2014). HBV can affect cell proliferation by mechanisms other than HB X protein. HBV core promoter mutations can promote cell proliferation through upregulation transcription of S-phase kinase-associated protein 2 by activating the transcription factor E2F1 (Huang et al. 2013).

Hepatitis C Virus

Hepatitis C virus (HCV) is a major risk for the development of HCC. It possesses a complex intraviral protein interaction network that can affects numerous functions in host cells of the virus (Hagen et al. 2014). Several pathways to promote cell proliferation are mediated by HCV core protein. The protein downregulates the CDK inhibitor p16 and via this mechanisms overcomes stress-induced premature senescence (Lim et al. 2012). It can promote HCC cell proliferation through enhancement of TGF-alpha expression (Sato et al. 2006), activate the MAPK/ERK signaling cascade in a EGF- and TGF-alpha-independent manner (Hayashi et al. 2000), downregulate the cell cycle inhibitor p21 (Shiu et al. 2013), enhance canonical Wnt/beta-catenin signaling to promote cell growth (Liu et al. 2011), and promote heparin-binding EGF-like growth factor expression and Akt activation (Nakamura et al. 2011). HCV core protein induces TGF-beta-dependent epithelial-mesenchymal transition/EMT and by itself activates latent TGF-beta via thrombospondin to drive interactions between hepatocytes and stroma (Benzoubir et al. 2013). It also epigenetically silences the Wnt antagonist secreted frizzled-related protein/SFRP1 via promoter methylation and enhances growth and invasion of HCC by induction of EMT (Quan et al. 2014).

Similar to HBV-associated proteins, HCV core protein can modulate microRNAs regulating cell proliferation. HCV core protein downregulates microRNA-152, leading to

upregulation of Wnt1 associated with enhanced cell proliferation of cultured HCC cells (Huang et al. 2014). On the other hand, the protein upregulates microRNA-155 to activate Wnt signaling (Zhang et al. 2012b).

Morphogenetic Fields, Liver Regeneration, and Cancer Growth

Growth, differentiation, and the generation of distinct tissue patterns are regulated by morphogenetic fields during ontogenesis, to a large part driven by the effects of homeotic genes which are also active in cancers. Morphogenetic fields denote complex patterns that determine the behavior of cells in a nonlocal manner and which represent molecular super-platforms that determine molecular pathways and networks in larger areas of tissues (the "fields"). Morphogenetic fields have been viewed as large-scale systems of physical properties that store and transmit patterning information for ordered growth and shape generation in embryogenesis, regeneration, and morphostasis/aging, but probably also cancer (Levin 2012). Such patterning systems may operate through transcriptional, epigenetic, and molecular networks determined by a "master patterner" and/or may work via endogenous bioelectrical signals (Seo 2012; Adams and Levin 2013; Levin 2013, 2014). Deregulated bioelectric gradients as a cause of massively altered geometric features of cancer tissues have been proposed as a major factor for carcinogenesis (Chernet and Levin 2013).

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_176

Abstract

Proliferative growth of cancers, including hepatocellular carcinoma (HCC) and other liver cancers, is counteracted by cell loss induced by various mechanisms of cell death. An intricate process to control cell mass in normal and neoplastic tissues is apoptosis, a complex form of tightly controlled cell death, and its numerous variants. Loss of tumor substance can also occur through necrosis which, in contrast to previous views, is a complex and controlled process rather than a passive phenomenon. In HCC, apoptosis is present as spherical eosinophilic bodies devoid of nuclei, the so-called apoptotic bodies, associated with drop-out of involved cells. The apoptotic response in HCC can be quantitatively assessed by immunohistochemical and molecular methods. Apoptosis in HCC not only involves the cancer cells, but also several classes of stromal cells, including cancer-associated fibroblasts and myofibroblasts, and stromal leukocytes. Death of these cells markedly affects the structure and function of the tumoral microenvironment.

Introduction

Proliferative expansion of cancers, including hepatocellular carcinoma and cholangiocarcinoma, is counteracted by discrete or sometimes massive cell loss mediated by several mechanisms. Loss of tumor substance can occur through necrosis, e.g., due to poor blood supply, a process that had previously been regarded as a "passive" phenomenon throughout, but is now known to be a controlled process in at least part of the situations. An intricate mechanism to control cell mass in normal tissues, and particular during morphogenesis and ontogenesis, is apoptosis in its diverse manifestations. In addition to normal tissues, apoptosis is an important pathway in the restriction of growth of malignant neoplasms and is therefore a promising field for the design of future anticancer therapies.

Classification of Cell Death

The Nomenclature Committee on Cell Death (NCCD) proposed unified criteria for the definition of cell death and of its various morphologies. The 2009 recommendations of the NCCD have been published (Kroemer et al. 2009) and are summarized in Table 1. Historically, the forms of cell death occurring in normal and cancer cells have been allocated to three types of death. Type I cell death corresponds to apoptotic cell death, type II cell death describes autophagic cell death, and type III cell death is defined as a form of non-lysosomal vesiculate degradation. Since, several other forms of apoptotic and non-apoptotic forms of cell death have been described, leading to a complex situation that requires reassessment of definitions and classifications. In many of the now recognized forms of cell death, the underlying molecular mechanisms have been elucidated, resulting in molecular definitions of cell death subroutines formulated by the NCCD (Galluzzi et al. 2012).

Morphology and Biology of Apoptosis in Liver Cancers

Hepatocellular Carcinoma

In hepatocellular carcinoma (HCC), apoptotic tumor cells present as spherical eosinophilic bodies with a dense cytoplasm. These apoptotic bodies or apoptotic corpses are no longer connected

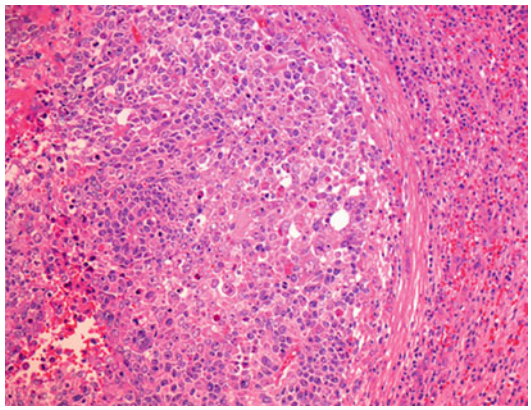

Fig. 1 Nodule of poorly differentiated hepatocellular carcinoma with apoptosis. Mainly in central parts, tumor cell drop-out with formation of apoptotic bodies is observed (hematoxylin and eosin stain)

with neighboring neoplastic cells, but seem to freely float in the tissual background (so-called drop-out or drop-out necrosis, a misnomer; Fig. 1). Apoptotic bodies occurring in well-differentiated HCCs having large and eosinophilic cells closely resemble apoptotic hepatocytes found in viral hepatitis, the Councilman bodies (Councilman-Rocha Lima bodies or "red bodies") originally described in yellow fever hepatitis (Councilman 1890; Rocha Lima 1912). Part of apoptotic bodies may contain small basophilic speckles, remnants of fragmented nuclei, or DNA. In bile-storing HCCs, apoptotic bodies sometimes stain yellow due to accumulation of intracellular bile. Apoptotic bodies are a rather rare finding in HCCs. In one study, apoptotic bodies were found in HCCs with a frequency of 4.2 (average; range 0–15) per 500 tumor cells (Paiva et al. 2002).

Apoptosis of HCC may be associated with a local immune response characterized by dense infiltrates of lymphocytes and plasma cells (medullary-like HCC; Zimmermann et al. 2002). In this situation, dying tumor cells and apoptotic bodies/corpses are surrounded by lymphoid cells and plasma cells that are sometimes in direct contact with the cancer cells. At the periphery of the inflamed area, lymph follicles with germinal centers can develop. In this area, also numerous S100 protein-reactive stellate cells accumulate, suggesting the presence of antigen-presenting cells. In HCCs with a marked apoptosis and immune reaction, parts of the neoplasm can undergo so-called spontaneous regression, as discussed in a separate chapter. In advanced tumor regression, clusters of apoptotic and atrophic HCC cells remain in a stroma densely populated by immune cells. In some cases, remnant cancer cells are only visualized by use of immunohistochemistry.

The apoptotic response of HCC cells can be assessed by use of immunohistochemical and molecular methods. HCC cells undergoing apoptosis expressed FasL, but not Fas (Zimmermann et al. 2002), while other studies found elevated expression of both Fas and FasL (Kubo et al. 1998; Roskams et al. 2000; Fukuzawa et al. 2001; Lee et al. 2001; Hammam et al. 2012; Fingas et al. 2013). Fas/FasL expression was decreased in proportion to the malignancy grade of HCCs (Ito et al. 1998, 2000a; Fukuzawa et al. 2001). In one investigation, FasL expression was only found in moderately or poorly differentiated HCCs (Ito et al. 2000a), and FasL expression was associated with worse prognosis after hepatectomy (Lee et al. 2004). Fas and FasL expression in HCC was significantly lower than in normal liver tissue (Kubo et al. 1998), and Fas is present in the cytoplasm of HCC cells rather than on the membrane (Higaki et al. 1996). Fas/FasL expression in HCC was enhanced in tumor margins (Fukuzawa et al. 2001). FasL expression in HCC cells was induced by HBV X protein (Shin et al. 1999). It was proposed that HCC cells expressing FasL may evade immune surveillance by inducing apoptosis in infiltrating T cells that express Fas. A strong expression of Fas and FasL was observed in hepatocytes surrounding HCCs, suggesting that normal liver cells have the ability to induce apoptosis in an autocrine or paracrine manner (Roskams et al. 2000). HCCs and HCC cell lines can express TRAIL/TNF-related apoptosis-inducing ligand receptor (Okano et al. 2003; Shiraki et al. 2005; Fingas et al. 2013). A fraction of HCCs express FADD

and TRADD proteins, whereby FADD expression was lower in HCC than in adjacent liver tissue and increased as a function of decreasing tumor differentiation. In contrast, expression of TRADD paralleled that of differentiation (Sun et al. 2000). The protein Bid, a mitochondrial membrane death ligand that oligomerizes Bak to release cytochrome c, showed a deceased expression in HCC cells, deficient Bid expression tendering cells resistant to apoptosis induced by Fas (Chen et al. 2001). In contrast to normal cholangiocytes, only very few HCC cells were positive for the anti-apoptotic protein, Bcl-2 (Terada and Nakanuma 1996). HCCs undergoing apoptosis express caspase-3 (Karamitopoulou et al. 2007). Sixty-eight percent of HCCs showed immunoreactivity for the executioner caspase-3, expression being correlated with elevated serum AFP levels (Persad et al. 2004). However, in subsets of HCC, caspase-3 is downregulated compared to non-tumor cells (Fujikawa et al. 2000). In contrast to normal hepatocytes, caspase-8 showed a strong nuclear staining of HCC cells, and low cytoplasmic and high nuclear staining intensity of caspase-8 correlated with impaired survival after hepatectomy (Koschny et al. 2013).

HCC apoptosis was analyzed by in situ DNA end labeling (TUNEL method). With this approach, the apoptotic rate was higher in HCCs showing a hepatocyte-like lineage and neuroendocrine features (Zhao and Zimmermann 1997b). HCC apoptosis can be assessed by nick end labeling (Terada and Nakanuma 1996). dUTP-biotin nick end labeling revealed end labeling indices of 0.35, 0.81, and 26.7 in well-, moderately, and poorly differentiated HCCs, respectively, suggesting an increased tumor cell turnover in high-grade lesions (Hino et al. 1996).

Cholangiocarcinoma

As in HCCs, malignant tumor progression in cholangiocarcinomas is related to failure to activate apoptosis (review: Celli and Que 1998). In comparison with HCC, morphologically

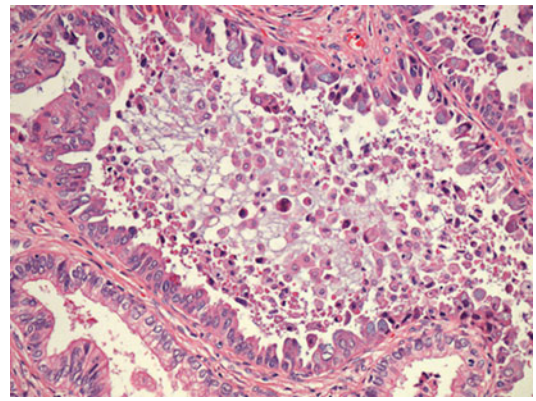

Fig. 2 In this cholangiocarcinoma, numerous neoplastic cells have been shed from the cell lining (drop-out), followed by accumulation of apoptotic cells within the tubule lumen (hematoxylin and eosin stain)

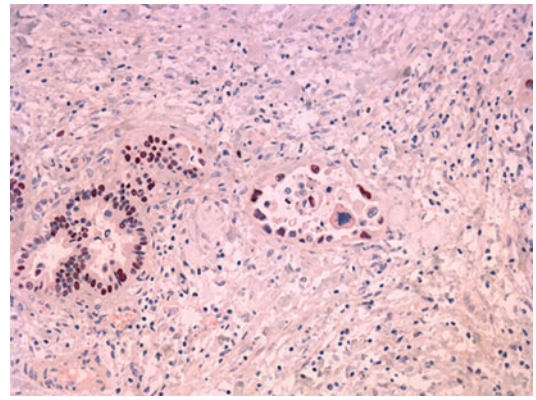

Fig. 3 Tumor cells in a proliferative cycle can suffer from drop-out and apoptosis. In this cholangiocarcinoma stained for proliferative activity, a cell in mitosis has been released from the cell lining of a tubule, is now an isolated element within the lumen, and will undergo apoptosis or anoikis (hematoxylin and eosin stain)

detectable apoptosis is less readily seen in part of cholangiocarcinomas, due to the high stromal content of these neoplasms. Apoptotic bodies are mostly found in mass-forming lesions having less stroma, and in tumors with an intraductal growth pattern (Figs. 2, 3, and 4). In solid growths, apoptotic bodies are predominantly found in central parts of the cancer strands. In intraductal cholangiocarcinomas, apoptotic cells may detach from tumor and float in the lumen, sometimes admixed with bile, mucus, or inflammatory exudate.

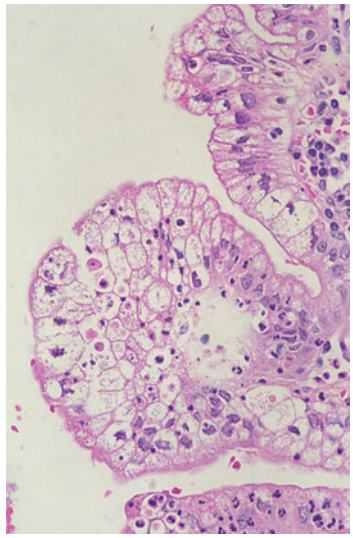

Fig. 4 Well-differentiated papillary cholangiocarcinoma. Apoptotic tumor cells are observed within the epithelial lining in the form of eosinophilic bodies that sometimes contain pycnotic nuclei or nucleus/chromatin remnants (hematoxylin and eosin stain)

Cholangiocarcinoma cells express several pro-and anti-apoptotic factors that can be assessed by immunohistochemistry to identify apoptotic cells. Cholangiocarcinomas express both Fas and FasL, whereby Fas expression decreased as a function of poor differentiation, while FasL was more often expressed in tumors with moderate or poor differentiation (Ito et al. 2000b). The percentage of Fas-expressing cells was higher in extrahepatic cholangiocarcinomas compared with intrahepatic tumors (Jhala et al. 2005). In intrahepatic cholangiocarcinomas, FasL was upregulated in early stages, whereas Fas was downregulated at progressed stages (Shimonishi et al. 2000). Hilar cholangiocarcinoma expresses FasL, associated with high levels of cell death among tumor-infiltrating lymphocytes (Li and Zou 2001). Pro-apoptotic TRAIL receptor was present in all cholangiocarcinomas, while TRAIL decoy receptors lacking the death domain were not expressed, but were detectable in normal hepatic tissue (Tanaka et al. 2000). Nuclear expression of the anti-apoptotic protein survivin is found in subsets of cholangiocarcinomas, associated with poor outcome (Javle et al. 2004). Cholangiocarcinomas and their dysplastic precursor lesions are reactive for the anti-apoptotic proteins Bcl-xL and Mcl-1 (Okaro et al. 2001). Immunoreactivity of Bcl-2 in cholangiocarcinoma cells seems to vary considerably. Bcl-2 was not detected in 1 investigation (Okaro et al. 2001); was found in 1 tumor among 20 cholangiocarcinomas (Terada and Nakanuma 1996); was present in 31.7 % of tumors in another study, where its expression was inversely related to nodal metastasis, perineural invasion, vascular invasion, and the proliferative status (Ito et al. 2000c); and was found in 8 out of 11 cholangiocarcinomas, similar to metastatic adenocarcinomas (Charlotte et al. 1994).

Liver Metastasis of Carcinomas

Regressive changes in liver metastasis of colorectal carcinomas are dominated by necrosis (see below). Apoptotic bodies are more frequently found in peripheral parts of the masses, close to the invasive border. The bodies appear as irregularly shaped, but often oval eosinophilic and homogeneous structures that are often situated as single objects or small clusters in the lumens of damaged adenocarcinoma tubules. These bodies represent condensed tumor cells having undergone drop-out from the epithelial lining of tubules. The apoptotic bodies may be accompanied by nuclear debris, cytoplasmic fragments, few neutrophils, and macrophages. In central parts of metastases, necrosis and apoptosis can occur together. In patients with colorectal carcinoma liver metastasis, apoptotic circulating tumor cells (CTCs) can be observed (Allen et al. 2014).

The mechanisms governing apoptosis and other forms of cell death in colorectal liver metastasis are only partially elucidated. Growth of metastasis depends on a shift in balance between proliferation and apoptosis. Apoptosis occurred more frequently in metastatic foci than in primary tumors of human colorectal carcinoma (Tatebe et al. 1996). There is evidence that this shift is regulated by factors derived from the primary tumor. For example, outgrowth of human hepatic colorectal cancer metastases occurs following resection of the primary

tumor, associated with a significant decrease of apoptosis in the metastasis (Peeters et al. 2006). This finding suggests that primary tumors secrete a factor that favors apoptosis in metastasis. In contrast, other studies did not find a difference of apoptosis behavior between primary and metastatic colorectal cancers (Seong et al. 2004). Development and progression of hepatic colorectal cancer metastases are regulated by differential expression of microRNA-192 which affects tumor cell apoptosis (Geng et al. 2014). Colorectal cancer cells associated with progression of disease exhibit low expression of M30, an early apoptosis indicator. This apoptosis resistance mechanism is important for metastasis (Kykalos et al. 2013). Liver metastasis of colorectal cancer is inhibited by cancer-derived CXCL16, a chemokine produced in the cancer microenvironment by CD8(+) T cells and natural killer cells (Kee et al. 2013), whereby chemokine-induced cell death may play a role. In fact, CXCL16 can suppress experimental hepatic colorectal cancer metastasis by promoting TNF-alpha-induced apoptosis by tumor-associated macrophages (Kee et al. 2014).

Cell Death in Tumor-Associated Microenvironments

Apoptosis and Necrosis of Stromal Cells

Stromal cells, myofibroblasts, and cancer-associated fibroblasts (CAFs), being the most important members, are critical for growth and spread of carcinomas (Mertens et al. 2013). Stromal cells of cancers, including liver carcinomas, are both locally produced via proliferation of resident mesenchymal cells and recruited from circulated mesenchymal stem cells. Recruitment of stromal cells is in part mediated by cancer cells and their products. Cholangiocarcinoma cells recruit stromal cells through secreting PDGF-D, which simulates migration of cancer-associated fibroblasts/CAFs via PDGFRbeta and Rho GTPase (Cadamuro et al. 2013). Such factors exert a prosurvival effect on stromal cells and shift cell turnover from loss through cell death to expansion. Apart from carcinoma cells, stromal cells of HCCs and cholangiocarcinomas can undergo apoptosis, a mechanism shaping the stromal composition. The turnover of the important myofibroblast precursor, hepatic stellate cell/HSC, is strongly regulated by apoptosis. Uncontrolled HSC proliferation in stromal expansion and fibrosis is counteracted by the Fas/Fas ligand pro-apoptotic system (Saile et al. 1997). Activated HSCs express the TRAIL receptor-2/death receptor-5 and are subject to TRAIL-mediated apoptosis, a mechanism that affects myofibroblast production and composition of the extracellular matrix (Taimr et al. 2003). The stromal population of mature, differentiated myofibroblasts is regulated by a balance between proliferation, growth arrest, differentiation, and apoptosis (Gressner 1998). Detection of this phenomenon requires special methods, such as immunostaining for pro-apoptotic factors or TUNEL assays. Activated stromal cells, predominantly myofibroblasts and cancer-associated fibroblasts/CAFs, can be primed for apoptosis by platelet-derived growth factor (PDGF) isomers via Puma-mediated Bak activation (Rizvi et al. 2014), a pathway that may be used in future treatment strategies. Stromal hepatic stellate cells and myofibroblasts are also sensitive to H_2O_2-mediated apoptosis, showing that oxidative stress is an important pro-apoptotic factor for these cell types (Larochelle et al. 2004; Thirunavukkarasu et al. 2004). Apoptosis of stromal cells, e.g., myofibroblasts, can be counteracted by various factors, including TGF-beta1 (Zhang and Phan 1999).

CAFs and myofibroblasts, which themselves are subject to cell death pathways, can affect cancer cell fate and progression by a complex balance between the promotion of growth and cell death. On the one hand, these stromal cells can drive the progression of cancer metastasis (Karagiannis et al. 2012), promote apoptosis resistance of cancer cells (Sirica 2011), and secrete PDGF-BB that induces hedgehog survival signaling in cholangiocarcinoma (Fingas et al. 2011). Apoptosis of stromal myofibroblasts is associated with upregulated MT1-matrix metalloproteinase (MMP) protein expression which induces pro-MMP-2 activation and in turn a proinvasive phenotype (Preaux et al. 2002). Deletion of CAFs suppresses tumor growth (Mertens et al. 2013). On the other hand,

bone marrow-derived stromal cells can increase the apoptosis rate of cancer cells and inhibit tumor metastasis (Hang and Xia 2014).

Apoptosis in Tumor-Associated Endothelial Cells and Angiogenic Compartments

The generation and turnover of endothelial cells located to tumor-associated blood vessels result from a delicate balance of proliferation and apoptosis. The shaping of a vascular network in progressing tumors depends on remodeling accomplished by apoptosis and other forms of cell death, a phenomenon that was studied in detail in involuting infantile hemangiomas (Razon et al. 1998). It is supposed that angiogenic systems in cancers are controlled by sensors that monitor the required number of endothelial and other vascular cells and provide signals to delete superfluous cells via apoptosis, similar to what seems to happen in ontogenesis. Limitation of neovessel density executed by receptor-mediated apoptosis is in part induced by thrombospondin-1 (Jimenez et al. 2000). Survival of endothelial cells during vasculogenesis and angiogenesis is influenced by pro-and anti-apoptotic factors secreted by cells of the stroma and tumor cells. Angiopoietin-1 and its receptor Tie-2 control survival of endothelial cells and by this regulate capillary tube formation (Hayes et al. 1999), acting as some sort of vasculogenic/angiogenic pacemaker. The morphogenesis of a functional neovessel network depends on survival of newly produced endothelial cells. VEGF, a strong promoter of angiogenesis, also markedly induces two members of the inhibitor of apoptosis/IAP family of proteins, survivin and XIAP (Tran et al. 1999), providing a potent survival strategy for these cells.

In the setting of programmed vascular regression, which also occurs in remodeling tumor vessel networks, macrophages can kill capillary endothelial cells in the G1 phase of the cell cycle (Diez-Roux et al. 1999). Also stromal cells are operational in endothelial cell apoptosis. Stromal tissue inhibitor of metalloproteinase-3/TIMP3, a potent inhibitor of angiogenesis, promotes endothelial cell apoptosis through a caspase-independent mechanism and targeting of a focal adhesion kinase/FAK-dependent survival pathway (Qi and Anand-Apte 2015). Apoptosis of endothelial cells can also be induced by solid tumor cells (Kebers et al. 1998) and is induced by ionizing radiation. Radiation-induced apoptosis of endothelial cells is dose dependent and occurs in a discrete wave 6–10 h after irradiation (Langley et al. 1997). Immortalized endothelial cells undergo p53-mediated apoptosis in a telomerase-independent manner (Maxwell et al. 1997). Apoptosis of tumor-associated endothelial cells plays a role in tumor spread and progression. Colorectal cancer liver metastasis in a mouse model is suppressed by apolipoprotein (a) kringle V via induction of apoptosis in tumor-associated endothelial cells (Ahn et al. 2014).

Apoptosis and Other Cell Death Forms in Cells Involved in Immune Responses and in Pro-apoptotic Pathways

HCCs, other primary liver cancers, and metastases are populated by various classes of leukocytes, mainly lymphocytes, tumor-associated macrophages (TAMs), myeloid-derived suppressor cells, dendritic cells, plasma cells, and granulocytes. Immunologic effector cells, including lymphocytes, monocytes, and TAMs, generate an inflammatory microenvironment in HCC which affects tumor progression, including metastasis (Galdiero et al. 2013). Here, TAMs have a pivotal role (Shirabe et al. 2012; Capece et al. 2013), and these cells induce apoptosis in tumor cells and nonneoplastic partner cells in stroma, including lymphocytes, and are also subject to apoptosis which regulates TAMs' cell turnover (Yao et al. 2014). Caspase-independent cell death of TAMs is also induced by autophagy (Xu et al. 2006). The fate of TAMs in the stromal niche is strongly dependent on the influx and survival of their precursors, the monocytes, which in turn derive from blood and hence from bone marrow. Monocytes can undergo apoptosis

induced by several mechanisms, but they are protected from apoptosis through regulation of TREM-1 (Cai et al. 2013). Triggering receptor expressed on myeloid cells 1 (TREM-1) is a signaling molecule that modulates several types of immune reactions and inflammatory responses and holds a critical position in the pathogenesis of infections and sepsis (Bouchon et al. 2000; Gibot 2006). TREM-1 is coupled to the ITAM-containing adaptor DAP12 (Tessarz and Cerwenka 2008). Bruton tyrosine kinase/Btk is a positive regulator in the ITAM-mediated TREM-1/DAP12 pathway (Ormsby et al. 2011). TREM-1 is selectively expressed on blood neutrophils and subsets of monocytes, but is also aberrantly expressed on diverse cancer cells. TREM-1 prolongs macrophage survival via induction of the anti-apoptotic protein Bcl-2 (Yuan et al. 2014), a mechanism that is probably important for maintenance of functional TAM populations. In cancers, expression of TREM-1 depends on an intricate interaction between tumor cells and stromal leukocytes. Cancer cells can directly upregulate TREM-1 expression in TAMs, and TREM-1 secretion by TAMs is in turn associated with cancer recurrence and poorer survival (Ho et al. 2008). TREM-1 is expressed in HCC cells, where it promotes proliferation, inhibits apoptosis of these tumor cells, and is associated with poor survival (Duan et al. 2015). On the other hand, TREM-1 is also produced by stromal hepatic stellate cells associated with HCC. TREM-1 which is produced by peritumoral stellate cells promotes migratory behavior of HCC cells and confers an aggressive tumor phenotype (Liao et al. 2012). TREM-1 controls Kupffer cell activation and by this affects hepatocarcinogenesis (Wu et al. 2012). Expression of TREM-1 is associated with tumor progression via its inhibition of tumor cell apoptosis and enhancing angiogenesis in colorectal cancer (Lee et al. 2014).

T cells and natural killer cells accumulate in the stroma of liver cancers, in part recruited by the action of activated stromal monocytes (Kuang et al. 2010). In some variants of HCCs, lymphocytic infiltration is dense and results in HCCs with lymphoid stroma. Infiltration by CD8(+) lymphocytes is associated with tumor cell apoptosis in HCCs (Ikeguchi et al. 2004). The sometimes dense lymphocytic infiltration in HCC is generated by the action of chemokines and chemokine receptors in part produced by stromal cells. CD8 (+) T cells infiltrating HCC play a role in apoptosis of these tumors, and apoptosis in HCC is regulated by the suppression of Fas/FasL expression mediated by tumor-infiltrating lymphocytes (Fukuzawa et al. 2001). In metastases, the CXCL16/CXCR6 axis, upregulated in various cancers, functions as an inducer for lymphocyte build-up around tumor sites (Deng et al. 2010; Koizumo et al. 2007). Fas/FasL on membranes or in the cytoplasm of HCC cells was increased in areas with lymphocytic infiltration surrounding cancer, a response mainly mediated by CD8(+) T cells (Fukuzawa et al. 2001). Apart from mechanisms promoting influx/homing of cells, the number of tumor-infiltrating lymphocytes/TILs is regulated by the balance of proliferation/immigration versus apoptosis. Intratumoral activated hepatic stellate cells can induce T-cell apoptosis (Xia et al. 2013), suggesting a distinct interactome between stromal cells and TILs. Expression of pro-apoptotic FasL is more frequent in liver metastases of colorectal carcinoma than in matched primary tumors, associated with increased apoptotic elimination of tumor-infiltrating lymphocytes/TILs (Mann et al. 1999).

Leukocyte-tumor cell interactions in part depend on the highly variable longevity of leukocytes, a phenomenon that affects the fine-tuning of mechanisms in the tumor microenvironment. Whereas subsets of lymphocytes are long-lived, and also TAMs can show an extended life-span, neutrophils have a very short survival time as soon as they have left the blood stream to settle within tissues. Short-lived neutrophils infiltrating the peritumoral tissue compartment links inflammatory responses to progression of HCC by fostering angiogenesis, mediated through the secretion of pro-angiogenic MMP-9. Neutrophils are recruited to this site by IL-17 secreted by HCC cells (Kuang et al. 2011). Neutrophils can also promote motility of cancer cells through a hyaluronan-mediated toll-like receptor 4/PI3K activation pathway (Wu et al. 2011). These mechanisms are blunted by early death of neutrophils, an effect that requires continuous replacement of lost neutrophils

egressing from the blood. Death of extravascular neutrophils is a complex process that involves both apoptosis and necrosis. Neutrophils in tumors are also subject to autophagy. HCC cells can release soluble factors that trigger an increase of functional autophagy-specific protein LC3 and autophagosomes in neutrophils. Increased neutrophil autophagy was correlated with sustained production of pro-metastatic oncostatin M and matrix metalloproteinase-9 (Li et al. 2015b).

Apoptosis in Hepatocellular Carcinoma and Cholangiocarcinoma: A Major Mechanism to Control Tumor Growth and Spread

General Remarks

Most liver cancers are in an unbalance regarding cell proliferation and apoptosis (Fabregat 2009; Guo et al. 2010), resulting in a serious derangement of cell number homeostasis that causes progressive cancer growth with intervening periods of growth silence or even tumor regression (reviews: Kountouras et al. 2003). Apoptosis in HCCs may be induced by factors involved in HCC etiology. For example, HCV viral proteins can induce mitochondrial dysfunction and may, through this pathway, lead to mitochondria-mediated apoptosis (Brault et al. 2013), and apoptotic signaling is modulated by the HBV X protein (Rawat et al. 2012). Binding of HBsAg to the ECHS1 binding protein enhances apoptosis through the mitochondrial pathway (Xiao et al. 2013). ECHS1 (enoyl-CoA hydratase short chain 1) is a protein that is overexpressed in various cancers, including HCC, and interacts with STAT3 (signal transducer and activator of transcription 3) and negatively regulates STAT3 signaling (Chang et al. 2013).

Pro-apoptotic Factor Expression in Hepatocellular Carcinoma

HCC cells can express a wide array of pro-apoptotic factors with highly variable expression patterns (Table 2).

Table 2 Pro-apoptotic factors expressed in hepatocellular carcinoma

Delta-like 3 downregulation
RhoA and RhoC proteins
DCL-1

There are significant differences in the expression of apoptosis-related factors/proteins between normal hepatic tissue and HCCs. HCC tissue expresses Fas (APO-1; CD95) more weakly and less frequently than noncancerous liver tissue, and while Fas is present in normal hepatocytes both on the cell membrane and in the cytoplasm, cell surface expression of Fas is variable in HCCs and HCC cell lines (Hamazaki et al. 1995; Higaki et al. 1996; Yano et al. 1996; Lee et al. 2001; Shin et al. 1998). In HCCs that express Fas, the expression pattern varies from few single cells to a honeycomb pattern. Low Fas expression is mainly found in HCCs of poor differentiation and an invasive phenotype (Ito et al. 1998, 2000a), while Fas ligand expression was detected in moderately and poorly differentiated tumors (Ito et al. 2000a) and was an indication of worse prognosis (Lee et al. 2004). Downregulation of Fas and upregulation of FasL in HCCs are regarded as important elements in evasion from

immune surveillance (Hammam et al. 2012). On the other hand, CD8(+) T cells that infiltrate peripheral parts of HCCs lead to upregulation of the Fas/FasL system in HCC cells to increase tumor cell apoptosis (Fukuzawa et al. 2001; Ikeguchi et al. 2004). Notwithstanding the fact that HCC cell can express Fas at low levels, these cells are often resistant to Fas-mediated apoptosis (Kubo et al. 1998). This is usually not an active process but rather the consequence of inadequate apoptotic stimulation (Natoli et al. 1995). Interestingly, HCCs can be surrounded by a population of normal hepatocytes that strongly express Fas and Fas ligand/FasL, suggesting that cancer may induce apoptosis in peritumoral cells (Roskams et al. 2000). Fas-related death signals, i.e., cFLIP (cellular FLICE-inhibitory protein), FADD (Fas-associated death domain), and NF-kappaB, are modulated in HCCs by the Wilms' tumor 1 gene (Uesugi et al. 2013). Fas also plays a role apoptosis and growth control of cholangiocarcinomas (Pan et al. 1999).

In HCC cells, apoptosis is potently induced by the TGF-beta signaling pathway, involving functional cooperation with Smad proteins and activator protein-1/AP-1 (Herzer et al. 2008). Pro-apoptotic signaling of TGF-beta1 is regulated by growth factors and integrin receptors located in the ECM (Ozaki et al. 2011). p53, frequently expressed in HCCs, promotes apoptosis, in interaction with several other proteins (Zhao and Zimmermann 1997a). One of the interacting partners of p53 in the apoptotic cascade is the transcription factor, PATZ1, which binds p53-dependent gene promoters (Valentino et al. 2013). Certain apoptosis-inducing proteins utilize the pro-apoptotic pathway of p53, e.g., nutlin-3 (Zheng et al. 2010). A promoter of apoptosis in HCC cells is the adipokine omentin-1, a protein which promotes apoptosis via regulating Sirt1-dependent p53 deacetylation (Zhang and Zhou 2013). The process of p53-induced apoptosis is a complex, multistep process. Generally, p53 mediates the transactivation of either cell cycle-regulating or pro-apoptotic target genes. The decision to enter an apoptotic pathway depends on the transcriptional regulator AATF. Genotoxic stress causes phosphorylation of AATRF through the p38MAPK/MK2 checkpoint kinase complex, followed by nuclear localization of AATF. In the nuclear compartment, AATF binds to Puma, Bax, and Bak promoters to suppress the DNA damage-induced expression of these pro-apoptotic p53 target genes (Höpker et al. 2012). HCC cells can express the second mitochondria-derived activator of caspase, Smac/DIABLO, a pro-apoptotic protein that releases inhibition of the IAP family from caspase-3 to induce apoptosis. Overexpression of Smac in HCCs promotes TRAIL-induced cell death (Okano et al. 2003).

Apoptosis is induced in HCCs by expression of the Tat-interacting protein 30/TIP30, a death pathway requiring mitochondrial participation. For TIP30-induced apoptosis, translocation of Bax is essential, and the process requires release of cytochrome c and Smac/DIABLO (Shi et al. 2008). Expression of klotho, a tumor suppressor involved in several cancers, including HCC, induces apoptosis in HCC cells through regulation of IGF-1R phosphorylation and subsequent activation of downstream Akt-p70S6K and ERK signaling (Shu et al. 2013). HCC cell apoptosis is promoted by the transcription factor, Krüppel-like factor 9/KLF9 via programmed cell death protein 5 (Fu et al. 2014). Apoptosis in HCC is promoted by DFNA5, a tumor suppressor that plays a role, as a mutated protein, in one form of autosomal dominant hearing loss (Wang et al. 2013a). DFNA5 is a pro-apoptotic protein that has been detected in several cancers (Op de Beeck et al. 2011) and is a paralog of DFNAB59/pejvakin, a protein involved in auditory neuropathy. Adiponectin impairs HCC progression by inducing apoptosis via modulation of c-Jun N-terminal kinase and mTOR pathways (Xing et al. 2015). Apoptosis in HCC cells is induced by downregulation of Delta-like 3, which is silenced in these neoplasms (Maemura et al. 2013). Apoptosis in HCC cells is regulated by several Rho proteins, including RhoA and RhoC and their expression inducers. RhoC is a key regulator of both growth and apoptosis in HCC cells (Xie et al. 2012). Apoptosis is induced in HCC cell populations by DLC-1 protein (DLC,

deleted in liver cancer), a pro-apoptotic GTPase-activating protein encoded by a gene on 8p21.3–22. DLC-1 is specific for RhoA and Cdc42, and its gene is frequently deleted in HCC (Wong et al. 2003), one mechanism for HCC apoptosis resistance. Restoration of DLC-1 expression in HCC cells induces apoptosis and inhibits cancer expansion (Zhou et al. 2004). A pro-apoptotic protein is Siva-1, a protein which induces both extrinsic (receptor-mediated) and intrinsic (non-receptor-mediated) apoptosis (Resch et al. 2009). Siva-1 binds to CD27, a component of the TNFR family. Siva-1 forms a functional complex with tyrosine kinase 2, a complex that augments the pro-apoptotic effects (Shimoda et al. 2010). A further binding partner of Siva-1 is pyrin, a protein mutated in familial Mediterranean fever/FMF. Through its binding, pyrin can recruit Siva to the apoptotic protein ASC specks (Balci-Peynircioglu et al. 2008). In mammalian cells, the open conformation of PTEN has a pro-apoptotic activity, counteracted by the tumor suppressor, p27Kip1, an enzyme that binds cyclin/CDK complexes in the nucleus but also exerts cytoplasmic functions (Andrés-Pons et al. 2012). Apoptosis of HCC cells is induced by suppression of serine/threonine kinase involved in centrosome separation and mitotic bipolar spindle formation, STK15/Aurora A/BTAK (Gao et al. 2008). A pro-apoptotic protein in HCCs acting in a caspase-independent manner is TIPE1 (tumor necrosis factor alpha-induced protein 8-like), a TIPE family member involved in apoptosis regulation. TIPE1 induces apoptosis in HCC cells by negatively regulating Rac1 and its downstream p65 and c-Jun N-terminal kinase pathways (Zhang et al. 2014). Certain microRNAs promote apoptosis in HCC cells. microRNA-141 promotes HCC apoptosis by targeting hepatocyte nuclear factor 3 beta (Lin et al. 2014). MicroRNA-1 induces apoptosis of HCC cells by targeting and downregulating the apoptosis inhibitor-5/API-5 (Li et al. 2015a). MicroRNA-206, markedly downregulated in HCC, is a promoter of apoptosis. Loss of this microRNA in HCC is associated with poor differentiation and advanced tumor stage (Yunqiao et al. 2014).

Downregulation of Apoptosis in Hepatocellular Carcinoma and Cholangiocarcinoma

An imbalance between pro-apoptotic and anti-apoptotic factors plays a significant role in the progression of HCCs and cholangiocarcinomas. As in normal tissues with cellular turnover, several types or species of anti-apoptotic factors are variably expressed in liver cancers (Table 3).

Important anti-apoptotic proteins in HCCs are endogenous inhibitors of apoptosis proteins (IAPs), key regulators of apoptosis, signal transduction pathways, and cytokinesis (Notarbartolo et al. 2004; Augello et al. 2009). IAPs were first identified as baculovirus proteins and in humans include XIAP, c-IAP1, c-IAP2, NIAP, survivin, Bruce, ILP-2, and livin/ML-IAP. IAPs are expressed in HCC and contribute to inhibition of apoptosis (Li et al. 2013). Apart from their role as apoptosis inhibitors, IAPs are regulators of innate immunity and inflammation and can act as E3 ubiquitin ligases acting on the Rho kinase Rac and thus modulate cell migration. IAPs are antagonized in HCC cells by a protein that is released

from mitochondria in response to apoptotic stimuli, i.e., Smac/DIABLO (second mitochondria-derived activator of caspase/direct inhibitor of apoptosis-binding protein with low pl).

HCC cells are often resistant to TNF-related apoptosis-inducing ligand/TRAIL, a member of the TNF family. TRAIL is regulated by two death receptors, TRAIL receptor-1 (TRAIL-R1) and TRAIL-R2, and two decoy receptors (Chen et al. 2003). TRAIL resistance of HCC cells may be caused by downregulation of TRAIL-R1 and TRAIL-R2 in these cells (Shin et al. 2002). Generally, the expression of these two proteins is lower in HCCs than in normal liver, and reduced TRAIL-R1 and TRAIL-R2 expression goes in parallel with a decrease of caspase-3 activity (Yano et al. 2003). In HCCs, TRAIL-R1 downregulation and upregulation of TRAIL-R2 and TRAIL-R4 correlated with tumor dedifferentiation (Koschny et al. 2013).

Bcl-2, an anti-apoptotic factor, is variably expressed in HCCs, and its role in these cancers is not clarified. A positive linear correlation was found between Bcl-2 expression and p53 protein expression, and Bcl-2 expression was inversely proportional with histologic grade (El-Emshaty et al. 2014). Expression of Bcl-2 in HCC is subject to regulation by B cell translocation gene 1/BTG1. In these tumors, BTG1 is downregulated, resulting in reduced apoptosis (Sun et al. 2014). Bcl-2 is frequently overexpressed in cholangiocarcinoma cells and alters the threshold for apoptosis (Harnois et al. 1997).

Survivin is an important suppressor of apoptosis, but it also accelerates cancer cell proliferation. In HCCs, expression of survivin was found in 41–74 % of tumors (Ikeguchi et al. 2002; Moon and Tarnawski 2003; Chau et al. 2007; Augello et al. 2009), and cancers without detectable survivin expression showed significantly higher apoptosis rates, whereas expression of survivin was associated with poor prognosis (Ikeguchi et al. 2002; Cho et al. 2010). Expression of survivin in HCCs is correlated with high risk of disease recurrence (Fields et al. 2004; Ye et al. 2007). Among survivin-positive HCCs, 63 % showed punctate nuclear staining, while the remaining tumors displayed cytoplasmic staining. A nuclear transfer of survivin was associated with poorer differentiation (Moon and Tarnawski 2003). Increased nuclear expression of survivin in HCCs is associated with p53 protein expression (Kannangai et al. 2005). Survivin expression in HCCs is inhibited by Smac/DIABLO (Bao et al. 2006). Nuclear survivin expression was also detected in cholangiocarcinomas (Javle et al. 2004; Kannangai et al. 2005; Shen et al. 2009). In addition to nuclear immunoreactivity, also cytoplasmic immunostaining for survivin was observed in cholangiocarcinomas, strong nuclear survivin expression being correlated with poor prognosis (Javle et al. 2004). Survivin is downregulated by p16 reactivation in HCC resulting in anoikis (Hu et al. 2011). In addition to survivin, a second IAP is overexpressed in HCC, i.e., livin/ML-IAP. Smac is a potent suppressor of survivin in liver cancer (Bao et al. 2006).

Expression of the anti-apoptosis protein Bcl-xL in HCC correlates with an aggressive growth phenotype and poor survival (Watanabe et al. 2004). BRE, a protein that binds to the cytoplasmic domains of TNFR1 and Fas, is overexpressed in HCCs and acts as an anti-apoptotic factor (Chan et al. 2008). Krüppel-like factor 6/KLF6 is a transcription factor that protects HCC cells from apoptosis via a Bcl-2-mediated mechanism (Sirach et al. 2007). In HBV-associated HCC, downregulation of Notch1 through the action of upregulated microRNA-429 suppresses apoptosis (Gao and Liu 2014). In HCV-associated HCCs, decreased apoptosis is mediated through downregulation of p21 ras (Baddour et al. 2013). Overexpression of glypican-3, a membrane-associated heparan sulfate proteoglycan expressed in many HCCs and involved in cell proliferation and survival, can both induce apoptosis (Pan et al. 2013) and counteract apoptosis, while targeting of glypican-3 with microRNA-520c-3p induces apoptosis in HCC cells (Miao et al. 2014). SERPINB3, which is progressively expressed from dysplastic nodules to HCCs, is a potent inhibitor of apoptosis (Pontisso 2014). Overexpression of DEK, an oncogene originally found as one of the partners of the translocation-associated DEK-CAN fusion

gene in a subtype of acute myeloid leukemia, in HCC confers poor prognosis via inhibition of apoptosis (Yi et al. 2015). An anti-apoptotic factor expressed in HCCs and pancreatic cancer is the clock gene, Period1/Per (Sato et al. 2009). Also the endogenous clock protein timeless is overexpressed in some HCCs and counteracts apoptosis (Elgohary et al. 2015). Expression of the tumor suppressor GRIM-19, a mitochondrial respiratory chain complex I protein, in HCC suppresses tumor growth via stimulation of apoptosis (Kong et al. 2014).

Part of the mechanisms involved in anti-apoptosis in liver cancer operate through inhibition of pro-apoptotic factors. HBV infection can inhibit TGF-beta-induced apoptosis of HCC cells (Liu et al. 2014b). The HBV core protein can inhibit Fas-mediated apoptosis of HCC cells through modulating the expression of mFas/FasL and sFas expression (Liu et al. 2014a). HCC cells can circumvent apoptosis via acquisition of resistance to TRAIL/TNF-related apoptosis-inducing ligand, a pro-apoptotic member of the TNF family (Shin et al. 2002). Loss of the pro-apoptotic protein FADD in HCC cells promotes an anti-apoptotic phenotype (Sun et al. 2000). Expression of an anti-apoptotic protein, BIRC6, in HCC results in blunted apoptosis through facilitating the degradation of the pro-apoptotic protein, p53 (Tang et al. 2015). HBV can inhibit apoptosis in HBV-related HCC by upregulation of microRNA-181 and consecutive downregulation of Fas expression (Zou et al. 2014).

Elimination of Apoptotic Bodies

Clearance of Apoptotic Bodies and Efferocytosis

The condensed cell corpses resulting from apoptosis and related death mechanisms (the apoptotic bodies) are structures that contain numerous and in part altered proteins that can exert diverse functions, including pathological signaling functions and cell injury. It is, therefore, important to provide prompt clearance of apoptotic bodies. This process includes engulfment of apoptotic bodies followed by degradation of the engulfed particles (Fadeel et al. 2004; Ravichandran and Lorenz 2007; Fullard et al. 2009). In epithelia, clearance of apoptotic cellular fragments can be visualized by immunohistochemical staining with M30 antibody. M30 recognizes a neo-epitope formed early in the apoptotic cascade by caspase cleavage of cytokeratin 18 (Leers et al. 2002). A special form of the apoptotic body clearance process is efferocytosis. Efferocytosis is a process characterized by the recognition and removal of apoptotic cells by phagocytes predominantly in the setting of inflammation. Engulfment and clearance of apoptotic bodies/corpses involve three membrane proteins, low-density lipoprotein receptor-related protein-1/LRP, ABCA1, and the LRP adaptor protein GULP/CED-6 (Su et al. 2002; Kiss et al. 2006). GULP acts via the mammalian engulfment receptor Jedi-1, an interaction which mediates phagocytosis of apoptotic bodies through a clathrin-dependent mechanism (Sullivan et al. 2014).

Factors Operational in Clearance of Apoptotic Bodies

In the process of apoptotic body clearance, stabilins as scavenger receptors play a significant role. Stabilin-1(CLEVER-1) is specifically expressed in alternatively activated macrophages (type II macrophages) and certain endothelial cells (Kzhyshkowska 2010; Palani et al. 2011). In the liver, stabilin-1 and stabilin-2 are involved in the clearance of oxidized low-density lipoproteins by sinusoidal endothelial cells (Li et al. 2011). Stabilin-1 is located is recruited to sites of surface recognition and engulfment of apoptotic corpses by macrophages (Park et al. 2009). Cell corpse clearance via engulfment also strongly depends on a receptor for membrane phosphatidylserine on apoptotic cells, stabilin-2, which itself has thymosin beta44 as its downstream molecule (Lee et al. 2008). A stabilin-2 domain modulates pH-dependent recognition of phosphatidylserine in apoptotic cells (Kim et al. 2010). Stabilin-2-mediated corpse engulfment requires the presence of the adaptor protein

GULP, a likely downstream effector in the stabilin-2 signaling pathway (Park et al. 2008). GULP is also involved in stabilin-1-mediated phagocytosis (Park et al. 2010). Engulfment of apoptotic cells also requires caspase activity (Shklyar et al. 2013) and the presence of three receptor kinases, Tyro-3, Axl, and Mer, collectively termed TAM receptors (Lemke 2013; Nguyen et al. 2013). The elimination of dying or dead neutrophils depends on the presence of lysophosphatidylserine on neutrophils acting as a clearance and proresolution signal and on Rac1 activity increasing the numbers of macrophages efferocytosing apoptotic cells (Frasch et al. 2011). Engulfment of apoptotic bodies by various phagocytic cells is negatively regulated by PTEN by modulating activation of Rac GTPase (Mondal et al. 2011). Efferocytosis is negatively regulated by cellular expression of the high mobility group box 1/HMGB1 protein, a conserved protein with numerous intracellular and extracellular functions. HMGB1, through its association with Src kinase and an inhibition of interactions between Src kinase and focal adhesion kinase, decreases phagocytic ability of macrophages for apoptotic cells (Banerjee et al. 2011).

Recognition of Apoptotic Cells by Leukocytes

How are apoptotic corpses recognized by phagocytes? Apoptotic cells and their bodies express surface molecules that are sensed by phagocytes which can obviously "analyze" the surface patterns or "surface code" of dead versus living cells, providing "find-me" or "stay away" signals (Biermann et al. 2013; Hochreiter-Hufford and Ravichandran 2013). A critical surface address is phosphatidylserine, which is expressed on apoptotic cells, is recognized by phagocytes, and is an "eat-me" signal (Toda et al. 2012; Biermann et al. 2013). Apoptotic and pyroptotic cells release a nucleotide-type "find-me signal" and "eat-me signal" (Elliott et al. 2009; Wang et al. 2013b). These "find-me" signals are mediated by the plasma membrane channel pannexin 1, an ATP nucleotide release channel which increases membrane permeability during apoptosis (Chekeni et al. 2010; Sandilos and Bayliss 2012). Proteolytic enzymes can confuse the recognition of apoptotic cells by phagocytes (Guzik et al. 2007; Guzik and Potempa 2008). Under special situations, not entire cells but rather parts of cells are eliminated by engulfment. Human intrahepatic cholangiocytes can engulf blebs from their apoptotic peers (Rong et al. 2013).

Apoptosis: The Phenomenon and Mechanisms of Programmed Cell Death

Introduction

Apoptosis is, apart from necrosis, the best known form of cell death (reviews: Saraste 1999; Fink and Cookson 2005; Fietta 2006; Elmore 2007; Duprez et al. 2009). This classical form of programmed cell death is morphologically characterized by cell shrinkage, membrane damage, chromatin condensation and fragmentation, degradation of the nucleosomal structures, and formation of an eosinophilic dense body representing the shrunken cell, the apoptotic body, or apoptotic corpse. The duration of classical apoptosis ranges from 12 to 24 h. Classical apoptosis requires activation of the caspase cascade (review: Elmore 2007). Apoptotic bodies have long been known, a typical example being the Councilman body found in livers with acute or active hepatitis. The other forms of cell death are discussed in later paragraphs.

Detection of Apoptosis and Apoptotic Cells

Apart from morphologic detection of apoptosis, which in light microscopic preparations depends on the presence of apoptotic bodies, numerous cytochemical, immunohistochemical,

Table 4 Methods for detecting apoptosis and apoptotic cells

Immunostaining for membrane molecules (Fas/CD95, FasL, TNFR1/CD120a, TNFR2/CD120b, TRAIL receptors, and others)
Immunostaining for cytoplasmic molecules (Bcl-2, Bid, caspases, IAPs, and others)
Annexin V staining (phospholipid externalization, annexin V binding)
Cytochrome c immunohistochemistry
Detection of phosphatidylserine, and apoptosis marker, on cell surfaces
Caspase assays (caged fluorophores, FRET; carboxyfluorescein caspase activity assay; flow cytometry)
Caspase cleavage product assays (cytokeratin 18 cleavage; poly-ADP-ribose polymerase/PARP cleavage)
Cathepsin assay
Exclusion assays for detection of membrane damage (trypan blue exclusion, propidium iodide exclusion)
Chromatin condensation assays
Visualization of altered DNA by DNA fluorochrome staining (acridine orange)
Labeling of DNA strand breaks by nick translation (ISNT) using exogenous DNA polymerase
Labeling of cells by end labeling (TUNEL), using exogenous terminal transferase for end labeling of DNA fragments
DNA fragmentation assays (non-radioactive DNA fragmentation assay; radioactive assays, alkaline elution analysis, DNA "ladders" in agarose gel electrophoresis, radioactive ladder analysis, ELISA of histone-complexed DNA fragments, 3H-TdR-based JAM test, nucleosome quantification ELISA, anti-single stranded DNA antibody assay)
ATP bioluminescence assay
Mitochondrial function and integrity assays (permeability transition by vital dye staining, membrane potential assay, mitochondrial antigen staining, cytochrome c release assays, Smac/DIABLO assays)
Cell death detection ELISA
Cellometer imaging cytometry

DNA fragmentation (internucleosomal DNA cleavage) assays are based on the phenomenon that, in early apoptosis, genomic DNA is cleaved into distinct fragments prior to cell membrane disintegration/cell lysis (prelytic DNA fragmentation). The DNA fragments have a characteristic size and form rungs in a ladder as seen in agarose gel electrophoresis or in radioactive ladder analysis

and molecular methods have been developed to identify apoptosis in cultured cells and tissues (reviews: Willingham 1999; Saraste and Pulkki 2000; Martinez et al. 2010; Table 4).

Pathways to Apoptosis

General Remarks

Apoptosis as a highly regulated process required a complex network of proteins. The diverse manifestations of apoptosis have been defined and standardized (Fink and Cookson 2005; Kroemer et al. 2009; Galluzzi et al. 2012). Previously, apoptosis had been clearly separated from necrosis, these two death processes having been regarded as completely unrelated. Recent findings have changed this view, as outlined below (Nikoletopoulou et al. 2013). Apoptosis signaling is initiated by several stress factors, including nutrient deprivation, hypoxia, heat, infections, ionizing radiation, and increased intracellular calcium concentration. Via intermediate factors, these stressors can trigger the release of a complex array of pro-apoptotic signals by a damaged cell. Two conserved protein families are central to apoptosis, i.e., the Bcl-2 family controlling mitochondrial integrity and a group of cysteinyl aspartate-specific proteases, the caspase family.

The Intrinsic Pathway to Apoptosis

The intrinsic pathway operates through mitochondria. Mitochondria play a crucial role in the initiation of apoptosis by delivering an array of pro-apoptotic factors that induce caspase activation, while the extrinsic pathway (see below) does not directly involve mitochondria (review: Otera and Mihara 2012). Mitochondria-induced apoptosis is closely linked to mitochondrial fusion and fission and crista disorganization. Via this pathway, apoptosis is connected with the function of key mediators of fusion and fission, mitofusins, and the intermembrane space GTPase OPA1. In the setting of apoptosis, the mitochondrial network disintegrates into small spherical structures, a process also regulated by the pro-apoptotic and anti-apoptotic Bcl-2 family proteins. This mitochondrial fragmentation is independent from caspases and is associated with crista disorganization and subsequent cytochrome c release. However, mitochondrial fragmentation is not always

associated with apoptosis. The fragmentation process is closely linked to the decay of crista folds, cristae remodeling, and opening of crista junctions to release cytochrome c, the protein OPA1 required for crista integrity. Disruption of OPA1 complexes during early apoptosis leads to widening of cristae and release of cytochrome c into the intermembrane space. Fission and fragmentation of mitochondria is counteracted by a organelle-protecting process initiated in mitochondrial damage, called stress-induced mitochondrial hyperfusion (SIMH). Under stress such as exposure to UV irradiation and cytotoxic drugs, the mitochondrial network becomes highly connected, forming a hyperfused structure.

Under normal conditions, mitochondrial integrity is maintained by the action of anti-apoptotic Bcl-2 family members which inhibit the pro-apoptotic Bcl-2 members, Bax and Bak, to induce mitochondrial injury. Following cell stress, anti-apoptotic Bcl-2 members are antagonized by the activation of the Bcl-2-homology 3 proteins (BH3-only proteins), Bim, tBid and Noxa, which relieve Bax and Bak inhibition. The BH3-domain protein, Bim, can activate Bak and Bax directly (Czabotar et al. 2009), but its interactions with prosurvival proteins are complex (Mérino et al. 2009). Specifically, Bax and Bak can also mediate apoptosis without association with the BH3-only activators, Bim, Bid, and Puma (Willis et al. 2007). The BH3 domain protein, Noxa, interacts with several partners, but specifically with Puma and Mcl-1. Like Puma, Noxa is induced by the transcription factor p53, but Noxa, together with the pro-apoptotic Bcl-2 family member Bok, is also transcriptionally induced by MAL, the myocardin-related transcription factor A/MRTF-A (Shaposhnikov et al. 2012). Noxa and Puma synergistically induce apoptosis (Wensveen et al. 2011). This pathway involves the anti-apoptotic Bcl-2 protein, Mcl-1 which is a gateway to TRAIL sensitization (Kim et al. 2008). In p53-induced apoptosis, Puma can be caught at the mitochondrial surface by Mcl-1, and upon DNA damage, Noxa releases Puma from Mcl-1 and thus induces apoptosis (Nakajima and Tanaka 2011).

Active Bax and Bak oligomerize and form a channel in mitochondria through which a chief mediator of apoptosis, cytochrome c, is released into the cytosol. Here, cytochrome c forms a multiprotein platform with Apaf-1 and ATP to recruit and activate procaspase-9, a superstructure termed the apoptosome. Apoptosomes are highly complex signaling platforms that assemble the protein network required for apoptotic cell death. The apoptosome is the critical structure in the mitochondrial apoptotic pathway. Its assembly is initiated by the binding of cytochrome c to the apoptotic protease-activating factor (Apaf-1) in an ATP-dependent manner (reviews: Cecconi 1999; Dickens et al. 2012; Reubold and Eschenburg 2012; Yuan and Akey 2013). This step results in the construction of a characteristic heptameric "wheel" composed of seven Apaf-1 residues and seven molecules of cytochrome 2. This heptamer is now capable to activate the initiator caspase-9, which then switches the downstream caspase cascade into action. Activation of procaspase-9 on the apoptosome is a crucial step in the intrinsic cell death pathway. The holoapoptosome possesses procaspase-9 recruitment domains that form a CARD-CARD disk that is flexibly tethered to the apoptosome, whereby disk assembly and procaspase-9 binding generate an asymmetric proteolysis machine (Yuan et al. 2010, 2011). Procaspase-9 activated in the apoptosome platform then activates the downstream executioner caspases caspase-3, caspase-6, and caspase-7, enzymes that directly mediate the apoptotic process.

The Caspase Machinery: Execution of the Intrinsic Pathway of Apoptosis

In the course of the orderly cellular suicide program of apoptosis, a critical role is played by the sequential activation of several caspases, a family of cysteine proteases. Procaspases are synthesized as single-chain zymogens that, for full activation, require a complex and highly regulated process linked to activation complexes. Initiator caspases, mainly caspase-2, caspase-8, caspase-9, and caspase-10, are sequentially activated from procaspases in activation platforms having caspase-activating protein complexes that also

provide a chip-like distinct spatial arrangement of procaspases facilitating self-activation. These platforms include DISC (death-inducing signaling complex) which activates caspase-8 and caspase-10; the apoptosome, which activates caspase-9; the PIDDosome, which activates caspase-2 (review: Park 2012); and the apoptosome, which activates procaspase-9.

Generally, caspase-activating complexes contain members of the death domain/DD superfamily. The large DD superfamily consists of four subfamilies: (1) the death domain/DD subfamily, (2) the death effector domain/DED subfamily, (3) the caspase recruitment domain/CARD subfamily, and (4) the pyrin domain/PYD subfamily (Park 2012). Each of these subfamilies comprises between 7 and 32 species in the human genome. Pyrin domains are located at the N-termini of several proteins functioning in apoptotic and inflammatory signaling pathways (Fairbrother et al. 2001). Caspases active in apoptosis can be recruited by a distinct family of proteins, i.e., proteins with a caspase recruitment domain (CARD) motif. However, certain CARD proteins have anti-apoptotic effects. CARDINAL, a novel CARD protein, potently suppresses NF-kappaB activation (Bouchier-Hayes et al. 2001). The pro-apoptotic DRAL-caspase-9 complex is triggered by the sonic hedgehog-Patched receptor system. Patched interacts with the adaptor protein DRAL/downregulated in rhabdomyosarcoma LIM-domain protein. Via this binding, Patched recruits a protein complex that contains DRAL, one of the caspase recruitment domain (CARD)-containing proteins TUCAN (family member, 8) or NALP1 (NLR family, pyrin domain containing 1), and apical caspase-9 (Mille et al. 2009). Apart from the activation of caspases, TUCAN/CARDINAL and DRAL-containing proteins participate in the modulation of NF-kappaB activation (Stilo et al. 2002).

Activation of initiator caspases results in the activation of the executioner caspases caspase-3, caspase-6, and caspase-7. Executioner caspases such as caspase-3 and caspase-7 are also involved in signal transduction pathways inside target cells, through their capability to interact with several kinases, phosphatases, and other signaling molecules. Via such pathways, caspase-3 can, e.g., in an apparently paradoxical manner, control cell proliferation and tissue regeneration (Boland et al. 2013). Caspase-3, caspase-7, and caspase-9 are potently inhibited by the X-linked inhibitor of apoptosis (XIAP). The activity of XIAP is impaired by mitochondrial Smac (second mitochondria-derived activator of caspase) release during apoptosis. In a feedback loop, XIAP itself inhibits the release of Smac by mitochondria (Flanagan et al. 2010). In comparison with other caspases, caspase-2 has a more restricted role and selectively cleaves only a relatively small group of proteins, including cytoskeletal proteins (Vakifahmetoglou et al. 2013), but has a central role in the PIDDosome, a structure discussed in more detail below.

Factors Modulating the Intrinsic Pathway

There is a group of highly conserved proteins that potently inhibit apoptosis, i.e., the inhibitors of apoptosis proteins/IAPs. IAPs have a central, but indirect role in caspase regulation of the modulation of immune signaling. c-IAP1 and c-IAP2, unlike XIAP, do not directly inhibit caspases, but interact with tumor necrosis factor receptor/TNFR-associated factor 2/TRAF2, resulting in the recruitment of TNFR1. In addition to their function as factors counteracting apoptosis, IAPs also affect cell shape and cell motility, due to their interaction with MAPK, NF-kappaB, and Rho GTPase signaling pathways. IAPs are critically important regulators of apoptosis in hepatic cells. Main members of IPA comprise survivin, livin, c-IAP1, c-IAP2, NIAP, and XIAP. A potent IAP is X-linked inhibitor of apoptosis/XIAP protein, a protein which inhibits caspase-3, caspase-7, and caspase-9. The activity of XIAP is in turn inhibited during apoptosis by mitochondrial Smac/DIABLO (second mitochondria-derived activator of caspase) release, while cytosolic XIAP feeds back to mitochondria to impair Smac release. c-IAPs (cellular IAPs) and XIAP can also act as endogenous inhibitors of the ripoptosome, in that they can limit RIP1 kinase recruitment.

The Ripoptosome

A specific intracellular protein platform is required to mediate cell death induced by c-IAPs (cellular inhibitors of apoptosis proteins). The ripoptosome is a large multiprotein platform of around 2MDa (Tebev et al. 2011). c-IAPs promote the spontaneous formation of the ripoptosome complex (Imre et al. 2011) or necrosome, containing RIP1, FADD, caspase-8, caspase-10, and caspase inhibitor cFLIP isoforms. It can stimulate caspase-8-mediated apoptosis as well as caspase-independent necrosis. Ripoptosome assembly requires RIP1's kinase activity. The ripoptosome platform is mainly generated upon genotoxic stress or loss of IAPs. The ripoptosome as a distinct signaling platform can switch modes between apoptosis and necroptosis and critically influences the outcome of membrane-bound receptor triggering (Feoktistova et al. 2011, 2012).

The Extrinsic Pathway to Apoptosis

The extrinsic apoptotic pathway is initiated by stimulation of death receptors of the tumor necrosis factor receptor (TNFR) family, including TNFR1, TNFR2, Fas, and TRAIL receptor. Fas interacts with its ligand, FasL. TNF receptor 1 (TNFR1) is an ubiquitous death receptor that is involved in both normal and malignant cells. One important factor related to TNF signaling is TRAIL (tumor necrosis factor-related apoptosis-inducing ligand; Apo-2L) which interacts with specific cellular receptors, e.g., TRAIL-R, DR4, and DR5 (Thornburn 2004; Kim et al. 2013). Notwithstanding its pro-apoptotic action, TRAIL is constitutively expressed in tissues. Its effects are modulated by the differential expression of four TRAIL receptors, DR1–DR4, which bind TRAIL but differ markedly in their ability to transduce the death signal (MacFarlane 2003). TRAIL can be induced on the surface of HCC cells by cytokines and certain cytostatic drugs (Shiraki et al. 2005). Apoptosis induced by these death ligands and receptors is executed by the formation of death-inducing signaling complex (DISC). On the cell surface, several members of the TNF death receptor superfamily are arranged to form DISC which activates procaspase-8 (Schleich et al. 2013). On human cells, eight death receptor members attributed to four structurally homologous groups or clades form a functional DISC, i.e., the p75 (NTR) clade (p75 neutrotropin receptor, death receptor-6, and ectodysplasin A receptor), the TNF receptor 1 clade (TNFR1 and DR3), the CD95 clade (CD95/Fas/APO-1), and the TNF-related apoptosis-inducing ligand receptor (TRAIL-R) clade (TRAIL-R1 and TRAIL-R2). In the DISC complex, Fas-associated death domain (FADD) recruits initiator caspase-8 or caspase-10. In the DISC, activation of procaspase-8 leads to induction of death receptor-mediated apoptosis (Lavrik and Krammer 2012).

Death-Fold Complexes: PIDDosome, MyDDosome, and Fas/FADD-DISC

The Death-Fold Superfamily of Proteins

The death-fold superfamily is composed of four homologous subfamilies characterized by homotypic restricted interactions (review: Kersse et al. 2011). The building blocks for the construction of the multimeric complexes include the death domains (DDs), the death effector domains (DEDs), the caspase recruitment domains (CARDs), and the pyrin domains (PYDs). These domains are engaged in the formation of three major multimeric death-fold complexes, i.e., the PIDDosome, the MyDDosome, and the Fas/FADD-DISC (Mace and Riedl 2010; Kersse et al. 2011; Dickens et al. 2012).

PIDDosome

The PIDDosome is an oligomeric signaling complex that activates caspase-2 under genotoxic stress, whereby the PIDDosome can act as a sensor for DNA damage (Tinel and Tschopp 2004; Bouchier-Hayes and Green 2012; Janssens and Tinel. 2012; Manzl et al. 2012; McCoy

et al. 2012; Jang et al. 2013). This platform consists of PIDD (p53-induced protein with a death domain/DD), RAIDD (receptor-interacting protein/RIP-associated ICH-1/CED-3 homologous protein with a death domain/DD), and procaspase-2 and is capable to activate caspase-2 via interaction of the partners in the complex. Assembly of the PIDDosome is accomplished by PIDD mediating and stabilizing the interaction between RAIDD and caspase-2. Caspase-2 CARD is an insoluble protein that is solubilized by its binding partner, RAIDD CARD (Jang and Park 2013). Depending on the differential activation of its components, the PIDDosome can exert various functions. Specifically, the PIDD component can operate as a switch for signaling either to cell survival or cell death. This PIDD switch functions in relation to the phosphorylation status of the PIDD death domain. Phosphorylation by ATM/Tel1 (ataxia telangiectasia mutated), a conserved phosphatidylinositol 3-kinase (PIKK) that acts in response to DNA damage and regulates telomere maintenance, results in RAIDD binding, caspase-2 activation, and cell death, while the non-phosphorylated state of PIDD fails in caspase-2 activation and engages prosurvival RIP1 (Ando et al. 2012).

MyDDosome

The so-called MyDDosome (or Myddosome) is a protein complex involved in signaling by Toll-like receptors/TLRs and the interleukin-1 superfamily, a signaling cascade critically involved in innate immunity. This signaling requires the adaptor protein, myeloid differentiation primary response protein 88/MyD88. MyD88 is a component of the MyDDosome, together with IRAK kinases, MyDD adaptor-like, and TRIF-related adaptor molecule (Motshwene et al. 2009; George et al. 2011; review: Gay et al. 2011). The central complex of the MyDDosome is formed by a helical assembly of the MyD88-IRAK4-IRAK2 complex. In this complex, MyD88 recruits IRAK4, and the MyD88-IRAK4 complex recruits the IRAK4 substrates IRAK2 or the related IRAK1 (Lin et al. 2010). The significance of MyD88 in innate immunity is illustrated by the observation that individuals with rare MyD88 point mutations suffer from life-threatening infections.

DOI 10.1007/978-3-319-26956-6_177

Abstract

In addition to classical apoptosis, necrobiologic processes active in cancer also include various forms of cell death related to apoptosis. These alternative and complex pathways are only incompletely studied in hepatobiliary tumors, but may play a significant role in the future, also for the development of novel therapies. A mode of cell death that occurs following detachment of cells from the extracellular matrix (ECM) is termed anoikis. As the ECM is highly abnormal in cancers, anoikis is an important death modality for tumor cells. An increasing number of cell death forms are independent from caspase pathways and are therefore not related to apoptosis. They include pyroptosis, pyronecrosis, ferroptosis, methuosis, parthanatos, paraptosis, caspase-independent mitotic death, oncosis, oxytosis, phenoptosis, and autoschizis. A distinct form of cell-in-cell death that occurs in various cancers characterizes emperipolesis, peripolesis, entosis, emperitosis, and cell cannibalism.

Introduction

In addition to classical apoptosis, which is the best known example of programmed cell death both in normal and neoplastic cells, there are several other cell death pathways that are either related to classical apoptosis or involve caspase-independent pathways and are thus not related to apoptosis (Duprez et al. 2009; Tables 1 and 2).

Anoikis and Synoikis

Anoikis and Homeless Cells

Anoikis ("death of homelessness") is defined as a mode of cell death that ensues upon cell detachment from the extracellular matrix (ECM), or the attachment of epithelial cells to an inappropriate matrix or substrate (Horbinski et al. 2010; Taddei et al. 2012; Paoli et al. 2013). Anoikis is an important prerequisite for metastatic spread in cancers (Kim et al. 2012). Regulators of anoikis include Mcl-1, Cav-1, Bcl-xL, c-FLIP, Bit1 and MAPK (Tan et al. 2013). Loss of matrix attachment depends on distinct alterations in composition and function of the cytoskeleton. The proapoptotic GTP-binding protein, death-associated protein 3 (DAP3), is critical for induction of anoikis. DAP3 is associated with FADD and activation of caspase-8 (Miyazaki et al. 2004). DAP kinase (DAPK), which undergoes activation upon induction by various death stimuli, and DAPK-induced cell death are associated with loss of matrix attachment (Ivanovska et al. 2014). DAPK is a Ca2+/calmodulin-regulated serine/threonine kinase that participates, as a member of a distinct interactome, in several signaling cascades, including the NLRP3 inflammasome (Bialik and Kimchi 2014). Anoikis is regulated by distinct signaling pathways (Zhan et al. 2004). Anoikis is an important mechanism to prevent and impair ectopic cell growth to inappropriate ECMs and is a guarantee for the maintenance of organ-typic tissue organization (review: Horbinski et al. 2010).

Anoikis in Various Neoplasms and Liver Cancers

Anoikis plays a significant role in fating of cancer cells. In particular, it markedly affects the

pathways that lead to individualization of tumor cells, a critical step in the early phases of invasive cascades. Specifically, it counteracts escape of viable cells from the primary tumor. Anoikis prevents shed epithelial cells and tumor cells from colonizing elsewhere and hence maintains normal architecture of normal tissues and may keep tumor architecture in control (Horbinski et al. 2010). Resistance to anoikis is a major mechanism that facilitates invasion and spread of cancer and is associated with anchorage-independent growth and epithelial-mesenchymal transition (EMT). Numerous pathways can lead to anoikis resistance, including changes in adhesion molecule expression patterns, increased growth factor/growth factor receptor expression, induction of EMT and associated pro-metastatic niches, and upregulation of pro-survival signaling (review: Paoli et al. 2013).

Anoikis resistance of HCC cells is a major mechanism promoting invasion and metastatic spread (Cao et al. 2009; Tan et al. 2013). A cancer microenvironment that undergoes remodeling associated with an altered extracellular matrix (ECM) protein platform can exert effects on HCC cell anoikis. MicroRNA-26a, which targets alpha5 integrin, promotes anoikis in HCC (Zhang et al. 2015). An elevated autocrine expression of the ECM protein, epidermal growth factor-like repeats, and discoidin I-like domains 3 (EDIL3) in HCC protects from tumor anoikis through integrin activation, creating a receptive microenvironment for the survival of detached HCC cells (Feng et al. 2014). Anoikis resistance is linked to the generation of epithelial-mesenchymal transition (EMT). Resistance to anoikis can be conferred by EMT via an E-cadherin-mediated pathway (Kumar et al. 2011). CD44 can provide an EMT signal pathway for the acquisition of a mesenchymal phenotype in HCC cells, resulting in anchorage-independent cell survival (Okabe et al. 2014). MicroRNA-424-5p, which reverses EMT and anoikis resistance in HCC, is downregulated in these tumors (Zhang et al. 2015).

A mitogen-activated protein kinase (MAPK) pathway is pivotal for anoikis resistance in HCC cells (Cao et al. 2014) and resistance requires expression of a membrane protease, RHBDL2 (Cheng et al. 2014). In HCCs, anoikis resistance is induced by an oncogene involved in tumor metastasis, AEG-1. AEG-1-promoted resistance is activated via the PI3K/Akt pathway and is characterized by the regulation of Bcl-2 and Bad (Zhou et al. 2014). Defects in the death receptor pathway of caspase activation can render tumor cells resistant to anoikis and hence promote metastasis (Simpson et al. 2008). The kinase receptor-interacting protein (RIP) is an upstream negative regulator of the NAD-dependent deacetylase, sirtuib-3 (SIRT3) in anoikis resistance (Kamarajan et al. 2012). Another protein that can regulate anoikis resistance in tumors is the CUB domain-containing protein 1, an SFK-binding phosphoprotein associated with anchorage independence of cancer cells (Uekita et al. 2007). HCC cells are protected from anoikis by the action of p21-activated kinase 1 (PAK1), which is upregulated by HBV X protein (Xu et al. 2012). Acquisition of anoikis resistance in HCC is produced through upregulation of CD147 (Ke et al. 2012) and by the aging suppressor gene product, Klotho, via activation of VEGFR2/PAK1 (Chen et al. 2013). Autophagy induced in different stages of tumorigenesis supports anoikis resistance (Sun et al. 2013; Yang et al. 2013). In HCC there is also a relationship between autophagy and anoikis. Induction of autophagy through upregulation of BNIP3 in HCC cells contributes to anoikis resistance via an mTORC1 signaling pathway (Sun et al. 2014).

Synoikis

There are mechanisms that allow tumor cells to circumvent anoikis. A distinct anti-anoikis mechanism is a process called synoikis (Shen and Kramer 2004). Synoikis denotes a tumor cell behavior in which tumor cell-cell contacts form a tissue-like population that promotes proliferation and survival in the absence of interactions with the extracellular matrix. Hepatoma cells can enter a synoikis-like survival mode mediated by angiopoietin-like 47ANGPTL4 (Zhang et al. 2008), a protein acting in lipid metabolism and

as an apoptosis survival factor for endothelial cells.

Lipoapoptosis: A Cell Death Mechanism for Steatotic Hepatocytes and Hepatocellular Carcinomas with Steatosis and Steatohepatitic Changes

An important proinflammatory mechanism in steatohepatitis and inflammatory changes in steatotic HCCs is lipoapoptosis induced by saturated free fatty acids (FFAs). Oxidative stress induced by lipotoxic molecules, in particular palmitate and stearate, plays a central role in pathways leading to lipoapoptosis and lipoapoptosis-associated hepatic inflammation. Saturated FFAs accumulate in hepatocytes in situations of compromised triglyceride synthesis, neutral fat being a safeguard by binding palmitate (Unger and Orci 2002; Malhi and Gores 2008; Alkhouri et al. 2009; Cazanave and Gores 2010; Zambo et al. 2013).

In hepatocytes, FFAs are well-known compounds to induce lipoapoptosis in a c-Jun-NH2-terminal kinase (JNK)-dependent pathway (Malhi et al. 2006). FFAs shift insulin-induced hepatocyte proliferation toward CD95/Fas-dependent apoptosis (Sommerfeld et al. 2015). Among fatty acids, palmitate is centrally involved in the induction of lipoapoptosis. Accumulation of palmitate in cells activates the endoplasmic reticulum stress response, resulting in induction of proapoptotic transcription factor C/EBP homologous protein (CHOP). CHOP-mediated lipoapoptosis is modulated by microRNA-615-3p which is repressed by palmitate to allow maximal expression of CHOP (Miyamoto et al. 2014). Palmitate activated by fatty acid transport protein 4 promotes an apoptosis cascade in hepatocytes characterized by increased JNK, PUMA, caspase-3, PARP-1 activation, and Rac1-mediated cytoskeletal reorganization (Seessle et al. 2015). One component of this pathway, the BH3-only protein PUMA, is a potent proapoptotic protein. PUMA expression is JNK1-dependent and contributes to lipoapoptosis in hepatocytes (Cazanave et al. 2009). Palmitate also promotes calcium release from the endoplasmic reticulum and thus induces mitochondrial dysfunction which induces oxidative stress (Egnatchik et al. 2014). FFAs can stimulate proteasomal degradation of cellular inhibitors of apoptosis protein 1 and 2 (cIPAP1 and cIAP2) in hepatocytes and thus promote apoptosis depending on death receptor 5 (DR5)-mediated signaling (Akazawa et al. 2013). Palmitate-induced lipoapoptosis is counteracted by several mechanisms. Lipoapoptosis mediated by palmitate-promoted upregulation of Bim and PUMA is attenuated by palmitoleate (Akazawa et al. 2010). MicroRNA-296 reduces lipoapoptosis in liver cells by directly targeting PUMA (Cazanave et al. 2011). Palmitate and stearate can also induce lipoapoptosis in cholangiocytes via caspase activation, nuclear translocation of FOXO3, and increased proapoptotic PUMA expression (Natarajan et al. 2014). In HCC cells in vitro, reduction of oxidative stress attenuates lipoapoptosis induced by hypoxia (Hwang et al. 2015).

Autosis

Autosis is a Na+,K+-ATPase-regulated form of stress-induced cell death promoted by a cell-penetrating autophagy-inducing peptide, Tat-Beclin 1, a derivative of Beclin 1. Stress factors involved in autosis comprise hypoxia and nutrient starvation. Morphologically, autosis is characterized by increased autophagosomes/autolysosomes and nuclear convolution at early stages of the process and focal swelling of the perinuclear space at later stages (Liu et al. 2013).

Protruded Type of Cell Death

Protruded type of cell death is a distinct form of parenchymal cell death that has first been observed in adrenal gland cells of normal rats (Chen-Pan et al. 1996). Protruded cells (p-cells) are characterized by an electron-lucent cytoplasm and ruptured membranes and their egress from the parenchymal tissue compartment into capillary

lumina. The egress of p-cells is either through endothelial gaps or following "rupture" of the capillary endothelial lining. The cytoplasmic matrices of dying p-cells were seen to scatter in the capillary lumen where the nuclei and mitochondria remained morphologically intact. A similar phenomenon has been observed in intercalated cell populations of the medullary collecting duct of the developing rat kidney, where superfluous intercalated cells are deleted by apoptosis followed by extrusion into the duct lumen (Kim et al. 1996).

Pseudoapoptosis

Pseudoapoptosis generally defines a death process that resembles initial stages of apoptosis, but is, in contrast to apoptosis, a reversible process. Cells undergoing pseudoapoptosis show blebbing, a deranged mitochondrial function, membrane lipid asymmetries, and a disorder of calcium homeostasis, but these changes can be reversed rapidly.

Non-apoptotic Forms of Cell Death

Introduction

Apart from apoptosis and its variants, several forms of ordered non-apoptotic cell death are known. Caspase-independent forms of cell death play an important role as safeguard mechanisms to protect the host from harmful cells in case of caspase failure ("regulated necrosis"; reviews: Bröker et al. 2005; Table 3).

Table 3 Forms of non-apoptotic cell death

Pyroptosis and the Pyroptosome

Pyroptosis is defined as a caspase-1-dependent, NLRP3 (Nod-like receptor family protein 3)-, and AIM2-inflammasome-mediated form of inflammatory programmed cell death, mostly triggered in macrophages by various, in part microbial, stimuli (reviews: Kohl and Grütter 2004; Fink and Cookson 2005). In contrast to apoptosis, pyroptosis results in the release of PAMPS (pathogen-associated molecular patterns) and immune system-activating cytokines. The activation of pyroptosis causes secretion of interleukin-1beta and pore-mediated cytolysis. Caspase-1 (synonym: interleukin-1-converting enzyme) is chiefly active as a mediator of inflammation by proteolytically processing interleukin-1beta from an inactive precursor to the active form and as an inducer of a rapid apoptosis program in macrophages as a response to intracellular bacteria, called pyroptosis. Pyroptosis is characterized by formation of a supramolecular assembly of several proteins, the pyroptosome (Fernandes-Alnemri et al. 2007; Fernandes-Alnemri and Alnemri 2008). The pyroptosome is located in the cytoplasm, not linked to an organelle, and co-localizes with NLRP3 (Wang et al. 2013b). PYNOD/NLRP10, an NLR-like protein that consists of a pyrin domain and a NOD, is an inhibitor of inflammatory reactions mediated by caspase-1 and the apoptosis-associated speck-like protein containing a caspase recruitment domain (ASC). PYNOD co-localizes with ASC and inhibits caspase-1-mediated processing of interleukin-1beta without inhibiting caspase-4-mediated caspase-1 processing (Wang et al. 2004; Imamura et al. 2010). ASC, which binds directly to caspase-1, is critical for caspase-1 activation in pyroptosis. ASC itself is one of the two only human proteins that contain a caspase recruitment domain or CARD together with a pyrin, AIM, ASC, and death domain-like (PAAD)/PYRIN/DAPIN domain. Proteins with CARD regulate caspases,

and ASC binds by its CARD to procaspase-1 to regulate the activity of this enzyme (Stehlik et al. 2003).

The initiation of pyroptosis requires the activity of cytosolic pattern recognition receptors (PRRs), molecules that act as sensors for the detection of various endogenous and exogenous danger-associated molecular patterns (including pathogen-associated molecular patterns, PAMPs; Broz and Monack 2011). The principal structures involved are Nod-like receptors containing a pyrin domain (PYD) (NLRPs) and AIM2-like receptors (ALRs), structures also involved in carcinogenesis (reviews: Drexler and Yazdi 2013; Ratsimandresey et al. 2013). Inflammasomes in their role in pyroptosis interact in a complex manner with components of the caspase system. An inhibitor of caspase-8, c-FLIP (cellular FLICE-inhibitory protein), is a contributor to canonical inflammasome (NLRP3 and AIM2) activation for the generation of caspase-1 and active interleukin-1beta. Specifically, c-FLIP is required for full NLRP3 inflammasome assembly and NLRP3 mitochondrial localization (Wu et al. 2014). NLRP3 activation also induces a form of programmed necrotic cell death through induction of the protein ASC (apoptosis-associated speck-like protein containing a CARD), a process that leads to neutrophil-mediated inflammation (Satoh et al. 2013).

Pyronecrosis

The term pyronecrosis has been employed to described a form of necrotic cell death occurring in macrophages infected with *Shigella flexneri* (Willingham et al. 2007). In contrast to pyroptosis, pyronecrosis does not require caspase-1. The process involves the pattern recognition receptor NALP3/cryopyrin/CIAS1 and the apoptosis regulator protein apoptosis-associated speck-like protein containing a CAR (ASC). Pyronecrosis can also be induced by intracellular *Staphylococcus aureus*, but the bacterium can also induce anti-apoptotic programs in phagocytes (Fraunholz and Sinha 2012). Human macrophages infected with high burdens of ESAT-6-expressing *Mycobacterium tuberculosis* undergo pyronecrosis (Welin et al. 2011).

Ferroptosis

Ferroptosis is a form of non-apoptotic cell death that is iron dependent (Dixon et al. 2012). Ferroptosis is triggered by the oncogenic RAS-selective lethal small molecule erastin, a member of the RAS-selective lethal compounds (RSL). Erastin targets voltage-dependent anion channels 2 and 3 and blocks cysteine uptake by the cysteine/glutamate antiporter (Dixon et al. 2012). RSL-induced cell death proceeds in the absence of caspase activation and chromatin fragmentation and is associated with increased intracellular levels of reactive oxygen species (ROS). The deficiency in cysteine leads to failure of antioxidant protection, leading to iron-dependent cell death. An essential regulator of ferroptosis in cancer cells is glutathione peroxidase (Yang et al. 2014). In cancer cells, ferrostatin-1 is a potent pharmacological inhibitor of ferroptosis (Dixon et al. 2012). Ferroptosis occurs in HCCs, and this form of iron-dependent cell death has also been observed following sorafenib exposure (Louandre et al. 2013).

Methuosis

In the non-apoptotic cell death mode termed methuosis (from Greek, *methuo*, to drink to intoxication), excessive stimuli can induce cytoplasmic uptake and accumulation of small bubbles that gradually merge into giant vacuoles, causing decreased metabolic activity of the involved cell, decay of cell membranes, and cell death. Cell shrinkage and nuclear fragmentation as in apoptosis are absent (Cai et al. 2013). The vacuoles originate from non-clathrin endocytic compartments and are distinct from lysosomes and autophagosomes (Overmeyer et al. 2011). Methuosis is mechanistically characterized by alterations in the trafficking of clathrin-independent endosomes and can be induced by the expression of active Ras, with the important

downstream effectors small GTPases, Rac1, ARf6, and the Arf6 GTPase-activating protein GIT1 (Bhanot et al. 2010).

Parthanatos

Parthanatos is a form of caspase-independent programmed cell death induced by apoptosis-inducing factor (AIF) release from mitochondria and its translocation into the nucleus, where it initiates DNA cleavage (David et al. 2009). An important inducer of parthanatos is mitochondrial oxidative stress (Andrabi et al. 2008; Chiu et al. 2011). The stress response in the nucleus involves poly-ADP-ribose (PAR) polymer, which is generated in the nucleus and transported to mitochondria to mediate AIF release following lethal PARP-1 activation (Wang et al. 2009a). Parthanatos is associated with ATP consumption due to NAD+ depletion by poly(ADP-ribose) polymerase 1 (PARP-1)-dependent poly-ADP-ribosylation (PARylation) on target proteins (Koh et al. 2005; Huang et al. 2013; Mashimo et al. 2013; Virag et al. 2013). Binding of poly-ADP-ribose (PAR) to AIF is a critical event for PARP-1-dependent parthanatos (Wang et al. 2011). Parthanatos results in cell and tissue demise resembling necrosis.

Paraptosis

Paraptosis is a form of active caspase-independent type III cell death characterized by vacuolization of the cytoplasm, rounding of cells, and other features resembling cell necrosis (Sperandio et al. 2000; Hoa et al. 2009). Paraptosis may be a distinct form of oncosis. The process needs gene activation. In contrast to apoptosis, paraptosis has no nuclear fragmentation and DNA fragmentation, lacks membrane blebbing, and reveals only minor chromatin condensation. Mitochondrial swelling is a late phenomenon. Damaged parapoptotic cells release danger signals, including high mobility group B-1, heat shock proteins, and proteases. Several types of cancer drugs can induce paraptosis, including taxol. Paraptosis depends on failure of large potassium channels (Hoa et al. 2009). Paraptosis is mediated by mitogen-activated protein kinases (MAPKs) and inhibited by AIP-1/Alix. Apoptosis is not inhibited by AIP-1/Alix (Sperandio et al. 2004). Alix (apoptosis-linked-gene-2-product; ALG-2) acts as a mediator of exosome biogenesis, in a syndecan-syntenin-Alix complex (Baietti et al. 2012; Bissig and Gruenberg 2014; Ghossoub et al. 2014). Alix also mediates egress of naked hepatitis B virus capsid particles from HBV-replicating cells (Bardens et al. 2011).

Caspase-Independent Mitotic Death (CIMD)

There is a form of mitotic cell death that is independent of caspase activation, a process termed caspase-independent mitotic death (CIMD) (reviews: Bröker et al. 2005; Kitagawa and Niikura 2008). CIMD mainly involves proteolytic pathways mediated by cathepsins, calpains, serine proteases, and DNases, all these enzymes participating in an activation cascade that ends up in the cleavage of numerous cellular proteins, nuclear proteins, DNA, and in cell disintegration (Torriglia and Leprêtre 2009). CIMD depends on p73, a p53 homologue and inducer of apoptosis (Ozaki and Nakagawara 2005), and also depends on apoptosis-inducing factor and endonuclease G (Niikura et al. 2007). CIMD is induced during early mitosis by partial depletion of the spindle checkpoint protein, BUB, and defective kinetochore-microtubule attachments. This process is mediated by an interactor of BUB1, i.e., BUB3, which upon escape from BUB1 binding interacts with p73 (Niikura et al. 2010). CIMD may serve to eliminate cells that are at risk to marked chromosome mis-segregation.

Oncosis

Oncosis is a prelethal condition characterized by marked cell swelling, organelle swelling, increased cell membrane permeability, and membrane blebbing. Failure of membrane ion pumps

due to energy exhaustion seems to be in the center of pathogenesis. Oncosis is predominantly found in situations of induced ATP depletion, e.g., by toxic agents. A second pathway involves deranged calcium homeostasis and increased cytoplasmic Ca2+ activating calpain-type proteases that destabilize cellular membranes (review: Fink and Cookson 2005).

Oxytosis

Oxytosis is an oxidative stress-induced form of cell death originally observed in nerve cells exposed to excess glutamate in the extracellular medium (Tan et al. 2001). The process is also termed oxidative glutamate toxicity or glutamate-induced oxytosis. Excess glutamate inhibits cellular uptake of cysteine, required for the synthesis of the protective molecule glutathione. Failure of glutathione production results in excess of mitochondria-produced reactive oxygen species followed by calcium influx, finally leading to cell death.

Enucleation-Induced Cell Death

A novel mechanism of cell death that is considered to play a role in cancer cells is enucleation. In vitro it is associated with the formation of an induced cytoplasmic network of stress fibers that extrude the nucleus from the cell, followed by cell death. Intact nuclei are found in the vicinity of the cytoplasts for a certain time (Paunescu et al. 2014).

Phenoptosis

Phenoptosis is a term that has been coined to denote a system of programmed cell death that purifies a population from individuals that have become unwanted or are damaging the entire system (Skulachev 1999). For example, phenoptosis may purify an entire organ from cells that no longer fulfill the required functions or damage the organ's homeostasis. It could be envisaged that such a system performs a surveillance and protection function, e.g., recognizing mutated and potentially neoplastic cells and eliminating them via apoptosis.

More than a century ago, August Weismann had formulated the hypothesis that death of old individuals had been established in nature and its biological evolution as a kind of adaptation, in order to rejuvenate the population (Weissmann 1889). This hypothesis was strongly criticized by Medawar (1952).

Autoschizis

Autoschizis is a form of cancer cell death characterized by a decrease in cell size occurring subsequent to loss of cytoplasm via self-excision, in the absence of organelle loss. In cells undergoing autoschizis, also nuclei decrease in size and exhibit chromatin decondensation. Degraded chromatin is present in cytoplasmic autophagosomes. Nucleoli segregate their components and are fragmented into small pieces. Cell death then develops through karyorrhexis and karyolysis (Gilloteaux et al. 2001, 2004, 2006; Jamison et al. 2002).

Cell-in-Cell Death in Cancer: Cell-in-Cell Structures, Emperipolesis, Peripolesis, Entosis, Emperitosis, and Cannibalism

CICS, Emperipolesis, and Peripolesis

Upon cell contact, cells can form cell-in-cell structures (CICS), characterized by a process through which one or more cells (the effector cell) penetrate into the cytoplasm of another cell (the host or target cell; reviews: Xia et al. 2008; Yang and Li 2012; He et al. 2013). In humans, CICS physiologically occur among stem and progenitor cells and certain immune cells such as T-cells. Classically, penetration of cells as CICS effector cells into other cells is termed emperipolesis (McFarland 1970; Xia et al. 2008; Figs. 1 and 2). A similar process is peripolesis, a phenomenon in which a cell (usually a lymphocyte) attaches itself to another cell, mostly

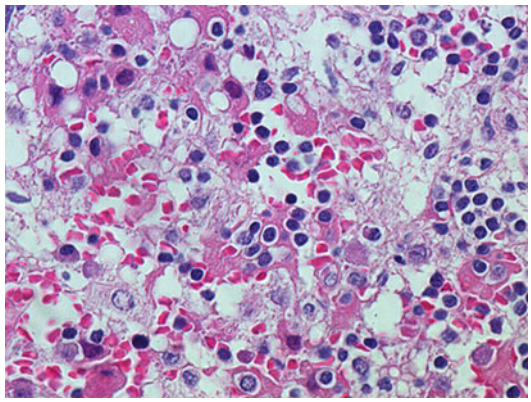

Fig. 1 Tumor cell emperipolesis. Cells with spherical and partly pycnotic nuclei are engulfed by phagocytic cells (hematoxylin and eosin stain)

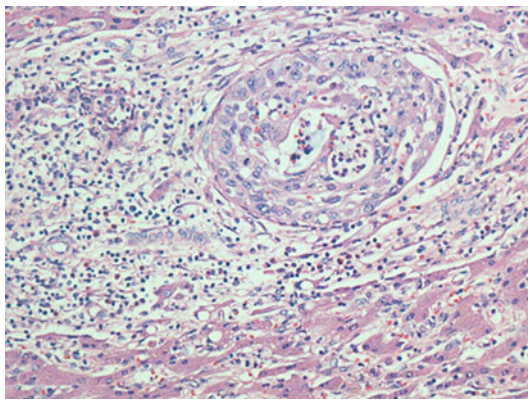

Fig. 2 Neutrophil emperipolesis by carcinoma cells (hematoxylin and eosin stain)

a macrophage or veiled cell, and proceeds to circle around it (Lyons et al. 1992). Cells of a distinct type can form CICS among themselves (homotypic CICS), but also different cell types can produce CICS (heterotypic CICS). Heterotypic CICS of normal cells are, e.g., granular leukocytes in megakaryocytes. In neoplasms, heterotypic CICS are a hallmark of Rosai-Dorfman disease, but they also occur in other neoplasms, such as carcinomas, where tumor cells can form cell-in-cell structures with leukocytes or stromal cells (Wang et al. 1976). Certain cancer cells can internalize platelets (Bhatia and Dey 2013). Homotypic CICS are also known for various cancers, showing tumor cells within tumor cells (tumor cell-tumor cell emperipolesis; Humble et al. 1956; Burns 1967; Chemnitz and Bichel 1973). The entry of effector cells into host cells can result in various fates of the cells involved. Emperipoletic lymphocytes can survive in their host cells, at least for a certain time. Immune effector cells surviving in tumor cells can attack their host cells by directly inserting into the nucleus of their tumor host cells (so-called lymphocyte-mediated cancer cell lysis; Wei and Hang 1989; Hang et al. 1991). However, it is assumed that in CICS most of the entering cells will undergo three major forms of cell death, i.e., cannibalism, entosis (non-apoptotic cell-in-cell death), and emperitosis (killer cell-mediated apoptotic cell-in-cell death; review: He et al. 2013).

Cellular Cannibalism: Cancer Cells Eat Their Way Free

Cannibalism is characterized by the phenomenon that normal cells and cancer cells can internalize other cells, such as neighboring tumor cells, leukocytes, and stromal cells, and "eat" them, a process that seems to augment their thriving and proliferative capacity (Sharma and Dey 2011; Caruso et al. 2012; Fais and Fauvarque 2012). In fact, tumor cells as cannibal cells may "eat" everything on their way, and often feed on sibling tumor cells, but also on cells encountered in their microenvironment, e.g., lymphocytes, natural killer cells, and granulocytes (Lugini et al. 2006; Qian and Shi 2009; Singhal et al. 2011). Cannibalizing of lymphocytes by tumor cells may damage the local antitumor immune response by inducing lymphocytopenia. There is evidence that metastatic tumor cells often employ cannibalism at the metastatic site, particularly under low nutrient supply (Fais 2007). The finding of cannibal tumor cells that internalize and eat nontumorous cells such as neutrophils and lymphocytes (Caruso et al. 2012) is termed xeno-cannibalism (Sarode and Sarode 2014b), while feeding on sibling cells is called self-cannibalism or macroautophagy (Malorni et al. 2007; Matarrese et al. 2008). Certain cancers also show homotypic cell cannibalism, a process regulated by the nuclear protein 1 (Cano et al. 2012). Cannibalism is not restricted to cancer cells and was also found in granuloma

cells (Sarode and Sarode 2014a). Cells involved in cannibalism employ the actin cytoskeleton, ezrin, and caveolin-1 to engulf and internalize their "victims," followed by the formation of a cannibalistic vacuole which fuses with lysosomes to form enzyme-containing caveosomes. Cell death in cannibalism is mediated by lytic enzymes of lysosomes. Interestingly, this process mimics a phylogenetically very old and conserved mechanism that is, e.g., well-known from feeding amoebas. It is assumed that cannibalism provides the cannibal cell with additional nutrients that serve for growth and invasion. However, there are also indications that self- and xeno-cannibalism can result in cellular "hyperphagia" that ends up with an autophagic reaction leading to cell death (Tinari et al. 2008).

Entosis

A second form of CICS-associated cell death is termed entosis (Overholtzer et al. 2007; Routray et al. 2014). Entosis is in part similar to cannibalism and is strongly dependent on light chain 3 (LC3). Entosis is also called LC3-associated phagocytosis, or LAP. However, in homotypic entosis, a living tumor cell is internalized intactly into a sibling cell of the same type (Yang and Li 2012). In the course of entosis, invading homotypic effector cells are enveloped in a target cell vacuole followed by recruitment of LC3 to the vacuole membrane, a process that requires Rho-dependent signaling, actin polymerization, and adherens junctions that bind the cells involved together. Autophagy-associated proteins such as Atg5, Atg7, and the lipid kinase VPS34, rather than autophagosomal proteins, are involved in the process (Kim and Overholtzer 2013). The vacuole then fuses with target cell lysosomes, but cell death is caused by lysosome-mediated caspase-3-independent cell death (review: He et al. 2013) and is related to autophagic processes (Florey et al. 2011). Autophagic proteins lipidate LC3 onto phagosomes and other macroendocytotic vacuole membranes and are required for entotic degradation of cargo (Florey and Overholtzer 2012). Entosis can impair metastatic spread by eliminating potential metastatic cells that have detached from the ECM pro-metastatic niche, i.e., disturbance of cytokinesis; entosis is also thought to compromise the future replicative capacity of target cells via induction of an aneuploid or multinucleated state in surviving cells (Janssen and Medema 2011; Krajcovic et al. 2011; Krajcovic and Overholtzer 2012).

Emperitosis

In emperitosis, natural killer (NK) cells are internalized by cancer cells. Many of these heterotypic CICS result in NK cell death within the tumor cell host ("strike-back effect"; He et al. 2013), in part by re-picking up of secreted granzyme B back into the effector cell causing suicide (Wang et al. 2013a), but part of the internalized NK effector cells can kill the host cancer cell by release of cytotoxic proteins. In both situations, cell death proceeds through apoptosis. Internalization of NK cells into cancer cells requires ezrin and leads to a form of programmed cell death (Wang et al. 2009b). Active granzyme B converts entosis to emperitosis (Salvesen 2014), and rapid uptake of granzyme B leads to emperitosis, a death mechanism of immune killer cells inside tumor cells (Wang et al. 2013a). Granzyme B induces extramitochondrial reactive oxygen species production via caspase-dependent NADHP oxidase activation (Aguilo et al. 2010). Granzyme B itself can be degraded by autophagy, a pathway involved in the escape of cancer cells from NK-mediated lysis (Viry et al. 2014).

Mitotic Catastrophe

Introduction

Mitotic catastrophe (MC; anaphase catastrophe) is defined as a type of cell death occurring during mitosis and a mechanism for avoiding genomic instability. In principle, MC results from a combination of deficient cell cycle checkpoints (specifically the spindle checkpoint) and cellular damage. Failure of these checkpoints and failing cell cycle arrest before or at mitosis causes an

attempt of aberrant chromosome segregation, ending up with apoptosis at the metaphase/anaphase transition (reviews: Castedo and Kroemer 2004; Castedo et al. 2004; Vitale et al. 2011). Only parts of cells in MC fulfill a complete apoptotic program. These cells start to divide asymmetrically in the next round of cell division and form aneuploidy daughter cells. This is an important mechanism that explains the common occurrence of aneuploid cells in malignant neoplasms.

What are the pathways leading to MC? The tuning of an orderly progression through G2 is regulated by cyclin-CDK levels (Oikonomou and Cross 2011), and deviations from these orderly gradients may cause G2/M failure. Maintenance of the G2 cell cycle checkpoint arrest for premitotic DNA quality control and repair is regulated by the WEE1 kinase and pushed forward by Cdc25 (De Witt Hamer et al. 2011). Premitotic repair itself is accomplished by homologous recombination proteins which are associated with centrosomes (Cappelli et al. 2011). A prolonged mitotic phase caused by abnormal chromosome segregation allows cells to reenter the subsequent G1 phase without cytokinesis (the so-called mitotic slippage). This has been shown to induce a p53-dependent cell death program, the MC (Gonçalves et al. 2011). The process of MC is also induced by depletion of centrosomal proteins (Kimura et al. 2013) and the viral protein apoptin (Lanz et al. 2013). The gammaH2AX-ATM (ataxia telangiectasia mutated)-p53 pathway triggers apoptosis in MC (Niida et al. 2005; Imre et al. 2011). The polo-like kinase family member serum-inducible kinase (Snk/Plk2) is a p53 target gene. At the mitotic checkpoint, p53-dependent activation of Snk/Plk2 prevents MC following spindle damage, while silencing of Snk/Plk2 induces MC (Burns et al. 2003). Stabilized p53 prevents caspase-independent mitotic death, counteracted by polo-like kinase 1, which in turn is suppressed by p21/Waf1 (Lin et al. 2011, 2014). Stabilization of p53 during this process is accomplished by Nqo1, which acts as a gatekeeper for proteasomal degradation of p53 (Bui and Shin 2011). MC-induced cell death is associated with a characteristic rearrangement of the actin-containing cytoskeleton (Grzanka et al. 2011).

Morphological Features of MC in Cancer Cells

The abnormal segregation of chromosomes in MC, the asymmetrical cell division that may follow MC, and the distinct type of cell death accompanying MC lead to a wide array of cytological abnormalities of tumor cells. They comprise aneuploidy, aberrant mitotic figures, bizarre and giant nuclei, multiple micronuclei, nuclear blebs, strings and pockets, nuclear invaginations, multinucleated tumor giant cells, centrosome aberrations, and signs of cell death, eventually with apoptotic bodies (Caruso et al. 2011a, b). It has been suggested that highly aggressive tumors characterized by pleomorphic giant cells are those having frequently undergone MC. MC may thus be a target for cancer therapy (review: Galimberti et al. 2011).

MC Is More Often Found in Cancer Cells

In contrast to normal cells, which are capable to repair damaged DNA during a G1 arrest, cancer cells often lack a sufficiently long G1 phase and depend in regard to DNA control and repair on a G2 arrest. The molecular switch for the G2/M transition, the Wee1 kinase, is often overexpressed in cancer cells, one mechanism why cancer cells prematurely enter mitosis and hence undergo MC (review: De Witt Hamer et al. 2011). A further system involved in the induction of MC in tumors involves miRNAs. The tumor-suppressive miRNA/mir-663 gene induces MC-associated growth arrest in human gastric cancer cells (Pan et al. 2010). MC in tumors is also induced by cancer therapy, in particular radiation (Hendry and West 1997; Shinomiya 2001; Eriksson and Stigbrand 2010) and chemotherapy (Portugal et al. 2010). This form of MC in tumor cells is associated with treatment-induced senescence of these cells (Roninson et al. 2001). In radiation-induced MC, one potential mechanism is centrosome amplification, which is induced by radiation and which can result in the formation of multipolar mitotic spindles (Dodson et al. 2007).

In addition to a p53-related cell death pathway, p53 null cells or cells with defective p53 can undergo MC-associated cell death in the absence of a G1 checkpoint as a result of mechanical disruption induced by centrosome overduplication/amplification (Fragkos and Beard 2011). Cells overexpressing the centrosome protein CP110 or depleted of cyclin F, which targets CP110 for destruction, have more than two centrosomes and undergo MC. p27(Kip1) sequesters cyclin F, which prevents its interaction with and the subsequent degradation of CP110, resulting in centrosome amplification (Sharma et al. 2012). DNA-damage-induced centrosome amplification itself is a common event in malignant neoplasms and promotes genomic instability (Pannu et al. 2012). Centrosome amplification is mediated by Ckh1, which causes G2 checkpoint activation after DNA damage. Overriding G2 checkpoint leads to mitotic slippage, cell cycle reentry in G1, and subsequent G1 arrest associated with senescence or MC (Poehlmann et al. 2011). Centrosome amplification can occur through centriole disengagement (Inanç et al. 2010). Centrosome amplification is also induced by MCT-1, a centrosomal oncoprotein involved in mitosis. Knockdown of MCT-1 protein results in intercellular bridging, chromosome mis-congregation, cytokinesis delay, and MC (Shih et al. 2012). MC in tumor cells has been proposed to be an oncosuppressive mechanism that avoids genomic instability and causes transformed cells with a defective DNA to enter MC-associated apoptosis which eliminates the "dangerous" defective cells (review: Vitale et al. 2011). However, malignant neoplasms can also circumvent MC and its effects. In some malignancies, survivin (BIRC5) is upregulated and protects the cells from MC-associated cell death (Lamers et al. 2011). In HBV-positive hepatocellular carcinoma cells, disruption of kinase activities of ATM and ATR results in formation of multinucleated giant cells and promotes MC (Wang et al. 2012).

Necrobiology of Liver Cancer: Necrosis and Necroptosis

178

Contents

Abstract

Necrosis is a non-apoptotic form of cell death that comprises a broad spectrum of regressive changes and their causes. Formerly, all forms of necrosis, including that occurring in neoplasms, were regarded as a passive process, ischemic necrosis being a typical examples. Passive necrosis of the tissue in the absence of oxygen or other fuels, or due to physical stress such as heat or freezing, certainly occurs. However, recent findings show that various forms of necrosis are not an uncontrolled, passive, or even chaotic process, but rather a regressive change that is subject to programmed initiation and progression (regulated necrosis). Initiation of regulated necrosis requires a complex cross talk of target cells involving various signaling pathways that regulate cell survival versus non-survival. The signaling platform that regulates orderly initiation and progression of necrosis is the so-called necrosome, a platform that senses cellular ATP depletion and transmits signals of cellular stress to a system of kinases with a death domain. These are the receptor-interacting protein (RIP) serine/threonine kinases, RIP1 and RIP3, which act as execution switches in regulated necrosis. Programmed necrosis is also termed necroptosis, in analogy to apoptosis.

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_178

Necrosis: Unregulated Versus Regulated Necrosis

Necrosis, a long known non-apoptotic form of cell and tissue death that represents a broad spectrum of decay patterns also predominating in cancers, has previously been regarded as a "passive," unregulated, or even "chaotic" phenomenon. For example, ischemic necrosis was thought to happen because cells have exhausted their oxygen and fuel resources and then "just die." There are certainly forms of necrosis characterized by passive cell decay, e.g., in situations of massive and abrupt failure of oxygen and/or fuel supply, or due to physical stress such as heat or freezing. However, recent findings clearly show that certain forms of necrosis are not an uncontrolled process, but rather a regressive change that is as well programmed and controlled as apoptosis (regulated necrosis, RN; reviews: Leist and Nicotera 1997; Nicotera et al. 1999; Proskuryakov et al. 2002, 2003; Festjens et al. 2006; Golstein and Kroemer 2007; Vanlangenakker et al. 2008; Proskuryakov and Gabai 2010; Galluzzi et al. 2014).

Morphology of Tumor Necrosis in Liver Cancers

Necrosis of Hepatocellular Carcinoma: Macroscopy

The macroscopic presentation of necrosis in hepatocellular carcinoma (HCC) depends on the extent of the necrosis and cellular/stromal composition of the tumors. On cut surfaces of non-fixed tumors, small necrotic foci appear as whitish speckles or yellowish-white soft spots. Such necroses are mainly seen in neoplasms with a high parenchyma-to-stroma ratio and in poorly differentiated cancers with high cellularity. Multiple spotty necroses may be associated with small hemorrhages. Large necroses, which often occupy central parts of tumors, show a soft mass of grayish-white tissue with an either homogeneous or slightly granular texture. In cellular, stroma-poor (medullary) fresh neoplasms, the center of necrosis may drop off after cutting or part of the necrotic tissue sticks to the knife. Following fixation, the cut surface of large necroses typically shows cracks or slits. The centermost part of necrosis sometimes undergoes liquification, leaving a cyst-like space, but large cysts are unusual in HCCs. Tumors with lower cellularity and higher content in extracellular matrix and stroma usually display a more compact type of necrosis and more often a granular cut surface. In part of neoplasms with a medullary, highly cellular composition (encephaloid liver cancer; Rokitansky 1852), cutting with a knife results in release of viable cells and necrotic cells leaving a creamy matter on the blade (the "cancer juice" or "cancer milk" of old pathology descriptions). Large necroses may undergo massive hemorrhage, sometimes resulting in a lesion that can hardly be distinguished from a hematoma. In HCCs invading the biliary tract, bile can enter the tumor and cause yellow staining of necroses. Rarely, large necroses become infected, resulting in abscess formation in the necrotic tissue. Massive macroscopic necrosis is also found in HCCs invading the portal or hepatic veins and in tumors invading the biliary tract. Necrotic intrabiliary HCC can give rise to so-called intraductal tumor emboli. As liver cancers are highly arterialized, complete interruption of the arterial supply, i.e., due to thrombosis and/or extensive tumor invasion, results in massive ischemia followed by anemic tumor infarction. Marked necrosis of HCCs located close to the hepatic capsule may result in tumor rupture, necrotic tumor tissue with or without gross hemorrhage escaping through capsular gaps into the peritoneal space. In patients with ascites, necrotic tumor fragments are then found floating in the ascitic fluid and can settle in the pelvic Douglas recessus.

Necrosis of Hepatocellular Carcinoma: Histopathology

Histologically, necrosis usually presents the phenotype of coagulation necrosis, with an eosinophilic and slightly granular mass. Remnants of tumor cells may be seen as ill-defined eosinophilic

bodies (ghost cells), with or without chromatin dots. Pycnotic tumor cell nuclei and karyorrhectic structures are found (Figs. 1, 2, 3, and 4). Toward the periphery of tumor nodes, a gradual transition from necrotic cells to viable cells is seen. In case of preserved and perfused tumor vessels, the vessels are surrounded by a rim of viable carcinoma cells, forming a cuff up to about ten cells thick. The former architecture of the tumor is discernible in reticulin stains, where also the tumor vessels are visualized. The macrotrabecular structure of HCCs is often still present in reticulin preparations of necrotic tumors, an important element for diagnosis. Some necroses exhibit dystrophic calcifications.

Cholangiocarcinoma

In contrast to HCCs and metastatic carcinomas, many forms of extrahepatic and intrahepatic cholangiocarcinomas usually do not exhibit

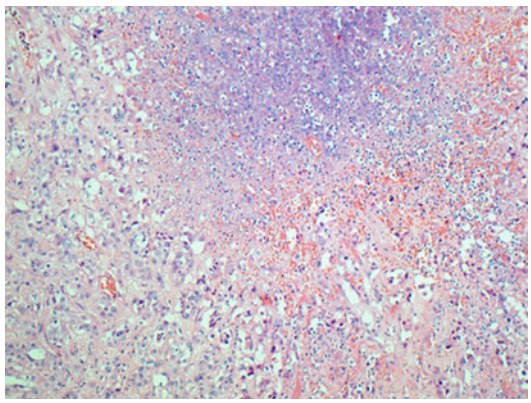

Fig. 1 Fresh hypoxic/ischemic tumor necrosis. The basophilic area (*top half* of figure) contains numerous nuclear debris (karyorrhexis) and pycnotic nuclei (hematoxylin and eosin stain)

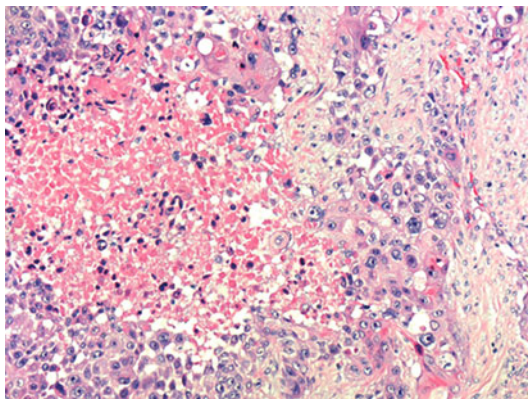

Fig. 2 Ischemic/hypoxic necrosis of hepatic carcinoma. Necrosis (*left half* of figure) is characterized by eosinophilic cell shadows (cells undergoing cytolysis and karyolysis) and accumulation of pycnotic, condensed nuclei, and karyorrhectic debris (hematoxylin and eosin stain)

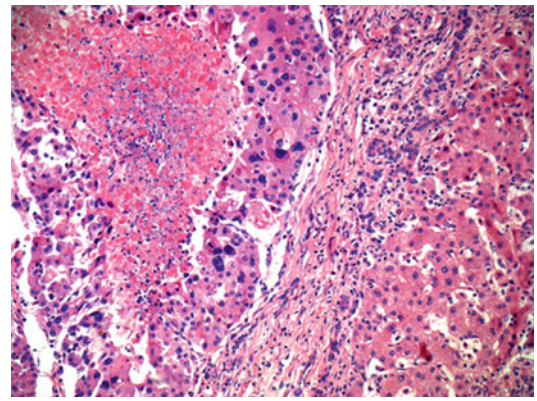

Fig. 3 Hepatocellular carcinoma with hypoxic/ischemic necrosis. Tumor tissue facing perfused blood vessels (*middle* and *left*) remains intact with a perivascular cell layer not exceeding approximately ten cells, while cells beyond this sufficient oxygen diffusion distance underwent necrosis (hematoxylin and eosin stain

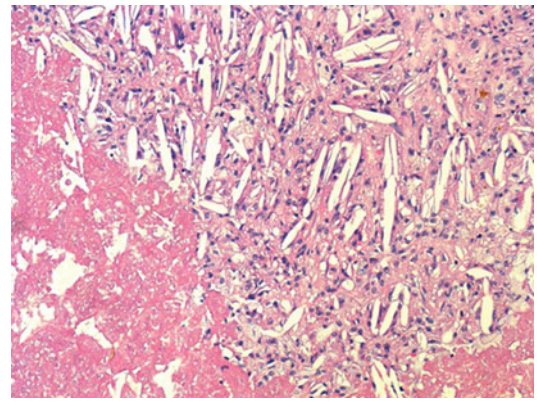

Fig. 4 In older tumor necrosis, cholesterol crystals can be formed from decay of cell membranes with cholesterol release, associated with a macrophage reaction (hematoxylin and eosin stain)

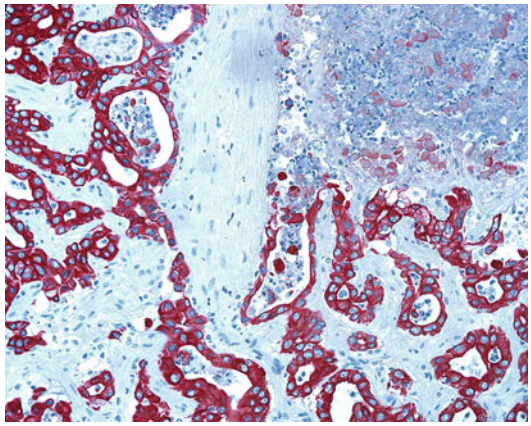

Fig. 5 Cholangiocarcinoma with focal necrosis (*right upper corner*). In this cytokeratin stain, necrotic tumor cells in part still express minor amounts of cytokeratins. There is an abrupt transition from viable to necrotic cancer tissue (CAM5.2 immunostain)

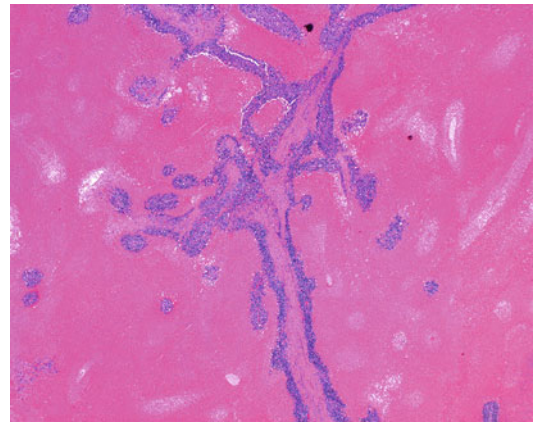

Fig. 6 Small cell undifferentiated carcinoma with hypoxic/ischemic necrosis. Most of the neoplasms consist of an eosinophilic necrotic mass. Preserved tumor cells form perivascular basophilic cuffs with a characteristic width depending on the oxygen diffusion distance (hematoxylin and eosin stain)

large, soft, and friable necroses, predominantly due to the high stromal content. Hilar/perihilar cholangiocarcinomas (Klatskin tumors) are firm tumors that are devoid of mass necrosis, but may show small necrotic foci at macroscopic examination. Larger necroses are eventually encountered in mass-forming intrahepatic cholangiocarcinoma, but are more commonly found in large intraductal tumors. In the latter, and similar to HCC, necrotic parts may detach from the main tumor (tumor amputation), float within the ductal system, and eventually cause obstruction (so-called tumor emboli). Histologically, tumor necrosis ranges from small necrotic foci to large areas with effacement of the tumor structure (Fig. 5). In tumors undergoing ischemic necrosis, amputation of stroma may be seen, with an abrupt transition of cancer cell-containing stroma to acellular areas. In connective tissue stains, the original structure of the stroma may still be discerned.

Liver Metastasis of Carcinomas

Necrosis of carcinoma metastases of the liver mainly depends on tumor type, differentiation/grade, tumor size, vascularization mode/hypoxia, and genomic instability. Massive metastatic necrosis is frequently found in large and poorly differentiated tumors, but also well-differentiated carcinomas can show marked necrosis in case they are large and poorly vascularized. Small metastatic foci often display necrosis when the neoplasms exhibit rapid proliferation associated with genomic instability and abnormal mitotic pathways and poor differentiation. In this situation, subsets of tumor cells can undergo a sudden "crash" visualized as necrosis with numerous shadow cells. Also small metastatic lesions are subject to hypoxia causing ischemic necrosis. Here, a thin rim of preserved cells, often with a thickness of around ten cells, remains as a cuff surrounding a feeding blood vessel, followed by a rather abrupt transition into necrotic tumor tissue (Fig. 6). This phenomenon is caused by sudden failure of oxygen diffusion into a zone beyond a distinct stretch of a few perivascular cells. Large metastases, in particular colorectal carcinomas, show a characteristic form of necrosis. It is characterized by a central zone of complete or almost complete tissue breakdown, with loss of texture, a pale eosinophilic mass with some shadow cells, few nuclear fragments, and traces of tumor vessels. The latter can be shown in more detail by the use of connective tissue stains and specifically reticulin stains. The central tumor necrosis can contain dystrophic calcifications. Long-standing

metastases can undergo cystic change. The lesions may also be infected by bacteria, but purulent inflammation of even abscess formation is unusual in large metastases, because neutrophils cannot infiltrate the necrotic tissue owing to loss of perfused vessels. In case the necrotic metastasis involves bile ducts in the vicinity, bile can enter the necrotic tumor, staining it yellow. The central necrosis blends into a more peripheral zone where some remnants of preserved carcinoma tissue are found. Tubular or cribriform structures may look like "amputated," with a necrotic part facing the tumor center and a viable part facing the tumor periphery. Many necrotic metastases exhibit a viable rim of cancer tissue at the periphery, where tumor blood flow is preserved, but there are also lesions that are apparently completely necrotic. In metastases having been treated with chemoembolization, the necrotic tissue contains visible embolization material, either within damaged blood vessels or freely within tumor tissue.

Necrosis and the Necrosome: Necrosis as a Controlled Process

In the initiation and progression of necrosis, cells involved in this process engage in a complex cross talk based on various signaling pathways that regulate survival versus non-survival. The platform that is in the center of this interactome and the associated signaling pathways is the so-called necrosome, a platform that reacts to intracellular ATP depletion (see below; reviews: Nicotera et al. 1998; Galluzzi et al. 2011). There is evidence that the receptor-interacting protein (RIP) serine/threonine kinases, RIP1 and RIP3 kinases, with a death domain, act as a central switch in initiation of necrosis, while progression is strongly influenced by reactive oxygen species (ROS) and calcium ions (Festjens et al. 2006). In the setting of necrosis, RIP1 and RIP3 are activated by numerous signals, including TNF, TRAIL, oxidative stress, and DNA damage-associated activity of poly-ADP-ribose polymerase (Vandenabeele et al. 2010b; Cho et al. 2011). In TNF-induced necrosis, mixed lineage kinase domain-like (MLKL) is a key RIP3 downstream component, whereby MLKL is recruited to the necrosome through its interaction with RIP3. MLKL is also required for the generation of ROS and a late-phase activation of JNK (Zhao et al. 2012). Activated RIP1 initiates mitochondrial permeability transition (MPT), which in turn results in mitochondrial collapse and the activation of various proteases that act on membranes and organelles, including phospholipases, calpains, and cathepsins, followed by the typical decay of organelles, destruction of the nuclear membrane, and fragmentation of the cell surface membrane (Proskuryakov and Gabai 2010). Normal and cancer cells undergoing necrosis release, during the dying process, numerous signaling substances, including chemokines and cytokines, that can drive a necrosis-associated inflammatory response. A central place in the initiation of this necrosis-associated inflammation is hold by the necrosome, which releases a spectrum of signaling components, specifically RIP1, RIP3, and caspase-8 (review: Wallach et al. 2011).

Secondary Necrosis

In some situations, apoptosis can undergo a transition to a form of necrotic cell death involving the activation of self-hydrolytic enzymes, irreparable damage of cell membranes, and swelling of cells and apoptotic bodies. This process is called secondary necrosis. In vivo, secondary necrosis occurs when massive apoptosis overwhelms scavenging capacity or when scavenger mechanisms are impaired (review: Silva et al. 2008; Silva 2010).

Necroptosis, Necrosome, Necroapoptosis, Aponecrosis, and Necrotaxis

Necroptosis and the Necrosome

In cells lacking the capacity to activate caspase-8 following death receptor binding, cell death does not occur by apoptosis, but rather by a process termed programmed necrosis, or necroptosis

(reviews: Dunai et al. 2011; Lu and Walsh 2012; Wu et al. 2012; Zhou et al. 2012; Fayaz et al. 2014; Giampietri et al. 2014; Linkermann and Green 2014; Murphy and Silke 2014; Van den Berghe et al. 2014; Wei et al. 2014). Necroptosis may represent an isolated element of what is necrosis in its modern concept and is mediated by the necrosome. Apart from its role in the elimination of neoplastic cells, necroptosis is a process active in the regulation of several types of inflammation (Pasparakis and Vandenabeele 2015). The RIP kinase (receptor-interacting protein kinase (RIPK))-containing necrosome is a multiprotein platform that triggers cell death by necroptosis. In principle, necroptosis is a cell death receptor-induced, but caspase-independent regulated type of programmed cell death with morphological resemblance to classical necrosis (Dunai et al. 2011). Necroptosis requires a functional ripoptosome/necrosome in the absence of caspase-8, hence depends on functional RIP1 and RIP3 serine/threonine kinases (RIPK1 and RIPK3; the RIP1-RIP3 necrosome; Lee et al. 2003; Cho et al. 2009; Moriwaki and Chan 2013; Khan et al. 2014; Newton et al. 2014) that are recruited by death receptors (Vandenabeele et al. 2010a; Smith and Yellon 2011) and can be induced by TNF that can activate the critical receptor-interacting protein kinase 3 (RIPK3) in the absence of RIPK1 (Moujalled et al. 2013). In the TNF alpha-induced necrosome, RIP1 is deubiquitinated by the cylindromatosis (CYLD) protein, CYLD thereby controlling RIP1 kinase activity during necrosome assembly (Moquin et al. 2013). A further protein contained in the necrosome is mixed lineage kinase domain-like (MLKL), a pseudokinase required for the necroptosis pathway downstream of RIPK3 (Murphy et al. 2013). Necroptosis caused by RIPK3 requires MLKL which in turn is activated by RIPK3 (Moujalled et al. 2014). The kinases of the RIP1/RIP3 necrosome can form a thioflavine-T- and Congo red-positive beta-amyloid-like signaling complex with a fibrillar core structure (Li et al. 2012). Necroptosis can also be induced by TRAIL (tumor necrosis factor (TNF)-related apoptosis inducing ligand), a well-known apoptosis inducer, via involvement of RIPk1-/RIPK3-dependent PARP-1 (poly-ADP-ribose polymerase-1) activation (Jouan-Lanhouet et al. 2012). The execution of necroptosis requires production of reactive oxygen species (ROS) by the mitochondria. This pathway is linked to RIPK1-dependent phosphorylation of STAT3, which in turn induces interaction with GRIM-19, a subunit of the mitochondrial complex I, with subsequent translocation of STAT3 to the mitochondria, where it induces ROS generation (Shulga and Pastorino 2012). Necroptosis can specifically be inhibited by small molecular inhibitors such as necrostatin-1 (Nec-1; Tischner et al. 2012), suggesting that modulation of necroptosis might be employed in cancer therapy (Yu et al. 2013). Necroptosis is linked to release mechanisms for DAMPs (damage-associated molecular patterns), in that RIP1 interacts with a Toll-like receptor 3-induced adaptor, TICAM-1/TRIF involved in DAMP release (Seya et al. 2012).

Necroapoptosis and Aponecrosis

The term necrapoptosis was chosen to emphasize shared mitochondrial pathways in apoptosis and necrosis, involving the mitochondrial permeability transition (MPT), a process characterized by opening of a high-conductance pore conducting solutes of a molecular mass $<$1,500 Da. The availability of ATP decides whether apoptosis or rather necrosis develop (Nicotera et al. 1998, 1999; Lemasters 1999; Lemsters et al. 1999). Others employed the term aponecrosis to denote this form of cell death intermediate between apoptosis and necrosis (Formigli et al. 2000).

Necrotaxis

Necrotaxis denotes an apparently distinct type of chemotaxis in which positive chemotactic or chemokinetic stimuli are released from necrotic tissue or apoptotic cells (Hu and Barnes 1970; Bessis 1974; Debru 1993). Necrotaxis may play a role in the clearance of necrotic or apoptotic cells and involves the attraction of phagocytes to

dead cells or fragments thereof. There is evidence that necrotic or apoptotic cells and tissue components can also repel phagocytes, a phenomenon termed negative necrotaxis (Ragot 1993).

The Apoptosis-Necroptosis Switch

Which mechanisms decide whether a cell death program switches from apoptosis to necroptosis or other forms of regulated necrosis? When caspase-8 is activated, it drives the process along the apoptosis program and blocks RIPK3-dependent necroptosis. Prolonged and marked activation of TAK1 kinase by TNF induces phosphorylation and activation of RIPK3 leading to regulated necrosis without caspase activation, whereby RIPK1 and RIPK3 promote TAK1 kinase in positive feedforward loop (Morioka et al. 2014). Depletion of RIPK3 or MLKL blocks TNF-driven necroptosis and drives the pathway toward a delayed RIPK1-dependent apoptosis (Remijsen et al. 2014).

Abstract

Autophagy is a process involved in the maintenance of cell and tissue homeostasis, control of protein composition of cells, aging, senescence, and neoplastic transformation. Autophagy induced by oxidative or hypoxic stress, nutrient deprivation, and DNA damage serves to eliminate altered or misfolded proteins, degrade damaged or superfluous organelles, and get rid of pathogens. There are three types of autophagy, i.e., macroautophagy, microautophagy, and chaperone-mediated autophagy. Macroautophagy transports cargo to lysosomes through the autophagosome, a membrane-bound vesicle. This pathway can interact with apoptosis and necroptosis in a complex manner. Autophagy is also connected with inflammasome function, inflammation, and immunogenic cell death. There are several specific autophagic pathways involving organelles, including mitophagy, pexophagy, lipophagy, and nucleophagy. Autophagy is closely connected with the mechanisms that induce and regulate senescence, a process by which normal cells cease to divide, perceived as aging mechanisms and a cancer barrier.

Introduction

Definitions

Autophagy (from Greek, "eating of self") is an important process of ordered self-degradation that plays a role in various pathophysiologic reactions, including nutrient deprivation, hypoxia, oxidative stress, and DNA damage. In particular, autophagy serves to eliminate altered, aggregated, or misfolded proteins that might damage the cell, degrade damaged organelles, and get rid of intracellular pathogens (reviews: Gozuacik and Kimchi 2004; Yang et al. 2005; Williams et al. 2006; Dengjel et al. 2008; Galluzzi et al. 2008; Esclatine et al. 2009; Dalby et al. 2010; Glick et al. 2010; Klionsky et al. 2010; Mehrpour et al. 2010; Dengjel et al. 2012; Liu et al. 2013). Autophagy can also regulate distinct forms of cell death, such as necroptosis (Ryter et al. 2014). There are three defined types of autophagy, i.e., macroautophagy, microautophagy, and chaperone-mediated autophagy (Feng et al. 2014). All types share the capacity to proteolytically degrade cell components in lysosomes.

Macroautophagy: The Autophagosomal Pathway

Macroautophagy transports cargo to the lysosome through a membrane-bound vesicle, the autophagosome which fuses with the lysosome to form the autolysosome. The biogenesis of an autophagosome starts with ER-or trans-Golgi-derived membrane component, the phagophore, which can engulf cytoplasmic proteins and organelles to become a cargo-loaden autophagosome. In microautophagy, cargo is directly delivered to the lysosome through a lysosomal invagination. In chaperone-mediated autophagy, targeted proteins are translocated through the lysosomal membrane in a complex with chaperones/heat shock proteins recognized by a lysosomal membrane receptor, LAMP-2A/lysosomal-associated membrane protein 2A (review: Glick et al. 2010). Formation of the critical phagophore as an initial cargo-seeking structure is tightly regulated by several signaling pathways.

Autophagosome Biogenesis

Autophagosome biogenesis requires deformation and induction of curvatures in the membranes. This bending activity is mediated by the Bax-binding protein, Bif-1 (endophilin B1), a protein which forms complexes with beclin 1. Bif-1 interacts with beclin 1 via UVRAG (Takahashi et al. 2007). Bif-1 accumulates in punctate foci where it colocalizes with light chain 3 protein, Atg5, and Atg9. Specifically, Bif-1-positive crescent-shaped vesicles expand by fusing with Atg9-positive membranes to complete autophagosome formation (Takahashi et al. 2009). Macroautophagy is regulated by endoplasmic reticulum stress, in that the unfolded protein response/UPR associated with ER stress

and reticulophagy can induce autophagy (Deegan et al. 2013).

Autophagy: Induction and the Autophagosomal Proteome

Autophagy is induced by numerous proteins (the autophagosomal proteome; Becker et al. 2012), some of which are oncogenes, including TGF-beta, Atg4c, beclin 1, Bif-1, BH3-only proteins, DAPK1, tuberous sclerosis complexes, death-associated protein kinase 1, LKB1, PTEN, and UVRAG (Maiuri et al. 2009; Morselli et al. 2009; Park et al. 2009a,b; Suzuki et al. 2010). The autophagic process is initiated by mTOR phosphorylation of the serine/threonine kinase ULK1 (autophagy-initiating kinase ULK1/Unc-51-like kinase 1; Dunlop and Tee 2013). ULK1 kinase is, however, also an mTOR-independent node in a complex kinase network (Bach et al. 2011). The Beclin-1 (Atg6) complex is an important initiation factor for the initial step of autophagosome formation and is directly targeted by signaling pathways that involve mTOR (Cao and Klionsky 2007; Pattingre et al. 2008). Beclin-1, which is a key regulator of autophagy, acts as a haploinsufficient tumor suppressor. Beclin 1 has several interaction partners. In the human phosphatidylinositol 3/PI(3)-kinase class III complex, beclin 1 directly interacts with Barkor (Beclin 1-associated autophagy-related key regulator), a protein that is required for autophagosome formation (Sun et al. 2008). A further mediator of the class III PI(3)kinase complex is Bif-1 (endophilin B1), a protein that interacts with beclin 1 through UVRAG. In response to nutrient deprivation, Bif-1 localizes to autophagosomes where it colocalizes with Atg5 and the microtubule-associated protein light chain 3 (Takahashi et al. 2007). Beclin 1 forms two distinct PI(3)-kinase complexes with Atg14 and UVRAG (Itakura et al. 2008). Beclin-1 interacts with the PI-3 kinase, Vps34/vesicular protein sorting 34, forming a complex which is selectively involved in autophagy. PtdIns3P synthesized by Vsp34 are crucial components for autophagy induction and accumulate in membrane extensions of the ER, structures called omegasomes. Proteins that interact with this complex in an autophagy-promoting manner are ubiquitin-like proteins (Atg12, Atg8, and Atg16L; Noda et al. 2008), Bif-1, UVRAG, Atg14L, and Ambra, while autophagy inhibitors include Rubicon and Bcl-2. Bif-1 is directly involved in phagophore biogenesis. Induction of autophagy requires the ULK1 protein kinase complex, which co-localizes with omegasomes (Karanasios et al. 2013).

The Lysosomal Degradation Pathway of Autophagy

At the end of any autophagic process is the lysosomal degradation pathway, an attractor for macroautophagic (autophagosomal), microautophagic, and chaperone-dependent autophagic processes (Shen and Mizushima 2014). Autophagic pathways and endosome/lysosome biogenesis are closely linked. Atg5, an autophagosomal protein, is required for the biogenesis of late endosomes and lysosomes in an autophagy-independent manner (Peng et al. 2014). The small GTPase Rab 11 plays an important role in the "docking" of autophagosomes to late endosomal compartments. Rab11 shifts from recycling endosomes to autophagosomes in response to autophagy induction via removing Hook, a negative regulator of endosome maturation, from mature endosomes (Szatmari et al. 2014).

In order to reach their degradation compartment, autophagosomes are transported along microtubule tracks of the cytoskeleton to fuse with late endosomes or lysosomes. As in other vesicular transport systems, the small GTPase Rab7 is implicated in autophagosomal transport and fusion. Autophagosomal membranes harbor the lipid PtdIns3P and phosphatidylethanolamine-conjugated Agt8/LC3/GABARAP family proteins. The FYVE and coiled-coil domain containing 1 (FYCO1) binds to both LC3, PtdIns3P and Rab7, and functions as an adaptor linking autophagosomes to microtubule plus end-directing molecular motors. FYCO1 is selectively recruited to autophagosomal membranes via a mechanism

involving a conformational change upon LC3-LIR interaction to expose the FYVE domain for PtdIns3P. The autophagy flux through lysosomes is regulated by DNA damage-regulated autophagy modulator 1/DRAM1 (Zhang et al. 2013). In the course of necrosis, dying cells release HMGB1, a mobility group box q1 protein with immunostimulatory functions. HMGB1 also plays important intranuclear, cytosolic, and extracellular roles in the regulation of autophagy, in that HMGB1 is Beclin 1-binding protein active in autophagy (Kang et al. 2011a). Autophagy-associated release of HMGB1 protects cancer cells from many chemotherapeutical agents, in that extracellular HMGB1 protects cancer cells from apoptosis through transcriptional upregulation of Mcl-1 (Zhan et al. 2012). On the other hand, the danger signaling protein HMGB1 induces a distinct form of cell death which in cancer cells depends on the presence of mitochondria. HMGB1 induces a rapid depletion of mitochondrial DNA, severe damage to the mitochondrial proteome, and the formation of giant mitochondria (Gdynia et al. 2010).

Autophagy and Apoptosis

Autophagy interacts with apoptosis in a complex manner (Booth et al. 2013). Beclin 1 fails to stimulate apoptosis (Boya and Kromer 2009). The antiapoptotic proteins Bcl2-2 and Bcl-xL negatively regulate autophagy by directly binding to beclin 1 (Luo and Rubinsztein 2010). This interaction involves a Bcl-2 homology 3/BH3 domain in beclin 1 (Levine et al. 2008) and can be abolished by ubiquitination of beclin 1 (Kang et al. 2011b). A critical negative regulator of Fas-mediated apoptosis, the Fap-1 protein phosphatase, is degraded by autophagy, providing a further link between apoptosis and autophagy (Joshi and Ryan 2013). The autophagosomal membrane serves as a platform for DISC-mediated caspase-8 activation (Young et al. 2012). On the autophagosome, caspase-8 aggregation is promoted by the p62/sequestosome-1, an atypical protein kinase C-interacting protein that is involved in various signaling pathways (Huang et al. 2013; Zotti et al. 2014). In the autophagic process, p62 directly interacts with Bcl-2 and disrupts the association between Bcl-2 and beclin 1 (Zhou et al. 2013). By its function in autophagosomal function, the scaffold protein p62 also links autophagy with oxidative stress pathways active in cancer, as this protein directly interacts with the ubiquitin ligase adaptor Kelch-like ECH-associated protein1/KEAP1, which results in constitutive activation of the transcription factor NF-E2-related factor 2/NRF2, two proteins involved in a stress response pathway and that are frequently mutated in cancer (Nezis and Stenmark 2012). KREAP1 itself is degraded by autophagy which thus regulates KEAP1 and redox homeostasis in the liver (Taguchi et al. 2012).

Autophagy-Mediated Necroptosis

Autophagy is linked to apoptosis and necroapoptosis in a complex manner. In particular, autophagy plays something as a "compensatory" role in the elimination of neoplastic cells having become resistant to apoptosis, acquired apoptosis resistance being a major element in the development of chemoresistance in therapeutic settings. Autophagy can modulate apoptotic pathways through the degradation of proapoptotic factor versus antiapoptotic factors. There is, e.g., a JNK-mediated autophagy pathway that induces the degradation of antiapoptotic cIAPs, thereby promoting autophagy-mediated necroptosis (RIP1- and RIP3-dependent necrosis). This pathway is dependent on JNK-mediated phosphorylation of Bcl-2 and Bcl-xL and dissociation of Bcl-2 or Bcl-xL from the autophagy factor, Beclin-1. In addition, this pathway involves formation of the ripoptosome that contributes to necroptosis (He et al. 2014).

Autophagy in Hepatocellular Carcinoma

Autophagy plays an important role in pathways of tumor cell elimination, but this mode of tumor suppression predominantly works in early cancer. In established or advanced tumors, autophagy acts as a cytoprotection mechanism to promote cancer

cell survival (Chen and Karantza-Wadsworth 2009; Chen and Debnath 2010; Dalby et al. 2010; Reyjal et al. 2014). Autophagy has a tumor promoter role by suppressing the p53 response, maintaining mitochondrial function, and promoting metabolic homeostasis (Guo et al. 2013). Autophagy also exerts an influence on cancer cells through its effects on stromal cells and immune cells, mainly tumor-associated macrophages/TAMs, acting against tumor cells. Autophagy in cancer-associated fibroblasts promotes tumor cell survival, mediated by induction of hypoxia-induced factor 1alpha (Martinez-Outschoom et al. 2010). Targeting of nuclear factor-kappaB by autophagy is involved in the polarization and activation of HCC-associated TAMs (Chang et al. 2013). Autophagy is a key factor in innate immunity and regulates the production of macrophages at different developmental stages of these cells (Chen et al. 2014).

Similar to normal cells, Beclin-1 plays an important role in autophagy regulation in HCCs. Beclin-1 levels are lower in HCCs than in nonneoplastic liver, suggesting a downregulation of autophagy in HCCs (Shi et al. 2009; Kotsafti et al. 2012). Autophagy in HCCs is stimulated by TGF-beta, associated with accumulation of autophagosomes in HCC cells, conversion of microtubule-associated protein light chain 3 and enhanced degradation rate of long-lived proteins. The induction of autophagy by TGF-beta occurs significantly earlier than the induction of apoptosis (Kiyono et al. 2009). The finding that p62 protein is increased in HCCs suggests that HCCs are autophagy defective (Bao et al. 2014). In HCCs, the autophagy-related marker LCs (light chain 3) predicts prognosis, in that LC3 expression is related with longer time to recurrence and overall survival (Lee et al. 2013). Autophagy enhances HCC progression by activation mitochondrial beta-oxidation, in that autophagy promotes hypoxia-inducible factor-1alpha-mediated proliferation through the maintenance of intracellular ATP linked to an activated mitochondrial beta-oxidation (Toshima et al. 2014). Autophagy is activated in metastatic colonization of HCC, but not in invasion, migration, and detachment of HCC cells (Peng et al. 2013). In HCC cells, inhibition of the Hedgehog signaling pathway induces autophagy via upregulation of the proapoptotic protein, Bnip3 (Wang et al. 2013). HCC cells exposed to endoplasmic reticulum stress revealed a significant accumulation of autophagosomes and increased conversion of LC3-I to LC3-II as well as an increased autophagic flux (Ma et al. 2013). microRNA-375 inhibits autophagy in HCC cells and reduces the viability of these neoplastic ells under hypoxic conditions (Chang et al. 2012).

Autophagy: Connections with Immunity and Inflammation, and Immunogenic Cell Death/ICD

Introduction

Autophagic pathways are closely linked with certain mechanisms that operate in immunity (Yuk and Jo 2013). Nod-like receptors (NLRs), proteins that are cytoplasmic sensors for microbial molecules (cytoplasmic pattern recognition receptors), interact with autophagy-associated proteins (Carneiro and Travassos 2013). This interaction has a broad range of effects, as the various species of NLRs have different functions. NRLRC5 and CIITA regulate antigen presentation, NLRP1, NLRP3, NLRC1, and NLRC4 act in pathogen/damage sensing, and NLRC3, NLRP6, NLRP12, and NLRX1 suppress or modulate inflammatory responses (Lupfer and Kanneganti 2013).

Inflammasomes

NLRs are components of the inflammasome, large multiprotein platforms and guardians of cell and tissue integrity, sensors of metabolic stress, and critical regulators of immune reactions (Lamkanfi and Dixit 2009; Jin and Flavell 2010; Schroder and Tschopp 2010; Gross et al. 2011; Leemans et al. 2011; Haasken and Sutterwala 2013; Tsuchiya and Hara 2014). The central role of inflammasomes in immunity is underlined by the fact that mutations in NLRP3 activity cause severe autoinflammatory disease (Lawlor and Vince 2014). Inflammasome

assembly depends on several NLR family members such as NALPs (pyrin domain-containing NLRs), NAIP, and IPAF.

Inflammasomes as Mediators of Cell Death

Apart from danger signals derived from infectious agents and cancer cells, the NLRP3 inflammasome is activated by reactive oxygen species released from dysfunctional mitochondria (Tschopp 2011), a further link to cell death pathways. Inflammasomes and their activated inflammatory caspases (caspase-1 and caspase-5) are critical mediators of immunity and inflammatory reaction directed against microorganisms and cells expressing neoantigens, including cancer cells (Martinon and Tschopp 2007; Wen et al. 2013). The canonical pathway in inflammasomes involves activation of caspase-1, which in turn results in the release of interleukins 1beta and -18 in response to danger signals. The noncanonical inflammasome pathway is mediated by caspase-11 and leads to release of interleukins 1beta, -18 and -1alpha, and promotes pyroptosis (Vigano and Mortellaro 2013).

Inflammasomes contain proteins that participate in immune mechanisms linked to cell death, including the adapter molecules ASC, IPAF, and cryopyrin/Nalp3 which regulate the inflammatory caspases, caspase-1, and caspase-5. In inflammasomes, activation of caspase-1 results in cleavage and activation of proinflammatory cytokines (Mariathasan 2007; Martinon et al. 2007). In HCCs, caspase-1 activated by hypoxia induces the release of IL-1beta and IL-18 which in turn promote invasion and metastasis (Yan et al. 2012). On the other hand, inflammasomes mediate pyroptotic and apoptotic cell death, in that active caspase-1 mediates pyroptosis through an unknown mechanism, and activated inflammasomes can recruit procaspase-8, thus initiating apoptosis (Aachoui et al. 2013).

It is expected that damage-sensing NLRs play a role in cancer cells undergoing injury, including liver cancer cells, and pave the track for autophagic cell elimination. Autophagy produces a link between tumor cell death and immunity (immunogenic tumor cell death, ICD) in that damage-associated molecular patterns/DAMPs enhance autophagy (Hou et al. 2013). DAMPs mediate immunogenic features of this form of cell death in their function as pattern recognition receptors that are in part emitted actively by cells undergoing ICD (Krysko et al. 2013). Proteins of the NLRP3 inflammasome, which orchestrates mechanisms of innate immunity and adaptive immune responses, are expressed in HCC cells as a function of tumor progression (Wei et al. 2014) and interact with proteins of the autophagic pathways. Reactive oxygen species escaping from injured mitochondria induce lysosomal damage in an NLRP3-dependent manner (Heid et al. 2013) and may thus modify lysosome-dependent autophagy. As mentioned above, the noncanonical inflammasome pathway related to caspase-11 activation promotes pyroptosis (Vigano and Mortellaro 2013).

Resistance to Apoptosis and Autophagy

Resistance to apoptosis is a key feature of many malignant neoplasms and is a phenomenon involved in cancer progression and treatment failure. Failure of apoptotic cell death can be circumvented by autophagy-related mechanisms that lead to elimination of cancer cells. Injured or stressed cells can release damage-associated molecular patterns/DAMps. Release of DAMP molecules contributes to autophagy induction and hence to cell decay. Autophagy in turn regulates DAMP release and degradation (Hou et al. 2013).

Organellophagy

There are numerous complex autophagic mechanisms that can elicit degradation and controlled elimination of damaged or superfluous organelles and cell nuclei. These processes are summarized under the term organellophagy (Table 1).

Table 1 Types of organellophagy

Type of phagy	Target of phagy
Mitophagy	Mitochondria
Pexophagy	Peroxisomes
Reticulophagy	Endoplasmic reticulum
Ribophagy	Ribosomes
Lipophagy	Lipid droplets (lipid organelles)
Ciliophagy	Cilia and associated structures
Nucleophagy	Nucleus
Nucleolophagy	Nucleolus

Mitophagy

Mitophagy as a Central Feature of Autophagy

In the setting of autophagic processes, mitophagy is a particularly important phenomenon. Mitophagy is the selective autophagic degradation of damaged and/or superfluous mitochondria and is regarded as an essential process for mitochondrial quality and quality control (reviews: Mijaljica et al. 2010a; Novak and Dikic 2011; Rambold and Lippincott-Schwartz 2011; Wang and Klionsky 2011; Hirota et al. 2012; May et al. 2012; Novak 2012; Okamoto and Kondo-Okamoto 2012). Mitochondria with their relatively small genome, their successive cycles of fission and fusion, and their exposition to oxidative stress are prone to damage, requiring a potent mechanism to eliminate "dangerously altered" mitochondria. There is evidence that mitophagy is an instrument not only to sense damaged mitochondria and eliminate them but that also the overall oxygen radical burden is sensed and the signal transmitted in a systematic or episodal removal of mitochondria (review: Gottlieb and Carreira 2010).

Mitophagy is an important mechanism to protect cells from the deleterious effects of damaged mitochondria, in particular apoptosis. Mitophagy can also mitigate an additional catastrophic event. Severe mitochondrial stress can cause the pathologic opening of the mitochondrial permeability transition pore(MPTP), followed by transient but massive release of calcium and radical oxygen species/ROS. This release reaction can trigger other mitochondria to undergo the same crisis, finally resulting in the activation of calcium-dependent proteases such as calpain, lipases (cPLA2), and ROS-activated iPLA2, steps that cause necrosis (reviews: Gottlieb and Carreira 2010). Mitophagy is the major instrument of the cell to regulate mitochondrial number and mass, and there is a regulatory cross talk between mitochondrial function and dysfunction, and mitochondrial abundance (Michel et al. 2011), suggesting the presence of a mitochondrial abundance sensor. Mitophagy belongs to the group of autophagic processes, which also comprise pexophagy, ER-phagy, ribophagy, golgiphagy, and nucleophagy. Autophagy, as discussed in a separate chapter, serves removing of altered proteins and dysfunctional organelles.

Mechanisms of Mitophagy

Injury of mitochondrial DNA, e.g., mtDNA mutations, can result in mitophagy (Gilkerson et al. 2012; de Vries et al. 2012). Mutations in the gene for ATPase type 13A2 (ATP13A2), involved in autosomal-recessive Parkinsonism (Kufor-Rakeb syndrome) are associated with a higher frequency of mtDNA lesions, increased oxygen consumption rates, fragmentation of the mitochondrial network, and mitophagy (Grünewald et al. 2012). Oxygen damage via reactive oxygen species (ROS) as potential mitochondrial damaging agents can normally be neutralized within the mitochondria through enzymatic activity. In case this system is overcharged, mitochondrial damage and mitophagy can occur (Lee et al. 2012). Elimination of mitochondria being overcharged with oxidized proteins via mitophagy is a mechanism suppressing cell damage by mitochondrial oxidative products (Kurihara et al. 2012). But also hypoxia causes mitochondrial injury leading to mitophagy.

PINK1-and Parkin-Mediated Mitophagy

The Parkinson disease-related proteins PINK1 (PTEN-induced kinase 1, a mitochondrially

localized serine/threonine kinase) and Parkin (PARK2, a cytosolically localized E3 ubiquitin ligase) are guardians of mitochondrial fidelity and are essential for targeting mitochondria for mitophagy (Matsuda and Tanaka 2010; Huang et al. 2011; Kane and Youle 2011; Springer and Kahle 2011; Youle and Narendra 2011; Jin and Youle 2012). The mitochondrial turnover of PINK1 and Parkin is tightly controlled. The mitochondrial intramembrane protease PARL cleaves human PINK1 within its conserved membrane anchor. Mature PINK1 is then free to be released into the cytosol or the mitochondrial intermembrane space. In PINK1-dependent mitophagy and following uncoupling of the outer mitochondrial membrane potential, the canonical import of PINK1 and PARL-catalyzed processing is blocked, leading to the accumulation of the PINK1 precursor. Accumulation of PINK1 precursor and its targeting to the outer mitochondrial membrane triggers mitophagy (Meissner et al. 2011). Generally, loss of PINK1 function causes oxidative stress via production of ROS and mitochondrial damage (Cui et al. 2011). Endogenous PINK1 forms a 700 kDa complex with the translocase of the outer membrane (TOM) on depolarized mitochondria. Association of PINK1 with TOM complex allows rapid reimport of PINk1 to rescue depolarized mitochondria from mitophagy (Lazarou et al. 2012). In Parkin-dependent mitophagy, PINK1, which is located in the mitochondrial outer membrane, recruits Parkin from the cytosol to the mitochondria as a first step leading autophagous destruction of the organelle. Complexes containing upstream Atg proteins (autophagy-related proteins), including ULK1 (the mammalian homologue of Agt1), Atg12, Atg14, DFCP1, WIPI-1, and Atg16L1, can associate with depolarized mitochondria. Atg9A and ULK1 structures are also recruited to damaged mitochondria as well as to the autophagosome formation site in the earliest steps of mitophagy, while the autophagosomal LC3 (MT-associated protein 1 light chain 3) family of proteins is involved in later stages of mitophagy (Itakura et al. 2012). LC3 interacts with microtubule-associated protein 1S/MAP1S bridging autophagic components with the microtubular system (Xie et al. 2011). In human endothelial cells, targeted mitochondrial damage upregulated the autophagy factors LC3B, Atg5, and Atg12, and this upregulation resulted in an improved mitochondrial membrane potential, enhanced ATP production, and an antiapoptotic effect (Mai et al. 2012). One of the effectors of the mitophagic cascade, Ulk1, is phosphorylated by AMP-activated protein kinase connecting energy sensing to mitophagy (Egan et al. 2011) and is regulated by the Hsp90-Cdc37 chaperone complex (Joo et al. 2011).

Parkin itself as an ubiquitin E3 ligase ubiquitinates intracellular proteins and via this mechanism induces clearance of cellular molecular debris and of organelles, including mitophagy, whereby ubiquitinylated outer mitochondrial membrane proteins, including mitofusins 1 and 2, are targeted for proteasomal degradation (Gegg et al. 2010; Chan and Chan 2011; Karbowski and Youle 2011; Khandelwal et al. 2011). In the pathway of mitophagy, Parkin binds to Ambra1 (activating molecule in beclin 1-regulated autophagy), a protein that promotes autophagy (Van Humbeeck et al. 2011). PINK1 and Parkin also exert important effects on mitochondrial motility. PINk1 phosphorylates Miro, a component of the primary motor/adaptor complex that anchors kinesin to the mitochondrial surface. The phosphorylation of Miro activates proteasomal degradation of Miro in a Parkin-dependent manner. By thus stopping mitochondria in their tracks, the PINK1/Parkin pathway may quarantine damaged mitochondria prior to their mitophagic clearance (Wang et al. 2011).

Execution of Mitophagic Pathways

Bnip3 (Nip3-like protein X; NIX), an atypical BH3-only protein causing mitochondrial dysfunction and cell death, can under certain circumstances also protect against cell death by inducing mitophagy. Bnip3 activation is a pro-mitophagic signal, and this pathway involves impairment of mitochondrial oxidative phosphorylation and is independent of apoptosis (Thomas et al. 2011). This response requires homodimerization of Bnip3, and clearance of

mitochondria is mediated in part via binding of Bnip3 to the microtubule-associated protein 1 light chain 3 (LC3) on the autophagosome (Hanna et al. 2012). On the other hand, Bnip3 mediated mitophagy is inhibited by activation of the p53-TIGAR axis (Hoshino et al. 2012).

Mdivi (mitochondrial division inhibitor) attenuates mitochondrial division in cells by selectively inhibiting the mitochondrial division dynamin-related protein (Cassidy-Stone et al. 2008). Dynamin-related protein 1 (Drp1) docks at mitochondria, regulating their positioning and activity (Baixauli et al. 2011). Mdivi is also a mitophagy inhibitor that operates via inhibition of Drp1 (Park et al. 2011; Givvimani et al. 2012). FUNDC1, a mitochondrial outer membrane protein, is a receptor for hypoxia-induced mitophagy. Hypoxia leads to dephosphorylation of FUNDC1 and enhances its interaction with LC3 for selective mitophagy (Liu et al. 2012). Following mitophagy, organelle remnants can enter a lysosomal degradation pathway, whereby a distinct system of mitochondria-derived vesicles (MDVs) generates the contact with lysosomes to deliver degradable cargo (Soubannier et al. 2012). BECN1s, a short splice variant of BECN1, function in mitophagy (Cheng et al. 2015).

Other Factors Regulating Mitophagy

The ATM gene mutated in ataxia telangiectasia plays a role in mitochondrial homeostasis. Atm-deficient thymocytes in mice show an altered mitochondrial homeostasis, suggesting that ATM plays a role in regulating mitophagy (Valentin-Vega and Kastan 2012). Melatonin, a highly efficient antioxidant, is involved in the control of mitophagy (Coto-Montes et al. 2012). Mitophagy is also mediated by the C2-domain containing protein, SMURF1 (Orvedahl et al. 2011).

Sequelae of Inhibited Mitophagy

It has been shown that inhibition or blockade of mitophagy leads to the accumulation of damaged, ROS-generating mitochondria, which in turn activate the NLRP3 inflammasome, a pathway positively regulated by reactive oxygen species/ROS. The NLR3P inflammasome acts as a sensor of damaged mitochondria, explaining the frequent association of mitochondrial damage and inflammatory diseases (Zhou et al. 2011).

Mitophagy in Carcinogenic and Hepatocarcinogenic pathways

HBV infection, a major driving force for hepatocarcinogenesis, disrupts mitochondrial dynamics in that it induces mitochondrial fission and mitophagy, two processes that attenuate apoptosis, while perturbation of mitophagy by silencing of Parkin enhances apoptotic signaling (Kim et al. 2013). This is a mechanism that can promote liver cell expansion in the setting of carcinogenic pathways. Generally, mitochondrial dynamics regulated by large GTPase family proteins is functionally linked with apoptosis (Otera and Mihara 2012). Autophagy triggered by oncogenic K-Ras mediates functional loss of mitochondria and mitophagy during cell transformation and early tumorigenesis, and mitophagy in this situation is a process that overcomes the cellular energy deficit triggered by insufficient glucose availability (Kim et al. 2011).

Pexophagy

Pexophagy is defined as the process of specific autophagic degradation and elimination of peroxisomes, organelles which are present in hundreds to thousands in mammalian cells (review: Till et al. 2012). As peroxisomes hold an important position in the metabolome of cells, their number and function is tightly controlled by environmental and genetic conditions. Metabolic situations requiring increasing levels of peroxisome functions lead to peroxisome proliferation and to an augmentation of peroxisomal biomass. Following such metabolic situations with a downregulation of peroxisomal function, superfluous peroxisomes are degraded by autophagy to again reach the baseline level of peroxisome numbers and mass.

In peroxisome autophagy, both macro- and microautophagy are involved (macropexophagy and micropexophagy). In the course of macropexophagy, peroxisomes are individually sequestered by membranes, resulting in pexophagosomes that fuse with degradation vacuoles. In micropexophagy, clusters of peroxisomes are enclosed within vacuolar membrane protrusions, or are integrated into a specific membrane complex, the micropexophagy-specific membrane apparatus/MIPA (Sakai et al. 2006).

In mammalian cells, the following main pathways of peroxisome elimination are recognized: the Lon protease system (Lon is a chaperone-like ATP-dependent protease involved in the degradation of misfolded and unassembled peroxisomal proteins); 15-lipoxygenase-mediated autolysis; and pexophagy. Pexophagy (in a process resembling macropexophagy in yeast) accounts for 70–80 % of peroxisome clearance in mammalian liver (Yokota and Dariush Fahimi 2009). In a hypothetical model of mammalian cell pexophagy, processed and lapidated LC3 (LC3-II) is integrated into the expanding phagophore membrane. LC3 may also mediate the association of the phagophore membrane with cytoskeletal microtubules through the Rab7 effector FYCO1 getting into contact with kinesin. Targeting of the LC3-labeled phagophore membrane to the peroxisome involves p62-mediated detection of ubiquitin motifs on peroxisomal membrane proteins, or by direct binding of LC3 to a distinct peroxisomal protein, Pex14 (review: Till et al. 2012).

Reticulophagy (ER-phagy) and Ribophagy

The homeostasis of the endoplasmic reticulum (ER), in particular its remodeling, is mediated by a distinct reaction called the unfolded protein response (UPR). In the course of a cell's life, numerous components of the cell body, including organelles, undergo a cycle of production and degradation. In cells, activation of UPR induces a distinct type of macroautophagy characterized by the elimination of ER elements, a process called ER-phagy, in analogy to pexophagy or mitophagy (Bernales et al. 2007; Cebollero et al. 2012). Reticulophagy is a specific form of starvation-induced autophagy. ER-phagosomes use membranes derived from ER itself, suggesting that ER can serve as a membrane source for autophagosome biogenesis. ER stress is characterized by a marked expansion of membrane compartments that contain unfolded proteins which may interfere with cell functions and induced cell injury. ER-phagy may serve to eliminate ER compartments with their damaging cargo. ER-phagy might, however, also prepare and deliver modified signaling lipoproteins in cancer cells, signal substances that can become cargo of exosomes.

In the setting of autophagy, the autophagic process can also selectively engulf sub-organellar structures, including ribosomes, a process termed ribophagy (Cebollero et al. 2012). Ribosomes are detectable within autophagosomes of normal mammalian cells and tumor cells, and ribosomal degradation via ribophagy displays distinct dynamics (Kristensen et al. 2008).

Lipophagy

Lipophagy, the process of elimination and degradation of cellular lipid droplets plays an important role in the reversion of hepatic steatosis, and probably also in lipid droplet turnover in steatotic hepatocytes, HCCs, and other lipid-rich liver tumors (Weidberg et al. 2009; Beller et al. 2010; Noguchi et al. 2011; Singh and Cuervo 2012; Christian et al. 2013). Lipophagy is a form of organellophagy because lipid "droplets" are now known to be complex organelles. Lipid droplets are heterogeneous and dynamic organelles with a complex and specific proteome, regulated assembly and maintenance, and controlled turnover (Digel et al. 2010; Hashemi and Goodman 2015). Lipophagy is one pathway to regulate lipid stores in several cell types (Liu and Czaja 2013; Carmona-Gutierrez et al. 2015). Except adipocytes and hepatocytes with macrovesicular steatosis, lipid droplets are small and mobile and interact with other organelles, including lysosomes,

processes mediated by Ras proteins (in particular Rab18), regulators of membrane traffic and caveolin, a membrane protein that provides a functional link between cell surface and lipid droplets (Martin et al. 2005; Murphy et al. 2009). During lipophagy in HCC cells, the small GTPase Rab7 is markedly activated, resulting in trafficking of multivesicular bodies and lysosomes to the cell surface to form a lipophagic synapse (Schroeder et al. 2015). Lipid droplets have been identified as a substrate for macroautophagy, whereby lipid droplets are sequestered in autophagosomes followed by fusion with lysosomes, where droplet constituents are degraded by lysosomal enzymes (Singh et al. 2009; Dong and Czaja 2011; Settembre and Ballabio 2014). In lipophagy, the large GTPase DNM2/dynamin 2 is involved by facilitating the scission of nascent lysosomes from autolysosomal tubules during autophagy (Schulze et al. 2013; Schulze and McNiven 2014). Lysosomes engaged in lipophagic processes can undergo signal exchange with the nucleus, where nutrient-sensing receptors are present to coordinate autophagy (Settembre et al. 2013; Lee et al. 2014).

Ciliophagy

Autophagy possibly regulates the biogenesis and turnover of cilia and associated cytoskeletal structures by a mechanism called ciliophagy. In addition, autophagy is involved in a pathway near the basal body that regulates cilium assembly (Pampliega et al. 2013, reviews: Pierce and Nachury 2013; Wrighton 2013). LC3, a protein of the autophagosomal membrane, interacts with a protein of the centriolar satellite, OFD1 (oral-facial-digital syndrome 1), and removes this protein from the satellite (Tang et al. 2013, 2014). Autophagy can also result in cilium shortening by a mechanism involving histone deacetylase 6 (Cloonan et al. 2014). Such mechanisms affect the sensing capability of cells, as the cilium is a major factor controlling cell polarity and shape, and is a sensor for cell position within a population. Ciliophagy may, therefore, play an important role in cancer.

Nucleophagy

Introduction

In normal and neoplastic cells, processes are active that act to repair nuclear damage through both repair of maintained nuclei and the coordinated removal of damaged nonfunctional nuclear components. Parts of the nucleus or the entire nucleus can be specifically degraded by an autophagic process termed nucleophagy. Degradation of entire nuclei was observed in murine seminal vesicle epithelial cells (Kovacs et al. 2000). In human liver cells, sequestration of mitotic phase chromosomes in autophagosomes was found (Sit et al. 1996). Senescent keratinocytes die through massive degradation of their nuclei (Gosselin et al. 2009). Dying senescent keratinocytes acquired a particular intracellular organization, whereby a cytokeratin network emerged and partitioned the cell into a cortical domain devoid of organelles and a central core domain containing a high number of autophagic vacuoles, mitochondria, and the nucleus. In muscle cell nuclei of patients with laminopathies caused by mutations of the genes encoding A-type lamins and emerin, perinuclear vacuoles are seen, that are sometimes larger than the nucleus. These vacuoles are autophagosomes/autolysosomes containing debris and myelin figures caused by the degradation of damaged or partially extruded nuclei. In the area of nuclear membrane interfacing with autophagosomes, accumulation of nuclear envelope proteins takes place, suggesting that nuclear autophagy/nucleophagy could contribute to the rapid repair of the nuclear membrane (Park et al. 2009a).

Mechanisms of Nucleophagy

In yeast cells, where nucleophagy has been studied in great detail, piecemeal microautophagy of the nucleus or nucleophagy (micronucleophagy) requires a direct interaction of the nuclear membrane with that of the fungal lytic compartment, the vacuole. During yeast micronucleophagy, the nuclear membrane as a dynamic structure

undergoes marked reorganization (Park et al. 2009a; Mijaljica et al. 2010b; Mijaljica and Devenish 2013). In Saccharomyces, starvation stress is followed by nuclear damage, with formation of nucleus-vacuole junctions through interactions between Vas8 in the vacuole membrane and Nvj in the perinuclear ER. Vesicles containing part of the nucleus emanate from these junction sites and finally pinch off into invaginations of the vacuole (Kvam and Goldfarb 2007; Dawaliby and Mayer 2010). This process has been termed piecemeal microautophagy of the nucleus, or PMN, a process that requires a number of ATG genes and the Ygr223c gene known to be involved in macroautophagy in yeast (Kvam and Goldfarb 2007; Krick et al. 2008, 2009; Nair et al. 2010). Micronucleophagy is a mechanism to protect against chromosomal instability (Boya and Codogno 2012).

Nucleophagy in Cancer Cells

Micronuclei, which arise as a result of deficient bipolar chromosome sequestration in cells with cell cycle perturbations, can be removed by autophagy/nucleophagy, detectable by ultrastructural analysis, and the presence of autophagy-associated factors (Rello-Varona et al. 2012). Micronuclei as such are discussed in a separate chapter.

Phagy by Multicellular Components: Angiophagy and Cancerophagy

In angiophagy, endothelial lamellipodia surround thrombotic/embolic material within hours of occlusion. This important mechanism markedly reduces hemodynamic washout and tissue plasminogen activator-mediated fibrinolysis. Within days, the thromboembolic material is completely engulfed by endothelium and extravasated into perivascular space, causing reconstitution of blood flow (Grutzendler et al. 2014). We anticipate that angiophagy in cancer tissue plays a role in the delivery of growth factors and angiogenic factors stored in thrombotic material to cancer tissue. Also circulating signal substances, microRNAs and exosomes may be transported by angiophagic endothelial pockets into the extravascular space of tumor tissue.

Senescence

Cellular senescence denotes a growth-arrest program by which cells prevent uncontrolled cell proliferation and thus limit the lifespan of cell populations. Initiating events of cellular senescence mainly comprise genomic damage, telomere shortening, epigenomic damage, deregulated mitogenic and proliferation-associated signals, and the activation of tumor suppressors (reviews: Sharpless and DePinho 2005; Shay and Wright 2005; d'Adda di Fagagna 2008; Chandeck and Mooi 2010; Campisi 2013; Ivanov et al. 2013; Abdelmohsen and Gorospe 2015; Mar et al. 2015). In cancerogenic pathways, senescence mechanisms are canceled, an effect counteracted by elements of a senescence-messaging secretome that limits the expansion of early neoplastic cells (Schmitt 2003; Dimri 2005; Hornsby 2007; Prieur and Peeper 2008; Kuilman and Pepper 2009; Collado and Serrano 2010; Serrano 2010; Byun et al. 2015; Roos et al. 2016). Normal cells chiefly senescence via the mechanism of replicative senescence. In this process, progressive loss of telomeres associated with DNA double-strand breaks is followed by a DNA damage response (DDR). Part of cancer cells circumvent this senescence reaction by persistent telomerase activity (Xu et al. 2015), whereas other cancer cells are subject to telomere dysfunction and are thus vulnerable to senescence mechanisms. Sensing of intrinsic DNA damage and the subsequent induction of cellular senescence have been implicated as an important barrier against malignant transformation and the development of cancers. On the other hand, senescence is, through the inflammasome platform (see above), associated with inflammation, which in turn promotes cancerogenesis (reviews: Pribluda et al. 2013; Lasry and Ben-Neriah 2015).

Senescence is closely connected with autophagy. Oncogene hyperactivation induces

autophagy to establish a permanent proliferative arrest (Galluzzi et al. 2016). Autophagy affects nuclear and nuclear lamina structure and via these mechanisms exerts an influence on cellular senescence. Loss and elimination of lamin B1, an important component of the nuclear lamina, is a typical feature of senescence (Freund et al. 2012; Dou et al. 2015), and this depletion in senescent cells triggers a large-scale change in gene expression and chromatin landscape (Shah et al. 2013). In senescence, the autophagy-lysosomal pathway causes processing of chromatin contributing to the stability of cellular senescence (Adams 2007; Funayama and Ishikawa 2007; Corpet and Stucki 2014; Ivanov et al. 2013). Autophagy also maintains stemness by preventing senescence (Garcia-Prat et al. 2016).

Neosis: A Pathway to Circumvent Senescence

Neosis is defined as a novel form of cell division which represents a mode of escape of cells from senescence and involved in neoplastic transformation and cancer progression. The process is one of those that are studied to explain several paradoxes concerning current concepts of cancerogenesis (review: Baker and Kramer 2007). Neosis is characterized by polyploidy giant cells which, before they die, give rise to several cells with viable genomes via nuclear budding and asymmetric cytokinesis. It is a parasexual somatic reductive cell division characterized by DNA damage-induced senescence/mitotic crisis and polyploidization; generation of aneuploid daughter cells through nuclear budding; asymmetric cytokinesis and cellularization conferring extended, but limited mitotic life span to the offspring; and is repeated several times to transiently display stem cell properties and eventually neoplastic properties. The most important event of neosis seems to be the generation of mitotically viable daughter genomes after epigenetic modulation from the nonviable polyploidy genome of the so-called neosis mother cell/NMC (Sundaram et al. 2004; Rajaraman et al. 2005, 2006; reviews: Erenpreisa and Cragg 2007; Wheatley 2010). Neosis is a process whereby p53 function-deficient tumor cells undergo self-renewal after genotoxic damage via senescing endopolyploid tumor cells/ETCs. ETCs show autophagic degradation and exhibit extrusion of DNA, and during these conditions, self-renewal transcription factors are activated. ETCs restoring after failed multipolar mitosis undergo subnuclei differentiation, and surviving subnuclei sequester nascent cytoplasm to form subcells. These preformed paradiploid subcells then become released from their linking chromosome bridges through autophagy and begin cell division (neotic ETCs; Erenpreisa et al. 2011). Neosis is thought to play a significant role in carcinogenesis pathways and the development of chemoresistance (Navolanic et al. 2004). Neosis may also operate in syncytia formed in the setting of the formation of unstable syncytia generated by cell fusion between tumor cells and normal cells (Parris 2005). In case acquired genotoxic DNA damage cannot be compensated, it is known that progression through mitosis following DNA damage initiates a p53-and caspase-independent cell death response (Varmark et al. 2009).

Netosis/ETosis: Netting Neutrophils and NETotic Cell Functions That Can Trap Cancer Cells?

In the extracellular space, neutrophils can generate DNA-containing fibrils forming a network, termed neutrophil extracellular traps (NETs; Brinkmann et al. 2010; Remijsen et al. 2011b). This process is termed NETosis or, more recently, ETosis, meaning death with release of extracellular traps/ETs (Guimaraes-Costa et al. 2012). NETs can trap microorganisms (bacteria, fungi), unicellular parasites, and host cells (macrophages, eosinophils, mast cells) followed by their phagocytosis-independent killing while minimizing injury to host cells. NETs can release modified antigens and DNA and play an important role in the regulation of innate immunity and modulation of autoimmunity, specifically in systemic lupus erythematodes (Carmona-Rivera and Kaplan 2014). NET is considered to be the missing link

between cell death and autoimmune disorders (Bouts et al. 2012; Darrah and Andrade 2013; Mesa and Vasquez 2013). Ultrastructurally, NET manifests as fibrillar lattice whereby individual NET fibers consist of DNA filaments and associated globular protein domains, together forming threads with a diameter of 50 nm. These threads can associate to form much thicker and longer elements. In the course of NETosis, neutrophil nuclei lose their shape, and the euchromatin and heterochromatin homogenize, followed by disintegration of the nuclear membrane and granule membranes, so that the NET components can mix (Fuchs et al. 2007). The pathogenesis of NET formation involves a classical step in neutrophil shape change, i.e., activation of protein kinase C by its physiological activator, diacyl glycerols or by phorbol esters, or interleukin-8, causing granule release of release of chromatin to form a compound extracellular network. NET formation also requires both autophagy and superoxide generation (Remijsen et al. 2011a). The mTOR pathway has a pivotal role in NET formation via regulation of autophagy (Itakura and McCarty 2013). NETs contain bacteriocidic proteins bound to DNA (histones, neutrophil elastase), proteins from azurophilic granules (myeloperoxidase, cathepsin G), specific neutrophil granules (lactoferrin), tertiary granules (gelatinase), and DNA that can be delivered to extracellular compartments. The release of these molecules from NETs requires reactive oxygen species/ROS, which trigger the dissociation of neutrophil elastase from a membrane-associated complex into the cytosol, where it activates its proteolytic activity in a myeloperoxidase-dependent manner. Activated neutrophil elastase in the cytosol binds and degrades actin to arrest actin dynamics (Metzler et al. 2014). Aggregated NETs promote the resolution of neutrophil-mediated inflammation by degrading cytokines and chemokines and disrupting neutrophil recruitment and activation (Schauer et al. 2014). The fate of NETs is not yet clarified. However, the extracellular DNA in NETs can associate with proteins, taken up by cells, and stimulate intracellular DNA sensors, including Toll-like receptor 9, to activate DAMPs/pattern recognition molecules (Pisetsky 2012). This is a major pathway linking nuclear components with chromatin-induced immunity (Brinkmann and Zychlinsky 2012).

A special form of NET is intravascular NET, also occurring in the liver and specifically in liver sinusoids and tumor vessels. Intravascular NET is closely associated by thrombosis, and both NET and pathologic thrombosis are regulated by peptidylarginine deiminase 4, an enzyme that mediates chromatin decondensation (Martinod and Wagner 2014). Extracellular histones released from NETs can themselves induce thrombosis and can trigger innate immunity by activating Toll-like receptors and the NLRP3 inflammasome (Allam et al. 2014). Intravascular NET formation is a controlled process in which platelets that have sensed circulating microbes via their TLR4 attach to neutrophils and activate them to generate NETs. This pathway is rapid and does not lead to neutrophil cell death. NETosis associated thrombosis plays a significant role in cancer growth and spread (Demers and Wagner 2014), as it influences homing of cancer cells in thrombotic niches and facilitates spread along platelet- and coagulation factor-containing tracks. NETs can also promote the differentiation and function of fibroblasts (Chrysanthopoulou et al. 2014) and may therefore participate in the generation of a cancer stromal niche.

Roles of Apoptosis and Non-apoptotic Cell Death in Cell Competition: Losers and Winners in Cancerogenesis

In a novel concept of the cellular interactome, termed cell competition, there are winner cells that identify and eliminate viable cells from an expanding cell population without engulfment. According to this concept of "cell war," the demise of loser cells caused by winner cells involves apoptosis of suboptimal or superfluous cells. Killed loser cells are subsequently eliminated by the phagocyte system (Tamori and Deng 2011; Lolo et al. 2012, 2013; Vivarelli et al. 2012). Cell competition may be involved in cellular cooperation in early tumor progression (Krepkin and Costa 2011). The mechanism of cell competition seems to play a role in the

generation of so-called cancerization fields, involving a competition between wild-type cells and mutated preneoplastic or neoplastic cells (Rhiner and Moreno 2009). In the cancerization field, a battle is thought to take place between less well-adapted cells (the losers) and best-adapted cells (winners). For this Darwinian-type model of cancerogenesis, a mechanism of cell-to-cell communication during cell competition has been proposed and termed, the "flower code," due to the involvement of the Drosophila cell membrane protein Flower/Fw conserved in multicellular animals and required to label cells as "winners" or "losers" (Rhiner et al. 2010; Casas-Tinto et al. 2011).

Abstract

Invasion and metastasis of cancer cells involve a complex sequence of events that has been summarized by the use of the term invasion cascade. This concept lists a sequential order of phenomena involved in the complex pathway that cancer cells undertake to invade host tissue and then form metastases. The pathway probably starts with cancer cells leaving a primary lesion by individualization, i.e., being released from a controlling cellular environment. Individualized cancer cells can, due to still unknown mechanisms, acquire a motile phenotype that allows them to migrate through tissues. Morphologically, migrating cancer cells resemble locomoting neutrophils, i.e., being polarized with a leading front and rear end and equipped with a contractile cytoskeleton. Polarized tumor cells may react to chemokinetic and chemotactic stimuli. Migrating tumor cells undergo a continuous shape change and can transverse narrow intercellular spaces. On the other hand, they can acquire a secretory phenotype for diverse species of histolytic enzymes that degrade the extracellular matrix, specifically matrix metalloproteinases. By these mechanisms, cancer cells can invade lymph vessels and blood vessels to be transported to remote regions, where regrowth to metastases can ensue.

Introduction

Invasive Growth and Its Morphology

Local invasion (infiltrative growth) and metastasis are among the most characteristic features of malignant neoplasms and are the main factors causing morbidity and mortality in cancer (reviews: Mareel et al. 2009; Friedl and Alexander 2011; Valastyan and Weinberg 2011). The most important and most common primary liver cancer worldwide, hepatocellular carcinoma (HCC), is characterized by a markedly invasive phenotype, high rates of macrovascular invasion and of local recurrence, and frequent intrahepatic and extrahepatic metastases. Also cholangiocarcinomas are invasive cancers that however differ from HCCs in their spreading pattern, in that they tend to more often invade perineural spaces and metastasize to locoregional lymph nodes. As numerous liver cancers are in an invasive stage at first diagnosis already, an understanding of invasion mechanisms are in the center of interest for current and future therapies (Mareel and Leroy 2003; Leber and Efferth 2009). Specifically, distinct molecular invasion signatures of the neoplasms are expected to be transmitted into specific, and possibly personalized, treatments.

Morphologically, invading cancer cells are capable to leave previously controlled tissue compartments, migrate into adjacent normal tissue, cause tissue destruction (the former "infiltrative-destructive growth" of cancer), and invade lymph and blood vessels (Figs. 1, 2, 3, 4, 5, 6, 7, 8, and 9).

The Invasion Cascade

Conventionally, features of invasion and metastasis are considered to follow a sequence of characteristic steps, the so-called invasion cascade, many of its aspects stemming from animal experimentation findings (Table 1).

This table, which exists in similar forms in numerous works, surmises that we deal with a true sequence of events, i.e., one step in fact

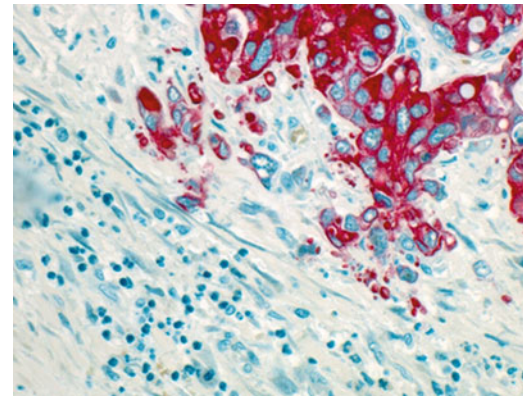

Fig. 1 Poorly differentiated hepatocellular carcinoma, invasion front. Note that neoplastic cells have separated from the cohesive tumor tissue. This cell individualization, caused by defective cell junctions, is an important step in tumor invasion (CAM5.2 immunostain)

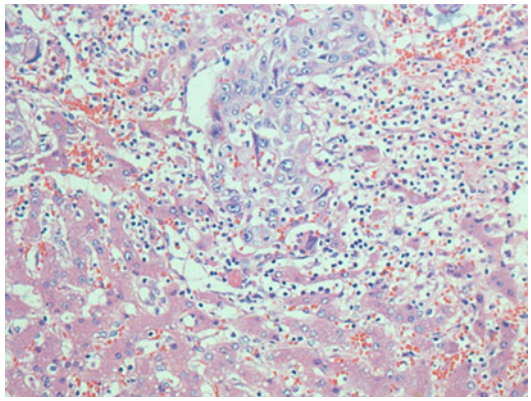

Fig. 2 Invasion of liver tissue by a poorly differentiated cholangiocarcinoma. The tumor shows focal necrosis (*right* part of figure; hematoxylin and eosin stain)

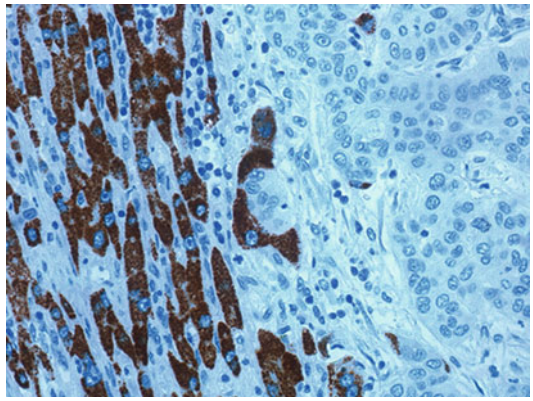

Fig. 3 Interface between hepatocellular carcinoma (*right half*) and invaded liver tissue. A carcinoma nest has infiltrated a hepatocyte plate (center; Hep Par1 immunostain)

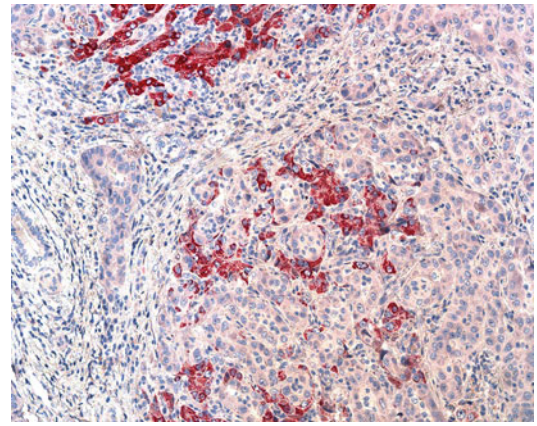

Fig. 4 Marked invasion of lobular hepatic parenchyma by cholangiocarcinoma. The hepatocyte plate architecture is effaced. An interlobular bile duct is seen to the left (Hep Par 1 immunostain)

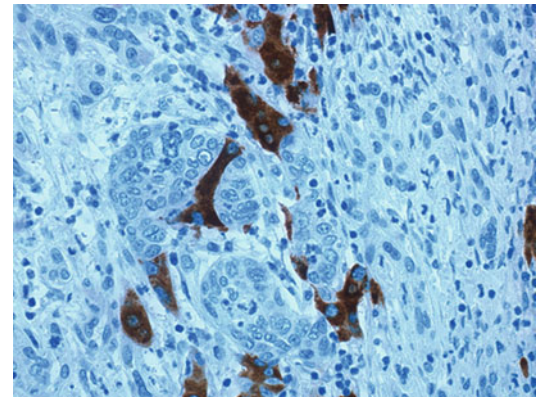

Fig. 5 Poorly differentiated carcinoma has extensively infiltrated liver tissue and caused hepatocyte atrophy. Remnant hepatocytes are trapped within carcinoma cell formations (Hep Par1 immunostain)

following the previous step. This view may help as a learning scheme but markedly misinterprets as to what really takes place in invasion. This is due to the fact that, firstly, a transformed cell becoming an invasive and metastasizing cell does not acquire completely novel features, but rather features that are otherwise found in cells different from the respective cell of origin. For example, the type of motility acquired by carcinoma cells is almost the same as that normally occurring in neutrophils and macrophages, but is not usually present in the epithelial cell of origin. Breaking of tissue barriers is a typical phenomenon for mature blood cells leaving the bone marrow, but is carefully avoided in epithelial linings or other compartment barriers in order to guarantee tissue homeostasis. Hence, invading cancer cells change to behavioral programs that are otherwise reserved for unrelated cells. Secondly, rather than acquiring features necessary for invasion one after another, it seems that cancer cells can acquire these characteristics synchronously, lose them again underway, to regain them afterward, a complex process in part regulated by contact with other cells *en route* or with the extracellular matrix. Thirdly, invading tumor

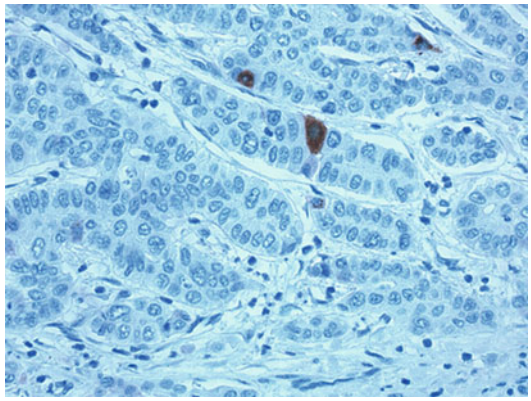

Fig. 6 In advanced parenchymal carcinoma invasion, only very few hepatocytes may be left (in this case, *three dark-brown* cells). In addition, two apoptotic hepatocytes are noted as very small cells with a brown granular cytoplasmic reaction product (Hep Par1 immunostain)

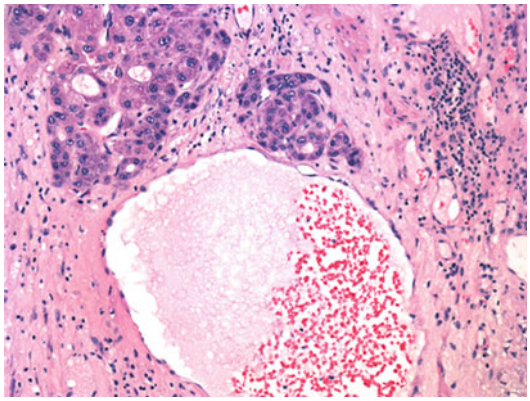

Fig. 7 Invading cholangiocarcinoma cells approaching the intima of dilated liver vein (hematoxylin and eosin stain)

cells keep their capability to proliferate, whereby, however, proliferation strongly depends on the actual status of the cell with respect to invasion. For example, a migrating cell cannot at the same time pass through a division cycle; it has to stop first and resume a nonpolarized phenotype. Conversely, ongoing proliferation will shut down certain mechanisms required for invasion, to resume them after mitosis. It is evident that the study of all these aspects on an invasion platform at the same time is highly difficult, so that certain aspects were and are artificially isolated to become amenable to analysis.

Intercellular Junctions: Altered Cell Junctions as a Pathway to Tumor Cell Individualization

Introduction

Cell junctions (intercellular bridges) are distinct and conserved structures that control the contacts between adjacent cells, maintain epithelial tissue integrity, create cell polarization, and provide pathways for signal exchange. Cell junctions as multiprotein complexes provide contacts between adjacent cells and between cells and the extracellular matrix. These junctions are a guarantee for the maintenance of tissue geometry, homeostasis, and barrier functions and are the machinery that allows the continuous reconstruction of tissue-specific cell arrangements in the course of cell turnover, where cells are lost and properly

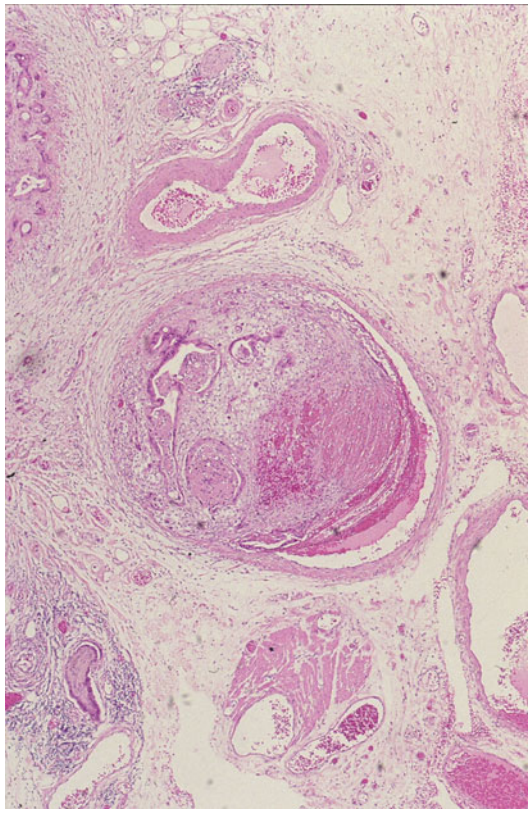

Fig. 9 Invasion of a dilated liver vein by adenocarcinoma, associated with thrombosis (hematoxylin and eosin stain)

Table 1 The invasion cascade of malignant neoplasms: a sequence of distinct steps

Malignant transformation as an initial step
Loss of contact of transformed cells with neighboring non-transformed cells
Individualization of the cancer cell
Exit ("dropout") from the normal tissue niche
Acquisition of novel adhesion features
Acquisition of cell motility and the capability to migrate
Capability to respond to chemokinetic and chemotactic stimuli
Active migration through tissues, whereby normal tissue barriers are no longer respected
Lysis of invaded tissues by use of histolytic enzymes (destructive growth; histolysis)
Recognition of and contact with blood vessels and lymph vessels
Transmigration of vessels (vascular invasion)
Contact with blood stream or lymph stream
Interaction with platelets and leukocytes in the streaming blood
Transport of circulating tumor cells
Homing to and adherence to endothelia at remote sites
Emigration from the blood stream or lymph stream into tissue
Growth of a metastasis

replaced via cell cycling. Cell junctions are highly dynamic microdomains that respond to various signals (McCole 2013). In particular, turnover of cytoskeletal and junction proteins is finely tuned by GTPases of the Rho family, specifically RhoA, Rac1, and Cdc42. Rho GTPases and junctional proteins form a signaling platform or a zonular signalosome which coordinates the functions of diverse cell junctions (Citi et al. 2014). In malignant neoplasms, in which cells leave distinct tissue compartments and destroy tissue barriers, cell junctions are dramatically altered or lost, also leading to failure of homeostatic signaling processes.

Tight Junctions: General Aspects

Tight junctions (TJs; zonula occludens) are occluding junctions that form a paracellular diffusion barrier that occludes epithelial cells from each other and maintains cell polarity. The structures forming circumferential bands are situated in the apical part of the lateral epithelial cell wall. TJs are characterized by a distinct ultrastructure and several specific proteins, including transmembrane barrier proteins (claudins, occludin, junctional adhesion molecule-A (JAM-A)) and peripheral scaffolding proteins which comprise ZOs (Zo-1, ZO-2, ZO-3; zonula occludens family proteins, membrane-associated guanylate kinase homologs), MAGI-1 (membrane-associated guanylate kinase with inverted orientation-1), afadin, PAR3, PAR6, MUPP1, and ZONAB. Claudins are tetraspan transmembrane proteins which undergo differential pathways of oligomerization to form TJs (Koval 2013). Occludin and ZO proteins form a complex that acts as a master regulator of TJ assembly/disassembly (review: Bewley et al. 2013). Scaffolding proteins are linked to actin and microtubules of the cytoskeleton through numerous linking proteins, such as

cingulin, paracingulin, myosins, and protein 4.1 (review: Van Itallie and Anderson 2014). Claudins are critical components of TJS and are present both in hepatocytes and cholangiocytes (Rao and Samak 2013; Van Itallie and Anderson 2013). In normal cholangiocytes, transcription and localization of TJ claudins are regulated by the transcription factor grainyhead-like 2 (Tanimizu and Mitaka 2013). ZO proteins have multiple and complex function that in part exceed TJ biogenesis. ZO-1 and ZO-2 play a central role in the establishment of a belt-like junction with paracellular permselective barrier function (Tsukita et al. 2009). The junctional protein ZO-2 can associate with other transmembrane proteins and transiently targets to the nucleus where it modulates gene expression (Traweger et al. 2013; Gonzalez-Mariscal et al. 2014). An important TJ protein is junctional adhesion protein-A (JAM-A), a protein which interacts with the cell polarity protein PAR-3 (Hirose et al. 2002). JAM-A is localized at primordial, spot-like cell-cell junctions in a non-phosphorylated form. In the course of TJ maturation, JAM-A is phosphorylated by protein kinase C (Ebnet 2013). The linking proteins, cingulin and paracingulin, are effectors of cytoskeleton-junction connections (Citi et al. 2012). Phosphorylated cingulin associates with cytoskeletal microtubules (Yano et al. 2013). Cingulin and paracingulin are also involved in GTPase signaling and therefore participate in the zonular signalosome. Specifically, both proteins control RhoA activation by interacting with RhoA guanidine exchange factors and spatially restrict downregulation of RAC1 activation (Guillemot et al. 2014). Biogenesis of TJs also depends on the zonula adherens (adherens junctions). Specifically, the adherens junction protein PLEKHA7 modulates assembly of TJs through E-cadherin protein complex- and microtubule-dependent mechanisms (Paschoud et al. 2014). The expression and proper localization of tight junction proteins is regulated by numerous factors that are in part deregulated in cancer cells. TJ formation and stability are impeded by tumor necrosis factor receptor-associated factor 4 (TRAF4) through a phosphoinositide-binding protein pathway, favoring cancer cell motility (Rousseau et al. 2014). Occludin localization is modulated by tumor necrosis factor alpha secreted by macrophages (Fletcher et al. 2014). Tight junction protein expression is under the control of microRNAs (review: Cichon et al. 2014). Factors that are involved in hepatocarcinogenesis can affect tight junction function and turnover. For example, HCV envelope structural components alter hepatocyte tight junction protein localization and retain occludin in the endoplasmic reticulum (Benedicto et al. 2008).

Tight Junction Deregulation in Liver Cancer

Biogenesis of TJs is crucial for cell polarity in hepatocytes and the construction of normal liver cell plates (Grosse et al. 2013). In HCC cells, TJs are disorganized, the tight junction networks not being oriented parallel to the canalicular lumen and reduction to structures with a single strand. In some discontinuous junctions, intramembrane particles are aligned to form a discontinuous network. Discontinuities and local proliferation of tight junctions are present. Disruption of tight junctions in HCC is correlated with an invasive phenotype. Vascular endothelial growth factor (VEGF) induces disruption of occludin-delineated tight junctions in HCC cells in a protein kinase C alpha-dependent manner, a mechanism for VEGF-mediated tumor invasion (Schmitt et al. 2004). Claudins as critical components of tight junctions are misexpressed in HCC (Bouchagier et al. 2014). Part of claudins are downregulated in cancers, causing tight junction dysfunction, while other claudins may be upregulated, e.g., claudin-7 (Brokalaki et al. 2012). In HCC, claudin-1 expression promotes epithelial-mesenchymal transition (EMT) and invasion (Stebbing et al. 2013). Claudin-1-mediated EMT proceeds via a c-Abl-ERK signaling pathway (activated c-Abl-Ras-Raf-1-ERK1/2; Suh et al. 2013). Occludin and ZO-1 showed significant downregulation in primary and metastatic HCCs, whereas these proteins were highly expressed in metastatic colorectal carcinoma

(Orban et al. 2008). However, another study demonstrated elevated occludin expression in HCCs (Bouchagier et al. 2014).

Gap Junctions as Communicating Structures

Gap junctions (GJs) are clusters of highly ordered intercellular communicating junctions. They consist of channels that connect the cytoplasm of adjacent cells. GJs keep the cells at a characteristic distance of 2–4 nm, the gap which is absent in tight junctions. Each GJ channel consists of two hemichannels (connexons), each provided by the two respective partner cells. Gap junction connexons are equipped with sets of distinct gap junction proteins, the connexins. Each hemichannel is composed of six connexins arranged like a rosette (connexin hexamer). Hexamers can contain one type of connexin (homologous or homomeric hexamer) or more than one type of connexin (heterologous or heteromeric hexamer). These six connexins encircle a central channel pore which can be open or closed. The pore permits the controlled exchange of signal substance between the partner cells. Apart from being components of connexons, connexins exert functions which affect other types of cell junctions. Connexin 32 can induce tight junction in liver cells via upregulation of the tight junction protein, MAGI-1 (Murata et al. 2005; Kojima et al. 2007).

Gap Junction Deregulation in Liver Cancer

Gap junctions in HCC cells were found only on the lateral plasma membrane and were not observed within the tight junction networks (Swift et al. 1983). Connexins have a central role in the regulation of cell growth control and carcinogenesis (Yamasaki et al. 1999). The expression patterns of connexins differ considerably between normal cells and cancer cells. In HCC cells, connexins 26 and 32 are downregulated, while connexin 43 is upregulated (Ma et al. 2003). Connexin 32 is the major liver gap junctional protein, while the cardiac-type connexin 43 is expressed at very low levels in normal hepatocytes (Oyamada et al. 1990). Expression of connexin 32 gradually decreases as liver disease progresses from cirrhosis to HCC (Nakashima et al. 2004). Experimentally, normal function of connexin 32 suppresses hepatocarcinogenesis (Hokaiwado et al. 2007). The low expression of connexins 26 and 32 in HCC is associated with an invasive phenotype (Sheen et al. 2004), suggesting a pro-invasive effect of gap junction failure. Overexpression of connexin 43 in HCC cells promotes cancer invasion via inhibition of cell-cell communication (Zhang et al. 2007).

Adherens Junctions as Anchoring Devices

Adherens junctions (AJs) form a group of adhering junctions, comprising zonula adherens, fascia adherens, and punctum adherens. All these junctions are anchoring junctions that anchor cells to each other and to the extracellular matrix (Machesky et al. 2008). Apart from adheres junctions, anchoring junctions also comprise desmosomes (maculae adhaerentes) and hemidesmosomes. These adhering junctions connect membrane domains of two cells linked to the respective cytoskeletons. A typical AJ is localized just underneath a tight junction, where it generates a belt-like adhesion (zonula adherens). All AJs share distinct proteins, including cadherins that are connected with the actin cytoskeleton via various anchoring proteins (catenins, vinculin, alpha-actinin; Wickline et al. 2013). AJs, through their link to the cytoskeleton, unify the actin network of adjacent cells to a transcellular cytoskeletal network that is broken in malignant neoplasms in order to individualize cancer cells for invasion.

Deregulation of Adherens Junctions in Liver Cancer

E-cadherin, a major component of adherens junctions, is differentially regulated in HCC cells (see

below). In most of these neoplasms, E-cadherin expression is reduced, while accumulation of cytoplasmic beta-catenin is enhanced (Du et al. 2009). In HCC cells, alterations in beta-catenin expression can be compensated by gamma-catenin expression in adherens junctions (Wickline et al. 2013). In hepatocytes, E-cadherin expression is modulated by the junctional adhesion molecule-A (JAM-A), a tight junction protein (Konopka et al. 2007). Cadherins and junctional proteins play a role in EMT (see below). Tumor-induced upregulation of the EMT-inducing proteins Twist, Snail, and Slug represses the vascular cadherin promoter (Lopez et al. 2009). In cancer cells, maintenance of adherens junctions is regulated by the metastasis suppressor, NM23-H1, the latter therefore being an important factor for the control of cell-cell adhesion and cell migration within the invasion cascade (Boissan et al. 2010). Adherens junctions are stabilized by MAGI1 (membrane-associated guanylate kinase, WW, and PDZ domain containing 1), a protein which therefore counteracts invasion and metastasis. MAGI1 is frequently downregulated in HCC (Zhang et al. 2012).

Focal Adhesions: Crucial Mediators of Cell-Matrix Adhesion

Introduction

Cell-cell and cell-matrix adhesion is a key mechanism to regulate cell homeostasis and the biologic behavior of normal cells and cancer cells (reviews: Reddig and Juliano 2005; Cao et al. 2007; Andl 2010). Numerous types of adhesion complexes and their specific proteins mediate cell and extracellular matrix (ECM) interactions and provide the sensing mechanisms that monitor the mutual relationships between cells and extracellular matrix. In the setting of the invasion cascade, differential expression of diverse adhesion molecules is a major pathway for the spread of tumor cells, as invading cells continuously engage in novel and reversible adhesive contacts with normal cells, partner tumor cells, and constituents of the ECM. Downregulation of certain adhesins in cancer cells contributes to tumor cell individualization, whereas upregulation of other adhesins may increase adhesion to the ECM substratum, e.g., basement membranes of blood vessels. Numerous adhesion molecules have been found to be altered in cancers, in part via differential production of microRNAs which target distinct adhesins.

A prominent role of deranged adhesion processes taking place in cancers is played by focal adhesions (FA), specialized areas on the cell surface where integrin receptors and associated proteins connect the proteins of the extracellular matrix with components of the cellular actin and microtubule cytoskeleton (Palazzo and Gundersen 2002; Wozniak et al. 2004). FA or focal contacts are large protein assembly complexes that spread mechanical force from cell adhesion sites to the cell body, and in particular to the cytoskeleton. FAs are also important mediators of various signaling pathways involved in cell-cell, cell-matrix adhesion, and cell proliferation and differentiation. In this functional network, FA and its specific kinase interacts with the Wnt/beta-catenin signaling pathway (Fonar and Frank 2011). FAs contain numerous proteins, such as actin, tubulin, signaling tyrosine kinases, c-Jun N-terminal kinase (JNK), focal adhesion kinase (FAK), Src kinase, Abl, integrin-linked kinase, phosphatases, actopaxin, and the actin-associated proteins paxillin, talin, vinculin, tensin, and the GTPases dynamin and Rho/Cdc42. These adhesions share part of the protein repertoires also found in podosomes and invadopodia (see below).

In FA, the two paxillin family members paxillin and leupaxin play particularly important roles (Schaller 2001; Chen and Kroog 2010). FAs contain the protein zyxin, which cooperates with caldesmon and Ena/VASP proteins to modulate integrin-dependent cell motility (Hoffman et al. 2006). VASP stands for vasodilator-stimulated phosphoprotein. Ena/VASP homology proteins or EVH proteins are proteins involved in cell motility due to their function as factors associated with actin polymerization and interactions with actin-associated proteins. Ena/VASC proteins are conserved regulators of actin assembly and turnover and are critically involved in cancer cell migration and invasion (Bear and Gertler

2009). In motile cells, Ena/VASP proteins are mainly located to the edge of lamellipodia and at the tips of filopodia. Important interaction partners of VASP are migfilin and several members of the kindlin protein family. The connections of the focal adhesion plaque to the actin cytoskeleton and filamin are mediated by the proteins, migfilin, a LIM-containing protein, and mitogen-inducible gene-2 (Mig-2), whereby migfilin, Mig-2, and filamin constitute a junction between cell-matrix adhesions and the cytoskeleton (Tu et al. 2003; Wu 2005). Via filamin binding, this protein complex is linked to the integrin system (Kiema et al. 2006). Migfilin, a protein with tandem LIM domains, also provides a link between kindlins and the cytoskeleton (Brahme et al. 2013). Kindlins 1 and 2 are actin cytoskeleton-associated proteins mutated in Kindler syndrome (Lai-Cheong et al. 2008). Kindlins play an important role in the regulation of integrin outside-in signaling (Qu et al. 2014; Liao et al. 2015; Ma et al. 2015). A further important Ena/VASP family actin regulator involved in chemotaxis and cell locomotion is Mena, which forms an adhesion-regulated complex with integrin alpha5beta1, a fibronectin receptor with a central role in cell adhesion, fibronectin signaling, and cell motility (Gupton et al. 2012). One Mena isoform is associated with the induction of a mesenchymal-like phenotype in cancer, associated with increased invasion (Di Modugno et al. 2012). The connection between FA and the actin cytoskeleton is mediated by a member of the nebulin family of actin-binding proteins, LIM-nebulette (Lasp-2), which also binds to vinculin and paxillin and enhances cell motility (Bliss et al. 2013). FA turnover is promoted by the cell adhesion system, hyaluronan and hyaluronan receptor/RHAMM, accompanied with an increase in protein tyrosine phosphorylation and an augmented motile cell response (Hall et al. 1994).

Focal Adhesion Kinase

A distinct set of protein kinases is recruited to focal adhesions (Eleniste and Bruzzaniti 2012). The function of focal adhesions is strongly mediated by focal adhesion kinase (FAK, p125), an enzyme also termed PTK2 (protein tyrosine kinase 2), encoded by the PTK2 gene. FAK is a cytoplasmic protein tyrosine kinase that is activated upon its interaction with integrins and is centrally involved in integrin-mediated signaling and regulation of cell adhesion and motility (Cary and Guan 1999; Shen and Guan 2001; Gao et al. 2015). FAK is phosphorylated in response to integrin signaling and growth factor stimulation. Most normal cells express FAK which is concentrated in focal adhesion plaques, but also exists at lower levels in the cytoplasm. FAK phosphorylates and activates several important proteins of focal adhesions, such as paxillin (review: Eleniste and Bruzzaniti 2012). The enzyme also interacts with numerous other proteins, including p53, PTEN, Src, JAK2, TGF-beta, and STAT1. FAK can also phosphorylate proteins involved in cell proliferation, including growth factor receptor-bound protein-7 (Chu et al. 2009).

Deregulation of Focal Adhesion Kinase and Focal Adhesions in Liver Cancer

Focal adhesion kinase (FAK) is deregulated in numerous cancers, in part associated with mislocalization of the kinase in regard to FA (Kornberg 1998; Hauck et al. 2002; Zhao and Guan 2009). The significance of FAK deregulation in cancers is mainly related to its central function in tumor cell motility and invasion (Schlaepfer et al. 2004) and to its interaction with critical transcription factors such as p53 (Golubovskaya and Cance 2007). The FA-associated kinase (FAK) is required for c-Met/beta-catenin-driven hepatocarcinogenesis (Shang et al. 2015) and regulates invasion-associated adhesion of HCC cells. In established HCCs, FAK is often overexpressed and predicts a higher incidence of extrahepatic metastasis, vascular invasion, and poor outcome (Fujii et al. 2004; Itoh et al. 2004; Jan et al. 2009). In part of the tumors, upregulation of the enzyme is correlated with HBV infection and contributes to tumor progression (Cai et al. 2009). The enzyme is involved in invasion and metastasis of HCC via stimulating the activity of matrix metalloproteinases MMP-2 and MMP-9 (Chen et al. 2010).

Upregulated FAK is involved in early events of integrin-mediated adhesion of circulating carcinoma cells and participates in prostaglandin E2-mediated adhesion, migration, and invasion of HCC cells (Bai et al. 2009). In contrast, downregulation of FAK inhibits metastatic cell adhesion in vivo within liver sinusoids (von Sengbusch et al. 2005). Numerous factors have been found to induce FAK activity in liver cancer. A major positive regulator of FAK expression in HCC and thus of tumor cell migration is microRNA-151, located to chromosome 8q24.3 and often amplified in HCC (Luedde 2010). In HCC cells, expression of FAK is promoted by CD147, which also favors actin polymerization and production of gelatinase (Qian et al. 2008). FAK in HCC is also promoted by epimorphin (syntaxin-2), an extracellular protein which is strongly elevated in hepatic stellate cells of the tumor stroma (Jia et al. 2011). Notch1, which is upregulated in many HCCs, stimulates FAK expression in HCC, including the phosphorylated FAK form, associated with enhanced migration and invasion of HCC cells (Hu et al. 2014). Calpain small subunit 1 (Capn4), a major prometastatic factor in HCC, contributes to invasion and metastasis by activation of the FAK-Src pathways. This is brought about by phosphorylation of distinct tyrosine residues of FAK and Src (Dai et al. 2014). Migration of HCC cells is stimulated by expression of the microtubule-associated protein JWA, acting through focal adhesion kinase expression and phosphorylation, RhoA activation, and MMP-2 activity (Wu et al. 2012). The non-receptor tyrosine kinase of the focal adhesion kinase (FAK) family, Pyk2 (proline-rich tyrosine kinase 2), is upregulated in more than 60 % of HCCs and promotes cell motility through induction of EMT (Sun et al. 2011). ACP5 promotes cell motility through modulation of the phosphorylation of focal adhesion kinase and is a factor for aggressiveness in HCCs (Xia et al. 2014). HCC cell migration mediated by focal adhesion kinase/AKT signaling is stimulated by the sonic hedgehog signaling pathway (Chen et al. 2013). The expression pattern of FAK in HCC cells is modulated by the desmosome complex component plectin, a protein that connects cytokeratins and integrin alpha6beta4 in hemidesmosomes anchoring to the extracellular matrix (Cheng et al. 2015). Plectin and its isoforms play an important role in cytoskeleton organization and dynamics. Specifically, plectin is a cross-linker that organizes the stable cytoskeletal meshwork important for maintenance of cell shape (Wiche 1998). The expression of plectin in HCC cells is related to the stability of cytokeratin 18, whereby both plectin and cytokeratin 18 can be downregulated in HCC (Liu et al. 2011b). Plectin deficiency in HCC is associated with tumor cell pleomorphism and abnormal keratin filament bundles (Liu et al. 2007–2008; Liu et al. 2011a). FAK transcription in HCC is also enhanced by a factor involved in short interfering RNA-mediated gene silencing, Argonaute2, frequently upregulated in HCC (Cheng et al. 2013). FAK is also involved in inflammatory pathways that promote liver cancer development and progression. The proinflammatory cytokine tumor necrosis factor alpha (TNF-alpha) activates FAK signaling and via this pathway activates cell migration and invasion (Mon et al. 2006). Activated stellate cells in the stroma of HCCs promote HCC migration and invasion via an activation of the FAK-MMP-9 signaling pathway (Han et al. 2014).

Apart from HCC, FAK is also deregulated in other liver cancers. It is reduced in intrahepatic cholangiocarcinoma, and this downregulation is associated with poor tumor differentiation, an invasive phenotype, and metastasis (Ohta et al. 2006). Expression of FAK is also associated with liver metastasis of colorectal cancer (Lark et al. 2003; Sun et al. 2014). Overexpression of FAK in human colorectal carcinoma liver metastases is a frequent finding and is independent from c-src or c-yes activation (Han et al. 1997). However, there is also evidence that FAK activity is reduced in liver metastases compared with matched primary colorectal cancers (Ayaki et al. 2001).

HCC cells frequently show abnormalities of FA structure and function. In addition to FAK, other components of FA may be abnormal in

liver cancer (Yam et al. 2009). c-Jun N-terminal kinase (JNK), an enzyme located in the focal adhesion plaque, promotes cell migration and invasion in murine HCC cells (Zhang et al. 2011). FA integrity in HCCs is regulated by agrin, a migration-promoting, matrix-sensing protein that is upregulated in HCC (Chakraborty et al. 2015). An integrin beta1-subunit-binding protein is integrin-like kinase which localizes to FA and is involved in cytoskeleton remodeling. Overexpression of this kinase in HCC promotes tumorigenicity and progression (Chan et al. 2011). A member of the focal adhesion protein group, actopaxin, is expressed in part of HCCs and affects tumor progression through modulation of cell migration and invasion (Nikolopoulos and Turner 2000). Actopaxin operates through the focal adhesion proteins ILK, PINCH, paxillin, and Cdc42 and through regulation of EMT (Ng et al. 2013). A focal adhesion protein altered in HCC is vinculin, regulated by CD147 in liver cancer cells. CD147 induces a vinculin expression pattern in FA of HCC cells promoting an invasive phenotype (Liang et al. 2014). HCC cell migration is stimulated by factors interacting with proteins of focal adhesion proteins. Argonaute2 protein, which plays a role in short interfering RNA-mediated gene silencing, upregulates focal adhesion kinase and by this step promotes tumor cell migration, proliferation, and colony formation (Cheng et al. 2013). The LIM domain protein migfilin which mediated links between adhesion plaques and the cytoskeleton is upregulated in HCC cells in vitro and decreases extracellular signal-regulated kinase (ERK) expression which in turn leads to increased invasion (Gkretsi and Bogdanos 2015). Kindlins, important migfilin partners located to FA, are also deregulated in HCC. Kindlin-1 and kindlin-2 are upregulated in HCC, associated with tissue and microvascular invasion, metastatic spread, and aggressive tumor biology (Ge et al. 2015; Ma et al. 2015). In contrast, kindlin-3 has tumor suppressor activities in several cancers (Djaafri et al. 2014). The roles of FA and FAK in tumor cell motility and migration is discussed in a later paragraph in more detail.

Cadherins

Introduction

In HCCs and cholangiocarcinomas, several groups of adhesion molecules are altered in a complex way, whereby these alterations in expression pattern change as a function of tumor progression (Cao et al. 2007). Cadherins (calcium-dependent adhesion molecules) form a large family or superfamily of transmembrane glycoproteins that mediate cell-to-cell adhesion in a calcium-dependent manner. The family includes cadherins proper, protocadherins, desmogleins, desmocollins, and others (Table 2). Cadherins are modified by numerous posttranslational modifications to become functional adhesins.

For cancer cell invasion, deregulation of classical cadherins plays an important role. E-cadherin (epithelial cadherin; CDH1; CAM 120/80; uvomorulin) is a single-pass type-1 classical cadherin which consists of an extracellular domain, a transmembrane domain, and an intracellular domain that binds to catenins, which mediate the connection of the multiprotein complex to the cytoskeleton via alpha-catenin. E-cadherin is expressed at adherens junctions, where it causes clustering of actin-containing cytoskeletal structures. In adherens junctions, the E-cadherin complex interacts with actin regulators, including Arp2/3, Ena/VASP, and WASP family proteins. Due to the composition of this

Table 2 Classification of cadherins (the cadherin superfamily)

Classical cadherins (CDHs)
CDH1 (E-cadherin)
CDH2 (N-cadherin)
CDH3 (P-cadherin)
CDH12 (cadherin 12)
Desmosomal cadherins
Desmogleins (DSG1, DSG2, DSG3, DSG4)
Desmocollins (DSC1, DSC2, DSC3)
Protocadherins (PCDHs)
PCDH1-18
Ungrouped cadherins
T-cadherin, CDHs 4–28

complex, adherens junctions are dynamical structures that are subject to remodeling, both in normal and cancer cells. E-cadherin is an important adhesion molecule acting in the invasion cascade and involved in epithelial-mesenchymal transition/EMT (Osada et al. 1996). It mediates homophilic cell-cell interactions and by this counteracts cell detachment and invasion (Frixen et al. 1991). N-cadherin (CDH2; neural cadherin) is required for gastrulation and the generation of left-right symmetry and mediates presynaptic to postsynaptic adhesion in certain neurons. P-cadherin (CDH3; placental cadherin) is an adhesin that interacts with several molecules, including beta-catenin and plakoglobin.

E-cadherin in Liver Cancer

Epithelial cadherin (E-cadherin) is often lost as a function of tumor progression and a transition to an invasive phenotype, this loss favoring adhesion failure and decomposition of adherens junctions (review: Canel et al. 2013). Loss of E-cadherin expression has complex sequelae that include failure of cell-cell adhesion and disruption of adherens junctions through breakdown of its cytoskeletal links, both causing disconnection of tumor cells from each other, tumor cell individualization, and invasive features (Behrens et al. 1991). Deregulation of E-cadherin in HCC is also a feature of epithelial-mesenchymal transition (Zhai et al. 2014; see below). Genomic alteration in the CDH1 gene encoding E-cadherin causing loss of function of this adhesin has been observed in numerous cancers. Downregulation of E-cadherin in HCCs depends on the tumor grade, expression being less reduced in well-differentiated than in poorly differentiated cancers (Endo et al. 2000). Generally, loss of E-cadherin in HCC confers an invasive phenotype with a more aggressive course (Cho et al. 2008; Hashiguchi et al. 2013; Chen et al. 2014a; Li et al. 2014), probably via loss of intercellular contact which promotes tumor cell individualization, a prerequisite for locomotion and invasion. Levels of E-cadherin were lower in multinodular and extranodular HCC growth types than in the single nodular type (Inayoshi et al. 2003). Fascin-1 expression correlates with repression of E-cadherin expression in HCC cells and augments their invasiveness (Hayashi et al. 2011). Mechanisms to reduce E-cadherin expression comprise somatic and germline mutations and epigenetic modifications of gene expression (review: Schmalhofer et al. 2009). E-cadherin is regulated by the Wnt/beta-catenin signaling cascade and is linked to the functions of the cytoskeleton (Schmalhofer et al. 2009). Reduced expression of E-cadherin was also detected in intrahepatic cholangiocarcinoma and other biliary tract cancers (Settakorn et al. 2005; Németh et al. 2009; Mao et al. 2013). In cholangiocarcinomas, E-cadherin cooperates with decorin-mediated inhibition of growth and migration (Yu et al. 2014) and is repressed by Slug in the setting of epithelial-mesenchymal transition (Zhang et al. 2010). Downregulation of E-cadherin in extrahepatic cholangiocarcinoma is associated with EMT, which favors an invasive growth pattern (Araki et al. 2011). Loss of liver E-cadherin in murine models induced a form of sclerosing cholangitis and hepatic carcinogenesis (Nakagawa et al. 2014). Enhanced expression of E-cadherin in noncancerous liver tissue was associated with recurrence of HCC following curative resection (Minata et al. 2013). Loss of E-cadherin is a feature of epithelial-mesenchymal transition which in turn affects invasion of cancer cells (see below). In fact, part of the effects exerted by E-cadherin in cancer occur in the setting of EMT, with which E-cadherin function is closely integrated (Wang et al. 2012).

N-cadherin in Liver Cancer

In normal liver, neural cadherin/N-cadherin is strongly expressed on cell-cell boundaries of hepatocytes and cholangiocytes. Here, N-cadherin is co-expressed with E-cadherin. Also reactive ductular proliferations express both of these cadherins (Mosnier et al. 2009). In HCCs, expression of N-cadherin varies in several investigations, being upregulated in part of studies (Seo et al. 2008), while others reported reduced

N-cadherin expression in more than 50 % of HCC, associated with poor tumor differentiation, increased migration, invasion, metastasis, and poor outcome (Zhan et al. 2012). In HCC, loss of N-cadherin was associated with concurrent loss of E-cadherin expression and poor outcome after liver resection (Cho et al. 2008; Liu et al. 2015). In cholangiocarcinomas, N-cadherin expression was more common in peripheral tumors than in perihilar ones (Mosnier et al. 2009). N-cadherin as an EMT-related molecule is an independent prognostic factor in extrahepatic cholangiocarcinoma (Nitta et al. 2014).

P-cadherin in Liver Cancer

P-cadherin (CDH3) is a further cadherin superfamily member involved in cancer biology. In HCC, P-cadherin is significantly downregulated compared to normal hepatocytes. In part of tumors, P-cadherin expression is completely lost, and this deregulation is associated with aggressive biology (Bauer et al. 2014). In cholangiocarcinoma cells, P-cadherin is frequently overexpressed and regulates cell migration in an EMT-independent manner (Baek et al. 2010). P-cadherin expression was found in about a third of intrahepatic cholangiocarcinomas and more frequently in extrahepatic cholangiocarcinoma, gallbladder carcinoma, and, most commonly, in dysplastic biliary epithelium, while no expression was seen in normal bile duct epithelia (Riener et al. 2010).

Other Cadherins in Liver Cancer

In diverse human cancers, the atypical cadherin FAT1/giant cadherin acts as an oncogene and tumor suppressor. FAT1 was increased in human HCC tissues. Overexpression of FAT1 is induced by hepatocyte growth factor and hypoxia-inducible factor 1alpha and is correlated with growth and invasion (Valletta et al. 2014). In intrahepatic cholangiocarcinomas, weak cytoplasmic staining for FAT was observed (Settakorn et al. 2005). Liver-intestine cadherin (LI-cadherin), another member of the cadherin superfamily, is expressed in part of biliary intraepithelial lesions (BillN) and the grade of BillN independently correlated with LI-cadherin expression (Inoue et al. 2011). In HCC, protocadherin 9 inhibits EMZ and cell migration via activation of glycogen synthase kinase-3beta of the ceta-catenin signaling pathway (Zhu et al. 2014). Protocadherins also play a role in the biology of extrahepatic cancers and their liver metastasis. Protocadherin 10 suppresses metastasis of colorectal carcinoma (Jao et al. 2014).

Integrins

Introduction

Integrins are heterodimeric adhesion receptors at the cell surface and connect the cytoskeleton with proteins of the ECM. Through their central function in cell-matrix adhesion processes, integrins are important mediators of cancer invasion and spread (Varner and Cheresh 1996; Hayashi 2010; Margadant and Sonnenberg 2010; Ganguly et al. 2013). The integrin family consists of 24 members formed by non-covalently associated alpha- and beta-chains. These heterologous molecules are differentially expressed in various cell systems (Valdembri et al. 2009). Integrin expression is regulated by a complex system of factors, in which TGF-beta signaling has a central place (Hayashi 2010). On the other hand, beta3 integrin enhances TGF-beta signaling, illustrating a close interaction between the two pathways (Feng et al. 2013). Alpha- and beta-subunits possess short cytoplasmic domains that interacts with numerous proteins. For example, the beta-tail of integrins interacts with proteins that display a band 4.1, ezrin, radixin, and moesin (FERM) domain. A protein important for motility and invasion having an integrin-binding FERM domain is myosin X, a factor important for filopodia formation. In adhesion construction and adhesion-mediated signaling pathways, integrins form a complex adhesome that has been compiled in a functional atlas of these molecules (Zaidel-Bar et al. 2007). This integrin adhesome contains a network of 156 components linked together and

modified by several hundred interactions. Apart from mediating adhesion processes, integrins are also active in complex signaling pathways involving a large number of components (the integrin interactome). Integrin signaling includes Src family kinases, Ras proteins, components of the Wnt signaling cascade, Notch, Raf, and caveolae-mediated signaling. Within this network, integrin regulating is in part accomplished by integrin epigenetics, involving DNA and histone modifications (Deb et al. 2012). A central role in cell adhesion and migration is played by alpha3beta1 and alpha6beta4 integrins (review: Giannelli et al 2002). Integrins cooperate with CD44 variants to bind to osteopontin, thereby stimulating cell motility and chemotaxis (Katagiri et al. 1999). Integrins interact with fibronectin. The fibronectin-integrin beta1 signaling pathway is involved in tumor cell migration and is inhibited by the product of a putative cancer gene, SERPINA5 (Jing et al. 2014). The pro-migration function of integrins is blocked by interaction with filamin, which binds to the beta7 integrin tail (Calderwood et al. 2001).

Deregulation of Integrins in Liver Cancer

Various types of integrins are expressed in normal liver and liver neoplasms and are predictors of disease severity (Liu et al. 2002; Jin et al. 2014). Generally, benign hepatocellular tumors, such as hepatocellular adenoma, and well-differentiated HCCs express the same set of integrins as the normal liver, while poorly differentiated HCCs express de novo integrins, such as alpha2-, alpha3-, and alpha6-containing integrins. Similarly, well-differentiated cholangiocarcinomas show an integrin spectrum identical to that of normal cholangiocytes, whereas poorly differentiated cholangiocarcinomas reveal downregulation of integrins (Volpes et al. 1993). Transcription of the alpha3 integrin gene in HCC is upregulated by TGF-beta1 signaling (Katabami et al. 2005). In some HCCs, integrins of the beta2 and beta3 types are downregulated, associated with deletion of collagen triple helix repeat containing 1 (CTHRC1), a protein whose gene is located to chromosome 8q22.3, frequently altered in HCC (Tameda et al. 2014).

Integrins markedly affect tumor cell invasion due to their receptor functions for components of the extracellular matrix, an important scaffold for growth and invasion of cancer cells. Part of integrins are laminin-binding proteins in tumors and via this mechanism strongly affect motility and invasion (Ziober et al. 1996; Belkin and Stepp 2000). Integrin beta-1 is an important molecule to mediate cell-matrix adhesive interactions of HCC cells, and this interaction influences tumor cell migration (Giannelli et al. 2001) and invasive spread (Masumoto et al. 1999; Nejjari et al. 2002; Tian et al. 2005; Mizuno et al. 2008). Integrin alpha6 beta1 is critically involved in the attachment of HCC cells to laminin (Torimura et al. 1999), and these integrin and laminin are coordinately expressed in HCC (Torimura et al. 1997). Integrin alpha5 is expressed in HCC with low metastatic potential, but is absent in highly metastatic HCC (Yao et al. 1997). Beta1 integrin is specifically phosphorylated by TGF-beta1 via Smad2 and Smad-3, a mechanism prompting HCC invasion (Fransvea et al. 2009). Apart from regulating adhesion and invasion of cancer cells, integrins also regulate proliferation and apoptosis (Ozaki et al. 2011). Integrin beta3 has a proapoptotic function in humans HCCs (Wu et al. 2009). In biliary cancers, integrin expression is linked to differentiation patterns. Beta1, beta4, and beta6 integrins are expressed in cholangiolocellular carcinoma, but not in cholangiocarcinoma (Soejima et al. 2014).

Integrins are involved in metastatic spread of cancers within the liver. The prometastatic activity of integrins is modulated by microRNAs. MicroRNA-134 acts as a metastasis suppressor by targeting integrin beta1 in HCC (Zha et al. 2014).

Adhesion Proteins Other Than Integrins and Cadherins

L1 cell adhesion molecule (L1CAM) is overexpressed in HCC, an alteration associated with poor tumor differentiation and advanced

progression (Guo et al. 2012). One of the most important adhesion molecules in epithelial cell-basement membrane interaction is alpha-dystroglycan, serving as a cell surface receptor for several basement membrane proteins, specifically laminin, agrin, and perlecan. The laminin-binding alpha-dystroglycan can act as a tumor suppressor (Bao and Fukuda 2010). Osteopontin secreted adhesive glycoprotein that is important for numerous adhesive processes of cancer cells and for the regulation of EMT. Osteopontin is overexpressed in HCCs, mainly in those with a dispersed growth mode and capsular infiltration (Gotoh et al. 2002), i.e., in tumors with a highly invasive phenotype. Intracellular osteopontin itself is an integral component of the CD44-ezrin/radixin/moesin complex involved in cell migration (Zohar et al. 2000). Agrin is expressed in both HCCs and cholangiocarcinomas (Tatrai et al. 2006) and is, apart from adhesion processes, also involved in angiogenic responses (Batmunkh et al. 2007). Expression of agrin in adherent and motile cells can induce the formation of actin-based filopodia-like protrusions, leading to activation of Cdc42 and Rac1 (Lin et al. 2010). Rac1 expression itself is inhibited in HCCs by TNF-alpha-induced protein 8-like 2, a negative immune regulator and inhibitor of oncogenic Ras (Cao et al. 2013). The adhesin CD24 is involved in various intercellular adhesion processes. The differential expression of CD24 is regulated by NDRG2 (N-myc downstream-regulated gene 2), in that upregulation of NDRG2 results in decreased CD24 expression, cell adhesion, migration, and invasion, while downregulation of NDRG2 is associated with an invasive HCC phenotype (Zheng et al. 2011). Expression of CD44v6 in HCC cells is modulated by overexpression of the A/B hnRNP subfamily member, HnRNP A1, resulting in increased invasion of HCCs (Zhou et al. 2013). CD44 alternative splicing is negatively regulated by a binding protein of PCBP1, THAP11, an essential factor involved in embryonal stem cell pluripotency and cell growth. In HCC cells, THAP11 inhibited CD44v6 expression and cell invasion (Lian et al. 2012). Similar to CD44, CD147/EMMPRIN is involved in adhesion processes and affects cell-ECM interactions in cancer (Hao et al. 2010). Adhesion of epithelial cells along their lateral line is promoted by the immunoglobulin superfamily member, CRTAM (class I-restricted T-cell-associated molecule), a protein related to nectin-like proteins (Garay et al. 2010). Adhesion and migration of HCC cells are positively affected by the regulatory factor SSX2IP (synovial sarcoma, X breakpoint 2 interacting protein), an acute myeloid leukemia-associated antigen. SSX2IP is capable to facilitate HCC metastasis in experimental models (Li et al. 2013).

Extracellular Matrix (ECM) as a Platform Regulating Invasive Processes

Introduction

The extracellular matrix (ECM; intercellular substance) of normal tissues and tumors is a highly complex, noncellular, multimolecular compartment which critically regulates the biology of cells embedded in it (reviews: Wu and Chen 2006; Frantz et al. 2010). Numerous proteins, proteoglycans, and glycosaminoglycans make part of a scaffold produced by stromal cells (mainly myofibroblasts, cancer-associated fibroblasts, immature mesenchymal cells, and stellate cells; Faouzi et al. 1999), but also by tumor cells in the setting of epithelial-mesenchymal transition. Synthesis and secretion of ECM molecules by stromal cells are markedly modulated by signaling performed by leukocytes present in the stroma, in particular tumor-associated macrophages, monocytes, lymphocytes, and neutrophils. Predominant proteins of the ECM include basement membrane proteins, several types of fibrous proteins (mainly collagens), proteoglycans, and glycosaminoglycans (Table 3). Based on its dynamical composition with numerous macromolecules active in signaling and various interacting stromal cells, tumor ECM is a master regulator of carcinogenesis, tumor progression, and metastasis. The ECM is a central structure for numerous signaling pathways, and interacting material for cell receptors, and a storage site for growth factors and other mediators (Quail and Joyce 2013).

Table 3 Constituents of the extracellular matrix (ECM)

Collagens
Fibrillar collagens (types I, II, III, V, XI)
Short-chain (net-forming) collagens (types VIII, X)
Fibril-associated collagens (FACIT) (types IX, XII, XIV)
Anchoring collagen (type VII)
Lace-lake collagen (type VI)
Collagens with transmembrane domains (types XIII, XVII)
Basement membrane collagen (type IV)
Other proteins
Fibronectin
Elastin and associated fibrillins
Tenascins
Proteoglycans
Heparan sulfate proteoglycans
Chondroitin sulfate proteoglycans
Keratan sulfate proteoglycans
Dermatan sulfate proteoglycans
Glycosaminoglycans
Hyaluronic acid (hyaluronan)

Role of Basement Membrane Proteins in Liver Cancers

The basement (BM) as a distinct structure forming an interface with the ECM and providing a scaffold for epithelial, endothelia, muscle, and Schwann cells plays a crucial role in mechanisms of cancer cell spread and invasion.

In normal tissues, the BM consists of two laminae, the basal lamina and the reticular lamina, the latter being attached to the former through type VII collagen anchoring fibrils and fibrillin microfibrils. The basal lamina is itself divided into a layer facing the epithelium or endothelium, the lamina lucida, and the ECM, the lamina densa. The lamina lucida mainly consists of laminins, entactin (nidogen-1), nidogen-2, netrins, agrin, and dystroglycans. Nidogens, netrins, and agrin are laminin-binding proteins. Dystroglycan is part of the dystrophin-glycoprotein complex (DGC) which forms a link that extends from laminin, agrin, and perlecan to alpha-dystroglycan to beta-dystroglycan to dystrophin/utrophin to F-actin. The lamina densa is composed of a network of type IV collagen fibrils coated with the heparan sulfate-rich proteoglycan perlecan. Agrin and perlecan create a collateral linkage to cell surfaces. The reticular lamina is rich in type III collagen.

With its complex composition and intricate contacts with cells and components of the ECM, the BM represents an important signaling platform for numerous cell processes and functions (review: Yurchenco 2011). In the adhesion and invasive process of HCCs and other liver cancers, basement membrane proteins play an active role, expression of laminin genes having a particular significance (Tian et al. 2005; Huang et al. 2008). Laminins form a complex family of proteins where each laminin is a heterotrimer consisting of one each of five alpha, four beta, and three gamma subunits, in vertebrates resulting in 15 laminin species. Laminins bind to a distinct 67 kDa receptor that is expressed in normal cells and cancer cells (Castronovo 1993).

Laminins and type IV collagen have an important effect on tumor cell motility and chemotaxis (Ogata 1998). In HCCs, laminin seems to be produced by sinusoidal-like channels (Donato et al. 1989). Laminin deposition to type IV collagen takes place along sinusoidal vascular channels (capillarization) and is associated with increased tumor cell adhesion and motility mediated by beta1 integrins (Tabarin et al. 1987; Torimura et al. 2001). Several laminin forms have been implicated in HCC invasion, including laminin-4 (LAMA4) and laminin-5 (Huang et al. 2008). In their pro-invasive function, laminins closely interact with the EMC adhesion receptors, integrins. Laminin-1 and laminin-11, which play an important role in motility and invasion, specifically bind to integrins alpha3beta1, alpha6beta1, and alpha6beta4 (Kikkawa et al. 2000). Similar to normal cells, tumor cells can bind to laminin through specific laminin receptors. In HCCs, laminin receptors are differentially expressed and upregulated whereby laminin-binding protein (67 kDa laminin receptor), alpha6 integrin, and beta1 integrin play a central role (Sobel 1993; Ozaki et al. 1998). There is an association between 67 kDa laminin receptor expression and metastasis of HCC (Zheng et al. 1997).

In HCCs this receptor is preferentially expressed in tumors with a high metastatic potential (Zheng et al. 1997). HCC cells strongly adhere, migrate, and spread in the presence of laminin-5 secreted by these neoplasms (Kikkawa et al. 2008; Santamato et al. 2011). This effect of laminin-5 and other laminins in part depends on its interaction with beta1 and beta4 integrins (Torimura et al. 1997; Bergamini et al. 2007). Aberrant expression of laminin gamma2 is correlated with invasion and an aggressive course in extrahepatic cholangiocarcinoma (Liu et al. 2014). In addition to their role as attachment sites for cancer cells, laminins can directly induce distinct alterations of neoplastic cells. For example, laminin-5 together with TGF-beta1 induces epithelial-mesenchymal transition (Giannelli et al. 2005) and via this pathway promotes invasion. In tumor stroma, hepatic stellate cells and myofibroblasts produce laminin-5 and thus stimulate migration of HCC cells (Santamato et al. 2011). Nidogen-2, a laminin-binding protein, is downregulated in HCC. This decreased expression is associated with tumor spread and progression (Cheng et al. 2012). HCC cells also express the BM protein agrin, which interacts with alphaV-type integrins and growth factors (Tatrai et al. 2006). The expression of BM proteins in HCCs varies according to tumor differentiation. In contrast to grade 2–4 HCCs, well-differentiated HCCs show cell cords forming a streak pattern devoid of accompanying reticulin and type IV collagen (Miyao et al. 1999).

Other Proteins of the Extracellular Matrix That Affect Cancer Cell Invasion

Fibronectin is upregulated in HCC and is predominantly present in the subendothelial spaces of sinusoid-like vascular channels and in the stromal ECM of these neoplasms (Isemura et al. 1982; Torimura et al. 1994; Koukoulis et al. 1995; Enjoji et al. 1998). Based on the distinct pericellular arrangement of fibronectin in HCC, it was suggested that this protein is produced by cancer cells themselves (Donato et al. 1989). In HCC stroma, fibronectin deposition is increased or decreased, increased amounts predominantly found in fibrolamellar carcinoma, clear cell HCC, and encapsulated HCC. Augmented fibronectin appears as thin or thick feathery strands in pericellular, periglandular, stromal, or perisinusoidal distribution (Jagirdir et al. 1985). Fibronectin represents a scaffold on which cancer cells can locomote. In the ECM, fibronectin affects tumor cell motility in close cooperation with integrin beta1, an interactome which can be modulated by several stromal factors. For example, SERPINA5, which is encoded by a gene subject to alterations in HCC, inhibits fibronectin-integrin-mediated HCC cell migration (Jing et al. 2014). The pro-invasive effect of fibronectin is promoted by neuropilin-1, which increases fibronectin fibril assembly (Yaqoob et al. 2012). One of the effects of the metastasis suppressor, Nm23-H1 (see below) is its impairment of HCC cell migration on fibronectin scaffolds by modulating glycosylation of integrin beta1 receptors (She et al. 2010). Increased fibronectin expression in tumor microenvironments is stimulated by neuropilin-1, a protein which controls communications between stromal myofibroblasts and soluble fibronectin (Yaqoob et al. 2012). Similar to fibronectin, vitronectin is a protein that is consistently expressed during invasion of HCC (Inuzuka et al. 1992; Chen et al. 2014b). Apart from affecting the invasive behavior of cancer cells, vitronectin expressed in the stroma of hepatic cancers contributes to local immune reactions via the recruitment of lymphocytes in an integrin-dependent manner (Edwards et al. 2006).

A protein that critically affects adhesions of cells in the ECM is tenascin, a glycoprotein which exists in several forms (review: Chiquet-Ehrismann 1993). In normal liver, tenascin is localized along the sinusoidal and other vascular walls, while it is upregulated in inflammatory and fibrotic disorders of the liver and is mainly present in stellate cells (Yamada et al. 1992). In liver cancers, tenascin is predominantly found in cells derived from stellate cells, i.e., myofibroblasts. Tenascin interacts with other proteins that hold a central place in adhesion processes, in particular integrins (Tanaka et al. 2014). Tenascin is upregulated in HCC in comparison with

hepatocytes of cirrhotic livers and is also augmented in small dysplastic liver cells (Zhao et al. 1996). Tenascin is mainly upregulated in fibrous septa and pseudocapsules of HCCs (Yamada et al. 1992). In intrahepatic cholangiocarcinoma, tenascin is expressed in the stroma and suggested to stimulate cancer cell proliferation (Terada and Nakanuma 1994). Tenascin expression in the stroma of these neoplasms was detectable in 68 % of cases, and specifically the presence of tenascin at the invasive front was associated with tumor growth, lymphatic invasion, and lymph node metastasis (Aishima et al. 2003). Tenascin-C also affects the invasive behavior of cancers metastasizing to the liver. In colorectal carcinoma cells, tumor-derived tenascin-C promotes epithelial-mesenchymal transition and via this mechanism favors invasion and spread (Takahashi et al. 2013). The stroma of liver cancers contains various types of interstitial and basement membrane collagens, including type III collagen (Gulubova 1997). These fibrillary proteins provide a scaffold for cell attachment and migration.

Proteoglycans of the Extracellular Matrix

Similar to fibrogenic liver diseases, HCCs with their variably developed stroma show alterations in the content of heparan sulfate-containing proteoglycans (Roskams et al. 1998; Tatrai et al. 2010), a feature that affects the ECM and its invasion-regulating properties. Certain proteoglycans are variably upregulated or downregulated in HCC, e.g., syndecans (Matsumoto et al. 1997). Syndecan-1 and syndecan-4 are involved in HCC cell migration induced by the RANTES/CCL-5 chemokine pathway (Charni et al. 2009). Heparan sulfate expression is also enhanced in the fibromyxoid stroma of intrahepatic cholangiocarcinomas as well as in hepatic colorectal carcinoma metastases (Sabit et al. 2001). Syndecan-3 and perlecan are strongly expressed in stromal vessel walls of liver cancers, and accumulation of perlecan in stroma may play a role as a growth factor reservoir (Roskams et al. 1998).

Glycosaminoglycans of the Extracellular Matrix

Hyaluronan (HA) is an abundant glycosaminoglycan which is important for ECM homeostasis, tissue remodeling, generation of cell-free spaces in tissue, regulation of inflammation, and angiogenesis. HA is also implicated in cell locomotion, both of normal and tumor cells. HA-induced autocrine motility mechanisms are mediated by the HA receptor, RHAMM (receptor for HA-mediated motility). HA is also capable to bind to CD44. HA-RHAMM binding activates a signal cascade that results in protein tyrosine phosphorylation of factors involved in motility and in targeting of focal adhesions (Hall and Turley 1995). Cell locomotion stimulated by TGF-beta1 depends on the HA/RHAMM interaction (Samuel et al. 1993).

Abstract

For the acquisition of active motility, cancer cells must undergo a shape change to acquire a polarized phenotype, similar to locomoting leukocytes. Polarity of motile cells is characterized by a leading front and a rear region. Polarity of normal and neoplastic cells depends on a distinct cortical actin skeleton and the generation of various cell junctions. Several cytoskeletal proteins promote polarity in normal and transformed cells, including Hugl-1, radixin, and claudin-1. Cell surface proteins interacting with other cells and matrix transmit signals to the machinery which generates polarity and motility. The motile response of polarized tumor cells is associated with the biogenesis of several types of cell projections, including blebs, pseudopods, lamellipodia, filopodia, and cytonemes. The function of these projections in cell migration critically depends on a complex cytoskeletal machinery. The expression of polarity- and motility-associated proteins in normal and neoplastic cells is subject to epigenetic modifications, specifically to numerous types of microRNAs. Motility and migration are induced by two basic forms of chemical stimulation, i.e., chemokinesis (induced random motility) and chemotaxis (induced directed motility). Several chemokinetic and chemotactic factors have been identified in cancers.

Tumor Cell Polarity: A Prerequisite for Cell Motility and Migration

Introduction

A critical prerequisite for motility-associated shape change is the establishment of a polarized phenotype of cells, characterized by a leading front and a rear region, the latter being devoid of lamellipodia or other cell projections (Keller and Zimmermann 1986; Zimmermann and Keller 1987; Zimmermann et al. 1988; Keller et al. 1991). On the other hand, loss of apicobasal polarity often results in a malignant phenotype in epithelial cells (McCaffrey and Macara 2011), suggesting that distinct types of cell polarity and shape change are required for a motile phenotype. In fact, a severely deranged control of cell polarity is an important feature of epithelial cancers (Halaoui and McCaffey, 2014). Cell polarity depends on an intricate interaction between cell surface molecules and the submembrane actin-containing cytoskeleton, and the microtubular apparatus, components that are critical for the establishment of shape change (Akhshi et al. 2014).

Polarity Proteins

Polarity of epithelial cells depends on a distinct cortical actin cytoskeleton and the development of various cell junctions. The generation and maintenance of a cortical actin network are regulated by spectrins which in turn are regulated by the tumor suppressor protein, Scribble (Elsum et al. 2012; de Vreede et al. 2014; Boeda and Etienne-Manneville 2015). Several proteins promote polarity in normal and transformed epithelial cells, whereby a central role is played by proteins that construct tight junctions (reviews: Kojima et al. 2009; Mariano et al. 2011). Claudins, which are critically important for the maintenance of tight junctions, are overexpressed in several types of cancers (review: Kominsky 2006). Tight junction proteins that strongly affect changes in polarity are the MARVEL proteins (MAL and related proteins for vesicle trafficking and membrane link), specifically tricellulin, occludin, and marvelD3 (Raleigh et al. 2010). A specifically important group of polarity-promoting protein is formed by the conserved PAR (partitioning-defective) proteins that function by generating cortical domains involved in dynamic asymmetries of cells (review: Nance and Zallen 2011). Human ASIP or PAR3 is a cell polarity protein with several isoforms that differ in their functions (Mishima et al. 2002; Hu et al. 2005). ASIP/PAR3/Bazooka is PDZ motif-containing proteins that localize asymmetrically at the cell periphery and mediate polarity and asymmetrical cell division (Fang and Xu 2001). ASIP/PAR3

directly associates with junctional adhesion molecule (JAM) (Ebnet et al. 2001) and promotes epithelial tight junction formation (Hirose et al. 2002). A second PAR protein operating in cell polarity is PAR6, which directly interacts with the morphogen CRB3, a human homologue of the apical transmembrane protein Crumbs (Lemmers et al. 2004). The Crumbs complex affects cell polarity through its regulation of cell junction formation (Médina et al. 2002). Crumbs proteins also interact with Scribble, a scaffold protein involved in cell polarity (Leong et al. 2009). In various epithelial cell types and their neoplastic offspring, Hugl proteins (the human homologues of *Drosophila* lethal giant larva proteins) play a significant role in the establishment of cell polarity. The Hugl-2 polarity protein in part acts via its induction of mesenchymal-epithelial transition (Kashyap et al. 2013). In epithelial cells, induction of polarity is associated with ROCK (Rho-associated kinase)-dependent apical constriction, a process regulated by two proteins, the polarity-regulated protein PAR3 and a FERM domain protein, Willin (Ishiuchi and Takeichi 2011). Willin is a novel 4.1 ezrin, radixin, and moesin (FERM)-containing protein (Gunn-Moore et al. 2005) which activates the Hippo signaling pathway kinases (Angus et al. 2012).

Polarity Changes in Hepatocytes and Invading Liver Carcinoma Cells

Acquisition of polarity changes in HCC cells is expected to involve mechanisms that also play a role in the cells of origin, i.e., hepatocytes and their progenitor cells. Hepatocytes arranged in hepatic cell plates possess a distinct apicobasal polarity which is crucial for their functional embedding between a sinusoidal compartment and the lumen of the canaliculus, which forms a gate to the outer world. The complex metabolic and transport functions of hepatocytes critically depend on this polarity, which is regulated by a distinct set of mechanisms (Hua et al. 2012; Müsch 2014). Apicobasal polarity of parenchymal cells also controls lymphocyte adhesion to hepatocytes and thus affects local immune responses (Reglero-Real et al. 2014) and influences the lateral diffusion of the CD81 HCV receptor (Harris et al. 2013). In normal hepatocytes, radixin, a member of the ezrin-radixin-moesin system that cross-links plasma membrane and the actin cytoskeleton, is required for the maintenance of an apical domain and hence apicobasal polarity (Kojima et al. 2003; Wang et al. 2006). Phosphorylated radixin is mainly localized to the basolateral membrane of liver cells (Suda et al. 2011), thus generating a polarization signal. Radixin phosphorylation also regulates the polarized cellular distribution of the multidrug resistance-associated protein 1/Mrp-1 (Suda et al. 2014). Hepatocyte polarization is linked to cytokinesis, in that polarity proteins are delivered to the site of cell division in a strict order. Daughter cells remain attached for a while through a disk-shaped structure which is a site for targeted exocytosis, the primitive canalicular domain. Oriented or asymmetric cell division will occur at the midpoint of this domain (Slim et al. 2014; Wang et al. 2014). Polarization and repolarization of hepatocytes requires recycling of intracellular constituents and organelles, in particular mitochondria, a process regulated by autophagy (Fu et al. 2013).

It is expected that HCC cells lose this mode of polarity when becoming motile cells, whereas HCC cells that form acinar/pseudoglandular structures resume apicobasal polarity and an apical canaliculus-like domain. The polarity mode of HCC cells is influenced by the expression of several surface proteins, in particular adherens junction and desmosome proteins (Cao et al. 2007). Generally, adherens junctions, tight junctions, and their associated proteins experience a marked redistribution in HCC (Cao et al. 2007). Claudin-1, acting through c-Abl protein kinase Cdelta, is involved in the acquisition of an invasive phenotype in liver cells (Yoon et al. 2010). Downregulation of claudin-10 in HCCs is associated with prolonged survival after surgery, while suppression of this claudin in HCC cells inhibits invasion (Ip et al. 2007). In cholangiocarcinoma, overexpression of claudin-4 is an early alteration and is associated with increased cell migration (Bunthot et al. 2012). PAR3, which plays a role

in normal cell polarity induction, is overexpressed in part of HCC, associated with an invasive phenotype and distant metastases (Jan et al. 2013). Cancer cell polarity is determined by apical proteins that determine polarity, including the Crumb homologue CRB3 (Li et al. 2015a; Mao et al. 2015). Hugl-1, the human homologue of the *Drosophila* lethal giant larvae, is a protein involved in the generation of cell polarity. Aberrant splicing of Hugl-1 in HCCs is associated with disease progression, truncated proteins promoting migration through polarity induction (Lu et al. 2009). LRRC1/LANO, a putative cell polarity regulator, is aberrantly upregulated in part of HCCs and confers a transformed phenotype associated with progression (Li et al. 2013). Planar cell polarity is stimulated by the collagen triple helix repeat containing-1/CTHRC1, a secreted glycoprotein which is overexpressed in HCCs and promotes an invasive phenotype (Chen et al. 2013c). In the signaling pathways affecting polarity and migration of cancer cells, altered functions of protein kinase C play a significant role (Keller et al. 1989; Zimmermann and Keller 1992, 1993; Niggli et al. 1996). The expression of polarity-associated proteins in cancer cells is regulated by microRNAs. In HCC, microRNA-296 controls cell motility by transcriptionally repressing the cell polarity-cell plasticity module, Scribble. Loss of this MiR in HCC causes aberrantly increased and mislocalized Scribble resulting in exaggerated random cell locomotion (Vaira et al. 2012).

Tumor Cell Motility and Migration: Role of Cell Protrusions

Introduction

Tumor cell motility, required for locomotion and migration, is a crucial step in cancer cell invasion. By use of their locomotion machinery, individualized cancer cells having lost their connections with neighboring cells and adhered to substratum can move in response to chemokinetic signals and chemotactic gradients (review: Bradbury et al. 2012). Chemokinesis denotes the phenomenon that normal or tumor cells are motile in a random manner in response to chemical stimuli. In contrast, chemotaxis is defined as a process whereby cells undergo a directional, nonrandom movement in response to chemical stimuli, the chemotactic factors. Positive chemotaxis is a movement toward the source of stimulus and negative chemotaxis a movement away from the stimulus. Initiation of cell motility and active locomotion/migration depends on marked changes in the cytoskeleton, shape change, determination of a front vs. a rear end, and the generation of specialized cell protrusions at the leading edge. These protrusions are blebs, pseudopods, lamellipodia, and filopodia. All these protrusions and their dynamics are regulated by the entire set of cytoskeletal protein networks summarized under the term cytoskeletome (Hall 2009; Klemke et al. 2013). Pseudopodal cell surface specializations play a central role in chemotaxis, chemokinesis, random or directed migration, and extracellular signaling (Insall 2013). A critical role in the initiation of locomotion is the definition a leading edge, which in turn depends on cell polarization and on cellular motility motors. In principle, two motors can drive the leading edge, i.e., actin polymerization and myosin-driven contraction of the cell cortex followed by formation of blebs and various types of pseudopods (Tyson et al. 2014).

Blebs

Blebs are cellular protrusions that are instrumental for cell motility and locomotion, in development, inflammatory reactions, and cancer. Blebs have a significant role in cell migration. The current view is that blebs are driven by hydrostatic pressure generated in the cytoplasm by a contractile action of the actin-myosin cortex of the cell (Paluch and Raz 2013).

Pseudopods

In general, pseudopods (pseudopodia, "false feet") are phylogenetically ancient, transient

protrusions of cells that confer an amoeboid shape. Pseudopods and their variants are crucial structures for motility and locomotion and engulfment of objects that will be phagocytosed. Depending on their shape and the species in which they develop, pseudopods are divided into filopodia and variants thereof, lobopodia, reticulopodia (reticulose pseudopods), and axopodia. Pseudopodial cell protrusions depend on the function of the cytoskeleton and involve the reversible assembly of F-actin subunits and generation of a microtubular network, cytoskeletal machines which in turn depend on a complex regulatory proteome which is altered in cancer cells. Morphogenesis of the various variants of pseudopods starts with the formation of a lamellipodium (see below), whereby the cell projects a membrane bud which is equipped inside with actin filaments forming the leading edge. Into this bud, cytoplasm flows creating the pseudopod. Lamellipodia not only are formed by eukaryotic cells engaged in phagocytosis but are also a feature of locomoting cancer cells.

Lamellipodia

Lamellipodia are flat, sheetlike cellular protrusions centrally involved in cell motility and locomotion. In principle, lamellipodia are an early phase of pseudopod formation. At the base of lamellipodia, unbranched and long F-actin filaments stream into the protrusion, progressing into a complex laterally branched actin network ending at the leading edge of the lamellipodium (Yamaguchi and Condeelis 2007; Bisi et al. 2013; Zimmermann and Falcke 2014). Initiation and orientation of lamellipodia is directed by F-actin bundles via an adhesion-based signaling pathway (Johnson et al. 2015). In their function as motility-promoting structures, lamellipodia adhere to the substratum and the ECM via adhesins, in particular integrins and cadherins. The actin dynamics characterizing lamellipodial turnover depends on cofilin and swiprosin-1, an actin-bundling protein (Kwon et al. 2013). Swiprosin-1 regulates F-actin accessibility to cofilin (Huh et al. 2013). Swiprosin-1 and swiprosin-2 are two homologous calcium-binding adaptor proteins (Dütting et al. 2011). Pseudopodia-induced motility of cancer cells also depends on an actin-binding adaptor protein, alpha-parvin, which is a constituent of pseudopodia/lamellipodia and promotes cancer cell locomotion and metastasis (Ito et al. 2014). The biogenesis of lamellipodia and other forms of cell protrusions is regulated by the Rho GTPases Rac1 and RhoA which are indispensable for protrusion generation and interactions with the extracellular matrix.

In lamellipodia, distinct sets of other regulatory proteins are accumulated, whereby the Arp2/Arp3 complex has a central role. This complex is a seven-subunit protein that operates in the initiation of actin assembly and the generation of actin network treadmilling (Koestler et al. 2013) and is a complex that steers cell migration (Dang et al. 2013). Arp273 itself is controlled by several associated proteins, including N-WASP, Scar/WAVE complexes, and Ena/VASP proteins. Ena/VASP motility-associated proteins are mainly located at the leading edge, where they are involved in the assembly of the actin cytoskeleton. Lamellipodial protrusions are tightly regulated by Ena/VASP proteins, which in turn bind to a distinct ligand, lamellipodin. Lamellipodin is a protein involved in actin polymerization and Ras signaling (Chang et al. 2013). Both lamellipodin and Ena/VASP localize to the tips of lamellipodia and filopodia, but lamellipodin also localizes to dorsal surface ruffles (Michael et al. 2010) and may interact with other actin-associated proteins (Krause et al. 2004). In the lamellipodial edge/tip, lamellipodin interacts with profilin 1, where it binds Ena/VASP and regulates lamellipodin distribution and accumulation (Bae et al. 2010). Lamellipodin cooperates with endophilin and Mena to regulate F-actin-dependent endocytotic processes (Vehlow et al. 2013). Endophilin is an N-BAR protein involved in membrane bending and interacting with plectin (Gallop et al. 2006; Mim et al. 2012; Vannier et al. 2013). In addition, lamellipodin directly binds active Rac, which regulates an interaction between lamellipodin and the Scar/WAVE complex involved in cell migration (Law et al. 2013). Actin turnover in lamellipodia is mediated cofilin, which has a role in breaking

down F-actin and controlling filament turnover (Vitriol et al. 2013). In cancer cells, a distinct kinase interactome regulates lamellipodia and migration, involving activation of myotonic dystrophy kinase-related Cdc42-binding kinase alpha/MRCKalpha by 3-phosphoinositide-dependent kinase 1/PDK1 (Gagliardi et al. 2014). Similar to invadopodia, lamellipodia express certain MMPs. In contrast to invadopodia, lamellipodia display a close association between membrane type 1-MMP (MT1-MMP) and TIMP-2, this co-localization affecting the regulation of MMP activity. The expression of MT1-MMP is associated with the adhesion molecule, CD44, which directly binds to MT1-MMP and promotes its proteolytic activity. While the protrusion of the lamellipodium requires the continuous growth of F-actin filaments toward the leading edge of the cell, microtubules are not essential for lamellipodium formation. However, microtubules are important components for tail retraction (rear retraction) in the setting of a moving/locomoting cell (Ballestrem et al. 2000; Wehrle-Haller and Imhof 2003).

Filopodia

In contrast to lamellipodia, filopodia (also termed microspikes) are rodlike, finger-shaped protrusions that mainly consist of a tight bundle of F-actin filaments (reviews: Faix and Rottner 2006; Gupton and Gertler 2007; Mattila and Lappalainen 2008; Faix et al. 2009; Arjonen et al. 2011; Boer et al. 2015). Filopodia form focal adhesions with the substratum, linking matrix proteins to the cell surface. Filopodia formation depends on non-branched processive actin assembly, in contrast to lamellipodia, and is promoted by the actin-bundling protein, fascin-1, a protein expressed in many malignant neoplasms and involved in migration and invasion (Vignjevic et al. 2006; Tan et al. 2013), fimbrin, and Ena/VASP (Barzik et al. 2014). The actin turnover in filopodia is also critically regulated by the actin-regulatory formin Daam1 (Hoffmann et al. 2014). A strong promoter of filopodia formation is the integrin-binding myosin-X, a protein with a FERM domain and a specific domain binding microtubules. Through the action of myosin-X, integrins are transported to the tips of filopodia. Via this mechanism, filopodia are engaged in integrin-mediated adhesion processes (Arjonen et al. 2011). The actin assembly process depends on the activation of the Rho system of small GTPases, in particular Cdc42 and their downstream effectors. The small GTPase RalA targets filamin, an actin cross-linking protein essential for filopodia genesis (Ohta et al. 1999). The direct regulator of actin polymerization and bundling, Mena (mammalian enabled), is a factor that induces both lamellipodia and filopodia (Lin et al. 2014). Filopodial biogenesis is also regulated by N-WASP, a profiling-binding protein involved in filopodia extension, its actin-depolymerizing activity, and by diaphanous formin and Ena/VASP proteins. The filamin-mediated promotion of filopodia is controlled by a factor that suppresses leading edge protrusion and promotes cell retraction, FilGAP/filamin A-binding Rho GTPase-activating protein (Ohta et al. 2006). Filopodia formation is also induced by the active formins (Mellor 2010), including mDia2/Drf3, which is also involved in biogenesis of lamellipodia.

Filopodia mainly serve as sensor organelles that monitor chemotactic and chemokinetic signals and transfer this sensed information to the motility-active cytoskeletal apparatus. In this sense, filopodia are "antennas" that guide the cells along their migration tract, also in invading cancer cells. Filopodia and their adhesion-promoting features are proinvasive structures in HCC. The filopodial component Mena induces migration and cell spread in HCCs (Lin et al. 2014).

Cytonemes: Spatiotemporal Information Transfer Structures and Pacemakers of Morphogen Gradients

Cytonemes ("cell threads") are a specialized class of highly adhesive, close-ended secretory filopodia and present as ultra-long and thin cell

projections. Typically, cytonemes are around 80 μm in length. Cytonemes are produced by several cell types, including neutrophils (Galkina et al. 2013, 2015) and cancer cells. Cargo located in filopodia such as myosin-X and beta-arrestin is transported into cytonemes, indicating the close relationship between filopodia and cytonemes. These structures serve as a communication system between cells and as a mechanism for spatiotemporal regulations. As cytonemes mediate complex signaling transfers among cells, they were compared to synaptic intercellular connections (Kornberg and Roy 2014; Roy and Kornberg 2015). The paracrine signaling accomplished by cytonemes plays a role in ontogenetic patterning, maintenance of tissue homeostasis, and the generation of morphogenetic fields. Cytonemes disperse morphogen signaling agents across developmental fields (Rogers and Schier 2011; Fairchild and Barna 2014; Kornberg 2014a). An important factor that affects ontogenic and morphogenic signaling is Hedgehog. Hedgehog signaling is known to employ distinct cellular structures for its spatiotemporal distribution. This signaling proceeds from the cilium to the nucleus (Goetz et al. 2009; Nozawa et al. 2013; Kornberg 2014b) and can also use cytonemes as a transport facility (Kornberg 2014b). It might be anticipated that morphogen gradients mediated by cytonemes also operate in neoplasms which mimic ontogenetic processes in a highly aberrant form. The formation of cytonemes is promoted by expression of the stem cell markers Lgr4 and Lgr5 via stabilization of nascent filopodia from an underlying lamellipodia-like network (Snyder et al. 2015).

Membranous Nanotube Connections (Tunneling Nanotubes)

In contrast to close-ended cytonemes as filopodial specializations, certain cells can produce open-ended conduits or cytoplasmic bridges that serve for the transfer of cytoplasmic material and organelles among cells. Such actin-based structures are termed membranous nanotube connections or tunneling nanotubes/TNTs (Gallagher and Benfey 2005; Rustom 2009; Lim and Tang 2012; Austefjord et al. 2014). Phylogenetically, TNTs are closely related to plasmodesmata of plants (Lee 2014). TNTs are generated between normal cells and among tumor cells. Of specific importance are TNTs produced between stem cells, including mesenchymal stem cells, and normal or neoplastic cells (Valente et al. 2015), because this pathway can serve to transmit stem cell information to post-progenitor cells. Intact mitochondria that are transported via TNTs from one cell to the other can restore mitochondrial injury/function failure or transfer normal or altered mitochondrial DNA and affect via this mechanism the biology of target cells (Wang and Gerdes 2015). Restoration of mitochondrial function through TNT-mediated organelle transfer is also accomplished by mesenchymal cells which possess a "native" mitochondrial complement (Las and Shirihai 2014). The transfer of mitochondria through TNTs is mediated by the mitochondrial Rho GTPase, Miro1 (Ahmad et al. 2014; Las and Shirihai 2014). Through TNTs, malignant neoplasms can perform intercellular communication by exchanging organelles and cytoplasmic matter (Lou et al. 2012; Ady et al. 2014). Via TNTs, cancer cells can exchange information with stromal cells, resulting in a complex tumor-stromal cross talk (Thayanithy et al. 2014). This mechanism can affect pathways to invasion and spread.

Tumor Cell Motility and Migration: Shape Change and Motility of Normal and Cancer Cells Are Mediated by Cytoskeletal Proteins (the Cytoskeletome) and Proteins Mediating Cell Surface-Cytoskeleton Connections

Introduction

Motility of normal cells and cancer cells critically depends on shape change, cell polarity, adhesion, and cell motors, which in turn are linked to a functional cytoskeleton and cytoskeleton-cell membrane connections (Wells 2006; Bozzuto et al. 2010). Similar to muscle cells, contractile

force in locomoting cells is provided by the actin-myosin system, a dynamic multiprotein machine that undergoes dramatic changes in cancer cells (Cramer 1999). Cell shape and its changes are also determined by the microtubule component of the cytoskeleton and a connectome linking the cell membrane with the nucleus and various organelles. The position of the nucleus within the cell is critical for polarity changes and the induction of motility. In cancer cells, highly abnormal nuclei with aberrant shapes and massively altered connections with the cytoskeleton markedly affect shape change, polarity, and cell motility. In extreme cases, a polyploid and abnormally shaped nucleus can cause complete failure of a tumor cell to locomote.

Actin Cytoskeleton Formation

Shape change and the acquisition of a motile phenotype critically depend on the generation of a contractile branched actin network, which in its biogenesis and turnover depends on numerous actin-associated factors which control actin monomer polymerization, F-actin stability, microfilament bundling, and the connection of the actin network with other components of the cytoskeleton, the cell membrane, and cell junctions (review: Gross 2013). Assembly and turnover of the actin skeleton is regulated by Rho effectors, i.e., several GTP-Rho-binding proteins (Narumiya et al. 1997), linking the actin machinery with the GTPase signalosome.

The generation of an F-actin cytoskeleton machine depends on numerous actin-binding proteins which promote nucleation and synthesis of F-actin and also regulate capping, severing, shortening, and degradation of F-actin to actin monomers. Important nucleators of actin formation that are altered in liver cancers are members of the formin family, formins being involved in the assembly of cytoskeletal components at cortical sites of the cell (Tanaka 2000). Together with WASP family members, formin coordinates the regulation of cell protrusions in cancer cells (Sarmiento et al. 2008). Formin is operational in cell migration and tumor cell invasion through its promotion of a motile cytoskeletal phenotype. Formin activity is suppressed by the metastasis suppressor, microRNA-335, which is a master regulator of tumor cell migration (Lynch et al. 2013). A formin upregulated in EMT, FHOD1, is expressed at the leading edge of locomoting cells and participates in the cytoskeletal changes occurring in migrating cancer cells (Gardberg et al. 2013). In their function as proteins promoting shape change and an amoeboid motility, formin-related proteins are active in these processes, including members of the diaphanous-related formin family. In normal and tumor cells, the actin-based cytoskeleton is also modulated by the microfilament regulatory protein, Mena, which affects EGF-elicited motility and invasion (Gertler and Condeelis 2011). In particular, the Mena invasive/MenaINV isoform promotes streaming motility and facilitates transendothelial migration. An important F-actin-binding protein that positively affects cell motility is coronin-1C, a member of the coronin family having seven coronin isoforms. Coronin-1 exerts a inhibitory effect on F-actin formation, while coronin-1B is required for cell protrusion formation and cell migration. Coronins also interact with microtubules and are involved in phagocytosis. A group of actin-binding proteins is involved in F-actin severing, including villin, gelsolin, and severin. Gelsolin is a major protein operating in actin filament assembly and disassembly. It is the most potent member of the actin-severing gelsolin-villin superfamily of proteins and is located in the cytoplasm and mitochondria. An important actin-severing protein is villin, a protein which contains multiple gelsolin-like domains and is involved in nucleation, bundling, capping, and severing of actin filaments. The six-repeat part of villin is responsible for calcium-dependent actin severing, whereas the villin headpiece is involved in calcium-independent actin cross-linking and bundling. Another actin-binding protein involved in tumor biology is cortactin. Cortactin can activate cortical actin nucleation and polymerization via its participation in the Arp2/Arp3 complex (Weed and Parsons 2001). Cortactin can also indirectly promote Arp2/Arp3 complex-mediated actin

polymerization by binding to N-WASP. Cortactin is not critically involved in lamellipodium formation, but is an essential molecule for biogenesis of podosomes and invadosomes (Yamaguchi and Condeelis 2007). Other actin-binding proteins which affect motility comprise Spire (a WH2 domain-containing actin nucleator; Baum and Kunda 2005; Chen et al. 2012).

Abnormal Expression and Function of Actin-Binding and Actin-Associated Proteins in Liver Cancer

An important regulator of cancer cell motility and invasion is cofilin, a protein that binds both monomeric and filamentous actin and which is involved in actin turnover through its actin-severing capacity. Cofilin activity depends on its phosphorylation status mediated by LIM kinases in a growth factor-dependent manner. Specifically, cofilin and actin-depolymerizing factor/ADF are inactivated in HCC cells by LIM kinase-1-mediated phosphorylation and reactivated by dephosphorylation by Slingshot-1 and Slingshot-2 protein phosphatases (Bernard 2007; Horita et al. 2008). Activated cofilin participates in the induction of lamellipodia and its overexpression augments tumor cell motility. Cofilin is markedly overexpressed in highly invasive cancers (review: Yamaguchi and Condeelis 2007). Alpha-actinin, which plays an important role in actin turnover, shows high expression levels in HCC cells (Nishiyama et al. 1990). The structure and function of the cytoskeleton is influenced by giant proteins that play an important role in myofibrillogenesis, the obscurins, proteins that modulate cytoskeletal function and intercellular adhesion proteins via their kinase domains (Hu et al. 2013; Perry et al 2013; Ackerman et al. 2014). Obscurin expression prevents EMT, while loss of obscurin activity promotes EMT and an invasive phenotype (Shriver et al. 2014). Downregulation of formin-like 2 is associated with poor prognosis in HCC, because this protein is an inhibitor of cell motility (Liang et al. 2011). Similarly, downregulation of DIAPH3/diaphanous-related formin-3, a noncanonical regulator of metastasis in several cancers located on chromosome 13q, results in tumor aggressiveness and a metastatic phenotype (Hager et al. 2012). Mena increases the activity of RhoA, induces HCC cell motility, and favors metastasis (Lin et al. 2014). Mena deficiency delays tumor progression and decreases metastasis in experimental neoplasms (Roussos et al. 2010). In HCC cells, coronin-1C is overexpressed and favors a motility phenotype, a response correlated with Rac1 activation (Wu et al. 2010; Wang et al. 2013a). Another actin-binding protein involved in regulation of tumor cell invasion is cortactin. Cortactin (the EMS 1 oncogene) has a central place in the actin cytoskeleton, is a Src kinase substrate, and is upregulated in many types of cancers as a result of amplification of chromosome locus 11q13 (Weaver 2008; Kirkbride et al. 2011; MacGrath and Koleske 2012). Cortactin phosphorylated by ERK1/ERK2 is recruited to sites of dynamic actin regulation and is required for carcinoma lamellipodia persistence (Kelley et al. 2010). Part of HCCs show amplification of the cortactin-encoding EMS 1 oncogene (Yuan et al. 2003). In HCC, overexpression of cortactin is correlated with a highly invasive phenotype showing marked vascular invasion and metastasis (Huang et al. 2012; Gang et al. 2013; Zhao et al. 2013). Upregulation of cortactin in HCC is associated with enhanced tumor cell motility (Chuma et al. 2004). Expression of the MPZL1 gene at 1q24.1–24.2 promotes HCC cell migration through Src-mediated phosphorylation of cortactin (Jia et al. 2014; Yeh et al. 2014). The actin-bundling protein, fascin-1, is overexpressed in part of HCCs, associated with downregulation of E-cadherin, dramatically increased tumor cell migration, and poor prognosis (Iguchi et al. 2009; Hayashi et al. 2011; Huang et al. 2012). Among F-actin-severing proteins, villin 1 is expressed in subsets of HCCs, and its expression is correlated with invasion (in particular vascular invasion) and tumor recurrence (Xieraili et al. 2012). Another actin filament-disassembling protein, gelsolin, is overexpressed in HCCs (Megger et al. 2013). In HCC cells, gelsolin binds to p53 protein and promotes the inhibition of p53-induced apoptosis by anchoring p53 in the cytoplasm (An et al. 2011).

In HCC cell lines, the isoforms of gelsolin differ from those of normal cells (Yin et al. 1984). Gelsolin also plays a role in lymphatic metastasis of HCC (Qazi et al. 2011). Secretory gelsolin is highly overexpressed in metastases of colorectal carcinoma (Tsai et al. 2012).

Cytoskeleton and WASP

A central role in organization and reassembly of the actin-based cytoskeleton is played by the Wiskott-Aldrich syndrome protein (WASP) and WASP family verprolin-homologous protein (WAVE) family (reviews: Miki and Takenawa 2003; Kurisu and Takenawa 2009; Helgeson et al. 2014). The WAVE regulatory complex (WRC) regulates cell motility by its capability to promote actin polymerization. The WRC controls actin fibrillogenesis in cooperation with Ena/VASP proteins, this system stimulating Arp2/Arp3 complex-mediated actin assembly (Chen et al. 2014). By its effects on cytoskeleton organization and remodeling, WASP-WAVE systems affects numerous basic cellular mechanisms, including shape change, adhesion, cell positioning, and cell motility. The action of WASP on the actin cytoskeleton is modified by certain WASP-interacting proteins of the verprolin family of proteins, i.e., WIP (WASP-/N-WASP-interacting protein), CR16 (corticoid regulated), and WIRE (Wlp related). WIRE can induce filopodia in cooperation with insulin receptor substrate/IRSp53 (Misra et al. 2010). N-WASP (neural Wiskott-Aldrich syndrome protein), which mediates motility and invasion of cancer cells, is highly expressed in HCCs and its expression is associated with poor prognosis (Jin et al. 2013). N-WASP promotes processive acceleration of actin barbed end assembly (Khanduja and Kuhn 2014). The WAVE2 protein is significantly enhanced in HCC, correlated with tumor multiplicity and an invasive phenotype (Yang et al. 2006). Overexpression of WAVE3 is correlated with increased invasiveness in HCCs (Ji et al. 2015).

Tumor Cell Motility and Migration: Cell Adhesion Mechanisms

Focal Adhesion Proteins as Mediators of Cell Motility and Migration

Several molecules localized to focal adhesions/FAs are critically involved in cell motility via their linking of FA with the cytoskeleton. FAs are situated at the convergence of integrin-mediated adhesion, various signaling pathways, and the actin cytoskeleton (Webb et al. 2003; Wozniak et al. 2004). These proteins mainly include paxillin, vinculin, talin, and actopaxin. A paxillin homologue expressed in FA of fibroblasts is Hic-5, associated with FA kinase and involved in the regulation of growth (Ishino et al. 2000). Paxillin is a focal adhesion adaptor that plays an important role in the connections between cell adhesion and actin cytoskeleton remodeling. Phosphorylation of paxillin required for cell migration is accomplished by c-Jun N-terminal kinase/JNK1 which is an enzyme essential for cell motility (Huang et al. 2003, 2004).

Paxillin positively affects the invasive and metastatic ability of HCC through its promotion of cell locomotion (Li et al. 2005). The differential expression of paxillin and related proteins in tumor FA is regulated by various factors, which are not yet well known. However, the Rho GTPases Rac1 and RhoA control the expression of the two FA components, paxillin and vinculin (Deakin et al. 2012). Hepatocyte growth factor-induced ERK-paxillin signaling in HCC cells is mediated by protein kinase C via phosphorylation of ERK/paxillin (Hu et al. 2013). Paxillin gene mutations do not to play a significant role (Kim et al. 2011). Similarly, altered expressions of the FA protein talin-1 in HCC is associated with an invasive phenotype and aggressive course (Kanamori et al. 2011). Talin-1 expression in HCC is usually lower than that of normal liver (Zhang et al. 2011), and high levels of talin-1 in HCCs were correlated with reduced migration and invasion (Fang et al. 2014). Actopaxin, a member of the focal adhesion proteins, regulates cell locomotion and migration, is frequently overexpressed in HCC, and plays a

role in invasion and metastasis (Ng et al. 2013). In HCC, agrin with its oncogenic role is an important regulator of focal adhesion integrity (Chakraborty et al. 2015).

Integrins, Integrin-Cytoskeleton Linkers, and Integrin-Linked Kinase

As outlined above, integrins are crucial mediators of cell-matrix adhesion and of connections between adhesive cell surfaces and the underlying actin cytoskeleton. Via this configuration, integrin receptors generate a functional bridge between cytoskeleton and the ECM and are thus critical operators for cell locomotion on matrix substrata.

A novel type of adhesion complexes is involved in adhesion of cells to the ECM in an integrin-dependent manner. These complexes (IPP complexes) consist of integrin-linked kinase (ILK), PINCH, and parvin (review: Sepulveda et al. 2005). Integrin-linked kinase/ILK is a central component of cell-matrix adhesions and a key regulator of integrin functions, including those involved in tumor cell migration. ILK interacts with the cytoplasmic domains of integrin beta and beta3 subunits. The ILK kinase domain is required for focal adhesion maturation (Stanchi et al. 2009). ILK forms a ternary complex with two adaptor proteins, PINCH (particularly interesting cysteine- and histidine-rich protein) and parvin, resulting in the formation of an ILK-PINCH-parvin complex. This complex regulates the transmembrane integrin receptor-actin cytoskeleton linkage essential for cell motility (Legate et al. 2006; Qin and Wu 2012; Ghatak et al. 2013). PINCH-1 is a widely expressed focal adhesion protein capable to form complexes with ILK and CH-ILKBP/actopaxin/affixin/alpha-parvin (Wu 2004) and capable to modulate cell shape and cell motility (Fukuda et al. 2003). PINCH and its partner, the tumor suppressor Rsu-1 (Ras suppressor 1), regulate hepatic tumorigenesis and control liver size (Donthamsetty et al. 2013). Affixin (or beta-parvin) is a focal adhesion protein that binds paxillin (Stiegler et al. 2012) and interacts with alpha-actinin and mediates integrin signaling for reorganizing of F-actin (Yamaji et al. 2004). Alpha-parvin is the same as actopaxin and is a paxillin-binding protein required for cancer cell invasion and matrix degradation requiring Rac1 for its activity. In such complexes, ILK is activated by a protein binding to this kinase, the small LIM-only protein LIMD2, a protein that is overexpressed in metastatic cancers and promotes cell motility (Peng et al. 2014). The ILK-PINCH-parvin complex supports integrin alphaIIb beta3 activation (Honda et al. 2013).

Binding to alpha-parvin and localization to focal adhesions of ILK depend on its kinase domain (Fukuda et al. 2009). Due to its binding to ILK, PINCH is recruited to integrin-rich sites in spreading cells (Tu et al. 1999). ILK also binds to kindlin-2, a mechanism that regulates cell adhesion (Fukuda et al. 2014). ILK plays a significant role in tumor cell migration and invasion, through phosphorylation of several intracellular substrates, including protein kinase B (PKB/Akt), glycogen synthase kinase-3 of the Wnt pathway, and myosin light chain (Persad and Dedhar 2003). PINCH-1 enhances the motile features of cancer cells and is suppressed by PINCH-2 by paracrine activity (Park et al. 2014). ILK function is modulated by binding of LIMD2, a member of the LIM domain protein family characterized by shuttling between cytoplasm and nucleus and coupling changes of gene expression to extracellular cues. LIMD2 is overexpressed in metastatic cancers and positively regulates cancer cell motility (Peng et al. 2014). ILK is overexpressed in HCCs and is associated with motility and invasion in these tumors (Chan et al. 2011).

Small GTPase and GTP-Binding Protein Signaling in Tumor Cell Motility

Rho GTPases/Rho effector pathways play a crucial role in liver cancer progression due to their central functions in organizing the cytoskeleton, affecting shape change, and promoting cell motility in various cancers, including HCC (Narumiya et al. 1997; Grise et al. 2009; Wong et al. 2010). An immediate downstream effector of

Rho is Rho-associated kinase (ROCK), an enzyme which acts on cytoskeletal proteins, including MLC2 (myosin light chain2), and deregulated in various cancers. The small GTP-binding protein Rho stimulates the actin-myosin system, causing invasion of cancer cells, whereby Rho is stimulated by 1-oleoyl-lysophosphatidic acid (Yoshioka et al. 1998). Rho kinase 2 is frequently overexpressed in HCC, associated with enhanced tumor cell motility and invasiveness due to activation of cytoskeletal proteins, specifically MLC2 (Wong et al. 2009). MLC2 in turn is modulated by MR-1/myofibrillogenesis regulator 1 in hepatoma cells, enhancing tumor cell locomotion (Ren et al. 2008). ROCK plays a critical role in intrahepatic metastasis of HCC through stimulation of tumor cell migration (Genda et al. 1999). An important member of the Rho GTPase-activating protein family is DLC1/deleted in liver cancer 1. This protein has suppressive activities in tumor development and metastasis. In HCC, DLC1 negatively regulates the Rho/ROCK/MLC pathway (Wong et al. 2008).

Distinct Growth Factors and Genes Acting as Promigration Factors

Hepatocyte Growth Factor and Its Receptor as a Motility and Promigration Factor

Hepatocyte growth factor (HGF) and its receptor c-Met form autocrine and paracrine loops to promote pro-motility cell shape change and migration (Xie et al. 2001). HGF and its receptor c-Met induce formation of lamellipodia, characterizing a polarized cell phenotype required for cell locomotion. Lamellipodia involving actin reassembly at the leading edge of motile cells are a very early step in cell migration. In lamellipodium formation, HGF induces the association between the constitutive complex of betaPIX and GIT1 with WAVE2, thereby facilitating HGF-induced WAVE2 transport required for lamellipodia (Morimura et al. 2009). Cell migration and invasion induced by c-Met is modulated by the Gab1-binding p21-activated kinase 4, Pak4. Interaction of Pak4 with Gab1 results in Gab1 phosphorylation which is essential for the activity of the Gab1 scaffold protein in reorganizing the cytoskeleton (Paliouras et al. 2009).

HGF expression is elevated in the majority of HCCs, and c-Met overexpression plays an important role in HCC cell motility and invasion (Schoedel et al. 2003). HGF as a ligand binds to its receptor, c-Met, which it phosphorylates within a few minutes following receptor binding, to rapidly decline afterward. c-Met receptor kinase-dependent stimulation of p42/p44 mitogen-activated protein kinases is critical for the proteinase-activated receptor-2 (PAR(2))-Met kinase-invasive signaling axis in HCCs (Kaufmann et al. 2009). Tumor cell migration is stimulated by hepatocyte growth factor (HGF) through phosphatidylinositol 3-kinase (Nakanishi et al. 1999). In HCCs, HGF is in part produced by stromal cells, in particular cancer-associated fibroblasts/CAFs (Jia et al. 2013). HBX, a protein of HB virus involved in hepatocarcinogenesis, promotes expression of c-Met by the extracellular signal-regulated kinase/ERK pathway (Xie et al. 2010). c-Met expression in HCC is positively correlated with expression of a protein critically involved in cell adhesion and migration, ezrin (Kang et al. 2010). MicroRNA-198 inhibits HCC cell migration through downregulation of the HGF/c-Met pathway (Tan et al. 2011), whereas microRNA-34a inhibits migration of HCC cells via downregulation of c-Met expression (Li et al. 2009). A similar effect is induced by microRNA-23b (Salvi et al. 2009). HGF-induced motility and invasion in HCC cells is inhibited by heparin, counteracting HGF-induced cell adhesion, and heparin also reduced HGF-induced activation of c-Met and MAP kinase (Ozen et al. 2012). In hilar cholangiocarcinoma, downregulation of Gab1 inhibited cell migration (Sang et al. 2013).

Other Genes and Proteins Promoting Shape Change and Motility in Liver Cancer Cells

Part of invasive features of liver cancers are reflected in chromosomal abnormalities and the

activity of oncogenes and tumor suppressors. A motile phenotype of HCC is induced by a protein encoded by a gene on chromosome 7q21–q22 involved in HCC, PFTAIRE protein kinase 1, a cell division cycle-2 related gene (Pang et al. 2007). A constitutive activation of ERBB3 (erythroblastic leukemia viral oncogene homologue 3)-dependent signaling through the neuregulin1/ERBB3 autocrine loop plays an important role in the regulation of HCC cell motility, migration, and invasion (Hsieh et al. 2011). Cell motility in HCCs is promoted by overexpression of a gene located to the interstitial chromosome 1q21–q22 region, frequently amplified in human cancers. The product is called GEF-H1, a guanine nucleotide exchange factor, and it probably acts through activation of RhoA signaling and modulation of EMT (Cheng et al. 2012). Notch signaling promotes HCC cell migration in conjunction to upregulation of MMPs. The Notch1/COX-2/Snail pathway involving EMT is associated with hypoxia-induced migration and invasion of HCC cells (Yu et al. 2013). Migration of embryonic liver cells and HCC cells is modulated by the homeobox protein, PROX1 (prospero-related homeobox 1). PROX1 directly binds to proximal promoter of the EMT mediator Twist1 gene to repress its transcription, and through this mechanism it reduces cell migration (Chang and Hung 2012). In cancer cells, PROX1 promotes an aggressive behavior through upregulating hypoxia-inducible factor alpha expression, with subsequent induction of EMT (Liu et al. 2013a). CPEB4 (cytoplasmic polyadenylation element-binding protein 4) is a potential tumor suppressor. Its downregulation by microRNA-550a facilitates HCC cell migration and invasion (Tian et al. 2012). Loss of Tg737 in HCCs is associated with cell migration and invasion in a hypoxia-dependent manner, partially through the polycystin-1, IL-8, and TGFbeta1 pathway (You et al. 2012). Tg737 is tumor suppressor gene that encodes a cilia-associated protein involved in the regulation of fetal hepatic progenitor cells and the biology of side population cells in HCCs (Song et al. 2010). As outlined elsewhere in more detail, ECM proteins markedly affect the invasive phenotype of cancer cells. Bone morphogenetic proteins exert a positive influence on HCC cell migration via activation of Smad which interacts with type XVI collagen of the ECM (Maegdefrau and Bosserhoff 2012). HCC cell migration is stimulated by ESM-1/endothelial cell-specific molecule-1, a secretory proteoglycan with a single dermatan sulfate residue. ESM-1 also induces cell cycle arrest by PTEN induction (Kang et al. 2011). Migration of HCC cells is strongly stimulated by Smad signaling activated by bone morphogenetic proteins (BMPs), a process inhibited by the BMP inhibitors chordin and noggin (Maegdefrau and Bosserhoff 2012).

In addition, invasion of HCC cells is stimulated by numerous factors that operate in highly diverse pathways, so that a common denominator of action cannot easily be recognized. HCC cell migration and invasion is suppressed by Dickkopf-1 (Dkk-1; Qin et al. 2007) and Dkk-4, a secreted protein that antagonizes the Wnt/beta-catenin signaling pathway, and is positively regulated by thyroid hormone/T3 acting on a thyroid hormone receptor expressed on tumor cells (Liao et al. 2011). Dkk-4 is downregulated in other gastrointestinal cancers, e.g., colorectal cancer (Baehs et al. 2009). HCC cell migration is stimulated by the glycoprotein stanniocalcin via activation of extracellular signal-regulated kinase 1/2 (ERK1/ERK2) (Wang et al. 2012). Ectopic expression of p16 protein in HCC increases cell migration in vitro and in vivo in a Cdc42-dependent manner, the stimulatory process requiring activity of the Cdc42 GTPase (Chen et al. 2013b). A direct transcriptional target of FOXM1 is tartrate-resistant acid phosphatase 5/ACP5, an enzyme important for osteoclastogenesis and bone resorption. HCC cell migration is induced by nuclear expression of the E3 ubiquitin ligase seven in absentia homologues (SIAH)-1 and (SIAH)-2, in part mediated by the transcription factor FBP-3 (Brauckhoff et al. 2011; Malz et al. 2012). SIAH family proteins are RING-domain proteins making part of ubiquitin ligase complexes that target proteins to proteasomes. SIAHs are involved in functional circuits of Ras, hypoxia-induced pathways, and DNA damage and are also active in a number of signaling pathways in cancer progression (Fang

et al. 2003; Lipkowitz and Weissman 2011). Part of HCC cells express proteinase-activated receptors (PARs), thrombin receptors of a G protein-coupled receptor subfamily. Stimulation of HCC cells with thrombin and PAR-selective peptide promotes migration of these cells (Kaufmann et al. 2007).

Regulation of Cell Motility and Migration by MicroRNAs

An increasing number of microRNAs (MiRs) affect tumor cell locomotion and migration in hepatocellular carcinoma, whereby most of these MiRs have a suppressive effect on tumor cell motility via diverse pathways (Table 1). These MiRs are potential targets of novel therapies.

MicroRNA-7 is reduced in HCC. This is an MiR which inhibits tumor cell migration and metastases via targeting phosphoinositide 3-kinase/Akt signaling pathways (Fang et al. 2012). MicroRNA-9 enhances migration of HCC cells through downregulation of the KLF17 protein expression. KLF17 is a transcription factor that directly acts on the promoter of EMT-associated genes, including ZO-1, vimentin, and fibronectin (Sun et al. 2013), and is downregulated in HCCs (Liu et al. 2013b). MicroRNA-10b, which is overexpressed in HCC, promotes migration of tumor cells through RhoC, uPAR, and metalloproteinases (Liao et al. 2014). This MiR also acts through CADM1 (Li et al. 2012). A second microRNA promoting HCC cell migration via CADM1 is microRNA-1246 (Sun et al. 2014). MicroRNA-17-5p is overexpressed in HCC. This MiR promotes tumor cell locomotion through the p38 mitogen-activated protein kinase-heat shock protein 27 pathway (Yang et al. 2010). MicroRNA-21 regulates migration and invasion of stem cell-like HCC cells via targeting PTEN, RECK, or PDCD4 protein translation (Zhou et al. 2013). STAT3 regulates migration of a stem cell-like subpopulation of HCC cells via microRNA-21 (Zhang et al. 2015a). MicroRNA-23b is a suppressor of HCC cell motility by down-modulation of c-Met and urokinase (Salvi et al. 2009). In HCCs, increased expression of microRNA-26a promotes migration by blocking EZH2 expression (Wang et al. 2015). MicroRNA-26a suppresses HCC cell migration and invasion of human HCC cells by targeting the IL-6-Stat3 pathway. By this pathway, protein levels of IL-6 inversely correlate with microRNA-26a in HCCs (Yang et al. 2013b). MicroRNA-30a, downregulated in HCC, is a suppressor of tumor cell motility and of EMT, through SNAI1 targeting (Liu et al. 2014a). MicroRNA-34a is low in HCCs and is a suppressor

Table 1 MicroRNAs affecting cell migration in hepatocellular carcinoma

MicroRNA (MiR)	Target	Effect[a]
MiR-7	PI3K/Akt signaling	Inhibition
MiR-9	KLF17	Inhibition
MiR-10b	RhoC, uPAR, MMPs, CADM2	Stimulation
MiR-17-5p	p38-MAPK signaling	Stimulation
MiR-21	PTEN, RECK	Inhibition
MiR-23b	c-Met	Inhibition
MiR-26a	EZH2	Stimulation
MiR-30a	SNAI1	Inhibition
MiR-34a	c-Met	Inhibition
MiR-100	Via lamellipodia	Inhibition
MiR-101-3p	Rab5a	Inhibition
MiR-124	ROCK2, EZH2	Inhibition
MiR-125b	Transcriptional activator	Inhibition
MiR-126	?	Inhibition
MiR-133a	MMP-9	Inhibition
MiR-135b	RECK, EVI5	Stimulation
MiR-139	c-Fos	Stimulation
MiR-141	Tiam1	Inhibition
MiR-142-3p	Rac1	Inhibition
MiR-150-5p	MMP-14	Inhibition
MiR-151	RhoGDIA	Stimulation
MiR-181a-5p	c-Met	Inhibition
MiR-193b	CCND1, ETS1	Inhibition
MiR-195	VEGF	Inhibition
MiR-197	KAI1	Inhibition
MiR-198	c-Met	Inhibition
MiR-206	MMP-9	Inhibition
MiR-224	Homeobox D10	Inhibition
MiR-362-5p	CYLD	Inhibition
MiR-424	c-Myb	Inhibition
MiR-433	cAMP response element-binding protein	Inhibition
MiR-525-3p	ZNF395	Stimulation

[a]*Inhibition* inhibition of migration, *stimulation* stimulation of migration

of cell migration by targeting c-Met (Li et al. 2009). Downregulation of microRNA-100 enhances migration and spread of HCC cells, because this MiR suppresses lamellipodium formation (Zhou et al. 2014). Downregulation of microRNA-101-3p by hepatitis B virus promotes migration of HCC cells by targeting Rab5a (Sheng et al. 2014). MicroRNA-124 is reduced in HCC. This MiR directly targets ROCK2 and EZH2 and inhibits EMT and cell migration (Zheng et al. 2012). MicroRNA-125b suppresses migration and invasion of HCC cells by targeting transcriptional coactivator with PDZ-binding motif (Li et al. 2015b). Ectopic expression of microRNA-126 suppresses HCC cell migration, invasion, and colony formation in vitro (Chen et al. 2013a). MicroRNA-133a inhibits tumor cell migration by targeting MMP-9 in HCC, but is downregulated in these neoplasms, favoring a motile phenotype (Chen et al. 2015). In HCC, microRNA-135b promotes tumor cell locomotion by regulating RECK (reversion-inducing cysteine-rich protein with Kazal motifs) and EVI5 (ecotropic viral integration site 5), enhancing cell motility (Li et al. 2015c). Downregulation of microRNA-139 causes depression of c-Fos, promoting cell migration in HCC (Fan et al. 2013). MicroRNA-141, downregulated in HCC, is a potent suppressor of HCC cell migration by targeting the T lymphoma invasion and metastasis 1/Tiam1 gene (Liu et al. 2014). MicroRNA-142-3p suppresses cell migration by targeting Rac1 (Wu et al. 2011). Migration of HCC cells is suppressed by microRNA-144 by targeting E2F transcription factor 3/E2F3 (Cao et al. 2014) and AKT3 (Ma et al. 2015). MicroRNA-150-5p is an inhibitor of HCC cell migration and invasion by targeting matrix metalloproteinase-14 (Li et al. 2014b). Tumor cell migration is facilitated by gain of microRNA-151 through targeting RhoGDIA (Ding et al. 2010). MicroRNA-181a-5p, which suppresses HCC cell motility by directly targeting c-Met, is downregulated in HCC (Korhan et al. 2014). HCCs exhibit decreased expression of microRNA-193b, an MiR that inhibits migration by targeting CCND1 and ETS1 (Xu et al. 2010). Micro RNA-195 abolishes HCC cell migration and proliferation by targeting the TNF-alpha/NF-kappaB pathway (Ding et al. 2013). This microRNA also suppresses angiogenesis and HCC metastasis by inhibiting the expression of VEGF and Cdc42 (Wang et al. 2013b). MicroRNA-197 is increased in HCC and promotes migration of cancer cells by targeting the anti-metastatic protein KAI1/CD82 (Dai et al. 2014). HCCs show downregulation of microRNA-198. This MiR inhibits tumor cell migration by targeting the c-Met pathway (Tan et al. 2011). MicroRNA-206 overexpression in HCC cells inhibits migration of tumor cells via downregulation of MMP-9 (Liu et al. 2014). MicroRNA-224 promotes cell migration and invasion of HCC cells by targeting homeobox D 10 gene involved in MMP-9 signaling (Li et al. 2014a). Further important targets of this MiR are Cdc42, Bcl-2, and MAPK1 (Zhang et al. 2013). MicroRNA-362-5p promotes tumor cell migration and metastasis by targeting CYLD in HCC (Ni et al. 2015). MicroRNA-424 is downregulated in HCC and suppresses cell migration through c-Myb (Yu et al. 2014). MicroRNA-433 inhibits HCC cell migration by repressing expression and function of cAMP response element-binding protein (Yang et al. 2013a). MicroRNA-525-3p enhances migration of HCC cells by targeting zinc finger protein 395/ZNF395 (Pang et al. 2014).

Linking the Signaling of Proliferation and Invasion: The Wnt/Beta-Catenin Signaling Pathway

The Wnt/beta-catenin signaling pathway plays a significant role for the regulation of growth, invasion, and metastasis in numerous cancers studied so far, including HCC (Lee et al. 2014). Beta-catenin expression with its transfer to the nucleus is associated with elevated proliferative activity and higher IL-8 protein levels in HCC cells (Lai et al. 2011). Overexpression of beta-catenin in HCC is enhanced and activated by hypoxia and promotes EMT and expression of MMP-2 (Liu et al. 2010). On the other hand, a subset of HCCs with expression of mutant nuclear beta-catenin was characterized by a noninvasive phenotype and absence of portal venous spread (Mao et al. 2001). In high-metastatic HCC cell lines, the Wnt/beta-catenin signaling pathway was

upregulated, associated with increased expression of c-Myc and cyclin D1, whereas Dickkopf-1/Dkk-1 and Nm23 were downregulated (Qin et al. 2007). However, HCCs with upregulated Dickkopf-1/Dkk-1 show increased cell invasion through Dkk-1 activity in the noncanonical Wnt pathway (Tao et al. 2013). The beta-catenin and mitogen-activated protein kinase pathways are activated by fibroblast growth factor 19 (FGF19), which by this signaling pathway promotes HCC recurrence and a metastatic phenotype (Hyeon et al. 2013). A further protein that interacts with beta-catenin signaling and affects cancer cell growth and invasion is arrest-defective protein1/ARD1, the catalytic subunit of the major N-terminal acetyltransferase. Upregulation of ARD1 is associated with a metastatic phenotype in various cancers, and its autoacetylation stimulates cancer cell proliferation. In the Wnt/beta-catenin pathway, ARD1 acts via acetylation and activation of beta-catenin. In HCCs, ARD1 stimulates microvascular invasion (Shim et al. 2012). Wnt/beta-catenin signaling in HCCs is counteracted by SOX1 (sex-determining region Y-box 1), a transcription factor which acts as a tumor suppressor (Tsao et al. 2012). The proinvasive action of Wnt/beta-catenin signaling in HCC is also counteracted by microRNA-148b which downregulates expression of Wnt1 and beta-catenin (Zhang et al. 2015b). A novel mechanism that antagonizes Wnt signaling is exosomal release of beta-catenin, a mechanism that illustrates the significance of exosomal packaging and release of cytosolic proteins in the modulation of signaling pathways in normal and malignant cells (Chairoungdua et al. 2010).

Chemotaxis and Chemokinesis in Liver Cancer

Introduction

The chemokinetic and chemotactic factors that can elicit a motile response, with either random or directional movements, in liver cancer cells are not yet well characterized. As outlined above, a chemokinetic or chemotactic response depends on polarization, cell shape change, and the production of distinct cellular protrusions, including pseudopods (review: Van Haastert 2010). Polarization of the cell causes the redistribution of membrane receptors for chemokinetic/chemotactic stimuli at front vs. rear ends of the cell, a prerequisite for decision making with respect to locomotion guidance. In the course of chemotaxis, phosphatidylinositol 3,4,5-trisphosphate/PIP3 accumulates at the leading edge of motile cells where it induces the formation of pseudopodia, suggesting that PIP3 is a principal navigator of chemotaxis (Van Haastert and Veltman 2007).

Factors and Signals Affecting Chemokinesis and Chemotaxis in Liver Cancer

In contrast to leukocytes, where chemokinetic and chemotactic factors have been studied in great detail, relatively few factors have so far been identified to act as chemotaxins in cancers. Laminin and type IV collagens present in basement membranes exert a potent chemotactic action on HCC cells, which can express laminin receptors (Ogata 1998). Chemotaxis to laminin via production of pseudopods is mediated by the integrin beta1 receptor subunits, alpha3beta1 and alpha6beta1, in HCC cells (Fu et al. 2004, 2010). Among beta1 integrins, alpha6beta1 integrin is a major cell surface receptor that mediates HCC cell adhesion to type IV collagen and induction of chemotaxis (Fu et al. 2011). The chemokine, monocyte chemoattractant protein-1 (MCP-1), secreted by stromal myofibroblasts promotes migration of human HCC cells in a syndecan-1- and syndecan-4-dependent manner (Dagouassat et al. 2010). This pathway suggests that the stroma of these cancers can itself participate in the promotion of invasion. HCC cells respond with increased motility to elastin and elastin fragments. Chemotaxis to elastin-derived chemoattractants is restricted by laminin, and laminin regulates a tumor cell chemotaxis receptor through the laminin-binding integrin subunit alpha6 (Blood and Zetter 1993). Orientation chemotaxis and adhesion in HCC cells is positively influenced by metadherin (MTDH/astrocyte elevated gene-1

(AEG-1)), which is localized to the perinuclear area (Zhou et al. 2012), and which also induces EMT (Zhu et al. 2011). Cancer cell motility is strongly influenced by integrins. HCC cells predominantly express the integrins alpha1, alpha3, and beta1, while integrins alpha2, alpha5, and alpha6 show intermediate expression levels, and alpha2 has a minor expression only. Integrins mediate the chemotactic response of HCC cells toward laminin (Fu et al. 2004, 2010). Chemokinesis and chemotaxis of HCC cells are induced by chemokines and cytokines. RANTES (a CC chemokine, regulated on activation, normal T cell expressed, and presumably secreted) stimulates directed migration of HCC cells through activation of G protein-coupled receptors, CCR1, CCR3, and CCR5. RANTES binds to glycosaminoglycans of the ECM, which inhibit RANTES-induced migration of HCC cells (Sutton et al. 2007). In cancer cells expressing C-X-C motif chemokine receptor 4/CXCR4, stroma cell-derived factor 1 (C-X-C motif chemokine 12) induces directional locomotion and metastasis (Dillenburg-Pilla et al. 2015). CCR7-related chemotaxis in HCC cells is impaired by the CC chemokine receptor-like 1 (CCRL1) (Shi et al. 2015). Noncanonical Hedgehog signaling contributes to chemotaxis in cholangiocarcinomas via interaction with G protein-coupled receptors (Razumilava et al. 2014). HCC cells can themselves produce chemotactic factors that act on stromal cells, vascular cells, and leukocytes accumulating in stroma. HCC cells can secrete macrophage inflammatory protein-3alpha (MIP-3alpha) which chemotactically recruits endothelial progenitor cells (Shih et al. 2012). On the other hand, tumor endothelial cells can secrete monocyte chemotactic protein-1/MCP-1 which contributes to chemotaxis of HCC cells in a microRNA-21-dependent manner (Shih et al. 2015).

Abstract

Invasion of various tissues and vessels depends on distinct cellular structures involved in cell adhesion, initiation of tissue invasion, and degradation of the extracellular matrix (ECM). These structures are generally summarized under the term invadosomes, which in turn comprises the two major types of these specialized structures, i.e., podosomes and invadopodia. Podosomes are matrix-degrading adhesive structures formed by certain normal cells, such as macrophages and endothelial cells, and by invading cancer cells. The generation of podosomes strongly depends on protein kinase C-related signaling pathways. Podosomes can degrade ECM components through the shedding of wide array of proteases, specifically matrix metalloproteinases (MMPs). A special type of podosomes is invadopodia, which mediates basement membrane and tissue invasion of cancer cells. These protrusions are actin-based dynamic structures or "organelles" of transformed cells that are critically required for tumor cell invasion and extravasation. Tumor cells can extend invadopodia through the endothelial lining of vessels to the extravascular space prior to extravasation and metastatic growth.

Tissue Invasion: Invadosomes as Pacemakers of Invasion

Recent findings led to the identification of specialized cellular structures involved in adhesion, initiation of tissue invasion, and matrix degradation. These structures are generally summarized under the term invadosomes, which in turn contains the two major types of these structures, i.e., podosomes and invadopodia (Block et al. 2008). Podosomes and in particular invadosomes are characterized by the production of a wide array of enzymes that serve as histolytic factors that degrade tissues and specifically the extracellular matrix of tumors.

Podosomes

General Aspects

Podosomes ("feet bodies/particles") are matrix-degrading adhesive structures formed by invading normal cells, specifically macrophages, osteoclasts, and dendritic cell (Linder and Aepfelbacher 2003; Linder and Kopp 2005; Stylli et al. 2008; Symons 2008; Gawden-Bone et al. 2010; Murphy and Courtneidge 2011; Starnes et al. 2011; Schachtner et al. 2013). Podosomes or podosome rosettes also play a significant role in endothelial cell biology where they are involved in sprouty angiogenesis (Schlaepfer et al. 2004). Podosomes are induced by factors activating protein kinase C (Tatin et al. 2006), such as diacylglycerols and phorbol esters, and can, following their complete formation and activation, degrade EMC components through the shedding of proteases (Linder 2007). Podosomes are cylindrical cell protrusions located to the outer surface of the cell membrane, measuring up to 2 μm in diameter. Both podosomes and the similar invadopodia are actin-based structures that develop from the ventral cell membrane of cells in contact with a substratum. Podosomes carry the lipid membrane of the cell surface region from which they emerge (Yamaguchi and Oikawa 2010). In locomoting cells, podosomes are situated at the front border (leading edge) between lamellipodia and the lamellum. Podosomes have a central role in migration and invasion of matrix mediated by matrix degradation and therefore are important structures in inflammation and cancer. In contrast to invadopodia, which are small structures, podosomes grow to relatively large structures. Podosomes are usually visualized by phalloidin staining, this toxic cyclopeptide binding to filamentous actin/F-actin. In phalloidin or antibody staining, podosomes appear as isolated punctate structures on the ventral surface of cells. They are often localized behind the leading edge in case of podosomes, while invadopodia are more often clustered under the nucleus. Podosomes consist of a central core structure containing F-actin and actin regulators and a

peripheral ring structure (the podosome ring) showing integrins, vinculin, paxillin, and other proteins (Wernimont et al. 2008). In podosome rings, plectin, alpha-II spectrin, talin, and focal adhesion kinase are present, while these proteins are absent in invadopodia (Takkunen et al. 2010). In the course of the formation of a podosome ring, plectin accumulates at the early ring domain of the cell surface, whereby this deposition requires myosin contractility (Gad et al. 2008). In part of cells, including cancer cells, podosomes are clustered in the form of ringlike arrangements, the podosome rosettes. Rosette formation is strongly stimulated by Src kinases, protein kinase C, Rho family GTPases, ezrin, and certain integrins (review: Murphy and Courtneidge 2011). Formation of podosome rosettes is stimulated by ezrin interacting with cortactin and associated with adhesion of cells to fibronectin (Kocher et al. 2009). Furthermore, phosphorylation of moesin by Jun N-terminal kinase is important for podosome rosette formation (Pan et al. 2013a). Podosome rosette formation is stimulated by focal adhesion kinase (Pan et al. 2011) and by hepatoma-derived growth factor through the activation of the phosphatidylinositol 3-kinase/Akt pathway (Kung et al. 2012). Podosome rosette formation is suppressed by protein tyrosine phosphatase SHP2 (Pan et al. 2013b), and Src-induced rosette formation is inhibited by p53 via the upregulation of caldesmon (Mukhopadhyay et al. 2009).

Biogenesis and Morphogenesis of Podosomes

Podosomes contain a complex set of proteins making part of the actin-based engine, including actin, myosin IIA, the Arp2/3 complex, N-WASP, cortactin, gelsolin, and cofilin. For the generation of podosomes, actin cytoskeleton remodeling through Arp2/3-mediated actin polymerization and dynamic microtubules are required (Linder et al. 2000; Snyder et al. 2011; van den Dries et al. 2013). Rapid and spatially restricted remodeling of the actin cytoskeleton is a crucial step in the initiation of podosome formation. The site of first appearance is a surface microdomain where actin-containing stress fibers and focal adhesions intersect (Kaverina et al. 2003). Certain actin-associated proteins are involved in this process. A central role is played by the Arp2/3 pathway, whereby the Arp2/3 complex promotes actin assembly and competes with caldesmon in this function (Morita et al. 2007). Other actin-associated protein comprises Src-cortactin (Luxenburg et al. 2006; Clark et al. 2007), WASP (Tsuboi 2007), caldesmon, and paxillin (Badowski et al. 2008). Caldesmon has an important role in podosome biogenesis and function. Ectopic expression of caldesmon reduces the number of both podosomes and invadopodia (Yoshio et al. 2007). Furthermore, the actin-mediated morphogenesis of podosomes is modulated by integrins located at the podosome site. Integrin-linked kinase/ILK, located in an area surrounding the actin-rich podosome core, regulates podosome maturation (Griera et al. 2014). WASP (Wiskott-Aldrich syndrome protein) is an adaptor protein critical for podosome formation (Dovas et al. 2009) and operates in conjunction with the WASP-interacting protein/WIP. WIP is responsible for the stability and localization of WASP to sites of actin assembly in podosomes (Chou et al. 2006; Garcia et al. 2012) and is involved in ruffle formation (Banon-Rodriguez et al. 2013). WASP also interacts with the F-BAR domain protein, FBP17, a protein that promotes actin nucleation (Tsujita et al. 2013). Integrins can prevent the Src-induced cell rounding, but cannot impair the formation of podosomes (Huveneers et al. 2008).

It is suggested that an actin-microtubule cross talk in the cytoskeleton is critical for the morphogenesis of podosomes. There is evidence that protrusion of the podosome depends on the activity and function of the microtubule-associated kinesin motor component, KIF1C (Kopp et al. 2006). In early sites of podosome formation, vimentin deposition colocalizes at the stress fiber-focal adhesion interface, and plectin colocalizes with vimentin. Plectin is an important protein in cytoskeleton organization (Wiche 1998). Apart

from well-known members of the actin assembly engine, podosomes also contain other proteins, such as the cytoplasmic scaffold protein Tks5 (synonym: Fish), which accumulates in podosomes under stimulation by Src. The presence of Trk5 in podosomes is required for cell invasion (Courtneidge et al. 2005). In the process of podosome formation, Tks5 recruits AFAP-110, p190RhoGAP, and cortactin, essential for podosome morphogenesis (Crimaldi et al. 2009). The early morphogenesis of podosomes is preceded by the formation of cell surface ruffles at the dorsal surface of cells. Ruffle formation is associated with morphogenesis of podosomes and depends on an interaction between palladin and the receptor tyrosine kinase, Eps8, this interaction promoting assembly of the actin cytoskeleton (Goicoechea et al. 2006). Palladin is a protein that promotes podosome formation and assembly (Goicoechea et al. 2009), but it also regulates cell and ECM interactions via maintenance of a normal actin cytoskeleton architecture (Liu et al. 2007). Podosome size and number are regulated in macrophages by the Rho GTPase effector PAK4, a member of the p21-associated kinase family, and its regulator alphaPIX (PAK-interacting exchange factor), two factors which induce highly localized changes in actin dynamics (Gringel et al. 2006).

Podosome Functions

Podosomes are dynamic mechanosensors that sense torsional tractions underneath the podosome rings, whereby interactions between myosin tension and actin dynamics are essential for podosome regulation (Collin et al. 2008). Podosomes play an important role in the degradation of extracellular proteins. Podosomes express sets of proteases that hydrolyze several proteins and glycoproteins of the ECM. In dendritic cells, protrusive podosomes employ MMP-14 for matrix degradation and endocytosis (Gawden-Bone et al. 2010). Fully developed podosomes operate within a network of stimulatory and inhibiting factors. Podosome-mediated degradation of basement membrane collagen is induced by TGF-beta (Rottiers et al. 2009). Other proteins known to modulate podosome function are the Cdc42 regulators. Cdc42 GTPase-activating protein/CDC42GAP regulates podosome-associated cell motility through mediation of extracellular signal-related kinase/ERK activity (Szczur et al. 2006).

Invadopodia

General Aspects

There are several structures at the cell surface that are specialized in creating distinct intercellular and cell-matrix adhesions. A long-known example is the focal adhesion, which contains clusters of transmembrane integrin receptors which are tethered at one end to the ECM and at the other end to stress fibers of the actin network. A second adhesion structure which is critically involved in cancer invasion is the invadopodia.

Selected References (Gimona and Buccione 2006; Weaver 2006; Yamaguchi et al. 2006; Gimona et al. 2008; Stylli et al. 2008; Albiges-Rizo et al. 2009; Buccione et al. 2009; Saltel et al. 2011; Bravo-Cordero et al. 2012; Klemke 2012; Sibony-Benyamini and Gil-Henn 2012; Yamaguchi 2012; Génot and Gligorijevic 2014; Paz et al. 2014).

Invadopodia mediate basement membrane and tissue invasion of cancer cells and are characterized by the integration of several cytoskeletal processes that involve modulation of contractile forces and mechanotransduction (Lohmer et al. 2014; Tokui et al. 2014). Invadopodia are actin-based protrusions or "organelles" of transformed cells and tumor cells that form distinct cell-matrix adhesion sites. Invadosomes are critically required for cancer cell extravasation. In the course of intravascular spread of tumor cells, these cells can, after homing to distant endothelial surfaces, extend invadopodia through endothelium into the extravascular space prior to their extravasation and metastatic growth (Leong et al. 2014).

Invadopodia share several features with podosomes, but are morphologically different from podosomes, as they have a different structure, occur in larger numbers, and are more active in their capability to degrade matrix (Tolde et al. 2010; Artym et al. 2011). Adhesion rings surround invadopodia, a feature shared with podosomes (Branch et al. 2012). Typical invadopodia are smaller than podosomes and occur in larger numbers per cell. They measure from 0.1 to 0.8 μm in diameter and can reach a length of 2 μm or more. Invadopodia can form clusters around membrane invaginations close to the site of the Golgi complex.

Molecular Composition and Biogenesis of Invadopodia

Similar to podosomes, invadopodia possess a complex microfilament machinery regulating F/G-actin switching mediated by a now impressive number of actin-associated proteins, including N-WASP, cortactin, tensin, formins, Src kinases, the Arp2/3 complex, paxillin, cofilin, and gelsolin (Gimona 2008; Albiges-Rizo et al. 2009). Invadopodia are constructed of an N-WASP-dependent branched actin network and a Rho GTPase Cdc42-based pathway involved in invadopodial-membrane protrusion (Albiges-Rizo et al. 2009). The actin network of invadopodia, which contains cortactin, is regulated by a multimolecular complex containing Src kinase, the formin mDia1, actin, and Spire1, a protein which serves as the connection to Rab3A GTPase (Weaver 2008; Lagal et al. 2014). As an important component of the invadopodial machine, myosin 1e is located to the invadopodial core where it may act as a scaffold, linking the plasma membrane to the actin cytoskeleton (Oudekirk and Krendel 2014). In their interaction with the extracellular matrix, invadopodia are potently induced by dense fibrillar collagen via a kindlin2 serine phosphorylation signaling pathway (Artym et al. 2015). Furthermore, invadopodia are equipped with a complex set of regulatory and signaling proteins (Table 1). In particular, pathways leading to invadopodia formation are linked with a signaling cascade that also critically affects cell proliferation and differentiation, Wnt/beta-catenin signaling. Specifically, the Wnt5a-Ror2 axis is involved in enhanced formation of invadopodia (Endo et al. 2015). Biogenesis of invadopodia is strongly induced by Cdc42, while the adaptor protein is required for the degradative activity of invadosomes (Di Martino et al. 2014). A further

protein which markedly promotes formation of invadopodia is the cytoskeletal protein WAVE3, which induces cancer cell invasion and metastasis via induction of MMP-9 and other MMPs (Davuluri et al. 2014). Invadopodia biogenesis depends on diaphanous-related formins (Lizarraga et al. 2009). Paxillin, which plays a role in several steps of invadopodia biogenesis and function, is a focal adhesion-associated, phosphotyrosine-containing protein that possesses several domains for protein-protein interactions. These domains are the necessary docking site for several cytoskeletal proteins, including vinculin and actopaxin, tyrosine kinases and serine/threonine kinases, and GTPase-activating proteins and numerous adaptor proteins (Turner 2000; Schaller 2001; Pignatelli et al. 2012b). Paxillin is associated with the paxillin kinase linker/PKL, a protein regulating directed cell migration (Yu et al. 2009). At sites of ECM degradation, an invasion-related complex constructed of paxillin, cortactin, and protein kinase Cmu associated with invadopodia (Bowden et al. 1999). For the function of the actin-based network, the atypical GTP-binding protein dynamin is required, dynamin being a central modulator of cellular protrusive events (McNiven et al. 2004). In the protruding edge of invadopodia and similar structures, actin-associated proteins are accumulated. The interaction of these proteins is coordinated by a member of the F-BAR family of proteins, CIP4/Cdc42-interacting protein 4, in a Rac1/WAVE1-dependent manner (Saengsawang et al. 2013).

Induction and Regulation of Invadopodia in Cancer Cells

In cancer cells, numerous factors can elicit the biogenesis of invadopodia. A major role is played by a complex interaction of cancer cells with the extracellular matrix (ECM) located to tumor stroma. Invadopodia are strongly induced upon contact of tumor cells with distinct domains of the ECM (review: Hoshino et al. 2013a). This contact promotes the activity of several signaling pathways that induce actin cytoskeleton rearrangement, the recruiting of actin-associated proteins, and the generation of cell protrusions (Destaing et al. 2011; Linder et al. 2011). Similar to lamellipodia and related cell protrusions, formation of invadopodia depends on interactions between focal adhesions and the actin cytoskeleton. Via focal adhesions and integrin receptors, invadopodia interact with proteins in the extracellular matrix/ECM. Among ECM proteoglycans and proteins, hyaluronan interacting proteins RHAMM play a role in invadopodia induction (Gurksy et al. 2012). Generally, adhesion signaling has a central role in invadopodia formation, with the critical involvement of protein kinase C and Src kinases (Destaing et al. 2011). Src signaling to induced invadopodia is a regulated protein involved in cell migration and invasion, TM4SF5/transmembrane 4 L six family member 5 (Jung et al. 2013). Src kinase associates with diaphanous formin-1, actin, and Spire-1 in a complex that contributes to invadopodia biogenesis (Lagal et al. 2014). Invadopodia formation is stimulated by proteins that induce epithelial-mesenchymal transition/EMT, e.g., Twist1 (Eckert et al. 2011) and the focal adhesion protein Hic-5, a paxillin homologue (Pignatelli et al. 2012a), linking EMT with mechanisms that determine tissue invasion. Invadopodia are induced by Src-mediated phosphorylation of ASAP1 (Bharti et al. 2007) and by the activation of Cdc42, e.g., by the stromal cell-derived protein palladin (Goicoechea et al. 2014). Src kinases orchestrate several steps of invadopodia biogenesis in a distinct spatiotemporal pattern (Boateng and Huttenlocher 2012). The latter mechanism illustrates the close interaction between tumor cell and matrix for the induction of invadosomes. Invadopodia are induced by a key regulator of the F/G-actin switch mechanism, Abl interactor 1/Abi 1, which affects invadopodia formation in an Src-dependent manner (Sun et al. 2009). Formation of invadopodia depends on the activity of GTPases, e.g., RhoGTPases, which provide signals to the cytoskeleton through small G proteins of the Rho family (Spuul et al. 2014). Invadopodia contain the Arf GTPase-activating protein ASAP1, whereas ASAP3 is not expressed (Ha et al. 2008). The contact between cancer cells and ECM also

involves a complex mode of pH sensing. Several pH regulators such as V-ATPases and Na(+)/H(+) exchangers are expressed in invadosomes, and these sensors/regulators control the acid microenvironment to provide a milieu for appropriate activation of MMPs and other degradases (Brisson et al. 2012).

A second major pathway that induces invadopodia in cancer cells is epithelial-mesenchymal transition (EMT). Formation of invadopodia is stimulated by EMT taking place upon contact of tumor cells with the extracellular matrix. Apart from its central role in EMT induction, the transcription factor Twist1 is capable to induce invadopodia formation, probably via its transcriptional target, PDGFRalpha (Eckert et al. 2011). Also the EMT-inducing factor TGF-beta induces invadopodia formation via ectopic expression of the focal adhesion protein, Hic-5 (Pignatelli et al. 2012a). In the setting of EMT, podosome-like structures occurring in noninvasive carcinoma cells switch to actin comet-embedded invadopodia containing MMP-1. In the course of this transition, the podosomes become smaller and achieve the shape of numerous invadopodia, structures in which talin is replaced by tensin. Therefore, EMT can induce the production of the potent degrading engine required for cancer invasion (Takkunen et al. 2010). Invadopodia are also induced by a factor involved in the regulation of EMT, CD147/basigin (Grass et al. 2012).

Invadopodia maintenance and function are regulated by integrins, Src tyrosine kinase signaling, cortactin, AMAP/ASAP1, the adaptor protein Tks5/Fish, receptor tyrosine kinases, Rho family GTPases, ARF6, and dynamin 2. Beta1 integrins are required for the formation of competent invadopodia, whereby beta1 integrin interacts with the tyrosine kinase Arg and stimulates Arg-dependent phosphorylation of cortactin (Beaty et al. 2013). Beta1A integrin is a master regulator of podosome and invadopodia organization and function (review: Destaing et al. 2010). ASAP1 is an Arf GTPase-activating protein/GAP containing a BAR domain and is a substrate for Src kinase.

Tissue and Matrix Destruction (Histolysis) as a Major Mechanism of Cancer Invasion

Introduction

Both invadopodia and lamellipodia engage in contacts with the underlying extracellular matrix (ECM) and are then stimulated to secrete matrix metalloproteinases (MMPs; see below; Coussens and Werb 1996; Stamenkovic 2000; Linder 2007; Linder et al. 2011; van Horssen et al. 2013). The contact between invadopodia and ECM is a complex process that involves signals from matrix rigidity and myosin II-FAK/Cas pathways (Alexander et al. 2008). Typical MMPs produced by invadopodia are MMP-2 and MMP-9 and in part of neoplasms also MT1-MMP (Watanabe et al. 2013). Expression and secretion of these enzymes causes pericellular proteolysis in cancer (Sevenich and Joyce 2014). Invadopodia express latent MMP-2 and membrane type 1 MPP at the cell surface, where they are activated (Chen and Wang 1999). ECM degradation by invadopodia is regulated by the action of the phosphoinositide-binding protein, ZF21, a protein that promotes cancer cell migration and invasion (Hoshino et al. 2013b). The function of invadopodia also requires several types of ADAMs, which interact with integrins in invadopodia and cooperate with certain invadopodial adaptor proteins, such as Tks5/Fish. Physiological type I collagen can induce a special type of invadosomes, the linear invadosomes. Linear invadosomes, cortactin- and N-WASP-containing protrusions that can degrade matrix, result through replacement of podosomes or invadopodia upon contact with type I collagen present in collagen-rich ECMs (Juin et al. 2012).

Matrix Metalloproteinases (MMPs): Types and Classification

Matrix metalloproteinases (MMPs) are enzymes that are implicated in remodeling of the extracellular matrix (EMC), including the basement membranes (Deryugina and Quigley 2006; Friedl and Wolf 2009; Shiomi et al. 2010). MMPs are

Table 2 Types of metalloproteases (MMPs) and their substrates

Type of MMP	Substrate(s)
Membrane-bound MMPs	
MT1-MMP (MMP-14)	Collagens I–III, gelatins, aggrecan, laminin
MT2-MMP (MMP-15)	Nidogen, tenascin, aggrecan, perlecan, laminin
MT3-MMP (MMP-16)	Collagen III, gelatins, fibronectin
MT4-MMP (MMP-17)	Gelatins, fibrinogen
MT5-MMP (MMP-24)	Proteoglycans
MT6-MMP (MMP-25)	Collagen IV, gelatins, laminin, fibronectin
MMP-23	Gelatin
GPI-linked MMP	
Secreted MMPs	
MMP-1 (interstitial collagenase)	Collagens I–III, VII, and X, gelatins, proteoglycans
MMP-2 (gelatinase A)	Gelatins, collagens, laminin, fibronectin
MMP-3 (stromelysin-1)	Gelatins, laminin, fibronectin, proteoglycans
MMP-7 (matrilysin-1)	Proteoglycans, gelatins, elastin, tenascin, entactin
MMP-8 (neutrophil collagenase)	Collagens I–III, gelatins, aggrecan
MMP-9 (gelatinase B)	Gelatins, collagens III–V, aggrecan, elastin
MMP-10 (stromelysin-2)	Aggrecan, laminin, fibronectin, collagens III–V
MMP-11 (stromelysin-3)	Fibronectin, laminin, aggrecan, gelatins
MMP-12 (metalloelastase)	Elastin, aggrecan, fibronectin, collagen IV
MMP-13 (collagenase-3)	Collagens I–IV, IX, X, and XIV, aggrecan, tenascin
MMP-19 (RASI-1)	Collagen IV, gelatin, fibronectin, tenascin
MMP-20 (enamelysin)	Amelogenin, aggrecan, gelatin
MMP-21	?
MMP-26 (matrilysin-2)	Gelatin, collagen IV, fibronectin, vitronectin
MMP-27	?
MMP-28 (epilysin)	?

classified as two main types of proteases, i.e., those that are anchored to the cell surface membrane and a second group that is secreted into the extracellular space (Table 2).

General Roles and Regulation of MMPs in Liver Cancer

Generally, MMPs play pleiotropic roles in cancer, exceeding aspects of mere "degradomics" but also including effects on cell adhesion, growth signaling, and other pathways (Kleiner and Stetler-Stevenson 1999; Overall and Dean 2006). The activity of MMPs is regulated and controlled at several levels, such as enzyme activation or inhibition at the cell surface, complex formation, and compartmentalization in various subcellular compartments. Within normal and cancer cells, MMPs can be localized at the cell surface, in the cytosol, and in organelles and the nucleus. The role of intracellular MMPs has not yet been clarified in detail (review: Mannello and Medda 2012). Downregulation of the Notch signaling pathway impairs HCC cell migration (Zhou et al. 2013b) and inhibits HCC cell invasion by inactivating MMP-2 and MMP-9 expression via the extracellular signal-regulated kinases 1 and 2 (ERK1/2) signaling pathways (Zhou et al. 2012), while high levels of Notch1 augment MMP-2 and MMP-9 and promote a highly invasive HCC phenotype. Conversely, sonic hedgehog, a ligand of hedgehog, is frequently expressed in HCC cells and decreases the expression of MMP-9 via the ERK pathway (Lu et al. 2012). High Notch1 expression in HCCs was correlated with tumor size, tumor grade, venous invasion, and the metastatic state (Zhou et al. 2013a). In its inhibitory action on migration and invasion, Notch1 operates by regulating CD44v6, E-cadherin, MMPs, and uPA via the COX-2 and ERK1/2 pathways (Zhou et al. 2013). Downregulation of Notch1 inhibits HCC cell invasion by inactivating the COX2/Snail/E-cadherin pathway involved in EMT (Zhou et al. 2013c). Secretion of multiple MMPs is promoted by HGF via the transcription factor Ets-1 which activates MMP transcription (Ozaki et al. 2003). Secretion of MMPs by stromal cells is stimulated by CD147 (EMMPRIN; basigin), a cell surface glycoprotein that belongs to the immunoglobulin superfamily and is strongly expressed on the surface of many tumor cell types. Basigin exists in several isoforms with differential functions. Basigin stimulates the

secretion of VEGF and hyaluronan, promoting angiogenesis and anchorage-independent growth (Nabeshima et al. 2006). These effects are abolished by depletion of CD147, mainly downregulating MMP-11 and VEGF (Jia et al. 2007). CD147 exerts its pro-metastatic effects also in HCCs (Xu et al. 2007; Zhang et al. 2007c; Jia et al. 2008). In HCC cells, downregulation of CD147 inhibits gelatinase production, interferes with tumor cell adhesion to type IV collagen, and alters cytoskeletal structure (Qian et al. 2008). One basigin isoform, basigin-3, inhibited proliferation of HCC cells and MMP induction (Liao et al. 2011). CD147 interacts with integrin alpha6beta1, stimulating invasion and MMP secretion in HCC cells (Dai et al. 2009). A further protein with which CD147 interacts is annexin, a Ca(2+)- and phospholipid-binding protein subject to phosphorylation by tyrosine kinases and protein kinase C. This interaction promotes migration and MMP-mediated invasion of HCC cells. The pro-invasive and pro-metastatic effect of basigin/CD147 is counteracted by the basigin isoform, basigin-3, in HCC (Liao et al. 2011).

Expression of the Diverse Metalloproteinases in Liver Cancer

Several members of the large MMP family are expressed or overexpressed in HCCs and cholangiocarcinomas and affect the development of a metastatic phenotype (Yamamoto et al. 1999; Bodey et al. 2000; Giannelli et al. 2002; McKenna et al. 2002; Ishii et al. 2003; Ozaki et al. 2003; Matsunaga et al. 2004; Okamoto et al. 2005; Gao et al. 2006; Altadill et al. 2009). Generally, expression of MMPs in cancer cells is augmented by EMT. The EMT factor, Twist1, activates MMPs and by this induces tumor cell invasion (Zhao et al. 2011). Snail, an inducer of EMT, accelerates cancer invasion by an EMT-associated upregulation of MMPs (Miyoshi et al. 2004, 2005). Expression of MMPs increases as a function of increasing stage (Gao et al. 2006). Secretion of MMPs by stromal myofibroblasts is suppressed by TGF-beta1, while the hormone relaxin binding to its cognate receptor, relaxin family peptide receptor 1, upregulates MMPs (Chow et al. 2012).

MMP-1

MMP-1 is involved in both tumor cell invasion and the generation of metastases, also in HCCs (Ogasawara et al. 2005). MMP-1 proteolytically activates protease-activated receptor-1 (PAR-1). In HCCs, the MMP-1/PAR-1 signaling axis is strongly activated and associated with tumor invasion and progression (Liao et al. 2011, 2012). Increased expression of MMP-1 and MMP-2 in HCCs is correlated with tumor differentiation (Ogata et al. 1999). However, other studies arrived at different results. For example, high levels of MMP-1 transcripts were detected in well-differentiated cancer cells of early HCCs, but not in moderately to poorly differentiated HCCs, suggesting an MMP-1-mediated role in early invasive processes, such as destruction of portal tracts (Okazaki et al. 1997).

MMP-2

Expression of MMP-2 is involved in HCC invasion, and its activity is influenced by several genetic variants that modulate the enzyme's effects in the invasive pathway (Wu et al. 2008). Expression of MMP-2 in HCCs is associated with dedifferentiation in HCC (Ogata et al. 1999) and was correlated with intra- and extrahepatic metastases (Liu et al. 2003). Expression of MMP-2 predicted lymph node metastasis in HCCs (Xiang et al. 2011). The secretion of MMP-2 is stimulated by the transcription factor, Snail, which is expressed in HCC cells and mediates EMT. On the other hand, downregulation of Snail in HCC cells is associated with increased expression of the adhesion molecule, E-cadherin, and downregulation of MMP-2 (Chen et al. 2012a). MMP-2 is also upregulated by osteopontin (Chen et al. 2011a,b), through the SDF-1/CXC4 axis (Zhang et al. 2011), via Notch signaling (Zhou et al. 2012), by secreted clusterin (Chen et al. 2012a), Rock2 (Huang et al. 2014), and by sonic hedgehog signaling through focal

adhesion kinase/AKT signaling (Chen et al. 2013a). Osteopontin itself is downregulated by microRNA-181a (Bhattacharyya et al. 2010). The activity of MMP-2 in HCC is strongly controlled by TIMP-2 (Musso et al. 1997; Giannelli et al. 2002). MMP-2 expression is downregulated by microRNA-29b, a microRNA that suppresses angiogenesis, invasion, and metastasis (Fang et al. 2011). As with other MMPs, MMP-2 is regulated by tissue inhibitor of metalloproteinase-2/TIMP-2. Strong expression of TIMP-2 in hilar cholangiocarcinomas is associated with inhibition of cancer invasion and metastasis (Xiao et al. 2004). MMP-2 is also expressed in subsets of gallbladder carcinoma (Karadag et al. 2008).

MMP-3

Expression of MMP-3 is associated with the prognosis of HCV-related HCCs (Okamoto et al. 2010). In HGF-induced invasion of HCC cells, MMP-3 is involved, in that HGF stimulates the secretion of pro-MMP-3 (Monvoisin et al. 2002). Upregulation of MMP-3 in hepatoma cells is associated with a downstream mediation of autocrine motility factor (Yu et al. 2004). MMP-3 is also induced by HBV X protein, which is a known promoter of cell migration (Yu et al. 2005). The pro-metastatic activity of MMP-3 depends on its genetic polymorphism, in that the MMP-3 5A allele was the most prominent MMP-3 enzyme to promote invasion (Okamoto et al. 2010). Expression of MMP-3 in HCC cells is reduced by microRNA-30a-3p (Wang et al. 2014).

MMP-7

Similar to other MMPs, MMP-7 has recently been demonstrated to act in the invasion cascade, also in metastatic HCCs (Gao et al. 2006). In particular, MMP-7 expression is a prognostic factor in cholangiocarcinoma, whereby cholangiocarcinoma cells show strong immunoreactivity for this enzyme (Miwa et al. 2002). Expression of MMP-7 is associated with poor prognosis in patients with intrahepatic cholangiocarcinoma (Hirashita et al. 2012) and is an unfavorable postoperative prognostic factor in perihilar, hilar, and extrahepatic cholangiocarcinomas (Itatsu et al. 2008), and serum MMP-7 seems to be a valuable diagnostic marker in discrimination of cholangiocarcinomas from reactive biliary pathologies (Leelawat et al. 2009). One non-synonymous variant of MMP-7 was found to confer risk of liver cirrhosis in patients with HCC (Hung et al. 2009). MMP-7 engages in a signaling pathway together with beta-catenin. Upregulation of MMP-7 expression by beta-catenin is promoted by DKK1, which is overexpressed in HCCs (Chen et al. 2013b). Similar to sclerostin, DKK1 (Dickkopf-related protein 1) is an antagonist of the Wnt/beta-catenin signaling cascade. DKK1 promotes invasion and metastasis in HCCs, associated with increased RhoA and JNK levels (Tao et al. 2013). In cholangiocarcinomas, DKK1 is related to lymphatic metastasis and an aggressive course (Shi et al. 2013). This phenomenon may be caused by the induction of an invasive phenotype by DKK1. MMP-7 expression is downregulated in HCCs by the tumor suppressor, fibulin-5 (Tu et al. 2014).

MMP-9

MMP-9 has an important role in HCC invasion (Arii et al. 1996; Sun et al. 2005; Nart et al. 2010; Tao et al. 2010; Yeh et al. 2010; Thieringer et al. 2012) and is also involved in invasion of hilar cholangiocarcinoma (Li et al. 2005). Upregulation of MMP-9 is found in a majority of HCCs and is subject to MMP-9 gene polymorphism (El-Samanoudy et al. 2014). Overexpression of MMP-9 mRNA may be associated with the progression of small HCCs with a diameter of <=2 cm (Sakamoto et al. 2000). MMP-9 expression is a significant predictor of recurrence after liver transplantation in HCC patients (Zhang et al. 2006). The MMP family members, MMP-2 and MMP-9, are critical for the invasive potential of numerous malignancies, including HCC. Overexpression of MMP-9 in HCCs is correlated with growth and invasion in

small tumors already (Sakamoto et al. 2000) and is associated with macrovessel invasion in larger tumors (Nart et al. 2010). High expression of MMP-9 was associated with both time to recurrence and overall survival, while high expression of MMP-2 was only correlated with time to recurrence (Chen et al. 2012b). MMP-9 cleaves osteopontin to produce a fragment that is essential for osteopontin-induced invasion of HCC cells (Takafuji et al. 2007). MMP-9 is also expressed in tumor-associated macrophages (TAMs) located at the invasive front of murine HCC (Roderfeld et al. 2010). MMP-9 cooperates with focal adhesion kinase (FAK), whereby this mechanism that is active in HCC cell migration is stimulated by activated hepatic stellate cells (Han et al. 2014). In addition to its role as mediators of histolysis, MMPs may cause other biologic effects, e.g., angiogenesis in cancers (Bergers et al. 2000). In mice, hepatocyte-specific expression of MMP-9 promoted liver tumor development (Thieringer et al. 2012).

The induction and localization of MMP-9 are regulated by several factors. MMP-9 signaling in HCC is promoted by activated hepatic stellate cells (Han et al. 2014), which occur in tumor stroma. MMP-9 activity for mediating invasion is regulated by the calcium-binding protein S100A4 (Zhang et al. 2013) and is strongly regulated by protein kinase C-dependent NF-kappaB activation in HCC cells (Hah and Lee 2003). Trafficking of MMP-9 in invadopodia is regulated by Rab GTPases, specifically Rab40b (Jacob et al. 2013). Induction of MMP-9 expression in HCC is stimulated by interleukin 23 through NF-kappaB induction (Li et al. 2012). Expression of MMP-9 is promoted by the PRL (phosphatase of regenerating liver) phosphatase, a group of distinct protein tyrosine phosphatases. Activation of MMPs is mediated by Twist-induced EMT, whereby specifically MMP-2 and MMP-9 are secreted (Zhao et al. 2011). The activity of MMP-9 and MMP-2 is attenuated by the protein, RECK (reversion-inducing cysteine-rich protein with Kazal motifs), an important regulated metalloproteinase. Downregulating of RECK in cholangiocarcinomas is associated with enhanced MMP-2/MMP-9 activity and a metastatic phenotype (Namwat et al. 2011). HBV viral X protein induces MMP-9 gene expression via activation of ERK and PI-3K/AKT pathway activation (Chung et al. 2004), whereas hepatitis C virus NS3 protein enhances cancer cell invasion by activating MMP-9 activity (Lu et al. 2015). MicroRNA-133a inhibits HCC cell migration and invasion by targeting MMP-9 (Chen et al. 2015). The expression of MMP-9 is inhibited by microRNA-491, which also blocks EMT in HCC (Zhou et al. 2013d). MMP-9 is upregulated in other hepatic and biliary tract cancers, including cholangiocarcinoma. In cholangiocarcinomas, MMP-9 expression is enhanced by downregulation of microRNA-138 (Wang et al. 2013b). MMP-9 expression is enhanced in gallbladder carcinoma (Karadag et al. 2008).

MMP-10

Strong immunoreactivity for MMP-10 was found in HCCs, especially in the extracellular matrix adjacent to blood vessels (Bodey et al. 2000). MMP-10 can be activated by C-terminal-truncated HBV X protein, a process stimulating HCC invasion (Sze et al. 2013).

MMP-11

MMP-11 is strongly expressed in both tumor cells and stromal cells surrounding cancer. There is evidence that MMP-11 is a tumor lymphatic metastasis-associated MMP (Jia et al. 2007). MMP-11 is downregulated by CD147 (basigin), affecting the lymphatic metastasis pattern of HCC in a mouse model (Jia et al. 2007). Expression and secretion of MMP-11, together with VEGF, is inhibited in HCCs by ectopic expression of microRNA-125a (Bi et al. 2012).

MMP-12

Overexpression of MMP-12 was found in 58 % of human HCCs, and its expression was significantly correlated with an invasive phenotype (in particular venous invasion) and poor prognosis in HCC (Ng et al. 2011).

MMP-14

Membrane type 1 MPP (MT1-MMP, MMP-14) promotes invasiveness in HCC cell lines (Murakami et al. 1999), is overexpressed in highly invasive HCCs (Harada et al. 1998), and induces metastases in HCC, but MMP-14 gene polymorphisms also contribute to HCC susceptibility (Chen et al. 2011c). Increased MMP-14 mRNA expression by tumor cells in HCCs may have prognostic significance (Määtä et al. 2000). An aggressive phenotype is observed in HCCs that show atypical localization of MT1-MMP in the tumor cell nuclei (Ip et al. 2007). By its enzymatic activity, it not only degrades extracellular matrix but it also induces a signaling pathway stimulating cell adhesion and proliferation (Ip et al. 2005). MT1-MMP confers a proteolytic activity to invadopodia (see above), particularly upon tumor cell contact with ECM. This activity is regulated by the v-SNARE TI-VAMP/VAMP7 (Steffen et al. 2008). The cell surface level and endocytosis of MMP-14 are also regulated by the planar cell polarity-associated protein, VANGL2, a protein that also induced invadopodium formation (Williams et al. 2012). In tumor cells, endocytosis of MT1-MPP by clathrin- and caveolae-dependent pathways is counteracted by mechanisms stabilizing the enzyme at the cell surface (Poincloux et al. 2009). MT1-MPP is targeted by microRNA-150-5p which inhibits HCC migration and invasion. In metastasizing liver cancers, expression of this MiR is reduced (Li et al. 2014). MT1-MMP can be upregulated by HBV X protein (Ou et al. 2007). Similar to MT1-MMP, also MT3-MMP expression was associated with an invasive phenotype in HCCs (Arai et al. 2007).

Tissue Inhibitors of Metalloproteinases (TIMPs) in Liver Cancer

Tissue inhibitors of metalloproteinases (TIMPs; four members, TIMP-1, TIMP-2, TIMP-3, and TIMP-4) are important regulator proteins that interfere with the activity of certain MMPs. TIMP-1 inhibits MMP-9, while TIMP-2 inhibits MMP-2. Both TIMPs were detected in HCC tumor cells, stromal cells, and endothelial cells, whereby expression signals were stronger for TIMP-1 than for TIMP-2 (Joo et al. 2000; Matsumoto et al. 2004), which is of special interest in the light of the MMP expression patterns in HCCs. In one study, TIMP was preferentially expressed in the capsule of HCCs (Fukuda et al. 1991). Metastatic HCCs showed lower levels of TIMPs (Gao et al. 2006), and HCC tissue expression levels of TIMP-2 were higher in patients without metastases (Giannelli et al. 2002). However, TIMP-1 can create a premetastatic niche in the murine liver through stromal cell-derived factor 1/CXCR4-dependent neutrophil recruitment (Seubert et al. 2015). Expression of TIMPs is heterogeneous and varies considerably among HCC nodules, but there was no clear correlation between the TIMP expression levels, differentiation grade, and invasion, although TIMP expression was also detectable in HCC metastases (Nakatsukasa et al. 1996). In cholangiocarcinoma, expression of TIMP-1 was strong and was associated with the extent of invasion (Nakatsukasa et al. 1996). In cultured cells, expression of TIMP-1 was negatively regulated by the EMT effector, Twist1 (Okamura et al. 2009). In addition to TIMP-1 and TIMP-2, TIMP-3 is involved in the regulation of cancer invasion. Transfection of TIMP-3 in HCC cell lines suppresses invasive capacity (Zhang et al. 2007b). In HBV-associated HCC, TIMP3 can be epigenetically silenced (Lai and Lo 2005).

There are protease inhibitors different from TIMPs. The serine protease inhibitor, clade B, member 1/SERPINB1, is a member of the SERPINB family involved in suppression of migration and invasion in various cancers. SERPINB1 expression in HCCs is correlated with tumor invasion and an aggressive course (Cui et al. 2014).

Metzincin Superfamily Members: ADAMs

A disintegrin and metalloproteinases (ADAMs) or MDCs (metalloprotease-like, disintegrin-like, cysteine-rich proteins) are membrane-bound

metzincins and the adamalysin subfamily. Twenty-two members of ADAM family are known (reviews: Porter et al. 2005; Edwards et al. 2008). ADAMs possess a domain structure similar to that of MMPs, but in contrast to the latter, ADAMs display a cysteine-rich domain, an epidermal growth factor-like repeat domain, and the disintegrin domain, but lack the hemopexin-like domain of MMPs (review: Klein and Bischoff 2011). The main functional activity of ADAM metalloproteases is ectodomain shedding of various receptors, growth factors, Notch, cytokines, and other signaling substances involved in cellular homeostasis ("ADAM sheddases"). For example, ADAM17 is critically involved in post-shedding activation of pro-TNF-alpha and is therefore also termed tumor necrosis factor-alpha convertase or TACE. For several cell membrane signaling proteins, cleave by ADAM sheddases prepares what is called regulated intramembrane proteolysis or RIP, resulting in intracellular domains that can be translocated to the nucleus for the regulation of gene transcription (Edwards et al. 2008).

Various malignant neoplasms express several species of ADAMs, particularly ADAM8, ADAM9, ADAM10, ADAM12, ADAM15, ADAM17, ADAM19, and ADAM28 (review: Mochizuki and Okada 2007; Duffy et al. 2009). In cancer invasion and spread, the critical function of ADAMs is the metalloproteinase activity of these enzymes (Rocks et al. 2008). Similar to MMPs, the metalloprotease domain is shielded by a pro-domain that involves the cysteine switch mechanism. For activation of the protease, this protecting shield is removed in the trans-Golgi network by the action of proprotein convertases, such as furin (Klein and Bischoff 2011). ADAM8 is overexpressed in HCCs in comparison with normal liver. Expression levels were positively correlated with tumor size, grade, recurrence, and metastasis (Zhang et al. 2013). Downregulation of ADAM10 expression inhibits invasiveness and metastasis of human HCC cells, associated with increased E-cadherin protein levels and a related change in cell migration (Yue et al. 2013). ADAM12 mediates the shedding of the epidermal growth factor receptor (EGFR) ligand, heparin-binding EGF-like growth factor/HB-EGF, in a Notch-dependent manner. Released EB-EGF induces the formation of invadopodia under hypoxic conditions (Diaz et al. 2013). ADAM17 is involved in the cleavage of the ectodomain of numerous transmembrane proteins. ADAM17 is overexpressed in HCC under hypoxic conditions and enhances the phosphorylation of the EGFR (Wang et al. 2013a). ADAM17 is targeted by microRNA-145 which suppresses invasion of HCC cells (Yang et al. 2014). In HCCs, ADAM17 is also regulated by microRNA-122, a tumor suppressor microRNA (Tsai et al. 2009). ADAM28 is implicated in tumor growth and progression in several human cancers (Mochizuki and Okada 2009). It operates through cleavage of the proapoptotic von Willebrand factor. Tumor cells with low expression levels of ADAM28 display a higher rate of apoptosis (Mochizuki et al. 2012).

ADAMTS and ADAMTS-Like Proteins

ADAMTS (a disintegrin and metalloprotease with thrombospondin motifs) are a family of extracellular proteases that is distinguished from ADAM metalloproteases by the presence of multiple copies of thrombospondin 1-like repeats. ADAMTS bind to and process various components of ECM proteins and proteoglycans, including heparin; procollagens I, II, and II; aggrecan; brevican; versican; decorin; fibronectin; and von Willebrand factor. ADAMTS are involved in the regulation of critically important processes such as morphogenesis, angiogenesis, and carcinogenesis. For example, of the at least 20 members in this family, ADAMTS2 is a procollagen N-proteinase; ADAMTS4 and ADAMTS5 are aggrecanases active in the hydrolysis of cartilage aggrecan (review: Tang 2001). Overexpression of ADAMTS1 results in shedding of semaphorin 3C from the ECM, a step that stimulates cell migration (Esselens et al. 2010). The seven ADAMTS-like proteins are proteins that lack proteolytic activity but possess ADAMTS ancillary domains. The proteins have important regulatory roles in the ECM (review: Apte 2009).

Other Proteases Involved in Cancer Invasion and Progression

In invadopodia, few other proteolytic enzymes are expressed, including serine proteinase/seprase, aspartate proteases, threonine proteases, dipeptidyl dipeptidase, and cysteine cathepsins (Jevnikar et al. 2012; Rakashanda et al. 2012). A group of calcium-dependent cysteine proteases is the calpains, enzymes involved in several homeostatic mechanisms. Among the various calpain members, m- and m-calpain are involved in regulating cell migration and invasion. In comparison with normal hepatocytes, these two calpains are elevated in HCC cells and regulate HCC cell migration and invasion (Chen et al. 2013c).

Several types of enzymes active on matrix proteins are produced and secreted by leukocytes infiltrating the tumor stroma. Macrophages express a distinct metalloelastase, a member of the MMP family. Expression of metalloelastase by tumor-associated macrophages in HCC is correlated with angiostatin generation and survival, in that tumors having no metalloelastase expression and hence a reduced angiostatin showed poorer survival (Gorrin Rivas et al. 1998). Human neutrophils produce an elastase that can degrade TIMP-1, a process accelerated by heparin (Nunes et al. 2011).

HCCs can express and secrete various ectopeptidases, including neprilysin (CD10), aminopeptidase N (CD13), and angiotensin-I-converting enzyme (CD143), whereby this expression differs considerably between normal liver and HCCs. In HCCs, neprilysin immunoreactivity is found on canalicular domains, a feature with diagnostic significance (Borscheri et al. 2001). In comparison with normal parenchyma, CD10 is low in HCCs, while CD13 and CD143 were mildly increased. CD13 may be involved in the regulation of cell polarity, whereas CD143 may influence angiogenesis (Rocken et al. 2004).

Thrombin can induce cell migration in HCCs. HCCs express several proteinase-activated receptors (PAR), mainly the thrombin receptors PAR(1), PAR(3), and PAR(4). PAR form a novel G-protein-coupled receptor subfamily. Stimulation of HCC cells in vitro with thrombin increased migration across a collagen barrier (Kaufmann et al. 2007). The urokinase system involves three key components, urokinase-type plasminogen activator (uPA), uPA receptor (uPAR), and plasminogen activator inhibitor type 1 (PAI-1). This system is activated in several tumor types and potently affects tumor invasion and metastasis. Urokinase-type plasminogen activator (uPA) is a key protein in the plasminogen activation system and is critically involved in proteolytic steps in tumor invasion. In human HCCs, uPA and c-met overexpression are coordinated in a complex fashion. Following its binding to its c-met receptor, HGF can upregulate uPA in a dose-dependent manner and by this mechanism augments HCC invasion (Lee et al. 2008). High levels of uPA in HCCs were correlated with macrovessel invasion and metastasis, and in tumors expressing uPA, uPAR, and PAI-1, a more prominent invasion phenotype was observed (Zheng et al. 2000). Overexpression of microRNA-23b in HCC cells leads to uPA and c-met downregulation and to decreased migration (Salvi et al. 2009). Plasmin- and trypsin-mediated activation of MMPs is inhibited by TFPI-2 (tissue factor pathway inhibitor), an extracellular matrix-associated Kunitz-type serine proteinase inhibitor. TFPI-2 inhibits the invasion of HCC cells (Xu et al. 2011).

Non-protease Proteins Involved in ECM Degradation

In the setting of the invasion process, heparan sulfate chains of heparan sulfate proteoglycans located in the ECM are cleaved by the endoglycosidase heparanase. Heparanase is upregulated in HCCs with an invasive-metastatic phenotype (El-Assal et al. 2001; Xiao et al. 2003; Edovitsky et al. 2004; Zhang et al. 2007a). In these neoplasms, heparanase also promotes angiogenesis (Ilan et al. 2006). HCCs also synthesize heparin-degrading sulfatases, sulfatase 1 (SULF1) and sulfatase 2 (SULF2). These two enzymes

desulfatize heparan sulfate proteoglycans localized to cell surface and ECM. SULF1 and SULF2 are differentially expressed in HCCs, in that SULF1 is downregulated in up to a third of HCCs, while SULF2 is upregulated in up to 60 % of primary HCCs, and SULF2 activates MAP kinase and AKT pathways, promoting HCC growth and invasion (Lai et al. 2008).

In the invasion process, several nonstructural proteins of the extracellular matrix play a significant role. These proteins are called matricellular proteins and belong to various protein families. Well-known members include CCN family member cysteine-rich angiogenic inducer 61 (Cyr61/CCN1), CCN6, osteopontin, secreted protein acidic and rich in cysteine (SPARC), angiopoietin-like protein 4 (ANGPTL4), and thrombospondin-1 and thrombospondin-2 (review: Chong et al. 2012).

Abstract

Progressive growth, invasion, and metastasis of carcinomas depend on the generation, structure, and function of tumor stroma. Several types of stromal cells are in close contact with neoplastic cells, forming a system of interacting elements with important biologic sequelae for both partners. The stroma of carcinomas harbors several types of spindle cells. A major component of stroma are cancer-associated fibroblasts (CAFs) which serve as a guidance substratum for proliferating and migrating cancer cells and also form a niche for cells of the host's immune system. CAFs affect angiogenic pathways and invasion. Liver cancer stroma contains myofibroblasts, derived from hepatic stellate cells, resident fibroblastoid cells, and mesenchymal stem cells. Myofibroblasts are potent regulators of growth and invasion. Spindle cells of tumor stroma produce and secrete various stromal proteins that critically regulate tumor progression, invasion, and metastasis. Stromal cells are also important elements that mediate epithelial-mesenchymal transition (EMT), a mechanism playing a significant role in tumor invasion. EMT is induced by a wide array of distinct factors that are in part expressed by cancer cells. The stroma provides, through its leukocytes, an inflammatory microenvironment affecting the behavior of cancer cells.

Stroma and Stromal Cells Are Critical Mediators of Cancer Cell Invasion

Introduction

The stromal microenvironment and its cell systems play an important role in the promotion of cancer cell invasion and metastasis (reviews: De Wever and Mareel 2003; Mareel and Madani 2006; Albini 2008; Horimoto et al. 2012; Sleeman 2012). Several aspects are treated in more detail in the chapters on hepatic metastases and on tumor stroma. Here, aspects that more specifically relate to invasion pathways are briefly outlined.

Cancer-Associated Fibroblasts

Cancer-associated fibroblasts (CAFs) form a central cellular component of stroma. These cells may serve as a guidance substratum for migrating cancer cells, but they also provide a niche for dormant tumor cells and leukocytes, in particular monocytes, tumor-associated macrophages/TAMs, lymphocytes, and neutrophils. Furthermore, CAFs affect angiogenic pathways and by this exert an influence of growth and invasion. The biogenesis of CAFs is complex and only partially elucidated. Recruitment of CAFs in cholangiocarcinoma is regulated by platelet-derived growth factor-D and Rho GTPases (Cadamuro et al. 2013). Stromal fibroblasts and myofibroblasts are important effectors of mechanisms involved in cancer cell invasion and metastasis (De Wever and Mareel 2003; De Wever et al. 2008; Hinz 2010; Cirri and Chiarugi 2012).

Myofibroblasts

Myofibroblasts/MFBs in the liver and in the stroma of hepatobiliary tumors originate from three sources, i.e., hepatic stellate cells (HSCs), resident fibroblastoid cells, and circulating mesenchymal stem cells, the latter in part being bone marrow derived. Due to complex interactions, MFBs and cancer-associated fibroblasts (CAFs) affect growth and invasion of HCC cells. Stimulation of stromal cells by epithelial cancer cells results in pro-invasive and pro-metastatic pathways. Spindled stromal cells that express alpha-SMA and have the phenotype of MFBs are associated with low differentiation of HCCs, macrovascular invasion, and metastasis (Yang et al. 2013b). Cancer cells can interact with stromal cells, including myofibroblasts, through cell-to-cell fusion. The mechanisms by which MFBs promote liver cancer invasion are only partially known. Hepatic MFBs can secrete monocyte chemoattractant protein-1/MCP-1, a protein which promotes migration of human HCC cells (Dagouassat et al. 2010). Bone marrow-derived MFBs can be stimulated to secrete metalloproteinases (Lecomte et al. 2012).

Stromal Proteins

An important stromal protein for cancer cell invasion is osteopontin. Osteopontin plays a crucial role as a factor promoting a metastatic phenotype, also in HCCs (Anborgh et al. 2010). Osteopontin is subject to numerous posttranslational modifications, including glycosylation, phosphorylation, proteolytic cleavage, and cross-linking through transglutamination. In addition, the expression pattern of osteopontin is regulated by genetic variation at locus −443 of the osteopontin promoter (Dong et al. 2013). Expression of osteopontin is regulated by the Rac exchange factor Tiam1. Senescence of fibroblasts induces decreased Tiam1 levels and increased osteopontin levels (Liu et al. 2012a), suggesting that activity of senescent fibroblastoid cells and cancer stroma affects migration and invasion via a Tiam1-osteopontin pathway. Tiam1 itself is downregulated by microRNA-141, an effect that suppresses migration and invasion of HCC cells (Liu et al. 2014b). In tumors, osteopontin is produced both by tumor cells and stromal cells, and both of these cells also express osteopontin receptors, giving rise to a complex interactome and a cross-talk between cells involved in a concerted pro-metastatic action (Anborgh et al. 2010). Activated hepatic stellate cells are a source of osteopontin and thus promote HCC invasion and metastasis (Song et al. 2015). Osteopontin upregulates several factors in HCC cells via its binding to osteopontin receptors expressed on these cells, i.e., integrin alpha(V)beta 3 and CD44V6. Via the mechanism of activation of MMP-2 secretion and expression of urokinase-type plasminogen activator (uPA), osteopontin is a key mediator of vasculogenic mimicry in HCC (Liu et al. 2011). Osteopontin is upregulated in well-differentiated HCCs by the transmembrane receptor CXCR7, a mechanism augmenting the risk of extrahepatic metastases (Xue et al. 2013). In stroma, liver cancer cells also interact with diverse proteins and proteoglycans of the extracellular matrix, including basement membrane proteins. Malignant neoplastic cells also interact with elastin, interactions that modulate cancer invasion and spread (Timar et al. 1995; Lapis and Timar 2002). The 67 kDa elastin-laminin receptor plays a role in tumor invasion (Fülöp and Larbi 2002). Elastin fragments resulting from elastin degradation act as matrikines that can promote cell cycle progression and are active as chemotactic agents (Duca et al. 2004).

Epithelial-Mesenchymal Transition (EMT) in Liver Cancer Invasion

Introduction

Epithelial-mesenchymal transition (EMT) plays a central role in the development of the liver (Firrincieli et al. 2010) and is critically involved in pathways of invasion and metastasis of numerous cancers, including HCC (Guarino 2007; Guarino et al. 2007; Van der Zijl et al. 2009; Yilmaz and Christofori 2009; Thomson et al. 2011; Meng and Wu 2012; Zheng et al. 2013) and cholangiocarcinomas (Specht et al. 2013; Gu and Choi 2014). EMT is characterized by loss of epithelial cell markers (E-cadherin and plakoglobin), upregulation of mesenchymal markers (vimentin, N-cadherin), and increase of MMP-2. Several switches that induce EMT have been identified, including the Snail/Slug family of transcription factors, Twist, deltaEF1/ZEB1, SIP1/ZEB2, E12/E47, the TGF-beta/Smad signaling system, the Wnt/beta-catenin signaling system, and p53. EMT is associated with a decreased expression of E-cadherin. A protein that reduces the actin-belt density in the circumferential ring, Tara (Trio-associated repeat of actin), is enriched in cadherin-based adherens junctions and promotes expression of E-cadherin and an epithelial phenotype (Yano et al. 2011). Repression of E-cadherin in cancer cells undergoing EMT is correlated with expression of the actin-bundling protein fascin-1, a protein involved in EMT formation and in invasiveness of HCC cells. Overexpression of fascin-1 dramatically increases the migratory potential of HCC cells, illustrating the important role played by EMT in cancer cell migration.

In the course of EMT, epithelial cancer cells acquire features shared with mesenchymal cells,

in particular stromal cells. It is this alteration that results in the unique phenomenon that carcinomas can generate their own and specific pro-invasive microenvironment, both in primary tumors and at distant sites, the so-called premetastastic niche. EMT can, however, lead to even more complex pathways. EMT induced by inflammatory stimuli, e.g., mediated by tumor-associated lymphocytes, monocytes, and macrophages (see below), can confer to cancer cells and stromal cell-like immune-modulatory properties that affect invasion and metastatic dissemination (Ricciardi et al. 2015). These findings illustrate a high degree of functional and structural plasticity of tumor cells.

Altered Snail Expression in Liver Cancer

An important inducing factor of EMT is Snail1. Through an N-terminal SNAG domain, Snail interacts with several corepressors to suppress distinct target genes, such as the E-cadherin promoter, downregulation of E-cadherin being an important step in EMT (Wang et al. 2013a). In EMT-associated motility signaling, Wnt5a-Ror2 signaling is a critical step (Ren et al. 2011). In HCC cells, Snail expression is enhanced by the action of Notch1, whereby this inductive pathway increases as a function of loss of HCC cell differentiation (Kim and Jung 2014). Macrophage-secreted interleukin-8 is also a factor that enhances Snail expression in HCC and thus promotes EMT (Fu et al. 2015). Ectopic expression of Snail1 in cancer cells promotes EMT, resulting in motile and invasive properties of EMT-cancer cells. Snail upregulates MMP family members in HCC cells (Miyoshi et al. 2004), possibly by its promotion of EMT. By inducing EMT, Snail promotes an invasive phenotype in HCC (Yang et al. 2009). Snail is upregulated by a factor that is associated with poor prognosis in HCC, metastasin, a calcium-binding protein associated with tumor metastasis (Zheng et al. 2013). Snail-induced EMT in HCC is also stimulated by hypoxia-inducible factor-1 alpha, associated with alterations in E-cadherin, N-cadherin, and vimentin expression (Zhang et al. 2013c). Snail signaling promoting EMT is activated by the CXCR2/CXCL5 axis (Zhou et al. 2015). MicroRNA-30a inhibits EMT by suppressing the activity of Snail1/Snail (Kumarswamy et al. 2012). Similarly, microRNA-148a suppresses EMT and metastasis in hepatoma cells via inhibition of Snail signaling (Zhang et al. 2014). Snail1 transcriptionally represses a protein which suppresses HCC migration and invasion, Cezanne2. Cezanne 2 interacts with TNF receptor-associated factor (TRAF) 6 and cleaves polyubiquitin from TRAF6 substrates, and it regulates expression of MMP-2, MMP-9, and ICAM1/interacellular adhesion molecule 1 Xu et al. 2014).

Altered Slug Expression in Liver Cancer

Slug is a transcription factor that promotes EMT, but also promotes invasion, metastasis, and vasculogenic mimicry in HCC (Sun et al. 2013a; Yamada et al. 2014). Slug promotes HCC cell progression by increasing Sox2 and Nanog expression (Zhao et al. 2015). It also transcriptionally regulates CD147 which promotes EMT via TGF-beta signaling (Wu et al. 2011). Slug-induced EMT is stimulated by the Gas6/Axl pathway, which enhances the expression of Slug (Lee et al. 2014c). Its expression is suppressed by microRNA-204, which inhibits EMT in cholangiocarcinoma cells (Qiu et al. 2013). Krüppel-like factor 4, a tumor suppressor in HCCs, can revert EMT by binding to and suppressing the expression of Slug (Lin et al. 2012). On the other hand, Krüppel-like factor 8 (KLF8) is involved in TGF-beta1-induced EMT associated with E-cadherin loss (Zhang et al. 2013b). Slug can induce expression of fascin, an actin-bundling protein involved in shape change and motility (Li et al. 2014). In HCC, Slug expression confers a cancer stem cell phenotype associated with EMT (Sun et al. 2014), and it promotes vasculogenic mimicry (Sun et al. 2013a).

Altered Twist Expression in Liver Cancer

Twist1, a highly conserved transcription factor of the basic helix-loop-helix protein family, is an important inducer of EMT (review: Puisieux et al. 2006). Twist already acts at the level of human mesenchymal stem cells (Isenmann et al. 2009), suggesting that it has central role in basic decision mechanisms of cell lineage determination. Twist1 also favors EMT by regulating other pro-EMT factors, such as Sox5 (Wang et al. 2015). Twist and Snail1 are upregulated by a protein interacting with Smad3, Tribbles homolog 3/TRIB3, a factor that enhances the transcriptional activity of Smad3 via triggering the degradation of Smad ubiquitin regulatory factor 2/Smurf2, resulting in decreased elimination of phosphorylated Smad3 (Hua et al. 2011). For becoming active, Twist1 is phosphorylated by protein kinase B (PKB/Akt), a kinase that is ubiquitously expressed in diverse cell lineages (Vichalkovski et al. 2010). The pro-EMT action of Twist1 depends on Snail2, whereby Twist1 binds on the proximate Snail2 promoter to induce its transcription (Casas et al. 2011). Twist expression is positively correlated with activation of the STAT3 signaling pathway and reduced E-cadherin expression (Zhang et al. 2012).

EMT induced by Twist1 is a potent mechanism for the induction of invasion and metastasis in HCC (Lee et al. 2006; Xu and Chen 2007; Matsuo et al. 2009; Yamada et al. 2014). Twist1 expression promotes migration and invasion of HCC cells via EMT induction (Matsuo et al. 2009), but part of the pro-invasive effect of Twist1 is mediated by induction of angiogenesis (Niu et al. 2007) and of vasculogenic mimicry (Sun et al. 2010, 2011a). In AFP-secreting HCCs, Twist1 is downregulated by microRNA-675, which in turn enhances the proliferative and growth capacities of these neoplasms (Hernandez et al. 2013). Similar to Twist1, also ectopic expression of Twist2 in HCC promotes EMT and invasion via regulation of CD24 (Liu et al. 2014a).

Altered Transforming Growth Factor-Beta (TGF-Beta)/Smad Signaling System in Liver Cancer

It is known for a long time that transforming growth factor beta1/TGF-beta1 overexpression in HCCs is correlated with invasiveness and metastasis of this tumor type (review: Lee et al. 2012). In general, the TGF-beta/Smad pathway is critically involved in the interaction between HCC and its stromal microenvironment (Li et al. 2012a). However, many of the effects of TGF-beta1 on liver cancers and other malignancies are related to its function as an inducer of EMT. TGF-beta is a potent inducer of EMT and through this pathway markedly affects HCC biology and progression (Reichl et al. 2012; Katsuno et al. 2013; Mima et al. 2013). Similar to fibroblast growth factor-2, TGF-beta can induce transdifferentiation of carcinoma cells into fibroblastoid cells that are highly migratory (review: Miyazono et al. 2012). Several factors cooperate with TGF-beta1 in its EMT-promoting activity, including CD44s, the standard isoform of CD44 (Mima et al. 2012), connective tissue-derived growth factor/CTGF, the vitamin D receptor downstream target dermatopontin (Li et al. 2009), and the receptor tyrosine kinase Axl (Reichl et al. 2014). TGF-beta-induced EMT is dependent on Smads, which are known to affect invasion and prognosis of cancer cells (Huang et al. 2012). Smad3 is an important mediator of TGF-beta signaling. In the setting of EMT, Smad3 regulates E-cadherin expression through a microRNA-200 pathway (Ahn et al. 2012). In its induction of EMT, TGF-beta1 cooperates with laminin-5/Ln-5 (Giannelli et al. 2005).

EMT induced by TGF-beta is a major factor for invasion and metastasis of HCCs (Reichl et al. 2012). Several mechanisms cause altered TGF-beta-induced EMT in liver cancers. In liver cancer, including cholangiocarcinoma, Smad proteins promote invasion (Huang et al. 2012), probably due to their role in EMT. High phospho-Smad2 nuclear positivity in HCC cells was associated with upregulation of EMT-associated markers, E-cadherin and vimentin, whereby a

E-cadherin(low)/vimentin(high) phenotype was closely associated with high-grade malignant behavior (Mima et al. 2013). Via regulation of the Smad3-E-cadherin pathway, microRNAs 200a and 200b mediate EMT in HCCs and promote cell migration (Hung et al. 2013). Smad signaling to promote HCC cell migration is also activated by bone morphogenetic proteins (Maegdefrau and Bosserhoff 2012). Induction of EMT in HCCs by TGF-beta1 is also mediated by a downstream effector of TGF-beta1, the transcription factor GLI1 (glioma-associated oncogene 1), via direct upregulation of Snail1 (Zheng et al. 2012). In TGF-beta-induced EMT in HCC, expression of CD147 transcriptionally regulated by Slug plays a role. In this mechanism, CD147 induces the expression of E-cadherin in HCC cells (Ru et al. 2015). TGF-beta II receptor expression was reduced in HCCs, this downregulation being associated with poor differentiation, large vessel invasion, and intrahepatic metastasis (Mamiya et al. 2010). TGF-beta receptor 1 and fibroblast growth factor are targeted by microRNA-140-5p, which by this mechanism suppresses metastasis of HCC (Yang et al. 2013a). The expression of the TGF-beta receptor 2 involved in HCC migration is itself regulated by microRNA-590-5p (Jiang et al. 2012). CTGF expressed in tumor stromal cells induced EMT in HCCs and through this mechanism promotes growth and invasion (Xiu et al. 2012). Laminin-5, which is overexpressed in part of HCCs, cooperates with TGF-beta1 in the induction of EMT (Giannelli et al. 2005). TGF-beta-induced EMT is epigenetically regulated by microRNA-29a in HCC (Kogure et al. 2014). In addition to EMT, TGF-beta1 expression also affects the construction of microvasculature in HCCs (Balzarini et al. 2012) and gives rise to tumor-initiating cells that drive tumor progression (Meindl-Beinker et al. 2012; Wu et al. 2012).

Other Altered Signaling Pathways as EMT-Promoting Mechanisms in Cancer

CD44s is associated with the acquisition of a mesenchymal phenotype in HCC, regulating anchorage-independent capacity (Okabe et al. 2014). EMT is driven by the activation of the Wnt/beta-catenin signaling pathway in HCC (Liu et al. 2010). A factor involved in telomere maintenance and growth of HCCs is sirtuin1 (SIRT1). A partner factor, SIRT2, mediates EMT in HCCs by a signaling pathway based on protein kinase B/glycogen synthase kinase-3beta/beta-catenin (Chen et al. 2013). EMT in cancer cells is induced by chemokines, e.g., CCL18 which is predominantly expressed in monocytes and macrophages (Meng et al. 2015a). In the induction of EMT, p53, which is mutated in a significant fraction of HCCs, plays an important role. Regulation of EMT by p53 protein involves beta-catenin signaling, in that nuclear accumulation of beta-catenin is modulated by p53 (Wang et al. 2013b). Expression of FoxM1 induces EMT and invasion in HCC (Raychaudhun and Park 2011; Meng et al. 2015b), and overexpression of FOXC1 stimulates Snail and EMT (Xia et al. 2013). In its stimulation of EMT, FOXC1 contributes to HCC microvascular invasion (Xu et al. 2012). Induction of EMT in HCCs is promoted by a non-receptor tyrosine kinase of the focal adhesion kinase/FAK family, PYK2 (proline-rich tyrosine kinase 2), which is an inducer of EMT-mediated cell motility (Sun et al. 2011c). In HCC cells, EMT is potently induced by the tight junction component, claudin-1, via the c-Abl/Raf/Ras/ERK signaling pathway (Stebbing et al. 2013; Suh et al. 2013). EMT in HCC is facilitated by the stress-activated protein kinase (APK)-interacting protein 1 (SIN1), a protein which holds a central position in AKT regulation. SIN1-induced EMT is associated with increased venous invasion, tumor number, and prognosis (Xu et al. 2013). Siva1 suppresses EMT and metastasis of tumor cells by inhibiting stathmin and stabilizing microtubules (Li et al. 2011). Siva1 is a specific proapoptotic E3 ubiquitin ligase acting on p53 and the tumor suppressor alternative reading frame/ARF. EMT in HCC cells is also promoted by glypican-3, a membrane-associated heparan sulfate proteoglycan frequently upregulated in HCC (Wu et al. 2015). The sirtuin family

member SIRT1, involved in histone deacetylation, promotes HCC metastasis through induction of EMT (Hao et al. 2014). EMT in metastatic HCC is induced by overexpression of brachyury, which in turn enhances Akt activation by inhibiting PTEN and therefore stabilization of Snail, an EMT inducer (Du et al. 2014). A protein involved with EMT induction, Golgi glycoprotein 73/GP73, is expressed in subsets of HCCs and is negatively correlated with E-cadherin (Sun et al. 2011b; Bao et al. 2013). EMT promoting HCC metastasis is induced by metadherin, which is preferentially expressed in HCC with poor differentiation, satellite formation, microvascular invasion, and lymph node metastasis (Zhu et al. 2011). Cathepsin Z, encoded by a gene located to a locus frequently amplified in HCC, i.e., 20q13.3, induces EMT and an invasive-metastasizing phenotype (Wang et al. 2011). Bone morphogenetic protein-9/BMP-9, a member of the transforming growth factor-beta superfamily, induces EMT in HCC cells, its expression in the tumors paralleling that of the EMT factors Snail and vimentin, while E-cadherin and ZO-1 are downregulated (Li et al. 2013). EMT is induced by tumor-derived secretory clusterin, which is upregulated in these neoplasms as a function of tumor progression (Wang et al. 2012). BTB/POZ domain-containing protein 7 (BTBD7) regulates EMT-associated proteins in HCCs and via this pathway promotes invasion and metastasis (Tao et al. 2013b). EMT in human HCCs is induced by the transcriptional coactivator with PDZ-binding motif/TAZ, one of the nuclear effectors of Hippo-related pathways (Xiao et al. 2014b). BAG3/Bcl2-associated athanogene 3, a co-chaperone of heat-shock protein 70, is overexpressed in HCC tissues and regulates EMT and angiogenesis in these neoplasms (Xiao et al. 2014a). EMT pathways are strongly modulated by factors controlling autophagy, pathways also modulating metastatic colonization of cancer cells (Peng et al. 2013). On the other hand, autophagy suppresses tumorigenesis of HBV-associated HCC via degradation of MiR-224 (Lan et al. 2014).

MicroRNAs as Regulators of EMT in Liver Cancer

MicroRNAs play an important role in cancer invasion and metastasis (review: Aigner 2011). Several species of microRNAs affect EMT in liver cancers and thus migratory and invasive features of these neoplasms.

MicroRNA-9 affects EMT via Krüppel-like factor 7 (KLF17) which in turn regulates vimentin and ZO-1 expression (Sun et al. 2013b). In HCC cells, upregulated microRNA-10a regulates Eph tyrosine kinase receptor A4-mediated EMT (Yan et al. 2013). Overexpression of microRNA-106b activates EMT and via this effect promotes cell migration and metastasis of HCC (Yau et al. 2013). MicroRNA-200 family members are involved in EMT in HCC (Ding et al. 2012). They show decreased expression in poorly differentiated HCCs, associated with decreased expression of E-cadherin, EMT, and enhanced motility (Hung et al. 2013). Epigenetic activation of microRNA-200 family members, which contributes to H19-mediated metastasis suppression in HCCs, promotes EMT, H19 being underexpressed in many HCCs (Zhang et al. 2013a). EMT in HCCs is modulated by microRNA-490-3p through targeting endoplasmic reticulum-Golgi intermediate protein 3/ERGIC3. Overexpression of ERGIC3 by this mechanism promotes EMT, followed by increased growth and cancer cell invasion (Zhang et al. 2013d). MicroRNA-520g, a MiR inducing EMT, cancer cell migration, and invasion by targeting Smad7, is upregulated in HCC (Kan et al. 2015). MicroRNA-612 counteracts the development of EMT in HCCs and thus suppresses the invasion and metastasis cascade (Tao et al. 2013a). MicroRNA-214 targets Twist and by this mechanism counteracts EMT. In intrahepatic cholangiocarcinoma, this MiR is markedly downregulating, favoring EMT and invasion (Li et al. 2012b). MicroRNAs are also involved in the pathways leading to liver metastasis of extrahepatic cancers. Colorectal carcinoma liver metastases display higher levels of microRNA-200c, whereas the invasive front of primary colorectal carcinoma showed decreased expression of

this MiR, suggesting an important role of this MiR in the metastatic pathway linked to epigenetic regulation (Hur et al. 2013).

Certain microRNAs inhibit EMT in liver cancers. MicroRNA-148a suppresses EMT and metastasis of HCC cells by targeting Met/Snail signaling but is downregulated in these cancers (Zhang et al. 2014). Also microRNA-26b inhibits EMT in HCC by targeting the USP9X gene, which in turn affects EMT via Smad4 and the TGF-beta signaling pathway. Again, this anti-invasion MiR is downregulated in HCC cells (Shen et al. 2014). Similarly, the microRNA-122/HNF4alpha/Rho axis negatively regulates EMT and invasion of HCC cells (Wang et al. 2014a). MicroRNA-204 inhibits EMT in intrahepatic cholangiocarcinoma cells by targeting Slug (Qiu et al. 2013).

Modulation of EMT-Mediated Invasion in Liver Cancer by Tumor-Associated Leukocytes and Exsomal Signaling

Leukocytes present in cancer stroma, including tumor-associated macrophages/TAMs and neutrophils, are capable to induce EMT in liver cancers. Alternatively activated (M2) macrophages can promote EMT via Snail and M2-derived CCL22, thereby augmenting invasion in HCC (Yeung et al. 2015). Macrophages located to the HCC stroma induce EMT by secretion of IL-8 via activation of the Snail/JAK2/STAT3 pathway (Fu et al. 2015). Activated macrophages downregulate the expression of E-cadherin in HCC cells and thus promote EMT (Wang et al. 2014b). TAMs can promote cancer stem cell-like properties through TGF-beta1-induced EMT in HCC, associated with the acquisition of a highly invasive phenotype (Fan et al. 2014). Snail, a potent promoter of EMT, positively regulates EMT in part via enhancing the recruitment of macrophages (Hsu et al. 2014). Similarly, Twist1 induces the macrophage chemoattractant CCL2 and through this pathway recruits macrophages (Low-Marchelli et al. 2013). EMT can also be promoted by signals delivered from microvesicular bodies/exosomes produced by leukocytes (review: Vella 2014).

The Vascular Bed in Hepatocellular Carcinoma: Entry Site for Invading Tumor Cells (Angioinvasion)

Invasion of the Microvascular Bed

In HCC, trabecular and acinar formations are separated from each other by intervening sinusoid-like and sometimes dilated vascular channels. These channels do not represent true sinusoids, because they display junctions between endothelial cells, deposition of collagen, and basement membrane-like material in a perivascular space representing an analogue of Disse's space, associated with flattening of tumor cell microvilli, i.e., a change corresponding to sinusoidal capillarization (Livni et al. 1977). Microvascular invasion plays a significant role in pathways leading to tumor progression and metastatic spread in HCCs (Suh et al. 2012). Microvascular invasion of HCC cells is promoted by expression of the transcription factor FOXC1, which induces EMT (Xu et al. 2012). Expression of hepatocyte nuclear factor 1beta/HNF1beta (but not HNF1alpha) in HCCs is associated with increased microvascular invasion and predicts an aggressive course (Shim et al. 2012).

Recently, a novel vascular pattern has been found in HCC and identified as system promoting metastasis. This pattern is characterized by vessels that encapsulate tumor cell clusters, forming cobweb-like networks. The presence of this pattern predicted higher metastasis and recurrence rates of HCC in an EMT-independent manner (Fang et al. 2015).

Invasion of Large Veins of the Liver

Macrovessel invasion is a frequent phenomenon in HCC and characterizes a distinct tumor phenotype associated with younger age, aggressive cancer behavior, and poor liver functional reserve

(Lee et al. 2014b). Large veins, and in particular the portal vein, are invaded directly, i.e., by ingrowth of carcinoma through the vessel wall, followed by formation of a tumor thrombus. However, there is increasing evidence that the frequency and the dimension of macrovascular invasion, above all by HCC, are not only determined by inherent tumor invasion as such,but are rather also regulated by other factors. For example, early-stage venous invasion of HCC followed by metastatic spread is controlled by expression of the metastasis-related microRNA-185 (Zhi et al. 2013). Vascular invasion in HCCs is also associated with expression of the GTP-binding protein Gem, a Ras-related protein (Huang et al. 2014). Such findings illustrate that vascular invasion is more complex than anticipated and will considerably alter our conventional views regarding the pathogenesis of vascular spread.

Invasion of the Lymphatic System and Lymphangiogenesis

The normal liver possesses a complex network of lymphatics with distinct relationships between lymph vessels and other anatomic structures. Intrahepatic lymphatics can be reliably visualized by use of podoplanin staining/D2-40 antibody (Yokomori et al. 2010). Almost 100 % of small intrahepatic portal vein branches are accompanied by lymph vessels, seen in portal tracts, while only 17 % of sublobular/hepatic veins, and 0 % of central veins, were accompanied by lymphatic vessels (Ohashi et al. 2010). Along large septa, lymphatics also reach to the subcapsular region (Yokomori et al. 2012), which affects spread from one lobe to the other. Invasion of lymphatics followed by lymphatic metastasis is clinically more important in cholangiocarcinomas and hepatic metastases than in HCC. In colorectal cancer liver metastasis, intrahepatic lymphatic invasion but not blood vessel invasion was a major prognostic factor (Lupinacci et al. 2014). In such metastases, lymphatic vessel density differed in metastases depending on metastatic sites, suggesting a heterogeneous lymphatic microvascular environment (Kwak et al. 2014). Similar to blood vessels, invasion of lymphatic channels depends on motility, adhesion, and proteolytic features of tumor cells. Due to major differences in vessel wall anatomy and the expression of homing receptors, blood vessel angioinvasion differs considerably from lymphangioinvasion. Lymphatic invasion and metastasis are controlled by complex molecular networks that alter lymphatic endothelia and their interactions with homing and transmigrating tumor cells. Lymphatic endothelia located near tumors change their adhesive properties, a mechanism that facilitates invasion and intralymphatic spread (review: Achen and Stacker 2008).

Lymphatic spread of cancers critically depends on tumor-induced lymphangiogenesis, which depends on the expression of lymphangiogenic growth factors. Similar to blood vessels, lymphatic channels neoformed in tumors are produced both by vasculogenesis and angiogenesis depending on preformed vessels. Bone marrow-derived cells have been implicated as lymphatic endothelial progenitors (Van't Hull et al. 2014). Circulating mononuclear cells that are CD34+VEGFR3+ CD133+ have the capacity to differentiate toward lymphatic endothelial cells (Salven et al. 2003; Tan et al. 2014). Cultured cells with this phenotype can differentiate to cells that express lymphatic-specific markers, such as VE-cadherin, CD51/61, CD105, LYVE-1, and podoplanin (Salven et al. 2003). Lymphangiogenic factors mainly comprise VEGF-C and VEGF-D interacting with the cognate receptor tyrosine kinase VEGF receptor-3/VEGFR-3, which is expressed on lymphatic endothelial cells and is critical for tumor lymphangiogenesis (He et al. 2002; Deng et al. 2015). Expression of VEGFR3 is modulated by neuropilin-2, the receptor of semaphorin-3F/SEMA3F (Ou et al. 2015). Expression of VEGF-C is subject to positive regulation by TGF-beta signaling which in turn is coordinated by the transcription factor, SIX1/sine oculis homeobox homolog1 (Liu et al. 2014d). In addition to these two VEGFs, VEGF-A, hepatocyte growth factor, and platelet-derived growth factor BB have lymphangiogenic activity, and lymphangiogenesis also depends on Wnt/beta-catenin signaling (Ghose et al. 2015). Certain chemokines and their

receptors favor the contact between tumor cells and lymphatics (Achen and Stacker 2008; Lee et al. 2014a).

Local formation of new lymphatic channels affects invasion and progression of liver cancers and cholangiocarcinoma (Karkkainen et al. 2002; Ji 2006; Tobler and Detmar 2006; Da et al. 2008; Das and Skobe 2008; Chen et al. 2010). Interestingly, tumor-associated lymphangiogenesis has a significance not only at the primary tumor site but also in lymph nodes, where primary neoplasms can induce a premetastatic lymphovascular niche prior to the arrival of metastasizing cells (review: Hirakawa 2009). The mechanisms of this niche formation are not yet known, but may be related to lymphatic spread of lymphangiogenic factors and/or transfer of tumor- or macrophage-derived exosomes with pro-lymphatic signal cargo. Tumor-associated lymphangiogenesis is correlated with prognosis after resection of HCCs, correlates with prognosis in intrahepatic cholangiocarcinoma, and reflects lymph node metastasis in hilar cholangiocarcinoma (Thelen et al. 2008, 2009, 2010). Lymphangiogenesis in HCC is associated with distinct expression patterns of VEGFs, in part with polymorphisms of VEGF and VEGFR genes (Scartozzi et al. 2014). VEGF-C, a factor which drives both blood vessel angiogenesis and lymphangiogenesis, is expressed in subsets of HCC, chiefly in poorly differentiated neoplasms. Upregulation of VEGF-C is correlated with larger tumor size, intrahepatic recurrence, and extrahepatic metastasis of HCC (Yamaguchi et al. 2006). On the other hand, certain tumor suppressors act via blocking of VEGF-mediated lymphangiogenesis. Smad4, a tumor suppressor and important downstream effector of TGF-beta signaling, reduces lymphangiogenesis by attenuating VEGF-C production (Liu et al. 2014c). In VEGF-induced lymphangiogenesis, HCCs upregulated the critical receptor VEGFR3. The expression of this receptor can be modulated by factors involved in hepatocarcinogenesis. For example, VEGFR3 is upregulated by the hepatitis B virus X protein (Lian et al. 2007). In hilar cholangiocarcinoma, nerve growth factor-beta overexpression was highly correlated with VEGF-C overexpression and lymphatic spread (Xu et al. 2010). Lymphatic spread of gallbladder carcinoma uses the lymphatic route, with distinct networks of podoplanin-reactive lymph vessels (Wakai et al. 2010). Lymphangiogenesis of gallbladder carcinoma is promoted by TNF-alpha through NF-kappaB-mediated upregulation of VEGF-C (Du et al. 2014). TNF-alpha-mediated lymphangiogenesis acts through the TNF receptor 1 and depends on a modulation of VEGF-C/VEGFR3 signaling (Ji et al. 2014). Intrahepatic lymphatic invasion of metastatic colorectal carcinoma cells is an indicator of aggressive course, recurrence, and poor survival (Korita et al. 2007). In colorectal carcinomas, lymphangiogenesis is mediated by neuropilin-2 via VEGF-C/VEGFR3-independent signaling (Ou et al. 2015).

Podoplanin, a type 1 transmembrane sialomucin-like glycoprotein that is induced by the homeobox gene Prox-1 and detectable by use of the D2-40 antibody, is widely expressed in normal and tumor cells (Raica et al. 2008) and is a marker of lymphangiogenesis in neoplasms. Podoplanin is strongly expressed in epithelioid hemangioendothelioma of the liver (Fujji et al. 2008), but is very rarely detectable in neoplastic cells other liver tumors, while it is strongly expressed in tumor lymphatics. In addition to its role as a lymphatic endothelium marker, podoplanin directly affects tumor biology (Dang et al. 2014). Apart from lymphatic endothelia, podoplanin is expressed in stromal myofibroblasts and cancer-associated fibroblasts/CAFs of tumors (Pula et al. 2013; Shindo et al. 2013). In intrahepatic cholangiocarcinoma, lymphatic spread is related to VEGF-C expression and the presence of D2-40 (podoplanin)-positive myofibroblasts (Aishima et al. 2008), suggesting that these stromal cells affect lymphatic spread. Expression of podoplanin by cancer cells can induce lymphangiogenesis and lymph node metastasis, a response mediated by endothelin-1, villin-1, and tenascin-C (Cuemi et al. 2010).

Angiogenesis as a Requirement for Invasion and Spread

Tumor-induced angiogenesis plays a significant role in invasion and metastatic spread. This issue is discussed in detail in a separate chapter.

The Inflammatory Microenvironment (IME) of Hepatobiliary Carcinoma: A Platform Critically Affecting Invasion and Spread of Cancers

Introduction

An inflammatory milieu (inflammatory microenvironment, IME) has been established as an important component of HCC development, invasion, and progression. IME depends on a complex cross-talk between epithelial cells of the tumor, stromal cells, hepatic fibroblastoid cells and stellate cells, and diverse types of infiltrating leukocytes, including tumor-associated lymphocytes (TILs), natural killer cells, tumor-associated macrophages (TAMs), Tie2-expressing monocytes, myeloid-derived suppressor cells, neutrophils, eosinophils, and dendritic cells. Similar to mechanisms of innate immunity, the most important leukocytes that modulate tumor behavior comprise monocytes/macrophages, neutrophils, and myeloid-derived suppressor cells (Smith and Kang 2013). The effects of stromal leukocytes on cancer cell invasion are in part mediated by secreted chemokines and cytokines.

Tumor-Associated Macrophages (TAMs)

The IME of HCC is critically influenced by the presence of tumor-associated macrophages (TAMs), which have a pivotal role for tumor invasion, progression, and angiogenesis (Shih et al. 2006; Kong et al. 2013; Yeung et al. 2015). TAMs expressing the scavenger receptor CD163 (Fabriek et al. 2005) are obligate partners for cancer cell migration and invasion (review: Condeelis and Pollard 2006). In the stroma of HCC, TAMs occur as two forms, M1 and M2, whereby M2 cells acquire a polarized phenotype and become activated, leading to the production by these cells of cytokines, chemokines, growth factors, TIMP-1, and MMPs, specifically MMP-9 (Capece et al. 2013; Zajac et al. 2013). CD68(+) M1-like macrophages promote HCC cell motility and locomotion via activation of the F-kappaB/focal adhesion kinase signaling pathway (Wang et al. 2014b). Upon contact and interactions with HCC cells, activated TAMs secrete IL-6, a pleotropic cytokine which acts as growth factor for hepatocytes and HCC cells via triggering the downstream signal transducer and activator of transcription 3/STAT-3 and extracellular signal-regulated kinase/ERK pathways, which control several proliferation-associated target genes. Apart from proliferation, TAM-derived IL-6 promotes HCC metastasis and EMT, the latter having an important effect of tumor progression. IL-6 also affects local immune reactions, in that it promotes T memory helper 17 (Th17) cell expansion in HCC (Kuang et al. 2010). M2-polarized TAMs can induce EMT and EMT-associated invasion through TLR4/IL-10 signaling (Liu et al. 2013). Stromal monocytes and macrophages secrete the chemokine CCL18, which promotes EMT and an invasive cancer phenotype (Meng et al. 2015a). TAMs promote progression of HCCs via STAT3 signaling, whereby aggressive and large tumors have higher levels of phosphorylated STAT3 (Mano et al. 2013). TAM contact-induced formation of tumor cell invadopodia is associated with activation of the RhoA GTPase signaling pathway (Roh-Johnson et al. 2014). Apart from the secretion of factors that regulate invasive tumor cell behavior and EMT, TAMs can modulate the expression of distinct proteins in and on cancer cells, a novel interactome that is involved in tumor-stromal cell cross-talk. TAMs can induce the expression of the macrophage-specific receptor CD163 in cancer cells (Maniecki et al. 2012), promoting a tumor cell type capable to migrate and invade.

Myeloid-Derived Suppressor Cells

Myeloid-derived suppressor cells (MDSCs) constitute a heterogeneous cell population contributing to immune tolerance, immunosuppression, tumor escape, and tumor progression (Brandau et al. 2013). These cells form a major group of effector cells in the tumor-related inflammatory microenvironment (Gabrilovich et al. 2007; Dolcetti et al. 2008; Youn and Gabrilovich 2010; Young et al. 2010; Bianchi et al. 2011; Caronni et al. 2015; Keskinov and Shurin 2015). The MDSC macropopulation is characterized by a CD11b+Gr-1+ phenotype, lacking expression of macrophage and dendritic cell markers. Morphologically, MDSCs consist of a mixture of monocytoid and granulocytic cells. In fact, the population consists of two principal types of MDSCs, i.e., cells with a granulocyte-like morphology and immunophenotype (granulocytic MDSCs or GrMDSCs; existing in two subtypes) and monocytic MDSCs/MoMDSCs (Peranzoni et al. 2010; Dumitru et al. 2012; Youn et al. 2012).

Together with regulatory T cells/Tregs, MDSCs have an important role in the progression of HCC, including those related to HBV infection and in the pathogenesis of metastases (Khaled et al. 2013; Solito et al. 2014; Condamine et al. 2015; Kondo and Shimosegawa 2015). MDSCs increase in frequency as a function of tumor growth, and their abundance is inversely correlated with the frequency of CD3+ T cells (Younos et al. 2011). In HCCs and colorectal cancer metastases, MDSCs are recruited by expression of CCL2 and CCL5, the CC chemokine receptor 1/CCR1 (Rodero et al. 2013; Borsig et al. 2014; Hirai et al. 2014), and the action of pyruvate kinase M2/PKM2 (Liu et al. 2015). In cancer, production of MDSCs is driven by the endoplasmic reticulum stress and the release of endoplasmic reticulum disulfide oxidase, ERO1-alpha, which mediates formation of disulfide bonds in collaboration with protein disulfide isomerase. ERO1-alpha promotes recruitment of granulocytic MDSCs via oxidative protein folding (Tanaka et al. 2015). The accumulation of MDSCs in cancer requires microRNA-494 via targeting PTEN (Liu et al. 2012b). MDSCs in cancers and specifically in HCC favor tumor cell invasion and spread through various mechanisms. MDSC infiltration favors angiogenesis/tumor vascularization and by this promotes metastasis (McLean and Buckanovich 2008; Rodero et al. 2013). Tumor-infiltrating MDSCs of the monocytoid type mediate CCR5-dependent recruitment of regulatory T cells (Tregs) in high numbers, cells which favor tumor growth (Schlecker et al. 2012). MDSCs can also act as tumor suppressors. They can produce a cystatin-like protein that inhibits metastasis (Boutté et al. 2011).

Neutrophils (Tumor-Associated Neutrophils, TANs)

As potent microphagocytes, neutrophils frequently accumulate close to necrotic tumor areas, where they are involved in clearance of debris and degraded cells. It was previously thought that this is the exclusive function of these cells in tumors. However, there is now evidence that neutrophils have more complex functions when infiltrating cancers. These granulocytes can, depending on the microenvironment, promote tumor growth and stimulate cancer cell invasion (Dumitru et al. 2013; Mishalian et al. 2013). Through the action of their granule proteins and production of reactive oxygen species/ROS, neutrophils can counteract tumor invasion and progression via tumor cell cytotoxicity and enhancement of antitumoral immune defense. Neutrophils with this activity are termed N1 neutrophils. Factors secreted in tumor stroma, such as TGF-beta and inteferons, induced a distinct polarized type of neutrophil with a different morphology termed N2, a cell type that favors tumor growth and invasion (review: Piccard et al. 2012). Neutrophils home to normal and tumor vessels and are stimulated to leave the intravascular pool via chemokinetic and chemotactic mechanisms, whereby CXCL8 (IL-8) binding to the receptor CXCR1 plays a central role (Bakele et al. 2014). Tumor-associated neutrophils (TANs; CD11b+/Ly6G+), attracted by TGF-beta, differ from normal

neutrophils in that they are hypersegmented, are more cytotoxic to tumor cells, and express higher levels of pro-inflammatory cytokines (Fridlender et al. 2009). In normal tissues and cancer tissues, most normal neutrophils are subject to apoptosis and are therefore short lived (Haslett et al. 1994). In contrast, TANs are long lived due to their expression of antiapoptotic Mcl-1 but less proapoptotic Bax (Wu et al. 2011). The induction of a tumor-associated granulocyte population with a greater survival has an important impact on tumor cell biology. Apoptotic and necrotic neutrophils, also those located to tumor stroma, are cleared via macrophage phagocytosis (Silva 2011). Glucocorticoids induce protein S-dependent phagocytosis of apoptotic neutrophils by macrophages (McColl et al. 2009).

The mechanisms via which neutrophils augment cancer cell invasion are only partially elucidated (Piccard et al. 2012). Neutrophils promote motility of cancer cells via a hyaluronan-mediated TLR4/PI3K activation loop (Wu et al. 2011). The pro-invasion activity of TAMs is strongly linked to expression of proteolytic enzymes. Neutrophils are a major source of MMP-9 in tumors and produce TIMP-free MMP-9 which is also active in angiogenesis (Ardi et al. 2007, 2009; Deryugina et al. 2014). Synthesis of MMP-9 by TANs is upregulated by aldosterone (Gilet et al. 2015). Neutrophil gelatinase is associated with lipocalin-2, a protein overexpressed in numerous cancers and involved in the expression of adhesion proteins involved in invasion, including cadherins (Lippi et al. 2014). TANs express elastase, which not only hydrolyzes elastin but also degrades E-cadherin on cancer cells (Gaida et al. 2012), possibly affecting the induction of EMT. Elastase also cleaves the CXCR1 receptor and by this mechanism modulates reactivity to the attractant, IL-8 (Bakele et al. 2014). Neutrophils can secrete ADAM9, which contributes to ECM protein degradation (Roychaudhuri et al. 2014). Apart from direct pro-invasive features, neutrophils can favor invasion indirectly, e.g., via angiogenesis. Neutrophils have proangiogenic properties via secretion of VEGFs, regulated by various factors. VEGF-A production by neutrophils is increased by aldosterone via PI3K, ERK1/2, and p38 pathways (Walczak et al. 2011). Apart from VEGFs, neutrophils stimulate angiogenesis through MMP-9 and fibroblast growth factor, a mechanism modulated by plasminogen activator inhibitor-1/PAI-1 (Tashiro et al. 2012).

In HCC, intratumoral neutrophil infiltration is promoted by the proangiogenic CXC-type chemokine family member CXCL5, which is overexpressed in part of these neoplasms and induces tumor invasion (Zhou et al. 2012). This chemokine exerts a similar effect in intrahepatic cholangiocarcinoma, where it recruits neutrophils and contributes to recurrence and metastasis (Zhou et al. 2014). In HCC, neutrophils are enriched in the peritumoral stroma, whereby IL-17 is a critical mediator for the recruitment of these cells. Neutrophils in peritumoral HCC stroma are a main source of matrix metalloproteinase-9, where this enzyme fosters invasion and angiogenesis (Kuang et al. 2011). Longevity of TANs in HCC is regulated by expression of the autophagy-specific protein LC3. LC3-reactive TANs exhibit a long-lived phenotype with retained Mcl-1, more intact mitochondria, and a low cleaved caspase-3 level, i.e,. an antiapoptotic phenotype (Li et al. 2015).

Bystanders of Inflammatory Responses: Hepatic Stellate Cells and Other Mesenchymal Cells

Activated hepatic stellate cells (HSCs) have an important position in the fibroinflammatory environment generated in HCC and CC. Activated HSCs play a critical role in fibrogenesis and stromagenesis associated with these two malignancies and participate in the creation of a matrix platform where inflammatory reactions can take place. Within normal liver and the stromal platform, hepatocytes or tumor cells engage in a cross-talk which produces a permissive proangiogenic microenvironment, in part via induction of VEGF-A and MMP-9 expression (Coulouam et al. 2012). The interaction between HSCs and cholangiocarcinoma cells is regulated by the stromal cell-derived factor 1-CXCR4 signaling axis, this pathway affecting the migration

capability of cholangiocarcinoma cells (Gentilini et al. 2012). Mesenchymal stem cells located in an inflammatory microenvironment of HCCs can induce EMT followed by a promotion of tumor progression (Jing et al. 2012).

Effects of Chemokines and Cytokines

Several members of the chemokine family of signaling substances are critical components of cancer-related inflammation and can affect cancer invasion and spread (O'Hayre et al. 2008; Allavena et al. 2011). Motility and invasion of liver cancer cells are modulated by several chemokines, cytokines, and factors regulating leukocyte motility. HCC cell migration is induced by ectopic production of macrophage migration inhibitory factor/MIF, a factor also involved in angiogenesis (Ren et al. 2003). MIF is also a factor that stimulates IL-8 and VEGF production, thus positively affecting angiogenesis (Ren et al. 2003). IL-8, expressed in HCC, itself stimulates HCC cell chemotactic and invasive activities (Kubo et al. 2005). HCC cell migration is strongly stimulated by chemokine ligand 12/CXCL12, which is expressed in these neoplastic cells (Liu et al. 2008). HCC cell migration is stimulated by the CC chemokine RANTES (regulated upon activation, normal T cell expressed and secreted; CCL5), under involvement of focal adhesion kinase, mitogen-activated protein kinase, and Rho kinase. This response depends on an interaction of RANTES with the proteoglycans, syndecan-1 and syndecan-4. CXCL5, a member of the CXC-type chemokine family, contributes to intrahepatic spread and metastasis of intrahepatic cholangiocarcinoma via recruiting intratumoral neutrophils (Zhou et al. 2014). CXCL5 mediates the interaction of cholangiocarcinoma cells with cancer-associated fibroblasts/CAFs of the tumor stroma (Okabe et al. 2012). Cholangiocarcinoma cell invasion is also enhanced by CXCL12, modulated by activation of CXCR4 and its signaling pathways that involve MEK1/2 and Akt (Leelawat et al. 2007). In HCCs, TGF-beta suppresses the expression of microRNA-34a, leading to enhanced production of the chemokine CCL2, which in turn promotes venous metastasis (Yang et al. 2012). The tumor-derived inflammatory chemokine CCL2 can directly activate endothelial cells and together with monocytes facilitate tumor cell extravasation (Borsig et al. 2014). Cytokines released from activated TAMs can induce EMT in cholangiocarcinoma cells (Techasen et al. 2012).

Mechanisms of Invasion and Metastasis: Prometastatic and Antimetastatic Factors

184

Contents

Abstract

Metastatic spread of cancer cells is a highly complex process which depends on inherent features of tumors, including the expression of prometastatic genes and metastasis suppressors, characteristics of invasion, factors of angioarchitecture and angiogenesis, and remote homing mechanisms. Tumors, including hepatobiliary cancers, can express diverse prometastatic proteins, such as metastatin-1, MTA1, FOXQ1, NDRG1, and MACC1. Hepatocellular carcinoma (HCC) shows downregulation of distinct metastasis suppressors. One major member is KAI1 (CD82), a tetraspanin. Non-metastasizing tumors exhibit normal levels of KAI1, whereas metastasizing variants show low levels of KAI1 expression. Further metastasis suppressors downregulated in liver cancers comprise Nm23-H1, MTSS1, and HTPAP. The ability to produce metastasis in hepatobiliary cancers is also strongly associated with the expression of a growing number of microRNAs that have a wide array of target proteins involved in metastatic spread. Cellular informations involved in the regulation of metastasis are in part exchanged among tumor cells and stromal cell partner through exosomes and other vehicles that transfer signal cargo.

Introduction

Metastatic spread of cancer cells is a highly complex process that depends on inherent features of tumors (expression of so-called prometastatic genes and metastasis suppressors), invasion characteristics, architecture of the vascular and lymphatic systems, and remote homing mechanisms. In diffuse HCC, in which the liver is studded with minute and usually uniformly shaped and sized nodules, the multiple small and seemingly synchronous metastases are thought to result from widespread intrahepatic spread through the portal venous system, involving both liver lobes (Okuda et al. 1981). However, intrahepatic vascular spread through the portal venous system is not a passive process but rather depends on the expression of tumor-specific factors that facilitate vascular invasion and tumor cell homing. Extrahepatic metastasis of liver cancers is critically influenced by circulating tumor cells that, by distinct homing mechanisms and the generation of premetastatic niches, are associated with dissemination and implantation of cancer cells at distant sites (review: Jacob et al. 2007).

Prometastatic Genes and Their Products

S100A4 or metastatin-1 is a metastasis-associated protein, which also plays a role in HCCs, where it is associated with tumor differentiation, invasion, and recurrence (Cui et al. 2006; Liu et al. 2013). S100A4 participates in an S100A4-microRNA-155-SOCS1-MMP-9 axis pathway in HCCs, whereby S100A4 can be secreted by liver cancer-associated mesenchymal stem cells (Yan et al. 2013). It physically and functionally interacts with Smad3, a mediator of the TGF-beta signaling pathway. Through this pathway, S100A4 increases cancer cell invasion ability induced by TGF-beta (Matsuura et al. 2010). S100A4 regulates migration and invasion in HCC cells through NF-kappaB-dependent MMP-9 signaling (Zhang et al. 2013). Nuclear expression of S100A4 increases cholangiocarcinoma invasiveness and metastasis, in part by inducing release of MMP-9 (Fabris et al. 2011). A further metastasis-associated gene in HCC is MTA1, expressed in about 40 % of HCCs (Hamatsu et al. 2003). Overexpression of the FOXQ1 oncogene is strongly linked to an aggressive and metastasizing phenotype of HCC (Wang et al. 2013a), through transactivation of ZEB2 and versican V1 expression (Xia et al. 2014), while FOXC2 contributes to invasion and metastasis of extrahepatic cholangiocarcinomas (Watanabe et al. 2013). Aggressive HCCs conferring poor prognosis more often and more strongly express N-myc downstream-regulated gene 1/NDRG1, a multifunctional protein associated with carcinogenesis; NDRG1 modulates the expression of genes associated with transmembrane transporter activity, activity of chemoattractants, cell adhesion, and proliferation (Cheng et al. 2011). Another member of the NDGR family, NDGR2, is associated with tumor suppression as is a protein highly responsive to various stresses. Hyperthermia-induced NDRG2 upregulation inhibits invasion and spread of HCC through suppression of ERK1/ERK2 signaling (Guo et al. 2013). Upregulation of metastasis-associated in colon cancer 1 (MACC1) is associated with metastasis of various malignancies in humans. MACC1 is highly expressed in HCCs and is localized in the tumor cell nuclei. This expression is associated with cell migration and increased expression of MMP-2 and MMP-9 (Gao et al. 2013). MACC1 in HBV-associated HCCs is associated with enhanced tumor progression and poor outcome (Qu et al. 2012). MACC1 also affects proliferation and apoptosis in HCCs (Yang et al. 2013a). Overexpression of the T-lymphoma invasion and metastasis 1 (Tiam1) protein, a metastasis-related factor, correlates with HCC metastasis and poor prognosis (Huang et al. 2013). Ectopic expression of COTE1 (FAM189B; family with sequence similarity 189, member B), a putative oncogene, promotes cellular invasion and metastasis of HCCs, acting by associating with WW domain oxidoreductase (WWOX), a known tumor suppressor (Zhang et al. 2012).

Metastasis Suppressors

Several genes and their products that promote or inhibit metastasis have been identified. Downregulation of the tetraspanin, KAI1 (CD82), expression is associated with formation of metastasis and disease progression in HCC (Guo et al. 1998). KAI1 is a widely expressed tetraspanin that is a regulator of behavior of numerous cancer types, including HCC (Jackson et al. 2005; Liu and Zhang 2006; Yang et al. 2008; Malik et al. 2009; Kim et al. 2010; Romanska and Berditchevski 2011; Tsai and Weissman 2011). Whereas in nonmetastatic HCC cancer cells exhibit KAI1 mRNA signals similar to normal control cells, HCC cells from metastatic tumors exhibited only faint KAI1 signals (Guo et al. 1998, 2009). Similarly, the expression rate of KAI1 in HCC cells as determined by RT-PCR was higher in tumor without intrahepatic metastases than in those with metastases (Sun et al. 1998). The activity of the KAI1 metastasis suppressor is regulated by its palmitoylation, this step being necessary for integrity and activity of the tetraspanin (Zhou et al. 2004). KAI1 inhibits the protrusion and retraction phenomena in cell movements by attenuating actin organization in the submembrane cytoskeleton (Bari et al. 2011; Liu et al. 2012a). KAI1 suppresses hepatocyte growth factor-induced migration of HCC cells in vitro via upregulation of Sprouty2 (Mu et al. 2008) and regulates the maturation of integrin beta1 to become functional on the cell surface (Jee et al. 2007). Sprouty2 (SPRY2) is an intracellular regulator of receptor tyrosine kinase signaling involved in the control of cell growth and differentiation. Tetraspanins such as CD82/KAI1 also form a network that modulates the surface expression of MMP-1 (Schröder et al. 2013). CD82/KAI1 also affects HCC biology, including invasive pathways, by its interference with the Wnt signaling pathway. It inhibits canonical Wnt signaling by controlling the cellular distribution of beta-catenin in carcinoma cells (Chigita et al. 2012). For its action as a metastasis suppressor, the COOH-terminal region of KAI1 is essential. The protein VANGL1, a further member of the tetraspanin family, also termed KITENIN (KaI1 COOH-terminal interacting tetraspanin), selectively interacts with KAI1 and enhances metastasis in cancer via promoting tumor cell adhesion and invasion (Lee et al. 2004; Rowe and Jackson 2006). KITENIN is also associated with activation of AP-1 target genes in HCCs through MAP kinase cascade signaling, resulting in the upregulation of MMP-1 and MMP-3 (Cho et al. 2011). Further metastasis suppressors include Nm23-H1, MTSS1, and HTPAP. The metastasis-associated gene Nm23-H1 encodes an 18 kDa nucleoside diphosphate kinase, and its expression is associated with pro-oncogenic effects (Lee et al. 2012) but a low-metastasis phenotype, while its decreased expression in HCCs is associated with tumor metastasis (Fujimoto et al. 1998; Shimada et al. 1998). Nm23-H1 and Nm23-H2 isoforms are highly expressed in HCCs, but mainly Nm23-H1 predicted intrahepatic metastasis (Iizuka et al. 1995). Wild-type p53 upregulates the expression of Nm23-H1, while mutant p53 does not (Chen et al. 2003). Nm23-H1 maintains adherens junctions and via this mechanism limits the invasive potential of cancer cells (Boissan et al. 2010). Metastasis suppressor 1 (MTSS1) is downregulated by microRNA-182, a microRNA significantly upregulated in HCCs, and depression of MTSS1 favors metastasis (Wang et al. 2012). A potent suppressor of HCC metastasis is phosphatidic acid phosphatase (PAP) and its co-regulated factors, the pro-inflammatory genes IL-8 and TLR2 (Ren et al. 2011).

MicroRNAs Associated with Metastasis of Liver Cancer

A number of microRNAs have been identified to directly or indirectly affect metastasis and metastatic patterns in liver cancer (Budhu et al. 2008; Table 1).

MicroRNA-26a, which is expressed at low levels in aggressive HCCs, suppresses metastasis by targeting interleukin-6-STAT3 signaling pathways (Yang et al. 2013b). MicroRNA-30d

Table 1 Prometastatic microRNAs in hepatocellular carcinoma

MicroRNA (MiR)	Target
MiR-26a	IL-6-STAT3 signaling
MiR-30d	Galphai2
MiR-29b	Matrix metalloproteinase-2
MiR-100	ICMT-Rac1 signaling
MiR-126	?
MiR-134	Integrin-beta1
MiR-135a	Metastasis suppressor-1
MiR-137	AKT2
MiR-139	Rho-kinase 2
MiR-140-5p	TGF-beta receptor
MiR-143	Fibronectin
MiR-146a	VEGF
MiR-151	RhoGDIA
MiR-181a	Tumor suppressor WIF-1
MiR-182	Metastasis suppressor 1
MiR-195	VEGF
MiR-214	Fibroblast growth factor receptor 1
MiR-331-3p	Protein phosphatase
MiR-372	ATAD2 oncogene
MiR-503	Rho guanine nucleotide exchange factor
	19
MiR-550a	Polyadenylation element-binding protein
	4

promotes HCC invasion and metastasis by targeting Galphai2 (Yao et al. 2010). MicroRNA-29b directly targets matrix metalloproteinase-2 in HCCs and through this mechanism suppresses invasion, angiogenesis, and metastatic spread (Fang et al. 2011). Tumor progression and a metastatic phenotype in HCC patients are correlated with downregulation of microRNA-100 (Chen et al. 2013). Downregulation of microRNA-100 in HCCs enhances metastasis through stimulation of the ICMT (isoprenylcysteine carboxyl methyltransferase)-Rac1 (Ras-related C3 botulinum toxin substrate 1) signaling pathway (Zhou et al. 2014a). In HCCs, microRNA-126 is downregulated. This is associated metastatic recurrence, as microRNA-126 inhibits HCC cell migration, invasion, and angiogenesis (Du et al. 2014). MicroRNA-134 operates as a potent metastasis suppressor by targeting the key mediator of tumor cell adhesion and migration, integrin beta1 (Zha et al. 2014). MicroRNA-135a contributes to metastatic spread of HCC by inducing portal vein tumor thrombus formation. The functional target of this microRNA is metastasis suppressor 1 (Liu et al. 2012b). Suppression of tumor growth and metastasis in HCC by microRNA-137 is mediated by targeting AKT2 (Liu et al. 2014). MicroRNA-139, downregulated in HCC, is a potent metastasis suppressor through targeting Rho-kinase 2 (Wong et al. 2011). Targeting TGF-beta receptor 1 and fibroblast growth factor 9 is the mechanism whereby microRNA-140-5p suppresses HCC metastasis (Yang et al. 2013c). MicroRNA-143, which is upregulated in HCCs, is transcribed by the action of NF-kappaB and promotes metastasis by repressing the expression of fibronectin (Zhang et al. 2009). MicroRNA-146a, exhibiting low expression in HCC, suppresses cancer metastasis through targeting VEGF (Zhang et al. 2015). This MiR also enhances angiogenic activity of endothelial cells in HCC by promoting PDGFRA expression (Zhu et al. 2013). Another MiR that acts in metastasis suppression via targeting of VEGF is microRNA-195 (Wang et al. 2013b). Angiogenesis and angiogenesis-related metastasis are also suppressed by microRNA-122, a tumor suppressor in HCCs (Tsai et al. 2009). Gain of microRNA-151 facilitates tumor cell migration in HCC through downregulation of RhoGDIA (Ding et al. 2010). MicroRNA-181a promotes tumor growth and metastasis of colorectal carcinoma by targeting the tumor suppressor WIF-1 (Ji et al. 2014). In HCCs, microRNA-182 is overexpressed. This MiR downregulates the metastasis suppressor 1 and thus contributes to metastasis (Wang et al. 2012). Downregulation of microRNA-214 and overexpression of fibroblast growth factor receptor 1 contribute to HCC metastasis (Wang et al. 2013c). MicroRNA-331-3p promotes metastasis of HCC by targeting PH domain and leucine-rich repeat protein phosphatase, an enzyme involved in EMT (Chang et al. 2014). The highly expressed oncogene ATAD2, which promotes metastasis, can be downregulated by microRNA-372 (Wu et al. 2014). MicroRNA-503, downregulated in HCC, inhibits HCC metastasis through targeting of Rho guanine nucleotide

exchanger factor 19 (Zhou et al. 2014b). MicroRNA-550a promotes HCC metastasis by directly targeting cytoplasmic polyadenylation element-binding protein 4 (Tian et al. 2012). Part of microRNAs affect HCC metastasis through their effects on epithelial-mesenchymal transition.

Subcellular Transfer of Proinvasive and Prometastatic Information Among Cancer Cells: Exosomes and Other Vehicles of an Invasive Phenotype

Introduction

Informational molecules that exchange a proinvasive and prometastatic message between target cells are carried by specialized vehicles, comprising exosomes (exosomic vesicles, itinerant exosomes), argosomes, cytonemes, and tunneling nanotubes (Lakkaraju and Rodriguez-Boulan 2008; Morello et al. 2013; Raposo and Stoorvogel 2013; Minciacchi et al. 2015). Exosomes transporting and spreading oncogenic signals and cancer genes are called large oncosomes and play a significant role for the functions of the cellular interactome in cancer (Rak and Guha 2012; Rak 2013). Oncosomes can mediate intercellular transfer of functional microRNAs (Morello et al. 2013) and other important regulating molecules.

Exosomes, Argosomes, and Multivesicular Bodies

Exosomes derive from multivesicular bodies originating from endosomal sorting complexes required for intracellular transports, i.e., ESCRT-0, ESCRT-I, ESCRT-II, and ESCRT-III, all multimeric protein complexes acting as an endosomal sorting complex/ESCRT (Colombo et al. 2013). Following ubiquitination, the ESCRT engine can be utilized to generate multivesicular bodies, but formation of multivesicles can also be driven by the later exosome cargo itself in a ubiquitin-independent manner (review: Lakkaraju and Rodriguez-Boulan 2008). Multivesicular bodies engage in contact with distinct cell surface domains, in particular with cholesterol- and sphingolipid-rich microdomains termed lipid rafts. From these domains, exosomes emerge and are loaded with lipid raft proteins, such as GPI-anchored proteins and tetraspanins. Exosomes are released both constitutively and in a regulated manner (Lakkaraju and Rodriguez-Boulan 2008). Exosomes in principle contain the protein, RNA, and DNA components of the cells from which they originate. By use of their cargo, exosomes can influence numerous biological processes, including the establishment of short-distance morphogen gradients, the generation of planar polarity, the capability for locomotion, the cell-cell and cell-matrix adhesion, and the expression of matrix-degrading enzymes. By these mechanisms, exosomes can transfer an invasive phenotype among target cells. Argosomes are a specialized form of exosomes that transport Wingless-associated information and organelles and are transported from cell to cell by the exocytic fusion of microvesicular bodies that contain Wingless.

Tunneling Nanotubes

Information between cells can also occur through subsets of F-actin-based transient tubular connections termed tunneling nanotubes (review: Abounit and Zurzolo 2012). Tunneling nanotubes are specialized tubular conduits than can transport cargo from one cell to the other. Connections of neighboring cells can also be mediated by filopodial bridges or cytonemes, structures which enable ligand-receptor-mediated transfer of cell surface-associated cargoes among cells (Sherer and Mothes 2008). Cytonemes are actin-based close-ended filopodial bridge structures that can connect neighboring cells by fusion of filopodia-like protrusions and induce flux-limited spreading of information (Lim and Tang 2012; Verbeni et al. 2013). Cytoneme-mediated cell-to-cell signaling plays a significant role in development, cancerogenesis, and establishment of an invasive phenotype (Gradilla and Guerrero 2013).

Abstract

Tumor stroma forms a distinct microenvironment that critically regulates the development and behavior of malignant neoplasms, including hepatobiliary cancers. The formation of stroma is a complex process and a decisive pathogenic mechanism for cancer growth, differentiation, invasion, and metastatic spread. Hepatic neoplasms show striking coevolution of cancerous cells and their associated stromal microenvironment, including components of the extracellular matrix. Tumor stroma provides the proliferating cancer cell population with nutrients, oxygen, and growth factors that are stored in this microenvironment. Stroma is also the cell system that initiates and regulates tumor angiogenesis. The cell systems that mediate all these complex functions include mesenchymal stem cells as a major source of stromal spindle cells, hepatic stellate cells, cancer-associated fibroblasts, myofibroblasts, endothelial cells and their progenitors, and a large number of various leukocytes. Mesenchymal stem cells as a source of stromal cells and cells of premetastatic niches in part originate from extrahepatic sites, mainly blood and bone marrow. Stromal leukocytes provide a distinct inflammatory microenvironment for cancer that mediates growth control and provides chemokines and cytokines involved in invasion and spread. Inflammatory stromal cells comprise tumor-associated macrophages, lymphocytes, myeloid suppressor cells, and granulocytes.

Introduction: Stroma as a Specific Tumor Microenvironment That Is Critical for Growth, Invasion, and Metastasis

Generally, stroma forms a tumor microenvironment that critically regulates the development and behavior of malignant epithelial neoplasms, including hepatocellular carcinoma (HCC), cholangiocarcinomas (CCs), and carcinoma metastases (Li et al. 2007; Wu et al. 2012; Hernandez-Gea et al. 2013; Quail and Joyce 2013; Wang and Chen 2013; Lee and Campbell 2014).

In this context, biogenesis of tumor stroma ("stromatogenesis"; Sivridis et al. 2004) is a decisive pathogenic mechanism in cancer progression. Hepatic tumors show coevolution of their cancerous cells and the associated stromal microenvironment, including components of the extracellular matrix (ECM; Fang et al. 2013). The tumor stroma has a central role in providing the proliferating cancer cell populations with oxygen and nutrients, via the stroma-associated microvasculature. The stroma is also an important depot and outlet structure for various growth factors and signaling substances. In addition, stromal cells can express gene signatures that affect tumor growth, differentiation, apoptosis, and angiogenesis (Gao et al. 2011).

In regard to the amount of stroma formation, HCCs and CCs differ considerably, as many CCs, and in particular the desmoplastic hilar/perihilar CCs, typically develop a rich stroma, while most HCCs are characterized by a relatively poor stroma. However, there is evidence that there is an important phenotypic overlap between HCC and CC, suggesting a continuous liver cancer spectrum. For example, the rare scirrhous HCC expresses progenitor cell markers, shows expression of core epithelial-mesenchymal transition-related genes, and seems to have traits intermediate between HCC and CC (Seok et al. 2012).

Morphology of Cancer Stroma

General Features

The stroma of carcinomas is currently regarded as a "reactive" tissue induced by the malignant epithelial tissue. However, this view might change in the future, as there is evidence that malignant cells interact with their apparently benign partners in a complex way that also includes the production of epithelial-stromal cell hybrids through cell-to-cell fusion. Via exchange of genetic information, either by cell contact or through exosomes (see below),

stromal cells might receive oncogenic information that originally characterized the malignant epithelial lineage. In contrast, the spindle cell tissue of sarcomas is a malignant neoplastic tissue per se; therefore, it should not be termed a stroma. In carcinomas, including hepatocellular carcinoma and cholangiocarcinoma, the amount of stroma varies widely, ranging from a minor component to tumors predominantly consisting of stroma. This variability in stroma formation was found to be a striking feature in the old cancer pathology literature and had led to carcinoma terminologies based on the relation between epithelial and stroma, i.e., carcinoma solidum simplex (about equal amounts of epithelia and stroma), carcinoma solidum scirrhosum (stroma is clearly the predominant component; scirrhous carcinoma), and carcinoma solidum medullare (epithelia predominating, with poor stroma; medullary carcinoma). These different proportions of stroma versus epithelia are manifest in the gross presentation of the tumors, scirrhous carcinomas being firm and sclerosed; medullary carcinomas soft and friable, like marrow (hence the term medullary); and simplex-type carcinomas being somewhere between these two extremes.

Stroma of Hepatocellular Carcinoma

In ordinary HCCs, the stroma is characterized as often delicate strands of fibroblastoid tissue interposed between tumor cell plates and acinar structures. However, these neoplasms often display intervening sinusoid-like, sometimes dilated, vascular channels that are not, or barely, accompanied by a spindle cell stroma. Ordinary HCCs regularly show stromal sheaths around tumor arteries and, less prominently, tumor-draining veins. Larger amounts of spindle cell stroma consisting of cancer-associated fibroblasts/CAFs and myofibroblasts/MFBs are found in HCCs producing significant tumor capsules. The spindle cells located within the stroma cytomorphologically either present as elements that closely resemble fibroblasts, i.e., cells with an amphophilic to slightly eosinophilic and sometimes even basophilic cytoplasm (depending on the ribosome content reflecting protein synthesis), and elongated nuclei with blunt ends, or as cells resembling smooth muscle cells in the case of MFBs. The fibroblastoid stromal cells may be difficult to distinguish from activated, elongated histiocytes/macrophages (tumor-associated macrophages; TAMs). Less common variants of HCCs, in particular sclerosing HCC, scirrhous HCC, and fibrolamellar HCC, exhibit a marked stromal development with deposition of large amounts of extracellular matrix proteins, glycoproteins, and proteoglycans. In areas of recent stroma formation, the spindle cell cellularity is usually high, and the ECM can show a slight basophilia, while older stroma parts display a reduced cellularity, inactively looking spindle cells, and larger amount of ECM fibrils, sometimes with van Gieson-positive coarse collagen bundles.

Stroma of Cholangiocarcinoma

In comparison with ordinary HCC, most cholangiocarcinomas, and particularly the hilar/perihilar region, are characterized by rich stroma development, often with marked desmoplasia. Desmoplasia is, e.g., a hallmark of Klatskin tumors that are macroscopically highly sclerosed, firm, or even stony hard neoplasms. A variable but sometimes marked stroma formation is also observed in several types of carcinomas metastatic to the liver. In many situations, the amount and composition of stroma in metastatic lesions reflect the stroma pattern of the primary tumor, but this is not always the case. In the course of a change in differentiation, stromagenesis may be downregulated, resulting in hypercellular tumors with poor stroma, unlike the primary lesion. On the other hand, carcinomas with minor stroma formation may show a marked desmoplasia in their metastases. The amount of stroma formed in metastases is not only linked to features inherent to the tumor, but also depends on the microenvironment of the metastatic site and the recruitability of stromal cells from the local metastatic niche.

Stroma of Hepatic Metastases

The morphology of the stroma of hepatic metastases varies markedly as a function of the tumor type involved. There are desmoplastic cancers that show a stromal reaction in liver metastases very similar to that of the primary tumor, e.g., carcinomas of the breast, stomach, and pancreas. On the other hand, there are tumors which downregulate stroma in their hepatic metastases. Whereas colorectal carcinoma shows a well-developed stroma in primary lesions, large liver metastases either show marked desmoplasia or exhibit a stromal reaction only in the center, often camouflaged by extensive necrosis. In many cases, the stromal pattern most representative for the entire situation is that actually found in the region of the invasion front.

Secondary Alterations of Tumor Stroma

Tumor stroma can undergo secondary alterations. In the course of desmoplasia and increasing deposition of collagen, stromal sclerosis and hyalinosis can develop, visualized as an eosinophilic fibrotic tissue of low cellularity. In sclerotic stroma, the fibrillary texture of collagen bundles is still recognizable, also in van Gieson's stain, while in stromal hyalinosis, a more or less homogeneous eosinophilic and hypocellular mass with only minor fibrillary texture is seen. In its original meaning, "hyaline" as a purely descriptive term denotes a more transparent or even "glassy" feature of tissues (Greek ualinoz, transparent). There are rare hepatobiliary tumors that show marked hyaline change of their stroma. One prominent example is hepatobiliary cystadenoma with hyaline stroma (Cacciaguerra et al. 1996; Beasley 1998). Hepatic cancers, but mainly cholangiocarcinomas, can show myxoid change of the stroma, characterized by a prominent accumulation of proteoglycans and glycosaminoglycans in the ECM, shown as basophilic or amphophilic areas staining with alkaline alcian blue, sometimes with a fine microcystic or vesicular structure. Myxoid vesicles can coalesce to larger myxoid cysts, not to be confounded with accumulations of extracellular mucin in mucinous/colloid carcinomas.

Stroma can show fresh or old hemorrhage, associated with hemosiderosis or other forms of deposition of stainable iron. Rarely, stainable iron is present as incrustation of stromal matrix fibers. Degradation of blood and/or of necrotic tumor cells leads to release of cholesterol and its esters, visualized as cholesterol clefts and eventually a foreign body reaction to crystals (cholesterol granulomas). Mucin released from carcinomas may produce mucin clefts in stroma or large mucin accumulations that cause dissection of stroma, sometimes with formation of mucin granulomas made up of mucin-ingesting, PAS- and alcian blue-positive macrophages/histiocytes (mucinophages). Stroma can also contain bile released from HCC cells or from damaged bile ducts invaded or surrounded by cancer. In case of tumor infection, the stroma can contain numerous leukocytes or even undergo purulent inflammation with abscess formation. Mainly sclerosed stroma can develop focal calcifications, either in the form of granular basophilic, von Kossa-positive deposits, sickle-shaped mineralizations, or, much less commonly, psammoma body formation. Rarely, stroma can undergo metaplastic changes, such as formation of bone (osseous metaplasia) or adipose tissue, probably related to the presence of multipotent mesenchymal stem cells in the stroma. Chemotherapy and/or radiotherapy can induce nuclear atypia and multinuclearity of stromal cells.

Function of Stroma in Liver Cancers and Hepatic Metastases

Stroma in Hepatocellular Carcinoma

Although histologically not prominent in many ordinary HCCs, development of a stromal microenvironment is a constant feature in these neoplasms and plays a significant role in tumor biology (Tu et al. 2014). There are small groups of HCC with a prominent desmoplastic stroma, including sclerosing HCC and fibrolamellar HCC.

The stromal microenvironment markedly influences HCC progression both in its primary tumors and its metastases (Wang and Chen 2013).

Stroma in Cholangiocarcinoma

Similar to HCC, stroma development (desmoplasia) in cholangiocarcinomas (CCs) plays a central for tumor growth, invasion, and progression (Lee and Campbell 2014; Sirica and Gores 2014). In contrast to ordinary HCC, desmoplasia is more developed in CCs and is, e.g., for hilar CCs, a morphological hallmark. Molecular profiling of CC stroma resulted in the identification of distinct stromal proteins that affect the behavior of cancer cells. In intrahepatic CC, several stromal ECM and non-ECM proteins are upregulated including collagen 4A1, laminin gamma 2, TGF-beta2, tenascin, osteopontin, and periostin. Stromal osteopontin expression is associated with an invasive tumor phenotype and predicts poor prognosis (Sulpice et al. 2013).

Stroma in Liver Metastasis

The development of tumor stroma is a central mechanism for metastasis of diverse extrahepatic cancers, in particular colorectal carcinoma (reviews: Joyce and Pollard 2009; Conti and Thomas 2011; Quail and Joyce 2013; Urech 2014). The development of an abundant stroma in primary tumors affects the probability of metastatic disease. In colorectal carcinomas, production of a rich desmoplastic stroma is associated with a shorter time interval between diagnosis of primary tumor and diagnosis of liver metastasis in comparison with tumors with poor stroma or a pushing morphology (Nyström et al. 2012). Stromal fibroblasts and other spindle cells in hepatic metastases are induced by carcinoma cells and mainly originate from resident fibroblasts (Mueller et al. 2007). In the metastatic stromal niche, epithelial tumor cells and their mesenchymal partners, which in part originate from bone marrow-derived cells, undergo a complex and dynamic crosstalk driven by stromal cell factors, cytokine-cytokine receptor networks, and ongoing genetic and epigenetic alterations of cancer cells (Sleeman 2012). Through these pathways, the metastatic stromal niche acquires a characteristic molecular composition that exerts trophic effects on tumor cells and favors growth and further spread of metastatic cells (Descot and Oskarsson 2013). This molecular pro-metastatic signature can be propagated by circulating tumor cells and stromal mesenchymal cells to induce so-called premetastatic niches. Such niches may originate both from primary tumors and metastases and are one major mechanism for the generation of re-metastases from already established metastases. Stromal cells and their mesenchymal stem cell precursors express distinct secretomes of factors that modulate tumor cell behavior (Zimmerlin et al. 2013).

Stromal Cells

Introduction

In the liver, stromal biogenesis is closely linked to the complex hepatic set of non-parenchymal cells (Table 1; reviews: Bouwens et al. 1992; Cortez et al. 2014). Stromal leukocytes (lymphoid and plasma cells, macrophages, dendritic cells, and myeloid suppressor cells) are discussed in a separate chapter.

Table 1 Types of cells located in tumor stoma

Mesenchymal stem cells (MSCs)
Hepatic stellate cells (HSCs)
Myofibroblasts (MFBs)
Cancer-associated fibroblasts (CAFs)
Endothelial cells, endothelial progenitors, and other microvessel cells
Tumor-associated macrophages (TAMs)
Tumor-associated neutrophils (TANs)
Myeloid-derived suppressor cells
Dendritic cells
Lymphocytes and plasma cells
Mast cells
Eosinophils

Mesenchymal Stem Cells as a Source of Tumor Stromal Cells

Mesenchymal stem cells (MSCs) derived from extrahepatic sites, and specifically from bone marrow and blood, can home to the liver and give rise to hepatic differentiated cells, including hepatocytes (Aurich et al. 2009). MSCs can also home in the stroma of hepatic malignancies and play a role in tumor development and progression (reviews: Cuiffo and Karnoub 2012; Kidd et al. 2012; Barcellos-de-Souza et al. 2013; Hernanda et al. 2013, 2014; Sun et al. 2014). Subsequent to homing, migration of stem cell-derived mesenchymal cells toward cancer cells is directly simulated by motility factors secreted by HCC cells (Garcia et al. 2011). In the prospective stromal niche, primed MSCs fated to become connective tissue cells can differentiate into stromal cells, including CAFs and a subset of myofibroblasts/MFBs (Zhu et al. 2014). An obligate intermediate stage of differentiation from MSC to mature CAFs is an enigmatic mesenchymal progenitor termed fibrocyte (review: Bellini and Mattoli 2007). Fibrocytes (telocytes), which in their relationship with MSCs are derived from hematopoietic stem cells, circulate in the blood and are recruited to connective tissue remodeling sites as CD34+ cells, including inflammatory tissue fibrosis, wound healing, and tumor stroma (Zhang et al. 2013b). CD34+ fibrocytes constitute a tissue reserve of fibroblastoid stromal and connective tissue cells (Diaz-Flores et al. 2014). In the pathway leading from MSCs to CAFs, differential expression of CD44 plays a role, in that CD44 attenuation in MSCs limited their expression of CAF markers (Spaeth et al. 2013). MSCs have an effect on growth, differentiation, and invasion of cancer cells. The migration and homing behavior of MSCs is in itself modulated by HCC cells (Garcia et al. 2011).

Hepatic Stellate Cells as a Source of Stromal Cells: General Aspects

Hepatic stellate cells (HSCs) are a subpopulation of pericytes with a broad spectrum of functions (Tsukamoto et al. 2012). Apart from their central role as cells differentiating into myofibroblasts and mediating hepatic fibrosis (see below), HSCs play vital roles in several other hepatic physiological and pathological pathways, including regeneration, damage repair, carcinogenesis, and cancer invasion and metastasis (Ju et al. 2009a; Kang et al. 2011). In cancer stroma, HSCs often accompany CAFs, with which they interact (Carloni et al. 2014). HSCs also interact with quiescent and regenerating hepatocytes in a complex fashion and are activated by adherent hepatocytes (Mabuchi et al. 2004). Activation of HSCs within tumor stroma depends on a complex network of factors that includes growth factors and the tumor suppressor menin encoded by the MEN1 gene (Zindy et al. 2006). HSCs can migrate into hepatic tumor stroma where they interact with carcinoma cells.

Hepatic Stellate Cells in Hepatocellular Carcinoma

As a source of the most important stromal cells, MFBs, HSCs are critically involved in development and progression of liver cancers (Rombouts and Carloni 2013; Yu et al. 2013; Coulouam and Clément 2014). Peritumorally activated HSCs predict an aggressive phenotype in HCCs, with poor clinical outcome (Ju et al. 2009a; Sun et al. 2013). This is mainly due to promotion of tumor growth and invasion by these cells. HSCs in contact with HCC cells induce proliferation and migration of these tumor cells, via activation of NF-kappaB- and extracellular-regulated kinase (ERK)-mediated pathways (Amann et al. 2009) and crosstalk mediated by TGF-beta (Gupta et al. 2014; Yoshida et al. 2014). Activated HSCs can promote HCC migration and invasion also through activation of the FAK-MMP-9 signaling pathway (Han et al. 2014). HSCs stimulate HCC cell migration via production of laminin-5 (Santamato et al. 2011). Deposition of laminin-5 in HCCs induces EMT (Giannelli et al. 2005) and is associated with a more invasive and metastatic phenotype (Giannelli et al. 2003). In tumor stroma, HSCs express the triggering receptor

expressed in myeloid cells/TREM-1, a transmembrane receptor. Secretion of TREM-1 by HSCs augments the migratory behavior of HCC cells and is associated with tumor aggressiveness (Liao et al. 2012). HSCs can secrete stromal cell-derived factor-1 (SDF-1) which as part of the SDF-1-CXCR4 signaling axis can induce epithelial-mesenchymal transition (EMT), which in turn promotes tumor cell migration and invasion (Li et al. 2014). HSCs in HCC stroma are also capable to promote tumor angiogenesis through VEGF secreted by these cells (Lin et al. 2014). Activated HSCs in HCC can promote metastasis through secretion of osteopontin which enhances the invasive and migratory features of HCC cells (Song et al. 2015). On the other hand, HCC cells modulate the function and survival of HSCs, e.g., via glypican-3 which regulates HSC viability through hedgehog signaling (Magistri et al. 2014). Glypican-3 overexpressed in HCCs modulates fibroblast growth factor-2 and bone morphogenetic protein-7 signaling (Midorikawa et al. 2003). The function of HSCs and their effects on tumor cells are also influenced by the status of the tumor-bearing liver. HSCs from steatotic rodent livers stimulated growth of HCC metastases to a greater degree than HSCs from normal livers, suggesting that liver steatosis provides a pro-metastatic microenvironment (Mikuriya et al. 2015).

Hepatic Stellate Cells in Cholangiocarcinoma

The presence of HSCs and their MFB offspring is related to progression in cholangiocarcinomas/CC (Okabe et al. 2009). This is in part due to the general pro-growth and pro-invasive role of tumor stroma, of which HSCs and MFBs are major components. In CCs, stromal HSCs can secrete stroma-derived factor-1 and generate an SDF-1-CXCR4 axis that promotes cell migration (Gentilini et al. 2012). This axis also operates in the induction of EMT in intrahepatic CC (Okamoto et al. 2012). HSCs in CC also stimulate migration and invasion through the establishment of hedgehog signaling between cancer cells and stromal cells (Kim et al. 2014).

Liver Metastases

HSCs play a role in the induction of premetastatic niches. In early phases of liver metastasis formation, cancer cell clusters forming micrometastasis are associated with an organized network of HSCs and laminin deposits. These HSCs are involved in cancer cell recruitment to the niche and angiogenesis, transforming an avascular primordial niche into a vascularized metastasis (Eveno et al. 2014).

Myofibroblasts: Introduction

The myofibroblast (MFB) is a modulated fibroblast that has acquired the capacity to express alpha-smooth muscle actin (alpha-SMA), an isoform of actin that characterizes vascular smooth muscle cells. Apart from alpha-SMA, endosialin (tem1) is a marker for tumor-associated MFBs (Christian et al. 2008). Tem1 is a binding partner of the metastasis-related protein Mac-2 BP/90K (Becker et al. 2008). In the liver, most MFBs derive from hepatic stellate cells (HSCs) through a distinct transdifferentiation mode induced by paracrine signals produced by tumor cells or cells in the tumor microenvironment. HSC-MFB transdifferentiation (HSC activation) depends on cell surface receptor activation, signal transduction, membrane-to-signal transfer, gene transcription, and epigenetic regulation (review: Kang et al. 2015). A subset of MFBs also originates from a fibroblast-MFB transition, a step that can be inhibited by relaxin through a notch-1-mediated inhibition of TGF-beta/Smad3 signaling (Sassoli et al. 2013). A third group of MFBs derives from PDGF-responsive peribiliary fibrogenic cells distinct from HSCs and from portal mesenchymal cells/portal fibroblasts (Kinnman et al. 2003; Lemoinne et al. 2013; Wells 2014). Portal myofibroblasts play a role in vascular remodeling underlying liver cirrhosis (Lemoinne et al. 2014). HSCs and MFBs can also develop via mesothelial-mesenchymal

transition (Li et al. 2013b). Differentiation along a MFB lineage goes in parallel with the expression of palladin by these cells, whereby overexpression of palladin promotes an invasive phenotype to tumors (Brentnall et al. 2012). Similar to hepatic stellate cells, MFBs display contractility in stroma, regulated by relaxin via inactivating RhoA/Rho-associated protein kinase (Huang et al. 2011). Relaxin also inhibits the differentiation of MFBs (Samuel et al. 2009).

MFBs have an important role in connective tissue remodeling and are central to the biologic effects of tumor stroma (reviews: Chau et al. 1992; Desmoulière et al. 2004). In particular, stromal MFBs influence progression of HCCs, CCs, and carcinoma metastases and thus display prognostic effects (Ooi 1999; Sirica 2011; Liao et al. 2013; Slany et al. 2013). MFBs form a major cellular component of stroma in HCCs (Schmitt-Gräff et al. 1991; Enzan et al. 1994). MFBs are also an important stromal cell population of cholangiocarcinomas (Terada et al. 1996; Sirica 2011). In these neoplasms, myofibroblasts promote progression through activation of epidermal growth factor (EGF) receptor expression. Stromal MFBs produce heparin-binding EGF which induces EGFR activation, disruption of adherens junctions, and migratory/invasive behavior in cholangiocarcinoma cells (Clapéron et al. 2013). MFBs also produce periostin in the stroma, a TGF-beta-inducible protein that closely interacts with type I collagen, tenascin, and integrin surface receptors to promote focal adhesion kinase activation and invasion (Sirica et al. 2014). In colorectal carcinomas, the abundance of stromal MFBs markedly influences tumor progression and metastasis (Tsujino et al. 2007).

Functions of Myofibroblasts in Tumor Stroma

Both in chronic fibrous hepatopathies and cancer stromal development, MFBs play a central role. In certain situations, most of stromal cells of desmoplastic carcinomas have the features of MFBs, which exert a decisive influence on cancer cell growth, migration, invasion, and metastasis (review: Otranto et al. 2012). MFBs are responsible to synthesize and secrete many or most of the proteins detectable in the extracellular matrix (ECM) of tissues, including tumor stroma. MFBs in stroma show transcripts of collagens typically found in tumor stroma, i.e., type III, type IV, and VI collagens and less type I and type V collagens (Gulubova 1997; Faouzi et al. 1999). The effective collagen deposition by MFBs is inhibited by relaxin, a hormone which also decreases these cells' differentiation (Williams et al. 2001). MFBs exert an influence on stromal vascular function and angiogenesis (Fausther and Dranoff 2014). MFBs can synthesize endothelin-1, which modulates hepatic stellate cell function by promoting their contraction in the setting of stromal remodeling. Endothelin-1 synthesis by MFBs is a step stimulated by ECM fibronectin via a Src/ERK-regulated signaling pathway (Zhan et al. 2009).

Myofibroblasts in Tumor Capsule/ Pseudocapsule Formation

MFBs with their function as potent producers of extracellular matrix are critically involved in the generation of tumor capsules (tumor encapsulation; Kojima et al. 1999), a phenomenon that influences tumor progression and spread (Lockwood et al. 2003). MFBs are the main cells responsible for collagen production and deposition within tumor capsules surrounding HCCs (Ooi et al. 1997; Bridle et al. 2001).

Cancer-Associated Fibroblasts (CAFs)

In addition to myofibroblasts, several other spindle cell lineages have been identified in cancer stroma, including a metabolically active subset of cells termed cancer-associated fibroblasts (CAFs).

Selected References: Orimo and Weinberg 2006; Anderberg and Pietras 2009; Gonda et al. 2010; Pietras and Östman 2010; Räsänen and Vaheri 2010; Xing et al. 2010; Xouri and

Christian 2010; Cirri and Chiarugi 2011, 2012; Li et al. 2012; Tripathi et al. 2012; Madar et al. 2013; Marsh et al. 2013; De Wever et al. 2014; Kharaishvili et al. 2014; Öhlund et al. 2014; Paulsson and Micke 2014.

The term, CAF, denotes cell populations that are not yet well defined, and some authors classified CAFs as myofibroblasts (MFBs). In fact, there is some overlap between CAFs and MFBs. CAFs are detectable in both HCCs and CCs (Sirica et al. 2011) and also form an important cell lineage in the stroma of metastatic cancers. CAFs form a heterogeneous cell population that can originate from several cell types, including "normal" resident fibroblasts, precursors of MFBs, preadipocytes, immature reticulum cell-like cells, pericytes, vascular smooth muscle cells or their progenitors, and mesenchymal stem cells (MSCs) derived from bone marrow (Orimo and Weinberg 2006; Bagley et al. 2009; Räsänen and Vaheri 2010). Mesenchymal cells are recruited to HCC by the action of autocrine motility factor produced by HCC cells (Bayo et al. 2014), suggesting that tumor cells themselves can generate a cellular complement of their stroma. There is also evidence that CAFs derive from epithelial cells via epithelial-mesenchymal transition/EMT. Markers of CAF comprise vimentin, fibroblast-specific protein 1, and platelet-derived growth factor receptor alpha/beta. In addition, at least 12 new proteins have been detected in CAFs (Bozoky et al. 2013), suggesting that CAFs are more than just activated normal fibroblasts. One subset of CAFs expresses fibroblast activation protein/FAP (an atypical serine protease; Hamson et al. 2014), a protein involved in stroma-induced cancer invasion (Wang et al. 2013). Among these FAP-positive cells, a population coexpresses the pan-leukocyte marker CD45, suggesting that these cells are variant of tumor-associated macrophages (TAMs) (Tchou et al. 2014). Part of CAFs express CD44, a functional molecule supporting the stemness of cancer cells in the tumor-associated microenvironment (Kinugasa et al. 2014). Fibroblast-specific protein 1 (FSP1) regulates cell cycle progression and cytoskeletal integrity in stromal cells, but it also identifies an inflammatory subpopulation of macrophages in the liver (Österreicher et al. 2011).

In tumor stroma, mesenchymal stem cells can be transformed into CAFs by a myeloid zinc finger 1 (MZF1)-TGF-beta1-dependent pathway mediated by osteopontin (Weber et al. 2014). CAF development may also be related to EMT as the pro-EMT protein Twist1 is an important regulator of CAFs (Lee et al. 2015). The transcriptional regulator heat shock factor 1 (HSF1) is frequently activated in CAFs, in which it drives a transcriptional program involving stromal-derived factor 1 (SDF-1) and TGF-beta (Scherz-Shouval et al. 2014). In CAFs derived from normal, "standard" fibroblasts, the switch to CAFs is regulated by the action of distinct microRNAs (Aprelikova and Green 2012), such as microRNA-31, microRNA-155, and microRNA-214 in ovarian cancer (Mitra et al. 2012). The turnover of stromal CAFs is regulated by apoptosis. As activated cells, CAFs are primed for cell death. Platelet-derived growth factor primes CAFs for apoptosis through Puma-mediated Bak activation (Rizvi et al. 2014).

CAFs and epithelial cancer cells form a cooperating cell system that critically affects the structure and function of cancer microenvironments in organs and tissues (Bhattacharya et al. 2012b). Through their secretome (Al-Toub et al. 2013; De Boeck et al. 2013), CAFs have numerous effects on critical mechanisms of cancer cell behavior, including proliferation, migration, invasion, and spread. CAFs can, in contact with carcinoma cells, inhibit cell proliferation and apoptosis (Berdiel-Acer et al. 2011), in part through TGF-beta signaling (Calon et al. 2014). CAFs induce EMT of cancer cells through paracrine TGF-beta signaling (Yu et al. 2014). The metastasis-associated protein S100A4 induces a network of inflammatory cytokines that activate stromal cells to acquire protumorigenic properties (Bettum et al. 2014). Downregulation of microRNA-148a in CAFs results in WNT10B-mediated stimulation of tumor cell motility (Aprelikova et al. 2013). CAFs can secrete factors that promote cancer cell invasion and metastasis. Inactivation of the retinoblastoma (Rb) protein in

CAFs promotes epithelial cell invasion (Pickard et al. 2012). Elevated expression of platelet-derived growth factor (PDGF) by CAFs is associated with increased migration invasion and metastasis, a PDGF effect mediated by the secretion of the glycoprotein, stanniocalcin-1 (STC1) (Peña et al. 2013). Stromal cells are a source of matrix metalloproteinases (MMPs), including MMP-2 (Longerich et al. 2004).

CAFs modulate tumor stroma in a paracrine fashion (Karagiannis et al. 2012), whereby they secrete plasminogen activators, matrix metalloproteinases, growth factors, and cytokines. Activation of plasminogen to plasmin, mediated by urokinase-type plasminogen activator and tissue plasminogen activator, is an important step in tumor cell growth and invasion induction (review: Räsänen and Vaheri 2010). CAFs show upregulation of genes related to growth and progression of HCCs, such as CCL2, CCL26, IL6, and LOXL2 genes (Lin et al. 2012; Lin and Chuang 2013). The proliferation of stromal fibroblasts is promoted by TGF-beta, overexpressed in HCCs (Yamazaki et al. 2011). Human primary fibroblasts expressing the ING protein, ING4, show a secretory phenotype that promotes tumor cell proliferation (Moreno et al. 2014). CAFs, similar to normal fibroblasts, are capable to migrate, collective migration being enhanced by overexpression of the tight junction-associated proteins claudin-11 and occludin (Karagiannis et al. 2014). CAFs can also be stimulated to develop invadopodia, e.g., following stimulation with palladin. Via invadopodia, palladin-stimulated CAFs can remodel the microenvironment of the extracellular matrix and promote invasion of cancer cells (Brentnall 2012; Goicoechea et al. 2014). CAFs produce and secrete a small leucine-rich proteoglycan, asporin, which is involved in cancer progression (Satoyoshi et al. 2014). The cancer niche component periostin is produced by CAFs, supporting cancer growth through ERK signaling (Kikuchi et al. 2014). Through their interaction with diverse immune and inflammatory cells, CAFs can modulate the immunologic niche in tumor stroma (Harper and Sainson 2014) and engage in close interactions with tumor-associated macrophages (TAMs) (Chiarugi 2013). CAFs and their humoral mediators provide a complex network of regulatory signals that modulate recruiting and function of inflammatory cells in stroma (review: Servais and Erez 2013).

A further effect on tumor invasion exerted by CAFs is their modulation of interstitial flow. Interstitial fluid flow promotes tumor cell invasion by modulating CAF-tumor cell interactions. In experimental models, interstitial flow drove TGF-beta1- and collagenase-dependent fibroblast migration (Shieh et al. 2011), probably mediated by chemotactic factors distributed by flow.

CAFs play an important role in tumor progression (Östman and Augsten 2009) and can secrete several factors that affect tumor biology. For example, they can show upregulation of the TGF-beta/BMP family member, GDF15/MIC-1, in tumor stroma, followed by increased tumor migration and invasion (Bruzzese et al. 2014). CAFs can secrete CXCL14, a potent protumorigenic factor (Augsten et al. 2014), and produce podoplanin, a protein associated with an aggressive phenotype of colorectal cancer (Yamanashi et al. 2009). These cells also produce the glycoprotein stanniocalcin-1 which is a mediator of metastasis by PDGF receptor function in colorectal cancers (Peña et al. 2013). CAFs accumulating in the stroma of colorectal carcinoma metastases promote proliferation of cancer cells and show a distinct expression profile of numerous upregulated genes (Nakagawa et al. 2004).

Stromal Leukocytes: Tumor-Associated Macrophages (TAMs)

As described in the chapter on immune reactions directed against hepatocellular carcinoma, tumor-associated macrophages (TAMs) are located in stroma and engage in complex interactions with stromal fibroblasts and other stromal cells. CAFs and other spindled stromal cells possess a signaling instrumentarium that can recruit various immune cells and cells involved in inflammatory reactions (Raz and Erez 2013), including TAMs. In their interaction with CAFs and myofibroblasts, TAMs generate a distinct microenvironment with

growth-promoting or suppressive features (Dutsch-Wicherek and Kazmierczak 2013). TAMs also promote tumor invasion by their activity as matrix-degrading cells (Madsen and Bugge 2013). TAMs can promote cancer stem cell-like properties in HCC cells through EMT induced by TGF-beta1. The acquisition of this phenotype favors the acquisition of an invasive and aggressive tumor biology (Fan et al. 2014). Another immune cell population that forms an interactome with CAFs is tumor-infiltrating lymphocytes rich in regulatory T cells (Tregs). Tregs suppress the generation of CAFs via promoting CAF cell cycle arrest at the G2/M transition (Fu et al. 2013). TAMs can affect the recruitment of Tregs, but activated monocytes in HCC stroma also promote the expansion of proinflammatory memory T helper 17 cells (Kuang et al. 2010).

Stromal Leukocytes: Myeloid-Derived Suppressor Cells

Myeloid-derived suppressor cells (MDSCs) are bone-marrow-derived cells that play an important role in the regulation of tumor immunity, but they also modulate tumor growth and invasion (Caronni et al. 2015; Keskinov and Shurin 2015). MDSCs home to tumor stroma and interact with cancer cells in this microenvironment. Together with regulatory T cells (Treg), a category of tumor-associated lymphocytes, MDSCs are key components of the so-called immunosuppressive tumor microenvironment (TME). TME is associated with pathways that downregulate tumor immunity and promote tumor immune evasion by inhibiting T-cell responses (Khaled et al. 2013). MDSCs expand in growing tumors and cause T-cell dysfunction favoring tumor progression (Lindau et al. 2013). Specifically, a distinct population of MDSCs CD14(+)HLA-DR(-/low) is present in HCCs and can induce CD4(+)CD25(+)Foxp3(+) T cells/Tregs in these cancers (Arihara et al. 2013). In HBV-associated HCCs, MDSCs affect the induction and function of Tregs and thereby modulate tumor progression, but also modify the mode of persistent HBV infection (Kondo and Shimosegawa 2015). MDSCs inhibit natural killer (NK) cells in HCC patients via the NKp30 receptor located on NK cells (Hoechst et al. 2009). Infiltration of HCC tissue by MDSCs is enhanced by IL-17A produced by gamma/delta T cells in a CXCL5-/CXCR2-dependent manner, whereby CXCL5 is produced by tumor cells. This pathway is a mechanism by which stromal IL-17A can modulate tumor growth via immune modulation (Ma et al. 2014). Recruitment of MDSCs is also promoted by pyruvate kinase M2 (PKM2), a member of the pyruvate kinase family expressed in HCC (Liu et al. 2015).

Stromal Leukocytes: Tumor-Associated Neutrophils (TANs)

Neutrophils are attracted to tumor tissues to become a distinct stromal cell population termed tumor-associated neutrophils (TANs). TANs enter the tumor microcirculation where they roll on and attach to the endothelium, perform transmigration, and actively invade the tumor as highly motile, polarized cells. Here, they fulfill various functions, including phagocytosis of tumor cell debris, toxic oxidative damage to normal and neoplastic cells, promotion of tumor cell growth, induction of cancer cell invasion, and induction of metastasis (Houghton 2010). The pro-growth and pro-invasion effects of TANs are relatively new features that have formerly been neglected. The toxic versus tumor-promoting features of TANs are considered to be future treatment targets (Gregory and Houghton 2011). TANs exert these effects through the secretion of cytokines, chemokines, growth-promoting molecules, and matrix metalloproteinases (reviews: Houghton 2010; Galdiero et al. 2013). Homing of TANs into tumor stroma varies considerably among diverse cancer types, but several cancers are capable to recruit large numbers of TANs. In contrast to resting neutrophils, which have a survival time of hours to few days, neutrophils activated in inflammation and in tumors have a longevity that is increased severalfold (review: Kolaczkowska and Kubes 2013). As neutrophils undergo necrosis and apoptosis in tissues, they

must be continuously replaced by new cells entering tumor vessel networks. TANs are attracted to liver cancers through several mechanisms. Chemokinesis and positive chemotaxis can be induced by products of necrotic or apoptotic tumor cells. However, stroma can also contain specific chemoattractants active for TNAs. In intrahepatic cholangiocarcinoma, the CXC-type chemokine CXCL5 exerts a direct chemoattractant effect on neutrophils via a PIK3-Akt signaling pathway (Zhou et al. 2014).

TANs can directly influence the invasive behavior of cancer cells (Imai et al. 2005). They promote motility of these cells through a hyaluronan-mediated pathway involving the hyaluronan receptor TLR4 and PI3K (Wu et al. 2011). One subset of neutrophils is engaged in angiogenesis (Kuang et al. 2011). VEGF-A recruits a proangiogenic, MMP-9-delivering population of neutrophils that induces angiogenesis (Christoffersson et al. 2012). The cells are an important source of matrix metalloproteinases (MMPs) in stroma and can secrete pro-MMP-9, similar to but more potently than tumor-associated macrophages (TAMs). TAN-derived activated MMP-9 plays a major role in tumor angiogenesis. In TANs, pro-MMP-9 is a pre-stored cargo that can rapidly be released, whereas TAMs require time to differentiate, change into a M2 phenotype, produce pro-MMP, and shut down TIMP-1 expression (Deryugina et al. 2014). But also in TANs, release of proangiogenic MMP-9 is associated with downregulation of TIMP-1, thus providing non-inhibited, fully active MMP (Bekes et al. 2011). Neutrophil infiltration in HCCs is associated with increased levels of the CXC chemokine receptor CXCR6, which contributes to a proinflammatory tumor microenvironment (Gao et al. 2012).

Tumor necrosis, a common alteration in both primary liver cancers, and in particular HCC, and metastases, markedly affects tumor infiltration by TANs. Sterile inflammation in tumors followed by cell death/necrosis is induced by damage-associated molecular patterns (DAMPs). One critical component of DAMPs in normal and neoplastic tissues is high-mobility group box 1 (HMGB1), a nuclear nonhistone protein released to the extracellular space as a response to various stimuli (Kostova et al. 2010). In epithelial cell populations, HMGB1 (amphoterin) and its receptor RAGE (receptor for advanced glycation end products) play an important role in necrosis and necrosis-associated inflammation, including inflammatory responses in cancer (Sims et al. 2010). HMGB1 triggers the recruitment of neutrophils, a central mechanism for neutrophil accumulation in necrotic tissues (Huebener et al. 2015). HMGB1, which is loosely bound to chromatin, is released from necrotic cells, but not apoptotic cells (Lotze and DeMarco 2003). Necrosis-associated stimulation of the HMGB1-RAGE system and associated neutrophil reactions affect the biology of liver cancers. Activation of the HMGB1-RAGE system induces NF-kappaB activation in HCCs, associated with enhanced tumor cell migration and invasion (Chen et al. 2014). RAGE is overexpressed in HCC, and activation of the RAGE receptor signaling in HCCs stimulates cell proliferation (Yaser et al. 2012) and enhances the angiogenic potential of these neoplasms through upregulation of VEGF expression (Takino et al. 2012). These effects are associated with poor prognosis in HCC patients (Ito et al. 2014).

Neutrophils also effect homeostasis in normal and neoplastic tissues due to their distinct modes of survival and death. The survival of neutrophils differs between normal tissues and tumors. TANs in HCC show increased autophagy with enhanced functional LC3 protein and autophagosomes, associated with a long-lived phenotype with more intact mitochondria and low cleaved caspase-3 (Li et al. 2015). However during inflammation, including inflammatory responses taking place in tumor stroma, neutrophils undergo apoptosis after a certain time. Neutrophils possess components of both extrinsic and intrinsic apoptotic pathways (Geering and Simon 2011). Early apoptotic neutrophils and TANs are cleared by macrophages, while late apoptotic neutrophils/TANs provoke proinflammatory reactions including secretion of tumor necrosis factor-alpha.

Neutrophils also undergo a distinct mode of cell death called NETosis characterized by the

formation of neutrophil extracellular traps (NETs) containing diverse nuclear proteins and peptides that affect microorganisms, normal cells, and cancer cells (Vorobjeva and Pinegin 2014). Neutrophils also undergo a distinct form of necrosis, termed secondary necrosis. Phagocytosis of secondary necrotic neutrophils by macrophages results in a proinflammatory pathway characterized by release of macrophage inflammatory protein-2 (MIP-2) which in turn promotes neutrophil infiltration.

The presence and number of TANs in liver cancers is associated with biology of disease, and their high number in HCCs is a poor prognostic factor (Li et al. 2011). In HCCs, the neutrophil-lymphocyte ratio has prognostic significance (meta-analysis: Xiao et al. 2014). That TANs have a significant influence on liver cancer growth and invasion is underlined by the observation that the presence of increased numbers of neutrophils in cholangiocarcinoma is associated with worse patient survival. In particular, neutrophils correlated with the presence of vascular invasion in these tumors (Gu et al. 2012). Neutrophils also affect metastatic pathways. Circulating neutrophils are associated with distant metastasis in a number of carcinomas. TANs can promote cancer cell adhesion and arrest in sinusoidal vessels. Neutrophils can themselves adhere to arrested cancer cells and may facilitate interactions between cancer cells, blood vessel cells, and stromal cells (Spicer et al. 2012).

Stromal Leukocytes: Tissue Mast Cells

In carcinomas, the stroma can contain tissue mast cells in variable numbers (Aaltomaa et al. 1993; Jing et al. 1993). This phenomenon is also found in HCCs and cholangiocarcinomas (Terada and Matsunaga 2000; Grizzi et al. 2003). Mast cells play a role in production and turnover of various connective tissues (Hartveit 1993). In the stroma of intrahepatic cholangiocarcinomas, the density of mast cells was significantly higher than that of portal tracts of normal livers, and mast cell densities of these cancers were higher than those in HCCs (Terada and Matsunaga 2000), what might reflect the stronger desmoplastic reaction of cholangiocarcinomas in comparison with HCCs. High densities of peritumoral mast cells were positively correlated with early HCC recurrence and poorer outcome (Ju et al. 2009b), while another study failed to show any significant correlation between mast cell density and stage or grade of HCCs (Grizzi et al. 2003).

Stromal Microvasculature, Endothelial Cells, and Endothelial Progenitors

Effects of Stroma on Vasculogenesis and Angiogenesis

In its function as a main supportive cell and matrix system for cancer cell growth and spread, the stroma provides a reactive (nonneoplastic) microvascular system (stromal microvasculature, SMV) for the energy requirements of the neoplastic cells. This microvascular system is driven by angiogenesis and vasculogenesis and functions through a complex interaction between cancer cells and stromal cells. The production and turnover of ECM is closely linked with remodeling of the stromal vascular system. The endothelial cells of SMV differ in several respects from normal, preexisting endothelial systems of the liver. The proteoglycan, agrin, is selectively deposited in microvessels of HCCs and is a marker for blood vessels growing in malignant hepatic neoplasms (Tatrai et al. 2009). In comparison with HCCs, cholangiocarcinomas showed a higher expression level of agrin, suggesting a differential function of agrin in tumor-induced neoangiogenesis (Batmunkh et al. 2007). Sinusoid-like vascular channels of HCCs accumulate, in the setting of their capillarization, the basement membrane protein matrilin 2 (Szabo et al. 2008). Stromal cells can themselves promote stromal and tumor angiogenesis. Stromal cells also alter endothelial cell-ECM interactions and cause differential expression of factors affecting angiogenesis, such as the matricellular protein thrombospondin 2 (TSP2) (Calabro et al. 2014). CAFs can express podoplanin (Pula et al. 2013b), and this expression correlates with VEGF-C expression,

suggesting that stromal podoplanin is involved in tumor lymphangiogenesis (Pula et al. 2013a).

Tumor stroma also modulates the development and function of pericytes, cells that mediate blood vessel maturation and limit tumor cell metastasis (Raza et al. 2010). Recruitment of pericytes to stroma is regulated by platelet-derived growth factor-B (PDGF-B), while endothelial PDGF-B retention is indispensable for integration of pericytes into vessel walls (Jain and Booth 2003). Overexpression of PDGF-BB decreases growth of colorectal carcinomas, an effect associated with increased coverage of endothelial cell tubes and a blunted angiogenesis (McCarty et al. 2007).

Endothelial Cells and Endothelial Progenitors in Tumor Stroma

Endothelial cells and their progenitors circulate in the blood of highly vascularized liver cancers in higher numbers. Endothelial progenitor cells can home to stroma and stromal vascular channels, undergo maturation to endothelial cells, and integrate into newly formed vessels (Ganss 2006). The tumor stroma and its ECM exert a proangiogenic effect on these homing cells and participate in maturing and branching of tumor vessels. As liver cancer progression strongly depends on angiogenesis, the priming of endothelial progenitors has an impact on tumor biology. Apart from their role of cells providing for angiogenesis, endothelial cells located in the tumor stroma have additional functions. Through paracrine regulation, endothelial cells affect the migratory and invasive behavior of cancer cells, both stimulatory and inhibitory. For example, expression of perlecan by endothelial cells can suppress cancer cell invasiveness (Franses et al. 2011). Endothelial progenitor cells can secrete monocyte chemotactic protein-1 (MCP-1), which in turn contributes to chemotaxis of HCC cells by inducing microRNA-21 biogenesis and favors intrahepatic HCC metastasis (Shih et al. 2015). Through endothelial-mesenchymal transition (EndoMT), endothelial cells can contribute to the emergence of stromal cells (Medici and Kalluri 2012).

Stromal Extracellular Matrix (ECM)

Introduction

The ECM is a highly dynamic compartment that plays a central role in the biology of HCCs, CCs, and other malignancies (Wu et al. 2006; Duncan 2013). The tumor ECM shows a turnover that is mediated by the controlled release and activation of numerous hydrolases and the peptide hormone, relaxin, a member of the insulin superfamily critically involved in ECM remodeling and the sinusoidal microcirculation. Relaxin binds to a receptor expressed by connective tissue cells, including stromal cells, relaxin family peptide receptor-1 (RXFP1).

ECM Proteins, Proteoglycans, and Glycosaminoglycans: General Aspects

There is a group of ECM molecules preferentially overexpressed in the ECM of hepatobiliary malignancies (Table 2).

Basement Membrane Proteins

Many tumors are rich in several proteins that are constituents of basement membrane (BM),

Table 2 Proteins and proteoglycans of tumor ECM

Proteins

Versican

including laminins, type IV collagen, agrin, and nidogen (Hashmi and Marinkovich 2011). BM proteins form a critical set of ECM proteins and glycoproteins that mediate cell adhesion, cell motility, and invasive features. One specifically important group of BM proteins is the laminins which hold a central position in the tumor invasion cascade (reviews: Aumailley 2013; Simon-Assmann 2013). Laminins constitute a group of at least 16 isoforms of alpha/beta/gamma heterotrimers constructed from five alpha, three beta, and three gamma chains. Critical receptors for laminins in several cell systems are integrins of several classes.

HCCs express distinct combinations of integrins (Volpes et al. 1993; Ozaki et al. 1998) and are thus capable to interact with ECM and specifically BM laminins in various ways. There are distinct patterns of laminin expression in the various types of hepatic tumors (Grigioni et al. 1987). Extracellular laminin expression is already detectable in nodular preneoplastic hepatic lesions, and the amount of laminin gradually increases in the course of hepatic carcinogenesis (Albrechtsen et al. 1988). Laminins can markedly modulate the differentiation status of HCC cells. For example, they modulate cytoskeletal proteins, in that laminins induce the expression of cytokeratin 19 in HCC cells and hence modify the biologic behavior (Su et al. 2003). Expression of laminin alpha 4 in HCCs is an important factor mediating invasion and metastasis (Huang et al. 2008). Laminin alpha 5 promotes ectopic adhesion of HCC cells through integrins and/or Lutheran/basal cell adhesion molecule (Kikkawa et al. 2008). Laminin-5 is expressed in almost all intrahepatic CCs, but was absent in scirrhous HCC (Okamura et al. 2005). Expression of type IV collagen, a BM component, decreased in HCCs as a function of a lower differentiation grade (Zhao et al. 1996), and this decrease is probably a function of the disruption of the BM structures in the course of tumor progression (Patriarca et al. 1993). When detectable, type IV collagen is usually observed at the level of sinusoid-like vascular channels (Grigioni et al. 1987). Nidogen-2 is an ubiquitous BM protein that is significantly decreased in HCCs. This downregulation is associated with tumor progression parameters (Cheng et al. 2012).

Abnormal expression of basement membrane proteins in stroma is also found in cholangiocarcinomas. Intrahepatic cholangiocarcinomas aberrantly express laminin gamma 2 chain, predominantly in the intraductal and periductal infiltrating cancer types, and most strongly in the region of the invasive front, suggesting a role of this laminin in tumor invasion and progression (Aishima et al. 2004).

Fibronectin

Fibronectin is an important ECM protein that exerts several biologic functions, including the mediation of adhesion processes. Fibronectin is expressed in a majority of moderately to well-differentiated HCCs, together with other ECM components, but is absent in poorly differentiated neoplasms (Szendröi and Lapis 1985). Fibronectin and laminins are usually found in a peritrabecular or periacinar expression in HCCs (Donato et al. 1989), and in the perivascular space (Torimura et al. 1994), and are expressed in greater amounts in peritumoral capsules (Grigioni et al. 1990).

Tenascins

Tenascins are ECM glycoproteins which in a pleiotropic manner affect cell proliferation, differentiation, adhesion, and motility. There are four members of the tenascin protein family, i.e., C, R, W, and X. Tenascin-C and tenascin-W inhibit cell spreading through binding to fibronectin, while tenascin-R and tenascin-X also display anti-adhesive properties. Tenascin-W is a marker for activated tumor stroma (Degen et al. 2007). Tenascin is usually expressed in CCs (Terada and Nakanuma 1994) and is less expressed in stroma-rich variants of HCCs (Okamura et al. 2005), but tenascin expression is generally stronger in HCCs than in cirrhotic nodules (Zhao et al. 1996). In HCCs, tenascin prevails in capsular tissue and in septa, but is poorly expressed in the wall of

sinusoid-like vessels (Yamada et al. 1992). In intrahepatic CCs, tenascin expression at the invasive front is associated with poor prognosis (Aishima et al. 2003).

Matrilins

Matrilins form a small family of proteins with currently four members and characteristic von Willebrand factor A domains and epidermal growth factor-like domains. Matrilin 1 (cartilage matrix protein) is mainly expressed in cartilage, while matrilins 2 and 4 are widely distributed in ECMs (review: Deak et al. 1999). Matrilin 2 is strongly expressed in HCCs, but mainly in its capillarized tumor vessels (Szabo et al. 2008).

Microfibrils and Fibrillins

The ECM contains a distinct group of fibrils termed microfibrils, mainly consisting of fibrillins. Fibrillin-1, the main component, multimerizes into bead-like structures that can self-assemble to microfibrils (Baldwin et al. 2014). Initiation and maturation of microfibrils are controlled by several factors, e.g., fibronectin, which interacts with fibrillin-1. Fibrillin-rich microfibrils are involved in developmental and morphogenetic processes of many tissues and affect ECM turnover through modulation of TGF-beta/bone morphogenetic protein signaling (Massam-Wu et al. 2010). Fibrillins form an intricate ECM network implicated in storage and release of growth factors. In normal liver tissue, fibrillin-1 and elastin co-localize in vessel walls and portal tract connective tissue, while fibrillin-1 alone is expressed along sinusoids and at the limiting plate and close to bile duct basement membranes. In HCCs, fibrillin-1 is present between neoplastic hepatocytes and between stromal cells and is associated with fibronectin (Dubuisson et al. 2001; Kinsey et al. 2008). Microfibrils are associated with distinct glycoproteins, the MAGPs (microfibril-associated glycoproteins). Mammalian cells express two MAGPs, MAGP1 and MAGP2 (Segade 2009).

Elastin

An ECM fibril that is involved in the regulation of cancer cell behavior is elastin, an important matrikine, but less information is available regarding cellular interactions of this complex fibril system (Lapis and Timar 2002; Rodgers and Weiss 2005). Elastin fibrils are present in the normal liver and are expressed in tumor stroma (Lapis and Timar 2002). Elastin peptides (matrikines as degradation products of elastin) present in the ECM can stimulate receptor signaling, cell cycle progression, and chemotaxis, can induce release of proteases from stromal cells, and may act as invasion enhancers for tumor cells (Yusa et al. 1989; Uemura and Okamoto 1997). Certain cancer cells can synthesize elastin and express lysyl oxidase, possibly affecting angiogenic responses (Lapis and Timar 2002). Hepatocellular carcinomas and cholangiocarcinomas express several members of the thrombospondin family of proteins, including cartilage oligomeric matrix protein (COMP Xiao et al. 2004).

Proteoglycans

Basement membranes and other components of the ECM contain a distinct set of proteoglycans. Heparan sulfate proteoglycans play a specifically important role in processes that regulate adhesion between cancer cells and these cells with the ECM (review: Roskams et al. 1998). Many cancer cells, including HCC and CC cells, can synthesize syndecans, in particular syndecan-1. A second important ECM proteoglycan is perlecan, which is a multifunctional molecule affecting numerous biological processes (review: Knox and Whitelock 2006). Stromal cells of cholangiocarcinomas can synthesize basement membrane-type heparan sulfate proteoglycans, MFBs being the main source of these EMC molecules (Sabit et al. 2001). The basement membrane protein, matrilin-2, is produced in the course of capillarization of sinusoid-like vascular channels in HCCs and cirrhosis (Szabo et al. 2008). Proteoglycans are not only located to the ECM, but they are also components inherent to cell surface,

including those of neoplastic cells. One important group is the glypicans (GPC), of which six families are known (GPC1–GPC6). An important GPC of HCCs is glypican-3, which also is a potent diagnostic marker. GPCs are linked to the cell surface membrane by a glycosylphosphatidylinositol anchor (review: Filmus 2001).

ECM proteins, proteoglycans, and glycosaminoglycans are effectors and modifiers of cancer cell growth, differentiation, and invasion.

Syndecans are known to affect various functions of cancer cells. They can bind a variety of ECM ligands and play a role in the regulation and modulation of tumor cell proliferation, cell-cell adhesion, cell-matrix adhesion, and invasion (review: Carey 1997). High expression of syndecan-1, together with paxillin, in HCCs is associated with increased differentiation and decreased invasion and metastasis of this neoplasm (Li et al. 2005), whereas reduced syndecan-1 expression in HCCs characterized tumors with a high metastatic potential (Matsumoto et al. 1997).

In human HCCs, elevated levels of glycosaminoglycans and altered sulfation patterns of chondroitin sulfate were associated with the differentiation status of HCCs. In the course of decreasing differentiation of HCCs, chondroitin sulfates, nonsulfated and disulfated chondroitin sulfate disaccharide units, and low-molecular glycosaminoglycans progressively increased, while the expression of heparan sulfate decreased (Lv et al. 2007). Stromal cell-derived growth factor-1 is associated with the heparan sulfate proteoglycan, syndecan-4, which is located at the HCC cell membrane; this association is promoting cell growth (Sutton et al. 2007).

Mechanisms Promoting Tumor Stroma Formation

Humoral Factors

Stroma formation is regulated by TGF-beta isoforms (beta1–beta3), whereby TGF-betas are produced by both tumor cells (HCC and CC) and stromal cells, indicating a complex auto-paracrine regulation network (Abou-Shady et al. 1999; Meindl-Beinker et al. 2012). Connective tissue growth factor (CTGF) produced by HCC cells is associated with increased stromagenesis in xenografts (Mazzocca et al. 2010). In CCs, platelet-derived growth factor (PDGF) and Rho GTPases regulate the recruitment of cancer-associated fibroblasts (Cadamuro et al. 2013).

Stroma and Epithelial-Mesenchymal Transition (EMT) and Mesenchymal-Epithelial Transition (MET)

Epithelial-mesenchymal transition (EMT) and mesenchymal-epithelial transition (MET) have an important function in cancer biology, specifically for invasion and metastatic spread, and both mechanisms are forms of epithelial-mesenchymal plasticity or EMP. EMT and MET are functional circuits in the normal liver and in inflammatory liver disease and are important mechanisms in cancer invasion and progression (reviews: Micalizzi et al. 2010; Jing et al. 2011). EMT and MET not only fundamentally alter the metabolome of cells but also change the orientation and intrinsic shape features of cells involved, e.g., cell polarity (Royer and Lu 2011), an effect that has a great impact on all mechanisms that generate an invasive phenotype. In the normal adult liver, EMT is induced by TGF-beta via upregulation of Snail1, whereby the action of TGF-beta is regulated by the microRNA-200 (Schliekelman et al. 2011). Several other factors are inducers or modulators of EMT and MET, including Twist, Snail1, FoxM, FoxQ1, Slug, metadherin, block of proliferation1 (BOP1), RUNX3, RANKL, vimentin expression, the collagen receptor discoidin domain receptor 2, VEGFR1, the ZEB1/ZEB2 protein axis, CD15, the Cas family protein NEDD9, and SerpinB3 (Kong et al. 2011a). Overall, EMT and MET are promoted by the activation of a multifactor transcriptional network (Venkov et al. 2011). In HCCs, EMT is induced by high expression of microRNA-191 (He et al. 2011). In tumors, including HCCs and CCs, EMT is also influenced by the action of distinct stromal cell populations, e.g., myeloid-derived suppressor

cells (Toh et al. 2011) and cancer stem cells (Kong et al. 2011b). Cancer stem or progenitor cells represent a transitioning cell population between hepatic epithelial cells and stromal cells (Deng et al. 2011).

EMT is associated with hepatic tumor stromal biology in a complex fashion (Mikulits 2009; Kim et al. 2010; Marijon et al. 2011). The stromal microenvironment of tumors significantly affects both EMT and MET (Ding et al. 2013). HCC cell-stroma crosstalk guides EMT at the tumor edge via pathways involving TGF-beta and platelet-derived growth factor (van Zijl et al. 2009). In HCC, loss of the adhesion molecule, E-cadherin, is a key molecular event in EMT regulated by inhibitory transcription factors such as Twist and epigenetic mechanisms. In these neoplasms, EMT-associated downregulation of E-cadherin is also accomplished by a corepressor binding to several transcription factors, C-terminal-binding protein 1, a factor upregulated in HCCs (Zhang et al. 2013a). Epithelial-to-fibroblast conversion in HCCs is associated with distinct cytoskeletal changes that affect E-cadherin expression (Murata et al. 2009).

EMT taking place at the cancer cell-stroma interface forms a platform that markedly influences the growth and invasion behavior of cancer cells. Switching of the cytoskeletal and polarity phenotype of epithelial cells undergoing EMT modulates their motility behavior and, in the case of tumor cells, their metastatic capacity (Wells et al. 2011). The EMT regulator Twist1, a protein modulating E-cadherin expression, activates matrix metalloproteinases in HCCs and via this pathway promotes tissue invasion (Zhao et al. 2011). EMT is promoted by the ECM protein periostin, produced by both HCCs and CCs (Morra and Moch 2011). In HCCs, EMT and EMT-associated growth are also regulated by the expression of osteopontin (Bhattacharya et al. 2012a). There are subtypes of HCC in which EMT-associated features differ from those of ordinary HCCs. For example, B-viral HCCs with high expression of CD133, a stem cell marker, showed upregulation of EMT and of invasion-associated genes (Na et al. 2011). In the stroma, where mesenchymal stem cells settle after homing, these cells may undergo fusion with cancer cells, e.g., cells of HCCs (Li et al. 2013a), a process that might participate in mechanisms for EMT.

Metabolic Functions of Stroma, Humoral Factors, and Mechanisms of Stromal Signaling

Stromal cells and cancer cells form a complex interacting cell system (the stromal interactome) that is characterized by humoral network regulating the relationships between the cells in "paracrine cooperativity" (Luciani et al. 2011). MFBs of tumor stroma secrete factors that promote proliferation of HCC cells. Conversely, HCC cell in vitro induces the proliferation of MFBs (Nhieu et al. 1998), suggesting the presence of mutually active growth augmentation loop. The chemokine, stromal cell-derived factor-1 (SDF-1), is produced by stromal cells, but also HCC cells in an autocrine loop, SDF-1 interacts with the G protein-coupled receptor, chemokine receptor (C-X-C motif) 4, reorganizes the HCC cell cytoskeleton, induces tyrosine phosphorylation of focal adhesion kinase, and activates matrix metalloproteinase-9, thus stimulating cell growth, migration, and invasion (Sutton et al. 2007). Stromal MFBs promote HCC cell migration through secretion of monocyte chemoattractant protein-1 (MCP-1) (Dagouassat et al. 2010) and increase the invasiveness of HCC cells through the secretion of hepatocyte growth factor (Neaud et al. 1999). Stromal cells of HCCs produce fibroblast growth factors 1 and 2 which may promote tumor angiogenesis (Chow et al. 1998). In CCs, MFBs secrete platelet-derived growth factor BB, promoting hedgehog survival signaling (Fingas et al. 2011). The crosstalk between stromal cells and CC cells was found to be mediated by platelet-derived growth factor D (Berasain and Avila 2013). Stromal spindle cells can express podoplanin, a protein that induces stromal lymphangiogenesis important for lymphatic cancer spread (Kitano et al. 2010).

Stromal Cell Exosomes and Other Communication Systems in Stroma

As outlined in more detail in the chapter on liver metastasis, there are several types of subcellular structures that are capable to load information molecules, such as signal substances and noncoding RNAs, and transfer this cargo to other cells. These vehicles mainly include exosomes and oncosomes, both acting as "signalosomes" (Masyuk et al. 2013; Nazarenko et al. 2013). Exosomes are small membrane vesicles derived from endosomal multivesicular structures (Bobrie et al. 2011). Via TGF-beta expressed at the exosomal surface, exosomes can activate fibroblasts and stimulate the differentiation of myofibroblasts from fibroblasts (Webber et al. 2014). As exosomes can produce adenosine from ATP, they play a role in adenosine-mediated signaling processes (Clayton et al. 2011). Exosomes can carry molecules that operate in target cell selection for cancer cells, e.g., tetraspanins that select certain endothelial surfaces (Rana et al. 2012). Microvesicles are also derived from endothelial cells and carry in this case distinct carcinoembryonic antigen-related cell adhesion molecule (CEACAM), a factor that influences other stromal cells, in particular T cells (Muturi et al. 2013).

In cancers, exosomes and related cargo carriers are released by both carcinoma cells and stromal cells. Tumor cell-derived microvesicles can interact with stromal mesenchymal cells, modulate the composition and function of the microenvironment, and by this affect tumor invasion (Haga et al. 2015). In tumor stroma, CAFs can produce exosomes that are then taken up by epithelial cancer cells, a process that may modulate the growth, invasion, and metastatic modes of cancer cells. Exosomes – or oncosomes in this case – provide for a system of crosstalk between stromal cells and cancer cells, and for the programming of premetastatic niches, in part by delivering microRNAs (Morello et al. 2013; Rana et al. 2013). Apart from exosomal vesicles that can fuse with target cells to deliver their information cargo, exchange of information in stroma also takes place through direct cell-cell fusion (Howcroft et al. 2011).

Stroma as a Sensing Cell System Controlling Tumor Prosperity

The tumor stroma is an apparatus that senses critical alterations of the tumor's metabolome, including hypoxia and oxidative stress. CAFs and other stromal cells differ in their metabolism from epithelial cancer cells, but can engage in metabolic coupling, providing fuel to cancer cells, including amino acids, ketones, and lactate (Hart 2011). CAFs can undergo anaerobic glycolysis and release lactate to "feed" adjacent cancer cells, a mechanism driving mitochondriogenesis in the neoplastic cells. This stromal-epithelial lactate shuttle is therefore suggested to play an important role in the steering of tumor cell adaptation to critical metabolic stress (Whitaker-Menezes et al. 2011). Also stromal CAFs can transfer energy and biomass to anabolic cancer cells (Martinez-Outschoom et al. 2014; Miles and Sikes 2014), suggesting a stroma cell-cancer cell feeding circuit. There is evidence that oncogenes can induce the development of such metabolic symbiotic circuits (Lisanti et al. 2013). Reactive oxygen species produced in tumor stroma can be used by stromal cells for the generation of signaling within the microenvironment. CAFs exploit reactive oxygen species via a proinflammatory signature leading to stemness and EMT (Giannoni et al. 2011). CAFs interacting with cancer cells produce high levels of the chemokines CCL2 (chemokine C-C motif ligand 2) and subsequently enhance endogenous reactive oxygen production (Li et al. 2014).

Industasis

Introduction

Classical views regarding the spread and growth of cancer have it that malignant neoplastic cells are capable to leave a primary tumor,

individualize, invade the adjacent normal tissues, and dislocate to remote areas, where they may home and restart growth to form metastases. In fact, it is long known that cells of both metastasizing and non-metastasizing cancer circulate in the blood of patients (Ashworth 1869; Butler and Gullino 1975). In addition to cancer cells, nonmalignant cells can also enter into the efferent blood of organs and tissues, e.g., through injury or surgical interventions (Raa et al. 2005). These so-called stray cells may get into physical contact with disseminated cancer cells or incipient tumor cells and exert an influence on them in regard to their future biology. Specifically, stray cells may alter local signaling networks, modulate Darwinian type of competitions between cells of the target niche (Tubiana 2009), generate novel cell-cell communications via junctional complexes (Trosko and Ruch 1998; Trosko and Chang 2001), or exchange genetic material with spread cancer cells and precancerous cells, including components of the mitochondrial genome (Ralph et al. 2010).

Nemosis

Nemosis (from the Greek goddess of retribution, Nemesis) denotes a process of cell death that was originally termed programmed necrosis. Nemosis occurs through cell-to-cell contact of diploid fibroblasts which become activated through this contact leading to programmed cell death associated with cytoskeleton degradation (Bizik et al. 2004; Vaheri et al. 2009). In contrast to cancer cells, normal fibroblasts do not grow to form multicellular, spheroid-like aggregates, but rather grow in the form of layers on substratum. If forced to form clusters, contact among fibroblasts in these clusters results in an activated associated form of "retributional" cell death, probably as a control mechanism counteracting abnormal growth patterns. Nemosis is more close to a variant of necrosis than apoptosis. In the course of nemosis, involved cells release numerous signal substances, growth factors, and inflammation mediators. Therefore, nemosis plays a significant role in the transmission of the fibroblast activation status into the microenvironment, the nemotic factor release generating a novel signaling network suitable to reorganize and reassemble the cellular system involved. By the nemotic response, the mesenchymal cells can induce inflammation, epithelial cell proliferation (Peura et al. 2009), and angiogenesis (Enzerink et al. 2010).

There are certain differences in fibroblast/stromal cell nemosis between non-transformed cells and cancer cells (Räsänen et al. 2009). As cancer-associated fibroblasts (CAFs) and other stromal cells are continuously activated in the stroma of carcinomas, nemosis is expected to take place in stroma. Generally, CAFs are more strongly activated to upregulate inflammatory mediators and to express alpha-SMA than normal fibroblasts in the setting of nemosis (Räsänen et al. 2009). Fibroblast clustering in tumors followed by nemosis is associated with the increased production of hepatocyte growth factor by these cells, causing spread and invasion of cancer cells (Kankuri et al. 2005). Stromal fibroblast nemosis also induces angiogenic responses of endothelial cells (Enzerink et al. 2010). The interaction between epithelial cells and fibroblasts has a strong impact in nemosis. Whereas normal epithelial cells inhibit fibroblast nemosis, cancerous epithelia promote a nemotic response (Räsänen et al. 2008). But also normal fibroblasts and stromal cells can affect malignant cells via nemosis. For example, fibroblast nemosis arrests growth and induces differentiation of human leukemia cells (Kankuri et al. 2008).

General Pathology of Hepatobiliary Tumors: Angiogenesis

Angiogenesis in Liver Cancer 186

Contents

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_186

Abstract

Angiogenesis, the formation of new tumor vessels, is a critical mechanism for the development and progression of hepatobiliary cancers, which are often highly vascular tumors. In contrast to normal tissues, tumor vessels frequently form highly atypical branching patterns, with irregular diameters and abrupt changes from large to small diameters. This abnormal vasculature of malignant neoplasms serves as an important diagnostic element in modern tumor imaging. The principal cells mediating angiogenesis in neoplasms are tumor endothelial cells, and auxiliary cells involved in tumor angiogenesis include perivascular cells, stromal cells, tumor-associated monocytes and macrophages, and other leukocytes. Initiation and progression of angiogenesis, which requires a vigorous proliferative response of tumor endothelial cells and their precursors, involves the action of numerous angiogenic factors. Similar to normal tissues, the main factors comprise vascular endothelial growth factors, angiopoietins, basic fibroblast growth factor, platelet-derived endothelial growth factor, endoglin, and ephrin. Hepatobiliary cancers also express several anti-angiogenic factors. Tumor angiogenesis is markedly modulated by factors secreted by stromal leukocytes and by epigenetic mechanisms, mainly numerous microRNAs expressed by tumor cells and stromal cells.

Introduction

Angiogenesis is a complex process that involves a multicomponent network of pro-and anti-angiogenic factors and holds a central position in tumor growth and progression (review: Semela and Dufour 2004). In most cancers, angiogenic and anti-angiogenic factors are produced and released by cancer cells, while others have their origin in endothelial cells and several types of myeloid cells located in the tumor stroma. Basically, angiogenesis in liver cancers proceeds along the same pathways as in the normal liver and specifically in liver regeneration, with some remarkable differences. Under induction and guidance by distinct secreted factors, resting endothelial cells in the tumor bed are activated to migrate, proliferate, and form new vessel structures. In the course of this process, endothelial cells of preexisting vessels individualize by loss of intercellular contact and decay of basement membranes, followed by invasion of new angiogenic territories via secreted proteases. Proteolytic degradation of extracellular matrix also releases angiogenic factors that are stored in matrix compartments. In the setting of sprouting vasculogenesis and formation of new vascular tubes, basement membranes are formed, sometimes incomplete in tumors, and the new tumor vessels undergo maturation and are stabilized by distinct factors and supportive pericytes. This entire process goes in parallel with tumor growth and is constantly adapted to new vascularization demands by an intricate regulatory system, forming a multicomponent interactome between cancer cells, vascular cells, stromal cells, and homing leukocytes. In dormant neoplasms, angiogenesis is switched off or is active at a low level, while vascularized, rapidly growing cancers activate numerous genes involved in the angiogenic response. The transition to an aggressive phenotype with high vascularity has been termed angiogenic switch, transforming a dormant neoplasm into an invasive and spreading cancer and representing a rate-limiting step for tumor progression. The angiogenic switch is based on the upregulation of numerous angiogenic factors and a downregulation of anti-angiogenic factors (Pang and Poon 2006; Almog et al. 2009; Baeriswyl and Christofori 2009; Moserle et al. 2009; Almog 2013; Benzekry et al. 2014). In the present chapter, main aspects of angiogenesis are presented for two main liver cancers, hepatocellular carcinoma and cholangiocarcinoma, followed by a short survey on general aspects of angiogenesis and lymphangiogenesis.

Angiogenesis in Hepatocellular Carcinoma: Morphology and Cell Systems

Introduction

Angiogenesis is a critical mechanism for the development and progression of hepatocellular carcinomas (HCCs), which are often highly vascular tumors. In humans, the earliest steps of angiogenesis in HCCs are not well known, as very small or incipient HCC lesions are difficult to study in this respect. It is assumed that the first lesions that consist of collections of few cells may be devoid of an own vascular system, whereas neovascularization is certainly present in small HCCs. Generally, growing HCCs are characterized by arterialization of the vascular supply and capillarization of sinusoidal channels (Pang and Poon 2006; Yang and Poon 2008; Muto et al. 2015).

Morphology of Angiogenesis in Liver Cancers

The morphology and biology of tumor vessels produced in the setting of tumor angiogenesis differs in several respects from normal blood vessels (Ribatti et al. 2007; Hida et al. 2011). Tumor vessels exhibit an abnormal branching pattern and have irregular diameters, sometimes with abrupt changes from large to small diameters instead of a gradual transition. Tumor vessels can form highly atypical arrays, with densely placed larger vessels and an increase in microvessel density. These patterns are under constant dynamic change, due to ongoing angiogenesis, loss of newly formed vessels by tumor-induced destruction, angiophagy, thrombosis and necrosis, and vessel repair. The abnormal vasculature of tumors serves as an important diagnostic element in modern tumor imaging. Endothelial cells in tumor micro-and macrovessels form heterogeneous populations (Hida et al. 2013) and differ in several respects from those in normal tissues. In particular, tumor vessels also display a distinct molecular heterogeneity (Aird 2009).

Histologically, tumor vessels often have an incomplete basement membrane; show an irregular endothelial lining interspersed with tumor cells, homing leukocytes, and adherent platelets; are incompletely covered by supporting pericytes; and are leaky. Many tumor vessels show a lining of both fully developed endothelial cells and focally thin, flat, and fragile (attenuated) endothelial cells lacking expression of typical lineage markers, resulting in mosaic vessels (di Tomaso et al. 2005). The ratio of intact vs. attenuated endothelial cells may have an impact on tumor cell emigration and homing of immune cells. Part of the tumor vasculature is specialized and fit for selective cell transfer. Some tumors contain high endothelial venules that serve for trafficking of immune cells, in particular T and B lymphocytes (Bellone and Calcinotto 2013; Martinet et al. 2011, 2013). Within the vessel lining, tumor cells can interdigitate with endothelial cells. The contribution of cancer cells to the lining of mosaic tumor vessels can be significant and may reach 25 % of the luminal surface in certain neoplasms (Chang et al. 2000). Part of endothelial cells forming new tumor vessels are tumor cell derived, suggesting that tumor vessels in angiogenesis are not always genetically stable (Pezzolo et al. 2007). In addition, tumor cells of certain neoplasms can themselves form vessel-like blood-containing spaces, called vasculogenic mimicry. HCCs are typically arterialized and contain high densities of arterioles. The hypervascularity seen in certain HCCs by the use of angiography or modern MRI techniques is mainly due to the production of intratumoral arterioles. The density of alpha-SMA-reactive arterioles is higher in moderately and poorly differentiated tumors than in well-differentiated tumors and is correlated with proliferative activity of cancer cells (Morinaga et al. 2001).

Biology of Angiogenic Cells in Hepatocellular Carcinoma

The principal cells mediating angiogenesis in tumors are tumor endothelial cells/TECs, but

auxiliary cells include perivascular cells, stromal cells (including myofibroblasts and CAFs), tumor-associated monocytes and macrophages, and other leukocytes. Normal endothelial cells form a rather stable and quiescent cell population with a slow turnover time (months to years) and a proliferation fraction of 0.01 % or less. Upon initiation of the angiogenic switch, numerous preexisting endothelial cells undergo transition from G0 to S phase of the cell cycle, leading to a dramatic increase of the proliferation fraction associated with upregulation of endothelial cell surface markers. TECs form a heterogeneous population of endothelial cells that differ more or less from normal endothelial cells as a function of tumor type and cancer progression (review: Hida et al. 2013). TECs arise from normal preexisting endothelial cells or from circulating progenitor cells (see below), but not from tumor-initiating cells/TICs (Ghanekar et al. 2013). Normal endothelial cells and TECs may not maintain their lineage status, but can transform into mesenchymal cells of the stroma, a phenomenon termed endothelial-to-mesenchymal transition/EndoMT and a mechanism that downregulates microvessels (Ten Dijke et al. 2012). This process probably plays a role in the dynamic evolution of tumor microenvironment and pro-metastatic niches. The proliferative activity of endothelial cells in HCCs was higher in peripheral parts of tumors than in central parts (Imura et al. 2004). TECs in HCC manifest increased angiogenesis capability and augmented resistance to apoptosis (Xiong et al. 2009). Whereas sinusoidal endothelia in the normal liver are not reactive for the progenitor cell marker CD34, CD34 is strongly and diffusely expressed in sinusoid-like vascular channels of advanced HCCs, while CD34 positivity is irregular and focal (Ruck et al. 1995; Cui et al. 1996; Kimura et al. 1998). A switch in endothelial cells to CD34 positivity already takes place in dysplastic nodules, the former adenomatous hyperplasia (Kimura et al. 1998). Intratumoral capillary endothelial cells in HCCs express an adipokine receptor, T-cadherin, reactivity being stronger and diffuse in poorly differentiated tumors and only focal in well-differentiated HCCs (Adachi et al. 2006).

Proliferation of TECs promoted by angiogenic factors parallels other marked changes in TEC biology. Activated TECs become motile cells reacting to chemokinetic and chemotactic stimuli. This motility is required for the placing of tip cells in vascular sprouting (see below) and migration of TECs into the tumor bed. Invasion of tissue by TECs is associated with the breakdown of the surrounding basement membrane and extracellular matrix, basement membranes later being reconstituted, at least in part, during tumor vessel maturation (Baluk et al. 2003, review: Semela and Dufour 2004). By an interacting cell network that also includes blood-borne cells such as macrophages, proteolytic enzymes are secreted, including matrix metalloproteinases/MMPs, tissue plasminogen activator, and cathepsins, whereby the secretion of these enzymes is partially controlled by angiogenic factors produced by tumor cells, stromal cells, and myeloid cells. Important sources for MMPs, in particular MMP-9/gelatinase B, are cancer-associated fibroblasts/CAFs (Vandooren et al. 2013; Farina and Mackay 2014; Taguchi et al. 2014). Proteases expressed during angiogenesis also serve to liberate growth factors. For example, MMP-9 plays a major role in releasing VEGF sequestered in the extracellular matrix (Bergers et al. 2000).

Endothelial Progenitor Cells as Mediators of Vasculogenesis in Hepatocellular Carcinoma

In numerous neoplasms, endothelial progenitor cells are operational in tumor vascularization. Similar to normal tissues, these progenitors derive, at least in part, from circulating CD133(+)CD34(+) stem cells that are capable to home the tumors, in particular to incipient stroma and pro-metastatic niches (reviews: Ribatti 2004; Patenaude et al. 2010). For tumor vasculogenesis in HCC, endothelial progenitor cells (EPCs; CD133+) have been proposed to play an important role (Nolan et al. 2007; Ping and Bian 2011; Moschetta et al. 2014), albeit other authors did not find a contribution of EPCs to tumor endothelium (Wickersheim et al. 2009). EPCs can, in certain

tumors, populate new blood vessels that emerged from local endothelial cells, giving rise to complex mosaic patterns (Chen et al. 2014b). In HCCs, higher circulating levels of EPCs were observed in patients with advanced unresectable tumors as compared to patients with resectable tumors (Ho et al. 2006). Part of EPCs mediating angiogenesis in HCC originate from bone marrow-derived endothelial precursors (Yu et al. 2007a; Sun et al. 2012; Yoder 2012; Zhu et al. 2012b; Carrion et al. 2013), and also multipotent adult progenitor cells/MAPCs contribute to HCC neovasculature (Barajas et al. 2007). Part of EPCs express the lineage markers, CD133, CD34, and VEGFR2 (Ho et al. 2006). An EPC contribution may occur at an early stage and throughout the entire process of HCC growth (Zhu et al. 2012a). Circulating EPCs are elevated in patients with liver cirrhosis and/or HCC (Sieghart et al. 2009). These cells belong to two major phenotypes, i.e., myeloid-derived EPCs (colony-forming unit-endothelial cells, CFU-ECs) and outgrowth EPCs (endothelial colony-forming cells, ECFCs). Priming, mobilization, recruitment, and homing of EPCs are a multistep event that requires regulation by several factors, including adhesion molecules, angiogenic factors, interacting tumor cells, stromal cells, and a hypoxic microenvironment. Cancer cells interact with EPCs in a complex manner and modify the biologic behavior of these cells. HCC cells induce chemotaxis, migration, and an invasive phenotype in CFU-ECs via secretion of macrophage inflammatory protein-3alpha which binds to the CCR6 receptor on CFU-ECs, but HCC cells do not induce chemotactic migration in ECFCs (Shih et al. 2012a).

The upregulation of angiogenic factors in HCC causes recruitment of endothelial progenitor cells into microvessels, both in the tumor itself, but also in peritumoral cirrhotic tissue, which forms a highly angiogenic area (Yu et al. 2010b). In fact, normal and cirrhotic liver surrounding HCCs are an important source of angiogenic cells, suggesting that HCCs are embedded in an angiogenic "hot-spot area." Hypoxic and angiogenic peritumoral liver tissue forms a niche of endothelial progenitor cells (Yu et al. 2010a).

Angiogenic Factors in Hepatocellular Carcinoma

Vascular Endothelial Growth Factors

An important proangiogenic factor in tumors is vascular endothelial growth factor (VEGF), which interacts with specific receptors on endothelial cells. HCC cells express VEGF, and the VEGF receptors are upregulated in HCCs in comparison with normal liver tissue (Shimoda et al. 1999; McMahon 2000; Shimamura et al. 2000; Mitsuhashi et al. 2003; Moon et al. 2003; Deli et al. 2005; Ribatti et al. 2006; Sharma et al. 2013; Zhang et al. 2014). In patients with cancer, angiogenic factors are produced, taken up, stored, and transported by platelets (Walsh et al. 2014), resulting in net platelet angiogenic activity/NPAA which, in certain tumors, correlated with progression and prognosis (Yao et al. 2014).

Apart from tumor cells, also hepatic stellate cells may express VEGF, possibly in the setting of autocrine/paracrine loops. Increased VEGF expression is already present in early steps of hepatocarcinogenesis (Park et al. 2000). In advanced HCC, increased VEGF expression is more frequently found in hypervascular tumors and those with poor differentiation and is associated with tumor progression (Torimura et al. 1998). Both VEGFR1 (Flt-1) and VEGFR2 (Flk-1) are expressed in subsets of HCCs, whereby four categories of tumors were proposed, i.e., receptor double negative, Flt-1 single positive, Flk-1 single positive, and receptor double positive. Poorly differentiated HCCs were either receptor double negative or double positive (Amaoka et al. 2006). Expression of VEGFR1 correlated with the endothelial CD31 expression pattern (Dhar et al. 2002). Part of HCCs also express a VEGF involved in lymphangiogenesis, VEGF-C, expression being detectable more often in large tumors and those with intrahepatic recurrence and extrahepatic metastases. VEGF-C was also found in HCC cells forming tumor casts in portal and hepatic veins (Yamaguchi et al. 2006). VEGFs and VEGFRs are subject to therapies with receptor kinase inhibitors, such as sorafenib and

sunitinib (Adnane et al. 2006; Takahashi 2011; Johnson et al. 2013; Kim and Abou-Alfa 2014; Scartozzi et al. 2014) and cabozantinib (blockade of VEGFR2 and MET; Xiang et al. 2014), or humanized monoclonal antibody against VEGF-A, bevacizumab. The mechanisms leading to upregulation of angiogenic factors, including VEGFs, in HCC are only partially elucidated. VEGF expression in HCC is promoted by ATPase inhibitory factor 1 (IF1), a factor highly expressed in large and aggressive tumors, via activating NF-kB signaling. Via this pathway, IF1 also upregulates Snail followed by active epithelial-mesenchymal transition (Song et al. 2014).

Angiopoietins

Angiopoietin-1 (Ang1) and its antagonist angiopoietin-2 (Ang2) regulate the Tie2 receptor (vascular endothelial receptor of tyrosine kinase) and are expressed in various tumors (Yu 2005; Bach et al. 2007). Both Ang1 and Ang2 are expressed in HCCs, the factors being present in tumor cells and stromal cells, including hepatic stellate cells and myofibroblasts, while the Tie2 receptor is expressed in endothelial cells, hepatic stellate cells, and smooth muscle cells (Torimura et al. 2004). In HCC, Ang2 is predominantly expressed on cancer cells themselves, while Ang1 is mainly present in stromal and endothelial cells (Bupathi et al. 2014). In contrast to the normal liver, Ang2 is more often expressed, and its expression level is higher in hypervascular tumors and those with poor differentiation, suggesting a reversal of Ang1 and Ang2 expression (Mitsuhashi et al. 2003; Zhang et al. 2006). Ang2 expression is correlated with expression of the Tie2 receptor in tumor vessels (Sugimachi et al. 2003) and closely associated with tumor angiogenesis and microvessel density (Chen et al. 2001; Wada et al. 2006). The production of Ang1 and Ang2 is correlated with HCC vascularity, indicating that the factors play a role in HCC angiogenesis (Torimura et al. 2004). Ectopic expression of Ang2 promotes rapid progression of HCC, supporting an important role of this factor in HCC neovascularization (Tanaka et al. 2003; Zhang et al. 2006). Upregulation of Ang2 in HCC was associated with poor overall survival (Miyahara et al. 2013). In hepatocyte lineages, Ang2 expression is promoted by the HBV X protein (Sanz-Cameno et al. 2006). HCC tissue expresses significantly lower levels of angiopoietin-like protein 4/ANGPTL4 than non-tumor liver tissue, via an epigenetic downregulation mechanism. This downregulation is associated with advanced stage (Ng et al. 2014).

Basic Fibroblast Growth Factor

Basic fibroblast growth factor/bFGF is an angiogenic factor in HCC (Nomura et al. 2013). In tumors expressing bFGF, the proliferative activity of tumor endothelial cells (PCNA labeling) was significantly higher than that in bFGF-negative HCCs (Imura et al. 2004). FGF8, FGF17, and FGF18 are involved in autocrine and paracrine signaling in HCC and promote angiogenesis (Gauglhofer et al. 2011).

Platelet-Derived Endothelial Cell Growth Factor

Platelet-derived endothelial cell growth factor (PD-ECGF; thymidine phosphorylase) is an angiogenic factor that is expressed in malignancies. Expression of PD-ECGF was detected in about 50 % of HCCs, with immunostaining of both cytoplasm and nuclei. In addition to HCC cells, reactivity is also present in stromal cells and tumor-infiltrating lymphocytes. Reactivity for PD-ECGF was associated with elevated tumor microvessel density and higher grade (Guo et al. 2001).

Endoglin and Ephrin

Endoglin (CD105) is a cell surface glycoprotein involved in the development of blood vessels and vascular repair (Duff et al. 2003; van Laake et al. 2006). Endoglin is a receptor for TGF-beta1 and TGF-beta3 and modulates TGF-beta signaling via interacting with

TGF-betaR1 and/or TGF-betaR2. Endoglin is expressed in HCCs, restricted to endothelial cells of capillary vessels and sinusoid-like channels (Dhar et al. 2002; Minhajat et al. 2006; Yu et al. 2007b). CD105 microvessel density was positively associated with expression intensity of VEGF (Yao et al. 2007). Lower CD105 microvessel density was associated with larger and more aggressive tumors (Ho et al. 2005). In livers harboring HCC, diffuse endoglin reactivity was also noted in microvessels of adjacent nonneoplastic liver tissue, mainly in sinusoidal endothelial cells (Yu et al. 2007b), and this reactivity was associated with early tumor recurrence (Ho et al. 2005). CD105 is detectable as a belt-like reactivity in peritumoral tissue in HCC patients (Nakamura 2009). Ephrins and their receptors are involved in tumor angiogenesis. Ephrin-A1 affects several signaling pathways depending on MAP/ERK and PI3K and has an integral role in angiogenesis and vasculogenesis. Ephrin-B2 regulates VEGFR2 function in neoplasms (Hainaud et al. 2006; Sawamiphak et al. 2010). Several ephrin types can be expressed in HCCs. The expression of ephrin-B1 was significantly higher in these cancers than in normal liver tissue, and ephrin-B1-positive tumors had a higher vascular density and a more rapid progression (Sawai et al. 2003). Ephrin-A1 is preferentially expressed in AFP-producing HCC cells, expression in HCCs being higher than in the cirrhotic or normal liver tissue (Iida et al. 2005). Ephrin-A1 is upregulated by hypoxia in cancer cells (Song et al. 2013).

Cytokines and Chemokines

Chemokines (CC, CXC, C, and CX3C) are involved in several important aspects of cancer biology, including chemokinesis and chemotaxis, proliferation, apoptosis, and modulation of angiogenesis (Kiefer and Siekmann 2011; Bosisio et al. 2014). The angiogenic effect of certain cytokines and chemokines in HCC and other hepatic malignancies is also recognizable in hepatic inflammatory disorders where immunologic effector cells are the source of these factors, e.g., in HCV infection (Hassan et al. 2014). Seven ELR-positive CXC chemokines promote migration and proliferation of endothelial cells and are potent angiogenic substances, also in tumors. Three members of the CC chemokine family, CCL2, CCL11, and CCL16, can also induce neovascularization. Several CXC ligands (CXCL 4,9,10 and 11) cause an angiostatic effect via binding to a common receptor, CXCR3 (Dias et al. 2001; Salcedo and Oppenheim 2003; Keeley et al. 2011; Kiefer and Siekmann 2011; Santoni et al. 2014). Proangiogenic chemokines can elicit an angiogenic response in HCC (Keeley et al. 2011). The chemokine IL-8 (CXCL8), which is produced by macrophages and stored in endothelial cell vesicles, is expressed in part of HCCs and related to angiogenesis in these neoplasms (Nomura et al. 2013). An important role is played by CXCR3, a receptor for at last five CXCL chemokines (Billottet et al. 2013). A further chemokine that is involved in angiogenesis is stromal cell-derived factor-1, a protein that exclusively binds to the CXCR4 receptor and regulates endothelial cell branching morphogenesis (Salvucci et al. 2002). CXCR7 stimulates HCC angiogenesis through activation of the MAPK signaling pathway (Lin et al. 2014). Stromal cell-derived factor-1 produced by platelets is involved in the recruitment of progenitor cells to vascular compartments (Stellos and Gawaz 2007).

Thrombospondin and Vasohibins

Thrombospondin 1/THBS1 is a matricellular protein that can modulate angiogenesis and in many situations acts in an angiostatic manner in nonneoplastic cell systems (Lawler 2002). In principle, THBS1 acts as a molecular facilitator that promotes a union among several other factors, such as cytokines, membrane receptors, and proteases, allowing cross talk between receptor clusters (review: Chen et al. 2000). THBS1 binds to its receptor on microvascular endothelium, CD36, necessary for anti-angiogenic activity and acting through inhibition of VEGFR2 signaling (Simantov and Silverstein 2003; Chu et al. 2013; Klenotic et al. 2013). In HCCs, THBS1 is expressed in both tumor cells and stromal cells and acts as an

angiogenesis modulating factor that promotes invasion and progression (Poon et al. 2004).

Vasohibin-1 is an endothelium-derived negative feedback regulator of angiogenesis that is induced by FGF-2 and VEGF-A. Vasohibin-1 expression in tumor vessel endothelial cells regulates tumor angiogenesis (Hosaka et al. 2009; Ito et al. 2013), but the effects of vasohibin-1 on tumor endothelia is complex and depends on the status of target vessels. In HCC, vasohibin-1 expression is correlated with neovascularization (Murakami et al. 2014). Patients with vasohibin-1-expressing HCCs had a significantly reduced overall survival (Wang et al. 2012). Vasohibin-2 as a proangiogenic factor is highly expressed in part of HCC and promotes angiogenesis in these tumors (Xue et al. 2013). Its expression is a function of differentiation, and this factor also modulates chemoresistance (Li et al. 2014). Vasohibin expressed by HCC cells augments the angiogenic response through induction of epithelial-mesenchymal transition/EMT, whereby vasohibin-2 is induced by microRNA-200 (Xue et al. 2014).

Angiogenic Factors with Complex or Not Well-Studied Functions

Neuropilin-1, which plays a role in arteriogenesis in normal and cancerous tissues, is expressed in HCC and peritumoral tissue (Zhuang et al. 2014). Platelet-derived growth factor/PDGF and its receptors are involved in HCC angiogenesis. The expression of PDGFRA in HCC vessels is induced by microRNA-146a (Zhu et al. 2013). Prostaglandins produced in HCC via the action of the cyclooxygenase/COX system positively affects angiogenesis (Cervello and Montalto 2006; Zhao et al. 2006). Angiogenin (ribonuclease 5) belonging to the vertebrate RNase superfamily was identified as tumor angiogenic factor, but is now known to be a factor that generally stimulates proliferation and survival. Angiogenin stimulates ribosomal RNA transcription (Sheng et al. 2014). The embryonic morphogen Nodal is expressed in subsets of HCC and is associated with angiogenesis and an aggressive cancer phenotype (Chen et al. 2014a). Twist, a bHLH transcription factor promoting epithelial-mesenchymal transition/EMT, is expressed in part of HCCs and is associated with an elevated tumor microvessel density (Che et al. 2011). Upregulation of Twist in HCC is correlated with intrahepatic and extrahepatic metastasis and poor prognosis (Niu et al. 2007). HCCs express protein phosphatase of regenerating liver 3/PRL-3 as a metastasis-associated phosphatase. PRL-3 promotes angiogenesis in these neoplasms (Zhao et al. 2008). A factor involved in epithelial-mesenchymal transition, BAG3 (Bcl2-associated athanogene 3; a co-chaperone of Hsp70), is expressed in HCC and augments invasion and angiogenesis via VEGF induction (Xiao et al. 2014). Several types of microRNAs target angiogenic and anti-angiogenic factors and thus influence tumor angiogenesis (Pecot et al. 2013). HCCs express acylglycerol kinase (AGK), a factor associated with an aggressive phenotype and increased tumor angiogenesis (Cui et al. 2014). In several tumors, including HCC, angiogenesis is promoted by activation of NF-kappaB signaling. Golgi phosphoprotein 3 (GOLPH3) is frequently upregulated in HCC, and its expression is correlated with clinical stage, survival, and promotion of angiogenesis. This effect is mediated by NF-kappaB signaling and promotion of K63-linked polyubiquitination of TNF receptor-associated factor 2/TRAF2, receptor-interacting protein/RIP, and NF-kappaB essential modulator/NEMO as activators of NF-kappaB (Dai et al. 2015). In HCC, angiogenesis and metastatic spread are stimulated by ATPase inhibitory factor 1/IF1, via upregulation of Snail1 and increased transcription of VEGF (Song et al. 2014).

Angiogenic Factors and Biology of Disease in Hepatocellular Carcinoma

Angiogenesis induced by various angiogenic factors strongly affects growth and progression of HCC. Silencing of VEGF not only abolishes angiogenesis, but also inhibits growth of HCCs (Wu et al. 2013). HCCs with high Ang2 expression were associated with a shorter survival time than those with low Ang2 expression (Mitsuhashi

et al. 2003). The expression patterns of angiogenic factors in HCCs are associated or correlated with biology of disease. Increased serum VEGF in patients with HCC was correlated with tumor recurrence, disease-free survival, and overall survival (Chao et al. 2003). However, only part of angiogenic factors can serve as predictors of outcome. For example, VEGF-A and VEGF-C could not predict recurrence in HCC patients (Ho et al. 2007).

Inhibitors of Angiogenesis in Hepatocellular Carcinoma

Endostatin, a 20 kDa C-terminal fragment of collagen XVIII, is an endogenous inhibitor of angiogenesis that exists in *a short and long* form. Endostatin targets both tumor blood vessels and lymphatic vessels and is, therefore, also an inhibitor of lymphangiogenesis (Zhuo et al. 2010, 2011). HCC cells can express *the long* form in contrast to cholangiocarcinoma cells that express *the short* form. *The long* form seems to be specific to the hepatocyte lineage, while the *short* form is also produced by stromal cells in liver cancer, including myofibroblasts (Musso et al. 2001). In HCC, increased endostatin expression correlated with elevated VEGF levels and poor prognosis (Hu et al. 2005). Angiostatin inhibits angiogenesis when expressed in HCCs (Soff 2003; Tao et al. 2004). Angiostatin expression in HCC results in decreased microvessel density (Kim et al. 2004). An angiogenesis inhibitor in tumors is angioarrestin, a protein related to angiopoietins. Angioarrestin inhibits VEGF-induced endothelial cell proliferation, adhesion, migration, and tubular network formation (Dhanabal et al. 2002; Dhanabal et al. 2005). Generation of angioarrestin in HCC requires expression of human macrophage metalloelastase/HME as a processing enzyme (Gorrin Rivas et al. 1998). Expression of VEGF in HCC is suppressed by the tumor suppressor XAF1 (X-linked inhibitor of apoptosis/XIAP-associated factor 1), whereby most HCCs showed a downregulation of XAF1 (Zhu et al. 2014a). Angiogenesis can be inhibited by downregulation of angiogenic factors. In HCC, microRNA-26a inhibits angiogenesis by reducing a VEGF-A pathway (Chai et al. 2013) and by targeting the HGF/cMet pathway (Yang et al. 2014; Greenhill 2014). MicroRNA-29b antagonizes angiogenesis by targeting and downregulating MMP-2 expression (Fang et al. 2011a), microRNA-503 targets VEGF-A and FGF2 and via this mechanism inhibits angiogenesis (Zhou et al. 2013), and microRNA-223 antagonizes angiogenesis by targeting beta1 integrin and preventing growth factor signaling (Shi et al. 2013).

Induction and Driving Forces of Angiogenesis in Hepatocellular Carcinoma

Hypoxia and Hypoxia-Inducible Factors

Hypoxia promotes the progression of liver cancers via affecting cell proliferation and invasion, but tumor hypoxia is also a strong driving force for angiogenesis in many malignancies, including HCCs (Kim et al. 2002; Hirota and Semenza 2006; Ji 2014; Wilson et al. 2014). The local oxygenation status in tumors is monitored by oxygen sensors, of which hypoxia-inducible factors (HIFs) and their hydroxylating dioxygenases are the prominent members (review: Verma 2006). For angiogenesis, hypoxia acts through upregulation of VEGF gene expression, via increased VEGF gene transcription and an increase in VEGF mRNA stability (von Marschall et al. 2001). VEGF expression in HCC is tightly regulated by HIF-1alpha, a transcription factor that upregulates angiogenic factors under hypoxia (Wu et al. 2014). HIF-1 plays an important role in the progression and angiogenesis of HCC (Luo et al. 2014). In experimental HCC cells, plasminogen activator inhibitor 1/PAI-1 is a HIF-2alpha target gene. HIF-2alpha increases PAI-1 to decrease local concentrations of active plasmin, thereby supporting angiogenesis (Geis et al. 2014). HBV X protein, a protein involved in hepatocarcinogenesis, increases the expression of VEGF via stabilizing HIF-1alpha, active HIF-1alpha upregulating VEGF (Moon

et al. 2004). In contrast to VEGF, hypoxia does not upregulate Ang1 and Ang2 in HCC (Torimura et al. 2004). HCV core protein induces hypoxia-inducible factor 1alpha-mediated VEGF expression in HCC cells (Zhu et al. 2014b). Apart from VEGF-mediated pathways, HIF-1alpha also affects invasive features of HCC. For example, it promotes transcription of the chemotactic peptide CXCL6 in HCC cells, inducing chemotactic migration of HCC cells (Tian et al. 2014). Hypoxia induces the secretion of platelet-derived growth factor-BB by HCCs, which in turn increases the secretion of VEGF-A by activated hepatic stellate cells (Lu et al. 2015). Hypoxia-induced angiogenesis is regulated by distinct microRNAs which are upregulated under hypoxic conditions, above all in tumors (Madanecki et al. 2013). Hypoxia-responsive microRNAs target the argonaute 1 protein leading to desuppression of VEGF and promotion of angiogenesis (Chen et al. 2013). Hypoxia-related mechanisms are also operational in tumor lymphangiogenesis (Ji 2014).

Factors Not Driven by Hypoxia

Apart from hypoxia, other factors can induce angiogenic factors. Early steps of vasculogensis and angiogenesis in tumors mainly involve the generation of endothelial tubes, which in the course of further expansion of the vessel network undergo maturation, including arterialization which depends on smooth cell production. Tumor arteriogenesis in HCC is induced by the apelin/APJ signaling system, a multifunctional pathway involved in endotheliogenesis and the generation of smooth muscle cells (Muto et al. 2014). A strong promoter of angiogenic factor expression in HCC is macrophage migration inhibitory factor/MIF, which increases VEGF and IL-8 in these neoplasms and induces angiogenesis in HCC (Ren et al. 2003; Hira et al. 2005). Distinct expression patterns of matrix metalloproteinases affect angiogenic responses in HCC (Ishii et al. 2003). TNF-like weak inducer of apoptosis/TWEAK, a TNF family member expressed by HCC cells, modulates tumor-associated angiogenesis via induction of IL-8 and MCP-1 in endothelial cells (Kawakita et al. 2004).

Epigenetic Mechanisms in Liver Cancer Angiogenesis

MicroRNAs as Regulators of Angiogenesis in Cancer

Intracellular and extracellular microRNAs/MiRs play a significant role in both normal angiogenesis/vasculogenesis and tumor angiogenesis, as these MiRs critically affect numerous signaling pathways in endothelial cells (Finn and Searles 2012). Deregulation of microRNAs is an important mechanism that modulates angiogenesis in primary cancers and metastatic disease (Gramantieri et al. 2008; Png et al. 2011; Geng et al. 2014; Zeng et al. 2014; Zhou et al. 2014; Dang and Myers 2015). Promotion of tumor angiogenesis depends on differential expression of miR-296 and miR-378 (Bonauer et al. 2010). The potent angiogenic factors, VEGF-A and fibroblast growth factor 2, are downregulated by microRNA-503 which targets these factors (Zhou et al. 2013). miR-93 promotes tumor angiogenesis by targeting integrin-beta8 (Fang et al. 2011b). MicroRNA-26a suppresses angiogenesis in HCC by targeting the hepatocyte growth factor-cMet signaling pathway, resulting in VEGF-A downregulation. This miR is reduced in part of HCCs, associated with enhanced angiogenesis (Greenhill 2014; Yang et al. 2014). MicroRNA-29b suppresses the ability of HCC cells to promote capillary tube formation via downregulating matrix metalloproteinase-2 expression. In HCC, miR-29b expression is low, associated with aggressive tumor biology (Fang et al. 2011a). Downregulation of microRNA-214 in human HCC contributes to tumor hypervascularity through activation of hepatoma-derived growth factor paracrine pathway for tumor angiogenesis (Shih et al. 2012b). The endothelial cell-specific microRNA-302c suppresses HCC growth through metadherin-mediated inhibition of endothelial-mesenchymal transition/EndMT (Zhu et al. 2014c).

Epigenetic Pathways in Tumor Angiogenesis Other Than MicroRNAs

In addition to microRNAs, epigenetic alterations in tumor angiogenesis include histone modifications and chromatin modifiers. Cancers subject to hypoxia exhibit upregulation of hypoxia-inducible factor (HIF) alpha which plays an important role as inducer of VEGF signaling. The actions of HIF-alpha strongly depend on epigenetic modifications including acetylation mediated by histone acetyltransferases and histone deacetylation mediated by histone deacetylases (Ellis et al. 2009). Expression of cell adhesion molecules, e.g., intercellular adhesion molecule-1/ICAM-1 in endothelial cells is modulated by histone modifications. ICAM-1 downregulation in tumor endothelial cells is associated with ICAM-1 promoter histone 3 deacetylation and loss of histone H3 methylation, resulting in ICAM-1 silencing (Hellebrekers et al. 2006). Histone modifications operate in the transcription control of vascular endothelial growth factor receptor 3 involved in tumor lymphangiogenesis (Hertel et al. 2014). In cancers, angiogenesis-induced metastasis is also regulated by epigenetic histone modifications (Sahin et al. 2010). Yin Yang 1/YY1 is a member of the polycomb family involved in epigenetic mechanisms. YY1 acts as a positive regulator of angiogenesis by interacting with the VEGF-A signaling system. Binding of YY1 to VEGF-A is required to maintain steady-state VEGF-A expression. Hypoxia, a frequent and critical alteration in cancers, impairs YY1 binding to VEGF-A, downregulates YY1 and Dicer, and changes posttranscriptional VEGF-A regulation via accumulation of primiRNA200b/c instead of mature miR (Infante et al. 2015).

Tumor Exosomes (TEXs)

Exosomes are microvesicular structures that are derived from endosomes and released from numerous normal and cancer cells. Exosomes are among the most efficient mediators of intercellular communication and signaling and play a critical role in tissue patterning, regeneration, carcinogenesis, and tumor progression (Dignat-George and Boulanger 2011; Martinez and Andriantsitohaina 2011). Exosomes can contain proangiogenic factors and are released by tumor cells and endothelial cells of tumor vessels. A further source of exosomal proangiogenic factors are macrophages, neutrophils, and myeloid-derived suppressor cells located to the tumor stroma (Yang et al. 2011; Burke et al. 2014). Tumor exosomes (TEXs) as potent nanoscale messengers communicate with tumor cells themselves, stromal cells, endothelial cells, and circulating cells. As outlined in more detail in a later paragraph, cargo transported by microvesicles/exosomes is involved in the transfer of proangiogenic signals in cancers, including liver cancer (Kahlert and Kalluri 2013). The exosomal cargo in angiogenesis consists of angiogenic factors, cell adhesion molecules, and Notch ligands (Muturi et al. 2013; Sharghi-Namini et al. 2014). Signal components and growth factors carried and released by exosomes can induce endothelial cell proliferation and tube formation in a paracrine manner (Hood et al. 2009; Taverna et al. 2012). Transport and release of the Notch ligand Delta-like 4 by exosomes mediates development of tip cells and suppression of endothelial stalk cells in vascular sprouting (Sharghi-Namini et al. 2014). Exosomal TGF-beta1 induces the differentiation of tumor-promoting stromal myofibroblasts (Webber et al. 2014), whereas exosomes derived from mesenchymal stem cells can suppress angiogenesis by downregulating VEGF expression (Lee et al. 2013). Exosomes produced by myeloid-derived suppressor cells/MDSC transport and deliver cargo that transforms macrophages into tumor-promoting and proangiogenic M2 macrophages (Burke et al. 2014). Microvesicle-delivery of microRNA-150 promotes secretion of VEGF by M2-type TAMs (Liu et al. 2013). Exosomes involved in angiogenesis are promoted by hypoxia (Salomon et al. 2013), and endothelial cells require microRNA-214 to secrete exosomes that induce angiogenesis (van Balkom et al. 2013). In cancer

angiogenesis, release and transfer of exosomes is mediated by sortilin/neurotensin receptor-3 in a complex (TES complex) involving two tyrosine kinase receptors, TrkB and EGFR (Wilson et al. 2014), and by WNT5A, a component of Wnt signaling pathways (Ekström et al. 2014). Exosomes are one pathway by which hypoxia can drive angiogenesis, as exosomes are preferentially released from hypoxic tumor cells (Tadokoro et al. 2013). Part of proangiogenic effects of exosomal cargo is mediated by exosomal microRNAs (Zhang et al. 2015a). Exosomes may serve as a reservoir of anti-apoptotic microRNAs (Yu et al. 2015), a potential mechanism to favor endothelial cell survival.

Exosomes also carry a secretome that facilitates the emergence of epithelial-mesenchymal transition/EMT which in turn promotes invasion and angiogenesis of cancers (Greening et al. 2015). MicroRNAs carried by TEX are capable to induce premetastatic niches and proinflammatory niches that are programmed for later tumor angiogenesis (Rana et al. 2013). Premetastatic niche angiogenesis proceeds directly through binding and uptake of TEX by cells of the niche microenvironment, or indirectly through TEX taken up by bone marrow-derived, circulating stromal cell progenitors, endothelial cell progenitors, and mesenchymal stem cells primed to become stromal or vascular cells (Thuma and Zöller 2014). Exosomes released from pluripotent mesenchymal stem cells promote angiogenesis (Zhang et al. 2015b). Exosomal components may induce the differentiation of stromal tumor-promoting myofibroblasts and thus favor a proangiogenic microenvironment (Webber et al. 2015). On the other hand, cargo of exosomes can contribute to a cancer-associated immunosuppressive microenvironment, causing impairment of proangiogenic actions of monocytes and macrophages (Taylor and Gercel-Taylor 2011). Apart from complete nucleated cells, platelets can release microvesicles that promote tumor angiogenesis through the induction of CD41-MAPK kinase signaling pathways and upregulation of MMP-9 (Janowska-Wieczorek et al. 2005).

Tumor Angiogenesis: Roles of Tumor-Associated Macrophages (TAMs), Tie2-Expressing Monocytes (TEMs), Myeloid-Derived Suppressor Cells, Lymphocytes, Neutrophils, and Stromal Cells

Introduction

Several types of immune-related myeloid cells are involved in angiogenesis. They include circulating monocytes, Tie2-expressing monocytes (TEMs), myeloid-derived suppressor cells (MDSCs), tumor-associated macrophages (TAMs), and neutrophils (reviews: Schmieder et al. 2012; Chambers et al. 2013). Among these cell types, TAMs seem to play the most important role for tumor angiogenesis, but their Tie2-expressing monocyte precursors are also important for the initiation of tumor angiogenesis in HCC (De Palma et al. 2007, 2013; Guo et al. 2013; Matsubara et al. 2013).

TEMs and TAMs as Driving Forces in HCC Angiogenesis

The stroma of liver cancers contains various numbers of immune system cells acting as proinflammatory and proangiogenic elements, specifically TEMs, TAMs, and tumor-associated lymphocytes (Stockmann et al. 2014). These cells in part originate from circulating, bone marrow-derived cells, from locally proliferating cells, and stem/progenitor cells that home to the stromal niche. The homing mechanisms that cause accumulation of these cells within tumors are only partially elucidated. Tumor endothelium releases Ang2 and further facilitates recruitment of Tie2-positive monocytes into tumors (Riabov et al. 2014). In HCC, the presence of TEMs and TAMs is associated with angiogenesis (Matsubara et al. 2013). In the inflammatory microenvironment of HCC, TAMs acquire an M2-polarized phenotype and are associated with angiogenesis and increased microvessel density (Capece et al. 2013; Fujita et al. 2014) and can exert angiogenic functions by secreting proangiogenic factors

and matrix metalloproteinases. TAMs as alternative M2 cells modulate angiogenesis through secretion of the cytokine IL-1, which initiates and propagates inflammation and induces angiogenesis via proangiogenic inflammatory mediators (Carmi et al. 2009, 2013; Voronov et al. 2014). Also IL-8 is involved in tumor angiogenesis (Medina et al. 2011). TAMs secrete TNFalpha which coordinates inflammation and angiogenesis in HCC (Hammam et al. 2013). TNFalpha that targets to neoangiogenic vessels enhances lymphocyte infiltration in tumors (Calcinotto et al. 2012). Tie2 signaling cooperates with TNFalpha in promoting the proinflammatory activation of macrophages (Garcia et al. 2014). Interaction of TAMs with tumor cells increases the secretion of EMMPRIN (CD147, basigin) by tumor cells. EMMPRIN promotes the expression of VEGF and matrix metalloproteinases in endothelial cells and induces angiogenesis (Amit-Cohen et al. 2013). In their angiogenic function, TAMs are subject to regulatory pathways, including Toll-like receptor signaling (Belmont et al. 2014).

Tie2-expressing monocytes/TEMs are a diagnostic marker for HCC, and their presence in stroma correlates with tumor angiogenesis (Buonaguro 2014; Dapas et al. 2014; Germano and Daniele 2014). Tie2-expressing monocytes promote tumor angiogenesis in a paracrine manner (De Palma and Naldini 2009; Ribatti 2009). In the normal liver substance, these monocytes with a vigorous angiogenic potential are selectively induced by liver resection and accumulate near the site of liver regeneration (Schauer et al. 2014). The proangiogenic activity of Tie2-expressing monocytes is regulated by hypoxia and Ang2 (Lewis et al. 2007), whereby this depends on Ang2-regulated angiogenesis gene expression in monocytes (Coffelt et al. 2010). Differentiation of Tie2-expressing monocytes is induced by macrophage colony-stimulating factor (Forget et al. 2014).

Tumor-Associated Lymphocytes (TALs)

The network of angiogenesis-associated myeloid cells is modulated by other immune cells, including tumor-associated lymphocytes (TALs). Tumor-infiltrating regulatory T cells (TREGs) in cancers are positively correlated with angiogenesis, probably by generating immune tolerance units in the tumor microenvironment (Ning et al. 2012). On the other hand, angiogenic factors modulate immune reactions (Ohm and Carbone 2001), in part through affecting the function of monocytes/macrophages, including TAMs, and of other myeloid cells. Ang2 can stimulate Tie2-expressing monocytes to suppress T cell activation and to induce expansion of regulatory T cell (TREG) expansion (Coffelt et al. 2011). VEGF affects dendritic cell maturation and by this exerts and influences on local immune reactions (Oyama et al. 1998). Placental growth factor downregulates T helper immune responses through modulation of dendritic cell function (Lin et al. 2007).

Tumor-Associated Neutrophils (TANs)

In patients with cancer, heterogeneous populations of circulating neutrophils have been identified. One subset is formed by low-density neutrophils (LDNs) that accumulate continuously with cancer progression. LDNs display impaired neutrophil function and immunosuppressive properties, in contrast to mature, high-density neutrophils/HDNs. LDNs consist of two populations, i.e., cells that are derived from HDNs in a TGF-beta-dependent manner and immature myeloid-derived suppressor cells/MDSCs (see next paragraph), illustrating the overlap between TANs and one subset of MDSCs (granulocytic MDSCs; Dumitru et al. 2012; Pillay et al. 2013; Sagiv et al. 2015). Tumor-associated neutrophils (TANs) represent a distinct subpopulation of neutrophils that home to compartments within tumor stroma and in part within carcinoma epithelial formations (Dumitru et al. 2013). Similar to normal mature neutrophils, circulating neutrophils that will become TANs can adhere to microvascular endothelium via the action of cellular adhesion molecules/CAMs (Jain et al. 1996). On the other hand, tumor angiogenesis can reduce endothelial adhesion molecule

expression, thereby modulating neutrophil homing (Dirkx et al. 2003). TANs secrete various cytokines, part of which are proinflammatory and proangiogenic factors (Tecchio et al. 2013), and are a major source of proangiogenic matrix metalloproteinases (Deryugina et al. 2014). TANs also positively affect angiogenesis via integrin alphaMbeta2 (Soloviev et al. 2014). Neutrophils, chief mediators of acute and chronic inflammation, are enriched in peritumoral stroma of HCCs via IL-17-mediated recruitment. TANs can promote tumor angiogenesis via secretion of neutrophil-derived cytokines such as fibroblast growth factor-2, angiopoietin-1, and IL-17 (Tecchio and Cassatella 2014). Neutrophils also promote angiogenesis in HCCs through secretion of matrix metalloproteinase-9 (Kuang et al. 2011). Neutrophils in tumors can also contribute to lymphangiogenesis via increasing VEGF-A bioavailability and secretion of VEGF-D (Tan et al. 2013). Apart from neutrophils, eosinophils, which respond to hypoxia, can promote angiogenesis (Nissim Ben Efraim and Levi-Schaffer 2014).

Tumor-Associated Myeloid-Derived Suppressor Cells (TAMDSCs)

Myeloid-derived suppressor cells (MDSCs; immature myeloid cells; myeloid suppressor cells) are a heterogeneous class of bone marrow-derived cells that have a marked potential to suppress immune responses via induction of deficient T cell function (Monu and Frey 2012). Two major types of MDSCs are distinguished, i.e., granulocytic MDSCs and monocytic MDSCs. Granulocytic MDSCs share many features with neutrophils, including their capability to induce angiogenesis (Brandau et al. 2013). MDSCs associated with tumors (tumor-associated MDSCs; TAMDSCs) exhibit additional functions, specifically, they can promote tumor progression, mainly through their proinvasive, proinflammatory, and proangiogenic actions (Ye et al. 2010; Condamine et al. 2015). Soluble mediators produced by inflammatory cells in tumor-associated, MDSC-induced stromal inflammation can positively affect tumor angiogenesis (Caronni et al. 2015). There is evidence that a subset of MDSCs can directly promote angiogenesis in tumors (myeloid angiogenic cells, MACs; Chambers et al. 2013). Homing of MDSCs to cancer tissue and specifically to carcinoma stroma is a complex and poorly understood process. IL-18 promotes the differentiation of bone marrow-derived progenitor cells into monocytic MDSCs (Lim et al. 2014). MicroRNA-494, upregulated by TGF-beta1, is required for the accumulation and function of tumor-expanded MDSCs through targeting of PTEN (Liu et al. 2012).

Stromal Inflammation Promotes Tumor Angiogenesis (Inflammation-Induced Angiogenesis)

Inflammatory processes are a critical component of tumor progression, and part of this component consists of inflammation-induced angiogenesis. Inflammation-associated angiogenesis is promoted by CCL2-dependent monocytes (Ehling et al. 2014) and neutrophils. Via binding to the Tie2 receptor on macrophages, Ang1 can switch macrophages to a proinflammatory phenotype (Seok et al. 2013), which in turn can exert novel functions in the tumor stroma, such as MMP secretion and production of chemokines and cytokines acting on tumor cells.

Stromal Cells as Pacemakers of Tumor Angiogenesis

In addition to immune cells/leukocytes homing to tumor stroma, stromal cells themselves affect tumor angiogenesis and lymphangiogenesis. Hepatic stellate cells/HSCs have angiogenic features in liver cancer and are themselves stimulated by HCC cells (Sancho-Bru et al. 2010). HSCs are capable to secrete VEGF-A upon stimulation by factors produced by HCC cells, including PDGF-BB (Lu et al. 2015). Generation and maintenance of integrity of tumor microvessels is influenced by perivascular alpha-SMA-positive stromal cells/myofibroblasts, originating from HSCs. Low densities of these cells in HCCs are associated with poor microvessel integrity (Wang et al. 2013).

Subsets of cancer-associated fibroblasts (CAFs) are podoplanin-positive and involved in angiogenesis and lymphangiogenesis (Pula et al. 2013). VEGFs and their receptors are also expressed on subsets of hepatic progenitor cells, VEGF being involved in the expansion of the progenitor cell niche in liver disease (Franchitto et al. 2013).

Angiogenesis in Cholangiocarcinomas

Angiogenesis plays a significant role in cholangiocarcinoma, and both tumor-associated angiogenesis and lymphangiogenesis are correlated with tumor progression (Möbius et al. 2007; Thelen et al. 2010). Several angiogenic factors expressed in other tumors also promote angiogenesis in cholangiocarcinomas (Glaser et al. 2010). In intrahepatic cholangiocarcinomas (IHC), both angiogenesis and lymphangiogenesis are induced. In these cancers, a high microvessel density (MVD) is associated with advanced primary stage and recurrence, while a high lymph vessel density was correlated with nodal spread and recurrence (Thelen et al. 2010).

VEGFs and other angiogenic factors are expressed in cholangiocarcinomas, sometimes in correlation with microvessel density (Möbius et al. 2007; Cherry-Bohannan et al. 2012). Among 33 cholangiocarcinomas, 75.6 % were VEGF positive, 36 % were positive for Ang1, 57.6 % for Ang2, and 45.5 % for thrombospondin-1, whereby VEGF and Ang2 expression was associated with higher microvessel density levels (Tang et al. 2006). In regard to VEGF expression, there are certain differences between intra-and extrahepatic cholangiocarcinomas (Wiggers et al. 2014). In extrahepatic cholangiocarcinoma, VEGF expression was an independent negative predictor of prognosis (Hida et al. 1999). The neovasculature in cholangiocarcinomas can release Ang2 into circulation, providing a novel candidate for tumor monitoring (Voigtländer et al. 2014). Tumor angiogenesis also plays a role in gallbladder cancer development and progression (Okita et al. 1998), but did not affect prognosis (Sugawara et al. 1999). In gallbladder carcinoma, HIF-1alpha- and HIF-2alpha-induced VEGF expression was correlated with angiogenesis (Giatromanolaki et al. 2006), and thrombospondin-1 expression was associated with angiogenesis in these cancers (Harino et al. 2008). VEGFs are also overexpressed in hepatic progenitor cells located to ductular reaction (Franchitto et al. 2013). Similar to HCCs, tumor-associated, alternatively activated macrophages modulate angiogenesis in that they can secrete VEGF-A and MMP-2 in these neoplasms (Hasita et al. 2010).

As in HCC, angiogenesis is counteracted by several factors, whereby the sensors monitoring the balance between angiogenesis and anti-angiogenesis have not been clarified. Endothelin-1 binding to endothelin receptors ET(A) and ET (B) expressed in cholangiocarcinoma cells decreases the expression of VEGF-A, VEGF-C, EGFR-2, and VEGFR-3 in these neoplasms (Fava et al. 2009). In cholangiocarcinomas, angiogenesis is inhibited by microRNA-101 through targeting of VEGF (Zhang et al. 2013).

Angiogenesis in Benign Nodular Hepatocyte Lesions

Focal nodular hyperplasia (FNH) is a mass-forming lesion in part caused by an abnormal vascularization and focally deranged hepatic blood flow. In FNH, Ang1 is significantly upregulated, whereas Ang2 is downregulated, with a markedly increased Ang1/Ang2 ratio, much higher than in HCC, suggesting an Ang switch. As also the Tie2 receptor is expressed in FNH, the Ang1/Tie2 system may be involved in angiogenesis in this lesion, specifically in the generation of dystrophic and hyperplastic blood vessels (Paradis et al. 2003).

Lymphangiogenesis in Liver Cancers

Introduction

The lymph vessel system and lymphangiogenesis play a central role in progression and spread of cancers, including HCC and CC (Thelen et al. 2009). The principal mechanisms of

lymphangiogenesis in tumors resemble those in angiogenesis, but several other signaling pathways are involved, and tumors possess distinct lymphatic vessel subtypes (reviews: Al-Rawi et al. 2005; Witte et al. 2006; Sundar and Ganesan 2007; Cao et al. 2013; Chung and Iwakiri 2013; Stacker et al. 2014). Lymphangiogenesis in tumors depends on proliferation and migration of lymphatic endothelial cells (LECs), processes activated by several signals, including VEGF-C, VEGFR-3, and PDGFRbeta (Chen et al. 2012). In tumors, the cellular source of VEGF-C and VEGF-D for inducing lymphangiogenesis has been identified to be a subset of macrophages located in the stroma and expressing large amounts of these two factors (Schoppmann et al. 2002). VEGFR-3 signaling is critically involved in early phases of metastasis (Matsumoto et al. 2013). PDGFRbeta is a key mediator of tumor lymphatic vessel formation and acts downstream of Prox1 (Miyazaki et al. 2014). The proinflammatory cytokine, IL-6, promotes tumor lymphangiogenesis through VEGF-C induction in tumor cells, a process modulated by Src (Huang et al. 2014). Lymphatic cell migration, protection from apoptosis, and stimulation of lymph channel formation in tumors are promoted by apelin, the ligand of the G-protein-coupled APJ receptor (Berta et al. 2014; Yu et al. 2014). Lymphangiogenesis in tumors is also promoted by stromal cancer-associated fibroblasts/CAFs upon stimulation with the chemokine CXCL14 (Augsten et al. 2014) and is regulated by the neuropilin/semaphorin signaling system (Migliozzi et al. 2014). It was suggested that cancer cells themselves, or distinct subsets thereof, are capable of producing factors that promote lymphangiogenesis. On the other hand, this process is probably also stimulated by cancer stem cells (Li and Li 2014) and various cell types located to the tumor stroma, including immune cells.

Relatively few factors are known to inhibit lymphangiogenesis in tumors. Paralemmin-1 is a filopodia-and cell spine-inducing protein belonging to the paralemmin protein family, other members being paralemmin-2 and palmdelphin (Hu et al. 2001, 2005; Arstikaitis et al. 2008). Paralemmin-1 is expressed in LECs, represses LEC migration, and delays the formation of tubelike structures of LECs (Albrecht et al. 2013). Bone morphogenetic protein-9 inhibits lymphatic vessel formation through activin receptor-like kinase 1 during cancer progression (Yoshimatsu et al. 2013). The cytokine IL-27 inhibits proliferation of LECs by STAT1-regulated gene expression (Nielsen et al. 2013). MicroRNA-26a can induce endothelial cell cycle arrest and inhibit migration by targeting BMP/SMAD1 signaling (Icli et al. 2013). Lymphangiogenesis in cancers is closely related to metastatic spread. Newly formed lymphatic vessels in and around tumors not only increase lymph flow and its transport of cellular cargo, but lymphatic endothelial cells control tumor cell entry and exit from the lymphatic channels, and interact with immune cells (see below; Podgrabisnka and Skobe 2014).

Lymphangiogenesis and Lymphatic Spread in Hepatocellular Carcinoma

In HCCs, VEGF-C expression is higher in larger tumors and those of moderate or poor differentiation and is also detectable in large venous tumor casts, suggesting VEGF-C expression to be related to tumor progression (Yamaguchi et al. 2006).

Lymphangiogenesis and Lymphatic Spread in Cholangiocarcinomas

In intrahepatic cholangiocarcinomas, a higher lymphatic vessel density was present in the periphery and peritumoral area of poorly differentiated tumors, and lymphatic invasion predominated in these two areas. Lymphatic invasion was correlated with VEGF-C expression (Aishima et al. 2008).

Role of Lymphatic Vessels Other Than Tumor Cell Transport

There is increasing evidence that lymphatic vessels in and around tumors not only act as a physical route for tumor cell spread, but also form

important components of the cancer cell microenvironment and the pro-metastatic niche. Lymphatic endothelial cells exert immunomodulatory functions and regulate adaptive immunity (Card et al. 2014). Mechanisms involved comprise T cell suppression, inhibition of dendritic cell maturation, induction of T cell tolerance, and transendothelial antigen transport (review: Swartz 2014). Lymphatic vessel endothelium cells (LECs) induce peripheral tolerance by direct presentation to CD8(+) T cells and activation of these cells, and by deletion induced via programmed cell death-1 (PD-1) ligand 1 (Tewait et al. 2012). LECs interact with dendritic cells and regulate their homing and activation (Russo et al. 2013). On the other hand, LEC function in tumors and associated lymph nodes is modulated by immune effector cells and their chemokines/cytokines (Kataru et al. 2014). Lymphatic vessels serve as conduits for immunologic effector cells, and LECs control the homing and exit of immune cells. Tumor-associated macrophages/TAMs induce lymphangiogenesis via interaction with tumor cells and secretion of VEGF-C and VEGF-A (Ding et al. 2014). Tumor-derived interleukin-1 promotes lymphangiogenesis and M2-type macrophages that promote a metastatic microenvironment (Watari et al. 2014). Lymphangiogenesis is enhanced by podoplanin-positive monocytes (PPMs) and platelets (Watson et al. 2014), in that PPMs express VEGFR3 and proangiogenic transcription factors and interact with platelets expressing the podoplanin receptor, CLEC-2. Upon this interaction, platelets secrete the lymphangiogenic cytokine, interleukin-1beta (Hur et al. 2014).

Abstract

Morphogenesis and biogenesis of new blood vessels comprise two major mechanisms, vasculogenesis and angiogenesis. Vasculogenesis denotes the de novo formation of blood vessels from progenitor cells or stem cells that home to tissues and accomplish the development of the vascular system during ontogenesis. In contrast, angiogenesis is defined as the sprouting of new blood vessels from differentiated endothelial cells present in preexistent vessels. Angiogenesis is the form of blood vessel neoformation occurring in cancers. It involves a sprouting process involving endothelial cell commitment (priming), migration, proliferation and vascular tube morphogenesis (sprouting angiogenesis), and intussusceptive microvascular growth, in which existing vessel lumina are separated and reconstructed. This complex sequence of events is regulated by an array of distinct proangiogenic factors, antiangiogenic factors, and vessel maturation factors. The remodeling of newly formed vessel networks requires tightly controlled apoptotic processes. Similar angiogenic modes, but with involvement of different angiogenic factors, operate in lymphangiogenesis.

Vasculogenesis and Angiogenesis

Definitions

Vasculogenesis denotes the de novo formation of blood vessels from progenitor cells or stem cells ("angioblasts") that home to tissues and accomplish the development of the vascular system during ontogenesis. In contrast, angiogenesis is defined as the sprouting of new vessels from differentiated endothelial cells (ECs) present in preexisting vessels.

Vascular Stem Cells in Vasculogenesis

The concept of vasculogenesis requires the availability of precursor or progenitor cells with stem cell features, either recruited from the local vasculogenic mesoderm or derived from remote cellular sources such as the bone marrow (Xu 2005; Kim et al. 2014). Cells with such characteristics are termed angioblasts or hemangioblasts (Eichmann et al. 2002; Rose et al. 2015). Locally committed hemangioblasts originating in the mesoderm operate during ontogenesis, and the offspring of stem cells is capable to home to target sites. It was, e.g., demonstrated that endothelial cells selected from differentiating mouse embryonic stem cells incorporate at sites of neovascularization (Marchetti et al. 2002). Following ontogenesis, connective tissues are the source of mesenchymal stem cells that can also give rise to vascular cells (Murray et al. 2014). Vascular stem cells show a characteristic spectrum of markers, including CD133(+), CD34(+), Soxq0, Sox17, and S100beta (Tang et al. 2012). The generation and priming of vascular stem cells, including mesenchymal stem cells, are subject to regulation mediated by several species of microRNAs (Xing et al. 2014).

Conversely, in the adult organism, cells from other sources, and in particular those derived from the bone marrow, play a significant role. The bone marrow harbors stem cells or stem-like cells, including mesenchymal stem cells and hemopoetic stem cells, which can be committed to several lineages, including the hemangioblast, a phenomenon called stem cell plasticity (Poulsom et al. 2002). Part of these proangiogenic progenitor cells are nestin-positive mesenchymal stem cells (Pacini and Petrini 2014). In the context of vascular morphogenesis, stem cell plasticity would infer that progenitor cells located outside the vascular cell compartment proper can home to preexisting vascular structures and either become a local stem cell in the new niche or be directly committed to enter a vascular cell, and in particular an endothelial cell, lineage, with so-called transdifferentiation. Currently, it is difficult to analyze which of these mechanisms is involved, requiring the tracing of a single cell (Poulsom et al. 2002) in order to test the potential somatic site of engraftment. Furthermore, several aspects of the concept of bone marrow-derived stem cells

with or without plasticity have recently been reappraised or criticized. The existence of bone marrow-derived, circulating precursor cells for endothelia has been suggested many years ago, based on the study of Barr bodies (Williams and Alvarez 1969). That circulating endothelial precursors play a role in the reconstitution of blood vessels has now been confirmed (Asahara et al. 1999; Takahashi et al. 1999; Lin et al. 2000; Nishikawa 2001; Rafii et al. 2002a; Hirschi and Goodell 2002). Endothelial cells can differentiate and expand from CD133(+) bone marrow cells, a subset of CD34(+) hematopoietic progenitors (Quirici et al. 2001; Ahn et al. 2010; Borlongan et al. 2011), but also multipotent adult progenitor cells (MAPC) with a CD34(−) phenotype and copurifying with mesenchymal stem cells from postnatal human bone marrow can give rise to cells with an angioblast phenotype (Reyes et al. 2002). The question as to the extent of the replacement of vascular endothelial cell by circulating stem cells under normal conditions (i.e., the so-called maintenance vasculogenesis) has not conclusively been settled, although several studies support this phenomenon (Gunsilius et al. 2000), also in the liver (Gao et al. 2001). There is evidence that such progenitor cells are operational mainly in situations of vascular damage, i.e., under non-maintenance conditions (Sinclair 1972; Tomita et al. 1999; Lagaaij et al. 2001). The homing to and incorporation into vessels of bone marrow-derived endothelial progenitors may depend on the local expression of distinct factors, in particular stem cell-active cytokines, in the target tissue. It has been shown that vascular endothelial growth factor increases the engraftment of such cells into the vasculature of newborn murine recipients (Young et al. 2002) and that mobilization and recruitment can be promoted by adenoviral vectors expressing angiogenic factors (Rafii et al. 2002b). The recruitment and translocation of stem and progenitor cells in and from the bone marrow require the shedding of soluble Kit ligand (sKitL) via the action of matrix metalloproteinase-9 (MMP-9), as based on experiments with MMP-9-deficient mice (Heissig et al. 2002).

Angiogenesis: The Principal Vascularization Mode in Cancers

Angiogenesis is the form of blood vessel neoformation that occurs both during development and adult life, and it characterizes most of the vessel neoformation occurring in cancers. In normal tissues, angiogenesis is involved in the remodeling, distinct structuring, and expansion of primordial networks generated by vasculogenesis. In principle, angiogenesis is based on two pathways, (1) a sprouting process involving endothelial cell commitment (priming), migration, proliferation, and vascular tube morphogenesis (sprouting angiogenesis) and (2) intussusceptive microvascular growth (IMG, intussusceptive angiogenesis), in which existing vessel lumina are separated and reconstructed by insertion or interposition of distinct tissue pillars or intervascular tissue structures and by in situ loop formation. In more detail, sprouting angiogenesis denotes the process whereby a new blood vessel branch (the sprout) develops from a preexisting vessel. Generation of a new sprout requires the presence of a distinct guiding cell which acts as a pacemaker for the new branch and determines the axis of growth. This cell is the tip cell, a motile endothelial cell localized at the tip of the new sprout. Behind tip cells, endothelial stalk cells proliferate and form the new microvessel lumen. Following VEGF signaling, the delta-like 4/Notch signaling system controls the selection of tip cells which are the guides for sprouting angiogenesis (Jakobsson et al. 2009), a process counteracted by synaptojanin-2 (Adam et al. 2013). The interactions between VEGFs and Notch have a key role in vascular patterning and in the pathways where endothelial cells compete for the tip cell position (Jakobsson et al. 2009, 2010). Tip cells express a set of distinct genes and secrete endothelial-specific molecule 1, Ang2, and apelin which bind on cognate receptors on endothelial stalk cells (del Toro et al. 2010), supporting the role of tip cells as sprouting organizers. Recruiting of new formed endothelial cells to the sprout requires, apart from cell proliferation, endothelial cell motility and

migration, a process that is critical for pattern formation during vasculogenesis (review: Czirok 2013). Migration of endothelial cells in the sprouting process is inhibited the receptor tyrosine kinase modulator, sprouty4 (Gong et al. 2013). The sprouting process also shares features with epithelial-mesenchymal transition/EMT, in that sprouting endothelial cells express the EMT-inducers, Slug and Snail (Welch-Reardon et al. 2014). Subsequent to sprouting, the new vascular sprouts require lumen formation, a process called tubulogenesis and regulated by an endothelial cell lumen signaling complex or proteins, involving MT1-MMP, collagen-binding integrin alpha2beta1, junction adhesion molecules(JAMs B and C), polarity proteins Par3 and Par6b, and the Rho GTPase Cdc42-GTP (Stratman et al. 2009; Sacharidou et al. 2012). In a first step, a network of proteolytically generated vascular guidance tunnels is produced, followed by flow-induced remodeling and arteriovenous endothelial cell sorting and differentiation (Davis et al. 2011).

Blood Vessel Maturation and Organ-Specific Vascular Morphogenesis

Following vasculogenesis and angiogenesis, further steps in the generation of a functional vascular system involve vessel maturation (recruitment of pericytes, extracellular matrix assembly, generation of smooth muscle cells, pruning of neovasculature), acquisition of vessel identity, organotypic differentiation, and assembly of vessels into networks according to distinct patterning modes. Vascular morphogenesis is closely linked to mechanisms involved in the production of intricate branching patterns in order to serve the specific needs of a given tissue or organ and to maximize the vascular surface/contact area. Patterning modes resulting in distinct vascular networks may also operate in tumor angiogenesis. So far, relatively little is known as to whether branching and pattern formation are mainly intrinsic mechanisms working via self-organized endothelial cells or whether extrinsic tissue elements are involved as well.

Perivascular Cells

Pericytes, which exist in several subtypes, are a distinct form of vascular mural cells mainly supporting venules, capillaries, and sinusoids. Together with smooth muscle cells, pericytes are critically involved in stabilizing endothelial cell-to-cell contacts and may influence vessel-type-specific differences of the endothelial phenotype (Kurzen et al. 2002). They have also been implicated in angiogenesis. Recruitment of supporting pericytes is thought to be essential for the modulation of endothelial sprout growth, vessel maturation, stability, and survival (D'Amore 1992). The vascularization switch that results in pericyte recruitment depends on a Notch1 pathway (Guichet et al. 2015). Pericytes limit the proliferative response of endothelial cells (Hirschi et al. 1998) and play a role in vascular pruning and vessel remodeling (Nguyen and D'Amore 2001), survival of blood vessels (Chatterjee and Naik 2012), and production of extracellular matrix proteins in vessels (Birbrair et al. 2014). In experiments using the chorioallantoic membrane (CAM), it surfaced that small CAM vessels exhibited ramified alpha-smooth muscle actin-negative cells with delicate desmin staining indicating the presence of pericytes, and these cells were also recruited into experimental tumor nodules during tumor angiogenesis (Kurz et al. 2002). During angiogenesis, pericytes may act as some sort of switch permitting vessel enlargement and branching: in early VEGF-induced angiogenesis, detachment of pericytes from microvessels ensues, followed by extensive vessel enlargement and generation of mother vessels, the latter subsequently differentiating along several lines into mature, pericyte-coated or myocyte-coated vessels of varying types (Sundberg et al. 2002). Several factors are involved in the recruitment of pericytes. In the embryo (but not in the adult), PDGF is involved in pericyte function (Lindahl et al. 1998). Rat pericyte-like cells respond

in vitro to TGF-beta1 (Asashima et al. 2002), and TGF-beta mediates the differentiation to pericytes (Darland and D'Amore 2001) Furthermore, it has recently been demonstrated that pericytes markedly and stably express angiopoietin-1, but not angiopoietin-2, Tie-1, or Tie-2, suggesting that the role of angiopoietin-1 in vessel maturation can be extended to vessel maturation after the phase of angiogenesis in adult tissues (Sundberg et al. 2002). Pericytes can originate from plutipotent stem cells (Orlova et al. 2014).

Vascular Smooth Muscle Cells

The maturation and the acquisition of functional capacity of blood vessels larger than capillaries and sinusoids require the production of vascular smooth muscle cells (VSMCs), specialized vascular mural cells that participate in a complex interactome with endothelial cells, pericytes, and adventitial cells. VSMCs and pericytes are critical cells for the stabilization of immature endothelial tubes. VSMCs proliferating in, and homing to, endothelial tubes migrate from the media toward the intimal layer. Similar to endothelial cells, VSMCs can originate from stem cells (Hirschi and Majesky 2004; Klein et al. 2010; Cheung and Sinha 2011; Kennedy et al. 2014; Marchand et al. 2014). Circulating CD14(+) bone marrow-derived mononuclear cells can acquire a spindle-shaped phenotype and then express VSMC-specific markers in reponse to PDGF-BB (circulating smooth muscle progenitor cells). Lineage markers include alpha-SMA, desmin, smooth muscle calponin, and myosin light chain kinase (Hegner et al. 2005). However, part of these CD14(+) progenitors become cells that co-express CD68, being "SMC-like macrophages" that are involved in inflammatory vascular reactions (Iwata et al. 2010; Daniel and Sedding 2011). The differentiation of stem cells toward a VSMC lineage is regulated by several factors, including PI3K/Akt/mTOR signaling (Hegner et al. 2009). Vascular progenitors can be primed to generate two lineages, i.e., concurrent generation of functional VSMCs and endothelial cells (Marchand et al. 2014). Apart from circulating progenitor cells, also nestin(+) tissue-resident multipotent stem cells can contribute to VSMC production (Klein et al. 2014). Vascular wall-resident CD44(+) multipotent stem cells give rise to VSMCs and pericytes (Klein et al. 2011), suggesting a lineage relationship between these two cell types.

Arteriogenesis

Arteriogenesis critically depends on a switch that decides the fate of a tip cell-driven endothelial tube to become equiped with smooth muscle cells, generates an adventitia, and synthesizes various elastin-containing lamellae. This complex sequence of events is induced and regulated by several factors. The determination of the arterial phenotype is controlled by various proteins, including ephrinB2, neuropilin-1, connexin-40 (CX40), apelin, and Alk-1. Neuropilin-1, a coreceptor for VEGF164 (Kawasaki et al. 1999), is preferentially expressed in chick arteries (Moyon et al. 2001), and CX40, a gap junction protein, is specifically expressed in murine dorsal aorta and smaller arteries during ontogenesis. Apelin, the ligand of G-protein-coupled APJ receptor, is a a widely distributed peptide with various functions in the cardiovascular system (Yu et al. 2014a). It is involved in blood vessel generation and maturation and affects both early steps of endothelial cell production and shaping and late steps of vessel maturation (Kidoya and Takakura 2012). Apelin is strongly expressed in vascular endothelial cells and labels sprouting vasculogenesis, both in normal tissues and tumors (Liu et al. 2015). Apelin also provided a link between perivascular adipose cells and endothelial angiogenic processes, in that, e.g., apelin production is augmented by hypoxia in adipose cells, thus creating an angiogenic regulation platform (Kunduzova et al. 2008). In arteries, the apelin/AJP system is expressed in endothelial cells and smooth muscle cells but is also present in periadventital adipocytes (Kostopoulos et al. 2014). Various apelin forms exert differential

function in arterial vessels. Apelin-13 regulates potassium channels in arterial smooth muscle cells (Modgil et al. 2013) and promotes smooth muscle cell proliferation via a Jagged-1/Notch3 signaling pathway (Li et al. 2013c).

Arterial differentiation occurs in association with peripheral, sensory nerves, and VEGF164 and VEGF120 are sufficient to promote expression of arterial markers in isolated embryonic endothelial cells in vitro (Mukouyama et al. 2002). Probably, these VEGF isoforms represent a permissive signal for determinants such as ephrinB2. In fact, mutant mice lacking the the 164 and 120, but not the 188, isoforms of VEGF exhibit a defect in ephrinB2 expression in vessels in vivo (Stalmans et al. 2002). Observations using the murine limb skin suggest that peripheral nerves are the source of VEGF isoforms, thus promoting blood vessel association and arterial differentiation (Mukouama et al. 2002). These authors showed that mutations eliminating peripheral sensory nerves or Schwann cells prevent proper arteriogenesis and that, in vitro, sensory neurons or Schwann cells can induce arterial marker expression (ephrinB2, neuropilin1, connexin40) in embryonal endothelial cells, VEGF 164/120 being necessary and sufficient for this specific induction. Nerves by themselves are growth stimulated by neutrotrophic factors expressed by blood vessels, including NGF, NT3, and BDNF, the latter also being a survival factor for endothelial cells (Scarisbrick et al. 1993; Francis et al. 1999; Donovan et al. 2000).

Angiogenesis: Angiogenic and Antiangiogenic Factors

Introduction

Angiogenesis critically depends on a balance between pro-and antiangiogenic factors. Biochemically, proangiogenic factors form a very heterogeneous group of molecules (Table 1) with various cellular sources and highly different mechanisms of action. Angiogenesis and antiangiogenesis are chiefly mediated by core groups of relatively few factors, while a host of other factors modulate angiogenic responses or have supplementary functions.

Table 1 Proangiogenic factors

Vascular endothelial growth factors (VEGFs) and their receptors (VEGFRs)
Angiopoietins
Angiopoietin-like proteins (Angptls)
Fibroblast growth factors
Placenta growth factor
Platelet-derived endothelial cell growth factor
Cytokines
Endoglin

Thrombomodulin
Angiomotins
Platelet-derived growth factor
Transforming growth factor-beta
Tumor necrosis factor-alpha
Hepatocyte growth factor
Leptin
Platelet endothelial cell adhesion molecule-1
Granulocyte colony-stimulating factor
Wt1 tumor suppressor
Nitric oxide

Vascular Endothelial Growth Factors

Vascular endothelial growth factors (VEGFs) control the development of the vascular system and the growth and function of blood vessels and lymphatic vessels in the adult organism (vasculogenesis and angiogenesis). VEGFs comprise five related members of homodimeric proteins, i.e., VEGF-A, VEGF-B, VEGF-C, VEGF-D, and placenta growth factor (PIGF). These five types of VEGFs are subject to further diversification through alternative splicing (VEGF-Axxxb) and posttranslational changes, such as proteolytic processing, steps that modulate the binding features to VEGF receptors, heparin sulfate and neuropilins. Several VEGFs are regulated by hypoxia and hypoxia-inducible factors (HIFs), a mechanism that is of great importance in hypoxic malignancies (review: Koch et al. 2011). VEGFs interact with three related tyrosine kinase VEGF receptors (VEGFRs),

i.e., VEGFR1, VEGFR2, and VEGFR3. The angiogenic effects of the VEGF family members are chiefly mediated by the receptor VEGFR2, while the function of VEGFR1, which is expressed in endothelial and non-endothelial cells, is less well known, although two VEGFs, VEGF-B and PIGF, exclusively bind to this receptor (review: Cao 2009). VEGF-A signaling plays a crucial role in ontogenesis through promotion of vasculogenesis and angiogenesis. It regulates proliferation and migration of endothelial cells, vascular permeability, and the selection of tip cells and stalk cells in sprouting angiogenesis and regulates organ homeostatis in adults (review: Matsumoto and Ema 2014). Conversely, VEGF-C and VEGF-D hold a central place in lymphangiogenesis (see below). Placenta growth factor (PlGF) is a member of the VEGF family that exclusively binds to VEGFR1. It is angiogenic under certain circumstances, affects vessel permeability (leakiness), is active in monocyte chemotaxis, and potentiates the activity of VEGF, participating in autocrine and paracrine regulation of angiogenesis (Yonekura et al. 1999). PIGF can activate monocytes and has arteriogenic properties through this mechanism (Pipp et al. 2003). By displacing VEGF from VEGFR-2/Flt1, which may be a non-signaling reservoir for VEGF, PlGF delivers VEGF to promote Flk-1-mediated signaling (Park et al. 1994). The somewhat controversial data relating to angiogenic activities of PlGF have been clarified by the observation that PlGF-1 acts as a natural antagonist of VEGF when both factors are synthesized in the same cell populations, via the formation of functionally inactive heterodimers (Eriksson et al. 2002). It is well known that endothelial cell lineages of various vascular systems are diverse and organ/tissue specific with respect to several features, although the response to key angiogenic factors is ubiquitous. These differences may, at least in part, depend on the vessels' microenvironment (Aird et al. 1997), and recent observations have demonstrated a peptide vascular address system (Ruoslahti and Rajotte 2000). Novel findings relevant to organ-specific angiogenic functions include the identification of endocrine-gland-derived VEGF (EG-VEGF), which is the human homolog of black mamba venom protein A or mamba intestinal toxin 1 (LeCouter et al. 2001). It may be expected that other such cell-or tissue-specific factors, including those for the liver vascular bed, will be detected, permitting an additional system of signal refinement (LeCouter et al. 2002). Several factors regulate the activity of VEGFs. The expression of VEGFs is regulated by microRNAs. MicroRNA-329 targets a coreceptor of VEGFR2, CD146, and through this mechanism suppresses angiogenesis (Wang et al. 2013). Fibroblast growth factor receptor substrate 2 (FRS2alpha) regulates VEGF-A- and VEGF-C-dependent activation of receptor kinase signaling (Chen et al. 2014a).

Angiopoietins and Related Proteins

Angiopoietins (Angs) form a family of four members (Ang1 to Ang4) and are potent inducers of angiogenesis (Thomas and Augustin 2009). Ang1–4 are ligands of the Tie2 tyrosine kinase receptor, while Tie1 is an orphan receptor which can heterodimerize with Tie2 and thus modulates Tie2 signaling (Fagiani and Christofori 2013; Barton et al. 2014). The most prominent Ang members in angiogenesis are Ang1 and Ang2. Ang1 regulates blood vessel maturation, mediates endothelial cell migration, adhesion, and survival, and also controls the stability of newly formed vessels. Specifically, Ang1 reduces number and size of endothelial gaps in venules, thus descreasing plasma leakage and stabilizing the vessels (Baffert et al. 2006). The action of Ang1 on endothelial cells depends on the relative levels of the Tie2 and the inhibitory coreceptor Tie1. Ang2 has a complex functional pattern. It disrupts connections between endothelium channels and their perivascular cells, inducing vessel cell apoptosis and vessel regression, but in cooperation with VEGF, it promotes neovascularization. In the presence of VEGF-A, Ang2 can promote vascular sprouting, while it induces vascular regression in the absence of VEGF-A (review: Fagiani and Christofori 2013). Ang2 is also involved in remodeling and stabilization of lymphatic vessels (review: Wu and Liu 2010).

The inhibitory Tie1 is cleaved and hence inactivated by VEGF, cytokines, and changes in shear stress. Cleavage of Tie1 enables Tie2 to mediate the angiogenic action of the ligand, Ang1 (review Singh et al. 2011). Ang3 (mouse) and Ang4 (human) are interspecies orthologs. Ang3 is tethered on cell surfaces through heparan sulfate proteoglycans (Xu et al. 2004). Ang4 is a third protein binding to the Tie2 receptor (Valenzuela et al. 1999). Both Ang3 and Ang4 phosphorylate the Tie2 receptor, but only Ang4 induces migration and survival in endothelial cells. Ang2 plays an essential role in liver regeneration, as it is expressed in a dynamically regulated and phase-specific manner in emerging sinusoidal endothelial cells, a cell system that serves as a pacemaker in lobule expansion. Ang2 expression is present in a later angiogenic phase of liver regeneration and controls sinusoidal VEGFR2 expression (Hu et al. 2014). A group of proteins that are structurally similar to angiopoietins are the angiopoietin-like proteins (Angptls/ALPs), encoded by eight genes (Angptls 1–8; Santulli 2014). These proteins, having a host of synonyms, form orphan ligands and have complex functions in angiogenesis and metabolism (Arca et al. 2013; Aoi et al. 2014). Angptl2 positively regulates endothelial cell colony and vascular lumen formation through its effects on cell migration (Richardson et al. 2014).

Fibroblast Growth Factors

Fibroblast growth factors (FGFs) belong to a family with more than 20 members, of which acidic FGF (aFGF) and basic FGF (bFGF) have been described in greatest detail. bFGF has a strong angiogenic capacity, and both endothelial cells produce bFGF in an autocrine manner and tumor cells release bFGF in a paracrine fashion (review: Pang and Poon 2006). FGF signaling plays a central role in both vascular formation and maintenance and is integrated in a complex regulation network (Murakami and Sakurai 2012). bFGF binds to endothelial cells via the tyrosine kinase receptors FGFR1 and FGFR2 and through heparin sulfate proteoglycans and integrins.

Endoglin

Endoglin (CD105) is a cell surface glycoprotein and member of the TGF-beta receptor complex that operates in the development of blood vessels and vascular repair (Duff et al. 2003; van Laake et al. 2006). Endoglin expression is modulated by TGF-beta and Smad3 through a distinct promoter site and is associated with betaglycan and the formation of higher order complexes with TGF-beta signaling receptors.

Ephrins

Ephrins are a family of proteins that bind the Eph/erythropoietin-producing hepatocellular receptor tyrosine kinase family. Ephrins and their Eph receptor are differentially expressed in several cell systems, including vascular endothelial cells and leukocytes. For ephrin signaling, distinct Eph receptor clusters are required (Janes et al. 2012). The known ephrins differ in their capacity to promote angiogenesis. Ephrin-B2 controls VEGF-induced angiogenesis and lymphangiogenesis via promoting the internalization of VEGFR3 (Wang et al. 2010). Ephrins and ephrin receptors also play a role in arterial versus venous phenotype decision making, in that ephrin-B2 marks the endothelium of artery precursors and EphB4 the endothelium of venous precursors (Wang et al. 1998).

Thrombomodulin

Soluble thrombomodulin is an example of a factor that maintains an angiogenic response by presenting endothelial cell loss. It is a paracrine anti-apoptotic factor for vascular endothelial cells (Chao et al. 2014). Thrombomodulin is a membrane-bound anticoagulant expressed on endothelial cells. In the course of endothelial cell

stress, thrombomodulin is released as a soluble form (Martin et al. 2013).

Neuropilin-Semaphorin Signaling System

Through a connection with VEGFs, the neuropilin-semaphorin signaling system is linked to angiogenesis and lymphangiogenesis, also in tumors (Chaudhary et al. 2014). Neuropilins are the coreceptors for class 3 semaphorins and some members of the VEGF family (Sakurai et al. 2012; Bussolino et al. 2014; Zachary 2014). Neuropilin-1 and neuropilin-2 receptors form complexes with type A plexins, which serve as signaling receptors for specific class-3 semaphorins (SEMA3). Neuropilin-2 is transcriptionally regulated by GATA-binding protein 2 (GATA2) and LIM domain only 2 (Lmo 2). Through this pathway, neuropilin-2 regulates VEGF-induced angiogenesis and lymphangiogenesis (Coma et al. 2013). Semaphorin-3A and semaphorin-3F, secreted by several tumors, cooperate to repel endothelial cells, inhibit migration, and promote their apoptosis (Guttmann-Raviv et al. 2007). Also semaphorin-3B is an angiogenesis inhibitor that is inactivated by pro-protein convertases (-Varshavsky et al. 2008). Inhibition of endothelial cell motility/migration by class 3 semaphorins works through collapse of the actin cytoskeleton via neuropilins and plexins (Gaur et al. 2009). Neuropilin-1 is upregulated in HCC and is involved in vascular remodeling (Bergé et al. 2011). In tumors, semaphorin-3F serves as an inhibitor angiogenesis (Kessler et al. 2004).

Angiogenic Factors Acting Through the Cytoskeleton and Tight Junctions and Endothelial Cell Motility

p80-angiomotin promotes angiogenesis via its simulatory action on endothelial cell migration and regulation of endothelial cell-cell junctions (Bratt et al. 2005). A splice isoform of angiomotin is p130-angiomotin, a protein that associates with actin and controls endothelial cell shape (Ernkvist et al. 2006). p80-angiomotin interacts with the protein angiomotin-like 1, a protein involved in actin cytoskeleton-based processes (Gagné et al. 2009). Angiomotin also participates in a tight junction-associated complex containing merlin, Patj, and Pals1, mediating merlin-induced regulation of mitogenic signaling and tumor suppression (Yi et al. 2011). Migration and proliferation of endothelial cells during angiogenesis also requires angiomotin-like 2, a tight junction protein which promotes MAPK/ERK activation via c-Src (Wang et al. 2011). Generally, angiomotin family proteins are activators of the LATS2 kinase tumor suppressor which is part of the Hippo signaling pathway that promotes contact inhibition of tumor cell growth by phosphorylating and inhibiting the transcriptional coactivator YAP (Paramasivam et al. 2011; Oka et al. 2012). Endothelial motility is also regulated by the cytoskeleton-associated protein, epithelial protein lost in neoplasm (EPLINalpha), an actin-regulating protein that has antiangiogenic properties (Sanders et al. 2010).

Signal Pathways as Angiogenic Factors

Transforming growth factor-beta (TGF-β) has been reported to play an important role in inducing angiogenesis, mainly in cancers (Pepper 1997a), modulated by the action of angiotensin II and its type 1 receptor, AT1R (Miyajima et al. 2002). Also integrins are involved in angiogenesis (Hynes 2002). A major regulator of tumor angiogenesis is the Wilms tumor suppressor Wt1, expressed in various cancers (Wagner et al. 2014). Wt1 promotes endothelial cell proliferation and migration via activation of the ETS-1 transcription factor (Wagner et al. 2008). Prostaglandins can induce the proliferation of endothelial cells in vitro and in vivo (Form and Auerbach 1983), mainly mediated by the induction of VEGF (Majima et al. 2000). Kinins, potent vasoactive peptides generated from high molecular kininogen via activation of the intrinsic coagulation/kallikrein system, can promote prostaglandin release and induce vascular cell proliferation. Kininogens, a substrate for kallikrein, are present

in vascular smooth muscle cells (Okamoto et al. 1998), and tissue kallikreins (kallikrein-like proteases) are also active in vessel walls (Saed et al. 1990). This question has been studied in more detail by the use of a rat model, the kininogen-deficient Brown Norway Katholiek rat. These mutant rats lack the capacity for kinin generation, related to their inability to secrete relevant kininogen moieties from the liver. Angiogenesis is significantly suppressed in these animals, suggesting that endogenous kinin generated from the tissue kallikrein-kinin system may enhance angiogenesis in several situations (Hayashi et al. 2002), probably via B1 and B2 receptor signaling.

Angiogenesis: The Role of Matrix Metalloproteinases

One important role of microvascular endothelial cells is to actively remodel the extracellular matrix (ECM), including basement membranes. On the other hand, the ECM exerts an impact on the layout of the microvasular system, including the generation of typical vascular networks. Proliferating and migrating endothelial cells must be enabled to grow along ECM components, involving attachment mechanisms and matricolytic capacities (Pepper 1997b). In this remodeling process, metalloproteinases (MMPs) play a significant role. Synthesis, secretion, and ectivation of MMPs go in parallel with the migratory and invasive behavior of endothelial cells, but the mechanisms involved in the regulation of vessel-associated MMPs are only partially clarified. Recently, it has been elucidated that strain exerted by hemodynamic forces (blood pressure, vessel wall tension, and shear stress), known to be strong stimuli for vascular morphogenesis, can act via the MMP cascade (Haas et al. 2000). Levels of Egr-1, a zinc finger immediate-early response transcription factor, are increased upon endothelial cell shear stress, and this Egr-1 response is mediated by the extracellular signal-related kinase 1/2 mitogen-activated protein kinase pathway (Schwachtgen et al. 1998). Egr-1 is known to be an important activator for several ECM genes playing a role in vascular morphogenesis, including PDGF A and B, TGF-beta, and MMPs, and putative nucleotide recognition elements for Egr-1 appear in the promoters of MT1-MMP (Haas et al. 1999). By the use of rat microvascular endothelial cells, it surfaced that cyclic strain upregulates the Egr-1-mediated expression of MT1-MMP, thus supporting the view that hemodynamic parameters exert a regulating role in vascular morphogenesis (Yamaguchi et al. 2002).

Hypoxia-Induced Angiogenesis: Oxygen Sensing and Hypoxia-Related Pathways

Hypoxia and oxygen sensing play a central role in pathways leading to angiogenesis (Fraisl et al. 2009). Hypoxia-inducible factor-1 (HIF-1) is a transcriptional complex controlling homeostatic responses to tissue oxygen availability and acting as an oxygen sensor. An αβ heterodimeric complex, HIF-1α, is the oxygen-regulated subunit of HIF-1. While HIF-1α is stable in hypoxia, oxygen presence targets it to the proteasomal degradation pathway via the ubiquitination complex pVHL, the protein of the von Hippel-Lindau (VHL) tumor suppressor gene and a component of an E3 ubiquitin ligase complex. The E3 ligase complex involved in HIF-1α capture (VCB E3 ligase) consists of pVHL, elongins B and C, Cul (cullin)2, and Rbx1. Capture is regulated by hydroxylation of specific prolyl residues in two functionally independent regions of HIF-1α, this hydroxylation being accomplished by a group of 2-oxoglutarate-dependent nonheme dioxygenases, and there is a single, conserved hydroxyproline-binding pocket in pVHL (Hon et al. 2002).

Antiangiogenesis

Antiangiogenic Factors

The process of angiogenesis depends on a delicate balance between the effects of pro-and antiangiogenic factors. Numerous molecules counteracting angiogenesis have been identified (Table 2).

Table 2 Antiangiogenic (angiostatic) factors

Thrombospondin-1
Endostatin
Angiostatin
Angiomotins
Fibstatin
Vasohibin
Decorin
Angioarrestin (angiopoietin-like protein 1)
Properdistatin
Interleukin-12
Tissue inhibitor of metalloproteinase 1, 2
Macrophage metalloelastase
Interferons
Parathyroid hormone-related peptide

The Thrombospondin Family

The thrombospondin (TSP) family consists of five glycoproteins with various functions. Thrombospondins 1–5 form two subgroups. Subgroup A contains the homotrimers thrombospondins 1 and 2, while subgroup B consists of the homopentameric thrombospondins 3, 4, and 5. TSP1 and TSP2 are secreted ECM proteins of the matricellular protein group, i.e., proteins without a primary structural role in the ECM but rather a modulator function. TSP1 and TSP2 have several functions, including antiangiogenesis (Lawler 2000, 2002; Qin et al. 2014), and exert their effects through CD36, CD47, and integrins. CD36 and beta1 integrin receptors associate with VEGFR2 and form a platform regulating angiogenesis, the thrombospondin interactome (Lawler and Lawler 2012; Resovi et al. 2014). TSP1 activates latent TGF-beta1 and is a potent chemotactic factor for neutrophils and monocytes (Mansfield and Suchard 1993, 1994). Double-TSP1/TSP2-null mice in comparison with the single-null mice exhibited an apparent phenotype representing the sum of the anomalies seen in single-null mice, but double knockouts displayed a hypovascular repair tissue in wound healing, similar to TSP1-null mice, and different from TSP2-null mice, which exhibit a hypervascular healing response, suggesting a predominating role of TSP1 in repair neovascularization and differential spatial and temporal expression patterns of TSP1 and TSP2 (Agah et al. 2002).

Endostatin

Endostatin, a 20 kDa COOH-terminal fragment of collagen type XVIII, is a potent antiangiogen (O'Reilly et al. 1997; Fu et al. 2009). It blocks in vitro endothelial cell migration, promotes cell cycle arrest, and induces apoptosis (Dhanabal et al. 1999), but it also affects non-endothelial cells, e.g., renal branching morphogenesis and tubulogenesis (Karumanchi et al. 2001), the latter phenomenon also showing up in the clinical situation of Knobloch syndrome, where a truncated collagen type XVIII lacking the endostatin fragment occasionally produces abnormal renal collecting ducts (Sertie et al. 2000). In the setting of antiangiogenesis, endostatin has nucleolin as its receptor (Shi et al. 2007). The pathways of endostatin signaling have only partially been elucidated so far, but impinging of the Wnt signal pathway is involved. In *Xenopus* embryogenesis, endostatin at high levels suppresses Wnt-dependent transcription and stimulates proteasome-mediated degradation of beta-catenin in a Siah 1 protein-independent manner, and the endostatin-induced inhibition of endothelial cell migration and S phase entry is rescued by the downstream transcriptional activator, (TCF)-VP16 (Hanai et al. 2002). The role of endostatin as an antiangiogenic factor has also been demonstrated in the C3(1)/SV 40 transgenic murine model of tumor angiogenesis inhibition (Yokoyama et al. 2000; Calvo et al. 2002) and in antiangiogenic therapy employing a recombinant adenovirus to elevate systemic endostatin levels (Feldman et al. 2000).

Angiostatin

Angiostatin is a potent inhibitor of angiogenesis. It binds to and inhibits the cell surface protein p80-angiomotin, a proangiogenic scaffold protein that increases motility and migration of endothelial cells through its phosphorylation-dependent

action of the actin cytoskeleton (Dai et al. 2013). Angiomotins belong to the motin family of proteins, which also contains angiomotin-like A and angiomotin-like 2 (Bratt et al. 2002; Chan et al. 2013; Moleirinho et al. 2014). Angiostatin inhibits endothelial MMP-2 and MMP-14 expression in a hypoxia-dependent manner (Radziwon-Balicka et al. 2013). Apart from endothelial cell, angiostatin also inhibits the activation and migration of neutrophils (Aulakh et al. 2014).

Fibstatin

Fibstatin, an antiangiogenic factor, is an extracellular FGF-2-binding polypeptide with fibronectin domains (Bossard et al. 2004). Fibstatin cooperates with CXCL4L1 to inhibit angiogenesis and lymphangiogenesis (Prats et al. 2013).

Vasohibins

Vasohibins form a protein family that inhibit migration, proliferation, and network formation by endothelial cells and downregulate angiogenesis in vivo (Watanabe et al. 2004; Sato and Sonoda 2007). Vasohibin is induced by VEGF, suggesting a regulatory loop for angiogenesis versus angiostasis (Shimizu et al. 2005).

Decorin and Other Antiangiogenic Factors

Decorin, a small leucine-rich proteoglycan of the extracellular matrix, inhibits angiogenesis through induction of an autophagic program for endothelial cells resulting in endothelial cell depletion (Neill et al. 2013). By the use of a homology-based gene mining approach, an angiopoietin-related cDNA identical to angiopoietin-like protein 1 has been isolated and the gene product shown to be an antiangiogenic protein, termed angioarrestin (Dhanabal et al. 2002, 2005). The recombinant protein was found to block several steps in the angiogenic cascade, including endothelial cell proliferation, migration, tubular network formation, and adhesion to ECM proteins. A further angiogenesis inhibitor is parathyroid hormone-related peptide or a ten-amino-acid peptide from its N terminus, inhibiting endothelial cell migration in vitro and angiogenesis in vivo by activating endothelial cell protein kinase A (Bakre et al. 2002).

MicroRNAs as Regulators of Angiogenesis and Vasculogenesis: The Critical Roles of AngiomiRs

Several endothelial cell functions and angiogenic pathways are critically regulated by microRNAs (miRs), such as miR-27a/b, miR-126, the miR-17-92 cluster, miR-200b, and miR-93 (Urbich et al. 2008, 2012; van Solingen et al. 2009; Bonauer et al. 2010; Yao et al. 2015). Proangiogenic miRs are termed AngiomRs. Part of miRs involved in angiogenesis are induced by angiogenic stimuli, including hypoxia. Hypoxia is a strong inducer of angiogenesis and in part acts via increased endothelial expression of proangiogenic miRs (Madanecki et al. 2013). Hypoxia-responsive miRs target argonaute 1, which anchors the miR-induced silencing complex (miRISC) to promote angiogenesis (Chen et al. 2013). MiRs are also involved in the regulation of angiogenic progenitor cells, which exploit distinct miR modalities (Chang et al. 2014). AngiomiR-126 expression affects circulating CD34(+) mononuclear cells to have proangiogenic features (Mocharla et al. 2013). MiR-126 modulates angiogenic growth of endothelial progenitors circulating in blood (Goerke et al. 2015). The angiogenesis-regulating potential of mesenchymal stem cells, which can give rise to endothelial progenitors, is inhibited by miR-494 (Chen et al. 2015). Certain miRs directly interact with angiogenic factors. MiR-199b modulates vascular cell fate by targeting the Notch ligand Jagged1 and enhancing vascular endothelial growth factor (VEGF) signaling (Chen et al. 2014b). MiRs are involved in a late step of angiogenesis, i.e., blood vessel stabilization. This process is promoted by miR-143/145, a microRNA that is transferred from smooth muscle

cells to endothelial cells by the action of TGF-beta (Climent et al. 2015). Factors critically active in miR synthesis by themselves affect angiogenesis, e.g., Dicer and Drosha, which promote endothelial miR expression (Kuehbacher et al. 2007). Apart from proangiogenic actions of miRs, certain miRs counteract angiogenesis or are true antiangiogenic factors. Members of the miR-17-92 cluster exhibit a cell-intrinsic antiangiogenic function in endothelial cells (Doebele et al. 2010). MiRs are also involved in pathways leading to the release of exosomes by endothelial cells. For example, endothelial cells require miR-214 to produce progangiogenic exosomes (van Balkom et al. 2013).

The exchange of proangiogenic miRs in angiogenic tissue areas is complex and involves several cell types. Macrophages are active in the transfer of miRs and can traffick signals among cells of their vicinity (Ismail et al. 2013).

Role of Macrophages, Tie2-Expressing Angiogenic Monocytes, Other Leukocytes, and Stromal Cells in Angiogenesis

Monocytes, Macrophages, and Myeloid-Derived Suppressor Cells as Proangiogenic Cells in Normal Tissues

There is increasing evidence that monocytes, macrophages, and myeloid-derived suppressor cells play an important role in angiogenesis. The role of these cell systems in angiogenssis has been elucidated by studying vascular recovery in irradiated tumor microenvironments, a situation where also a contribution of bone marrow-derived monocytoid cells can be observed (Russell and Brown 2013). Immune cells such as monocytes and macrophages can secrete several angiogenic and lymphangiogenic factors (David Dong et al. 2009; Jaipersad et al. 2014; Loffredo et al. 2014). A main execution pathway is mediated by macrophage-derived chemokines, in particular members of the CXC and CC chemokine families that are potent inducers of angiogenesis, while a group of CXC chemokines are angiostatic (Owen and Mohamadzadeh 2013). Macrophages can commit endothelium-derived progenitor cells to angiogenesis (Zordan et al. 2014). Subsets of monocytes/macrophages express Tie2 and are therefore capable to respond to angiopoietins. Monocytes with angiogenic features are recruited to the operational site via LRP1/LDL receptor-related protein, an endocytic and cell-signaling receptor regulating cell migration (Staudt et al. 2013). A large reservoir of monocytes with angiogenic properties is the expanding adipose tissue compartment (Navarro et al. 2014). Macrophage colony-stimulating factor increases Tie2-expressing monocyte differentiation and angiogenic function (Forget et al. 2014). Ang1 stimulates monocytes/macrophages followed by TNF-alpha expression and a proinflammatory action, suggesting that Ang1 transforms macrophages toward a proinflammatory phenotype (Seok et al. 2013). Angiopoietin-2 (Ang2) regulates gene expression in Tie2-expressing monocytes, increasing their proangiogenic capacity (Coffelt et al. 2010). There are subsets of leukocytes that can exert antiangiogenic functions. A subpopulation of monocytes are myeloid calcifying cells, procalcific cells expressing osteocalcin. These cells overexpress thrombospondin-1 and inhibit angiogenesis (Menegazzo et al. 2013). Macrophage-derived factors inducing or modulating angiogenesis in normal tissues and tumors are delivered either by secretion into the pericellular fluid or from the cargo of exosomes/microvesicles. MicroRNA-150 which promotes capillary tube formation is transferred from monocytes to endothelial cells by microvesicles (Li et al. 2013b).

Stromal Cells: Role in Angiogenesis and Partners of Endothelial to Mesenchymal Transition (EndoMT)

Cells of the tumor stroma can affect angiogenesis and antiangiogenesis. An important role is played by cancer-associated fibroblasts (CAFs), myofibroblasts, and hepatic stellate cells, all of which can interact with endothelial cells and

their progenitor cells. Tumor-activated hepatic stellate cells can exert a proangiogenic role via hypoxic induction of VEGF in these cells (Olaso et al. 2003). There is also evidence that connective tissue cells or stromal cells can become a source of endothelial cells. Multipotency factors such as Okt4 and Klf4 can convert fibroblasts to functional endothelial cells (Li et al. 2013a). On the other hand, endothelial cells can be converted to mesenchymal cells, a process termed endothelial to mesenchymal transition (EndoMT/EndMT) (Rieder et al. 2011; Lin et al. 2012; Piera-Velazquez and Jimenez 2012). EndoMT is induced by TGF-beta mediated by microRNA-21 (Kumarswamy et al. 2012). EndoMT may be involved in the acquisition of stem cell characteristics, because conversion of endothelial cells can result in several mesenchymal lineages, including fibroblasts, mural cells, osteoblasts, chondrocytes, and adipocytes (Medici and Kalluri 2012).

Exosomes and Microvesicles in Angiogenesis

Exosomes derived from myeloid-derived suppressor cells, macrophages, and T lymphocytes carry active proteins and miRs that modulate angiogenesis (Ribeiro et al. 2013; Burke et al. 2014). Exosomal cargo can also induce apoptosis and autophagy (Baixauli et al. 2014). Exosomes can carry active matrix metalloproteinase-1 and via this pathway promote angiogenesis (Hakulinen et al. 2008). Exosomal constituents can also positively affect endothelial cell growth and angiogenesis by promoting cell survival, e.g., via the transport and release of survivin (Khan et al. 2015). Exosomes containing Delta-like 4 (Dll4), a membrane-bound Notch ligand, induce capillary sprout retraction by regulating stalk cell and tip cell biology (Sharghi-Namini et al. 2014). Apart from leukocytes, CD34(+) progenitor cells primed to become endothelial cells release exosomes that exert paracrine proangiogenic activities (Sahoo et al. 2011). The transfer of angiogenic exosomes from cell sources to target cells is complex and is not a passive process. Sortilin, a multifaceted receptor also termed neurotensin receptor 3, mediates the release and transfer of exosomes through assembly of a tyrosine kinase receptor complex (the TES complex) found in exosomes and characterized by the linkage of the two tyrosine kinase receptors TrkB and EGFR with sortilin (Wilson et al. 2014). Part of exosomal cargos mediating angiogenesis are microRNAs (miRs). Exosomes released under hypoxic condition can contain miR-135b which regulates cell-to-endothelial-cell communications in angiogenesis (Fan 2014). Exosomes can also carry mitochondrial DNA (Guescini et al. 2010) which may modulate angiogenesis by its proinflammatory actions.

General Aspects of Lymphangiogenesis

In contrast to blood vessels, the lymphatic vascular system is not a closed- but an open-ended and one-way transit system, which has an impact on ontogenic mechanisms of lymphangiogenesis. According to Sabin's model (the centrifugal model), primitive lymph sacs take their origin from endothelial cells budding from early venous vessels, the peripheral lymphatic system then spreading from these primordial sacs by sprouting (Sabin 1904). On the other hand, lymph vessel cells may arise independently from peripheral mesenchyme surrounding the lymph sacs (the centripetal model; Kampmeier 1969). In particular (and similar to blood vessel morphogenesis) it has been proposed that cells of lymphatics derive from stem-like precursor cells, the so-called lymphangioblasts, shown to contribute to centripetal lymphangiogenesis in chimeric quail-chick embryos (Schneider et al. 1999; Wilting et al. 2000a, b). There is evidence that bone marrow-derived mesenchymal stem cells drive lymphangiogenesis (Maertens et al. 2014). Lymphangioblasts are also present in the avian chorioallantoic membrane and express a lymphangiogenic switch gene, Prox1 (Papoutsi et al. 2001). In the setting of normal lymph vessel development, lymphangioblasts or lymphatic

endothelial cell (LEC) precursors upregulate lymphatic vessel endothelial hyaluronan receptor-1 (LYVE1), followed by induction of the transcription factor SOX18. SOX18 promotes Prox1 expression, the first marker of LEC priming. The future LECs retain VEGFR3, defining VEGFR3+ abd CD34+ lymphatic progenitor cells (Tan et al. 2014). The progenitor cells express neuropilin-2, rendering these cells capable to respond to VEGF-C signaling coming from adjacent mesenchymal cells. LECs expand under the induction of VEGF-C and also VEGF-D (Tammela and Alitalo 2010).

Novel and in particular molecular aspects of lymphangiogenesis have been reviewed, particularly with respect to tumor lymphangiogenesis (Witte et al. 2001; Partanen and Paavonen 2001; Alitalo and Carmeliet 2002; Stacker et al. 2002; Jussila and Alitalo 2002; Achen and Stacker 2006; Ji 2006; Karpanen and Alitalo 2008; Tammela and Alitalo 2010). Major achievements in our knowledge on critical factors and their signaling pathways in lymphangiogenesis are related to transgenic mouse models, including VEGF-C transgenic mice, soluble VEGFR-3 transgenic mice, mice with enhanced VEGF-C and VEGF-D activity, Ang2 knockout mice, and Prox1 null mice. Apart from these "classical" mediators of lymphangiogenesis, other factors are involved, including Notch signaling, bone morphogenetic proteins, Ras, mitogen-activated protein kinase, PI3 kinase pathway, calcineurin signaling, and endothelin-1 (Rosano et al. 2013; Caprara et al. 2014; Coso et al. 2014; Zheng et al. 2014b). The complexity of lymphangiogenesis is underlined by the finding that cells other than LECs are involved in the process, including macrophages and neutrophils. In inflammatory lymphangiogenesis, neutrophils contribute to lymphatic vessel formation via secreting VEGF-D and increasing bioavailability of VEGF-A (Tan et al. 2013).

Among the members of the VEGF family, two are critically implicated in lymphangiogenesis, i.e., VEGF-C and VEGF-D. VEGF-C regulates the growth of lymphatic vessels and is produced as a preprotein, which is proteolytically cleaved, the processed forms (homodimers of the VEGF homology domains) having sequentially increased affinity for VEGFR2 and VEGFR3 (Joukov et al. 1997). The signals of VEGF-C, acting on blood vessel endothelia via VEGFR-2 and on lymphatic vessels via VEGFR-3, promote the migration and proliferation of the respective endothelial cells and induce vascular permeability (review: Stacker et al. 2002). The expression of VEGF-C does not appear to be regulated by hypoxia (Enholm et al. 1997) but rather by proinflammatory cytokines (Ristimaki et al. 1998). In mouse embryos, a paracrine expression pattern is observed between VEGF-C and VEGFR-3 at sites of the first detectable lymphatic sprouts, suggesting a critical role of VEGF-C in early phases of lymph vessel development (Kukk et al. 1996; Lohela et al. 2009). The overexpression of VEGF-C in the skin of VEGF-C transgenic mice results in lymphatic vessel hyperplasia (Jeltsch et al. 1997), and VEGFR-3 signaling alone is sufficient for this effect, based on experiments with a mutant VEGF-C exclusively binding to VEGFR-3 (Veikkola et al. 2001). However, VEGF-C exerts its specific actions on lymphatics only when cells are already primed for a lymphatic endothelial lineage because, in the chorioallantoic membrane model, VEGF-C will promote angiogenesis in phases where lymphatic vessel cells are not yet present (Oh et al. 1997). For its activity, VEGF-C requires proteolytic cleavage by ADAMTS-3, a step stimulated by collagen-and calcium-binding epidermal growth factor domains 1 (CCBE1), mutated in Hennekam lymphangiectasia-lymphedema syndrome (Jeltsch et al. 2014). The cleaved, mature form of VEGF-C can bind to VEGFR-2 and has an increased affinity for VEGFR-3. Receptor dimerization determines which type of vessel formation ensues: Binding of dimeric VEGF-C stimulates receptor dimerization, whereby VEGFR-3/VEGFR-3 homodimers promote lymphangiogenesis, while VEGFR-2/VEGFR-3 heterodimers promote (hem)angiogenesis. Internalization of the VEGFR3 receptor is modulated by the Slit2/Robo4 pathway (Yu et al. 2014b). Apart from VEGF-C, VEGF-

D is a potent pro-lymphangiogenic molecule that depends in its function on a SOXF-mediated transcriptional network (Duong et al. 2014). The expression of VEGFR-3, mutations of which have been linked to human hereditary lymphedema, becomes restricted chiefly to developing lymphatic vessels after midgestation. The binding sites of VEGF and VEGF-C in mouse embryos overlap in early ontogenesis, later to diverge to target blood and lymph vessel systems, respectively, in parallel with lymphangiogenesis (Lymboussaki et al. 1999). The VEGF/VEGFR system acting in lymphangiogenesis is inhibited by several mechanisms. Tumor lymphangiogenesis can be suppressed by blocking VEGFR-3 signaling (He et al. 2002). The MMP family member, ADAMTS1, inhibits lymphangiogenesis by attenuating phosphorylation of the LEC-specific VEGF receptor (Inagaki et al. 2014). Blockade of the VEGFR-3 signal pathway also inhibits fibroblast growth factor-2-induced lymphangiogenesis (Kubo et al. 2002).

Apart from certain forms of VEGF, angiopoietins are also involved in lymphangiogenesis. Deficiency of angiopoietin-2 causes abnormal lymphatic vessels, while induced overexpression in animals promotes lymphatic hyperplasia. The main function of angiopoietin-2 in lymphatic vessels is the regulation of interendothelial cell-cell junctions (Zheng et al. 2014a). An important role in the fating of early endothelial cells to become lymphatic endothelia is played by the homeobox gene, Prox1. In the mouse, Prox1 is expressed in a subpopulation of endothelial cells that, after budding from early veins, gives rise to lymphatics. In Prox1-null mice, budding and sprouting of lymphatic cells are not affected in a first phase, but are prematurely arrested, and these mice are then devoid of lymphatic vasculature (Wigle and Oliver 1999). In experiments with Prox1-null mice, budding and migration of endothelial cells from the cardinal vein are no longer polarized, following a random path, and these cells switch in differentiation to a blood vessel phenotype (Wigle et al. 2002), suggesting that Prox1 is a key gene maintaining budding and sprouting of future lymphatic endothelia and hence determining a lymphatic fate.

Staging of Liver Cancer

Staging of Hepatocellular Carcinoma, Hepatoblastoma, and Cholangiocarcinomas

188

Contents

Abstract

Staging of hepatocellular carcinoma (HCC) and other hepatobiliary cancers is critical for optimal treatment and a complex task that depends on multiple factors, such as tumor extent at diagnosis and liver function. In recent years, several staging systems have been developed that have markedly improved the methods to arrive at optimal risk stratification procedures and the formulation of novel treatment approaches. However, still no single staging system is successfully applicable to any patient with hepatobiliary cancer. Apart from HCC, intricate and highly reproducible staging systems have been developed for extrahepatic cholangiocarcinoma, intrahepatic cholangiocarcinoma, and hepatoblastoma.

Staging of Hepatocellular Carcinoma

Introduction

Staging of HCC is critical for guiding optimal treatment and a complex task that depends on multiple factors, including tumor extent at diagnosis and liver function. This has led to a situation in which no single staging system is successfully applicable to any patient with HCC (Burns and Greene 2005; Pons et al. 2005; Vauthey et al. 2010; Maida et al. 2014). For example, the AJCC/UICC system is suitable for predicting outcome following resection or transplantation,

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_188

while the Barcelona Clinic Liver Cancer scheme is useful in the assessment of patients with advanced, unresectable HCC.

Staging Systems

Several staging systems and classifications for HCC have been proposed and established (Tables 1 and 2).

The most often used staging systems for HCC include the Okuda staging classification (Okuda et al. 1985), CLIP (the Cancer of the Liver Italian Program, a primary staging system for HCC; No authors 1998; modification, Huo et al. 2006), GRETCH system (Chevret et al. 1999), Barcelona Clinic Liver Cancer staging classification (BCLC; Llovet et al. 1999), Chinese University Prognostic Index (CUPI; Leung et al. 2002), Vauthey staging system (Vauthey et al. 2002), Japanese Integrated Staging (JIS; Kudo et al. 2003; modified: Nanashima et al. 2006), SLiDe score (Omagari et al. 2004), Tokyo score (Tateishi et al. 2005), American Joint Committee on Cancer (AJCC) TNM system (seventh edition, TNM-7; Sobin et al. 2009a, b; Edge et al. 2010), Taipei Integrated Scoring system (Hsu et al. 2010), and Hong Kong Liver Cancer staging system (Yau et al. 2014).

Table 1 Staging systems and classifications for hepatocellular carcinoma: overview

Okuda staging classification
CLIP score (Cancer of the Liver Italian Program score)
GRETCH
BCLC (Barcelona Clinic Liver Cancer) staging classification
CUPI (Chinese University Prognostic Index)
Vauthey staging system
Japanese staging system and JIS (Japan Integrated Staging) score
SLiDe score
Tokyo score
AJCC/UICC
Taipei Integrated Scoring system
Hong Kong Liver Cancer staging system

The Okuda classification was widely used and includes parameters related to the liver functional status (albumin, bilirubin, ascites) and to tumor stage, i.e., more or less than 50 % of liver area involved. End-stage patients are Okuda stage III. CLIP contains a combination of four variables that provide a seven-stage classification.

BCLC B denotes intermediate stage of HCC in the BCLC staging system, a highly heterogeneous patient group whereby patients present with varying tumor burden and liver function, often treated with transarterial chemoembolization (TACE). Due to the inherent difficulties to characterize intermediate-stage HCCs, an expert panel has proposed four substages, B1–B4, to better describe and stratify these tumors (Bolondi et al. 2012). The French GRETCH system combines five variables (portal invasion, AFP, bilirubin, alkaline phosphatase, and the Karnofsky health status) that stratify patients into three stages. The Vauthey staging encompasses a simplified staging relying on the TNM system with a simplified T classification; in addition, it incorporates the presence and degree of fibrosis on liver biopsy. The JIS score is based on the Liver Cancer Study Group of Japan (LCSGJ) and combines Child-Pugh grade (grade A, score 0; grade B, score 1; grade C, score 2) and TNM staging by the LCSGJ criteria (stage I, score 0; stage II, score 1; stage III, score 2; stage IV, score 3). The SLiDe scoring system is a combined approach based on stage (S), liver damage (Li), and des-gamma-carboxyprothrombin (De), whereby stage and liver damage are used as in the revised fourth edition of the Japanese staging system edited by the Liver Cancer Study Group of Japan. The AJCC/UICC TNM-7 (seventh edition; Table) staging system is particularly suitable for classifying early HCC (Cheng et al. 2011). A modified TNM-7 has been proposed for patients undergoing hepatectomy, based on the observation of no difference between pT3a and pT4, but pT3b patients having a worse outcome than those with pT4. The authors proposed to combine current pT3a and pT4 together as a new pT3 and to change pT3b to a new pT4 (Huang et al. 2013).

Table 2 Criteria and parameters of HCC staging systems (selection)

Okuda staging classification		
Positive features		
Tumor involving >50 % of the liver		
Ascites		
Albumin <3 g/dl		
Bilirubin >3 mg/dl		
Stage I		No positive features
Stage II		One or two positive features
Stage III		Three or four positive features
CLIP score		Score
Child-Pugh stage		
A		0
B		1
C		2
Tumor morphology		
Uninodular and extension = <50 %		0
Multinodular and extension = <50 %		1
Massive or extension >50 %		2
Alpha-fetoprotein (ng/dl)		
<400		0
= >400		1
Portal vein thrombosis		
No		0
Yes		1
BCLC		
Stage A (early HCC)		
A1 PST 0	Single tumor	No portal hypertension, normal bilirubin
A2 PST 0	Single tumor	Portal hypertension, normal bilirubin
A3 PST 0	Single tumor	Portal hypertension, abnormal bilirubin
A4 PST 0	Three tumors, all <3 cm	Child-Pugh A-B
Stage B (intermediate HCC)		
PST 0	Large multinodular	Child-Pugh A-B
Stage C (advanced HCC)		
PST 1–2	Vascular invasion or extrahepatic spread	Child-Pugh A-B
Stage D (end-stage HCC)		
PST 3–4	Any	Child-Pugh C
PST: performance status test

Stage IIIC	T4	N0	M0
Stage IVA	Any T	N1	M0
Stage IVB	Any T	Any N	M1

On the other hand, another study found no survival difference between patients with T3a and T3b tumors nor between those with T3b and T4 tumors, while tumor multiplicity, bilobar disease, tumor size >5 cm, and microvascular invasion were potent prognosticators (Chan et al. 2013). The Taipei Integrated Scoring system is based on the calculated total tumor volume and specifically showed prognostic ability when used in combination with Child-Turcotte-Pugh and AFP levels (Hsu et al. 2010). The Hong Kong Liver Cancer staging system includes patient performance status, Child-Pugh grade, tumor status (size, number of nodules, presence of intrahepatic vascular invasion), and presence of extrahepatic vascular invasion or metastasis.

Prognostic Value of Staging Systems

The various staging systems have been analyzed in comparative investigations in regard to their prognostic value (Kudo et al. 2004; Huang et al. 2005; Marrero et al. 2005; Cillo et al. 2006; Kee et al. 2007; Minagawa et al. 2007; Chun and Ahn 2011; Maida et al. 2014; Zhang et al. 2014). In a cohort of US patients of any stage, the BCLC revealed the best independent predictive power for survival when compared with TNM, CLIP, CUPI, JIS, GRETCH, and Okuda (Marrero et al. 2005), and a similar conclusion was drawn by Kim and coworkers (2012). In a comparative analysis of the prognostic values, the seventh AJCC staging system (TNM-7 system) revealed better prognostic power than the sixth for patients with HCC but not better than that of the BCLC system, the AJCC system being capable to adequately stratify early HCC cases, but having lower prognostic power in advanced-stage HCC (Minagawa et al. 2007; Chun et al. 2011; Chan et al. 2013). By comparing the JIS system, TNM sixth edition system, LCSGJ criteria, CLIP, Advanced Liver Cancer Prognostic System (ALCPS), GRETCH scoring, CUPI, Okuda scoring system, Tokyo scoring system, and BCLC, ALCPS, CLIP, and CUPI were the preferred scoring systems for the prediction of overall survival and 3-month

survival in patients with advanced HCC (Li et al. 2013). Distinct HCC stages are associated with varying frequencies of extrahepatic metastases (EHM). For the modified AJCC/UICC stages T1, T2, T3, and T4, the frequencies of EHM in 314 newly diagnosed HCCs were 0 %, 7.6 %, 25.0 %, and 27.0 %, respectively (Yi et al. 2013).

Molecular Staging Systems

In addition to staging systems based on morphologic parameters, tumor classifications referring to distinct molecular features of HCC are currently developed. Molecular signatures will be employed to refine stratification of HCC stages so far defined in order to improve treatments, including the future generation of personalized therapies. By integrating plasma insulin-like growth factor-1 (IGF-1) concentration into the CLIP score (a strategy called I-CLIP), an improved stratification of patients with unresectable HCC could be obtained (Kaseb et al. 2011a, b). The Glasgow Prognostic Score is an inflammation-based prognostic score (inflammation-based index, IBI) that can serve as an independent marker for poor prognosis in patients with HCC in various stages of disease (Pinato et al. 2012; Kinoshita et al. 2013). Combined determination of AFP mRNA and vascular endothelial growth factor (VEGF) proved to be prognostically accurate for discriminating risk of death (ROC) and survival probability estimated by Cox analysis (Vitale et al. 2011).

Staging of Hepatoblastoma and Pediatric Hepatocellular Carcinoma

The TNM staging system is not widely used for hepatoblastomas. In North America, the Children's Oncology Group staging system is widely employed. It is based on postoperative evaluation and hence relies less on imaging findings (Table 3).

Table 3 Children's Oncology Group staging of liver cancer

Stage I	Tumor completely resected
Stage II	Tumor grossly resected with microscopic residual disease
Stage III	Tumor unresectable or resected with gross residual disease
	Nodal involvement
	Tumor spill
	Gross residual intrahepatic disease
Stage IV	Distant metastases

Table 4 Liver sections as defined by the PRETEXT system

Left lateral section:	Liver segments 2 and 3
Left medial section:	Liver segments 4a and 4b
Right anterior section:	Liver segments 5 and 8
Right posterior section:	Liver segments 6 and 7

In contrast, the pretreatment extent of tumor system or PRETEXT system is based on imaging findings. The PRETEXT system was designed by the International Childhood Liver Tumor Strategy Group (SIOPEL) for risk stratification of pediatric liver tumors (Aronson et al. 2005; Roebuck et al. 2006, 2007a, b; Meyers et al. 2007, 2009; McCarville and Roebuck 2012). PRETEXT staging is based on Couinaud's system of liver segmentation. In the system, the liver segments are grouped into four *sections* (Table 4). In the original PRETEXT system, the caudate lobe (segment 1) was ignored.

In addition to liver segment involvement, PRETEXT also assesses involvement of the inferior vena cava (IVC) or hepatic veins (designated V), involvement of the portal vein (designated P), extrahepatic abdominal disease (designated E), and distant metastases (designated M). The original system is compiled in Table 5.

PRETEXT, which showed to have a good prognostic value in infants and children with hepatoblastoma, is employed to describe tumor extent before any therapy. Analysis of data and of experience has uncovered certain limitations of this system. A revised PRETEXT system has been proposed (2005 PRETEXT; Roebuck et al. 2007a; Table 6).

Table 5 PRETEXT staging system (original version)

Stage	Definition
PRETEXT I	One section involved, three adjoining sections free
PRETEXT II	One or two sections involved, two adjoining sections free
PRETEXT III	Two or three sections involved, no two adjoining sections free
PRETEXT IV	All four sections involved
V+	Involvement of the IVC and/or all three hepatic veins
P+	Involvement of the main portal vein and/or both left and right portal vein branches
E+	Extrahepatic disease in the abdomen
M+	Distant metastases

The changes are specified as follows: involvement of the caudate lobe at diagnosis is coded as C1, irrespective of the PRETEXT group. As imaging techniques are more performant, biopsy proof of involvement is not necessary in all situations. In the 2005 revision, patients with direct extension of tumor through the diaphragm (a rare event) are coded as E1 without biopsy proof. Peritoneal tumor nodules are assumed to be metastases and are coded as E2. All other patients should be coded as E0. Patients with ascites are coded as E0a, E1a, or E2a. Abdominal lymph node metastases, previously coded as E+, are now coded as N. Tumor focality (F) denotes the presence of a solitary vs. more nodules. Patients with one hepatic tumor nodule are coded as F0, while all those with more than one nodule are coded as F1, regardless of tumor size or PRETEXT stage. Patients with tumor rupture are coded as H1. Patients with no evidence of tumor rupture or hemorrhage, and those with only subcapsular or biopsy-related bleeding, are coded as H0. Patients with no lymph node metastases are N0, those with nodal metastases limited to the abdomen (caudal to the diaphragm and cranial to the inguinal ligament) are N1, and those with extraabdominal nodal metastases are N2. In regard to portal vein involvement, the original version did not specify what "involvement" means. Involvement based on imaging means complete venous obstruction or circumferential encasement. In the revised version, P1 means

Table 6 2005 PRETEXT staging: additional criteria (Roebuck et al. 2007a)

C:	
Caudate lobe involvement	C1, tumor involving the caudate lobe
	C0, all other patients
E:	
Extrahepatic abdominal disease	E0, no evidence of extrahepatic abdominal disease (except M or N)
	E1, direct extension of tumor into adjacent organs or diaphragm
	E2, peritoneal nodules
F:	
Tumor focality	F0, patient with solitary tumor
	F1, patient with two or more discrete tumors
H:	
Tumor rupture or intraperitoneal hemorrhage	H1, imaging and clinical findings of intraperitoneal hemorrhage
	H0, all other patients
M:	
Distant metastases	M0, no metastases
	M1, any metastases (except E and N)
N:	
Lymph node metastases	N0, no nodal metastases
	N1, abdominal lymph node metastases only
	N2, extraabdominal lymph node metastases (with or without abdominal lymph node metastasis)
P:	
Portal vein involvement	P0, no involvement of the portal vein or its left or right branches
	P1, involvement of either the left or the right branch of the portal vein
	P2, involvement of the main portal vein
V:	
Involvement of the IVC and/or hepatic veins	V0, no involvement of the hepatic veins or inferior vena cava (IVC)
	V1, involvement of one hepatic vein but not the IVC
	V2, involvement of two hepatic veins but not the IVC
	V3, involvement of all three hepatic veins and/or the IVC

evidence of involvement of one major branch of the portal vein, and P2 (= original P+) is involvement of the main portal vein, its bifurcation, or both of its main branches, as well as those with cavernous transformation. Detection of portal vein invasion is coded as with the suffix "a" (e.g., P2a). For inferior vena cava and hepatic veins, the original V + has been defined in more detail, in analogy to the portal vein. V1 and V2 indicate involvement of one or two main hepatic veins, respectively, while V3 means involvement of either the IVC or all three of hepatic veins. As in the portal vein, invasion is coded with the suffix "a."

Together with serum AFP levels, PRETEXT is useful for risk stratification of hepatoblastomas. High-risk patients are those with any of the following: serum AFP less than 100 mg/l, PRETEXT IV, and additional PRETEXT criteria (E1, E1a, E2, E2a, H1, M1 (any site), N1, N2, P2, P2a, V3, V3a). All other patients are standard risk (Roebuck et al. 2007a).

Staging of Hilar/Perihilar Cholangiocarcinoma (Klatskin Tumor)

Preoperative evaluation of the tumor extension (staging) is important in order to judge resectability, extent of surgery, and prognostication of outcome. Most staging systems refer to invasive tumors that have reached a certain extension. Early carcinoma of the extrahepatic ducts was defined as being carcinoma confined to within the mucosa and fibromuscular layer (Tsunoda et al. 1989), but with the exception of carcinoma in situ, the concept of early cancer in its various manifestations does not make part of staging systems.

Several methods have been proposed to stage tumor extension, with a varying spectrum of impact. Following the Bismuth-Corlette classification, several staging systems have been proposed and updated or reviewed (Hiriart et al. 2011). Currently, the new editions of UICC and the American Joint Committee on Cancer (AJCC) staging, the Japanese Society of Biliary Surgery (JSBS) classification, and the modified Memorial Sloan Kettering Cancer Center (MSKCC) classification are used worldwide for PHC staging. These systems not only refer to tumor extent but also to local biological factors (reviews: Kim 2005; Nishio et al. 2005; Chung et al. 2008; Hasebe et al. 2008; Blechacz et al. 2011; DeOliveira et al. 2011; Juntermanns et al. 2013; Koerkamp et al. 2014). Alternative staging systems have recently been proposed (DeOliveira et al. 2011). Aspects of the new staging systems have been commented and reviewed (Hiriart et al. 2011; Nagino 2011). The Bismuth-Corlette classification has been employed to define the longitudinal tumor extension in PHC, whereas the T-staging system of the AJCC defines lateral tumor extension, and resectability of PHC can be evaluated by means of the Blumgart T-staging system combined with the AJCC T-stage system.

Classification and Staging Based on Longitudinal Extension

Hilar/perihilar carcinomas have been classified according to their anatomical location and extension with respect to their relation to the confluence and the longitudinal tumor extension (the Bismuth-Corlette classification; Bismuth and Corlette 1975). The Bismuth-Corlette type I cancer is defined by a lesion confined below the main confluence of right and left hepatic ducts. Bismuth-Corlette type I tumors extend to the confluence of the right and left hepatic ducts. Type IIIa is a tumor that extends to the bifurcation of the right hepatic duct, and a type IIIb tumor extends to the bifurcation of the left hepatic duct (Bengmark et al. 1988). Type IV tumors extend to the bifurcation of both the right and left hepatic ducts. The Bismuth-Corlette classification provides an anatomical classification of the tumor which is a widely used preoperative standard to assess PHC, but has been shown to have low accuracy in cases of PHC undergoing resection, and it is not indicative of survival (Chung et al. 2008; Paul et al. 2011). There is a relationship between longitudinal growth extension and histological type of tumor. The common sclerosing (desmoplastic)

variant of PHC tends to be circumscript, while exophytically growing, and in particular papillary, carcinomas tend to show long-range mucosal spread.

Classification and Staging Based on Lateral Extension

The principal staging system describing lateral extension of tumors and their invasion of duct-associated soft tissues is the TNM staging system, as specified in the seventh edition of the UICC manual (Sobin et al. 2009a; Table 7).

There are some differences between the sixth and the seventh editions of the UICC/AJCC classifications for PHC. Specifically, the seventh edition improved separation of patients with intermediate-stage tumors compared with the sixth edition (Juntermanns et al. 2013). Similar to the Bismuth-Corlette system, there is a relationship between the T stage and the predominant growth pattern and tumor differentiation. In T1 tumors, exophytically growing, polypoid, and papillary carcinomas are overrepresented. In contrast, T2 tumors, which grow through the duct wall, typically exhibit a nodular invasive mass encasing the duct and showing periductal tumor infiltrates. It may be problematic to distinguish T1 and T2 tumors, because the determination of the border of the bile duct may be difficult, even histologically. The outer border of the bile duct is defined by the outer smooth muscle layer, but the distribution of smooth muscle bundles varies along the bile duct, with only few and scattered myocyte bundles in the proximal-most parts of extrahepatic ducts and a continuous sheath in the distal-most part (Hong et al. 2000). In addition, nodular-sclerosing forms of PHC elicit a cellular stromal reaction (desmoplasia) in the invasive part of the tumor, often effacing the anatomo-histologic features of the involved duct (review: Chung et al. 2008). In T3 and T4 tumors, gross vascular invasion makes part of the phenotype. As specified in Chung et al. (2008), vascular involvement on cross-sectional imaging is present if vascular occlusion, ipsilateral hepatic atrophy, stenosis or contour deformity, or tumor contact

Table 7 UICC staging of extrahepatic cholangiocarcinoma (seventh edition, 2009)

***Primary tumor* (*T*)**			
TX		Primary tumor cannot be assessed	
T0		No evidence of primary tumor	
Tis		Tumor in situ	
T1		Tumor confined to the bile duct, with extension up to the muscle layer or fibrous tissue	
T2a		Tumor invades beyond the wall of the bile duct to surrounding adipose tissue	
T2b		Tumor invades adjacent hepatic parenchyma	
T3		Tumor invades unilateral branches of the portal vein or hepatic artery	
T4		Tumor invades the main portal vein or its branches bilaterally, or the common hepatic artery, or the second-order biliary radicles bilaterally, or unilateral second-order biliary radicles with contralateral portal vein or hepatic artery involvement	
***Regional lymph nodes* (*N*)**			
NX		Regional lymph nodes cannot be assessed	
N0		No regional lymph node metastasis	
N1		Regional lymph node metastasis including nodes along the cystic duct, common bile duct, common hepatic artery, and portal vein	
***Distant metastasis* (*M*)**			
MX		Distant metastasis cannot be assessed	
M0		No distant metastasis	
M1		Distant metastasis	
Stage grouping

where more than 50 % of the perimeter of the vessel is detected are observed. In order to improve preoperative T staging, several propositions have been published.

Staging System Developed to Evaluate Resectability

The preoperative clinical T-staging system of Blumgart (Blumgart preoperative staging), defined by the radial/lateral and longitudinal tumor extent, accurately predicts resectability of PHC (Jarnagin 2000; Jarnagin et al. 2001; Matsuo et al. 2012; Table 8). In other words, the system evaluates the longitudinal and lateral spread patterns based on the Bismuth-Corlette and TNM staging systems (Chung et al. 2008). In this staging system, T3 cancers correspond to Bismuth-Corlette type IV or bilateral or main portal vein invasion, or Bismuth-Corlette type III cancers with contralateral portal vein invasion or hepatic atrophy are considered poor candidates for surgery.

Staging of Lymph Node Involvement

The TNM system of the sixth edition of the AJCC manual is simple and specifies with the code N1 that regional (locoregional) lymph node metastasis is present (see the table above). Regional lymph nodes are hilar, celiac, periduodenal, peripancreatic, and superior mesenteric nodes. A detailed lymph node numbering system has been developed by the Japanese Research Society for Gastric Cancer (Nishi et al. 1998). An alternative regional lymph node group system has been proposed by Kitagawa et al. (2001; Table 9).

Table 8 Blumgart preoperative staging (Jarnagin et al. 2001)

T-stage criteria	
T1	Tumor involving biliary confluence +/− unilateral extension to second-order biliary radicles
T2	Tumor involving biliary confluence +/− unilateral extension to second-order biliary radicles and ipsilateral portal vein involvement +/− ipsilateral hepatic lobar atrophy
T3	Tumor involving biliary confluence + bilateral extension to second-order biliary radicles, or unilateral extension to second-order biliary radicles with contralateral portal vein involvement, or unilateral extension to second-order biliary radicles with contralateral hepatic lobar atrophy, or main or bilateral portal venous involvement

Staging of Extrahepatic Cholangiocarcinomas

The American Joint Committee on Cancer (AJCC) has designated a TNM staging system for extrahepatic bile duct cancer that is widely used (*AJCC Cancer Staging Manual*, seventh edition; Edge et al. 2010). T3 and T4 tumors differ in regard to the organ that is invaded, invasion of the pancreas being defined as T3, and that of the duodenum as T4 tumor in the T classification of the American Joint Committee on Cancer (AJCC). Stages defined by the TNM classification apply to all primary carcinomas arising in the extrahepatic bile duct or in the cystic duct and do not apply to intrahepatic cholangiocarcinomas, sarcomas, or carcinoid tumors. The AJCC TNM

Table 9 Definition of regional lymph node groups (According to Kitagawa et al. 2001, and the classification by the Japanese Society of Biliary Surgery)

TNM classification	Kitagawa system
N1	N1
Hilar	Pericholedochal (numbers 12 h, 12c, 12b)
Cystic duct	
Pericholedochal	
N2	N2
Periportal	Periportal (numbers 12p, 12a)
Periduodenal	Common hepatic (numbers 8a, 8p)
Peripancreatic	Posterior pancreaticoduodenal (number 13a)
Celiac	Celiac (number 9)
Superior mesenteric	Superior mesenteric (number 14)

Numbers in brackets indicate lymph node groups according to the classification of the Japanese Society of Biliary Surgery

Table 10 AJCC Staging of distal bile duct carcinoma: primary tumor (Edge et al. 2010)

TX	Primary tumor be assessed
T0	No evidence of primary tumor
Tis	Tumor in situ
T1	Tumor confined to the bile duct histologically
T2	Tumor invades beyond the wall of the bile duct
T3	Tumor invades the gallbladder, pancreas, duodenum, or other adjacent organs without involvement of the celiac axis or the superior mesenteric artery
T4	Tumor involves the celiac axis or the superior mesenteric artery

Table 11 AJCC classification of lymph node involvement (Edge et al. 2010)

NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Regional lymph node metastasis

system applying to distal extrahepatic cholangiocarcinomas is shown in Table 10.

Assessment of pT2 and pT3 varies somewhat as a function of the anatomical compartment involved. The extrahepatic biliary tract histology varies along its length, in that there is little smooth muscle in the wall of proximal duct parts compared to distal duct parts, rendering the assessment of invasion depth difficult in some situations. It has been proposed to measure the maximum invasion depth from the surface epithelium (basement membrane) to the deepest point of tumor invasion. The current pT3 stage of distal extrahepatic bile duct carcinomas can be subdivided into superficial (pT3a) and deep pancreatic invasion (pT3b). In the TNM system, special cases can further be defined by certain prefixes and suffixes. The suffix "m" denotes the presence of multiple primary tumors in a single site and is recorded in parentheses (pT(m)NM). The prefix "y" indicates those cases in which classification takes place during or after initial multimodality therapy. For example, the cTNM or pTNM is identified by a "y" prefix. ycTNM and ypTNM thus categorize the extent of tumor actually present at the time of that examination. The prefix "r" denotes a recurrent tumor when staged after a documented disease-free interval. The prefix "a" indicates the stage determined at autopsy (aTNM) (Washington et al. 2010).

Carcinomas with invasion confined to within the mucosa and fibromuscular layer have been defined as early carcinoma (Tsunoda et al. 1989). In a study of 95 patients, survival rates for patients with pT3 and pT4 were similar, and duodenal invasion was present in 39 % of the patients with pancreatic invasion, whereas pancreatic invasion was observed in 86 % of those with duodenal invasion, suggesting that T classifications should undergo further stratification procedures (Ebata et al. 2007).

For lymph node involved in patients with CDBD, available classifications mainly include the AJCC system (Table 11) and the system of the Japanese Society of Biliary Surgery (Tables 12, 13 and 14).

The AJCC staging system for distant metastasis is shown in Table 15.

AJCC stage/prognostic groups are compiled in Table 16.

Staging of Intrahepatic Cholangiocarcinoma (ICC)

Stage classification (staging) of ICC is a rather complex and evolving matter that has been discussed in several publications (Adam and Benjamin 1992; Blechacz et al. 2009, 2011; Nathan et al. 2009; Kokudo and Arita 2010; Uenishi et al. 2014). Historically, the same classification has been applied and validated in the West for hepatocellular carcinoma (HCC) and ICC (UICC/AJCC; Sobin and Wittekin 1997; Vauthey et al. 2002), while two TNM staging systems had been specifically developed in Japan for HCC and ICC (Okabayashi et al. 2001; the Liver Cancer Study Group of Japan 1997; Yamasaki 2003; Tables 17 and 18). The past Western staging systems for cholangiocarcinoma, including the sixth edition of AJCC, which were based on HCC therefore also referred to tumor size as a prognostic factor. In ICC, tumor size as a prognosticator is controversial, as part of the studies found a prognostic effect (Weber et al. 2001; Endo et al. 2008; Shen

Table 12 Nomenclature and numerical classification of lymph nodes and lymph node groups General Rules for Surgical and Pathological Studies on Cancer of the Biliary Tract (Japanese Society of Biliary Surgery 1997)

Number 8, nodes along the common hepatic artery
Number 9, nodes around the celiac artery
Number 10, nodes at the splenic hilum
Number 11, nodes along the splenic artery
Number 12, nodes in the hepatoduodenal ligament
12a, nodes along the hepatic artery
12b, nodes along the bile duct
12c, nodes around the cystic duct
12p, nodes posterior to the portal vein
12abp1, nodes along the superior hepatoduodenal ligament
12abp2, nodes along the inferior hepatoduodenal ligament
Number 13, posterior pancreaticoduodenal nodes
13a, above the papilla of Vater
13b, below the papilla of Vater
Number 14, nodes around the superior mesenteric artery
14a, nodes at the origin of the superior mesenteric artery
14b, nodes at the origin of the inferior pancreaticoduodenal artery
14c, nodes at the origin of the middle colic artery
14d, nodes at the origin of the jejunal arteries
Number 15, nodes along the middle colic artery
Number 16, para-aortic nodes
16a1, nodes around the aortic hiatus of the diaphragm
16a2, nodes from the superior margin of the celiac trunk to the inferior margin of the left renal artery
16b1, nodes from the inferior margin of the left renal artery to the superior margin of the inferior mesenteric artery
16b2, nodes from the superior margin of the inferior mesenteric artery to the aortic bifurcation
Number 17, anterior pancreaticoduodenal nodes
17a, above the papilla of Vater
17b, below the papilla of Vater

Table 13 Nodal involvement for middle (mid-region) CDBD (CDBD-M): classification according to the Japanese Society of Biliary Surgery (1997)

n0, no evidence of regional lymph node involvement
n1, nodal involvement in the primary lymph node group close to the tumor (lymph node numbers 12b and 12c)
n2, lymph node metastasis in the secondary lymph node group (lymph node numbers 8, 12a, 12p, and 13a)
n3, lymph node metastasis in the third group (lymph node numbers 9, 13b, 14, 16a, 16b, and 17)
n4, lymph node metastasis in the fourth group

Table 14 Nodal involvement for distal CDBD (CDBD-D): classification according to the Japanese Society of Biliary Surgery (1997)

n0, no evidence of regional lymph node involvement
n1, nodal involvement in a primary lymph node group close to the tumors (lymph node numbers 12b2 and 13a)
n2, lymph node metastasis in the secondary lymph node group (lymph node numbers 8, 12 except 12b2, and 13b)
n3, lymph node metastasis in the third group (lymph node numbers 9, 13b, 14, 16a2, 16b1, and 17)
n4, lymph node metastasis in the fourth group (beyond the third group)

Table 15 AJCC classification for distant metastasis in distal cholangiocarcinoma (Edge et al. 2010)

M0	No distant metastasis
M1	Distant metastasis

Table 16 AJCC anatomic stage/prognostic groups (stage groupings) (Edge et al. 2010)

Stage	T	N	M
0	Tis	N0	M0
IA	T1	N0	M0
IB	T2	N0	M0

et al. 2009), while other investigations did no demonstrate a prognostic effect of tumor size (Choi et al. 2009; Uchiyama et al. 2011). In the seventh edition of the American Joint Committee on Cancer (AJCC) staging manual, a novel staging specific for ICC was proposed (Edge 2009; Table 19). This new staging system is largely based on data found in the Surveillance, Epidemiology, and End Results (SEER) program on numerous patients having undergone cancer-directed surgery for ICC (Nathan et al. 2009). Nathan and coworkers demonstrated that the sixth edition of the AJCC system staging was

Table 17 Liver Cancer Study Group of Japan staging system for ICC

T factor:			
T1		Meets requirements (see below)	
T2		Meets two of the three requirements	
T3		Meets one of the three requirements	
T4		Meets none of the three requirements	
Three requirements:			
Number of tumors:		Solitary	
Size of tumor:		2 cm or less	
Negative invasion:		Portal vein, hepatic vein, serosal membrane	
N factor:			
N1		No metastasis to lymph node	
N2		Metastasis to any lymph nodes	
M factor:			
M0		No distant metastasis	
M1		Positive distant metastasis	
Stages (Yamasaki 2003)			
Stage I	T1	N0	M0
Stage II	T2	N0	M0
Stage III	T3	N0	M0
Stage IVA	T4	N0	M0
	Or any T	N1	M0
Stage IVB	Any T	Any N	M1

Table 18 Lymph node groups in ICC by tumor location (Liver Cancer Study Group of Japan)

Tumor location		
Groups or locoregional lymph nodes		
N1	N2	N3
Right lobe	Hepatoduodenal ligament	Along left gastric artery
Distant lymph nodes		
		Along common hepatic artery
		Along celiac artery
		Posterior surface of pancreatic head
Left lobe	Right cardiac region	Along left gastric artery
Distant lymph nodes		
	Lesser gastric curvature	Along common hepatic artery
	Hepatoduodenal ligament	Along celiac artery
		Posterior surface of pancreatic head

Table 19 AJCC/UICC staging system for intrahepatic cholangiocarcinoma (seventh edition)

TNM stage	
T1	Solitary tumor without vascular invasion
T2	Solitary tumor with vascular invasion or multiple tumors 5 cm or less
T3	Multiple tumors more than 5 cm or tumor involving major branch of the portal or hepatic veins
T4	Tumors with invasion of adjacent organs other than the gallbladder or tumors with perforation of visceral peritoneum
N0	No regional lymph node metastases
N1	Regional lymph node metastases
M0	No distant metastases
M1	Distant metastases
UICC stage	
I	T1N0M0
II	T2N0M0
IIIA	T3N0M0
IIIB	T4N0M0
IIIC	AnyTN1M0
IV	AnyTAnyNM1

unable to distinguish prognostically T2 from T3 tumors. In their study it also surfaced that tumor number and vascular invasion were significant prognostic markers, and the lymph node status had prognostic values. The novel seventh edition of the AJCC staging system has, among others, the advantage that it is simpler than the sixth edition system and focuses on multiple tumors, vascular invasion, and lymph node metastasis (review: Nathan and Pawlik 2010).

In this seventh edition, the TNM classification of ICC is separated from that for hepatocellular carcinoma. This novel staging system has been intended to replace the two Western and ideally also the two Eastern staging systems currently in use (Ribero et al. 2011), but its clinical relevance strongly depends on performing routine lymphadenectomy at the time of surgery for ICC (Farges et al. 2011).

Based on some inconsistencies, some modifications of the TNM staging system have been proposed. ICC with multiple tumors was classified as pT4 disease; periductal invasion was excluded from

determinant of the T categories; and metastasis to gastrohepatic lymph nodes was treated as distant metastasis (Igami et al. 2011). Serosal invasion is not a T factor, because it has been found that serosal invasion in patients with MF-ICC has no impact on survival of patients after hepatic resection (Uenishi et al. 2005). For MF-ICC, a specific staging system was formulated. Stage I disease was defined as a solitary tumor without vascular invasion; stage II disease was defined as a solitary tumor with vascular invasion; stage IIIA disease was defined as multiple tumors with or without vascular invasion; stage IIIB disease was defined as any tumor with regional lymph node metastasis; and stage IV disease was defined as any tumor with distant metastases. It turned out that these MF-ICC staging categories were suitable for predicting biology of disease and treatment response (Okabayashi et al. 2001). There is increasing evidence that current staging systems have to be adapted to the main growth pattern types of ICC, as general ICC staging systems may not be suitable to properly stratify each type (e.g., MF-ICC) in the same way (Okabayashi et al. 2001; Uenishi et al. 2014). In a recent investigation performed to identify predictors of outcome in MF-ICC, tumor size, tumor number, and vascular invasion were independently associated with survival after curative resection, whereas periductal invasion and serosal invasion were not (Uenishi et al. 2014).
