So far, four G protein-coupled receptors for LTs have been isolated, and several GPCRs are reported for their involvement in peptide LT signaling [84]. BLT1 is the high-affinity LTB_4 receptor [85] and expressed in granulocytes, eosinophils, dendritic cells, and macrophages. BLT1 is not expressed in naïve T cells, but it is induced in differentiated T cells including CD4-positive Th1, 2, 17 and CD8-positive effector cell [86–88], not in central memory cells. BLT2 was originally reported as a low-affinity LTB_4 receptor [89], but later reported as a high-affinity receptor for 12-HHT that is produced simultaneously with thromboxane A_2 by activated platelets [90,91] (Figure 26.1a). BLT2 is expressed in the cells that are present at the border of the body such as intestinal epithelial cells and keratinocytes, maintains barrier function of intestine and skin [92], and accelerates skin wound healing [93]. Recently, we identified one BLT1-like and two BLT2-like receptors in zebrafish [94], showing that BLT1 and 2 have been conserved during evolution. Two subtypes of CysLT receptors have been pharmacologically characterized and two GPCRs were cDNA cloned as CysLT1 [95,96] and CysLT2 [97,98] receptors. Molecular identity of these two receptors is established, but several additional GPCRs were reported to modify peptide LT signaling. LTE_4 was reported to act through P2Y12 [99] and GPR17 was reported as a dual receptor for peptide LTs and nucleotides [100]. Recently, GPR99 was reported as an important receptor for LTE_4-dependent edema using GPR99-deficient mice [101].

26.3.2 LTB4 and BLT1 in Acute and Chronic Inflammation

As LTB_4 has been known as a potent chemoattractant for granulocytes, the peritonitis model was used to evaluate the contribution of BLT1 in acute inflammation. Two independent groups reported the attenuated peritoneal inflammation

in BLT1-KO mice with much reduced numbers of eosinophils [102–104]. Interestingly, BLT1 deficiency caused a small reduction in granulocytes number in the peritoneal exudate, suggesting the presence of other neutrophil chemoattractants in addition to LTB_4. The importance of BLT1 in eosinophil attraction was confirmed by a nematode infection model, and the lack of BLT1 resulted in the reduced eosinophil accumulation and attenuated nematode killing in mice [105]. The importance of LTB_4/BLT1 axis in acute inflammation was confirmed in several disease models such as allergic skin inflammation [106,107] and in neutrophil swarming phenomenon after bacterial infection [108].

In addition to acute inflammation, LTB_4/BLT1 plays important roles in subacute and chronic inflammation. BLT1 expressed in macrophages activate macrophage chemotactic protein-1 (MCP-1) expression through NF-kB signaling, leading to atherosclerosis [109]. Recently, a BLT1 antagonist BIIL284 was shown to decrease atherogenesis in ApoE-null mice [110]. BLT1 was also reported to enhance the formation of abdominal aortic aneurysm caused by continuous infusion of angiotensin II [111]. In addition to peptide LTs, LTB_4 is also involved in bronchial asthma. We showed that BLT1-deficient mice showed much reduced eosinophil migration and production of Th2 cytokines in peribronchial lymph node cells and reduced airway hypersensitivity [112]. The attenuated asthmatic phenotype was confirmed by the other groups, and BLT1 expressed in dendritic cells [113] and effector T cells [114] was responsible for the asthmatic reactions. LTB_4/BLT1 signaling is involved in Th17 reaction, because BLT1-deficient mice showed attenuated phenotype in a Th1/17-biased disease model experimental autoimmune encephalomyelitis with much attenuated accumulation of granulocytes, mononuclear cells, and monocytes into the spinal cord [115]. LTB_4/BLT1 axis also participates in insulin resistance, in which LTB_4/BLT1 signals in macrophages, hepatocytes, and myocytes augment insulin resistance induced by high fat diet [116]. BLT1 is also expressed in osteoclasts, and osteoclastic activity was enhanced by LTB_4. BLT1-deficient mice were protected from osteoporosis induced by ovariectomy [117], suggesting the possible application of BLT1 antagonist to protect osteoporosis in the future. BLT1 is also involved in inflammatory pain [118] and itch behavior in mice [119–122] possibly by recruiting inflammatory cells.

26.3.3 Roles of BLT2 in Inflammation and Tissue Homeostasis

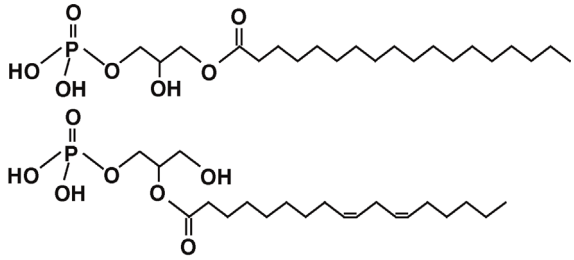
Despite the well-characterized roles of BLT1 in acute and chronic inflammation, the roles of BLT2 are still under investigation and debate [123,124]. BLT2 is expressed in mast cells [90] and allergen stimulation increased the expression leading to the enhanced production of Th2 cytokines [125]. We also found that BLT2 is also expressed in human and mouse T lymphocytes [126] and negatively regulates allergic airway eosinophilia [127]. In mice, high BLT2 expression is observed in intestinal epithelial cells and epidermal keratinocytes [128]. BLT2-deficient mice were more susceptible to inflammatory colitis induced by oral administration of dextran sodium sulfate and exhibited severe loss of body weight and overproduction of inflammatory cytokines in the gut [92], suggesting the anti-inflammatory role of BLT2 in intestine. The roles of BLT2 in keratinocytes

were also investigated. *In vitro* study showed that UVB radiation-induced apoptosis [129] of keratinocytes and matrix metalloproteinase (MMP)-1 expression [130] in HaCaT cells were dependent on the production of reactive oxygen species through BLT2. Based on the finding that BLT2 couples to pertussis toxin-sensitive Gαi protein that generally mediates cell movement, we focused on the role of BLT2 in keratinocyte migration and skin wound healing using BLT2-deficient mice. BLT2-deficient mice showed much retarded wound healing after skin punching. Aspirin-treated wild-type mice also showed retarded wound healing, and this aspirin-dependent delay of wound healing disappeared in BLT2-deficient mice, clearly showing that COX-dependent production of 12-HHT stimulate wound healing by stimulating BLT2 in keratinocytes. Stimulation of BLT2 on keratinocytes enhanced the expression of MMPs that was required for keratinocyte migration and skin wound healing. Topical application of a synthetic BLT2 agonist to punched skin greatly accelerated wound healing, showing the possible application of BLT2 agonists as therapeutic tools for intractable skin ulcers [93]. We also found that skin barrier function is impaired in BLT2-deficient mice with increased water loss and antigen uptake through the skin. As a result, BLT2 maintains epidermal barrier function by upregulating several tight-junctional proteins including claudin 4 and enhancing tight junction [131]. We and others have reported the possible roles of BLT2 in oncogenesis, cancer metastasis [132–138], and angiogenesis [139]; however, extensive studies are required to confirm these actions of BLT2.

26.3.4 CysLTs in Acute and Chronic Inflammation

In contrast to BLT1 mainly expressed in inflammatory cells and important for recruitment of immune cells to the site of inflammation, CysLT receptors are expressed in vascular and smooth muscle cells in addition to inflammatory cells. Thus, the phenotypes of knockout mouse of CysLT receptors are different from those of BLT1-deficient mouse. LTD_4 has been known as a potent bronchoconstrictor, and LTD_4/CysLT1-dependent contraction of bronchialsmooth bronchial smooth muscle are known to last longer than that of histamine [84]. Blockage of LTD_4/CysLT1 is beneficial for the asthmatic patients, and several CysLT1 antagonists have been clinically used to prevent and treat bronchial asthma, and more recently allergic rhinitis. CysLT1 antagonists were developed before the molecular identification of CysLT1 [95]. After the molecular identification of human [95,140], mouse CysLT1 [96], and CysLT2 [96,98], mice deficient in either CysLT1 or CysLT2 were generated and analyzed for their phenotype using several inflammatory disease models.

CyLT1-deficient mice showed decreased vascular leakage in IgE-dependent passive cutaneous anaphylaxis [141], and attenuated allergic lung inflammation by the house dust mite [142], showing that CysLT1 mediates Th2 type immune responses in addition to its role as a local inflammatory mediator. Attenuated zymosan-induced peritoneal vascular permeability and IgE-dependent passive cutaneous anaphylaxis were also confirmed in mice deficient in LTC_4 synthase [143]. Thus, acute inflammatory responses caused by peptide LTs seem to be mediated mainly by CysLT1 receptor. Although the *in vivo* roles of CysLT2



had not been clarified, CysLT2-deficient mice showed reduction in IgE/antigen-mediated microvascular permeability [141]. Although the involvement of peptide LTs in tissue fibrosis was reported [144], CysLT2 was reported as an important receptor involved in peptide LT-dependent chronic inflammation and subsequent tissue fibrosis. Bleomycin-induced lung fibrosis [141] and skin fibrosis in atopic dermatitis model [145] were much attenuated in CysLT2-deficient mice, but not in CysLT1-deficient mice, showing the fibrosis-promoting effects are mainly mediated by CysLT2 receptor.

According to the results obtained by the analyses of CysLT1/CysLT2 double-knockout studies, the presence of other CysLT receptors was predicted [146]. Several GPCRs (GPR17, GPR99, and P2Y12) were found to bind or modify classical CysLT receptors 1 and 2. GPR17, an orphan GPCR that was reported to be activated by both uracil nucleotides and peptide LTs [147], was later reported as a negative regulator of CysLT [100]. Kanaoka *et al.* identified a LTE_4 signaling in mice lacking both CysLT1 and CysLT2 and identified that GPR99 as an LTE_4 receptor [101]. GPR99 has been known as a GPCR for a ketone body 2-oxoglutarate and is expressed in skeletal muscle and kidney [148]. CysLT1/CysLT2/GPR99 triple knockout mice lost the vascular leak caused by LTE4, suggesting that GPR99 is a high-affinity LTE_4 receptor (CysLT3?) [101]. In mast cells, CysLT2 interacts with CysLT1 and downmodulates CysLT1 signaling [149]. Thus, the identity of CysLT3 and interplay of CysLT receptors are still puzzling [150] and further studies are required to clarify the roles of peptide LTs and their receptors in acute and chronic inflammation.

26.3.5 Lysophospholipid, Lysophosphatidic Acid, and Sphingosine 1-Phosphate

Lysophospholipids (LPLs) are phospholipids with only one acyl chain. They include LPA, S1P, lysophosphatidylcholine (LPC), lysophosphatidylethanolamine (LPE), lysophosphatidylinositol (LPI), lysophosphatidylserine (LysoPS), and lysophosphatidylglycerol (LPG). LPLs had long been thought to be merely byproducts of the arachidonate cascade and cholesterol metabolism. However, they have been shown to induce multiple cellular responses such as stimulation of proliferation, migration, and mast cell degranulation and suppression of apoptosis. Moreover, in the past two decades, a number of studies have identified multiple receptors and synthetic enzymes specific to each LPL. From studies on their receptors and producing enzymes and studies on LPLs themselves, the pathophysiological roles have been identified, especially for LPA and S1P. The structures of LPA and S1P (Figure 26.5) are similar. LPA generally has a glycerol backbone to which both a phosphate group and a fatty acid are linked by an ester bond and phosphodiester bond, respectively. It should be noted that a fatty acid is linked to either the *sn*-1 or *sn*-2 hydroxy group of the glycerol backbone (Figure 26.5). By contrast, S1P has shingosine base in its structure. The two ester bonds of LPA and the one ester bond of S1P are the targets of degrading enzymes. In this chapter, we review the receptors and synthetic enzymes for LPA and S1P and summarize their pathophysiological functions.

sphingosine 1-phosphate (S1P)

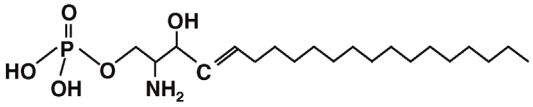

Figure 26.5 Structure of lysophosphatidic acid and shingosine-1-phosphate.

26.3.6 Receptor for LPA and S1P

Like PGs and LTs, LPA, and S1P exert their functions via G protein-coupled receptors. Eleven GPCRs specific either to LPA (6 GPCRs) or to S1P (5 GPCRs) have been identified [151] (Table 26.2). LPAs also act as ligands for other types of receptor such as peroxisome proliferator-activated receptor γ (PPARγ) [152] and transient receptor potential V1 (TRPV1) [153], but we shall not consider them in this chapter. After their discovery, multiple nomenclatures have been proposed. In this chapter, we principally follow the nomenclature proposed recently by Kihara *et al.* [151] (Table 26.2).

26.3.6.1 Receptors for LPA

In 1989, van Corven and coworkers reported that LPA-induced cell proliferation is G protein (Gi)-dependent and indicated that the LPA receptor was GPCR [154]. In 1996, Hecht *et al.* first reported that endothelial differentiation gene 2 (EDG2/LPA_1) was a cellular receptor for LPA [155]. After the discovery of EDG2/LPA_1, the second and third LPA receptors, EDG4 (LPA_2) and EDG7 (LPA_3), were discovered by virtue of their homology to EDG2 [156,157]. More lately, Noguchi *et al.* reported that P2Y9/GPR23 (LPA_4) reacted specifically with LPA [158]. GPR92/LPA_5 and P2Y5/LPA_6 are close homologues of LPA_4/P2Y9/GPR23. Accordingly, they reacted specifically with LPA and thus were classified as LPA receptors [159–161]. Thus, there are currently six GPCRs for LPA. They have been classified into two families, EDG and P2Y. EDG family members consist of LPA_1/EDG2, LPA_2/EDG4, and LPA_3/EDG7, and P2Y family members consist of LPA_4/P2Y9, LPA_5/GPR92, and LPA_6/P2Y5.

Each LPA receptor shows different substrate specificities; LPA_3 and LPA_6 are activated specifically by LPA with unsaturated fatty acid at the *sn*-2 position of the glyerol backbone [161,162]. LPA_5 is more strongly activated by alkyl-LPA than by

Table 26.1 Receptors for PG and LT.

Ligand	Receptor	Expression	Key Functions	Possible Diseases
PGE_2	EP1	Widespread; lung, stomach, kidney, and brain	Gastric protection	Hyperalgesia, neuropathic pain, and stress behavior
	EP2	Bronchial and vascular smooth muscle, myometrium, cumulus cells, T cells, leukocytes, macrophages, microglia, and endothelium	Bronchodilation, tocolytic action of pregnant uterus, regulation of fertilizaiton, and Th1/Th17 differentiaiton	Th1/Th17-mediated immune inflammation, inflammatory cancer, and vascular inflammation
	EP3	Widespread; brain, dorsal root ganglion, heart, platelets, kidney, urinary bladder, stomach, lung, and myometrium	Regulation of neurotransmission, gastric acid secretion, and urinary osmolality	Fever generation, hyperalgesia, and allergic inflammation
	EP4	Widespread; myocardium, ductus arteriosus, stomach, uterus, gastrointestinal tract, bone, synoviocytes, T cells, and dendritic cells	Ductus arteriosus closure, gstrointestinal homeostasis, Th1/Th17 differentiaiton, dendritic cell migration, and bone resorption	Immune inflammation, bone remodeling, hyperalgesia, inflammatory bowel disease, and cancer
$PGF_2\alpha$	FP	Corpus luteum, uterine smooth muscle, endometrium, eye, kidney, and fibroblasts	Regulation of parturition	Lung fibrosis and inflammatory tachycardia
PGD_2	DP1	Ileum, stomach, lung, and uterus; platelets (human), vascular smooth muscle, mast cells, and dendritic cells	Vasodilatation, sleep induction, mast cell maturation, and inhibition of Langerhans cell migration	Allergic inflammation
	DP2 (CRTH2)	Widespread; stomach, small intestine, heart, thymus, colon, and spinal cord; eosinophils and Th2 cells	Th2 lymphocyte activation, chemotaxis, and degranulation of eosinophils	Allergic inflammation
PGI_2	IP	Endothelial cells; vascular smooth muscle, heart, kidney, dorsal root ganglion, T cells, and synoviocytes	Cardiovascular homeostasis, gastroprotection, and pain sensation	Inflammatory edema, hyperalgesia, and immune inflammation
TxA_2	TP	Platelets, vascular and bronchial smooth muscles, and thymocytes	Hemostasis and thrombosis	Atherosclerosis, asthma, and hepatic microcirculatory failure
LTB_4	BLT1	Granulocytes, macrophages, differentiated T cells, and dendritic cells	Chemotaxis	Arthritis, multiple sclerosis, and asthma

(*continued*)

Table 26.1 (*Continued*)

Ligand	Receptor	Expression	Key Functions	Possible Diseases
12-HHT LTB_4	BLT2	Keratinocytes, intestinal epithelial cells, and endothelial cells	Migration, adhesion, and wound healing	Colitis and skin ulcer
LTC_4 LTD_4	CysLT1	Leukocytes, spleen smooth muscle, and intestine	Migration contraction	Asthma
	CysLT2	Leukocytes, spleen adrenal medulla, lung, and heart	?	?
LTE_4	GPR99	Kidney	?	?

Table 26.2 Receptors for LPA and S1P.

LPLs	Receptor	Expression	Key Functions	Possible Diseases
LPA	LPA_1/Edg2	Ubiquitous, neurons, fibroblast, osteoblast, and chondrocyte	Neural cell survival, migration, chondrogenesis, and myelination	Fibrosis, neuropathy pain, dyschondroplasia, and hydrocephalus
	LPA_2/Edg4	Lymphocytes intestine	Protection of cell death	UV- or anticancer drug-induced intestinal cell death
	LPA_3Edg7	Uterus, testis, and lung	Implantation	Endometriosis
	LPA_4/P2Y9	Ubiquitous, endothelial cells, and stromal cells	Lymphovessel formation and hematopoiesis	?
	LPA_5/GPR92	Blood cells	Immunosuppression	?
	LPA_6/P2Y5	Epithelial cells, endothelial cells, and macrophages	Hair follicle formation	Congenital alopecia
S1P	$S1P_1$/Edg1	Endothelial cells and lymphocytes	Embryonic blood vessel formation, lymphocyte egress, and endothelial barrier	Autoimmune disease
	$S1P_2$/Edg5	Ubiquitous	Vascular tone, endothelial barrier, inner ear maintenance, and endothelial barrier function	Loss of hearing and balance, and seizures
	$S1P_3$/Edg3	Ubiquitous	Endothelial barrier function	?
	$S1P_4$/Edg6	Lymphocytes	?	?
	$S1P_5$/Edg8	Oligodendrocytes and NK cells	?	?

acyl-LPA [163]. While LPA_5 does react with LPA, it also responds to a dietary protein hydrolysate (peptone) at nanomolar concentrations [164] and to farnesyl pyrophosphate [165]. These LPA receptors are expressed by particular cells in different organs and activate multiple intracellular signaling pathways, which accounts for their many biological functions.

26.3.6.2 Receptor for S1P

In 1998, two years after the discovery of the first LPA receptor, LPA_1/EDG2, Hla and coworkers showed that S1P was the ligand for EDG1 [166]. Because there were six other EDG family members (EDG3-8) at that time, they were tested for their reactivity to LPA and S1P. To date, five S1P receptors, namely, EDG1, EDG3, EDG5, EDG6, and EDG8, have been identified and named $S1P_1$, $S1P_3$, $S1P_2$, $S1P_4$, and $S1P_5$, respectively [151]. Thus, the eight EDG receptors are divided into two groups: EDG LPA receptors (EDG2/LPA_1, EDG4/LPA, and EDG7/LPA_3) and EDG S1P receptors (EDG1/$S1P_1$, EDG5/$S1P_2$, EDG3/$S1P_3$, EDG6/$S1P_4$, and EDG8/$S1P_5$) (Table 26.2). Unlike LPA, S1P does not have any known receptors within the P2Y family.

26.3.7 Synthetic Pathways and Enzymes for LPA and S1P

LPA is produced under various conditions both in cells and in biological fluids, where multiple synthetic reactions occur [167]. Historically, at least two pathways have been postulated. In serum and plasma, LPA is mainly converted from lysophospholipids. By contrast, in platelets and some cancer cells, LPA is converted from phosphatidic acid (PA). Each pathway requires at least two phospholipase activities. One pathway involves phospholipase A_1 (PLA_1)/PLA_2 plus lysophospholipase D (lysoPLD) activities and the other pathway involves phospholipase D (PLD) plus PLA_1/PLA_2 activities [167] (see Figure 26.6). It should be noted that all these enzymes are extracellularly secreted enzymes, as shown by signal sequences at the N-terminus. This feature is unique to LPA-producing enzymes because all the other lipid mediators covered in this chapter such as PGs, LTs, and S1P are produced intracellularly and are then extracellularly delivered by transporters specific to each lipid mediator. S1P is produced intracellularly, in which sphingosine is converted to S1P by a kinase reaction [168]. We should keep it mind that energy (i.e., ATP) is required for S1P production, while it is not for LPA production. The most marked difference between the productions of S1P and LPA is that the former requires energy (i.e., ATP), while the latter does not.

26.3.7.1 Synthetic Pathways and Enzymes for LPA

At least two pathways have been postulated for bioactive lipid LPA production [167]. In the first pathway, lysophospholipids are produced by phospholipase A_1 (PLA_1) or phospholipase A_2 (PLA_2) and then converted to LPA by lysoPLD. In the other pathway, phosphatidic acid is hydrolyzed by PLA_1 or PLA_2, generating LPA. Extracellular LPA production mainly involves two phospholipases, autotaxin (ATX)/lysoPLD and phosphatidic acid-selective phospholipase $A_1\alpha$ (PA-$PLA_1\alpha$). Inside the cell, LPA is generated as intermediates by addition of fatty

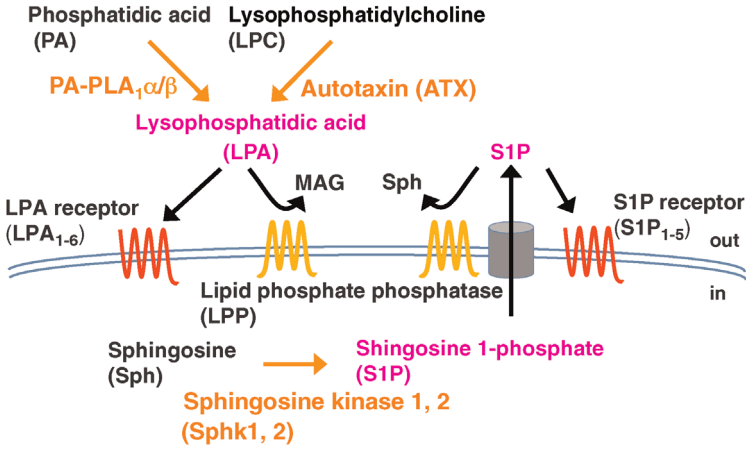

Figure 26.6 Synthetic, degrading, and action of lysophosphatidic acid and shingosine-1-phosphate. There are two pathways for LPA production. First, lysophospholipids generated by phospholipase A_1 (PLA_1) or PLA_2 reaction are subsequently converted to LPA by lysophospholipase D (lysoPLD) reaction. Second, phosphatidic acid is converted to LPA by PLA_1 or PLA_2 reaction. In extracellular LPA production, mainly two phospholipases, autotaxin (ATX)/lysoPLD, and phosphatidic acid-specific phospholipase $A_1\alpha$ (PA-$PLA_1\alpha$) and β (PA-$PLA_1\beta$) are crucial. LPA has six cognate cellular receptors. S1P is produced from sphingosine by two kinases called sphingosine kinase 1 and 2 (Sphk1 and 2) and acts on five receptor specific to S1P. Both LPA and S1P are degraded to monoacyl glycerol and sphingosine, respectively, by phosphatases called lipid phosphate phosphatases (LPP).

acyl-CoA to glycerol-3-phosphate in the course of *de novo* phospholipid biosynthesis. This LPA-producing pathway is conserved in lower organisms such as *Escherichia coli* that do not have LPA receptors. At present, there is no evidence that this pathway contributes to the extracellular functions of LPA production. In this section, we describe the latest findings in LPA-producing enzymes, especially ATX and PA-$PLA_1\alpha$.

LPA Production by ATX

ATX is a member of the nucleotide pyrophosphate phosphodiesterase (NPP) family and is also referred to as NPP2. Some NPP family members such as NPP1 and NPP3 hydrolyze nucleotides such as ATP [169]. ATX was originally found as an autocrine motility-stimulating factor identified in the supernatant of human malignant melanoma cell cultures [170]. However, the mechanism by which ATX stimulated cell motility was unknown. In 2002, we and others showed that an enzyme (lysoPLD) that acts on various LPLs and produces LPA by its phosphodiesterase activity is identical to ATX [171,172]. ATX is a secretory glycoprotein with a molecular weight of about 100 kDa. Multiple ATX isoforms are generated by alternative splicing sites [173]. ATX activity depends on divalent cations such as Co^{2+} or Mn^{2+}. The preferred substrates of ATX are LPLs such as LPC with a short fatty acid (12: 0, 14: 0, and 16: 0) or an unsaturated fatty acid (18:2 and 20: 4). Recently, the crystal structure of ATX was determined and showed that these substrate specificities can be explained by the structure of the catalytic

pocket [174,175]. ATX is unique among NPP family members in having a deep hydrophobic pocket for substrates. LPA acyl chains are accommodated in this hydrophobic pocket. Unsaturated fatty acids bend sharply at the unsaturated bonds, confirmong that highly unsaturated fatty acids bind more stably.

LPA Production by PA-PLA$_1\alpha$

Phosphatidic acid-selective phospholipase A_1 (PA-PLA$_1\alpha$) has sequence similarity to phosphatidylserine-specific phospholipase A_1 (PS-PLA$_1$). These enzymes, both with molecular weights of about 55 kDa, are classified into pancreatic lipase family, which includes hepatic lipase and lipoprotein lipase [176]. Although PA-PLA$_1\alpha$ has a signal sequence at the N-terminus like other lipases, it is mainly detected in the membrane fraction in both tissues and cultured cells, indicating that PA-PLA$_1\alpha$ is a membrane-binding protein rather than a secreted protein. PA-PLA$_1\alpha$-expressing cells constantly produce LPA from phosphatidic acid. Thus, the LPA produced by PA-PLA$_1\alpha$ is an LPA with an unsaturated fatty acid at the *sn*-2 position of the glycerol backbone. Interestingly, LPA_3 and LPA_6 receptors are more strongly activated by 2-acyl LPA than by 1-acyl LPA [161,162]. Therefore, PA-PLA$_1\alpha$ might supply the ligand for these LPA receptors.

PA-PLA$_1\alpha$, which is encoded by *LIPH*, is the gene responsible for autosomal recessive hypotrichosis [177]. Many mutations in *LIPH* have been identified in some family lineages with hypotrichosis [178–180]. A gene encoding LPA_6 receptor (*LPAR6*) has also been identified as a causative gene for the same disorder [181,182], which suggests that LPA produced by PA-PLA$_1\alpha$ promotes the formation of hair follicles. In 2011, PA-PLA$_1\alpha$ KO mice showed a hair abnormality (wooly hair) as was observed in human [183]. That study also demonstrated that, in wild-type mice, PA-PLA$_1\alpha$ and LPA_6 receptors are highly expressed in epidermal cells in the inner root sheath of hair follicles. Together, these findings show that PA-PLA$_1\alpha$ and LPA_6 receptors regulate growth or differentiation of epidermal cells in the follicles. Interestingly, similar abnormal hair (wooly hair) was also found in TACE or TGFα knockout mice [184,185] and in mice with mutations in EGFR genes [186]. The activation of LPA_6 induces TACE-dependent ectodomain shedding of TGFα followed by activation of EGFR, as described above. It is now accepted that a PA–PLA$_1\alpha$–LPA–LPA_6 axis regulates the differentiation and maturation of hair follicles via a TACE-TGFα-EGFR pathway.

26.3.7.2 Synthetic Pathways for S1P

As stated above, S1P is produced intracellularly from sphingosine (Sph) by a kinase reaction. Two such kinases, named shingosine kinase 1 and 2 (SphK1 and 2), have been identified. In 1998, Kohama and coworkers identified SphK1 by purifying it from kidney extract [187]. SphK2 was subsequently identified by its sequence homology to SphK1 [188]. S1P produced intracellularly is delivered to the extracellular millieu by transporters specific to S1P. ABC-type transporters and another transporter, named Spns2, have been identified [168]. Endothelial cells and red blood cells release S1P, which is picked up and chaperoned by ApoM on high-density lipoprotein particles and albumin [189]. *In vitro*, S1P can be converted from sphingosylphosphorylcholine (SPC) by ATX [190]. However, unlike LPC, which is present in the blood at several hundred micromolar level, the

SPC concentration is below 1 μM. Thus, ATX does not appear to be involved in S1P production.

26.3.8 Degradation Pathway for LPA and S1P

LPA and S1P are also known as lipid mediators, indicating that they are locally produced and degraded rapidly. In fact LPA and S1P are highly unstable. Although several routes for the degradation of LPA and S1P have been postulated, the most probable route is a dephosphorylation reaction. Several membrane-bound enzymes responsible for degradation of LPA and S1P have been identified. Lipid phosphate phosphatases (LPPs or PLPPs) are tetra-spanning membrane proteins that remove the phosphate groups from LPA and S1P [191]. LPA and S1P are also referred to as lipid phosphates. Importantly, these enzymes degrade lipid phosphates extracellularly and, thus, negatively regulate LPA and S1P signaling by degrading LPA and S1P. S1P is also degraded to hexadecenal and ethanolamine phosphate by a cytosolic enzyme called S1P lyase [192]. S1P lyase is evolutionally conserved from yeast to mammals and has another role in the sphingolipid to glycerophospholipid metabolic pathway.

26.3.9 Pathophysiological Roles of LPA and S1P in Inflammation

26.3.9.1 Role of LPA and S1P in Angiogenesis

ATX-deficient mice are embryonic lethal due to severe vascular defects at embryonic days (E) 9.5–E10.5 [193]. None of the LPA receptor-deficient mice have shown such a phenotype, although LPA_4-deficient mice are partially embryonic lethal with bleeding [194]. Therefore, in mammals, it was unclear which LPA receptors are involved in embryonic vascular development and how embryonic vascular development is regulated by ATX. Yukiura *et al.* reported that ATX as well as six LPA receptors are highly conserved in zebrafish and that gene knockdown with antisense morpholino oligonucleotides showed that ATX also has a critical role in embryonic blood vessel formation [195]. They also suggested that LPA_1, LPA_4, and LPA_6 have a redundant role. As stated above, the level of LPA is also regulated by degradative pathways that involve three lipid phosphate phosphatases (LPP1–3). LPP3-deficient mice are also embryonic lethal with vascular defects [196]. This suggests that an ATX–LPA–$LPA_{1,4,6}$ axis is involved in embryonic vascular formation and that appropriate degradation of LPA mediated by LPP3 is essential for development. Yukiura *et al.* also showed that in cultured endothelial cells (HUVEC), LPP3 is predominantly expressed in cell–cell contact sites and inhibits LPA signaling mediated by LPA_6 in the contact sites, thereby restricting LPA_6 signaling in noncontact sites [197]. The precise role of LPA in embryonic blood formation (probably vasculogenesis) remains to be determined. Interestingly, ATX is often overexpressed in cancer tissues. Thus, ATX may promote cancer progression by promoting blood vessel formation in cancer tissues.

Like LPA, S1P is essential for vascular maturation during embryonic development. $S1P_1$ was shown to be essential for vascular maturation during embryonic development. Disruption of the *S1P1* gene in mice caused embryonic lethality because of massive hemorrhage at embryonic days (E) 12.5–E14.5 [198]. $S1P_1$ is

expressed in both endothelial cells and vascular smooth muscle cells. However, endothelial cell-specific $S1P_1$ knockout mice showed a similar vascular defect, indicating $S1P_1$ expressed in endothelial cells has a major role in regulating embryonic blood vessel formation in this period [199]. Unlike $S1P_1$ knockout mice, neither $S1P_2$ knockout mice nor $S1P_3$ knockout mice exhibited significant embryonic lethality or obvious phenotypic abnormalities. $S1P_1/S1P_2$ double-null and $S1P_1/S1P_2/S1P_3$ triple-knockout embryos displayed a substantially more severe vascular phenotype than did embryos with only $S1P_1$ deleted [200]. Thus, the $S1P_1$, $S1P_2$, and $S1P_3$ receptors have redundant or cooperative functions for the development of a stable and mature vascular system during embryonic development. *In vitro*, S1P strongly strengthens the cell–cell adhesion of HUVEC [201], indicating that S1P is involved in the maturation of preformed vessels. Mice with single knockouts of SphK1 and SphK2 appear to be normal, although each has decreased blood S1P levels [202,203]. Interestingly, however, SphK1 and SphK2 double-knockout mice, like $S1P_1$ knockout mice, were embryonic lethal [203].

26.3.9.2 Fibrosis

Fibrosis is a cell-mediated abnormal wound healing and extracellular matrix remodeling response. It manifests itself as a combination of overgrowth of cells and hardening and/or scarring of tissues, which together can cause the failure of multiple organs including lung, kidney, liver, and skin. The principal cell type involved is the fibroblast, although injured epithelial cells are implicated in fibrosis of the lung and kidney and stellate cells are specifically associated with liver fibrosis. Myofibroblasts differentiate from fibroblasts in response to profibrotic mediators that are released during the early inflammatory response following tissue injury [204]. Unlike fibroblasts, myofibroblasts express α-smooth muscle actin (α-SMA) and produce extracellular matrix (ECM), which, under chronic inflammatory conditions, is produced in excess, leading to the formation of a fibrotic lesion. Several lines of evidence support the idea that LPA and S1P are involved in the progression of various types of fibrosis.

Recently, LPA-LPA_1 signaling has been shown to have a critical role in the progression of bleomycin-induced pulmonary fibrosis [205]. LPA_1 knockout mice were found to be completely resistant to treatment with bleomycin. LPA was initially identified as a fibroblast chemoattractant in bronchoalveolar lavage (BAL) fluid from injured mice. In mice, LPA_1 knockout dramatically attenuated bleomycin-induced fibroblast accumulation and vascular leakage, but did not change fibroblast proliferation, expression of matrix components, or leukocyte recruitment. Idiopathic pulmonary fibrosis (IPF) patients have elevated levels of LPA in BAL fluids and the BAL fluid-induced fibroblast migration *in vitro* [206]. The migration-stimulating activity was attenuated by Ki16425 (a potent LPA_1 and LPA_3-specific antagonist). These results show that the LPA-LPA_1 axis is critically involved in pulmonary fibrosis in humans. An LPA-LPA_1 axis is also involved in renal fibrosis [207]. Unilateral ureteral obstruction (UUO)-induced renal TIF, for which a mouse model has been developed, was found to be associated with an increased release of LPA by the kidney. In addition, expression of LPA_1 mRNA was significantly increased after UUO. In mice, LPA_1 knockout significantly

attenuated UUO-induced elevations of collagen type III and α-smooth muscle actin mRNA (a fibrosis marker) and F4/80 mRNA (an inflammatory marker) in the kidney. LPA_1 knockout also decreased the expressions of connective tissue growth factor (CTGF) and transforming growth factor β (TGFβ), which are thought to play crucial roles in tubulointerstitial fibrosis (TIF). These results were also obtained in mice treated with Ki16425.

The serum ATX level correlates significantly with liver fibrosis stage in humans and is a better predictor of cirrhosis than either the serum hyaluronic acid level or the aminotransferase-to-platelet ratio index, which is an established marker of liver fibrosis. In another cohort, the serum ATX level correlated significantly with liver stiffness, a novel reliable marker of liver fibrosis [208]. Liver stiffness was the second-best predictor of fibrosis in males (area under receiver-operating characteristic curve (AUROC), 0.799) and females (AUROC, 0.876), the best predictor of cirrhosis in males (AUROC, 0.863), and the third-best predictor of cirrhosis in females (AUROC, 0.872).

26.3.9.3 Neuropathic Pain

Neuropathic pain is also associated with morphological and biochemical abnormalities, such as demyelination and upregulation of the expressions of the γ-isoform of protein kinase C (PKCγ) [209] and the α2δ1 subunit of the voltage-gated calcium channel (Caα2δ1) [210]. Peripheral nerve injury can lead to neuropathic pain that is characterized by allodynia (pain as a result of nonnoxious stimuli) and hyperalgesia (an increased response to normally painful stimuli). Morphological and biochemical abnormalities such as demyelination and upregulation of the γ-isoform of protein kinase C (PKCγ) and the α2δ1 subunit of the voltage-gated calcium channel (Caα2δ1) expression are also associated with neuropathic pain. Intrathecal injection of LPA induced neuropathic pain with the above-mentioned abnormalities [211]. Interestingly, BoTXC3 (a Rho inhibitor) and Y-27632 (a ROCK inhibitor) attenuated the LPA-induced neuropathic pain. Pharmacological and genetic deletion of LPA_1 also completely abolished neuropathic pain induced by not only intrathecal LPA but also by partial sciatic nerve ligation (general neuropathic pain model). These data suggest that LPA–LPA_1 signaling has a crucial role in the initiation of neuropathic pain. Lysophosphatidylcholine (lysolecithin) was also found to induce neuropathic pain-like symptoms [212]. These behaviors were completely abolished in LPA_1 knockout mice and partially rescued in ATX heterozygous mice. ATX heterozygous mice were also more resistant to abnormalities induced by partial sciatic nerve ligation. Therefore, LPA may be synthesized from LPC by ATX at the site of the nerve injury. These results suggest that inhibition of the ATX–LPA–LPA_1 axis is a potential drug target for treatment of the initial phases of neuropathic pain.

26.3.9.4 Roles of S1P and LPA in Lymphocyte Circulation

After T cells are activated by antigen-presenting cells in lymphoid organs, they must return to the circulation to reach sites where antigens are present. It was unclear how the exit of T cells from lymphoid organs is regulated. Cyster and coworkers showed that $S1P_1$-deficient hematopoietic cells, especially T cells, are

not present in the periphery because they can not exit the thymus [213]. Although $S1P_1$-deficient B cells are present in peripheral lymphoid organs, they are severely deficient in blood and lymph. Now, it is well accepted that $S1P_1$ is essential for lymphocyte recirculation and that it regulates the egress of T cells from both thymus and peripheral lymphoid organs. An immunosuppressant drug, FTY720, inhibits lymphocyte emigration from lymphoid organs by downregulating $S1P_1$, creating a temporary pharmacological $S1P_1$-null state in lymphocytes. Now, FTY720 (Fingolimod) is a promising drug for reducing the rate of relapses in relapsing-remitting multiple sclerosis [214].

On the other hand, LPA has been proposed to stimulate the entry of lymphocytes into high endothelial venules (HEVs). Bai *et al.* reported that lymphocyte transmigration across the basal lamina of the HEVs is at least partly regulated by LPA produced by ATX [215]. ATX is selectively expressed by HEVs. Attenuation of ATX *in vivo* impaired the extravasation of lymphocytes from HEVs, inducing the accumulation of lymphocytes in endothelial cells. Interestingly, the accumulation was abrogated by LPA. Although the LPA receptors involved in LPA-regulated lymphocyte extravasation from HEVs are not known, LPA_2 and LPA_5 are the dominant LPA receptors in lymphocytes [216]. These LPA receptors are also targets for drugs that modulate the distribution of lymphocytes.

26.4 Concluding Remarks

Here, we summarized recent progress on bioactive lipid mediators including prostaglandins, leukotrienes, and lysophospholipids. In clear contrast to peptide hormones, the structures of lipid mediators are the same among various animal species, which prompts us to develop new drugs targeting biosynthetic enzymes and receptors for lipid mediators based on the findings obtained from animal disease models. Many subtype-specific agonists and antagonists for receptors for lipid mediators are currently under development, and we will evaluate and develop new drugs targeting lipid mediators in the near future.

27.1 Introduction

Acute inflammation is a universal protective response that serves to combat noxious infectious agents and to orchestrate the healing process following an injury. While saving life in the wild and therefore highly conserved across species, the association of chronic inflammatory events with contemporary diseases of affluence is likely the cost/benefit trade-off (i.e., the price we pay) for retaining a once essential physiological response that evolved in, and was optimized for, a more hostile natural environment [1]. Inflammatory processes are generally associated with changes in cellular status toward a more oxidized redox tone compared to a normal cell, a situation characterized by an increased production of *r*eactive *o*xygen *s*pecies (ROS) and accompanying "oxidative stress." In much of the clinical and some of the biochemical literature, oxidative stress is equated with the production of "free radicals" and tissue damage. As this can undoubtedly be the result of an ongoing process associated with enhanced free radical formation and an inadequate cellular capacity for defense to deal with these chemical threats, the range of reactive species formed are not limited to oxygen but can also be derived from nitrogen/nitrogen oxides and sulfur. As we will see throughout the course of this chapter, not all species are particularly reactive, "free" in terms of their ability to move about, or "radicals" by chemical definition. Moreover, the negative connotation of "stress" implies the involvement of something rather unfavorable that ought to be curbed (in the case of reactive oxygen species by antioxidants, for example) in order to hasten recovery from the stressful situation. The last two decades have taught us that this is a gross oversimplification of the situation at hand, that free radical production is part of normal life and needed for proper cellular functioning, and that tampering with any of its key regulatory elements comes at a price. This chapter attempts to shed some light on the

Inflammation: From Molecular and Cellular Mechanisms to the Clinic, First Edition.

enigmatic world of "free radicals" as it relates to human physiology and disease, with particular emphasis on inflammation. We will briefly review the properties of some important classes and key representatives and look at their role in the intricate network of regulatory processes that fuel our cellular machinery, allowing cells and tissues/organs to quickly adapt to changes in environmental conditions, energetic and metabolic demand, and nutritional status.

27.2 What Are Free Radicals?

A free radical is any atom or molecule with a single unpaired electron. This property makes free radicals particularly reactive. The single electron can be lost to another molecule, an "oxidation" reaction; or equally the free radical can gain a second electron off another molecule to form an electron pair, a "reduction" reaction. These "redox" (a catchy term signifying coupled *red*uction/*ox*idation) reactions always occur together as electrons move from one molecule to another [2].

Although indirect measures had inferred the existence of free radicals in processes such as the action of ultraviolet and/or ionizing radiation and carcinogenesis earlier, their first direct observation in biological systems was not until 1954 when Barry Commener, Jonathan Townsend, and George Pake demonstrated that free radical production dramatically increases in response to increased metabolic activity in yeast preparations and germinating seeds; they also detected free radicals in other living materials including plant leaves, various animal tissues, eggs, and flies [3,4]. In many cases, these radicals were surprisingly stable and appeared to be associated with proteins and polymeric compounds. This advance discovery was made possible by the availability of a new technique called electron paramagnetic resonance (EPR) or electron spin resonance (ESR) spectroscopy, a nondestructive technique using microwave radiation in a magnetic field. Two years later, Denham Harman proposed his theory that free radical-induced damage (now known as oxidative stress) could underlie the physiological process of aging – a theory that is still being actively investigated today [4,5]. Yet despite these developments, even in the late 1960s free radicals were believed by many to be simply too reactive to serve any physiological role in normal cellular processes [6]. Since then, successive discoveries of new free radicals and their widespread cellular effects have not only disproved this view but also opened up new areas of cellular biology and created novel fields of medical research. Arguably this process began in 1968 when Joe McCord and Irwin Fridovich discovered the enzyme superoxide dismutase (SOD) and described its widespread tissue distribution [7]. We now know that superoxide ($O_2^{\bullet -}$) is central to many physiological and pathophysiological cellular functions by acting as a signaling molecule. In contrast to the protein-associated radicals detected by Commoner and colleagues, superoxide is very small, mobile, and highly unstable, decomposing spontaneously to form other reactive species (see below). It is formed not only as a by-product of aerobic respiration in mitochondria but also intentionally by a group of enzymes called NADPH oxidases (NOX) [2]. It has also become clear that superoxide is not the only transient free radical produced inside

cells [6]. Nitric oxide (NO) was the next small molecule containing an unpaired electron demonstrated to fulfill important cell messenger functions. It is formed in virtually all mammalian cells via oxidation of the amino acid L-arginine by a family of enzymes called nitric oxide synthases (NOS) [8–10]. In 1990, Beckman *et al.* suggested that superoxide and nitric oxide could react with each other to form peroxynitrite ($ONOO^-$) [11]. Peroxynitrite itself is not a radical but a powerful prooxidant and also a source of nitrogen dioxide ($^\bullet NO_2$) and the extremely reactive hydroxyl radical ($^\bullet OH$), which reacts with most other compounds in the cell including DNA and membrane lipids [6,11]. While this can obviously have disastrous consequences (e.g., hydroxyl reactions may underlie some of the toxic side effects caused by chemotherapeutic agents such as doxorubicin), it also makes hydroxyl radicals powerful antimicrobial agents with important roles in phagocytosis and possibly also in potentiating the effects of antibiotics [2,12–14].

Within a short period of time, several other reactive molecules were being discovered and an interesting metamorphosis took place; changing their role from unavoidable harmful waste products of aerobic respiration that are better kept at bay to the latest hype of cellular messengers. New small-molecule mediators (some of which are gases at normal pressure and temperature and therefore termed "gasotransmitters") were discovered in quick succession. These included carbon monoxide (CO), hydrogen sulfide (H_2S), and sulfur dioxide (SO_2), with several other candidates including nitrous oxide (N_2O) and ammonia (NH_3) joining in [15]. Almost "overnight," a new, incredibly complex and intricate cellular signaling network emerged with many different interactions, resulting in a functional cross-talk between different signaling pathways. This unique cellular signaling system is now known to be part of the "redox code," a wider set of principles governing interwoven regulatory networks that orchestrate cellular and bodily functions. From the way energy is derived from food to how we adapt to changes in environmental conditions, the redox code has significant implications for health and disease and is likely to become increasingly important as we practice more "personalized medicine" over the coming years [16].

27.3 Oxidative Stress and the Redox Code

Given that redox reactions occur millions of times every day throughout the body and are essential to normal cellular processing in mitochondria, for example, it is not surprising that three of the four most common elements in the universe (hydrogen, oxygen, and nitrogen – with the fourth common element being carbon) all easily form free radicals even though they are not radicals themselves [2,17]. For example, oxygen reacts with hydrogen to form the hydroxyl ion ($^\bullet OH$), with nitrogen to form nitric oxide ($NO^\bullet$) and it can also form superoxide ($O_2^{\bullet -}$). These, along with secondary reaction products such as hydrogen peroxide (H_2O_2) and peroxynitrite ($ONOO^-$) or related reactive compounds such as nitrogen dioxide (NO_2) are collectively known as reactive oxygen species and *r*eactive *n*itrogen *s*pecies (RNS), respectively. However, while most of these compounds (see Table 27.1) are indeed rather reactive, many of them are not

Table 27.1 Overview of the general properties of exemplary ROS, RNS, and RSS.

	ROS	RNS	RSS
Examples	Superoxide Hydrogen peroxide Hydroxyl Radical	Nitric oxide Nitrogen dioxide Peroxynitrite	Hydrogen sulfide Thiyl radicals Sulfite Polysulfides
Production enzymes	Mitochondrial respiratory chain; Cyt P-450; NOX1-5	nNOS, iNOS, eNOS	CSE, CBS, MST; SOX
Exemplary Actions	Oxidative burst	Vasodilation	Redox regulation
Major Clearance Pathways	SOD/Cat, Peroxidases, reaction with biological targets, leading to, for example, lipid oxidation	Reactions with metals, oxygenated heme proteins, oxygen (slow) and thiols	Reactions with metals, heme proteins and oxygen (slow); mitochondrial oxidation

Abbreviations: Cyt P-450: cytochrome P_{450}; NOX: NADPH oxidase; SOD: superoxide dismutase; Cat: catalase; nNOS/iNOS/eNOS: neuronal/inducible/endothelial nitric oxide synthase; CSE: cystathionine y-lyase; CBS: cystathionine ß-synthase; MST: 3-mercaptopyruvate sulfurtransferase; and SOX: sulfur oxidases.

actually radicals. More recently, a third class of compounds, *r*eactive *s*ulfur *s*pecies (RSS), has come to the fore, but much less is known about their specific pathways of formation and overall biological relevance at present [18].

Most of these reactive species are believed to fulfill very specific and highly localized signaling functions, but they can also interact with unwanted cellular targets such as lipids in the cell membrane, essential cellular proteins, or even DNA itself [2]. This may both lead to local cell/tissue damage and enzyme inactivation and give rise to the formation of harmful by-products, which can impair cellular functioning or even result in cell death if production rates exceed the natural clearance capacity. In the case of ROS, this became known as the hallmark of oxidative stress (a situation in which the production of ROS exceeds the cellular antioxidative defense capacity) in the mid-1980s and this term has since become one of the most frequently used terms in redox biology, with a PubMed search at the end of 2015 finding well over 150 000 results [2,19].

The phrase "oxidative stress" incorrectly suggests that a shift in balance between ROS formation and inactivation has universally negative effects on cells and wrongly implies that excess free radical production is typically unintended, which is not the case. More importantly, this term makes no suggestion as to the important physiological role of free radicals, particular in the context of cellular signaling.

In 2015, Helmut Sies and Dean Jones proposed a new and much improved framework, aptly called the redox code, to describe how redox reactions help with both temporal and spatial cellular organization. They suggest that while the cell uses its genetic code to store and transfer information (in the form of DNA), the redox code is essential to how the cell processes, uses, and manipulates that

information to appropriately respond to (and cope with) changes in environmental conditions. As a corollary of this new concept, free radicals are yet another essential way of transferring cellular information, just like DNA [16].

The redox code has four main principles:

1) High flux electron transfer pathways (i.e., oxidation/reduction reactions) organize metabolism through linking different metabolic pathways to each other.
2) Redox pathways also link metabolism to protein structure due to proteomic switches sensitive to redox status, affecting protein activity including enzymatic reactions and molecular trafficking (discussed in more detail below).
3) Differing levels of activation and deactivation of redox pathways (particularly hydrogen peroxide pathways, H_2O_2) allow rapid and precise spatiotemporal cellular signaling.
4) Being able to use the above properties of redox pathways is essential for cells and cellular microcompartments to quickly adapt to changing environmental stimuli and remain healthy – failure of these processes is a major contributory factor to the progression of a wide range of disease processes [16].

To better understand these principles, we first need to look at how free radicals are produced and investigate their normal role in cellular metabolism and aerobic respiration, which occurs deep inside the mitochondria, before looking at each group of reactive species in more detail.

27.4 Free Radical Production: The Mitochondrion

Aerobic respiration – producing cellular energy in the form of adenosine triphosphate (ATP) from oxygen and either glucose or fatty acids – is essential to mammalian life. This process is constantly being performed in almost every cell of the human body (a notable exception is the red blood cell that has no mitochondria) at the level of the mitochondrial inner membrane. Successive redox reactions release energy at each stage of the electron transport chain, and >90% of all ROS in the cell are estimated to be produced as a result of electron leakage during this process, affecting mitochondrial coupling efficiency and thus ATP production. Besides the basal electron leak, which is unregulated and believed to be largely a consequence of the activity of mitochondrial anion carriers, there is an inducible leak that is controlled by a family of uncoupling proteins (the physiological role of UCP1 in brown adipose tissue, for example, is heat production). The escape of electrons at Complexes I and III, that is, prior to the reduction of oxygen to water at the level of Complex IV (cytochrome c oxidase) of the mitochondrial respiratory chain, causes superoxide production [20]. Oxygen normally undergoes four reduction steps (uptake of four electrons and successive reaction with protons) to ultimately produce water. When this process is interrupted at any point, then superoxide, hydrogen peroxide, or hydroxyl radicals will be left depending on whether only one, two, or three reduction reactions have occurred, respectively (see Figure 27.1).

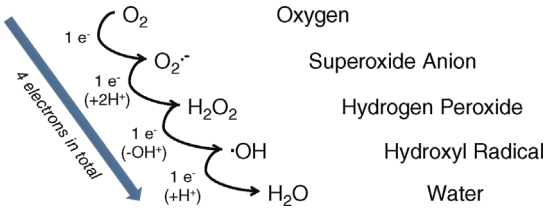

Figure 27.1 In mitochondria, oxygen is subjected to controlled reduction to water in four stages, with free radical intermediate stages (superoxide and the hydroxyl radical) (reproduced with permission from Ref. [2].)

These molecules are collectively known as reactive oxygen species and of particular relevance to the pathophysiology of inflammation.

27.5 Reactive Oxygen Species

Oxygen is the most abundant element in the Earth's crust. It has an unusual electron configuration with two unpaired electrons, making it formally a diradical. Although in its ground state (as the triplet $^3O_2$) it is only a relatively weak oxidant, however, if given more energy it can easily be converted into more reactive molecules [21]. As well as regulating essential cellular processes such as cell differentiation and proliferation, these ROS are hugely important to both the innate immune response and the development of inflammation [22]. One of the most important ROS is superoxide.

27.5.1 Superoxide

Superoxide ($O_2^{\bullet -}$) anions are produced by enzymes that oxidize the cofactor nicotinamide adenine dinucleotide (NAD^+ or NADH, depending on whether it is oxidized or reduced, respectively). This cofactor is essential for respiration as it links the citric acid cycle to Complex 1 at the start of the electron transport chain. NAD^+ can also be phosphorylated itself to form NADPH, and together these two pathways form one of the most important elements of the redox code. Indeed, the discovery of NADPH oxidases (NOX enzymes) was one of the strongest pieces of evidence to suggest that redox reactions have important cellular signaling functions in their own right. They were first discovered as components of phagocytic membranes, forming an important part of innate immunity, but are now known to be expressed widely throughout cells/tissues. Five distinct NOX enzyme isoforms (NOX1-5) have now been identified – all are outward-facing multisubunit complexes that are assembled in the plasma membrane to become functionally active and have only one known function – making either superoxide or hydrogen peroxide [2].

Superoxide can also be generated through other enzymatic reactions. For example, xanthine oxidase reduces oxygen to form ROS such as superoxide ($O_2^{\bullet -}$), hydrogen peroxide (H_2O_2), or hydroxyl radicals ($^{\bullet}OH$) as xanthine is converted to uric acid [2,23]. Equally, cytochrome P-450, cyclooxygenase (COX), and

lipoxygenase enzymes have all been suggested to also produce ROS, often as unwanted by-products when functioning abnormally in pathological states. Perhaps unsurprisingly, therefore, many of these enzymatic pathways are now also widely targeted in clinical practice with pharmacological inhibitors such as cyclooxygenase inhibitors (e.g., nonsteroidal inflammatory drugs such as ibuprofen) or xanthine oxidase inhibitors (e.g., allopurinol).

By far the largest source of superoxide production, however, remains the mitochondrion. Superoxide can be produced on the outer mitochondrial membrane, the mitochondrial matrix, and on both sides of the inner mitochondrial membrane. Complexes I, II, and III all leak electrons to react with oxygen and form superoxide as a relatively stable intermediate. While Complex III appears to be the main source of superoxide production in heart and lung mitochondria, Complex I produces most superoxide in the brain under physiological conditions and also appears to be most important in different pathological states such as Parkinson's disease and also in aging [24].

27.5.2 Hydrogen Peroxide, Hydroxyl Radical, and Oxidative Damage

Although hydrogen peroxide is not technically a free radical as it does not have a free electron, it is still a physiologically important ROS as it can easily be converted into very reactive hydroxyl radicals, particularly in the presence of iron via either the Fenton mechanism ($Fe^{2+} + H_2O_2 \rightarrow Fe^{3+} + {}^{\bullet}OH + {}^{-}OH$) or the Haber–Weiss reaction ($O_2^- + H_2O_2 = Fe^{3+} \rightarrow {}^{\bullet}OH + {}^{-}OH + O_2$) [2].

Hydroxyl ions are, in fact, so reactive (and thus very short-lived) that they will react with almost anything they come across in the cell. Being completely nonselective, they often cause cellular damage by oxidizing lipids, reacting with structural proteins or DNA itself. Some of these oxidation products are widely used as biomarkers of oxidative stress, and their circulating and urinary concentrations tend to be markedly elevated under inflammatory conditions. Importantly, several of these products are not only biomarkers of ROS but also have signaling properties in their own right.

The ease with which lipids undergo peroxidation (by reacting with ROS or RNS) depends on the number of double bonds they have – for example, arachadonic acid is relatively easy to oxidize with four double bonds, while oleic acid only has one double bond and is rather resistant to oxidation (but can be nitrated, see below). The peroxidation process is initiated when lipids (LH) react with ROS or RNS to form lipid radicals ($L^{\bullet}$), which can quickly react further with molecular oxygen to form a lipid peroxyl radical ($LOO^{\bullet}$). Once this second stage has occurred, a self-propagating chain reaction develops as the peroxyl radicals ($LOO^{\bullet}$) abstract hydrogen from further lipid molecules (LH) to produce more lipid radicals ($L^{\bullet}$), which are then peroxidized again ($LOO^{\bullet}$), propagating the chain reaction. This vicious cycle stops only when either the oxygen supply is exhausted or an antioxidant molecule (e.g., vitamin E) can supply a hydrogen atom instead of another lipid molecule and terminate the process [2,25].

Of note, the level of cellular damage caused by oxidative reactions very much depends not only on the amount but also on the type of reactive species present.

For example, the hydroxyl radical can react with all four DNA bases (adenine, guanine, cytosine, and thymine) possibly resulting in transition mutations (e.g., AT → GC or vice versa), impairing gene expression, altering downstream protein synthesis, and ultimately changing cellular function. Meanwhile, hydrogen peroxide does not react with DNA bases at all and does not cause any of these effects. Equally, superoxide cannot react with DNA bases alone, although it does so in the presence of nitric oxide – another reactive species with very important physiological functions but derived from nitrogen instead of oxygen [2].

27.6 Reactive Nitrogen Species

27.6.1 Nitric Oxide

Nitric oxide ($NO^{\bullet}$) was originally known as "endothelial derived relaxing factor" (EDRF) because it was first discovered in the cardiovascular system, where it acts as a potent endogenous vasodilator. Soon thereafter, it was found to also play important roles in the central and peripheral nervous system, the gastrointestinal tract, lung, and kidneys, as a modulator of mitochondrial function and as a crucial component of innate host defense responses [26]. The discovery that EDRF was actually NO, a deceivingly simple free radical and one of the 10 smallest molecules in nature, earned three American pharmacologists (Robert Furchgott, Louis Ignarro, and Ferid Murad) the Nobel Prize in 1998 [27,28]. This controversial decision received widespread attention by the scientific community inasmuch as the Honduran–British pharmacologist Salvador Moncada, one of the most cited scientists in the world whose research made a major contribution to our understanding of how NO is formed and acts, was curiously excluded from consideration by the Nobel committee [29].

However, it was not this sort of attention that fascinated, and continues to attract, so many research scientists, biomedical researchers, and medical doctors to NO, but rather its widespread significance for physiology across the microbial, plant, and animal kingdoms as well as its unusual character as a biological signaling molecule. Unlike many other cellular transmitters, it was not stored in specific vesicles to be released on demand but rather enzymatically produced as needed (although bound forms of NO later became known to serve specialized functions); most peculiarly, NO is a gas at normal pressure and temperature that could cross cell membranes by simple diffusion. It also did not interact with specific cell surface receptors in a lock-key fashion, a principle pharmacologists were most accustomed to at the time, but rather by binding to the heme group of the soluble isoform of guanylate cyclase (sGC) and other heme proteins. This intracellular enzyme converts GTP into the second messenger cyclic GMP, which not only exerts direct downstream effects on phosphodiesterases and ion channels but also causes protein phosphorylation through protein kinase G (PKG) [30]. We now know that NO is just one of several representatives of a growing family of "gasotransmitters," although so far the only radical species.

27.6.2 Enzymatic and Nonenzymatic Production of Nitric Oxide

NO is produced by a family of iso-enzymes called nitric oxide synthases. NOS converts the amino acid L-arginine into L-citrulline and NO in a two-stage process, whereby electrons flow from the reductase domain to the oxidase domain of the enzyme. First, a two-electron oxidation produces *N*-hydroxy-L-arginine as an enzyme-bound intermediate before a second three-electron reaction converts this to L-citrulline and NO. Citrulline can be recycled back to arginine by the cell. Like superoxide production by NOX enzymes, both processes depend on NADPH – however, unlike NOX, NOS is also dependent on the presence of oxygen. In fact, half of each molecule of oxygen is incorporated into the final product, NO. As well as oxygen and NADPH, this process requires a number of other cofactors such as calcium, calmodulin, flavin adenine dinucleotide (FAD), flavin mononucleotide (FMN), and tetrahydrobiopterin (BH_4), linking NO production to other intracellular signaling pathways.

Three different isoforms of NOS exist in mammalian systems. Named either by the tissue in which they were first noted to be expressed or by the chronological order of their successful cloning, all are coded by separate genes on different chromosomes and have different physiological functions. Neuronal nitric oxide synthase (nNOS or NOS-1) and endothelial nitric oxide synthase (eNOS or NOS-3) are both calcium-dependent enzymes regulated by cytokines, hormones, microbial products (e.g., LPS), and other micromilieu factors. As nNOS and eNOS are both constitutively expressed, they are sometimes called "cNOS" and typically only produce pico- to nanomolar concentrations of NO lasting for seconds to minutes (as long as intracellular [Ca^{2+}] is elevated). Meanwhile, inducible nitric oxide synthase (iNOS or NOS-2) is a homodimeric enzyme predominantly found in smooth muscle cells and macrophages; unlike nNOS and eNOS, its activity is calcium-*i*ndependent and *i*nduced by *i*mmunogical/*i*nflammatory stimuli – hence the name. In contrast to the constitutive NOS isoforms, iNOS produces much higher fluxes of NO, depending on the level of expression leading to micromolar concentrations and lasting for hours to days [2,30,31]. Earlier literature also described a specific mitochondrial isoform (mtNOS), but since no DNA encoding for a fourth NOS could be identified this was likely a splice variant of either eNOS or nNOS that was imported into mitochondria under specific experimental conditions.

Besides the level of expression and intracellular localization of NOS, its interaction with other proteins (e.g., caveolin for eNOS) and post-translational modification at specific phosphorylation sites all play a major role for NO output. Other major determinants of NO production in cells and tissues are the availability of cofactors and substrate. L-arginine is taken up through specific transporters, while intracellular NOS substrate concentrations are additionally influenced by the concomitant expression of arginase, an enzyme important for protein formation that utilizes arginine for the production of ornithine and urea. Although the K_m for oxygen has been determined for all three NOS isoforms *in vitro*, how important tissue oxygenation is for NO output *in vivo* is not so clear. Nevertheless, acute hypoxia (which is typically associated with increased ROS production), enhanced arginase expression (a hallmark of inflammation), and

decreased BH_4 availability (secondary to folate deficiency or oxidative stress) all have the potential to reduce NO availability and/or synthesis.

Some NO may also be produced by the spontaneous decomposition of nitrous acid (HNO_2), which arises as a product of protonation of swallowed nitrite (NO_2^-), in the stomach. Some nitrite may be ingested with the diet, but the major proportion of it is the result of commensal bacterial reduction of nitrate (NO_3^-) in the oral cavity. Nitrate is the final oxidation product of NO and a dietary constituent (particularly rich in green leafy vegetables); approximately 20–25% of the circulating nitrate is actively secreted into our saliva where the commensal bacterial flora reduces it to nitrite, which is subsequently swallowed with the saliva to end up in the stomach. Most of this nitrite is absorbed and contributes to circulating nitrite levels in blood, but a small amount may arise in the form of NO as described above. Microbial organisms are well known to reduce nitrate and nitrite through a stepwise respiratory process called denitrification ($NO_3^- \rightarrow NO_2^- \rightarrow NO \rightarrow N_2O \rightarrow N_2$). Although NO is produced as an intermediate, denitrification ultimately results in the formation of nitrous oxide (N_2O) and nitrogen (N_2), in particular under anaerobic conditions [31,32]. More recently, xanthine oxidoreductase has been shown to also act as a mammalian nitrate reductase [33]. These interconversions of RNS by a combination of bacterial and mammalian enzymes have become known as the "mammalian nitrogen oxide cycle" [34].

There is another route through which RNS can be produced nonenzymatically. When solar radiation is shone on the skin, both UVA (315–400 nm) and blue light (420–460 nm) can bioactivate preformed stores of *S*-nitrosothiols and nitrite in the uppermost layer of the skin (the epidermis) to release RNS including NO or peroxynitrite into the circulation [35,36]. The physiological outcome of this process seems to depend on the redox state of the skin tissue being irradiated. Under unstressed (more reducing) conditions, this process seems to favor NO production, which is associated with beneficial hemodynamic effects such as vasodilation and reduced blood pressure; it may also make NO equivalents available to exert preconditioning-like, protective effects on internal organs including the heart [37]. When more oxidative conditions are present, this process seems to favor the production of peroxynitrite and other potentially harmful RNS enhancing radiation-mediated cell death [35].

27.6.3 Nitrogen Dioxide, Peroxynitrite, and RNS Metabolism

Like NO, nitrogen dioxide (NO_2) is also a radical. It is the first oxidation product of NO, and as long as NO is in excess it immediately reacts further with another molecule of NO to form dinitrogen trioxide (N_2O_3), which hydrolyzes to nitrous acid (HNO_2; at physiological pH, it exists largely in the form of nitrite, NO_2^-). *In vivo*, NO and nitrite are both oxidized to nitrate (NO_3^-) in red blood cells, and the latter is used as a marker of whole body NO production [38]. NO_2 also forms in combustion engines and wherever fossil fuels are burned, but human exposure can also be from cigarette smoke. As a strong oxidant, NO_2 is a pulmonary irritant that can lead to permanent lung damage when inhaled chronically or at high levels. *In vivo*, NO_2 and N_2O_3 may also be formed by the action of methemoglobin

(and possibly other hemoproteins) on nitrite, and as part of the downstream chemistry associated with the formation of peroxynitrite [39].

Peroxynitrite ($ONOO^-$) is an important RNS that principally arises as a direct reaction product of the combination of the two radicals, NO and $O_2^{\bullet-}$ [11]. It is a potent prooxidant that can both oxidize sulfhydryl groups to sulfenic and sulfinic acids and entertain nitrosation reactions, giving rise to *S*-nitrosothiols; in addition, tyrosin is oxidized to dityrosine. Moreover, peroxynitrite is (via generation of NO_2) a powerful nitrating species that leads to formation of nitrotyrosine and nitrotryptophan residues in proteins. Nitrotyrosine (NO_2Tyr) formation is a hallmark of inflammation and considered a footprint of enhanced combined ROS and RNS production. However, it may also be indicative of the peroxidative chemistry in the presence of nitrite since $ONOO^-$ can also be formed by the action of myeloperoxidase (MPO) and other peroxidases on nitrite – an action that requires the additional presence of H_2O_2 [40]. Whether this post-translational protein modification contributes to cell toxicity or rather helps limiting local peroxynitrite concentrations and therefore serves an anti-inflammatory role remains unclear [41]. Similarly unclear is whether the nitration of different targets (tyrosine versus tryptophan residues) is associated with different outcomes. Much less is currently known about nitrotryptophan compared to nitrotyrosine, but this is likely merely a reflection of the specificity of detection. While NO_2Tyr formation has traditionally been associated with oxidative damage and pathophysiological processes, more recent evidence suggests it is also a post-translational protein modification involved in physiological cell signaling and organ development [42].

As with oxidative stress, not all nitration is necessarily bad. NO and nitrite-dependent nitration of unsaturated fatty acids (e.g., oleic acid and conjugated linoleic acid both in endogenous lipids and in extra virgin olive oil), for example, leads to formation of various nitrated fatty acids (NO_2FA). These species have recently been demonstrated to exert potent anti-inflammatory and beneficial metabolic regulatory effects by acting, at nanomolar concentrations, as specific ligands to peroxisome proliferator-activated receptor-gamma (PPARγ) [43].

27.6.4 RNS as Anti-infectious Agents

Although now widely known as "inducible" NOS, this particular isoform was originally named iNOS because it was first characterized in immunological macrophages; we today know that it is also expressed at lower levels by other myeloid (e.g., dendritic, neutrophils, and eosinophils) and nonmyeloid cells (e.g., hepatocytes). As well as having similar roles to ROS in phagocytosis, RNS including NO also have both direct and indirect antimicrobial actions and exert regulatory control over different immune cells, particularly T cells [31]. To this end, iNOS-derived RNS can directly interrupt microbial functioning and reproduction through reactions with respiratory chain and cell cycle components, nucleic acids, and metabolic (e.g., Krebs cycle) enzymes as well as by interfering with iron uptake and transport. They can also directly inhibit virulence factors associated with many pathogenic organisms [44,45]. New targets for direct RNS antimicrobial action are still being discovered – some result in immediate

microbial cell death, others delay microbial growth just enough for other components of the immune system to successfully target and clear infectious agents [31].

NO is also associated with cell death through different indirect effects. Interferon gamma (IFN-γ)-induced production of NO by iNOS has also been shown to indirectly trigger apoptotic cell death in macrophages infected with *Mycobacterium tuberculosis* [46]. And in murine macrophages infected with *Listeria*, ß-interferon triggered iNOS activity/NO production has been shown to contribute to cell death through cellular necrosis [47]. NO also indirectly inhibits microbial virulence factors such as *enterohemorrhagic Escherichia coli*'s (EHEC) cardinal virulence factor, Shiga-toxin [48], and indirectly mediates bacterial biofilm dispersal [49]. The realization of this effect on *Pseudomonas aeruginosa* colonies have led NO to being used in clinical trials as an adjunctive therapy in cystic fibrosis patients who are often chronically colonized with difficulty to clear *Pseudomonas* infections [50,51]. This effect of NO on bacterial biofilm formation may also be important for other pathogens, particularly those that have become resistant to multiple antibiotics as dispersal from biofilm into planktonic phenotype renders bacteria considerably more susceptible to the bacteriostatic or bactericidal actions of antibiotics.

Many of the indirect anti-inflammatory effects of NO appear to be mediated by an elaborate redox cross-talk of the three nuclear transcription factors, HIF-1, Nf-kB, and Nrf2, which coordinate oxygen-dependent responses, pro- and anti-inflammatory processes, and cellular antioxidant defense systems, respectively. All three transcription factors are under strict redox control and therefore sensitive to minute changes in cellular redox status, which is influenced by ROS and RNS and additionally modulated by reactive sulfur species.

27.7 Reactive Sulfur Species

Redox biology has focused on effects mediated by ROS and RNS for many years, but reactive sulfur species including thiyl radicals (R-S$^{\bullet}$), hydrogen sulfide (H_2S) and its longer-chain cousins, the per- and polysulfides (R-SSH, R-S_xSH) are increasingly being implicated in important physiological and pathophysiological processes and constitute a significant component of the redox code. They are principally formed from thiols (organic compounds that contain a sulfhydryl (–SH) group) [16,18]. However, because of the instability of RSS (and the associated challenges in detecting and studying them), and with interest in this area of free radical biology having only developed relatively recently compared to both ROS and RNS, the biological implications of RSS reactions are currently much less well understood [18].

27.7.1 Thiyl and Other Sulfur-Based Radicals

Alkylthiyl radicals (R-S$^{\bullet}$) can be formed from thiols physiologically in three main ways: hydrogen abstraction, enzymatic oxidation, or reaction with ROS. For

example, they are commonly produced enzymatically through extremely rapid peroxidase-catalyzed thiol oxidation reactions or via reactions involving the reduction of carbon-based radicals during DNA repair mechanisms. They can also be formed by reactions of both hydroxyl radical and peroxynitrite with thiols – particularly under conditions of increased oxidative stress. Although thiol oxidation is undoubtedly one of the most common mechanisms of RSS production, already-oxidized sulfur-containing compounds can often be oxidized further to produce other sulfur-based radicals [18]. Thiyl radicals are also generated during the homolytic cleavage of S-nitrosothiols (RSNO), i.e. when these compounds release NO.

Thiyl radicals are very unstable and typically react further with other biological targets immediately after they have been formed. For example, oxidation produces either sulfenic or sulfinic acids, they can be reduced back to thiol compounds, or dimerization results in the formation of disulfides ("R-S-S-R"-containing compounds). As disulfides are key structural elements of many cellular proteins and enzymes, changes in cellular redox status have the potential to alter protein structure and enzyme function [16,18].

Of the four common sulfur-containing amino acids (methionine, cysteine, homocysteine, and taurine), only methionine and cysteine are involved in protein synthesis. Methionine is normally the initiating amino acid in the synthesis of every eukaryotic protein; however, it is often buried deep inside the hydrophobic core of the protein once the protein folds into its tertiary structure. Cysteine, which is important for determining a protein's secondary and tertiary structures, often forms and breaks disulfide bonds very easily in response to changes in cellular redox status [52]. This structural and functional plasticity, an integral part of the redox code, allows cells to constantly adjust protein structure and enzymatic function through structural conformational changes induced by the oxidation or reduction of cysteine thiol groups [16,18,52].

Cysteine (and other thiol) groups also play important roles in other methods of cellular communication as they are essential to the production of hydrogen sulfide (H_2S) [18,53].

27.7.2 Hydrogen Sulfide

H_2S is produced from cysteine, cystine, and/or homocysteine by three enzymes of the transsulfuration pathway: cystathionine γ-lyase (CSE – also known as CTH), cystathionine β-synthase (CBS), and mercaptopyruvate sulfurtransferase (MST), depending on substrate availability and tissue type [53,54]. It shares with NO its affinity to metals (i.e., it binds to heme proteins), but unlike NO, it is not a radical. H_2S is inactivated either through heme-mediated reactions or through mitochondrial oxidation into sulfite and thiosulfate. At high concentrations, it inhibits mitochondrial respiration, but at lower levels it also serves as a mitochondrial substrate; this process not only makes H_2S the first noncarbon respiratory fuel to be characterized in mammals [55] but also means that H_2S concentrations are explicitly linked to cellular respiration. The products of sulfide respiration can either go on to exert various physiological effects themselves or be further oxidized into sulfate by sulfur oxidases (SOX) [53].

Although the realization that H_2S may be an important signaling molecule is a rather recent event, pharmacological concentrations of H_2S/HS^- have already been shown to have an astonishing variety of protective or beneficial physiological actions, and inhibition of its formation has been linked to pathophysiology [54,56–58]. H_2S appears to directly interact with various protein structures, have potent antioxidant properties, and modulates the effects of some RNS [53,54]. Of particular significance in this context appears to be its interaction with the NO signaling pathway, a growing area of research that has become known as the "NO/H_2S cross-talk." This interaction occurs both at a functional level and by direct chemical reaction; the latter gives rise to formation of several new products including sulfur/nitrogen hybrid molecules (e.g., nitrosopersulfide, $SSNO^-$) and longer-chain sulfur species (S_x^{2-}, polysulfides) [59]. The latter have recently come to the fore as potential mediators of the action of H_2S as a signaling molecule [60], and their cysteine and glutathione adducts were found in surprisingly high concentrations in murine tissues [61]. These longer-chain sulfur species are of interest not only because they are considerably more reactive than regular thiols but also due to the ease with which their sulfur–sulfur bonds can break to form two sulfur radical species (e.g., a pentasulfide anion falls apart spontaneously to generate one trisulfur radical and one persulfide radical: $S_5^{2-} \rightarrow {}^{\bullet}S_3^- + {}^{\bullet}S_2^-$) [62].

27.7.3 Could RSS have been Mistaken for ROS?

An interesting development in the free radical/oxidative stress field is the recent realization of commonality in chemical reactivity between ROS (derived from the reduction of oxygen) and RSS (originating from the oxidation of H_2S) (see Figure 27.2). This was first pointed out in the context of toxicity from dietary thiols [63], and more recently has been discussed in a review about the possible role of H_2S in evolution [64], to be followed up by a specific report on the cross-reactivity of RSS with five probes/techniques commonly used to detect ROS [65]. All those reagents and detection methods that are widely used to ascertain the production of ROS and/or to quantify the extent of oxidative stress in biological systems were also found to react with RSS, in some cases with considerably higher sensitivity to polysulfides than to H_2O_2. The authors of this work also pointed out the similarity; these findings suggest that RSS may be considerably more prevalent in biological systems than hitherto assumed, calling for a careful reassessment of the significance of ROS in cell signaling and questioning the role of ROS as the most biologically important oxidants. Moreover, this discovery may also be of relevance to the development and treatment of prooxidative conditions with antioxidants.

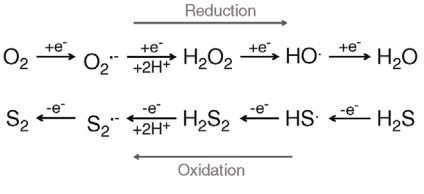

Figure 27.2 Similarity in intermediary products of redox interconversion of ROS (from oxygen, O_2) and RSS (from hydrogen sulfide, H_2S) [65].

27.8 Making Redox Regulation Work: ROS, RNS, and RSS Acting in Concert at the Level of Thiols

As we have seen, ROS, RNS, and RSS can interact with a variety of biological targets, depending on the chemical reactivity of individual species. By far the most important targets in terms of redox signaling are free sulfhydryl (–SH) groups in peptides and proteins as these represent the "nanotransducing" regulatory elements integral to a proper functioning of the redox code [66]. This is made possible by the versatility of sulfur to exist in many different oxidation states and molecular forms, as illustrated in Figure 27.3.

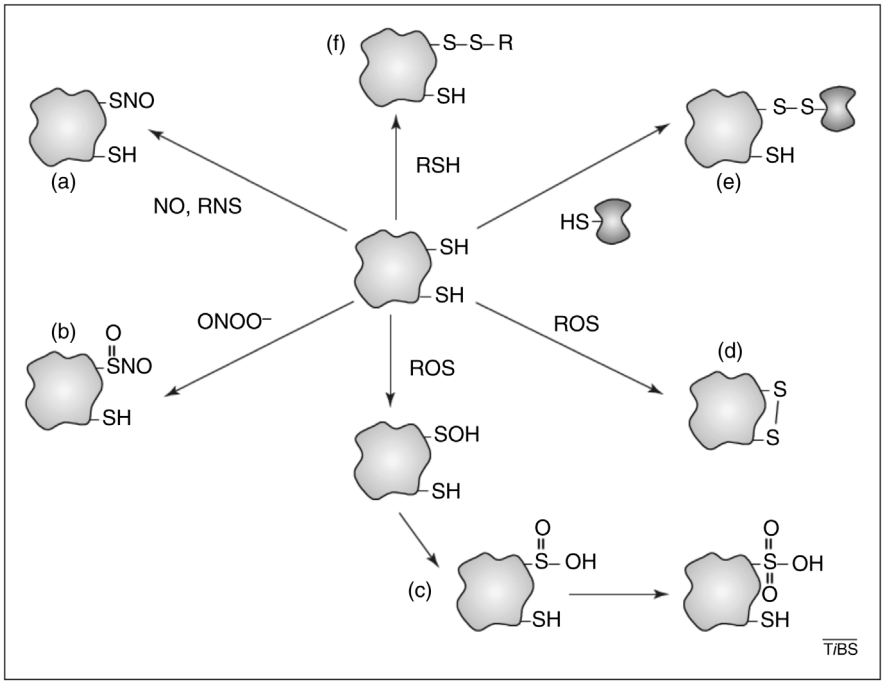

Figure 27.3 The many faces of cysteine as signal transducing element. (a) Reactive nitrogen species including nitric oxide can mediate S-nitrosylation to yield an *S*-nitrosothiol (SNO). (b) RNS, including peroxynitrite ($ONOO^-$), can also mediate S-nitration to yield *S*-nitrothiols. (c) Sequential oxidation of cysteine thiols yields sulfenic (–SOH), sulfinic ($–SO_2H$), or sulfonic ($–SO_3H$) acid derivatives. Alternatively, (d) oxidation by ROS and RNS (peroxynitrite, *S*-nitrosothiols, etc.) can result in a disulfide bridge (cystine) between two adjacent thiols in a protein. (e) Similar disulfide bridges can also be formed between different proteins as well as between a protein and a hydrogen sulfide (H_2S) metabolite (not depicted) to form a mixed disulphide (persulfide). (f) Reaction between protein thiols and low molecular weight thiols (e.g., glutathione, cysteine etc.) and other reactive sulfur species) can yield mixed disulfides (R-S-S-R′). Each of these thiol modifications has the possibility of eliciting different biological responses (reproduced with permission from Ref. [66]).

27.9 Antioxidants/Free Radical Scavengers

The term "antioxidant" originates from industrial contexts in the early nineteenth and twentieth centuries where it was used to describe compounds that prevented oxygen consumption. Their manufacturing uses ranged from preventing rusting of ferrous metals to minimizing the damage petroleum fuels caused to combustion engines. In the biological context, the term is now used to describe any molecule able to donate an electron to a reactive free radical (i.e., one single electron) and thereby successfully neutralize it before it can do any damage. Although it is possible to get an idea about the relative reactivity of certain molecules towards free radicals by calculating and comparing one-electron reduction potentials based on their physicochemical properties (and thus to predict a reaction hierarchy or "pecking order") [67], this is an oversimplification of the situation *in vivo* and usually of little help to determine which is the most important antioxidant. Not all antioxidants are equally well suited to scavenge free radicals everywhere, and their efficiency to act as antioxidants depends on many other factors including their local concentration, water versus fat solubility (which determines cell/tissue distribution), the nature of the free radical it is supposed to protect against, and the ease with which it can be produced and regenerated. Most antioxidants have more or less specific enzyme systems in place that serve to quickly regenerate the reduced form with the help of reducing equivalents, such as NADH and NADPH, once it has reacted with an oxidant. In fact, an elaborate network of interconnected antioxidant generating/replenishing systems exists, acting together to protect nuclear constituents, intermediary enzymes, structural proteins, lipids, hormones, and other messengers from damage.

Many antioxidants are sourced from our diets, such as vitamin C (ascorbic acid) or vitamin E (α-tocopherol), although many of them are also produced endogenously during normal metabolic processes, including albumin, glutathione, melatonin, and uric acid. In addition to the finite amounts of small-molecule (and protein) antioxidants, a number of endogenous enzymes such as SOD and catalase fulfill important antioxidant functions as part of the bodily antioxidative defense system [25].

27.9.1 Dietary Antioxidants

Vitamin C (ascorbic acid) is a potent water-soluble electron donor giving it antioxidant properties. It also functions as an essential cofactor in several metabolic processes; unusually, and although it is ubiquitous to many animal and plant species, it cannot be synthesized in humans and hence must be part of our diet. Even though direct experimental evidence that vitamin C supplementation can reduce oxidative DNA damage is very limited, vitamin C-rich diets (e.g., those high in fruit and vegetables) have repeatedly been associated with a lower incidence of cardiovascular disease in epidemiological studies [25,68,69]. The importance of vitamin C for health has been well documented throughout history because of scurvy – a disease caused by vitamin C deficiency resulting in lethargy, petechia, and bleeding from mucous membranes. Scurvy is one of the oldest

diseases known to man – ancient Egyptians noted that onions and vegetables (now known to be rich in vitamin C) reverse its symptoms, as described in the Papyrus of Ebers in 1550 BC – yet it has remained endemic to mariners, prisoners of war, and polar explorers throughout the eighteenth, nineteenth, and twentieth centuries [70].

Vitamin E is a collection of four tocopherols and four tocotrienols. All are lipid soluble, but α-tocopherol is the most abundant and probably the most important form in humans as it also has the highest bioavailability. It plays an important role in terminating the lipid peroxidation chain reaction (see above) by directly reacting with lipid radicals [25,71,72]. Dietary polyphenols seem to serve a similar role.

27.9.2 Endogenous Antioxidants

Melatonin is a naturally occurring hormone with powerful antioxidant effects. Being lipid soluble, it can easily cross cell membranes and the blood–brain barrier, but unusually once it has been oxidized it cannot be reduced again, making it a terminal antioxidant[25].

Uric acid is one of the most common antioxidants found in the blood stream, and a considerable portion of the total antioxidant capacity of plasma is due to uric acid [25]. Another abundant extracellular antioxidant is serum albumin. It has long been used as a resuscitation fluid in critical illness and known to fulfill many important physiological functions (e.g., osmotic control, binding and transport of metals, hormones, and drugs); its free radical scavenging properties are linked to its amino acid content and tertiary structure. In addition to a few tryptophan and methionine residues, (which can also confer antioxidant protection), it contains a single reduced thiol group at Cys-34 that appears to be the major target of ROS, RNS, and RSS and responsible for the majority of its antioxidant/anti-inflammatory properties.

NO is not only an important cell signaling molecule but also an efficient "chain-breaking antioxidant" by virtue of its efficient reaction with lipid radicals before they have a chance to react with oxygen [73]. As a radical, NO can also intercept other oxygen-based radicals such as superoxide (to form peroxynitrite) and the hydroxyl radical (to form nitrous acid, HNO_2) – these radical–radical reactions are among the fastest reactions known in biology.

Glutathione is a cysteine containing tripeptide (Glu, Cys, and Gly) synthesized *in vivo* from constituent amino acids. The free sulfhydryl (SH) group in its constituent cysteine gives it powerful antioxidant properties allowing it to be reversibly oxidized and reduced many times. Together with its relatively high (millimolar) concentration inside cells, this property makes it one of the most important cellular antioxidants and a critical element of the redox code [25]. By contrast, extracellular glutathione concentrations (and that of other low molecular weight thiols) are very low – this is where the free SH group of serum albumin dominates as thiol protectant of other plasma constituents and cell surface constituents.

Glutathione is also particularly important clinically for the treatment of paracetamol overdoses. Paracetamol is one of the most commonly used analgesic agents in the world. Unlike NSAIDs, it has relatively little anti-inflammatory

activity and is normally exceptionally well tolerated with minimal side effects in the normal therapeutic range. However in excess (i.e., >4 g per day), it can rapidly be fatal through severe hepatotoxicity and liver failure. More than 30 000 patients are hospitalized in the United States of America every year due to paracetamol toxicity with up to 50% of these overdoses being accidental [2,74]. Although the majority of paracetamol is metabolized into nontoxic breakdown products, 5% is converted by cytochrome P_{450} enzymes into *N*-acetyl-*p*-benzoquinoneimine (NAPQI). NAPQI is a very reactive electrophilic intermediate that causes hepatotoxicity through covalently binding to cysteine-containing proteins in the liver, producing ROS- and RNS-mediated mitochondrial dysfunction – hence rapid clearance is essential for health. Normal detoxification of NAPQI is through reacting with glutathione to form nontoxic cysteine and mercapturic acid conjugate products. However, large doses of paracetamol (either as one large dose or as multiple staggered doses that accumulate) can quickly exhaust hepatic glutathione stores, at which point the rate of NAPQI clearance is limited by the rate that hepatocytes can synthesize glutathione. The treatment for paracetamol overdose, *N*-acetylcysteine, works by restoring hepatic levels of glutathione to allow NAPQI clearance to continue [2,75].

27.9.3 Cells Respond to Oxidative Stress through Increased Antioxidant Gene Expression

The redox code proposes that proteomic functioning can be controlled kinetically through adjusting redox potentials and the effect they have on sulfur switches [16]. Indeed, an increased antioxidant production is the natural response to acute and prolonged exposure to oxidants through exactly this mechanism. Under normal cellular conditions, kelch-like ECH-associated protein (Keap1) binds to and stabilizes nuclear erythroid 2-related factor (Nrf2) stabilizing it in the cytoplasm. However, increased ROS, RNS, or RSS production oxidizes sulfur residues in the cysteine components of Keap1 causing transformational changes that induce its release from Nrf2. Once free from Keap1, the Nrf2 transcription factors can migrate into the nucleus and bind to the so-called antioxidant response elements (ARE), activating the transcription of antioxidant genes to upregulate the production of SOD, glutathione reductase/peroxidase, heme oxygenase, and many other components of the antioxidative defense network [2].

27.9.4 Antioxidants: Harmful or Beneficial?

For some time, dietary supplementation of antioxidants was proposed as a safe way of reducing the harmful effects caused by excess cellular free radicals, yet many studies that tried to prove this effect have failed to do so. A meta-analysis of many of those studies suggests that antioxidant supplementation may worsen outcomes even further and actually increase all-cause mortality [76]. This finding may now not be that surprising once we acknowledge that these compounds are an integral part of and important control elements to the redox code, which help balance redox potentials and modulate cellular signaling systems appropriately to environmental challenges. Interfering with the natural

ARE system by curbing oxidant signaling inputs will fool the system into believing its natural defense systems are appropriately balanced, leading to an unintentional downregulation of antioxidant poise. Since one particular dietary antioxidant cannot fulfill all the functions of the many constituents of this heterogenous redox network, an inevitable result is increased damage of regulatory elements with eventual failure of important signaling pathways. Together with lifestyle-related factors, including an unfavorable diet and inappropriately low physical activity, this will give rise to what may soon be called "redox diseases."

27.10 The Redox Code in Health and Disease

We have known for some time about the essential role free radicals play in physiological processes such as the innate immune response and aging. However, as our understanding of the redox code improves, we are seeing that alterations in free radical production are also important to disease progression under an increasing number of chronic inflammatory conditions, from atherosclerosis to cancer.

27.10.1 Inflammation and the Innate Immune Response

The early stages of inflammation are characterized by innate immune responses such as "the respiratory burst," with free radical (particularly ROS) formation by phagocytic cells such as neutrophils, monocytes, and eosinophils forming a key part of this process.

Phagocytes surround and engulf material labeled as foreign by the innate immune system (e.g., invading bacteria labeled by complement), encapsulating it in phagocytic vacuoles. NADPH oxidases are then activated in the wall of the vacuole, producing superoxide and hydrogen peroxide inside the vacuole. Hydrogen peroxide converts to hydroxyl ions via the Fenton mechanism ($Fe^{2+} + H_2O_2 \rightarrow Fe^{3+} + {}^{*}OH + {}^{-}OH$) or the Haber–Weiss reaction ($^{\bullet}O_2^- + H_2O_2 \xrightarrow{Fe^{3+}} {}^{*}OH + {}^{-}OH + O_2$), as discussed in Section 27.5 on ROS. Second, MPO (an enzyme secreted into the phagocytic vacuole) catalyzes H_2O_2 to convert chloride, bromide, or iodide ions into the respective hypohalous acids, for example, chloride into hypochlorous acid (HOCl). Together, these reactive species then kill the invading organism inside the vacuole [2]. This mechanism, in concert with the peroxynitrite-mediated chemistry discussed above, is what kills invading pathogens and forms a vital part of the innate immune response. Given the aggressiveness of this part of intracellular "chemical warfare," it is not difficult to see how this could become problematic if inappropriately activated and/or prolonged in the absence of a pathogen to combat because the redox-related "switch-off signal" is lacking or because the set-point for redox control moved to an inappropriate level due to enhanced ROS/RSS tone secondary to impaired NO production.

27.10.2 Aging

As organisms grow older, they become more susceptible to disease, many of their biological functions deteriorate and their chance of dying within a given period of

time increases significantly [77]. It is now almost 60 years since Denham Harman first proposed that this process of aging (which he defined as "growth, decline, and death") could be due to the "deleterious effects of free radicals on cell constituents" [5].

Lipid peroxidation, DNA oxidation, and protein oxidation are all known to increase with advanced age. The redox balance of thiol/disulfide groups has also been shown to shift meaning that redox changes in one compartment can result in transformational changes in other cellular compartments through structural and conformational changes, giving one potential mechanism to underlie the increasing functional impairment seen with aging [77]. The redox status of a cell's microenvironment may also be one of the key determinants in how quickly that cell becomes senescent (stops replicating) – a natural cellular process that is clearly associated with aging. For example, hydrogen peroxide and increased ROS production caused by exposure to UV light or $p21^{ras}$ have all been shown to accelerate cellular senescence in experimental models *in vitro* [77–80].

Different drosophila lines with mutations to increase their resistance to oxidative stress and increased expression of both SOD and catalase have also all been shown to have longer than expected life spans in experimental studies [81–83]. Similar effects have been shown in other model experimental species with mitochondrial DNA being particularly important to the free radical aging theory. Mitochondrial DNA appears to be particularly susceptible to free radical-mediated damage during aging and accumulating deletion mutations may also directly contribute to the generation of sarcopenic phenotypes in skeletal muscle – a phenotype particularly common and well associated with advanced age [77] as well as chronic hypoxic situations, from living at high altitude over COPD to critical illness.

However, despite almost 60 years of work investigating this free radical theory of aging, all of the above evidence only shows an association between free radical production and aging, and often only *in vitro* – a "cause and effect" relationship *in vivo* has yet to be demonstrated.

27.10.3 Diabetes Mellitus

The hallmarks of diabetes are hyperglycemia and increased insulin resistance – both of which are associated with increased free radical formation. Hyperglycemia itself both causes, and is also caused by, increased ROS production. Increased glucose oxidation, nonenzymatic glycation of proteins, and the subsequent oxidative degradation of glycated proteins result in production of disproportionately high levels of ROS, which in turn results in further glucose oxidation setting off a vicious cycle [84]. The resultant cell damage caused by this enhanced oxidative stress, including lipid peroxidation and damage both to cellular organelles and to intracellular proteins and enzymes, also contributes to increased insulin resistance [84].

Type I diabetes, however, is caused not by increased resistance but by a lack of insulin production caused by the destruction of pancreatic beta cells. This process is caused by immune-mediated targeting of insulin-producing beta cells, and this

appears to be at least partially mediated through increased ROS production by white immune cells [85].

ROS are also associated with the development of complications in diabetes. Extensive animal studies have demonstrated that oxidative stress may be a final common pathway in the development of diabetic neuropathy and that antioxidants can prevent or reverse hyperglycemia-induced nerve dysfunction [86]. Hyperglycemia also increases the ability of vascular cells to oxidize low-density lipoproteins (LDL) by lowering the bioavailability of endothelial NO, increasing the pathogenesis of atherosclerosis [77,87].

27.10.4 Cardiovascular Disease: Atherosclerosis

Atherosclerosis is a common multifactorial inflammatory condition characterized by thickening and hardening of arterial vessel walls and the formation of fatty plaques under their endothelium. Diabetes, hypertension, and hyperlipidemia are all well-known risk factors for the development of atherosclerotic lesions, but excessive ROS production and resulting oxidative stress may provide the common link associated with the development and progression of atherosclerosis [77].

Oxidative stress increases cellular invasion of the arterial wall by increasing the expression of cellular adhesion molecules (e.g., ICAM-1) and protein kinases, resulting in migration of monocytes, macrophages, and T cells. Both monocytes and macrophage cells in particular possess scavenger receptors for oxidized LDL and increase manganese SOD (Mn-SOD) expression, resulting in enhanced H_2O_2 production in response to oxidized LDL binding. This increase in ROS not only causes further lipid peroxidation, but also results in more oxidized LDL binding, propagating this process further; it also increases apoptotic cell death of macrophages, further destabilizing the plaque [77].

Besides leading to a progressive narrowing of the intravascular lumen one of the biggest risks posed by atherosclerosis is that the plaques rupture and release fatty acids and inflammatory products into the blood. Immediate thrombus formation occurs to wall off this break in the endothelium, but this thrombus will also cause either partial or total occlusion of the vessel lumen, resulting in downstream tissue ischemia or infarction, respectively, for example, a myocardial infarction (MI) caused by a thrombus over an atherosclerotic plaque causing occlusion of a coronary artery. Interestingly, reperfusing these tissues after a period of ischemia may also cause free radical- mediated injury [2].

27.10.5 Ischemia Reperfusion Injury

Ischemia and reperfusion result in increased free radical formation through a number of different mechanisms. First, tissue ischemia results in cellular ATP depletion. Lack of oxygen reduces forward flux through the electron transport chain (which produces 34 molecules of ATP for every molecule of glucose) and instead the cell is forced to rely on glycolysis for ATP production, which only produces two molecules of ATP from every glucose molecule. Lack of flow through the electron transport chain increases the proton gradient across the

mitochondrial membrane increasing the likelihood of mitochondrial ROS production as this proton-motive force leaks back across the membrane but without enough substrate to result in complete oxidation to water [2,77].

Ischemia also encourages the conversion of the xanthine dehydrogenase enzyme into xanthine oxidase (XO). As ATP production is decreased under hypoxic conditions (see above), concentrations of catabolic breakdown products such as ADP, AMP, and adenosine accumulate. Ultimately, ATP is catabolized to hypoxanthine, which XO converts into uric acid, with huge amounts of superoxide and hydrogen peroxide produced as by-products of this reaction [2,77,88]. Finally, ischemic conditions also increase the release of free metal ions such as Fe^{2+} and Fe^{3+}, which can cause increased ROS production through the Fenton mechanism or the Haber–Weiss reaction, as discussed earlier [2].

These reperfusion-induced free radical effects have numerous important clinical implications, such as in transplant surgery when a removed organ is rapidly reperfused after being surgically fixed in the recipient, potentially resulting in cellular necrosis and subsequent organ failure or graft rejection [2]. Similar harmful free radical-mediated reperfusion effects have also been described in stroke medicine where thrombolysis treatment may paradoxically cause further injury in some cases [89].

27.11 Looking to the Future: Newly Discovered Signaling Roles, the Reactive Species Interactome, and an Increasing Need to Assess the Role of Free Radicals in Personalized Medicine

With our increasing knowledge of free radical species interactions, it has become increasingly clear that ROS, RNS, and RSS have broad signaling effects well beyond individual cells. For example, it has recently been demonstrated that changes to extracellular redox status can result in downstream alterations to cellular metabolic function, with a more reduced extracellular state maximally increasing hepatocellular mitochondrial activity [90]. The stable breakdown products of reactive species present in extracellular fluids such as blood or lymph could conceivably link individual cells and provide a particular microenvironment that has the potential to modulate immune cell function and that of other circulating blood cells; equally, it may provide a read-out of the redox tone and stress or energetic status of cells in distant organ systems.

Free radicals also signal between host tissues and commensal organisms or invading pathogens. For example, subtle changes in oxygen gradients may also govern how our gut microflora interacts with our intestinal cells [91]; the enterosalivary recirculation pathway (where commensal bacteria in the mouth and GI tract sequentially reduce dietary nitrite and nitrate) is an important component of the mammalian *N*-oxide cycle contributing to an elevation of circulating levels of nitrite and a mild but notable reduction in blood pressure [92–94]. Similarly, microbial generation of H_2S (e.g., as a result of sulfate reduction) may significantly contribute to total body sulfide content and also

lower blood pressure, although this microbial sulfide circulatory pathway is currently much less clearly defined [95,96]. Recent data from a large epidemiological cohort study demonstrating the modulation of nitrate's effects on blood pressure by sulfate intake [97] are testament to the potential for interaction between different reactive species and highlight the complexity of these interactions in the context of the host/microbial cross-talk *in vivo*.

Reactive species could link physiological, environmental or pharmacological stressors to the development of particular disease states. With the current drive to increasingly "personalize" medicine, free radicals that characterize specific disease activity (disease-specific "biomarkers") could be utilized to target clinical interventions. Trying to identify and produce reliable assays for these markers has consequently become a major focus of current research.

27.11.1 Prognostic Markers in an Increasingly Personalized World of Medicine

Emerging evidence suggests that certain reactive species, in particular RSS, could turn out to be excellent clinical biomarkers – of interest in this context are the total concentration of circulating protein thiols as well as free and protein-bound low-molecular-weight thiols [98].

Interestingly, the ratio of reduced to oxidized small aminothiols (e.g., cysteine and glutathione) never reaches equilibrium – even in a dynamic and constantly changing redox system – and shows diurnal variation [99]. The relative proportion of reduced over oxidized thiols also decreases with age [100]. These observations suggest that this is a tightly regulated system even though we currently know little about its maintenance and regulation [98]. Even more unexpectedly, given the overall complexity of intra- and extracellular redox systems, the concentration of total free thiol groups in plasma or serum alone has been associated with clinical outcomes in a number of widely varied and seemingly unrelated clinical conditions [98]. These include blood dyscrasias, malignancies, endocrine disorders such as diabetes mellitus and thyroid disease, cardiovascular conditions, renal pathologies, neurological complaints, dermatological conditions, respiratory diseases, and other inflammatory disorders [101–107]. Known disease risk factors such as smoking, aging, alcoholism, and obesity all correlate with the degree of thiol oxidation [108].

Given that the single free cysteine residue of human serum albumin accounts for almost two-thirds of all free thiols [109], accounting for the total protein level will also indirectly account for total thiol content, and protein-adjusted free thiols can therefore approximate for the ratio of reduced:oxidized thiols [98]. Measured in this way, protein-adjusted serum free thiol levels closely predicted outcome in both kidney transplant recipients and patients with congestive cardiac failure [110,111] as well as correlated independently with overall life span [112].

27.11.2 The Reactive Species Interactome

We started this chapter by introducing the concept of the "Redox Code" – a set of principles that place redox species (e.g., thiols, NAD^+, or ROS/RNS) at the heart

of cellular reactions and define how redox systems enable and protect certain biological functions in both space and time [16]. However, even this concept does not fully explain the complexity and integrative nature of redox systems; how free radical species interact with multiple downstream physiological targets to produce such varied effects; why antioxidants seem to have such small effects on an organism's function, or why free thiols are of prognostic value in terms of clinical outcome.

A new concept has recently been proposed that goes even further in recognizing this higher level of complexity, organization, and integrative function – the *Reactive Species Interactome* [98]. This concept explains how ROS, RNS, and RSS (probably alongside other small reactive species yet to be identified and investigated) interact among themselves and with other biological targets in a highly adaptable, flexible, and controlled manner, thereby enabling effective sensing of and rapid adaptation to changes in environmental conditions and stressors. To this end, the *Reactive Species Interactome* can be understood as a stress adaptation system that confers stability and resilience to cells and tissues in a world of constant change. This system allows energetic demand and supply to be matched by fine-tuning intermediary metabolism to ensure the whole organism stays fit-for-purpose and copes with daily stresses. In the *Reactive Species Interactome*, blood and lymph act as the central communication conduit between cells and organs and provides a readout of whole-body redox status, offering opportunities for biomarker-guided personalized medicine once we understand the significance of each metabolite (the concentrations of which can be measured in blood). Remarkably well preserved through evolution across different species and kingdoms, the complexity of this system has evolved to confer a high level of reserve capacity and redundancy to protect the organism against a variety of stressors. This explains its importance in the development of different disease states when it is allowed to become unbalanced or other factors intervene [98]. It also offers opportunities to use a combination of appropriate biomarkers to interrogate the status of the entire system for risk stratification and to guide interventions aimed at restoring health. Clearly, this novel concept requires further investigation but free radical chemistry and redox systems biology undoubtedly hold much promise for the future of clinical medicine.

27.12 Conclusions: Free Radicals, the Reactive Species Interactome, and Its Importance to the Inflammatory Response

Although it is now over 60 years since their first discovery, it is only relatively recently that we have started to see how important free radicals are to cellular signaling. While we have understood their importance to immune processes and inflammation for much longer, our understanding of the cellular redox code at the systems level is still at its infancy.

Free radicals are essential to the successful functioning of our innate immune response but ROS, RNS, and RSS conspire to carry out many other important

cellular signaling functions. Nevertheless, unopposed excess free radical formation is undoubtedly harmful with oxidative stress being associated with a number of inflammatory conditions and processes from diabetes to aging. The emerging concept of an overarching redox code offers a useful framework to explain how these interactions impact both beneficial and deleterious processes. These range from organizing catabolism, anabolism, and metabolism through high-flux electron carrier systems such as NAD(P)H, to linking energy usage to protein structure and to cysteine-based redox reactions, and forming signaling networks both by dividing the cell into smaller functional intercommunicating microcompartments and by arranging organizational networks between cells and even across different tissues. The redox code offers the cell an intricate, precise, and functioning chemical signaling system, which neatly links information storage to information processing while allowing the flexibility to meet varying metabolic demands depending on environmental conditions and challenges. Extending this idea further with the emerging concept of the "Reactive Species Interactome," a highly flexible, adaptive, and rapidly responsive integrative system with free radicals and redox status at its heart offers unprecedented potential for disease diagnosis, guidance of therapeutic interventions, and risk stratification.

Free radical production is essential for normal life and needed for proper cellular functioning. Arguably "inflammation" could be considered simply to be the result not of a bodily malfunction of some sort but rather the consequence of or "price to be paid" for a necessary adjustment of key regulatory elements of the whole-body redox web to keep all systems still functioning. As our understanding of these processes grows, the *Reactive Species Interactome* will almost certainly offer many new potential therapeutic targets and become an increasingly important component in the personalized medicine of the future.

28.1 Introduction

Increased proteolytic activity at inflammatory sites has been described for decades. However, the role of proteases in inflammation was underestimated, due to the belief that proteases were merely involved in debris clearance from inflammatory sites and tissue remodeling. A number of studies have now involved proteases as true signaling molecules that have ubiquitous roles in inflammatory response, ranging, for instance, from antimicrobial activities to permeability functions and inflammatory mediator processing.

Herein, we will discuss the origin and function of proteases at inflammatory sites, and the relevance that this knowledge brings to possible intervention in chronic inflammatory disorders.

28.2 Host Proteases and Inhibitors: Origin and Distribution

Proteases, which represent up to 2% of the human genome, are defined as proteins able to cleave specifically other proteins, either at their extremities (for exopeptidases) or at the core of the protein (for endopeptidases, also named proteinases). The proteolytic mechanism of proteases involves specific residues, which define the class of proteases, thereby called serine, cysteine, metallo-, aspartic, or threonine proteases (Figure 28.1 and Table 28.1). Some proteases reside and act from the intracellular milieu, while others can be secreted (see Figure 28.1). Upon inflammation, increased proteolytic activity is detected at the inflammatory site, and the origin of these proteases can be either eukaryotic or prokaryotic. Whether originating from microbes or from the host, protease hyperactivity could initiate the inflammatory response or could be a consequence of tissue inflammatory response. From the host side, upon inflammation, proteases can be released either by inflammatory cells or by resident noninflammatory cells.

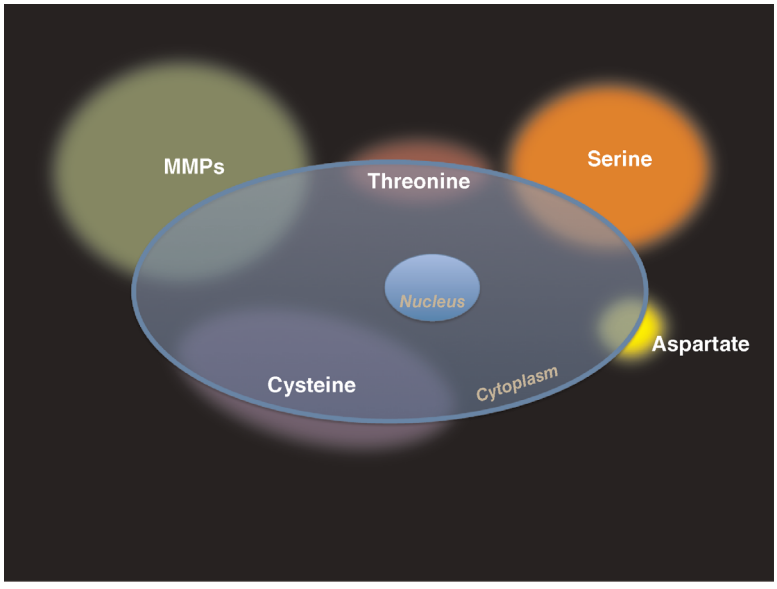

Figure 28.1 Eukaryotic cell proteases according to their catalytic mechanisms and their intracellular/extracellular representation. The size of the protease circles is proportional to their cellular representation.

28.2.1 Inflammatory Cells

Among infiltrated leukocytes, neutrophils constitute a major source of proteases. Within their granules, large amounts of elastase, proteinase-3, and cathepsin G are contained and released upon cell activation [1]. Macrophages are also rich in proteases, producing metalloproteinases (MMPs), in particular MMP-12, and also in caspases and cathepsins such as cathepsins L and D [2]. Proteases also constitute the major protein content of mast cells, which release tryptase, chymase, cathepsin G, or granzyme B [3].

28.2.2 Resident Cells

At mucosal surface, epithelial cells constitute an important source of proteases: mesotrypsin, matryptase, and even elastolytic activity have been associated with epidermal or intestinal epithelium [4–8]. In the case of elastolytic activity, this was clearly associated with chronic inflammation of the gut [5]. All other resident cells express intracellular cysteine proteases, such as the large family of intracellular caspases, but they can also release serine proteases upon damage. This has been demonstrated for endothelial cells, keratinocytes, or even neurons or fibroblasts. Finally, all cell types express intracellular proteases of the proteasome system, which are crucial regulators of the intracellular protein turnover. These proteases, which belong to the families of the cysteine or metalloproteinases, target ubiquitinylated proteins and change their degradation fate inside all cells. The proteasome system is a major component of cellular homeostasis and is not

specifically associated with inflammation, but in an inflammatory context, changes in the proteasome functions have been described (see Section 28.3).

28.2.3 Protease Inhibitors

Protease inhibitors have coevolved with proteases, with the aim of controlling the destructive nature of proteases. Protease inhibitors can either be circulating inhibitors produced for the most part in the liver and released within the circulation or could be produced on site, by resident cells, or infiltrated inflammatory cells (see Table 28.2). Serpins are mostly systemic protease inhibitors that

inhibit a wide range of extracellular serine proteases. Locally released protease inhibitors such as secretory leukocyte protease inhibitor (SLPI) or Elafin are produced *in situ* both by resident cells and by infiltrated leukocytes, and inhibit elastases and proteinase-3, in addition to trypsin, chymotrypsin, cathepsin G, and tryptase for SLPI. Tissue inhibitors of metalloproteinases (TIMPs) are ubiquitous and inhibit a wide range of MMPs (see Table 28.2). A family of protease inhibitors has been uncovered in the skin, the Kazal family, and it seems to be specific for the inhibition of kallikreins (KLKs). This family of protease inhibitors includes LEKTI (lympho-epithelial Kazal-type inhibitor), LEKTI2, and SPINK6 (serine protease inhibitor of Kazal type 6) (see Table 28.2).

28.3 Host Protease's Functions in Inflammation

Association of dysregulated proteolytic activity with inflammation has been largely described and has often been associated with the degradative functions of proteases. However, proteases dispose of a very large arsenal of mechanisms to intervene in inflammatory processes and to participate in symptoms generation (see Figure 28.2).

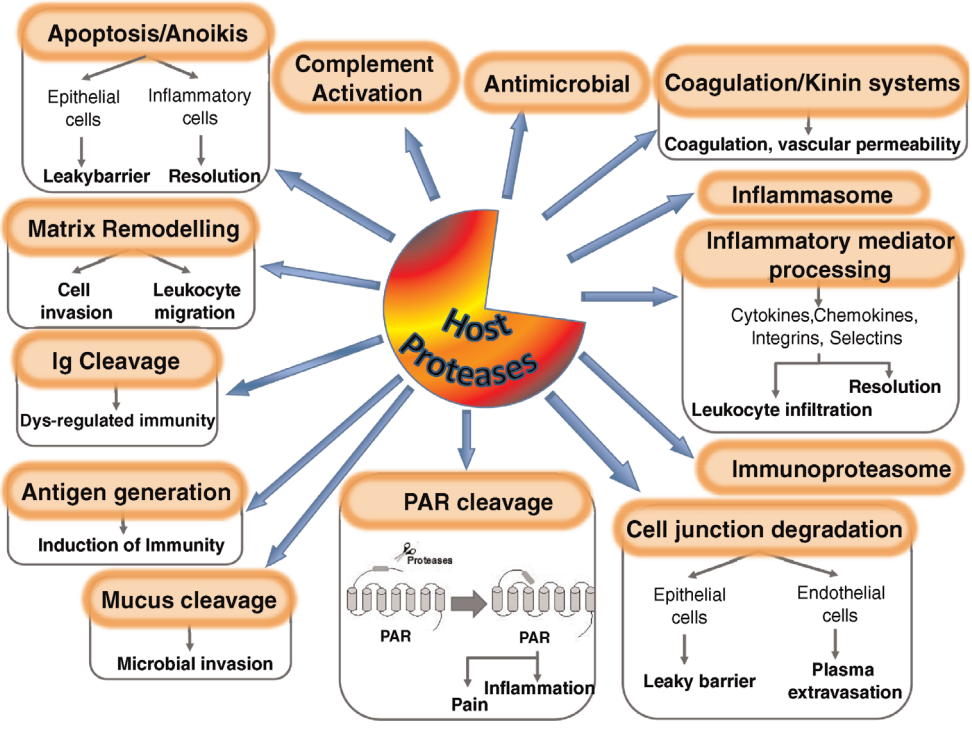

Figure 28.2 Mechanisms of action of host proteases at inflammatory sites and their consequences.

28.3.1 Antimicrobial Functions

Proteases and in particular those from neutrophils (including neutrophil elastase, proteinase-3, cathepsin G, and neutrophil serine proteinase-4) display strong antimicrobial functions. They can (1) directly kill bacteria, they can (2) activate by cleavage host immune proteins to generate active antimicrobial peptides, they can (3) target and inactivate bacterial virulence factors, resulting in attenuated microbial potency. and finally, (4) they participate in the formation of neutrophil extracellular traps (NET) (see Chapter 10).

Neutrophil elastase can directly kill bacteria such as *Klebsiella pneumonia* or *Escherichia coli* by cleavage of the outer membrane protein A (OmpA), resulting in the loss of bacteria membrane integrity and cell death [9]. Neutrophil proteases can also act in combination to enter the bacteria capsules and provoke membrane holes. This is what was observed with the Gram-positive *Streptococcus pneumonia*, killed by the concerted action of neutrophil elastase, cathepsin G, and proteinase-3 [10].

Extracellular cleavage of the host protein hCAP-18 by proteinase-3 or KLK5 and KLK7 from epithelial cells generates the antimicrobial peptide LL-37 [11–13]. Similarly, cleavage of the complement protein C3 or of the tissue-factor pathway inhibitors (TFPI-1 and TFPI-2) by neutrophil elastase leads to the release of powerful antimicrobial peptides that kill a wide range of bacteria [14].

Proteases can also target microbial virulence factors. For example, neutrophil elastase cleaves the invasins and the mobility protein IscA of *Shigella flexneri*, preventing thereby bacterial dissemination. Cathepsin G cleaves the *Staphylococcus aureus* adhesion clumping factor A [15].

Finally, neutrophil elastase is absolutely required for NET formation (see Chapter 10), where it cleaves histones to facilitate DNA decondensation. Within the NET, neutrophil proteases can exert the same antimicrobial actions described above, being in direct and privileged contact with microbes, while limiting damage in adjacent healthy tissues.

28.3.2 Inflammatory Mediator Processing

By their ability to cleave other proteins, proteases can either activate or deactivate protein targets. Indeed, they can transform an inactive precursor protein or a repressed receptor into an active mediator or a derepressed receptor. On the contrary, they can also degrade proteins and thereby inactivate active proteins. In an inflammatory context, proteolytic cleavage of some chemokines and cytokines preforms is necessary to transform them into active molecules. Proteinase-3 and cathepsin G are known to cleave CXCL-8 and CXCL-5, respectively. The cleaved fragments of these two chemokines acquire through proteolytic cleavage a higher chemotactic activity toward neutrophils. KLK7 is able to cleave the proform of Interleukin (IL)-1β (IL-1β) into an active form of IL-1β [16]. Proteinase-3 also activates IL-1, IL-18, and tumor necrosis factor-alpha (TNFα). In both cases, proteinase-3 clearly exerts proinflammatory effects, amplifying the activity of proinflammatory cytokines and chemokines. However, proteinase-3 can also exert anti-inflammatory effects by degrading the proinflammatory cytokine

IL-6. Cathepsin G can also be anti-inflammatory, degrading and inactivating mature TNFα and IL-6. The net effect of proteolytic modifications on chemokine and cytokine activation or degradation is still unclear. The overall pro- or anti-inflammatory effect of proteolytic activity depends on the nature and quantity of proteases released in the inflammatory microenvironment and on the kinetic of cytokine and chemokine release. Selectins and integrins also constitute proteolytic targets. Chymotrypsin, collagenase, stromelysin, and a disintegrin and metalloproteinase (ADAM)-17 metalloproteinase are able to shed selectins at cell surface. Cathepsins cleave integrins, thereby inhibiting the attachment of migrating cells to extracellular matrix components. These evidences demonstrate that proteases can regulate the initial steps of leukocyte recruitment in an inflammatory context, controlling rolling and adhesion events through the cleavage of selectins and integrins.

28.3.3 Junction Molecule Degradation

Cell–cell junctions constitute an important element of tissue homeostasis, which is disrupted in inflammation. These cell–cell junctions are disrupted in blood vessels, between endothelial cells, thereby allowing microvascular leakage, leukocyte transmigration, plasma extravasation, and edema (one of the cardinal signs of inflammation). Upon inflammation, cell–cell junction disruption also occurs at mucosal surfaces between epithelial cells, thereby leading to a leaky mucosal barrier that allows the passage of luminal content and further innate immune response. Proteases, by degrading cell junction proteins, are associated with both microvascular and mucosa barrier leakages.

Neutrophil elastase and cathepsin G cleave the vascular E-cadherin adherent junction protein on endothelial cell, thereby participating in the disruption of endothelial barrier and the transendothelial passage of leukocytes toward inflammatory sites [17,18]. Thrombin is also able to disassemble claudin-5 from the endothelial cell junction [19].

A number of studies have reported the disrupting effects of proteases on barrier function. However, evidence that proteases are acting through a direct degradation of junction proteins is scarce. Chymases are able to alter tight junction proteins such as occludins and zonula occcludens (ZO)-1 in intestinal epithelial cells [20]. KLK5, a form of trypsin produced by the epidermis, is able to degrade desmoglein-1, thereby causing barrier defects [21–23]. Indeed some members of the KLK family are expressed in the most superficial layer of epidermis, where they are involved in maintaining barrier integrity and function. Among the KLK family composed of 15 serine proteases, only KLK5, KLK7, KLK8, and KLK14 are known to be present as active forms in the *stratum corneum* [24]. In normal skin, these proteases are known to play prominent roles. In particular, it has been well documented that KLK5, KLK7, and KLK14 contribute to desquamation by degrading desmosomal cadherins, such as desmoglein1 and desmocollin1 [25], whereas caspase-14 is needed to complete the processing of filaggrin [26,27]. However, in the absence of inhibition as illustrated in Netherton syndrome, or after skin injury, proteolytic activity could be increased and detrimental. Hyperactivity of KLK5 through desmoglein1 degradation leads to hyperdesquamation [21,23], and

elastase-2 hyperactivity leads to skin dehydration [6]. This detrimental effect of proteases is not solely mediated by junction protein degradation. Activation of protease-activated receptors (PARs) is largely implicated (see Section 28.3.8).

28.3.4 Mucus and Surfactant Protein Cleavage

An important element of the mucosal barrier is the mucus layer. This is a matrix produced by mucosal epithelial surface and consists in a protective coating. It is made of glycoproteins known as mucins, which are secreted by specialized epithelial cells. The role of the mucus layer is to physically restrain microorganisms in the lumen, blocking their access to the underneath tissues. Mucins are large highly glycosylated proteins. A defective mucus layer leads to severe pathologies associated with chronic inflammation and infection, such as cystic fibrosis or inflammatory bowel diseases (IBD). Bacterial proteases have been largely studied for their properties to degrade mucus (see Section 28.4). In contrast, few studies have investigated the role of host proteases in mucus properties, but a recent study has demonstrated that mice deficient for the metalloproteinase meprin-β have a mucus layer strongly attached to epithelial cells in the intestine. This attachment can be reversed by exposure to meprin-β. Whether this plays a positive or negative role in a context of inflammation is not clear yet. Neutrophil elastase is known to induce mucus instability at lung surfaces. In chronic obstructive pulmonary diseases, rapid consumption of secreted proteases by an increased presence of protease inhibitors enhances mucin gel stability and possible mucus retention [28]. These two examples suggest that host proteases are important for mucus detachment from the epithelial mucus producing cells and that protease deficiency might lead to mucus retention. Host proteases are also important in signaling mechanisms to induce mucus production [29]. Indeed, neutrophil elastase is one of the most potent mucus secretagogue, not only inducing globlet cell degranulation and secretion of mucins but also acting at the transcriptional and post-transcriptional level, to increase the expression of mucins [29]. Although their mechanism of action has been less studied, proteinase-3 and cathepsin G also stimulate mucus secretion. Neutrophil elastase, Human airways trypsin-like protease and ADAM-17/TACE all display sheddase activity on the epidermal growth factor (EGF) receptor ligand transforming growth factor (TGF)-α, leading to downstream production of mucins [29].

Along with mucins, surfactant proteins are also important protective molecules present on the lung epithelial surface and can be targeted by host proteases. Neutrophil elastase, proteinase-3, and cathepsin-G are able to degrade surfactant proteins, resulting in the loss of biophysical and immunomodulatory properties of surfactant proteins [30].

28.3.5 Immunoglobulin Cleavage

Immunoglobulins (Ig) are highly sensitive to proteolytic cleavage by proteases. Several studies have reported the effects of microbial proteases on Ig degradation (see Section 27.4) and the subsequent modification of immune response. It is

not known yet whether host proteases are also capable of degrading Ig in an inflammatory context. However, considering the very large amount of host proteases that are released at inflammatory sites, and the large spectrum of their proteolytic actions, it is conceivable that host proteases could also cleave Ig or Ig receptors and thereby modify the immune response. Indeed, *in vitro* studies suggest that host proteases are capable of Ig degradation. MMP-3, MMP-12, cathepsin G, and neutrophil elastase are able to cleave Fab fragments and the amino-terminal amino acid sequence of the Fc fragment of human IgG. Similar fragments to the ones obtained by *in vitro* cleavage induced by these host proteases were recovered in synovial fluids of rheumatoid arthritis patients, suggesting that proteolysis of IgG in the joints by host proteases could occur *in vivo* and could contribute to joint inflammation [31].

28.3.6 Immunoproteasome, Antigen Presentation, and Processing

In lysosomal compartment of cells lies a very acidic network of vesicles, where proteases (aspartic and cysteine proteases) are the proteins the most represented. These proteases are constitutively expressed in most cell types, but a particular strong representation exists in antigen-presenting cells: macrophages and dendritic cells [32]. These proteases consist mostly of cathepsins and an endopeptidase named asparagine endopeptidase (AEP).

The main function of these intracellular proteases in antigen-presenting cells is to participate in the two well-established roles of class II major histocompatibility complex (MHC) pathways: (1) initiation of the removal of the invariant chain chaperone from class II MHC molecules and (2) the generation of suitable peptides for class II MHC binding [32]. Indeed, the uptake of exogenous antigens by macrophages or dendritic cells is followed by proteolytic degradation in endo/lysosomal compartments. Little is known about the precise identity of the specific enzymes that generate particular MHC class-II-bound peptides *in vivo* [33]. However, AEP has a central role in the generation of specific T-cell epitopes from several antigens. The protease initiates proteolytic events presumably, eliciting unfolding of the antigen to generate substrates for other enzymes, such as cathepsin D and cathepsin E [34,35]. Cathepsin L and cathepsin S are the best characterized proteases involved in the endosomal processing of the invariant chain, a chaperone molecule, which is associated with MHC class II molecules in the endoplasmic reticulum [35]. Cathepsins are also involved in antigen cross presentation of pathogen antigens, which are internalized, degraded, and presented by MHC class I, a crucial step to prime CD8 T cell responses. Numerous mechanisms can regulate the activity of endolysosomal cysteine proteases. Transcriptional regulation, trafficking, environmental pH, and activation of the proenzyme by the presence or absence of inhibitors are among those mechanisms [32,36]. There is no consensus on the transcriptional level of cathepsins after exposure to an inflammatory stimulus such as interferon-gamma (IFNγ), but the regulation of cathepsins mRNA seems to be highly sensitive to environmental changes, such as the presence of cytokines in the milieu, cell adhesion to substrates, and cell–cell contact [37–40].

Proteases other than the endolysosomal proteases are able to influence the initiation and polarization of adaptive immune responses. Studies have shown that neutrophil elastase may cleave the dendritic cell costimulatory molecules CD40, CD80, and CD86, which are essential for the stimulation of adaptive immunity. This proteolytic cleavage blocks the maturation of dendritic cells in response to lipopolysaccharide, reducing T-lymphocyte stimulatory capacity [41]. Together with neutrophil elastase, cathepsin G can cleave T-cell surface proteins that are involved in cell–cell interactions and activation, which may lead to reduced T-lymphocyte functionality in neutrophil-rich areas [42].

28.3.7 Matrix Remodeling

The extracellular matrix is a highly dynamic structure that is strongly remodeled upon inflammation. It is remodeled by the infiltration of microbial agents in the case of nonsterile inflammation, by the infiltration of inflammatory cells, and by tissue damage and destruction at inflammatory sites. In the resolution phase, active mechanisms also remodel the extracellular matrix, in order to reestablish tissue functions and homeostasis (see Chapter 60). The extracellular matrix interacts with cells to regulate migration, proliferation, and differentiation, and cleavage of extracellular matrix constitutes the main regulatory process of these functions. Clearly, MMPs, ADAMs, and ADAMTS are the main proteases responsible for matrix remodeling. They are controlled by the presence of TIMPs (see Table 28.2). Excessive extracellular matrix degradation is often associated with chronic inflammatory diseases, and could lead to a loss of organ function. Excess deposition of collagen-rich extracellular matrix and inappropriate inhibition of MMPs could also lead to fibrosis, a debilitating condition that can occur in most organs exposed to chronic inflammation. Therefore, it is crucial that the role of proteases in extracellular matrix remodeling could be tightly controlled in chronic inflammatory disorders.

28.3.8 Receptor Activation

Proteases may also modulate the inflammatory response by acting on receptors, and several studies report the involvement of receptor activation in proteases-induced effects on inflammation.

Cathepsin G is known to interact with the G protein-coupled formyl peptide receptor, and this interaction leads to the activation of MAP kinase pathways and further chemotactic effects for neutrophils [43]. However, the exact mechanism of action of cathepsin G on the formyl peptide receptor is unknown.

Neutrophil elastase also seems to have receptor-dependent effects involving the Gram-negative bacteria receptor Toll-like receptor(TLR)-4. Proteolytic intervention on this receptor leads to interleukin-8 upregulation and, therefore, potential chemoattraction of inflammatory cells. Proteolytic activity is necessary for this effect, but the mode of activation of the receptor is still unknown [44].

The mechanism by which proteases activate cell receptors that has been the most studied and fully characterized is the activation of the protease-activated receptor family (see Figure 28.3). Four members belong to this family of receptors,

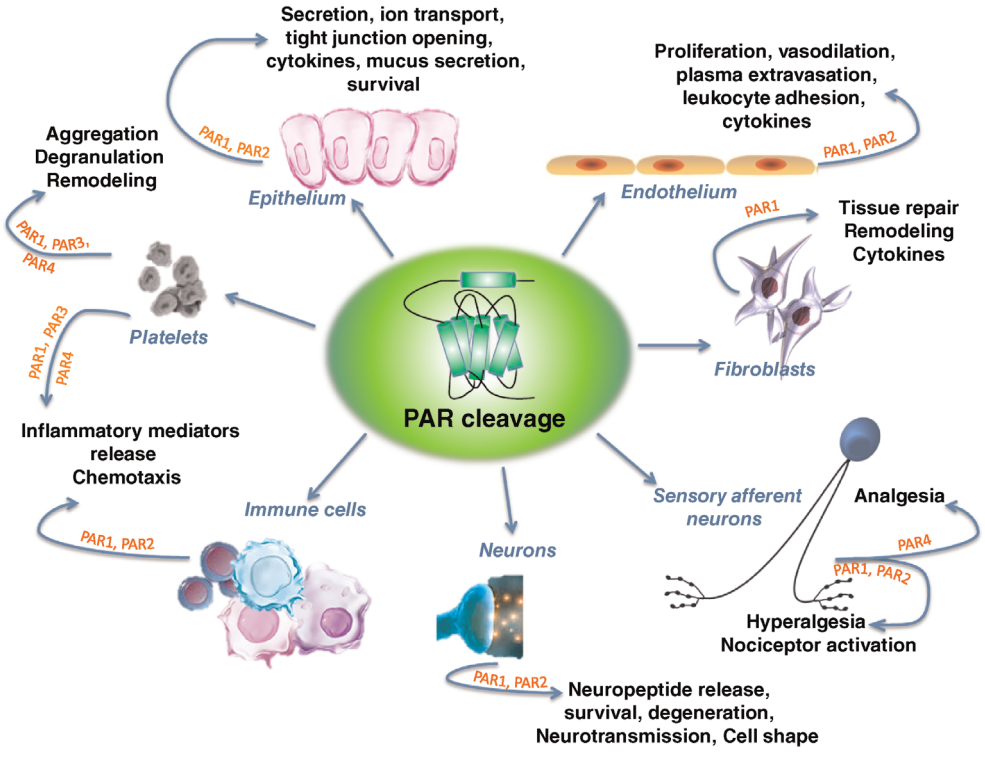

Figure 28.3 Inflammation-related effects of PAR activation on cells.

PAR1–4, and they are activated by the proteolytic cleavage of their extracellular N-terminal domain [45]. This proteolytic cleavage leads to the release of a new N-terminal domain that acts as a tethered ligand, which then binds and activates the receptor for further intracellular signaling (see Figure 28.3). Initially, canonical sites of activation have been described and were thought to be the only sites of activation. Small peptides corresponding to these canonical cleavages could be synthesized and used as pharmacological agonist tools. However, more recent studies have determined that cleavage sites other than the canonical sites are present on the N-terminal domain of these receptors, and cleavage at these noncanonical sites could induce different signaling pathways, therefore, identifying possible biased agonism for these receptors [46]. While the first receptor of this family was identified in the field of vascular research for its role in platelet aggregation (PAR1 was identified as the receptor responsible for thrombin-induced platelet aggregation in humans) [47], early studies have also uncovered the role of these receptors in inflammation. PAR1 and PAR2 activation are leading to all the cardinal signs of inflammation: *rubor et tumor, cum calor et dolor* [48,49]. Further studies have demonstrated that the expression of these receptors is highly ubiquitous and activation of these receptors on different cell types leads to a wide range of inflammatory features (see Figure 28.3). They are present on endothelial cells, where their activation leads to microvascular leakage [45]. They are present in epithelial cells (lung, intestine, bladder, skin, etc.), where activation of PAR1

and PAR2 affects epithelial barrier function by a mechanism involving not only the mobilization of myosin light chain kinase and the relocalization of junction proteins but also the induction of apoptosis in the case of PAR1 [50–54] and the induction of cell survival in the case of PAR2 [55]. Activation of PARs on epithelial cells also induces the release of chemokines such as interleukin-8, and modifies ion exchanges [56,57]. For instance, PAR2 activation on keratinocytes leads to the release of IL-8, TNFα, and thymic stromal lymphopoietin (TSLP) [58,59]. PARs are present on sensory neurons. The activation of PAR1 and PAR2 on primary afferents provokes the release of neuropeptides such as substance P or calcitonin gene-related peptide [60,61] and activation of pain pathways [62], while PAR4 activation seems to be analgesic [63,64]. PARs are also present in inflammatory cells, where their cleavage leads to cell activation. This has been particularly studied in lymphocytes and mast cells, where their activation could lead to the release of proinflammatory cytokines [45]. In the case of PAR2 activation on mast cells, studies have demonstrated that it induces the release of histamine, playing a role in scratching and itch [65]. Overall, PAR activation seems to coincide with proinflammatory effects, although some studies in specific conditions and tissues have also described discrete anti-inflammatory properties [45]. However, most of the studies investigating the consequences of PAR activation have used small synthetic peptides corresponding to the canonical site of cleavage or proteases known to cleave at these sites. The pharmacology of these receptors and their function in inflammation would need to be further studied taking into account biased agonism and proteolytic cleavage at sites other than the canonical site. The corollary of these studies would be the determination at sites of inflammation of the proteases that are present and that activate the different PARs.

28.3.9 Apoptosis or Anoikis

Programmed cell death is an important step of chronic inflammatory disorders (see Chapters 10 and 18), and it is tightly controlled by proteolytic activity. Intracellular caspases and autophagins are obviously major actors of these processes. Apoptosis is induced by the activation of cysteine proteases, including caspases 8, 9, and 3 [66]. Other caspases are also known for their pro-inflammatory properties, for instance, caspase 1 and 4. Overall, caspases through their role in inducing cell death regulate inflammatory and immune responses [66]. Proteases other than caspases are also capable of inducing apoptosis or anoikis. Among them, thrombin and granzymes are proteases that are released in the extracellular milieu at inflammatory sites. If apoptosis is induced in inflammatory cells such as neutrophils, this process favors the resolution of inflammation. Protease-triggered neutrophil apoptosis would, therefore, be protective in chronic inflammatory disorders. In contrast, if apoptosis occurs in tissue cells, it could lead to excessive tissue destruction and potential loss of function. There, protease-triggered apoptosis would further feed inflammatory processes and be detrimental to tissue repair. The proteolytic mechanisms involved in caspase intracellular signaling associated with apoptosis have been largely described [66]. The mechanisms of extracellular proteases-induced apoptosis have been less investigated,

but some studies describe a role for PAR activation, and in particular PAR1 activation, which is able to induce apoptosis in intestinal epithelial cells, contributing both *in vitro* and *in vivo* to a loss of barrier function [50].

28.3.10 Coagulation and Fibrinolysis

Apart from their role in hemostasis, coagulant and fibrinolytic proteases are important mediators of inflammation (see Chapter 32) (Figure 28.4) [67]. Coagulation proteases circulate in the blood under their zymogen form (Factor X and plasminogen). They enter damaged tissues as a consequence of vascular rupture, and there, they become activated and contribute to extracellular coagulation and fibrinolysis. These proteases can act through the activation of PARs, evoking cell-mediated actions on blood and vascular cells (endothelium and platelets), on structural cells (fibroblasts, smooth muscles, neurons, etc.) or on inflammatory cells (macrophages). PAR1 is the prototypical receptor of thrombin and Factor Xa [68], although PAR4 can also be activated by thrombin, and most recently thrombin signaling in PAR2 has been discovered [69]. Coagulation proteases can

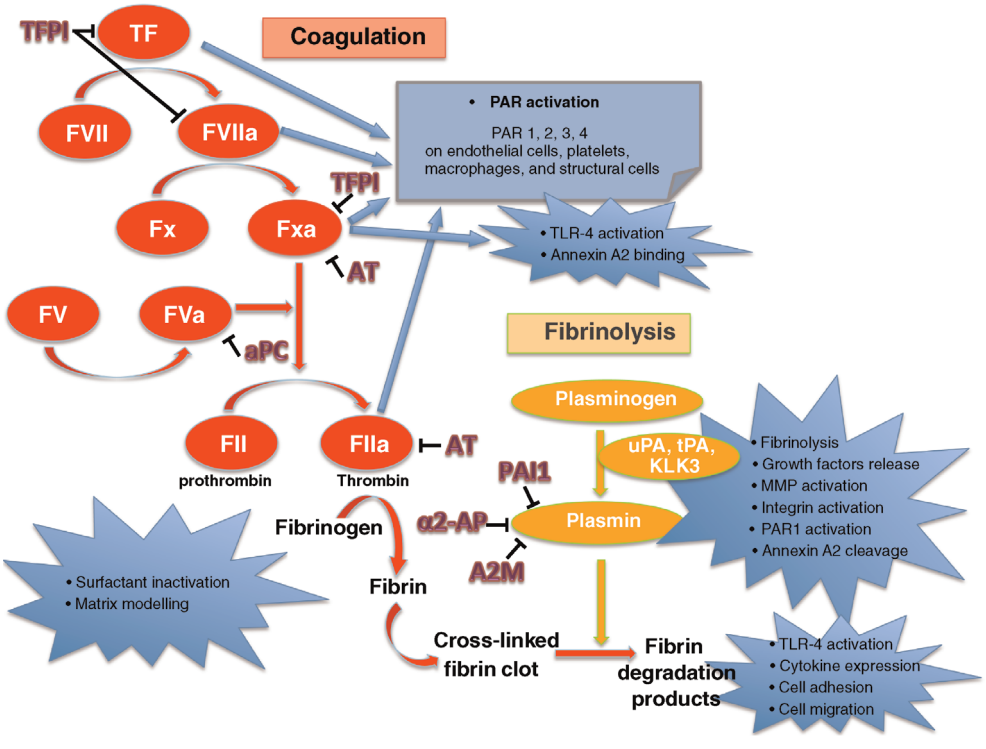

Figure 28.4 Intervention of coagulant and fibrinolytic proteases in inflammatory processes. In tissue injury and disease, the proteases FXa, FVIIa, tissue factor (TF), thrombin, plasmin, uPA, and tPA not only participate in extravascular coagulation (red pathway) or fibrinolysis (orange pathway) but also influence inflammation (blue background). These proteases are controlled by protease inhibitors (in purple), such as antithrombin (AT), tissue factor protease inhibitor (TFPI), activated protein C (aPC), and plasmin activator inhibitor (PAI1)

signal through PARs by binding the receptor at hirudin-like sites and further cleaving PAR extracellular domain, as it was demonstrated for thrombin and PAR1. Fibrinolysis proteases can also use cofactors, such as integrins; plasmin by binding $\alpha_9\beta_1$ integrin is localized at the cell surface, where it is protected from inhibitors, and gets closer to PAR1, increasing its affinity for this receptor. Finally, coagulation proteases also use receptor dimerization, as illustrated by the PAR1–PAR4 cooperation in platelets [70].

Coagulation proteases also act by proteolytic cleavage of other proteases and growth factor transactivation. Plasmin catalyzes the proteolytic activation of MMPs and releases latent forms of growth factors such as EGF and TGFβ. Plasmin activates MMP-1, MMP-2, MMP-3, MMP-9, MMP13, and MMP-14. The effects of plasmin on EGF receptor signaling involve heparin-binding EGF, an EGF receptor ligand, which is released from cell surface by MMP proteolysis [71]. Similarly, plasmin is able to mobilize matrix-bound TGFβ, contributing to collagen synthesis [72].

Urokinase (uPA) and tissue-type plasminogen activator (t-PA), the proteases that convert plasminogen into plasmin, also signal through other receptors: the uPAR and the LDL receptor-related protein 1 [67]. This signaling, in an inflammatory context, involves integrin recruitment and conveys remodeling. By interacting with uPAR, uPA activates coreceptors, including the formyl-peptide receptor 2 (see Chapters 57 and 58), the EGF receptor, and integrins. This signaling regulates migration, chemotaxis, and cytokine production [67].

Coagulation and fibrinolysis systems also contribute to inflammation by their role in the formation and degradation of fibrin. Fibrinogen cleavage by thrombin releases fibrinopeptides A and B, which are potent chemoattractants for neutrophils, monocytes, and macrophages [73]. Fibrin and fibrin degradation products activate cells at inflammatory sites (resident or infiltrated cells), via the binding of TLR-4 or CD11b/CD18 integrins [74]. Fibrin D dimers stimulate the production of cytokines by peripheral blood monocytes, and fibrin E fragment induces both cytokine expression in leukocytes and leukocyte migration [75,76]. Fibrin degradation products are potent chemoattractants for neutrophils and fibroblasts, but they also induce cytokine expression. Other fragments have anti-inflammatory and immunosuppressive effects. Factor Xa involves for its signaling annexin A2 binding and is required for adenoviral activation of TLR4/MyD88 signaling in infected cells. By activating TLR-4, annexin A2 regulates proliferation in smooth muscle cells and cytokine production in macrophages [71,77].

Overall, coagulant and fibrinolytic proteases evoke mostly proinflammatory and remodeling actions in inflammation, and targeting the inflammatory effects of these proteases, without disturbing their role in hemostasis, could constitute a beneficial strategy for the treatment of inflammatory diseases.

28.3.11 Kinin–Kallikrein System

The kinin–kallikrein system is an endogenous multiprotein cascade, which triggers the enzymatic hydrolysis of kininogens, ultimately ending into the release of bradykinin-related peptides (Figure 28.5). Those peptides constitute potent vasoactive peptides that act on bradykinin receptors (B1 and B2) and play essential roles in inflammatory features, including vasodilation, vascular

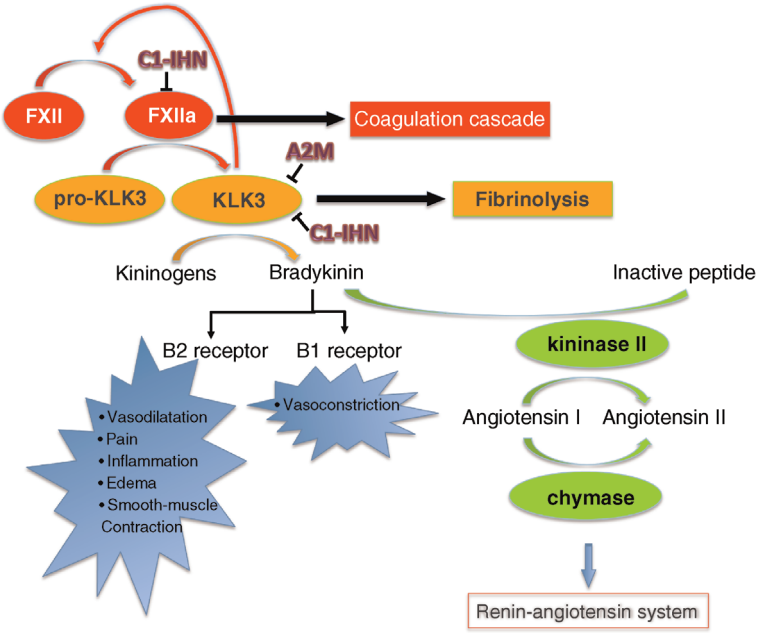

Figure 28.5 The plasma kallikrein–kinin system is linked to inflammation (blue), thrombosis (red), fibrinolysis (orange), and the renin–angiotensin system (green). It is controlled by inhibitors (purple): A2 M, alpha 2-macroglobulin, and C1-IHN, complement 1 inhibitor. Abbreviations: KLK: kallikrein; F: factor.

permeability, smooth muscle contraction, and pain [78]. Indeed, bradykinin induces the four classical signs of inflammation, heat, redness, swelling, and pain, when injected into animal tissues. After tissue injury, bradykinin is among the very first mediators to be released, taking part in the silent phase of inflammation. Therefore, even during the very early events of inflammation, well before the recruitment of inflammatory cells, proteases of the kinin–kallikrein system are playing a significant role in the initiation of inflammation. B2 receptor activation seems to play a prominent role in acute inflammatory response, inducing vasodilation, edema, and hyperalgesia, while B1 receptor seems to substitute the effects of B2 receptor in chronic inflammatory processes [79].

28.3.12 Complement System Activation

Another first-line defense machinery in which proteases play a preponderant role is the complement system (see Chapter 30). Similarly to the kallikrein–kinin system, this pathway starts with inactive precursors produced by the liver and present in normal condition in the blood stream. The activation of this system relies on a proteolytic cascade, which ultimately leads to active proteins playing a role in important defense mechanism of the host against pathogens: opsonization, chemotaxis, cell destruction, and pathogen agglutination. During the proteolytic cascade, the complement factors C3a and C5a are produced from the proteolytic conversion of their precursors C3 and C5 by the C3 and C5 convertases,

respectively. Both C3a and C5a display anaphylatoxin activity by inducing mast cell degranulation, smooth muscle contraction, and powerful chemoattraction of neutrophils and monocytes. Therefore, all proteases able to convert C3 and C5 into active C3a and C5a might potentially initiate or enhance the inflammatory host response. Complement proteases have very narrow specificity and low substrate turnover. The structure and activities of complement proteases have been extensively reviewed. Interestingly, not all complement proteases have a natural endogenous inhibitor. Much attention has been focused on controlling the formation or activity of complement protease complexes C3bBb and C4b2a, as these generate the inflammatory peptides C3a and C5a. However, the development of selective and potent inhibitors for complement proteases is still ahead of us.

28.3.13 Inflammasome

Inflammatory caspases include caspase-1, caspase-4, caspase-5, and caspase-11. All inflammatory caspases participate in the activation of the inflammasome, which drives the induction of an inflammatory form of programed cell death, also known as pyroptosis (see Chapter 20).

Caspase-1 is activated by different pathways: the nucleotide-binding domain (NOD), the leucine-rich repeat, and the NOD-like receptor pyrin domain-containing protein (NLRP)-1, as well as NLPR3 and CARD-containing protein 4. The caspase 1 inflammasome orchestrates antimicrobial effector functions, tissue repair, metabolic regulation, and cell survival [80], but the most investigated of its roles is its ability to cleave interleukin-1β and interleukin-18. Caspases 4, 5, and 11 interact with and activate caspase 1 [81]. They activate the NLRP3 inflammasome in response to Gram-negative bacteria and intracellular presence of LPS, and it is believed that this is through this activation that caspase 1 is further activated to cleave interleukin-1β and interleukin-18. Direct cleavage of IL-1β and IL-18 by caspase 4 has been proposed, but it still has to be confirmed. Activation of caspases 4, 5, and 11 also leads to pyroptosis and to the release of interleukin1α independent of caspase 1.

Caspase 8 is not really considered as a protease of the inflammasome, but it is recognized for its role in apoptosis and in the control of inflammation. Indeed, it is required for the activation of NF-κB signaling and is involved in both direct and indirect cleavage of pro-IL1 and pro-IL-18 into bioactive proteins [82]. This effect could either be exerted together with the caspase 1 inflammasome or independently [83]. In contrast, other evidence shows that caspase 8 can inhibit inflammation, through the inhibition of the inflammasome [84], the inhibition of interferon responses [85], and the activation of necroptosis [86].

28.4 Microbial Proteases and Inflammation

Different inflammatory pathologies are associated with infection, and this diversity depends both on the pathogen species and on their specific site tropism

within the host. Proteases delivered by pathogens are believed to take part in inflammatory-driven processes, and some of them are specifically designed to help the microbes resisting the hostile host environment. Pathogen-derived proteases are, therefore, often considered important virulence factors. The strategies that pathogens have developed to hamper host effectors, modulating proinflammatory pathways, impact all major innate immune host responses as illustrated in this section (Table 28.3).

Table 28.3 Major identified pathogen-associated microbial proteases.

Protease category	Microbial Proteases	Examples of Pathogens
Aspartic	Type 4 prepilin peptidase	EHEC
	Preflagellin	Archaeal bacteria
	PLA	*Y. pestis*
	Sap5p	*C. albicans*
Cysteine	Sortases	*E. faecalis*
	Gingipains	*P. gingivalis*
	Staphopain	*S. aureus*
	Derp 1	*D. pteronyssinus*
	Cruzipain	*T. cruzi*
	Falcipains (2 and 3)	*P. falciparum*
	Clostripain	*C. histolyticum*
Serine	Subtilisin	*Clostridium difficile*
	Protease IV	*P. aeruginosa*
	HtrA	*S. flexneri*, *C. jejuni*, and *H. pylori*
	ASP	*A. sobria*
	SCP	*Stretococcus* group *A*
	EspP-alpha	EHEC
Metalloproteinases	Fragilysin	*Enterotoxigenic* and *B. fragilis*
	Gel E	*E. faecalis*
	Elastase B	*P. aeruginosa*
	Alkaline protease	*P. aeruginosa*
	Collagenase	*Salmonella thyphimurium*
	HA/P	*V. cholerae* and *H. pylori*
	56 K	*S. marcescens*
	ZmpB	*B. cenocepacia*
	SSlE	EPEC and EHEC
	Vibriolysin	*Vibrio*
	IgA1 protease	*S. pneumoniae*

28.4.1 Effects on Barrier Function

Microbial proteases are able to modify the three components of mucosal barrier function: the IgA presence, the mucus, and the epithelial junction integrity.

IgA's function at mucosal surfaces is to block the access of antigens and pathogenic microorganisms to their epithelial receptors, in order to facilitate the luminal elimination of those microorganisms. This process, known as immune exclusion, is of high importance in mucosal homeostasis. For instance, *Blastocystis ratti*, an enteric protozoan parasite, is able to degrade IgA via an aspartic protease activity [87]. In lung infection, IgA is degraded by elastase B of *Pseudomonas aeruginosa* [88]. *S. pneumoniae* express IgA1 protease, which restricts bacterial agglutination by polymeric and secretory IgA and interferes with IgA1-mediated bacterial killing [89]. *Burkholderia cenocepacia*, a microorganism causing lung infection in 4–7% of cystic fibrosis patients, has a metalloprotease ZmpB that cleaves IgA [90]. For all these microbial species, IgA-degrading activities favor host colonization/infection through host defense evasion.

Another important element of the mucosal barrier is the mucus layer. The nematode *Trichuris muris* causing trichiriasis (diarrhea, abdominal pain, and fatigue) expresses a serine protease able to degrade Muc2 [91]. Similarly, *E. histolytica* displays cysteine protease activity, which is able to degrade Muc2 in its C-terminal domain and to break down the colonic mucus layer [92]. Both enteropathogenic *E. coli* (EPEC) and entero-hemorrhagic *E. coli* (EHEC) express SslE, a mucin-degrading enzyme [93,94]. Mucus proteolytic digestion by the *Helicobacter pylori* hemagglutinin/protease (HA/P) has been suggested as an important mechanism by which this pathogen could drive its pathogenic effects, that is, gastric inflammation and adenocarcinoma [95]. Finally, *Vibrio cholerae* also produces HA/P, which is required for vibrio translocation through a mucin gel, suggesting an important role of this protease in cholera pathophysiology [96]. *Trichomonas vaginalis*, a parasite colonizing the vaginal mucosa, produces mucin-degrading cysteine proteases [97]. All these pathogen-derived mucinase activities might help the microbes to reach the underlying epithelium and promote an efficient infection of the host.

Cell–cell epithelial junctions constitute the last physical impediment element of mucosal barrier function. Among junctional proteins, E-cadherin of adherent junction represents a particularly appealing target for microbial proteases. This applies to a number of food-borne pathogens involved in enteric pathologies such as EPEC, *S. flexneri*, *Campylobacter jejuni*, and *H. pylori* through the action of a conserved serine protease named HtrA [98]. The zinc protease fragilysin from *Bacteroides fragilis* also cleaves E-cadherin, directly disrupting adherent junction, thereby also impacting tight junction integrity [99]. An additional colitogenic bacterium, *Enteroccocus faecalis* secretes a gelatinase activity enzyme, GelE, which has the capacity to degrade E-cadherin [100]. Finally, *Candida albicans*, the causal agent of oral or genital infection called candidiasis, also produces an E-cadherin-degrading protease, Sap5p, which contributes to mucosal tissue invasion [101]. With regard to the tight junction proteins, occludin extracellular domain is cleaved by the *V. cholerae* metalloprotease HA/P, also described above

for its mucinase activity. This induces conformational changes of occludin intracellular domain and subsequent ZO-1 dissociation from tight junction [102]. In the airway infection context, elastase B expressed by *P. aeruginosa* has been shown to degrade TJ components in lung epithelial cells [103]. Furthermore, tight junction degradation is also operated by *Der p* 1, the major allergenic cysteine protease of *Dermatophagoides pteronyssinus* house dust mite (HDM) [104]. Recent evidence also indicates the presence of *Der p 1* in the gastrointestinal tract with functional consequences on the integrity of epithelial barrier. Likely, *Der p 1* is also able to alter the barrier function in intestinal epithelial cells by degrading ZO-1 [105]. Several gingipains, cysteine-like proteases from *P. gingivalis*, are thought to degrade junctional proteins of both adherent junctions and tight junctions, that is, E-cadherin and occluding. This mechanism may help bacterial penetration through the deep connective gum tissue [106].

Through their IgA-, mucin-, and cellular junction-degrading properties, the above-mentioned microbial proteases are suggested to play a prominent role in the local disruption of mucosal barrier. This obviously impacts epithelial permeability, pathogen invasion, and subsequent host immune response modulation. Upon mucosal barrier impairment and once within the tissue, pathogens are able to activate different host immune/inflammatory response pathways in which microbial proteases also play a direct role. Among them are the control of vascular permeability, anaphylatoxin production, and cytokine secretion.

28.4.2 Effects on Vascular Permeability

In addition to host proteases being able to activate the kallikrein–kinin cascade, microbial proteases have been shown to participate in proteolysis at several steps and thereby to induce increased vascular permeability, plasma protein extravasation, and further infection-associated edema. The vast majority of them belong to the group of bacterial proteases. For instance, *S. aureus* is capable of kinin production via the cysteine protease staphopain [107]. Like *S. aureus*, *Streptococcus* groupA and *Clostridium histolyticum* also express a cysteine protease able to generate kinins [108]. More specifically, the cysteine protease clostripain has been shown to exert kinin-releasing activity [109]. In the context of gingival tissue infection, *P. gingivalis* gingipains are able to perform the conversion of prekallikrein into active kallikrein and to convert kininogen into kinin [110]. Additional bacterial species such as *Serratia marcescens* have been shown to generate kinins through metalloprotease activities (56 K zinc protease) [111]. Vibriolysin proteases produced by *Vibrio* bacteria have also been shown to activate the kallikrein–kinin cascade *in vitro* [112] and *in vivo* [113].

Enzymes from protozoan parasites and arthropod species have also been shown to play a role in this pathway. This is illustrated by the cysteine protease cruzipain, produced by *Trypanosoma cruzi*, causing agent of the Chagas disease [114]. The malaria-causing parasite, *Plasmodium falciparum*, secretes cysteine proteases falcipain-2 and -3 that can produce vasoactive kinins from human kininogen [115]. Finally, literature reports the kinin-generating ability of a serine protease from the house dust mite *Dermatofagoides farina (Df)* [116] and its effect on vascular permeability enhancement in guinea pigs [117].

28.4.3 Effects on Complement Proteins

Pathogens produce some proteases that enhance or impede the complement system pathway. These functions might participate to the modulation of inflammation as well as pathogen subsistence within the host tissue.

In addition to its kinin-producing ability mentioned above, the cysteine protease gingipain R is able to convert C5 into active C5a, adding another potential pathophysiological function to this *P. gingivalis* protease in the progress of periodontitis [118]. A similar C5a-generating activity is attributed to ASP, a serine protease from *Aeromonas sobria* [119]. This pathogenic bacterium is associated with gastroenteritis and skin infection. Moreover, the Df serine protease from house dust mites displays C3a- and C5a-producing activity and this protease is believed to play a dual role as an allergen and an anaphylatoxin-triggering agent [120]. The microbial protease-generated anaphylatoxins, C5a and C3a, by binding to the corresponding receptors on mast cells trigger the degranulation of mast cells and the release of granule contents.

In contrast to proteases with C3a and/or C5a prodelivering action, some pathogens also express proteases, which degrade components of the complement cascade. This feature might appear as a way for the pathogens to counteract the host system immune defense. This escape mechanism may give advantage to the pathogen and favor its survival within the host milieu. Among the complement factor-degrading enzymes, three of them belong to the *P. aeruginosa*. The C3 complement factor is a substrate for two metalloproteases, alkaline protease and elastase B, as well as for a serine protease named protease IV [121,122]. Elastase B is also able to inactivate C1, C5, C8, and C9, while protease IV degrades C1q and alkaline protease cleaves C2, thereby impeding downstream complement effector functions. In *Streptococcus* group A, *S*treptococcal *C*5a *P*eptidase (SCP) is secreted and remains bound to the surface of the bacteria, where it is able to degrade C5a [123]. Furthermore, C3 and C5 are also the targets of EspPα protease that belongs to the serine protease autotransporters of Enterobacteriaceae family produced by EHEC [124]. The colitogenic bacterium *E. faecalis* secretes a gelatinase activity GelE, which has the capacity to degrade C3 [125]. Finally, in *Yersinia pestis*, the causative agent for plague, the aspartic acid surface protease PLA, is an important virulence factor with both C3-degrading and plasminogen activator functions [126].

28.4.4 Effects on Cytokine/Chemokine Production

Several studies report the effect of pathogen proteases on the production of CXCL8 with evidence or not of PAR2 or TLR implication. In the human macrophage cell line Thp1, *P. gingivalis* gingipains have been shown to increase CXCL8 expression, with synergetic effects between TLR and NOD1/2 signaling pathways [127]. In addition to gene expression regulation, the biological activity of CXCL8 is directly modulated by proteolytic activity of gingipains. Soluble forms of gingipain R and K increase CXCL8 biological function, while the bacterial surface-bound gingipain has an opposite destructing function on CXCL8 [128]. This CXCL8-digesting effect could help the bacteria biofilm to

maintain within the plaque. PAR2 pathway is stimulated by gingipain RgpB protease and this is associated with the production of another important proinflammatory cytokine, IL6 in an oral epithelial cell line [129]. In addition, proinflammatory neuropeptides CGRP and substance P are also upregulated by RgpB [130].

Regarding intestinal inflammation, a number of enteric microbes are able to modulate the production of CXCL8. As an illustration, a diarrhea-causing enteric protozoan parasite mentioned above, *E. histolytica*, produces cysteine proteases that induce CXCL8 release from human colonic epithelial cells and possess IL1-beta-converting enzyme activity [131]. In addition, colitogenic EPEC and EHEC strains produce two proteases with opposite effects on CXCL8 production; while the zinc protease NleC is immunosuppressive through direct interference with the NF-κB pathway and CXCL8 production in Hela cells [132], SslE is a secreted protease able to upregulate this chemokine by intestinal epithelial cells [94]. CXCL8 secretion is also stimulated by fragilysin, a zinc protease from *B. fragilis* bacteria [133].

In the context of respiratory tract infection, several microbial proteolytic activities have been shown to modulate CXCL8 secretion. This includes a serine protease from *S. aureus* [134] and LepA and elastase B from *P. aeruginosa* [135,136]. In addition, metalloprotease activities from this pathogen are able to degrade chemotactic molecules such as human regulated on activation normal T-cell exrepssed and secreted (RANTES), monocyte-chemoattractant protein (MCP)-1, and epithelial neutrophil-activating protein 78 (ENA-78) [137]. Finally, the *D. pteronyssinus* HDM produces a cysteine protease *Der p 1* that releases CXCL8 from respiratory epithelial cells [138]. In conclusion, the ability of proteases to control the expression level of cytokines/chemokines and to degrade them represent an important mechanism by which the pathogen may stimulate or decrease host inflammatory response.

28.5 Proteases as Targets in Inflammatory Pathologies

Considering the multitude of mechanisms by which proteases influence the inflammatory response, they constitute obvious targets for inflammatory pathologies. Overall, more pro- than anti-inflammatory effects of proteases have been considered so far for therapeutic options, and delivery of protease inhibitors has been considered for the treatment of several inflammatory diseases. However, depending on the tissues, proteases might have different mode of action and potentially important physiological functions that would have to be conserved. Moreover, the use of large-spectrum inhibitors versus more specific inhibitors is still an open question. Finally, different pharmacological options have to be considered: (i) the use of small synthetic inhibitors, (ii) the delivery or enhancement of natural endogenous protease inhibitors, or (iii) the use of blocking antibodies.

28.5.1 Gut

The use of large spectrum inhibitors in gut inflammatory pathologies would bear a number of side effects, when considering the physiological functions of

proteases in the intestine. However, severe increased proteolytic activity is associated with inflammatory bowel disease [139], as well as with low-grade inflammation irritable bowel syndrome (IBS) [140], suggesting that protease inhibition is an important possible therapeutic avenue to consider in gut pathologies. From all the families of proteases that are upregulated in IBD, MMP inhibitors have been extensively considered. First, because synthetic inhibitors suitable for use in humans have been developed for cancer. Second, because strong anti-inflammatory properties have been demonstrated for MMP inhibitors in animal models of colitis. However, in humans, MMP inhibitors appear to be more efficient at helping mucosal healing and extracellular matrix restructuration than exerting anti-inflammatory effects. Indeed, the use of MMP inhibitors has revealed anti-inflammatory effects of MMPs, thereby identifying MMP inhibitors as anti-targets for inflammation [141].

Upon active protease identification, studies have identified some interesting proteolytic targets for IBD. Elastase and trypsin activities seemed particularly upregulated [4], and as a corollary, elastase inhibitor Elafin and trypsin inhibitor serpin A1 are downregulated in tissues of IBD patients [4,140], associated for the latter with a more aggressive disease [142]. The delivery of Elafin, the natural endogenous inhibitor of elastase and proteinase-3 in the intestine of IBD patients has been proposed, as positive results have been obtained in animal models of colitis [5]. The use of genetically modified food-grade bacteria has been used to deliver such endogenous protease inhibitors. Commensal or probiotic bacteria colonizing the gut have been genetically transformed to express human epithelium-derived protease inhibitors such as Elafin or SLPI. Strong anti-inflammatory properties have been described for lactic acid bacteria genetically modified for the expression of protease inhibitors [5,143]. Treatments with these recombinant bacteria were drastically more effective than treatments with bacteria recombinant for other anti-inflammatory mediators such as TGF or IL-10 [143]. In addition, local delivery of protease inhibitors by using food-grade bacteria probably also decreases the possible side effects of protease inhibition therapeutic intervention.

Polymorphisms of several genes of the ubiquitine–proteasome system have been identified in IBD patients [144,145]. Proteasome inhibitors, such as bortezomib, which was successfully developed for cancer treatment, could be shortly tested for IBD.

In low-grade intestinal inflammation such as IBS, trypsin and tryptase activities are upregulated. Supernatants from IBS patients signal to sensory neurons in a protease- and PAR-dependent manner, suggesting that proteases, through PAR activation, are major mediators of sensory neuron hyperactivity and possibly of visceral hypersensitivity associated with this disease [140]. The forms of trypsin present in tissues from IBS patients have yet to be determined, and consensus is not reached on whether this activity originates from the host, from the microbiota, or from both. A better knowledge on the nature of the proteases responsible for such activities constitutes a necessary step to further consider and determine specific protease inhibitors for the treatment of IBS symptoms.

28.5.2 Airways

MMPs have been implicated in asthma, and polymorphisms in MMP genes may contribute to a predisposition to asthma [146]. Altered levels of MMPs are

reported, with, for instance, an increased level of MMP-9 in lung tissues and sputum. MMP-1, -2, -7, -10, -12, and 19 have also been implicated [147]. However, when MMP inhibitors such as tetracyclines have been investigated as potential treatments for asthma, the results obtained were not clear-cut. Doxycycline, for example, was reported to decrease eosinophilic inflammation in some models but was reported ineffective in others [147]. While some *in vivo* studies may have found some interest for MMP broad-spectrum inhibitors, their valuable clinical use is still unclear. The disappointment faced in other pathologies (such as the gut) has lowered the enthusiasm to test these drugs in an inflammatory context, off-target effects with these broad-spectrum MMP inhibitors being expected. Evidences from animal models of chronic obstructive pulmonary disease (COPD) suggest that targeting MMPs may be more valuable in the context of alveolar destruction. The effectiveness of MMP inhibitors as treatment of COPD in humans remains unknown, since few clinical trials have been conducted so far. A recent trial of 55 patients with stable moderate to severe COPD report that treatment with a selective MMP-9/MMP-12 inhibitor was well tolerated, but only limited clinical outcomes were noticed [148]. Further studies will be required to conclude on the value of MMP inhibitors.

The main thrust of protease inhibitors for the treatment of asthma has concentrated on mast cell proteases and in particular on tryptase. This interest was driven by data showing that tryptase can contribute not only to airway bronchoconstriction and hyper responsiveness but also by the fact that tryptase may have a major role in fibrosis and matrix remodeling [149]. However, phase I clinical trials have been discontinued in development for the treatment of asthma, since at certain doses, tryptase inhibitors exhibited signs of bronchospasms, while in phase IIa studies, the compounds did not reveal any bronchospasm activity and was on the contrary quite efficient at preventing airway response in asthmatics [150].

A form of alpha-1-anti-trypsin (AAT) has been available for the treatment of AAT deficiency since 1987. Intravenous administration of plasma-purified AAT augments serum and lung levels of AAT, while it increases antielastase capacity in patients deficient in the expression of AAT. In cystic fibrosis patients, AAT administration induces a fall in neutrophil elastase activity, although the overall bacterial loading in the sputum of those patients is not modified (for review, see Ref. [151]). The delivery of AAT in right amounts and at the right place (diseased versus less diseased areas) has been questioned and still has to be improved in cystic fibrosis patients to gain better efficacy.

Recombinant SLPI has been administered to individuals with cystic fibrosis and results in a decreased neutrophil elastase activity and decreased IL-8 expression at the epithelial surface of the lung [152]. Safe delivery of Elafin has also been reported in healthy individuals (Proteo Biotech AG), but phase II reports have never been reported yet. For both natural protease inhibitors, local delivery might be important to establish therapeutic benefits, and in the lung, such delivery has been proven to be challenging.

Neutrophil elastase inhibitors have been developed to treat lung inflammatory diseases. The molecules developed were mostly small synthetic molecules. All were potent and selective neutrophil elastase inhibitors, and yet, none of these compounds have demonstrated sufficient promises to make it to the market.

These compounds were developed on the assumption that neutrophil elastase was the major driving mechanism of lung inflammation and did not take into account the beneficial effects of neutrophil elastase as an antimicrobial agent. This fact might explain the low efficacy and side effects neutrophil elastase inhibitors have demonstrated in clinical trials.

Bortezomib, a proteasome inhibitor, can rescue CFTR, resulting in the appearance of mature CFTR and functional chloride channels. A reduction of IL-8 expression levels due to the proteasome inhibition was also demonstrated [153]. The effects of Bortezomib in lung inflammatory diseases could be shortly investigated and would bring some new knowledge on the use of proteasome inhibitors. The side effects that this drug might have, in particular on the normal proteasomal degradation, are yet to be studied.

28.5.3 Skin

Several studies point to aberrant expression and enhanced enzymatic activity of kallikreins, in atopic dermatitis [154–157]. Based on that, topical administration of protease inhibitor could represent a new strategy to reestablish skin barrier function and thereby limit antigen entry and inflammation (patent reference WO2005117955 A1). However, no clinical trial using kallikrein inhibitors for atopic dermatitis treatment has been reported yet.

Individuals with the inflammatory skin disease rosacea show high baseline levels of cathelicidin and KLK5 [13]. Interestingly, subcutaneous injection of KLK5 in mice, with a dose corresponding to the amount of serine protease activity that is found in lesional skin of individuals with rosacea, induces an increased proportion of the mature cathelicidin. This was accompanied by erythema and leukocyte infiltration [13]. In addition to its direct antimicrobial effects, LL-37 has the capacity to be both proinflammatory and angiogenic [158]. These properties are not shared by other forms of active cathelicidin in the healthy skin. The reason why KLK5 protease activity and cathelicidin are increased in the skin of rosacea patients is still unknown, but this illustrates the importance of the large web of epidermal KLK proteases in skin inflammation. To date, a clinical trial was initiated to treat patients suffering from rosacea to modulate KLK5 and hCAP18 expression. Patients were treated by topical application of azelaic acid 15% gel to the involved skin, twice daily for 16 weeks. KLK5 and cathelicidin mRNA decreased in rosacea skin after several weeks of this treatment and this correlated with clinical improvement, that is, reduction of erythema and inflammatory papules [159].

Netherton syndrome is a severe genetic skin disease due to the absence of LEKTI inhibitor leading to an uncontrolled kallikrein activity. Two different pathways but both leading to inflammation are triggered in this pathology. First, LEKTI deficiency causes premature detachment of corneocytes from the rest of epidermis. Excessive activity of KLK5 and KLK7 leads to desmosome cleavage in the upper granular layer through desmoglein-1 degradation. KLK5 is a protease processing proelastase-2 into proteolytic active enzyme. In Netherton syndrome skin, elastase-2 hyperactivity participates also to epidermal permeability. Barrier disruption by itself stimulates keratinocyte proliferation, as well as cytokine and

chemokine production (IL-1β, IL8, TNFα, granulocyte macrophage colony-stimulating factor (GM-CSF), and TSLP), which are all major features of skin inflammation [160–162]. In addition, barrier breach causes dehydration and facilitates allergen and microbe penetration and inflammation due to sensitivity of keratinocyte to UV.

Finally, KLK5 also initiates a proallergic signaling cascade, leading to overexpression of the pro-Th2 TSLP, CXCL8, and TNFα cytokines via the direct activation of PAR2 on keratinocytes. This proinflammatory context leads to the development of a broad range of allergic manifestations including atopic dermatitis with elevated serum IgE levels [23,162,163]. However, here again, no clinical trial has started yet to investigate the potential effects of KLK inhibitors.

28.5.4 Joints

Different proteases are determinant to cartilage degradation and inflammation in osteoarthritis. These proteases include metalloproteinases, which degrade not only the cartilage macromolecules and the collagen but also serine and cysteine proteases. From animal studies, and in particular studies performed with genetically engineered mouse models, three proteases appear to be major targets for osteoarthritis treatment: ADAMTS-5, MMP-13, and cathepsin K [164]. Animal model studies have proven efficacy of these protease inhibitors both on progression of structural damage to the joint and on osteoarthritis-associated pain [165–169]. Phase I clinical trials have been completed and did not raise any safety issues for ADAMTS-4/5 inhibitors (NCT00427687 and NCT00454298, www.clinicaltrials.gov). GlaxoSmithKline also recently reported a ADAMTS-5 neutralizing antibody. Therapeutic protocols have not yet been reported for MMP-13 inhibitors, but Novartis has reported three phase II clinical trials testing a cathepsin K inhibitor (NCT00170911, NCT00100607, and NCT00371670). Results from these studies have yet to be posted.

MMPs seem to be important in rheumatoid arthritis, as increased MMP activity was reported from synovial tissues of patients [170]. Only animal models have been used to investigate the potential efficacy of MMP inhibitors, with some level of success [171]. However, here again, the anti-inflammatory effects discovered for some MMPs have lowered the enthusiasm for further clinical studies. A more accurate knowledge on the enzymes and their different cellular origin, together with their precise role in disease processes, is required for MMP inhibition approaches to be successful in rheumatoid arthritis clinics.

Calpain-1 is an important player of neutrophil motility, and the discovery of the recent series of alpha-mercaptoacrylate inhibitors that are able to target regulatory domains of calpain-1 has raised considerable interest in possible therapies. These compounds are now considered as potential future oral therapies for rheumatoid arthritis, but bioavailability still seems to be an issue [172].

As for IBD, inhibition of the immunoproteasome is considered for rheumatoid arthritis, as it plays a critical role in T-cell expansion, cytokine production, and T helper differentiation [173]. In animal models of arthritis, inhibition of the immunoproteasome ameliorated disease symptoms [174]. The unique role of the immunoproteasome subunit low molecular mass polypeptide-7 (LMP7) in

controlling pathogenic immune response and chronic inflammation provides a strong therapeutic rationale for targeting LMP7 in autoimmune disorders such as rheumatoid arthritis.

28.5.5 Pancreatitis

Pancreatic digestive enzymes are stored as inactive precursors in pancreatic zymogen granules. Under physiological conditions, digestive enzyme activation is strictly controlled to prevent autodigestion of the pancreas. SPINK1 is considered to be the first-line safeguard system that can inactivate about 20% of total trypsin activity if trypsinogen is accidentally converted into trypsin in acinar cells. Hereditary chronic pancreatitis is a very rare form of early onset of chronic pancreatitis. Gene mutations of cationic trypsinogen (*PRSS1*), anionic trypsinogen (*PRSS2*), cystic fibrosis transmembrane conductance regulator (*CFTR*), chymotrypsinogen C (*CTRC*), and calcium-sensing receptor (*CASR*) have been identified as being associated with hereditary chronic pancreatitis. In the case of the *PRSS1* gene, pancreatitis can be caused by various molecular mechanisms. Mutations in this gene can lead to inhibition of trypsin degradation, to increased autoactivation of trypsinogen into active trypsin, to disturbance of intracellular transport resulting in colocalization of trypsinogen with lysosomal enzyme cathepsin B, or to triplication and duplication of the copy number of trypsinogen gene. Because the intrapancreatic balance between trypsin and SPINK1/PSTI (pancreatic secretory trypsin inhibitor) activity is important for pancreatitis, mutations in the *SPINK1* gene that affect SPINK1 binding with trypsin are considered to contribute to the onset of pancreatitis. There have been many reports on the association between mutations in the *SPINK1* genes and pancreatitis in patients, since excessive amounts of pancreatic trypsinogen are transformed into active trypsin, leading to activation of other zymogens and autodigestion of the pancreas [175]. Aprotinin was the first protease inhibitor used in clinical trials for acute pancreatitis. However, no benefit was observed when administered either intravenously or intraperitoneally. Numerous clinical trials were conducted using a small chemical compound as serine protease inhibitor such as gabexate mesilate, nafamostat mesilate, and ulinastatin. They have demonstrated a reduction in complications and mortality, but the trials are very small and meta-analysis failed to show benefits of these medications significantly reducing the rate of death in moderate to severe pancreatitis [176–179].

28.5.6 Traumatic Brain Injury

Traumatic brain injury is a major cause of mortality and an important medical challenge. To date, despite improvements in acute intensive care, no specific therapies to ameliorate the effects of traumatic brain injuries are available. The kallikrein–kinin system is a promising therapeutic target for traumatic brain injury as it mediates key pathologic events of traumatic brain damage, such as edema formation, inflammation, and thrombosis. Plasma kallikrein or Factor-XII has an essential role in thrombosis [180]. Factor-XII depletion protected

knockout mice from pathogenic thrombus formation without increased risk of bleeding. Aprotinin is known to inhibit several serine proteases, including plasma kallikrein. A reduced protease activity has been associated with a lower mortality rate [181]. There are also promising results from recent studies in murine models suggesting a therapeutic potential for the serine protease inhibitor C1-inhibitor (inhibition of activated plasma kallikrein) and cystein protease/calpain inhibitor [182,183].

28.6 Conclusions

Protease inhibition has reached the level of "hot topic" for the development of new therapeutic strategies to treat chronic inflammation. Initially considered for cancer treatment or antiviral therapies, and initially focused on large spectrum inhibitors, protease inhibition strategies have evolved and are now embracing the challenge of targeting specific proteases. Several approaches are nowadays conceived: protease inhibition by small synthetic molecules, biological therapies, and natural protease inhibitors' delivery or enhancement are among them. All these strategies aim at reequilibrating proteolytic homeostasis in diseased tissues and are based on the multiple proinflammatory roles described for most proteases (see Figures 28.2 and 28.6). However, a strong need to characterize the proteolytic

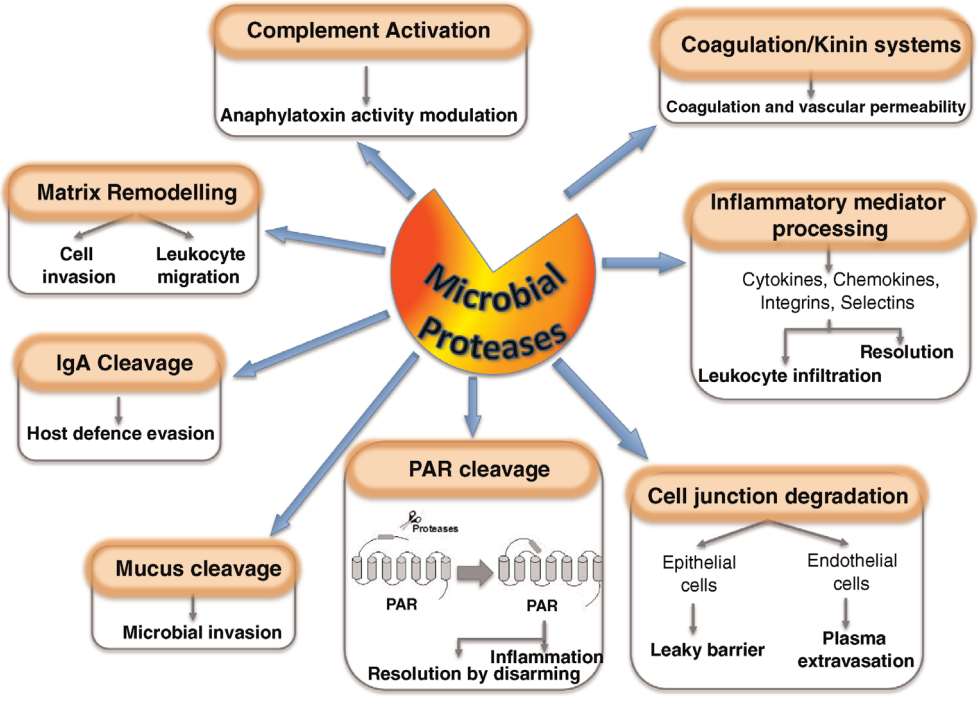

Figure 28.6 Mechanisms of action of microbial proteases at inflammatory sites and their consequences.

profiles associated with chronic inflammatory pathologies, and even within the same pathology between patient's subgroups, has emerged. Such knowledge will first allow determining the role of the identified proteases in pathologies, and based on this, could point to the relevance of considering specific proteases as pharmacological targets. Targeting specific proteases and specific activities in the context of chronic inflammatory disorders should avoid therapeutic failure associated with strong side effects or weak efficacy. Determining the proteolytic profiles associated with inflammatory pathologies should also point to other roles for some proteases, including potential anti-inflammatory effects. Finally, in future studies, by further establishing disease-associated proteolytic profiles, to a given profile, adapted therapeutic strategies could be applied, targeting individual or a combination of proteases.

List of Abbreviations

AAT	alpha-1 antitrypsin
ADAM	a disintegrin and metalloproteinase
AEP	asparagine endopeptidase
CARD	caspase activation and recruitment domain
CASR	calcium-sensing receptor
CFTR	cystic fibrosis transmembrane conductance regulator
CGRP	calcitonin gene-related peptide
CTRC	chymotrypsinogen C
CXCL	chemokine C-X-C motif ligand
EGF	epidermal growth factor
EHEC	enterohemorrhagic *Escherichia coli*
EPEC	enteropathogenic *Escherichia coli*
ENA	neutrophil activating protein
GM-CSF	granulocyte macrophage colony-stimulating factor
HDM	house dust mite
IBD	inflammatory bowel disease
IBS	Irritable bowel syndrome
Ig	immunoglobulin
IL	interleukin
KLK	kallikrein
LEKTI	lympho-epithelial Kazal-type inhibitor
MAP	nitogen-activated protein
MCP-1	monocyte chemoattractant protein-1
MHC	major histocompatibility complex
MMP	matrix metalloproteinase
NET	neutrophil extracellular traps
NLRP	NOD-like receptor pyrin domain protein
NOD	nucleaotide-binding oligomerization domain
Omp A	outer membrane protein A
PAR	protease-activated receptor
RANTES	regulated on activation normal T-cell expressed and secreted
SLPI	secretory leukocyte inhibitor
SPINK	serine protease inhibitor of Kazal type

TFPI	tissue factor pathway inhibitor
TGF	transforming growth factor
TIMP	tissue inhibitor of metalloproteinase
TLR	toll-like receptor
TNF	Tumor necrosis factor
t-PA	tissue-type plasminogen activator
TSLP	thymic stromal lymphopoietin
uPA	urokinase
ZO	zonula occludens

Psychiatric Disorders and Inflammation

Robert Dantzer

The University of Texas MD Anderson Cancer Center, Department of Symptom Research, 1515 Holcombe Blvd, Houston, TX 77030, USA

29.1 Introduction

In most psychiatry textbooks, psychiatric disorders are described in terms of alterations in neurotransmitter systems that psychotropic drugs aim at normalizing. All current antipsychotic drugs target the brain dopaminergic system, whereas antidepressants aim to increase deficient serotoninergic and noradrenergic neurotransmission. The skillful use of these drugs has greatly improved quality of life for patients with psychiatric disorders by helping them control their symptoms.

However, symptom control does not equate with cure. Since the introduction of most psychotropic drugs in the 1950s–1960s, no progress has been made in the eradication of psychiatric disorders and the elucidation of their pathophysiology. In addition, the stagnation of drug discovery in psychiatry has forced many pharmaceutical companies to put an end to their investment in research and development. In this gloomy context, some faint rays of hope are slowly emerging, thanks to the progress made in molecular and cellular neurobiology and the knowledge generated by the powerful steamroller of genomics and postgenomics. In a multistage genome-wide association study of about 37 000 patients with schizophrenia and 113 000 controls, expected associations were found between schizophrenia and genes expressed in the brain, including the gene coding for the dopamine receptor D2 (the target of all effective antipsychotic drugs) and several genes involved in glutamatergic neurotransmission and synaptic plasticity [1]. However, strong associations were also identified with genes expressed in tissues with important immune functions, particularly B-lymphocyte lineages. In another genome-wide association study carried out in 60 000 patients with schizophrenia, major depressive disorders, or bipolar disorder, associations between these conditions and multiple immune and neuronal signaling pathways were found [2].

The possible role of immune-mediated events in the pathophysiology of psychiatric disorders is not a totally new story. A long tradition of research into the possible viral causes of schizophrenia has resulted in the discovery of circulating autoantibodies against various neurotransmitter receptors and

Inflammation: From Molecular and Cellular Mechanisms to the Clinic, First Edition.

synaptic proteins [3–5]. A modern version of this scenario is the reactivation of human endogenous retroviruses in response to early infection by banal viruses, for example, herpes and influenza viruses [6]. Other scenarios are also possible, including reactivation of latent infection by the intracellular parasite *Toxoplasma gondii* [7].

The positive findings obtained in many studies on the association between inflammation and symptoms in patients with psychiatric disorders have aroused neurobiologists' interest in the expression and action of inflammatory mediators in the brain. Surfing on the same wave, clinicians have been quick to investigate the possible therapeutic action of anti-inflammatory compounds, including nonsteroidal anti-inflammatory agents and biopharmaceuticals. Although these treatments are still far from being curative, much has been learned in the process. The objective of this chapter is to review this literature and examine its limitations.

29.2 Association Studies between Inflammation and Psychiatric Disorders

If inflammation plays a role in the symptoms presented by patients with psychiatric disorders, there should be evidence for associations between symptoms and biomarkers of inflammation. Several recent meta-analyses of the published literature point to such a positive association.

Schizophrenia is a progressive neurodevelopmental disorder, meaning that it has its roots in alterations in early brain development [8]. The possibility that inflammatory processes occurring during development participate in the pathogenesis of schizophrenia has been examined in studies relating increased maternal levels of C-reactive protein (CRP) and tumor necrosis factor (TNF)-α to schizophrenia in adult offspring (reviewed in Ref. [9]). In a prospective study from the Avon Longitudinal Study of Parents and Children, children with high serum levels of interleukin (IL)-6 at 9 years of age were found to have a twofold increased risk for psychotic disorder at 18 years of age, independent of typical confounders such as sex, body mass, and psychological and behavioral problems [10].

A meta-analysis specifically focused on CRP identified eight studies, of which five were included in a pooled analysis. There was a significant increase in CRP in patients compared to controls, although the possible interfering role of metabolic alterations in response to treatment and smoking was not systemically controlled for [11]. An earlier meta-analysis of cross-sectional studies of cytokine alterations in patients with schizophrenia had already identified increases in IL-1 receptor antagonist (IL-1ra), IL-6, and soluble IL-2 receptor (sIL-2r) and decreases in IL-2, with the same limitations as the meta-analysis on CRP [12]. A meta-analysis of 26 cross-sectional or longitudinal studies showed a positive correlation between CRP levels and the severity of positive, but not negative, symptoms of schizophrenia [13]; CRP levels were also positively correlated with body mass index. These immune alterations are already present in medication-naïve first-episode psychosis, as evidenced by highly significant effect sizes for elevated serum levels of IL-1β, sIL-2r, IL-6, and TNF-α [14]. No increase in cytokine levels is apparent

with the repetition of psychotic episodes [13]. These results suggest that symptoms of schizophrenia are associated with inflammation.

The immune features of bipolar disorders are grossly similar to those of schizophrenia. Patients with bipolar disorders have increased levels of sIL-2r, TNF-α, soluble TNF receptor 1 (sTNFr1), sIL-6r, and IL-4, but not IL-6, compared to healthy control subjects [15–17]. Most of the reported alterations occur during manic episodes [17]. Euthymic patients generally have lower levels of TNF-α and sTNFr1 than do manic patients [17].

Most of the literature on cytokines and psychiatric disorders focuses on major depressive disorders. CRP, IL-6, IL-1β, and IL-1ra have repeatedly been found to be associated with depression [18], although the evidence for IL-1 and IL-1ra is far from consistent and that for TNF-α is mixed [19]. Antidepressants reduce the levels of IL-1β and IL-6 but not TNF-α [20]. Reductions in levels of CRP and IL-6 in response to antidepressants were also reported in another meta-analysis [21]. The differences in sIL-2r, TNF-α, and IL-1β between patients with major depressive disorders and controls appeared to be more marked in European than in non-European subjects, although there was no clear explanation for this finding [22]. A systematic search for the causes of heterogeneity between studies revealed an influence of the mode of definition of depression and the presence of comorbid somatic pathologies: differences in IL-6 levels between depressed subjects and healthy controls were maximized when patients were diagnosed according to Diagnostic and Statistical Manual of Mental Disorders Fourth Edition criteria or when melancholic features corresponding to a more severe form of depression were taken into consideration [23]. Smaller effect sizes for IL-6 were detected when patients had cardiovascular disease or another comorbidity such as Parkinson's disease or fibromyalgia. High body mass index was associated with higher effect sizes for IL-6, whereas age, sex, and smoking status had no apparent effect [23]. Longitudinal studies of the associations between biomarkers of inflammation and depression confirmed the robustness of the association with CRP compared to IL-6 [24].

In addition to meta-analyses that assess the current status of a hypothesis on the basis of results that are available in the literature, cumulative meta-analyses evaluate the extent to which further studies are unlikely to change the already-reached conclusions. In a cumulative meta-analysis, the results from individual studies are added chronologically and the aggregate effect estimate is recalculated after each study is incorporated. An analysis of this type has provided further support for a robust association between elevated IL-6 or CRP levels and depression, with little supplementary information resulting from studies on this topic carried out after 2006 for IL-6 or 2012 for CRP. In contrast, the data available on TNF-α and IL-1β were not consistent enough to confirm or refute the hypothesis of an association with major depression [25].

In summary, much evidence exists to suggest an association between inflammation and psychiatric disorders that is independent of diagnostic category. It is certainly remarkable that this association is apparent despite the heterogeneity of the studies and their relatively low methodological quality. Most of the studies are cross-sectional and lack consideration of the possible role of confounding factors such as age, obesity, lifestyle factors, comorbidities, and current medication. In

addition, serum or plasma cytokines were measured without any consideration being paid to the sensitivity of the assays and the fact that the cytokines are not hormones but paracrine or autocrine communication factors. This certainly explains why only circulating inflammatory biomarkers such as CRP and IL-6 provide reliable data.

Whether inflammation is another reflection of psychiatric disorders or a contributing factor to the disease process is not always clear, as most association studies are cross-sectional rather than longitudinal. The few longitudinal studies that have been carried out reveal that the two possibilities coexist. Repeated measures of inflammatory markers and mental disorders in an adult occupational cohort, the Whitehall II cohort study, revealed that subjects with high IL-6 had a greater likelihood of common mental disorders (mainly major depressive disorders and dysthymia, on the basis of response to the General Health Questionnaire) 6–11 years later and higher odds of new-onset mental disorders 11 and 16 years later [26]. There was no evidence of sex difference in this relationship, and it was little affected by adjustments for acute inflammation, obesity, smoking, and drug treatments. As emphasized by the authors, these findings support the hypothesis that persistently elevated levels of IL-6 contribute to the development of common mental disorders.

In the Avon Longitudinal Study of Parents and Children mentioned earlier in this section, children with elevated IL-6 levels at 9 years of age had a higher chance of presenting with depression and psychotic experiences at age 18 years, meaning that inflammation was a nonspecific predictor [10]. It is important to note that there is also evidence that mental disorders are predictors of inflammation. In the prospective population-based Great Smoky Mountains Study covering children in the community aged 9–16, 19, and 21 years, cumulative depression episodes predicted later CRP levels, whereas early CRP did not predict later depression [27]. These findings indicate that depression can promote inflammation. However, there is also the possibility that the inflammatory status underlying elevated CRP levels at an early age favors the development or reoccurrence of depressive disorders later in life, although this possibility was not tested [28].

29.3 Mechanisms of the Association between Inflammation and Psychiatric Disorders

Once inflammatory cytokines were cloned and characterized, it was not long before they were found to be expressed and active in organs other than those of the immune system – in particular, in the brain. For instance, IL-1β was quickly identified as one of the endogenous pyrogens that are released by activated monocytes and macrophages and that act on the brain during an infection to alter the set point for temperature regulation, resulting in the mounting of a fever response [29]. IL-1β was also demonstrated to be able to activate the hypothalamic–pituitary–adrenal axis and induce the stress response to infection described by Hans Selye several decades ago [30,31]. In the same manner, IL-1β and TNF-α were demonstrated to be responsible for behavioral alterations that develop in ill individuals during an infection [32,33]. This so-called “sickness

behavior" response is seen at the onset of febrile infectious diseases, when sick individuals are lethargic, depressed, and anorexic. They frequently isolate themselves from the rest of the group and they rarely engage in environment-directed activities. These drastic changes in behavior are commensurate with the necessity of sparing energy for mounting a fever, and they are part of an adaptive strategy to overcome the disease process [33].

Physiologists who engaged in studying the brain effects of cytokines were soon faced with the question of how cytokines that were supposed to be released in the general circulation during the host response to infection could reach the brain to cause fever, neuroendocrine activation, and sickness behavior. The initial hypothesis, at least in the context of endogenous pyrogens and fever, was that peripheral cytokines act on brain circumventricular organs, such as the organum vasculosum laminae terminalis, where the blood–brain barrier is leaky [34]. There, cytokines were thought to induce the synthesis and release of prostaglandin E2, which can easily penetrate the brain because of its lipophilic nature and then act on thermosensitive neurons in the hypothalamus. However, this hypothesis was invalidated by subsequent findings showing that (i) peripheral cytokines induce the synthesis and release of cytokines in the brain, as demonstrated initially by bioassays and confirmed subsequently by molecular biology techniques and immunohistochemistry [35–39], (ii) cytokine receptors are expressed in the brain [40–43], and (iii) antagonism of brain cytokines abrogates the brain effects of peripheral cytokines [44]. A major step forward was the demonstration that cytokines induced in the brain in response to peripheral cytokines are mainly produced and released by meningeal and perivascular macrophages and microglial cells within the brain parenchyma [39]. Astrocytes can also play a role, for instance, by producing IL-6 in response to microglial IL-1β and TNF-α [45].

If peripheral cytokines are able to induce the synthesis and release of the same cytokines in the brain, communication pathways must exist between the immune system and the brain that enable brain cells to monitor peripheral cytokines and respond to them in a coordinated manner. Circulating cytokines cannot play this role, because their release in the circulation corresponds to an overspill and they are not geared to act as endocrine factors (with the exception of IL-6, which targets the liver for the synthesis of acute-phase proteins). In contrast, afferent nerves that innervate the site of the body in which the inflammatory response takes place can play this role, because their activation is responsible for the symptoms of pain and heat – two of the four cardinal features of inflammation.

The neural pathway hypothesis was submitted to test by nerve sections. The initial experiments were carried out in vagotomized rodents, as studies of the brain effects of cytokines are usually based on intraperitoneal injections of lipopolysaccharide (LPS) or recombinant cytokines, and most of the sensitivity of the visceral cavity is conveyed to the brain by vagal nerves. Subdiaphragmatic vagotomy was found not only to block hyperalgesia and sickness behavior induced by LPS and IL-1β [46–49] but also to abrogate the induction of IL-1β expression in the brain [50] as well as the expression of c-Fos, the product of the early activation gene *c-fos*, in the brain neurocircuitry recruited by systemic inflammation [51]. The results of vagotomy experiments are not always easy to interpret, however, because this procedure impairs several important

physiological functions that can affect behavior. A more rigorous demonstration of the role of vagus nerves in the sickness response to systemic inflammation was achieved by reversible inactivation of the dorsal vagal complex, the brain area in which vagal sensory nerves terminate [52]. This was done by injecting a local anesthetic into the dorsal vagal complex of LPS-injected rats. This treatment abrogated LPS-induced decreases in social interactions and c-Fos expression in key immune response areas of the brain. Experiments directly comparing sickness-behavior and fever responses to LPS in vagotomized rats showed that the neural pathway of immune to brain communication is more important for the sickness-behavior response to LPS than for the fever response [53,54].

Transporters allowing circulating cytokines to enter the brain have also been described at the level of the blood–brain barrier [55]. Although their molecular nature has not yet been characterized, they are likely represented by cytokine membrane receptors that internalize their ligand. The role of the transporter that enables IL-1α to enter the brain was demonstrated in a very ingenious experiment based on the memory-impairing effects of this cytokine [56]. Human recombinant IL-1α injected intravenously into mice induced sickness behavior and at the same time impaired the retention of an avoidance/escape response learned just before the injection. This effect of IL-1α was mediated in the posterior division of the septum of the brain. Intraseptal injection of a blocking antibody specific to human IL-1α abrogated the memory-impairing effect of IL-1α injected intravenously, demonstrating that the human IL-1α needs to be transported from the blood into the brain to exert its effect.

The emphasis has recently shifted to brain vascular cells as key cells in the transduction of inflammatory signals between the periphery and the brain. In response to peripheral immune stimuli, these cells express receptors for IL-6 and IL-1 and prostaglandin-E2-synthesizing enzymes [57]. Genetic deletion of IL-1 or IL-6 receptors in brain vascular cells abrogated the fever response to LPS [58,59]. The same effect was obtained with blockage of cyclo-oxygenase-2 induction or microsomal prostaglandin E synthase 1 specifically in brain endothelial cells [60]. However, the sickness-behavior response to LPS was not abrogated in these mice, which agrees with the previously mentioned data showing predominance of the neural pathway of immune to brain communication for the sickness-behavior response to LPS [53,54]. In the event that inflammation takes place in the liver, the liver to brain communication pathway involves chemokine (C-C motif) receptor-like 2 (CCRL2)-positive monocytes rolling on the brain endothelium in a P-selectin-dependent manner and possibly trafficking into the brain in response to activation of microglia expressing monocyte chemoattractant protein-1 [61]. Inhibition of the interactions between monocytes and brain endothelial cells was sufficient to attenuate microglial activation and development of sickness behavior [62].

Inflammatory stimuli can also exert their effects on the brain by activating metabolic pathways. This is particularly the case of the tryptophan/kynurenine metabolism pathway, which plays a key role in the development of immune tolerance by depleting the microenvironment of the essential amino acid tryptophan, generating cytotoxic kynurenine metabolites, and favoring the formation of regulatory T cells [63]. The tryptophan/kynurenine pathway is dependent on the

activation of indoleamine 2, 3 dioxygenase (IDO1) in response to interferon (IFN)-γ and TNF-α. Activation of IDO1 metabolizes tryptophan into kynurenine, which is further metabolized into kynurenine metabolites by a complex chain of enzymatic reactions. Tryptophan serves as a precursor in the synthesis of serotonin, and major depressive disorders are supposedly associated with a deficit in serotoninergic neurotransmission. Most of the clinical studies on the role of IDO1 in inflammation-associated depression have been carried out in cancer patients with melanoma or kidney cancer treated with IFN-α or IL-2 and in patients with hepatitis C virus infection treated with IFN-α. In these quasi-experimental models of inflammation-induced depression, symptoms of sickness (fatigue, pain, decreased appetite, and sleep disorders) developed in all patients as early as immediately after the first immunotherapy treatment, whereas depression occurred only in one-third to one half of the patients and took several days to several weeks to develop [64,65]. These findings indicate that depression develops on a background of sickness in the presence of risk factors still to be identified. The distinction between sickness and clinical depression was further solidified by the demonstration that pretreatment with the antidepressant paroxetine blocked the symptoms of depression but not those of sickness in patients with cancer [66]. Immunotherapy-induced depression was associated with activation of IDO1 [67,68], with a linear relationship between the resulting decrease in circulating levels of tryptophan and the intensity of symptoms of depression [68].

In terms of mechanisms, it was initially proposed that activation of IDO1 is responsible for the development of depression in IFN-α-treated patients, because it decreases the bioavailability of tryptophan for the synthesis of serotonin while at the same time generating more kynurenine for the formation of neurotoxic kynurenine metabolites [69], including 3-hydoxy-kynurenine, a potent generator of reactive oxygen species, and quinolinic acid, an agonist of the *N*-methyl-D aspartate (NMDA) receptor. Experimental studies in mouse models of depression confirmed that pharmacological inhibition of IDO1 or genetic deletion of *ido1* abrogated inflammation-induced depression without interfering with sickness behavior [70,71]. Further studies in patients with hepatitis C treated with IFN-α showed that inflammation-induced depression was associated with decreased levels of tryptophan at the periphery but not in the cerebrospinal fluid [72], confirming the results from the brains of mice injected with LPS [71]. An increased formation of neurotoxic kynurenine metabolites was also observed in the cerebrospinal fluid of IFN-α-treated patients [72] and in the brains of LPS-treated mice [73]. Furthermore, blockade of NMDA receptors by ketamine abrogated the depression-like behavior induced in mice by LPS, confirming the role of quinolinic acid [73].

These findings, together with the results of other studies on the transport of circulating kynurenine into the brain during systemic inflammation [74], led to a reformulation of the original hypothesis of a role for IDO1 in the pathophysiology of inflammation-induced depression [75]. It is now thought that the development of symptoms of depression during systemic inflammation is mediated by the transport of excess peripheral kynurenine into the brain and its local metabolism in neurotoxic kynurenine metabolites, including quinolinic acid, which act in synergy with glutamate released by activated microglia [76]. In this scenario,

decreased brain serotoninergic neurotransmission would proceed not from decreased levels of plasma tryptophan but from an immune-mediated activation of the serotonin transporter [77]. Support for this possibility was provided by neuroimaging studies showing a positive correlation between plasma levels of TNF-α and brainstem serotonin transporter availability in neurologically healthy subjects and in patients with psoriasis [78].

Activation of the tryptophan/kynurenine metabolic pathway has also been implicated in the pathophysiology of schizophrenia, but with an emphasis on kynurenic acid rather than on quinolinic acid [79]. The production of kynurenic acid is increased in the brain of schizophrenia patients [80,81]. Kynurenine is metabolized either by kynurenine amino transferases (KATs) that are present in astrocytes or by kynurenine mono-oxygenase (KMO) that resides in microglial cells. Astrocyte activation is associated with a predominance of the first pathway, whereas microglia activation is associated with a predominance of the second pathway that leads to the formation of neurotoxic kynurenine metabolites. Kynurenic acid acts as an antagonist at NMDA receptors and α7 nicotinic acetylcholine receptors that modulates glutamate, dopamine, and cholinergic neurotransmission [82], The enhanced production of kynurenic acid could be a result of astrocyte activation or the consequence of decreased KMO expression. In either case, it leads to cognitive deficits characteristic of those observed in patients with schizophrenia. These cognitive deficits can be characterized in animal models of kynurenic-acid overproduction and corrected by KAT inhibitors.

It is not yet clear how the same nonspecific inflammatory process can lead to divergent effects, in this case activation of the KAT pathway in schizophrenia and the KMO pathway in major depressive disorders. A possible explanation still to be elaborated resides in the neurodevelopmental aspect of schizophrenia that is unique to this disease. It could be speculated that the long-term consequences of an experience of inflammation during early development differ from the shorter-term consequences of an episode of inflammation taking place in an already mature organism.

29.4 Other Causal Factors for the Relationship between Inflammation and Psychiatric Disorders

The high prevalence of major depressive disorders in physically ill patients with chronic inflammatory processes [83] can be explained by the mechanisms described above, that is, activation of immune to brain communication pathways. However, this does not easily apply to cases of major depressive disorders in which there is no evidence of intercurrent inflammatory process. Another set of causal factors for activation of the cytokine network needs to be identified.

Stress is a well-recognized causal factor in psychiatry, especially in the case of major depressive disorders and post-traumatic stress disorders [84,85]. An experience of social threat or adversity can upregulate the innate immune system, even in the absence of any physical or microbial injury [86]. Both early-life stress and stress during adulthood are associated with elevated inflammation. This

phenomenon is sufficiently robust to be studied in the laboratory, using, for instance, the Trier social stress test. In this test, participants are asked to prepare and present an impromptu speech and to perform a difficult mental arithmetic task in front of a nonresponsive intimidating audience. The presence of an audience is a necessary component of the stressfulness of this test, which has been found to lead to stimulated production of TNF-α [87]. In a different study, the inflammatory activity detected in participants who were exposed to the Trier social stress test was found to be associated with greater neural sensitivity to social rejection, as measured by activation of the dorsal anterior cingulate cortex and anterior insula [88].

Multiple pathways lead from stress to inflammation. The most obvious one is represented by the effect of stress mediators on innate immune cells. Increased cortisol levels are well known to be anti-inflammatory rather than proinflammatory. However, under some conditions, endogenously released glucocorticoids are capable of potentiating neuroinflammatory processes by priming microglia in an inflammasome-dependent manner [89]. This occurs in particular when stress takes place well in advance (24 h in the rat) of the immune event.

The involvement of the sympathetic nervous system in peripheral immune responses to stress is not mediated by circulating adrenaline or noradrenaline but by the noradrenergic innervation of primary and secondary lymphoid organs. Stress-induced activation of the sympathetic outflow to the peripheral immune system recruits immature glucocorticoid insensitive myeloid $CD11b^+$ cells in the blood and spleen in rodent models of repeated social defeat [90]. These myeloid cells can traffic to the brain and contribute to the excessive microglial activation that is observed in response to stressors. This results in enhanced anxiety-like and depression-like behavior. The effects of noradrenaline are mediated by activation of β-adrenergic receptors.

Bacterial translocation and alterations in the microbiome can also contribute to the inflammatory response to stress. Studies in laboratory animals indicate that exposure to stressors can significantly change microbial populations residing in the gastrointestinal tract and in particular reduce the relative abundance of bacteria in the genus *Bacteroides*, while increasing the relative abundance of bacteria in the genus *Clostridium* [91,92]. This effect of stress on the gut microbiome is not without consequence: exposure of antibiotic-treated mice to repeated social defeat abrogated the increased inflammatory response normally displayed by these animals [92]. Bacterial translocation has been proposed to drive inflammatory responses, oxidative and nitrosative stress, and autoimmune responses directed against neoantigenic determinants generated by oxidative and nitrosative stress that are present in depressed subjects [93,94].

29.5 Relations between Inflammation and Neuropathology

Despite the large number of studies published on the neuropathology of schizophrenia, there is little consensus among neuropathologists on the main histologic features of the brains of patients with schizophrenia. The wide distribution of patchy, fibrillary gliosis in the brains of these patients was interpreted to suggest

the occurrence of a low-grade inflammation process [95]. The development of neuroimaging approaches allowing acquisition of volumetric measurements of specific brain areas and assessment of structural and functional connectivity between brain areas has greatly facilitated the task of pathologists, as correlations between gray-matter and white-matter pathology and neuroinflammation can now be studied *in vivo*. In a systematic review of the existing neuropathological and neuroimaging studies, Najjar and Pearlman reported consistent evidence of an association between schizophrenia and microglial activation, particularly in white-matter rather than gray-matter regions [96]. In these studies, positron emission tomography was used to measure microglial activation by increased binding of the peripheral benzodiazepine receptor ligand PK11 195. Microglial activation mainly occurred near dystrophic and apoptotic oligodendrocytes, demyelinating axons, and swollen and vacuolated astrocytes. In contrast to what is seen in neurodegenerative disorders, astrogliosis is absent in the brain of patients with schizophrenia. The main feature appears to be oligodendroglial pathology that leads to impairment of myelination and limitation of normal development of white matter.

White-matter pathology is also observed in major depressive disorders, although the evidence is much more scarce. This anomaly consists of decreased oligodendrocyte density and function and is particularly apparent in the prefrontal brain region. However, these findings could be biased by the old age of the patients who have been examined and the occurrence of vascular lesions and impaired cerebral blood flow [97]. Major depressive disorders are also associated with reductions in the volume of brain areas such as the prefrontal and anterior cingulate cortices and subcortical structures such as the hippocampus, amygdala, hippocampus, and basal ganglia [98–100]. These alterations are thought to reflect dendritic atrophy, decreased neurogenesis, and impaired neurotrophic function. Activation of the KMO branch of the kynurenine pathway as measured by circulating levels of kynurenine metabolites was found to be associated with decreased striatal, hippocampal, and amygdalar volumes in patients with major depressive disorders [101–103]. These findings likely reflect inflammation-driven neurotoxic events in the brains of these patients.

29.6 Conclusions

Evidence for a possible role of low-grade inflammation in the pathophysiology of psychiatric disorders has been steadily accumulating over the years. Whether the inflammatory response is primary or secondary to the brain alterations that occur in patients with psychiatric disorders is still uncertain. Preclinical and clinical studies of the brain effects of inflammatory mediators have revealed that the brain is programmed to respond to these signals by switching on a hard-wired sickness-behavior response that enables the ill individual to cope with the constraint of the inflammatory response on the organism physiology. Whether psychiatric disorders correspond to alterations in the functioning of this protective response or in distorted fragments of it remains to be established. In the case of major depressive disorders, there is clear evidence for a primary role of inflammation in driving symptoms that can be found in other disease entities independent of the

clinical diagnosis (e.g., anhedonia and fatigue). However, it is still too early to ascribe specific symptoms to inflammation and to use this feature as a guide to personalized treatment in psychiatry. Progress in this field will be possible only when psychiatrists pay more attention to dimensional aspects of psychiatric disorders and their relationship with alterations in well-characterized neurobehavioral processes.

30.1 Introduction

The complement system, originally described as defense system limited to pathogen removal, is now an acknowledged critical driver of inflammation. Sensing of pathogens or other irritants leads to complement activation with generation of complement activation products and subsequent engagement of receptors for complement activation fragments on innate immune cells and induction of the acute inflammatory responses and pathogen clearance. However, complement also modulates T- and B-cell responses and, when complement activation is dysregulated, this may contribute to persistent inflammation, which is mostly driven by adaptive immunity. Furthermore, recently discovered new modes and locations of complement activation suggest that the impact of complement in immunity is more extensive than previously thought. There is need to conduct an intensive study to determine the intracellular location of complement activation products and the biological meaning of such data. This chapter provides an overview of the recently defined roles of complement in the inflammatory response, which is rigorously regulated, and appears to be in disarray in certain inflammatory disorders such as autoimmune diseases.

30.2 Pathways of Complement Activation

30.2.1 Complement Activation

The complement system is a critical part of innate immunity and a major initiator of the inflammatory reaction. This evolutionarily old system is required for the detection and removal of invading pathogens that have breached the protective epithelial borders separating the host from the environment [1,2]. The complement system is comprised of over 50 blood-circulating and membrane-bound proteins

Inflammation: From Molecular and Cellular Mechanisms to the Clinic, First Edition.

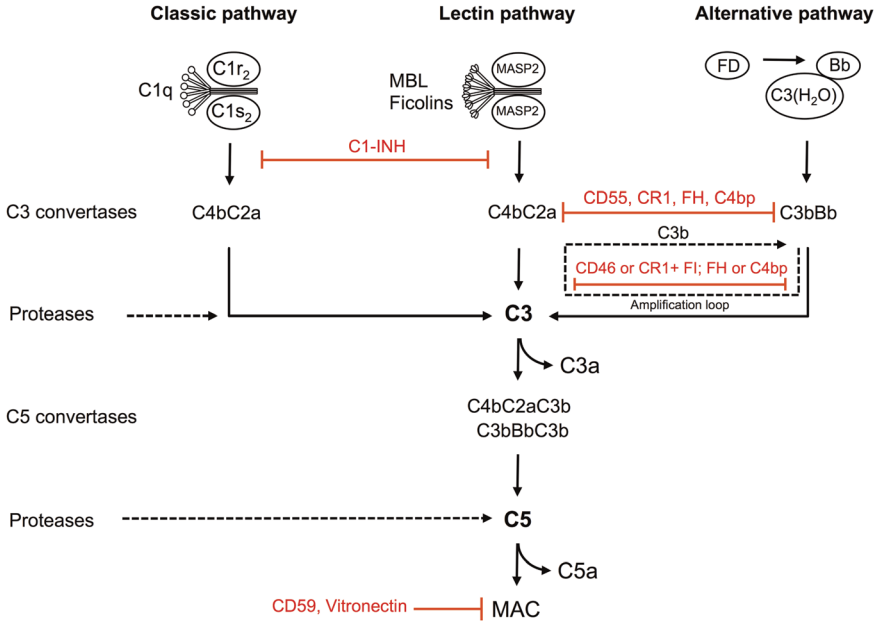

Figure 30.1 Complement activation and regulation. Complement can be activated through the classical, lectin, and alternative pathways with the initial deposition of C3b on a surface also initiating a feedback amplification loop. C3 convertase formation (C4bC2a for the classical and lectin pathways and C3bBb for the alternative pathway) leads to the generation of the opsonin C3b and the anaphylatoxin C3a and subsequent C5 convertase formation (C4bC2aC3b for the classical and lectin pathways and C3bBbC3b for the alternative pathway) generates C5b and the anaphylatoxin C5a, with C5b initiating the formation of the MAC in target membranes. Convertase-independent C3 and C5 activation also occurs via activating proteases. Several fluid phase and cell-bound regulators protect host tissue from unwanted complement deposition: C1 inhibitor (C1-INH) impedes the activity of C1r and C1s and MASP2 and deposited C3b (and C4b) are inactivated by serine protease Factor I and one of the several cofactors (cell-bound CD46 (MCP) and CR1 or fluid phase Factor H and C4b-binding protein, C4bp). Convertases are regulated through disassembly by regulators that have DAA (membrane-bound CD55 (decay accelerating factor, DAF) or CR1, Factor H, and C4bp) and the formation of the MAC is restricted by CD59 and vitronectin (protein S).

and regulators with the effector molecules existing mostly in a precursor state that can be activated rapidly in a cascade-like fashion following activation of the system. Complement activation occurs via three distinct pathways: the classical, the lectin, and the alternative pathway (Figure 30.1) [3,4]. The classical pathway is activated when the C1 complex (C1q, $C1r_2$, and $C1s_2$) binds to the Fc portion of IgG or IgM antibodies that bind to surfaces of pathogens, injured cells, or other antigens, resulting in cleavage of C2 and C4 to form the classical pathway C3 convertase. The lectin pathway is triggered by the recognition of pathogen-derived carbohydrates by mannose-binding lectin (MBL) or ficolins in complex with MBL-associated serine proteases (MASPs), which also cleave C2 and C4, leading to the formation of the lectin pathway C3 convertase. The alternative pathway activation is initiated when C3b-like molecules that are continuously generated in blood in low amounts via spontaneous hydrolysis ($C3[H_2O]$) bind covalently to a target surface and recruit

factors B and D to then form the alternative pathway convertase. The alternative pathway is also called "amplification pathway or loop" since it potentiates the activity of all three pathways [5] (Figure 30.1). C3 convertases cleave the central component C3 into the active C3a and C3b fragments and also "seed" the formation of C5 convertases, which process C5 into the biologically active C5a and C5b fragments. C5b assembles with circulating complement components C6–C9 to generate the pore-forming membrane attack complex (MAC) that promotes direct lysis of microorganisms [6].

It is increasingly acknowledged that convertase-independent cleavage of C3 and C5 by specific proteases is of greater physiological importance than previously thought. For example, several proteases of the coagglutination system [7,8] and of the cathepsin and granzyme families [9–12] process C3 and C5 into bioactive fragments, and these alternative modes of complement activation play key roles in trauma and sepsis [8,13].

30.2.2 Complement Regulation

Activated C3b and C4b (and C3[H_2O]) not only deposit on pathogens but also bind nondiscriminatively to host cells via hydroxyl and amino groups and, therefore, have the potential to induce tissue damage and inflammation [14]. Thus, complement activation is tightly regulated through a variety of complement inhibitors and regulators (Figure 30.1) that prevent uncontrolled complement activation in the fluid phase (no target) or on host cells (wrong target) [15–17]. Much of the control is focused on the alternative pathway amplification loop and involves proteolytic cleavage and inactivation of deposited C3b and C4b (cofactor activity), disassembly of formed C3 and C5 convertases (decay-accelerating activity, DAA), and inhibition of MAC formation and insertion (Figure 30.1) [18]. Interestingly and further discussed in detail below, several complement regulators not only protect host cells from complement attack but also transmit intracellular signals upon activation and participate actively in effector responses of immune cells during inflammatory processes [19].

30.3 Activation Products of Complement

C3, C4, and C5 are homologue proteins of about 200 kDa in size. C3 and C5 consist of two subunits (α and β chains) connected by disulfide bonds, while C4 is composed of three chains (α, β, and γ) [20]. Complement activation induces the proteolytic cleavage of these components at the N-terminus of their α-chains, generating the biologically active C3a, C4a, and C5a and C3b, C4b, and C5b fragments, respectively [1,2]. C3b and C4b (and their further degradation products) are *opsonins*. Following fragmentation of complement proteins, there are often physicochemical associations of certain complement fragments, that can result in new enzymatic activities. Opsonization of pathogens or other targets induces MAC (C5b-9) formation as detailed above and direct lysis but also "tags" these antigens for phagocytic uptake and removal by scavenger cells expressing

C3b- and/or C4b-binding receptors [21,22]. C3a and C5a are of approximately 12kDa size and are called *anaphylatoxins* as the interaction with their receptors, which are expressed in a mast immune cells, are indispensable in mediating the inflammatory reaction [23,24]. Of note, a receptor for C4a remains unidentified and C4a is, therefore, generally not considered an anaphylatoxin.

Although C3a and C5a often elicit similar functions, C5a is more potent and widely seen as the body's most effective chemoattractant functioning in the low nanomolar range [24]. Importantly, C5a-mediated functions are influenced by the amounts of C5a generated as low concentrations of this anaphylatoxin induce migration of myeloid cells to the site of complement activation, while higher concentrations of C5a provoke generation of superoxide, which can be converted to H_2O_2. In addition C5a can cause degranulation in myeloid cells [25]. Once generated, C3a and C5a are rapidly cleaved by several serum carboxypeptidases to C3adesArg and C5adesArg forms that lack the C-terminal amino acid arginine [26]. Initially, this reaction was thought to neutralize, control, and/or fine-tune the proinflammatory actions of the anaphylatoxins but it is now recognized that C3a and C5a and their respective desArg forms can mediate distinct immunological functions [27]. However, in general, most studies show that C5adesArg (lacking the C-terminal arginine) has little biological activity. The desArg form of C5a is generated in plasma by carboxypeptidase B and C5a loses most of its biological activity in the C5adesArg form [28]. It is not clear to what extent carboxypeptidase B is present in tissues.

Although opsonins and anaphylatoxins are considered the most critical among the complement activation products driving inflammatory processes, recent work suggests that sublytic MAC formation is an activator of the NLRP3 inflammasome and contributes substantially to the production of proinflammatory cytokines in activated cells [12,29].

30.4 Receptors for Complement Activation Products

Virtually all immune cells express receptors for complement activation fragments and signals triggered by the activation of these receptors are mediators of the inflammatory reaction.

30.4.1 Opsonin Receptors

Scavenger cells including monocytes, macrophages, and neutrophils express receptors for the opsonins C3b and C4b (or their degradation products iC3b, C3dg, and C3d) and are critical in the removal of opsonized pathogens and other antigens [24]. For example, engagement of CD35 (complement receptor 1, CR1), a large (~200kDa) transmembrane glycoprotein composed of 30 so-called short consensus repeats (SCRs), on neutrophils or macrophages by C3b and C4b deposited onto microbial surfaces induces the phagocytic uptake of these pathogens [30,31], an event that is synergistically supported by C5aR1 activation [32]. CD35 specifically expressed on erythrocytes also mediates "immune adherence clearance" that refers to the ability of CD35 to bind and transport

opsonized immune complexes or other inflammatory particles to the sinusoids of the liver and spleen for removal by resident macrophages (Kupffer cells) [33]. The complement receptors 3 (CR3, CD11c-CD18) and 4 (CR4, CD11b-CD18) are composed of two proteins each and belong to the β2 integrin family of adhesion molecules. They are present on neutrophils, monocytes, and macrophages and are also expressed in low amounts on activated T, B, and NK cells [24,34,35]. CR3 and CR4 bind the inactivated form of C3b (iC3b), and activation of CR3 via iC3b has recently been shown critical to the induction of phagocytosis in neutrophils, monocytes, and macrophages. C1q is not a complement activation product per se but is, aside from being the recognition component of the C1 complex, the main opsonin to specifically tag apoptotic cells for their removal [36]. Different cell surface receptors exist for both the C1q globular head domain (e.g., gC1q-R) and the collagen-like stalk domain (e.g., cC1q-R, also known as calreticulin – C1qRP) [37], and the C1q receptor activation on monocytes and macrophages can stimulate macropinocytosis [38,39].

Importantly, engagement of these complement "opsonin receptors" initiates not only phagocytic uptake of antigens but also additional cell-specific effector responses, contributing to inflammation such as the neutrophil oxidative burst and proinflammatory cytokine production.

30.4.2 Anaphylatoxin Receptors

The anaphylatoxins mediate their effects through engagement of their respective receptors [23]. Whereas the C3aR binds only C3a, the C5aR1 can bind both C5a (K_d~2.5nm) and the desArg form of C5a (K_d~660nm) and the C5aR2 binds C5a with similar affinity to the C5aR1 but binds C5adesArg with a 10-fold higher affinity (K_d~12nm) compared to C5aR1 [40–42]. All three receptors are seven-transmembrane receptors, but only the C3aR and C5aR1 are G protein-coupled receptors [43]. The human C3aR shares 37% sequence homology with the C5aR1 and has a distinctive 175 amino acid insert in the second extracellular loop, while the C5aR1 and C5aR2 share 38% sequence homology [42]. The size of all three receptors ranges from about 42 to 61kDa and displays diversity depending on the cells on which the receptors are expressed (possibly due to different post-translational modifications) [44]. The C3aR has been detected on monocytes, macrophages, neutrophils, eosinophils, and basophils and in low amounts on T cells [24,45,46]. C5aR1 and C5aR2 seem to be expressed in tandem not only on most cells including immune cells of lymphoid and myeloid origin but also on endothelial and epithelial cells and vascular smooth muscle cells [47,48], and a "propensity" for cell surface expression of C5aR1 but mostly intracellular expression of C5aR2 has been reported [49].

C3aR1 and C5aR2 stimulation results in activation of heterotrimeric guanine nucleotide-binding proteins (G proteins) and induction of key signaling events that generally drive (proinflammatory) cell effector functions, such as modulation of cyclic adenosine monophosphate (cAMP) [50], calcium mobilization, and protein kinase C (PKC) and phosphatidylinositol 3-kinase (PI3 kinase) activation [51], and, ultimately, activation of mitogen-activated protein (MAP) kinases [21,52]. Because the C5aR2 lacks the structural motifs required for G protein

coupling, it was long considered a decoy receptor, in line with the early observation that C5aR2-deficient mice have increased lung injury in an immune complex-induced injury model [53]. C5aR2's potential to negatively regulate C5aR1-driven signals is still controversial and appears to operate via competition for C5a/C5adesArg binding [54] and/or inhibition of C5aR1-mediated responses through direct interactions with β-arrestin, which inhibits G protein binding to receptors [49]. In contrast to suggestions that C5aR2 functions to reduce inflammatory injury, especially after immune deposition of IgG immune complexes, according to a recent report [55] dealing with acute lung injury (ALI) caused by airway deposition of IgG immune complexes, C5a of LPS shows strikingly reduced ALI intensity in either C5aR1$^{-/-}$ or C5aR2$^{-/-}$ mice. This suggests that engagement of both receptors is necessary in "full-blown" ALI. However, an increasing body of work suggests distinct and specific roles for C5aR2 with clear proinflammatory functions as defined in C5aR2$^{-/-}$ mice that show strongly attenuated house dust mite (HDM)-induced asthma [56]. Blockade of C5aR2 also has led to increased survival in sepsis [57] and, contrasting with earlier observations, reduced lung injury in an immune complex-based model performed by another group [48]. These discrepancies remain unresolved, but a picture emerges where C5aR2 function is complex, possesses potential plasticity, and is likely dictated by the cell type on which C5aR2 is expressed, the nature of the antigen encountered, and the general microenvironment in which immune cell activation occurs.

30.5 Role of Complement in Innate and Adaptive Immunity

The normal inflammatory response driven by complement-activated innate immune cells is characterized by a rapid (acute) onset, a fairly short "effector phase," and a clear termination point that is accompanied by the initiation of tissue repair pathways; thus, the acute inflammatory response is normally mild and self-limiting. However, in situations where the inflammation-causing insult is not eliminated or where complement activity is dysregulated, inflammation may persist and can become chronic. Chronic inflammation is characterized by a more prominent adaptive immune response and complement activation fragments can directly support B- and T-cell activation in these settings. A recent review describes in-depth linkages between the complement and the innate immune system [58].

30.5.1 Complement, Innate Immunity, and Acute Inflammation

Anaphylatoxins and complement-derived opsonins orchestrate the rapid arrival and activation of innate immune cells to the site of insult (Figure 30.2), events that are accompanied by the visual signs of inflammation: redness, swelling, and heat, along with pain. Neutrophils and mast cells are among the first responders during inflammation [59] and C3a induces migration of mast cells and eosinophils to inflamed tissues [60], while specifically C5a functions as key chemoattractant to recruit neutrophils, mast cells, monocytes, macrophages, and eosinophils to the

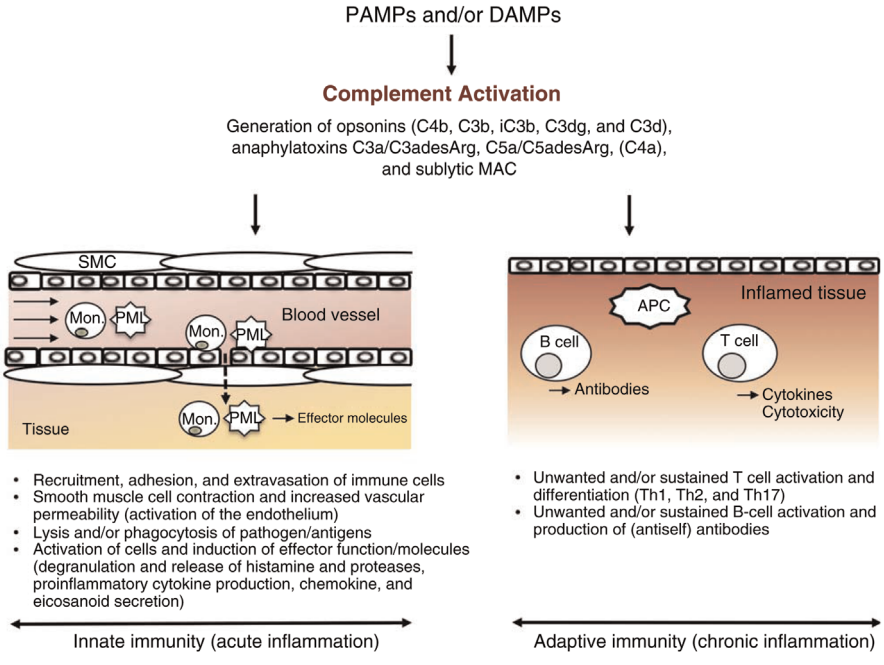

Figure 30.2 Key contributions of complement activation to the innate (acute) and adaptive (chronic) inflammatory response. Model summarizing the key effects of opsonins and anaphylatoxins on immune and endothelial cells during the acute inflammatory response and on T and B cells during chronic inflammation. Other complement activation fragments contributing to inflammation and mentioned in the chapter (e.g., C1q, CR1, CR3, and CR4) are not shown to keep the schematic focused. Abbreviations: APC, antigen-presenting cell; DAMP, danger-associated molecular pattern; Mon, monocyte/macrophage; PAMP, pathogen-associated molecular pattern; PML, polymorphonuclear leukocyte; SMC, smooth muscle cell.

site of infection [14,61]. However, anaphylatoxin receptor stimulation not only mediates immune cell mobilization and migration but also activates neutrophils, mast cells, and eosinophils and induces the degranulation and release of proinflammatory molecules such as tumor necrosis factor (TNF), histamine, and chemokines (IL-8) from these cells [62–64]. Further, C5aR1 signaling activates the lipoxygenase pathway and arachidonic acid metabolism [65] leading to increased eicosanoid production in neutrophils and monocytes. Moreover, C5aR1 activation is a strong inducer of reactive oxygen species production in neutrophils and mediates killing of phagocytosed bacteria [66]. Both C3aR and C5aR1 activation induces increased expression of adhesion receptors and secretion of proinflammatory TNF and IL-1β in neutrophils and monocytes, and C3aR and C5aR2 activation has been shown to regulate IL-6 production in these cells [63,67]. The "opsonin receptors" also contribute directly to the inflammatory response as CD35 engagement on macrophages induces IL-12 [68], while CR3 and CR4 stimulation increase LPS-induced TNF and IL-6 secretion in monocytes [69].

TNF, IL-1β, IL-6, and IL-12 are central to the inflammatory response, because they are critical activators of innate and adaptive immune cells and of the

endothelium (and induce, sustain, or increase anaphylatoxin receptor expression on many cells). In conjunction with this, activation of C3aR and C5aR1 on vascular endothelial cells induces increased expression of adhesion molecules such as E-cadherin and vascular cell adhesion protein 1 (VCAM-1) [70]. An enhanced expression of chemokines (monocyte chemoattractant protein 1, MAC-1, and macrophage inflammatory protein-2, MIP-2) [71] also occurs resulting in amplified attachment and subsequent extravasation of blood leucocytes into tissue surrounding the vessels. In addition to promoting vascular permeability (which also allows for the penetration of protective antibodies or other larger proteins into the tissue), the anaphylatoxins increase the contraction of smooth muscles in some vessels, thereby leading to increased blood flow and cell movement [72].

Recently, a direct link has been described between C3aR stimulation and the activation of the NOD-, LRR-, and pyrin domain-containing protein 3 (NLRP3, also known as NALP3) inflammasome, involving monocytes [73]. In addition, sublytic activation of the MAC mediates NLRP3 activation in human lung epithelial cells by triggering release of Ca^{2+} from the endoplasmic reticulum [74], and C1q has been identified as an NLRP3 activator (but also a negative regulator in macrophages [75]) in human retinal epithelial cells. Given the central roles for complement and the inflammasomes in innate immunity, delineating the functional crosstalk(s) between these two systems will likely help to better define the mechanisms regulating inflammation in health and disease.

30.5.2 Complement, Adaptive Immunity, and Chronic Inflammation

30.5.2.1 Humoral Immunity

The complement system is now acknowledged as vital bridge between innate and adaptive immunity [76]: CD21 (complement receptor 2, CR2) is expressed in B cells and follicular dendritic cells (FDCs), two main players in humoral immunity. Engagement of CD21 by iC3b, C3dg, or C3d reduces the threshold for B-cell receptor (BCR) activation by several magnitudes and is required for optimal protective antibody production and antigen shuttling to B-cell germinal centers [77]. Although the underlying mechanisms are not fully understood, CD21 also contributes to the maintenance of B-cell tolerance and memory [77]. Uncontrolled or continued complement activation in chronic inflammation, therefore, adds to unwanted antibody responses that underlie a range of chronic inflammatory diseases such as rheumatoid arthritis (RA), systemic lupus erythematosus (SLE), and so on [78]. Of note, pathologically reduced complement levels are associated with chronic vessel wall inflammation (vasculitis) as a result of decreased complement-mediated clearance of immune complexes and uncontrolled *in situ* immune complex deposition [79].

30.5.2.2 T-cell Immunity

Complement activation products also impact T-cell activation and regulation, either indirectly by influencing the maturation and cytokine production of antigen-presenting cells (APCs) or directly by engaging complement receptors/regulators expressed by T cells [80]. Combined signaling by the C3b/C4b-binding

complement regulator CD46 (membrane cofactor protein, MCP) and the C3aR expressed in $CD4^+$ T cells has been established as a prerequisite for IFN-γ production and human Th1 induction [9,81,82] and dysregulation of CD46-mediated signaling events in T cells have been identified in chronic disease settings including multiple sclerosis (MS) [83] and RA [84]. The role of C3a/C5a/C5adesArg in T-cell immunity has mainly been studied in mouse models and demonstrated that the anaphylatoxin receptors are critical to the induction and regulation of Th1, Th2, and Th17 and natural regulatory T-cell (Treg) responses [85,86]. While C3aR expression is required for Th2 induction in a HDM-driven model of asthma, C5a in general seems to negatively regulate both Th2 responses and the induction and function of induced Tregs [80]. C5a also modulates Th17 cell differentiation by altering the local production of IL-23, IL-6, and TGF-β by dendritic cells (DCs) or macrophages and can either enhance or inhibit Th17-cell differentiation depending on the inflammatory context, and both C5aR1 and C5aR2 contribute to Th17 regulation [85]. Furthermore, C1q, possibly via binding to its receptors calreticulin or C1qRp and CD35 [39,87], regulates T-cell responses mostly in a negative fashion (by reducing cell proliferation and cytokine secretion), suggesting that C1q deficiencies may directly lead to pathologically increased T-cell responses observed in patients with SLE. In sum, the idea that complement not only contributes to acute but also chronic inflammation (Figure 30.2) is now becoming more mainstream, as is the view that complement activation needs to be controlled tightly "in either direction" to prevent inflammatory disease.

30.6 Evidence for Intracellular Activation of Complement

Although the liver is the main source of serum-circulating (systemic) complement [1,2], epithelial cells, endothelial cells, adipocytes, microglial cells, astrocytes, and immune cells can produce complement components [12,88], and complement activation fragments generated locally by cells impact heavily on their respective (effector) functions [12,46]. Specifically, during the cognate interaction between T cells and APCs, both partners not only upregulate C3aR and C5aRs expression but also produce several complement components including C3 and C5 and Factors B and D [46,89,90]. This leads to subsequent C3 and C5 convertase formation on activated T- and APC-cell surfaces and generation of complement activation fragments that then engage T-cell and/or APC-expressed complement receptors (Figure 30.3). Such autocrine complement production impacts the DC maturation and not only mediates upregulation of MHC class II molecules and costimulatory proteins CD40, CD86, and cytokine production but also induces directly Th1 cells [46,91]. Local complement production by epithelial cells contributes to the inflammatory response in ischemia/reperfusion injury after transplantation or myocardial infarction [92], where restoration of blood flow in oxygen-deprived organs induces cell damage mediated mainly by C3a, C5a, and MAC formation. Furthermore, generation of complement activation fragments locally is involved in inflammatory pathologies of the brain and the central nervous system including Alzheimer's disease and multiple sclerosis (MS) [93].

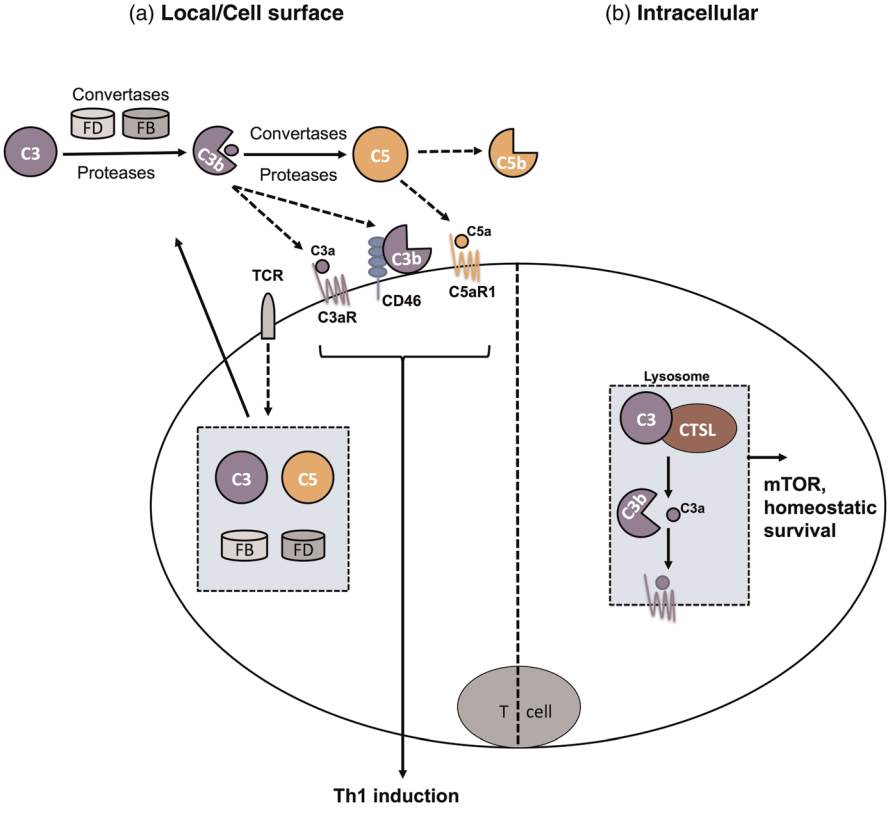

Figure 30.3 Local and intracellular complement C3 activation and function. (a) Locally occurring complement is triggered when the stimulating signal (e.g., TCR stimulation) initiates the generation and secretion of C3, C5, and Factors B and D leading to C3 and C5 convertase formation in the extracellular space and on the cell surface and ultimately the generation of the complement activation fragments C3a, C3b, C5a, and C5b. These bind to their respective receptors on the T cell and induce cellular responses. Note that this local activation mode has also been described for APCs (where it induces maturation and cytokine production). (b) Intracellular complement activation in $CD4^+$ T cells occurs through continuous cleavage of C3 by the protease cathepsin L. The resulting bioactive C3a stimulates intracellular C3aR for tonic mammalian target of rapamycin (mTOR) activation and homeostatic cell survival. Intracellular C3 activation also occurs in a wide range of myeloid and nonmyeloid cells; however, the C3-activating protease differs depending on the cell type (not shown). Abbreviations: CTSL, cathepsin L; FB, Factor B; FD, Factor D.

It has recently been demonstrated that C3 activation occurs intracellularly via cathepsin L-mediated cleavage of C3 and that C3a generated via this "pathway" stimulates intracellular C3aR signaling that then drives a specific cellular response (homeostatic survival) distinct from the engagement of cell surface-expressed C3aR (IFN-γ production) [80] (Figure 30.3). Further, as dysregulation of intracellular complement activation partakes in the sustained T-cell response and chronic inflammation in RA [80], one can envision that changes in the intracellular complement activation machinery will also contribute to the uncontrolled responses of innate immune cells in acute inflammatory settings.

Thus, the roles of complement in the inflammatory response involve complex mechanisms, distinct locations, and are considerably more multifaceted than previously thought.

30.7 Roles of C5a, C5aRs, and C3aR in Inflammatory Disorders

30.7.1 Acute Respiratory Distress Syndrome (ARDS)

This disease was described in the 1960s and is accompanied by bilateral granular densities in lungs as detected by radiographs or CT scans. There are usually severe problems with gas exchange, with hypercapnia (elevated pCO2 in blood), along with reduced pO2 in blood. Lung lesions of ARDS (acute respiratory distress syndrome) are associated with a mortality rate of 40%, characterized by edema fluid in alveolar walls and in spaces, together with large numbers of polymorphonuclear (PMN) and red blood cells (RBCs), and deposits of fibrin along alveolar walls ("hyaline membranes") and in alveolar spaces [94,95]. The integrity of vascular and alveolar epithelial barriers has clearly been breached. It has been known for some time that C3 activation products (C3b, iC3b, etc.) and C5a are present in bronchoalveolar lavage fluids (BALFs), along with the presence of activated factor B [96]. Fundamentally, there are few clues as to what has triggered ARDS, what has caused complement activation, and there are no US Food and Drug Administration (FDA) approved drugs to treat ARDS. Anti-inflammatories (steroids, NSAIDS, etc.) have not been reliably effective.

30.7.2 Sepsis

Sepsis caused by infectious agents (bacteria, viruses, and protozoa) has long been known to be associated with robust activation of complement, resulting in consumptive depletion of both complement proteins and clotting factors [97]. Over the past two decades, the incidence of fatal outcomes in sepsis has dropped from 50–60% to 20%, due entirely to improved supportive care: reduced barotrauma by modifying ventilation procedures that employ reduced inflation pressures, aggressive fluid resuscitation treatment, and early employment of broad-spectrum antibiotics [97]. Evidence for complement activation is reflected in reduced CH50 values in plasma and the presence of C5a in plasma. Not surprisingly, C5aR1 levels in blood PMNs often drop dramatically in septic patients, and the plasma contains cell membrane-defined microparticles that are positive for granule content (from PMNs) together with C5aR1 [98].

In the setting of polymicrobial sepsis in mice, administration of a neutralizing antibody to the middle portion or to the C-terminal regions of C5a greatly improved survival (e.g., from 20 to 80%) and reduced evidence of multiorgan failure [99–101]. To what extent similar interventions in septic humans will improve the outcome of sepsis in humans will depend on current phase II clinical trials in Germany.

It should be noted that there has been a clinical focus on the role of Toll-like receptor (TLR) 4 in sepsis. TLR4 is a well-known receptor for lipid A from bacterial endotoxin (LPS), and there has been an assumption that sepsis in humans might be effectively treated with a compound that blocks TLR4. The FDA-approved drug, Eritoran, is an analog of lipid A, but it lacks one of the four fatty acids of lipid A. It binds with high affinity to TLR4 but does not activate the receptor, competing with the agonist, lipid A, in plasma. Unfortunately, clinical trials in patients with sepsis were cut short after 6 months because of lack of efficacy of the drug [102]. Another clinical trial using activated protein C (Xigris) in patients with sepsis failed to show clinical efficacy and was subsequently withdrawn from use in humans with sepsis [103]. Obviously, there is intense ongoing activity to define a complement inhibitor that can interfere with the activation cascade leading to blockade of C5a or targets essential for its appearance in sepsis.

30.7.3 Acute Lung Injury

This disorder occurs both in humans and in experimental animal models of acute lung injury (ALI), chiefly involving rodents. At a recent consensus conference in Berlin, it was decided to avoid use of the term ALI in human lung disorders, restricting the classification to ARDS [104]. Experimental ALI shares many of the physiological features of ARDS (severe defects in gas exchange in lungs, resulting in reduced arterial pO2 and elevated pCO2). In addition, experimental ALI has been associated with evidence of "consolidation" of lungs, with diffuse bilateral radiographic densities caused by lung edema and PMNs in alveolar walls and spaces. These changes are associated with a series of physiological abnormalities: greatly increased respiratory rate together with increased minute ventilation and inspiratory flow rate. Values for inspiratory and expiratory times and total respiratory cycles fell dramatically [55]. Most of these parameters were reversible in animals surviving ALI.

Experimental ALI was induced in wild-type (WT) mice by airway deposition of IgG immune complexes, recombinant mouse C5a (essentially endotoxin free), or LPS, the latter two being given intratracheally. Lung injury peaked 6–8h later. There was a striking appearance of extracellular histones in BALFs. Histone presence was PMN-dependent and resulted in an intensely phlogistic local environment [55]. Histones appeared to be the most immediate cause of intense lung injury involving both alveolar epithelial and vascular endothelial cells. Histone appearance in BALFs of mice with ALI required availability of caspase 1 and NLRP3 [105]. It seems likely that C5a activated the expulsion of formed neutrophil extracellular traps (NETs) that resulted in the appearance of extracellular histones. Histones also had the capacity to activate the NLRP3 inflammasome [105,106], resulting in IL-1β release from phagocytes, further amplifying the inflammatory response [105]. These features are described in Figure 30.4. The extent to which these events occur in human ARDS seems high. Histones have been found in BALF obtained from patients with ARDS [55]. When $C5aR1^{-/-}$ or $C5aR2^{-/-}$ mice were used, dramatic reduction in lung injury was found, with reduced albumin leak into lungs, varying from 80 to 94%.

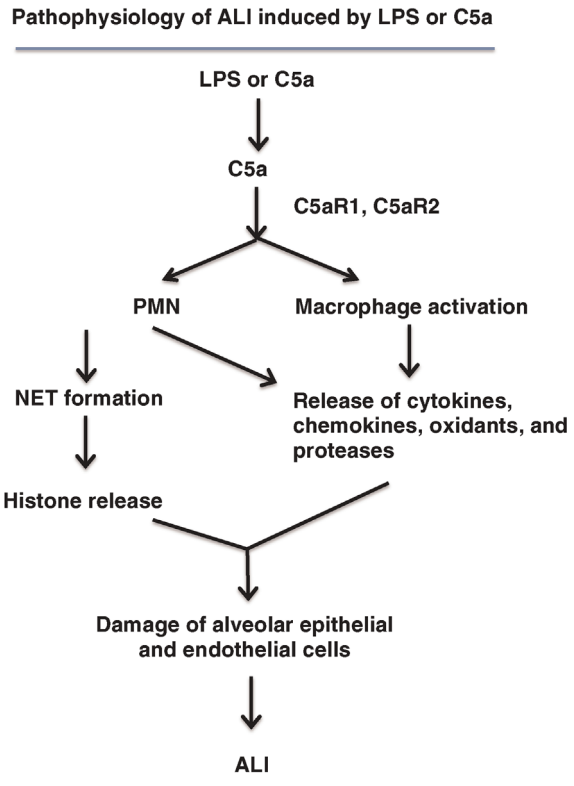

Figure 30.4 Pathophysiology of ALI induced by LPS or C5a. Acute lung injury (ALI) can be induced by airway deposition of LPS or C5a, resulting in an acute inflammatory response in the distal airway (alveolar compartment). Complement C5a itself or after complement activation via LPS results in C5a interacting with its receptors (C5aR1 and C5aR2) on lung macrophages, alveolar epithelial cells, and other cell types results in recruitment of PMNs. The end result is endothelial cell and alveolar epithelial damage, resulting in the loss of the vascular and airway barriers. Activation of recruited PMNs results in their formation of NETs that not only capture or kill bacteria but also release histones that are highly proinflammatory and procoagulative. This sequence of events in ALI often results in severe structural damage, which is usually reversible.

There were accompanying reductions in PMN appearance in BALF from mice lacking C5a receptor. We also found the reductions in levels of extracellular histones in BALF from mice that lacked one of the C5a receptors. When we examined BALF from humans with ARDS, extracellular cellular histones were also present [55]. When recombinant purified histones were injected into mouse airways, intense inflammatory responses ensued, associated with alveolar edema and the presence of PMNs and fibrin deposits, together with thrombi in pulmonary veins, which indicates that, in lung, histones are intensely prothrombotic.

Based on the data described above, the pathogenesis of ALI is described in Figure 30.4. The three initiators of ALI C5a, LPS, and IgG immune complexes triggered the early activation of complement, resulting in generation of C5a. C5a interacted with C5aRs, leading to NET formation in PMNs. This also resulted in

the appearance in BALF of extracellular histones. We recently showed that extracellular histones directly activated the NLRP3 inflammasome, which could be largely responsible for the appearance of both IL-1β and IL-1β in the BALFs from mice developing ALI. In addition, histone appearance apparently resulted from NET formation by PMNs, resulting in the release of extracellular histones [105].

30.7.4 Biological Roles of C3a and C5a Receptors

Substantial effort has been focused on defining the roles of C3a and C5a receptors in a variety of biological responses, most involving some type of inflammatory response. Several strategies have been employed, most using mice with genetic deficiency of the receptor under study. Only one C3a receptor, C3aR, has been identified. In the case of C5a, two C5a receptors have been identified, C5aR1 and C5aR2, the latter previously known as C5L2. While it is clear that C3aR and C5aR1 are surface associated, C5aR2 was originally described on the surfaces of PMNs. A controversy ensued, suggesting that when human blood PMNs were very carefully and gently purified, most of C5aR2 was intracellular. Furthermore, it was suggested that the ligand for C5aR1 was C5a, while C5adesArg was the ligand for C5aR2. There has also been a controversy related to the biological functions of each of the two C5 receptors. At present, those issues remain unresolved.

In the setting of polymicrobial sepsis in mice, participation of both C5aR1 and C5aR2 appears to be required for the full development of the complications of sepsis (the "cytokine storm," development of multiorgan failure, appearance of plasma histones, and compromised survival) [57]. For development of ALI in mice, induced by airway instillation of C5a, LPS, or IgG immune complexes, full development of inflammatory injury requires availability of both C5a receptors. The absence of either C5a receptor resulted in nearly complete blockade of lung injury leading to>90% reduction of injury [55], suggesting that there may be sequential engagement of both receptors.

In terms of allergic asthma in mice sensitized to ovalbumin or recombinant cockroach antigen, aerosol delivery of the antigen results in an effector response characterized by prompt "airway hyperresponsiveness" with airway constriction, followed by peribronchial edema mucous secretion, all resulting in inflamed and dysfunctional upper airways. Earlier studies suggested that global deficiency of the C3aR attenuated this string of events [107], as did the absence of C5aR1. In early studies with C5a null mice, these animals were protected from development of the series of events leading to asthma. The conclusions of these studies suggested that C3a and C5a via their receptors promoted proallergic functions required in the effector phase of asthma development. Together, these studies suggest a regulatory role for C5a and C3aR in asthma, while C5a and its receptor(s) is/are required for "allergic sensitization." C5a and C5aR1 promote the full-blown effector phase of asthma, all of which makes it very difficult for research groups to develop therapeutic interventions targeted at the complement in the setting of human asthma.

30.8 Role of Complement in Selected Human Diseases

30.8.1 Vasculitis

There are many forms of vasculitis affecting arterioles in humans. However, medium-sized arteries and large arteries may also be affected. The inflammation process appears in the walls of vessels, associated with PMNs, fibrin deposits, and sometimes necrosis (referred to as necrotizing vasculitis). In patients with SLE, sera often contain DNA–anti-DNA immune complexes, and deposits of IgG and C3 are frequently seen in the affected vessels [108,109]. There is also emerging evidence in SLE that patients develop autoantibodies to citrullinated histones, which may intensify vasculitis [110]. Lesions of vasculitis also occur in arterioles of individuals who have developed reactivity to drugs, but details of the precise cause of the vasculitis are scant and, importantly, there are no reliable biomarkers of vasculitis except for those that are nonspecific (elevated serum levels of C-reactive protein).

30.8.2 Examples of Complement-related Glomerulopathies in Humans

Listed below are three examples of complement-related glomerulopathies occurring in humans. These disorders are rather common, and each features the presence of complement activation products in the kidney. Figure 30.5 contains three examples of complement-related glomerulopathies (Figure 30.5b–d) that are described below, together with an example of a normal human kidney tissue section (Figure 30.5a).

30.8.2.1 Membranous Glomerulonephritis

Membranous glomerulonephritis (MGN) is a slowly progressive glomerular disease featuring focal segmental glomerulosclerosis (fibrosis and capillary obliteration), occurring in adults between the ages of 30 and 50 years (Figure 30.5b). Most cases of this disorder are of unknown cause. Autoantibodies to the phospholipase (PLA) 2 receptor on podocytes of glomeruli have been identified in 85% cases of MGN [7]. MGN may also be secondary to autoimmune disorders, infections, drugs, heavy metals, and malignant tumors. Glomerular deposits of C3 and C4 are found, along with deposits of the complement-derived membrane attack complex (C5b-9, MAC). These deposits occur on surfaces of podocytes, which play a key role in regulating glomerular filtration of proteins. The presence of these complement activation products appears to be correlated with the inability of podocytes to restrain filtration of albumin and larger proteins in the glomerular filtrate. An autoantibody to the PLA2 receptor on podocytes may cause local complement activation and glomerular dysfunction. At present, there is an interest in using rituximab, which depletes B cells, thereby reducing the levels of the autoantibody [82].

30.8.2.2 C3 Glomerulonephritis

C3 Glomerulonephritis (C3GN) features extensive C3 deposits in glomeruli (in mesangial and subepithelial locations) (Figure 30.5c) [111]. Heavy deposits may occur in which case the process has been referred to as “dense deposit disease.”

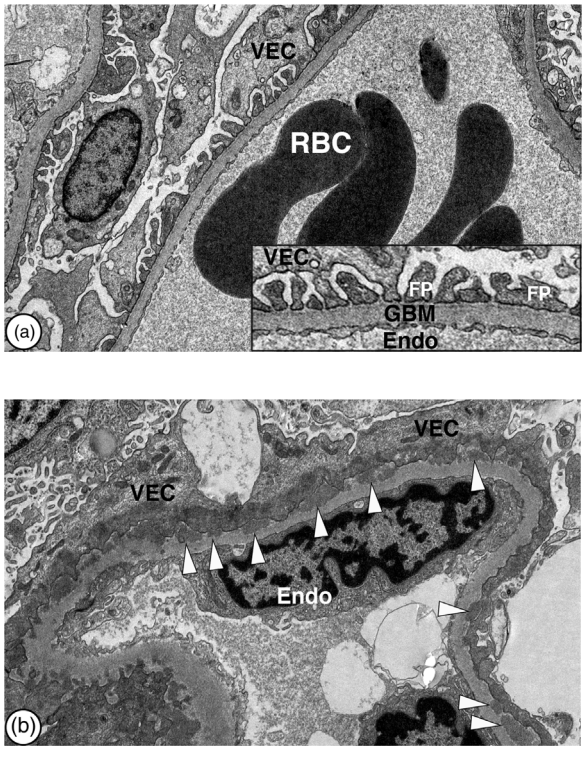

Figure 30.5 Transmission electron micrographs of human renal biopsies. (a) Normal. The renal glomerulus is the site of urinary filtrate production. Composed of three layers: visceral epithelial cells (VEC) or podocytes, fenestrated endothelial cells (Endo), and a thick (~350nm) glomerular basement membrane (GBM). The podocytes have interdigitating cell processes or foot processes (FP) which adhere to the glomerular basement membrane and have specialized intercellular junctions, (slit diaphragms), which restrict the permeability of macromolecules such as large molecular weight plasma proteins. (b) Membranous Glomerulopathy. Idiopathic membranous glomerulopathy is most frequently due to the binding of an autoantibody directed against a VEC antigen, the phospholipase A2 receptor. Binding of the autoantibody, leads to shedding of the antigen into the subepithelial space, between the epithelial cell and the glomerular basement membrane (arrowheads), where the antigen-antibody lattice activates complement. The terminal complement components bind to the VEC cell surface causing sublethal injury resulting in increased protein in the urine and ultimately, increased basement membrane accumulation or sclerosis. (c) C3 Glomerulopathy – dense deposit disease. Seen as a rare complication of hereditary defects in complement regulation or an acquired defect due to C3 nephritic factor, there is a distinctive morphologic abnormality in which an electron dense deposit forms a ribbon-like band in the GBM (arrowheads) with unregulated C3 activation and attendant recruitment of inflammatory cells (WBC) in the glomerular vasculature. (d) Atypical hemolytic uremic syndrome. aHUS is a rare but devastating form of complement-mediated glomerular injury leading to extensive endothelial injury with marked swelling of the endothelial cells that partially or completely exclude the capillary lumen, with consequent fragmenting of RBCs forming schistocytes (SC) and extensive platelet (*) aggregation with resulting thrombocytopenia.

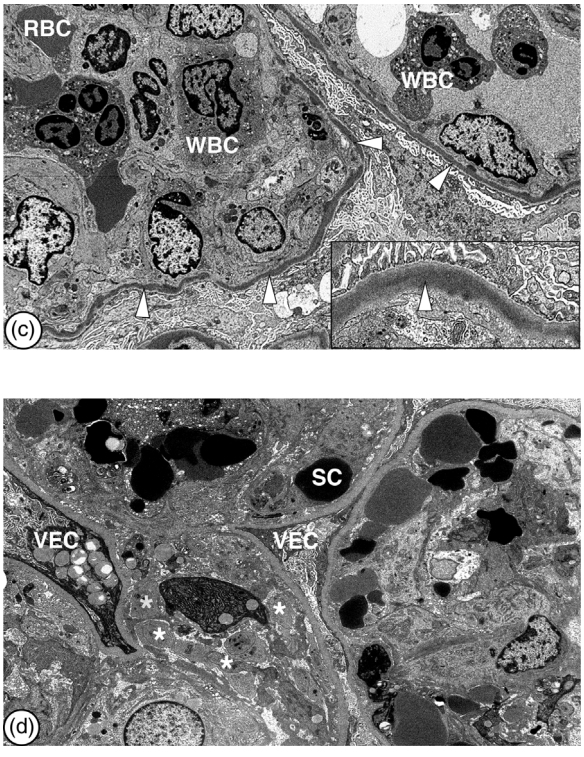

Figure 30.5 (*Continued*)

Causes of these responses are poorly understood, but in some cases defective Factor H (a regulatory factor for the complement system) has been linked to C3GN. C3GN also occurs in patients with persistent infectious diseases (e.g., group A Streptoccocal infections, meningococcal infections, etc.). There may be progressive proteinuria and renal dysfunction. In patients treated with a renal transplant, C3GN develops in >50% of the transplanted kidneys. There is no effective clinical intervention available for C3GN.

30.8.2.3 Hemolytic Uremic Syndrome and Related Disorders

Thrombotic microangiopathies include the hemolytic purpura and hemolytic uremic syndrome (HUS) (Figure 30.5d) [112]. In all cases, inflammatory glomerular injury develops, together with microvascular injury, often with thrombosis, along with glomerular and interstitial tubular injury. Typical HUS often occurs in children following shigella infection. Atypical HUS often develops in children and may be associated with autoimmune diseases involving complement-activating antibodies (antifactor H, antiphospholipid antibody, etc.) that trigger complement activation [113,114]. It has been suggested that the terminal complement pathway, featuring the generation of the MAC, results in acute glomerular injury and vasculitis in atypical HUS. HUS may lead to progressive renal dysfunction and interstitial fibrosis. A mAb to human C5 has been FDA-approved for treatment of patients with HUS [115].

30.8.2.4 Systemic Lupus Erythematosus and Lupus Nephritis

SLE is one of the more common autoimmune diseases known to be associated with consumptive depletion of serum complement (C1q, C3, and C4). At least 50% of patients with SLE develop progressive renal dysfunction [116]. The morphology of lupus nephritis is associated with diffuse proliferation of glomerular mesangial cells, dense matrix deposition in glomeruli together with dense subendothelial deposits of IgG, IgA, and IgM in glomerular capillary walls. Lupus nephritis may advance to glomerular sclerosis (fibrosis) and progressive renal dysfunction. As is well established, patients with SLE often have systemic manifestations featuring inflammation involving skin, joints, kidneys, and the central nervous system. Vasculitis often develops, along with deposits of immune complexes, especially in renal glomeruli. Renal dysfunction is a major problem in patients with SLE and evidence of consumptive depletion of plasma complement often develops. At present, clinical therapy includes immunosuppressive drugs as well as antibodies (rituximab) that suppress B-cell function. Typically, 25% of SLE patients develop progressive renal dysfunction that results in end-stage renal disease.

30.9 Strategies to Block Complement Activation and Complement Activation Products

30.9.1 Compstatin

Compstatin is a cyclic trideca peptide that inhibits the C3 convertase converge, preventing downstream generation of biologically active split products of C3 as well as the downstream C5 and its activation products, C5a, C5b, and the MAC (C5b-9). Compstatin, over the past decade, has been subject to numerous modifications that have improved its solubility in biologic solvents, its inhibitory potency for complement blockade, and its pharmacokinetics, resulting in a water-soluble peptide with subnanomolar binding affinity [117]. In its most recent version, it has a half-life approximately 12h in the circulation of subhuman primates of and appears to be nontoxic. With its primary target being blockade of C3, compstatin blocks C3 cleavage that results in its active fragments, C3a and C3b [108]. The latter is a major opsonic factor promoting phagocytosis of microorganisms bearing C3b on their surfaces. Theoretically, excessive blockade of C3 could compromise the phagocytosis-promoting properties of C3b, thus impairing the protective opsonic-promoting properties of C3. However, such problems can be overcome by applications of compstatin to clinical settings in which there is little evidence that an infectious agent is at play. Clinical considerations currently under assessment include age-related macular degeneration, hemodialysis that is often associated with complement activation, and preservation of organs to be used for transplantation [60].

30.9.2 C1 Esterase Inhibitor

The C1 esterase inhibitor (C1INH) blocks C1r, C1q, and MASP2, thereby reducing activation of the classical pathway of complement. However, it is

acknowledged that C1INH has broader blocking activities as demonstrated by reduced generation by kallikrein of bradykinin, diminished activation of factor XII of the clotting system, and suppressed activation of matrix metalloproteinases [59]. While C1INH has been used in patients with severe sepsis, ischemia reperfusion injury and a variety of other conditions, where there were suggestions of clinical improvement, the FDA has restricted its clinical use in hereditary angioedema [118].

30.9.3 C5 Blocking Antibodies

There is abundant evidence that C5 is a major source of powerful proinflammatory products (C5a, C5b-9) in a variety of conditions (e.g., sepsis, excessive inflammatory responses to infectious agents, ischemia reperfusion injury, hemolysis occurring in a variety of situations, etc.) and it has therefore been postulated that targeting C5 should yield protective outcomes. Several anti-C5 antibodies have been produced in a variety of forms: intact IgG, Fab fragments, and single-chain Fv molecules. The humanized Fab and scFv versions block lysis of chicken RBCs and porcine aortic endothelial cells upon complement activation. With some antibody preparations, generation of C5a and C5b was also blocked [119]. The FDA approved a humanized mAb to human C5 ("Eculizumab") for treatment of patients with paroxysmal nocturnal hemoglobinuria (PNH). These patients present with MAC-induced activation of the clotting system and platelet aggregation in arterioles of the kidney. Further, increased MAC activation in this setting has been connected with reduced blood flow to glomeruli, resulting ultimately in renal dysfunction. To date, the use of the C5 blocking mAb appears to be safe and reports of incidences of increased infections are, somewhat unexpected, rare [120]. However, a major problem with the mAb is its cost. In the setting of PNH, the annual cost of treatment with Eculizumab may exceed $500 000 per year. There are experimental peptides that bind to human C5 and block its activation, but these compounds have not reached the point of clinical trials, and there is a question of whether such drugs might be in violation of patents held by Alexion, the producer of the mAb described above that has been approved for use in PNH.

30.9.4 C5a Antibodies

Based on extensive evidence that sepsis often leads to consumptive depletion of complement (CH50 levels), there is a body of evidence in the case of polymicrobial sepsis in rodents that generation of C5a and its interaction with C5a receptors is linked to adverse outcomes of sepsis (multiorgan damage and failure and mortality) [121]. Development of neutralizing rabbit antibodies (IgG) to C5a led to protection against adverse outcomes in sepsis in monkeys [122], but the number of animals included into the study was too small to generate data with robust statistical significance. At present, phase II clinical trials in humans with sepsis are being carried out in Germany (refer to InflaRx, www.inflarx.com/). The clinical efficacy of this mAb in septic humans remains to be determined.

30.10 Conclusions for Role of C3aR and C5aR

Published data emphasize that C5a and C5aR promote proinflammatory outcomes, especially including activation and recruitment of neutrophils and monocytes to extravascular sites where cellular injury and disruption of extracellular matrix occur. In the case of C5aR2, there continues to be controversy as to whether C5a interaction with this receptor is proinflammatory or anti-inflammatory. It is difficult to reconcile the current literature. With respect to C3aR, it appears that the bulk of the current literature would suggest that its interaction with C3a suppresses inflammatory responses, at least in the setting of asthma triggered by extrinsic antigens and in ischemia reperfusion of the intestine. Clearly, much more needs to be done before we have an understanding of how these agonists and receptors function biologically.

Acknowledgments

This work was supported by US National Institutes of Health grants, GM-29507 and GM-61656, the Godfrey D. Stobbe Professorship and University of Michigan Department of Pathology departmental funds (to P.A.W.) and by the Division of Intramural Research, National Heart, Lung, and Blood Institute (to C.K.). We thank Paul D. Killen for kindly providing transmission electron micrographs of human renal biopsies.

31.1 The Molecules (HSP Families)

In every living cell in every tissue, HSPs carry out important housekeeping functions and often are molecular chaperones. Their protein folding and transport functions make them crucial for the survival of both prokaryotic and eukaryotic cells. Their expression is strongly upregulated under a variety of stress conditions, that is, high/low temperature, oxidative stress, nutrient deficiency, infection, inflammation, and in general conditions that lead to protein unfolding.

Based on their monomeric molecular size, HSPs can be categorized into six families, the s(mall)Hsp (HSPB), DNAJ (Hsp40), Hsp70 (HSPA), Hsp90 (HSPC), Hsp100 (HSPH), and the chaperonins (HSPD/E and CCT), each family having at least one member but often many more [1], as a result of gene duplications during evolution. Also between species, the number of members of a specific family varies widely. Some families also comprise constitutively expressed members that under normal, unstressed conditions contribute to protein transport and folding (e.g., in most eukaryotic cells highly expressed HSPA8 (Hsc70)).

In general, the HSP families are evolutionary strongly conserved and some have members that are immunologically highly cross-reactive with their microbial homologues (see Table 31.1). These families are the subject of the following sections.

Other less conserved HSP families (such as the HSP90 family, the HSP100 family, and the small HSP family, which includes HSP27 and α-B crystallin) have been reviewed elsewhere [2,3].

31.2 Biological Function of HSPs (Chaperones)

31.2.1 The Markers of Cellular Stress

Events in cells under stress are the result of phosphorylation and dephosphorylation-based protein alterations. These lead to a stress-specific

Table 31.1 Strongly conserved HSP families in mammals and typical microbial homologues.

HSP Family	Family Members in Mammals	Cellular Location	Functions	Typical Microbial Homologues
HSP70 (HSPA)	HSP70 Hsc70 BiP/Grp78 mHSP70/Grp75	Cytosol, nucleus Cytosol, nucleus ER Mitochondrion	Chaperoning nascent polypeptide chains, (re)folding, and transport over subcellular organelle membranes	DnaK (*E. coli*), Ssa1-4, Kar2 (*S. cerevisiae*)
HSP60 (HSPD)	HSP60/cpn60	Mitochondrion	Chaperone activity: (re)folding, assembly of multimeric protein structures	GroEL (*E. coli*)
DNAJ (HSP40)	Hdj1 and Hdj2	Cytosol	Cochaperone for HSP70 activities	DnaJ (*E. coli*), Ydj1 (*Saccharomyces cerevisiae*)
HSP10 (HSPE)	HSP10/Cpn10	Mitochondrion	Cochaperone for HSP60 activities	GroES (*E. coli*)

pattern of protein modifications. Subsequently, as part of a general survival strategy of cells, there will be inhibition of translation initiation and the cell will move toward translation of only mRNA essential for the production of proteins needed for survival [4]. In other words, genes that become activated are meant to assist the repair of cellular damage. Different stressors will lead to the activation of distinct sets of stress-related genes. Above all, upregulated heat shock proteins are the markers of a cell that is responding to stress in an adequate manner.

31.2.2 Molecular Basis of the Heat Shock Response

The transcriptional component of the HSP response is directed by a family of so-called heat shock factors (HSF). HSF-1 is the main HSF. HSF-1 is present normally in a latent monomeric (nonstressed) state and is converted into a DNA-binding trimer when cells are stressed [5]. It has been of interest to elucidate the mechanisms that control the monomeric nature of latent HSF. Besides the originally described intramolecular interactions between amino- and carboxy-terminal leucine zippers that regulate this activity [6], there is now convincing evidence that the primary reason for equilibrium between repressed and active HSF-1 is competition for the chaperoning activity of HSP90, HSP70, and HSP40. HSF-1 seems to remain partially in the latent state due to interactions with these three chaperones. This equilibrium is disrupted by sudden appearance of nonnative client proteins that result from cell stress, whereby the chaperones move into their sequestering activities. As a result, HSF-1 self-associates and forms DNA-binding trimers. The actual binding will occur with the heat shock elements (HSEs) that are located upstream of the HS genes. This leads to elevated transcription of HS genes [7]. Besides HSF-1, the presence and activity of which is conserved in humans, *Drosophila*, *Caenorhabditis elegans*, and yeast, there are three additional HSFs (HSF-2, HSF-3, and HSF-4) present in vertebrates and

these exhibit diverse functional properties during development, stress, and life span [7]. It is known that the trimerization of HSF-1 is impeded during aging, leading to a reduction in the heat shock response and therefore production of heat shock proteins in elderly individuals. It is possible that this in itself contributes to the higher incidences of protein deposition diseases and some inflammatory diseases in later life.

31.2.3 Triggers for the Heat Shock Response

The stressors that initiate the heat shock response can be of both environmental and physiological origin. Besides heat shock, other environmental initiators include heavy metals, UV irradiation, inhibitors of energy metabolism, and certain amino acid analogs. Physiological triggers may include factors involved with growth and development, but more relevant for this chapter, the triggers may also include factors involved with pathophysiological states or diseases. Most relevant in this context are fever, the stress of ischemia, infection, tissue damage, and stress caused by the mediators of inflammation. The latter may include reactive oxygen species (ROS) that at higher concentrations lead to oxidative stress that may damage many cellular components [8] and lipid mediators of inflammation [9]. Proinflammatory cytokines, such as IL1 and TNFα, may lead to the heat shock response in an indirect manner, through their induction of the lipid mediators of inflammation and also ROS [8].

As a result of this, inflammatory diseases will lead to induction of the stress response in cells. Other diseases that induce stress responses are diseases associated with protein folding malfunctions, such as Alzheimer, Parkinson, ALS, Huntington, some metabolic diseases, and cancer (see Figure 31.1).

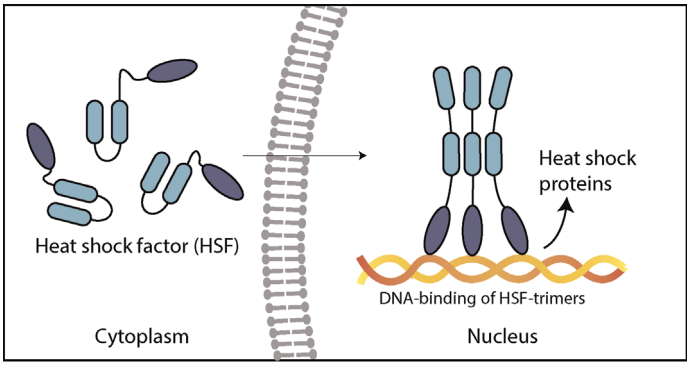

Figure 31.1 Induction of the heat shock response can result from the factor in the environment or factors connected to pathophysiology, leading to trimerization of HSF and subsequent DNA binding in het HSP promoter region.

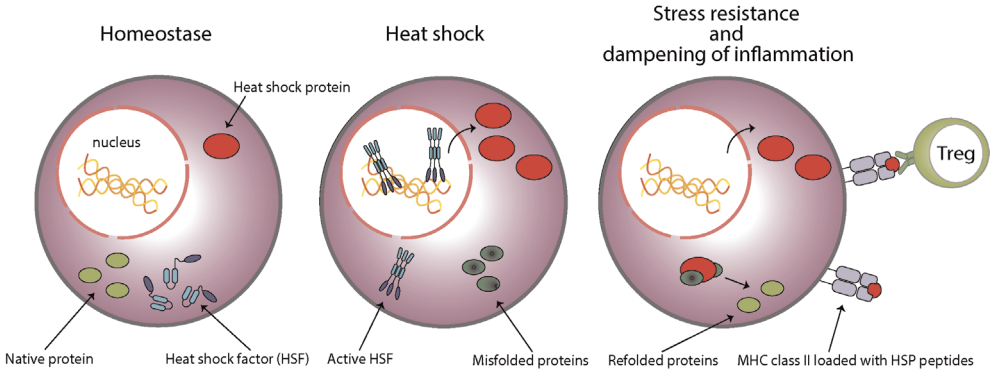

Figure 31.2 The various molecular and cellular events associated with homeostasis, heat shock (stress), and immune regulation.

31.2.4 The Chaperone Functions of HSP Families

The primary function of heat shock proteins is their chaperoning activity. A great deal of pioneering work was done for GroEL, which is the prokaryotic (*Escherichia coli*) equivalent of HSP60 in mammals [10]. GroEL is a folding catalyst, of which the monomers are assembled into a 7-mer-ring structure. Two of the rings stacked upon each other form together a subcellular structure that becomes capped by two GroES (HSP10) molecules at either site. Unfolded or misfolded proteins enter this structure and by the transient interactions that occur with the HSP60 molecules in the inside of the structure, proteins can become properly folded. The activity of HSP60 is ATP dependent. In mammals, the HSP60 molecules are present in this formation in the mitochondria where proteins become refolded after having entered this subcellular organelle. Intuitively, one may well accept the unique degree of evolutionary conservation of HSP60, because of the delicate and complex structure in which HSP60 functions. Only subtle changes in primary structure seem to occur, which leads to the presence of large areas of sequence conservation between HSP60 homologues present in plants, microbes, and vertebrates. Knockout mice do not exist for most HSP due to the vital functions of HSP.

Similar levels of conservation are seen for members of some other HSP families, such as HSP70. The HSP70 family (HSPA1A/B) in conjunction with DNAJB1 (HSP40) are the strongest stress inducible proteins. The human genome sequencing revealed that there are encoded 13 different HSP70 molecules. The majority of them are present in the cytosol and it seems that they have their specialized functions. The HSP70 family chaperones act in an ATP-dependent manner and interact with the proteins that are handed over to them by HSPB and DNAJ molecules. The substrate-binding domains of HSP70 interact only with short linear polypeptides; therefore, the molecule can bind and assist the folding of a large variety of substrates. HSPA8 (Hsc70) is omnipresent in all cell types and is, therefore, held to be an essential housekeeper that takes care of the folding and chaperoning of molecules that are transported over intracellular membranes. Similar activity may have HSPA5 (BiP) in the endoplasmatic reticulum. While

some HSP70 members are exclusively dependent on stress for their presence, some of the HSP70 family members are constitutively expressed in cells.

The HSPH (HSP110) molecules are nucleotide exchange factors for the HSPA family of molecules. HSPC (HSP90) molecules are proteins that function as ATP-dependent molecular chaperones that regulate the signaling conformation and expression of multiple client proteins. Among these client proteins are receptors, such as the corticosteroid hormone receptors and kinases, and also critical inflammatory mediators.

31.2.5 HSP70 as a Prominent Peptide Donor for the MHCII Ligandome

Cells under stress move into a strategy that enables them to economize their exogenous protein needs. Autophagy (or autophagocytosis) (from the Greek auto, "self" and phagein, "to eat") is the basic catabolic mechanism that involves cell degradation of redundant or dysfunctional cellular components through the actions of lysosomes [11]. The breakdown of cellular components promotes cellular survival during starvation by maintaining cellular energy levels. Autophagy allows the degradation and recycling of cellular components. During this process, targeted cytoplasmic constituents are isolated from the rest of the cell within a double-membrane vesicle known as autophagosome. The autophagosome then fuses with a lysosome and its cargo is degraded and recycled. There are three different forms of autophagy, namely, macroautophagy, microautophagy, and chaperone-mediated autophagy (CMA). In this last form of autophagy, there is a functional role of HSP70 family members. CMA is a pathway that involves the recognition of peptides by a HSP70 (Hsc-70)-containing complex. This means that a protein must contain the recognition site for this complex that will allow it to bind to its chaperone, forming the CMA–substrate/chaperone complex. This complex then moves to the lysosomal membrane-bound protein that will recognize and bind with the CMA receptor. Upon recognition, the substrate protein gets unfolded and it is translocated across the lysosomal membrane with the assistance of the lysosomal HSP70 chaperone. The frequent presence of HSP70 peptides in MHCII molecules has already been documented [12]. Given the role of HSP70 in CMA it may well be no surprise that cell stress forms one of the drivers of the loading of HSP70 fragments into MHCII molecules. A telling example was presented by Dengjel *et al.* [13], when they analyzed the MHCII ligandome of human B cells, stressed by nutrient deprivation, and found multiple HSP70-derived peptides. Among the detected peptides was a peptide already discovered in the mouse as a prominent MHCII-restricted target antigen for anti-inflammatory regulatory T cells [14–16].

31.3 The Immunology of HSPs

31.3.1 Immunodominance of Prokaryotic HSP

Already before the actual discovery of HSP in bacteria, it was known that the immune response (antibodies) against prokaryotic microorganisms was dominated by the response against a molecule with the descriptive name: common

antigen of Gram negatives [17]. Upon cloning of GroEL (HSP60) from *E. coli*, it became clear that this so-called common antigen was HSP60. The driving force behind such immunodominance may be trivial. Given the conservation of this molecule, it is possible that the repetitive and frequent contact with these molecules, as they are present in all bacterial species, leads to a certain level of immunological memory at the level of B and T cells with specificity for these molecules. And understandably, the focus of such responses would then be on the more conserved antigenic epitopes, as these would be encountered most often.

Alternative explanations are, however, also possible. Irun Cohen has argued that, highly evolved as the immune system is, there exists a hierarchy in the way the immune system scans the outside world of antigens [18]. In other words, the immune system has a built-in capacity to put focus on recognition of stress proteins. If this would be true, one could speculate about the evolutionary forces that direct such an immunological focus on these proteins. The interest of the immune system in recognizing HSP must stem from the fact that it is advantageous to respond to HSP. And indeed, in the case of infection, adaptive immune responses directed against microbial HSPs, including responses to epitopes shared among various pathogens, seem to have an effective role in protective immunity [19].

31.3.2 Cross-reactivity with Self-HSP

The high level of immunogenicity associated with microbial HSP is, however, difficult to explain given the high degree of cross-reactivity with self-HSP. Self-tolerance would theoretically put a break on immune responses directed to such conserved molecules. Nonetheless, B- and T-cell-mediated cross-reactivity of the adaptive immune response has been observed in several experimental systems. Immunization with bacterial HSP60 protein or peptides has been found to lead to the production of self-HSP cross-reactive antibodies in models of induced atherosclerosis [20]. However, this was not the case in all studies. For example, comparison of epitope specificities of anti-HSP60 IgG-type antibodies in the sera of healthy subjects, patients with coronary heart disease, and inflammatory bowel disease has, however, not shown a great deal of microbial self-cross-reactivity [21].

Interestingly, some studies documented that self-antigens including HSP, myosin, tubulin, and aldolase with highly conserved structures show similar patterns of binding with natural antibodies and form a well-defined cluster as demonstrated by cluster analysis of immunoreactivity data [22]. The results of the latter study favor the hypothesis that HSP belongs to a subset of highly conserved and immunodominant self-antigens that are the primary target for natural autoantibodies in normal human IgG. A more recent discussion on the role of HSP60 and HSP70 as natural biomarkers and critical antigens in autoantibody repertoires can be found in [23].

For T cells, it was found that immunization with mycobacterial HSP60 induced T-cell responses to several HSP60 T-cell epitopes (peptides), among which there were some very conserved sequences [24]. In this study on inbred Lewis rats, there were nine major histocompatibility complex class II-restricted epitopes

recognized in mycobacterial HSP60. Of these, there turned out to be one, covering the 256–270 sequence, which primed for cross-reactive T-cell responses to the corresponding region of rat HSP60. Interestingly, this peptide containing the 256–270 epitope was the only one able to confer protection against adjuvant-induced arthritis. Similarly, administration of a T-cell line specific for this epitope protected against this disease. Preimmunization with the 256–270 epitope induced T cells that not only responded to heat-shocked syngeneic antigen-presenting cells but also protected against CP20961-induced arthritis, indicating that activation of T cells, recognizing an epitope in self-HSP60, can protect against arthritis induced without mycobacteria [24].

Also for HSP70 T-cell cross-reactivity was observed. A conserved mycobacterial HSP70 sequence was found to be immunogenic and to induce T cells that cross-reacted with the rat homologue sequence. Upon analysis of cytokines produced by these peptide-specific T cells, high IL-10 production was found, as was the case with T cells responsive to whole HSP70 protein. Nasal administration of this peptide was found to lead to inhibition of subsequent adjuvant arthritis induction. The data presented here shows the intrinsic capacity of conserved bacterial HSP to trigger self-HSP cross-reactive T cells with the potential to downregulate arthritis via IL-10 [25].

In a more recent study, we have discovered a conserved T-cell epitope in mycobacterial HSP70 in Balb/c mice. Also in this case, the peptide (called B29) synthesized on the basis of this epitope sequence, induced T-cell responses that cross-recognized multiple homologous peptides present in endogenous HSP70 family members [14]. Interestingly, this peptide was found to trigger the development of regulatory T cells (Tregs) and the transfer of such induced Tregs into naïve recipient mice showed the *in vivo* activation of the cells. Apparently, the cross-recognition of the endogenous HSP70 homologues led to their activation. One of the induced markers was lymphocyte activation gene 3 (LAG3) and selection of the LAG3 positive cells by cell sorting produced a population a Tregs that at the extremely low number of only 4000 cells suppressed inflammation upon transfer.

31.4 HSPs Protect in Models of Inflammatory Disease

First observations on the role of HSP in inflammatory disease models were made in the model of adjuvant arthritis in rats. In this model, disease is induced with heat-killed mycobacteria in oil, and Holoshitz and coworkers had developed mycobacteria (*Mycobacterium tuberculosis*) specific arthritogenic T cell lines and clones by repeated Mt stimulations *in vitro*. Depending on the conditions, the lines were also capable of protecting the animals against induced disease upon *in vivo* transfer. The latter observation was the basis of a series of studies that led to the development of the so-called T-cell vaccination as a possible therapeutic approach for autoimmune diseases. This approach has progressed into the phase of clinical trials, in multiple sclerosis, for example. T-cell vaccination employs a classic vaccine strategy of injecting an attenuated form of the disease-causing agent – in this case T cells – that have been selected and expanded from patients

and then reinjected after irradiation to induce protective immunity. This anti-T-cell immunity consistently results in selective deletion or regulation of the targeted pathogenic T cells *in vivo* [26].

Although in the above-mentioned T-cell-induced adjuvant arthritis some fractionation of mycobacterial antigens was done, there was no solid clue on the precise nature of the mycobacterial antigen that was recognized by the cells. By mere coincidence, the antigen was discovered to be HSP60 when molecular cloning of the first mycobacterial genes in *E. coli* was done and one of the successfully cloned proteins was seen to stimulate the cells [27]. When the same cloned protein was found to protect rats against adjuvant arthritis, it became clear that an interesting relationship between HSP and inflammatory disease could exist.

Induction of disease with the HSP60 molecule itself was, however, not possible. And epitope mapping with an overlapping series of HSP60 peptides showed that the arthritis producing T cells were recognizing a nonconserved (180–188) epitope of mycobacterial HSP60. Although a certain degree of molecular mimicry was found for this epitope with cartilage proteoglycans [28], which could possibly explain the arthritogenic nature of the cells, there was no evidence for any cross-recognition of the endogenous mammalian HSP60 associated with the adjuvant arthritis cell lines and clones. Thus, although seminal observations around HSP and inflammation were made in the adjuvant arthritis model, the mechanisms of HSP-mediated dampening of inflammation were elucidated in other experimental models (see Section 31.6).

Nonetheless, as the anti-inflammatory protective effects of HSP were attributed to induction of self-homologue cross-reactive T-cell responses, the question was raised as to whether this protective effect could be extended to other highly conserved and immunodominant microbial antigens with mammalian homologues. Therefore, we immunized Lewis rats with conserved bacterial antigens (superoxide dismutase, aldolase, GAPDH, and HSP70). Although all antigens appeared highly immunogenic, we only found a protective effect in experimental arthritis after immunization with bacterial HSP70. The protective effect of HSP70 was accompanied with a switch in the subclasses of HSP70-specific Abs, suggesting the induction of Th2-like response. The most striking difference between immunization with HSP70 and all other immunodominant antigens was the expression of IL-10 found after immunization with HSP70. Even more, while immunization with HSP70 led to antigen-induced production of IL-10 and IL-4, immunization with aldolase led to increased production of IFN-gamma and TNF-alpha. Thus, the protective effect of conserved immunodominant proteins in experimental arthritis seems to be a specific feature of HSP. Therefore, HSP may offer unique possibilities for immunological intervention in inflammatory diseases [29].

Immunomodulation with other HSP, such as glucose-regulated protein 96 (gp96), was also documented in the model of NOD diabetes in mice and in MBP or proteolipid protein-induced EAE [30]. Although transfer experiments showed that the observed protection was T-cell mediated, there was no evidence for a role of Treg since the active population was not in the CD25+ T-cell population.

Thus, altogether HSPs have many biological functions, including the signaling of inflammatory stress and the induction of regulatory control through the adaptive immune response.

31.5 HSP as Inflammatory Mediators

31.5.1 HSP are DAMPs?

For inflammation, in a generalized sense, two main types of activators are known: nonself-antigens (known as pathogen-associated molecular patterns (PAMPs)), which are present in or released from infectious invaders, and self-antigens known as damage-associated molecular patterns (DAMPs), which are host molecules (such as high-mobility group box 1 protein (HMGB1)) released from damaged cells under necrotic but not apoptotic conditions. In many ways and under many different experimental conditions, HSPs are frequently mentioned as prime examples of DAMPs. There are, however, several qualities inherent to HSPs that disqualify them as DAMPs. We have reviewed the arguments recently [31,32]. First, DAMPs are intracellular molecules normally hidden from recognition by the immune system, whereas HSPs are freely present in the extracellular fluids and are also frequently exposed at the outer surface of cells (both eukaryotic and prokaryotic cells). Second, Toll-like receptor 2 (TLR2) and TLR4 are seen as two of the main receptors involved in the recognition of HSP60 and HSP70. These HSPs are released from cells under necrotic conditions, but it has been shown that TLR2 and TLR4 are not required for the host response to DAMPs that are derived from necrotic cells. Moreover, other receptors for HSPs, such as the HSP70 scavenger receptor SRA1, have been shown to confer a suppressive rather than an activating signal to host cells. Third, *in vitro* cultured dendritic cells have been shown to adopt a tolerizing phenotype, rather than a mature or activated phenotype, in the presence of HSPs. Fourth, as already argued in this chapter, in experimental models of autoimmunity and of tissue or tumor transplants, immunization with HSPs was shown to lead to the induction of regulatory T cells, which suppressed disease or transplant rejection.

One major obstacle to reach a proper interpretation of the findings made in this area is that much of the original experimental work was carried out with recombinant HSPs that were contaminated with remnants of *E. coli* LPS and other stimulatory components of bacterial origin. One may assume that much of the proinflammatory effects seen in the earlier work was caused by the presence of these, difficult to remove, contaminants [33].

Unfortunately, this may have contributed to the existence of a number of possibly conflicting or difficult to reconcile reports. For example, recombinant human HSP70 was reported to promote the antigen-presenting function of DCs and to convert T-cell tolerance to autoimmunity (Millar *et al.*, 2003). Around the same time, others reported that an LPS-free recombinant mycobacterial HSP70 induced IL-10 production and immunomodulation through a delayed maturation of bone marrow-derived DCs [35].

31.6 HSP are DAMPERs of Inflammation

Given the risks associated with unregulated forms of inflammation, many inflammation-associated factors have their built-in function in the dampening

of inflammation. As we have seen, the models have provided ample evidence for the anti-inflammatory effects of HSP. A large variety of mechanisms may be responsible for this.

31.6.1 Effects of HSP on Mediators of Inflammation

Rothbard *et al.* reported that systemic administration of one of the smaller HSPs (HSPB5) had a downmodulating effect on inflammation through the temperature-dependent binding of acute-phase proteins such as complement factors [36].

Another central component of inflammation is, of course, NF-κB. Translocation of this transcription factor to the nucleus leads to expression of inflammation-promoting genes, such as those coding for inflammatory cytokines IL-6 and IL-12. HSPs have been found to mediate the degradation of the p65 subunit of NF-κB. In LPS-treated dendritic cells, HSP70 was shown to have an active role in transport of the NF-κB-PDLIM2 (an ubiquitin E3 ligase that targets the p65 subunit) to the proteasome for degradation. In other words, HSP70 inhibits proinflammatory NF-κB signaling by acting as a bridge between an ubiquitin E3 ligase and the proteasome ([37], ra119). Long before the elucidation of the exact molecular events leading to this NF-κB inhibition, the phenomenon was known already. One of the earlier observations was on HSP70 and its suppressive effect on astroglial-inducible nitric oxide synthase by decreasing NF-κB activation [38]. More general claims that the heat shock response blocked Iκ-B degradation and NF-κB nuclear translocation were also made already long before [39]. A further review on how the heat shock response and the NF-κB signaling pathway interact at multiple levels is available ([40], S89–95). This review mentions that the heat shock response inhibits TNFα, IL-1β, IL-8, RANTES, complement factor 5, and ICAM-1 in mononuclear cells.

It can be debated whether these effects of the heat shock response on inflammatory effector mechanisms are specific or just the result of gene expression prioritization for those genes that are essential for survival. Several findings, however, have argued in favor of specificity of the heat shock response and its anti-inflammatory effects. For instance, overexpression of HSP70 by stable transfection was shown to inhibit cytokine-mediated expression of NO synthase in cultured cells [38] and HSF-1 was found to repress the proIL-1 promoter [41].

31.6.2 HSP are Targets for a Default Regulatory Immune Response

For the functional activity of Tregs to control inflammation, it has already been argued by others that the recognition of an antigen by the very small number of autoantigen specific T cells in a polyclonal T-cell population would probably not suffice. A better scenario would be the activity of a collection of polyclonal Tregs that recognize complexes of MHC class II loaded with ubiquitous self-peptides [42]. As already mentioned above, HSP peptides are abundant in the MHCII ligandome, especially at sites of inflammation. Therefore, the repertoire of T cells with TcRs that enable such T cells to detect the presence of HSP peptides are well positioned to react adequately and to mitigate the inflammatory process.

31.6.3 HSP and Tregs

The mycobacterial HSP70 peptide B29, mentioned above, was found to induce very effective Tregs [14]. The responding CD25+, Foxp3+ T-cell population, when injected into mice, suppressed induced arthritis through its cross-recognition of endogenous B29 homologues present in multiple members of the HSP70 family of molecules. The transferred T cells were positive for the CD90.1 congenic marker, and when transferred these cells were easy to differentiate from the CD90.2 positive host cells. In this manner, the continued presence of the transferred Tregs was documented for at least 50 days and when during suppression of disease the cells were killed *in vivo* by the infusion of a cytotoxic CD90.1-specific antibody, disease was seen to reappear. These experiments are well indicative of the fact that endogenous HSPs can be effective targets for Tregs in inflammatory conditions. Also during active disease, the transfer of B29-specific CD25+ Tregs was seen to fully inhibit disease.

Direct relevance of HSP70 for the function of Tregs and Foxp3 was shown by the manipulation of histone/protein deacetylases (HDACs) in Tregs by the use of HDAC inhibitors. The inhibitors were shown to prevent and suppress induced colitis in mice and the effect was shown to be associated with increased numbers and function of Tregs. Subsequent experiments in HDAC9−/− mice showed that they were resistant to colitis and had increased HSP70 levels. With immunoprecipitation, a direct interaction between HSP70 and Foxp3 was demonstrated [43].

31.6.4 HSP Coinducing Substances

Endogenous upregulation of HSP, as argued above, does promote the presence of HSP peptides in MHCII molecules, which are then recognized by CD4+ cells, and possibly with some preference by Tregs. In this manner, such endogenous upregulation can contribute to the control of inflammation. For this reason, HSP coinducers are of interest. HSP coinducers are substances that promote the synthesis of HSPs when cells are subjected to stressors. HSP coinducers are not stressors themselves and are, therefore, not capable of inducing a stress response in cells by themselves. A well-known HSP coinducer is the compound geranylgeranylacetone, despite its sometimes less pronounced activities [44]. Interesting coinducers are hydroxylamine derivatives such as bimoclomol. Some of them were developed and tested for their capacity to induce control of disease through their cytoprotective effects, such as in cardiovascular diseases [45].

In our laboratory, we have uncovered the HSP coinducing activity of carvacrol, one of essential oils present in Oregano species. Carvacrol was already known as an antimicrobial agent that was used for food conservation purposes. When tested on mammalian cells, human and mouse, HSP70 was found to be upregulated when the cells were exposed to carvacrol followed by heat stress. Interestingly, when carvacrol was orally administered in mice, the animals were found to show an increased T-cell response to HSP70 as tested in an *ex vivo* T-cell proliferation assay. In addition, with quantitative RT-PCR, an enhanced presence of mRNA coding for HSP70 was detected in the Peyer's patches of carvacrol-treated animals.

Apparently, the harsh environment of the gut tissues or the rapid replication of intestinal cells created already the stress needed for a further effective coinduction of HSP by carvacrol. Similarly, oral carvacrol prior to arthritis induction in the mouse model inhibited the disease. This inhibitory effect was shown to be T-cell-mediated by the successful suppression of disease following transfer of CD3+ T cells obtained from carvacrol-treated mice [46].

31.7 The Clinical use of HSP in Chronic Inflammatory Diseases

31.7.1 HSP Peptides and Proteins

Peptides and proteins for immunotherapy are usually selected from proposed autoantigens that are held responsible for initiating the pathological reactivity directed against self. However, at the time of actual diagnosis, human autoimmune diseases are already characterized by a secondary inflammatory process in which multiple antigens are targets of the immune system (a process known as epitope spreading). The antigens that are specifically upregulated at the site of inflammation and are immunologically dominant (bystander antigens) are, therefore, attractive candidates for antigen-specific immunotherapy. Induced tolerogenic immune responses to such bystander antigens could lead to a local downregulation of the ongoing inflammatory process that propagates the disease. Peptides developed from HSPs have the potential to serve as effective bystander antigens.

Until now, only few clinical trials with HSP peptides were reported. Vaccination with HSP60-derived peptide p227 protected against type 1 diabetes in both NOD mice and humans, as shown in a successful phase II clinical trial [47].

The first HSP peptide tested in RA in a phase I trial was dnaJP1 in patients with early RA. Mucosal administration of dnaJP1 led to a shift in T cells from a proinflammatory to a regulatory phenotype [48]. There were no relevant side effects seen. More recently Koffeman *et al.* performed a placebo–controlled phase II/III trial with dnaJP1 in RA patients [49]. After oral administration, clinical improvement was reported. The short-term effects of intravenous administration of HSP10 were investigated in a randomized, double blind, multicenter study. In this study with 23 treatment-resistant RA patients, disease activity scores improved significantly during the 12 weeks of therapy in the high-dose group. Most adverse events were mild [50].

At present, a first phase I/IIa clinical trial with BiP in RA patients has been carried out and the results will be made public soon. The primary end point was very successful, there was no toxicity in any patient at any time over the three months monitored that was attributable to BiP. Some of the tested biomarkers were seen to respond favorably to the treatment (Corrigall, personal communication).

31.7.2 TolDC Loaded with HSP Peptides

Dendritic cells (DCs) play a central role in the immune system, they launch effective immunity against invading pathogens and simultaneously preserve

tolerance to self and harmless antigens encountered daily. DCs contribute to maintenance of immunological homeostasis by promoting peripheral tolerance, among others, via the induction of antigen-specific regulatory T cells and induction of energy or deletion in effector T cells. These unique traits make them possible targets for tolerance-inducing cellular therapies. DCs are indispensable for tolerance induction as ablation of DCs in mice results in spontaneous autoimmunity [51]. Indeed, several studies have shown that transfer of autologous dendritic cells, *in vitro* modulated to obtain tolerogenic capabilities, that is, tolerogenic DC (tolDC), can prevent the induction of autoimmunity in animal disease models such as arthritis, EAE, and diabetes [52]. Moreover, first clinical phase I trials in diabetes and RA using *ex vivo* manipulated human tolDCs have been performed showing their safety *in vivo* and the practical feasibility of DC transfer therapy [53].

Recently, we have started to study the functionality of tolDCs in our experimental arthritis model. Dendritic cells were cultured from bone marrow from wild-type Balb/c mice (BMDCs). To create tolerogenic DCs, dexamethasone and the active form of vitamin D3 (1,25-dihydroxyvitamin D3) were added to the culture and LPS was used to induce maturation. The tolDCs were loaded with HSP70 peptide B29 and put in coculture with CD4+ T cells isolated from a mB29b (HSP70 epitope)-TCR transgenic mouse.

The tolerogenic characteristics were shown by a reduction in maturation markers, a reduced production of IL-12p70 and the production of IL-10. Furthermore, after stimulation with tolDC, CD4+ T cells developed a Treg-like character, indicated by an increased IL-10 production. These results indicate that HSP peptide-loaded TolDCs are able to induce a regulatory phenotype in HSP-specific CD4+ T cells. Given this result, it may be clear that this use of tolDC may offer attractive therapeutic chances. HSP peptides can be produced under GLP conditions and are not restricted to a certain autoimmune disease, requiring the use of a disease-specific autoantigen.

32.1 Introduction

Virtually all patients with severe inflammatory conditions have coagulation abnormalities. These abnormalities range from subtle activation of coagulation that can be detected only by sensitive markers for coagulation factor activation to somewhat more stronger coagulation activation that may be detectable by a small decrease in platelet count and subclinical prolongation of global clotting times. In its most extreme form, coagulation activation my lead to fulminant disseminated intravascular coagulation (DIC), characterized by simultaneous widespread microvascular thrombosis and profuse bleeding from various sites [1,2]. Patients with severe forms of inflammation-associated coagulopathy may present with manifest thromboembolic disease or clinically less apparent microvascular fibrin deposition, which predominantly presents as multiple organ dysfunction [2,3]. Alternatively, severe bleeding may be the leading symptom [4], but quite often a patient with DIC has simultaneous thrombosis and bleeding. Bleeding is caused by consumption and subsequent exhaustion of coagulation proteins and platelets, due to the ongoing activation of the coagulation system [5]. In its most severe form, this combination may present as the Waterhouse–Friderichsen syndrome, commonly seen during fulminant meningococcal septicemia, although many other microorganisms may cause this clinical state [6].

32.2 Incidence of Inflammation-associated Coagulopathy

Clinically relevant coagulation abnormalities may occur in 50–70% of patients with severe systemic inflammation, whereas about 35% of patients will meet the criteria for DIC (see further) [7,8]. In general, the incidence of thrombocytopenia (platelet count $<150 \times 10^9$/l) in critically ill medical patients is 35–50% [9,10]. Typically, the platelet count decreases during the first four days in the intensive

care unit [11]. Systemic inflammatory states, for example, as associated with severe sepsis, is a clear risk factor for thrombocytopenia in critically ill patients and the severity of sepsis correlates with the decrease in platelet count [12]. Main factors that contribute to thrombocytopenia in patients with severe systemic inflammatory states are impaired platelet production, increased consumption or destruction, or sequestration in the spleen or at the endothelial level. Impaired production of platelets in the bone marrow may seem contradictory to the high levels of platelet production-stimulating proinflammatory cytokines, such as tumor necrosis factor (TNF)-α and interleukin (IL)-6, and high concentration of circulating thrombopoietin in patients with inflamation, which theoretically should stimulate megakaryopoiesis in the bone marrow [13]. However, in a substantial number of patients with systemic inflammation marked hemophagocytosis may occur, consisting of active phagocytosis of megakaryocytes and other hematopietic cells by monocytes and macrophages, hypothetically due to stimulation with high levels of macrophage colony-stimulating factor (M-CSF) [14]. Platelet consumption probably also plays an important role, due to ongoing generation of thrombin. Platelet activation, consumption, and destruction may also occur at the endothelial site as a result of the extensive endothelial cell–platelet interaction that may vary between different vascular beds in various organs (see further) [15]. A prolonged global coagulation time (such as the prothrombin time (PT) or the activated partial thromboplastin time (aPTT)) occurs in 14–28% of patients [16]. Other coagulation test abnormalities in patient with severe systemic inflammatory states include high fibrin split products (in up to 99% of patients) [17,18] and low levels of coagulation inhibitors, such as antithrombin and protein C [18,19].

32.3 Clinical Relevance of the Interaction between Inflammation and Coagulation

There is evidence that activation of coagulation in concert with inflammatory activation can result in microvascular thrombosis and thereby contribute to multiple organ failure [20]. First, there are several reports of post-mortem findings in patients with systemic inflammatory conditions with coagulation abnormalities and DIC [21,22]. These autopsy findings include diffuse bleeding at various sites, hemorraghic necrosis of tissue, microthrombi in small blood vessels, and thrombi in mid-size and larger arteries and veins. The demonstration of ischemia and necrosis was associated with fibrin deposition in small and mid-size vessels of various organs [23]. Importantly, the presence of these intravascular thrombi appears to be clearly and specifically related to the development of organ dysfunction. Second, experimental animal studies of inflammation-elicited coagulopathy show fibrin deposition in various organs. Experimental bacteremia or endotoxemia causes intra- and extravascular fibrin deposition in kidneys, lungs, liver brain, and various other organs. Amelioration of the hemostatic defect by various interventions in these experimental models appears to improve organ failure and, in some but not all cases, mortality [24–27]. Interestingly, some

studies indicate that amelioration of the systemic coagulation activation will have a profound beneficial effect on resolution of local fibrin deposition and improvement of organ failure [4,28]. Last, clinical studies support the notion of coagulation as an important determinant of clinical outcome. DIC has shown to be an independent predictor of organ failure and mortality [3,29]. In a consecutive series of critically ill patients, the mortality of patients with DIC was 43%, as compared to 27% in those without DIC. In this study, mortality was also directly related to the severity of the coagulopathy [30].

32.4 Pathogenetic Pathways in the Coagulopathy of Sepsis

In recent years, the mechanisms involved in the pathological derangement of coagulation in patients with inflammatory conditions have become increasingly clear. Apparently, various mechanisms at different sites in the hemostatic balance act simultaneously toward a procoagulant state. It has become clear that the most important mediators that orchestrate this imbalance of the coagulation system elicited by inflammation are cytokines [31]. Increasing evidence points to extensive cross-talk between these two systems, whereby inflammation leads to activation of coagulation and coagulation also considerably affects inflammatory activity [32]. Interestingly, systemic activation of coagulation and inflammation may have some organ-specific manifestations, which are relevant for the specific organ dysfunction (see further) [33].

32.4.1 Initiation of Inflammation-induced Activation of Coagulation

Tissue factor plays a central role in the initiation of inflammation-induced coagulation [34]. Blocking tissue factor activity completely inhibits inflammation-induced thrombin generation in models of experimental endotoxemia or bacteremia [26,35]. The vast majority of cells constitutively expressing tissue factor are found in tissues not in direct contact with blood, such as the adventitial layer of larger blood vessels. However, tissue factor comes into contact with blood when the integrity of the vessel wall is disrupted or when endothelial cells and/or circulating blood cells start expressing tissue factor. The *in vivo* expression of tissue factor seems mostly dependent on IL-6, as demonstrated in studies showing that inhibition of IL-6 completely abrogates tissue factor-dependent thrombin generation in experimental endotoxemia, whereas specific inhibition of other proinflammatory cytokines had less or no effect [31,36]. Inflammatory cells in atherosclerotic plaques produce abundant tissue factor and upon plaque rupture there is extensive tissue factor exposure to blood [37]. In severe sepsis, mononuclear cells, stimulated by proinflammatory cytokines, express tissue factor, which leads to systemic activation of coagulation [38]. Even in experimental low-dose endotoxemia in healthy subjects, a 125-fold increase in tissue factor mRNA levels in blood monocytes can be detected [39]. A potential alternative source of tissue factor may be endothelial cells, polymorphonuclear cells, and other cell types. It is hypothesized that tissue factor from these sources is shuttled between

cells through microparticles derived from activated mononuclear cells [40]. It is, however, unlikely that these cells actually synthesize tissue factor in substantial quantities [38,41].

Upon exposure to blood, tissue factor binds to factor VIIa. The complex of tissue factor–factor VIIa catalyzes the conversion of factor X to Xa, which will form the prothrombinase complex with factor Va, prothrombin (factor II), and calcium, thereby generating thrombin (factor IIa). One of the key functions of thrombin is to convert fibrinogen into fibrin. The tissue factor–factor VIIa complex can also activate factor IX, forming a tenase complex with activated factor IX and factor X, generating additional factor Xa, thereby forming an essential amplification loop. The assembly of the prothrombinase and tenase complex is markedly facilitated if a suitable phospholipid surface is available, ideally presented by activated platelets. In the setting of inflammation-induced activation of coagulation, platelets can be activated directly by endotoxin or by proinflammatory mediators, such as platelet activating factor. Thrombin itself is one of the strongest platelet activators *in vivo*.

32.4.2 Role of Platelets in Inflammation-induced Coagulation

Activation of platelets may also accelerate fibrin formation by another mechanism. The expression of TF on monocytes is markedly stimulated by the presence of platelets and granulocytes in a P-selectin-dependent reaction [42]. This effect may be the result of nuclear factor kappa B (NF-kB) activation induced by binding of activated platelets to neutrophils and mononuclear cells [43]. This cellular interaction also markedly enhances the production of Il-1b, Il-8, MCP-1, and TNF-α [44]. The expression of P-selectin on the activated platelet membrane will mediate the adherence of platelets to endothelial cells and leukocytes [45].

Upon disruption of the integrity of the vessel wall or upon endothelial cell perturbation, as may occur in the systemic inflammatory response in critical illness, a swift and complex interaction between circulating platelets, endothelial cells, and subendothelial structures may occur [46]. The result of this interaction is platelet adhesion to the vessel wall and forming aggregates with each other, thereby materializing microvascular obstruction. The interaction between the platelets and the vessel wall is mediated by cellular receptors on the surface of platelets and endothelial cells, such as integrins and selectins, and by adhesive proteins, such as von Willebrand factor and fibrinogen. Von Willebrand factor is a large polymer of disulfide-linked subunits, each comprising 2050 amino acid residues and up to 22 carbohydrate chains [47]. The molecular mass of the multimers range from about 500 kDa to more than 10 000 kDa. The multimers may form coiled molecules or thin filaments up to 1250 nm long (which means as large as a platelet). Data from clinical studies indicate that large von Willebrand factor multimers may be hemostatically more active than smaller molecules [48]. The biochemical basis for this observation probably relies on the fact that they contain a relatively large number of the domains that will support multiple interactions between the vessel wall, subendothelial matrix, and cellular receptors on platelets. Besides playing a role in platelet vessel wall interaction, von Willebrand factor may also be a ligand for platelet receptors IIb/IIIa, thereby

competing with fibrinogen. Under normal circumstances, the size of von Willebrand factor multimers is regulated by ADAMTS13, also known as von Willebrand factor-cleaving protease. It has been suggested that a relative insufficiency of ADAMTS13 in critical illness contributes to disturbed platelet–vessel wall interaction [49]. Hypothetically, endothelial disruption with massive release of ultra large von Willebrand factor and relative insufficient cleavage due to consumption of ADAMTS13 play a role in the increased platelet–vessel wall interaction in patients with sepsis. Several authors studied the relation between ADAMTS13 activity and the extent of sepsis in patients. They found an association between decrease in ADAMTS13 activity and increase in both renal failure as well as DIC caused by sepsis. Ultra large von Willebrand factor multimers were detected in patients with severe sepsis-induced ADAMTS13 deficiency [48,50,51]. Others have confirmed the association between the low ADAMTS13 levels and the severity of sepsis [52].

32.4.3 Downregulation of Physiological Anticoagulant and Fibrinolytic Pathways during Inflammation

Procoagulant activity is regulated by three important anticoagulant pathways: antithrombin (AT), the protein C system, and tissue factor pathway inhibitor (TFPI). During inflammation-induced activation of coagulation, the function of all three pathways can be impaired [53] Antithrombin appears to be incapable of adequate regulation of thrombin activity during inflammation for several reasons. Antithrombin levels are continuously consumed by the ongoing formation of thrombin and other activated proteases that are susceptible to antithrombin complex formation and antithrombin is degraded by elastase released from activated neutrophils. In addition, impaired synthesis of antithrombin because of liver failure and extravascular leakage of this protease inhibitor as a consequence of capillary leakage further contribute to low levels of antithrombin. Similarly, there are several reasons for severe injury to the protein C system in inflammatory states. Enhanced consumption, impaired liver synthesis, and vascular leakage may also result in low circulating levels of protein C. Second, activation of the cytokine network, in particular high levels of tumor necrosis factor-α (TNF-α), results in a marked downregulation of thrombomodulin in endothelial cells, thereby prohibiting adequate protein C activation [54]. The third mechanism contributing to the inflammation-induced prothrombotic state is impaired fibrin degradation, due to high circulating levels of PAI-1, the main physiological inhibitor of fibrinolysis. In clinical studies in patients with severe infection and inflammation, a high plasma level of PAI-1 was one of the strongest predictors of mortality [34].

32.4.4 Antithrombin and Inflammation

The serine protease inhibitor antithrombin is the main inhibitor of thrombin and factor Xa. Without heparin, AT neutralizes coagulation enzymes in a slow, progressive manner [55]. Heparin induces conformational changes in AT that result in at least a 1000-fold enhancement of AT activity. Thus, the clinical

efficacy of heparin is attributed to its interaction with AT. Endogenous glycosaminoglycans, such as heparan sulfates, on the vessel wall also promote AT-mediated inhibition of thrombin and other coagulation enzymes. Besides the mechanisms by which inflammation leads to low levels of antithrombin (see above) proinflammatory cytokines can cause reduced synthesis of glycosaminoglycans on the endothelial surface, which will also contribute to reduced AT function, since these glycosaminoglycans can act as physiological heparin-like cofactors of AT [56].

Antithrombin possesses anti-inflammatory properties, many of which are mediated by its actions in the coagulation cascade [57]. Most importantly, thrombin inhibition by antithrombin blunts activation of many inflammatory mediators. For example, thrombin activates platelets and endothelial cells, which in turn contribute to local inflammation [58]. Activated platelets secrete inflammatory mediators such as IL-1, which stimulate leukocyte activity. In particular, recruitment and adhesion of neutrophils and monocytes to blood vessels within the microcirculation promote inflammation. Increasing evidence suggests that antithrombin possesses potent anti-inflammatory properties independent of its anticoagulation activity [58]. Most of these effects have been demonstrated *in vitro* or *in vivo* at high concentrations. Nevertheless, these mechanisms may be important in clinical settings that are driven by a combined activation of inflammation and coagulation. Perhaps most importantly, antithrombin induces prostacyclin release from endothelial cells [59–61]. Prostacyclin inhibits platelet activation and aggregation, blocks neutrophil tethering to blood vessels, and decreases endothelial cell production of various cytokines and chemokines [62]. Additional anti-inflammatory actions of antithrombin are mediated by direct interaction with leukocytes and lymphocytes. Antithrombin binds to receptors, such as syndecan-4, on the cell surfaces of neutrophils, monocytes, and lymphocytes and blocks the interaction of these cells with endothelial cells [34]. Inhibition of leukocyte–endothelial cell interactions by antithrombin may be mediated by prostacyclin release, downregulation of P-selectin, or prevention of leukocyte activation. Thus, antithrombin directly hinders leukocyte migration and adhesion to endothelial cells, which in turn impacts the severity of capillary leakage and subsequent organ damage. Given the wide-ranging impact of antithrombin on coagulation and inflammation, there are multiple potential clinical applications of antithrombin in different clinical settings that encompass thrombotic states generally not associated with inflammation (e.g., pregnancy) and in coagulation-related disease states with powerful proinflammatory elements (e.g., sepsis)

32.4.5 Activated Protein C and Inflammation

Activated protein C (APC) appears to play a central role in the pathogenesis of systemic inflammation and associated organ dysfunction [54]. There is ample evidence that an insufficient functioning of the protein C pathway contributes to inflammation-associated coagulopathy [63,64]. In patients with severe inflammation, the protein C system is found malfunctioning at virtually all levels. First, plasma levels of the zymogen protein C are low or very low, due to impaired

synthesis, consumption, and degradation by proteolytic enzymes, such as neutrophil elastase [65–67]. Furthermore, a significant downregulation of thrombomodulin, caused by proinflammatory cytokines such as TNF-α and IL-1, has been demonstrated, resulting in diminished protein C activation [68,69]. Low levels of free protein S may further compromise an adequate function of the protein C system. In plasma, 60% of the cofactor protein S is complexed to a complement regulatory protein, C4b binding protein (C4bBP). Increased plasma levels of C4bBP as a consequence of the acute-phase reaction in inflammatory diseases may result in a relative protein S deficiency, which further contributes to a procoagulant state during sepsis. Although it has been shown that the β-chain of C4bBP (which mainly governs the binding to protein S) is largely unaffected during the acute-phase response [70], support for this hypothesis comes from studies showing that the infusion of C4bBP in combination with a sublethal dose of *Escherichia coli* into baboons resulted in a lethal response with severe organ damage due to DIC [71]. Finally, but importantly, in sepsis the EPCR has shown to be downregulated, which may further negatively affect the function of the protein C system [72]. Apart from these effects, sepsis may cause a resistance toward APC by other mechanisms, which are partly dependent on a sharp increase in factor VIII levels (released from endothelial cells), but partly occur by yet unidentified mechanisms [73].

There is compelling evidence that besides their role as an important regulator of coagulation activity, components of the protein C system also have an important function in modulating inflammation [74,75]. APC plays an important role in attenuating the systemic inflammatory response in sepsis as demonstrated in experiments showing that blocking the protein C pathway in septic baboons exacerbated the inflammatory response. In contrast, administration of APC ameliorated the inflammatory activation upon the intravenous infusion of *E. coli* [27]. Similar experiments in rodents showed identical results and demonstrated a beneficial effect on inflammatory effects in various tissues [76]. Support for the notion that APC has anti-inflammatory properties comes from *in vitro* observations, demonstrating an APC-binding site on monocytes, which may mediate downstream inflammatory processes [77,78] and from experiments showing that APC can block NF-kB nuclear translocation, which is a prerequisite for increases in proinflammatory cytokines and adhesion molecules [79]. These *in vitro* findings are supported by *in vivo* studies in mice with targeted disruption of the protein C gene. In these mice with genetic deficiencies of protein C, endotoxemia was associated with a more marked increase in proinflammatory cytokines and other inflammatory responses compared to wild-type mice [80,81].

It is likely that the effects of APC on inflammation are mediated by the EPCR [74]. Binding of APC to EPCR influences gene expression profiles of cells by inhibiting endotoxin-induced calcium fluxes in the cell and by blocking NF-κB nuclear translocation [78,79]. Blocking the EPCR with a specific monoclonal antibody aggravates both the coagulation and the inflammatory response to *E. coli* infusion [72].

Apart from its effect on cytokine levels, APC has been shown to inhibit leukocyte chemotaxis and adhesion of leukoyctes to activated endothelium [82,83]. This notion was confirmed in a hamster endotoxemia model at

concentrations of recombinant human APC (rhAPC) that preclude a significant anticoagulant effect [84]. Morevover, in a human model of endotoxin-induced pulmonary inflammation, systemic administration of rhAPC resulted in significant local anti-inflammatory effects [85]. A potential mechanism is that APC inhibits expression of platelet-derived growth factor in the lung [86]. In addition, it has been shown that APC protects against the disruption of endothelial cell barrier in sepsis, probably by interfering with EPCR and PAR-1 on endothelial cells [87–89].

32.4.6 Thrombomodulin and Inflammation

Thrombomodulin (CD141) is a transmembrane multidomain glycoprotein receptor that is expressed predominantly not only on vascular endothelial cells but also on monocytes, neutrophils, osteoblasts, synovial cells, and dendritic cells [90–92]. Thrombomodulin exhibits several properties in coagulation, fibrinolysis, innate immunity, and inflammation that are based largely on its distinct structural domains. Thrombomodulin is a membrane protein with several domains, including a lectin-like domain, six epidermal growth factor (EGF)-like repeats, a transmembrane domain, and a short cytoplasmatic tail [74]. The binding of thrombin to thrombomodulin occurs at the site of the EGF repeats [93]. This binding not only results in an about 100-fold increase in the activation of protein C but also blocks the thrombin-mediated conversion of fibrinogen into fibrin and inhibits the binding of thrombin to other cellular receptors on platelets and inflammatory cells. The central domain of thrombomodulin is comprised of six EGF-like repeats, three of which provide critical cofactor activity for thrombin-mediated generation of APC and of activated thrombin activatable fibrinolysis inhibitor (TAFI). Protein C activation by thrombin-thrombomodulin is further augmented by the endothelial protein C receptor (EPCR). In addition to its pivotal role in activating PC and TAFI [94], thrombomodulin also has direct anti-inflammatory properties that are mediated at least in part by its N-terminal C-type lectin-like domain [91,95]. This structure interferes with neutrophil adhesion, complement activation, and cytokine generation, and mice lacking the lectin-like domain of thrombomodulin (thrombomodulinLeD/LeD mice) exhibit increased sensitivity to tissue injury in models of endotoxemia, lung and myocardial ischemia–reperfusion, and inflammatory arthritis. Importantly, deletion of the lectin-like domain of thrombomodulin did not influence the capacity of thrombomodulin to activate PC, indicating that the anti-inflammatory effects of this part of thrombomodulin are not mediated by APC. A recent study in experimental pneumococcal pneumonia showed that mice lacking the terminal lectin-like domain had a markedly better survival compared to wild-type mice, associated with lower bacterial loads in blood and liver and less inflammatory changes in various organs [90].

Thrombomodulin plays a central role in the pathogenesis of sepsis [91,96]. First, thrombomodulin is essential for the activation of protein C to activated protein C; as such, thrombomodulin plays a key role in the anticoagulant and anti-inflammatory properties of the protein C system. Second, thrombomodulin binds thrombin, thereby preventing it from exerting prothrombotic and

proinflammatory effects. Third, thrombomodulin-bound thrombin activates TAFI, which has been demonstrated to suppress bradykinin activity and complement activation. In sepsis, the expression of thrombomodulin is largely downregulated [68]. The proinflammatory cytokines TNF-α and interleukin-1 may significantly down regulate the cellular expression of thrombomodulin, as suggested by cell culture experiments. Observations in patients with severe Gram-negative septicemia indeed confirmed the downregulation of thrombomodulin *in vivo* and impaired activation of protein C [69]. In this study, histological analysis of skin biopsies from patients with meningococcal sepsis showed decreased endothelial expression of thrombomodulin, both in vessels with and without thrombosis. However, *in vivo* studies suggest that EPCR is not downregulated in sepsis but upregulated and that this effect is mediated by thrombin. The formation of thrombin may induce the shedding of EPCR by the endothelium, due to activation of metalloproteinases by thrombin. It is presently unknown whether thrombomodulin is also cleaved by similar mechanisms.

32.4.7 TFPI and Inflammation

The third inhibitory mechanism of thrombin generation involves TFPI, the main inhibitor of the tissue factor–factor VIIa complex. The role of TFPI in the regulation of inflammation-induced coagulation activation is not completely clear. Experiments showing that administration of recombinant TFPI (and thereby achieving higher than physiological plasma concentrations of TFPI) blocks inflammation-induced thrombin generation in humans, and the observation that pharmacological doses of TFPI are capable of preventing mortality during systemic infection and inflammation suggests that high concentrations of TFPI are capable of importantly modulating tissue factor-mediated coagulation [24,97].

32.5 Modulation of Inflammation by Coagulation *in vivo*

Communication between inflammation and coagulation is bidirectional, such that coagulation can also modulate inflammatory activity. Coagulation proteases and protease inhibitors not only interact with coagulation protein zymogens but also with specific cell receptors to induce signaling pathways (Figure 32.1). In particular, protease interactions that affect inflammatory processes may be important in critically ill patients. *In vivo* evidence for a role of coagulation-protease stimulation of inflammation comes from experiments showing that the administration of recombinant factor VIIa to healthy human subjects causes a small but significant three–fourfold rise in plasma levels of IL-6 and IL-8 [98].

A pivotal mechanism by which coagulation proteases modulate inflammation is by binding to protease activated receptors or PARs. Four types (PAR 1–4) have been identified, all belonging to the family of transmembrane domain, G protein-coupled receptors [99]. A typical feature of PARs is that they serve as their own ligand. Proteolytic cleavage by an activated coagulation factor leads to exposure of

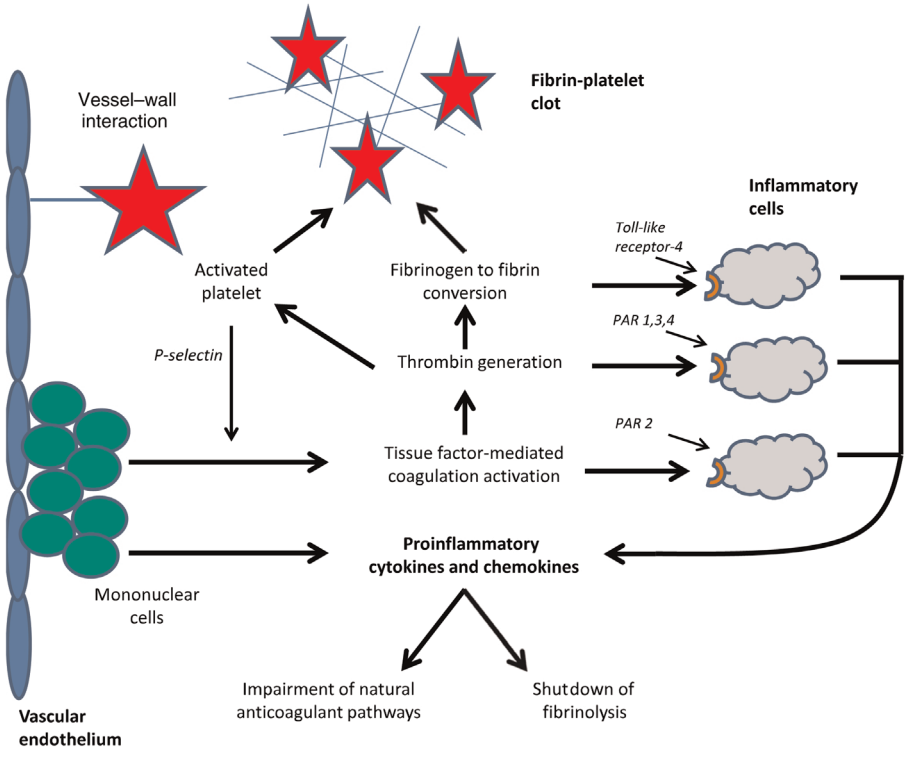

Figure 32.1 Communication between inflammation and coagulation.

a neo-amino terminus, which activates the same receptor (and possibly adjacent receptors), initiating transmembrane signaling. PARs are localized in the vasculature on endothelial cells, mononuclear cells, platelets, fibroblasts, and smooth muscle cells [99]. PAR 1, 3, and 4 are thrombin receptors and PAR-1 can also serve as receptor for the tissue factor–factor VIIa complex and factor Xa. PAR-2 cannot bind thrombin, but can be activated by the tissue factor–factor VIIa complex or factor Xa. Binding of thrombin to its cellular receptor may induce the production of several cytokines and growth factors. Binding of tissue factor–factor VIIa to PAR-2 also results in upregulation of inflammatory responses (production of reactive oxygen species and expression of MHC class II and cell adhesion molecules) in macrophages and was shown to affect neutrophil infiltration and proinflammatory cytokine (TNF-α and IL-1β) expression. The *in vivo* relevance of PARs has been confirmed in various experimental studies using PAR inhibitors or PAR-deficient mice [100–102].

32.5.1 Extracellular DNA, Histones, and Neutrophil Extracellular Traps

Recent observations have pointed to an important role of extracelluar DNA and DNA-binding proteins (such as histones and high-mobility group box 1 protein) in the pathogenesis of DIC. This cell-free DNA and DNA-binding components are released from nucleosomes of degraded cells and may form a surface on which

assembly of activated coagulation factor complexes may be greatly facilitated [103]. In addition, histones activate platelets and therby stimulate thrombin generation [104]. Activation and binding of neutrophils by DNA components results in the formation of neutrophil extracellular traps (NETs) that have recently been identified as important contributors to vascular thrombosis and inflammation [105]. NETs may provide the availability of inflammatory cells expressing tissue factor [106]. Activation of coagulation is further enhanced by the proteolytic cleavage of physiologic anticoagulants by abundant neutropilic elastase in NETs [107]. NETs may also induce endothelial cell death and detrimental inflammatory activity, an effect likely mediated by NET-associated proteases or cationic proteins, including histones [105,108].

32.6 Injured Endothelium and Microparticles

Microparticles may play a role in endothelial dysfunction. Elevated levels of circulating endothelium-derived microparticles have been observed in patients with sepsis. Microparticles are circulating fragments of cell membranes released from activated or perturbed cells. They appear to be able to shuttle membrane-associated receptors from cell to cell and may provide a suitable surface on which plasma protease interactions can take place [109]. Microparticles have procoagulant activity resulting in thrombin generation *in vivo* via a tissue factor/factor VIIa-dependent mechanism. Microparticles may play a role in the pathogenesis of sepsis in several ways. They are potent vascular proinflammatory and procoagulant mediators, can interfere in inflammatory processes, and are involved in maintenance of vascular tone [110]. Recent observations demonstrated that leucocyte – but even more strongly – endothelial cell-derived microparticles were associated with an early and severe derangement of coagulation during severe inflammation, suggesting that endothelium-derived microparticles can be considered as relevant biomarkers of early vascular injury and DIC under inflammatory conditions. The utility and accuracy of measuring microparticles in the setting of systemic inflammatory states needs some further research and prospective validation; however, the test seems promising and deserves further exploration.

32.7 Systemic versus Localized Responses

Although the mechanisms mentioned above have been demonstrated to occur *in vivo* as a general response upon proinflammatory stimuli, it is likely that marked differences in the procoagulant response as well as the underlying pathogenetic pathway may exist between cells and tissues [33]. This may be caused by differences in cell-specific gene expression, environmental factors, and organ-specific differences. First, localization of coagulation activity may relate to a cell-specific gene expression. For example, inflammatory mediators enhance PAI-1 gene expression in a complex and tissue-specific way [111]. Recent studies have

demonstrated that the von Willebrand factor promotor contains cell-specific elements, and similar response elements may be involved in protein synthesis in cells in general [112]. Second, the tissue environment may determine whether specific gene transcription occurs [113]. It is not completely clear why specific sites and organs are at greater risk of developing microvascular thrombosis and also local differences in the consequences of (micro)thrombosis are still poorly understood. Environmental factors underlying the inflammatory response are thought to play a role in this differential coagulative response as well. In mice with disturbances in the plasminogen–plasmin system subjected to hypoxia, the formation of fibrin is induced and is particularly evident in the lungs [114]. In contrast, these same mice respond to endotoxemia with fibrin deposition in the microvasculature of the kidney in particular. Similarly, mice with a functional thrombomodulin deficiency had a marked increase in pulmonary fibrin deposition after hypoxic challenge [115]. In addition, when mice with a functional defect in the thrombomodulin gene were challenged with endotoxin in sublethal amounts, fibrin formation was apparent in the lungs, but not in any other organ studied. In the latter model, fibrin was only temporarily present and disappeared after 24 h [116]. These models illustrate the assumption that fibrin formation is a localized phenomenon, rather than a generalized process.

Lastly, various organ systems may markedly differ in their endothelial cell response toward inflammation and injury. In general, endothelial cells play a central role in the coagulation response upon systemic inflammation [117]. The endothelium plays a central role in all major pathways involved in the pathogenesis of hemostatic derangement during severe inflammation. Endothelial cells appear to be directly involved in the initiation and regulation of thrombin generation and the inhibition of fibrin removal. Endothelial cells may express tissue factor, which is the main initiator of coagulation. In addition, physiological anticoagulant pathways, such as antithrombin, the protein C system, or tissue factor pathway inhibitor, are mostly located on endothelial cells and endothelial cell dysfunction is directly related to impaired regulation of coagulation. Also, endothelial cells are the main storage site of plasminogen activators and inhibitors and can acutely release these factors, thereby importantly mediating fibrinolytic activity or inhibition. Proinflammatory cytokines are crucial in mediating these effects on endothelial cells, which themselves may also express cytokines, thereby amplifying the coagulative response [31]. Although not completely clear, various organs may differ in all these endothelial cell-related factors influencing local coagulation activation and fibrin deposition.

32.8 Organ-specific Responses by Endothelial Cells

In their excellent overview, Rosenberg and Aird postulate that endothelial cells integrate different extracellulair signals and cellular responses in different regions of the vascular bed [112]. Various exogenous stimuli, such as shear stress, inflammatory mediators, and growth factors, exert their action on endothelial cells and the response of the endothelial cells to transduce the signal may vary between various tissues and even from endothelial cell to endothelial cell within a

tissue. As a result, the pro- or anticoagulant response of endothelial cells may differ between organs. Experiments in mice with a targeted deletion of the anticoagulant part of the thrombomodulin gene showed abundant fibrin formation in lungs, heart, and spleen [118]. Mice with homozygous deficiencies of plasminogen activators form clots in liver, heart, and lungs, but not in brain or kidneys [119]. Plasminogen activator inhibitor-deficient mice have fibrin deposition predominantly in kidneys [111]. Rosenberg and Aird state that various mechanisms play a role in the individual response of endothelial cells. Cell to cell communication may have important effects, as evidenced by the fact that PAI-1 expression in endothelial cells is upregulated if the culture is incubated with medium from aorta or umbilical vein cell culture but, in contrast, is downregulated by addition of conditioned medium from vascular smooth muscle cells [120,121]. In addition, cell signaling pathways may vary between endothelial cell subtypes. For example, hemodynamic changes may have opposite reactions in nitric oxide mRNA expression in endothelial cells from the aorta or from the pulmonary artery [122]. Another example is provided by the experiment showing that endothelial cells from renal and cerebrovascular vessels have decreased prostacyclin production and more apoptosis when exposed to plasma of patients with thrombocytopenic thrombotic purpura, whereas endothelial cells derived from lungs and liver do not respond to this same stimulus [123]. Lastly, also at the level of transcription a differential phenotype of endothelial cells between various organs can be demonstrated. Coagulation proteins, such as von Willebrand factor, have been shown to respond to various promoters by expressing this factor in different tissues, for example, exclusively in heart and skeletal muscle or in brain [113].

32.9 Diagnostic Approach to the Inflammation-induced Coagulopathy

According to the current understanding of inflammation-associated coagulation abnormalities, the determination of soluble fibrin in plasma appears to be crucial [124,125]. In general, the sensitivity of these assays for severe coagulation activation or DIC is relatively higher than the specificity. Indeed, initial clinical studies indicate that if the concentration of soluble fibrin has increased above a defined threshold, a diagnosis of DIC can be made [17,126]. Most of the clinical studies show a sensitivity of 90–100% for the diagnosis of DIC but a rather low specificity [127]. Fibrin degradation products (FDPs) may be detected by specific ELISAs or by latex agglutination assays, allowing rapid and bedside determination in emergency cases [128]. None of the available assays for fibrin degradation products discriminates between degradation products of cross-linked fibrin and fibrinogen degradation, which may cause spuriously high results [129]. The specificity of high levels of fibrin degradation products is, therefore, limited and many other conditions, such as trauma, recent surgery, inflammation, or venous thromboembolism, are associated with elevated FDPs. More recently developed tests are specifically aimed at the detection of neo-antigens on

degraded cross-linked fibrin. One of such tests detects an epitope related to plasmin-degraded cross-linked γ-chain, resulting in fragment D-dimer. These tests better differentiate degradation of cross-linked fibrin from fibrinogen or fibrinogen degradation products [130].

Consumption of coagulation factors leads to low levels of coagulation factors in patients with inflammation-associated coagulopathy. In addition, impaired synthesis, for example, due to impaired liver function or a vitamin K deficiency, and loss of coagulation proteins, due to massive bleeding, may play a role as well [131]. Although the accuracy of the measurement of one-stage clotting assays in this situation has been contested (due to the presence of activated coagulation factors in plasma), the level of coagulation factors appears to correlate well with the severity of the coagulopathy [131]. Measurement of fibrinogen has been widely advocated as a useful tool for the diagnosis of DIC but, in fact, is not very helpful to diagnose DIC in most cases [5,132]. Fibrinogen acts as an acute-phase reactant and despite ongoing consumption plasma levels can remain well within the normal range for a long period of time. In a consecutive series of patients, the sensitivity of a low fibrinogen level for the diagnosis of DIC was only 28% and hypofibrinogenemia was detected in very severe cases of DIC only. Sequential measurements of fibrinogen might be more useful and provide diagnostic clues.

Thrombelastography (TEG) is a method that has been developed decades ago and provides an overall picture of *ex vivo* coagulation. Modern techniques, such as rotational thrombelastography (ROTEM), enable bedside performance of this test and have again become popular recently in acute care settings [133]. The theoretical advantage of TEG over conventional coagulation assays is that it provides an idea of platelet function as well as fibrinolytic activity. Hyper- and hypocoagulability as demonstrated with TEG was shown to correlate with clinically relevant morbidity and mortality in several studies [134,135], although its superiority over conventional tests has not unequivocally been established [136]. Also, TEG seems to be overly sensitive to some interventions in the coagulation system, such as administration of fibrinogen, of which the therapeutic benefit remains to be established. There are no systematic studies on the diagnostic accuracy of TEG for the diagnosis of coagulation-induced coagulopathy; however, the test may be useful for assessing the global status of the coagulation system in critically ill patients.

For the diagnosis of the most extreme form of coagulation activation in critically ill patients, disseminated intravascular coagulation, a simple scoring system has been developed [137]. The score can be calculated based on routinely available laboratory tests, that is, platelet count, prothrombin time, a fibrin-related marker (usually D-dimer), and fibrinogen. Tentatively, a score of 5 or more is compatible with DIC, whereas a score of less than 5 may be indicative but is *not* affirmative for nonovert DIC. By using receiver-operating characteristics curves, an optimal cutoff for a quantitative D-dimer assay was determined, thereby optimizing sensitivity and the negative predictive value of the system [127]. Prospective studies show that the sensitivity of the DIC score is 93%, and the specificity is 98% [138,139]. The severity of DIC according to this scoring system is related to the mortality in patients with sepsis [30]. Linking

prognostic determinants from critical care measurement scores such as Acute Physiology and Chronic Health Evaluation (APACHE-II) to DIC scores is an important means to assess prognosis in critically ill patients. Similar scoring systems have been developed in Japan [140].

32.10 Supportive Treatment of Coagulation Abnormalities during Severe Inflammation

The keystone of the treatment of hemostatic abnormalities in patients with severe inflammation is the specific management of the underlying disease. However, in many cases additional supportive treatment, aimed at circulatory and respiratory support and replacement of organ function, is required. Coagulation abnormalities may proceed, even after proper treatment has been initiated. In those cases, supportive measures to manage the coagulation disorder may be considered and may positively affect morbidity and mortality. The increase in the insight into the various mechanisms that play a role in the coagulation abnormalities associated with sepsis has indeed been accommodating in the development of such supportive management strategies.

Low levels of platelets and coagulation factors may increase the risk of bleeding. However, plasma or platelet substitution therapy should not be instituted on the basis of laboratory results alone; it is indicated only in patients with active bleeding and in those requiring an invasive procedure or otherwise at risk for bleeding complications [141]. The presumed efficacy of treatment with plasma, fibrinogen, cryoprecipitate, or platelets is not based on randomized controlled trials but appears to be rational therapy in bleeding patients or in patients at risk for bleeding with a significant depletion of these hemostatic factors [142]. It may be necessary to use large volumes of plasma to correct the coagulation defect. Coagulation factor concentrates, such as prothrombin complex concentrate, may overcome this obstacle, but these compounds may lack essential factors, such as factor V. Moreover, in older literature, caution is advocated with the use of prothrombin complex concentrates in DIC, since it may worsen the coagulopathy due to small traces of activated factors in the concentrate. It is, however, not clear whether this is still relevant for the concentrates that are in use. Specific deficiencies in coagulation factors, such as fibrinogen, may be corrected by administration of purified coagulation factor concentrates.

Experimental studies have shown that heparin can at least partly inhibit the activation of coagulation in severe inflammatory conditions [143]. Uncontrolled case studies in patients with sepsis and DIC have been claimed to be successful. However, a beneficial effect of heparin on clinically important outcome events in patients with DIC has never been demonstrated in controlled clinical trials [144]. Interestingly, withdrawal of heparin was found to be detrimental to the prevention of severe thrombotic events in patients with sepsis (such as cerebral stroke, myocardial infarction, or pulmonary embolism) in patients with sepsis [145]. Therapeutic doses of heparin are indicated in patients with clinically overt thromboembolism or extensive fibrin deposition, like purpura fulminans or acral

ischemia. Patients with sepsis may benefit from prophylaxis to prevent venous thromboembolism, which may not be achieved with standard low-dose subcutaneous heparin [146].

In view of the deficient state of physiological anticoagulant pathways in patients with severe infammation, restoration of these inhibitors may be a rational approach [53]. Since activated protein C and antithrombin are the most important physiological inhibitors of coagulation and based on successful preclinical results, the use of concentrates of these factors in patients with sepsis has been studied relatively intensively. Most of the randomized controlled trials concern patients with sepsis, septic shock, or both. All trials, showing some beneficial effect in terms of improvement of laboratory parameters, shortening of the duration of DIC, or even improvement in organ function, however, failed to reduce the 28-day mortality.

The most promising intervention at this moment is recombinant soluble thrombomodulin. Recombinant human soluble thrombomodulin binds to thrombin to form a complex that inactivates thrombin's coagulant activity and activates protein C. Several preclinical studies in experimental sepsis models have shown that soluble thrombomodulin is capable of improving the derangement of coagulation and may restore organ dysfunction [53]. In phase I–II clinical studies, the pharmacokinetic profile of recombinant soluble thrombomodulin was determined [147]. In a subsequent phase III randomized double-blind clinical trial in patients with DIC, administration of the soluble thrombomodulin had a significantly better effect on bleeding manifestations and coagulation parameters than heparin, but the mortality rate at 28 days was similar in the two study groups [148]. DIC patients ($n = 234$) were randomized to receive soluble thrombomodulin (ART-123) at a daily dose of 0.06 mg per kg for 30 min, or unfractionated heparin (8 U per kg per hour for 24 h) for 6 days, using a double-dummy method. The primary efficacy end point was DIC resolution rate. DIC was resolved in 66.1% of the thrombomodulin group, compared to 49.9% of the heparin group (difference 16.2%; 95% confidence interval (CI) 3.3–29.1). Patients in the thrombomodulin group also showed more marked improvement in clinical course of bleeding symptoms. The incidence of bleeding-related adverse events up to 7 days after the start of infusion was lower in the thrombomodulin group than in the heparin group (43.1% versus 56.5%, $P = 0.0487$) [148]. When limiting these results to patients with severe infection and sepsis, DIC resolution rates were 67.5% in thrombomodulin-treated patients and 55.6% in the control group, and 28-day mortality rates were 21.4 and 31.6%, respectively. Mortality rates of patients who recovered from DIC were 3.7% in the thrombomodulin group and 15% in the heparin group [149]. Recently, soluble thrombomodulin was evaluated in a phase II/III clinical study in 750 patients with sepsis and disseminated intravascular coagulation. Twenty-eight-day mortality was 17.8% in the thrombomodulin group and 21.6% in the placebo group. Markers of coagulation activation were lower in the thrombomodulin group than in the placebo group. There were no differences between groups in bleeding or thrombotic events.

Fever: Mediators and Mechanisms

Joachim Roth

Justus-Liebig-University, Department of Veterinary-Physiology and -Biochemistry, Frankfurter Strasse 100, 35392 Giessen, Germany

33.1 Introduction

Fever is a frequently observed sign in critically ill patients, which occurs in response to many types of infectious or noninfectious stimuli. It is just one component of a complex array of host defense responses, which develop during the time course of systemic inflammation. Collectively termed acute-phase response (APR), there is a pronounced systemic reaction to disturbances of homeostasis by infections, tissue injury, trauma/surgery, neoplastic growth, or immunological disorders; fever is one of the most prominent components of the APR, a hallmark of disease [1–3]. Depending on the severity of a given inflammatory insult or environmental conditions, phases of fever and phases of hypothermia can alternate during systemic inflammation [4–6]. Recently, the hypothermic component of body temperature (T_b) alterations during systemic inflammation gained some attention in experimental research [7,8]. Still, the main focus of this chapter is the febrile response, the regulated and actively established increase of T_b, which occurs along with all the other components of the APR. Special emphasis will be directed to putative exogenous and endogenous mediators of fever and to the transfer of peripherally generated inflammatory signals to those brain structures, which are implicated in the manifestation of the febrile response.

In this context, it has to be considered that fever is not an isolated brain-mediated modification, which occurs during systemic inflammation. There is rather a characteristic pattern of disease-related and brain-controlled symptoms, which have collectively been termed sickness behavior. Some of these symptoms (see also Chapters 32 and 37) are anorexia and adipsia, hyperalgesia, anxiety, fatigue and sleep disturbance, lethargy, loss of interest in usual activities, social withdrawal, signs of depression, listlessness, malaise, and cognitive dysfunction [9–11]. Although exogenous and endogenous mediators of fever and sickness behaviors are – at least in part – overlapping or identical, the brain sites

Inflammation: From Molecular and Cellular Mechanisms to the Clinic, First Edition.

and neural circuitries that are employed to generate fever or to establish behavioral and cognitive modifications are distinct [10,12–14].

According to the classical view, fever develops in a characteristic sequence of steps starting with the appearance of the pathogenic agent, the "exogenous pyrogen" in the afflicted host. In case of infection, the exogenous pyrogen frequently belongs to a family of molecules termed pathogen-associated molecular patterns (PAMPs, see Chapter 2). This exogenous pyrogen, in turn, causes the release of fever-producing substances by the host's polymorphonuclear leukocytes and by other cells. These substances are, therefore, called "endogenous pyrogens" [1,15,16]. Traditionally, a number of cytokines (see, for example, Chapters 23, 24, and 26), namely, interleukin (IL)-1β, IL-6, tumor necrosis factor-α (TNF-α), interferons (IFNs), and others were identified and characterized as the endogenous pyrogens [1,17–20]. Nowadays, it is clear that there are further peripherally elaborated substances, other than cytokines, which fulfill criteria of an endogenous pyrogen, depending on the experimental model used to investigate fever. For example, lipopolysaccharide (LPS), the most frequently studied experimental fever-inducing agent, employs the complement (C) fragment C5a (see also Chapter 33) and peripherally generated prostaglandin E_2 (PGE_2) for the initiation of the rapidly developing first phase of the febrile response [21–24]. The most important endogenous pyrogens are introduced in detail in Section 33.2 of this chapter, after a brief look at the physiological and neuroanatomical background for the phenomenon fever. Thereafter (Section 33.3), the putative mechanisms for the transfer of the inflammatory message across the blood–brain barrier to the critical brain sites for the generation of fever are dealt with. Some new discoveries on this issue were published in the past few years [25–29]. The substances, which might influence the brain-intrinsic neuronal circuitries to activate efferent pathways to those peripheral effector organs that trigger fever, are discussed in Section 33.4 of this chapter. These are called centrally acting endogenous pyrogens. Some, but not all of them, are identical to peripherally generated endogenous pyrogens, but classical neurotransmitters such as noradrenaline (NA) are included as well [3]. Indeed, for most fevers a sustained brain-intrinsic formation of PGE_2 seems to be essential for the maintenance of an increased T_b.

Finally, a look at clinical fevers and possibilities for and outcome of fever treatment will close this chapter. Within this section, the arguments for fever being a friend or rather a foe will also be introduced [30].

33.2 Fever: Physiological and Neuroanatomical Considerations

33.2.1 Fever Defined

In the latest version of the "glossary of terms for thermal physiology" [31], fever is defined as "*a state of elevated core temperature which is often, but not necessarily, part of the defensive responses of organisms to the invasion of live or inanimate matter recognized as pathogenic or alien by the host. The rise in core temperature*

is usually designated as due to a change in the thermocontroller characteristics resulting in an elevation of the set point of body temperature. The higher temperature is actively established and defended by the operation of heat-producing and heat-conserving thermoeffectors . . . core temperature is eventually reduced when the set point of temperature regulation returns to its normal level. While any rise in body temperature may be due to fever, those rises which are not accompanied by supportive changes in thermoeffector activities, are termed hyperthermia. The humoral mechanisms underlying fever consist of the alteration of the neuronal control of body temperature by agents named pyrogens." Indeed, there is evidence from numerous experimental studies that the rising phase of fever is accompanied by appropriate thermoeffector activities such as increase in metabolic heat production by shivering or nonshivering thermogenesis (NST), reduced peripheral blood flow, or depressed panting ([3], for review). On the other hand, there is a problem with this physiological definition of fever; this problem is related to the term "elevation of the set point of body temperature." According to the classical concept [31–33], the "set point" is defined as a reference temperature that is compared with the regulated value of T_b. Any difference between this reference value and the actual T_b is an error signal that elicits corrective thermal responses proportional to the deviation with the aim to restore the T_b to its proper reference level. A neuronal correlate to such a reference signal has never been detected and obviously does not exist.

Another model for the physiological manifestation of fever was suggested that does not require a set point and a reference in the form of a neuronal signal [34]. According to this model, fever is achieved by the modification of thresholds and gains for the various thermoregulatory effectors, as shown schematically in Figure 33.1.

In this context, "threshold temperature" is defined as a given T_b, which activates appropriate and available thermoeffector responses, when a deviation from this specific T_b occurs [31]. As illustrated in the upper part of Figure 33.1, the rate of heat production of a nonfebrile subject begins to increase at a T_b slightly below 37 °C, while heat dissipation mechanisms are activated at a T_b of slightly above 37 °C. After challenge with a pyrogen (lower part of Figure 33.1), these threshold temperatures are symmetrically shifted to values of 39.3 °C (heat production) and 39.7 °C (heat dissipation).

Different thermoeffectors are activated at distinct threshold temperatures. In most cases, cutaneous vasoconstriction in humans is activated at a higher mean T_b compared to the T_b at which shivering or NST is initiated. During the course of fever, these thresholds can change, so that actual T_b responses can vary, for example, according to environmental conditions ([3,6], for review).

According to current concepts of the organization of the thermoregulatory system, the efferent neuronal pathways for the activation of individual thermoeffectors (skin vasomotor tone, shivering, NST, salivary secretion, panting, or warm- and cold-seeking behaviors) form independent loops that operate in a coordinated manner [35–38]. It was, therefore, suggested that the "set point"-based definition of the fever should be replaced by a "balance point"-based definition [6,39]. Accordingly, the balance point during fever would be above that during normothermia [6]. Based on these concepts, the question arises how a

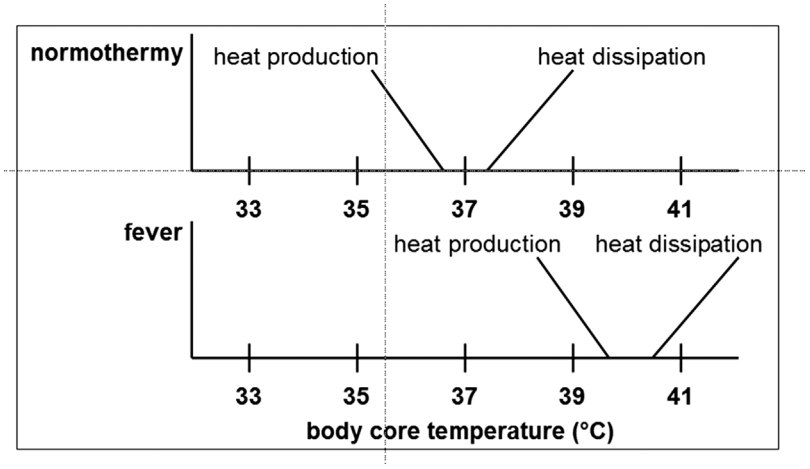

Figure 33.1 Thermoregulatory thresholds under normal conditions (normothermy, upper part) and during the rising phase of fever (fever, lower part). In normothermic subjects, heat production increases in a linear fashion when T_b is decreasing below 36.8 °C; heat dissipation is increasing when T_b is climbing above 37.2 °C. During the rising phase of fever, both thermoregulatory thresholds are symmetrically shifted to higher values, meaning that heat production is activated when T_b is decreasing below 39.3 °C, while heat dissipation is activated at a T_b higher than 39.7 °C.

given pyrogen interferes within the identified components of the thermoregulatory system, which consist of a sensory afferent part, a central integrative part, and an efferent part terminating at the distinct effector organs [38]. PGE_2 is a critical terminal mediator of many fevers and it exerts direct effects on neurons. In the following section, we therefore use PGE_2 as a representative example for a pyrogen directly acting at critical relay stations of the neuronal thermoregulatory circuitries.

33.2.2 Possible Sites of Action for Putative Pyrogens within the Neuronal Thermoregulatory Circuitries

Rapid thermoregulatory responses occur when changes in environmental or ambient temperature (T_a) are monitored by thermosensors in the skin. For example, skin cooling is monitored by ion channels of cold-sensitive nerve fibers, and this information is transmitted as a feedforward signal to the central thermoregulatory structures located within the preoptic anterior hypothalamic area (POA) of the brain [39]. We recently showed that a subpopulation of these cold-sensitive neurons is also stimulated by PGE_2 [40]. By acting on peripheral sensory nerves (Figure 33.2), PGE_2 could thus contribute to the manifestation of cold defense responses, which are observed when fever is initiated.

Depending on the pyrogenic stimulus, its strength, and the route of its administration, there is some evidence that PGE_2 can contribute to the initiation of fever ("early phase," see Sections 33.3 and 33.4) by activating afferent nerve fibers from the skin [41,42], from the vagus nerve [3,43–45], or from the trigeminal nerve [46].

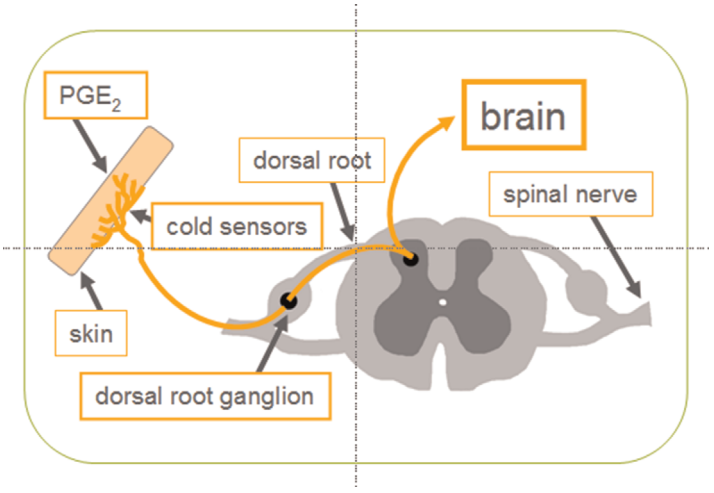

Figure 33.2 Schematic illustration of the first part of the initial components of the thermoafferent pathway, starting from the cold-sensitive nerve fibers in the skin and reaching the dorsal horn of the spinal cord. Recently, a population of neurons from dorsal root ganglia was detected, which is activated by cold/menthol and by PGE_2 [40]. Since the activation of cutaneous cold sensors evokes appropriate cold defense responses, a stimulation of these fibers by PGE_2 could moderately contribute to the rapidly developing rising phase of fever.

The information generated by peripheral thermosensors is transmitted to the spinal dorsal horns (Figure 33.2), where secondary neurons receive and transport the signals via collaterals to the lateral parabrachial nucleus (LPB) in the pons. LPB neurons, in turn, project to the critical site within the POA, the median preoptic nucleus (MnPO), which is activated via glutamatergic neurotransmission ([47], for review). MnPO and the closely located medial preoptic area (MPO) seem to be essential for the manifestation of fever (Figure 33.3, Sections 33.3 and 33.4). These structures represent the so-called "pyrogenic zone" within the POA, where smallest amounts of PGE_2 cause a rise of T_b [48].

The neurons within the MnPO, which receive the glutamatergic input from the LPB and are responsive to skin cooling, use, in part, gamma amino butyric acid (GABA) as neurotransmitter [47,49,50]. It was proposed that these GABAergic neurons inhibit warm-sensitive neurons within the POA, which in turn exert a tonic inhibitory influence on thermogenic neurons located in the dorsomedial hypothalamus (DMH) and in the rostral raphe pallidus nucleus (rRPa, Figure 33.3). After disinhibition by external cooling or by the appearance of PGE_2 within the POA, appropriate thermoeffector responses are activated via DMH/rRPa and descending neuronal pathways to brown adipose tissue (BAT), blood vessels, or skeletal muscles ([38,47], for review). Within these central thermoregulatory pathways, receptors of the subtype EP3 for PGE_2 (and possibly receptors for other pyrogenic or thermogenic substances, see Section 33.4) are present not only in the MnPO but also in the rRPa [51]. It was, therefore, speculated if the rRPa represents a subsidiary fever center in addition to the MnPO/MPO area, but injections of PGE_2 into the rRPa had no pyrogenic effect [52].

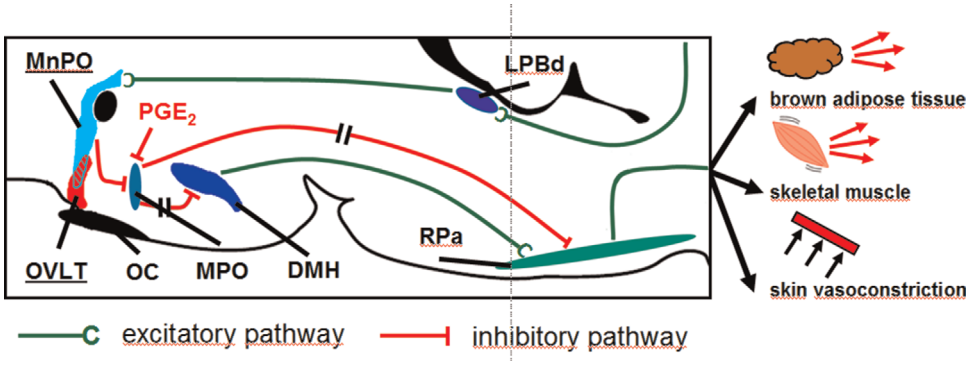

Figure 33.3 The neurons in the dorsal horn of the spinal cord, which receive the afferent input from cutaneous cold sensors (see Figure 33.1), project to the LPB. From there, the thermoafferent information is transmitted to the MnPO. In a cold environment, neurons within the MnPO are activated via glutamatergic neurotransmission. These neurons are also influenced by PGE_2 in a manner that nearby MPO neurons are inhibited by a GABAergic mechanism, resulting in a disinhibition of cold-defensive or fever-generating responses. The efferent pathways to brown adipose tissue (nonshivering thermogenesis), skeletal muscles (shivering, "chills"), or peripheral blood vessels (vasoconstriction) are routed via the DMH or the raphe pallidus nucleus (RPa). In summary, disinhibition of heat-generating and heat-conserving responses can be achieved either by the peripheral cooling or by the appearance of PGE_2 within the MnPO during fever (modified according to [38,47,49]). OC = optic chiasm; OVLT = organum vasculosum laminae terminalis.

33.2.3 Experimentally Induced Fever

Experimental fever research aims to generate reproducible, stereotypic febrile responses of more or less constant height and duration. This approach allows the evaluation of the physiological processes that underlie the distinct phases of fever (see Section 33.2, Figure 33.4). Experimental fever further enables researchers to identify and characterize putative endogenous mediators produced and released outside and inside the brain during the course of the febrile response. A variety of experimental fever models have been developed for these reasons ([3], for review). Many substances ("exogenous pyrogens"), which evoke fever when injected into experimental animals, are ligands of Toll-like receptors (TLRs, see Chapter 8). Depending on the nature of these substances, they are called "bacterial, viral, or fungal mimetics," although these synthetic molecules do not completely reflect a natural infection. These experimental approaches have in common that specific components of innate immunity are readily activated by the injection of all these molecules. With regard to putative endogenous mediators or mechanisms responsible for the manifestation of distinct febrile responses, there is thus some analogy among the various models of experimentally induced fevers, but there are also some differences [3]. In the beginning of experimental fever research, the rabbit was frequently used as animal model due to the high pyrogenic sensitivity of this species [1]. Nowadays, the preferred pyrogenic agent is LPS and animal subjects used in the majority of current experimental fever research are rats and mice. More recently, genetically modified mice were

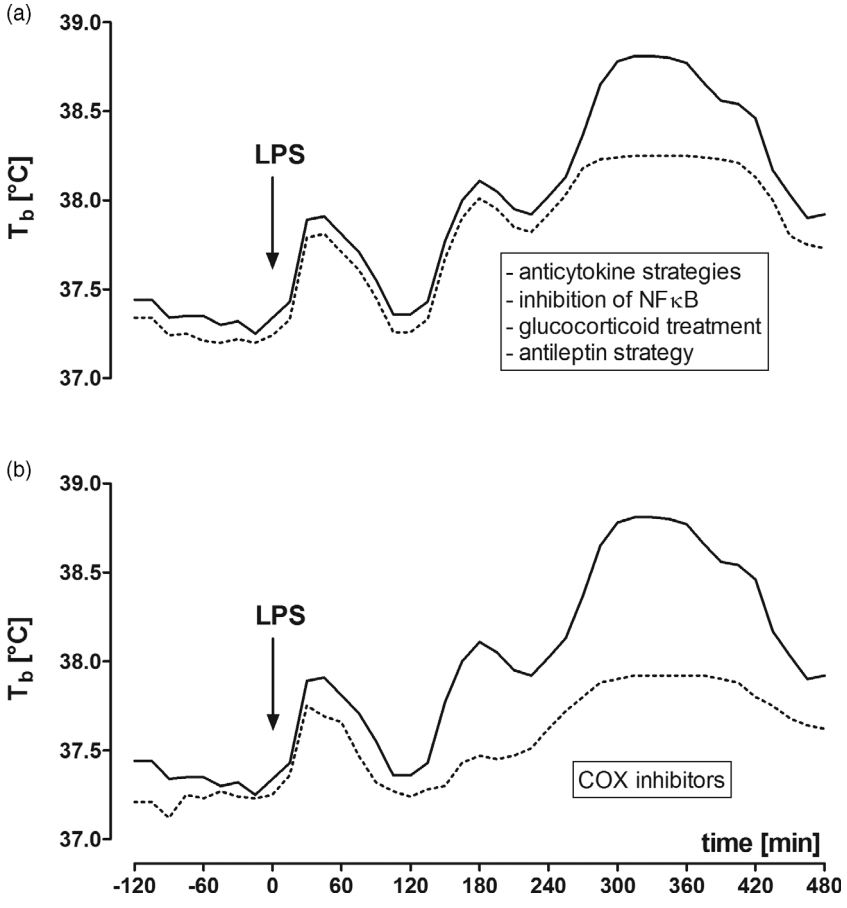

Figure 33.4 Schematic illustration of the course of experimental fever in rats in response to intraperitoneal injection of a moderate LPS dose. At time "0," LPS was injected either alone (continuous lines) or in combination with a drug that reduces fever (interrupted lines). From 0 to 60 min, rats show a stress-induced increase in T_b due to the injection procedure, followed by a biphasic febrile response. Drugs that inhibit production or biological action of cytokines, or leptin cause an attenuation of the longer second fever phase (a). Drugs, which inhibit formation of PGE_2 (COX inhibitors) cause an attenuation of both fever phases (b) (3,19,58–61] for further details).

employed to characterize specific molecules, even specific cell types or organs, in the manifestation of fever or other brain-controlled illness responses [22,25,26,28,53–57]. Again, in most of these studies, LPS was used as the exogenous trigger of fever.

At low to moderate doses, LPS evokes a prototypic and reproducible fever that consists of several sequential phases [1,3,6,24] usually with a total duration of about 6–8 h. At high doses, LPS can cause a T_b fall followed by a rise, which can last several days [5,62]. Characteristic fevers, evoked in rats by injections of a moderate dose of LPS and their modulation by distinct pharmacological interventions, are shown and discussed in Section 33.2 (Figure 33.4).

33.3 Putative Peripherally Generated Endogenous Pyrogens

In 1948, Beeson introduced the concept of the "endogenous pyrogen." He obtained a heat labile substance from isolated peritoneal macrophages, which induced fever in healthy rabbits [15]. The assumption of this concept was that after injection of an "exogenous pyrogen" (e.g., LPS), the "endogenous pyrogen" would appear in the circulation of the LPS-stimulated animal to induce fever. Later, it turned out that this substance is represented by a family of small proteins termed cytokines ([1,17,20]; see also Chapters 23–27). With a few exceptions, circulating cytokines are not detected in healthy individuals, but appear in the blood during various states of disease to regulate and coordinate immune responses. Pathogens share highly conserved microbial components called "pathogen-associated molecular patterns" (PAMPs). These activate the innate immune system via TLRs (see Chapter 8). Employing a number of intracellular adapter proteins, activation of the transcription factor nuclear factor-κB (NF-κB) occurs, translocating it into the nucleus of the PAMP-stimulated cell [63–65]. Here, the transcription of a number of target genes is initiated, some of which are related to fever. These include cytokines (TNF-α, IL-1β, IL-6, and others), chemokines, adhesion molecules, receptors, and the inducible (i) forms (as opposed to constitutive) of inflammatory enzymes including nitric oxide synthase, cyclooxygenase-2 (COX-2), and microsomal prostaglandin E synthase-1 (mPGES-1). COX-2 and mPGES-1 are strongly coupled in their induction after an inflammatory insult and considered to be the critical enzymes for the generation of PGE_2 during fever [66]. LPS, the most potent exogenous pyrogen, employs a second, faster way for peripheral formation PGE_2 by activation of the complement cascade via the alternative pathway ([67], see Section 33.2.2). In addition to TNF-α, IL-1β, IL-6, and PGE_2, there are more peripherally produced molecules with intrinsic pyrogenic properties upon stimulation of TLRs by a given PAMP ([3], for review).

33.3.1 The Classical Pyrogenic Cytokines: TNF-α, IL-1β, and IL-6

Following the systemic injection of LPS or other agonists of TLRs, TNF-α, IL-1β, and IL-6 appear in the blood in a characteristic sequence, which made them appropriate candidates to act as circulating pyrogens. TNF-α is the first of these cytokines to appear in the bloodstream, followed by a rather small elevation of IL-1β and a longer lasting and bigger rise of IL-6 ([1,3,19,20], for review). These cytokines, together with other molecules (PGE_2), influence the production of each other or the inhibition of it. These interrelationships underlie the so called "cytokine cascade," this is the self-amplification and the generation and release of other cytokines in a complex, integrated network. In this context, studies employing mice deficient in a given cytokine ("knockout mice, KO mice) have to be interpreted with caution due to redundancies so that the lack of one cytokine may be compensated by another cytokine [53]. Another critical issue is that KO mice lack a given cytokine not only in the periphery but also in the brain, where several cytokines seem to participate in the manifestation of fever (see Sections 33.3 and 33.4).

The following further arguments support a role of peripheral TNF-α, IL-1β, or IL-6 for the generation of fever after appearance of an exogenous pyrogen. Systemic injections of all the three of these cytokines can evoke strong (IL-1β) to moderate (IL-6) fevers in man or experimental animals, although pharmacological rather than physiological doses are sometimes required to evoke a febrile response [1,3,19]. Several tools have been employed, which aimed to neutralize, antagonize, or block the formation of single circulating cytokines after injection of a given exogenous pyrogen [1,5,19,58,68–71]. In most cases, these interventions selectively modified (attenuated) the so called "late phase" but not the initial phase of the febrile response (Figure 33.4a).

Similarly, systemic inhibition of the early inflammatory transcription factor nuclear factor kappa B (NFκB), which is involved in the stimulus-induced formation of the cytokine cascade, exerted an inhibitory effect on LPS fever. This inhibition was restricted to the late phase of the febrile response [59]. The same effect occurs after treatment of experimental animals with glucorticoids [60], which also depress production of cytokines. Interestingly, treatment of rats with an antiserum against the cytokine-like hormone leptin also attenuates the late phase of LPS fever. This observation suggested a role for leptin as mediator of inflammation and fever [72,73].

Based on all these observations, the classic endogenous pyrogens (cytokines) seem to contribute to the maintenance of experimentally induced fever, while there has to be a trigger for the initiation of the "early phase" of fever. At least in response to intravenous injections of LPS, the onset of fever indeed seems to precede the appearance of pyrogenic cytokines in the blood [3,23,45]. This temporal discrepancy as well as the outcome of many anticytokine approaches (Figure 33.4b) inspired the search for another trigger for the onset of fever, which would have to be produced rapidly after an exogenous pyrogen appears in the given experimental animal.

33.3.2 Putative Peripheral Triggers for the Early Phase of Experimental Fever: PGE2, Complement Fragment C5a, or Oxygen Radicals

PGE2 is a derivative of arachidonic acid, which is cleaved from membrane phospholipids by phospholipase A2 (PLA2). In the brain, an alternative pathway to produce arachidonic acid for PGE2 synthesis seems to operate ([27,28]; see also Section 33.3). In a second step, arachidonic acid is converted to PGH2 by constitutive (COX-1) or inducible (COX-2) cyclooxigenase. Finally, PGH2 is isomerized to PGE2 by prostaglandin E synthase (PGES). COX-2 and microsomal PGES-1 are inducible enzymes that are regulated transcriptionally by NFκB and STAT3. These transcription factors are activated by numerous exogenous and endogenous pyrogens [26,59,70,74]. In contrast to the various "anticytokine strategies" (Figure 33.4a), systemic treatment with COX inhibitors, thereby preventing formation of PGE2, attenuates not only the late phase but also the early phase of fever induced by LPS (Figure 33.4b) or other exogenous pyrogens [60,61,75,76]. Based on the observation that peripheral, but not central, administration of antibodies against PGE2 selectively reduced the first phase of the febrile response, it was suggested that peripherally derived PGE2 is the trigger

for the early phase of fever [24]. Macrophages of the lung and the liver have been identified as the cells, which produce PGE2 via induced expression of COX-2 and mPGES-1 to trigger fever [77].

For the experimental LPS–fever model, several studies provided evidence for a central role of liver Kupffer cells (Kc, hepatic macrophages) in the formation of PGE_2 as a peripheral trigger of the febrile response ([3], for review). According to these studies, the febrigenic process is initiated by the arrival of LPS in the liver and its uptake by Kc [78], causing virtually immediately the activation of the complement (C) cascade and thereby the generation of the complement fragment C5a [21,22]. C5a, in turn, stimulates the Kc very rapidly to release constitutive COX-1- and COX-2-dependent PGE_2 [23,79]. Indeed, via this mechanism, peripheral PGE_2 is elevated at the onset of fever [79] and thus a likely candidate to trigger the first phase of fever (Figure 33.4b). It should, however, be noted that the rapid activation of C5a is a specific feature of LPS but not of other exogenous pyrogens [3].

The production of free oxygen radicals by neutrophils and macrophages is enhanced immediately after LPS challenge. It has, therefore, been suggested that these products could play a role in fever production. Methylene blue, an inhibitor of superoxide and hydroxyl radical formation, was administered to rabbits prior to a challenge with LPS. The usual febrile response to LPS was, indeed, consequently depressed in these animals, apparently supporting a role for oxygen radicals in the manifestation of fever [80,81]. The authors of these studies, therefore, suggested that the LPS-induced rise of T_b could normally result from the rapid and excessive production of reactive oxygen species that, in turn, could be sensed by redox-sensitive sites of glutamate receptors in the brain. They also suggested that the antipyretic activity of aspirin could, therefore, be due to its antioxidant activity rather than to its inhibition of prostaglandin formation. A major objection to this hypothesis is its rejection of PGE_2 as a critical mediator of fever [82], whereas most data support its essential role not only as a neuronal mediator in the brain but also as a peripheral trigger of the febrile response (see above).

Having introduced the central thermoregulatory circuitries in the brain and some of the putative peripheral mediators of fever, the question how the peripherally generated pyrogenic message is transferred into the brain is addressed.

33.4 Transfer of Fever-generating Signals Across the Blood–Brain Barrier

As discussed in Section 33.1 and shown in Figure 33.3, the structures, where PGE_2 (or any other pyrogenic substance) causes the febrile shift of the thermoregulatory balance point to a higher level, are located inside the blood–brain barrier (BBB). Intensive research was directed to the possible mechanisms of how a peripherally appearing or generated pyrogen might transport a message to the relevant thermoregulatory structures. Here, three possible routes for the transfer of febrile signals to the brain are going to be introduced: (i) the circumventricular organs

lacking a tight BBB, (ii) cells forming the BBB and acting as relay stations for the transfer of febrigenic signals to the brain, and (iii) the activation of afferent nerves by peripherally generated pyrogens (Figure 33.2).

33.4.1 Sensory Circumventricular Organs (Cvos)

Sensory Cvos form a subgroup of the CVOs and include the *area postrema* (AP), the *organum vasculosum laminae terminalis* (OVLT), and the subfornical organ (SFO). The OVLT and SFO are located within the lamina terminalis in the anterior wall of the third ventricle (AV3 V), while the AP is situated in the dorsal vagal complex in the medulla oblongata [3,83]. The parenchyma capillaries of the sensory CVOs possess a fenestrated endothelium, thus allowing circulating hydrophilic signal molecules, including endogenous pyrogens, to enter the brain. The parenchyma of the CVOs is composed of neurons and glial cells, and bidirectional neuronal connections between sensory CVOs and preoptic anterior hypothalamic nuclei have been identified. Thus, the neural signal transfer of inflammatory information into the brain, that is, the MnPO (Figure 33.3), is possible [84]. With regard to fever, special attention has been directed to the OVLT due to its proximity to the MnPO/MPO. The hypothesis that the OVLT may serve as a portal of entry for circulating pyrogens based on the classical observation that electrolytic ablation of the OVLT prevented fever in response to the peripheral injection of LPS [85]. Although there are some problems with the interpretation of lesion studies [86], there are other arguments in support of a role for sensory CVOs in the detection of circulating cytokines or even PAMPs. There is an extensive expression of receptors for cytokines and even TLRs in all of the three sensory CVOs ([3,83,87], for review). This means that cells within sensory CVOs can directly respond to PAMPs with the expression of inflammatory genes, thereafter with production of a second pool of cytokines, and other cellular responses [88]. Clearly, the sensory CVOs belong to the most responsive sites within the CNS to systemic inflammatory stimulation [89]. However, their role as essential or exclusive central sensors of cytokines or PAMPs is challenged by the fact that cells of the BBB in the surrounding regions including MnPO/MPO, endothelial cells, and perivascular macrophages are equipped with receptors for PAMPs and cytokines ([3], for review) and are also highly responsive to inflammatory stimulation [90,91].

33.4.2 Cells Forming the Blood–Brain Barrier

Cells forming the BBB (vascular endothelial cells and perivascular cells) within the entire brain have the capacity to secrete cytokines (IL-6), PGE_2, and other mediators into the brain parenchyma after their respective inflammatory stimulation from the luminal (blood) side [90–92]. These cells thus seem to play an important role in the transduction of inflammatory signals from the blood to the brain [93]. With regard to LPS-induced fever, the expression on BBB-associated cells of TLR4 and of receptors for pyrogenic cytokines on brain endothelial cells is especially relevant. Consequently, all these pyrogens have the capacity to directly activate the brain endothelium. In brain endothelial cells, and also in cells within

the sensory CVOs, activation of inflammatory transcription factors occurs during systemic inflammation. NF-κB is induced either directly by PAMPs (LPS and others) binding to their respective TLRs or by the pyrogenic cytokines IL-1β and TNF-α. Circulating IL-6 employs the transcription factor signal transducer and activator of transcription-3 (STAT3); pronounced nuclear translocation of STAT3 occurs in brain endothelial cells and astrocytes of sensory CVOs upon stimulation with IL-6 ([3,74], for review). More recently, the activation of a third transcription factor, nuclear factor IL-6 (NF-IL-6), was demonstrated in brain cells during LPS-induced fever, again predominantly in sensory CVOs and brain endothelial cells [94]. In contrast to NF-κB and STAT3, the nuclear translocation of NF-IL-6 coincides with the late phase of fever, so that its putative role in the maintenance or even the termination of fever was suggested [29,95].

In the context of fever, the target genes of NF-κB and STAT3 include COX-2 and mPGES-1. Some new studies suggest that in the brain not phospholipase A2 (PLA_2) but rather monoacyglycerol lipase, through hydrolysis of the endocannabinoid 2-arachidonoylglycerol, provides the source of arachidonic acid and thereby the substrate for COX-2/mPGES-1 [27,28]. As already mentioned in Section 33.2, the coupled induction of COX-2 and mPGES-1 is important for inflammatory formation of PGE_2. The co-localized expression of both these inducible enzymes in brain endothelial cells is regarded as the crucial prerequisite for PGE_2 synthesis in the brain during fever [25,93,96]. The activation of NF-κB or STAT3 in brain endothelial cells is indeed associated with the appearance of COX-2 and mPGES-1 in these cells [70,97–99]. Consequently, the formation of PGE_2 specifically by brain endothelial cells has been suggested to be essential for the production of LPS-induced fever [100]. Further evidence for a critical role of the brain endothelium in fever production is derived from studies in which mice with brain endothelial-selective deletions of IL-1-receptors, IL-6-receptors, or COX-2/mPGES-1 were employed [25,26,101]. In all these studies, the febrile response of mice was impaired, and the lack of IL-1- or IL-6 receptors further resulted in an inhibition of NFκB (IL-1 receptor deletion) or STAT3- (IL-6 receptor deletion) mediated induction of COX-2.

Within the MnPO/MPO, one could assume that the PGE_2 produced by endothelial cells is released abluminally and might diffuse to the responsive preoptic neurons (Figure 33.3). However, it has to be mentioned that the inflammatory induction of COX/mPGES-1 does not occur exclusively within the brain sites, which are implicated in fever and other components of the brain-controlled illness responses. For example, a strong inflammatory genomic activation occurs in endothelial cells of vessels located in the cortex [67]. It has recently been shown that COX-2-derived PGE_2 production in the cortex contributes to changes of neurovascular coupling by inducing hyperemia [102]. Still, the functional consequences of the inflammatory activation of brain intrinsic PGE_2 formation in so many different brain areas requires more attention in future research. Taken together, all these studies indicate that the genomic activation of brain endothelial cells by PAMPs or cytokines and the subsequent formation of PGE_2 via inducible COX-2/mPGES-1 are essential for the manifestation of fever, at least for the longer second fever phase (Figure 33.4). A faster signal transfer mechanism might be required to account for the early initiation of fever [3].

33.4.3 A Rapid Signal Transfer from the Periphery to the Brain via Sensory Nerves

During the 1990s, intensive research was directed toward a possible transmission of peripheral immune signals to the brain via sensory nerves with special focus on the vagus nerve [9–11,19,45]. The question whether such an alternative and rapid communication pathway between the activated immune system and those parts of the brain, which are involved in fever induction, makes a quantitative contribution to the febrile response was later on discussed with some controversial arguments [3,103,104]. The evidence for a participation of afferent sensory nerves in the manifestation of fever is summarized in this section.

33.4.3.1 The Afferent Vagus

Initial evidence for a role of the vagus nerve based on observations that bilateral truncal vagotomy attenuated or abrogated various inflammation-induced sickness responses including fever [3,9,10,19,43,44]. Subsequently, some controversy arose with regard to this issue [103,104]. Some studies showed that just fevers induced by low doses of pyrogens could be blocked by vagotomy, while the febrile responses to a challenge with high doses of LPS or pyrogenic cytokines were unimpaired [103,105]. The reason for this discrepancy may be caused by the fact that high concentrations of circulating pyrogens will readily activate the humoral inflammatory signal transfer to the brain (Sections 33.3.1 and 33.3.2), so that the neuronal contribution of the vagus nerve is overridden and difficult to detect [106]. It turned out that the involvement of vagally transmitted signals predominantly contributed to the early phase of fever induced by moderate doses of pyrogens and that this effect is mediated by the hepatic branche of the vagus nerve [103]. In this context, it should be reconsidered that the onset of LPS-induced fever shows a temporal relation to the uptake of LPS by liver Kupffer cells [78] and that the C5a-dependent rapid production of PGE_2 by these cells is a putative trigger for the early LPS-induced fever phase [22,23,79]. Kc-derived PGE_2 was, therefore, proposed to activate afferent fibers of the hepatic branches of the vagus nerve, which in turn forward this inflammatory message to the afferent projection areas of the vagus nerve within the nucleus of the solitary tract (NTS) [3,45]. The further processing of these neuronal signals, which have to reach the fever-inducing areas within the MnPO/MPO (Figure 33.3), will be addressed in Section 33.4.2.

33.4.3.2 Afferent Neuronal Signals from Other Nerves

Earlier studies provided some evidence that cutaneous afferent nerve fibers can, to a small degree, contribute to the manifestation of fever in an experimental model of localized subcutaneous inflammation. Injections of a low dose of LPS into a subcutaneous compartment resulted in a febrile response that was attenuated by coadministration of a local anesthetic [41]. It was proposed that some inflammatory mediator might have activated cutaneous cold-sensitive afferent nerve fibers. The activated cold sensory neurons, in turn, could have evoked the characteristic pattern of cold defense reactions, which are typical for the rising phase of fever [3]. PGE_2 turned out to be a likely candidate for an effect

like this [40], Figure 33.2). The febrile response, which was induced by a local subcutaneous injection of LPS, could be attenuated by coadministration of a low dose of a COX inhibitor into the subcutaneous site of inflammation. The same amount of the COX inhibitor was ineffective when injected into another site remote from the locus of LPS injection [42]. Similar observations were reported by another group, in this case for fever induced by injections of LPS into periodontal tissue. An inflammatory stimulation of the respective afferent fibers of the trigeminal nerve by locally produced PGE_2 seemed likely, due to the fact that fever was attenuated by injections of local anesthetics or COX inhibitors into the inflamed tissue [107].

Neural transmission of peripheral inflammatory signals to the brain has the advantage to operate faster than the humoral transmission, which requires transcriptional and translational processes in the periphery and/or at the BBB. With regard to a localized inflammation, another benefit of the neural signal transfer is that nerve terminals within the inflamed tissue can directly transmit the inflammatory status from the critical site of action to the brain [106]. Neural pathways may have the task to provide a first alarm-like response that originates at the site of a local inflammatory reaction and triggers almost immediately some nonspecific host defense responses including the initiation of an early phase of fever [3].

33.5 Centrally Acting Pyrogenic Mediators and Processing of Febrile Signals in the Brain

33.5.1 The Role of PGE2 in the MnPO

Within the MnPO, PGE_2 is thought to be released from brain endothelial cells into the brain parenchyma (see Section 33.3.2) and would there exert effects on neurons, which are compatible with generation of fever. Such neuronal effects could include direct inhibition of warm-sensitive neurons [47,49]. Four subtypes of PGE_2 receptors (EP_1–EP_4) have been described so far, which are all G protein-coupled receptors employing distinct signal transduction pathways [108]. In the MnPO, there is pronounced expression of EP_3 and EP_4 [108]. The EP3 receptor is critical for PGE_2-mediated fever since EP3 receptor-deficient mice fail to produce fever in response to centrally injected PGE_2 and to peripheral or central injections of other pyrogens [109,110]. Furthermore, the selective deletion of EP3 receptor genes in the MnPO of mice results in the depression the febrile responses to LPS or PGE_2 [55], confirming that this brain site is the presumptive site of the pyrogenic action of PGE_2. Indeed, EP3-expressing MnPO neurons are the origin of descending neuronal chains, which activate heat-generating and heat-conserving responses [49–51].

33.5.2 The Role of Noradrenaline in the POA

Intra-POA released noradrenaline (NA) seems to be an important central mediatior of the early phase of LPS-induced fever in connection with PGE_2-mediated stimulation of afferent fibers of the vagus nerve [3]. The noradrenergic

A1 and A2 cell groups in the medulla oblongata receive excitatory inputs from afferents from the abdominal (hepatic) vagus nerve. This excitation is transmitted to the POA via the ventral noradrenergic bundle, where a rapid increase in NA release can be monitored after peripheral injection of LPS [111]. Another major noradrenergic brain stem nucleus, the locus coeruleus, has also been proposed to participate in the mediation of fever [112]. The suggested mode of action of NA on neurons within the POA is similar to that, which was postulated for PGE_2, an inhibition of warm-sensitive neurons and thereby disinhibition of thermogenesis [3,111]. Indeed, in guinea pigs, intrahypothalamic microinjections of NA cause an increase of the thermoregulatory balance point by shifting the threshold T_b for heat production to a higher level [113]. Intra-POA release of NA might thus contribute to fever, for instance, during the rapidly developing first fever phase [3].

33.5.3 Other Centrally Acting Endogenous Pyrogens (Cytokines, Chemokines, and Other Substances)

There are a number of other substances, which cause an increase in T_b, supported by appropriate thermoeffector responses, when injected into the cerebral ventricles (intracerebroventricular, i.c.v.) of experimental animals. These substances include cytokines, chemokines, and other substances. The fact that i.c.v. injections of all these molecules evoke a fever-like response alone does not prove that one or several of these substances play a significant role within the brain to establish fever induced by a given exogenous pyrogen. The putative centrally acting pyrogenic substance should be produced and released in the brain after injection of an exogenous peripheral trigger of fever (LPS or other PAMPs, living bacteria, or other stimuli). Finally, drugs, which inhibit production or biological action of the centrally acting pyrogen, should have an inhibitory influence on fever.

IL-6 belongs to those cytokines, which are produced by cells forming the BBB during systemic inflammation and released into the brain ([20,106]; for review). I. c.v. injections of IL-6 in IL-6-KO and in other mice cause pronounced fever [1,114,115], while an i.c.v. injection of IL-6-antibodies attenuated the febrile response to experimental *E. coli* infection [116]. Other cytokines/chemokines including IL-1β, IL-8, MIP-1, or CINC-1 also fulfill the criteria of being centrally acting pyrogenic cytokines [71,117–120]. Central IL-8 and MIP-1 even induce fevers, which develop independent of PGE_2.

Other centrally acting substances with intrinsic pyrogenic properties include endothelin [121], endocannabinoids [57,122], opiods [123], and others ([3], for review). For some of these centrally acting pyrogenic substances (NA, IL-1β, and IL-6), the mechanism of action seems to be similar to that employed by PGE_2, that is an inhibition of warm-sensitive preoptic neurons [3,124–126]. Still, the precise roles of all these centrally acting pyrogenic molecules remain to be further characterized.

33.6 Clinical Aspects of Fever

Fever is one consequence of the complex process of inflammation. It usually occurs during various kinds of infections, but almost 50% of all clinical fevers are

of noninfectious origin (trauma, surgery, cerebral bleeding, tumors, thromboembolic events, autoimmune diseases, and others) [127]. The temporal patters of infectious or noninfectious clinical fevers are not comparable to the courses of experimental fevers as shown for LPS-induced fever in Figure 33.4. Some of the most prominent clinical febrile courses have recently been reviewed [3]. In brief, some fevers are characteristic of prolonged elevations of T_b with just small fluctuations ("continuous fever," for example, seen in patients with pneumonia [128–130). Fevers with larger fluctuations are called "remittent." When longer febrile episodes are interrupted by longer intervals without elevated T_b, these fevers are called "recurrent," malaria being a prominent example of this pattern ([3], for review). "Biphasic" clinical fevers have nothing to do with the two phases of LPS-induced fever (Figure 33.4). They rather consist of two phases lasting several days with two peaks, interrupted by a phase of reduced fever, which is observed in dengue and yellow fever [130]. For further patterns of clinical fevers and more details on the diseases that are typical for a given pattern, some review articles are recommended [128–130]. The causes of all these different patterns are still speculative. There are just few studies aiming to obtain insight into molecular mechanisms of clinical fevers [131], although some experimental fever models have been developed, which might better reflect naturally occurring fevers than systemic bolus injections of LPS or other PAMPs [116,132,133].

33.6.1 Is Fever Beneficial or Harmful? Some Classical Arguments

It is not that only species with the abilities for neuronal/autonomic thermoregulation, mammals, and birds develop infectious fever. Using appropriate behaviours to elevate T_b, infected invertebrates and poikilothermic vertebrates adjust T_b to higher levels [134]. Hasday *et al.* [135] concluded that a fever-like response must have developed about 600 million years ago together with heat shock and innate immune responses. The energetic costs of fever are remarkable [3,136]. The fact that a febrile response persisted for so many millions of years despite its metabolic costs has frequently been used as an argument that fever must be of adaptive value [134,135]. Another putative valuable component of fever relates to a direct effect of enhanced T_b on growth or survival rates of infectious microorganisms. There are just a few examples for such an effect, but in the majority of all infectious diseases T_b will not increase to levels that inhibit growth of a given pathogen or even kill it [2,30].

Still, in classical studies performed by Kluger and colleagues [137,138], the behaviorally established fever of lizards made them resistant to usually lethal bacterial infections, whereas the suppression of this kind of fever by treatment with antipyretics reduced the animals' survival rates. The mechanistic background for Kluger's observations is predominantly based on the stimulating effects of febrile temperatures on various components of the innate and adaptive immunity ([1,3], for review). In a recent review, Evans *et al.* worked out all the cellular components of immune responses, which are thermally regulated by febrile temperatures [139]. The cells, which are positively influenced by febrile temperature, include dendritic cells, macrophages, natural killer cells, B cells, T cells, neutrophils, and vascular endothelial cells. Further

molecular components include heat shock proteins and IL-6-signaling and adhesion molecules required for coordinated trafficking of immune cells to the site of inflammation or into tumor tissue [139]. Another argument, explaining why lizards, rabbits, and other species of experimental animals [134,139] show higher mortality, when fever is suppressed by COX inhibitors, relates to the drastic influence of these drugs on the entire inflammatory process ([30], for review). PGE_2, the synthesis of which is suppressed under the influence of COX inhibitors, not only is an important mediator of inflammation but also regulates the strength of the inflammatory response as part of a negative feedback loop, for example, by inhibiting excessive formation of TNF-α [30,61]. Thus, there are possible explanations for repeatedly observed adverse effects of fever suppression under experimental conditions in laboratory animals, induced by treatment with nonsteroidal anti-inflammatory drugs (NSIADs). Here, the question arises whether a direct transfer to the clinical setting is possible or not. This question is important in so far as the enhanced immune functions under the influence of a febrile T_b can be associated with both positive and negative consequences. The most important positive consequence would be an accelerated pathogen clearance. A negative effect could be collateral tissue damage at a given site of infection due to excessive formation of reactive oxygen and other radicals by cells of the innate immune system [1–3,30,134,135].

33.6.2 Is Fever Beneficial or Harmful? No Clear Response from Clinical Studies

Critically ill patients frequently show abnormalities in T_b, not only fever but also hypothermia, especially during septic blood infections ([30], for review). Several independently performed clinical studies aimed to determine association between the T_b abnormalities and the final outcome (survival). The worst prognosis was determined for hypothermic patients [140–143]. This observation is not surprising in so far as the condition of septic patients with severe hypothermia is rather poor in most cases [4]. For febrile patients, the prognosis was better but not for those who showed very high fevers (>39.5 °C) of noninfectious origin [142]. As there may be groups of patients, who may benefit from antipyretic therapy, a brief look at clinical studies seems warranted, in which fever was reduced either by physical cooling or pharmacologically by use of NSIADs. There are single clinical studies, which report an improved outcome for septic patients when fever was controlled and depressed by means of external cooling [144]. Other studies reported higher mortality rates of critically ill patients when fever was treated physically or pharmacologically [145]. Due to these sharp inconsistencies, Niven *et al.* [146] provided a systematic review and meta-analysis of the outcome of antipyretic therapy in critically ill patients. Just 5 out of 755 published reports fulfilled the strict criteria for the meta-analysis, among them the two studies cited above [144,145]. The analysis resulted in a tie: it could not be determined whether treatment of fever is harmful or beneficial [146]. It seems that this question has to be addressed by using selected groups of critically ill patients. Indeed, it might be the case that fever can have negative impact on the outcome in ischemic stroke, traumatic brain injury, or diseases of the cardiovascular and pulmonary

systems [127,129], while it may be beneficial in many other infectious diseases ([30], for review).

Although there are mechanistic arguments that support the view of an adaptive value of fever, the transfer to the clinical situation is still difficult and complicated due to the large number of distinct infectious or noninfectious diseases, which are accompanied by fever.

33.7 Concluding Remarks

Intensive experimental research on fever in the past 25 years provided a broader understanding not only of the phenomenon fever per se but also of several other aspects of how a peripherally generated inflammatory process propagates into the brain. Research in the 1990s focused on the roles of single cytokines in the manifestation of the febrile response [1,3,18–20]. Later on, the discovery of TLRs and the presence of this family of receptors at the interface between blood and brain challenged the exclusive role of cytokines as circulating pyrogens [11,64,65,87]. Other components of innate immunity, which are relevant specifically for LPS-induced fever, include complement fragments [3,21,22] and, perhaps, oxygen radicals [80,81]. The participation of afferent nerves in the early induction of fever is discussed controversially, but an inflammatory activation of afferent fibers of the vagus and other nerves by peripheral PGE_2 is well established [3,9–11,40]. Starting in the 1990s and continuing to present times, the critical role of the coupled induction of COX-2/mPGES in brain endothelial cells was intensively studied [25,70,93,96–100]. More recently, the source of arachidonic acid in the brain for the brain-intrinsic formation of PGE_2 has been identified [27,28]. A transcription factor (NF-IL-6) with early pro- and late anti-inflammatory properties was characterized; the properties of this transcription factor might reflect the natural reprogramming of inflammatory processes within the brain during infectious diseases [29,74,94,95].

In spite of all this progress, a direct transfer of the knowledge derived from experimental research on fever is difficult to be transferred to the clinical situation. Namely, the question of whether fever is a friend or foe for the critically ill patient remains unresolved [30,127,135,146]. A possible strategy for the clinician to obtain some responses to this question might be a detailed analysis of groups of individuals with specific disease states to define whether fever and the strength of the disease-associated inflammatory processes are beneficial or harmful for the given condition [30]. For experimental researchers, on the other hand, it is recommended to develop experimental models of fever, which better reflect the conditions of natural infections or other diseases of noninfectious origin, which are known to be associated with fever.

List of Abbreviations

AA	arachidonic acid
AP	area postrema

APR	acute-phase response
BAT	brown adipose tissue
BBB	blood–brain barrier
C	complement
COX	cyclooxygenase
DMH	dorsomedial hypothalamus
DRG	dorsal root ganglion
EP3	prostaglandin E2 receptor subtype 3
GABA	gamma amino butyric acid
ICV	intracerebroventricular
IFN	interferon
IL	interleukin
Kc	Kupffer cells
KO	knockout
LPB	lateral parabrachial nucleus
LPBd	lateral parabrachial nucleus, dorsal subregion
LPS	lipopolysaccharide
MIP-1	macrophage inflammatory protein
MnPO	median preoptic nucleus
MPO	medial preoptic area
NA	noradrenaline
NF-IL-6	nuclear factor IL-6
NFκB	nuclear factor kappa B
NOS	nitric oxide synthase
NST	nonshivering thermogenesis
OVLT	organum vasculosum laminae terminalis
PAMP	pathogen-associated molecular pattern
PGE_2	prostaglandin E2
PGES	prostaglandin E synthase
PLA_2	phospholipase A2
PLC	phospholipase C
POA	preoptic anterior hypothalamic area
rRPa	rostral raphe pallidus nucleus
SFO	subfornical organ
STAT3	signal transducer and activator of transcription 3
T_a	ambient temperature
T_b	body core temperature
TLR	Toll-like receptor
TNF-α	tumor necrosis factor-α
WT	wild type

34.1 Introduction

The classic description of an inflammatory reaction consists of four cardinal signs *rubor*, *tumor*, *calor*, and *dolor* (redness, swelling, heat, and pain). Inflammation is an essential component of a large (if not the largest) group of painful syndromes including arthritis, musculoskeletal and visceral disorders, neuropathy, cancer, wounds, and surgery [1]. Since chronic diseases with an inflammatory component represent our greatest health threat [2], pain management is bound to play an increasingly important role in the treatment of acute and chronic illness.

The International Association for the Study of Pain (IASP) defines pain as "an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage" [3]. Pain is always subjective and a sensation in parts of the body. At the same time, it is unpleasant and therefore also an emotional experience. Nociception is neurophysiological activity in peripheral sensory neurons (nociceptors) and higher nociceptive pathways, and is defined by the IASP as the "neural process of encoding noxious stimuli." Nociception is not synonymous to pain. Pain is always a psychological state, even though it often has a proximate physical cause. This chapter will discuss mechanisms underlying the generation and inhibition of inflammatory pain.

34.2 Basic Concepts of Pain

Pain may be roughly divided into two broad categories: physiological and pathological pain. Physiological (acute, nociceptive) pain is an essential early-warning sign that usually elicits reflex withdrawal and thereby promotes survival by protecting the organism from (further) injury. In contrast, pathological (chronic) pain is an expression of the maladaptive operation of the nervous

Inflammation: From Molecular and Cellular Mechanisms to the Clinic, First Edition.

system and is considered a disease in its own right [4]. The IASP defines it as "persistent or recurrent pain lasting longer than three months" [5]. It is "pain that persists past normal healing time and hence lacks the acute warning function of physiological nociception" and affects an estimated 20% of people worldwide [5].

34.2.1 Excitatory Mechanisms

Physiological pain (nociception) is mediated by a sensory system consisting of primary afferent neurons, spinal interneurons, and ascending tracts and several supraspinal areas. Trigeminal and dorsal root ganglia (DRG) give rise to high-threshold Aδ- and C-fibers innervating peripheral tissues (skin, muscles, joints, and viscera). These specialized primary afferent neurons, also called nociceptors, transduce noxious stimuli into action potentials and conduct them to the dorsal horn of the spinal cord (Figure 34.1). When peripheral tissue is damaged, inflammation usually ensues and primary afferent neurons are directly activated and/or sensitized by chemical, mechanical, and/or thermal stimuli. Examples are protons (acidosis) (Table 34.1), sympathetic amines, adenosine triphosphate (ATP), glutamate, neuropeptides (calcitonin gene-related peptide, substance P), nerve growth factor, prostanoids, bradykinin, lipids, proinflammatory cytokines, or chemokines [6–9] (see also Chapters 22–33 on inflammatory mediators and Chapter 68 on nonsteroidal anti-inflammatory drugs). Many of these agents lead to opening of cation channels in the membrane of primary afferent neurons. Such channels include the capsaicin-, proton-, and heat-sensitive transient receptor potential vanilloid-1 (TRPV1), acid-sensing ion channels (ASICs) or the ATP-gated purinergic $P2X_3$ receptor. These channels enable an inward current of Na^+ and Ca^{++} ions into the peripheral nociceptor terminal. If this depolarizing current is sufficient to activate voltage-gated Na^+ channels (e.g., Nav1.8), they too will open, further depolarizing the membrane and initiating a burst of action potentials that are then conducted along the sensory axon to the dorsal horn of the spinal cord [7,10].

Transmission of input from nociceptors to spinal neurons that project to the brain is mediated by direct monosynaptic contact or through multiple excitatory or inhibitory interneurons. The central terminals of nociceptors contain excitatory transmitters such as glutamate, substance P (sP), and neurotrophic factors. These activate postsynaptic *N*-methyl-D-aspartate (NMDA), neurokinin (NK1), and tyrosine kinase receptors, respectively. Repeated nociceptor stimulation can sensitize both peripheral and central neurons (activity-dependent plasticity; "wind up") [51]. Later, sensitization can be sustained by transcriptional changes in the expression of genes coding for various neuropeptides, transmitters, ion channels, receptors, and signaling molecules (transcription- dependent plasticity). Important examples include the NMDA receptor, cyclooxygenase-2 (COX-2), Ca^{++} and Na^+ channels, cytokines, and chemokines expressed by neurons and/or glial cells [52]. In addition, physical rearrangement of neuronal circuits by apoptosis, nerve growth, and sprouting occurs in the peripheral and central nervous system [4], and spinal microglial cells release mediators (e.g., brain-derived neurotrophic factor, cytokines, etc.) that increase neuronal excitability

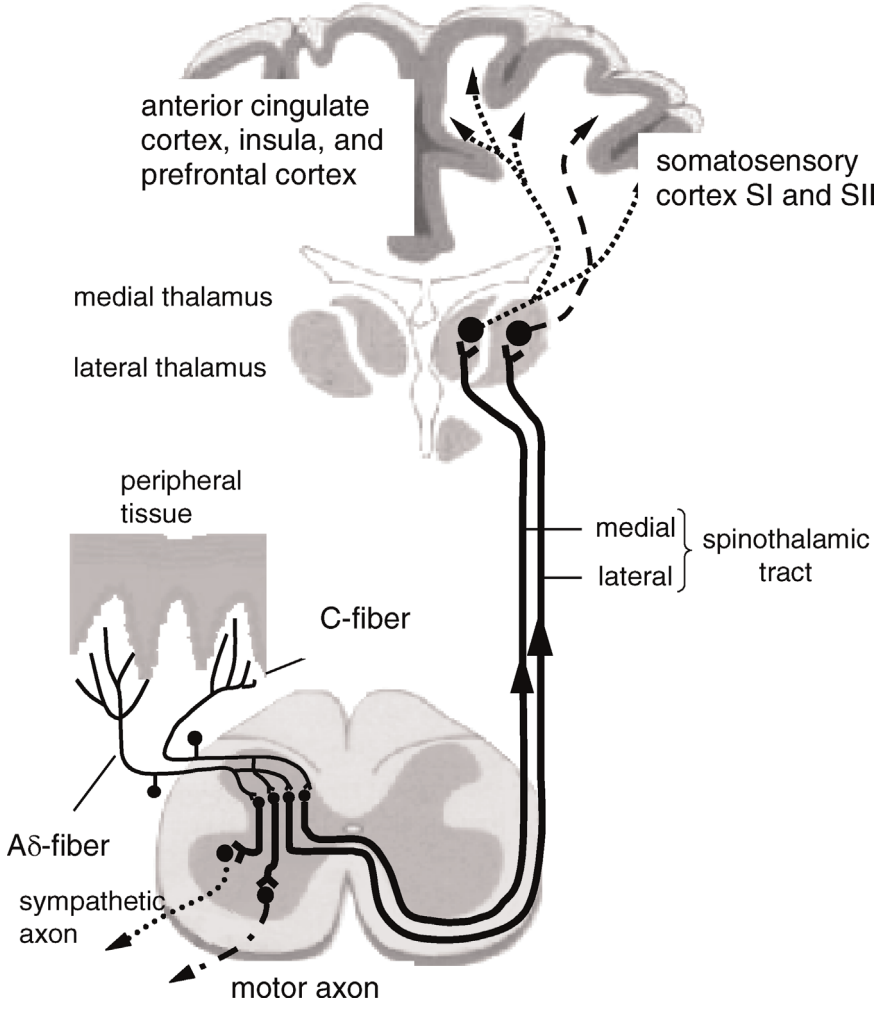

Figure 34.1 Nociceptive pathways (adapted with permission from Ref. [11]).

and enhance nociception [52]. Both induction and maintenance of central sensitization are critically dependent on the peripheral drive by nociceptors, indicating that therapeutic interventions targeting such peripheral neurons may be particularly effective, even in chronic pain syndromes [51].

After synaptic processing, the peripheral input is conveyed to higher centers via the spinothalamic, spinoreticulothalamic, and spinoparabrachial pathways. This activity relays through the brain stem and thalamus to the somatosensory cortex and associated areas (Figure 34.1). The parabrachial region of the brain stem connects to the ventromedial nucleus of the hippocampus and the central nucleus of the amygdala, brain regions involved in the affective/aversive components of pain. There is no single brain area essential for pain but rather activation of a distributed group of structures. Many impulses from supraspinal centers are

integrated in the midbrain periaqueductal gray, a pivotal region for descending modulation of nociception [52,53].

34.2.2 Inhibitory Mechanisms

Concurrent with the events described above, powerful endogenous inhibitory mechanisms unfold both in the periphery and in the central nervous system. Two families of neuromodulators binding to class A inhibitory G protein-coupled receptors (GPCRs) have been extensively investigated, the opioids and the cannabinoids [9,54–56]. In inflamed peripheral tissue, nociception can be suppressed by interactions between leukocyte-derived opioid peptides (OP) and

peripheral nociceptor terminals carrying opioid receptors (OR) [55, 57–59], by lipid endocannabinoids derived from primary afferent neurons and neighboring nonneuronal cells [9,55], and/or by anti-inflammatory cytokines [6]. In the central nervous system, inhibition of nociception is mounted by opioids, cannabinoids, GABA, or glycine, which activate their respective presynaptic receptors to reduce excitatory transmitter release [52,54]. In addition, the opening of postsynaptic K^+ or Cl^- channels by opioids or GABA, respectively, evokes hyperpolarizing inhibitory potentials in spinal dorsal horn neurons. During ongoing nociceptive stimulation, spinal interneurons upregulate gene expression and production of opioid peptides [60,61]. Powerful descending inhibitory pathways from the brain stem also become active by operating mostly through noradrenergic, serotonergic, and opioid systems. A key region is the periaqueductal gray. It connects to the rostral ventromedial medulla, which projects along the dorsolateral funiculus to the spinal dorsal horn [62]. The integration of signals from excitatory and inhibitory pathways, cognitive, emotional, and environmental factors results in the central perception of pain.

Besides disease-modifying drugs (e.g., steroids, biologicals, etc., see Chapters 59 and 63), two classes of analgesic compounds are mainly used in the treatment of inflammatory pain, COX inhibitors and opioids (see Section 3.2). The COX inhibitors (nonsteroidal anti-inflammatory drugs) are covered in Chapter 68. The following section will discuss the opioid system in more detail.

34.2.2.1 Opioid Receptors and Signaling

Opioid receptors are expressed by central and peripheral neurons, by neuroendocrine (pituitary and adrenals), immune, and ectodermal cells (reviewed in Refs [56,59,63]). Three main types of opioid receptors are defined, the mu-, delta-, and kappa receptors [64,65]. After binding of a ligand, conformational changes allow intracellular coupling of heterotrimeric Gi/o proteins to the C-terminus of the receptor. At the Gα subunit, GTP replaces GDP and dissociation of the trimeric G protein complex into Gα and Gβγ subunits ensues. The former inhibit adenylyl cyclases and cAMP production, whereas the latter directly interact with different ion channels in the cell membrane [66,67]. All three opioid receptors can modulate pre- and postsynaptic Ca^{++} channels, suppress Ca^{++} influx, and thereby attenuate the excitability of neurons and/or reduce the release of pronociceptive neuropeptides [68]. In addition, opioid receptor activation leads to opening of G protein-coupled inwardly rectifying K^+ (GIRK) channels, thereby preventing neuronal excitation and/or propagation of action potentials [63,67,69]. Opioids also inhibit Na^+-, Ih-, TRPV1, and ASICs in DRG neurons, as well as excitatory postsynaptic currents evoked by glutamate receptors in the spinal cord [70–74]. The result is decreased transmission of nociceptive stimuli at all levels of the neuraxis and profoundly reduced perception of pain.

34.2.2.2 Plasticity of Opioid Receptors and Signaling Pathways

Persistent inflammatory pain is associated with multiple adaptations in the nervous, endocrine, and immune systems [6,60,61,75]. In the late 1980s, evidence began to accumulate that antinociceptive effects can be mediated by opioid receptors localized on peripheral sensory neurons [57,76]. Initial studies showed

that the systemic or local application of opioid agonists elicited significantly more pronounced analgesic effects on inflamed than noninflamed tissue of animals and humans (reviewed in Refs [76,77]). This intriguing finding stimulated extensive research into the underlying mechanisms.

Alterations in opioid receptor expression occur at the mRNA and protein levels and can be subject to epigenetic regulation [64]. With regard to opioid receptor synthesis, it was found that peripheral tissue inflammation can induce differential upregulation of opioid receptor types and their mRNAs in DRG neurons. This upregulation is dependent on neuronal electrical activity, on cytokine production in the inflamed tissue, and may be related to cytokine-induced binding of transcription factors to opioid receptor gene promoters (reviewed in Refs [59,78]). Furthermore, it was shown that the peripherally directed axonal transport of opioid receptors was augmented and opioid receptor expression on DRG membranes was enhanced [79,80]. The axonal transport was stimulated by cytokines and nerve growth factor produced within the inflamed tissue [81,82], resulting in increased density and antinociceptive functionality of opioid receptors on peripheral nerve terminals [57,80,83]. On the other hand, short-lasting inflammatory stimuli do not significantly alter the number of opioid receptors on peripheral sensory nerve terminals (reviewed in Ref. [59]). Inflammation is also accompanied by a disrupted perineural barrier facilitating the access of opioid agonists to their receptors [84,85].

In cultured sensory neurons, bradykinin was found to stimulate the trafficking of intracellular opioid receptors to the plasma membrane [86]. Furthermore, priming with bradykinin, PGE2, or a protease-activated receptor agonist led to more potent inhibition of neuropeptide release and of cAMP accumulation by opioid agonists [86,87]. Also, painful paw inflammation and activation of sensory neurons by capsaicin or P2Y receptor agonists enhanced membrane recruitment of opioid receptors [88,89]. On the other hand, pretreatment of cultured DRG neurons with proinflammatory chemokines resulted in internalization and functional inhibition of opioid receptors [90]. *In vivo*, local pretreatment with bradykinin or arachidonic acid enabled [91], whereas the genetic ablation of bradykinin receptors reduced [92] peripheral opioid antinociception (reviewed in Ref. [59]).

With regard to signaling pathways, G protein coupling of opioid receptors was shown to be augmented during peripheral tissue inflammation [80]. Earlier studies had shown that low extracellular pH (as seen in inflammation, see Table 34.1) increased opioid agonist efficacy, possibly by altering the interaction of opioid receptors with G proteins and adenylyl cyclase [93,94]. This may augment inhibition of cAMP, Ca^{++}, Na^{+}, and TRPV1 and/or ASIC currents, and/or neuronal hyperpolarization via opening of GIRK channels [59,69–72]. Under conditions of elevated cAMP (as seen in inflammation), morphine can inhibit TRPV1 translocation to the plasma membrane [95]. Furthermore, extracellular recordings from sensory nerve fibers supplying injured tissue demonstrated opioid inhibition of spontaneous and stimulus-evoked action potentials [96–99]. A recent study reported the computer-assisted development of a pH-dependent opioid analgesic (NFEPP) that selectively activates peripheral opioid receptors in injured (acidotic) tissue without eliciting adverse side effects (apnoea, reward, motor disturbance, constipation) in noninflamed tissues (brain, intestinal wall) [49].

Opioid receptors are also expressed by immune cells (reviewed in Refs [59,100]). There is evidence that such opioid receptors contribute to analgesia [101], and they were shown to modulate various immune cell functions. However, the latter effects were mostly examined *in vitro*, they were often contradictory and dependent on specific experimental conditions (e.g., cultured cell types, duration of cultures, doses, and timing of opioid exposure) (reviewed in Ref. [100]). Based on such studies, immunosuppressive effects of opioids were frequently proposed, but they have not been verified in clinical or epidemiological studies [102,103]. In addition, opioid receptors were shown to modulate cellular growth, inflammation, and wound healing (reviewed in Refs [104,105]).

In summary, the expression, accessibility, axonal transport, and signaling of opioid receptors on DRG neurons are modulated by inflammation and these mechanisms apparently contribute to enhanced analgesia [59,104]. This is consistent with the notion that tissue injury "unmasks" peripheral opioid effects, whereas the local application of opioids in normal tissue does not reliably produce analgesia [76,106,107].

34.2.2.3 Endogenous Opioid Receptor Ligands

Endogenous opioid receptor ligands are derived from the precursors proopiomelanocortin (encoding β-endorphin), proenkephalin (encoding Met-enkephalin and Leu-enkephalin), and prodynorphin (encoding dynorphins). These peptides contain the common Tyr-Gly-Gly-Phe- Met/Leu sequence at their amino terminals, known as the opioid motif. Beta-endorphin and the enkephalins are antinociceptive agents acting at mu- and delta-opioid receptors. Dynorphins can elicit both pro- and antinociceptive effects via *N*-methyl-D-aspartate receptors and κ-opioid receptors, respectively. A fourth group of tetrapeptides (endomorphins) with yet unknown precursors do not contain the pan-opioid motif but bind to mu-receptors with high selectivity. Opioids are expressed throughout the central and peripheral nervous system, in neuroendocrine tissues, and in immune cells [63,78,108]. Opioid peptide-containing immune cells extravasate and accumulate in inflamed tissue. These cells upregulate the gene expression of opioid peptide precursors and the enzymatic machinery for their processing into functionally active peptides [108–110]. In response to stress, catecholamines, corticotropin releasing factor, cytokines, chemokines or bacteria, and leukocytes secrete opioids, which then activate peripheral opioid receptors and produce analgesia by inhibiting the excitability of nociceptors, the release of excitatory neuropeptides, or both [59,111] (Figure 34.2). The clinical relevance of these mechanisms has been confirmed in studies demonstrating that patients with knee joint inflammation express opioid peptides in immune cells and opioid receptors on sensory nerve terminals within synovial tissue [112–114]. After knee surgery, pain and analgesic consumption were enhanced by blocking the interaction between endogenous opioids and their receptors [112,115], and pain was reduced by stimulating opioid secretion [116].

Interestingly, endogenous opioids from inflammatory cells appear to produce additive/synergistic interactions rather than tolerance at peripheral opioid receptors [113,117,118]. After release, extracellular opioid peptides are susceptible to rapid enzymatic inactivation by aminopeptidase N and neutral endopeptidase ("enkephalinases"). Both are expressed in the central nervous system, peripheral

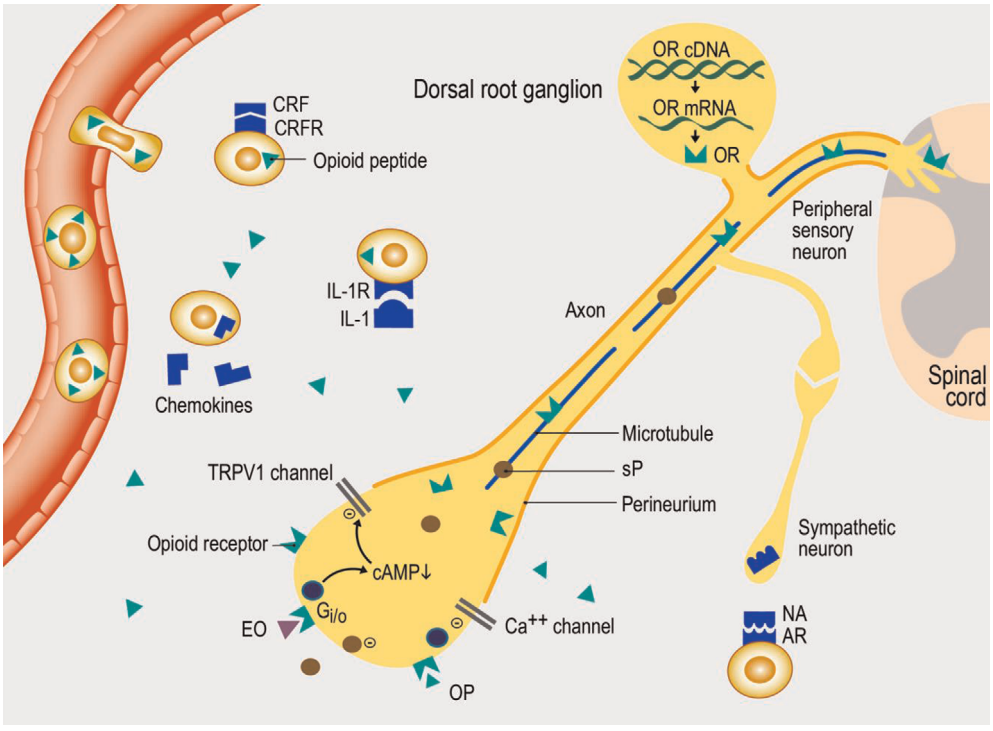

Figure 34.2 Endogenous antinociceptive mechanisms within peripheral inflamed tissue (adapted with permission from Ref. [59]). Opioid peptide-containing circulating leukocytes extravasate upon activation of adhesion molecules and chemotaxis by chemokines. Subsequently, these leukocytes are stimulated by stress or releasing agents to secrete opioid peptides. For example, corticotropin-releasing factor (CRF), interleukin-1β (IL-1), and noradrenaline (released from postganglionic sympathetic neurons) can elicit opioid release by activating their respective CRF receptors (CRFR), IL-1 receptors (IL-1R), and adrenergic receptors on leukocytes. Exogenous opioids (EO) or endogenous opioid peptides (green triangles) bind to opioid receptors that are synthesized in dorsal root ganglia and transported along intraaxonal microtubules to peripheral (and central) terminals of sensory neurons. The subsequent inhibition both of ion channels (e.g., TRPV1, Ca^{++}) and of substance P release results in antinociceptive effects.

nerves, and leukocytes. Preventing the extracellular degradation of endogenous opioid peptides by enkephalinase inhibitors, both in central and in peripheral compartments, has been shown to produce analgesic effects in many animal models and in some human trials [55,119]. This strategy avoids unphysiologically high concentrations of exogenous agonists at the receptor and, thus, diminishes the risk for development of receptor downregulation, tolerance, desensitization, off-site, or paradoxical excitatory effects [55,119].

34.3 Clinical Concepts of Pain

There is a tradition to distinguish between acute (e.g., intra- or postoperative), chronic malignant (related to cancer and its treatment) and chronic

nonmalignant (e.g., arthritic and neuropathic) pain. Little evidence exists to suggest that different somatic or psychological mechanisms warrant such a distinction and overlaps apparently exist. For example, cancer invasion can elicit inflammatory pain and/or neuropathic pain from invasion of the tumor into tissues innervated by primary afferent (nociceptive) neurons (e.g., pleura, peritoneum, etc.). Inflammation can contribute to both acute (e.g., postoperative) and chronic (e.g., arthritic) pain [5].

34.3.1 Biopsychosocial Concept and Multidisciplinary Management

All chronic (but also acute) pain syndromes have in common the complex influences of biological (tissue damage), cognitive (memory and expectations), emotional (anxiety and depression), and environmental factors (reinforcement and conditioning). The interplay between biological, psychological, and social factors results in the persistence of pain and illness behaviors [120,121]. Treating only one aspect of this complex syndrome is obviously insufficient, particularly in chronic pain. Therefore, a biopsychosocial concept of pain has been adopted. In a multimodal approach, pain management addresses physical, psychological, and social skills and underscores the patients' active responsibility to regain control over life by improving function and well-being [121,122]. This encompasses various pharmacological and nonpharmacological (psychological and physiotherapeutic) treatment strategies (for review, see Ref [123]).

34.3.2 Analgesic Drugs

Besides disease-modifying drugs (e.g., steroids and biologicals, see Chapters 59 and 63), an important component of pain therapy is the use of traditional analgesic drugs. Such compounds interfere with the generation and/or transmission of impulses following noxious stimulation in the nervous system (nociception). This can occur at peripheral and/or central levels of the neuraxis. Analgesics aim at modulating either the formation of noxious chemicals (e.g., prostaglandins) or the activation of neuronal receptors/ion channels transducing/transmitting noxious stimuli (e.g., opioid receptors, NMDA receptors, and Na^+ channels). The most widely used compounds are nonsteroidal anti-inflammatory drugs (see Chapter 68) and opioids. Other classes such as adrenergic receptor (AR) agonists, neurotrophin antagonists, neuropeptide (e.g., calcitonin gene-related peptide) receptor antagonists, kinin receptor antagonists, prostaglandin E receptor antagonists, cannabinoids, and ion channel (e.g., TRP, P2X) blockers are under investigation but not in routine use. Local anesthetics block Na^+ channels and are applied in local and regional anesthetic techniques. Mixed drugs combine different mechanisms, for example, noradrenaline (NA) reuptake inhibition and opioid agonist effects (tramadol and tapentadol), or opioid agonist and NMDA antagonist effects (ketamine). Various routes of drug administration (e.g., oral, intravenous, subcutaneous, intrathecal, epidural, topical, intraarticular, and transmucosal) can be used. In addition, placebo treatments have shown impressive analgesic effects, mediated by opioid and nonopioid mechanisms (for review, see Refs. [123,124]).

34.3.2.1 Opioids

Consistent with the expression of opioid receptors at all levels of the neuraxis, opioid agonists can effectively inhibit clinical pain after peripheral (topical and intraarticular), neuraxial (intrathecal, epidural, and intracerebroventricular), or systemic (intravenous, oral, subcutaneous, sublingual, and transdermal) administration [56,63,125–128]. The commonly available opioid drugs (morphine, codeine, methadone, fentanyl, and derivatives) are primarily mu-receptor agonists [125,129,130]. Systemically and spinally administered opioids can produce similar side effects (e.g., respiratory depression), depending on dosage and rostral/systemic redistribution. All three opioid receptor types mediate analgesia but have differing side effects [56,63]. Tolerance and physical dependence may occur with prolonged administration of pure agonists, and abrupt discontinuation or antagonist administration can result in a withdrawal syndrome [63,71].

The long-term use of opioids in chronic pain is increasingly scrutinized. While conventional opioid agonists are undisputed in the treatment of severely acute and cancer pain, their long-term use in chronic nonmalignant (e.g., neuropathic, musculoskeletal, and inflammatory) pain has not proven effective [131]. Instead, addiction, overdoses, death rates, and abuse of prescription opioids have reached epidemic proportions and have become a public health problem [132–135]. Meta-analyses show clinically insignificant reduction of pain scores, and epidemiological data suggest that quality of life or functional capacity are not improved [131,136]. Adverse side effects (nausea, sedation, constipation, dizziness, respiratory depression, cardiac arrhythmia, cognitive deficit, and endocrinopathy) and lack of analgesic efficacy have led to the dropout of high numbers of subjects in long-term studies [131,134,137–141]. Instead, chronic pain requires a multidisciplinary approach encompassing various pharmacological and nonpharmacological (psychological and physiotherapeutic) treatment strategies [75,123].

Experimental and clinical studies have demonstrated that peripheral opioid receptors mediate a substantial proportion of analgesia produced by systemically applied opioids (reviewed in Refs [56,104]. A recent clinical trial showed that the selective blockade of peripheral opioid receptors led to a 55% increase in systemic morphine requirements for sufficient pain relief during the first 4 h after surgery [142]. Peripheral application of opioids became of considerable interest because many pain syndromes depend to a significant degree on the peripheral activation of DRG neurons and side effects may be reduced [51]. The most extensively studied and well-established regimen is intraarticular morphine administration in inflammatory pain following surgery [126,128,143,144]. Meta-analyses showed that its analgesic efficacy is similar to local anesthetics [145]. In many small clinical trials, locally applied opioids (e.g., dermal formulations, gels, etc.) have shown analgesic actions in inflammatory pain associated with skin ulcers, cystitis, cancer-related oral mucositis, corneal abrasion, neuropathic pain, chronic arthritis, and bone injury (reviewed in Ref. [127]). For systemic administration, novel opioid receptor ligands are being developed. While earlier attempts to demonstrate peripheral opioid analgesia in healthy

tissue failed, potent antinociception was consistently detected in models of nerve damage, inflammatory, visceral, cancer, and bone pain (reviewed in Refs. [56,59,76]). Current research pursues the development of systemically applicable opioid agonists and enkephalinase inhibitors that do not permeate blood–brain, intestinal, or placental barriers [50,55,56,104,119,146,147] or do not activate central and intestinal opioid receptors [49]. In addition, gene therapeutic approaches enhancing the expression of peripheral opioid receptors and peptides are being investigated [148,149]. Thus, the selective activation of peripheral opioid receptors promises advantages such as anti-inflammatory actions and the absence of side effects typical for conventional opioids (sedation, nausea, apnea, fetal/neonatal depression, and addiction), nonsteroidal analgesics (gastrointestinal ulcers, bleeding, stroke, and myocardial infarction), or disease-modifying drugs (steroids and biologicals, see Chapters 59 and 63) [125,150].

34.3.3 Translation of Basic Research into Clinical Applications

Basic research on pain continues at a rapid pace, but its translation into clinical applications has been difficult [151,152]. Many obstacles have been discussed, including overinterpretation of data, reporting bias toward neglecting negative results, and flawed design of experimental and clinical studies [137,152,153]. Animal studies are indispensable, continue to be improved, and have successfully predicted adverse side effects of drug candidates [151,153]. However, for ethical reasons, many models are restricted to days or weeks, while human chronic pain can last for months or years. Therefore, animal models do not mirror the truly chronic clinical situation and should be more cautiously termed as reflecting "persistent pain" [137,151,153,154].

Brain imaging is an area of intense research in patients with various pain syndromes, but such studies have not yet provided reproducible findings specific for a disease or a pathophysiological basis for individual syndromes [154]. Similarly, imaging opioid mechanisms in the human brain has been limited mostly to single-dose studies in healthy volunteers and has not substantially advanced our understanding of pain relief or opioid use in patients [155]. Neuroimaging can only detect alterations associated with nociceptive processes, whereas clinical pain encompasses a much more complex subjective experience that critically relies on self-evaluation. Thus, imaging cannot provide an objective proxy biomarker or predictor for pain [156].

Personalized pain therapy based on genetics is an attractive concept. The mu-opioid receptor gene *OPRM1* was among the first genes screened for functional relevance with regard to analgesia. The human single-nucleotide polymorphism (SNP) *OPRM1* 118 A>G is the most thoroughly investigated candidate to date. However, as emerged from meta-analyses, this SNP appears to be without major clinical relevance as a solitary variant [157,158]. Thus, although basic research has produced some evidence for a genetic control of pain, such findings are not expected to serve as a guide to individualized ("personalized") clinical pain therapy any time soon [154,159]. Nonetheless, efforts continue to find other genetic variants predicting analgesic efficacy and side effects [160–162].

34.4 Conclusions and Outlook

Pain is a symptom and an essential component of inflammation. Depending on the duration of pain, treatment must be tailored toward both pathophysiological mechanisms and individual needs of the patient. In keeping with the biopsychosocial concept, pain treatment comprises not only interventions or drugs but also physio- and psychotherapeutic strategies. Besides disease-modifying drugs (e.g., steroids and biologicals, see Chapters 59 and 63), the most widely used compounds are COX-inhibitors (see Chapter 68) and opioids. However, the long-term use of opioids in chronic nonmalignant pain has not proven effective and carries the risk of addiction, overdosage, and abuse [131,132,135]. Thus, it is crucial to select suitable patients and to consider alternative (e.g., nonpharmacological) therapeutic approaches.

Several avenues of research (e.g., peripheral opioid receptors, biologicals, and cannabinoids) are being pursued to find new treatment approaches reducing current risks. A field of intensive investigation is the endocytic trafficking and processing of opioid receptors in sensory neurons, particularly the influence of injury and the implications for tolerance development and efficacy and potency of opioid agonists. Furthermore, the recent flurry of studies on GPCR structures enables novel approaches to elucidate ligand-biased signaling and allosteric, oligo-, and heteromeric modulation of opioid receptor function. A recent example is the computer-assisted development of a novel opioid analgesic (NFEPP) that selectively activates peripheral opioid receptors in injured (inflamed) but not in noninflamed tissues (brain, intestinal wall), thereby precluding adverse side effects such as respiratory depression, addiction potential, motor disturbance, and constipation [49]. Whether genetic or epigenetic variations in opioid receptor expression play a significant role in clinical efficacy of opioid analgesics needs further investigation [64]. For example, species differences in the expression of GIRK channels and opioid effects on DRG neurons have been demonstrated, raising questions about the most suitable animal species to model humans [69].

In addition, the role of leukocytic opioid receptors in pain modulation needs to be explored further [101]. An area that has not received much attention is the influence of opioids on inflammation and wound healing. Although there is ample evidence of beneficial effects from basic research, clinical studies are lacking to date [104]. Similarly, clinical studies on the augmentation of effects of endogenously released opioid peptides by inhibiting their degrading enzymes are needed [55,119].

The epidemic of opioid misuse in chronic pain illustrates the persistent problems resulting from nonselective activation of ubiquitous opioid receptors throughout central and peripheral compartments. Thus, the potential of peripheral actions is increasingly recognized by researchers and clinicians [51,55,59,126,128,144,147]. Peripheral opioid receptor activation can reduce pain and inflammation, while avoiding sedation, respiratory depression, addiction, and adverse effects typical of biologicals, steroids, and nonsteroidal analgesics [49,50]. Beyond the described ongoing efforts, technology-oriented research (e.g., nanocarriers) is needed to find novel approaches to peripheral restriction of opioids [50]. For oral application, such compounds should be able to penetrate the gastrointestinal but not the blood–brain or placental

barriers [163]. For topical application, they should sustain slow release of the active drug. Manipulating the perineurium of peripheral sensory neurons is another interesting approach [84,85]. In contrast to available anti-inflammatory agents (steroids, NSAIDs, and biologicals) or local anesthetics, peripherally acting opioids carry little risk for organ toxicity or infection, making them interesting candidates for development of novel drugs and formulations with a wider benefit to risk window.

Inflammation, Hormones, and Metabolism

Muska Khpal and Mervyn Singer

University College London, Bloomsbury Institute of Intensive Care Medicine, Gower St, London WC1E 6BT, UK

35.1 Introduction

Inflammation is usually a self-limiting and protective response to infection or tissue damage. However, dysregulated inflammation can progress to multiorgan dysfunction and, ultimately, death. Precise pathophysiological mechanisms remain elusive [1] due in part to the immense complexity of the host response, with variation in the presentation, progression, and response to treatment. There is considerable cross-talk between neuroendocrine and immune systems [2]. They regulate each other and share common receptors, peptide signaling, and functional pathways. Immune function is controlled through the hypothalamic-pituitary–adrenal, –gonadal, and –thyroidal axes [3], the renin–angiotensin–aldosterone system, and adipokines [4,5]

Another aspect of the interaction between metabolism and inflammation is the requirement for an adequate energy supply. Some immune cells rely to a greater extent on oxidative metabolism, whereas others, such as neutrophils, are more glycolytic in nature. These metabolic differences influence the expression of cytokines and, ultimately, the immune response.

This chapter will describe hormonal influences on the immune response, and the influence of bioenergetics on metabolism in immune cell function.

35.2 Thyroid Hormones

Thyroid hormones play critical roles in metabolism and immune regulation [6–8]. Thyroxine (T4; 3,5,3′,5′-tetraiodothyronine) constitutes approximately 90% of the circulating thyroid hormone; the remainder is the much more biologically active T3 (3,5,3′-triiodothyronine) [7]. Only a small proportion (0.03% of T4 and 0.3% of T3) is nonprotein bound, determining activity. Regulation is by negative feedback involving TRH, TSH, and thyroid hormones themselves [8]. During acute illness, hormone levels fluctuate, relating to both severity and duration of

Inflammation: From Molecular and Cellular Mechanisms to the Clinic, First Edition.

illness. In severe or prolonged illness, T3, T4, and TSH fall while reverse (inactive) T3 rises [7]. This "sick euthyroid" or "nonthyroidal illness" (NIST) syndrome relates to a poor prognosis.

35.2.1 Macrophages

Thyroid hormones influence macrophage function by regulating chemosis, phagocytosis, and production of inflammatory markers and reactive oxygen species (ROS). Hypothyroid rats demonstrated increased phagocytosis and ROS release upon administration of *Streptococcal* cell wall [9], while the reverse was true for T4-induced hyperthyroid rats [10]. However, murine peritoneal showed no effect from T3 incubation but increased phagocytosis on incubation with T4 [11]. Supplementation of T3 or T4 enhanced phagocytosis in mice given *Neisseria meningitides* by increasing macrophage binding to bacteria and increasing their bacteriocidal ability [12]. T3 administration to mice induced unpolarized macrophages to display an M1 phentoype, as revealed by expression analysis of surface proteins, gene markers, and cytokine release in response to Toll-like receptor (TLR) ligands including lipopolysaccharide (LPS) and interferon (IFN)-γ [13]. Anti-inflammatory M2 activation was reversed [13]. In rat Kupffer cells, high doses of T3 increased proinflammatory functions, including the respiratory burst, nitric oxide synthase activity, and tumor necrosis factor (TNF)-α expression [8].

35.2.2 Neutrophils

Thyroid hormones increase neutrophil bacteriocidal activity by stimulating cytochrome P450, myeloperoxidase and NADPH oxidase to increase superoxide generation [14,15]. Oxidative injury is normally limited via superoxide dismutase (SOD) activity that converts superoxide to hydrogen peroxide. Thyroid hormones, particularly T3, regulate SOD-1 activity and thus oxidative stress [16]. Neutrophils from patients with low T3 levels had impaired phagocytosis [17]. TSH administration increased neutrophil phagocytic activity within the reticuloendothelial system [18].

35.2.3 Natural Killer Cells

Thyroid hormones have a biphasic action on natural killer (NK) cells; low dietary levels of T3 enhanced IL-2 receptor expression, whereas higher levels decreased expression [19]. This may be due to cellular apoptosis, decreased receptor expression, or loss of cellular membrane components [20]. Intraperitoneal thyroxine enhanced murine NK cell activity without increasing IFN-γ; however, *in vitro* administration of thyroxine with IFN markedly enhanced NK activity [21].

35.2.4 Lymphocytes

Hypothyroidism induces splenic and lymph node involution and impairs humoral and cell-mediated immune responses [22] These effects are reversible with

thyroid hormone [23]. Hyperthyroid states may, however, enhance or suppress primary antibody responses and T and B lymphocyte proliferation [22,23]. T4 promotes IgM production in mice and stimulates the humoral response to *Salmonella typhi* [8]. In aged mice, T4 treatment promotes cellularity of thymus, spleen, lymph nodes, and bone marrow, increases peripheral blood leukocyte numbers and T lymphocyte mitogenesis, and enhances phagocytic function of peritoneal exudate cells [24]. T lymphocytes cultured with T3 and T4 also demonstrate increased apoptosis and ROS production [25]

35.3 Steroid Hormones

Activation of the hypothalamic–pituitary–adrenal (HPA) axis induces hypothalamic CRH release into the hypophyseal portal blood supply [26]. Centrally secreted CRH has an indirect anti-inflammatory effect via release of glucocorticoids (GCs), while peripherally secreted CRH has a direct proinflammatory action [27,28]. Central CRH stimulates pituitary ACTH (adrenocorticotropic hormone) release that, in turn, induces expression of GCs, mineralocorticoids, and androgenic steroids. GCs regulate metabolic processes and both innate and adaptive immune responses including cell-mediated lytic activities and cytokine production by monocytes/macrophages, T lymphocytes, and NK cells. GCs bind to specific DNA motifs and alter expression of transcription factors [29]. They either regulate activation of target genes by direct protein–protein interactions with transcription factors such as NF-κB [30] or act synergistically with PPAR-γ and PPAR-α to suppress NF-κB- and IRF-3-dependent target genes [31]. Proinflammatory cytokines are suppressed, while anti-inflammatory cytokines are upregulated [32]. Aldosterone also activates immune responses [33], expression of NADPH oxidase (which increases production of superoxides and ROS in vascular tissue), and secretion of mediators such as prostaglandins and vascular endothelial growth factor [34].

35.3.1 Macrophages

CRH increases secretion of proinflammatory cytokines and ROS in macrophages [35,36], an effect mediated by TLR-4 [37]. A combination of ACTH and IFN-γ reduced monocyte cytotoxicity that could be reversed with substance P [38]. GCs modulate leukocyte function at different levels including gene expression, enzymatic activity, and cellular migration. GCs repress expression of proinflammatory cytokines, chemokines, inducible nitric oxide synthase (iNOS), and COX-2 [30,39]. While these reduce oxidative stress and phagocytotic activity, macrophage function may be enhanced at low corticosterone concentrations [40]. GCs prevent leukocyte migration and accumulation at inflammatory sites due to decreased CCR-7 expression [41]. Aldosterone can induce inflammation by decreasing expression of glucose-6-phosphate dehydrogenase that reduces $NADP^+$ to NADPH and increases NF-κB activation [42]. This, in turn, increases production of adhesion molecules, chemokines and proinflammatory cytokines [43]. Macrophages possess mineralocorticoid receptors,

expression of which increases in response to IFN-γ secreted by T lymphocytes. Aldosterone treatment increased cardiac expression of adhesion molecules, COX-2, osteopontin, and MCP-1 and promoted inflammatory arterial lesions with perivascular macrophages [44].

35.3.2 Neutrophils

GCs increased blood neutrophils by impairing endothelial cell adhesion and migration to inflammatory sites by reducing neutrophil attractants and suppressing endothelial adhesion molecules [45–47]. Aldosterone upregulated proangiogenic factors produced by neutrophils (e.g., VEGF-A) in a dose- and time-dependent manner [46,47].

35.3.3 NK Cells

GCs adversely affected NK cell activity [48]; however, chronic GC treatment increased IFN-γ and IL-6 levels via histone acetylation [49].

35.3.4 Lymphocytes

CRH induced IL-2 receptor expression and chemotaxis of mononuclear leucocytes to inflammatory sites [36] and stimulated lymphocyte proliferation and secretion of IL-1 and IL-2 [50,51]. GCs caused lymphopenia by inducing apoptosis and synthesis of nonlysosomal endonucleases [52] and reduced proliferation and activation of lymphocytes by directly inhibiting IL-2 and IL-2 receptor production [45]. GCs also suppress production of IL-12, the main inducer of Th-1 responses, thereby leading to a Th-2 shift. GCs also upregulated Th2-induced production of anti-inflammatory cytokines [53], reduced splenic and lymph node B-cell numbers, attenuated B-cell progenitor proliferation, and suppressed IgG production [54,55]. On the other hand, GCs can exert an immunostimulatory response, for example, induction of acute-phase proteins, enhancement of delayed-type hypersensitivity responses, and stimulation of T-cell mitogenesis [40,49].

35.4 Sex Hormones

Sex hormones such as progesterone, estrogen, and testosterone play key physiological roles in reproduction, inflammation, and metabolism [56]. These regulate activity of various immune cells including lymphocytes, macrophages, granulocytes, and mast cells [57]. Sexual dimorphism in both humoral and cell-mediated immune responses is well documented. In general, postpubertal females are immunologically more active due to higher innate, antibody-mediated, and cellular responses [58,59]. Males are more susceptible to infections and have poorer outcomes [60]. Pregnancy increases susceptibility to infection due to reduced cell-mediated immunity. Autoimmune disease such as rheumatoid arthritis and multiple sclerosis may be ameliorated in pregnancy [61,62].

35.4.1 Macrophages

Testosterone reduces TLR-4 expression by macrophage/monocytes, thereby reducing the proinflammatory response [63]. Testosterone also inhibits NF-κB [64] and increases synthesis of anti-inflammatory cytokines such as IL-10 [65]. Estrogens enhance both cell-mediated and humoral immune responses. Estradiol increases the number of granulocyte progenitor cells [66] that contribute to resistance against infections by stimulating synthesis of proinflammatory cytokines while inhibiting anti-inflammatory cytokine production [67]. Low concentrations of estrogens enhance proinflammatory cytokine production in monocytes, while high concentrations reduce production [68]. Estradiol can also enhance TLR-4 expression on the surface of peritoneal macrophages and increase TNF-α production [69]. Progesterone is typically immunosuppressive; it inhibits TLRs, regulates miR-155 and NF-κB activation [70,71], and inhibits NO production in murine macrophages [72].

35.4.2 Neutrophils

Estrogen, progesterone, and testosterone either do [73] or do not [74] influence superoxide generation. Estrogen decreased production of neutrophil chemoattractants at inflammatory sites, with resulting decreases in neutrophil accumulation [75]. Similarly, estradiol limited release of the potent neutrophil chemoattractant CXL-8 from human monocytes *ex vivo* [76]. Estrogens limited neutrophil adhesion to activated endothelial cell monolayers under shear stress conditions, directly affecting neutrophil transmigration and tissue infiltration [75]. Estrogen also reduced proinflammatory mediator release from neutrophils [77].

35.4.3 NK Cells

Females have lower levels of NK cell activity [78], which declines even further during pregnancy [79]. High doses or prolonged administration of estradiol results in decreased NK cell number and activity [80]. However, low doses or short exposures had no significant effect [81]. Several reports indicate higher NK cell activity in men [82], while progesterone reduces NK cell activity [70].

35.4.4 Lymphocytes

Cell-mediated immune responses differ between genders. The T lymphocyte count is reduced in males, but no difference was seen in TH-1- or -2-mediated cytokine production [83]. There are currently no data available on any gender differences in B-lymphocyte count. Estrogens increase bone marrow progenitor B cells in mice by protecting them from apoptosis, inhibiting estrogen-mediated inhibition of suppressor T cells and increasing survival in splenic B cells [66]. *In vitro* studies suggest that estrogen increases immunoglobulin production in both sexes [84], whereas testosterone is inhibitory [85]. Androgens may suppress the proliferation of immature thymocytes, accelerate thymic apoptosis, and limit B-cell lymphopoiesis. Progesterone inhibits the TH-1 response

and proinflammatory cytokine production, while promoting TH-2 responses, including synthesis of anti-inflammatory cytokines [68,83]. Progesterone also suppresses antibody production [86].

35.5 Pituitary Hormones

35.5.1 Arginine Vasopressin

Arginine vasopressin (AVP) or antidiuretic hormone is a nonapeptide produced in the paraventricular and supraoptic nuclei of the hypothalamus, stored in axonal terminals, and transported to the pituitary gland where it is released on demand. AVP is a critical stress response hormone that increases rapidly in septic shock, but it then falls to inappropriately low levels relative to the degree of hypotension [87]. AVP is found in thymic epithelial cells and in B lymphocytes in rat spleen where its expression increases in adjuvant arthritis [88,89]. AVP binds to (i) V1a receptors to increase vascular tone and thus blood pressure, (ii) to V2 receptors to mediate its antidiuretic effect and to increase von Willebrand factor, and (iii) to V1b receptors in the central nervous system, the effects of which are unclear [87]. V1b may play a role in the acute response to stress. AVP and CRH have synergistic effects on the release of ACTH. V1b knockout mice have an impaired acute stress response because of a blunted ACTH response [90]. Proinflammatory cytokines downregulate V1a receptors in lung, liver, kidney, and heart [91]. AVP also decreases NF-κB activation and, subsequently, IL-6 levels [92]. AVP action on renal V2 receptors inhibited TLR-4 and NF-κB activation and downstream molecules in the collecting ducts of endotoxic rats [93]. AVP also regulates immune function using hypothalamic receptor systems.

35.5.1.1 Macrophages

AVP receptors are present on human PBMC [94]. AVP is reported to be both proinflammatory [95] and anti-inflammatory [96] in activated macrophages. It inhibits CD14 expression, which is essential for endotoxin binding by macrophages and thus NF-kB activation [96]. AVP also inhibits endotoxin-induced upregulation of MAP kinases and AP-1 [97] and can stimulate prostaglandin synthesis [98].

35.5.1.2 Lymphocytes

AVP is expressed in peripheral mononuclear cells including T and B cells [89,99]. AVP modulates helper signaling and activates T cells to increase IgM production, but it may be a negative regulator of B-cell receptor signaling [100,101]. V1a knockout mice have a shift in immunoglobulin balance from IgM (high)/IgD (high) to the more mature IgM (low)/IgD (high) expression in B cells [101].

35.5.1.3 NK Cells

Brattleboro rats with AVP deficiency have increased NK cell activity [87].

35.5.2 Prolactin

Prolactin (PRL) is a 24 kDa, single-chain peptide secreted by the anterior pituitary [102]. Prolactin has pronounced effects on growth, reproduction, and osmoregulation in many species. Within the immune system, PRL is produced by T and B lymphocytes, macrophages, thymocytes, mononuclear, and NK cells [103]. However, in PBMC, PRL production is mainly associated with the T lymphocyte fraction. PRL receptors are ubiquitously expressed by hematopoietic cells in murine thymus, spleen, lymph nodes, and bone marrow [104]. PRL modulates cells in the immune system by altering their potential to proliferate, differentiate, and/or undergo apoptosis [105]. PRL also activates the Janus family of tyrosine kinases and signal transducers, as well as transcription activators and cytokines [106].

35.5.2.1 Macrophages

In vitro treatment of murine peritoneal macrophages with PRL resulted in the production of cytokines, NO, and chemokines such as RANTES [107].

35.5.2.2 Neutrophils

PRL can stimulate neutrophils in a dose-dependent fashion [108].

35.5.2.3 NK Cells

Studies demonstrate both decreased NK cell activity in hyperprolactinaemia or no change [105]. Resting and the IL2-activated cytotoxic functions of NK cells were also depressed by high doses of PRL *in vitro* [105].

35.5.2.4 Lymphocytes

Pharmacological suppression of PRL impaired normal lymphocyte function and lymphocyte-dependent immune host defenses against Listeria and mycobacteria [109]. Lymphocytes can also produce a PRL-like protein that promotes lymphocyte proliferation [110]. In T lymphocytes, IL-2, IL-1β, and IL-4 could reduce PRL mRNA, while IL-10 and IFN-γ had no effect [111]. PRL can increase ornithine decarboxylase activity, an enzymatic step integrally involved in initiating the immune response [112]. PRL activates protein kinase C pathways and regulates expression of immunologically relevant genes such as C-myc and IFN regulatory factor-1 [113]. Hypoprolactinemic animals are deficient in mounting various B- and T-cell-mediated immune responses, while high PRL inhibits suppressor (CD8+) T cells [104].

35.6 Growth Hormone

Growth hormone (GH) is produced by the pituitary under stimulation by growth hormone-releasing hormone and inhibition by somatostatin [107].

35.6.1 Macrophages

Human mononuclear cells can synthesize GH and this appears to be directly involved in immune regulation [107]. GH acts on GH receptors on monocytes

and macrophages to increase proliferation [114]. GH primes phagocytes for enhanced production of ROS, hydrogen peroxide, and proinflammatory cytokines [107,115]. GH also decreases macrophage NF-κB activity [116]. *In vivo* studies demonstrated beneficial effects of GH and IGF-1 pretreatment on survival and bacterial killing capacity in animals challenged with infectious bacteria [117].

35.6.2 NK Cells

NK cell activity is decreased in GH-deficient patients but enhanced by IGF-1 [117].

35.6.3 Lymphocytes

Human lymphocytes synthesize and secrete GH and can bind IGF-1. IGF-1 aids the differentiation of lymphoid precursor cells, thymic T-cell progenitors, and bone marrow pro-B lymphocytes [117,118]. IGF-I also induces immunoglobulin production and proliferation of human plasma cell lines [119]. Human GH can act directly, increasing adhesion molecule binding by human T cells to murine matrix proteins *in vitro* [119]. GH increases trafficking and localization of T-cell progenitors from bone marrow to thymus. It can also directly promote immunoglobulin production and *in vitro* proliferation of human plasma cell lines [119].

35.7 Adipokines

Obesity is a growing epidemic in developed countries. Chronic energy overload leads to cellular damage by mitochondrial dysfunction, endoplasmic reticulum stress, and ROS production. This leads to a chronic state of inflammation known as meta-inflammation [120]. The link between obesity and inflammation was first established when a positive correlation was found between adipose mass and TNF-α expression [121]. Adipose tissues are a heterogeneous group of adipocytes, stromal preadipocytes, immune cells, and endothelium [122]. White adipose tissue (WAT) acts as an endocrine organ that stores fat and produces several adipokines such as adiponectin, leptin, resistin, and visfatin, cytokines (such as TNF-α, IL-1, and IL-6), mediators of clotting such as PAI-1, and certain complement factors [123]. Brown adipose tissue (BAT) is the site of nonshivering thermogenesis [124]. Nutritional excess, in particular consumption of a high-fat diet, can directly alter gut microbiota, increasing endotoxin-producing bacteria that can then activate TLRs and nucleotide-binding oligomerization domain-like receptors (NLRs). These detect damage-associated molecular patterns (DAMPs), increasing production of proinflammatory cytokines and recruitment of immune cells. NLRs can contribute to meta-inflammation by inducing inflammasome-dependent caspase-1 activity; this leads to maturation and further secretion of proinflammatory cytokines [125]. Another mechanism implicating adipocytes in meta-inflammation is the production of hypoxia-induced factors, which results from reduced oxygen tension in adipocytes. This may be due to adipocyte hypertrophy or an increased proportions of saturated fatty acids, increasing

oxygen consumption due to uncoupling of mitochondrial respiration away from ATP production. Compromised adipose tissue vascularization, thereby restricting oxygen availability, is a further mechanism [126]. Changes in oxygen tension are detected by HIF-1α that, in turn, increases chemokine and leukotriene B4 production by adipocytes, macrophages, and endothelial cells.

35.7.1 Leptin

Leptin, a 16 kDa pleiotropic protein encoded by the obese gene (Ob) [127], belongs to the type I helical cytokine family, which also contains growth hormone, prolactin, oncostatin M, and cytokines such as IL-6, IL-12, and IL-15 [128,129]. Leptin is mainly produced by white adipose tissue in proportion to body fat mass [130]. Immune cells such as monocytes express mRNA for the ObRa and ObRb isoforms of the leptin receptor, while neutrophils express mRNA for the ObRa isoform only [131]. Activation of the ObRb by leptin sets off a cascade of intracellular signal transduction pathways [132,133]. Leptin deficiency is associated with impaired cell-mediated immunity, an increased incidence of infectious disease, and an associated increase in mortality [131].

35.7.1.1 Macrophages

Leptin promotes phagocytosis and production of leukotriene B4, COX2 and nitric oxide. It is a chemoattractant, increasing secretion of cytokines and chemokines [128,134]. Leptin increases proliferation of circulating cells and reduces apoptosis in a dose-dependent manner [135]. Leptin also increases the expression of monocyte surface markers such as HLA-DR, CD11b, and CD11c [136].

35.7.1.2 Neutrophils

Leptin is a neutrophil chemoattractant, inducing chemotaxis without causing cell activation [137]. The ObRa activates p38/MAPK pathway and SRC kinases without JAK2/STAT3 activation, and it can induce neutrophil locomotion [131] and ROS production [128,138].

35.7.1.3 NK Cells

Leptin is involved in all processes of NK cell development, differentiation, proliferation, activation, and cytotoxicity [128,136]. NK cells express both ObRa and ObRb. STAT3 influences NK cell cytotoxicity by transcription of genes encoding IL-2 and perforin [128]. Leptin also mediates activation of NK cells indirectly by modulation of proinflammatory cytokines by monocytes and macrophages [136].

35.7.1.4 Lymphocytes

Leptin maintains thymic parenchyma via direct antiapoptotic effects on T cells through stimulating expression of IL-7, a thymocyte growth factor [135]. Lymphocytes express ObRb receptors; leptin binding increases secretion of proinflammatory cytokines via JAK2/STAT3 and p38/MAPK/ERK1/2 pathways. Leptin inhibits memory T-cell proliferation and stimulates naïve T-cell proliferation, exacerbating the inflammatory response. Leptin polarizes naïve T-cell

cytokine production toward a proinflammatory phenotype [135] and increases expression of adhesion molecules, for example, ICAM-1 [128].

35.7.2 Adiponectin

Adiponectin is produced mainly by adipocytes and also by skeletal muscle, cardiac myocytes, and endothelial cells [123,124,139]. Adiponectin acts on AdipoR1, AdipoR2, and T-cadherin receptors; AdipoR1 is found ubiquitously, whereas AdipoR2 is commonly found in the liver [140].

35.7.2.1 Macrophages

AdipoR1 and AdipoR2 are expressed in macrophages. AdipoR1 is more abundant initially and decreases upon differentiation into mature macrophages, whereas AdipoR2 remains constant [141]. On LPS stimulation, adiponectin suppresses expression of T lymphocyte chemokines [142], reducing macrophage differentiation, migration, and phagocytosis [123]. Adiponectin switches the macrophage phenotype from (M1) to the anti-inflammatory, alternatively activated M2 [143]. Adiponectin also enhances the ability of macrophages to remove early apoptotic bodies, crucial in preventing inflammation and immune system dysfunction. Adiponectin also reduces induction of ICAM-1, VCAM-1, E-selectin, and IL-8 [144].

35.7.2.2 Dendritic Cells

Adiponectin reduces expression of major histocompatibilty complex class II, CD80 and CD86, and production of IL-12/p40, but increases expression of the inhibitory programmed death-1 ligand (PDL-1) [145]. Activation of AdipoR1 receptors stimulates IL-10 production via AMPK and p38/MAPK pathways; IL-10 promotes further anti-inflammatory actions that are dependent on STAT3 and SOCS3 pathways [146]. Stimulation of these pathways inhibits NF-κB activation, thereby attenuating DC ability to stimulate antigen-specific T-cell responses.

35.7.2.3 NK Cells

NK cells preferentially express AdipoR1, but they can express both types either on the cell surface or intracellularly. Adiponectin also inhibits TLR ligand-induced IFN-γ production, but has no effect on degranulation or cytotoxicity [139].

35.7.2.4 Neutrophils

Adiponectin exerts anti-inflammatory effects by inhibiting production of superoxide and chemokines [147] and decreasing phagocytosis [148].

35.7.2.5 Lymphocytes

All lymphocytes secrete small amounts of adiponectin, whether they are dormant or activated [149]. This can induce significant inhibitory effects on hematological precursors leading to neutropenia [149]. Adiponectin acts on mice splenocytes to inhibit T-cell proliferation and cytokine production [150]. In humans, it also affects apoptosis [151]. Adiponectin promotes $CD4^+$ T cell differentiation toward

a TH-1 lineage, through activation of p38/MAPK and STAT4, and induction of T-beta [152].

35.7.3 Ghrelin

Ghrelin is mainly secreted from the oxyntic mucosa cells in the stomach, though small quantities are expressed by immune cells [153]. Ghrelin levels are increased by fasting, low BMI, and by hormones such as leptin, GHRH, thyroid hormones, testosterone, and parasympathetic activity [154,155], and disease states such as cancer-induced cachexia, renal failure, and sepsis [118,156,157]. In inflammatory diseases, ghrelin expression correlates with disease severity and sequelae. The physiological functions of ghrelin include control of energy homeostasis [158], promotion of adipocyte survival, differentiation and metabolism [159], cardioprotection [160], and skeletal muscle regeneration [161]. The function most relevant to this chapter is its potent anti-inflammatory action on lymphocytes, monocytes, and dendritic cells (DCs) [162,163]. Ghrelin, via GHS-R1a, reduces mortality and attenuates the inflammatory effects of LPS [164,165].

35.7.3.1 Macrophages

Monocytes are the main targets of the anti-inflammatory action of ghrelin [164]. Ghrelin inhibits oxidative stress, cellular apoptosis, cell adhesion, and proinflammatory cytokine expression [162–164]. Tissue macrophages only express the GHS-R in inflammatory conditions [166]. Ghrelin reduced stress-induced increases in phagocytic activity via inducible NO synthase [167]. Delayed administration of ghrelin had a protective effect in endotoxemia and sepsis by decreasing the secretion of high-mobility group box 1 (HMGB1) [168].

35.7.3.2 NK Cells

In septic mice, ghrelin increased NK cell recruitment [169]. Beneficial effects occurred within 24 h, with the reverse occurring thereafter, leading to diminished cellular defenses against bacteremia and reduced survival.

35.7.3.3 Neutrophils

Ghrelin suppressed neutrophil accumulation and production of the neutrophil chemoattractant IL-8 plus TNF-α and MPO in airways of patients with chronic respiratory infections [163]. Ghrelin also decreased adhesion molecule expression on vascular endothelial cells [170]. These effects reversed after 24–48 h with suppression of the anti-inflammatory response [169].

35.7.3.4 Lymphocytes

The GHS-R, acetylated ghrelin, and GH levels decline with progressive thymic aging [171]; this was partially reversed by administration of acetylated ghrelin in aged mice. Ghrelin infusions increased progenticor cell numbers in the bone marrow and thymus [172]. This was associated with improved peripheral TCR diversity of both CD4+ and CD8+ T cells [172]. Caloric restriction promoted a rise in ghrelin levels, correlating directly with greater T-cell output [173].

35.7.4 Other Adipokines

35.7.4.1 Resistin

Resistin belongs to a family of secretory proteins, called resistin-like molecules (RELMs) or found in inflammatory zone (FIZZ). RELM-α (FIZZ1) is present mainly in adipose tissue, RELM-β (FIZZ 2) in the gastrointestinal tract and tumors, while RELM-γ is found in hematopoietic tissue where it has cytokine-like functions [174,175]. Mouse resistin is highly expressed in WAT by macrophages and monocytes, while human resistin is expressed predominantly in bone marrow [175].

The role of resistin in inflammation is not completely understood; however, elevated levels are seen in both septic and nonseptic critical illness and other inflammatory conditions [176,177]. Human resistin is predominantly expressed in macrophages and neutrophils [178], and in human adipose tissue mainly by nonadipocyte-resident inflammatory cells [179]. Expression and secretion of resistin by monocytes is induced by inflammatory stimuli and cytokines [176,180,181]. Resistin drives expression of cell adhesion molecules, matrix metalloproteinases, and pentraxin-3, which promote endothelial cell–monocyte adhesion and infiltration [182]. Resistin impairs the ability of dendritic cells to uptake antigens and produce proinflammatory cytokines [183], and the effector function of T cells, such as proliferation and differentiation into TH-1 cells [183]. Resistin indirectly induces expression of FoxP3, a key regulator of the development of regulatory T cells in PBMCs [183]. Resistin inhibited PMNL chemotaxis in uremic patients and decreased the oxidative burst to *Escherichia coli*, but did not influence phagocytosis of opsonized *E. coli* [184]. The exact role and mechanism of resistin in inflammation, however, remains elusive

35.7.4.2 Visfatin

Visfatin is an adipokine that modulates insulin activity by binding to the insulin receptor [185]. Visfatin is upregulated in acute lung injury, sepsis, trauma, and other conditions [186]. During inflammation, visfatin levels increase in immune cells such as macrophages, DCs, neutrophils, and lymphocytes [187]. Proinflammatory cytokines increase visfatin levels via NF-κB- and AP-1-dependent mechanisms [188]. In turn, visfatin upregulates proinflammatory cytokines in PBMCs and CD14+ monocytes [188]. Visfatin also induces expression of cell adhesion molecules, metalloproteinases-2 and -9, and monocyte atttractant protein-1 [186,189]. Visfatin inhibits neutrophil apoptosis and prolongs neutrophil survival in sepsis [190]. Visfatin also stimulates pre-B lymphocyte activation and increases expression of CD80 and CD40 in monocytes [188]. These provide important signals that augment and sustain T-cell responses. Visfatin affects primary lymphocyte responses by causing a dose-dependent proliferative response in monocytes [188]. Visfatin induces granulocytic differentiation of CD34+ hematopoietic progenitor cells through sirtuin activation and G-CSF upregulation. Visfatin also acts as a potent chemotactic factor, particularly for CD14+ monocytes and CD19+ B cells [188].

35.8 Melanocortins

Melanocortins – including α-, β-, and γ-melanocyte-stimulating hormone (MSH), and adrenocorticotropic hormone – are involved in several physiological functions, including inflammation and immunomodulation [191] and energy homeostasis [192]. The MC1 and MC3 melanocortin receptors play a role in immune regulation and may be expressed by several immune cells including neutrophils, monocytes, dendritic cells, and B lymphocytes [193,194]. The MC5 receptor also has immunomodulatory effects in B lymphocytes and mast cells [195,196]. Melanocortins, in particular α-MSH, can inhibit in various inflammatory conditions, for example, experimental bowel disease [197], brain inflammation [198], and ischemia [199].

35.8.1 Macrophages

Melanocortin receptors (MCRs), especially MC1, MC3, and MC5 are found on several macrophage cell lines [200]. Addition of α-MSH to monocytes significantly reduced proinflammatory cytokine release [201] and upregulated anti-inflammatory factors [202,203]. α-MSH reduced expression of CD86 and CD40 on monocyte-derived DCs [204] and is also involved in the inhibition of chemotactic migration of neutrophils [205]. *In vivo* α-MSH reduced endotoxin-induced liver cell infiltration by macrophages and neutrophils [201].

35.8.2 NK Cells

Intracerebroventricular administration of α-MSH, which blocks many IL-1 effects, significantly blunted shock-induced suppression of both T lymphocyte proliferation and NK cytotoxicity [206].

35.8.3 Neutrophils

In addition to the above effects, exogenous α-MSH administration inhibited cytokine-induced chemotaxis via a direct effect on MC1 receptors [207].

35.8.4 Lymphocytes

B lymphocytes express MC1 and MC3 receptors, while T lymphocytes express no MCRs [208]. α-MSH suppressed antigen-stimulated lymphocyte proliferation, specifically the anti-CD3/CD28-induced proliferation of spleen cells and CD4+CD25 T lymphocytes [209]. α-MSH also downregulated CD86, a major T-cell costimulatory molecule, in LPS-stimulated monocytes [203].

35.9 Neuropeptide Y

Neuropeptides act as neurotransmitters, hormones, and paracrine factors involved in control of all components of the immune system. Examples of

neuropeptides include calcitonin gene-related peptide, substance P, adrenomedullin, and neuropeptide Y [210]. Neuropeptide Y (NPY) is the most abundant and widely distributed neuropeptide present in the mammalian central and peripheral nervous system. NPY influences the regulation of multiple physiological and psychological processes, including energy homeostasis [211] and neuroendocrine secretion [212]. NPY treatment prolonged survival in endotoxemic rats [213].

35.9.1 Macrophages

NPY binds to Y1, Y2, and Y5 receptors on macrophages to increase adhesion, chemotaxis, phagocytosis, and production of cytokines and superoxide anions [214,215]. However, in old mice, NPY decreases chemotaxis and phagocytosis [215]. High cAMP and low PKC correlate with a decrease in chemotaxis and phagocytosis [214,216].

NPY administration inhibited IL-6 release from splenic macrophages; this was potentiated by norepinephrine but reversed by the β-agonist, isoproterenol [217]. NPY thus induces either an increase or decrease in cAMP formation depending on the catecholaminergic pathway activated [217]. NPY increased *ex vivo* production of pro-inflammatory cytokines from healthy volunteer blood samples [218] but decreased TNF-α release in response to LPS, and IL-1β and IL-2 release in response to concavalin A in murine peritoneal macrophages [214]. NPY directly increased ROS release in murine peritoneal monocytes [219,220].

35.9.2 NK Cells

NPY inhibits NK cells activity directly in an age- and dose-dependent manner [221,222]. Increased sympathetic activity and elevated NPY levels correlate with reductions in NK cell activity [222].

35.9.3 Neutrophils

Human neutrophils have a low-level presence of NPY receptors [223]. NPY stimulation inhibited phagocytosis through activation of the Y5 receptor-potentiated ROS production [223]. NPY modulated the fMLP-evoked respiratory burst in a dose-dependent manner [224]. NPY also influences the adhesion abilities of leukocytes in a time- and dose-dependent manner via activation of Y2 receptors [223,225,226].

35.9.4 Lymphocytes

NPY attenuated LPS-induced alterations of T lymphocytes by specifically modulating trafficking patterns [225]. NPY elevates IL-4 and reduces IFN-γ production in splenic lymphocytes [227]. *In vitro* studies show a shift toward TH-2 cells by NPY stimulation [227,228]. NPY thus alters the commitment of T-helper cells to a specific phenotype, leading to potentially altered immune function *in vivo* [228].

35.10 Orexin

Orexins are neuropeptides of which there are two isoforms, orexin A (hypocretin-1) and orexin B (hypocretin-2) [229,230]. Orexin A is suppressed by bacterial LPS and by TNF, which, in turn. reduces food intake and causes lethargy [231,232]. In murine sepsis, orexigenic activity was decreased within the hypothalamus [233].

35.10.1 Macrophages

Orexins modulate peritoneal macrophage function, with Orexin B being more potent. They also activate phagocytosis of mouse peritoneal macrophages [234].

35.10.2 Neutrophils

Orexin A decreases ischemia-reperfusion-induced lipid peroxidation and myeloperoxidase activity, an index of neutrophil infiltration [235]. Endogenous orexin A has a suppressor effect on inflammatory processes by modulating production of free radicals and cytokines that, in turn, attenuate leukocyte infiltration or direct tissue damage [235,236].

35.11 Bioenergetics + Metabolism

Cellular energy metabolism is a crucial part of the machinery that ensures proper functioning of immune cells [237] Mitochondria play the principal role in providing sufficient energy in most cells, in addition to their vital functions in heme and steroid biosynthesis, cell cycle regulation, apoptosis, calcium signaling, and redox homeostasis and signaling. Induction of an inflammatory response may lead to mitochondrial dysfunction via several mechanisms including direct inhibition and/or damage by reactive oxygen and nitrogen species and an overall decrease in mitochondrial biogenesis including decreased expression of genes encoding for the mitochondrial electron transport chain, yet an increase in uncoupling proteins [238],

Consistent with their evolutionary origin as probacteria, DNA from mitochondrial represents a source of mitochondrial DAMPs, which also activate pattern recognition receptors (PRRs). Proinflammatory mediators may initially increase mitochondrial membrane potential, Ca^{2+} buffering capacity and resistance to apoptotic signaling. However, prolonged exposure increases ROS production leading to further oxidative stress and cell damage [239].

35.11.1 Dendritic Cells

DC immunogenicity is positively influenced by PRRs and negatively by signals that prevent DC activation and full functional maturation. The anti-inflammatory transcription factor PPAR-γ is a negative regulator of DC maturation and function; it profoundly inhibits IL-12 expression and inhibits DC capacity to prime naive CD4+ T cells *in vitro* [240]. Resting DCs derive ATP predominantly

from oxidative phosphorylation within their mitochondria; however, activation by inflammatory mediators shifts this to a greater dependence on glycolysis [241]. This shift provides the additional energy required for DC activation and cytokine production [241]. This process involves signaling through PI3 K/Akt [242].

35.11.2 Macrophages

PPAR-γ is also expressed by macrophages and T cells, where it inhibits macrophage activation and the production of monocyte inflammatory cytokines [240]. In addition, hypoxia-inducible factor-1 (HIF-1) plays an important role in the commitment to glycolysis by orchestrating the decision to commit pyruvate to either acetyl-CoA or lactate [243]. Macrophages contain high levels of HIF-1α as they often reside at sites of low oxygen tension. HIF-1α, which is also induced by TLR agonists and proinflammatory cytokines, promotes glycolysis that is essential for macrophage activation [244]. The polarization of macrophages into its two functional states (M1 and M2) is influenced by its bioenergetic state: M1 macrophages possess higher glycolytic activity, which is required to produce proinflammatory cytokines, while IL-4 activated M2 macrophages use oxidative glucose metabolism as their main metabolic pathway to provide a sustained source of energy for tissue remodeling and repair [245].

35.11.3 Neutrophils

Neutrophils also depend on glucose for ATP production via glycolysis; their rate of mitochondrial respiration is very low. This O_2-independent mechanism for ATP generation is beneficial in that it allows neutrophils to function at inflamed or infected sites where local O_2 tensions may be very low [246]. Upon activation by TLR agonists, or phagocytosis of antibody-coated particles, neutrophils use large quantities of molecular oxygen to generate O_2^- and other oxidants via a respiratory burst catalyzed by NADPH oxidase [246]. The presence of nonfunctional mitochondria may lead to the loss of mitochondrial membrane potential that, in turn, may release cytochrome C and initiate apoptosis [247]. However, under inflammatory conditions such as sepsis, neutrophil apoptosis is delayed [190]. Leukocytes exposed to endotoxin or isolated from septic patients showed both immunoparalysis and a generalized metabolic defect affecting both glycolysis and oxidative metabolism that were restored on patient recovery [248]. Neutrophil mitochondria maintain their membrane potential through the glycerol 3-phosphate shuttle, a pathway that allows receipt of electrons from glycolysis by complex III of the electron transport chain to simultaneously contribute to redox balance and avoid apoptosis [242].

35.11.4 Lymphocytes

In vitro inhibition of mitochondrial oxidative phosphorylation or glycolysis diminished T-cell proliferation, indicating that mitochondrial metabolism and glycolysis support T-cell proliferation [242]. Similarly, B-cell receptor activation is regulated by ROS and inactivation of receptor-coupled phosphates, allowing

activation of downstream signaling pathways. Plasma cells produce higher levels of phospholipids compared to naive B cells, and plasma cell differentiation is dependent on mitochondrial citrate conversion to acetyl-CoA and oxaloacetate in the cytoplasm [249]. In prolonged sepsis, the initial shift to glycolysis offers host defense through enhanced proinflammatory cytokine production [248]. Blocking mitochondrial activity diminished cytokine production and increased mortality from fungal infection.

Microenvironmental Regulation of Innate Immune Cell Function

Emily R. Watts, Eilise Ryan, Sarah R. Walmsley, and Moira K.B. Whyte

University of Edinburgh, MRC/University of Edinburgh Centre for Inflammation Research, Queen's Medical Research Institute, 47 Little France Crescent, Edinburgh, EH16 4TJ, UK

36.1 Introduction

The innate immune system is the first line of defense against invading pathogens. It has a dual role to provide initial control of the infection and to initiate an adaptive immune response. The lack of specificity of the mediators of the innate response mean that a balance must be struck between effective immunity without excessive "self" injury. It is becoming increasingly clear that the cells of the innate immune system have the capacity to fine-tune the response and that much of this tuning depends on the context in which cellular activation occurs. In this chapter, we will discuss the factors in the microenvironment that may regulate and augment the innate immune response.

The innate immune system consists of physical barriers such as epithelial layers and mucus in the airways, soluble factors such as the complement system, and cells such as neutrophils, macrophages, and dendritic cells. We will focus on the role of neutrophils and macrophages and on the coordinated response that they generate to infection or injury. This response depends on many factors in the environment including oxygen availability, availability and utilization of metabolites, pathogen factors, and host damage signals and is mediated via an array of inflammatory (and anti-inflammatory) mediators. Crucially, the balance of all of these factors will change throughout the course of the immune response and as we will see, the outcome of any immune response is highly context dependent (Figure 36.1).

Neutrophils are the most abundant leukocyte in the peripheral blood. In the steady state, only mature neutrophils are released from the bone marrow and their release into the bloodstream depends on a balance of retention signals and release signals as well as growth factor signals from other immune cells, such as dendritic cells and T cells. In sepsis, however, there is a dramatic recruitment of immature neutrophils from the bone marrow to the circulation ("left shift") [1]. The half-life of a circulating neutrophil is short (only a few hours) and, unusually, they undergo

constitutive apoptosis in the absence of activating stimuli. Neutrophils are rapidly recruited to areas of tissue injury. Monocytes and macrophages represent a diverse population of cells. Tissue macrophages (TM) are a heterogeneous population of cells with specific phenotypes and roles suited to their anatomical and physiological niche. They include Langerhans cells in the liver, alveolar macrophages in the lung, and microglial cells in the brain. Increasing evidence suggests that these cells are long-lived and are embryonically derived. They are able to self-renew, rather than recruiting replacements from the circulating monocyte population. Tissue macrophages have many roles, but predominantly they act as immune sentinels, surveying for infection or injury. Monocytes are released from the bone marrow and circulate in the peripheral blood. They are recruited to the sites of infection and inflammation and depending on other factors in the microenvironment can differentiate into activated macrophages with variable phenotypes.

The interactions between neutrophils and macrophages change dramatically over the course of infection: Tissue macrophages identify a pathogen or other danger signal. They, along with damaged tissue and endothelial cells, will produce proinflammatory cytokines and chemokines that recruit other immune effector cells, particularly neutrophils and circulating monocytes. Recruited neutrophils and monocytes, once activated, will carry out bacterial killing and generate inflammatory mediators that may result both in host cell damage and in pathogen eradication. Once the infection is cleared, rapid resolution of the inflammatory response is key in minimizing further host cell damage. Resolution of inflammation is increasingly recognized as an active and carefully coordinated process, not just a defervescence of the inflammatory response. Resolution requires apoptosis of the large population of infiltrating neutrophils and efferocytosis of these cells to safely remove them and their toxic granule contents from the site of injury. Resolution also requires the production of anti-inflammatory mediators such as lipoxins and a phenotypic switch in macrophage population with increased activation of the "anti-inflammatory" M2 macrophage population.

Through the action of neutrophils and monocyte/macrophages, the innate immune response is rapidly built up and, upon successfully completing its job, is carefully deconstructed without the release of harmful inflammatory products.

36.2 The role of Hypoxia in Regulating Innate Immune Cell Function

36.2.1 Physiological Response to Hypoxia

Cells of the innate immune system may function within a wide range of hostile environments. Both experimental models and clinical studies have confirmed profound hypoxia in a range of inflammatory and infective scenarios including colitis, arthritic joints, and pleural infection [2–5] (Figure 36.2).

For effective immunity, neutrophils and macrophages must, therefore, be adapted to function in these hypoxic environments. Cellular responses to hypoxia are predominantly mediated by a family of transcription factors called hypoxia-

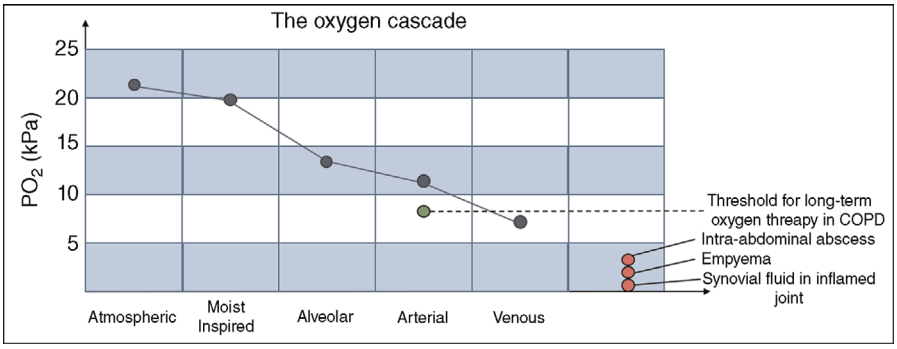

Figure 36.2 The oxygen cascade demonstrating levels of hypoxia under inflammatory conditions.

inducible factors (HIFs). The HIF consists of a heterodimer comprising a single constitutively expressed beta subunit (the aryl hydrocarbon receptor nuclear translocator, ARNT) and an α subunit whose oxygen-dependent degradation determines activity. To date, three α subunits have been identified, HIF-1α, HIF-2α, and HIF-3α corresponding to isoforms with distinct but overlapping activity. In its active form, HIF binds hypoxic response elements, upregulating transcription of genes with diverse functions required for adaptation to hypoxia including erythropoiesis, angiogenesis, glucose transport and metabolism, and control of proliferation and apoptosis. Hydroxylation of prolyl residues within the oxygen-dependent degradation domain (ODDD) of HIFα is catalyzed by a family of prolyl hydroxylases (PHD 1, 2, and 3, also called EGLN 2, 1, and 3 respectively). These 2-oxaloglutarate (2OG)-dependent hydroxylases have an absolute requirement for molecular oxygen, thus providing the "oxygen sensor" controlling HIF activity. Following hydroxylation, HIFα binds with increased avidity to the von Hippel Lindau protein (VHLp) that targets it for destruction through its E3 ubiquitin ligase activity. HIF activity is also regulated by the factor inhibiting HIF (FIH) that hydroxylates an asparagine residue in the HIFα subunit and thus prevents interaction with the cofactor p300 that is required for transcriptional activity. HIFα can also be stabilized by inflammatory factors such as LPS (a TLR-4 ligand) and plays a key role in linking hypoxia and inflammation.

36.2.2 Hypoxia and Innate Immune Cell Survival

Hypoxia has been shown to enhance neutrophil survival [6], mediated by HIF-1α-dependent NFκB activity [3]. The impact of hypoxia on monocyte/macrophage survival is more complicated. A number of studies in human and murine macrophage cell lines have shown hypoxia-induced apoptosis [7,8]. However, in both cell lines subpopulations of hypoxia-resistant macrophages were induced by either prolonged hypoxia or repeated cycles of hypoxia. Furthermore, studies of murine bone marrow-derived macrophages (BMM) show increased survival in hypoxia compared to normoxia when the survival stimulus CSF-1 was depleted [9]. In the same study, human monocytes also showed enhanced viability in hypoxia, but the same was not true of human monocyte-derived macrophages

(MDM s) that were able to survive in the absence of CSF-1 with no enhanced viability seen in hypoxia. These data suggest that hypoxia may have pro- or antiapoptotic effects on monocyte/macrophage populations and that this is context and cell-type specific. The role of HIF in mediating monocyte/macrophage hypoxic survival responses is also less clear than in neutrophils. Circulating monocytes show increased cytoplasmic levels of HIF-1α under hypoxic conditions, but there is no increase in nuclear HIF-1α levels until the cells are differentiated into MDMs [10] suggesting that monocytes may utilize alternative pathways to mediate hypoxic adaptation. This difference may reflect the usually adequate oxygen supply that monocytes experience in peripheral blood.

Clearly hypoxic survival is advantageous in that it allows these cells to function where they are most needed to avoid or minimize disseminated infection. In keeping with this, key innate immune functions are preserved under hypoxic conditions.

36.2.3 Chemotaxis in Hypoxia

In *in vitro* studies, neutrophil chemotaxis has been shown to be maintained or increased in hypoxia. Chemotaxis in response to formyl-Met-Leu-Phe (fMLP) and expression of key integrins LFA-1 and Mac-1 were found to be increased in hypoxia [11]. There was no shape change and chemotaxis in response to IL-8 was unchanged in hypoxia compared to normoxic conditions [12]. Preserved chemotaxis also seems likely *in vivo*; for example, inflammatory bowel disease mucosa is noted to have areas of marked hypoxia [13] and to have high numbers of infiltrating neutrophils. Monocytes and macrophages also migrate effectively to hypoxic areas. Hypoxia in macrophages leads to increased surface expression of CD11b/CD18 (Mac-1) [14], which may aid their ability to migrate into ischemic and inflammatory tissues. Hypoxia also alters endothelial cell expression of chemoattractants such as VEGF and endothelin [15], facilitating enhanced monocyte migration. Hypoxic sites such as tumors and inflammatory lesions have high numbers of myeloid-derived cells. Once monocytes have migrated to tissues, distinct differences in their cytokine profile are induced by hypoxia. These essentially upregulate cytokines that act on and attract neutrophils such as CXCL2, CXCL8, and CXCL5, while simultaneously retaining monocytes by downregulating chemokines that promote monocyte migration and motility, namely, CCL2(MCP-1), CCL8, and CCL23, among others [16]. While this change in profile of chemokines differs to some degree in macrophages compared to monocytes, upregulation of CXCL8 with simultaneous downregulation of CCL2 has also been demonstrated in macrophages [17]. Variations in the expression of matrix metalloproteinases (MMPs) may also impact monocyte retention at sites of inflammation. MMPs degrade the extracellular matrix to facilitate immune cell migration and may be up- or downregulated by hypoxia depending on the cell type. MMP9 is expressed at lower levels in hypoxic human monocytes and this results in reduced migration toward CCL-2 [16]. MMP1, however, is upregulated in macrophages in hypoxia [18]. The body of evidence suggests that once monocytes have been attracted to the site of inflammation/hypoxia, certain key changes are induced by this environment to ensure their tissue retention.

36.2.4 Secretory Function in Hypoxia

Neutrophils undergo a carefully orchestrated process of secretion and degranulation in order to carry out their effector functions. This involves early mobilization of secretory vesicles whose contents include surface receptors, such as CD11b, CD16, and the fMLP receptor, and late mobilization of azurophillic granules whose contents are cytotoxic and include neutrophil elastase and myeloperoxidase. *In vitro* assessment of hypoxic neutrophils has shown preserved cell surface expression of CD11b, preserved IL-8 secretion, and enhanced elastase production in fMLP-stimulated neutrophils [12].

36.2.5 Phagocytosis in Hypoxia

This key immune cell function is highly adapted to cope under the stress of hypoxic environments and the phagocytic function of macrophages is increased in hypoxic conditions. Hypoxia improves not only the number of phagocytosing macrophages but also the quantity of particles ingested by each macrophage. Interestingly, this rate increases with time spent in hypoxia. This has been confirmed to be HIF dependent and studies suggest it relates to a combination of HIF-1α and p-38 MAPK activity [19]. Neutrophil phagocytosis depends on expression of cell surface receptors including CD11b and CD16. As detailed above, the expression of these receptors is maintained in hypoxia. Furthermore, studies of human neutrophils cultured in hypoxia show a significant increase in the uptake of heat-inactivated *Streptococcus pneumoniae* compared to those cultured in normoxia [20]. Using flow cytometry, phagocytosis of *Escherichia coli* [11] was also found to be unchanged in hypoxia compared to normoxia. Innate immune cells, therefore, demonstrate enhanced or at least maintained phagocytosis in hypoxic environments.

The role of the hypoxic signaling pathways is highlighted by the study of neutrophils from patients with mutations in the VHLp that would normally target HIFα for degradation. Neutrophils from these patients demonstrate enhanced phagocytosis in normoxia equivalent to the effect of hypoxia on healthy control neutrophils. In macrophages, silencing of PHD3 (and again subsequent increased HIFα activity) also results in increased phagocytosis [21].

36.2.6 Bacterial Killing

Bacterial killing is, however, less well preserved in hypoxia than other innate functions. The respiratory burst generated by NADPH oxidase is essential for the killing of certain bacteria. This multicomponent enzyme generates reactive oxygen species (ROS) through electron transfer from cytosolic NADPH to intraphagasomal O2. Oxygen is also required for the generation of reactive nitrogen species (RNS) that are part of the neutrophil and macrophage armory against pathogens. These ROS and RNS are highly toxic to invading pathogens. The critical importance of the NADPH oxidase is highlighted by the overwhelming infections that characterize the clinical course of patients with chronic granulomatous disease, in which there is a mutation in one of the components of

the NADPH oxidase. Given the requirement for molecular oxygen to generate ROS, it was predicted that hypoxia would limit the neutrophil's ability to generate an effective respiratory burst. This was confirmed in *in vitro* experiments that showed not only that hypoxic neutrophils had reduced capacity to generate intra- and extracellular ROS but also that this resulted in impairment of *Staphylococcus aureus* killing [12]. Killing of other pathogens, however, can occur independent of ROS activity as demonstrated by the preserved killing of *E. coli* in the study.

The reduction in ROS production may also impair bacterial killing by macrophages, but again this depends on the pathogen. There have been reports of improved *E. coli* bacterial killing in macrophage cell lines under hypoxic conditions *in vitro*, in a HIF-dependent manner [22]. However, *in vivo* experiments by Wiese *et al.* revealed impaired killing of *E. coli* and *S. aureus* in hypoxia. As would be expected, this was largely due to reduced NADPH oxidase and NO synthase activity [23].

The impact of hypoxia on neutrophil energetics and metabolism will be discussed later.

36.2.7 Antigen Presentation

While macrophages are key players in the innate immune system, they also have a major role interfacing between the innate and the adaptive immune responses. As professional antigen-presenting cells, their interaction with T cells is crucial in triggering adaptive immunity. Hypoxic macrophages have been shown to effectively interact with the TCR of CD8+ T cells and induce signal transduction to activate these cells.

Cellular adaptation to hypoxia may also play a role in inflammatory pathologies with prolonged inflammation leading to increasing tissue damage. Chronic obstructive pulmonary disease (COPD) is a chronic lung disease, most often related to cigarette smoking. It is characterized by chronic lung inflammation, recurrent infections, and local and sometimes systemic hypoxia. Both neutrophils and macrophages are implicated in this chronic inflammation and their persistence in COPD airways may be in part due to the alterations in their function in response to hypoxia. Neutrophil degranulation persists despite hypoxia, as detailed above, and this can lead to further tissue damage with neutrophil elastase being a well-recognized cause of lung damage in COPD [24]. Despite the evidence above that macrophage phagocytosis is preserved in the hypoxic environment, other factors including cigarette smoke, have been shown to have a deleterious effect on efferocytosis of apoptotic cells, resulting in failure of resolution [25]. We can see then that in some pathologies, the adaptations the innate immune system has evolved for hypoxia, which may be useful in the context of acute infection, can have deleterious effects over the longer term.

36.3 Metabolism and Nutrient Availability

The microenvironment plays a role in directing cellular metabolism in both macrophages and neutrophils with wide-ranging implications for immunity. In

addition to traversing a wide range of oxygen tensions, immune cells will also be exposed to highly variable availability of nutrients during their life span.

Many immune cells and tumor cells can carry out glycolysis even under conditions of oxygen availability, avoiding oxidative phosphorylation as their main route for ATP formation. In highly proliferative tumor cells and lymphocytes, this can be advantageous as it allows generation of the key components required for generation of a new cell [26]. Tissue resident macrophages are able to both proliferate and maintain their population in this way. Circulating monocytes are also able to proliferate but not to the extent of tumor cells or T cells as described. Activated macrophages and neutrophils are terminally differentiated with little or no capacity to proliferate. Despite this, monocytes, macrophages, and neutrophils are all able to carry out aerobic glycolysis. The benefits of this are twofold: not only does myeloid cell aerobic glycolysis make these cells well adapted to hypoxic environments but it also allows the cells to utilize metabolic intermediates and enzymes for other key functions. Both circulating neutrophils and monocytes change from relatively inert/inactive cells patrolling the body to highly active effectors of the immune response characterized by high rates of protein synthesis and membrane recycling that require generation of proteins and lipids. This is facilitated by the increased availability of metabolic building blocks achieved by alterations in metabolism [27]. The mammalian target of rapamycin (mTOR) is a key player in integrating metabolic and inflammatory signals to regulate innate immune cell function. The mTOR pathway may be activated by cytokines, growth factors, or TLR ligation. Activation results in active mTOR complexes (mTORc1 and 2) that in turn have wide-ranging effects on neutrophils and macrophages. mTORcs regulate translation and post-translational modifications, and the high number of new proteins generated early in macrophage activation is partially dependent on post-translational modifications mediated by PI3-K/mTOR activity. mTOR has been shown to activate HIF, PPARγ (peroxisome proliferator-activated receptor gamma) and MYC that in turn drives synthesis of lipids, proteins, and nucleic acids. mTORc1 is also able to sense amino acid and energy (i.e., ATP) levels and alter cellular metabolism accordingly.

In addition to their role in biosynthesis, it is becoming increasingly clear that metabolic enzymes and intermediates play key roles in modulating the innate immune response. As such, Krebs cycle intermediates that are not required for ATP generation can function to modulate the immune response (Figure 36.3).

Succinate is a key inflammatory signal in M1 macrophages through its ability to stabilize HIF-1α and thus upregulate IL-1β [28]. Succinate competitively inhibits 2OG-dependent enzymes including the PHDs to prevent HIFα degradation and may also indirectly affect HIFα stability via its effects on ROS production [29]. Elevated succinate levels in neutrophils of patients with succinyl dehydrogenase B mutations are also associated with enhanced survival, but this is independent of HIFα. Instead, the impaired function of SDHB results in impaired mitochondrial complex II function and reduced oxidative stress [30]. Finally, succinate accumulation may alter cellular metabolism through post-translational modification (i.e., succinylation) of proteins involved in glucose and lipid metabolism [31].

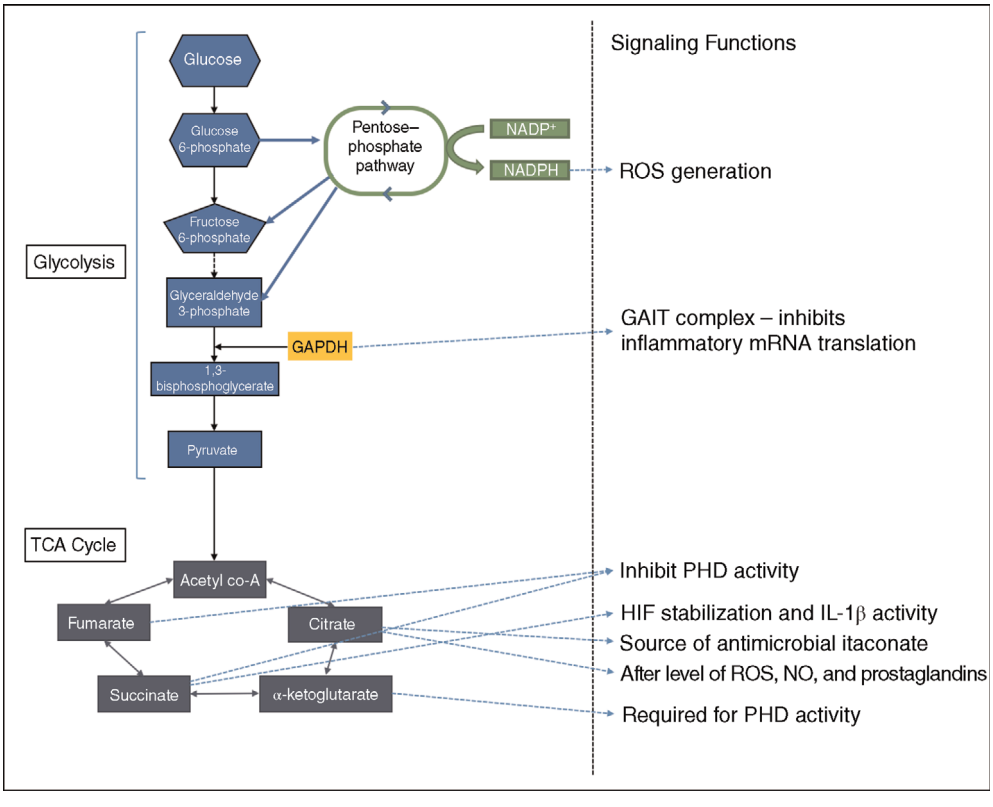

Figure 36.3 The role of metabolic intermediates in augmenting innate immunity.

The mitochondrial citrate transporter CIC transports citrate from the mitochondria to the cytosol and influences level of inflammatory molecules in macrophages: CIC knockdown results in reduced levels of ROS, NO, and prostaglandins [32]. Citrate metabolism is also important in the generation of the antimicrobial metabolite itaconate (ITA). Although traditionally thought of as a bacterial product, ITA has also been shown to be produced by macrophages through the decarboxylation of *cis*-aconitate (which is generated from citrate in the Krebs cycle) [33]. The immune responsive gene 1 (Irg-1) has been identified as the *cis*-aconitate decarboxylase and has been shown to be elevated in inflammatory M1 macrophages. Intriguingly, macrophages activated with LPS show a distinct metabolic phenotype from hypoxic macrophages, although both phenotypes show increased HIFα stabilization. LPS-activated macrophages show persistent metabolism of pyruvate to generate a pool of citrate that is then available for itaconate production [34]. Silencing of Irg-1 (and thus reduction in itaconate production) in macrophages has been shown to inhibit their antimicrobial activity. Thus Irg-1 represents another link between metabolism and immunity [35].

Enzymes involved in glucose metabolism also have additional roles in immune cells. GAPDH is involved in glycolysis. It has also been shown to be part of the

GAIT (IFN-γ-activated inhibitor of translation) complex that in response to IFN-γ binds inflammatory mRNA, supressing their translation. The two functions are likely to be mutually exclusive, thus under conditions of high rates of glycolysis, the inflammatory mRNAs can be translated unchecked [36].

The close links between metabolism and immunity are highlighted by the very different metabolic phenotypes exhibited by M1 and M2 macrophages. Unlike their proinflammatory counterparts, M2 macrophages show increased oxidative phosphorylation and decreased production of NO and TNF-α. Furthermore, macrophage metabolism of arginine plays a key role in determining M1/M2 phenotypes: it may be metabolized via NOS to NO and citrulline or by arginase to generate ornithine and urea. The former is favored by M1 macrophages, while arginase activity is favored by M2 macrophages.

As we will see later, there are a multitude of cytokine factors that can also determine macrophage phenotype. This again demonstrates that no single environmental factor acts in isolation.

36.4 Impact of Host–Pathogen Interactions on Innate Immune Cell Function

Both host and pathogen have evolved strategies to emerge from their interaction with advantage. In tissue, an effective innate immune response must:

a) recognize pathogen and recruit other immune cells to the area, typically with an initial marked influx of neutrophils and a subsequent monocyte–macrophage recruitment important for clearing and resolution. This is triggered by both the pathogen itself and the tissue damage associated with infection via pathogen-associated molecular patterns (PAMPs) or "self-" damage-associated molecular patterns (DAMPs), respectively;
b) rapidly engulf and kill pathogen;
c) induce an adaptive immune response; and
d) clear infected and apoptotic cells to enable resolution of inflammation.

Pathogens may subvert innate immune function at any of these stages to persist and/or progress to systemic infection. A pathogen may avoid recognition, prevent recruitment of innate immune cells, avoid (or indeed enhance) phagocytosis, prevent antigen presentation, and subvert apoptosis of both neutrophils and macrophages to suit their needs.

36.4.1 Damage-associated Molecular Patterns Activate the Innate Immune System

Infective or sterile tissue injury will result in the generation of DAMPs, predominantly from necrotic cells. DAMPs include ATP, heat shock proteins (HSP), mitochondrial DNA and formylated peptides, and nucleic acids. The presence of DAMPs in the microenvironment has a significant impact on the innate immune response, creating microenvironmental "danger signals" that favor immune cell recruitment.

Extracellular ATP enhances neutrophil recruitment, but the mechanism is complex and not a simple chemotactic signal. Extracellular ATP may alter cell adhesion through an indirect mechanism: ATP can upregulate macrophage IL-1β via a different receptor ($P2X_7$ receptor) that in turn can increase expression of adhesion molecules on the endothelium. Chemotaxis is, however, amplified by neutrophil release of ATP in response to stimuli such as fMLP, which then acts in an autocrine fashion to ligate the G protein-coupled $P2Y_2$ receptor and control orientation. This signal is further amplified by signaling via the adenosine A3 receptor in neutrophils [37]. ATP secreted from apoptotic cells also induces monocyte recruitment, again in a $P2Y_2$ receptor-dependant manner.

Mitochondria-derived peptides also act as DAMPs. They are formylated peptides that resemble bacterial peptides and signal via the same cell surface receptors on neutrophils (FPRs) to mediate neutrophil chemotaxis. A hierarchy of processes is proposed to control neutrophil chemotaxis in response to DAMPs and mitochondrial formylated peptides are found to be crucial for the last stages of migration [38].

36.4.2 Pathogen Avoidance of Immune Cell Recognition

Tissue damage due to infection will also cause generation of DAMPs, but this will be augmented by danger signals from the pathogens themselves. Pathogens have developed a range of strategies to alter the function of innate immune cells and avoid eradication.

Pathogens may evade the innate immune system by avoiding recognition. A polysaccharide capsule "hides" PAMPs from receptors such as TLRs in *Haemophilus influenzae* and in Streptococci. Pathogens may also alter their PAMPs to avoid recognition; for instance, *Helicobacter pylori* can chemically alter its LPS and flagella to avoid TLR4 and TLR5 recognition, respectively.

Following recognition, key phagocytic receptors generate a cascade of intracellular signals often mediated by tyrosine kinase activity and polyphosphoinositol generation. *Yersinia* species and *Salmonella typhimurium* generate tyrosine phosphatases (YopH and SptP, respectively) to counteract these signals and avoid uptake [39]. Downstream signaling may also be influenced by the pathogen: enteropathic *E. coli* utilize a type III protein secretion system to translocate toxic effector proteins into host cells. One such effector, nleE, has been shown to stabilize IκB that inhibits NFκB signaling following TLR activation [40].

36.4.3 Preventing Innate Immune Cell Recruitment

Pathogens may also alter the infectious microenvironment to prevent the recruitment of innate immune cells. In response to pneumococcal infection in the lung, there is an influx of neutrophils that both engulf and kill the pneumococcus. This initial highly inflammatory response is found to be protective in mouse models of pneumonia. Neutrophil recruitment has been shown to be impaired by a zinc metalloproteinase (Zmp) produced by *S. pneumoniae*: ZmpC was found to inhibit PSGL-1 (p-selectin glycoprotein ligand-1), thus preventing selectin-mediated neutrophil rolling within blood vessels and resulting in reduced

recruitment and enhanced virulence of the pathogen [41]. *S. aureus*, an important pathogen in human disease, has evolved a number of strategies to evade the innate immune system including manipulating immune cell recruitment and survival (see below). For example, the chemotaxis inhibitory protein of staphylococci (CHIPS), through binding to C5a receptors, reduces the initial influx of neutrophils and macrophages to the sites of *S. aureus* infection [42].

36.4.4 Manipulating Phagocytosis and Antigen Presentation

Opsonisation is a process whereby a pathogen is "tagged" by immunoglobulin and complement proteins and this facilitates its uptake and destruction by phagocytes. This process may be targeted by a pathogen to prevent uptake. Both *S. pneumoniae* and *S. aureus* produce immunoglobulin proteases to avoid Fc receptor-mediated uptake. *S. aureus* and *S. pneumoniae* may also scavenge opsonins such as Factor H, a key activator of complement [39].

Mycobacterium tuberculosis is a hugely successful pathogen in humans. Its capacity to persist within the host is in part due to the subversion of innate immunity. It has been found to not only interfere with normal phagolysosome maturation in macrophages but also inhibit the assembly of the NADPH oxidase machinery by binding to the RAC1 component, thus reducing the generation of ROS that would otherwise facilitate mycobacterial killing [43]. *M. tuberculosis* is also able to interfere with antigen presentation in macrophages, thus impairing the activation of adaptive immune responses. Chronic TLR stimulation by mycobacterial lipoproteins results in downregulation of MHC class II transcription. *M. tuberculosis* infection also interferes with trafficking of MHC class II molecules to the cell surface, further reducing the capacity of the macrophage to present *M. tuberculosis* antigen and activate the adaptive response [44].

36.4.5 Subversion of Immune Cell Death

Intracellular pathogens may gain an advantage by slowing or reducing apoptosis and hijacking the immune cell as a "Trojan Horse." Other pathogens accelerate apoptosis of phagocytes in order to limit their capacity to phagocytose and kill.

Neutrophils achieve bacterial killing via extracellular release of granules during degranulation and through release of ROS and granule contents into the phagolysosome following phagocytosis of a pathogen. Phagocytosis ordinarily induces the neutrophil's apoptotic machinery (phagocytosis-induced cell death, PICD) [45] allowing subsequent efferocytosis by macrophages and clearance of the pathogen. This pathway may be hijacked by a number of intracellular pathogens that through prolonging neutrophil survival are able to perpetuate infection. *Chlamydia pneumoniae* is an obligate intracellular pathogen. It is effectively taken up by neutrophils through phagocytosis but not effectively killed [46]. It not only delays constitutive neutrophil apoptosis but also causes enhanced MIP-1β-mediated macrophage recruitment and increased phagocytosis of infected neutrophils by macrophages, thus allowing propagation of the infection [47].

S. aureus PAMPs include LTA that is recognized by TLR2 and peptidoglycan (PGN) that is an agonist for the intracellular pattern recognition receptor NOD 2. TLR 2 ligation leads to NFκB-mediated neutrophil survival that may initially favor the host [48], allowing further activation of the innate response by the neutrophil. However, if the pathogen is able to persist inside the cell (as *S. aureus* has been shown to do), the host advantage may be lost as the cell becomes a reservoir of infection. The effect of *S. aureus* on apoptosis is not straightforward; there is some evidence of neutrophils showing enhanced PICD in response to *S. aureus* exposure, possibly allowing safe removal of both neutrophil and pathogen and thus resolution. The *S. aureus* pore-forming toxin Panton–Valentine leucocidin (PVL) can induce neutrophil necrosis or apoptosis with higher concentrations of PVL favoring necrosis [49]. *S. aureus* certainly manipulates neutrophil cell death, but this is context dependent and also crucially dependent on multiplicity of infection (MOI) [48].

Conversely, if a pathogen is able to accelerate neutrophil apoptosis sufficiently, it can impair the immune response. Pyocyanin is a toxic metabolite released by *Pseudomonas aeruginosa* that has been found to induce rapid neutrophil apoptosis via lysosomal alkalinisation and subsequent destablization of Mcl-1 and caspase activation [50]. In murine models, pyocyanin production is associated with reduced bacterial clearance.

The examples above are only a small selection of the ways in which pathogens may alter the microenvironment and subvert innate immune cell function.

36.5 Inflammatory Mediators

Both neutrophils and macrophages have the capacity to modify the immune response through the production of a wide range of pro- and anti-inflammatory mediators. Their migration and activation are, in turn, guided by the expression of such mediators. There will, therefore, exist a complex interplay between pathogen, damaged host tissues, and neutrophils and monocytes/macrophages.

36.5.1 Oxidants

Neutrophils and macrophages generate ROS both by NOX2 activity and by mitochondria, that is, mROS. They also generate RNS by interaction of NO-produced inducible nitric oxide synthase (iNOS) with ROS (Figure 36.4).

While these oxidants have important antimicrobial actions, they are also important signaling molecules and can dramatically alter the innate immune response. ROS are predominantly active within the phagolysosome, but they may also diffuse into the cytosol and may cross the cell membrane into the extracellular environment. The more volatile the species, the more rapidly it will react with other target molecules. Conversely, less reactive species such as H_2O_2 may diffuse further and have both paracrine and autocrine effects.

RNS may have both pro- and anti-inflammatory effects and the outcome of the response will depend on location, duration, concentration, and interaction with

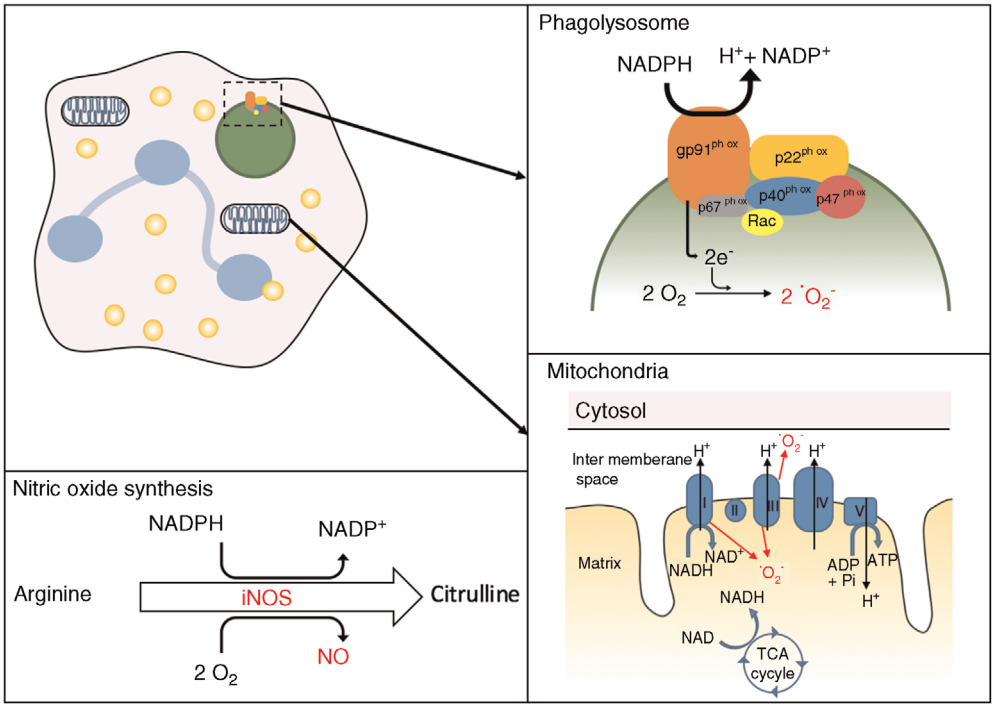

Figure 36.4 Sources of oxidants in neutrophils.

cofactors. The localization of iNOS within neutrophils and macrophages is not fully characterized, but it is seen within small vesicles in the cytosol [51].

As they are potent oxidizing agents, ROS and RNS have the capacity to alter the redox state of the cell that, in turn, has implications for signaling. ROS and RNS may also act directly as signaling molecules. Tyrosine phosphorylation is pivotal in cell proliferation, differentiation, and in cell to cell communication. It is involved in transducing signals from diverse mediators including fMLP, TNF-α, and GM-CSF. Oxidants may alter the balance of phosphatase versus kinase activity either through inhibition of phosphatase activity or through induction of kinase activity [52]. A further layer of complexity is added when we consider that the effect may be direct or indirect and that the alterations in phosphorylation may be activating or inhibitory. Examples of key enzymes subject to oxidant regulation include Syk (implicated in integrin signaling in neutrophils), MAP kinases such as ERK and protein kinase C (PKC).

Mitochondria are increasingly recognized as more than simply the energy generator of the cell especially in neutrophils that carry out little or no aerobic respiration. As discussed above, mitochondrial TCA cycle intermediates play a key role in signaling in immune cells. Mitochondrial ROS (mROS) are implicated in a wide range of immune cell functions. mROS are required for effective bactericidal activity in macrophages. TNF-α and ligation of TLR 1, 2, and 4 lead to an increase in mROS generation via TNF receptor-associated factors (TRAFs) [53], neatly linking "danger signals" with antimicrobial activity.

Increased levels of mROS are also an important signaling mechanism. mROS have been shown to stabilize HIF-1α and to upregulate NFκB activity downstream of TNF receptor signaling. mROS are also required for activation of inflammasome components such as NLRP3, a key player in recognizing and leading the response to various DAMPs and PAMPs. mROS are also implicated in a number of adaptive immune cell functions including T-cell activation. As they are able to alter the redox state of the cell, mROS may also affect other signaling pathways by analogy to NOX2-derived ROS.

Key neutrophil and macrophage functions are affected by ROS/RNS-mediated signaling changes. FcR signaling is blocked in the absence of ROS *in vitro* and the neutrophils of patients with CGD show a failure of amplification of FcR-mediated phagocytosis [54]. Macrophage phagocytosis is intricately linked to ROS and RNS generation. Redox signaling in dying cells modifies their uptake by macrophages; for example, the presence of oxidized phosphatidylserine (PS) on the surface of an apoptotic cell is a key "eat me" signal. In addition, redox reactions within the macrophage may alter phagocytic function. One example is the delay in fusion of the phagosome and lysosome caused by RNS. This is proposed to allow time for more proficient antigen processing and thus antigen presentation by the macrophage [55]. Oxidative stress (leading to excessive oxidation of proteins, lipids, and nucleic acids) can directly trigger apoptosis. CD45 and SHP-1 that modulate apoptosis have oxidant-dependent activity and peroxynitrate (a NO derivative) can also induce apoptosis in neutrophils. Oxidants can also alter gene expression. ROS can activate NFκB expression that in turn upregulates key cytokines including IL-1, IL-6, IL-8, and MIP2. ROS may also participate in LPS-mediated NFκB signaling in macrophages. Finally, TNF-induced NFκB activity is also ROS dependent.

Leukocyte ROS may also affect local cells including the vascular endothelium where it is shown to increase phospholipase D and P-selectin expression (and thus neutrophil binding).

The requirement for molecular oxygen for ROS and RNS generation means that there exist links between hypoxia and oxidant availability and activity. Bacterial killing by NADPH oxidase-derived ROS may be impeded in hypoxia and interestingly, iNOS is a HIF target gene.

36.5.2 Cytokines and Chemokines

Neutrophils are exquisitely sensitive to the cytokine environment and possess a wide range of cytokine receptors. Cytokines acting upon neutrophils can be divided into different classes with different structures, different receptors, and different signaling pathways.

Type I cytokines consist of four α-helices and include IL-4, IL-6, G-CSF, and GM-CSF. Type II cytokines contain six α-helices and include IFN-α, β, and γ and IL-10. Both Type I and type II cytokine signaling is mediated by JAK-STAT pathways.

The IL-1 superfamily includes the three known forms of IL-1 (IL-1α, IL-1β, and IL-1Ra) and IL-18. IL-1β is a critical regulator of the inflammatory response and is predominantly produced by macrophages and may also be produced by epithelial

cells and fibroblasts. In neutrophils, its main effect is to prolong survival. As well as being secreted by macrophages, IL-1β may also act as a transcription factor in macrophages in an autocrine fashion.

TNF-α is a key inflammatory cytokine. It is produced in large quantities by activated macrophages and can act upon both macrophages and neutrophils. It is important in priming and activating neutrophils and in macrophages can result in increased NFκB activity and sustained IFN-β production that acts in synergy with the TNF-α in orchestrating the inflammatory response [56].

Neutrophil functions are guided by the presence of cytokines and other inflammatory mediators. Neutrophil priming describes the phenomenon whereby exposure to a "priming" stimulus results in an amplified response from the neutrophil following subsequent activation. Neither the priming stimulus nor the activating stimulus in isolation is able to unleash the full antimicrobial arsenal of the neutrophil, but together they induce a potent effector cell function. Priming agents include pathogen-derived factors such as LPS and the influenza A virus and "self" inflammatory mediators such as TNF-α, IL-8, and GM-CSF [57]. These priming stimuli may be generated by other immune cells or by endothelial cells. The consequences of priming are manifold: classically, priming is measured by enhanced ROS production and increased phagocytic activity; however, primed neutrophils may also alter the makeup of their surface receptors, thus changing their capacity to respond to subsequent cytokine signals. Primed neutrophils also show enhanced degranulation and survival. The physiological importance of priming is clear: a fully activated neutrophil is potentially highly toxic to host tissue, but neutrophils must be activated quickly to be effective when required to fight infection. The intermediate primed stage avoids having high numbers of active neutrophils in the circulation, but it means that in response to a danger stimulus, there is a rapidly available population of potent effector cells available.

Interestingly, priming may be reversible in response to certain stimuli, including platelet activating factor (PAF). This "depriming" is also a safety mechanism – if after a period of priming, the neutrophil is not fully activated it can "stand down" again, retaining the capacity to be reprimed and fully activated at a later stage [58]. Recent studies in acute lung injury (ALI) suggest that a failure of this depriming may contribute to the neutrophil-mediated cell damage seen in this condition [59].

Chemokines are small molecules with characteristic conserved cysteine residues. They are subdivided based on the position of these residues (CXC and CC chemokines). Their receptors are seven-transmembrane G protein-coupled receptors whose downstream signaling includes activation of PI3-kinase required for chemotaxis. Chemokines are released by cytokine-activated endothelial and epithelial cells, resident tissue cells, and other leukocytes in injury or infection, leading to neutrophil chemotaxis. This response is then amplified as neutrophils themselves secrete further chemokines to recruit further effectors of the immune response.

Survival stimuli for the short-lived neutrophil include not only bacterial products such as LPS but also a number of cytokines, such as GM-CSF, G-CSF, IL-1β, IFN-γ, and TNF-α. Their downstream signaling converges on overlapping pathways including PI3 K, ERK, and NFκB to tip the balance of pro versus anti-apoptotic factors and delay apoptosis.

Cytokines have a myriad of roles in monocyte/macrophages. They not only govern recruitment and activation but also polarization of macrophages that is critical in determining the outcome of the immune response through both cytokine production and through polarization of the subsequent T helper cell response.

The concept of macrophage polarization is a much debated topic. Most cytokine-directed polarization is driven by signal transducer and activator of transcription (STAT) proteins: the balance between STAT1 activation and STAT3/6 activation determines the functional outcome for the macrophage. Other transcriptions factor families are also involved, though, including HIF and PPAR family members.

IFN-γ is the key cytokine in the polarization of M1 macrophages. IFN-γ and TLR4 ligation, triggers activation of transcription factors including NFκB, IRF-1, and STAT 1 that, in turn, leads to transcription of proinflammatory genes including TNF, IL-1β, IL-6, type I interferon, CXCL-10, and iNOS. IL-4 and IL-13 polarize macrophages to an M2 phenotype. They share the IL-4Ra receptor subunit and IL4R ligation leads to activation of Jak kinases and subsequent activation of STAT 6 that mediates transcription of M2 genes including IL-10, PGE2, ARG1, CCL-17, and CCL-22.

The different subsets of macrophages also exhibit differential chemotactic behavior. M1/M2 recruitment appears to be phase dependent with initial recruitment to a site of inflammation favoring M1 macrophages with later recruitment of M2 macrophages. The physiological benefits of this are clear: initial antimicrobial activity with subsequent anti-inflammatory and healing activity. The mechanisms by which this is controlled are not fully elucidated. The two populations show some differences in chemokine receptor expression and also subcellular localization of receptors, thus providing a mechanism for fine-tuning of migration in response to cytokines and chemokines [60].

The M1/M2 paradigm is likely to be an oversimplification and there may be more of a spectrum of macrophage phenotypes whose development depends on the complex interaction of many factors. Cytokines, oxygen levels, pathogens, and the tissue in which the cell is differentiating all affect polarization and contribute to the macrophage phenotype that develops. In addition, there is significant interplay between these polarization mechanisms with simultaneous activation and suppression of certain genes; for example, NFκB upregulates HIF-1α. An increased HIF-1α:HIF-2α ratio is known to favor M1 polarization and a predominance of HIF-2α favors M2 polarization. STAT6 works with Kruppel-like factor (KLF) 6 to inhibit NFκB, thus reducing HIF-1α and further skewing the cell toward M2 activation [61]. There is a fascinating link between Th2/M2-type responses, immunity against helminthes, and tissue repair. In helminth infection, the large size and migratory capacity of the pathogen means a highly inflammatory type 1 response is likely to be more damaging to host than to pathogen. An alternative response is, therefore, induced that encourages not only control of parasitic infection but also tissue repair. There is a clear overlap in the cytokine and signaling profiles of antihelminth immunity and tissue repair with STAT 6, IL-4, and IL-13 being crucial mediators of both. Alternatively activated macrophages are not only more effective than naïve macrophages at killing helminths but also contribute to tissue repair in helminth infection [62]. This is illustrated by

the nematode *Nippostrongylus brasiliensis* whose migration through the lung causes significant tissue damage. The repair of this damage is mediated by M2 macrophages via IL-4R signaling [63].

36.5.3 Lipid Mediators in the Innate Immune Response

Prostaglandins and leukotrienes are predominantly proinflammatory lipid mediators. Alternative breakdown of their precursors can, however, generate anti-inflammatory products such as the specialized proresolving mediators that include lipoxins, resolvins, and protectins (Figure 36.5).

Prostaglandin E2 (PGE2) is the predominant prostaglandin in innate immune modulation. Levels depend on the activity of COX2-driven synthesis and 15-hydroxyprostaglandin dehydrogenase (15-PGDH)-mediated degradation of PGE2. There are four different PGE2 receptors that mediate heterogeneous effects. The receptors have varying affinity, varying expression, and varying desensitization to PGE2 and so the nature of the PGE2 signal determines the outcome. Thus, PGE2 can have seemingly contradictory effects. It contributes to

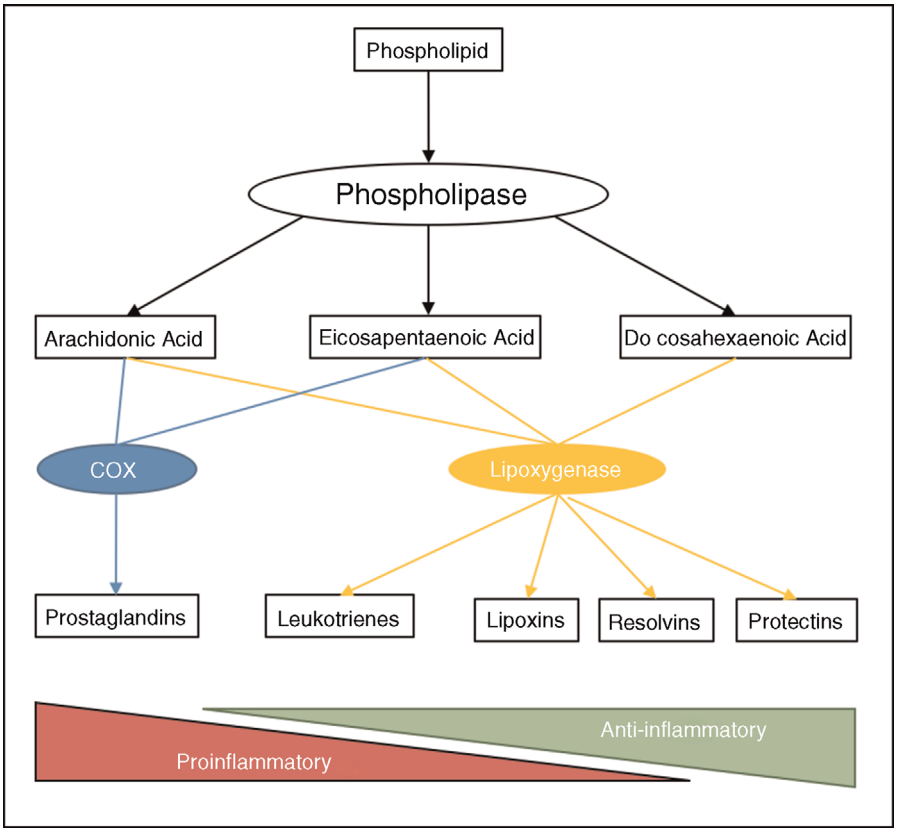

Figure 36.5 Generation of lipid mediators. Differential metabolism of arachidonic acid, eicosapentaenoic acid, and docosahexaenoic acid generate a range of mediators that can have pro- or anti-inflammatory effects.

an influx of neutrophils and macrophages and mediates vasodilation, but it also reduces phagocytosis and bacterial killing. PGE2 may also play a role in polarizing the adaptive immune response by reducing IL-12 production by macrophages and thus favoring a Th2-type response.

Leukotrienes are also products of arachidonic acid metabolism. Cysteinyl leukotrienes (CsyLT) are important in airway inflammation in asthma and CysLT antagonists are commonly used in asthma treatment. Leukotriene B4 (LTB4) is an important chemoattractant for neutrophils and, similar to the CXC and CC chemokines, ligates a G protein-coupled receptor. Interestingly, increased levels of LTB4 are found in the airways of patients with COPD, potentially contributing to the increased neutrophil- and macrophage-driven inflammation through increased recruitment of these cells [64].

Certain cytokines and chemokines lead to downregulation of the innate inflammatory response and myeloid cells can also have key anti-inflammatory roles. Interest is mounting in specialized proresolving mediators (SPMs), a group of proresolution lipid mediators including lipoxins, resolvins, protectins, and maresins. They share a common pathway of origin: phospholipase A2 enzymatically cleaves essential fatty acids to create arachidonic acid, eicosapentaenoic acid (EPA), and docosahexaenoic acid (DHA) creating the precursors for SPMs. Lipoxins are the best characterized of this group and we discuss them in more detail next to illustrate these proresolution mediators.

Lipoxins are synthesized via two different pathways (via lipoxygenase action on LTA4 or arachidonic acid directly). Both pathways can generate lipoxin A4 and lipoxin B4. Lipoxins possess powerful anti-inflammatory effects: they reduce neutrophil chemotaxis and are highly effective at blocking leukotriene B4-mediated migration [65]. They also control neutrophil proliferation and reduce persistent neutrophilic inflammation, acting via a number of mechanisms. They prevent accumulation of nuclear NFκB and consequently reduce IL-8 levels [66]. Lipoxins bind to the ALX/FPR2 receptor and restore apoptosis pathways to aid resolution of inflammation. They competitively inhibit serum amyloid A (SAA) that is antiapoptotic (signaling via ERK and Akt pathways). SAA is also found in increased levels in COPD airways and this pathway has been mooted as a potential therapeutic target in COPD [64].

Lipoxin A4 and B4 increase monocyte migration and adherence [67] and lipoxin A4 augments macrophage nonphlogistic neutrophil phagocytosis [68]. In contrast to its restoration of apoptosis in neutrophils, lipoxin A4 prolongs the life span of macrophages, through the PI3K/Akt pathway [69]. Interestingly, macrophages pretreated with lipoxin A4 demonstrated upregulation of NrF2, the potent activator of antioxidant responses, when exposed to apoptotic stimuli [70].

36.5.4 Microvesicles

Microvesicles (MVs) are microparticles (diameter of 0.1–2 μm) formed from plasma membrane and shed by most cell types. The number of circulating microvesicles is increased in inflammatory and immune-mediated illness. Platelet-derived MV production begins with increased cytoplasmic calcium activation of calpain. Endothelial-derived MVs are triggered by oxidized LDL (among other

signals) and leukocyte MVs in response to NO-mediated signaling. Microvesicles shed by cells of the innate immune system are highly influenced by their microenvironment and the nature of their target cells. MVs may possess either pro- or anti-inflammatory functions.

Neutrophils treated with a broad spectrum NO inhibitor produce more microvesicles causing an increase in IL-8-mediated chemotaxis. Similar to platelet MV production, this is mediated via calpain activity [71]. Coincubation of neutrophil-derived microvesicles with human umbilical vein endothelial cells (HUVEC) induced release of the proinflammatory cytokine IL-6, while incubation with human macrophages induced the anti-inflammatory TGF-β [72,73]. These intriguing particles are under investigation as potential therapies for inflammatory disorders such as arthritis [74].

Conversely, the increase in microvesicle formation by stimulation of a murine macrophage cell line was abrogated by a NO inhibitor. Macrophage MV production was increased following TLR stimulation, particularly via TLR4 and TLR2. Increasing NO levels paralleled increasing MV production when cells were stimulated with LPS, and NO donors could independently increase murine macrophage MV production. Microvesicles derived from "resolving exudate" have been shown to improve macrophage efferocytosis of apoptotic cells, further demonstrating the varied roles these molecules play in the innate immune system [75].

36.6 Conclusions

The cells of the innate immune system are adapted to function in hostile inflammatory environments. They are able to sense a wide range of microenvironmental factors and integrate these signals to alter their phenotypes and respond appropriately to allow effective immunity with minimal damage to host tissues. However, these mechanisms can dysfunction – they may be hijacked by pathogens to subvert the immune system or become disordered in pathologies characterized by prolonged or excessive inflammation resulting in tissue damage. The overall outcome of the immune response is a highly regulated product. Cells of the innate immune system never act in isolation; they influence and are influenced by the microenvironment, and interactions between the innate compartments add further complexity. The outcome of all the extracellular factors depends on up- or downregulation of intracellular signaling pathways. Key pathways include HIF, NFκB, apoptosis pathways, ROS and RNS generation, MAPK and AKT signaling, and mTORc, and there is significant cross-talk between these pathways. The integration of all the different signals will thus alter the phenotype of the innate immune response.

Epigenetics of Inflammation

Vidula Vachharajani and Charles E. McCall

Wake Forest University, Medical Center, Medical Center Blvd., Winston-Salem, NC 27157, USA

37.1 Epigenetics and Homeostasis Protection

Darwinian evolution principles designed a sensing, defending, and mending stress response to protect homeostasis and promote life. The first homeostasis survival process recorded by humans eventually was called inflammation, which a flame pictorial originally symbolized [1]. Later, physiologic properties of red color (rubor), heat (dolor), pain (dolor), swelling (tumor), and altered function (functio laesa) were added to the universal concept. It also became clear that inflammation departs from homeostasis in order to *defend and mend* an injury and return. Also appreciated was that inflammation could resolve or become chronic. Mounting data now support that epigenetic chromatin remodeling *sequentially* and *spatially* directs the course of inflammation.

Epigenetic control over inflammation involves both *innate* and *adaptive* immune cells and nonimmune tissues [2]. This chapter emphasizes well-characterized epigenetics of myeloid-derived circulating monocytes and tissue macrophages, as they become part of inflammation. However, depending on the spatial features of inflammation, epigenetics changes during inflammation reprogramming of dendritic cells, natural killer cells, eosinophils, basophils, and T lymphocytes, as well organ- and tissue-specific cells. This chapter also discusses the emerging and complex field of epigenetics in developmental epigenetics that program the many heterogeneities of yolk sac versus tissue-derived macrophages after they take residence tissues like lung, brain, and adipose tissue. Unfortunately, this field of immune epigenetics rarely looks at translation to clinical inflammatory diseases discussed in this chapter, and it is not known yet if or how these phenotype variances impact acute or chronic inflammation. Accordingly, epigenetic mapping of inflammation is immature, though growing. Figure 37.1 depicts the general homeostasis concept of inflammation epigenetics. Table 37.1 lists content sections. Table 37.2 provides a glossary.

8. Summary

Table 37.2 Glossary of epigenetics.

DNA CpG methylation and hydroxyl-methylation: DNA epigenetic marks
Epigenetic code: chromatin functional marks on histone and DNA
Epigenome: genome-wide chromatin epigenetic code
Epimutations: stable epigenetic changes
Euchromatin: DNA accessible to transcription
Heterochromatin: reversibly silenced chromatin; also called facultative heterochromatin
Nucleosome: an orderly body of packaged histones and DNA
Immunometabolism: integrated immune and metabolic pathways
Inflammation initiation and adaptation: sequentially directed effector to repressor epigenetic reprogramming
Poised enhancer–promoter: rapidly transcribe monocyte sequences with predictable histone marks
Sirtuins: NAD+ redox sensors that critically regulate inflammation reprogramming as homeostasis guardians

37.2 Epigenetic Principles

The term “epigenetics” was introduced in 1942 [3]. Its classic definition emphasizes heritable changes in gene function not dependent on germ line DNA. This chapter uses a broader definition, in which nonreplicative chromatin histone proteins and DNA and transcription factors work together to temporally direct inflammation.

37.2.1.1 Epigenetic Language

The "epigenetic language or code" [4] – *sometimes divided into "readers, writers and erasers" – spatially and temporally maintains, activates, or silences gene expression by modifying histones and DNA*. Dynamic and flexible epigenetic reprogramming directs the development of immune cells and prepares them for defending and mending. During epigenetic reprogramming, mutations may permanently alter the epigenome by passing vertically as cells replicate (epimutations). Both histone and DNA epigenetic marks may be inherited [5].

Histones package nuclear but not mitochondrial DNA into orderly and repetitive nuclear chromatin structures called nucleosomes, which contain two tetrads of histones H2A, H2B, H3, and H4 with approximately two turns of 146 base pairs of DNA wrapped around the tetrad [6]. Linker histones (e.g., H1 linker histone) juxtapose DNA entering or leaving nucleosomes. Subtype histone variants (e.g., histone H2Z) "enter or leave" nucleosomes to modify their functions by remodeling or repositioning. Other important epigenetic regulators are histone protein 1 (HP-1) and high-mobility group (HMG) proteins, which also influence chromatin structure and function [7].

The term *euchromatin* signifies an "open" state with exposed DNA sequences that can support gene transcription. More compact chromatin called *heterochromatin* permanently or reversibly silences transcription [8]. Shifts between active euchromatin and reversibly silent heterochromatin – sometimes called *facultative heterochromatin* – dynamically direct gene expression reprogramming and inflammation phenotypes [9]. *Thus, flexible chromatin epigenetic coding and structural remodeling support the departure from and return to homeostasis during inflammation*.

Covalent post-translation chromatin modifications support histone epigenetic changes by adding or removing acetyl, methyl, phosphate, ubiquitin, and adenosine diphosphate (ADP) ribose to exposed side chains [10]. The best understood histone-coding marks are acetylation, methylation, and phosphorylation. Coding also adds or removes methyl to cytosine plus guanine (CpG) containing DNA. Chemical histone or DNA modifications generate epigenetic "coding" function by interacting with transcription factors, cofactors, and RNA polymerizes [8,11]. Epigenetics also controls micro-RNA or long coding RNA expression [12].

Acetylation of specific histone lysines (e.g., H3K9ac) often supports transcription, while methylation replacement of acetyl (e.g., H3K9me3) promotes silent heterochromatin formation, although this formula may vary. Histone H3K4me1 and H3K27ac commonly mark potentially active (poised) gene enhancer regions needed for rapid defense [13,14]. Switching between acetylation and methylation histone coding activates or represses gene transcription. DNA methylation, demethylation, and hydroxyl (OH) methylation controlled by specific epigenetic writers or erasers also dynamically increase or decrease gene transcription. Epigenetic reprogramming is also gene set-specific in that it programs physiologic pathways such as nutrient selection, protein synthesis, surface receptors, autophagy, and mitochondrial function, among others. Open access Epigenome Web-based sites provide access to epigenome information (www.blueprint-epigenome.eu; http://www.ncbi.nlm.nih.gov/epigenomics). Figure 37.2 conceptualizes epigenetic reprogramming of chromatin structure and function.

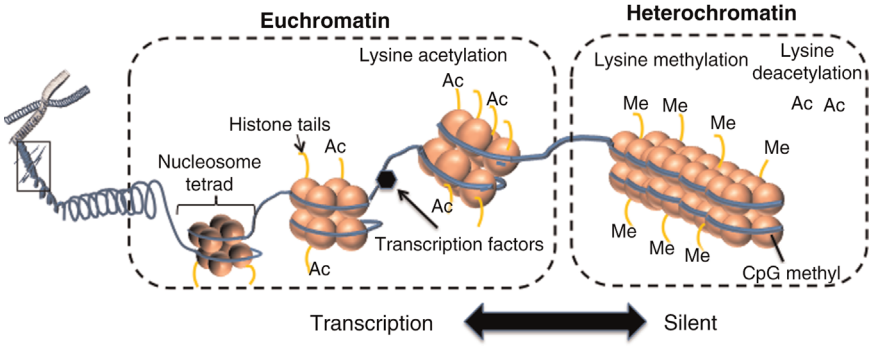

Figure 37.2 Chromatin structure and function: each nucleosome consists of an octamer of two copies of histones H2a, H2b, H3, and H4 encircled by about two turns of DNA (~146 base pairs). Reciprocal properties of lysine acetylation/deacetylation or methylation/demethylation combined with other post-translational changes such as phosphorylation, SUMOylation, and ubiquitination contribute along with DNA CpG methylation to dynamic shifts in euchromatin to reversibly silent heterochromatin. Interactions of chromatin and cofactors and transcription factors (e.g., NFκB) bound to accessible DNA direct transcription of genes encoding proteins and functional noncoding mRNAs.

37.3 Epigenetics of Successful Inflammation

37.3.1 Preepigenetic Sensing and Signaling

Preepigenetic sensors and signals transmit external and internal stress information to nuclear chromatin. First, external or internal cell sensing receptors detect danger signals (*alarmins*) and inform a signaling network [15]. Among external alarmins are pathogen-associated molecular patterns (PAMPs) from microbes and toxins sensed by Toll-like receptors (TLRs) [16], and other signals to complement receptors, immune globulin receptors, and receptors recognizing nutrients such as glucose, fatty acids, and amino acids. Internal alarmins include free nuclear or mitochondrial DNA, histones, and excessive oxygen and nitrogen-derived species (ROS, NOS, etc.), which are sensed by the *inflammasome* or *endoplasmic reticulum* (ER) stress response proteins [17]. Internal nutrient sensors (e.g., mTOR) inform epigenetics though sensing aminoacid levels. Sensing to signaling stress responses converge on common checkpoints such as the NFκB family, stress kinases p38, c-Jun N-terminal kinase (JNK), and extracellular signal-related kinase (ERK) [18]. Cyclic nucleotides and AMP sensor AMP kinases also inform nuclear epigenetics. Transcription factors binding to cognate DNA sequences with histone interactions make the definitive step to generating mRNA from RNA polymerase II.

The paradox that monocyte NFκB factor p65 could transfer into the nucleus but is unable to bind DNA and to transcribe proinflammatory genes pioneered the concept that epigenetics directs shifts between *initiation* and *adaptation* during acute inflammation [19]. To initiate a "defend and mend" response, preepigenetic stress sensors and signals converge their information on nuclear chromatin. First responder genes are quicker to initiate inflammation than others,

and epigenetically poised enhancer and promoter regions prompt the most rapid responses [14].

37.3.2 Epigenetically Poised Enhancer–Promoter Regions

A poised transcription state of DNA enhancer and promoter regions modifies chromatin structure, nucleosome positioning, and starts, but does not finish, mRNA transcription [14]. This first responder "language or epigenetic code" develops innate immune monocytes/macrophages to a differentiated and immune-poised state. Poised *enhancer* regions are marked by methylated histone H3K4me1, acetylated H3K27ac, demethylated DNA CpG, and constitutively bound PU.1 DNA-binding protein. Triple methylated H3K4me3 marks poised promoter regions, while closed promoters display repressor marks such as H3K9me2 and H3K27me3 polycomb complex. Poised epigenetic enhancer–promoter signatures await arrival of DNA binding of transcription activating factors such as nuclear factor kappa B p65 (NFκB p65), activator protein 1 (AP-1), and interferon regulatory factors (IRF) at their cognate DNA sequences. Then RNA polymerase II activity rapidly extends mRNA.

Poised enhancer–promoters rapidly trigger cytokine/chemokine gene expression to initiate inflammation after environmental stress receptors sense and signal the nucleus. First responders include tumor necrosis factor alpha (TNF-α) and interleukin 1 (IL-1). Intermediate responders transcribe their mRNAs after first responders, a process that often requires protein synthesis; examples include interleukin 6 and other proinflammatory cytokines and chemokines [13]. Memory T cells also are regulated by poised promoters to enable quick response to immune-specific antigens [20]. Also, very low intensity stress signals may "prime" or "train" innate immune memory by epigenetically generating poised enhancers [21].

Developmental processes epigenetically inform the identity of monocytes and macrophages, which are unique in their ubiquitous ability to become part of all organs. Tissue macrophages gain early identity in the fetal yolk sac and later from bone marrow origin [22,23]. An important emerging concept is that environment-specific cues dictate the location of macrophages among various tissues develops their enhancer identity [24]. For example, macrophage enhancers when in the blood differ from those in brain, lung, liver, spleen, and peritoneum. These differences are apparently environment-specific and plastic, since new macrophages coming into the region change and can change again if they migrate into another tissue. Unfortunately, most knowledge in epigenetics does not link to how inflammation – successful or unsuccessful – is affected by the developmental or acquired nuances, if at all. Such research might enlighten understanding disease such as Alzheimer's disease, alcoholic/nonalcoholic liver disease, acute/chronic kidney disease, and heart failure, among others.

37.3.3 Inflammation Initiation

During inflammation initiation, the poised repressor complex is replaced by an active euchromatin state of demethylated and acetylated H3K9, phosphorylated

H3S10, and hypomethylated CpG promoter DNA [25–27]. The precise mechanisms controlling enhancer–promoter derepression that launches initiation includes ubiquitination and proteasome degradation of basal repressor histone deacetylases and methyl-demethylase depressors [13]. Nuclear translocated and activated transcription factors then bind the "more" accessible euchromatin DNA transcription factor cognate sequences. *Initiation* reprogramming is gene-specific for several thousand protein-encoding genes and noncoding long and short regulatory mRNAs. Almost equal numbers of mRNAs increase and decrease during inflammation initiation, perhaps supporting the homeostasis yin/yang concept [28]. The dual activating and repressing function of many transcription factors interacting with cofactors (e.g., NFκB RelB) also underscore the importance of homeostasis. This yin/yang balance raises the possibility that both derepression and direct activation of transcription determines [29,30].

Most characteristics of gene-specific epigenetic *initiation* reprogramming are rapid responder proinflammatory/effector immunity cytokine and chemokine encoding genes and gene sets that regulate cell nutrition and cell survival. The repressed genes may include anti-immune mediators such as I kappa B family [31]. Epigenetic reprogramming also requires nucleosome repositioning, in which histone subtypes replace the canonical histone structure. Sequential epigenetic nucleosome repositioning occurs during inflammation *initiation* and *adaptation* [32].

Epigenetic inflammation reprogramming during *initiation* rapidly (minutes to hours) generates an *immune effector* state, in which microbicidal ROS form from different cell sources (e.g., xanthine oxidase, NADPH oxidase, and increased mitochondrial electron chain activity) and antimicrobial proteins become active as defense components. Initiation also activates *anabolic pathways* linked to the nonoxidative glucose-dependent pentose phosphate pathway in which nucleic acids are synthesized. Thus, post-transcriptional and post-translational processes also support homeostasis "defend and mend" distal to the epigenetic reprogramming chromatin network. Surprisingly, inflammation *initiation* in innate immune phagocytes after even mild or extreme stress is short-lived and reprogramming epigenetically switches to *adaptation* that begins in less than 12 h and is well established within a 24 h [27].

37.3.4 Inflammation Adaptation

A switch from "defend to mend" evolves as epigenetic reprogramming directing successful inflammation reprogramming toward its resolution. Epigenetic changes in chromatin and DNA direct *adaptation* reprogramming by switching euchromatin to heterochromatin [7]. Transcriptionally active NFκB p65 is replaced by NFκB factor RelB, which recruits a multi protein complex to generate silent heterochromatin, which is reversible. This repressor complex contains lysine transmethylase (G9a), heterochromatin protein 1 (HP-1), histone H1 nucleosome linker protein, DNA CpG transmethylases DNMT 3a/3b, and likely many other epigenetic modifiers [7,33].

Epigenetic-based adaptation is gene specific [34] and "silences" immune effector genes encoding cytokines that initiate inflammation and activates genes

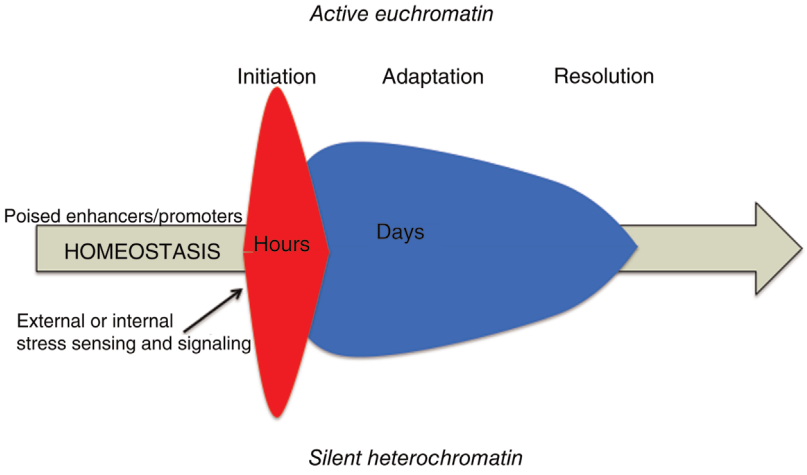

Figure 37.3 Epigenetics of successful inflammation: an orderly epigenetic and post-translational program informed by stress sensing and signaling temporally directs departure from and return to homeostasis. The *initiation* process shown in red instructs a rapidly mounted innate immunity program, which epigenetically reprograms genes responsible for immune effector and synthetic anabolic pathways. During this time, several thousand genes increase or decrease transcription, including those encoding proinflammatory mediators and glycolysis-dependent anabolic pathways. Within hours of initiation onset, homeostasis protective events launch an epigenetically controlled *adaptation* program shown in blue, which counters the effector immunity program and switches to reprogramming genes that limit inflammation and promote catabolic fatty acid oxidation to support a low-energy state. Successful inflammation then retrieves homeostasis by poorly understood mechanisms.

encoding antimicrobial peptides and IKB-α. RelB both represses chromatin at proinflammatory cytokines and chemokines and activates euchromatin at anti-inflammatory genes to promote a phenotypic shift in monocytes [25]. What directs RelB to perform in these two directions is unclear, but it is likely, at least in part, determined by its partnering with distinct cofactors, such as deacetylases and transacetylases as it concomitantly generates silent heterochromatin and activates euchromatin. Dual regulators also may change function based on post-translational processes such as phosphorylation or methylation. Of particular importance for inflammation resolution is disassembling the epigenetic repressor complex member (e.g., RelB, HP-1, and G9a), which is needed to restore homeostasis during successful inflammation [7], and the clinical shift is often evident within 2 or 3 days. Figure 37.3 conceptualizes epigenetic *adaptation* reprogramming during successful inflammation.

37.3.5 Inflammation Resolution and Epigenetic Memory

Successful inflammation resolution parallels epigenetic adaptation deprogramming. During resolution, NFκB p65 regains its capacity to bind and activate transcription of inflammation *initiation* genes (e.g., TNF-α) as RelB expression and function decrease [35]. Glucose and fatty acid metabolism, mitochondrial function (discussed subsequently), and microvascular leukocyte adherence

properties also return to homeostasis during inflammation resolution [36], as does tissue function. As adaptation resolves, monocytes are able to again defend and mend against new threats. Little is known, however, about how *adaptation* transitions to *resolution* at a more molecular level, or how often or how long epigenetic codes persist as epimutations. For example, studies in mice find that macrophage/dendritic cell epigenetic memory can persist in T cells for months after severe lung inflammation resolves [37]. Figure 37.3 conceptualizes the epigenetics of successful inflammation with homeostasis retrieval.

37.4 Epigenetics of Unsuccessful Inflammation

Unsuccessful inflammation occurs in billions of humans afflicted by chronic inflammatory diseases and the near 20 million who die each year of acute systemic inflammation from infection [38]. Many more suffer from unsuccessful inflammation in the form of chronic diseases such as diabetes, obesity, chronic lung failure, renal failure, liver failure, and dementias; aging is also accompanied by chronic inflammation. Important unknowns are what mechanisms arrest chronic inflammation in *initiation* and acute inflammation in *adaptation* state.

37.4.1 Acute Inflammation with Epigenetic Dysregulation

The initial environmental alarmin strength and its persistence, such as infection severity, determines the magnitude and duration of the acute inflammatory response and its eventual outcome. Above a presumed threshold of NFκB p65 DNA binding and transactivation, an extreme *initiation* response rapidly inflicts potentially lethal damage from reactive oxygen or nitrogen species (ROS or NOS), cell death pathways, and cardiovascular collapse. This epigenetically open and severe *initiation* state with its cytokine and ROS "storms" predicts early death or a sustained period of epigenetically controlled *adaptation* with immunometabolic failure [27,39]. During this postacute state, death rates remain high from severe immunosuppression and multiorgan dysfunction. Together, early and late deaths from uncontrolled acute systemic inflammation with sepsis may exceed 50% mortality globally and over 20% in more health-advanced regions [40]. Over 60% of the mortality during the acute systemic inflammation results during late/adaptation state [41]. The later effects of inflexible immune, metabolic, and bioenergy responses correlate with the high lethality. Organ dysfunction of liver, kidney, heart, and brain contributes to physiological collapse. Sustained original infections along with new viral/bacterial infections testify to the presence of an almost inert or hibernating state [42–44].

The fundamental driving force behind the failure of unsuccessful acute inflammation to epigenetically correct its inflexibility is not known, but maintaining the silent heterochromatin by RelB and its transcription repressor complex signify a resistance to restoring a flexible state of chromatin across thousands of genes [36]. It further suggests homeostat failure. During this time, ATP is low and cell death pathways may remain active in this catabolic state [45]. What prevents this epigenetic state from reversing is completely unknown.

Possibilities include alterations in redox balance between oxidized and reduced adenine nucleotides and repressed ability to generate ROS. Figure 37.4 conceptualizes the features of uncontrolled inflammation at the epigenetic level.

37.4.2 Chronic Inflammation with Epigenetic Dysregulation

Chronic inflammation reflects a low-grade and prolonged initiation or reduced adaptation; by definition it is unsuccessful epigenetic programming. In chronic inflammation, a persistent external or internal environmental stress stimulus resets the epigenetic homeostat in the proinflammatory state [46–48]. Known examples include elevated nutrients (glucose of proinflammatory fatty acids exterior to the immune cells during obesity with metabolic syndrome), abnormal microbial intestinal and immune cell interface in inflammatory bowel diseases, cholesterol and lipid deposits in inflammatory cells in atherosclerosis, amyloid plaques in Alzheimer's dementia, and chronic infections such tuberculosis. Possible epigenetic code inflexibility mechanisms include: (1) persistent acetylation activator histone codes and activated transcription factors (e.g.,

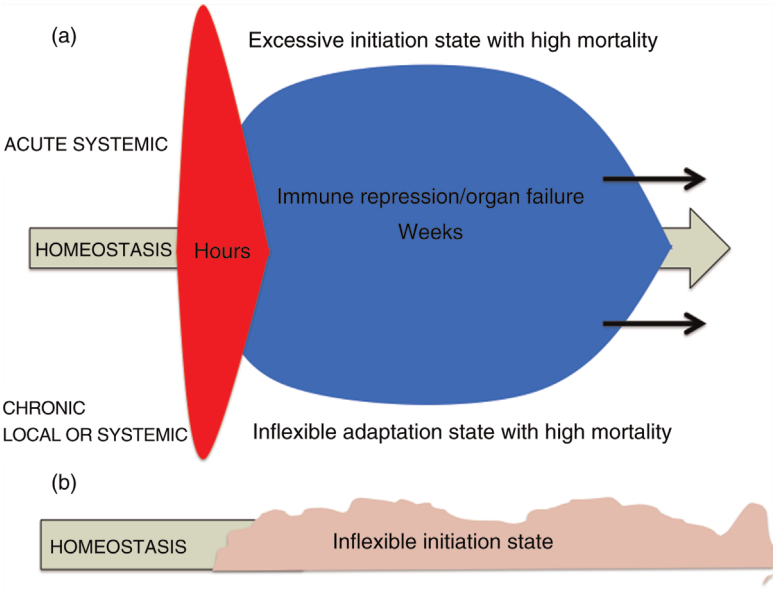

Figure 37.4 Epigenetics of unsuccessful inflammation. Evidence supports that the same sets of genes are involved in successful and unsuccessful inflammation, suggesting that dysregulated homeostasis protective reprogramming contributes to unsuccessful inflammation. This quantitative versus qualitative concept is depicted in (a) showing acute inflammation and (b) showing chronic inflammation. (a) If the inflammation homeostasis protector axis is set too low or the stress level is overwhelming, *the initiation state magnitude* reaches levels incompatible with cell and organ life, as depicted in the red zone. When the *adaptation state becomes inflexible* and persists in its catabolic and immune repressed state, infections cannot clear, organs cannot heal, and survival decreases as shown in the blue zone. (b) Chronic inflammation fails to temporally progress through initiation to adaptation to homestasis retrieval, suggesting that the inflammation homeostat is chronically set too low and/or is unable to progress through adaptation to resolution. However, the epigenetics of chronic inflammation is unclear.

NFκB p65) [49], (2) constitutively reduced *adaptation* [50], (3) inflexible nutrient overload with imbalanced mitochondria fueling [51], (4) persistently elevated ROS and NOS, which activate or inactivate inflammatory mediators [52]. Taken together conceptually, it is clear that chronic inflammation has a broken epigenetic homeostat with an abnormal epigenetic landscape not yet mapped. As depicted in Figure 37.4, chronically unsuccessful inflammation differs from acute in that it appears arrested in the *initiation* state. There is either too much *yin* or too little *yang*.

Two fundamentally important unknowns about unsuccessful acute and about chronic inflammation are as follows: (1) Why does lethal acute systemic inflammation get arrested in the adaptation state? (2) What prevents chronic inflammation from epigenetically directing adaptation and resolution?

Successful treatments depend on understanding the answers to these questions.

37.5 Epigenetics and Immunometabolism

Mounting evidence implicates cell nutrient selection as determinants of immune cell type and function. Glucose and amino acids fuel *initiation* (defend) and fatty acids fuel *adaptation* [25,53]*, and homeostasis retrieval rebalances the selection of cell nutrients*. The terms immunometabolism or meta-inflammation describe a duel partnership between metabolism and immunity, and this relationship is epigenetically coupled (see Figure 37.5).

37.5.1 Immunometabolism and Chronic Inflammation

A series of discoveries in obese human adipose tissue and later as a systemic response in obesity launched the immunometabolic and bioenergy concept. Proinflammatory macrophages (sometimes referred to as M1 classic monocytes and macrophages) that produce TNF-α become dominant over resident macrophages (sometimes called the M2 alternative type) in obesity with chronic inflammation [54,55]. This M2 to M1 macrophage polarity shift promotes chronically unsuccessful inflammation by misbalancing *initiation* and *adaptation* epigenetic polarity. This inflammatory process involves other cells: T effector proinflammatory lymphocytes also dominate over T regulatory lymphocytes in obese adipose tissue, and neutrophils and eosinophils contribute to immunometabolic imbalance [56]. Importantly, chronic obesity-induced inflammation promotes *systemic* metabolic dysregulation characterized by the diabetes phenotype, which is M1 macrophage *initiation* state dependent.

Fuel preferences by M1 effector and M2 regulatory/alternative macrophages and T effector CD4+ and CD8+ versus T repressor cells clearly differ [55,57]. Virtually all effector immune cells studies support a need for glycolysis to optimally mount their defense and anabolic properties, while repressor immune cells use catabolic fatty acid oxidation for a low-energy state. Cell nutrient selection between glucose and fatty acids becomes *inflexible* during obesity with chronic inflammation [51], but reversal or repair of the abnormal epigenetic

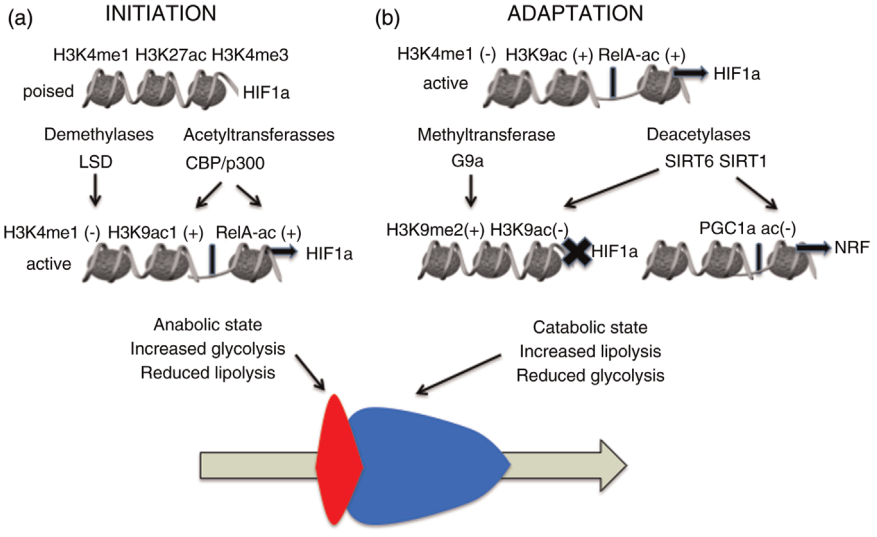

Figure 37.5 Epigenetics and immunometabolism: fueling the flame from poised promoters directly connects inflammation with cell nutrient selection. (a) Shows that NFκB p65 and HIF1a are epigenetically linked through histone acetylation and demethylation, which support increased glucose receptor expression and glucose uptake, promotes pentose shunt activity in monocytes, and directs aerobic or anaerobic glycolysis and glucose oxidation during inflammation *initiation*. This nutritional pathway is required for an optimal defense state – ROS generation, cell constituent synthesis, and ATP production – during which time lipolysis and fatty acid ß oxidation are decreased in favor of lipid synthetic processes. A critical switch from glycolysis to fatty acid oxidation as shown in (b) is a hallmark of inflammation adaptation and catabolic low-energy state of reduced pyruvate oxidation. Nuclear NAD+ generation and SIRT1 and SIRT6 deacetylase activation command this homeostasis switch, with SIRT6 repressing HIF1a and SIRT1 activating PGC1a and its control over lipolysis and mitochondrial biogenesis through nuclear respiratory transcription factors (NRFs). Histone H3K9 deacetylation followed by G9a histone methyl transferase activity promotes HIF1a gene silencing.

homeostat retrieves immunometabolic homeostasis and represses the chronic inflammation of obesity. For example, epigenetic dysregulation due to overnutrition is reversed by weight loss, supporting the notion that maintaining proper selection and flexibility of bioenergy fuel sources is essential to avoid chronic inflammation – also suggesting that pharmacologic approaches are tenable.

37.5.2 Immunometabolism and Acute Inflammation

Acute inflammation also couples immunity and metabolism through epigenetic programming [26,27]. This concept is becoming critically important for understanding acute inflammation. In naïve monocytes or macrophages, robust TLR4-induced inflammation *initiation* first increases glucose flux and generates a Warburg-like aerobic glycolysis state [21] controlled by hypoxia-inducible factor 1 alpha (HIF-1α) before switching to *adaptation* [21]. This stress recognition pathway concomitantly reprograms immunity and metabolism by gene-specific histone acetylation, nucleosome remodeling, NFκB p65 acetylation, HIF-1α

acetylation, and concomitant transactivation of immune effector/glycolysis controlling genes. Functionally, acetylated histone lysines and HIF-1α protein acetylation lead to a direct increase in glucose 1 transporter (GLUT1), hexokinases, glycolysis to lactate pathway, and pentose phosphate pathway (PPP) activity. When *initiation* epigenetically switches to *adaptation*, fueling by glycolysis switches toward increased fat uptake. This is accompanied by internal lipolysis, followed by fatty acid mitochondrial import, ß oxidation, and "feeding" of reducing NADH and FADH reducing equivalents to run the electron transport chain proton pump for ATP generation. During this nutritional and bioenergy switch, decreased ribosome expression and disrupted mTor pathways limit protein synthesis.

Bioenergy switching during initiation from an anabolic to a catabolic state resembles a starvation or hibernation state that seeks to conserve energy [58,59]. Nuclear receptors, such as peroxisome proliferative activated receptor (PPAR) and cofactor PGC 1-α [60], retinoic acid receptors, and estrogen-related receptors epigenetically promote the starvation or hibernation state, which depends on fat as primary fuel [61]. This "physiologic divorce" from using glucose carbons for energy compromises host defending and anabolic mending processes. Clinically, it is characterized by severe immunosuppression, persistent organ dysfunction, and high mortality rates.

37.5.3 Distinct Differences in Immunometabolic Coupling Occur During Acute versus Chronic Inflammation

In acute inflammation, immunometabolic epigenetic switching of monocytes from *initiation* to *adaptation* is rapid (within 6–12 h of *initiation*) [21]. In successful acute inflammation, the immunometabolic pathways both adapt and return to homeostasis. If unsuccessful inflammation, both the immune and metabolic responses concomitantly become inflexible; a state in which immunometabolic homeostat has failed.

In chronic inflammation, inflexibility differs by occurring in the initiation state, which through sustained system-wide dominance of the M1 monocyte and macrophage maintains the metabolic diabetic phenotype and the proinflammatory phenotype. Inflexible fueling of fat metabolism maintains a dominant proinflammatory response. Although there is evidence of concomitant anti-inflammatory M2 activity, chronic inflammation appears to unsuccessfully *adapt* and homeostasis *restoration* fails. Uncontrolled acute and chronic inflammations are similar in that they both are reversible, although they use different approaches.

Does metabolism inform or even direct nuclear epigenetic processes? Evidence supports that metabolism regulates histone acetylation/deacetylation states by modifying the availability of acetate and methyl for epigenetic use [10]. Acetyl CoA generated in mitochondria or cytosol from glucose and fat-derived carbons provide acetate for acetylation, and amino acid metabolism-derived *S*-adenosyl methionine (SAM) provides methyl for epigenetic coding. Reactive oxygen-derived and nitrogen-derived species from cytosol or mitochondria also can inform nuclear epigenetic processes through transfer to the nucleus and direct oxidation and reduction of nuclear proteins and DNA, which can change epigenetic functional pathways [62].

37.6 Sirtuins: An Epigenetic Homeostat

The spatial and temporal features of inflammation with its orderly and epigenetically controlled movement away from and back to homeostasis suggest that a common regulatory axis "guards" metabolic and immune homeostasis at epigenetic and post-translational levels. NAD+-dependent sirtuin (SIRT) family of redox-sensing deacylases and ribosylases are the leading homeostat checkpoint candidates [63]. First discovered in yeast, heterochromatin generator and metabolic sensor was *silent mating-type information regulator-2* (Sir2), an NAD+ -sensing protein with lysine deacetylase activity [64].

The sirtuin mammalian counterpart of yeast Sir2 founder protein, nuclear SIRT1, is an epigenetic checkpoint and homeostasis rheostat (homeostat), which reprograms chromatin structure of specific gene sets during inflammation [65]. Nuclear SIRT1 both represses NFκB p65-dependent euchromatin activation through deacetylation and concomitantly induces NFκB RelB-dependent silent heterochromatin formation, as inflammation *initiation* switches to *adaptation*. Accordingly, SIRT1 as a master inflammation rheostat proximally controls NFκB p65 and RelB participation in epigenetics by reciprocally decreasing *initiation* and promoting *adaptation*. In successful acute inflammation, the SIRT1 homeostat remains flexible, is turned down and immunometabolism returns to homeostasis with inflammation *resolution*. In an unsuccessful acute inflammation, sustained increases in NAD+ levels keep SIRT1 in an activated state [66], maintaining heterochromatin-based immune and metabolic inflexibility with its low-energy "hibernation" state – supporting the potentially lethal combination of immune repression and bioenergy failure [58,59].

As another example of the critically important SIRT1 homeostat, SIRT1 informs RelB to increase SIRT3 expression as a moderator of mitochondrial physiology [67]. SIRT1 through RelB, but not SIRT3, also supports mitochondrial biogenesis. The epigenetic functions of SIRT1 are directly controlled by redox, in which oxidized cysteines deactivate and reduced cysteines activate its function [68], supporting that redox control may direct epigenetic landscape reprogramming.

As the third example of the SIRT1 homeostat, SIRT1 proximally controls SIRT6 expression, the master regulator of glycolysis. Together, nuclear SIRT1 and 6 are reciprocal directors of glycolysis (SIRT6 reduces) and lipolysis and fatty acid oxidation (SIRT1 increases) [69]. SIRT1 and 6 distinctly deacetylate histones but similarly inactivate NFκB p65. SIRT6 by deacetylating histone H3K9 represses HIF-1α expression to limit GLUT1 expression, glucose flux, and glycolysis [70]. SIRT1 deacetylates peroxisome proliferator-activated receptor gamma coactivator 1 alpha (PGC1-α) to promote lipolysis and fatty acid oxidation [71]. Further supporting SIRT1 homeostat function are reports that reduced SIRT1 levels and activity amplifies inflammation *initiation*. Moreover, many chronic inflammatory diseases are associated with low SIRT1 levels [72]. Thus, SIRT1 is a master homeostasis checkpoint that informs the epigenetically controlled immunometabolic axis.

It is plausible that all SIRT family members cooperate to guard homeostasis [73]. They dominate in different cell compartments: nuclear SIRT1, 6, and 7; cytosolic SIRT2 with translocation to nucleus during acute inflammation; mitochondrial SIRT 4, 5, and 6. SIRT1 and 6 coordinate nuclear epigenetic pathways,

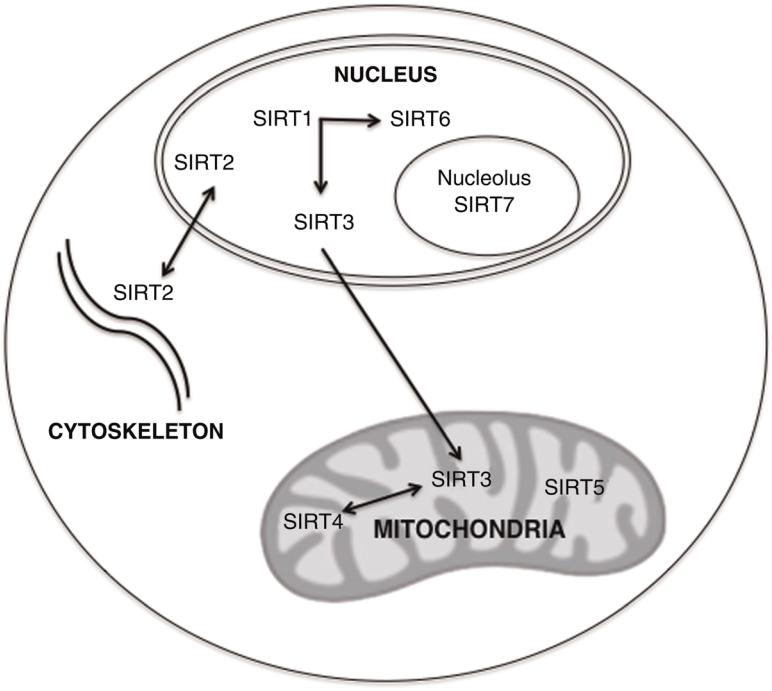

Figure 37.6 Sirtuins in inflammation: shown are locations of seven-family member SIRTs. Nuclear SIRT1 control of nuclear SIRT6 and mitochondrial SIRT3 expression and levels in mitochondria direct epigenetic immune, metabolic, and bioenergy reprogramming and its switching from initiation to adaptation. Low levels of SIRT1, SIRT2, and SIRT3 occur in chronic inflammation states such as obesity with diabetes. Other members of the SIRT family likely participate in homeostasis regulation. SIRT4 has reciprocal controls with SIRT3 and its expression may be separately regulated as a resolution contributor. Mitochondrial SIRT5 function as a desuccinylation agent may support energetics. SIRT2 is the major SIRT expressed in adipose tissue and shuttles between cytosol and nucleus. SIRT7 located in the nucleolus represses expression of ribosomes and may contribute to generating the catabolic state.

while SIRT3, 4, and 5 balance mitochondrial function with SIRT4 counter-regulating SIRT3 function by repressing fatty acid oxidation and glutamine metabolism [74]. SIRT2 is the dominant SIRT-expressed adipose tissue, regulates fat cell development, and supports obesity-associated immunometabolic reprogramming [75]. SIRT7, the least understood of sirtuins, is located in nuclear nucleoli and represses ribosomal DNA function and protein synthesis, which accompanies inflammation *adaptation* [76]. Figure 37.6 conceptualizes epigenetic homeostat properties of Sirt1 and its possible connections with other sirtuins family members.

37.7 Epigenetic-based Inflammation Treatment

37.7.1 Emerging Data Support that Targeting SIRT1 Homeostat Function may Treat Unsuccessful Inflammation

The *adaptation* inflammation state during severe systemic stress responses like sepsis persistently increases NAD+ and elevates SIRT1 levels and activity [66].

Mounting data support the potential of targeting SIRTs as novel treatments for inflammatory disease. For example, marked increases in survival occur in septic mice when a single dose of a SIRT1 inhibitor is administered after *initiation* switches to *adaptation* in septic mice with uncontrolled acute inflammation and high mortality [36]. This sepsis rescue rebalances immunity, metabolism of glucose and fatty acids, and mitochondrial function. Further supporting clinically applicable rheostat properties of SIRT1, studies show that increasing SIRT1 in low sepsis states like obesity substantially improves diabetes and decreases inflammation [77]. Although early results support that epigenetic therapeutic targeting of uncontrolled inflammation can be beneficial, indeed lifesaving, more research is needed to determine how effective the SIRT homeostasis axis is as a treatment target for unsuccessful acute or chronic inflammation and to identify what mechanisms dysregulate the SIRT homeostat. Critically important will be identifying epigenetic biomarkers, in order to identify which side of the epigenetic axis to target. Figure 37.7 depicts epigenetic-based prevention and rescue during acute systemic sepsis inflammation (upper panel) and chronic inflammation (lower panel). Table 37.3 lists immune, metabolic, and bioenergy processes improved through homeostasis retrieval.

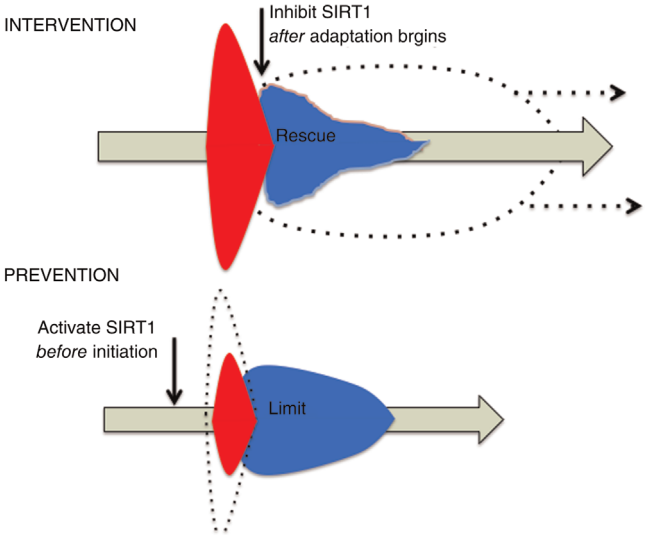

Figure 37.7 Epigenetics-based inflammation treatment: better understanding of homeostasis pathways is leading to new targets for inflammation *intervention* during sepsis or *prevention* in obesity with secondary stress. Based on the SIRT1 homeostat paradigm, administering a SIRT1 inhibitor to septic mice after initiation switches to adaptation rescues septic mice from death by reducing immune, metabolic, and bioenergy dysregulation (upper panel). In contrast to adjusting a high homeostat downward, preactivating SIRT1 in obese mice, whose SIRT1 levels are low, limits initiation magnitude, reduces sustained immune repression, and increases survival (lower panel).

Table 37.3 Targeting the Sirt1 epigenetic-based homeostat for sepsis inflammation treatment.

Sepsis	Immunity	Vascular	Metabolic	Bioenergy	Survival	Ref.
In vivo (mice): SIRT1 inhibition administered during early adaptation and immune repression	Rebalances effector/repressor Cytokine response Increases microbial clearance Restores NFκB p65 competence	Improves blood pressure and vascular flow Restores E-selectin and ICAM-dependent microvascular leukocyte endothelial adherence response	Rebalances glucose and fatty acid oxidation	Reduces mitochondrial stress	Markedly improves	[36]
Ex vivo (mice): SIRT1 inhibition of splenocytes or macrophages	Reverses silent heterochromatin Removes repressor complex	Not applicable	Rebalances glucose and fatty acid oxidation	Rebalances electron transport chain	Not applicable	[67] [69]
Ex vivo (humans): +/− SIRT1 inhibitor	Reverse silent heterochromatin Removes promoter repressor complex	Not applicable	Rebalances glucose and fatty acid oxidation	Rebalances oxidative phosphorylation and oxidoreductases	Not applicable	[35] [66] [67] [69]
In vitro (humans): Monocyte cell model Pharmacologic and genetic approaches	Reverses silent heterochromatin Controls epigenetic repressor complex on promoters. Regulated by NFκB p65 deacetylation	Not applicable	Rebalances glucose and fatty acid oxidation	Rebalances glucose/fatty acid oxidation and oxidoreductases		[7] [30–33] [35] [66] [67] [69]
In vivo (obesity in mice): Administering SIRT1 agonist before sepsis onset	Limits initiation magnitude	Reduces amplified microvascular leukocyte/platelet endothelial adherence	Not done	Not done	Markedly improves	[77]

37.8 Summary

Epigenetic reprogramming of immunity, metabolism, and mitochondrial bioenergetics plays a crucial role in directing the course of inflammation. In monocytes and macrophages, and likely in adaptive immune T cells, epigenetic processes first maintain and depart from a poised enhancer–promoter region after external or internal environmental alarmin signals reach nuclear chromatin. Feedforward processes reorganize active euchromatin into silent heterochromatin as inflammation *initiation* switches to *adaptation*. Successful inflammation restores homeostasis; unsuccessful inflammation does not.

Mounting evidence integrates inflammation with immunity and metabolism and supports that members of the NAD+-sensing sirtuin family, particularly SIRT1, control a homeostat that epigenetically controls immunometabolic and mitochondrial bioenergy reprogramming. When this homeostasis control axis becomes inflexible, acute and chronic inflammatory diseases occur. Applying treatment approaches based on SIRT-dependent epigenetic reprogramming of immunometabolic and mitochondrial bioenergy pathway is a promising new concept. Identifying critical checkpoint nodes connecting nuclear epigenetic processes with extranuclear processes could expand prevention and intervention treatment strategies for inflammatory diseases, thereby reducing the global health burden of unregulated inflammation.

38.1 Introduction

In 1906, an Austrian pediatrician Clemens von Pirquet described cases of serum sickness in children receiving antibody preparations and used for the first time the term *allergy* to describe this phenomenon [1]. Since then, we have learned a lot about the initiation, development, and different types of allergic inflammation, as well as the immunological mechanisms involved in allergic reactions. There are four types of allergic reactions based on the main pathogenesis mechanism, historically defined as four types of hypersensitive reactions by Gell and Coombs [2], and later redesigned by Pichler [3]. Type I, Th2-dependent, IgE-mediated hypersensitivity includes mast cell degranulation upon surface IgE cross-linking and represents the main pathogenic mechanism of the most common allergic disorders such as allergic rhinitis, as well as skin prick test reactions. It is sometimes called "classical allergy" to differentiate with other less often allergic reactions such as drug allergies or contact dermatitis. Type II reactions, the antibody-dependent cellular cytotoxicity, are characterized by the cellular/tissue antigen–antibody (IgG/IgM) reactions that are able to activate complement and/or recruit cytotoxic cells, which finally lead to the tissue injury and function loss. The typical examples are the Goodpasture disease, thrombocytopenia, or autoimmune hemolytic anemia. Type III hypersensitivity is described by the formation of immune complexes, when antibody, most often IgG, binds to a soluble antigen. These immune complexes are further deposited within the vascular walls of various organs such as joints or kidney and lead to inflammation. Traditional examples are serum sickness, systemic lupus erythematosus, and several forms of glomerulonephritis. In classical Gell and Coombs description, type IV hypersensitivity, usually described as cell-mediated (or delayed-type)

hypersensitivity, sensitized Th1 and Th17 cells, as well as cytotoxic lymphocytes release cytokines, activate macrophages and/or activate cell-mediate cytotoxicity programs that all lead to tissue injury and cell destruction. Examples of type IV reactions include contact dermatitis, diabetes type 1, multiple sclerosis, or some stages of tuberculosis. Another subclass of type IV hypersensitivity reactions play a major role in allergic diseases such as asthma and atopic dermatitis. In this subclass, Th2 cells, type 2 innate lymphoid cells (ILCs) play a major role in tissue inflammation, eosipnophilia, and IgE production. This group of type IV hypersensitivity usually coacts with type I hypersensitivity reactions in allergic diseases [3].

At present, it is known that the immune mechanisms underlying each allergic disorder are very complex and, in most cases, exchange or coexist at different stages of allergic disease. However, the modified Gell and Coombs classification is useful to grasp this complexity and put the clinical manifestations of the allergic diseases into a more pathomechanistic context.

38.1.1 Overview of Mechanisms of Allergic Inflammatory Response

The immune response in allergic diseases consists of sensitization/memory and effector/elicitation phase. Upon sensitization phase, innate immune cells such as airway cells, gut epithelial cells, or skin keratinocytes sense the allergens and their microenvironment via the pattern recognition receptors (PRRs) and particularly release thymic stromal lymphopoietin (TSLP), IL-33, IL-25, and GM-CSF, initiating the inflammatory response cascade [4–6]. Dendritic cells and monocytes/macrophages sample the allergen and travel to the draining lymph nodes to present the antigen to T cells inducing the differentiation and clonal expansion of allergen-specific $CD4^+$ Th2 cells. These cells produce IL-4 and IL-13 and induce class switch to the ϵ immunoglobulin heavy chain in B cells and the production of allergen-specific IgE antibodies (Abs). In addition, they support eosinophilia with IL-5. Allergen-specific IgE binds to the high-affinity FcϵRI on the surface of mast cells and basophils, which travel to different tissues, ready to react, degranulate, and release the wide range mediators upon the next encounter with the same allergen. At the same time, a memory pool of allergen-specific T and B cells is also generated. Type 2 ILC particularly release IL-5 and IL-13 and take an important part in the early phase of initiation of inflammation [7]. They react within a few hours with IL-33 released from epithelium, whereas Th2 cells require clonal expansion for at least 1 week to act. Although ILCs do not show any memory, Th2 cells display an antigen/allergen-specific memory with their increased frequency in the circulation and affected organs.

The effector phase usually happens as an immediate-phase response (IPR) and can be followed by the late-phase response (LPR) [8]. The new encounter with the causative allergen induces cross-linking of the IgE–FcϵRI complexes on the surface of sensitized effector cells, leading to the release of mediators including histamine, responsible for the classical symptoms of IPR such as increased vascular permeability, extravasation of fluid into the tissues, and smooth muscle contraction. Sneezing, watery discharge from eyes and nose, rash, or asthmatic bronchospasm are the classical symptoms of the IPR. The symptoms might be followed by the LPR, which occurs 6–12 h later, due to the other mediators

released from mast cells such as leukotrienes or upon the persistence of the allergen. Activated allergen-specific Th2 cells, accompanied by the innate lymphoid cell 2 (ILC2), produce IL-4, IL-5, IL-9, and IL-13, which play a key role in the maintenance of allergen-specific IgE levels, eosinophilia, recruitment of inflammatory cells to inflamed tissues, and persistence of the allergic inflammation into the chronic form [7,9,10].

In summary, various types of both innate and adaptive immune cells producing multiple mediators, including lipids, purines, cytokines, chemokines, soluble receptors, small molecules like histamine, adenosine, and reactive oxygen species take part in initiation, development, and maintenance of allergic inflammation.

38.2 Innate Immunity and Its Role in Allergic Inflammation

38.2.1 Microbial Pattern Recognition by the Innate Immune System

Both innate immunity cells and cells of adaptive immunity have a big repertoire of potent innate immunity receptors called PRRs to quickly recognize the most common and ubiquitous microbial, fungal, and viral threats. Through the evolution and natural selection, human organism adapted to survive and to recognize highly conserved molecular structures of these organisms called pathogen-associated molecular patterns (PAMPs) by PRRs [11]. These receptors also recognize other alarming situations in the body through sensing damage-associated molecular patterns (DAMPs), released by dying cells [12,13]. In many cases, activation of these receptors starts to initiate the cascade (Figure 38.1). There are two main types of PRRs: transmembrane or cytosolic signal-transducing receptors and secreted by the cells' soluble receptors.

Transmembrane and cytosolic PRRs such as Toll-like receptors (TLRs), NOD-like receptors (NLRs), RIG-I-like receptors (RLRs), AIM2-like receptors (ALRs), C-type lectin receptors (CLRs), and protease-activated receptors (PARs) are expressed constitutively in epithelial cells, dendritic cells, monocytes, and macrophages as well as T and B cells [14]. Their expression and activation often increases dramatically upon activation by the microbial PAMPs. Activation of these receptors leads to initiation of the immediate cell response through several mechanisms depending of the cell type, including NF-kB pathway triggering, activation of inflammasome and release of IL-1β in macrophages and DCs, release of interferons and various cytokines, chemokines, and lipid mediators in epithelial cells, aiming at the immediate and local threat elimination, and activation of the adaptive arm of immune response [14,15].

Secreted PRRs such as antimicrobial peptides (α- and β-defensins, cathelicidin (LL-37), dermcidin, and regIIIγ), collectins (mannose-binding lectin and surfactant protein A and D), and pentraxins (C-reactive protein) can directly kill invading pathogens or are involved in their opsonisation to facilitate phagocytosis and chemoattraction of innate and adaptive effector cells [16]. Some PRRs, such as CD14 and MD-2, can be both secreted or membrane-bound and serve as costimulators/adaptors for transmembrane PRRs, such as TLR4 in recognition of bacterial endotoxin.

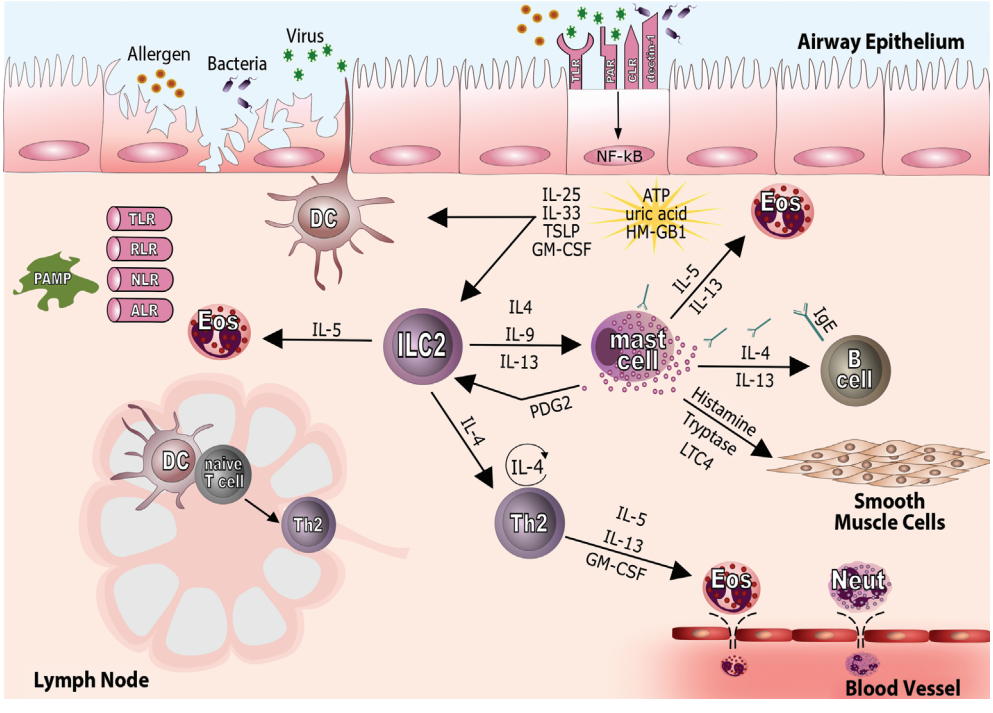

Figure 38.1 Airway epithelium response to allergens. Enzymatically active allergens invading airway epithelial cells may be recognized by PRRs such as TLRs, CLRs, PARs, and dectin-1, causing their activation and initiation of intracellular signaling pathways that result in production of various cytokines, chemokines, interferons, and lipid mediators. Activation of PRRs also leads to the release of endogenous danger signals such as ATP, uric acid, and HMGB1. Penetration of proteolytic allergens through the tissue may facilitate their access to submucosal dendritic cells. Upon activation, mature dendritic cells migrate to draining lymph nodes to present the antigen to the naive T cells through the MHC class II molecules that induce differentiation and clonal expansion of allergen-specific Th2 cells. Release of Th2-type cytokines (IL-4 and IL-13) by Th2 cell and ILC2 initiate class-switch recombination in B cells, leading to production of allergen-specific IgE antibodies that bind to the high-affinity receptor for IgE – FcεRI – on the surface of mast cells and basophils. Degranulation of these cells results in the release of wide range mediators responsible for smooth muscle contraction, vasodilation, goblet cell hyperplasia, and increased vascular permeability. TSLP, IL-25, and IL-33 released by epithelial cells potentiate Th2 responses. IL-5 and IL-13 produced by ILC2 contribute to early inflammation stage.
ALR: AIM2-like receptor, ATP: adenosine triphosphate, CLR: C-type lectin receptor, DC: dentritic cell, Eos: eosinophil, GM-CSF: granulocyte macrophage colony-stimulating factor, HM-GB1: high-mobility group box 1, IgE: immunoglobulin E, IL: interleukin, ILC: innate lymphoid cell, LTC4: leukotrien C4, Neut: neutrophil, NF-κB: nuclear factor κB, NLR: NOD-like receptor, PAR: protease-activated receptor, PDG2: prostaglandin D2, PAMP: pathogen-associated molecular pattern, RLR: RIG-I-like receptor, Th: T helper cell, TLR: toll-like receptor, TSLP: thymic stromal lymphopoietin

38.2.2 Epithelial Cells

Airway and gut epithelium, skin keratinocytes, and other epithelia are at the interface of the human body and the environment. Thus, they form a complex

physicochemical barrier and the first line of defense against environmental insults such as viruses, bacteria, fungi, parasites, allergens, and inorganic particles. Epithelial cells regulate both innate and adaptive immunity, among others, through the production of various costimulatory molecules, chemokines, cytokines, and lipid mediators in response to environmental stimuli, sensed by PRRs [17]. After sensing of allergens, epithelial cells can produce IL-1, IL-25, and IL-33, TSLP, and GM-CSF [17,18]. These cytokines start to orchestrate Th2 immunity. Upon allergen exposure, epithelial cells can also react by releasing danger signals such as adenosine triphosphate (ATP), uric acid, and high-mobility group box 1 (HMGB1), which increase local inflammation and might mount and further strengthen Th2 response [19]. When allergens have additional protease activities and/or they are accompanied by microbial components, such as endotoxin or inorganic particles, epithelial activation can lead to a mixed Th2 and Th17 or even Th1 immunity [20,21]. Different allergens activate several of these mechanisms and additional environmental factors such as viral infections, cigarette smoke, and diesel exhaust particle exposure might modify the final outcome in the direction of an IgE response against coexposed allergens. Infection with respiratory viruses or exposure to cigarette smoke increases the surface expression of TLR4 and MD-2, thus decreasing the threshold for allergen recognition [22]. Moreover, infection with several common respiratory viruses, such as human rhinovirus (HRV), the causative agents of the common cold, leads to impairment of nasal and bronchial epithelial barrier integrity [23] and as a consequence to facilitation of allergen uptake through the network of dendritic cells and monocytes [24,25]. Barrier function of epithelial cells in general plays an important role in allergy sensitization and further symptoms upon allergen exposure. Recent genome-wide association studies (GWAS) found novel links between genes involved in epithelial integrity such as cadherin-related family member 3 (CDHR3) and increased risk of atopy and asthma. CDHR3 and protocadherin (PCDH1) are highly expressed in epithelium [26,27]. They control epithelial polarity and integrity and might in this way facilitate allergic sensitization. It has been shown that epithelium of asthmatic patients has decreased barrier integrity and excess of Th2 cytokines such as IL-13 and IL-4 lead to further barrier impairment [28]. In summary, after recognition of allergen, epithelial cells response leads to activation of the network of DCs, ILC2, basophils, and monocytes that stimulate type 2 ILCs and polarize Th2 responses in naïve T cells [29].

38.2.3 Dendritic Cells

Dendritic cells are one of the most potent antigen-presenting cells (APCs), which play a crucial role in sensitization to allergens [30,31]. They reside beneath the epithelium in the skin and at the mucosal sites in the airways and gut. They can even extend dendrites between the epithelial cells in order to "patrol" and sample the external environment. Once they capture the allergen, they migrate to the draining lymph nodes and present the processed antigenic peptides to T cells. They present antigen within an antigen-binding cleft of major histocompatibility complex (MHC) molecules. These events start at the APC cell surface with the capture and endocytosis of antigens, followed by a complex sequence of

enzymatic activities leading to the association of antigenic peptides with MHC molecules and expression back to the cell surface. Intracellular molecules such as host self-antigens and intracellular invading pathogens' (e.g., viruses) proteins are processed and presented in the context of MHC class I to CD8+ T cells. This process plays a central role in recognition of the self-antigens and induction of immediate cytotoxic response in case of viral infection of the cell. In contrast, CD4+ T cells recognize antigenic peptides when presented by APC in the context of a class II MHC molecule together with the appropriate costimulatory signals. Allergen-specific Th2 subset is further activated and clonally expanded upon activation signals coming from combined actions of DCs, ILCs, and Th2 cells. In humans, there are two main groups of circulating DCs: (i) myeloid dendritic cells (mDCs) and (ii) plasmacytoid dendritic cells (pDCs) [31]. mDCs can be further divided into type 1 mDCs expressing BDCA1 and type 2 mDCs expressing BDCA3 [32]. Both mDCs and pDCs and their subsets express a different repertoire of PRRs and costimulatory molecules and thus display a diverse cytokine signature and further translate this cytokine profile to activation of specific subsets of CD4+ T cells [33]. In general, mDCs induce naive CD4+ T cells to produce IFN-γ, whereas pDCs stimulate naïve CD4+ cells to generate Th2 cytokines. However, in humans, there is also a special subset of fully mature pDCs that are also able to induce functional Treg cells [34,35], indicating that pDCs constitute a unique DC subset exhibiting intrinsic tolerogenic capacity [36–38].

38.2.4 Monocytes and Macrophages

Monocytes and macrophages show pleiotropic biological activities, including ability of antigen presentation, phagocytosis, cytotoxicity, and secretion of pro- and anti-inflammatory mediators (cytokines, chemokines, growth factor, etc.). The importance of monocytes in case of allergen sensitization has been shown in mice and humans [24,25].

Monocytes in general are the circulating precursors of tissue macrophages. However, recent fate-mapping experiments clearly showed that in many tissues there are resident macrophages, which develop during embryonic differentiation and play a pivotal role in tissue homeostasis in health and upon inflammation [39]. Macrophage function depends, to a large extent, on the monocyte activation process. Monocytes are heterogeneous population of cells, and on the basis of the expression level of CD14 (LPS receptor) and CD16 (FcγRIII), three functionally different subpopulations can be distinguished, namely, classical (CD14++CD16-), intermediate (CD14++CD16+), and nonclassical (CD14+CD16++) monocytes [40]. Nonclassical monocytes are referred to as proinflammatory cells because, in contrast to remaining two subpopulations, after stimulation, they release high amounts of tumor necrosis factor-alpha (TNF-α), but not IL-10 [41]. In fact, CD14+CD16++ monocytes are the major source of TNF-α on the periphery. These cells show an array of similarities to the M1-type macrophages, previously classified as classically activated macrophages. These cells are mainly involved in antimicrobial and antitumor responses. Therefore, they produce and release high amounts of proinflammatory cytokines, including IL-1, IL-6, IL-12, IL-23, and TNF-α. Furthermore, they posses high capacity for antigen

presentation to naïve T cells and polarize adaptive immune response toward Th1/Th17. On the other hand, CD14++CD16+ monocytes represent intermediate state of monocyte activation and maturation toward macrophages and show functional similarities to the M2-type macrophages (M2 a, b and c), previously referred to as alternatively activated macrophages. M2-type cells show an array of anti-inflammatory activities, including secretion of various anti-inflammatory mediators (e.g., IL-10, TGF-β, IL-1Ra, PGE_2 and others), induction of regulatory T cells, and lack of cytotoxic activity [42–44]. These populations are involved in suppression of adaptive immune response, inhibition of cytotoxic cell activity, rearrangement, reconstruction, and neovascularization of destroyed tissues.

38.2.5 Mast Cells and Basophils

Mast cells are one of the central effector cells in allergic inflammation. Upon first encounter with allergen, newly produced specific IgE binds the surface of mast cells through the FcεR1, the high affinity receptor for IgE. Upon next encounters with this allergen or cross-reacting allergen, tissue mast cells recognize it by at least two specific IgE molecules bound to the adjacent FcεR1 molecules [45]. This immediately activates mast cells and they respond by degranulation and release of granule contents that are preformed mediators such as histamine and several lipid mediators. Histamine, heparine, tryptase, chymase, prostaglandin D_2, cysteinyl leukotriens, and carboxypeptidase A3 are all preformed mediators released by activated mast cells [46]. At the same time, the production of many cytokines, chemokines, and growth factors is initiated by these mast cells. This rapid response of local mast cells leads to bronchoconstriction, vasodilation, increased vascular permeability, and increased mucus production in the bronchi of asthmatic patients or itching and eczema in case of skin manifestations. This response can be prolonged to the late phase, both due to the release of lipid mediators such as leukotrienes and due to infiltration of other effector cells such as eosinophils, monocytes, and neutrophils. Mast cells are distributed in all tissues, but they are found in high numbers especially near body surfaces, including the airway epithelium, the gut, and the skin [47,48]. Skin prick tests, widely used to document existence of specific IgE in the clinics, are based on the reaction of the resident skin mast cells in response to the applied allergen. Mature mast cells do not circulate in the blood; instead, hematopoietic stem cell-derived circulating mast cell precursors migrate to the peripheral tissues, where they complete their differentiation and maturation and become resident cells [49]. In contrast, basophils circulate in the blood in their mature form under the homeostatic conditions. They also express FcεRI, bind IgE and respond to allergen cross-linking in a similar way to mast cells. They release histamine and lipid mediators. They can also be a potent source of IL-4 and IL-13. Basophils are also used to document allergic sensitization in the basophil activation test, as the second-line test in allergy diagnosis [50].

38.2.6 Eosinophils

Eosinophils have been always associated with allergic disorders and helminthic parasite infection, but their roles in both of these states are not entirely clear [51].

They develop in the bone marrow from pluripotent progenitors, and in response to inflammatory stimuli they migrate into the blood and then accumulate in the peripheral tissues, such as lungs, skin, and gut in case of allergic disorders. They are important biomarkers of allergic disease [52]. Eosinophils contain many granules, contents of which are released upon activation. Human eosinophil-specific granules contain four major and proteins unique for eosinophils: eosinophil peroxidase, major basic protein (MBP), eosinophil cationic protein (ECP), and eosinophil-derived neurotoxin (EDN). They also contain many preformed cytokines, enzymes, and growth factors. Eosinophils have also other granules storing Charcot–Leyden crystal protein (also known as galectin 10 and eosinophil lysophospholipase), as well as lipid bodies, which are the sites of synthesis of prostaglandins, cysteinyl leukotrienes, and thromboxane [51]. Eosinophils travel to the peripheral tissues in response to the several cytokines and chemokines, from which IL-5 and eotaxin (CCL11) are the most potent, respectively. Eosinophils have surface receptors for these agents, IL-5Rα and CCR3. Several Th2-inducing cytokines, such as TSLP, IL-25, IL-33, and other cytokines might indirectly promote eosinophilia by stimulating IL-5 production. HMGB1 and other danger-associated molecular patterns acting through TLRs and other PRRs on eosinophils are also able to induce recruitment and activation of these cells. Eosinophils communicate extensively with tissue-resident mast cells, which prolong their survival in the tissue [53]. They can induce DCs recruitment, as well as regulate specific adaptive responses among others by release of Th2-type chemoattractants such as CCL17 and CCL22, which promote the recruitment of Th2 cells and also through their interactions with DCs [54]. Eosinophils can also prime B cells for the production of antigen-specific IgM [55].

38.2.7 Innate Lymphoid Cells

Recent studies have identified a novel group of lymphoid cells, called innate lymphoid cells (ILCs), which lack rearranged antigen receptors. These cells can be divided into three majors groups, based on their phenotypic characteristic and functional properties [56,57]. ILC1s constitutively express T-bet and they can produce IFN-γ upon stimulation with IL-12 and IL-15. They are present in the intestines of patients with Crohn's disease and they might act in parallel with pathogenic CD8+ cells [58]. ILC2s were initially described in the gut, but they are also abundant in the lung and many mucosal barriers. ILC2s require the transcription factors RORα and GATA3, as well as Notch signaling and IL-7 and IL-33 for their development [56]. They produce IL-5, IL-9, and IL-13 after activation with epithelial cytokines IL-33 and IL-25, which promotes Th2 responses [57]. Thus, they control mucosal environment in helminthic infections and once dysregulated, they might induce and maintain proallergic inflammation [56]. Indeed, several studies confirmed their important role in the pathophysiology of allergic inflammation and asthma, as well as their involvement in the response to viral infections [59,60]. ILC2s express CD25 (IL-2Ra), CD90 (Thy1), variable amounts of CD117 (c-Kit), and CD127 (IL-7Ra). In addition, ILC2s express variable amounts of CD278 (ICOS), ST2 (IL-33R) and IL-17RB (IL-25 receptor), which makes them prone to respond and expand in the presence of IL-33, IL25, and IL-2 [57]. ILC3s require the transcription factors RORγt and

GATA3 for development, and in response to IL-1β and IL-23 they produce IL-17, IL-22, and IFN-γ [57]. Extensive research is going on for the investigation of further subsets and functions of ILCs.

38.2.8 NKT Cells

Natural killer T (NKT) cells express invariant T-cell receptor (TCR) and they are able to rapidly release many cytokines such as IL-4, IL-5, IL-13, IL-17, and IFN-γ after activation, thus exhibiting features of both T cells and NK cells, and they are able to amplify adaptive immune responses. Different subsets of NKT cells have been described in the pathogenesis of both allergic [61] and nonallergic asthma and especially bronchial hyperresponsivness of asthmatic bronchi [62–64].

38.2.9 Natural Killer Cells

Natural killer (NK) cells do not express CD3, CD4, or CD8 and they are especially important both in killing tumor and virus-infected cells, and in controlling certain microbial infections. They can produce high levels of cytokines including IFN-γ, TNF-α, TGF-β, IL-5, IL-10 and IL-22 after stimulation. However, they also contribute to allergic inflammation by increasing Th2 cytokines and eosinophilia as demonstrated after depletion experiments in a mouse model [65]. In addition, a tiny NK cell subset that secretes mainly Th2 cytokines but not IFN-γ has been shown to contribute to IgE production in humans [66]. On the other hand, TLR9-ligand-activated NK cells producing high levels of IFN-γ were shown to play a protective role in the development of asthma [67]. A tiny regulatory subset of NK cells that secretes IL-10 and suppresses T-cell responses has been demonstrated in humans [66].

38.2.10 Role of Microbiota in Allergic Inflammation

The enormously huge number of bacterial species inhabits human body, which constantly interacts with the innate and adaptive parts of immune system. All barrier tissues in the gut, lung, or skin are colonized by many bacterial species. It has been shown that the composition of microbiome, interactions of microbial products with other components of the diet and life period in which humans are colonized by the specific bacterial strains, they have a huge impact on the development of allergy, obesity, and cancer [68]. Several studies have suggested that risk factors associated with allergic sensitization such as lack of maternal exposure to pets or livestock during pregnancy, maternal consumption of antimicrobials during pregnancy, cesarean birth, formula feeding, and early-life antimicrobial exposure, all concentrated in the pre- and early postnatal phases of life, are influencing neonatal and maternal microbiome composition [68]. The infant gut microbiome accumulates bacterial diversity over the first years of life, although the source of this bacterial diversity remains unknown. In several allergic disorders, it has been found that the early aberrant microbial colonization

that lacks commensal species or has lower number and diversity of commensals takes place. Moreover, animal studies and epidemiological cohorts with interventions with the use of several bacterial species or bacteria-rich environment supplemented early in life or supplemented to mothers during pregnancy prevented allergic sensitization. For example, early-life introduction of a cocktail of Clostridium species or a diversity of bacteria significantly decreased circulating IgE concentrations in adulthood [69,70]. In terms of mechanism, it has been shown that several microbial-derived metabolites, especially short-chain fatty acids (SCFAs) such as butyrate and acetate, or propionate increased by consumption of yogurts or due to fermentation of complex dietary carbohydrates can prevent the development of allergy and asthma by influencing the regulatory T-cell compartment among several other mechanisms [30,71,72].

38.3 Adaptive Immunity and its Role in Allergic Inflammation

The most important and defining feature of the adaptive immune system is its memory. In response to antigen stimulation, specific T and B lymphocytes start to clonally expand. They express specific antigen receptors on their surface, the expression of which is shaped early in the fetal life by the sequences of recombination of genes encoding these receptors. Initially, T and B cells start to "learn" to be antigen specific in the thymus and in the bone marrow, where the process of recombination of the antigen receptor genes is initiated. This is the part of the process called central tolerance. Due to this process, they can differentiate self- from the nonself-antigens. Through the expression of antigen-recognizing T-cell receptor (TCR) and B-cell receptor (BCR), T and B cells can bind and become activated by a specific antigen. First encounter with the specific antigen activates lymphocytes and leads to the generation of long-lived, antigen-specific memory T and B cells by their clonal expansion and increased frequency in lymphatic organs. Upon the next encounter with the same antigen, there is a relatively faster recognition by these memory cells. Both cellular (mediated by T cells) and humoral (mediated by B cells) responses are generated more rapidly than during the first exposure to this antigen and more memory cells are produced.

38.3.1 Central and Peripheral Tolerance Mechanisms

Central tolerance occurs in the primary lymphoid organs, such as thymus in case of T cells and bone barrow in case of B cells, while peripheral tolerance is shaped in peripheral lymph nodes, spleen, tonsils, Peyer's patches, and other tissues [73]. The lack of effective central and peripheral tolerance mechanisms leads to autoimmune disorders and allergic diseases.

In the thymus medullary thymic epithelial cells, dendritic cells and macrophages present tissue-specific autoantigens to the immature T cells in the context of major histocompatibility complex I and II. Aire, the autoimmune regulator

gene in the medullary thymic epithelial cells and other antigen-presenting cells in the thymus, regulates this process. Aire is a transcription factor that promotes ectopic expression of tissue-specific antigens on medullary thymic epithelial cells [74]. When T cells react to the self-antigens with high affinity, they are depleted in the process called negative selection. Nonself-reacting T cells expressing CD4 or CD8 subsequently exit to the periphery. A small fraction of T cells that express low-affinity receptors for self-antigens that have escaped negative selection in the thymus are subjected to the peripheral tolerance mechanisms. In addition, some self-reactive CD4+ T cells that are not deleted by negative selection develop into central regulatory T (Treg) cells in the process also regulated by Aire. These central Treg cells circulate in the periphery as mature T cells and inhibit immune or inflammatory responses against self-antigens. B cells expressing immunoglobulin receptors with high affinity for self-components also undergo negative selection. They are eliminated in the bone marrow in the process of deletion and/or receptor editing. Similar to T cells, B-cell clones expressing receptors with low affinity might escape these central tolerance mechanisms and circulate to the periphery [73].

In the periphery, immune tolerance must be reinforced and maintained. There are several mechanisms of peripheral immune tolerance, including anergy, exhaustion, and immune regulation [75]. These mechanisms prevent overactivation of immune system to self-antigens and thus prevent autoimmunity, as well as control dysregulated immune responses to harmless antigens, which prevents allergic inflammation. Therefore, the fundamental strategy of allergen-specific immunotherapy for allergic diseases is to correct dysregulated immune responses by inducing peripheral allergen tolerance. Anergy happens in the periphery when CD4+ T cells receive signal through TCR only, without engagement of costimulatory receptors such as CD28 on antigen-presenting cells. On the other hand, on the surface of T cells, there are molecules, such as CTLA4, PD-1, and ICOS through which coinhibitory signals might be delivered [76]. Sustained expression of can also cause T-cell exhaustion. These terms need to be revisited, because in the nature there is no condition that T cells are not exposed to ligands for their costimulatory receptors, such as CD28, CD2, or ICOS. In addition, PD-1 and CTLA4 are strong tyrosine phosphatase-linked receptors, which have suppressive capacity by dephosphorylating tyrosines and acting as antagonists to tyrosine kinases. Another mechanism of peripheral tolerance is mediated by neighboring cells' death-inducing ligands, which activate processes leading to apoptosis of autoreacting cells. Moreover, effector T cells might be also suppressed by cytokines released by tissue cells and more effectively by regulatory T cells (Tregs).

38.3.2 Antigen Recognition by T Cell

Antigen-presenting cells (APCs) process intracellular or extracellular antigens and present on their surface in the context of MHC class I and II to CD8+ or CD4+ T cells, respectively. In general, APC present intracellular antigens to CD8+ T lymphocytes in the context of MHC class I, so as they are ready to quickly recognize the intracellular threats such as viruses and intracellular bacteria and

remove such cells in the series of cytotoxic events [77]. MHC class I molecules are expressed by all nucleated cells. Peptides originated from endogenous proteins, degraded in the cytosolic and nuclear proteasomes, are transported into the endoplasmic reticulum (ER) by trasporter associated with antigen presentation (TAP) proteins. In the ER, peptides are loaded onto the complex consisted with the polymorphic heavy chain of MHC class I and light chain-β2 microglobulin. Fully formed and stable complex is then transported to the plasma membrane and presented to CD8+ T cells (Figure 38.2). Naïve CD8+ T cells are able to directly recognize peptide–MHC class I complexes, but they require additional costimulation from APC to become potent effector CD8+ T cell with cytotoxic potential [78]. Extracellular antigens, including allergens, captured by the APCs, are engulfed in the process of endocytosis, phagocytosis, or macropinocytosis. The proteins are then degraded in the endosomal pathway. MHC class II molecules are primarily expressed by professional APCs such as DCs, macrophages, and B cells. α and β chains of MHC class II molecules are also assembled in the ER and stabilized by the invariant chain (Ii) and then transported to endosomes, where invariant chain is digested and only residual class II-associated Ii peptide (CLIP) stays in the MHC class II heterodimer. Next, there is an exchange of CLIP into the specifically recognized peptide, determined by the highly polymorphic sequences of MHC class II molecules. Fully assembled peptide–MHC class II complexes are then transported into plasma membrane to be presented to CD4+ T cells (Figure 38.3). Several costimulatory signals from APCs and cytokines such as IL-1 and autocrine IL-2 are required for CD4+ T cell to be activated after antigen recognition [78].

38.3.3 T Cell Subsets

As mentioned above, there are two classes of T lymphocytes carrying T-cell receptor (TCR) consisting of α and β chains and coreceptors CD4 and CD8 that determine their function in the adaptive immune response. CD8+ T cells are the highly specified, antigen-specific cytotoxic T cells (CTLs), whose function is to release the preformed mediators and/or to initiate cell death program by the interactions with the cell surface molecules. They are highly important in the immunity against viruses and intracellular bacteria. Activation of CD8+ cell arm of the adaptive immunity is an integral part of immunization by vaccination as well as in antitumor immunity. CD4+ T cells are traditionally seen and called T-helper cells (Th) cells, since the signals from them, after recognition of antigens, lead and direct other immune cell responses.

38.3.3.1 Th1/Th2 Paradigm

CD4+ T cells play an essential role in the development of fully mature, integrated cellular and humoral adaptive immune response. In the secondary lymphoid tissue after recognition of an antigen and signals from the costimulatory molecules from APCs, CD4+ T cells differentiate into the effector cells, with distinct functional properties defined by the pattern of cytokines they secrete. Compared with naive T cells, effector T cells do not require costimulation to be fully activated and they respond rapidly to antigen by producing high levels of

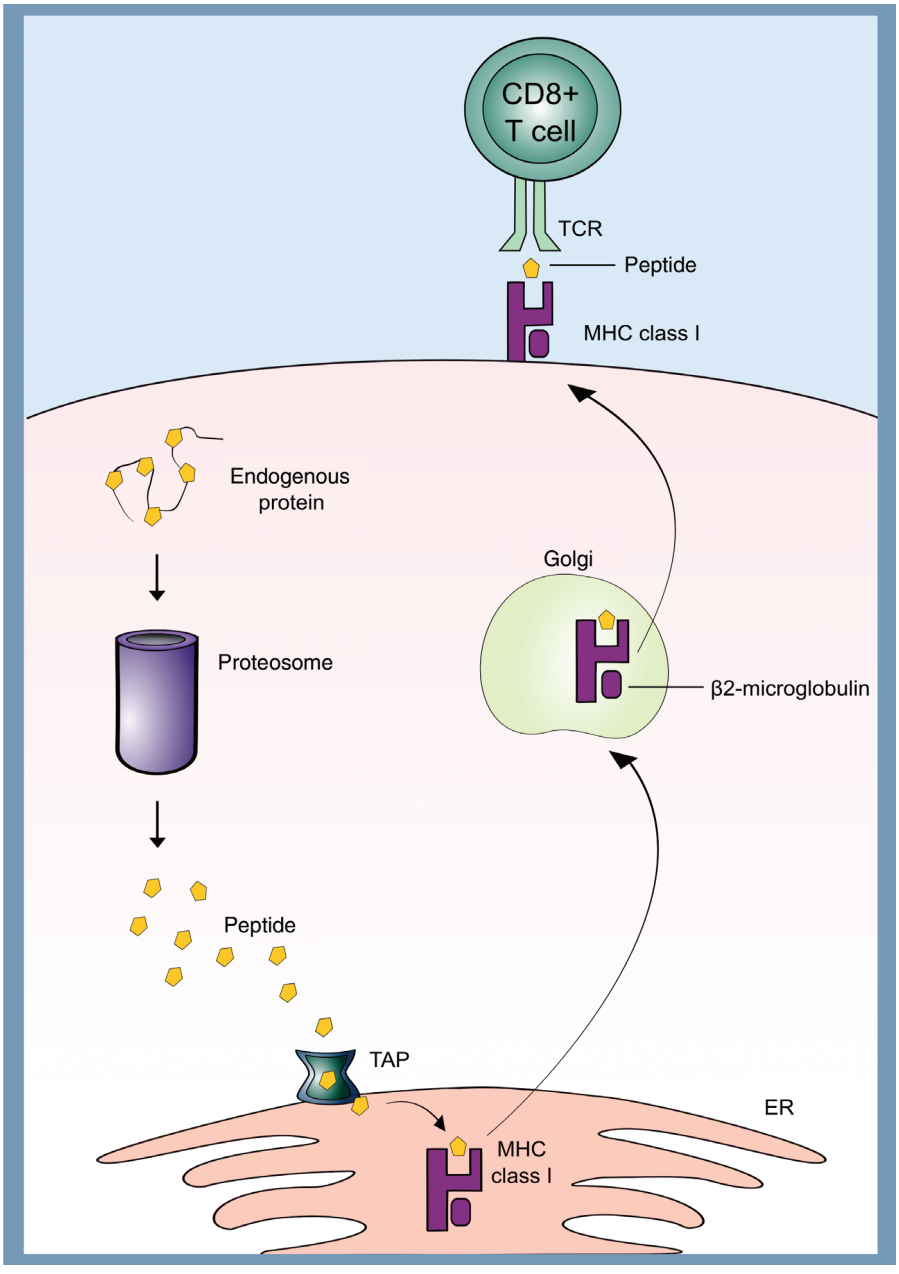

Figure 38.2 Antigen presentation in the context of MHC class I. MHC class I is involved in the presentation of endogenous antigens (viral antigens) to $CD8^+$ T cells. Endogenous proteins undergo degradation in the proteasome and subsequent transportation to the endoplasmic reticulum via transporter associated with antigen presentation (TAP) proteins. In the ER lumen, peptides are loaded onto the MHC class I composed of polymorphic heavy chain of MHC class I and β2-microglobulin. Then, peptide–MHC class I complexes are transported to the plasma membrane and presented to $CD8^+$ T cells.

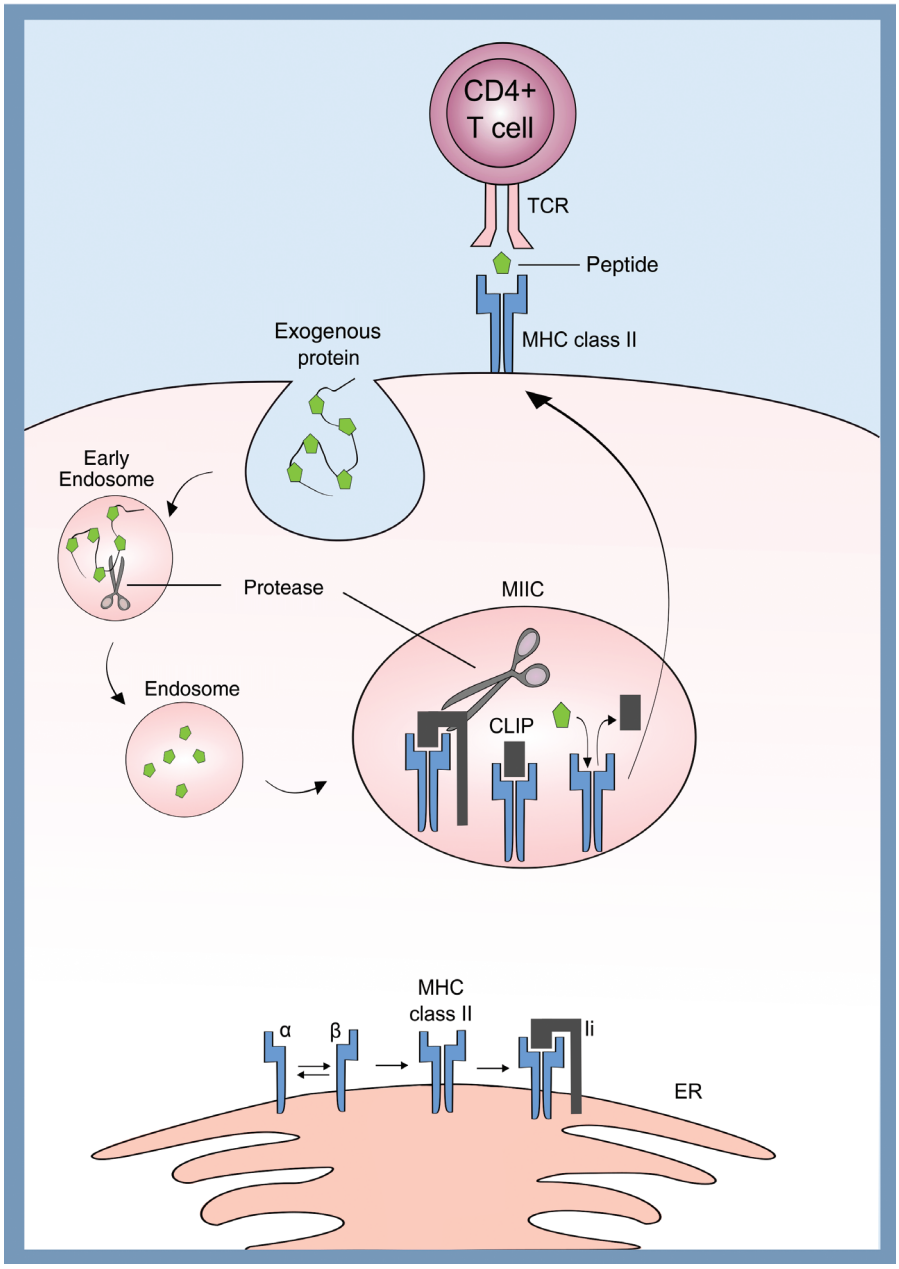

Figure 38.3 Antigen presentation in the context of MHC class II. MHC class II is involved in the presentation of exogenous antigens (i.e. bacterial antigens, allergens, etc.) to $CD4^+$ T cells. Assembly and stabilization of MHC class II via association with the invariant chain (Ii) take place in endoplasmic reticulum. Ii-MHC class II complexes are transported to the endosome where Ii chain is digested into CLIP that stays in the peptide-binding groove. Then, CLIP is replaced by the final peptide. Fully assembled peptide–MHC class II complexes are transported to the plasma membrane and presented to $CD4^+$ T cells.

cytokines and chemokines, which then direct the immune response. Many activated effector CD4+ T cells die following activation and an immune response through the process of activation-induced cell death, but a subset of CD4+ T cells will persist as memory cells for the life of the host. CD4+ memory T cells persist in lymphoid organs as central memory cells and in nonlymphoid tissues as effector memory cells. Th1 cells secrete mainly IFN-γ and differentiate with IL-12 secreted from DCs, while Th2 cells release IL-4, IL-5, and IL-13 in response to IL-4 secreted by basophils, mast cells, other Th2 cells, and ILC2. Th2 cells, after recognition of the antigen, presented by B cells, and engagement into CD40-CD40L costimulatory process, secrete IL-4 and IL-13, which leads to the immunoglobulin class switching and formation of IgE. The fate of CD4+ T cells into the development of Th2 responses depends upon master transcription factor GATA3 and master signal transducer STAT-6. Binding of IL-4 to IL-4R and IL-13 to IL-13R results in the phosphorylation of STAT-6. Phosphorylated STAT-6 translocates to the nucleus and binds to STAT-6 transcriptional elements and interacts with GATA-3. GATA3 promotes Th2 differentiation through instructing Th2 commitment, selectively stimulating the growth of Th2 cells, and suppressing Th1 differentiation [79]. On the contrary, T-bet is a major transcription factor for inducing IFN-γ production and Th1 cell differentiation [79]. Since the discovery of these two subsets of Th cells in 1986 [80], it was postulated that Th1 responses are predominant in infections and autoimmunity in parallel to CD8+ T cell cytotoxic responses, while unbalanced Th2-dependent responses underlies the pathogenesis of allergic diseases. The right balance between Th1 and Th2 responses was thought to be essential in prevention of IgE-dependent diseases. Indeed, infants with higher levels of IFN-γ in their cord blood less likely develop atopy, which is defined as a positive skin prick test to the allergens [81]. Moreover, expression of T-bet and IFN-γ production is decreased in the airways of patients with allergic asthma [82], similar to Th1-inducing cytokine IL-12 from DCs [83], and the expression of IL-12R on T cells [84]. Studies in the past two decades and accumulated knowledge on highly specialized novel subsets of Th cells such as Th17, Th9, Th22, and T follicular helper (T_{fh}) and the insights into the regulatory T-cell (T_{reg}) function have changed the simple dualistic view of Th1/Th2 imbalance in the pathogenesis of allergic diseases and other conditions. Proper immune regulation plays an essential role in autoimmunity, transplantation tolerance, tumor development, chronic infections, and successful pregnancy [7,85].

38.3.3.2 Other T-Helper Subsets

Th17 Cells

Th17 cells have been identified as a new T-cell lineage secreting mostly large amounts of IL-17 [33,34]. These cells are essential for the elimination of extracellular pathogens [86,87], and they are also involved in the development of psoriasis, Crohn's disease, and rheumatoid arthritis [88]. They might produce several cytokines such as IL-17A, IL-17F, IL-22, or IL-26 after activation [89–91]. The master transcription factor involved in Th17 cell fate is retinoic acid receptor-related orphan receptor γt/C2 (RORγt/RORC2) [92]. It has been shown that Th17 cells might play a pathogenic role in the development of asthma, yet probably in the

separate endotype from classical Th2-derived type of this disease [35,93]. Th17 cells contribute more to neutrophilic inflammation in acute airway inflammation models [94,95]. However, IL-17 is demonstrated to be the main cytokine driving the granulocyte influx observed into the lungs of allergic asthma models [96,97]. Also in humans, Th17 cells contribute to allergic airway disease by inducing airway smooth muscle cell migration as well as to neutrophilic asthma, chronic rhinosinusitis, and mixed eosinophilic and neutrophilic forms of these diseases [98].

Th9 Cells

TGF-β alone or in combination with IL-4 promotes the development of Th2 cells selectively secreting IL-9 [48,49]. The proviral integration 1 (PU.1) has been shown to be an important transcription factor for the Th9 cells' development and their association with allergic disease [99]. It has been shown that IL-9 released by Th9 acts both on other T-cell subsets and on B cells and mast cells. Moreover, it plays a role in promoting eosinophilic inflammation and other features of allergic asthma phenotype such as increased mucus secretion, elevation of IgE, and development of bronchial hyperresponsiveness [100–104]. The expression of IL-9 and IL-9 receptor is increased in bronchial tissue of atopic asthmatic subjects [105]. Moreover, mice that selectively overexpress IL-9 in the lung develop asthma-like symptoms [100,101].

Th22 Cells

Th22 cells are characterized by particularly high IL-22 production, which might be also produced by other T cells such as Th0 and Th17 cells [91,106–108]. In mice, there is no separate IL-22-producing T-cell subset; IL-22 is always coproduced with other cytokines, mainly IL-17, by Th17 cells [109]. In humans, though, separate Th22 cells have been recently characterized [110]. IL-22 acts on the mucosal sites, as mainly epithelial cells express IL-22R. However, the exact role of IL-22 in the development of allergy and asthma is not fully understood yet. It was reported that Th22 cells together with Th17 cells contribute to accumulation of airway smooth muscle cells, in asthma [88,98]. On the other hand, IL-22 could also inhibit allergic airway inflammation in the effector phase by altering the function of DCs and inhibiting IL-25 production from lung epithelial cells [111].

T Follicular Helper Cells (Thf)

T follicular helper cells are located in the germinal centers and can be identified by the surface expression of the CXC chemokine receptor 5 (CXCR5) and programmed cell death 1 molecules. They help B cells in clonal expansion and survival, as well as in the development of memory B-cell responses, and production of antibodies. Tfh cells might be a separate lineage, but this is still a matter of debate. Tfh cells generated *in vivo* in the course of Th1, Th2, or Th17 responses may secrete IFN-γ, IL-4, IL-13, or IL-17 signature cytokines in addition to IL-21 and CXCR5 [79,85].

38.3.3.3 Regulatory T (Treg) Cells

Regulatory T cells (Tregs) are essential in the maintenance of immune self-tolerance and homeostasis. They suppress abnormal or excessive immune

responses at several levels and by implementing various mechanisms. Treg cells comprise two main groups: (i) thymic-derived, naturally occurring CD4+CD25+, which constitutively express the transcription factor Foxp3, called natural Tregs (nTreg) or thymic Treg (tTreg), and (ii) the peripherally induced Tregs, called inducible Treg (iTreg) or more recently peripheral Treg (pTreg) [34,112]. nTreg cells are produced by the thymus as an antigen-primed and are functionally mature T-cell subpopulation specialized for immune suppression. Their main function is to reach the inflammation sites and suppress effector lymphocytes, especially helper T (Th)-cell subsets: Th1, Th2, Th17, and follicular Th (Tfh) cells [79,112]. nTreg cells constitutively express FOXP3, high levels of the alpha chain of the IL-2 receptor (CD25), and the suppressor costimulatory molecules CTLA4 and PD1 [113,114]. iTregs can arise from naïve CD4+ T cells in the periphery upon stimulation with TGF-β and IL-2. They also start to express Foxp3 and exhibit several regulatory functions, although in humans Foxp3 expression might be transient, can also happen in activated Th2 cells, and may not lead to acquiring regulatory properties [115,116]. Foxp3 is a master transcription factor in Treg cells' development and function as it was shown in patients with mutations in *FOXP3* gene that lead to the immune dysregulation polyendocrinopathy enteropathy-X-linked syndrome or the X-linked autoimmune and allergic dysregulation syndrome. These diseases are characterized by typical severe autoimmune and allergic phenotypes [117,118]. Similar phenotypes are observed in mice with *Foxp3* mutations (scrufy mice) that display comprehensive impairment in generating functional Treg cells [119]. nTreg and iTreg can be distinguished by several markers, including reported recently neuropilin 1 and helios [120]. There is a recent view that different Treg populations can be generated and specialized to control mainly the function of particular subsets of CD4 T cells. Upon IFN-γ stimulation, Foxp3+ Tregs upregulate T-bet and they are able to suppress T-bet expressing activated Th1 cells [121]. Similarly, it was noted that conditionally deleting Irf4 in Tregs selectively allowed the uncontrolled expansion of Th2 cells, suggesting that IFN regulatory factor 4 (IRF4) expression, important in Th2 differentiation, also played a role in differentiation of those Tregs that could control Th2 cells [122]. Moreover, to suppress pathologic Th17 cells, Tregs require STAT3 expression, which is essential in Th17 cell differentiation [123]. In humans, there is a population of iTreg cells generated in the periphery after antigenic stimulation, characterized by high levels of IL-10 production and playing a key role in the maintenance of healthy immune response to allergens [124,125]. They are called Tr1 cells. The suppressive capabilities of those cells are based on IL-10 and TGF-β [125–127]. In humans, Tr1 cells expand during the course of allergen-specific immunotherapy and inhibit the proliferation and cytokine responses of naïve CD4+ T cells as well as established Th1 and Th2 cells, including allergen-specific Th2 cell lines. Moreover, they directly or indirectly suppress effector cells such as mast cells, basophils, and eosinophils; suppress dendritic cells; suppress IgE production by B cells; and enhance IgG4 production [128–130]. It was shown that the homeostasis in healthy individuals and its disturbance in allergic patients depends on the imbalance between three different allergen-specific T-cell subtypes, Th1, Th2, and Tr1 [131,132]. What is even more important, during allergen-specific

immunotherapy, is that the success of the treatment depends on restoring the right proportion of those cells' populations. For example, during the exposure to venom allergen, venom-specific IL-10-secreting Tr1 cells are clonally differentiated from allergen-specific Th1 and Th2 cells [124]. Moreover, functional allergen-specific Treg cells in humans can be generated in the secondary lymphoid tissue, such as tonsils in the mechanism partially depending on plasmacytoid dendiritic cells [38]. Moreover, it has been shown that in case of chronic inflammatory conditions, represented by stimulations with IL-1β and IL-6, this allergen-specific T-cell tolerance in human tonsils and peripheral blood can be disrupted [133].

38.3.4 B Cells and Immunoglobulins

B cells and antibodies constitute the second essential part of the adaptive immunity, the humoral immune system. They form a potent weapon against viruses, bacteria, fungi, and parasites. Defects at the several stages of B-cell development, negative and positive selection, maturation, and antibody production may lead to autoimmunity, malignancy, immunodeficiencies, and allergy [134]. B lymphocytes develop in the bone marrow from hematopoietic precursor cells. At the early stage, B-cell precursors contact bone marrow stromal cells. During these processes, B-cell precursors undergo negative and positive selection steps, and their B-cell receptor is initially rearranged (Figure 38.4). Then, these immature B cells migrate to the peripheral lymphoid tissues, mainly spleen, where they differentiate into the mature naïve B cells, becoming either follicular IgM^+IgD^+ (majority of them) or marginal zone (MZ) B cells [135]. These mature naïve follicular IgM^+IgD^+ B cells recirculate through the secondary lymphoid organs (SLO) such as tonsil, lymph nodes, and also spleen until they encounter their cognate antigen and become fully activated, mostly in the presence of Th cells and further differentiate into either specific antibody-producing plasma cells or into long-lived memory B cells. Before antigen encounter, naive mature B cells express high levels of the chemokine receptor CXCR5 that allow them to respond to CXCL13 produced by follicular stromal cells of any secondary lymphoid tissue and lead them to the B-cell–rich follicles [135].

38.3.4.1 B-Cell Activation and Fate

As mentioned above, in the follicles of SLO mature B cell encounters its cognate antigen that is usually attached to the surface of neighboring APCs such as dendritic cells or macrophages [136]. Recognition of this antigen by the BCR, in a form of immunological synapse, is the first signal for B-cell activation [135]. BCR consists of a plasma membrane immunoglobulin (at this stage IgM or IgD) coupled to a signaling module Igα (CD79a)-Igβ (CD79b) dimer. LFA1 is an integrin also strongly involved in this process. Also, activation of the B-cell coreceptor complex, consisting of CD21, CD19, and CD81, enhances the BCR-dependent reaction. The first signal through BCR after antigen recognition leads to the several actin rearrangements in the B cells, which promotes antigen uptake by receptor endocytosis and starts the antigen processing into the MHC class II molecules, as well as induces CCR7 on B cells, stimulates them to traffic to the border of the T- and B-cell zones in

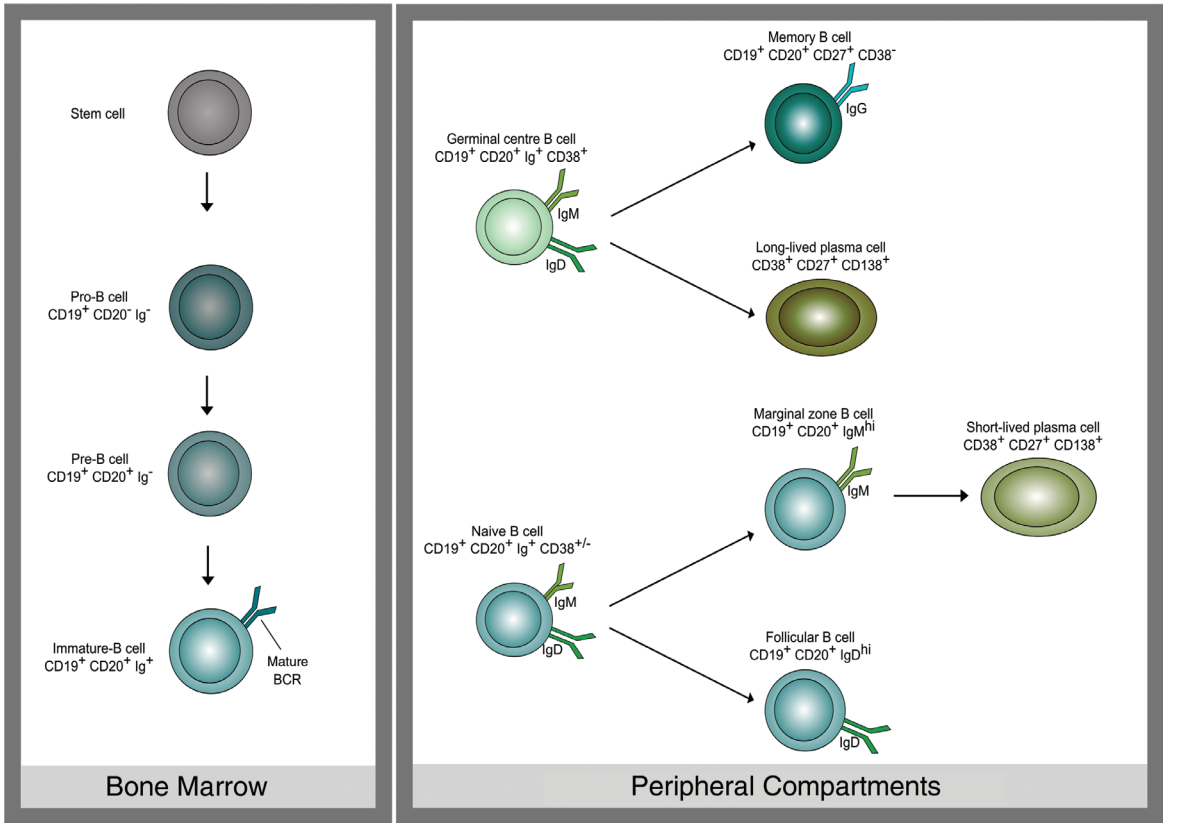

Figure 38.4 B-cell developmental stages. The B-cell development starts in bone marrow, where B cells develop from the hematopoetic precursor, and further progresses through the pro-B cells, pre-B cells, and immature B cells. Immature B cells migrate to peripheral compartments to differentiate into the mature naïve B cells. Depending on the specificity of their BCR, they might become follicular B cells or marginal zone B cells. Follicular B cells recirculate through the secondary lymphoid organs until they become fully activated by encountering their cognate antigen and in the germinal center develop into the memory B cells or long-lived plasma cells. Marginal zone B cells may develop into the short-lived plasma cells.

SLO and interact with Th cells. Interaction between Th cells and B cells consists of two essential processes: (i) antigen recognition through the TCR and MHC class II presented by B cell and (ii) the costimulatory signaling through CD40 on B cells and CD40 ligand (CD40L) on T cells [135]. Interaction between B and T cells is reciprocal. T cells provide help to B cells through CD40–CD40 ligand interaction and cytokine production, B cells provide peptide–MHC class II complexes in the context of costimulatory molecules to T cells, which facilitates their survival and cytokine production. After the initial interaction with Th cells, B cells can differentiate into extrafollicular plasma cells, germinal center (GC) B cells, or early memory B cells that have the capacity to recirculate [137]. BCR antigen recognition strength and differential expression of chemoattractant receptors are key factors in determining the fate of particular B cells [138]. The cytokine profile from interacting Th cells is the main determinant of the immunoglobulin class switch and final Ab production by plasma cells [137]. For example, classical Th2 cytokines IL-4 and IL-13 induce class switch recombination (CSR) to antigen specific IgG4 and IgE through activation of STAT6. IL-9 enhances IL-4–dependent IgE production in B cells through activation of STAT3 and STAT5, although IL-9 alone does not have this effect. TGF-β induces CSR to IgA through activation of Smad and Runx. IL-10 is known to induce CSR to IgG1, IgG3, IgG4, and IgA. IL-21 induces CSR to IgG1, IgG3, and IgA and also enhances IL-4-dependent CSR to IgE through activation of STAT3 [139]. The combined BCR, cytokine, and costimulatory activation signals in B cells induce activation-induced cytidine deaminase (AID) and other components of the somatic hypermutation (SHM)/class switch machinery, thus changing the affinity of the BCR and the isotype of immunoglobulin (IgM to IgG, IgA, or IgE) [140]. As a consequence of somatic hypermutation, BCR increases or decreases affinity for antigen. B cells with high-affinity BCR are preferentially activated, clonally expanded, and as a consequence high-affinity antibodies against this antigen are produced by plasma cells. Development of both short-lived and long-lived plasma cells depends on the expression of the transcription factor B lymphocyte-induced maturation protein 1 (Blimp-1), a master gene of plasma cell development [141]. Long-lived plasma cells are terminally differentiated and they do not divide. They travel to BM and reside there.

38.3.4.2 Immunoglobulins

Immunoglobulins consist of two heavy chains and two light chains. Each heavy chain or light chain has two major domains referred to as the constant region and the variable region. Heavy-chain variable regions are encoded by one V gene, which encodes most V-region amino acids, as well as one of the 23 diversity (D) and one of the 6 joining (J) gene segments. Only two types of genes encode the light-chain variable regions: V genes and J genes. Immunoglobulin remarkable diversity has four major sources: multiple V(D)J genes in the germline, random assembly of heavy chains and light chains, junctional nucleotide variability introduced during pre-B-cell immunoglobulin gene rearrangement, and somatic hypermutations (SHM) of immunoglobulin variable regions [142]. There are five classes of antibody molecules: IgM, IgD, IgG, IgA, and IgE. The IgG and IgA classes have more than one member. There are four IgG (γ) subclasses designated

as IgG1, IgG2, IgG3, and IgG4, and their constant regions exhibit 90% homology with each other. The two subclasses of IgA are similarly related to each other. There are two types of light chains: κ and λ. There are four λ subtypes but there is only one form of κ. These nine classes and subclasses of antibodies have different expression levels in serum and tissues, anatomic locations, and effector functions. IgA1-2, IgM, and IgG1-4 are involved in the antigen neutralization. IgM is most potent in complement fixation, although IgG1-3 and IgA1-2 are also involved in this process. IgG1-3 and IgE are also involved in antibody-dependent cellular cytotoxicity (ADCC). Finally, IgE is strongly involved in immediate hypersensitivity reactions [142].

38.3.4.3 Other B-cell Functions and B-cell Subsets

B cells at the different stage of their development can secrete various cytokines and thus they have additional functions. They can release a broad variety of cytokines, such as IL-2, IL-4, IL- 6, IL-10, IL-17, IFN-α, IFN-γ, TNF-α, TGF-β, and LT, and thus they can be classified into distinct subsets depending on the particular cytokine profile [143]. Due to the cytokine release, they can promote immune responses by regulating Th1/Th2/Th17 and neutrophil responses, induce macrophages, and DC and NK cell activation, as well as regulate their own differentiation and antibody-producing capabilities [144]. On the other hand, there are several lines of evidence that among them are also potent regulatory cells that can suppress proinflammatory responses of monocytes, DCs, CD4+, and CD8+ T cells [145]. In particular, human IL-10-secreting B regulatory cells (Br1) play an essential role in allergic inflammation [146]. They are able to suppress allergen-specific $CD4^+$ T-cell proliferation. In addition, the major bee venom allergen phospholipase A (PLA)-specific B cells from non-allergic beekeepers showed increased expression of IL-10 and IgG4 and the frequency of IL-10-secreting PLA-specific B cells increased in allergic patients receiving allergen-specific immunotherapy. Moreover, IL-10-overexpressing human B cells acquired a prominent immunoregulatory profile by upregulation of the suppressor of cytokine signaling-3 (SOCS3), glycoprotein A repetitions predominant (GARP), CD25, and PD-L1 [147]. They also secreted less IgE and potently suppressed proinflammatory cytokines in PBMCs, maturation of DCs, and antigen-specific proliferation *in vitro*.

38.4 Cytokines of Allergic Inflammation

Many cells including T cells, ILCs, epithelial cells, basophils, mast cells, eosinophils, monocytes, macrophages, and B cells produce cytokines that are involved in initiation and maintenance of type 2 immune responses. These cytokines, namely, IL-4, IL-5, IL-9, IL-13, IL-25, IL-33, and TSLP have a default role in the immunity against helminthes as well as a counterbalance to severe type 1 inflammation. However, in case of a dysregulation of immune responses, they might lead to initiation and maintenance of allergic responses. Therefore, several clinical trials in allergic diseases have targeted those cytokines or their receptors [7].

38.4.1 IL-4

IL-4 is produced primarily by Th2 cells, ILC2, basophils, mast cells, and eosinophils. It plays an important role in mounting protective immunity against helminthes and other extracellular parasites. It is a central cytokine for naïve CD4+T-cell development into Th2 cells after antigen stimulation [148–150]. In addition, IL-4 is critical to inducing class switch to IgE and IgG4 or IgG1 in human and mouse B cells, respectively. IL-4 stimulates the expression of MHC class II molecules, BCR, CD23, and IL-4R in B cells. IL-4- and IL-4Rα-deficient mice have compromised Th2 differentiation and the serum levels of IgG1 and IgE are reduced [151]. It also inhibits type 1 immune responses including Th1 cells and M1 macrophages. There have been several clinical trials targeting IL-4 and IL-13 or their receptors with more promising results on anti-IL-13 approaches for the treatment of allergic asthma and atopic dermatitis [152].

38.4.2 IL-5

IL-5, together with IL-4, plays a central role in allergic inflammation. It is predominantly produced by Th2 cells, ILC2, and also by mast cells, activated eosinophils, and NK and NKT cells. IL-5 receptor shares the β chain with IL-3 and GM-CSF, and together with these cytokines it leads to growth, activation, differentiation, survival, and mobilization of eosinophils to the inflammatory site. Therefore, eosinophils are one of the first cells influxing the site of inflammation in the lungs in asthma or gut in food allergy, and their number increases in the blood, which is used as a biomarker. IL-5 levels, Th2 cells, and eosinophils are increased in bronchoalveolar lavage and in biopsies of asthmatics and they correlate with severity of the disease [153]. IL-5-deficient mice are resistant to induction of experimental asthma [154]. Anti-IL-5 therapy has provided promising results in eosinophilic asthma, eosinophilic osephagitis, and chronic rhinosinusitis [152,155,156].

38.4.3 IL-13

IL-13 is mainly secreted by activated Th2 cells, ILC2, mast cells, basophils, eosinophils, and NKT cells [157]. One receptor chain, IL-4Rα is shared between IL-13 and IL-4; therefore, they have in many cases overlapping functions except an effect on Th2 differentiation because T cells do not express IL-13 receptor. IL-13 induces IgE class switch in B cells, recruits mast cells and eosinophils, and prolongs their survival [158]. IL-13 in addition to TGF-β has been linked to tissue remodeling and fibrosis [159,160]. Epidemiological data pointed out that several polymorphisms in IL-13 and IL-4 pathways significantly increase the risk of asthma, escalate asthma exacerbation frequency in childhood, and are correlated with elevated eosinophilia and total IgE in the blood [161,162]. IL-13 KO mice do not develop goblet cells hyperplasia in experiential asthma models [163,164].

38.4.4 IL-25 (IL-17E)

IL-25 is a member of the IL-17 family of cytokines. It is produced by Th2 cells, mast cells, and epithelial cells [18,165–167]. Eosinophils and basophils from

atopic individuals can also release IL-25. IL-25 stimulates the production of IL-4, IL-5, and IL-13 in non-B/non-T (NBNT) c-kit+FcεRI$^-$ cells in mesenteric lymph nodes, in a subset of natural killer T cells [168], and in ILC2 [169]. IL-25 also enhances IgE synthesis, induces mucus production and epithelial hypertrophy, and augments the numbers of eosinophils in blood in murine model of asthma [169]. Transgenic mice that express IL-25 only in lungs have increased numbers of eosinophils and CD4+ T cells upon allergen-specific challenge [167]. Anti-IL-25 treatment reduced several inflammatory outcomes in chronic rhinitis model in mice, suggesting a role for IL-25 also in the pathogenesis of chronic rhinosinusitis with nasal polyps [170]. IL-25 KO mice cannot get rid of parasite infection efficiently [171], because of the inefficient induction of Th2-type cytokine responses, and are very prone to Th1-dependent experimental autoimmune encephalomyelitis.

38.4.5 IL-33

IL-33 is a member of IL-1 family of cytokines. It plays a significant role in regulation of immune responses at the mucosal sites, together with TSLP [172]. It is predominantly produced by epithelial cells upon injury, but it can also be released by smooth muscle cells and fibroblasts. IL-33 acts through ST2 receptor, which is expressed in Th2 cells, mucosal ILC, mast cells, and NKT cells [173,174]. Soluble ST2, released by fibroblasts, monocytes, and macrophages upon activation by proinflammatory mediators, inhibits binding of IL-33 to its receptor and is a negative regulator of its activity. In mice, IL-33 induces airway inflammation through a process depending on IL-5-producing T cells but not IL-4 [175]. Administration of neutralizing antibodies or transfer of soluble ST2 impairs Th2-type inflammation in experimental induced asthma mice [176,177]. IL-33 is increased in serum of patients with anaphylaxis. It can also activate human eosinophils and mediate degranulation of mast cells in the absence of allergen [178,179].

38.4.6 TSLP

TSLP is produced among others by keratinocytes, airway epithelial cells, intestinal epithelial cells, thymic stromal cells, tonsilular crypt epithelial cells, mast cells, and basophils [180]. TSLP is released in response to viruses, bacteria, parasites, TLR engagement, and cytokines, such as IL-1β, TNF-α, IL-4, and IL-13 [180]. TSLP acts on DCs, monocytes, CD4+ T cells, mast cells, and B cells promoting building of the Th2 inflammatory response often in cooperation with IL-25 and IL-33 and other cytokines [180–182]. In antigen-presenting DCs, TSLP increases the expression of several costimulatory molecules, which further promotes the generation of IL-4-, IL-5-, and IL-13-producing T cells and inhibits IL-10 and IFN-γ production [183]. TSLP plays an essential role in allergic asthma. The expression of TSLP is increased in the asthmatic airways and in the skin of atopic dermatitis patients and correlates with disease severity [184,185]. Anti-TSLP treatment showed promising efficacy in reducing allergen-induced inflammation in clinical trials [186,187]. TSLP is also associated both with atopic dermatitis [188] and with chronic rhinosinusitis with nasal polyps [189].

39.1 Introduction

Sepsis is a syndrome of life-threatening organ dysfunction triggered by an excessive, dysregulated host response to infection. The immune system represents a complex interlinked system of activated cells, receptors, secreted proteins, enzymes, and structural and chemical defense elements such as epithelium and associated antimicrobial proteins, which protects the individual against infection. Pathogens access a normally sterile area following breach of epithelial or mucosal barriers, and this leads to a local infection. Rapid and highly effective innate immune responses usually result in local containment and clearance of the pathogens with limited systemic consequences. However, pathogens may overwhelm these early innate immune responses or, more commonly, can trigger an excessive systemic innate immune response in some individuals. This can lead to activation of multiple neural, cardiovascular, bioenergetic, metabolic, hormonal, endothelial, coagulation, and other pathways that can induce deleterious effects remote from the site of infection [1]. This is recognized clinically as organ dysfunction and conceptualized as "sepsis" [2].

39.2 Epidemiology

39.2.1 Incidence

Multiple epidemiology studies report the proportions of patients with severe sepsis, that is, infected patients with new-onset organ dysfunction – now termed "sepsis" by the new definitions (see later) from middle–high income countries [3]. The incidence of intensive care patients with infection-related organ function is approximately $10 \pm 4\%$ [4]. This figure is likely to be higher in developing countries but data are scanty. The population-treated incidence of "old-definition"

Inflammation: From Molecular and Cellular Mechanisms to the Clinic, First Edition.

sepsis (i.e., presumed infection and ≥2 of 4 systemic inflammatory response (SIRS) criteria) was estimated at 437 per 100 000 person-years and 270 per 100 000 person-years for infection plus organ dysfunction [3]. Extrapolating from these incidence estimates, 19.4 million patients are treated globally per annum for severe sepsis [3]. The incidence of sepsis is apparently increasing, especially in countries where national databases exist or where reporting is linked to remuneration [5–12]. Because of inconsistent use of definitions and coding for severe sepsis and septic shock, it is uncertain how real this increase is. Kumar *et al.* reported a 239% increase in discharge coding for severe sepsis from a nationally representative US hospital database over a 7-year period [13]. Using the same database, Rhee *et al.* reported a rise in cases of sepsis from 126 to 342 per 100 000 hospital discharges between 2003 and 2011, yet bacteremia rates fell (from 10 to 8 cases per 100 000) [8]. How much of the increase is due to previous underreporting and how much to reimbursement "gaming" is unknown [14]. Nevertheless, a steadily aging population, an increasing prevalence of comorbidities, an increasing complexity of surgical interventions, and widening use of immunosuppressive agents are likely to be increasing the risk of developing sepsis.

39.2.2 Acute Mortality

Depending on case-mix characteristics, cohort recruitment year and healthcare provision, acute mortality from sepsis varies widely from 11 to 80% [5–12]. Despite the lack of new therapies, alongside the increasing incidence of sepsis, mortality rates do appear to be reducing over time [9,15]. How much is due to improvements in the general processes of care and how much due to an altered denominator and incorporation of less sick patients is uncertain [15], although there does appear an improvement in outcome independent of changes in the generic case-mix characteristics of critically ill populations.

39.2.3 Implications of Improvements in Acute Mortality

Improving early outcomes in the context of an increasing incidence could potentially result in a higher prevalence of sepsis survivors with significant morbidity. This issue needs better characterization as sepsis survivors have ongoing inflammation for as long as 1 year posthospital survival and an increased risk of longer-term mortality [16]. Nearly, one in six sepsis patients who survive hospitalization die within the first year of discharge. If sepsis "causes" this increase in postacute mortality is uncertain, due to incomplete accounting of confounders during analysis and bias in study design [17].

39.3 Sepsis: Biology

39.3.1 Host Immune Response

The danger signals in sepsis could be either from the pathogen (pathogen-associated molecular patterns, PAMPs) or from intracellular constituents released by tissue damage (damage-associated molecular patterns, DAMPs) [18].

Perpetuation of inflammation by the innate immune system following bacterial clearance may be secondary to DAMPs [19].

39.3.2 PAMPs

Pathogen-associated molecular patterns are structures conserved among microbial species. The most common pathogens implicated in sepsis are bacteria, fungi, and, less commonly, viruses [20]. The lipoteichoic acid motif in Gram-positive bacteria and lipopolysaccharides present in the Gram-negative bacterial cell wall are examples of bacterial PAMPs. Common viral PAMPs include double-stranded or glycine/uracil-rich single-stranded ribonucleic acid (RNA). Fungal PAMPs include mannans, zymosans, mannosides, and beta-glucans [21].

39.3.3 DAMPs

Damage-associated molecular patterns are cell-derived endogenous molecules that have the potential to initiate and/or perpetuate the immune responses seen in sepsis. DAMPs include extracellular matrix products (such as hyaluronic acid, fibronectins, etc.), plasma components (such as fibrinogen, complement proteins, etc.), cytoplasmic proteins (such as heat shock proteins, high mobility group box protein 1, HMGB1, and cytokines), nonprotein molecules (e.g., adenosine triphosphate, uric acid, and heparin sulfate), Mitochondria, and nucleic acids (e.g., cellular and mitochondrial DNA, and RNA) [18,22].

39.3.4 Pattern Recognition Receptors Detect Danger Signals

PAMPs and DAMPs are sensed by pattern recognition receptors (PRRs), germ line-encoded receptors that act as transducers to initiate host immune responses. Innate immune cells (macrophages, dendritic cells, neutrophils, and monocytes) and nonimmune cells (such as fibroblasts, endothelial cells, and epithelial cells) express PRRs. Five PRRs subclasses have been described thus far – Toll-like receptors (TLRs), nucleotide oligomerization domain-like receptors (NODs), retinoic acid-inducible gene (RIG-1)-like receptors, C-type lectin receptors, and absence-in-melanoma 2 (AIM-2)-like receptors. PRRs could either be on the cell surface or intraellular. The sensing of PAMPs or DAMPs by PRRs triggers transcription of genes involved in inflammation. TLRs and NLRs are the key PRRs involved in bacterial recognition and signal transduction to immune cells [23].

39.3.5 Transduction of Danger Signals

Danger signals and PRR signaling alter gene expression. Subsequent transcription and translation is achieved using the signalosome and the inflammasome complexes. Inflammasomes are heterogeneous protein complexes assembled within the cytosol after sensing danger signals. These form a scaffold for procaspase-1 proteins and induce autoproteolysis and cleavage to generate active caspase-1. Active caspase-1-mediated proteolysis activates cytokines such as IL-1β and IL-18. Inflammasomes are also involved in proinflammatory cell death pathways

(pyroptosis) [24]. Most inflammasomes are of the NOD-like receptor (NLR) family, with relatively few non-NLR inflammasomes. The NLRP3 inflammasome is the best characterized to date and is activated by both DAMPs and PAMPs. When primed to a danger signal, there is an increase in cytosolic levels of the activated NLRP3 inflammasome. Aside from cytokine generation, caspase-1-mediated cell death is also an inflammasome-mediated effect. Active caspase-1-associated formation of cell transmembrane pores results in dissipation of cellular ionic gradients and cleavage of the chromosomal DNA without fragmentation, resulting in cell death [25]. The transcription of a plethora of pro- and anti-inflammatory cytokines are also induced by activation of the transcription factor NF-κB [26]. This, among other transcription factors, mediates many of the systemic responses seen in sepsis [27–32].

39.3.6 Immune Cell Abnormalities in Sepsis

Under physiological conditions, leukocytes travel in the higher-velocity, central laminar blood flow plane within blood vessels. Inflammation reduces vascular tone and increases adhesion molecule expression in endothelial cells via molecules such as P-selectin and E-selectin. Selectins interact with glycoproteins on neutrophil and monocyte surfaces, resulting in reversible adhesion and rolling. The next step is leukocyte adhesion to the inflamed endothelium. This is achieved by interaction between leukocyte integrin (CD11a:CD18; CD11b: CD18; and CD11c:Cd18) and endothelial adhesion molecules (ICAMs). Following this stage, leukocyte transmigration to the site of infection/inflammation occurs via the basement membrane, directed by a chemokine (CXCL8 and CCL2) gradient [33].

39.3.6.1 Neutrophils

Sepsis is usually characterized by neutrophilia with appearance of immature neutrophil subsets (such as band forms, meta-myelocytes, and myelocytes) in the peripheral circulation, a finding associated with poor prognosis [34–36]. In sepsis, neutrophils produce significant amounts of IL-10 [37,38], an anti-inflammatory cytokine that impairs monocyte–macrophage function [39]. Impaired neutrophil chemotaxis secondary to desensitization [40–42] and decreased respiratory burst capacity occur in sepsis [36,43,44]. Activated neutrophils impair T-cell function [45], while more immature neutrophil subsets are potentially cytotoxic to activated T cells [46]. In contrast to other immune cells, neutrophil life span is prolonged due to inhibition of apoptosis by reduced caspase-3, caspase-9 activity, and impaired release of mitochondrial cytochrome c [47–49].

39.3.6.2 Monocytes and Macrophages

In sepsis, monocytes are deactivated, impairing their antigen-processing ability [50,51]. This is associated with downregulation of HLA-DR expression in circulating monocytes [52,53], and a predisposition to secondary infections. Decreased HLA-DR expression is a risk factor for adverse outcomes from sepsis [53–56]. Monocyte deactivation is also associated with reduced inflammasome activity in patients with septic shock [57]. Macrophages have impaired

pathogen killing ability and altered cytokine production (reduced proinflammatory and increased anti-inflammatory cytokines) [54].

39.3.6.3 Dendritic Cells

Sepsis induces a greater expression of programmed death ligands (PD-L1 and PD-L2) on dendritic cells (DCs), resulting in impaired function [58]. Sepsis is also associated with DC loss secondary to apoptosis. Both these effects carry prognostic significance [59–62]. FDCs are antigen-trapping cells that reside in secondary lymphoid organs that are important for affinity maturation of the B-cell response. In sepsis, FDCs are depleted secondary to caspase-3-mediated apoptosis [63,64].

39.3.6.4 Natural Killer Cells

Aside from direct cytotoxicity toward microbe-infected cells, NK cells also contribute toward the cytokine responses seen in sepsis and impact other immune cell function [65,66]. In sepsis, NK cell numbers are diminished, while their cytotoxic function and ability to enhance cytokine secretion are both impaired [67–69]. The increase in NK cell apoptosis explains the reduced NK cell count observed in sepsis [54]. These findings may contribute toward the immunoparesis seen in sepsis.

39.3.6.5 Lymphocytes

Sepsis is associated with lymphopenia, the presence of which is associated with hypothermia, shock, bacteraemia, raised cytokine concentrations (TNFα, IL-6, IL-8, IL-10, and IL-15) and a higher risk of mortality [70–77]. Lymphopenia often persists beyond the acute illness [70] and can affect both B- and T-cell compartments [78]. In patients with sepsis, B- [68,76,79–83] and T-cell counts [68,69,76,81–85] are acutely decreased. Lymphopenia in sepsis is considered secondary to accelerated lymphocyte apoptosis via both intrinsic and extrinsic pathways [76,78,80–83,86–95]; implicated factors include elevated extrinsic pathway ligands and intrinsic pathway cellular stressors such as TNF, interleukins, and other cytokines and chemokines [18,19].

In patients with sepsis, upregulated inhibitory cell surface proteins such as PD1 [58,89,96] and BTLA (B- and T-lymphocyte associated; CD272) [97,98] are variably observed in B- and T-cell subsets. T cells also have impaired cytokine secretory ability (IL-6, IL-10, and interferon-gamma, TNFγ) when stimulated *ex vivo* [58]. However, cytokine secretion is largely preserved in an acute septic illness aside from interferon-gamma secretion [99]. There is also a decreased mRNA abundance of transcription factors that regulate CD4+ T cell plasticity, such as TGFβ1, T-bet, RORγ, and GATA3 [68,100]. The reduced mRNA abundance is associated with impaired generation of Th17 subsets of CD4+ T cells [68], which protect against bacterial and fungal infections [54]. Regulatory T cells (T_{reg}) impair proliferation and generation of other effector T-cell populations, resulting in immunosuppression [101]. Compared to other T-cell subsets, T_{reg} numbers and function are relatively preserved in sepsis [102–105]. Impaired TCR diversity is seen in sepsis and this recovers with clinical improvement [106].

CD28, a key costimulatory molecule for T-cell activation and proliferation, is downregulated [107].

B cells are activated, as suggested by increased CD69 expression [79,108,109]. BCR signaling is upregulated in trauma, which shares many gene expression patterns with sepsis [110]. Expression of CD86 and CD80 were increased in B cells taken from sepsis patients; of note, an increased proportion of CD80-positive B cells were associated with nonsurvival [79]. Using a murine influenza viral infection model, CD80 and CD86, coreceptors for T-cell activation by APCs and which are also involved in regulation of IgG secretion in activated B-cell subsets, were upregulated by an interferon-gamma mechanism [79,111–113]. In this context, IFN-1 administration to animal models resulted in improved outcomes, and this was associated with increased activation of B cells [108]. This study and others [108,114] imply that yet to be characterized B-cell functions have the potential to alter sepsis-related outcomes. When interpreted together, T-cell abnormalities in sepsis match the concept of T-cell exhaustion [115], while B-cell abnormalities imply impaired function over and above that which can be explained purely by T-cell abnormalities.

39.3.7 Metabolic Alterations in Sepsis

In additional to a greater metabolomic variance compared to matched healthy controls, sepsis-associated death is causally linked to alterations in the metabolomic profile [116]. Levels of 76 metabolites differed between septic survivors and nonsurvivors with alterations noted in the Krebs' cycle and fatty acid oxidation secondary to carnitine transport defects. A more recent study that included both transcriptomic and metabolomic profiling of septic patients highlighted mitochondrial dysfunction as a key defect in sepsis [117]. Other studies also report alterations in fatty acid oxidation [118,119].

39.3.8 Mitochondrial Function in Sepsis

Sepsis-associated mitochondrial dysfunction is multifactorial. It occurs secondary to impaired cellular oxygen delivery [120], increased production of endogenous mitochondrial respiration inhibitors (such as nitric oxide and other reactive species, carbon monoxide, and hydrogen sulfide) [121–123], and alterations in mitochondrial biogenesis [123]. Examining whole leukocytes taken from endotoxin-challenged volunteers, a decrease in mRNA abundance was seen in genes coding for mitochondrial respiratory chain complexes I–IV, ATP synthase, the Krebs' cycle, and the mitochondrial permeability transitional pore (MPTP) [124]. In circulating monocytes taken from septic patients [125,126], bioenergetic capacity was lower despite normal or raised levels of basal oxygen consumption [127]. This may contribute toward impaired immune function as it correlates with HLA-DR expression [125]. Although the mitochondrial dysfunction paradigm in sepsis is well accepted, the altered bioenergetic capacity in septic leukocytes is not universally observed [128]. In solid organs such as kidney, liver, and heart taken from patients who died of protracted sepsis [129] and in animal models [122], impaired mitochondrial function was seen alongside

hydropic changes in mitochondria and mitophagy, yet cell death was minimal. This has led to the hypothesis that mechanisms of organ dysfunction share similarities with hibernation physiology where cellular turnover is low and that organ dysfunction may even represent a late-stage adaptive process to a prolonged and severe insult [130].

39.3.9 Mechanisms of Organ Dysfunction in Sepsis

Organ dysfunction in sepsis is multifactorial and the precise underlying mechanisms remain unknown. Broadly, there are organ-specific pathways and more general shared systemic abnormalities [131]. These include systemic inflammation, impaired oxygen delivery due to macrocirculatory and microcirculatory abnormalities, alterations in cell cycle characteristics, and reprioritization of mitochondrial function toward cellular protection in the context of prolonged and excessive inflammation [19,130,132–134].

39.4 Clinical Management

The principles of clinical management of sepsis are enshrined within the Surviving Sepsis Campaign (SSC) guidelines [135]. These principles focus on prompt identification and treatment of infection (source control and antibiotics), alongside cardiovascular support to restore and maintain tissue perfusion using intravenous fluids ± vasoactive drugs. Organ support may be needed to support ventilator, renal, and cardiovascular function as a temporizing matter until the patient recovers enough function to cope unaided. Other interventions, such as correction of coagulopathy, rehabilitation, adequate nutrition, and infection control to prevent secondary episodes, are also necessary. These guidelines are based upon what evidence is available, though in many instances the quality of this evidence is poor and/or scanty.

39.5 Definitions

In 2016, the sepsis illness concepts provided by two previous International Consensus Conferences (1991 and 2001) [136,137] were revisited and new updated definitions and clinical criteria – "Sepsis-3" – published [138].

39.5.1 Limitations of Previous Definitions

Sepsis was previously defined as the presence of confirmed or suspected infection plus two or more systemic inflammatory response syndrome (SIRS) criteria [136,137]. These SIRS criteria (abnormalities in temperature, white count, respiratory rate, and/or heart rate) are, however, nonspecific [139] and very frequently seen in hospitalized patients, including many without infection [140]. Furthermore, 1-in-8 patients with infection-related organ failure admitted to

Australasian intensive care units did not have ≥2 SIRS criteria on ICU admission [139]. Finally, an evolving understanding of the underlying pathophysiology indicates that both pro- and anti-inflammatory activation occur early in the disease process, with both being of prognostic relevance [54,110]. The use of the SIRS criteria was thus dropped from the recent "Sepsis-3" definitions [138], though the individual components may still be clinically useful in the presumptive diagnosis of infection.

39.5.2 Sepsis-3 Definitions

Sepsis is now defined as *life-threatening organ dysfunction caused by a dysregulated host response to infection* [138]. Sepsis should be identified clinically using a change in Sepsis-related Organ Failure Assessment score (SOFA score) ≥2 temporally related to the infection. This system [141,142] consists of laboratory tests (platelet count for coagulation system, bilirubin for liver, and creatinine for kidneys), clinical assessment (Glasgow coma scale for neurology), and clinical interventions (vasoactive drugs for cardiovascular system and ventilation for respiratory system). A change in SOFA ≥2 from baseline accounts for patients with preexisting chronic organ dysfunction or those hospital inpatients who have developed organ dysfunction prior to the onset of the infection episode. In the absence of recent tests and any chronic ill health, a baseline score of 0 can be reasonably assumed. Patients with a SOFA score ≥2 around the time sepsis was diagnosed had a subsequent hospital mortality exceeding 10% [143].

Septic shock is now considered to be a subset of sepsis for patients who have a more severe illness with a higher likelihood of death than "sepsis" alone. Septic shock is now defined *as a subset of sepsis where underlying cardiovascular, cellular, and metabolic abnormalities are profound enough to substantially increase mortality* [144]. Septic shock is identified at the bedside using the following criteria: hypotension requiring vasopressors to maintain mean arterial pressure ≥65 mmHg (cardiovascular abnormality) plus a blood lactate >2 mmol/l (reflective of cellular/metabolic stress/abnormality) despite adequate fluid resuscitation. Using patients enrolled into the Surviving Sepsis Campaign database, hospital mortality was 42.3% for both hypotension and hyperlactataemia versus 30.1% (for hypotension alone), 25.7% for persisting hyperlactataemia despite fluid resuscitation, and 25.5% for patients with organ dysfunction but a normal lactate and not requiring vasopressors [144].

While SIRS represents components of the host systemic inflammatory response to an insult, it may be a completely appropriate host response and not necessarily a harbinger of clinical deterioration. On interrogating large US hospital population databases totaling over 5 million patients, approximately 850 000 patients were cultured and treated with antibiotics. Of 21 variables examined, three (respiratory rate ≥22 breaths/min, altered mentation, and a systolic blood pressure ≤100 mmHg) offered the greatest predictive validity of a poor outcome such as death or needing critical care. Having 0, 1, 2, or all 3 qSOFA criteria corresponded to an ultimate hospital mortality of <1, 2–3, 8, and >20%, respectively. Though needing to be prospectively validated, qSOFA offers a rapid, bedside tool for identifying patients at the risk of doing badly. Clearly, treatment

should not be delayed in the interim for patients with none or only one of the qSOFA criteria [143].

39.6 Conclusions

Sepsis is now considered to be a syndrome of life-threatening organ dysfunction triggered by an excessive, dysregulated host response to infection. The underlying pathophysiology is notable for its complexity, involving multiple systems and pathways and not just restricted to the immune and inflammatory systems. Mortality and morbidity remain high, thus maintaining the requirement for novel and effective therapeutics.

40.1 Introduction

Inflammation was once defined based on clinical signs such as rubor (redness), calor (heat), tumor (swelling), dolor (pain), and function laesa (dysfunction) [1]. Later inflammation was defined by the presence of immune cells in places where they usually do not occur. Nowadays, we define inflammation as induction or persistent expression of proinflammatory mediators causing these phenomena. It is obvious that inflammation can occur upon infectious and noninfectious triggers, the latter referred to as sterile inflammation. Triggers of sterile inflammation include trauma, toxic injury, malignancy, autoinflammation, alloimmunity, and autoimmunity [2]. Table 40.1 summarizes key differences between these three categories. Among these, autoimmunity is characterized by systemic or organ-specific inflammation of spontaneous onset, although autoimmunity can often be triggered by an episode of infection. Autoimmune disease becomes obvious mostly by organ injury and dysfunction, which focuses the attention of patients and doctors on this organ, which defines the patient's burden, complaints, and signs of the disease. However, the immunologist's perspective on autoimmunity is entirely different. Immunologists see autoimmunity as a problem of immune regulation in lymphoid organs such as thymus, spleen, and lymph nodes. The autoimmune attack of peripheral organs, organ inflammation, and organ dysfunction is already at the border of the immunologist's interest. Being aware of this entirely different perspective of researchers, clinicians, and patients on autoimmunity, we recommend dissecting the process into the pathogenesis of autoimmunity (mostly outside affected organs) and the pathogenesis of autoimmune tissue injury (mostly inflammation inside the affected organ). Hence, in this chapter, we approach the topic by first discussing the mechanisms of immune

Inflammation: From Molecular and Cellular Mechanisms to the Clinic, First Edition.

Table 40.1 Differences between autoinflammation, alloimmunity, and autoimmunity.

	Autoinflammation	Alloimmunity	Autoimmunity
Antigen	—	Foreign proteins of the same species	Proteins of the self
Genetic cause	Gene variants promoting spontaneous inflammation, often monogenic	—	Gene variants promoting loss of self-tolerance, often polygenic
Who is affected?	Children and young adults	Patients undergoing cell or organ transplantation	Adolescents and adults, women often more frequently affected
Central pathomechanism	Mutated pathway	MHC-II-driven alloantigen presentation via DC and B cells	MHC-II-driven autoantigen presentation via DC and B cells
Current treatment strategy	Cytokine antagonists targeting mutated pathway	Unselective immunosuppressants	Unselective immunosuppressants

tolerance, genetic and environmental factors that break immune tolerance, and the mechanisms of autoimmune tissue inflammation. Finally, we discuss systemic lupus erythematosus (SLE) as a paradigmatic example of systemic autoimmunity and tissue injury.

40.2 Immune Tolerance

The immune system's inherent property is to recognize, respond, and eliminate nonself-antigens, while not reacting harmfully to self-antigens, referred to as immune tolerance. The immune system must somehow avoid accidentally recognizing and destroying host tissues. Maintaining self-tolerance involves both the elimination of immune cells that can react with self-antigens and active inhibition of immune responses against self-antigens. In the first step of this process, a phenomenon termed "central tolerance" deletes T- or B-cell clones before the cells are allowed to mature if they possess receptors that recognize self-antigens with high affinity. Central tolerance occurs in the primary lymphoid organs: the bone marrow for B cells and the thymus for T cells. Because central tolerance is not perfect and some self-reactive lymphocytes enter into the periphery and secondary lymphoid tissues, additional safeguards limit their activity. These backup mechanisms called "peripheral tolerance," renders some self-reactive lymphocytes in secondary lymphoid tissues inactive and generates others that actively inhibit immune responses against self. The possibility of damage from self-reactive lymphocytes is further limited by the life span of activated lymphocytes, which is regulated by programs that induce cell death (apoptosis) following receipt of specific signals.

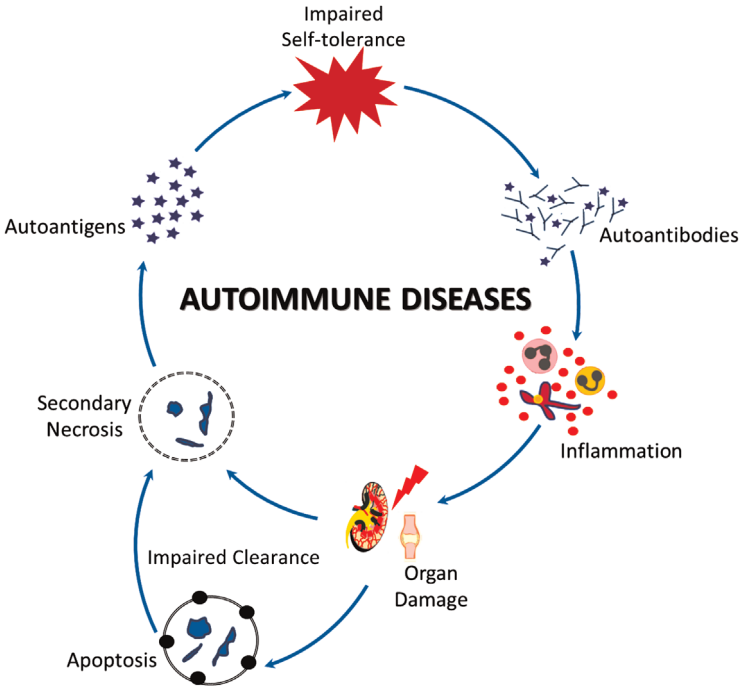

Figure 40.1 Progression of autoimmune diseases. Under healthy conditions, apoptotic cells are efficiently cleared by the immune system without an immune response. However, in situations of clearance deficiency, these cells progress to secondary necrosis causing accumulation of autoantigens. Not-ingested autoantigens are presented by the APCs to B cells, and thus break the tolerance to self. This subsequently leads to production of autoantibodies. Autoantibodies form complexes with autoantigens, called immune complexes that set up inflammation and tissue damage. This may lead to organ damage and, therefore, production of more autoantigens, setting up the loop leading to progression of autoimmune disease.

Apoptosis has an important role in establishing and maintaining immune tolerance (Figure 40.1). This is evidenced by the development of systemic autoimmune diseases in mice with naturally occurring mutations of death receptors like Fas or Fas ligand (FasL). Activated T cells express increased levels of Fas and FasL. In both B and T cells, engagement of Fas with FasL induces activation-induced cell death (AICD). Mice that carry inactivating mutations in Fas (lpr/lpr) or FasL (gld/gld) are able to develop autoimmune disease early in life [3]. Such a lack of self-tolerance can lead to autoimmune disease, whereas a host, displaying excessive tolerance may be more susceptible to pathogens. Ray Owen's experiments in cattle showed that a shared blood supply during development led to lifelong immune tolerance [4]. There are examples in which allografts, mismatched at a single HLA locus, are accepted with little or no immune suppression. In cases where the mismatched antigen is expressed by the mother, but not inherited by the offspring, there is the possibility that perinatal exposure induced subsequent tolerance to this antigen. Because human maternal cells do not normally cross the placental barrier, such specific tolerance to noninherited maternal antigens would be an exception rather than a common

place event. This self-tolerance is maintained by several mechanisms that prevent the maturation and activation of potentially self-reactive lymphocytes. The process of immune tolerance is often divided between central and peripheral mechanisms. Tolerance to self, acquired within the thymus, is called central tolerance, whereas tolerance acquired outside the thymus is called peripheral tolerance.

Central tolerance. Central tolerance refers to tolerance that is induced during development of T cells in the thymus and B cells in the bone marrow. The central tolerance mechanisms, clonal deletion, and receptor editing eliminate many autoreactive T cells in the thymus and autoreactive B cells in the bone marrow. Developing T cells with a high affinity for self-antigens are eliminated by clonal deletion. Strongly self-reactive immature B cells may be induced to make further immunoglobulin (Ig) gene rearrangements and thus evade self-reactivity. This phenomenon is called receptor editing. T cells also undergo T-cell receptor (TCR) editing in the thymus [5]. If editing fails, the self-reactive B cells are also eliminated by clonal deletion. Gene rearrangement to form the TCR is a random process that allows for the generation of T cells with an incredible repertoire of specificities. Invariably, some of these receptors will react against self-antigens. It is believed that lymphocytes specific for MHC plus self-peptides will encounter most of these self-antigens during development in the thymus. In contrast to mature T cells that respond to encounter with their specific antigen with a program of proliferation and differentiation, immature lymphocytes respond by undergoing clonal deletion. Although there are mechanisms to ensure a full repertoire of self is expressed in the thymus, it is invariable that some self-reactive cells will develop and migrate from the thymus to the peripheral lymphoid organs. Control of such "escaped" autoreactive cells is achieved through peripheral tolerance mechanisms.

Consider the mechanisms that generate diversity in T-cell or B-cell receptors. The genetic rearrangements that give rise to a functional T-cell receptor or Ig occur through a process called V(D)J recombination, commonly known as somatic recombination. During this process, generation of variable regions that react with self-antigens is almost inevitable. If this were allowed to occur frequently, such TCR or Ig receptors could produce mature functional T or B cells that recognize self-antigens and autoimmune disease would ensue. Clonal deletion eliminates developing lymphocytes whose antigen receptors bind strongly to self-antigens present in the generative lymphoid organs. In a classic experiment, Goodnow mated transgenic mice expressing hen egg white lysozyme (HEL) with mice expressing a transgenic immunoglobulin specific for HEL to demonstrate that self-reactive lymphocytes are removed or inactivated after encounter with self-antigen [6]. Clonal deletion of immature B and T lymphocytes is an important mechanism for maintaining tolerance to many self-antigens; this is also called central tolerance because it develops in the central (generative) lymphoid organs. Although both B and T cells participate in tolerance, T-cell tolerance plays the primary role.

T-cell Tolerance. The main process by which T lymphocytes acquire the ability to distinguish self from nonself occurs in the fetal thymus. This process, called clonal deletion, involves the killing of T cells that react against antigens present in

the fetus at that time. The self-reactive cells die by a process of programmed cell death called apoptosis. For negative selection to be efficient, the thymic epithelial cells must display a vast repertoire of "self-" proteins. A transcriptional factor called the autoimmune regulator (AIRE) enhances the synthesis of this array of self-proteins [7]. Mutations in the gene encoding the AIRE protein, which regulates protein expression in the thymus, result in the development of an autoimmune disease called autoimmune polyendocrinopathy. The AIRE also functions in the peripheral lymphoid organs such as the spleen and lymph nodes, where it contributes to peripheral tolerance.

Clonal deletion occurs at the double-positive (DP) to single-positive (SP) transition. The loss of over 95% of thymocytes reflects the stringent selection processes that shape the developing T-cell repertoire. Clonal deletion is a major mechanism of tolerance, in that T cells must be exposed to all self-antigens during thymocyte maturation. However, there are also self-antigens whose expression is restricted to a specific tissue or developmental time point. One possibility is that all proteins could be transported to the thymus by APCs. Recently, it was found that AIRE expression drives medullary thymic epithelial cells (mTECs) to express tissue-specific self-peptides in the thymus. Self-reactive developing T cells are thus exposed to tissue-specific self-peptides in the thymus and are deleted. AIRE-deficient humans and mice develop autoimmune polyendocrinopathy candidiais ectodermal dystrophy (APS-1 or APECED in humans), emphasizing the role of central tolerance in preventing T-cell-mediated autoimmune disease [8]. Negative selection ensures T cells displaying very high or very low receptor affinities for self-MHC undergo apoptosis and die in the cortex. Positive selection ensures T cells with TCRs that have intermediate affinities are rescued from apoptosis, survive, and continue along their pathway of maturation. T cells at this stage of maturation ($CD4 + CD8 + TCR^{low}$) go on to express TCR at high density and lose either CD4 or CD8 to become "single-positive" mature T cells. Less than 5% of thymocytes leave the thymus as mature T cells. Given the survival of some self-reacting T cells, a separate mechanism is required to prevent them from attacking the body.

B-cell Tolerance. B-cell precursors differentiate into immunocompetent B cells in the bone marrow; they do not pass through the thymus. Autoreactive B cells are eliminated by receptor editing and clonal deletion, which are recognized as mechanisms that lead to central tolerance. These processes reduce the occurrence of autoimmune diseases. On encountering antigens, the B cells form germinal centers and undergo affinity maturation to produce antibodies with higher antigen affinity and helps prevent antibody cross-reactivity with self-antigens. Immature B cells bearing an antigen receptor for a self-antigen can escape clonal deletion by changing their receptor in a process called receptor editing. David Nemazee and coworkers showed that some developing B cells could undergo receptor editing [9]. In this process, self-antigen recognition by immature B cells induces reactivation of the cell's V(D)J recombinase and the rearrangement and production of a new Ig light chain (edited), which changes the specificity of the receptor so that it no longer recognizes a self-antigen [9]. It is estimated that as many as 50% of self-reactive B cells undergo receptor editing.

However, tolerance in B cells is less complete than in T cells, an observation supported by the finding that antibodies mediate most autoimmune diseases. If receptor editing fails, the immature B cells that express high-affinity receptors for self-antigens and encounter these antigens in the bone marrow or the spleen may die by apoptosis. This process is also called clonal deletion. The antigens mediating clonal deletion – usually abundant or polyvalent self-antigens such as nucleic acids, membrane-bound lipids, and membrane proteins – deliver strong signals to IgM-expressing immature B lymphocytes that happen to express receptors specific for these self-antigens. Both receptor editing and deletion are responsible for maintaining B-cell tolerance to self-antigens that are present in the bone marrow. Negative selection of thymocytes removes autoreactive T cells; however, some autoreactive T cells do escape the thymus, because they have too low an affinity for self-antigens to induce clonal deletion. The body has evolved several other mechanisms to avoid autoimmunity, and one of such mechanisms is peripheral tolerance.

Peripheral Tolerance. Clonal deletion of either T cells or B cells during development is not perfect. Given the potential for autoimmune self-destruction, if the clonal deletion fails, there must be backup mechanisms to control autoreactivity for those few cells that manage to escape the thymus. Peripheral tolerance is necessary because some antigens are not expressed in the thymus and some tissue-restricted antigens are expressed only in adult life; therefore, some self-reactive T cells are not killed in the thymus. There are several mechanisms involved in peripheral tolerance; these mechanisms include immune privilege, anergy, and regulation. Clonal anergy is the term used to describe self-reactive T cells that are not activated because proper costimulation does not occur. The mechanism of clonal anergy involves the inappropriate presentation of antigen, leading to a failure of interleukin-2 (IL-2) production. Inappropriate presentation is due to a failure of "costimulatory signals" (e.g., CD28 on the T cell and B7 on the APC). For example, the inhibitory protein CTLA-4 on the surface of the T cells has a higher affinity than CD28 for B7 proteins, displaces CD28 and interacts with B7, resulting in a failure of T-cell activation. Thus, CTLA-4 is involved in the maintenance of unresponsiveness (tolerance) to self-antigens. Furthermore, B7 is an inducible protein, and failure to induce it in sufficient amounts can lead to anergy. In addition, the costimulatory proteins, CD40 on the APC and CD40L on the helper T cell, may fail to interact properly. The failure of costimulatory signals most often occurs when there is an insufficient inflammatory response at the site of infection.

The mechanisms mediating peripheral tolerance vary. Under normal conditions, an encounter of mature lymphocytes with antigen leads to induction of an immune response. However, presenting the antigen in some alternative form, time, or location may instead lead to tolerance. Antigens that induce tolerance are called tolerogens rather than immunogens. Here, context is important; the same chemical compound can be both an immunogen and a tolerogen, depending on how and where it is presented to the immune system. For instance, an antigen presented to T cells without appropriate costimulation results in a form of tolerance known as anergy, whereas the same antigen presented with costimulatory molecules can become a potent immunogen. One of the mechanisms of

B-cell tolerance is clonal exhaustion, in which the immunogen activates all of the B cells specific for it, leading to maturation of cells and transient antibody synthesis and thereby exhausting and diluting the B-cell response. It was found that T-cell tolerance is induced more rapidly and is longer lasting than B-cell tolerance. For example, T-cell tolerance may be induced in a single day, whereas B cells may require 10 days for induction. Maintenance of tolerance requires the continued presence of specific antigens. In immunocompetent adult animals, repeated administration of large doses of protein antigen or a massive single-dose administration of a polysaccharide antigen can induce a specific immunologic unresponsiveness termed high-dose tolerance.

T-cell Anergy. Cellular proliferation and/or potentiation of T-cell effector function are not inevitable consequences of TCR engagement. In fact, under some conditions, TCR ligation results in a state of T-cell unresponsiveness, known as T-cell anergy; this state appears to result either when the TCR is engaged without concomitant costimulation or when the ligand for the TCR is not of sufficient affinity to initiate the full spectrum of biochemical second messengers. This phenomenon was first noted by stimulating T cells in the presence of metabolically inactivated APCs. Subsequently, it was shown that CD28 costimulation could prevent the induction of anergy. Anergic cells are unable to proliferate or secrete cytokines upon TCR-mediated restimulation. Interestingly, supplementation of cultures with IL-2 can overcome the anergic state *in vitro*. Several unique experimental systems have recently provided insights into how TCR signaling events can lead to either anergy or full T-cell activation. Mice made transgenic for specific TCR complexes have proved to be useful models for studying differential responses to TCR engagement *in vivo* and *in vitro*. TCR transgenic mice produce T-cell repertoires that are largely restricted to a single specificity. T cells from such mice respond fully when presented with a specified peptide antigen, but exhibit an anergic response when that peptide is subtly altered. High doses of antigen are usually more tolerogenic, although repeated low doses can also induce tolerance in T cells. As a rule, T-cell tolerance is easier to induce and lasts longer than B-cell tolerance. Immune regulation includes regulatory T cells, which can actively suppress the immune system. By regulating the activation and proliferation of antigen-specific effectors, Tregs promote tolerance to self and suppress autoimmunity *in vivo*.

Regulatory T Cells (Tregs). Tregs play an important role in maintaining immune homeostasis. Tregs suppress the function of other T cells to limit the immune responses and allowing the establishment of immunological tolerance. Tregs are produced in the thymus as a functionally mature subpopulation of T cells and can be induced from naive T cells in the periphery. Alteration in the number and function of Tregs has been implicated in several autoimmune diseases including multiple sclerosis, active rheumatoid arthritis, and type 1 diabetes [10]. Tregs are vital for keeping the immune system in check, helping to avoid immune-mediated pathology. Treg cells can inhibit the proliferation of other T-cell populations *in vitro*, effectively suppressing autoreactive immune responses. They express on their surface CD4, CD25 (the chain of the IL-2 receptor), and a transcription factor, FoxP3, the expression of which is necessary and sufficient to induce differentiation to the Treg lineage. Foxp3 is a master regulator and expression of

the Foxp3 has been shown to correlate with regulatory activity in both humans and mice. The absence of Foxp3 either through spontaneous mutation or through targeted disruption of the gene leads to the absence of T cells with regulatory activity. Conversely, overexpression of Foxp3 leads to an excess of T cells with regulatory activity. Foxp3 genetic deficiency in humans and rodents leads to severe multiorgan autoimmunity [11].

Tregs manifest their functions through a myriad of mechanisms that include the secretion of immunosuppressive cytokines such as IL-9, IL-35, IL-10, and TGF-β, suppressing the activity of other nearby T cells and APCs. Cell contact-dependent suppression includes the high-affinity TCR and other costimulatory molecules such as CTLA-4 and GITR. Cytolytic activity-dependent mechanism kills T cells and APC through granzyme or perforin. Possible negative signals of Tregs include upregulation of intracellular cyclic AMP, which leads to inhibition of T-cell proliferation and IL-2 production. Activated Tregs may also down-regulate CD80/86 expression on APC. Depletion or inhibition of Treg cells before immunization may enhance immune responses to conventional vaccines and facilitate the development of antitumor immunity, leading to clearance tumours. Conversely, increasing the suppressive activity of Treg-cell populations could be useful in the treatment of allergic or autoimmune diseases and graft rejection. Tregs are broadly classified into natural or induced (adaptive) Tregs; natural Tregs (nTregs) are ($CD4^+CD25^+Foxp3^+$ T cells) generated in the thymus early in life to perform their key role in immune homeostasis (Table 40.2). Induced

Table 40.2 Regulatory T-cell subsets.

Property	Natural Treg (nTregs) nTregs	Induced Tregs (iTregs) Tr1	Th3
Development	Thymus	Periphery (MALT)	Periphery (MALT)
Phenotype	$CD4+CD25^+$ and $CD127^{low}$	$CD4^+CD25^-$	$CD4^+CD25^+$ from $CD25^-$ precursors
Other associated markers	$CTLA4^+$, $GITR^+$, and $FoxP3^+$	$CD25^{low\ variable}$, $CD45RB^{low}$, and $FoxP3^-$	$CD25^{low\ variable}$, $CD45RB^{low}$, and $FoxP3^+$
Suppression	Contact-dependent, granzyme B dependent, makes TGF-β	IL-10 mediated	TGF-β mediated
Target cells	APC and T effector cells	T effector cells	Not yet identified
CD28 Involvement	Thymic development and maintenance in periphery	Unnecessary for development or function	Unnecessary for development or function
In vivo role	Suppression of autoreactive T cells	Mucosal immunity and inflammatory response	Mucosal immunity and inflammatory response
In vitro expansion	Expandable using TCR/CD28 stimulation and IL-2	CD3, IL-10, and rehnoic acid	CD3 and TGF-β

$CD4^+Foxp3^+$ regulatory T (iTreg) cells develop outside the thymus in various tissues of the body including the mucosa-associated lymphoid tissue (MALT) throughout life and are typically induced by inflammation and disease processes, such as autoimmunity and cancer.

Natural Tregs. nTregs originate from the thymus as $CD4^+$ cells expressing high levels of CD25 together with the transcription factor FoxP3 [12]. The nTregs represent approximately 5–10% of the total $CD4^+$ T cell population. They are positively selected thymocytes with a relatively high avidity for self-antigens. The signal to develop into nTreg cells is thought to come from interactions between the T cell receptor and the complex of MHCII with self-peptide expressed on the thymic stroma. It seems that thymocytes that commit to the nTreg cell lineage are likely to receive unique stimulatory signals. nTregs are essentially cytokine independent and represent an alternative fate for autoreactive T cells. Most thymocytes that express receptors with high affinity for self-antigen die via clonal deletion. However, a small fraction appears to commit to the regulatory T-cell lineage and leave the thymus to patrol the body and prevent autoimmune reactions. These nTregs share the periphery with induced Tregs (iTrags) that can develop from mature T cells that are exposed to TGF-β and IL-10 cytokines. Suppression by these regulatory cells is antigen specific because it depends on activation through the T-cell receptor. nTregs regulate immune responses in a variety of means: directly inhibiting an antigen-presenting cell's ability to activate T cells, directly killing T cells, indirectly inhibiting T-cell activity by secreting inhibitory cytokines IL-10 and TGF-β, and depleting inflammatory cytokines such as IL-2. The existence of Treg cells that specifically suppress immune responses has clinical implications.

Induced Tregs. iTregs originate from the thymus as single-positive CD4 cells. They differentiate into CD25 and FoxP3 expressing Tregs (iTregs) following adequate antigenic stimulation in the presence of cognate antigen and specialized immunoregulatory cytokines such as TGF-β, IL-10, and IL-4. Under the influence of TGF-β, iTreg cells mature in peripheral sites, including MALT, from CD4+ Treg precursors, where they acquire the expression of markers typical of Tregs, including CD25, CTLA4, and GITR/AITR. Upon upregulation of the Foxp3, iTregs begin their suppressive effect. This includes the secretion of cytokines including IL-10 and TGF-β that may induce cell cycle arrest or apoptosis in effector T cells, and blocking costimulation and maturation of dendritic cells (DCs). iTreg cell populations include T regulatory 1 (Tr1) cells, which secrete IL-10, and T-helper 3 (Th3) cells, which secrete TGF-β. Both of them are involved in the suppression of autoimmunity. Tr1 cells do not express Foxp3, yet their properties *in vitro* are very similar to those of Foxp3+ Tregs [13].

Tolerogenic Signals of APC-presenting Autoantigen. DCs play a significant role in establishing self-tolerance through their ability to present self-antigens to developing T cells in the thymus. DCs are predominantly localized in the medullary region of the thymus. DCs in the circulation, skin, heart, and possibly other peripheral tissues, migrate to the thymus and present the peripheral tissue antigens. When antigen-presenting DCs make a high-affinity interaction with antigen-specific thymocytes, this interaction drives the interacting thymocytes to death, a process often referred to as clonal deletion, which fundamentally blocks

the self-reactive thymocytes from differentiating into mature T cells. Thymic DC presentation of self-antigens significantly contributes to the clonal deletion of $CD4^+$ thymocytes. In the absence of inflammation, classical DCs capture tissue antigens and migrate to the draining lymph nodes but do not produce cytokines and membrane molecules that are required to induce effective immune responses. The function of these DCs may be to present self-antigens to self-reactive T cells and thereby cause inactivation or death of the T cells or generate regulatory T cells. These mechanisms are important for maintaining self-tolerance and preventing autoimmunity.

Tolerogenic DCs are immature, maturation-resistant, or alternatively activated DCs that express low surface MHC molecules, and low costimulatory signals (e.g., CD80 and CD86), and an impaired ability to synthesize T-helper 1 cell-driving cytokines, such as IL-12p70, and high IL-10 production. Rapamycin is a potent immunosuppressive drug, impairs the maturation of DCs in response to "danger signals," such as high-mobility group box 1protein (HMGB1), Toll-like receptor (TLR) ligands, or CD40 ligation. Immunosuppressive drugs such as corticosteroids, cyclosporine, and so on have been used to target DC differentiation and function. All these molecules prevent DC maturation and/or activation or impair the capacity of DCs to produce IL-12p70. In addition, some of these agents prevent the nuclear translocation of nuclear factor-κB (NF-κB) family members, which are required for the differentiation of DCs [14].

Immune Privilege Sites. Immune-privilege sites are regions in the body that prevent the expression of inflammation within an immune-mediated environment. That is, when foreign antigens are introduced into the immune privilege site, the zone does not induce an autoimmune response, something that would usually occur in other areas of the body. Immune-privileged sites fail to induce an immune response because they are effectively sequestered from the cells of the immune system. The concept of "immune privilege" was first described by Medawar more than 60 years ago. Medawar believed that tolerance in these areas was due to limited lymphatic drainage [15]. In this model, lymphocytes cannot easily gain entrance to the privileged site and foreign antigens deposited there are not transported to secondary lymphoid organs, which prevents initiation of an immune response. The sites of immune privilege include the anterior chamber of the eye, cornea, fetus in pregnant females, uterus, testes, and brain. Each of these sites is characterized by an absence of lymphatic vessels and in some cases by an absence of blood vessels. Immune-privilege sites are thought to have evolved in order to protect sensitive areas of the body that are unable to regenerate their tissues and have vital functions. Both the eye and the brain have a limited capacity for regeneration, and immune-mediated inflammation in either organ could have devastating consequences.

Multiple mechanisms have been proposed to account for immune privilege. One mechanism that likely contributes to tolerance is a low level or complete absence of expression of classical MHC class Ia protein in cells of the eye and brain, especially cells with little or no capacity for regeneration [16]. The reduced expression of MHC class Ia molecules is required to protect some of these cells from cytotoxic T lymphocytes (CTL)-mediated cell lysis. In the case of the developing fetus, the cells of the villous trophoblast lack expression of class I

MHC. Cells in these areas also express cell surface and soluble factors that downregulate the immune response. For example, ocular cells express proapoptotic cell surface molecules such as Fas ligand (FasL) and TRAIL [17]. These TNF family members may contribute to apoptosis of infiltrating T and other inflammatory cells bearing "death receptors." Cytokines produced at sites of immune privilege are also likely to contribute to the inhibition of inflammation. The presence of high levels of the anti-inflammatory cytokines TNF-β and migration inhibitory factor (MIF) leads to inhibition of NK cell-mediated cytolytic activity. Consequently, the alloantigens of the graft are not able to sensitize the recipient's lymphocytes, and the graft has an increased likelihood of acceptance even when HLA antigens are not matched. The privileged location of the cornea has allowed corneal transplants to be highly successful. A potential solution for graft rejection would be triggering immune privilege mechanisms within a specific area, allowing the body to accept the transplanted tissue.

In addition to the various mechanisms of central and peripheral tolerance, an effective means to avoid self-reactivity is sequestration or compartmentalization of self-antigens. However, one possible consequence of sequestration is that the antigen is never encountered by developing lymphocytes, and thus active tolerance to the sequestered antigen is not established. If barriers between the immune cells and the sequestered antigens are breached, the newly exposed antigen may be seen as foreign because it was not previously encountered. Trauma to one eye that allows entry of immune cells can result in inflammation in that eye, leading to tissue destruction and impaired vision. Other immune privilege mechanisms involve the production of immunosuppressive and anti-inflammatory cytokines. This mechanism, observed in ocular macrophages and DCs, is thought to regulate immune response. The remarkably successful field of corneal transplantation in clinical practice is undoubtedly associated with corneal immune privilege. Antigens introduced into the anterior chamber elicit a unique form of immune regulation (anterior chamber-associated immune deviation) that inhibits T-cell-mediated inflammation and graft rejection [18]. Furthermore, the use of various transgenic mouse models has facilitated the identification of critical pathways, which upon disruption can modify the immune privileged status of the eye. Understanding these pathways has clinical implications for the transplantation field and for the treatment of autoimmunity.

40.3 Genetic Factors that Break Immune Tolerance

The broad antigen receptor diversity in lymphocytes is a result of two processes of somatic genome modification. At first, in the central compartments like bone marrow for B cells and thymus for T cells, lymphocytes undergo V(D)J recombination rearrangement of the B-cell receptor (BCR) and TCR genes during differentiation. Second, somatic hypermutation substitutes single nucleotides of BCR genes during the late phase of an immune response in peripheral lymphoid tissues. Because of these two processes, lymphocyte receptor diversity allows to react to a large variety of antigens [19–21]. Although, a significant fraction of these receptors can react to self-antigens, autoimmune diseases are

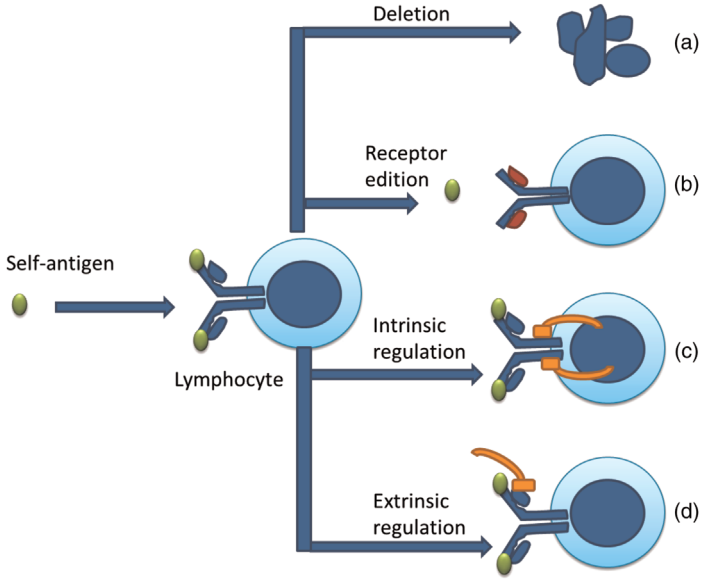

Figure 40.2 Major checkpoint mechanisms that regulate the development of B and T lymphocytes: (a) clonal deletion (apoptotic death of self-reacting lymphocytes, (b) receptor editing (V(D)J rearrangement of the self-reactive T-cell receptor or B-cell receptor, (c) intrinsic regulation of self-reactive receptor activation, and (d) extrinsic regulation of self-reactive lymphocyte activation.

relatively rare [22]. A series of checkpoints limit the reactivity of autoreactive lymphocytes to self-antigen (Figure 40.2): (1) deletion of self-reactive lymphocytes by inhibition of the Bcl-2-dependent survival pathway and/or activation of death receptor pathways. (2) Editing of self-reactive receptor by V(D)J recombination and somatic hypermutation [21]. (3) Intrinsic inhibition of BCR/TCR activation either by downregulation of BCR/TCR or by induction of inhibitory receptors (CD5 and CTLA4), or induction of phosphatase or ubiquitin ligases [23,24]. (4) Extrinsic control of lymphocyte activation either by downregulation of survival factors (BAFF and IL-7) or by inhibition of costimulation (anergy), or by limiting innate immunity.

Self-antigen ligating the BCR on immature B cells sets off a series of cellular events. Whenever the interaction with self-antigen exceeds a certain threshold, the immature B cells internalize the BCR and halt the maturation process [25]. This process downmodulates the expression of CD62 ligand (CD62L) [25], suppresses the receptors for BAFF (B-cell-activating factor) [26], and continues the expression of Rag1 and Rag2, which are required for V(D)J recombination for receptor editing [27,28]. B cells with unsuccessful editing of self-reactive BCR undergo cell death in the bone marrow or soon after arriving in the spleen [25]. B-cell deletion is a consequence of withdrawal of survival factors like BAFF or induction of proapoptotic factors like BIM. Vice versa, *Bim*-deficient mice are prone to spontaneous autoimmunity and produce anti-DNA autoantibodies [29].

In contrast to the BCR that can recognize antigen directly, the TCR is activated only upon antigen presentation by APCs. The self-peptide/MHC complex on the

surface of cortical thymic epithelial cells is presented to the TCR on naïve T cells. In case of TCR ligation by self-peptide, the respective T cell will start to proliferate, a process referred to as positive selection. Along this process, certain chemokine receptors are upregulated that promote the migration of such positively selected T cells into the thymic medulla where these are encountered with medullary thymic epithelial cells and dendritic cells, which express B7.1 (CD80) and other costimulatory molecules along with self-peptide/MHC [30]. The engagement of a costimulatory signal induces negative selection of autoreactive T cells. Deregulated self-tolerance is clearly observed in studies with mice lacking medullary MHC or B7 molecules or blocked by respective antibodies [20,31]. Deficiency of ZAP70 (ζ-chain-associated protein kinase of 70 kDa) allows autoreactive T cells to escape deletion [32]. GRB2 (growth factor receptor-bound protein 2) [33], MINK (misshapen–Nck interacting kinase-related kinase) [34], activation of ERK (extracellular signal-regulated kinase), p38, and JNK (Jun kinase) activation are also required for the efficient self-reactive T-cell deletion [30]. BIM, FAS, and Nur77 are required for the induction of apoptosis of self-reactive T cells [29,35]. Mice and humans with defects in FASL and FAS exhibit spontaneous lymphoproliferative autoimmune disease with similarities to human systemic lupus [36].

However, the mechanisms of central immune tolerance are not sufficient to control all self-reactive lymphocytes. Bone marrow and thymus do not express all self-antigens and autoreactive lymphocytes persist at low numbers in the secondary lymphoid organs. Hence, peripheral tolerance is required. The following lists the genes and factors that are required for peripheral tolerance:

- Recruitment of the tyrosine phosphatase SHP1 (SH2 domain-containing protein tyrosine phosphatase 1) and lipid phosphatase SHIP (SH2 domain-containing inositol-5-phosphatase) to the activated BCR and induction of CD5 receptor on the surface by self-reactive BCR cells is required for the inhibition of BCR signaling in self-reactive B cells (anergy) [24,37,38].
- Surface expression of CTLA4 (cytotoxic T-lymphocyte antigen 4) is induced at a high threshold of TCR self-reactivity and inhibits T-cell activation. Lack of CTLA4 causes accumulation of self-reactive T cells in peripheral lymphoid and nonlymphoid tissues. In addition, variants of the CTLA4 gene are associated with susceptibility to thyroid autoimmunity and type 1 diabetes in humans and mice [39–41]. Ubiquitin ligases CBL-B, GRAIL, and ITCH tag ubiquitin to TCR-CD28 or cytokine signaling molecules and inhibit the signaling and promote internalization of the TCR followed by proteolytic degradation [42,43]. cbl-b deficiency along with MHC haplotype causes type 1 diabetes in rats [44]. Mice lacking itch, cbl-b, or its close relative c-cbl develop large numbers of activated T cells and produce high titers of autoantibodies [45,46].
- In the periphery, survival of B cells depends upon BAFF that induces expression of antiapoptotic Bcl-2 [26], a prosurvival factor like PIM2 in B cells to promote survival [47,48]. Antagonism of BAFF or low expression of the BAFF receptor on self-reactive B cells eliminates these cells. Also, IL-7 plays an important role in the survival of mature T cells in the periphery [49,50]. IL-7 expression is usually low but in case like T lymphocytopenia IL-7 levels increase to

proliferate the naïve T cells. This could also provide an opportunity for self-reactive T cells to proliferate as well. This could explain why T lymphocytopenia predisposes people to autoimmune disease [51].

Moreover, the association of MHC gene variants with autoimmune disease is not surprising. Ability of T cells to respond to a particular antigen depends on genotype-dependent variants of MHC conformation. It is less likely that the susceptibility to an autoimmune disease is determined by differences in the ability of different allelic variants of MHC molecules to present autoantigenic peptides to autoreactive T cells [52,53]. Rather, certain MHC molecules may drive the positive selection of self-peptide-reactive T cells. Apart from MHC class molecules, there are numerous other genes that participate in the regulation of immune tolerance or checkpoints for the lymphocyte development. Mutations associated with genes like AIRE, BIM, ZAP70, CBLB, CTLA4, FAS, and ROQUIN have been shown to cause autoimmune diseases both in animal models and in humans.

Monogenic or Polygenic Autoimmune Diseases. Autoimmune diseases due to single-gene defects are rare, but studies with single-gene mutations in animal models have offered an important understanding how defects in the immune system can lead to autoimmunity. Some examples of monogenic autoimmune diseases and responsible genes are given in Table 40.3. In contrast to the monogenic autoimmune diseases, pathogenesis of polygenic autoimmune disease is much more complex. These diseases are the result of a combination of susceptibility alleles at multiple loci and environmental factors (such as smoking, pathogen exposure, and hormone levels). Recently, genome-wide association

Table 40.3 Examples of monogenic autoimmune diseases.

Gene	Human Disease	Mouse Mutant/ knockout	Mechanism of Autoimmunity
AIRE	APS-1	Knockout	Decreased expression of self-antigen in thymus
CTLA4	Graves's and T1D	Knockout	Failure of T-cell anergy and reduced threshold of autoreactive T-cell activation
FOXP3	IPEX	Knockout and mutation	Decreased generation of Tregs
FAS and FASL	ALPS	Mutation	Failure of apoptosis of autoreactive lymphocytes
Complement factor C4	SLE	Knockout	Defective clearance of immune complexes
Trex-1	AGS and chilblain lupus	Mutation	Increased-type IFN signaling

APS1: autoimmune polyendocrine syndrome-1; T1D: insulin-dependent diabetes;
IPEX: immunodysregulation polyendocrinopathy enteropathy X-linked syndrome;
ALPS: autoimmune lymphoproliferative syndrome; SLE: systemic lupus erythematosus;
AGS: Aicardi–Goutières syndrome

Table 40.4 Association of some genomic loci with autoimmune diseases.

Genes of Interest	Function	Diseases
PTPN22	T- and B-cell receptor signaling	RA, T1D, and CD
CTLA4	Transmits inhibitory signals to T cells	T1D and RA
MHC	Major histocompatibility complex	All autoimmune disorders
CD2/CD58	Activation of T lymphocytes	RA and MS
IL10	Downregulates immune responses, including cytokines, MHC class II, and costimulatory molecules	IBD, SLE, and T1D
IL2/IL21	IL2/IL21T cell trophic growth factors	CeD, IBD, RA, and T1D
IL12B	p40 subunit common to IL-12 and IL-23	IBD and PS
IL2RA	IL-2 receptor α chain	MS and T1D
TNFAIP3	Induced by TNF and pattern recognition receptor activation; inhibits NF-κB signaling	RA, SLE, and PS
TNIP1	Interacts with TNFAIP3	SLE and PS
PRDM1	Transcriptional repressor of IFN-β; induces B cell maturation	RA and SLE
BLK	B lymphoid tyrosine kinase	SLE and RA
PTPN2	T-cell protein tyrosine phosphatase	IBD and T1D

AS: ankylosing spondylitis; CeD: celiac disease; IBD: inflammatory bowel disease; MS: multiple sclerosis; PS: psoriasis; RA: rheumatoid arthritis; T1D: type 1 diabetes mellitus.

studies (GWAS) have identified a large number of major loci with many associations shared between various autoimmune diseases Table 40.4.

40.4 Environmental Factors that Break Immune Tolerance

Infection and Tissue Injury. In many clinical scenarios, genetically predisposed individuals require an exposure to a pathogen or tissue injury to trigger the onset of autoimmune disease, but how?

1) *Molecular mimicry by antigens*: Viruses and other microbes may eventually share epitopes with self-antigens causing cross-reacting immune responses that attack not only the pathogen but also host tissue; for example, anti-streptococcal immunity can cross-react with cardiac tissue [54].
2) *Molecular mimicry by adjuvants*: Nuclear material such as nucleosomes or U1sn ribonucleoprotein released by dying cells during infection and trauma has a particle structure similar to that of viruses. The degenerated nucleic acid component lacks protective methylation creating autoadjuvants that mimic viral adjuvants and rather promote autoimmunity [55].

3) *Activation of costimulation*: As discussed earlier, one of the major checkpoint mechanisms of controlling self-reactive lymphocytes is to suppress their activation. Effective antigen presentation requires costimulation. Peripheral tolerance mechanisms suppress costimulatory signals to induce anergy in T cells. Cell surface pattern recognition receptors activation by PAMPs and DAMPs during infection or tissue injury upregulate the surface expression of costimulatory molecules and, thus, promote self-reactive T cells overriding peripheral tolerance.
4) *Superantigens*: Superantigens are proteins produced by a variety of microorganisms, especially bacteria or mycoplasmae, or virus-infected cells. Superantigens can ligate TCRs and mount an aggressive T-cell response with different antigenic specificities. This activation can also lead to autoimmunity [56].
5) *Bystander activation*: An activation of T cells via TCR-independent mechanisms can enhance the processing and presentation of self-antigens. Bystander activation may induce the spreading of the immune response toward different self-antigens, referred to as epitope spreading [56].
6) *Dead cell clearance defects*: Infections and abrupt tissue injury may cause massive cell death and accumulation of necrotic debris in the extracellular space. If this is accompanied by lack of efficient clearing mechanism, the prolonged exposure of intracellular autoantigens can promote autovaccination and autoimmunity [57].
7) *Modification of self-antigen* is another factor associated with autoimmune diseases. Smoking can promote citrullination of proteins like fibrinogen, type II collagen, α-enolase, and vimentin. These citrullinated proteins act as self-antigens. For example, anti-CCP antibodies serve as a biomarker for rheumatoid arthritis.

40.5 Autoimmune Tissue Injury: Tissue Inflammation

Immune Complexes. Immune complexes are formed as a result of binding of autoantibodies to soluble autoantigens. Once formed, immune complexes cause several responses including phagocytosis, opsonization, and complement deposition. They are normally cleared efficiently either by mononuclear phagocytes that have complement and Fc receptors or by red blood cells bearing both complement and Fc receptors, while impairment in clearance of immune complexes leads to their deposition and subsequent tissue injury, which is a hallmark of autoimmune diseases. Classically, a complement cascade involves binding of complement component C1q to the Fc portion of the antibody, which triggers the activation of the anaphylatoxins C5a and C3a that attract effector cells such as neutrophils and NK cells and stimulate the release of proteolytic enzymes as well as inflammatory cytokines. The autoimmune responses that are result of immune complex formation and subsequent tissue injury are classified as type III autoimmune responses. They are usually systemic and are characterized by autoimmune vasculitis. More common examples are systemic lupus erythematosus (discussed in detail in the following section), cryoglobulinemic vasculitis, and all forms of immune complex glomerulonephritis.

Cryoglobulinemia refers to the presence of circulating immunoglobulins called cryoglobulins in serum. The disease mainly involves vasculitis due to cryoglobulin-containing immune complexes [58]. Conditions that lead to cryoglobulinemic vasculits include lymphoproliferative disease, collagen disease, and hepatitis C virus (HCV) infection. However, factors that cause cryoprecipitation are not yet well understood [58]. Manifestations of this disease include (a) skin: erythematous, infarction, hemorrhagic crusts, and ulcers [58]; (b) musculoskeletal: arthralgia and myalgia [58]; (c) neurological: peripheral neuropathy [59]; (d) pulomonary: dyspnea, cough, or pleurisy [58]; and (e) renal: membranoproliferative glomerulonephritis [60,61]. Moreover, deposition of immune complexes in the glomerulus induces glomerulonephritis, for example, circulating polymeric IgA1-containing immune complexes contributes in the pathogenesis of IgA nephropathy [62].

Lymphocytes. Lymphocytes play a crucial role in autoimmune diseases. Autoimmunity is rather defined by the presence of autoreactive T and/or B lymphocytes in the periphery. Lymphocytes with less affinity toward antigen can become activated when the stimulus is strong; for example, naive T cells are activated when encountered by activated dendritic cells presenting an autoantigen and expressing high levels of costimulatory signals.

T Lymphocytes. T lympocytes are present in the inflamed tissues, for example, kidney, skin, joints, and so on. They recognize antigens via the T-cell antigen receptor in conjugation with CD3-defined complex of transmembrane proteins to activate the signaling process [63]. During autoimmune diseases, this signaling is altered leading to heightened response to even low-affinity autoantigens, to which normal T lymphocytes do not respond [63]. T lymphocytes are also known to provide excessive help to B lymphocytes to produce autoantibodies, for example, anti-dsDNA antibodies in SLE. It has been observed that CD4+ and CD3+CD4-CD8- T cells are present in large amount in patients with systemic autoimmunity and help B cells. Therefore, inhibition of this interaction was thought to suppress systemic autoimmunity; for example, such costimulatory pair of molecules includes CD40 and CD40 ligand. The expression of CD40L is increased on the surface of T cells during systemic autoimmunity [64]. Another costimulatory molecule called inducible T cell costimulator (ICOS) is an essential costimulatory receptor for follicular Th (Tfh) cells that provide help for extrafollicular B-cell differentiation, IL-21 production, and CD4 helper function [65,66]. Circulating Tfh cell number is also increased during systemic autoimmunity [67,68]. Furthermore, CD4T cells undergo specific differentiation to become IL-17 producing Th17 cells [69–72], and IL-17 is considered an important contributor to inflammation and autoimmunity [73]. Mice deficient in IL-17 are protected from lupus-like systemic autoimmunity [74]. Moreover, IL-17 blockade has proven beneficial in other autoimmune diseases including psoriasis, rheumatoid arthritis, and uveitis [75,76].

B Lymphocytes. The reciprocal roles of T lymphocyte help for B lymphocytes during an adaptive immune response and B lymphocyte help in CD4+ T cell activation are recognized as important attributors in the pathogenesis of autoimmune diseases [77–79]. B cells are activated when the antigen binds to the B-cell receptor [80]. Different functions of B cells during the pathogenesis of

autoimmune diseases involves the following: (a) Secretion of autoantibodies, for example, autoantibodies directed to DNA, chromatin proteins, and ribonucleoproteins, and so on during systemic autoimmunity in lupus [81], against ribonucleoprotein antigens during Sjögren's syndrome [82], against DNA topoisomerase I, RNA polymerases, and fibrillin-1 during systemic sclerosis [79]. (b) Presentation of autoantigens and costimulation, for example, stimulation of antigen-specific CD4+ T-cell proliferation after naive T-cell priming by DCs [83]. B cells and T cells also interact physically involving costimulatory molecules such as B7/CD28, CD40/CD40 ligand (CD40L), and OX40 ligand/OX40 on the surface of B cells and T cells, respectively [84,85]. (c) Secretion of proinflammatory cytokines; for example, B cells produce multiple cytokines including IL-10, IL-4, IL-6, lymphotoxin-α, TGF-β, and IFN-γ [86,87]. (d) Modulation of antigen processing and presentation. (e) Generation of ectopic germinal centers, within inflamed tissues that can be observed during periods of chronic inflammation [88].

Other innate lymphoid cells that do not possess TCRs and mediate cytotoxicity and secretion of cytokines that activate adaptive immune response include NK cells, CD56+ T cells, natural killer T (NKT) cells, gamma/delta (γδ) T cells, and mucosal-associated invariant T (MAIT) cells [89].

Monocytes and Macrophages. Monocytes and macrophages are essential weapons of the innate immune system with a plethora of immunological functions that involves cytokine production, phagocytosis, and antigen presentation. Abnormalities in functions of monocytes and macrophages are associated with a variety of autoimmune diseases [90,91]. They express several surface markers in order to recognize the environment and respond to it, and therefore any aberrations in the surface markers lead to incomplete immune response (Figure 40.3). For example, the Fc gamma receptors (FcγRs), essential for phagocytosis, cytolysis, degranulation, and inflammatory cytokine production [92], are dysregulated during systemic autoimmunity [91]. In particular, these receptors are required for the clearance of immune complexes, which are produced abundantly in SLE, and therefore deletion of FcγRs on the monocytes protected mice from development of lupus nephritis [93].

Moreover, monocytes and macrophages from patients with systemic autoimmunity exhibit abnormalities in antigen presentation, for example, decreased MHC II expression that is associated with defective upregulation of CD80 on APCs [94,95]. They also express higher CD86 compared to the healthy individuals [96]. Overexpression of the adhesion molecules, for example, ICAM-1 and costimulators molecules, for example, CD40 and CD69 also leads to aberrant monocyte migration as well as lymphocyte activation during autoimmune diseases [90,97]. However, the mechanisms underlying these phenotypic changes of monocytes and macrophages during autoimmune diseases are largely unknown. Contributions of both genetic and environmental factors in this have been described.

Aberrant activation of the immune system also causes increased production of inflammatory cytokines from monocytes and macrophages [98–100]. Elevated levels of Th2 cytokines, IL-6 and IL-10, during SLE help to promote IgG production. IL-6, in cooperation with IFN-1, is also required for B-cell maturation [101], whereas TNFα, IL-1β, IL-6, and TGFβ also play pathogenic roles in RA [100].

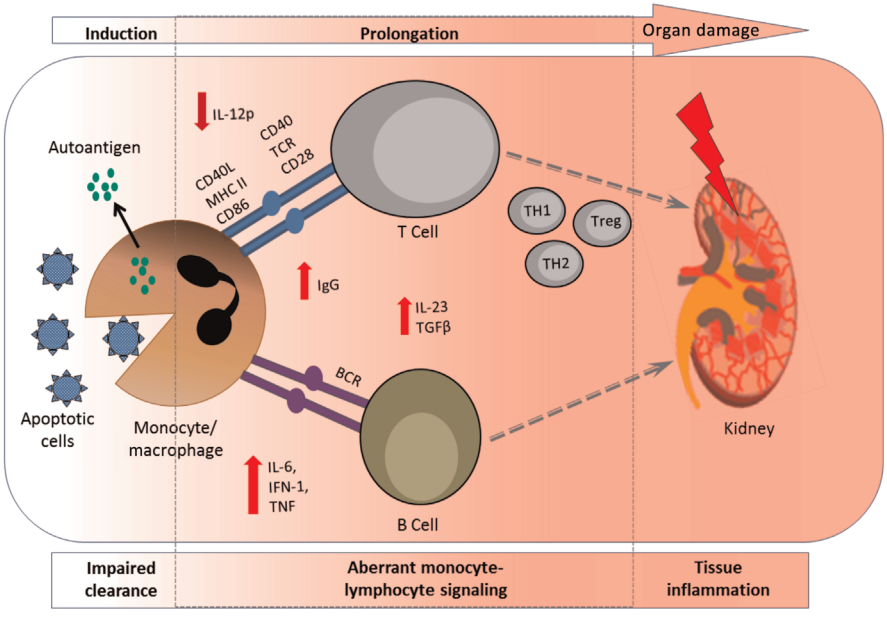

Figure 40.3 Role of monocytes and macrophages in pathogenesis of autoimmune diseases. Monocytes and macrophages participate at several levels during the pathogenesis of autoimmune diseases. They can misread apoptotic cells during their clearance and thus induce both inflammation and inappropriate presentation of autoantigens, initiating autoimmunity. Inappropriate antigen presentation leads to aberrant monocyte–lymphocyte signaling facilitating the prolongation of autoimmunity. At last, monocyte- and macrophage-mediated tissue inflammation may cause organ damage.

The phagocytosis of pathogens and homeostatic clearance of dying cells by monocytes and macrophages is essential for host defense. In systemic autoimmunity of the connective tissue diseases, the clearance of dying cells is impaired by monocytes and macrophages [102,103], which lead to increased availability of the intracellular autoantigens. These effects are partially because of reduced CD44 expression on the surface of monocytes [104], which is observed in SLE patients. Complement components also bind to apoptotic cells to promote phagocytosis by macrophages; however, antibodies against complement components, e.g. anti-C1q, impairs the clearance of apoptotic cells [105]. In addition to these mechanisms, autoantibodies may also directly act on macrophages [106].

Tertiary Lymphoid Organs. Tertiary lymphoid organs (TLOs) are formed when there is continued need for extravasation of leukocytes and a persistent source of antigen during an autoimmune attack [107] (Table 40.5). According to pathologists, the term TLO can be used only when all the following criteria are fulfilled [107]: (i) the organized infiltrate contains anatomically distinct yet adjacent T- and B-cell compartments; (ii) the T-cell area contains an extensive network of FRCs; (iii) PNAd+ or MECA79+ HEVs are present in the T-cell area; (iv) there is evidence of B-cell class switching and GC reactions in the B-cell

Table 40.5 Diseases in which TLOs have been found [107].

Disease	Location	Antigen Specific	References
Rheumatoid arthritis	Synovial space	Yes	[108,109]
	Lung interstitium	Yes	[110]
SLE	Tubulointerstitial nephritis	Yes (clonal restriction and mutated antibodies)	[111,112]
Diabetes	Periductally in pancreatic parenchyma	Yes, antiinsulin antibody responses	[113,114]
Primary biliary cirrhosis	Liver	No: absence of any clonal T- or B-cell proliferation	[115]
Secondary progressive multiple sclerosis	Meninges at deep cerebral sulci	Myelin and neuronal antigens: suggested	[116–118]
Hashimoto's thyroiditis	Thyroid gland	Thyroglobulin, thyroperoxidase	[119]
Autoimmune gastritis	Gastric lamina propria	Parietal cells	[120]
Myasthenia gravis	Thymus	Acetyl choline receptor: correlation of autoantibodies with infiltrates	[121]

follicles; (v) activation-induced cytidine deaminase (AID) enzyme is present; and (vi) FDCs are present. Often, it appears that not all criteria are fulfilled, but the organized structure can still function as a TLO [107].

The homeostatic chemokines and cytokines induce the formation of TLOs at the site of chronic inflammation (Table 40.5.). When LTα, CCL21 and CXCL13 are overexpressed from a tissue-specific promoter, ectopic lymphoid tissues are induced [107,122]. Similarly, either neutralization or genetic deletion of CXCL13, CXCR5, CCR7, or LTα inhibits TLO formation [108,123,124]. During this process, LTα signals the stromal cells to develop into follicular DCs and high endothelial venules, and CCL19 and CCL21 govern the organization of T-cell zone [107,123,125]. Moreover, deletion of IL7 causes absence of lymph nodes (LNs) in mice, whereas overexpression of IL7 causes development of additional LNs [107]. Also, RA patients show increased IL7 expression in the synovial tissue [126].

Similar to the secondary lymphoid organs, TLOs allow activation of naïve T cells and B cells by DCs within germinal centers [127]. The predominant APCs in TLOs are DCs [111]; however, their major constituents are the B cells [128]. Almost all TLOs show signs of B-cell class switching [128]. Plasma B cells found in the vicinity of TLOs secretes antibodies specific for the inducer of TLOs, whereas some B cells reach bone marrow and reside there as long-lived plasma cells [128].

TLOs are also considered as an inductive site for self-reactive T lymphocytes and antibodies. For example, the presence of T lymphocytes that destroy islets was detected in the pancreatic TLOs during the progression of diabetes in NOD mice [129]. Moreover, in lungs of RA patients, B cells in TLO produce rheumatoid factor and antibodies against citrullinated proteins [130]. TLOs have also been found in autoimmune thyroiditis or SLE [112,119].

Interindividual Variability of Organ Manifestations in Systemic Autoimmune Diseases. The confluence of remarkable advances in human genetics has furthered large amount of new information on genetic risk factors for human autoimmune diseases. For example, application of GWAS has revealed very important information on the common genetic risk variants, their frequencies in the population (risk allele frequency), and the risks on disease they confer (odds ratio) [131,132]. Most of the risk alleles identified by GWAS exert modest effect on the risk of disease (odds ratio >2), whereas only few risk alleles can exert large effect (odds ratio >3) [132,133]. In most of the autoimmune diseases, these important loci include HLA region [132,134,135]. However, other loci, for example, NOD2 and IL23R, contribute to Crohn's disease [136–138], and PTPN22 to type 1 diabetes and RA [139,140].

A recent large-scale GWAS of lupus nephritis provided strong evidence for multiple biologically relevant lupus nephritis susceptibility loci that are independent of HLA regions. For example, MHC locus rs9263871 located within *HCG27* had strongest association with lupus nephritis, independent of *HLA-DR2* and *HLA-DR3*, with an odds ratio of 1.7 [135]. Other loci outside the MHC region that are associated with lupus nephritis include rs1364989 on 4q11-q13, localized upstream of PDGF receptor-α [135]; rs274068 on 16p12.1, located within an intronic region of sodium-dependent glucose cotransporter *SCL5A11* [135]; rs7834765 on 8q24.12; and other two regions on 6p22 and 9p21 [135].

Some SLE susceptibility loci are also lupus nephritis susceptibility loci. For example, the most strongly associated SLE susceptibility locus rs2187668 within the HLA region is also associated with lupus nephritis [135]. Other such examples include rs2205960 within the 1q25.1 region near *TNFSF4* [135], and rs9888739 within ITGAM, located on chromosome 16p11.2 [135].

40.6 Lupus Nephritis, a Paradigmatic Example of Systemic Autoimmunity and Autoimmune Tissue Injury

In this chapter, the concept of systemic autoimmunity and autoimmune tissue injury is explained along the example of systemic lupus erythematosus. Systemic lupus erythematosus is a chronic autoimmune disease based on the loss of tolerance against nuclear autoantigens, which becomes evident by the presence of polyclonal antinuclear antibodies (ANA). The aberrant immunity of systemic lupus erythematosus can present as lymphoproliferation, immune complex disease, and inflammation in several organs [141,142]. Lupus nephritis is the most frequent organ manifestation. Genetic variants are fundamental for the development of lupus, but here the discussion is limited to the related disease mechanisms (Figure 40.4).

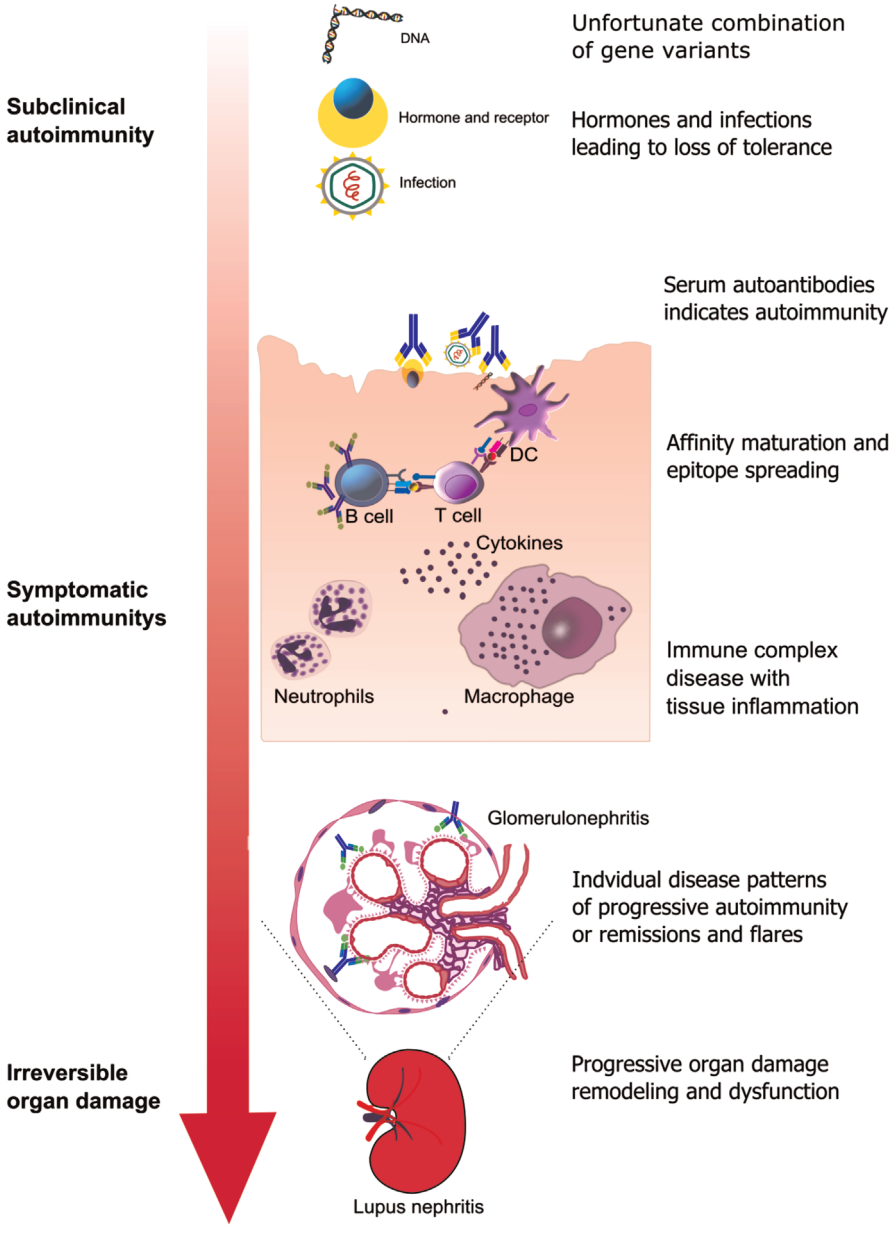

Figure 40.4 Evolution of autoimmune diseases. Autoimmunity is a very common phenomenon because everyone hosts some autoreactive lymphocyte clones that escaped negative selection in the thymus. Hormonal or environmental triggers such as infections promote an unspecific immune activation, which also drives a transient expansion of these clones that may cause a transient occurrence of autoantibodies in the circulation; for example, the occurrence of cryoglobulins after a mycoplasma infection does not develop without a distinct deposition. However, such phenomena do not necessarily lead to recurrent autoimmune disease unless other genetic variants compromise those elements that settle clonal expansion of autoreactive lymphocytes after disappearance of the infectious trigger. Gene variants in the autoantigen itself,

40.7 Pathomechanisms of Systemic Lupus Erythematosus

Aberrant Cell Death and Aberrant Handling of Dead Cells. Lupus, like any other autoimmune disease, is the result of autovaccination. The immunization process is imprinted into the immune memory via autoreactive long-lived plasma cells and memory T cells. These immune cells can hardly be eradicated by immunosuppressive drugs; hence, current drug options can only suppress disease activity but do not cure systemic lupus erythematosus [142,143]. Autovaccination and ANA formation imply that the nuclear autoantigens were accessible to antigen-presenting cells, a process normally prevented by rapid phagocytic clearance of dead cell corpses. Lupus patients are compromised in those mechanisms that normally assure low levels of chromatin in extracellular compartments. For example, certain gene variants modulate apoptotic removal of autoreactive lymphocytes [144,145] or the labeling of dead cells with opsonins such as complement factors or pentraxins. Also, the phagocytic clearance by macrophages can be impaired [81]. Recently, it was discovered that neutrophils undergoing NETosis releases nuclear material into the extracellular space [146–150], a process that drives autoimmunity on lupus [151].

Adjuvant mimicry Leading to Pseudoantiviral Immunity. Any persistence of dead cells and their components in the extracellular space holds the risk for autovaccination. This does not exclusively relate to autoantigens being exposed to the immune system, but it relates also to autoadjuvants that turn antigen presentation from tolerogenic to pathogenic. In this context, nucleic acids are important autoadjuvants. Delayed dead cell removal leads to degeneration of its components compromising elements that normally mask self-nucleic acids from being recognized as viral nucleic acids [152,153]. For example, the methylation of DNA and RNA inhibits their recognition by nucleic acid-specific Toll-like receptors that are important to translate viral nucleic acid recognition receptors into antiviral immunity [154]. Patients with systemic lupus erythematosus tend to process nuclear particles of dying cells as viral particles in which distinct nucleic acid structures activate these Toll-like receptors and thereby act as autoadjuvant. As the immune system mounts potent antiviral immunity against viruses, patients with systemic lupus erythematosus mount similar potent immune responses against those antigens that are presented in the context of these autoadjuvants. For example, ribonucleoprotein U1snRNP can be an agonist to Toll-like receptor TLR7 and trigger type I interferon release in plasmacytoid dendritic cells [155]. Immune complexes containing immunostimulatory RNA can activate B cells to produce antinuclear antibodies [156], a process regulated by SIGIRR [157,158].

its localization, and its antigen presentation, as well as in regulatory elements of the adaptive immune system, all can break the threshold of "loss of tolerance" and persistent autoantibody production. Autoimmune tissue injury then results from an ongoing attack of humoral and cellular effectors of the adaptive immune process directed against the autoantigen, which by nature persists and cannot be eliminated. Such antigens may be organ specific (e.g., autoimmune thyreoditis) or diffuse (e.g., in systemic lupus erythematosus). Autoimmune tissue inflammation then involves the same elements of innate and adaptive immunity that are involved in antimicrobial or antiviral host defense.

Similarly, DNA within immune complexes can activate TLR9 in plasmacytoid dendritic cells and promote B-cell proliferation [159]. Therapeutic inhibition of TLR7 and TLR9 can suppress type I IFN secretion, SLE, and lupus nephritis in mice [160–162]. The IFN receptor-dependent secondary gene expression ("signature") includes multiple antiviral genes, which should account for the unspecific symptoms shared by viral infections and SLE, such as fever, fatigue, arthralgia, and myalgia [163].

Expansion of Autoreactive Lymphocyte Clones. Dendritic cells and B cells are those antigen-presenting cells that regulate the behavior of the T-cell repertoire, that is, quiescence versus activation and proliferation [164]. Dendritic cells have a limited life span but upon persistent exposure to lupus autoantigens, activating TLR7 and TLR9 enhances their survival and renders them resistant to glucocorticoid-induced death [160]. Toll-like receptor activation of antigen-presenting cells changes their gene expression profile toward costimulatory molecules and proinflammatory cytokines, which shifts the interpretation of autoantigens from immune ignorance and lymphocyte anergy into lymphocyte activation and proliferation [165]. B lymphocyte stimulator (BlyS, also named B cell-activating factor, BAFF) and A proliferation-inducing ligand (APRIL) are only two lymphocyte mitogens secreted by activated dendritic cells and they also regulate B-cell differentiation and Ig class switching [166]. The two APRIL/BLyS receptors transmembrane activator and CAML interactor and B-cell maturation protein promote plasma cell survival [167]. B-cell maturation toward autoantibody-producing plasma cells involves interferon-related factor-4 [168]. T-cell activation involves MHC-II-mediated interaction with the clonal T-cell receptor (TCR), which implies that only T cells recognizing the presented antigen will get activated and undergo clonal proliferation.

Environmental Factors Promoting Systemic Lupus Erythematosus Activity. As viral infections activate the same kind of interferon-α-related immune response, viral infections can trigger disease activity of systemic lupus erythematosus [163]. In contrast, bacterial infections rather provide an unspecific immunostimulatory effect, in which the transient expansion of autoreactive lymphocyte clones is a bystander effect. Bacterial components also stimulate intrarenal immune cells and renal cells resulting in a transient aggravation of kidney injury. UV light causes keratinocyte death [169]. In case of a significant clearance defect, this process increases extracellular nuclear material and exposure of autoantigens and autoadjuvants to antigen-presenting cells [141]. Some drugs trigger drug-induced systemic lupus erythematosus by inhibiting methyltransferases, which unmasks endogenous nucleic acids for more potent activation of TLR7 and TLR9 [170,171].

40.8 Pathomechanisms of Lupus Nephritis Operating Inside the Kidney

Immune Complex Glomerulonephitis. The polyclonal autoantibody response in systemic lupus erythematosus accounts for the diagnostic hallmark of lupus nephritis, that is, the so-called "full house pattern" of IgM, IgA, and IgG deposits

inside the kidney's glomeruli [172]. However, antibody-deficient mice still develop lupus nephritis; hence, B cells are important for the disease pathogenesis beyond antibody secretion [173]. For example, B cells are important antigen-presenting cells that present autoantigens to autoreactive T cells and induce their clonal expansion [164]. Immune complexes can deposit in different compartments of the glomerulus, that is, the mesangium, the subendothelial, and the subepithelial space. In addition, they deposit along peritubular capillaries [174]. The histopathological classification of lupus nephritits acknowledges these distribution patterns; for example, immune complex formation in the mesangium is defined as class I and II, subendothelial immune complex formation as class III and IV, and subepithelial immune complexes as class V [175]. Initially, it was thought that circulating immune complexes passively deposit in the kidney, but this concept was disproved [176,177]. Glomerular immune complexes rather form *in situ* by binding to nuclear particles derived from glomerular cells [178]. Chromatin released from neutrophils undergoing neutrophil extracellular trap formation may be another source of intrarenal lupus autoantigens [146–151]. Heparin enhances DNA-I-dependent chromatin degradation and prevents chromatin binding to the GBM [179]. However, how do immune complexes cause glomerular injury? DNA antibodies can activate glomerular cells via different mechanisms. For example, DNA antibodies bind antigen also inside renal cells [177]. This process may involve cross-reactivity with α-actinin or annexin II on mesangial cells [180,181], but the role of this procs remains under debate [182,183]. Immune complex deposits also activate complement [172] demonstrating the dual role of complement in lupus nephritis [184]. On the one hand, complement deficiency impairs opsonization and removal of lupus autoantigens from the extracellular space; on the other hand, complement promotes immune complex-related inflammation inside the kidneys [185,186]. Immune complexes also activate glomerular cells via FcR receptors although data in this domain remains complex [187].

Toll-like Receptor Activation and IFN Signaling Inside the Kidney. Lupus immune complexes contain a nucleic acid component that activates not only TLRs in intrarenal macrophages and dendritic cells but also endothelial cells and mesangial cells to produce large amounts of proinflammatory cytokines and interferon-α and -β [188–195]. This intrarenal IFN signaling may contribute to lupus nephritis activity and triggers the formation of tubuloreticular structures or inclusions (TRI), that is, ultrastructural characteristic of IFN signaling [192,196]. Together, the activation of TLRs, complement receptors, and FcR activates renal cells to release proinflammatory mediators that further promote inflammation and cell injury inside the kidney [197,198].

Chemokines Recruit Leukocytes to the Kidney. All sorts of different leukocyte subsets infiltrate the kidney in lupus nephritis [199]. The different members of the chemokine family specifically recruit these different leukocyte subsets via distinct chemokine receptors and different chemokines direct leukocytes to different renal compartments [200]. For example, CCL2 recruits CCR2+ macrophages and T cells into both the glomerulus and the tubulointerstitium [201,202]. In contrast, CCR1+ cells only recruit to the interstitium and not to the glomerulus [203]. In addition to chemokines, renal cells secrete pentraxin-3, which inhibits leukocyte

recruitment by masking P-selectin on the luminal surface of activated endothelial cells [204–206]. In chronic forms of lupus nephritis, leukocytes can form perivascular tertiary lymphoid follicles inside the kidney, where clonal expansion and ongoing somatic hypermutation of B cells occurs in proximity to T cells, which contributes to local inflammation and tissue pathology [112,164,207–209]. These findings have encouraged physicians to test B-cell-targeted therapies in lupus nephritis [210,211]. Also, infiltrating T cells contribute to lupus nephritis, for example, CD3+/CD4+ or CD3+CD4/8 double-negative T cells that produce IL-17 [212]. Among the different macrophages phenotypes F4/80(hi)/CD11c(int) Gr1(lo)/Ly6C(lo)/VLA4(lo)/MHCII(hi)/CD43(lo)/CD62L(lo) macrophages were found to drive renal inflammation in lupus nephritis [90,213].

Aberrant Tissue Repair. Kidney injury triggers healing, which by itself can cause kidney dysfunction. Focal necrosis of the glomerular capillary loops induces an invasion of parietal epithelial cells that produce extracellular matrix and form focal scarring, referred to as "focal-segmental glomerulosclerosis." This process often progresses to global glomerulosclerosis and loss of function [214]. In addition, activated parietal epithelial cells can undergo hyperplasia and completely obstruct the urinary outfow [215,216]. This process can be triggered by GBM breaks that allow plasma leakage into Bowman's space, where mitogenic plasma components such as fibrinogen trigger parietal epithelial cell hyperplasia [217]. Subsequently, the parietal epithelial cells lose their polarity and produce matrix all around them, also leading to irreversible glomerular scarring, referred to as class VI lupus nephritis.

40.9 Summary

Autoimmunity is a form of sterile inflammation. In contrast to autoinflammation and alloimmunity, autoimmunity is driven by a spontaneous loss-of-tolerance against self-proteins and other structures of the self. The susceptibility to loss-of-tolerance is genetically determined by gene variants that break or weaken the checkpoints that ensure self-tolerance in the immune system. Infections often trigger loss-of-tolerance in susceptible patients, which then leads to autovaccination resulting in life-long persistence of immune memory. Therefore, cure of autoimmune disease is hardly possible unless immune memory that is laid down in long-lived plasma cells in bone marrow niches is eradicated. As such, therapy of autoimmune diseases focuses largely on the control of autoimmune tissue injury and tissue inflammation. Nevertheless, the driving force of autoimmune tissue injury is underlying autoimmune mechanisms taking place in lymphoid organs. MHC class II-mediated autoantigen presentation is at the heart of the pathogenesis and the critical interaction between antigen-presenting cells and autoreactive lymphocytes. Clonal expansion of the autoreactive lymphocyte clones leads to humoral and cellular immune responses. Immune complex disease, infiltration of autoantigen-specific T cells, and tertiary lymphoid organ formation all contribute to autoimmune tissue injury, inflammation, atrophy, and subsequently organ dysfunction. Interfering with the systemic and local pathomechanisms of autoimmune disease is the current strategy for induction of response,

maintaining a sufficient suppression of disease activity, and preventing relapse of a disease.

Psoriasis and Other Skin Inflammatory Diseases

Jaehwan Kim and James G. Krueger

The Rockefeller University, Laboratory for Investigative Dermatology, New York, NY 10065, USA

41.1 Introduction

Psoriasis vulgaris is a common inflammatory skin disease affecting 2–4% of the world population. As such, it has become one of the best understood T-cell-mediated disease for testing novel immune target treatments in humans. Since psoriasis immunopathogenesis represents amplifications of innate and adaptive immune systems in normal human skin, our understanding of psoriasis is now facilitating development of new treatments in other inflammatory skin diseases, such as atopic dermatitis and alopecia areata.

41.2 Normal Skin

41.2.1 Skin Structure and Its Function as an Immune Organ

Skin is composed of two layers, epidermis and dermis, which are distinct in architecture, but functionally interdependent. Epidermis is composed primarily of keratinocytes (>90%), with minority populations of Langerhans cells, melanocytes, and neuroendocrine (Merkel) cells [1]. The epidermal layer has downward invaginations termed rete ridges between dermal papillae, which form a honeycomb of interconnected ridges in three-dimensional structure. Dermis is a connective tissue composed of an extracellular matrix containing inflammatory cells such as T cells, dermal dendritic cells, macrophages, and mast cells. Among cellular components of skin, T cells, dendritic cells, and keratinocytes play key roles in skin function as an immune organ.

Healthy skin has the capacity to recruit recirculating T cells and also contains abundant resident T cells as a skin-associated lymphoid tissue (SALT) [2]. Skin-homing T cells are cutaneous lymphocyte antigen $(CLA)^+$ T cells, as they bind to dermal venules of the skin by interaction between CLA on the T cells and E-selectin on the endothelial cells [3]. Approximately 10% of T cells in the

Inflammation: From Molecular and Cellular Mechanisms to the Clinic, First Edition.

peripheral circulation of adults become differentiated for skin homing immunity through expression of CLA [4]. Beside those CLA^+ recirculating T cells, normal human skin also contains long-lived nonrecirculating resident memory T cells (T_{RM}) that persist in the absence of antigens and provide rapid on-site immune protection in the skin [5–7].

Dendritic cells play central roles in skin inflammation by taking up and processing antigens, activating antigen-specific T cells, and producing amplifying cytokines. The main dendritic cell populations in the skin are Langerhans cells in epidermis and myeloid dendritic cells and plasmacytoid dendritic cells in dermis. CD1a and langerin (CD207) are used as specific markers to distinguish Langerhans cells from other dendritic cell subsets, and the α_x integrin CD11c has been found to be the correct marker of dermal myeloid dendritic cells. Plasmacytoid dendritic cells are rare cell populations that can mount rapid and robust type 1 interferon (IFN) responses to viral/microbial infections [8,9].

Keratinocytes not only function as a barrier but also orchestrate innate and adaptive immune responses [4]. The outmost layer of epidermis (cornified layer) creates a physical barrier to inward bacterial penetration and outward water loss by a cross-linked protein membrane structure between which many layers of neutral lipids are deposited. Keratinocytes in granular layer, which is underneath the cornified layer, produce innate effector molecules such as antimicrobial peptides (AMPs), including cathelicidin LL37, defensins, and S100 proteins. Keratinocytes also participate in adaptive immune responses by directing migration of T-cell subsets into the skin through constitutive production of CCL27 (CTACK) and inducible production of chemokines such as CXCL9 and CCL20 [4,10].

41.2.2 Skin Response to Inflammation by Polarized T-Helper Cell Subsets

Keratinocytes in epidermis are highly responsive to cytokines made by polarized T-helper cell subsets, and the patterns of T-helper cell polarization determine characteristics of inflammatory skin diseases. For example, both psoriasis and atopic dermatitis are chronic inflammatory conditions with large infiltrates of T cells, but different T-helper cell polarization determines distinct clinical and histologic characteristics between psoriasis and atopic dermatitis: T_H17 polarization is predominant in psoriasis, while T_H2 polarization is predominant in atopic dermatitis [11]. Both diseases have T_H22 activation and T_H1 activation. Table 41.1 summarizes T-helper cell subsets with their main effector cytokines and functions in skin inflammation [12].

41.3 Psoriasis

41.3.1 Clinical, Histological, and Molecular Features of Psoriasis

Clinically, psoriasis vulgaris begins as a pinhead-sized papule on the skin that vertically grows to become raised, red, and scaly plaque, and radially expands to peripheral body surface area in progression to severe cutaneous disease

Table 41.1 Function of T-helper subtypes in skin inflammation.

T-helper Cell Subset	Effector Cytokines	Functions in Skin Inflammation
T_H1	IFN-γ	Induces hundreds of genes for innate and antiviral molecules in keratinocytes
T_H17	IL-17A	Highly induces antimicrobial peptides and psoriasin (S100A7)
	IL-17 F	Induces chemokine-recruiting neutrophils, dendritic cells, and T cells
T_H22	IL-22	Induces epidermal hyperplasia and inhibits terminal differentiation Induces S100A7, S100A8, and S100A9 (synergy with IL-17)
T_H2	IL-4	Inhibits epidermal cornification, but does not induce epidermal hyperplasia
	IL-5	Inhibits some AMPs, for example, human beta defensin 2 and 3
	IL-13	Involved in allergic responses and IgE switching

(Figure 41.1a). Psoriasis lesions are usually located on elbows, knees, scalp, and lumbosacral area, but it can be more extensive. Severe psoriasis is frequently associated with systemic inflammation and comorbidities, such as psoriatic arthritis, cardiovascular disease, diabetes, and depression [13–19]. About 80%

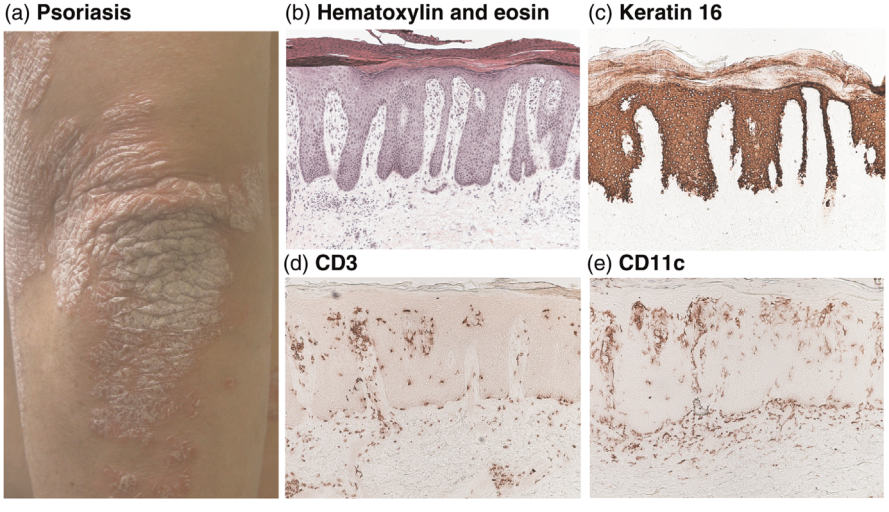

Figure 41.1 Clinical and histological features of psoriasis. (a) Psoriasis skin: raised, red, and scaly patches on the outside of elbow. (b) Histology of psoriasis skin biopsy with hematoxylin and eosin (H&E) stain: thickening of epidermis (acanthosis) with elongated downward projections (rete ridges). Thickening of stratum corneum (hyperkeratosis) with retention of nuclei (parakeratosis). (c) Keratin 16 stain: keratinocyte hyperproliferation of epidermis. (d) CD3 stain: $CD3^+$ T cell accumulation in epidermis and dermis. (e) CD11c stain: $CD11c^+$ myeloid dendritic cell accumulation in epidermis and dermis (all images 10× magnification).

of people with psoriasis have psoriasis vulgaris, but there are variant types of psoriasis – *small plaque psoriasis* in the Asian population, *guttate psoriasis* in childhood or young adulthood, *inverse psoriasis* in body folds, *pustular psoriasis* with white pustules surrounded by red skin, and *erythrodermic psoriasis* that leads to widespread redness over the whole body surface area.

Histologically, psoriatic plaque is caused by epidermal thickening (acanthosis) (Figure 41.1b), which represents keratinocyte hyperproliferation (Figure 41.1c). Keratinocytes in psoriatic plaques move through the epidermis over 4–5 days, a 10-fold acceleration over normal skin [20]. Because the normal process of differentiation cannot occur, there is a loss of the normal granular layer, thickened stratum corneum (hyperkeratosis), and retention of nuclei in the upper layers and stratum corneum (parakeratosis). There are often neutrophils collected in the epidermis and stratum corneum (spongiform pustule of Kogoj and Munro microabscess). In the dermis, abundant mononuclear cells, predominantly myeloid dendritic cells and T cells, are accumulated (Figure 41.1d and e).

Molecular changes in psoriasis skin are characterized by the immunologic interplays between T cells, dendritic cells, keratinocytes, and other inflammatory cells, which result in the production of psoriatic cytokines. Collectively, central IL-23/T_H17 pathway initiates immune response, and then polarized T-helper cell subsets (T_H17 cells, T_H1 cells, and T_H22 cells) amplify immune reactions (Figure 41.2). The cytokines IL-17, IFN-γ, and IL-22 from each T-helper cell subsets cause keratinocyte proliferation while producing cytokines, chemokines, and antimicrobial peptides [21–27]. This becomes a self-amplifying loop, where these products act back on the dendritic cells, T cells, and other inflammatory cells to perpetuate the cutaneous inflammatory process [4].

41.3.2 Cellular Players of Psoriasis Skin Inflammation

41.3.2.1 T Cells in Psoriasis Skin

Psoriasis lesions contain increased numbers of $CD3^+$ T cells (Figure 41.1d), and $CD4^+$ polarized T-helper cell subsets discretely produce IL-17, IFN-γ, and IL-22, with labeling of these cells as T_H17, T_H1, and T_H22, respectively (Figure 41.2) [4,28]. However, not only $CD4^+$ T-helper cell subsets but also other cell populations can produce IL-17. There are $CD8^+$ T cell populations that make the same range of cytokines (Tc17, Tc1, and Tc22). Innate lymphoid cells, which are immune cells that lack a specific antigen receptor yet can produce an array of effector cytokines, may be present in the skin and are potential source of IL-17 in psoriasis [29,30]. It was assumed that lesional IL-17-producing T cells expressed the αβ T-cell receptor only, but recent studies characterized many IL-17-producing T cells in human and murine psoriasis skin as γδ T cells [31].

Regulatory T cells (Tregs) are a heterogeneous group of cells that maintain antigen-specific self-tolerance and are one immune mechanism to prevent tissue damage due to inflammation [4]. When the above effector T cells are not being held in check by Tregs, unstrained effector T-cell effects lead to autoimmunity [32]. Some studies have shown Tregs to be dysfunctional in psoriasis suggesting that psoriasis may result from the inability to suppress autoinflammation [33,34]. The

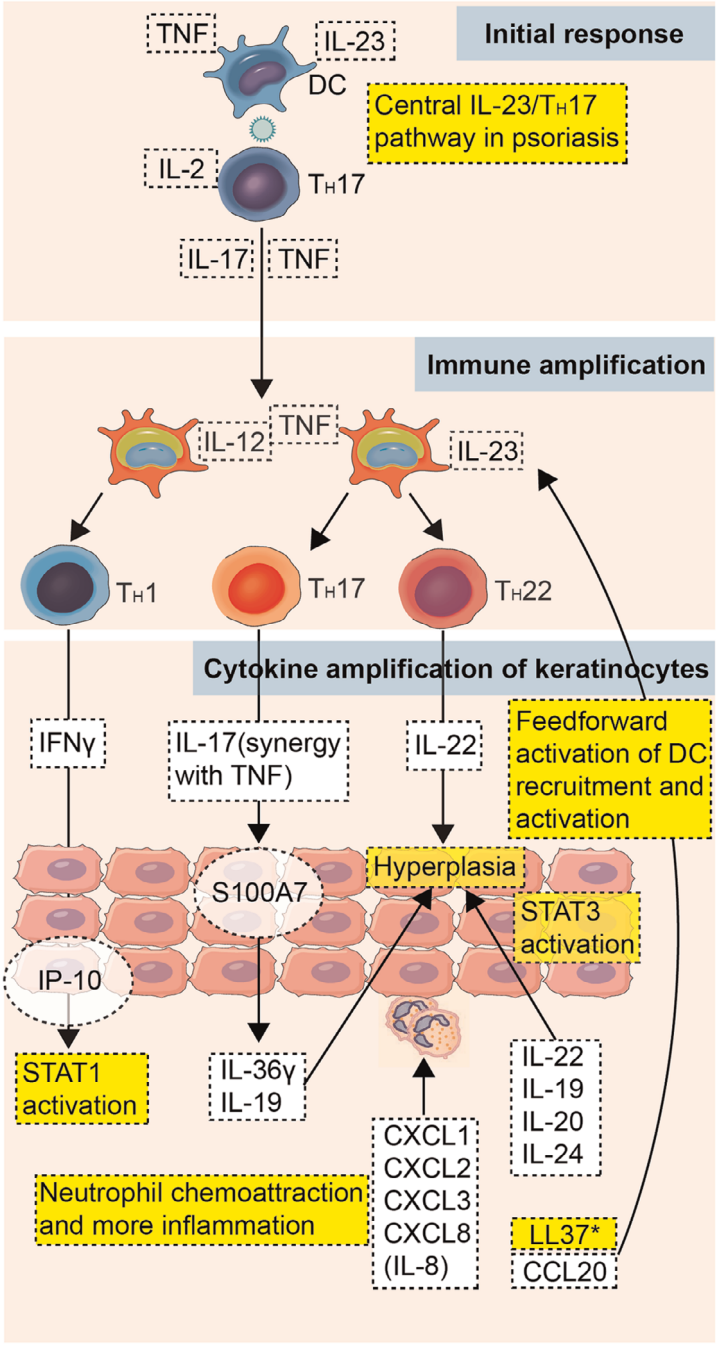

Figure 41.2 Psoriasis skin inflammation. Psoriasis immune pathways with cellular players and key cytokines in three different stages of skin inflammation: (1) initial response, (2) immune amplification, and (3) cytokine amplification of keratinocytes. As the immune circuits consist of a self-amplifying loop, psoriasis becomes an autoimmune skin disease. ∗LL37 is a possible autoantigen of psoriasis.

suppressor activity of $CD4^+$ $CD25^{high}$ Tregs was deficient in psoriasis patients' skin and blood in association with accelerated proliferation of $CD4^+$ responder T cells [35]. Also, $CD4^+$ $CD25^+$ $FoxP3^+$ Tregs versus activated effector T cell ratio in progressive psoriatic skin was much lower than the ratio in normal human skin [36,37]. The reduced ratio in blood was associated with the severity and progressive course of psoriasis. However, further studies are needed to elucidate contribution of Tregs to psoriasis.

41.3.2.2 Dendritic Cells Interplaying with T Cells

Dendritic cells may play central pathogenic roles in psoriasis, both by activating T cells and by producing amplifying cytokines and chemokines during inflammation (Figure 41.2) [38]. There are two main subgroups of myeloid dendritic cells in psoriasis: blood dendritic cell antigen (BDCA)-1/$CD1c^+$ "resident" dendritic cells and BDCA-1/$CD1c^-$ "inflammatory" dendritic cells [39]. Inflammatory dendritic cells include "tumor necrosis factor (TNF) and inducible nitric oxide synthase-producing dendritic cells" or Tip-DCs, and produce IL-12p40, IL-23p19, and IL-20 [40,41].

Both resident and inflammatory dendritic cells stimulate T cells robustly in an allogeneic mixed lymphocyte reaction and similarly induce allogeneic T cells to produce IFN-γ and IL-17 [42]. However, while there is a 30-fold increase in myeloid dendritic cells in the dermis of psoriatic skin lesions compared to uninvolved psoriatic or normal skin [43], this increase is in inflammatory dendritic cells, not resident dendritic cells [44]. In addition, effective treatment of psoriasis was correlated with decreased numbers of inflammatory dendritic cells in psoriasis lesions [45]. Myeloid cells expressing 6-sulfo-LacNAc (slan) have been proposed to be inflammatory dendritic cell precursors in psoriasis, driving strong T_H17 and T_H1 responses [46].

Plasmacytoid dendritic cells have been studied as important upstream initiators of psoriasis development. Plasmacytoid dendritic cell-derived IFN-α may stimulate the activation and amplification of pathogenic T cells through the induction of myeloid dendritic cell activation/maturation [9]. In addition, psoriasis exacerbation reaction by TNF antagonist has been explained by unopposed IFN-α production by plasmacytoid dendritic cells in genetically predisposed individuals [47].

The role of Langerhans cells in psoriasis immunopathogenesis is still unclear, but recent attention has focused on the potential importance of Langerhans cells in uninvolved skin sites of psoriasis patients. It has been demonstrated that Langerhans cell migration is impaired in early-onset psoriasis, and treatment with biologics significantly restored epidermal Langerhans cell migration in uninvolved skin [48–50].

41.3.2.3 Keratinocytes Triggering Innate and Adaptive Immune Responses

In response to stimulation, keratinocytes trigger innate and adaptive immune responses by producing cytokines, such as TNF or the chemokine CCL20, and effector molecules, such as antimicrobial peptide LL37 (Figure 41.2). CCL20 functions to recruit both myeloid dendritic cells and T_H17 cells into active

psoriasis skin [4,51,52]. CCR6, a receptor for CCL20, is expressed in T cells and almost all the mature dermal myeloid dendritic cells in the dermal aggregates [53]. CCL20/CCR6 chemokine system may be crucial in self-maintaining the interaction between lesional mature dendritic cells and T cells where T cells are effectively activated *in situ*.

LL37 has a dual role: (1) nucleic acid-mediated maturation of dendritic cells and (2) possibly a T-cell autoantigen [54]. For dendritic cell maturation, LL37 can bind self-DNA and LL37/DNA complexes activate plasmacytoid dendritic cells by binding to intracellular Toll-like receptor (TLR) 9 [55–57]. LL37 also binds self-RNA, and LL37/RNA complexes activate plasmacytoid dendritic cells through TLR7. Activated plasmacytoid dendritic cells initiate psoriasis development by producing IFN-α, which activates myeloid dendritic cells. LL37/RNA complexes can directly activate myeloid dendritic cells through TLR8. In addition, LL37 is recognized as an autoantigen by circulating T cells in 46% of psoriasis patients and up to 75% of patients with moderate to severe psoriasis [54]. LL-37-specific T cells produce pathogenic cytokines, including IL-17, and can be tracked in patient blood by tetramer staining.

41.3.2.4 Neutrophils in Psoriasis

Neutrophils are a first line of defense against an immune attack, possessing many intracellular antimicrobial peptides. In psoriatic skin, neutrophils are predominantly located in the epidermis, and there are abundant neutrophil chemokines, such as CXCL1, CXCL2, CXCL3, and CXCL8/IL-8 (Figure 41.2). In addition, neutrophils express IL-17, suggesting another potential role in psoriasis [58]. However, neutrophils are inconsistently found in chronic psoriasis lesions and are absent from some mouse models of psoriasis [4].

41.3.3 Key Inflammatory Molecules for Targeted Psoriasis Treatment

41.3.3.1 IL-12p40

In the past, T_H1 axis (IL-12 and IFN-γ) was considered to be the dominant pathogenic model for psoriasis [59]. T_H1 cells, producing IFN-γ, are abundant in psoriasis lesions and blood, and approximately 400 of the genes upregulated in psoriasis lesions can be traced to signal transducer and activator of transcription (STAT)1 activation, a key IFN-γ transcription factor [60] (Figure 41.2). Because IL-12, a heterodimer of p35 and p40, drives T_H1 polarization, an antibody against IL-12p40 (ustekinumab) was created to target IL-12 and inhibit T_H1 cells. This therapy proved immensely effective, as 70–80% of patients attained a 75% reduction in the Psoriasis Area and Severity Index (PASI) score (PASI75) within 24 weeks. The improvement was initially considered to validate the pathogenic role of the IL-12/T_H1 axis in patients with psoriasis [61]. However, the paradigm changed with the discovery of T_H17 cells, which is regulated by IL-23 [62,63]. IL-23 is composed of two subunits, p19 and p40 (shared with IL-12), and it became apparent that ustekinumab could be targeting either IL-12 or IL-23 in patients with psoriasis [64].

41.3.3.2 IL-23/T_H17

Selective antagonists to IFN-γ, IL-23, IL-17, and IL-22 were used to dissect contributions of polarized T-cell subsets (T_H1, T_H17, and T_H22 cells) to psoriasis immunopathogenesis [64]. Studies have shown that blockade of IL-17A (secukinumab and ixekizumab), IL-17 receptor A subunit (brodalumab), or IL-23p19 (guselkumab and BI 655066) can improve psoriasis (PASI75 response) in more than 80% of patients [65–69]. In contrast, IFN-γ and IL-22 have lesser pathogenic roles, given that single antagonism of these cytokines with neutralizing antibodies did not induce high-grade improvements in the majority of patients [70]. Therefore, the predominant pathogenic axis in psoriasis is IL-23/T_H17. IL-17 induces IL-19 and IL- 36γ in psoriasis lesions, which lead to epidermal hyperplasia [4] (Figure 41.2).

41.3.3.3 TNF-α

TNF-α can be produced by many cell types including keratinocytes, T cells, and dendritic cells [38,41,71]. There are synergistic effects between IL-17 and TNF, as a combination of the two cytokines induces greater changes in gene expression than either alone [27,72]. Role of TNF-α in psoriasis has been evaluated in clinical trials of TNF-α inhibitors (etanercept, infliximab, and adalimumab), and a key effect of TNF-α is thought to be regulation of antigen presenting cells, impairing dendritic cell and T-cell interactions [73,74]. As TNF-α activates IL-23 synthesis in dendritic cells, TNF-α blockade is linked to suppression of the IL-23/T_H17 axis [75] (Figure 41.2). TNF-α inhibitors are also highly effective in reducing skin inflammation as well as joint inflammation in patients with psoriatic arthritis.

41.4 Other Inflammatory Skin Diseases

41.4.1 Atopic Dermatitis

Atopic dermatitis is clinically different from psoriasis (Table 41.2) and mediated by different subsets (T_H2 in atopic dermatitis versus T_H17 in psoriasis). However, other T-cell subsets (T_H22, T_H17, and T_H1 cells) also contribute to atopic dermatitis, and there are many histologic similarities in chronic stages of atopic dermatitis and psoriasis, such as increased epidermal hyperplasia and large numbers of T cell and dendritic cell infiltrations [11,76]. Considering those commonalities, immune-based strategies that correct epidermal defects in psoriasis may be also effective in atopic dermatitis.

To control T_H2 cell-mediated inflammation in atopic dermatitis, monoclonal antibody to IL-4RA (dupilumab) has been studied as a potential therapy [77]. IL-4 and IL-13 are key effector cytokines of T_H2 cells and IL-4RA is a common receptor of those cytokines. Therefore, dual antagonism of IL-4 and IL-13 with dupilumab potently inhibits T_H2 effector responses [77]. Dupilumab also potentially blocks IL-17, because IL-4 is a key regulator of T_H17 activity in atopic dermatitis skin [77]. In early-phase studies, patients with dupilumab had a marked and rapid improvement in all the evaluated measures of atopic dermatitis disease activity, and side-effects profiles were not dose limiting [78].

Table 41.2 Clinical differences between atopic dermatitis and psoriasis [11].

	Atopic Dermatitis	Psoriasis
Onset	85% before age 5 year old	Adolescence or early adulthood
Asthma/atopy	Commonly associated	Not associated
Wet/dry skin	Oozing, wet skin with crusting and exudate	Dry skin
Demarcation	Not well demarcated from uninvolved skin	Sharply demarcated
Flexor/extensor	Flexors usually affected	Extensors usually affected
Scale	Fine white scales	Thick, silvery-white scales
Itching	Prominent	Rare
Impetigo	Frequent	Not evident
Viral dissemination	Common	No risk

41.4.2 Alopecia Areata

Alopecia areata presents as patchy, nonscarring hair loss, and approximately 10% of patients progress to alopecia totalis or even whole body hair loss (alopecia universalis) [79]. Alopecia areata is a T-cell-mediated inflammatory disease, but molecular profiles of cytokine pathways have not been fully elucidated [80]. We recently performed microarray and RT-PCR profiling of lesional and nonlesional scalp samples from alopecia areata patients and established alopecia areata transcriptomes: T_H1 axis (IFN-γ, CXCL10/CXCL9), T_H2 axis (IL-13, CCL18, CCL26, TSLP, and periostin/POSTN), T_H9/IL-9, IL-23 (p40 and p19), and IL-16 mediators were upregulated, while there were no increases in T_H17 and T_H22 axis. Those data suggests consideration of anti-T_H2, T_H1, and IL-23 targeting strategies for alopecia areata treatment. Similar to psoriasis and atopic dermatitis, clinical trials with selective antagonists are required to dissect key pathogenic pathways in alopecia areata.

41.5 Summary

Clinical and translational research in human subjects has enabled a better understanding of the skin inflammation in psoriasis, and subsequently the development of novel immune-targeted therapeutics [81]. The translational research strategies have been successfully applied to other inflammatory skin diseases, such as atopic dermatitis and alopecia, to discover potential therapeutic targets. However, many basic questions about skin inflammation remain to be answered. Further studies must confirm safety of long-term cytokine antagonism and elucidate tolerance mechanisms. Ultimately, immune signatures of various

skin inflammatory diseases could be characterized to accomplish personalized immune-targeted treatments of individual patients.

42.1 Inflammatory Articular Diseases

Inflammatory articular diseases encompass a spectrum of conditions that range from acute forms of septic or sterile arthritis to chronic, often polyarticular conditions. They may involve inflammation of synovial tissue of joints and other tissues, such as muscles and tendons, mucosal and epithelial tissues, and organs. With regard to etiology, the inciting inflammatory stimulus has been defined in some conditions, for instance, in septic arthritis (bacteria) and gout (uric acid crystals), while in others the etiopathogenesis is incompletely understood, for example, in spondyloarthritis (SpA) and rheumatoid arthritis (RA). The acute onset of some conditions suggests predominant involvement of innate immunity and autoinflammation, such as in gout and arthritis in adult-onset Still's disease. In other conditions, an often slower onset and the presence of autoantibodies suggest a more dominant role for adaptive and autoimmunity, like in RA and systemic lupus erythematosus. In a third group of conditions, the spondyloarthritides, an intermediate onset, absence of autoantibodies and alterations in microbiota, suggest that a combination of innate and adaptive immune responses is involved. Thus, a wide range of inflammatory cells and mediators is involved in different inflammatory rheumatic diseases.

Another layer of complexity is added by the fact that there is large variability in etiology and pathogenesis within the group of autoimmune arthritides. Furthermore, most of these conditions represent syndromes classified based on signs and

symptoms rather than pathogenetic entities. In spite of these limitations, research in the past decades has revealed a number of key immunologic mechanisms that drive inflammation in the different patient groups. Here, we will focus on the two most prevalent forms of chronic immune-mediated inflammatory disease of the musculoskeletal system: RA and SpA.

42.2 Rheumatoid Arthritis

42.2.1 Clinical Phenotype

RA is a chronic, systemic inflammatory disorder affecting synovial tissue in multiple joints [1]. The clinical presentation typically manifests itself as symmetric polyarthritis of the small joints of hand and feet, but any joint can be involved. Patients present with tenderness, swelling, and impaired movement of their joints. If untreated, the disease leads to damage of cartilage and bone, resulting in functional impairment. Extra-articular manifestations can also be observed, such as subcutaneous or pulmonary nodules, pleuritis, periodontitis, vasculitis, and interstitial pneumonitis [2,3]. In some patients, there are overlapping features with other immune-mediated inflammatory rheumatic diseases, such as Sjögren's syndrome and systemic lupus erythematosus. Over the past decades, treatment has markedly improved, because of the development of targeted therapies, a more aggressive, early treatment approach, and the introduction of the treat to target principle (aiming for disease remission) [4]. It should be noted however that there is still a big unmet need, as a significant proportion of patients do not achieve disease remission in spite of currently available treatments. Chronic use of immunosuppressive treatment is also associated with side effects. Therefore, development of new treatments, individualized health care, and innovation in treatment algorithms aiming for disease remission, cure, and prevention of the disease should define the research agenda for the next decade [5,6].

42.2.2 Etiology

RA may develop over years by interplay of genetic, environmental, and stochastic factors. Twin studies estimated the relative genetic contribution to RA to be around 60% [7]. Since 2007, genome-wide association studies have allowed the identification of >100 genetic risk factors for RA [8]. The largest genetic risk factor lies within the human leukocyte antigen (HLA) class 2 region and encodes the HLA-DRB1 molecule [9]. The alleles within HLA-DRB1 that are associated with RA encode amino acids that are part of the antigen-binding groove of the major histocompatibility complex (MHC) class 2 protein and are referred to as "the shared epitope." It is thought that these alleles enhance binding of specific antigens to MHC class 2 or the T-cell receptor and thereby lower the threshold of activation of specific T-cell clones [10]. The second largest genetic risk factor lies within the protein phosphatase nonreceptor 22 (PTPN22) gene [11]. It encodes lymphoid tyrosine phosphatase that negatively regulates downstream signaling from the T-cell receptor. Mutations within *PTPN22* confer risk or protection to multiple autoimmune diseases [12,13]. The majority of other candidate genes are

part of major, predominantly T-helper and B-cell associated, immunological signaling pathways, and include *CD40*, *CTLA4*, *CD28*, *TRAF6*, and the autoimmune regulator (*AIRE*) as well as genes involved in NF-κB signaling [13–15]. Interestingly, a number of these genes overlap with other autoimmune diseases [13,16,17]; they confer small effect sizes. A substantial proportion of genetic risk remains unexplained, suggesting that epigenetic inheritance of gene–environment or gene–gene interaction plays a role in RA development [18].

Besides the patient-related factors, female sex, and age, several environmental risk factors have also been associated with RA. The best established environmental factor for RA is cigarette smoking. An association has been found between ever smoking, the number of pack years, and RA [19,20]. Furthermore, obesity, parity, and diabetes mellitus have been associated with RA, while alcohol consumption and breastfeeding were associated with lower risk in some cohorts [19–23]. We have recently established in a prospective study that smoking and overweight increase the risk of development of arthritis in a cohort of autoantibody-positive individuals at risk for developing RA [19,24]. Several studies have shown a strong interaction between smoking and the development of anticitrullinated antibodies (ACPA) in shared epitope-positive subjects [20,25]. These autoantibodies may develop in response to inflammation at sites other than the synovium in genetically susceptible subjects, in particular in the lung and periodontium, while alterations in the gut microbiome may also play a role [26–30].

Current research focuses on the interaction between genes and environmental factors in different phases of the disease. Increasing evidence indicates that RA may start years before the onset of clinical arthritis, with a central role for autoreactive T and B cells. Autoantibody-positive RA is characterized by the presence of rheumatoid factor (RF), anticitrullinated peptide antibodies (ACPA), and other autoantibodies; they are found in around 70–80% of RA patients [31]. The earliest identified autoantibodies were termed RF and react with epitopes on the constant domain of immunoglobulin G [32]. Later, a number of other, less prevalent autoantibodies were defined, such as against glycoprotein 39, glucose-6-phosphate isomerase, and collagen type 2 and more recently against peptides that have been posttranslationally modified by carbamylation and acetylation [33–36]. A major breakthrough was the discovery of ACPA that recognizes epitopes of proteins that are posttranslationally modified by citrullination [37]. Citrullination is a physiological process that among others occurs in the context of inflammation. ACPA are directed against a number of epitopes, such as citrullinated fibrinogen, vimentin, enolase, and histones [38]. These have not yet been fully characterized and differ between patients. ACPA are highly specific for RA and are found in 50% of patients with early disease and 70–80% of patients with late disease [31,39]. Both RF and ACPA predict disease severity and radiological damage [39,40]. Studies in ACPA-positive versus ACPA-negative subjects suggest that these are distinct pathophysiological disease subsets. Specific polymorphisms in HLA-DRB1 have been associated with ACPA-positive RA and confer risk from progression of ACPA positivity to ACPA-positive RA [41]. ACPA-negative RA is also associated with HLA-DRB1, but less strongly and with only one of the four HLA-DRB1 polymorphisms that associate with ACPA-positive RA [42,43]. Also, some non-HLA genetic factors associate specifically

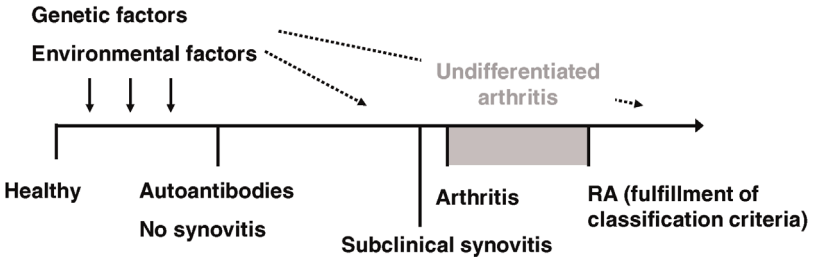

Figure 42.1 Timeline of autoantibody-positive rheumatoid arthritis (RA): the different stages of disease. Autoantibody formation may precede the development of clinical signs and symptoms of RA by several years. The presence of subclinical synovitis may probably last several weeks rather than months. (Reprinted with permission from Ref. [46].)

with ACPA-negative RA, such as CLEC16A and CLYBL. Of importance, RF and ACPA may be found years before onset of arthritis [44,45] (Figure 42.1).

In this phase, the ACPA response is not yet fully maturated. ACPA are of low avidity, have limited fine specificity, isotype distribution, and low titer up to a short interval before arthritis onset [47–50]. Their presence may concur with elevated levels of acute-phase proteins, chemokines, cytokines, and adipokines [51–53]. The recruitment of activated immune cells to the site of inflammation is generally preceded by a danger signal in a nearby lymph node followed by an immune reaction. Using ultrasound-guided core-needle biopsies of lymph nodes, we have recently demonstrated an increase in activated immune cells within lymph nodes of early arthritis patients as well as in autoantibody-positive individuals at risk for developing RA [24].

The presence of a type I interferon-activation status in peripheral blood mononuclear cells and the presence of increased numbers of T cells in peripheral lymph nodes appear associated with the development of arthritis in these individuals [24,54]). The synovial tissue of clinically and histologically uninflamed joints of patients with ACPA contain subtly increased numbers of CD8-positive T cells, most prominently in those individuals who subsequently develop arthritis after follow-up [55]. In some cohorts, smoking in subjects positive for the shared epitope is associated with ACPA positivity [56,57]. Given that smoking promotes citrullination of self-proteins, it might be directly linked to formation of ACPA in genetically susceptible subjects. Periodontitis, another possible risk factor for RA, has also been directly implicated in ACPA formation. Porphyroma gingivalis, one of the major bacteria involved in periodontitis, produces peptidyl-arginin deiminase (PAD), which mediates citrullination [58]. ACPA titers may be increased in the pulmonary and salivary secretions of some ACPA-positive individuals at risk for RA [59]. Taken together, the data suggest that autoantibody-positive RA may develop from a slow maturation of an aberrant autoimmune response in, for example, the lung through a second hit in the synovium, for instance, a viral infection or a trauma leading to citrullination in the joint, to autonomous disease progression in the joints [46]. Variation in the microbiome present in the gut has also been linked to RA, but clearly more research on individuals at risk of developing RA needs to be performed in a prospective manner to understand the importance of the relationship between the gut microbiome and the development

of RA [30]. Finally, recent research suggests that vagus nerve tone may modulate the immune response; reduced activity of the parasympathetic system is a predictor of arthritis onset in individuals at risk of developing RA [60].

42.2.3 Inflammatory Cells and Mediators Driving RA

Arthritis is the dominant clinical feature of RA, and is caused by inflammation of the synovial tissue that forms the inner layer of the joint capsule. The main function of the synovium is to provide nutrients to avascular structures such as the cartilage that lines the joint [61,62]. On a microscopic level synovial tissue consists of a number of cellular layers: the outermost layer is termed the intimal lining layer. It comprises one to three cell layers without a basal membrane. It consists of intimal macrophages and fibroblast-like synoviocytes (FLS). The synovial sublining consists of connective tissue with scattered FLS and contains relatively few cells and blood vessels. In patients with RA, the synovial tissue has become hypertrophic and is infiltrated with inflammatory cells. In the intimal lining layer, the number of intimal macrophages and FLS is increased. In the synovial sublining, FLS have proliferated and the amount of connective tissue is increased. Furthermore, it is infiltrated by variable numbers of T cells, plasma cells, macrophages, B cells, neutrophils, mast cells, natural killer cells, and dendritic cells [61–63]. This results in the formation of villous projections of synovial tissue into the joint space and overgrowth and invasion of synovial tissue at the junction with cartilage and bone. Proliferating synovial tissue in RA is referred to as pannus. The inflammatory response in RA involves both the innate and the adaptive immune system. Importantly, innate immunity and adaptive immunity are not two segregated systems, but these systems are largely intertwined and there is regulated cross-talk.

42.2.3.1 Innate Immunity and Stromal Cells

In RA, yet unknown factors activate innate immunity, thereby providing an adjuvant signal for the induction of adaptive immune responses that result in a breakdown of tolerance. The innate immune system involves many different cell types. In this section, we will discuss the most important players and their relative contribution to the inflammatory process in RA.

42.2.3.2 Fibroblast-Like Synoviocytes

FLS are mesenchymal cells that display many features of fibroblasts, including expression of collagen and CD90. However, they also express distinct molecules such as the adhesion molecule cadherin-11 that plays an important role in the formation of a defined intimal lining layer in diarthrodial joints [64,65]. Furthermore, FLS express uridine diphosphoglucose dehydrogenase, which is important to synthesize hyaluronic acid, a constituent of synovial fluid, and secrete lubricin, another critical protein for joint lubrication [66]. RA FLS create an abnormal stromal microenvironment that is thought to be crucial for the persistence of inflammation, not only by architecture, but also by secreting proinflammatory cytokines and chemokines, and by producing growth factors that stimulate neovascularization. These cells also secrete matrix metalloproteinases (MMPs)

that contribute to tissue destruction and receptor activator of nuclear factor-κB ligand (RANKL), which promotes osteoclast differentiation. In addition, RA FLS display unique features such as an invasive, tumor-like behavior that is normally not observed in fibroblasts [67,68]. This may be in part explained by epigenetic alterations, including changes in DNA methylation, histone methylation, or acetylation, and expression of microRNAs that affect gene expression [69]. FLS are able to interact with macrophages via the CD97/CD55 receptor–ligand system that may be involved in the spatial orchestration of the synovial lining layer and may contribute to maintenance and amplification of synovial inflammation [70], most likely by facilitating the retention of activated macrophages in the synovium [71]. Genetic deletion of CD55 or CD97 and targeting of CD97 with monoclonal antibodies in collagen-induced arthritis resulted in amelioration of disease [72,73].

42.2.3.3 Monocytes and Macrophages

Macrophages are derived from myelomonocytic cells and are key players of the innate immune system. In the inflamed RA synovial tissue, large numbers of macrophages are present, contributing to inflammation, which is substantiated by the observation that the number of CD68+ synovial sublining macrophages correlates with clinical signs and symptoms [63]. Clinical improvement after treatment is consistently associated with reduced macrophage numbers in the synovium [74]. The increased number of macrophages in RA synovial tissue can be explained by increased influx of circulating monocytes that differentiate locally in the inflamed synovial tissue, reduced efflux, enhanced local survival signals, reduced apoptosis [75], and local proliferation [76,77]. Using reinfusion of technetium-99m-labeled autologous monocytes in RA patients, we have demonstrated that monocytes migrate continuously into the inflamed synovial tissue, but at a relatively slow macrophage-replacement rate [78]. Consequently, blocking migration of monocytes to the inflamed synovial tissue may not be sufficient to induce clinical improvement unless cell egress is promoted as well. Macrophages are phenotypically heterogeneous, and are not only the main producers of proinflammatory cytokines like TNF, IL-1, IL-15, IL-18, IL-23, and IL-27 that play an important role in the persistence of inflammation, but they also generate inhibitory mediators such as IL-10, TGF-β, and soluble TNF-R (reviewed in Ref. [79]). Compared to other leukocytes, macrophages are more long-lived cells that also persist in inflammatory lesions during the resolution of inflammation and may actually contribute to this process [80]. Many macrophage subpopulations have been identified, mainly based on the expression of surface markers and/or production of certain cytokines [81]. For a long time macrophages have been characterized as either M1 (also known as classically activated/proinflammatory) or M2 (also known as alternatively activated/anti-inflammatory and involved in tissue repair). However, recently it has been recognized that macrophage populations are not fixed, but display plasticity and under certain circumstances can differentiate into one another [82]. Macrophages in RA synovial tissue can express a variety of markers, including those associated with M1 and M2 populations [79]. There is substantial heterogeneity in synovial macrophage populations and increased knowledge of the individual functions of these cells

may help to improve RA therapy by selective targeting of the proinflammatory macrophage subtype while leaving cells that contribute to resolution of inflammation unaffected.

42.2.3.4 Endothelial Cells

Endothelial cells (EC) play a crucial role in the pathogenesis of RA [83]. First, they express adhesion molecules and produce chemokines, thereby acting as the site of entry for immune cells into the synovial tissue [84]. In addition, EC proliferate and give rise to neovascularization, supplying oxygen and nutrients to activated stromal cells and immune cells, which contributes to the persistence of inflammation (reviewed in Ref. [85]). RA synovium contains a significant fraction of neoangiogenic, immature blood vessels [86]. In synovial tissue-containing lymphocyte aggregates, the so-called tertiary lymphoid structures (TLS), also highly differentiated EC, can be observed in high endothelial venules (HEV) [87]; these HEV may be central to the development of these structures [88].

42.2.3.5 Innate Lymphoid Cells

Innate lymphoid cells (ILC) are the most recently identified components of the innate immune system and have deserved a lot of attention over the last few years. ILC encompass both cytotoxic NK cells and lymphoid tissue inducer (LTi) cells, as well as more recently described noncytotoxic ILC populations. ILC are characterized by classic lymphoid cell morphology, but these cells lack the expression of cell-surface molecules that identify other immune cell types. The noncytotoxic ILC consist of three distinct groups: group 1 ILC (ILC1), group 2 ILC (ILC2), and group 3 ILC (ILC3), including LTi cells. Interestingly, the functional properties of ILC mirror to some extent those of CD4+ T cell subsets (Th1, Th2, and Th17) and depend on the same intracellular transcription factors: T-bet (ILC1), GATA-3 (ILC2) and ROR-γt (ILC3) [89]. ILC subsets have been identified in various inflammatory diseases, including RA, most notably ILC3 [88], but it is still early days for these cells and full characterization of the contribution of ILC subsets to the inflammatory response in RA remains to be determined.

42.2.3.6 Neutrophils and Mast Cells

In RA, neutrophils are mainly found in the synovial fluid [90]. Neutrophils possess great cytotoxic potential due to their ability to release both degrading enzymes and reactive oxygen species. In addition, neutrophils contribute to the production of cytokines and chemokines that drive inflammation, as well as to the regulation of immune responses via cell–cell interactions [91]. The notion that neutrophils are intimately involved in the clinical expression of the disease is supported by work showing that the development of clinical signs of RA is associated with increased synthesis of the chemokine CXCL8 (interleukin-8), which is a key driver of neutrophil migration [92].

Emerging evidence suggests that neutrophils may also contribute to autoimmune responses as they can release neutrophil extracellular traps (NETs)-containing chromatin associated with granule-derived enzymes. These NETs are not only capable of killing extracellular microorganisms but they also provide a source of autoantigens. This is relevant in the context of RA as citrullinated

proteins can be generated by neutrophil peptidylarginine deiminases, which replace arginine with citrulline residues [93]. The resulting citrullinated proteins can act as neoepitopes that may lead to loss of immune tolerance. As already discussed, ACPA can be detected before the onset of symptoms in patients with RA, and they are predictive of erosive disease. Furthermore, neutrophils from patients with RA have an increased propensity to form NETs containing citrullinated proteins, and sera from these patients contain autoantibodies recognizing these proteins [94,95]. Thus, in addition to their cytotoxic and proinflammatory role in RA, neutrophils may be a source of the autoantigens that drive the autoimmune processes underlying this disease [90]. Mast cells also contribute to synovial inflammation since they produce cytokines, chemokines, and proangiogenic factors, for instance, upon ligation of TLR [96].

42.2.4 Cross-Talk between Innate and Adaptive Immunity

Several cell types with predominantly innate immune functions may also induce adaptive immunity. These cells include the earlier discussed macrophages that are also capable of presenting antigen and inducing adaptive immune responses. Other cells that bridge innate and adaptive immunity are dendritic cells and γδT cells.

42.2.4.1 Dendritic Cells

Dendritic cells (DC) are professional antigen presenting cells (APC) and therefore not only have the capacity to stimulate innate immune responses (i.e., via TLRs) but they are also central for the induction of adaptive immune responses. DC may be categorized into various subtypes, including conventional myeloid DC (cDC) that are resident in lymphoid tissues and plasmacytoid DC (pDC). DC express MHC class II and costimulatory molecules such as CD80 and CD86 that interact with CD28 on T cells. This interaction usually takes place in secondary lymphoid organs (i.e., lymph nodes), but can also occur in local (inflamed) tissues [97]. DC can induce T-cell proliferation and differentiation into effector T cells (Th1, Th2, or Th17) or regulatory T cells (Treg). In RA synovial tissue, immature and mature DC subsets can be observed in close association with T- and B-cell follicles [98]. The number of pDC that are localized near perivascular lymphocytic infiltrates correlates with the presence of RF and ACPA. DC may contribute to ongoing inflammation through presentation of autoantigens and production of proinflammatory cytokines. DC can also have certain immunoregulatory functions in RA, such as the expression of the tryptophan depleting enzyme indoleamine-2,3-dioxygenase (IDO) or IL-10 [99], resulting in the capacity to induce tolerance (i.e., via the induction of Treg) [100]. The important role of DC–T-cell interaction in RA is substantiated by the beneficial clinical effect of CTLA4-Ig treatment, which blocks costimulation [101]. Interestingly, dendritic cells might also be used for immunotherapy in RA as a recent exploratory study demonstrated safety and biological activity after a single injection of autologous modified DCs exposed to citrullinated peptides in HLA risk genotype-positive RA patients [102].

42.2.4.2 γδ T Cells

γδ T cells are T cells that unlike most T cells do not express the TCRαβ chains, but γδ chains instead. They develop in the thymus and express a large diversity of antigen-binding TCRs. γδ T cells are mainly distributed in mucosal and epithelial tissues, and account for less than 5% of the total T cells in the peripheral blood. These cells respond more rapidly than αβ T cells. Upon activation, γδ T cells may express the IL-23R and IL-1R [103]. γδ T cells do not only produce proinflammatory cytokines such as IL-17 and IFNγ but they can also display antigen presenting functions through expression of antigen-presenting and costimulatory molecules, such as HLA-DR, CD80, CD86, and CD40, which is sufficient for strong induction of naïve αβ T-cell proliferation and differentiation [104]. Interestingly, DC and γδ T cells can also interact with one another, thereby mutually promoting each other's maturation and function through release of cytokines [105]. γδ T cells can also have immunoregulatory effects, for example, by suppressing the proliferation of CD4+ effector T cells under certain conditions [106]. In RA, γδ T cells have been demonstrated in the synovial tissue [107,108]. In the context of RA, it is important to note that γδ T cells have recently been demonstrated to inhibit human osteoclast formation and resorptive activity *in vitro* [109].

42.2.5 Adaptive Immunity

Despite the presence of autoantibodies from an early disease phase, genetic risk factors in adaptive immunity and the effect of B- and T-cell-directed therapies, it has not been formally proven that autoreactive B and T cells drive RA, nor which adaptive immune mechanisms prevail in each patient and disease phase.

42.2.5.1 T Cells

T cells and T cell-derived cytokines are present in RA synovial tissue from onset of arthritis [63,110]. These cytokines include TNF, IFNγ, GM-CSF, IL-22, IL-17A, and IL-17 F [111–115]. About half of synovial tissue T cells are expanded clones that are frequently shared between different joints [116]. Initially, it was thought that T helper 1 (Th1) cells were the main infiltrating subset, but after the discovery of Th17 cells and their detection in RA synovial tissue a larger role was attributed to these cells [117–119]. Th17 cells are increased in peripheral blood and synovial fluid of RA patients, also in early disease [120–122]. Th17 cells attract and activate monocytes and neutrophils and stimulate osteoclastogenesis [123]. *Ex vivo* Th17 cells, but not Th1 cells from RA patients, induce RA FLS to produce MMPs, IL-6, IL-8, and autocrine IL-17A production [121]. These effects are modulated by cyclo-oxygenase 2 and vitamin D [124,125]. Despite these data, IL-17A and IL-17 receptor A blocking agents were moderately effective at most in RA clinical trials [126–128]. Possible explanations might be found in mouse models of arthritis where inhibition of IL-17A was more effective early compared to later in the disease course [129,130]. In one model, IL-23-activated Th17 cells expanded together with B cells in germinal centers before arthritis onset and downregulated sialyltransferase in plasma cells in an IL-22- and IL-21-dependent manner. This resulted in proinflammatory glycosylation in autoantibodies and

autoantibody-mediated, but IL-23- and IL-17A- independent, arthritis in the effector phase [131]. Furthermore, Th17 cells have been demonstrated to exhibit plasticity and can transdifferentiate into regulatory T cells (Treg) during the resolution of inflammation. Consequently, IL-17 blockade may result in less Treg activity [132]. Another clue might lie in the recent identification of different Th17 subsets. These consist of classic Th17 cells, Th22 cells, and Th17.1 cells. The debate on the existence of Th22 cells as a separate subpopulation from classic Th17 cells in humans has not yet been resolved [133,134]. In RA, IL-22 is a growth factor for FLS and it plays a role in the communication with stromal cells to mediate terminal B–cell differentiation and production of autoantibodies that might be involved in osteoclastogenesis [135,136]. However, in an *ex vivo* coculture model of FLS with Th22 and Th17 cells, there was only a limited role for IL-22 in sustaining inflammation [136]. Th17.1 cells have both Th17 and Th1 characteristics. These cells express both IL17A and IFNγ and are found in relatively high numbers in peripheral blood and synovial tissue of RA patients [123,137,138]. They express high levels of GM-CSF and other proinflammatory mediators and are therefore hypothesized to be the most pathogenic Th17 subset. There is mounting evidence for conversion of classic IL17A+ cells into IL17+IFNγ+ and IFNγ+ T helper cells [139]. Of interest in this context, citrullinated peptide-specific T cells were identified in peripheral blood of RA patients that expressed a Th1 phenotype [140]. It remains to be determined what the phenotype of the dominant pathogenic T cells is, and whether this differs between patients, and between different phases of the disease.

42.2.5.2 B Cells

It is an open question to what extent RA is driven by RF, ACPA, or other autoantibodies and this might differ between tissues, such as cartilage, synovial tissue, and bone [141,142]. RA fluids and tissues contain increased numbers of B-cell products, such as free light chains and immune complexes that react with multiple autoantigens [141,143]. Immune complexes containing RF and ACPA have been shown to mediate increased proinflammatory cytokine production and enhance osteoclastogenesis *in vitro* [142,144]. The B-cell subset from which autoreactive B-cell clones originate is also under discussion. RA patients have been shown to have defects in early B-cell central tolerance checkpoints irrespective of disease activity [145,146]. Furthermore, RA patients have increased numbers of naturally occurring autoreactive B cells that show signs of diminished anergic tolerance [147]. Citrullin-specific B cells circulate at relatively high frequencies [148]. In the synovial tissue, B cells are only present in a proportion of patients, which suggests they may mainly reside in lymphoid tissue [149]. When present in synovial tissue, B cells are part of lymphocyte aggregates, together with T cells, surrounded by plasma cells in TLS [149]. A proportion of these B cells represent expanded clones that are highly enriched from blood [150]. In several studies a significant proportion (25–40%) of synovial tissue B cells from ACPA-positive patients were citrullin specific [151,152]. T-cell activation in TLS has been shown to be dependent on the presence of B cells [153]. It is controversial whether TLS amplify and refine local autoantibody

production [154], or occur secondary to the chronic inflammatory processes driving RA [149,155]. The B-cell depletive agent rituximab is only effective in a subset of patients, which might be explained by failure of rituximab to induce depletion of switched memory B cells in synovial and lymphoid tissue, together with the presence of inhibitory factors in clinical poor responders that remain to be identified [156].

Variability in clinical response to rituximab and other biological agents suggests the existence of RA subsets driven by qualitatively different autoimmune responses. New biomarkers predictive of the clinical response to treatments have been identified, which could provide further insight into the disease mechanisms in different subsets of RA. For instance, clinical response to rituximab is associated with high systemic levels of MRP 8/14 at baseline, whereas poor response has been linked to persistence of synovial tissue plasma cells, plasma cell products, and type 1 interferon signaling in peripheral blood mononuclear cells [143,156,157].

42.2.6 Structural Changes in RA: Cartilage Damage and Bone Erosions

The proliferating FLS and pannus are the major causes of cartilage damage in RA. FLS produce MMPs and other matrix degrading enzymes that can diminish cartilage integrity, particularly when endogenous inhibitors such as TIMPs fail to counterbalance MMP activity. Immune cells contribute to the destruction of bone and cartilage by the production of cytokines such as IL-17A and IL-1 together with reactive nitrogen species, causing apoptosis of chondrocytes resulting in destruction of cartilage and joint-space narrowing. Bone erosions occur rapidly in RA, are associated with inflammation, and are mainly caused by osteoclasts [158,159]. Osteoclasts, large multinucleated cells derived from the monocyte lineage, are the only cells capable of resorbing bone in the body. These cells are viewed as key innate immune cells in bone, as they express innate immune receptors, analogous to macrophages and dendritic cells, which regulate their ability to respond to inflammation in the joint, and direct their fate and function. In RA, development of osteoclasts occurs locally in the synovial tissue as a result of the expression of essential osteoclastogenic mediators, macrophage colony-stimulating factor 1 (M-CSF), and receptor activator of nuclear factor κB ligand (RANKL). In RA, osteoclasts are situated at the interface of inflamed synovial tissue and the periarticular bone surface, causing local bone destruction [160,161]. The main triggers of articular bone erosion are synovitis, including the production of proinflammatory cytokines and receptor activator of nuclear factor κB ligand (RANKL), as well as antibodies directed against citrullinated proteins [162]. Spontaneous repair of erosions rarely occurs and even potent anti-inflammatory therapeutic strategies, such as blockade of TNF or IL-6R, only results in limited signs of repair of bone erosions (reviewed in Refs [160,163]). Lack of repair is due, at least in part, to active suppression of bone formation by proinflammatory cytokines. More knowledge on the molecular pathways involved in bone loss and bone formation during inflammation is needed to facilitate the development of new targeted therapies to induce repair of bone erosions.

42.3 Spondyloarthritides

42.3.1 Clinical Phenotype

SpA are a group of related inflammatory arthritides that involve synovitis and enthesitis. They are related to and may involve psoriasis, inflammatory bowel disease (IBD), and uveitis. The main clinical syndromes are reactive arthritis that occurs after specific infections, psoriatic arthritis (PsA), arthritis associated with IBD, juvenile spondyloarthritis, undifferentiated spondyloarthritis, and ankylosing spondylitis (AS). AS primarily involves the axial tissues with inflammation of the ligamentous attachments and sacroiliac joints resulting in pain, stiffness, and immobility. It can be difficult to differentiate between these disorders because their clinical features may overlap. Different SpA subtypes may be found in different members of the same family and single patients may develop various clinical features over time. In contrast to RA, most types of SpA and especially AS are associated with new bone formation. PsA is not only associated with new bone formation but it can also involve bone erosions in a pattern different from RA. SpA treatment has markedly improved over the last decade, with the advent of novel targeted medicines. There is variability in the treatment response, irrespective of clinical phenotype, which suggests that the immunological mechanisms that drive SpA subtypes differ between patients.

42.3.2 Etiology

SpA is not associated with polymorphisms in the classical autoimmune genes, but is rather linked to alterations in genes involved in innate immune pathways, such as CARD9, and cytokine pathways including TNF, IL-1, and IL-23/IL-17 [164]. The lack of prototypic autoimmune features and the modest therapeutic efficacy of costimulation blockade (CTLA4-Ig) [165,166] and B-cell depletion (anti-CD20 therapy) [167,168] fuel the hypothesis that the pathogenesis of the disease is not primarily driven by altered adaptive immune responses, but rather by autoinflammatory pathways. The strong link with the genetic background and the importance of bacterial infections and mechanical stress in the development of the disease underscore this hypothesis. Twin studies have demonstrated that familial aggregation is more related to genetic than to environmental factors in AS [169,170]. Other SpA subtypes are also characterized by a strong genetic predisposition and susceptibility genes include HLA-B27 and IL-23R [164,171,172]. The major genetic risk factor is HLA-B27, an MHC class I molecule, and 80–90% of AS patients are positive for this HLA subtype. However, HLA-B27 only explains 20–40% of the genetic susceptibility to AS. In earlier times, it was hypothesized that HLA-B27 is involved in the presentation of specific bacterial peptides to cytotoxic T cells, resulting in activation of these cells and cross-reactivity with self-peptides [173]. However, it appears that HLA-B27 has a tendency to misfold inside the endoplasmatic reticulum, which may generate an unfolded protein response leading to the activation of NF-κB signaling, followed by increased production of proinflammatory mediators [174]. Furthermore, ER stress has been demonstrated to increase IL-23

production after TLR stimulation [175], which is also implicated in the pathogenesis of AS [176]. Therefore, HLA-B27 may have an intrinsic auto-inflammatory role. Tissue stress may contribute to the development of SpA. This is substantiated by the association between SpA and mechanical stress (development of inflammatory lesions at sites of high mechanical stress such as spine, entheses, and larger joints) and bacterial infections (in reactive arthritis after genitourethral or gastrointestinal infections). Consequently, it has been postulated that HLA-B27 in combination with mechanical stress or bacterial triggers leads to abnormal innate immune responses [177].

42.3.3 Cells and Mediators Driving Spondyloarthritides

Based on the susceptibility genes and the limited effect of targeted therapies that interfere with costimulation of B cells, the main driving force in SpA may be the innate immune system, including alterations in TNF and IL-23 signaling resulting in abnormal IL-17 responses [176,178]. This is substantiated by the overall beneficial effects of TNF blockade and IL-17 targeting therapies in SpA [179–184]. Detailed analysis of the inflamed synovial tissue of patients with peripheral SpA has provided further insight into the cell types and mediators of inflammation contributing to the disease. However, detailed analysis of the target tissue associated with remodeling, leading to osteoproliferation and ankylosis, has been hampered by the fact that it is difficult to obtain such tissues for in-depth analysis in humans.

42.3.4 Innate Immunity and Stromal Cells

42.3.4.1 Fibroblast-Like Synoviocytes

In many ways, FLS seem to be similar in RA compared to SpA, including surface expression of CD46, CD59, and the complement-regulatory protein CD55, as well as in cytokine production [185]. However, recently a novel and disease-specific myogene signature was identified in SpA synovial tissue and FLS, which includes genes involved in PDGF, TGFβ, and Wnt signaling [186]. These profibrotic pathways may contribute to osteoproliferation, which is a distinct feature of SpA.

42.3.4.2 Monocytes and Macrophages

SpA is characterized by a relative increase in the number of CD163+ macrophages compared to RA [187,188], although not in all studies [189]. The exact functional consequences of this possible difference remain to be determined, but M2 macrophages (associated with CD163 expression) have been demonstrated to correlate with disease activity and HLA-B27 positivity in SpA [187], as well as with subclinical ileal inflammation in AS, which is distinct from Crohn's disease [190]. In addition, CD163 expression was also associated with reduced lymphocyte activation as characterized by lower CD69 levels on synovial tissue T cells [187]. In line with this, synovial fluid from SpA patients contains less proinflammatory "M1" cytokines such as TNF, IL-1, and IL-12p40 compared to RA patients, whereas the "M2" cytokines IL-4, IL-13, and IL-10 are similar, which may result in a shift in the M1/M2 balance toward M2 polarization [191]. Besides these changes

in macrophage polarization, monocyte-derived macrophages from AS patients also exhibit differences in gene expression compared to healthy controls with a striking "reverse" IFN signature, which together with poor expression and responsiveness of the IFN gamma gene may suggest IFN gamma gene dysregulation as a contributor to disease pathogenesis [192].

42.3.4.3 Endothelial Cells

Compared to other inflammatory joint diseases, synovial tissue of SpA patients exhibits markedly increased neovascularization [193–195] and SpA patients have high serum levels of vascular endothelial growth factor (VEGF) [196], which is indicative of increased angiogenic activity in this disease. Angiogenesis not only contributes to inflammation by supplying oxygen and nutrients to activated stromal cells and immune cells, but activated EC are also involved in the active recruitment of new immune cells to the site of inflammation. In addition, two mechanisms have been described by which EC may contribute to new bone formation. First, EC can transform into mesenchymal stem cells that ultimately further differentiate into bone cells, a process called endothelial–mesenchymal transition (EndMT) [197]. Second, EC can recruit not only immune cells but also cells with broader differentiation ability, including osteoprogenitors [198]. Consequently, EC may not only contribute to the perpetuation of inflammation, but they may also be involved in pathological new bone formation in SpA.

42.3.4.4 Innate Lymphoid Cells

The contribution of ILC to the pathogenesis of SpA has as yet not been studied in great detail, since these cells have been described only recently. A recent study investigated ILC populations in the gut, peripheral blood, synovial fluid, and bone marrow of AS patients. There was expansion of ILC3, but not ILC1 and ILC2, in all of these compartments. Interestingly, these cells expressed IL-23R and produced both IL-17 and IL-22 [199]. Based on detailed analysis of gut biopsies, the authors hypothesized that ILC3 differentiate in the gut and may subsequently migrate to the inflamed joints due to the expression of specific integrins. More studies on ILC are required to draw firm conclusions on the role of these cells in AS and other SpA subtypes.

42.3.4.5 Neutrophils and Mast Cells

SpA synovitis is characterized by an increase in neutrophils and mast cells compared to RA [178,195,200]. Neutrophils could contribute to synovial inflammation, since accumulating evidence suggests that the majority of the IL-17 released in inflammatory arthritis is produced by innate immune cells, including neutrophils and mast cells, rather than T cells [201,202]. In SpA mast cells are not only increased in numbers but these cells also express more IL-17 than mast cells in RA. Targeting mast cells via a c-Kit inhibitor resulted in decreased levels of IL17 ex vivo [178].

42.3.5 Cross-Talk between Innate and Adaptive Immunity

The pathogenesis of SpA involves both arms of the immune response and is at the crossroads of immunity. Cells that bridge innate and adaptive immunity, such as γδT cells and dendritic cells, are thought to play an important role.

42.3.5.1 Dendritic Cells

Dendritic cells (DC) have been less studied in SpA compared to RA. These cells probably not only contribute to the pathogenesis of SpA via their direct effect on T cells, but also via proinflammatory cytokine production, including IL-12 and IL-23 [203]. *In situ* analysis of IL-23-positive cells in the spine of AS patients revealed that their numbers are significantly increased in the subchondral bone marrow of the facet joints compared to OA patients or normal control specimens obtained at autopsy. These IL-23-positive cells also comprised DC. Furthermore, the frequency of IL-23-positive cells was significantly higher than that of IL-12-positive cells in AS patients [204]. Monocyte-derived DC from HLA-B27+ axial SpA patients display altered functional capacity and deregulated gene expression. As a consequence, the capacity of these DC to stimulate CD4+ T cells was decreased [205]. Secretion of IL-12 and IL-23 by monocyte-derived DC from AS patients after TLR stimulation was however comparable to healthy controls [203]. Together, DCs are likely to contribute to the pathogenesis of SpA via IL-23 secretion, rather than via induction of effector T-cell responses.

42.3.5.2 γδT Cells, Invariant Natural Killer T Cells (iNKT), and Mucosal-Associated Invariant T (MAIT) Cells

There is increasing evidence that innate-like T cells, such as γδT, iNKT, and MAIT cells that function as a bridge between innate and adaptive immunity, may be involved in SpA pathogenesis [206]. MAIT cells express a genetically determined, restricted T-cell repertoire. They are more abundant in humans compared to mice and under physiological circumstances mainly reside in mucosal tissues and the liver. Their TCR reacts with nonpeptide antigens, such as bacterial vitamin metabolites, that are bound by the nonclassical class I antigen-presenting molecule MR1. They can also be activated by cytokines secreted by innate immune cells independent of TCR. IL-17-producing MAIT cells are relatively increased in blood and synovial fluid of patients with AS compared with healthy controls and patients with RA. Recently, it was demonstrated that circulating IL-17 secreting IL-23R expressing γδT cells are significantly increased in patients with active AS compared to healthy controls and RA patients [207]. In psoriasis patients, there is an increase in these cells in psoriatic skin with a reduction of the number of circulating γδT cells, suggestive of redistribution from the peripheral blood to the affected skin [208]. The dermal γδ T cells in psoriasis are poised to secrete IL-17 [209]. These data support the notion that γδT cells play a pathogenic role in psoriasis and they might also contribute to inflammation in PsA since these cells can also be found in synovial fluid of PsA patients [210].

42.3.6 Adaptive Immunity

It remains to be determined to what extent adaptive immunity is involved in SpA and whether this is based on a disturbed, overreactive alloimmune response or autoimmunity. SpA is often referred to as seronegative because of the absence of autoantibodies. However, recent work has suggested that autoantibodies against the bone remodeling molecules sclerostin and noggin as well as against the invariant chain peptide (CLIP/CD74), involved in MHC class II antigen loading,

may be involved [211,212]. The notion that humoral immunity is involved in some patients with SpA is supported by an open-label clinical trial in 20 patients with axial SpA using the anti-CD20 antibody rituximab, which was associated with improvement in 8 patients [167]. The association with the MHC class I allele HLA-B27 could suggest the involvement of CD8+ T cells. However, the search for CD8-restricted arthritogenic peptides did not yield any candidates. HLA-B27 may be involved in a different way, independent of CD8+ T cells, as HLA-B27 overexpressing rats develop disease independent of these cells [213]. Similarly, overexpression of TNF in mice is sufficient to generate a disease phenotype in the absence of B and T cells [214]. Besides HLA-B27, many candidate risk genes for SpA are involved in antigen presentation and T-cell activation. For instance, the risk genes ERAP1 and ERAP2 encode aminopeptidases that trim peptides to optimally fit in the antigen binding groove of MHC class 1 [215]. Polymorphisms in these genes may influence the capacity to present pathogenic peptides [216–218]. Alternatively, they may affect autophagy-associated HLA-B27 misfolding, endoplasmatic reticulum stress, or altered HLA-B27 surface expression that have also been implicated in SpA and that may induce activation of innate or innate-like immune cells [217–219].

Circumstantial human biologic evidence for a role of adaptive allo- or autoimmunity derives from studies of patient samples. Peripheral blood and synovial fluid of SpA patients contain elevated levels of IL–17A, IL-6, TGF–β, IFN–γ, and IL-22, and increased numbers of Th17 and Th22 cells [220–222]. Several studies suggest involvement of different T-cell subsets in different disease tissues and phenotypes. In a study in PsA and psoriasis patients Th17 and Th22 cells numbers were increased in peripheral blood in both conditions compared to healthy controls, but in synovial fluid of PsA patients only Th17 numbers were increased while Th22 numbers were lower compared to blood and IL-22 was absent in the synovial tissue [223]. In another study in PsA, there was proportionally more infiltration of CD4+ to CD8+ T cells in synovial tissue, while this ratio was reversed in synovial fluid [224]. In another study that compared PsA to RA, the number of CD4+ Th17 cells was increased in synovial fluid compared to blood in both conditions, but the number of synovial fluid IL-17A producing CD8+ T cells was only increased in PsA [225]. The latter correlated with disease activity and development of joint erosions. Th17 cells may contribute to development of bone erosions by stimulating osteoclastogenesis through RANKL, TNF, and/or IL–17 [123]. Of interest, a study that focused on IL-17 expression in inflamed facet joints of SpA patients found predominant expression of IL-17 by neutrophils and to a lesser extent by T cells and mast cells [201]. A recently developed mouse model supports the role of dysregulated adaptive immunity in SpA in the context of IL-23-driven innate immune activation [226]. This mouse model has a deficiency in the ZAP70 T-cell receptor-signaling protein, which leads to diminished central tolerance, alterations in the T-cell repertoire, and survival of autoreactive clones. After injection with the fungal component β-glucan, these mice develop a full SpA phenotype consisting of arthritis, enthesitis, spondylitis, uveitis, and Crohn's disease-like terminal ileitis. Arthritis and spondylitis were dependent on CD4+ T cells and IL-23 in this model, while enthesitis and ileitis depended on IL-23; enthesitis also required IL-17 and IL-22 [226,227]. Clinical

trials with IL-17A and IL-23 blocking agents have provided further experimental evidence for the role of these cytokines in the pathogenesis of SpA, although there was a variable response among different SpA-related conditions. Further investigations are expected to clarify the differences in the immune mechanisms that drive these interrelated conditions and whether adaptive immunity is involved through primary defects or whether it is secondary to defects in innate immunity. A picture emerges in which adaptive immunity modulates the disease process but it may not be necessary for the development of its signs and symptoms. This is illustrated by the fact that mice can develop a disease that resembles SpA in the absence of both T and B cells, as demonstrated in mice overexpressing TNF [214].

42.3.7 Bone Remodeling in SpA

In contrast to RA, SpA is characterized by osteoproliferation rather than bone degradation and joint erosions. Also, bone remodeling in SpA occurs to a large extent independent of (TNF-driven) inflammation as syndesmophytes and ankylosis may progress when inflammation is effectively blocked by anti-TNF therapies [228]. However, these processes may depend on other inflammatory pathways, involving cytokines such as IL-17, and clinical trials to formally study this notion are underway. Various hypotheses have been proposed with respect to the striking tissue remodeling that is observed in SpA, but research to further elucidate the mechanisms involved has been hampered by the difficulty to obtain tissues for detailed molecular analysis. Structural features of SpA may relate to important pathways of enchondral bone formation such as signaling by bone morphogenetic proteins (BMPs) and the Wnt pathways [229,230], but evidence for this is largely based on results obtained in animal experiments [231,232]. Stromal cells and mechanical stress appear to play a key role in the disease process. Recently, a novel and disease-specific myogene signature was identified in SpA synovitis, which included genes involved in TGFβ/BMP signaling. This signature was not modulated by TNF blockade [186]; the effects of IL-17-targeted therapies on this signature remain to be determined.

In conclusion, our knowledge of the mechanisms underlying bone remodeling in SpA is incomplete, but pathological bone formation is probably triggered by a combination of the inflammatory response and mechanical stress. Advanced understanding of the altered bone biology in SpA could facilitate development of novel targeted therapies to block osteoproliferation and prevent structural damage in patients.

42.4 Conclusions

In this chapter we have discussed the molecular and cellular mechanisms that contribute to synovial inflammation in inflammatory articular diseases with a focus on RA and SpA. We have highlighted both similarities and differences in the pathogenesis of these diseases, which may not only advance our understanding of the pathogenesis of these conditions but it may also help explain differential treatment responses: targeting IL-6R and B cells improves disease in RA, whereas

these treatments do not substantially ameliorate disease in SpA. For targeting IL-17 the case is reverse: excellent effects in SpA, but only modest effects in RA patients.

With the advent of new targeted therapies and a "reverse immunology" approach we may be able to further classify these diseases and build a new taxonomy [233,234]. This will enhance our understanding and simultaneously result in earlier appropriate treatment for patients. In addition, we notice a shift in the focus of research and treatment efforts to the early and preclinical phase of disease, with the objective to use the existing "window of opportunity" to either prevent disease or delay the onset of disease [6,235]. We expect that new treatment algorithms and preventive strategies will be developed in the coming years, which will be of great benefit for patients with inflammatory joint diseases or individuals at risk of developing these diseases.

Missing Heritability of Crohn's Disease and Implications for Therapeutic Targeting and Improved Care

Matthias Chamaillard

Université Lille, CNRS, Inserm, CHRU Lille, Institut Pasteur de Lille, U1019 – UMR 8204 – CIIL – Centre d'Infection et d'Immunité de Lille, 59000 Lille, France

43.1 Crohn's Disease: A Public Health Issue

Crohn's disease (CD) is a common relapsing–remitting intestinal illness that mainly affects young adults in industrialized countries. The CD patient's quality of life is profoundly compromised by severe diarrhea, abdominal pain, fever, weight loss, malnutrition, and bleeding. CD is associated with transmural inflammatory lesions that can potentially concern any part of the gastrointestinal tract. Some CD patients can also experience additional complications such as fistulae, abscesses, bowel strictures, and/or extraintestinal manifestations (mostly involving the eyes, skin, joints, and liver) [1]. While Crohn's disease can impair a patient's ability to work and his/her social interactions in various ways, its lifetime therapeutic management is far from optimal. In particular, invasive surgery and bowel resection is required in about two-thirds of Crohn's disease patients but it does not cure the disease. In addition, an overall 25–30% therapy refractoriness is seen, regardless of the biologics (most often antibodies against TNF-alpha) and/or immunosuppressive drugs, resulting in an accumulation of adverse events, including malignancies and serious infections [2]. Intriguingly, in Europe, the combined prevalence of CD is about 250–300 cases per 100 000 inhabitants, which results in as many as 2.2 million CD patients. The incidence is also on the rise in emerging countries, due to the influence of many genetic and environmental factors. Consequently, the annual economic burden of medical care of Crohn's disease patients ranges between €2.1 and 16.7 billion. In this context, there is an urgent need for more effective therapeutic interventions, which minimize complications and reduce the need for surgery in CD.

43.2 An Imperative Need for Understanding Missing Heritability in Crohn's Disease

A better understanding of the so-called missing heritability in CD remains a prerequisite for the overall disease understanding. Soon after its clinical

Inflammation: From Molecular and Cellular Mechanisms to the Clinic, First Edition.

description in the 1930s by Dr. BB. Crohn and his colleagues, epidemiological observations of patients with a family history of CD indicated that such an intestinal illness is a complex trait likely influenced by both environmental and genetic factors. Meanwhile, early-onset CD patients have more frequently a familial history of CD and experience more severe disease phenotypes than adults, suggesting a higher genetic load among familial cases of CD. Consistently, large European twin registries provided a valuable resource for estimating the heritability of CD. A greater concordance rate on disease location was revealed among identical twins when compared to fraternal twins, encouraging for the search of the causal genetic variations driving the association signal. Thanks to technological advances in genotyping, linkage studies provided some of the molecular basis for the involvement of genetic epistasis (also referred to as gene–gene interactions). Since the first genome-wide association study (GWAS) in 2005, over 160 risk alleles were identified by including additional cohorts and by performing meta-analysis. Besides patients with very-early-onset inflammation that have Mendelian-like form of CD [3], about 13.6% of the inherited risk of developing CD in adults is estimated to result from the combination of all risk alleles among which 16% are solely nonsynonymous variants [4]. Even if not all polymorphisms of the human genome have been studied so far, a bioinformatic compilation of GWAS has shown that nonsynonymous and synonymous coding single nucleotide polymorphisms have similar likelihoods and effect sizes for the association with human disease, as measured in the HapMap 3 project [5–7]. About 90% of alleles that are predisposing to such inflammatory condition are located in noncoding areas of the genome, as shown in the ENCODE project [8], indicating that the exome sequencing may not allow identifying the responsible susceptibility variants in most patients. These loci in noncoding regions presumably contribute to disease predisposition by regulating the expression of proteins that are relevant to intestinal homeostasis. Indeed, a unique, single synonymous variant may result in miRNA misuse, which predisposes to CD by altering the stability of the mRNA (rather than by deregulating the function) as what elegantly shown for the immunity-related GTPase M [9]. Meanwhile, whole-genome sequencing techniques revealed sequence differences that may explain some of the discordance between monozygotic twins. While copy number variants that predispose to CD are unlikely to explain all of the missing heritability of CD [10], more than ~36% of CD predisposing polymorphisms are expression quantitative trait loci (noted as eQTLs) [11] that may contribute to interindividual heterogeneity in gene expression. For example, the common risk allele C at SNP rs7746082 correlates with the reduced expression of the PR domain containing 1, with ZNF domain gene (encoding for the PRDM1 protein) in both ileal biopsy specimens and peripheral blood mononuclear cells of CD patients [12]. More recently, chromatin immunoprecipitation sequencing (ChIP-Seq) revealed an enrichment of several epigenetic marks in specific cell types of CD patients [13], including cell-specific active enhancer (e.g., H3K27Ac) or promoter (e.g., H3K4me1). Furthermore, a genome-wide methylome analysis revealed a link between a commonly observed complication of CD patients and differential DNA methylations that were primarily found within intergenic regions and introns [14]. Abnormal epigenetic reorganization of chromatin from CD patients may also

contribute to hyper/hypomethylation of promoters, modification of histone tails, and changes in miRNA expression of several genes that play a key role in intestinal homeostasis, such as immunity-related GTPase M [15]. While histone tail changes and methylation of promoters will allow transcriptional factors access to genes in an on–off mechanism, miRNA will optimally control gene expression as a remote control mechanism of cell function specificities, including cellular response to the CD-associated adherent-invasive *Escherichia coli* [9]. Furthermore, a loss of binding is predicted for hsa-miR-652 or hsa-miR-414 binding in the presence of the NOD2 risk haplotypes carrying the T allele at rs2066843 or the CARD9 risk haplotypes carrying the G allele at rs10781499, respectively, and the GTEx project [16]. In this context, studying the genetic of very-early-onset CD will provide information that promises a better understanding of the overall missing heritability of CD, while additional GWAS are unlikely to provide any additional valuable information on variants with larger effects.

43.3 Immunodeficiencies in Phagocytes as a Specific Cause of Crohn's Disease

Despite extensive efforts, only a few CD-predisposing genes have been clearly identified (including the genes encoding for the nucleotide-binding oligomerization domain 2, autophagy-related 16 like 1, and immunity-related GTPase M) [17–20]. In the gut, most of the aforementioned risk alleles are expressed by the mononuclear phagocyte system [21,22] that is mainly composed of monocytes, dendritic cells, and macrophages. The intestinal steady-state mononuclear phagocyte compartment comprises two types of conventional dendritic cells (CD11b− and CD11b+), both of which express the alpha E integrin CD103. In addition to these short-lived phagocytes, the steady-state lamina propria harbors a large population of resident, nonmigratory $CD11c^{lo}$ $CX3CR1^{hi}$ macrophages. Intriguingly, the latter phagocytic subset gain access to the gut lumen by forming transepithelial dendrites [23–26]. Our current understanding of the aforementioned genes suggests that a suppression of phagocyte function (e.g., defects in xenophagy) may contribute to disease development that may account for the greater colonization of patient's intestine by a large set of opportunistic microorganisms such as *Mycobacterium avium* subspecies *paratuberculosis* and adherent-invasive *E. coli* [27–29]. A fundamental attribute of such intracellular opportunistic microorganisms is the ability to avoid killing by macrophages by interfering with the endocytic pathway or by infiltrating the autophagic route for dissemination. Intriguingly, the development of another form of inflammatory bowel disease commonly referred to as ulcerative colitis is not influenced by these genes, distinguishing it from CD. The understanding of the contribution of the recently identified eQTLs in monocytes is now eagerly awaited for restoring phagocyte functions in CD [30]. It is indeed worth noting that bone marrow transplant has proved efficacy to resolve refractory CD that is caused by defects in interleukin-10 signaling [31].

43.4 Concluding Remarks

While the utility for diagnosis by genetic testing remains insignificant in the general population, opportunities for improved care may result from a better understanding of missing heritability. Indeed, it is a greater challenge for the research community to characterize noncoding variants that are predisposing to CD [32], as only underpowered studies have attempted to understand the synonymous allele contribution to the disease mechanism compared to non-synonymous polymorphisms. Furthermore, it is imperative for everyday clinical practice to evaluate the potential clinical value of cell-specific epigenetic markers in prospective studies that are currently being followed [33]. To this end, eQTLs studies with replicating cohorts are expected to be performed at the single-cell level by using specific cell types that are relevant for CD pathogenesis, such as monocytes. In this context, it is worth noting that the local microenvironment (including the gut microbiota) may determine the identity and functionality of intestinal phagocytes that are infiltrated into the tissue. This paradigm is essential as immunodeficiency affecting phagocytes (e.g., an abnormal bacterial handling) has been arguably reported within the mucosa of patients with CD.

Inflammation and Transplantation

William M. Baldwin, III and Robert L. Fairchild

Cleveland Clinic, Department of Immunology, Cleveland, OH, USA

44.1 Introduction

Many reviews consider organ transplantation primarily in the context of antigen-specific adaptive immune responses. This chapter will emphasize the innate immune responses to transplants. Antigen nonspecific inflammation and innate immune responses are unavoidable consequences of transplantation surgery. Excision of an organ from a donor results in ischemia followed by reperfusion after implantation into a recipient. Additionally, in clinical transplantation both the donor and recipient usually have preexisting conditions and undergo procedures before transplantation that can greatly augment innate immunity (Figure 44.1). These innate immune responses are superimposed on the exceptionally strong adaptive immune responses elicited by transplant antigens.

Innate and adaptive immune responses prevented successful organ transplantation until 1954 when a patient with renal failure received a kidney from his healthy twin brother [2]. Adaptive immunity was not elicited because the twins were genetically identical and therefore antigenically "matched." The facts that the kidney came from a healthy living donor and ischemic time was minimized were major factors contributing to the first success. Even with the greatly advanced immunosuppressive protocols used currently, unmatched kidneys from living donors – even living genetically unrelated donors – have significantly better outcomes than kidneys from deceased donors [3].

Inflammation has a significant effect on transplants because it can augment every step of the adaptive immune response, beginning with increased expression of antigens and progressing through more effective antigen presentation, greater expansion of responding cells, and augmented effector mechanisms.

In this chapter, we describe the modulatory effects of inflammation on successive steps of the adaptive immune responses to a transplant and then discuss therapeutic prospects to improve outcomes by modulating inflammatory responses in transplantation. We will concentrate on the available data from transplants in humans. Much of the discussion will be based on renal

transplantation because of the large pool of data on kidneys from living and deceased donors and other variables that are informative about the interaction of innate and adaptive immunity.

44.2 Inflammation Increases the Expression of Transplant Antigens

Defining the antigens that elicit the adaptive immune response to transplanted tissue was a fundamental advance in immunology, for which George Snell, Jean Dausset, and Baruj Benacerraf shared the 1980 Nobel Prize in Physiology or Medicine [4]. Snell used transplantation experiments with tumors and skin in genetically inbred mice to define strong and weak (subsequently termed major and minor) histocompatibility antigens [5]. Genetic and serological evidence indicated that the major histocompatibility antigens are the products of multiple genes that are closely linked in a region now termed the major histocompatibility complex (MHC). Foreseeing the importance of antigenic matching for successful transplants in humans, Dausset identified the first histocompatibility antigens on leukocytes in man (subsequently termed human leukocyte antigens or HLA). Benacerraf found that genes in the MHC regulate the strength of an immunological reaction. The multiple functions of the MHC were resolved as the genetics and structure of the molecules were solved [6].

Enormous antigenic diversity results from multiple genetic loci in the MHC, an extensive number of different alleles for certain loci and codominant expression

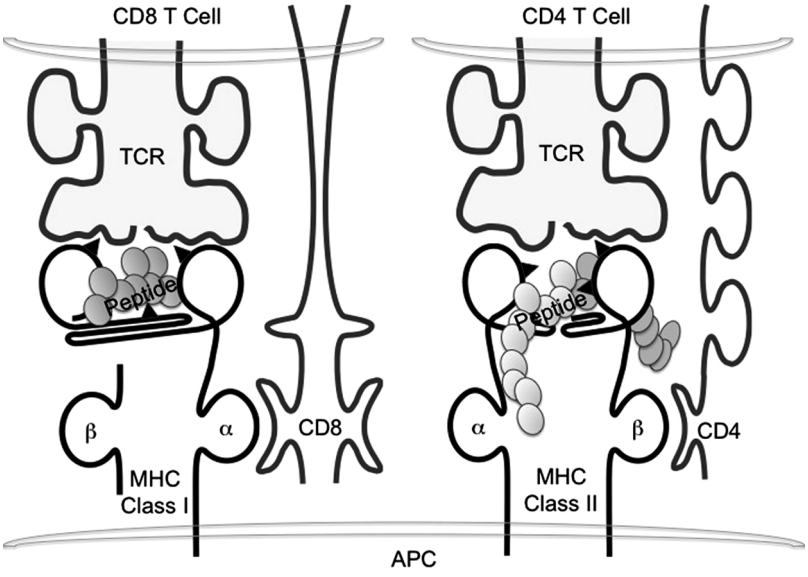

Figure 44.2 MHC molecules are grouped into two classes based on their structure and function. MHC class I antigens are heterodimers composed of a transmembrane alpha heavy chain (~45 kd) and a noncovalently associated beta chain (~12 kd). The alpha chain is extremely polymorphic. The beta chain is constant and imposes a tertiary structure on the alpha chain. MHC class II antigens are composed of two noncovalently associated transmembrane polypeptides: a less polymorphic alpha (~34 kd) and very polymorphic beta (~28 kd) chain. MHC classes I and II have binding grooves that contain short peptides (8–9 amino acids for class I and 13–24 amino acids for class II). The variability concentrated in the binding grooves is depicted by triangles. Antigen-specific receptors on T lymphocytes (TCR) bind to the peptide and the adjacent elements of the MHC molecule. The CD8 coreceptor on cytotoxic T cells and the CD4 coreceptor of helper T cells bind to nonpolymorphic domains of the MHC classes I and II molecules, respectively.

of the glycoprotein products on the cell surface. Antigens encoded by the MHC are grouped into two classes based on their structure and function (Figure 44.2). MHC class I antigens are composed of two polypetides: a transmembrane alpha heavy chain (~45 kd) encoded at the telomeric end of the MHC on chromosome 6 in humans and a noncovalently associated beta chain (~12 kd) that is encoded on chromosome 15. The beta chain is constant and imposes tertiary structure on the heterodimer. In contrast, the alpha chains of 3 MHC class I loci (HLA-A, B, and C) are extremely polymorphic with over 3000 genetic variants reported for the HLA-B locus [7]. In comparison, MHC class II antigens are composed of two noncovalently associated transmembrane polypeptides that are both encoded in the MHC: a less polymorphic alpha (~34 kd) and very polymorphic beta (~28 kd) chain. Three principal MHC class II antigens are expressed in human: HLA-DR, DP, and DQ. The extreme polymorphism of the MHC precludes complete antigen matching of unrelated donors with recipients on a genotypic level.

The evolutionary pressure for this diversity results from the protective function of these molecules as a surveillance system for potential pathogens. Crystallographic studies revealed that the three-dimensional structure of both MHC class I

and MHC class II forms a groove that binds short peptides (8–9 amino acids for class I and 13–24 amino acids for class II). When exposed to pathogens, peptide fragments are loaded into MHC for antigen presentation. In general, MHC class I is adapted to be loaded with peptides from intracellular organisms and MHC class II with peptides from extracellular organisms. The polymorphic variations of both MHC class I and MHC class II are concentrated in the binding groove and confer diversity in peptide presentation. This surveillance function underlies the association of some MHC polymorphisms with disease risks. When no exogenous peptides are present, the MHC molecules are loaded with endogenous peptides. Some of these endogenous peptides are recognized as minor histocompatibility antigens.

Antigen-specific receptors on T lymphocytes bind to the peptide and the adjacent elements of the MHC molecule (Figure 44.2). This interaction between T-cell receptors (TCR) and the peptides bound in the polymorphic domains of MHC limits the response to specific antigens. The low-affinity TCR interaction is strengthened by coreceptors on the T cells that bind to the nonpolymorphic domains of the MHC molecules. The CD8 coreceptor on cytotoxic T cells binds to conserved domains on MHC class I and the CD4 coreceptor of helper T cells binds to MHC class II.

The expression of both MHC class I and II antigens is dynamic and particularly responsive to inflammatory processes. This dynamic expression is an adaptive advantage for the surveillance function of MHC but has immunogenic consequences in transplants. Under normal quiescent conditions, MHC class I antigens are expressed at highest density on leukocytes, dendritic cells, and endothelial cells, but also at varying concentrations on most cells except erythrocytes. This allows any virally infected cell in the body to be eliminated by cytotoxic T cells. In contrast, MHC class II antigens normally are expressed by a more limited set of cells: dendritic cells, B cells, macrophages, and some endothelial cells.

The anatomic distribution and concentration of histocompatibility antigens shapes both the initiation of alloimmunity and the rejection of transplanted organs. Traumatic brain injury and ischemia–reperfusion upregulate the expression of MHC antigens on transplanted tissues [8,9]. Not only do individual cells increase expression of MHC antigens, but cells that normally only express MHC class I antigens also upregulate MHC class II antigens. As a result, all transplanted organs are more immunogenic immediately after transplantation, and organs from deceased donors are more immunogenic than organs from living donors [10].

44.3 Inflammation Increases the Presentation of Transplant Antigens

Following transplantation, the recipient is presented with histocompatibility antigens by multiple routes and different mechanisms. The three mechanisms of antigen presentation are termed direct, indirect, and semidirect. Direct presentation is unique to transplantation and results from recipient T cells, binding intact allogeneic MHC antigens on donor antigen-presenting cells.

Indirect presentation requires recipient antigen-presenting cells to take up donor antigens derived from damaged or dying cells or shed from living cells. These antigens undergo conventional processing and presentation as peptides in the groove of recipient MHC class II [11]. In semidirect presentation, portions of donor cell membrane with intact MHC molecules are integrated on the membrane of recipient antigen-presenting cells. Extracellular vesicles released from donor cells are one mechanism by which MHC molecules can be transferred to recipient antigen-presenting cells [12,13].

Each of these mechanisms of presentation differs qualitatively and quantitatively. Direct presentation to CD4 T cells requires donor antigen-presenting cells that express MHC class II antigen but recipient MHC class II molecules are not necessary. Therefore, the effectiveness of direct presentation was tested using mice that are genetically deficient for MHC class II molecules. These experiments demonstrated that CD4 T cells can cause acute rejection of allogeneic cardiac transplants in recipient mice that are MHC class II deficient [14]. Dendritic cells are the most potent agents of direct antigen presentation. The concept of dendritic cells has evolved from the first descriptions of "passenger leukocytes" that express MHC class II antigens [15] through very distinct short-lived cells that migrate out of transplanted organs [16] to the current view of a range of cells derived from a common precursor cell [17]. With the identification of increasing numbers of "markers" for subpopulations of dendritic cells and macrophages, more overlaps in function and transitional states have been discovered. Several important concepts have emerged. First, the different organs that are transplanted all have extensive networks of potential antigen-presenting cells that are diverse and responsive to the stresses of transplantation [17,18]. Second, subpopulations of dendritic cells function to present MHC class II antigens to CD4 T cells and MHC class I antigens to CD8 T cells. These cells are termed conventional or classical dendritic cells of myeloid origin (cDCs). Significant numbers of cDCs migrate out of transplants and interact with T cells in spleen, lymph nodes, and possibly bone marrow within days after transplantation [11,19]. Although many of these cells are destroyed by natural killer cells, it has been demonstrated that transfer of cDCs is an effective mechanism of generating vigorous T-cell responses to alloantigens [20]. Inflammatory dendritic cells are a third population of antigen-presenting cells in transplanted organs. These cells are derived from circulating monocytes that are recruited to sites of inflammation.

The direct response of T cells to intact allogeneic MHC antigens is exceptional in vigor and repertoire because the response is not confined to individual peptides in the binding groove. Instead, T cells with receptors that were selected in the thymus on templates of "self-MHC" molecules containing peptides cross-react with allogeneic MHC molecules. The binding affinity of individual receptors on a T cell for an allogeneic MHC may be low, but the cumulative avidity is increased by the density of allogeneic MHC molecules on the antigen-presenting cell. As a result, a polyclonal response is generated from 1 to 10% of the T-cell repertoire.

In contrast, T cells activated via indirect antigen presentation bind to peptides derived from donor antigens that are presented in the binding groove self-MHC molecules on recipient antigen-presenting cells. When allogeneic MHC antigens

are reduced to a few peptides, the response is narrowed to a few T-cell clones. The primary source of donor MHC antigens for indirect presentation is damaged or dying cells in the transplant. Therefore, inflammation associated with the logistics of transplantation process or subsequent infections or other complications can cause surges of donor antigen from the damaged tissue for indirect presentation [21].

Stresses such as ischemia–reperfusion also increase the basal release of microvesicles from cells [22]. Various forms of microvesicles are a source of intact MHC for semi-direct presentation [23]. Significant numbers of dendritic cells expressing both donor and recipient MHC molecules have been detected within 1 day after renal and cardiac allografts in experimental animals [24]. Although intact donor MHC is presented by the semi-direct mechanism, the density of antigen assimilated on individual recipient dendritic cells would likely be much less than on donor dendritic cells.

44.4 Inflammation Increases Antigen-Independent Activation Mediators

In addition to increasing the antigenic exposure, stresses associated with transplantation increase ancillary signals that modulate immune responses. Dendritic cells residing within healthy unstressed organs are immature and equipped with receptors to survey the milieu for pathogens. Pattern recognition receptors (PPR) such as toll-like receptors (TLRs) evolved with the dual function of binding signature molecules expressed by prokaryotes called pathogen-associated molecular patterns (PAMPs) and exposed on autologous tissues that are collaterally damaged by pathogens or other injury (damage-associated molecular patterns; DAMPs). The mechanisms connecting hypoxia and reperfusion to expression of DAMPs were detailed in previous chapters. Here we will concentrate on the known effects of DAMPs on transplants.

As illustrated in Figure 44.1, many steps in transplantation can release DAMPs and with the use of immunosuppression exposure to pathogens is also frequent. In the ideal situation of transplants from living donors, the period of ischemia followed by reperfusion is minimized. Moreover, fewer rejection episodes are incurred by organs from living than deceased donors. Consequently, recipients of organs from donors often are exposed to less immunosuppression and experience fewer infections. Exposure to PAMPs and DAMPs causes dendritic cells to mature. Mature dendritic cells express increased amounts of MHC class II molecules, upregulate costimulatory molecules (CD80 and 86), and produce various proinflammatory cytokines (Il-12, IL-6, TNFα and IL-1β). These cells also have increased migratory capabilities.

Increasing evidence implicates some DAMPs modulate the immune responses to transplants (Table 44.1). Experiments using genetically modified mice have established that TLR4 contributes to the inflammation caused by ischemia–reperfusion in kidneys [25]. TLR4 is expressed on intrarenal leukocytes within a day after ischemia–reperfusion and then these cells decline precipitously. TLR4

Table 44.1 DAMPs that have been demonstrated to modulate immune responses to transplants.

Source	Ligand	Receptor	References

	S100A8/A9	TLR4 and RAGE	[29]

expression is also increased on renal tubular epithelium on the first day after ischemia–reperfusion and this expression peaks at 3–5 days. The epithelial response is paralleled by increases in DAMPs that are known ligands for TLR4, including high-mobility group box 1 (HMGB1), hyaluronan, and biglycan. Mice constructed with a genetic ablation of TLR4 in their kidneys retained better renal function, incurred less tubular damage, and sustained fewer leukocyte infiltrates following ischemia–reperfusion. In complementary experiments, ischemia–reperfusion injury was effectively inhibited by blocking antibodies to HMGB1 [26]. Similarly, in humans TLR4 expression is upregulated on renal tubular epithelium following transplantation and kidneys that express genetic polymorphisms for nonfunctional TLR4 molecules have an increased incidence of immediate graft function [27]. As expected with longer ischemic times, renal tubular expressions of TLR4 and HMGB1 are higher in kidneys from deceased than living donors.

These findings support the concept that DAMPs that are ligands for TLR4 on renal epithelial cells promote inflammatory responses immediately after transplantation. TLR2 has also been implicated in experimental models of renal ischemia–reperfusion [30]. However, the effects of DAMPs on dendritic cells are more diverse and depend on the specific DAMP as well as the stage of maturation and type of dendritic cell.

HMGB1 has been linked to many steps in the maturation of dendritic cells for antigen presentation, including upregulation of MHC and costimulatory receptor expression on the cell surface, and increased production of proinflammatory cytokines [28]. In contrast, another DAMP that also is a ligand for TLR4, the S100A8/A9 heterodimer (calprotectin), protects the kidney from ischemia–reperfusion injury [29]. A third ligand for TLR4, hyaluronan, elicits a spectrum of effects. As an undegraded component of extracellular matrix, hyaluronan maintains quiescence and tissue integrity, but in sites of inflammation, hyaluronan is cleaved and the resulting fragments can exert pro- or anti-inflammatory effects depending on the fragment size [31]. The diversity of responses is related to the interaction of multiple receptors with hyaluronan. Depending on its size, hyaluronan can cross-link TLR4, CD44 (and its variants), Receptor for

Hyaluronan-Mediated Motility (RHAMM), and possibly TLR5 in various combinations.

Cold ischemic times of 24 h, which are not unusual for clinical renal transplants, induce dramatic changes in the dendritic cells of renal isografts between genetically identical rats [32]. Within 12 h after transplantation, about half of the donor dendritic cells migrate out of the kidney. Migration of dendritic cells is orchestrated by the downregulation or uncoupling of E-cadherin and chemokine receptors that retain immature cells in the tissue (CCR1, CCR2, and CCR5) and upregulation of other receptors (CXCR4 and CCR7) that direct the cells to T-cell compartments of the spleen and lymph nodes [33]. CCR7 is the receptor for CCL19 and CCL21, which are expressed on high endothelial cells and in the T-cell compartments of lymph nodes and spleens [34]. CXCL12 synergizes with the CCR7 ligands to direct dendritic cells to T-cell compartments where antigen presentation is most effective.

The surgically constructed vascular anastomoses allow dendritic cells to migrate from transplanted organs to the spleen. Migration of dendritic cells to lymph nodes has also been documented, even though the lymphatic vessels are not reconstructed [35–37]. The large numbers of leukocytes that emigrate from transplants via lymphatics are released into the peritoneal or thoracic cavity depending on the site of the transplant and reenter the lymphatic system of those cavities.

In addition to the efflux of antigen-presenting cells from the transplant, ischemia–reperfusion initiates an influx of leukocytes into the transplant. Both hypoxia and ligands for TLR2 and 4, such as uric acid, induce endothelial cells to exocytose contents of Weibel–Palade storage granules content, including von Willebrand factor and P-selectin [38]. These adhesion molecules initiate platelet accumulation and activation, which has been documented to occur within 20–40 min after the circulation is established to kidneys transplanted from deceased donors, but not from living donors [8]. This is accompanied by translocation of P-selectin from alpha-storage granules to the surface platelets. A more extended kinetic study of adhesion molecules demonstrated that expression of P-selectin was maximal between 2 and 6 h after transplantation in both renal isografts and allografts in rats [39]. Neutrophils that expressed both L-selectin and LFA-1 localized to the grafts by 2 h and maximized between 12 and 24 h. Expression of P-selectin glycoprotein ligand-1 (PSGL-1) is critical to neutrophil localization and subsequent immune responses to transplants because treatment with soluble PSGL inhibits not only neutrophil accumulation but also upregulation of E-selectin and MHC class II [40].

More recently, a subpopulation of resident macrophages in the kidney have been found to modulate the influx of neutrophils following ischemia–reperfusion [41]. The modulatory macrophages express the sialoadhesion molecule (CD169) and are located in close proximity to the capillary endothelium in the renal medulla. Depletion of this subpopulation of macrophages increases baseline ICAM-1 expression on endothelial cells.

Concomitant with upregulation of adhesion molecules, the microvascular endothelium and underlying epithelial cells produce chemokines and cytokines, including IL-1, IL-6, IL-8 (CXCL8), CCL2 (MCP-1), and TNFα that augment

migration of inflammatory cells into the transplant [42,43]. In human renal transplants, mRNA for IL-8, a potent neutrophil chemoattractant, increases in the reperfusion phase. The increase is greater in kidneys from deceased than living donors, and the increase correlates with duration of ischemia [44].

Besides releasing antigenic substrates, damaged and dying cells engage other components of the innate immune system [45]. The initial components of the complement cascade are essential for the clearance of damaged tissues. Both C1q and mannose binding lectin (MBL) bind to phospholipids and nuclear components that are exposed in the processes of regulated cell death and necrosis. With normal levels of cell turnover, C1q and MBL opsonize apoptotic bodies for phagocytosis by monocytes and macrophages without inducing inflammation [46].

These processes likely predominate when kidneys are transplanted from living donors. With deceased donors, however, brain death and longer ischemic times produce greater amounts of damaged and dying cells that bind C1q and MBL in quantities sufficient to activate more components of the complement cascade. Simultaneously, some of the regulators of complement activation that normally protect tissues from damage are downregulated following ischemia–reperfusion [47]. Under these conditions, the complement cascade progresses to activation of the terminal complement components that begins with the cleavage of C5. C5a, the small split product of C5, is a potent chemoattractant and activator of neutrophils and monocytes. These proinflammatory mechanisms may be favored in the kidney where local production of complement components and C5a receptors are upregulated by tubular epithelial cells in organs from deceased donors [48,49].

44.5 Immediate Adaptive Immune Responses to Allografts

The innate responses do not require any previous exposure to antigens and are immediately deployed in response to transplants because the receptors for DAMPs are constitutively expressed. In contrast, the preponderance of adaptive immune responses evolve after exposure to the allograft expands antigen-specific cells through proliferation and selection. However, previous exposure to transplant antigens or cross-reactive antigens can result in immediate adaptive immune responses to allografts.

Before 1969, about 20% of renal transplants from deceased donors were rejected within minutes to hours after circulation was reestablished [50]. This hyperacute rejection was characterized by extensive margination of neutrophils within 1 h, which progressed to endothelial damage, intracapillary fibrin microthrombi, and hemorrhage [51,52]. The first reports of hyperacute rejection implicated antibodies as the mediator because all of the patients had been exposed to transplant antigens through blood transfusions, pregnancies, or previous failed transplants. Consequently, most of the patients had measurable antibodies in their sera to donor tissue prior to transplantation. Moreover, IgG deposits were demonstrated in postoperative biopsies by immunofluorescence and antibody was eluted from the rejected transplant [52]. In 1969, Patel and Terasaki published convincing evidence that a serological cross-match test could

detect antibodies associated with hyperacute rejection [50]. Hyperacute rejection has been almost completely avoided since this test was introduced to screen potential recipients before transplantation.

Even in the absence of exposure to transplant antigens, some T cells do respond immediately to allografts. These immediate responders are memory T cells that accrue from a lifetime of exposure to pathogens and other environmental stimuli. The memory response of cross-reactive T cells is termed heterologous immunity [53]. Cross-reactivity occurs because the TCR interacts with only limited surfaces of the MHC molecule and the bound peptide. As a result, cross-reactivity is based on about five amino acids of the peptide that are projecting from the groove of the MHC and the adjacent surfaces of the MHC itself. After responding to an antigen, a population of memory T cells develops, which is primed for activation at a much lower threshold. This allows memory T cells to respond to cross-reactive peptide-MHC complexes with a much lower affinity for their TCR. Unequivocal evidence of cross-reactivity for transplant antigens has been demonstrated with clones of T cells produced to a virus that also respond to allogeneic cells [54].

In contrast to naïve T cells that are guided by CCR7 homing receptor to circulate through blood and lymphoid tissues, memory T cells upregulate adhesion receptors such as LFA-1 (CD11a) and CD44, which enhance emigration into transplants [55]. As a result, heterologous immunity manifests within hours after transplantation as an infiltrate memory T cell [56]. The influx of memory T cells is directed by the upregulation of adhesion molecules on endothelial cells. Extended ischemia times increases expression of adhesion molecules on vascular endothelium, which significantly increases the magnitude and effector functions of early memory T-cell infiltrates [57]. Infiltrating memory T cells are activated by direct antigen presentation on donor dendritic cells remaining in the graft and endothelial cells as well as by parenchymal cells [58,59].

44.6 *De Novo* Adaptive Responses to Transplants

In the absence of immunosuppression, *de novo* T-cell and B-cell responses can be detected in spleens, lymph nodes, and bone marrow within days after organ transplantation. The integrated structure and ordered movement of cells in spleen and lymph nodes promote effective interactions between antigen-presenting cells, T cells and B cells. Indirect presentation of alloantigens to naïve T and B cells is dependent on organized secondary lymphoid tissues. Acute rejection of cardiac allografts is abrogated in mice lacking spleen and lymph nodes [60]. T-cell responses to indirectly presented antigen were undetectable in these mice and the response to directly presented antigen is shifted from production of IL-2 and IFNγ to IL-4 and IL-10. These mice also did not produce detectable alloantibody responses. The absence of alloantibody responses is consistent with evidence that the spleen is the primary cite of alloantibody production to cardiac allografts in mice [61].

44.7 Acute Rejection Caused by T Lymphocytes

Extensive experimental data have established that thymus-derived lymphocytes can cause acute rejection of allografts. The experimental approaches include passive transfer of lymphocytes beginning with early work of Billingham, Brent, and Medawar [62], and extending through more refined transfers of subpopulations of T cells. T cells were further implicated by experiments demonstrating that transplants to neonatally thymectomized mice and mutant athymic mice were not rejected [63]. Finally, experiments with monoclonal antibodies and genetically modified mice have identified different functions for CD4 and CD8 T cells in acute rejection of organ allografts [14,64]. Cytotoxic CD8 that react to intact allogeneic MHC through direct presentation are capable of engaging MHC on allogeneic cells in grafts and causing cell death through the release of perforin and granzymes. In contrast, T cells generated in response to indirect antigen presentation cannot react to allogeneic MHC on the transplant except in cases where donor and recipients share MHC antigens. Otherwise, infiltrating dendritic cells or macrophages of recipient origin are required. Graft damage results from inflammation orchestrated by cytokines released from T cells. Although cytokines have very redundant effects, some have been found to correlate consistently with rejection. One of the most reproducibly detected is CXCL9 (Mig), which has been reported to correlate with acute rejection in biopsies of cardiac and renal transplants [65,66]. In a longitudinal study of endomyocardial biopsies, the expression of CXCL9 (Mig), CXCL10 (IP-10), CXCL11 (I-TAC), CCL5 (RANTES), CXCR3, and CCR5 were found to mirror the timing and grade of acute rejection episodes in cardiac allografts [65].

Improved immunosuppressive drugs have dramatically decreased acute T-cell-mediated rejection. From 1970 to 1977, only about 50% renal transplants from deceased donors survived 1 year [67]. Currently, 1-year renal graft survival is greater than 90% [68].

44.8 Antibody-Mediated Acute Rejection

Although hyperacute rejection provided proof of principle that antibodies can destroy allografts, antibodies were not considered a primary cause acute rejection until more sensitive markers were developed to detect antibody-mediated reactions in transplants. Routine immunofluorescent stains for IgM, IgG, and complement that were applied in hyperacute rejection did not provide evidence of antibody-mediated acute rejection [69]. The complement split product C4d became the first reliable diagnostic marker of acute antibody-mediated rejection [70,71]. C4d has several advantages for immunohistology. As a product of enzymatic cleavage, neoepitopes are exposed, which increase the specificity of monoclonals that react only with this activated complement component and not with the circulating native molecule. Sensitivity is increased because the enzymatic process cleaves many C4 molecules and C4d binds covalently with tissues. However, C4d was quickly recognized as an imperfect surrogate for complement-mediated injury to transplants [72]. Complement is

a multidimensional system that progresses from a largely anti-inflammatory series of mediators to extremely proinflammatory mediators [73]. The initiating components of the classical and lectin pathways of complement, C1q and MBL, are crucially important in clearing damaged and dying cells by macrophages without inciting inflammation [74]. Split products of the central complement component, C3, have a balance of modulatory effects on the immune system [75]. However, the progression of complement activation from C3 to C5 generates the soluble split product C5a, which is an extremely potent chemoattractant and activator for neutrophils and monocytes. Of relevance to antibody interactions, C5a stimulates macrophages to downregulate inhibitory FcgR and upregulate activating FcgR [76]. The potential harmful effects of the proinflammatory terminal complement components on endothelial cells are kept in check by multiple regulators of complement, many of which act on the enzymatic components of C1, MBL, C3 convertases, and C5 convertases. As a result, C5 and the subsequent complement components are only activated when the capacity for regulation is exceeded or the expression of regulators is decreased [48].

The vascular distribution of C4d reinforced the concept that endothelial cells are the primary targets of antibody action. Molecular assays on renal biopsies have delineated sets of gene transcripts that further implicate endothelial injury in association with circulating antibodies. These molecular signatures are frequently increased in the absence of C4d deposits [77] and are now incorporated into the diagnostic criteria for antibody-mediated rejection [71]. The recognition of a C4d negative category of antibody-mediated rejection is indicative of antibody functions that require either low levels of complement activation or no complement activation.

Several mechanisms of complement independent antibody functions have been defined in the context of transplants. Antibodies with sufficient avidity to cross-link MHC class I antigens stimulate endothelial cells to exocytose von Willebrand factor and P-selectin *in vitro* and *in vivo* [78,79]. These mediators rapidly bind and activate platelets and macrophages. Platelet storage granules contain a wide array of mediators that could potentially promote antibody-induced inflammation [80]. Of all these mediators, platelet factor 4 (PF4; CXCL4) is quantitatively most abundant [81]. In an experimental model of acute antibody-mediated rejection, PF4 and serotonin were recovered from renal allogarfts in much greater quantities than other cytokines stored in platelet alpha granules [78].

The expression of P-selectin by activated endothelial cells and platelets augments interactions with neutrophils and monocytes through P-selectin glycoprotein ligand-1 (PSGL-1). P-selectin expressing platelets attached to macrophages are evident by immunohistology in capillaries and venules of mouse and human renal allografts [78]. The effects of platelets on skewing macrophage function toward inflammation or wound healing functions in transplants is not known. However, PF4 has been demonstrated to elicit a distinct differentiation profile in macrophages *in vitro* that has been labeled M4 [82]. Clinically, antibody-mediated rejection has been associated with infiltrates of macrophages, and glomerular monocytes predict poorer graft outcomes [83].

In addition to regulating inflammatory responses by cross-linking MHC antigens on endothelial cells, antibodies can regulate neutrophil, monocyte, and NK cell function by binding with different types of Fc receptors [84]. Although the effects of activating (human FcγRI, FcγRIIA, and FcγRIIIA) and suppressing (human FcγRIIB) receptors for IgG have been appreciated for a long time [85], some single nucleotide polymorphisms and splice variants result in increased expression and function of specific Fc receptors on neutrophils and monocytes [86].

44.9 Chronic Rejection

Although advances in immunosuppressive drugs have steadily decreased the incidence and severity of acute rejection, progress in understanding and treating chronic deterioration of transplant function has been limited [87]. Many factors can be compounded over the course of years to result in chronic graft dysfunction. For example, with the persistent shortage of organs for transplantation, criteria for age and graft quality have been expanded, and these variables are associated with risk of chronic graft dysfunction. However, the dominant variable in clinical transplantation is immunosuppression. Excess immunosuppression can result in injury to the graft due to drug toxicity, opportunistic or recurrent infection, or cancer. Conversely, insufficient immunosuppression, either due to unrecognized subclinical rejection or nonadherence to medications, allows alloimmune responses to emerge. Surveillance biopsies of renal allografts with good function at 1 year confirm that about 75% of the transplants have no evidence of rejection, but the remainder have either subclinical cell-mediated rejection or subclinical antibody-mediated rejection [88]. Biopsies with subclinical antibody-mediated rejection were prognostic of a higher risk of eventual rejection over the subsequent 7 years. Antibody-mediated rejection is even more frequent in biopsies of renal transplants from patients with clinical evidence of rejection, and a large proportion of these patients are nonadherent [89]. The incidence of new antibody to donor HLA developing gradually increases following a first renal allograft to about 20% at 10 years, and is about three times higher in nonadherent patients [90]. Current diagnostic methods probably underestimate the contribution of antibody to chronic rejection. This relates to fluctuations in antibody levels over time and complement-independent effects of antibody [91]. Advances in molecular markers to identify tissue responses may begin to distinguish underlying mechanisms of graft injury.

44.10 Tolerance

The inherent risks of prolonged exposure to broad-spectrum immunosuppression have intensified the search for more specific regulation of the immune system. In 1953, Billingham, Brent, and Medawar demonstrated that inoculation of fetal mice (and rats, rabbits, and birds in later papers) with viable allogeneic tissue resulted not only in the acceptance of the initial tissue by the immature animal but also

tolerance of later transplants from the original or genetically identical donors [92]. Viable tissue introduced while the immune system is immature provides stem cells that can lodge in central lymphoid tissues (bone marrow and thymus) and participate in the negative selection of the lymphocytes. Negative selection is the normal process to eliminate lymphocytes that could react to autologous antigens. Deletion of lymphocytes by this mechanism is referred to as "central tolerance" [93]. Lymphocytes that escape deletion by central tolerance can be nullified by several mechanisms, including anergy and regulation, which are collectively termed "peripheral tolerance." Anergy and regulation occur when lymphocytes receive a signal through their antigen receptor but they either receive no second signal (anergy) or receive an inhibitory second signal (regulation). Tolerance is the ideal outcome for a transplant because it results in graft acceptance without compromising other immune functions.

In adults, tolerance can be attained when their immune system is ablated and then reconstitutes in the existence of allogeneic cells. The treatment protocols to ablate the adult immune system are complicated and intense. However, several strategies to achieve tolerance in adults are in clinical development [94–96]. When successful, these tolerance protocols will result in enduring graft function without immunosuppression. Again antibody-mediated rejection has been the most frequent cause of failure.

A minority of transplant recipients becomes tolerant to their transplants on conventional immunosuppression. Most often these patients independently decide to stop their medications and retain good graft function unlike the majority of nonadherent patients who experience acute or chronic rejection. Spontaneous tolerance has been most frequently reported for hepatic transplants (in the range of 20–40%) and much less frequently for renal transplants [97]. Extensive studies of these patients suggest that the mechanisms may be different for liver and kidney. Genes related to iron metabolism and natural killer cells have been found to be upregulated in peripheral blood of patients tolerant to hepatic but not in those tolerant to renal transplants [97,98]. In contrast, B cells and B-cell-related transcripts are increased in peripheral blood of patients tolerant to renal but not in those tolerant to hepatic transplants. However, these studies are based on small numbers of patients and there is not total agreement among different reports. Therefore, there are no tests that adequately predict patients who are prone to tolerance and can be safely allowed to discontinue immunosuppression. Attempts to purposefully wean patients off immunosuppression have been much more successful for hepatic than renal transplants. In one large study of 104 patients with hepatic transplants, the strongest predictor of successful withdrawal of immunosuppression was time after transplantation; the success rate was almost 80% for the patients undergoing withdrawal more than 10 years after transplantation compared to 12.5% success at less than 6 years after transplantation [99].

44.11 Tolerance and Accommodation of Blood Group Mismatched Transplants

A limited form of neonatal tolerance has been achieved for blood group incompatible cardiac transplants. Transplants mismatched for the major blood

group antigens are at risk for hyperacute rejection as the result of "natural" antibodies binding to the A and B antigens that are highly expressed on vascular endothelial cells. However, natural antibodies to A and B do not develop until after the first few months of life when the immune system is exposed to antigens on bacteria in the expanding gut flora that cross-react with blood group antigens. Blood group incompatible transplants performed before these cross-reactive antibodies are generated are not at risk for hyperacute rejection. Moreover, when newborns are transplanted with an A or a B antigen-incompatible heart, they are tolerized to the incompatible antigen and do not develop antibodies or B cells reactive to the blood group expressed on the graft [100]. Tolerance may be favored because these blood group antigens have distinctive properties [101]. The A and B antigens are carbohydrate groups that are expressed on a range of soluble and cell-bound proteins. This permits widespread exposure of the developing immune cells to these antigens.

After many years of avoiding blood group-incompatible renal transplants in adults because of the risk of hyperacute rejection, the increasing shortage of acceptable donor organs instigated reexamination of this source for living related donors who were well matched for HLA antigens. The major blood group antigens are encoded on a different chromosome than HLA (9 versus 6) and therefore inherited independently. As a result, about 40–50% of HLA-matched siblings are blood group incompatible. Hyperacute or acute rejection is avoided in these transplants by removal of antibodies through immunoadsorption or plasmapheresis before and during the first weeks after transplantation. Subsequent return of antibodies to the A or B blood group is often associated with the deposition of C4d on the vascular endothelium of the graft. However, these products of complement activation are usually not associated with evidence of inflammation or graft dysfunction [101]. This outcome is termed "accommodation." The mechanisms underlying accommodation are not fully understood, but upregulation of complement regulatory molecules on the vessels of the transplant may contribute.

44.12 Organ-Specific Inflammation

Since the introduction of cyclosporine, many organs, including liver, heart, lung pancreas, intestine, and various composite tissues, have been routinely transplanted. However, kidneys are the most frequently transplanted organs. In part this is due to greater number of donor organs because of the availability of living donors. Lobes of livers or lungs are also transplanted from living donors, but these operations have a higher risk and are usually limited to adult donors and pediatric recipients. There is more flexibility for kidneys from deceased donors as well because patients with delayed graft function can be supported on dialysis. Predictably, delayed graft function does increase the liability of tissue injury and decrease outcomes.

Although much of the experience with kidneys is applicable to other organ allografts, there are notable differences. The apparent immunogenicity of organs differs greatly in part due to the number and type of resident antigen-presenting cells, and also the content of lymphoid tissue. Most obviously, lungs and intestine

contain bronchial- and gut-associated lymphoid tissues (BALT and GALT). In addition, the lung and intestine are constantly exposed to microbial encounters. Lung transplants have also been found to be subject to inflammation from gastric reflux [102]. In contrast, the liver contains stellate cells that have been found to be tolerogenic [103].

This hierarchy of immunogenicity is evident in survival of experimental and clinical transplants. Clinically, transplants of kidney, liver, and heart have superior survival rates compared to lung or intestine. In mice, hepatic allografts are spontaneously accepted even between strains with major and minor histoincompatibilities [104].

The targets of rejection also vary among organs. Capillary endothelium is the primary target of acute rejection especially for antibody-mediated rejection, but endothelial cells are not uniform throughout the vascular system. For example, expression of adhesion molecules varies according to specific environmental and functional requirements [105,106]. In cell-mediated rejection, the infiltrating T cells encounter different parenchymal cells after emigrating through the endothelial layer.

The chronic changes induced in transplanted organs are also divergent. In hearts, the primary lesion is a proliferative neointima that impinges on blood flow in the epicardial coronary arteries and negligible pathological changes in capillaries [107]. In contrast, multilayering of glomerular and peritubular capillary basement membranes occurs in chronic rejection of renal allografts. This may reflect the different susceptibility of these organs to antibody-mediated injury. In lungs, the airways are sites of chronic rejection as would be predicted from constant exposure to inflammatory stimuli.

44.13 Treatment

The long-term success of the first renal allograft between genetically identical twins proved that transplanted organs could sustain life. However, transplants between genetically disparate living individuals before the development of immunosuppression were rejected acutely by antibody and cellular mechanisms [108]. Elion and Hitchings were awarded the Nobel Prize for developing a series of antiproliferative drugs including azathioprine that was the first effective immunosuppressive drug in transplants [109]. Azathioprine produced short-term renal allograft survival. Startzl added steroids to azathioprine and achieved the first long-term survival of renal transplants [110]. The major impact of steroids reflects the importance of modulating inflammatory responses to the transplant.

The introduction of cyclosporine A, a calcineurin inhibitor that decreases production of IL-2 and a set of inflammatory cytokines, including IL-4, IFNγ, and TNFα, controlled by the transcription factor nuclear factor of activated T cells (NFAT) elevated long-term survival of renal transplants and allowed the realization of transplants of other organs, including heart. Unfortunately, the benefits of calcineurin inhibitors are counterbalanced by serious adverse effects, including nephrotoxicity and new onset diabetes mellitus [111,112].

The adverse effects of chemically derived drugs has propelled development of biopharmaceutical or biologic agents, the most common of which are antibodies to immune competent cells, mediators, cell receptors, or adhesion molecules. Antibodies have the advantage of specificity and long half-life in the circulation. Monoclonal antibodies offer the advantage of standardized formulations and monoclonals produced in mice or other animals can be genetically "humanized" to diminish immune elimination. Soluble receptors or antagonists can be produced as fusion molecules with immunoglobulins to increase the half-life and to achieve higher affinity of dimeric forms. Examples of all of these types of biologics are in clinical application. One of the most commonly used biologic is antithymocyte globulin (ATG), polyclonal antibodies produced in rabbits to human thymocytes, that reacts primarily with T cells, but also with other leukocytes. Treatment with ATG at the time of transplantation and during the first few days afterward (induction therapy) causes leukopenia and decreases the incidence of acute rejection [113]. Monoclonal antibodies directed to the receptor for IL-2 are also used for induction therapy. More recently, CTLA4-Ig, a fusion protein between a soluble T cell costimulatory receptor (cytotoxic T-lymphocyte-associated protein 4) and immunoglobulin (Ig), has been demonstrated to provide effective immunosuppression and avoid nephrotoxicity [114].

Although these biologics have improved outcomes in transplantation, the resultant immune suppression is not antigen specific. Strategies to produce antigen-specific immune suppression have centered on enhancing the regulatory functions of immunity [115]. Regulation is a critical mechanism to modulate every phase of immune responses. Antigen-specific regulation is achieved by delivery of inhibitory signals in conjunction with the antigen. Inhibitory signals can be delivered through coreceptors or anti-inflammatory cytokines. Important inhibitory coreceptors on T cells include CTLA4, programmed cell death protein 1 (PD1), B- and T lymphocyte attenuator (BTLA), and lymphocyte-activation gene 3 (LAG3). IL-10 and TGFβ are anti-inflammatory cytokines that are produced by a variety of regulatory immune cells including T cells, B cells, dendritic cells, and myeloid-derived suppressor cells (MDSCs). Clinical studies are underway to expand regulatory cells *in vitro* for administration to patients [116].

44.14 Modulating Inflammation to Improve Transplantation in the Future

The recognition of inflammation as a fundamental component of transplantation has focused research on potential modulatory interventions. Transplants are particularly vulnerable to inflammation during procurement, transport, surgery, and reperfusion. These are all modifiable processes. Belzer pioneered the development of preservation solutions and perfusion pumps that counteracted organ deterioration during procurement and transportation [117]. Many of the advances were centered on metabolic and physiological considerations. More recently, immunological interventions have been introduced, including the use of

complement inhibitors [118]. The benefits of decreasing metabolic demands by cold storage is now challenged by evidence that normothermic perfusion can not only maintain viability but also reverse some injury [119,120]. Normothermic perfusion can decrease the antigenic content of organs by depleting emigrating donor leukocytes before transplantation [121]. Even more enticing is the potential to modify organs by the introduction of beneficial genetic alterations [122]. Application of these approaches will improve the currently acceptable organs and will greatly expand the available organs by allowing evaluation and repair of marginal organs.

Some existing interventions may need to be reevaluated for potential effects on the inflammatory component of transplantation. For example, new evidence suggests that cyclosporine A inhibits mitochondrial dysfunction during reperfusion [123]. Exploiting the effects of cyclosporine on reperfusion could enhance current protocols that focus only on its immunosuppressive functions [124].

In summary, inflammation is unavoidable in organ transplantation and if not modified can be a factor undermining graft outcomes.

Inflammatory Mechanisms in Chronic Obstructive Pulmonary Disease

Peter J. Barnes

National Heart and Lung Institute, Imperial College School of Medicine, Dovehouse St, London, SW3 6LY, UK

45.1 Introduction

Chronic obstructive pulmonary disease (COPD) is a major global epidemic that is increasing throughout the world as populations age and survive previous causes of death [1]. COPD is now the fourth ranked cause of death worldwide and predicted to become the fifth ranked cause of disability, affecting approximately 10% of people over 45 years [2]. In developed countries, COPD now affects females and males equally, reflecting the equal prevalence of smoking. It is now recognized that there are different clinical phenotypes of COPD, with some patients having predominantly small airway disease, whereas others have mainly emphysema. Other differences include the age of onset, the frequency of exacerbations, and the association with other diseases such as chronic cardiovascular and metabolic diseases (comorbidities). Several attempts have been made to segregate COPD patients into different clusters based on clinical and radiological characteristics, but it has been difficult to identify these phenotypes in different populations and there has been no link to underlying disease mechanisms (endotypes) [3,4].

COPD is associated with chronic inflammation of the airways and lung parenchyma, which increases further during acute exacerbations and is also associated with systemic inflammation [5]. Although the nature of this inflammation in COPD lungs has been well described, it is still uncertain how this relates to clinical outcomes, disease progression, and response to different therapies, and more research is needed to understand this better. Longitudinal studies of COPD populations over many years have demonstrated that only about 50% of patients diagnosed with COPD have an accelerated decline in lung function, whereas the remainder has a normal age-related decline but start from a lower value, presumably due to impaired lung development [6]. This implies that only half pof "COPD" patients have inflammation and the normal decliners presumably do not have so, although in most studies no distinction is made as the trajectory of lung function is unknown.

Inflammation: From Molecular and Cellular Mechanisms to the Clinic, First Edition.

More research is urgently needed to understand different patterns of lung inflammation in COPD and how they relate to clinical outcomes, response to therapy, and prognosis. In particular, it is necessary to understand how inflammation changes in response to different environmental stimuli and how it changes over time in the same patient. COPD from different causes may differ, but the COPD associated with indoor air pollution appears to have a very pattern of inflammation similar to that seen in smoking-related COPD, suggesting that the respiratory tract may respond to different risk factors in the same way [7]. This review discusses the nature of inflammation in COPD and the underlying molecular mechanisms that may identify new targets for more effective anti-inflammatory therapy in the future [8].

45.2 Pathology of COPD

The progressive airflow limitation in COPD results from two major pathological processes: remodeling and narrowing of small airways and destruction of the lung parenchyma with consequent loss of the alveolar attachments of these airways as a result of emphysema. These pathological changes appear to be the consequence of chronic inflammation in the lung periphery, the intensity of which increases as the disease progresses [9]. Even in mild disease there is obstruction and loss of peripheral airways [10]. Analysis of serial computed tomography scans suggests that small airway obstruction usually precedes the development of emphysema [11], but the mechanisms for this are not clear. The small airway obstruction and loss of alveolar attachments result in airway closure and air trapping on expiration that is worsened by exercise and dynamic hyperinflation may account for exertional dyspnea, the major symptom of COPD patients, even in patients with mild disease [12,13]. It is presumed that the peripheral location of inflammation in COPD reflects the sites of deposition of inhaled irritant particles, such as cigarette and wood smoke. Indeed, in COPD associated with household air pollution (biomass smoke) in developing countries, small airway disease is predominant, whereas in cigarette smokers small airway disease and emphysema often coexist [14]. The pattern of inhalation of irritants may also determine localization, since wood smoke is usually inhaled tidally, where cigarette smoke is often inhaled deeply with a breath hold. This may be seen particularly in smokers of cannabis (marijuana) cigarettes, who may develop marked emphysema [15].

45.3 Characteristics of COPD Inflammation

In COPD, there is a characteristic pattern of inflammation with increased numbers of neutrophils in the airway lumen and increased numbers of macrophages, T lymphocytes, and B lymphocytes [9,16,17]. The inflammatory response in COPD involves both innate and adaptive immune responses, which are linked through the activation of dendritic cells [18]. A similar pattern of inflammation and mediator expression is found in smokers without airflow limitation, but in

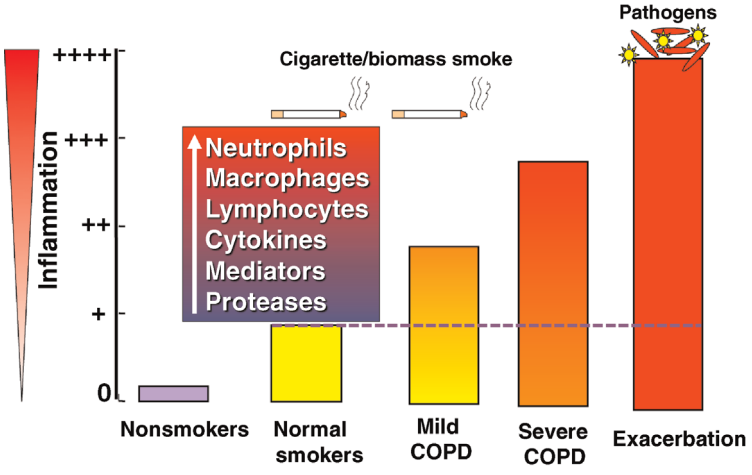

Figure 45.1 Amplification of inflammation in COPD compared to smokers who do not develop airway obstruction. Once established, this inflammation persists even after smoking cessation. Inflammation is further increased in acute exacerbations, triggered by bacteria or viruses.

COPD this inflammation is amplified and even further increased during acute exacerbations precipitated by bacterial or viral infection (Figure 45.1). The molecular basis for the amplification of inflammation is not yet fully understood but may be, at least in part, determined by genetic and epigenetic factors. The molecular mechanisms of amplification may determine which smokers are susceptible to the development of airway obstruction. Cigarette smoke and other irritants inhaled into the respiratory tract may activate surface macrophages and airway epithelial cells to release multiple chemotactic mediators, particularly chemokines, which attract circulating neutrophils, monocytes, and lymphocytes into the lungs. This inflammation persists even when smoking is stopped, suggesting that there are self-perpetuating mechanisms, although they have not yet been elucidated [19]. It is possible that long-lived memory T cells, bacterial colonization, or autoimmunity may drive the persistent inflammation in COPD patients.

45.4 Inflammatory Cells

The inflammation of COPD lungs involves both innate immunity (neutrophils, macrophages, eosinophils, mast cells, NK cells, γδ-T-cells, innate lymphoid cells, and dendritic cells) and adaptive immunity (T and B lymphocytes), but there is also activation of structural cells, including airway and alveolar epithelial cells, endothelial cells, and fibroblasts.

45.4.1 Epithelial Cells

Epithelial cells are activated by cigarette smoke and other inhaled irritants such as biomass fuel smoke to produce inflammatory mediators, including tumor

necrosis factor(TNF)-α, interleukin(IL)-1β, IL-6, granulocyte-macrophage colony-stimulating factor (GM-CSF), and CXCL8 (IL-8) [20]. Epithelial cells in small airways express transforming growth factor (TGF)-β, which then induces local fibrosis. Vascular endothelial growth factor (VEGF) appears to be necessary to maintain alveolar cell integrity and blockade of VEGF receptors (VEGFR2) in rats induces apoptosis of alveolar cells and an emphysema-like pathology [14]. A reduction in peripheral lung concentration of VEGF is found in smokers and COPD patients, but another growth factor hepatocyte growth factor (HGF) is increased in smokers and may therefore protect against the reflect of reduced VE GF on alveolar integrity, whereas in COPD both VEGF and HGF are reduced, which may contribute to development of emphysema [21]. Airway epithelial cells are also important in defense of the airways, with mucus production from goblet cells, and secretion of antioxidants, antiproteases, and defensins/cathelicidins. Cigarette smoke and other noxious agents may impair these responses of the airway epithelium, increasing susceptibility to infection. The airway epithelium in chronic bronchitis and COPD often shows squamous metaplasia, which may result from increased proliferation of basal airway epithelial cells but the nature of the growth factors involved in epithelial cell proliferation, cell cycle, and differentiation in COPD are not yet certain. Epithelial growth factor receptors (EGFR) show increased expression in airway epithelial cells of COPD patients and may contribute to basal cell proliferation, resulting in squamous metaplasia and an increased risk of bronchial carcinoma [22]. Club (Clara) cells may act as progenitor cells in peripheral airways and may be susceptible to damage from inhaled irritants. Conditional depletion of club cells in mice leads to squamous cell metaplasia and peribronchiolar fibrosis, similar to the pathology of COPD [23]. Club cell secretory protein is deficient in patients with COPD [24].

Mucus hyperplasia is a feature of many patients with COPD and is a response to chronic airway irritation by cigarette smoke and other pollutants. EGFRs play an important role on mucus hyperplasia and secretion and may be activated by neutrophilic inflammation through neutrophil elastase secretion, which releases TGF-α (Figure 45.2) [25]. Oxidant stress is also able to activate EGFR and induce mucus hypersecretion [26]. An EGFR inhibitor is effective in blocking lipopolysaccharide and TNF-α-induced expression of MUC5AC in human airway epithelial cells and inhibiting LPS-induced mucus secretion and hyperplasia in rats exposed to cigarette smoke [27]. However, an EGFR inhibitor (BIBW2948) was ineffective in reducing mucon gene expression in COPD patients and was poorly tolerated [28].

45.4.2 Macrophages

Macrophages play a key role in orchestrating chronic inflammation in COPD (Figure 45.3) [29]. Macrophage numbers are markedly increased (5-10-fold) in airways, lung parenchyma, BAL fluid, and sputum of COPD patients. Macrophages are localized to sites of alveolar wall destruction in patients with emphysema and there is a correlation between macrophage numbers in the parenchyma and severity of emphysema. Macrophages may be activated by cigarette smoke extract to release inflammatory mediators, including TNF-α,

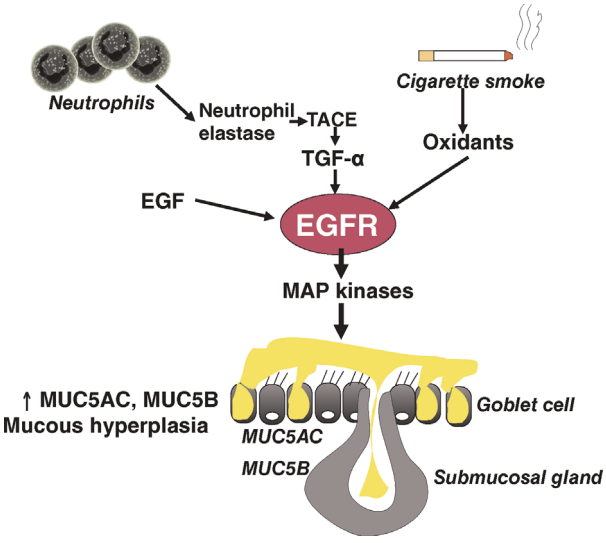

Figure 45.2 Mucus hypersecretion and hyperplasia in COPD. epithelial growth factor receptors (EGFR) may be activated by neutrophils through the effect of neutrophil elastase on TNF-α converting enzyme (TACE), which releases transforming growth factor-(TGF-α), a ligand for EGFR. EGFR may also be activated indirectly via oxidative stress. EGFR activates mitogen-activated protein (MAP) kinases, which increase expression of mucin genes MUC5AC and MUCB and also lead to hyperplasia of goblet cells and submucoisal glands.

CXCL1, CXCL8, CCL2 (MCP-1), LTB_4, and reactive oxygen species (ROS). Alveolar macrophages also secrete elastolytic enzymes, including MMP-2, MMP-9, MMP-12, cathepsins K, L, and S, and neutrophil elastase taken up from neutrophils [30]. Alveolar macrophages from COPD patients secrete more inflammatory proteins and have a greater elastolytic activity at baseline than those from normal smokers and this is further increased by exposure to cigarette smoke. Macrophages demonstrate this difference even when maintained in culture for 3 days and therefore appear to be intrinsically different from the macrophages of normal smokers and nonsmoking normal control subjects.

There are different phenotypes of macrophage that may be differentially activated and with different responses. The murine M1 of "classically activated" macrophages are proinflammatory, whereas M2 or "alternatively activated" macrophages are more anti-inflammatory and release IL-10 and show marked phagocytic activity [31]. However, these distinctions are less clear in human macrophages and the surface markers of these phenotypes less distinct. In general, it is likely that M1-like macrophages predominate in COPD but further studies are needed [32].

Matrix metalloproteinase-9 (MMP-9) is the predominant elastolytic enzyme secreted by alveolar macrophages from COPD patients. Most of the inflammatory proteins that are upregulated in COPD macrophages are regulated by the transcription factor nuclear factor-κB (NF-κB), which is activated in alveolar macrophages of COPD patients, particularly during exacerbations [33]. The

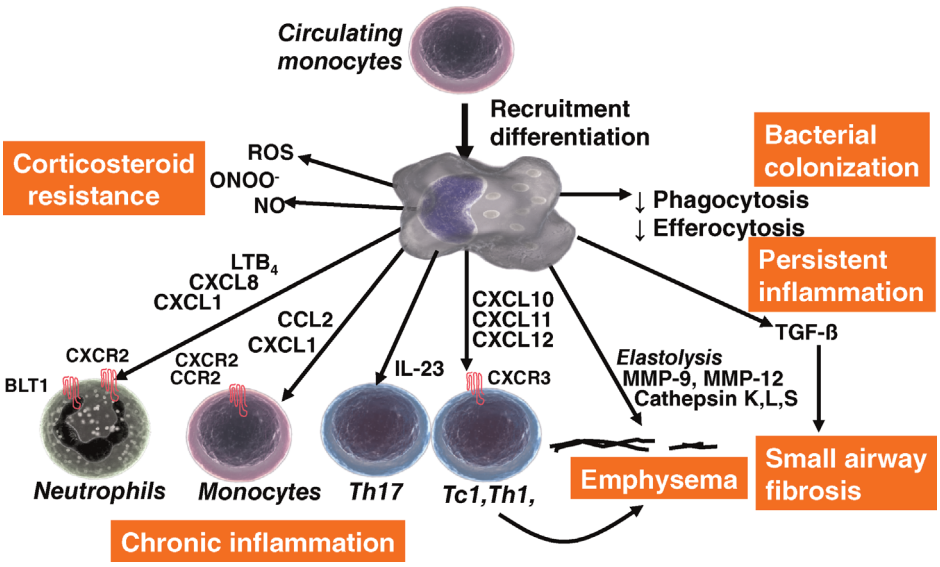

Figure 45.3 Central role of alveolar macrophages in COPD. Alveolar macrophages are derived from circulating monocytes that differentiate within the lung. They secrete many inflammatory proteins that may orchestrate the inflammatory process in COPD. Neutrophils may be attracted by CXCL8, CXCL1, and leukotriene B_4 (LTB_4), monocytes by CCL2, and Tc1 and Th1 lymphocytes by CXCL10, CXC11, and CXCL12. Release of elastolytic enzymes, including matrix metalloproteinases (MMP) and cathepsins, cause elastolysis contribute to emphysema together with cytotoxic T cells. Release of transforming growth factor (TGF)-β1 may induce fibrosis of small airways. Macrophages generate reactive oxygen species (ROS) and nitric oxide (NO), which together form peroxynitrite ($ONOO^-$) and may contribute to corticosteroid resistance. Defective bacterial phagocytosis may lead to bacterial colonization and defective efferocytosis.

increased number of macrophages in the lungs of smokers and COPD patients is due to increased recruitment of monocytes from the circulation in response to the monocyte-selective chemokines CCL2 and CXCL1, which are increased in sputum and BAL of patients with COPD [34]. Monocytes from patients with COPD show a greater chemotactic response to CXCL1 than cells from normal smokers and nonsmokers, but this is not explained by an increase in its receptor CXCR2 and appears to be due to greater receptor turnover [35]. Macrophages also release CXCL9, CXCL10, and CXCL11, which are chemotactic for $CD8^+$ Tc1 and $CD4^+$ Th1 cells, via interaction with the chemokine receptor CXCR3 expressed on these cells [36]. Macrophages from COPD patients release more inflammatory proteins than macrophages from normal smokers and nonsmokers, indicating increased activation [37].

Corticosteroids are ineffective in suppressing inflammation, including cytokines, chemokines, and proteases, in patients with COPD [38]. *In vitro* release of CXCL8, TNF-α, and MMP-9 from macrophages from normal subjects and normal smokers is inhibited by corticosteroids, whereas they are relatively ineffective in macrophages from patients with COPD [37]. The reasons for resistance to corticosteroids in COPD may be the marked reduction in activity

of histone deacetylase-2 (HDAC2), which is recruited to activate inflammatory genes by glucocorticoid receptors to switch off inflammatory genes [39]. The reduction in HDAC activity in macrophages is correlated with increased secretion of cytokines such as TNF-α and CXCL8 and reduced response to corticosteroids.

Both alveolar macrophages and monocyte-derived macrophages from COPD patients also show reduced phagocytic uptake of bacteria and this may be a factor in determining chronic colonization of the lower airways by bacteria such as *Haemophilus influenzae* or *Streptococcus pneumoniae* [40]. COPD macrophages are also defective in taking up apoptotic cells and this may contribute to the failure to resolve inflammation in COPD [41]. The nature of this defect in phagocytosis is not fully understood, but appears to be due to a defect in microtubular function that is required for phagocytosis rather than any abnormality of recognition of the phagocytosed particles [42]. Bacterial colonization of lower airways, found in at least 50% of COPD patients, may predispose to increased acute exacerbations and also to the increased risk of developing community acquired pneumonia in COPD patients [43].

45.4.3 Neutrophils

Increased numbers of activated neutrophils are found in sputum and BAL fluid of patients with COPD and correlate with disease severity, although few neutrophils are seen in airway wall and lung parenchyma, likely reflecting their rapid transit through these tissues. Smoking has a direct stimulatory effect on granulocyte production and release from the bone marrow and survival in the respiratory tract, possibly mediated by the hematopoietic growth factors GM-CSF and G-CSF released from lung macrophages. Neutrophil recruitment to the airways and parenchyma involves initial adhesion to endothelial cells via E-selectin, which is upregulated on endothelial cells in the airways of COPD patients [44]. Adherent neutrophils migrate into the respiratory tract under the direction of various neutrophil chemotactic factors, including LTB_4, CXCL1, CXCL5 (ENA-78), and CXCL8, which are increased in COPD airways. These chemotactic mediators may be derived from alveolar macrophages, T cells, and epithelial cells, but the neutrophil itself may be a major source of CXCL8. Neutrophils recruited to the airways of COPD patients are activated as there are increased concentrations of granule proteins, such as myeloperoxidase (MPO) and human neutrophil lipocalin, in the sputum supernatant [45]. Neutrophils secrete serine proteases, including neutrophil elastase (NE), cathepsin G, and proteinase-3, as well as MMP-8 and MMP-9, which may contribute to alveolar destruction. Airway neutrophilia is linked to mucus hypersecretion as neutrophil elastase, cathepsin G, and proteinase-3 are potent stimulants of mucus secretion from submucosal glands and goblet cells [46]. There is a marked increase in neutrophil numbers in the airways in acute exacerbations of COPD accounting for the increased purulence of sputum. This may reflect increased production of neutrophil chemotactic factors, including LTB_4 and CXCL8 [47]. Neutrophils from COPD patients show marked abnormalities in chemotactic response, with increased migration but reduced accuracy, reminiscent of the abnormal monocyte chemotactic responses [48].

45.4.4 Eosinophils

While eosinophils are the predominant leukocyte in asthma, their role in COPD is much less certain. Increased numbers of eosinophils have been described in the airways and BAL of patients with stable COPD, whereas others have not found increased numbers in airway biopsies, BAL, or induced sputum [39]. The presence of eosinophils in patients with COPD predicts a more favorable therapeutic response to bronchodilators and corticosteroids may indicate coexisting asthma or asthma–COPD overlap [49–51]. Approximately 15% of COPD patients appear to have clinical features of asthma [52]. The mechanisms for increased eosinophils in COPD patients are uncertain, but there has recently been considerable interest in the role of type 2 innate lymphoid cells (ILC2), which may be important in intrinsic asthma, but also in COPD [53,54]. ILC2 cells may be regulated by epithelial mediators such as IL-33, released as a result of epithelial cell injury (Figure 45.4). IL-33 expression is increased in basal epithelial progenitor cells in COPD and is associated with increased expression of IL-13 and mucin gene 5AC [55]. There appears to be considerable plasticity in ILCs and evidence that ILC2 cells may convert to ILC1 cells that release interferon(IFN)-γ after viral infection and exposure to IL-12 and IL-18 [56]. The presence of eosinophils in the airways may indicate a better response to corticosteroid therapy and therefore

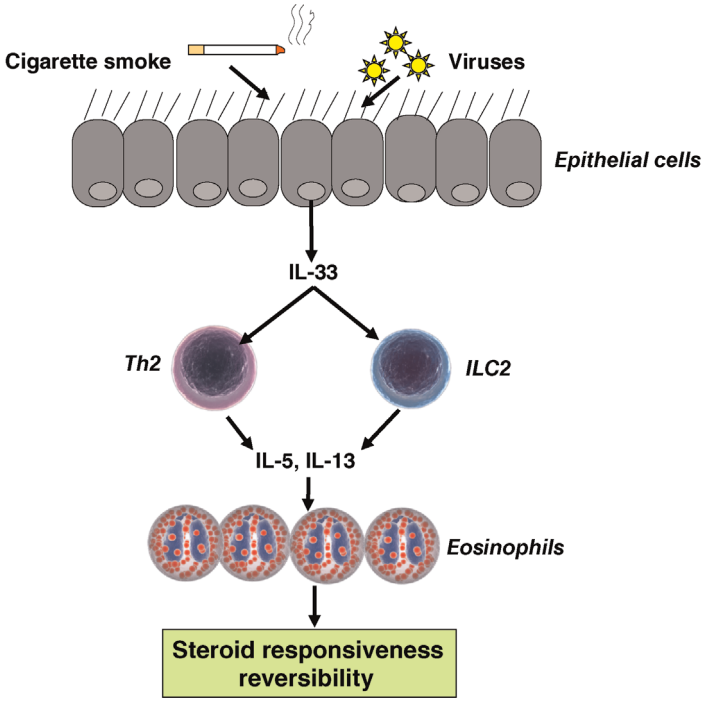

Figure 45.4 Eosinophilic inflammation in COPD. Both T helper 2 (Th2) and type 2 innate lymphoid cells (ILC2) may cause eosinophilic inflammation through the release of IL-5 and IL-13 and may result in a better response to corticosteroids and bronchodilators. Th2 and ILC2 cells may be activated by IL-33 from damaged epithelial cells.

may define a therapeutic phenotype of COPD patient. Sputum concentrations of IL-5 are correlated with sputum eosinophils and both are reduced by oral corticosteroids [57]. There is a relationship between bronchial wall eosinophils and blood eosinophils, so this may make it feasible to use blood eosinophil counts as a biomarker for steroid responsiveness in COPD patients [58]. In retrospective analyses of clinical trials, patients with increased blood eosinophils (>2% or >200/μl) show a greater reduction in exacerbations than in patients with lower eosinophils, although there was no difference in lung function or symptoms [59,60]. Increased numbers of eosinophils have been reported in bronchial biopsies and BAL fluid during acute exacerbations of chronic bronchitis [61].

45.4.5 Lymphocytes

There is an increase in the total numbers of T lymphocytes in lung parenchyma, peripheral, and central airways of patients with COPD, with the greater increase in $CD8^+$ than $CD4^+$ cells [9,36]. There is a correlation between the numbers of T cells and the amount of alveolar destruction and the severity of airflow obstruction. Furthermore, the only significant difference in the inflammatory cell infiltrate in asymptomatic smokers and smokers with COPD is an increase in T cells, mainly $CD8^+$ (Tc1), in patients with COPD [62]. There is also an increase in the absolute number of $CD4^+$ (Th1) T cells albeit in smaller numbers, in the airways of smokers with COPD and these cells express activated STAT-4, a transcription factor that is essential for activation and commitment of the Th1 lineage [63]. $CD4^+$ Th17 cells which secrete IL-17A and IL-22 are also increased in airways of COPD patients and may play a role in orchestrating neutrophilic inflammation [64,65]. Th17 cells may be regulated by IL-6 and IL-23 released from alveolar macrophages. $CD4^+$ and $CD8^+$ T cells in the lung of COPD patients show increased expression of CXCR3, a receptor activated by the chemokines CXCL9–CXCL11, all of which are increased in COPD [66]. There is increased expression of CXCL10 by bronchiolar epithelial cells and this could contribute to the accumulation of $CD4^+$ and $CD8^+$ T cells, which preferentially express CXCR3 (Figure 45.5) [67]. $CD8^+$ cells are typically increased in airway infections and it is possible that the chronic bacterial colonization of the lower respiratory tract of COPD patients is responsible for this inflammatory response.

As discussed earlier, ILCs are now thought to play an important role in regulation of lung immunity and may be regulated via danger signals and cell damage [68]. There is considerable plasticity between different subtypes of ILC in response to different triggers and cytokines. All three types of ILC have been identified in human lung [54]. In COPD, there is an increase in ILC3 cells, which secrete IL-17 and IL-22, and they may play a role in driving neutrophilic inflammation.

Autoimmune mechanisms may also be involved. Cigarette-induced lung injury may uncover previously sequestered autoantigens or cigarette smoke itself may damage lung interstitial and structural cells and make them antigenic. Oxidative stress may result in the formation of carbonylated proteins that are antigenic and several anti-carbonylated protein antibodies have been found in the circulation of COPD patients, particularly in severe disease [69]. Antiendothelial antibodies

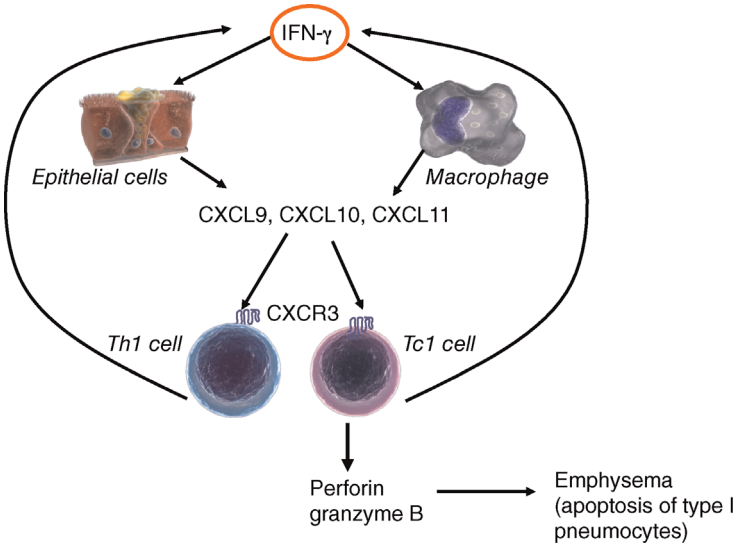

Figure 45.5 Lymphocytes in COPD. Epithelial cells and macrophages release the chemokines CXCL9, CXCL10, and CXCL12 that activate CXCR3 on Th1 and Tc1 cells, which release interferon (IFN)-γ, which in turn causes further release of these chemokines. Tc1 cells are cytotoxic because of the release of perforin and granzyme B, which may contribute to alveolar cell apoptosis and the development of emphysema.

have also been detected [70]. Autoantibodies may cause cell damage through the binding of complement, which is increased in the lungs of COPD patients [69]. Citrullinated proteins are also described in the lungs of COPD patients and may induce autoantibody formation, as in rheumatoid arthritis [71].

$CD8^+$ cells cause cytolysis and apoptosis of alveolar epithelial cells through release of perforins, granzyme-B, and TNF-α, and there is an association between $CD8^+$ cells and apoptosis of alveolar cells in emphysema [72]. There is evidence for immunological senescence in COPD with increased numbers of T cells with no expression of the costimulatory receptor CD28 ($CD4/CD28^{null}$ and $CD8/CD28^{null}$ cells) and these cells release increased amounts of perforins and granzyme B [73,74]. Senescence of T cells in COPD is associated with reduced expression of HDAC2 [75].

B lymphocytes are also increased in COPD lungs, particularly in patients with severe disease. B cells are organized into lymphoid follicles, which are located in peripheral airways and lung parenchyma [9]. B-cell activating factor is an important regulator of B-cell function and hyperplasia and in increase in lymphoid follicles of COPD patients [76].

45.4.6 Dendritic Cells

Dendritic cells are an important link between innate and adaptive immunity. The airways and lungs contain a rich network of dendritic cells that are localized near the surface, so that they are ideally located to signal the entry of foreign substances that are inhaled. Dendritic cells can activate a variety of other inflammatory and

immune cells, including macrophages, neutrophils, T lymphocytes, and B lymphocytes; so, dendritic cells may play an important role in the pulmonary response to cigarette smoke and other inhaled noxious agents. Dendritic cells appear to be activated in the lungs of COPD patients [77] and are linked to disease severity [78]. Numbers of dendritic cells are increased in the lungs of COPD patients and cigarette smoke increases their survival *in vitro* [79].

45.5 Inflammatory Mediators

Many inflammatory mediators have been implicated in COPD, including lipids, free radicals, cytokines, chemokines, and growth factors [80]. These mediators are derived from inflammatory and structural cells in the lung and interact with each other in a complex manner. Because so many mediators are involved, it makes it unlikely that blocking a single mediator will have significant clinical impact. Similar mediators that are found in the lungs of COPD patients may also be increased in the circulation and this systemic inflammation may underlie and potentiate comorbidities.

45.5.1 Lipid Mediators

The profile of lipid mediators in exhaled breath condensates of patients with COPD shows an increase in prostaglandins and leukotrienes. There is a significant increase in PGE_2 and $PGF_{2\alpha}$, and an increase in LTB_4 but not cysteinyl-leukotrienes [81]. This is a different pattern to that seen in asthma, which has increases in thromboxane and cysteinyl-leukotrienes. LTB_4 concentrations are increased in induced sputum and further increased in sputum and exhaled breath condensate during acute exacerbations [47,82]. LTB_4 is a potent chemoattractant of neutrophils, acting through high affinity BLT_1-receptors. A BLT_1-receptor antagonist reduces the neutrophil chemotactic activity of sputum by approximately 25% [82]. BLT_1 receptors have also been identified on T lymphocytes and there is evidence that LTB_4 is also involved in recruitment of T cells.

45.5.2 Cytokines

Cytokines are the mediators of chronic inflammation and several have been implicated in COPD [83]. There is an increase in concentration of TNF-α in induced sputum in stable COPD with a further increase during exacerbations. TNF-α production from peripheral blood monocytes is also increased in COPD patients and has been implicated in the cachexia and skeletal muscle apoptosis found in some patients with severe disease. TNF-α is a potent activator of NF-κB and this may amplify the inflammatory response. Unfortunately, anti-TNF therapies have not proved to be effective in COPD patients and may have serious adverse effects [84]. The reason for the failure of anti-TNF therapies in COPD is presumably because other proinflammatory cytokines druve the inflammatory process.

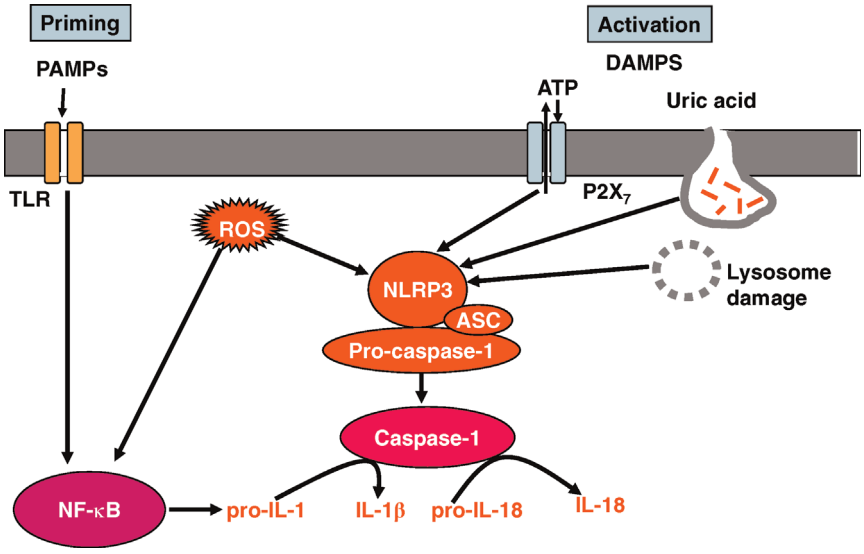

Figure 45.6 Inflammasome activation in COPD. The NLRP3 inflammasome is activated by two signals. The proming signal is activated by pathogens through pathogen-activated molecular patterns (PAMPs) with the generation of pro-IL-1β and pro-IL-8 by activation of nuclear factor-κB (NF-κB). The activation signal may include ATP (through $P2X_7$-receptors) and other damage-activated molecular patterns (DAMPS) such as uric acid. This causes the recruitment of the adaptor protein, apoptosis-associated speck-like protein containing a CARD (ASC), and pro-caspase-1 to generate caspase-1, which releases active IL-1β and IL-18.

45.5.3 Inflammasome

Inflammasomes are multiprotein signaling complexes that regulate the expression of the proinflammatory cytokines IL-1β and IL-18 in response to external and endogenous danger signals, resulting in neutrophilic inflammation [85]. Most attention has focused on NLRP3 inflammasomes, which are activated in several inflammatory lung diseases (Figure 45.6) [86]. The adaptor protein ASC is an important component of the NLRP3 inflammasome, which recruits pro-caspase-1 to the protein complex and is increased in lungs of COPD patients [87]. ASC accumulation is associated with the formation of extracellular "specks" that perpetuate the generation of IL-1β outside the cell. However, in patients with stable COPD, no increase in the NLRP3 inflammasome were found, apart from a small increase in patients with severe disease, possibly because an increase in inflammasome inhibitory molecules NALP7 and IL-37. It is more likely that NLRP3 inflammasome activation is linked to acute exacerbations, where pathogens, oxidative stress, and ATP, all of which activate NLRP3 inflammasome, are increased. The minimal role of the inflammasome in stable COPD is underlined by the failure of an IL-1β blocking antibody canakinumab to provide any clinical benefit in stable COPD [88].

IL-17, and other Th17 cytokines, are also increased in COPD sputum and airways and may play a role in orchestrating neutrophilic inflammation in the lungs [64,89]. These cytokines may also be released from ILC3 cells that are increased in COPD patients [54].

45.5.4 Chemokines

Several chemokines have been implicated in COPD and have been of particular interest since chemokine receptors are G-protein-coupled receptors, for which small molecule receptor antagonists have been developed [90]. CXCL8 concentrations are increased in induced sputum of COPD patients and increase further during exacerbations [33,36]. CXCL8 is secreted from macrophages, T cells, epithelial cells, and neutrophils, and is chemotactic for neutrophils via high affinity CXCR2, which are also activated by related CXC chemokines such as CXCL1. CXCL1 concentrations are markedly elevated in sputum and BAL fluid of COPD patients and this chemokine may be more important as a chemoattractant than CXCL8, acting via CXCR2, which are expressed on neutrophils and monocytes [34]. CXCL1 induces significantly more chemotaxis of monocytes of COPD patient compared to those of normal smokers and this may reflect increased turnover and recovery of CXCR2 in monocytes of COPD patients [35]. CXCL5 (ENA-78) shows a marked increase in expression in airway epithelial cells during exacerbations of COPD and this is accompanied by a marked upregulation of epithelial CXCR2.

CCL2 is increased in concentration in COPD sputum and BAL fluid and plays a role in monocyte chemotaxis via activation of CCR2 [34]. The chemokine CCL5 (RANTES) is also expressed in airways of COPD patients during exacerbations and activates CCR5 on T cells and CCR3 on eosinophils, which may account for the increased eosinophils and T cells in the wall of large airways that have been reported during exacerbations of chronic bronchitis. As discussed above, CXCR3 are upregulated on Tc1 and Th1 cells of COPD patients with increased expression of their ligands CXCL9, CXCL10, and CXCL11 [66]. CXCR3 ligands induce increased chemotaxis of monocytes and lymphocytes from COPD patients, which may reflect increased CXCR3 expression in COPD [91].

45.5.5 Proteases

The increase in elastase activity in COPD patients may contribute to the development of emphysema and to neutrophilic inflammation through the generation of chemotactic peptides such as acetylated Pro-Gly-Pro (matrikines), which are potent neutrophil chemoattractants that activate CXCR2 [92]. This may be self-perpetuating as neutrophils release MMP-9, which in turn generates more matrikine [93]. Human neutrophil elastase (HNE) not only has elastolytic activity but is also a potent stimulant of mucus secretion in the airways, mediated via EGFR [94]. MMP-9 is the predominant elastolytic enzyme in COPD and is secreted from macrophages, neutrophils, and epithelial cells.

45.6 Oxidative Stress as a Major Driving Mechanism

Oxidative stress occurs when ROS are produced in excess of the antioxidant defense mechanisms and result in harmful effects, including damage to lipids, proteins, and DNA. Oxidative stress is a critical feature in COPD [95].

Inflammatory and structural cells, including neutrophils, macrophages, and epithelial cells that are activated in the airways of patients with COPD, produce ROS. Superoxide anions ($O_2^{\bullet -}$) are generated by NADPH oxidase (NOX) and converted to hydrogen peroxide (H_2O_2) by superoxide dismutases (SOD). H_2O_2 is then converted to water by catalase. $O_2^{\bullet -}$ and H_2O_2 may interact in the presence of free iron to form the highly reactive hydroxyl radical ($^{\bullet}OH$). $O_2^{\bullet -}$ may also combine with NO to form peroxynitrite, which also generates $^{\bullet}OH$. Oxidative stress leads to the oxidation of arachidonic acid and the formation of a new series of prostanoid mediators called isoprostanes, which may exert significant functional effects, including bronchoconstriction and plasma exudation [96]. Peroxynitrite is also increased in the breath of COPD patients [97]. Nitric oxide may be increased in peripheral lung of COPD patients and appears to be linked to increased expression of inducible and neural NO synthases (NOS2, NOS1) [98].

The normal production of oxidants is counteracted by several antioxidant mechanisms in the human respiratory tract, including catalase, SOD, and glutathione, formed by the enzyme γ-glutamyl cysteine ligase, and glutathione synthetase. In the lung, intracellular antioxidants are expressed at relatively low levels and are not induced by oxidative stress, whereas the major antioxidants are extracellular. Extracellular antioxidants, particularly glutathione peroxidase, are markedly upregulated in response to cigarette smoke and oxidative stress. Extracellular antioxidants also include the dietary antioxidants vitamin C (ascorbic acid) and vitamin E (α-tocopherol), uric acid, lactoferrin, and extracellular superoxide dismutase (SOD3), which is highly expressed in human lung. Most antioxidants are regulated by the transcription factor nuclear erythroid-2-related factor-2 (Nrf2), which is activated by oxidative stress. However, in COPD lungs and cells, Nrf2 is not appropriately activated despite high levels of oxidative stress in the lungs [99] and this may be related to increased acetylation due to decreased HDAC2 [100].

ROS have wide-ranging effects on the airways and parenchyma and increase the inflammatory response. ROS activate NF-κB, which switches on multiple inflammatory genes resulting in amplification of the inflammatory response. Oxidative stress results in activation of histone acetyltransferase activity, which opens up the chromatin structure and is associated with increased transcription of multiple inflammatory genes [101]. Oxidative stress may also impair the function of antiproteases such as α_1-antitrypsin and SLPI, and thereby accelerates the breakdown of elastin in lung parenchyma. Oxidative stress markedly reduces HDAC2 activity and expression, through activation of phosphoinositide-3-kinase-δ (PI3 Kδ) and peroxynitrite-induced nitration of tyrosine resides [39]. This amplifies inflammation further and prevents corticosteroids from inactivating activated inflammatory genes. Through similar mechanisms, oxidative stress reduces the expression and activity of sirtuin-1, a key repair molecule that is implicated in aging. The reduction in sirtuin-1 in COPD lungs and cells may underlie the accelerated aging response seen in COPD [102,103]. Oxidative stress may also predispose to lung cancer, through the activation of growth factors and via DNA damage [104]. As discussed earlier, oxidative stress leads to formation of carbonylated proteins, which may be antigenic and stimulate the development of autoantibodies in COPD patients, which may cause persistence of inflammation [69].

45.7 Systemic Inflammation in COPD

Patients with COPD, particularly when the disease is severe and during exacerbations, have evidence of systemic inflammation, measured either as increased circulating cytokines, chemokines and acute phase proteins, or as abnormalities in circulating cells [105,106]. Persistent inflammation is associated with poorer clinical outcomes. Smoking itself may cause systemic inflammation, for example, an increased total leukocyte count, but in COPD patients the degree of systemic inflammation is greater. It is still uncertain whether these systemic markers of inflammation are a "spillover" from inflammation in the peripheral lung or are a parallel abnormality or related to some comorbid disease that then has effects on the lung. In any case, the systemic inflammation in COPD may contribute to its systemic manifestations and may worsen comorbid diseases. In a large population study, systemic inflammation (increased CRP, fibrinogen, and leukocytes) was associated with a two- and four-fold increased risk of cardiovascular disease, diabetes, lung cancer, and pneumonia but not with depression [107]. Using six inflammatory markers (CRP, IL-6, CXCL8, fibrinogen, TNF-α, and leukocytes), 70% of COPD patients had some components of systemic inflammation and 16% had persistent inflammation [106]. Patients with persistent systemic inflammation had increased mortality and more frequent exacerbations. Systemic inflammation appears to relate to accelerated decline in lung function and is increased further during exacerbations [108].

45.8 Defective Resolution of Inflammation and Repair

The reason why inflammation persists in COPD patients even after long-term smoking cessation is currently unknown, but if the molecular and cellular mechanisms for impaired resolution could be identified, this may provide a novel approach to COPD therapy. A major mechanism of airway obstruction in COPD is loss of elastic recoil due to proteolytic destruction of lung parenchyma, so it is unlikely that this could be reversible by drug therapy. However, it might be possible to reduce the rate of progression by preventing the inflammatory and enzymatic disease process. Similarly, the peribronchiolar fibrosis of small airways may not be reversible, but its progression may be halted by antifibrotic and anti-inflammatory therapies.

45.8.1 Proresolving Lipid Mediators

Resolution of inflammation is an active process that may be facilitated by several endogenous proresolving mediators, including lipoxins, E-series resolvins, D-series protectins, and maresins, all of which are derived from polyunsaturated fatty acids and act on distinct receptors [109]. These mediators promote the resolution of neutrophilic inflammation by preventing neutrophil recruitment and enhancing neutrophil removal by efferocytosis. Endogenous mediators or stable structural analogs that activate the same receptors may have therapeutic potential in promoting resolution of inflammation in COPD. Maresin-1 is the

most potent proresolving mediator that stimulates macrophage efferocytosis, so a stable analog of this mediator may be useful in COPD [110]. Defective efferocytosis by macrophages in COPD may prevent resolution of inflammation and may be the same defect that reduces bacteria phagocytosis [41,42].

45.8.2 Accelerated Aging

There is growing evidence that emphysema may be due to accelerated aging of the lungs and it hypothesized that accelerated aging may be due to defective function of endogenous antiaging molecules, such as sirtuins and FOXO proteins, as a result of increased oxidative stress in the lung [103,111]. SIRT1 is markedly reduced in the peripheral lung of patients with COPD and *in vitro* this is mimicked by oxidative stress, which reduces activity and expression of SIRT1, resulting in increased expression of MMP-9 [102]. The pathway linking oxidative stress to reduced SIRT1 expression involved PI3 K and activation of mammalian target of rapamycin (mTOR), which is activated in COPD and inhibited by rapamycin [112]. Since the same molecular pathways are shared by many of the comorbidities of COPD, which are also characterized by accelerated aging, it may be possible to identify novel targets and therapies to prevent disease progression and associated comorbidities [111]. Cellular senescence is found in COPD lungs [113] and senescent cells are known to secrete inflammatory proteins, including TNF-α, IL-1, IL-6, CXCL8, CCL2, and MMPs. This senescence-associated secretory profile (SASP) may account for the chronic low-grade inflammation that is found in COPD (Figure 45.7) [114].

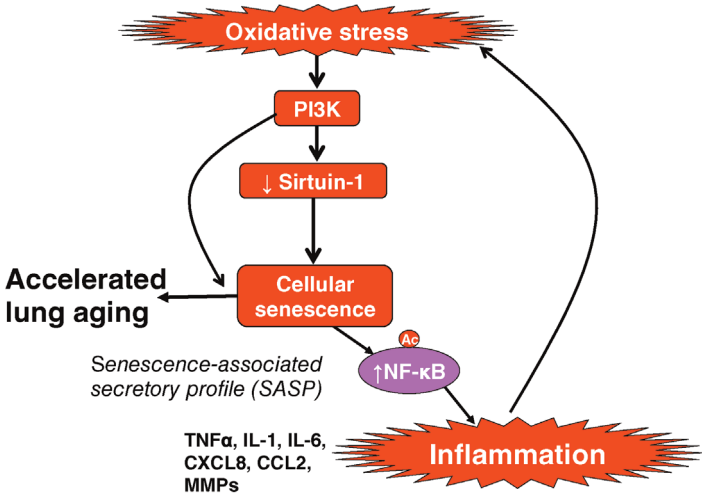

Figure 45.7 Accelerated aging and inflammation in COPD. Oxidative stress drives accelerated aging through activation of phosphoinositide-3-kinase (PI3 K) and reduction in sirtuin-1, which leads to cellular senescence and the release of inflammatory proteins (SASP), which further increase oxidative stress.

45.8.3 Airway Fibrosis

Increasing small airway fibrosis is an important mechanism of disease progression in COPD and is presumed to result from chronic inflammation, suggesting that effective anti-inflammatory treatments should prevent fibrosis. Fibrosis may be mediated via the activation of fibroblasts by fibrogenic mediators such as TGFβ, CTGF, and endothelin, which are secreted from epithelial cells and macrophages [115]. Endothelin-1 is also profibrotic and several endothelin receptor antagonists inhibit pulmonary fibrosis in animal models.

45.9 Future Implications

There is a need to identify phenotypes of COPD that respond to specific therapies and this will involve recognizing disease endotypes and biomarkers that predict response.

As already discussed, some patients with COPD have eosinophilic inflammation and this may be recognized by increased blood eosinophils, which may indicate patients who have a better therapeutic response to inhaled corticosteroids. Prospective studies are needed to define the cutoff point for blood eosinophils that indicate a good steroid response. Furthermore, COPD patients without elevated eosinophils would probably have inhaled corticosteroids withdrawn, which appears to be safe even in high-risk patients treated with high doses of inhaled corticosteroids [116].

Although inflammation is believed to be a key driving mechanism for COPD progression and exacerbations, it is apparent that in elderly COPD patients that cellular senescence may lead to low-grade inflammation, which may then drive further disease progression [114].

It is now recognized that there may be several coexisting mechanisms in COPD that interact in complex ways so that targeting a single pathway or mediator may not be effective in treating COPD, unless specific "responder phenotypes|" are identified. It is important to identify the molecular mechanisms that underlie susceptibility so that only a minority of smokers develop COPD. So far genome-wide association studies of COPD have been disappointing, but this may be because the studies include all types of COPD. It is also likely that epigenetic mechanisms such as DNA methylation play an important role in disease susceptibility and have yet to be explored.

Clinical studies to show effects of new drugs on disease progression are challenging since large numbers of patients studied over long periods (3 years) are necessary. It is important to identify biomarkers of disease "activity" or surrogate measurements that will predict the clinical efficacy of anti-inflammatory treatments in COPD patients. Analysis of sputum parameters (cells, mediators, and enzymes) or exhaled biomarkers (lipid mediators and reactive oxygen species) may be useful as biomarkers of inflammation [117].

COPD includes several different clinical and pathophysiological phenotypes, but so far it has been difficult to link any phenotype to a differential response to therapy, apart from the patients with eosinophilia discussed earlier. The PDE4

inhibitor roflumilast appears to work more effectively in a phenotype defined by disease severity, frequent exacerbations, and mucus hypersecretion, which may be a surrogate for neutrophilic inflammation [118]. Biomarkers that predict responsiveness to particular treatments are needed, particularly as treatment becomes more specific, such as targeting specific proteins. Patients with early disease who appear to decline more rapidly may show better responses to therapy, whereas currently the focus of treatment is on patients with late disease who have the most symptoms. If effective and safe anti-inflammatory therapies are developed for COPD, it may be more useful to introduce these early in the course of the disease to prevent disease progression and possibly to reduce the burden of concomitant comorbidities. This approach is akin to the therapy of systemic hypertension and hypercholesterolemia where treatment is given to prevent future risk.

Obesity: A Complex Disease with Immune Components

Yuejun Liu and Karine Clément

Institute of Cardiometabolism and Nutrition (ICAN), INSERM/UPMC UMRS 1166 "Nutriomics", Assistance-Publique Hôpitaux de Paris, Pitié-Salpêtrière Hospital, Boulevard de l'Hôpital, 75013 Paris, France

46.1 Introduction

Obesity has become a global epidemic and is one of the most significant public health challenges of the twenty-first century. Obesity contributes to a myriad of metabolic complications, including insulin resistance and diabetes, nonalcoholic fatty liver disease (NAFLD)/nonalcoholic steatohepatitis (NASH), atherosclerosis, cardiovascular disease, and cancers. Among these complications, NAFLD/NASH is now seen as one of the most severe, as it also increases the risk of cirrhosis and liver carcinoma. NAFLD/NASH also further heightens cardiovascular risk.

Inflammation is currently regarded as one of the crucial pathophysiological processes associated with the progression of obesity and its related complications [1–3]. Additionally, adipose tissue (AT) now appears to be a key driver of complications; thus, this endocrine organ is not merely a simple fat reservoir. The observation that AT secretes the proinflammatory cytokine tumor necrosis factor alpha (TNF-α) marked the first milestone in studies investigating the immunological role of AT [4]. Subsequently, the innate and adaptive immune cells of AT depots have been found to secrete a diverse panel of proinflammatory cytokines/chemokines [5]. According to body composition, the adipose organ is distributed throughout several depots: visceral AT (VAT, including omental and mesenteric) and subcutaneous AT (scAT). The scAT is also composed of two main layers, the superficial and deep scAT that are separated by the fascia superficialis.

The relative importance of each depot in producing low-grade inflammation is due to adipocyte size (i.e., hypertrophic adipocytes secrete proinflammatory molecules) and differences in inflammatory cell infiltration. AT comprises two main fractions that can be isolated following collagenase digestion: adipocytes and the stromal vascular fraction (SVF) [6]. The number and phenotype of SVF cells can significantly change and adversely affect metabolism under obese conditions [7].

Inflammation: From Molecular and Cellular Mechanisms to the Clinic, First Edition.

AT is thus an active endocrine organ that controls energy homeostasis through the systemic release of adipokines (i.e., adipose-derived inflammatory molecules). Among a large panel of known molecules, leptin and adiponectin hormones are specifically secreted by adipocytes, but both hypertrophic adipocytes and SVF cells can also secrete various proinflammatory and anti-inflammatory cytokines (IL-1α, IL-6, IL-8, TNF-α, and IL-10) and chemokines (MCP-1/CCL2, RANTES/CCL5). These mediators may act not only locally by influencing adipocyte differentiation and/or survival but also systemically through the modulation of neuron activity in the central nervous system [8]. Here, we discuss the peripheral actors implicated in obesity-related inflammation, with a focus on AT.

46.2 Systemic inflammation: Circulating Cells as Contributors

This concept of "low-grade inflammation" in obesity was first based on the fact that obese people present a moderate but chronic increase in circulating inflammatory mediators, such as acute-phase proteins, proinflammatory cytokines, and adhesion molecules [8,9]. Over the last 20 years, the number of described molecules has continued to expand. In addition, changes in circulating immune cells also contribute to low-grade inflammation in obesity. Interestingly, this impaired immune profile in obese subjects is frequently reversible with weight loss following clinical intervention [10].

Monocytes ($CD14^+$ cells) exist in a proinflammatory state in obesity [11] and clinical studies indicate that the frequency of the $CD14^+CD16^{++}$ nonclassical monocyte subpopulation and the $CD14^{++}CD16^+$ intermediate monocyte population increases in obese subjects and decreases with weight loss [12,13]. In mice, the $Gr1^+Ly\text{-}6C^{high}$ monocytes, comparable to human $CD14^+CD16^+$ monocytes, could be precursors of proinflammatory macrophages accumulating in AT [14], but this has not yet been clearly demonstrated. In addition to monocytes [15], lymphocyte phenotypes are also modified. In a small study exploring 10 obese and 10 lean subjects, obese subjects displayed a decreased frequency of cytotoxic $CD3^+CD8^+$T cells (CTL), but an increased frequency of $CD3^+CD4^+$ and $CD3^+CD8^+CD95^+$ T cells. Increased CD95 (Fas) expression on T cells may indicate impaired regulation of $CD8^+$ T cell apoptosis [16]. T cells express receptors such as toll-like receptor 4 (TLR4) and IL-21 receptor (IL-21R) [17]. Subjects at high risk of developing diabetes demonstrate decreased numbers of $TLR4^+CD4^+$ T cells, which is associated with increased fasting plasma glucose [17]. The number of circulating $IL\text{-}21R^+CD4^+$ T cells was also negatively correlated with BMI in these subjects [17]. It has also been shown that obese subjects have fewer natural killer (NK) cells compared to lean individuals. Unhealthy obese subjects had even fewer NK and CTL cells compared to metabolically healthy obese people. Moreover, NK cells appear less activated in metabolically healthy obese subjects than unhealthy subjects [18]. These clinical studies indicate that higher levels of CTL and NK cells may protect against metabolic complications, but these findings require further exploration in

larger populations to clearly determine the relationship with the progression of obesity complications.

Circulating neutrophils from obese subjects also release high levels of proinflammatory mediators such as IL-8, chemokine motif ligand 2 (CCL2), matrix metalloproteinase (MMP9), and myeloperoxidase (MPO). Neutrophils are activated by the chemokine (C-X-C motif) ligand 2 (CXCL2) *ex vivo* and may stimulate adhesion and angiogenic capacities of neutrophils to the endothelial cells of visceral white AT [19]. In overweight children, cell counts of most circulating immune cells (i.e., total leukocytes, neutrophils, monocytes, total $CD3^+$ T lymphocytes, and $CD4^+$ T helper cells) are also modified, suggesting that this is an early phenomenon during obesity development.

As mentioned previously, this type of chronic low-grade inflammation can be reversible after weight loss. Dietary intervention and bariatric surgery significantly decrease the proinflammatory activation surface markers on circulating immune cells such as CD11b granulocytes, CD66b monocytes, and CD69 and CD25T cells. The number of proinflammatory Th1 cells and also the Th1-to-Th2 cell ratio are reduced. The specific reduction in the Th1-to-Th2 cell ratio is associated with weight loss and a reduced waist circumference [20]. In a study in obese individuals, the upregulated mitogen-induced blastogenic responses of peripheral blood T and B lymphocytes were significantly reduced following a very low calorie diet intervention [21].

46.3 Macrophages in Obese Adipose Tissue

In 2003, two research groups [22,23] revealed accumulation of AT macrophages (ATM) in genetically and diet-induced obese mice and in obese humans. Subsequently, there have been many discussions surrounding the specific phenotype of these cells, which are dissimilar in rodents and humans. Increased CD68 gene expression or macrophage infiltration in obese AT is associated with impaired insulin sensitivity and severe insulin resistance [24–27] in some but not all human studies. Nevertheless, at least in obese mice, ATM are implicated in inflammatory pathway activation [23] and contribute to obesity-induced insulin resistance [22] (Figure 46.1). ATM span a broad phenotypic spectrum, although two main populations have been described: the classically activated M1 and alternatively activated M2 cells. M1 cells express CD11c surface markers and secrete proinflammatory cytokines such as TNF-α, IL-1β, IL-6, and inducible nitric oxide synthase (iNOS) in response to lipopolysaccharide (LPS) and Th1 cytokine IFN-γ treatment. M2 cells express CD206 and CD301, and classically secrete anti-inflammatory cytokines such as IL-10, IL-1 receptor antagonist (IL-1RA), and arginase 1 in response to Th2 cytokines IL-4 and IL-13 [28]. M2 cells in AT are located in the interstitial spaces surrounding adipocytes and are the dominant resident ATM in the lean state [29,30]. These cells are considered to be implicated in tissue remodeling and repair [30]. Obesity develops in rodents with a high-fat diet (HFD), along with a phenotypic switch from an M2-polarized to an M1 proinflammatory state [31]. Most ATM in obese mice, particularly M1 cells, primarily originate from circulating bone marrow-derived monocytes [23], for

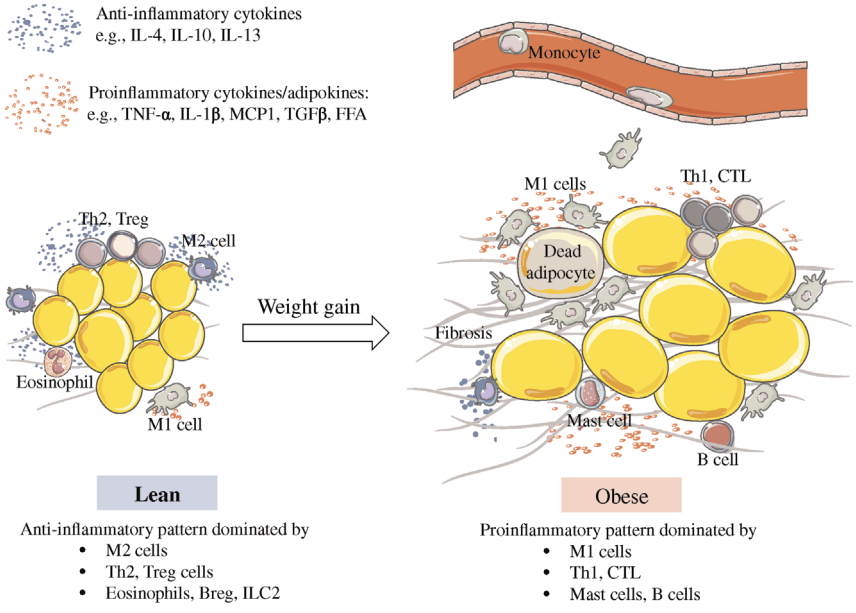

Figure 46.1 Adipose tissue inflammation in obesity. In the lean state, AT resident M2 cells, Treg cells, Th2 cells, group 2 innate lymphoid cells (ILC2s), eosinophils, and Breg cells predominate. The anti-inflammatory cytokines IL-4, IL-13 secreted by Th2 cells, eosinophils, and IL-10 secreted by Treg cells induce and maintain resident M2 cells, and improve insulin sensitivity. In the obese state, AT undergoes a switch from an anti-inflammatory cellular phenotypes to proinflammatory phenotypes (i.e., M1, Th1 cells, CTL, mast cells, and B cells), leading to adipose inflammation and insulin resistance. Adipose inflammation initiates tissue fibrosis that further aggravates inflammation. The proinflammatory cytokines and chemokines are released into circulation and subsequently enhance inflammation in other organs. A difficult issue is to examine whether this phenomenon exists during the progression of human obesity. Indeed, in human AT, macrophages express M2 markers and secrete a mixture of proinflammatory and anti-inflammatory molecules. The kinetics of macrophage accumulation and their phenotypic changes in human AT are not well understood.

example, circulating classical $Gr1^{+}Ly^{-}6C^{high}$ monocytes in diet-induced obese (DIO) mice [14]. ATM lipid content increases in obesity, and furthermore, leads to an accumulation of a small subpopulation of lipid-laden cells with foamy cytoplasm, named adipose foam cells. These adipose foam cells are implicated in local AT crosstalk that contributes to insulin resistance in obese rodents and humans [32].

During the transition from lean to obese states in humans, it is not clear if a switch from an M2-polarized state to an M1 proinflammatory state actually exists. Indeed, studies phenotyping these heterogeneous cells showed that macrophages from obese AT express M2 markers and secrete both proinflammatory and anti-inflammatory molecules [33]. The extravasation of monocytes into AT is not fully understood. Our team has demonstrated that monocytes express higher levels of the chemokine receptors CX3CR1, CCR2, and CCR5, and strongly respond to TLR4 and TLR8 stimulation in obesity, suggesting an increased cellular migratory capacity during obesity, which requires further investigation [13]. Monocyte

migration to inflamed AT probably occurs through many mechanisms, for example, an increased response to chemokines (e.g., monocyte chemoattractant protein-1 MCP-1/CCR2, CCL5/RANTES, osteopontin), and adhesion molecules (e.g., platelet endothelial cell adhesion molecule (PECAM)-1, intercellular adhesion molecule (ICAM)-1) [14]. Hypertrophic adipocytes initiate ICAM-1 and PECAM-1 adhesion molecule expression on endothelial cells, which concomitantly attracts monocytes to AT [34]. Adipocytes also produce increased IL-6, monocyte chemoattractant protein (MCP)-1, and inducible nitric oxide synthase (iNOS), which promote ATM infiltration and differentiation [6,34]. Cinti *et al.* showed that ATMs surrounding dead adipocytes form crown-like structures (CLS), which sequester and scavenge dead adipocytes. The release of cellular contents (e.g., toxic lipids) may also aggravate local inflammation [35]. In addition, a nonnegligible fraction of resident ATM was shown to undergo enhanced local proliferation in obesity. This process is induced by MCP-1 and specifically occurs in VAT where macrophage content and CLS density are enriched [36], emphasizing the involvement of resident ATM from alternative origins in obesity.

46.4 T, Treg, B, NK, and Mast Cells

Other innate and adaptive AT immune cells are also modulated in obesity. Similar to the M2 to M1 cell switch, obese AT undergoes a similar shift of T cells from protective Type 2 helper (Th2) cells to pathogenic Th1 and CTL [37–39] (Figure 46.1). Activated CTL produce IFN-γ, TNF-α, and IL-6 and participate in the formation of CLS, again amplifying AT inflammation [5,39,40]. Mice with genetic deletions of IL-7 receptor (IL-7R), a key regulator of T lymphocyte homeostasis, show attenuated ATM infiltration, improved glucose homeostasis, and insulin sensitivity [41]. Th2 cells regulate adipose M2 cells through secretion of IL-4 and IL-13 [37,42]. Overexpression of IL-13 in DIO mice prevents weight gain, insulin resistance, ATM infiltration, and AT inflammation [28]. Adipose resident $CD4^+$ $Foxp3^+$ Treg cells in obese mice are substantially decreased. These cells are considered to inhibit proinflammatory responses and ATM recruitment via the production of IL-10 and TGF-β. Modulation of Treg or Th2 cells could then protect against obesity-related insulin sensitivity, and also act as potential cellular targets to modulate inflammation and metabolic complications in obesity [38,43].

B cells accumulate in VAT and exacerbate adipose inflammation and insulin resistance through activating ATM, $CD4^+$, and $CD8^+$ T cells in DIO mice. This is likely driven by B-cell antigen presentation and the production of IgG antibodies [44–46]. As such, a particular profile of serum IgG autoantibodies was identified in obese individuals [44]. On the contrary, a subset of B cells – Breg regulatory B cells producing IL10 – negatively control AT inflammation and are reduced in obese mice. Transplantation of these cells into obese mice fat pads reduces the expression of CD44 and IFN-γ in $CD8^+$ T cells and TNF-α in macrophages [47].

Innate cells such as group 2 innate lymphoid cells (ILC2s) or eosinophils were also proposed as actors that maintain metabolic homeostasis. ILC2s are found in both mice and human AT, and are an innate source of IL-5 and IL-13. ILC2s can

regulate adaptive immunity (e.g., Treg cell accumulation) [48], eosinophil, and M2 responses, which are reduced in obesity [49,50]. ILC2s produce encephalin peptides, which induce the proliferation of PDGFRα^{+} adipocyte progenitors. Following activation by IL-33, these progenitors undergo differentiation toward beige cells that may improve AT metabolism [49,50]. Depletion of ILC2 in obese mice with a genetic background of impaired lymphoid development (Rag1$^{-/-}$ mice) exacerbates weight gain and glucose intolerance. Transferring ILC2s into obese mice leads to transient weight loss and improved glucose homeostasis [51]. Eosinophils produce IL-4 and IL-13, and further induce and maintain M2 cells. The absence of eosinophils aggravates weight gain, glucose intolerance, and insulin resistance in DIO mice [52]. Moreover, eosinophils in VAT can be activated by IL-33 via both direct pathways and an ILC2-mediated pathway [53], indicating close interactions between these adipose innate cells via key interleukins.

Finally, mast cells also contribute to this complex crosstalk and metabolic deteriorations. Obese humans and mice have increased WAT mast cells compared to lean [54], and these cells are preferentially located in AT fibrotic deposits [55]. The number of mast cells in scAT and oAT are positively correlated with fasting glucose and HbA1c in obese subjects [55]. A genetic deficiency of mast cells (*Kit*$^{W-sh/W-sh}$ mice) or their pharmacological stabilization in mice reduces weight gain, serum, and AT inflammation and improves glucose homeostasis and energy expenditure. Mast cells produce increased inflammatory cytokines (e.g., IL-6 and IFN-γ), angiogenic growth factors, and proteases (e.g., cathepsins), and probably enhance neovascularization and macrophage accumulation [54]. Invalidation of mast cell-secreted cathepsins, such as cathepsin L and K, protects mice from weight gain and insulin resistance [56,57]. However, one recent study attributed the protective effect against obesity and insulin resistance in mast-cell-deficient mice to the deficiency of hematopoietic c*Kit*, a growth factor required for mast cell differentiation and survival, rather than the mast cells *per se* [58]. Very recently, WAT mast cells from lean humans and mice were identified as being leptin-deficient and exhibiting anti-inflammatory properties, and transferring leptin-deficient mast cells into *ob/ob* mice improves glucose homeostasis [59]. All together, these studies show profound immune perturbations in obese fat. However, translating these observations from mice to humans has frequently proven difficult, in particular when exploring the links with obesity complications.

46.5 Many Other Inflammatory Cell Effectors

Nonimmune cells also contribute to AT inflammation, such as hypertrophic adipocytes that secrete a myriad of cytokines and chemokines. Mature adipocytes demonstrate increased expression of genes implicated in fibroinflammation, when cultured under proinflammatory conditions [60]. It was also shown that elevated adipocyte MHC II expression in obese subjects and mice enhances the dialog between adipocytes and resident T cells [61]. Our team has demonstrated that endothelial cells from obese VAT suppress lipolysis, adipokine secretion, and

insulin sensitivity of adipocytes, and increases the secretion of proinflammatory cytokines (e.g., IL-6, IL-1β), indicating that VAT endothelial cells contribute to AT inflammation [62].

Furthermore, preadipocytes and progenitors are also part of this complex interplay. Cocultured with macrophages, preadipocytes secrete elevated levels of proinflammatory cytokines [63]. A recent study showed that the fraction of adipose-derived stem cells (ADSCs) is reduced in obese mouse WAT. The delivery of lean mouse-derived ADSCs into obese mice attenuated adipocyte hypertrophy, reduced adipose CLS and TNF-α secretion, and sustained IL-10-secreting M2 cells, suggesting a crucial role of progenitors in adipose homeostasis. However, the relevance of a potential therapeutic approach targeting ADSCs in human obesity needs further investigation [64].

46.6 Impact of Adipose Inflammation on Local Biology: Numerous Molecular Effectors

Many inflammatory cells may contribute to obesity-induced insulin resistance via modification of local AT biology and enhanced lipolysis in mice. The role of molecular effectors and pathways has been highlighted as reviewed by Osborn and Olefsky [65]. Proinflammatory cytokines (e.g., TNF-α) are well known to impair insulin signaling, such as the IKKβ/JNK pathway that stimulates insulin receptor substrate (IRS-1) phosphorylation and inhibits the insulin receptor signaling cascade. Other kinases, for example, extracellular signal-regulated protein kinase (ERK), and the mammalian target of rapamycin (mTOR) are also implicated in IRS-1 phosphorylation. These proinflammatory kinases can regulate downstream transcriptional elements via transcription factor activator protein-1 (AP-1) and NF-κB. This results in amplified secretion of proinflammatory cytokines and perturbed metabolic signaling. *In vivo* studies demonstrate that genetic deletion of TNF-α, JNK, TLR2, or IKK improve metabolism in DIO or in *ob/ob* mice [8]. Proinflammatory cytokines (e.g., TNF-α, IL-1) enhance AT adipocyte lipolysis and increase circulating free fatty acids (FFA), which can alter the metabolism of other neighboring or distant organs (Figure 46.2). For example, FFA promotes the secretion of proinflammatory factors in AT, liver, and the pancreas through the TLR4 and JNK signaling pathways [66]. AT inflammation also disturbs normal adipogenesis via the downregulation of its key actor, peroxisome proliferator-activated receptor gamma (PPARγ) [8].

The inflammasome is yet another important effector. The inflammasome is a cytosolic multiprotein complex that is composed of an NLRP (NOD-LRR- and pyrin domain-containing) family member, the ASC inflammasome adaptor molecular, and the effector subunit pro-caspase 1. Obesity triggers inflammasome activation and the production of IL-1β, IL-18, TGF-β, and collagens [67]. Inflammasome-deficient mice demonstrate attenuated ATM activation, reduced effector-memory T cells, increased M2 cells, and improved glucose tolerance and insulin sensitivity upon HFD [68]. Saturated fatty acids and ceramides can activate the NLRP3 inflammasome through mechanisms involving defective autophagy and accumulated mitochondrial reactive oxygen species (ROS) [5]. However, the

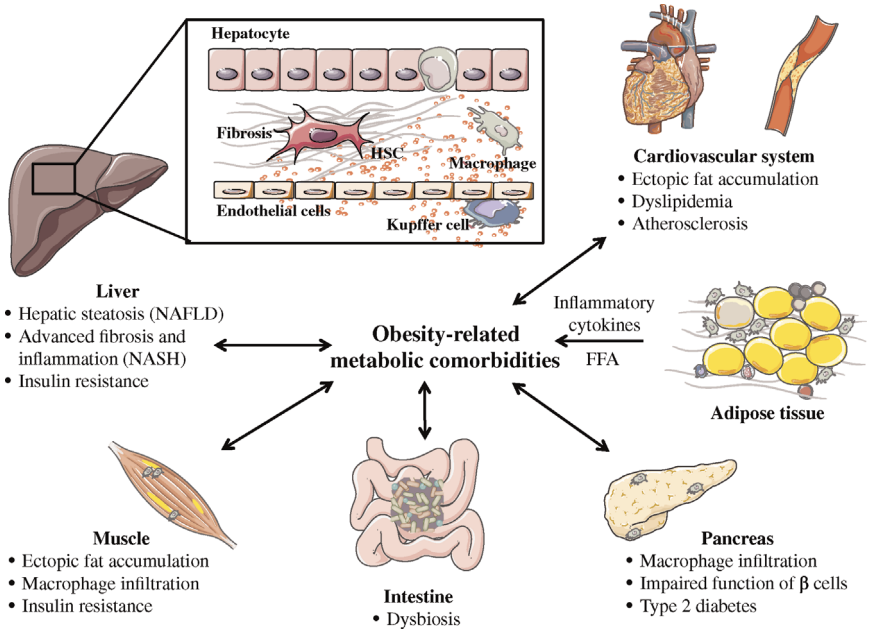

Figure 46.2 Obesity induces inflammation in diverse organs and leads to metabolic comorbidities. Inflamed AT in obesity results in increased lipolysis and free fatty acid (FFA) release, which play a crucial role in the mediation of insulin resistance and chronic low-grade inflammation throughout the body. In the liver, activated Kupffer cells and recruited macrophages produce proinflammatory cytokines, which further activate hepatic stellate cells (HSCs) to initiate fibrosis. Ectopic fat accumulation in the liver (steatosis) worsens insulin resistance. In skeletal muscle, elevated accumulation of lipids and proinflammatory macrophages impairs insulin signaling. In the intestine, the composition of the microbial population modifies, and lipopolysaccharide increases and aggravates systemic inflammation. In the pancreas, increased macrophage infiltration leads to impaired β-cell function and development of type 2 diabetes. In the cardiovascular system, lipid accumulation and proinflammatory mediators lead to dyslipidemia and atherosclerosis, and increases cardiovascular risk. Obesity-induced inflammation initiates pathological alterations in diverse organs and aggravates metabolic comorbidities.

role of the inflammasome complex in regulating AT leukocytosis in obesity has not yet been clearly deciphered.

46.7 Adipose Inflammation and Obesity Complications

The development of insulin resistance is crucial in the occurrence of obesity-linked comorbidities. In humans, it is unknown whether inflammation precedes insulin resistance or contributes to its maintenance once established. The accumulation of inflammatory cells such as macrophages and the secretion of proinflammatory cytokines in liver, skeletal muscle, and pancreas damage insulin signaling and aggravate whole-body insulin resistance as the disease progresses, regardless of the exact kinetic flow of events.

At least three major inflammatory signaling pathways are involved: (i) nuclear factor-κB-IκB kinase (NF-κB-IKK) signaling – a pathway activated by LPS, and

FFA via TLR4 activation in obesity. Inhibiting this pathway with anti-inflammatory agents such as salicylates, or by deletion of IKKβ or TLR4, improves insulin sensitivity [9,69]. (ii) The Jun N-terminal kinase (JNK)-activator protein-1 (AP-1) pathway, which is activated in AT, liver, and muscle also inhibits insulin signaling. Endoplasmic reticulum (ER) stress (for example, induced by palmitate) can activate JNK signaling and increase autophagy in adipocytes and pancreatic β cells that then aggravate insulin resistance. (iii) The inflammasome, as described above, activated by different molecules, primarily by proinflammatory cytokines, LPS, and secondary exogenous pathogen-associated and endogenous damage-associated molecular patterns. In all cases, the activation of these pathways leads to increased phosphorylaton of insulin receptors and insulin receptor substrates (IRS) at inhibitory sites and blocks downstream signals [9,69].

Insulin resistance develops particularly in those individuals with abdominal fat accumulations, a very well-known phenotype associated with increased cardiovascular risk [70,71]. The relationship between inflammatory cell accumulation in abdominal fat and cardiovascular complications is currently debated and needs extended investigation. For example, the presence of CLS in abdominal scAT from obese subjects is associated with worsened endothelium-dependent flow-mediated vasodilation [27]. However, the number of macrophages in scAT or VAT in severe obesity is not correlated with increased arterial intima-media thickness [72], a vascular phenotype associated with early cardiovascular risk. Nevertheless, relationships between AT-produced molecules and inflammatory cells from distant sites, and cardiometabolic phenotypes, have been described in overweight and obese subjects [73], although occasionally with inconsistent results. Among the key adipocyte-secreted hormones (i.e., adipokines), serum leptin is correlated with cardiovascular events, for example, myocardial infarction, stroke, and restenosis. Leptin stimulates the recruitment of intimal monocytes and the formation of foam cells, induces the secretion of proinflammatory and atherogenic cytokines, and the expression of C-reactive protein in human coronary artery endothelial cells [74,75]. Leptin is also prothrombotic as it enhances platelet aggregation and favors coagulation over fibrinolysis. Leptin also contributes to insulin resistance and diabetes through leptin–CRP interactions [75]. The adipokine resistin is regarded as a predictive inflammatory marker of coronary atherosclerosis [76]. It stimulates the expression and release of endothelin-1 by endothelial cells, and increases the expression of vascular cell adhesion molecule (VCAM-1) and MCP-1, and is therefore involved in cardiovascular disease. On the contrary, another key adipokine with anti-inflammatory properties, adiponectin, appears protective for the heart and vessels and is decreased with obesity and insulin resistance [77].

It is possible that liver alterations might generate a different picture (Figure 46.2). Liver Kupffer cells are regarded as hepatic resident macrophages and are activated toward an M1 phenotype in obesity. Activated Kupffer cells and recruited macrophages promote steatosis and produce proinflammatory cytokines [78]. TGF-β produced by Kupffer cells stimulates hepatic stellate cells to secrete extracellular matrix and induces fibrosis [79]. A “two-hit” hypothesis was initially proposed to describe liver injury in NAFLD/NASH: triglyceride accumulation in liver (steatosis) as the “first-hit,” followed by inflammation and

subsequent fibrosis (NASH) as the "second-hit" [80,81]. Adipose tissue inflammation is now considered as occurring concomitantly with liver damage. Van der Poorten *et al.* found that visceral fat volume is associated with hepatic inflammation and fibrosis, and is thus an independent predictor of advanced steatohepatitis [82]. In severe obesity, we showed that increased macrophage abundance in omental AT and deep scAT is associated with severe hepatic fibroinflammation. This association was independent of altered glycemic status [24,83,84]. These studies indicate that adipose-derived factors may contribute to NASH progression, notably via the release of adipose-derived molecules in the hepatic portal system.

Mechanistically, leptin promotes AMPK, activates lipid oxidation, inhibits lipogenesis by downregulating SREBP1-c, and upregulating PPARα [85,86]. In addition, leptin increases the expression of TGF-β1 in Kupffer cells, activates fibrogenetic hepatic stellate cells, and induces the production of key extracellular matrix components, such as α-smooth muscle actin, collagens, and tissue inhibitor of metalloproteinase 1 (TIMP1) [87,88]. Adiponectin is demonstrated to impede hepatic lipogenesis via the downregulation of SREBP1-c [89] and the stimulation of fatty acid oxidation and glucose utilization by activating AMPK [90]. In obese subjects, low circulating adiponectin is a predictive factor of steatosis and severe liver injury [91]. In contrast, some studies have shown that cirrhotic and hepatocellular carcinoma patients had elevated levels of serum adiponectin, which was associated with higher serum bile acids and decreased liver fat [92]. These data suggest that chronic hypoadiponectinemia in obesity may be an early trigger of cirrhotic and hepatocellular carcinoma formation. However, subsequent adiponectin increases might be induced by altered hepatic homeostasis [79,92]. Besides the above key proinflammatory and anti-inflammatory adipokines, AT contributes to the production of cytokines such as TNF-α and IL-6 that are markedly involved in NAFLD/NASH. [93,94]. For example, circulating IL-6 positively correlates with liver inflammation and fibrosis in NAFLD patients [82]. Glycoprotein 130 (gp130), a common signal transducer of IL-6, mediates AT lipolysis and stimulates hepatic steatosis and insulin resistance [95]. These observations led to the concept that the two-hit hypothesis might be too restrictive. Many other factors could be regarded together as "multihit" mediators involved in the progression from NAFLD to NASH, such as gut-derived bacterial toxins or dysregulated hepatocyte apoptosis, and among them, obesity-induced inflammation should be considered a pivotal player [81].

46.8 Obesity as a Profibrotic Disease?

A main consequence of long-term chronic tissue inflammation is the development of fibrosis defined as an excessive deposition of extracellular matrix (ECM) components (such as cross-linked collagens) and impaired degradation [96]. Obesity is associated with a high risk and prevalence of comorbidities with a strong fibrotic component, affecting different organs such as liver, kidney, heart, and lung. Fibrosis accumulation was discovered in obese rodent and human AT using picrosirius red staining. In obese subjects, scAT fibrosis is increased [97,98]

(Figure 46.1) and associates with adipocyte dysfunction and fibroinflammation [60]. Lysyl oxidase (LOX) is an important matrix fiber cross-linking enzyme that contributes to a tissue's mechanical properties [99]. LOX expression is upregulated in HFD or *ob/ob* mice and in obese subjects [60], whereas it is decreased after weight loss [100]. Inhibition of LOX activity leads to improved metabolism and reduced inflammation [101]. ScAT fibrosis in humans is associated with both altered stiffness and modified glucose homeostasis [102]. An important ECM component, collagen VI, which accumulates in obese AT, is also associated with insulin resistance [103,104]. Col6α1 expression in obese humans was found positively associated with ATM markers such as CD68 [104,105]. In mice, genetic ablation of membrane type 1-matrix metalloproteinase (MT1-MMP), a membrane-anchored metalloproteinase degrading collagen I, leads to increased periadipocyte fibrosis and severe metabolic complications such as hepatic steatosis [106]. In contrast, the absence of collagen VI in HFD or *ob/ob* mice results in uninhibited adipocyte expansion, reduced macrophage infiltration, and is associated with metabolic and inflammatory improvements [107]. Thus, the fact that the pericardial fat secretome (i.e., adipose tissue around the heart) promotes myocardial fibrosis [108] and that scAT pericellular fibrosis is associated with liver fibrosis [102] indicates that AT itself may promote profibrotic conditions at proximal or distant organ sites. The discovery of fibrosis in AT has added further complexity to the pathological alterations observed in obese AT.

Efforts are now being made to better understand fibrotic mechanisms associated with inflammatory events in obese AT. ATM and preadipocytes are considered to be important fibrotic effector cells. The profibrotic mediators (e.g., TGF-β, PDGF) produced by ATM directly attract and activate fibroblasts and control ECM deposition [96]. Vila *et al.* proposed that ATM TLR4 mediates the development of obesity- and endotoxemia (bacterial lipopolysaccharide-produced)-associated AT fibrosis through the TGF-β pathway [109], indicating the potential link between intestinal inflammation, the gut microbiome, and AT fibrosis. Human preadipocytes cultured with activated macrophage-conditioned medium overexpress a panel of ECM genes, along with increased collagen I and fibronectin proteins, and show increased migration and proliferation ability [63,98]. Endothelial cells (i.e., cells that could convert into myofibroblasts via epithelial mesenchymal transformation) and pericytes (i.e., main cellular component of blood vessels and potential adipocyte progenitors) both exhibit proinflammatory and profibrotic phenotypes and are capable of altering adipocyte function [62,110]. AT mast cells whose accumulation is preferentially located in fibrotic depots and positively associated with collagen, macrophage, and endothelial cell accumulations [55] are thought to be ECM producers, or at least contribute to ECM remodeling. Importantly, adipocytes themselves could also possibly produce fibrosis as significantly increased peri-adipocyte fibrosis is found in AT [97].

Alternative human and mouse studies proposed that ATM accumulation could be secondary to AT fibrosis [101,111], suggesting that other cellular or molecular factors might contribute to fibrosis initiation. For instance, the role of other immune cells accumulating in AT during obesity, for example, $CD4^+$ Th1 and

$CD8^+$ T cells [112], and their role in fibrosis needs to be further studied. As in many obesity-related fibrotic diseases, the complex pathophysiological mechanisms implicated in AT fibrosis remain to be elucidated, and may involve chronic low-grade inflammation, insulin resistance, lipotoxicity, aberrant secretion of many adipokines, oxidative stress, hypoxia, and gut microbiota alteration [1,113].

46.9 Toward New Obesity Phenotypes and New Therapeutics?

The discovery of AT inflammation and fibrosis led to a reassessment of the role of AT in obesity, and the generation of several different AT expansion models. Thus, two models of healthy or unhealthy AT expansion have been proposed [114]: healthy AT expansion comprises AT enlargement via effective recruitment of adipocyte precursor cells and increased numbers of small adipocytes, along with adequate angiogenic responses, appropriate ECM remodeling, and minimal inflammation; in contrast, unhealthy AT expansion consists of rapid growth of existing adipocytes, limited angiogenesis, high degrees of macrophage infiltration, and massive fibrosis [114]. The latter model supports the hypothesis that AT fibrosis and associated mechanical stress (e.g., stiffness) may limit AT expansion during obesity development. Fibrotic depots produce constraints on adipocytes that may lead to adipocyte dysfunction, ectopic fat storage, and metabolic disorders linked to ectopic fat accumulation in other organs (liver, muscle, heart, and pancreas) [115].

However, the picture might be more complex than initially thought. Asterholm *et al.* indeed showed in mouse models that adipocyte inflammation is necessary for healthy AT expansion and remodeling. The impairment of proinflammatory signals in AT leads to less efficient adipogenesis, affects VAT expansion, and impairs intestinal barrier function. In those mice, the absence of proinflammatory signals led to increased ectopic lipid accumulation, elevated hepatic steatosis, and impaired glucose tolerance [116].

46.10 If a Certain Degree of Inflammation Is Beneficial, Is It Really Relevant to Consider a Therapeutic Modulation of Low-Grade Inflammation in Humans?

Rodent studies have provided many potential drug targets. Manipulation of proinflammatory and anti-inflammatory cytokines has been tested with contrasting results, particularly when translating the findings in humans.

For most of the tested drugs, the objective was to improve insulin sensitivity and diabetes status. An illustration of this approach is the use of thiazolidinediones (TZDs), agonists for PPARγ, to control type 2 diabetes. TZDs activate PPARγ and subsequently suppress proinflammatory pathways, reduce ATM, enhance anti-inflammatory Treg cell stimulation, and increase circulating adiponectin and FGF21 [8,9]. Two main TZD drugs, rosiglitazone and pioglitazone,

were widely used to treat T2D with good efficacy. However, the use of these two drugs are now restricted or even suspended in some regions, such as Europe, due to safety concerns: rosiglitazone increases the risk of myocardial infarction and cardiovascular death [117] while pioglitazone increases the risk of bladder cancer [118]. Yet, the US Food and Drug Administration (FDA) recently lifted the rosiglitazone restriction based on newly reviewed data analysis. In addition, a recent meta-review with large, pooled, multipopulation analysis did not show any association between the incidence of bladder cancer and the cumulative use of pioglitazone [119], suggesting these two drugs might return to market after careful reevaluation.

Salsalate, an analog of salicylate, was also tested as an antidiabetic drug [120]. Clinical trials have confirmed that salsalate treatment improves insulin clearance and insulin resistance, reduces HbA1c and systemic triglycerides, and diminishes early glycation end products [9]. Similar effects have also been observed in patients treated with aspirin [121]. However, the beneficial effects remain quite modest.

Although anti-TNF-α antibodies do not significantly improve insulin sensitivity in obese or metabolically sick subjects, they decrease plasma glucose in obese subjects [122,123], improve insulin sensitivity and HbA1c, and decrease new-onset diabetes in subjects with severe immune diseases such as rheumatoid arthritis [124]. The antagonist of another key cytokine, IL-1, was also suggested as a favorable therapeutic molecule. The IL-1R antagonist enhances insulin secretion in β cells, decreases HbA1c, and reduces CRP and IL-6 circulating proinflammatory markers in overweight or obese diabetic subjects [125]. Neutralizing IL-1β antibody is found to decrease fasting glycemia, HbA1c, CRP, and IL-6 [126,127]. The treatment of the anti-inflammatory cytokine IL-10 in mice protects against IL-6-induced impairment of insulin action and signaling activity in liver and muscle [128]. Recently, a majority of infiltrating cells surrounding adipocytes were found to be CD44-positive macrophages. Administration of anti-CD44 monoclonal antibodies in HFD mice reduced AT inflammation and suppressed weight gain, fasting glycemia, insulin resistance, and liver steatosis [129]. These findings in rodents suggest the potential therapeutic possibilities of IL-10 or CD44 antibodies, which require further investigation in humans.

Administering the JNK-inhibitory peptide markedly ameliorates insulin resistance and improves glucose tolerance in diabetic mice [130]. Again, the efficacy of JNK inhibitors and its safety in humans remains to be evaluated. Two different chemical chaperones that reduce ER stress in cells and whole animals are able to effectively reduce glycemia, restore insulin sensitivity, improve fatty liver disease, and enhance insulin action in liver, muscle, and AT in obese and diabetic mice [131]. Furthermore, in a small clinical study, one of these chaperones was found to improve hepatic and muscle sensitivity and to increase liver insulin signaling [132], suggesting that the control of ER stress might have clinical benefit. Resveratrol (RES), an AMP-activated protein kinase activator, reduces hepatic steatosis, macrophage infiltration, insulin resistance, and improves memory alteration in HFD-fed mice, indicating that RES can be applied to treat obesity-related inflammation, metabolic deterioration, and memory deficiency [133].

Therapies that inhibit the chemotaxis or accumulation of immune cells into metabolic tissues can also improve insulin sensitivity, at least in rodents. Short-term treatment with CCR2 antagonists reduces ATM infiltration and ameliorates insulin resistance without significant improvement in body mass or hepatic steatosis [134]. Clinical studies showed similar but modest improvements in insulin resistance [135] and fasting glycemia [136] in diabetes. Leukotrinene B4 (LTB4) is a proinflammatory lipid mediator and promotes leukocyte chemotaxis through binding to its receptor LTB4R1. Administration of LTB4R1 inhibitor in HFD mice led to considerably improved glucose tolerance, decreased serum insulin and FFA levels, reduced inflammation, and ATM infiltration [137]. Treatment with CD3-specific antibody or its nonmitogenic $F(ab')_2$ fragment decreases the predominance of Th1 cells over $Foxp3^+$ Treg cells in VAT and improves insulin resistance and glucose hemostasis in mice existing on a HFD [138].

Another therapeutic example is linked to mast cells. A clinical study previously showed that administration of mast cell stabilizer with glimepiride had beneficial effects on systemic inflammation, and glucose and lipid homeostasis in obese diabetic individuals [139]. This suggests that development of molecules targeting mast cells could be promising, but this hypothesis requires exploration at a larger scale.

Nutraceutical or dietary methods have also been investigated. The fish oil ω-3 fatty acids, docosahexaenoic acid (DHA), and eicosapentaenoic acid (EPA) exert anti-inflammatory effects via binding to the G protein-coupled receptor (GPR) 120 in macrophages and adipocytes. The supplementation of ω-3 fatty acids in obese mice reduces ATM content and M1 proinflammatory genes, increases M2 anti-inflammatory genes, and improves systemic insulin sensitivity [140]. However, fish oil supplementation has had controversial results in human studies, and the amount of fish oil required to attain a GPR-120-mediated anti-inflammatory effect is too high [9]. Recently, a high-affinity GRP agonist was demonstrated to improve insulin resistance, chronic inflammation, and hepatic steatosis in obese mice, indicating that this GRP120 agonist molecule could be a promising new insulin-sensitizing drug for obese subjects [141]. Various spices have also been shown to exert antioxidant and anti-inflammatory activities in obesity. Among them, curcumin, a yellow pigment extracted from curry power, has been demonstrated to interact with adipocytes, macrophages, and hepatic stellate cells. Curcumin inhibits NF-κB and Wnt/β-catenin, activates PPARγ, and therefore results in downregulation of genes encoding TNF-α, IL-6, MCP1, leptin, and resistin and upregulation of genes encoding adiponectin. These curcumin-initiated modifications improve insulin resistance, hyperglycemia, hyperlipidemia, and other complications related to obesity in both animal and human studies. These results suggest that adding spices containing curcumin to a daily diet could be a favorable method to prevent obesity-associated insulin resistance [142].

Finally, intestinal microbiota is regarded as responsible for endotoxemia-induced inflammation and the onset of various metabolic complications in obesity. One animal study showed that antibiotic treatment decreased metabolic endotoxemia and cecal LPS content in DIO and *ob/ob* mice, and was associated with improved glucose tolerance, weight gain, inflammation, oxidative stress and macrophage infiltration [143]. Moreover, the administration of polymyxin B,

which eliminates Gram-negative bacteria, can improve hepatic steatosis [144,145]. Thus, these findings indicate that pharmacological drugs targeting gut microbiota inflammation could be useful therapeutic strategies for obesity and related metabolic complications.

In conclusion, major progress has been made regarding the understanding of immune-inflammatory and profibrotic processes occurring during obesity development. These novel findings reveal complex crosstalk between AT immune cells, impacting AT biology and the biology of distant organs. Although there are many studies proposing potential new targets, it is absolutely necessary to further explore whether, and in whom, these strategies will alleviate obesity and improve metabolic complications with acceptable side effects.

Acknowledgments

The authors thank the funding support they obtained for the studies of low-grade inflammation and fibrosis in obesity and in particular the French Foundation for Medical Research (FRM), the National Agency of Research (ANR Adipofib), the European Commission (Metacardis and Epos FP7 programs) and the "Programmes Hospitalier de Recherche Clinique" (APHP). They also warmly thank Rachel Peat at ICAN for English correction and editing.

Inflammation and Type 2 Diabetes

Marleen M.J. van Greevenbroek, Casper G. Schalkwijk, and Coen D.A. Stehouwer

Maastricht University Medical Centre+, Department of Internal Medicine & CARIM School for Cardiovascular Diseases, P. Debyelaan 25, Maastricht, 6229 HX, The Netherlands

47.1 Introduction

In 2014, the overall worldwide prevalence of diabetes was estimated to be 8–9%, according to the world Health Organization and the International Diabetes Federation. Currently, there are approximately 387 million people with diabetes, and this number is expected to increase to 590 million by the year 2035. Of these diabetes patients, 10% have type 1 diabetes and 90% have type 2 diabetes. Up to 50% of the people with type 2 diabetes are unaware of the fact that they have the disease.

In this chapter, we will discuss the current insights into how inflammation, particularly obesity-associated low-grade inflammation, may contribute to development of insulin resistance and β-cell failure, and hence comprise a major culprit for the development of type 2 diabetes. When available, we will focus on human data. We will approach this topic from the view of the obesity – inflammation – type 2 diabetes axis, since obesity comprises the most relevant risk factor for type 2 diabetes, worldwide.

47.2 Diabetes – Background and Epidemiology

In type 1 diabetes, the β-cells of the pancreas are destroyed by an autoimmune process. Pancreatic β-cells are the only insulin-producing cells in the body, and patients with type 1 diabetes therefore depend on insulin therapy for survival. Type 1 diabetes is often characterized by an acute onset, often at early age, that is, childhood, puberty, or early adulthood. In type 2 diabetes, various cells of the body show a decreased response toward the metabolic actions of the hormone insulin. This is also known as insulin resistance. Insulin resistance is a slowly developing condition and is usually counteracted by a compensatory increase in the

production of insulin by the pancreatic β-cells. Type 2 diabetes will develop when insulin production of the β-cell is no longer sufficient to compensate for this increased demand for insulin. Because of the gradual onset of the disease, especially people with recent onset type 2 diabetes may be unaware of their condition. Type 2 diabetes used to be a disease that developed in adulthood but in recent years a steep increase in the incidence in youth, particularly in obese adolescents, has been seen [1,2]. Notably, already in the period when insulin resistance is compensated by increased insulin production, and full-blown type 2 diabetes cannot yet be formally diagnosed, chronic conditions such as cardiovascular disease are already developing. The exact underlying cause of type 2 diabetes is not known, but it is generally accepted that obesity and inflammation are important drivers of this disease.

The prevalence of type 1 and type 2 diabetes has been increasing over the past 20–30 years. Between 1980 and 2008, the worldwide number of people with diabetes has more than doubled [3]. The reasons for this increase are multiple. On the one hand, they are driven by population growth and aging. But on the other hand, environmental factors and lifestyle comprise relevant, and potentially modifiable, contributors. The worldwide prevalence of type 2 diabetes is projected to increase. Obesity is considered an important driver of the increase in diabetes prevalence. In the past three decades, both cardiovascular disease and diabetes, in particular obesity-induced type 2 diabetes, have been recognized as inflammatory diseases. The systemic low-grade inflammatory response that is often observed in obesity detrimentally affects both insulin signaling and β-cell function and may thus contribute to the development of type 2 diabetes and its complications [4]. Given the higher burden on the health care system and the community at large, the focus on increasing prevalence of diabetes is mainly on type 2 diabetes. Yet, there are also indications for an increasing prevalence of type 1 diabetes [5]. Several environmental risk factors have been identified for this increase. Some of these environmental risk factors such as viruses may initiate autoimmunity toward the β-cell, other exposures may put on overload on the already affected β-cell and thus accelerate the disease process [5]. Diabetes, especially type 2 diabetes, has long been regarded as a disease of affluence. However, currently more than 80% of deaths due to diabetes occur in low- and middle-income countries.

47.3 Obesity, Fat Distribution, and Inflammation

At the population level, the risk of developing type 2 diabetes rises with an increase in obesity. More specifically, it appears that particularly individuals with a larger amount of upper body fat are more often type 2 diabetes patients than those with less upper body fat, even with comparable body mass index (BMI) [6,7]. Upper body fat is also referred to as central obesity or abdominal obesity. Central obesity is generally associated with more visceral fat. This is the adipose tissue that surrounds the abdominal organs. Visceral fat may also be referred to as abdominal and/or omental fat. The visceral fat depot comprises 10–15% of total body fat [8]. It is generally considered an unhealthy fat depot and a relevant contributor to obesity-associated low-grade inflammation. The largest fat depot in the human

body, that is, subcutaneous fat, comprises 70–80% of total body fat and is often regarded as neutral or, when located around the hips and buttocks, even protective with respect to low-grade inflammation [9,10]. One exception may be made for deep subcutaneous fact in the abdominal area that may behave similar to visceral rather than to superficial subcutaneous fat [11]. There are also additional fat depots that are less pronounced in volume than subcutaneous and visceral fat, but appear highly relevant with respect to regulatory and metabolic functions. These additional fat depots are usually referred to as "ectopic" fat. Ectopic fat can occur as small but distinct fat depots that are located in close vicinity of specific organs, for example, the perirenal, perivascular, as well as epicardial and pericardial fat depots. Ectopic fat also can occur as accumulation of triglycerides in the parenchymal cells of tissues and organs that are usually not lipid-laden, such as hepatocytes and muscle cells. Both types of ectopic fact may contribute to (local) inflammation and to dysregulation of normal function and metabolism. There is accumulating evidence that a large capacity for storage of triglycerides in the superficial subcutaneous fat may actually result in less "overflow" of triglycerides into visceral and ectopic fat depots [12,13]. A high capacity for triglyceride storage in subcutaneous fat may contribute to the so-called (metabolically) healthy obese phenotype that has consistently been shown in approximately 25–30% of obese individuals [14]. Taken together, current data suggest that specific fat depots, including visceral and ectopic fat, are the culprit fat depots with respect to generation of an inflammatory response and insulin resistance. Prevention of overall adipose tissue dysfunction, of (visceral) fat inflammation, and of ectopic fat deposition may all contribute to preserving a metabolically healthy obese phenotype [14].

It is currently well accepted that the state of chronic low-grade inflammation that is induced by obesity [15–17] includes attraction and activation of an array of local and systemically derived immune cells in the adipose tissues, as well induction of systemic inflammation (see also Chapter 50). The adipogenic nuclear transcription factor peroxisome proliferator activated receptor (PPAR)-γ is a master regulator of adipocyte differentiation and promotes the storage of fatty acids in the large triglyceride droplet of the adipocyte [18]. PPAR-γ is also a key regulator of inflammatory and immune responses [19]. Adiponectin is the major anti-inflammatory adipokine. It is also one of the few adipokines for which the plasma concentration is lower in obese than in lean individuals [20]. Accumulation of abdominal fat can induce inflammation via several mechanisms. Expansion of adipose tissue and adipocyte hypertrophy may be associated with local hypoxia, which in turn generates signals to recruit macrophages [21]. In addition, the high rate of protein synthesis during adipose tissue expansion may lead to accumulation of unfolded or misfolded proteins. Hypoxia and intracellular presence of unfolded and misfolded proteins can both lead to endoplasmic reticulum (ER) stress [22,23]. This may then further contribute to the production of inflammatory and chemotactic signals.

Adipose tissue macrophages are mostly derived from bone marrow, although some are local, and their number is higher in obesity [24]. Macrophages that are located within the adipose tissue may be pro- or anti-inflammatory, depending on their activation status [25]. Classically activated macrophages (referred to as M1

macrophages) are considered proinflammatory, alternatively activated macrophages (referred to as M2 macrophages) on the other hand primarily function to resolve or dampen the M1-induced inflammatory response and are therefore considered anti-inflammatory. Although the M1 versus M2 status is a gradient rather than a black-and-white phenomenon, macrophages present in adipose tissue in obesity appear to be predominantly polarized toward the M1 phenotype [26]. Local production of chemo-attractants that enhance the homing of monocytes to adipose tissue depots may contribute to adipose tissue inflammation. Such signals can, for instance, be produced by adipocytes of the expanding adipose tissue. Hypertrophic adipocytes begin to secrete low levels of tumor necrosis factor (TNF)-γ, which stimulate preadipocytes and endothelial cells to produce monocyte chemotactic protein (MCP)-1 (also known as CCL2) [27]. Macrophages in adipose tissue are overrepresented around dead or dying adipocytes, thereby forming so-called crown-like structures [28,29]. Also in humans there is an increase in macrophages in obese adipose tissue. For instance, in a study of monozygotic twins acquired obesity was characterized by adipocyte hypertrophy and increased expression of the macrophage marker CD68 and TNF-α in subcutaneous abdominal adipose tissue [30]. These cellular and humoral proinflammatory changes in acquired obesity were associated with an increase in insulin resistance [30]. The exact signals from human adipose tissue that initiate macrophage infiltration still need to be identified.

In recent years, the role of other immune cells, including cells of the adaptive immune system such as proinflammatory T cells in obesity-induced type 2 diabetes, has gained significant interest. Human adipocytes and preadipocytes appear to possess the full machinery to prime inflammation and attract T cells independent of macrophages [31]. Moreover, subcutaneous adipose tissue of type 2 diabetes patients has increased presence of not only macrophages but also of proinflammatory T cells [32]; in mice fed a high-fat diet, infiltration of T cells actually preceded the infiltration of macrophages [32,33]. T cells derived from adipose tissue of obese mice produced more interferon (IFN)-γ than those from control mice [34] and hampered preadipocyte-to-adipocyte differentiation [35]. T cells that are infiltrated in adipose tissue may not only attract macrophages but also skew macrophage differentiation toward the M1 phenotype. In contrast, induction of T-regulatory cells was beneficial and reduced adipose tissue inflammation and insulin resistance [36,37]. Notably, the anti-inflammatory master switch in adipocyte differentiation, PPAR-γ, was recently identified as major driver of visceral adipose-tissue-resident regulatory T cells [38].

47.4 How Does Inflammation Cause Type 2 Diabetes?

For development of type 2 diabetes, at least two major events are necessary. First, the development of insulin resistance, and second the development of β-cell decay (see also Figure 47.1). Insulin resistance is a state in which the sensitivity (and hence the response) of target cells to the hormone insulin is reduced. In insulin resistance, particularly the metabolic actions of insulin are reduced (Section 47.4.1). Insulin resistance leads to an increased demand for insulin.

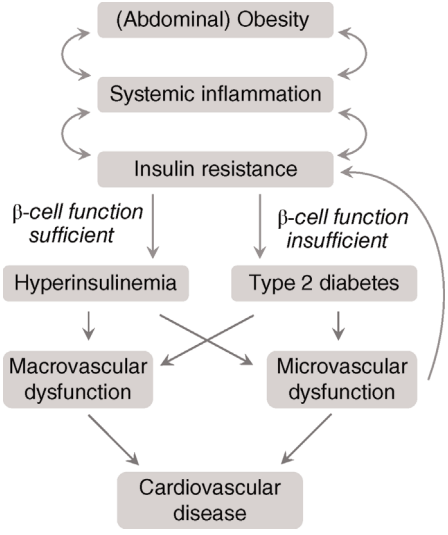

Figure 47.1 The main events that underlie the development of obesity-associated type 2 diabetes, that is, development of insulin resistance and the development of β-cell failure. When fat accumulates in the abdominal and ectopic depots, a persistent low-grade inflammatory response will develop. This low-grade inflammatory response will lead to cellular insulin resistance and also attract proinflammatory immune cells to adipose tissue, which can worsen the inflammatory response. Insulin resistance increases the demand for insulin. As long as the pancreatic β-cells can meet the increased demand for insulin with sufficient compensatory insulin production, this will lead to a state of normoglycaemia with hyperinsulinaemia. This is generally associated with dyslipidaemia and hypertension and is often associated with the metabolic syndrome. When, on the other hand, the secretion capacity of the β-cells is no longer sufficient, persistent hyperglycemia and hence type 2 diabetes will develop. The major vascular complications of type 2 diabetes, that is, macrovascular and microvascular disease are each presumed to start prior to the development of hyperglycemia. However, once diabetes develops, the progression of disease may be further accelerated.

The main driver for this is the physiological set-point of the body to maintain plasma glucose homeostasis. When insulin signaling is impaired, less glucose will be taken up by the cells and plasma glucose increases. Higher plasma levels of glucose stimulate the pancreatic β-cells to increase their insulin production. This will lead to a new balance in which normal plasma glucose is maintained but insulin concentrations are increased. For this reason, insulin resistance is in its early stages is characterized by normoglycemia but hyperinsulinaemia. The increased insulin production by the pancreatic β-cells to maintain normoglycaemia is referred to as compensatory β-cell function. This insulin resistant phase with higher circulating insulin concentrations but (relatively) normal glucose concentrations can be maintained for years. Notably, despite the normal glucose levels this is not a healthy condition. Hyperinsulinaemia is, among others, associated with dyslipidaemia and atherosclerosis [39]. Subsequently, in case of prolonged and/or worsening insulin resistance, β-cells may no longer be able to meet the persistent high demand for insulin. This will then lead to insufficient hepatic and peripheral glucose disposal, eventually to higher circulating concentrations of glucose and development of type 2 diabetes. The systemic low-grade

inflammatory response that is often observed in obesity detrimentally affects both insulin signaling and β-cell function and may thus contribute to the development of type 2 diabetes (Figure 47.1).

47.4.1 Inflammation Causes Insulin Resistance

Binding of insulin to its functional receptor induces autophosphorylation of tyrosine residues on the intracellular part of the receptor. In the metabolic pathway of insulin signaling, the insulin receptor substrate (IRS) then docks the insulin receptor and is trans-phosphorylated in its tyrosine residues via the kinase activity of the phosphorylated insulin receptor. These early events in insulin signaling comprise the key steps in metabolic insulin signaling that are particularly affected in case of insulin resistance. Subsequently, additional members of the metabolic insulin signal transduction pathway will dock onto the phosphorylated-IRS molecules. Most importantly, phosphatidylinositol-3-kinase (PI3 K) and Akt/protein kinase B (PKB) are recruited and activated in order to induce downstream effects [40]. Insulin signal transduction via PI3 kinase mainly affects metabolic pathways such as GLUT-4 translocation, inhibition of hormone-sensitive lipase, increased glycogen synthesis/decreased gluconeogenesis, and increased nitric oxide (NO) production, with the exact response depending on the metabolic machinery of the target cell. The other main pathway of insulin signal transduction involves signal transduction via the Ras G-protein/mitogen-activated protein kinase (Ras/MAPK) pathway instead of via IRS. Stimulation of Ras/MAPK signaling by insulin induces mitogenic, rather than metabolic, intracellular responses [40].

Several events can interrupt signaling via the insulin receptor. In general, these are physiological mechanisms that bring about a timely interruption of the insulin signal in order to prevent overshoot and maintain a beneficial physiological insulin response. First, protein phosphatases can dephosphorylate the insulin receptor and the IRS proteins. Second, there may be ligand-induced downregulation of the insulin receptor. Third, insulin receptor signaling inhibits its own signal via induction of pathways that inhibit insulin receptor-mediated signal transduction. This latter physiological negative feedback mechanism is induced when insulin activates mTOR and protein kinase C (PKC)-ζ. These intracellular serine/threonine kinases can then, either directly or indirectly (e.g., via IkappaB kinase beta (IKK-β)), phosphorylate the serine/threonine residues that are present in IRS. Phosphorylation of IRS on serine/threonine residues hampers the tyrosine phosphorylation of IRS via insulin receptor. Thus, serine/threonine phosphorylation of IRS interrupts, or at least reduces, insulin signal transduction via the IRS proteins [41]. In addition, serine/threonine phosphorylation can induce dissociation of IRS proteins from the insulin receptor [42,43], induce degradation of IRS proteins [44,45], remove IRS proteins from complexes that keep them in close proximity to the insulin receptor [46–48], and turn IRS proteins into inhibitors of insulin receptor kinases [49]. So taken together, serine/threonine phosphorylation is a key event in the control and inhibition of insulin signal transduction via the metabolic (IRS- PI3K-AKT/PKB) pathway (see Figure 47.2).

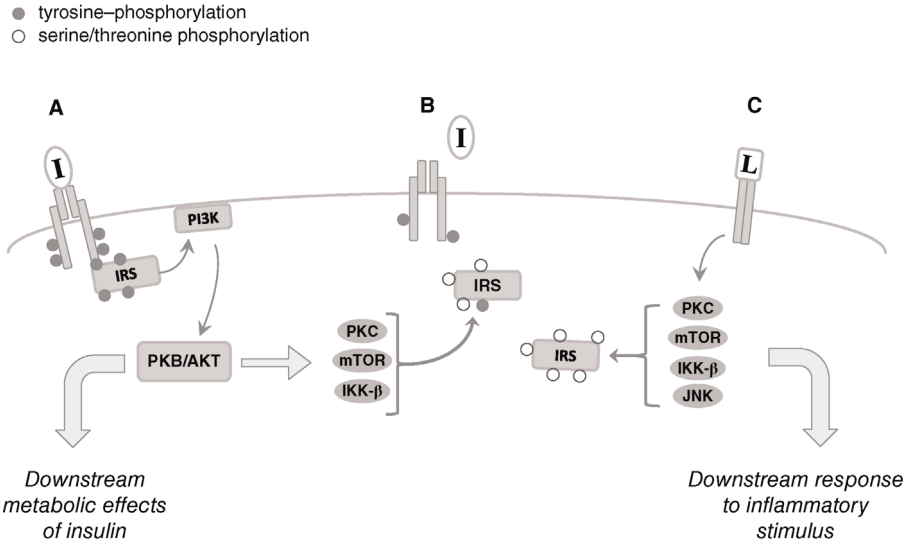

Figure 47.2 The central roles of tyrosine-phosphorylation and serine/threonine–phosphorylation in the control of insulin signal transduction. A: Binding of insulin (I) to its receptor leads to tyrosine autophosphorylation of the intracellular part of the receptor. The insulin receptor substrate (IRS) docks to the receptor and is transphoshorylated on tyrosine residues. Subsequently, the metabolic pathway of insulin signaling via phosphatidyl-inositol-3-kinase (PI3 K) and Akt/protein kinase B (PKB/AKT) is activated. B: activation of PKB/AKT also induces a response that aims to interrupt the insulin signal transduction in order to achieve a sufficient but proportionate insulin response. This includes the activation of factors that induce serine/threonine phosphorylation of IRS. This interrupts the signal transduction via IRS. C: Signaling of various inflammatory ligands (L) via their respective receptors can also induce serine/threonine phosphorylation of IRS. This subsequently hampers tyrosine phosphorylation of IRS in response to binding of insulin to its receptor and thus contributes to insulin resistance.

Notably, a state of chronic low-grade inflammation can directly hamper the efficiency of insulin signal transduction and induce insulin resistance via activation of these physiological negative feedback mechanisms of normal insulin signaling [50]. Various intracellular and extracellular substances that are increased in obesity-associated low-grade inflammation can actually induce serine/threonine phosphorylation of the IRS proteins. As such, they can hamper insulin signaling but in this case with pathophysiological consequences [50]. These substances include, for example, the proinflammatory cytokines TNF-α [51,52], interleukin (IL)-6 [53], IL-1α [54], and saturated fatty acids [55]. These factors employ various intracellular serine/threonine kinases such as IKK-β, Jun-NH2 -terminal kinase (JNK), PKC, and mTOR [50,55]. IKK-β is particularly interesting in this respect since it is a central effector protein in the inflammatory responses that are activated upon stimulation of the intracellular protein transcription factor nuclear factor (NF)-κB. The factors mentioned above primarily affect signal transduction via IRS. And indeed it has been shown that in obesity and in type 2 diabetes, particularly the PI3 K pathway was impaired, while insulin signaling via MAPK remained largely unaffected [56].

Saturated fatty acids, TNF-α, and IL-6 have all been demonstrated to induce insulin resistance in healthy humans [57,58]. This strongly suggests that the above-described induction of insulin resistance by inflammatory factors is indeed relevant in humans, even though most of the available information was obtained in cell and animal studies. Obese, hypertrophic, and/or insulin-resistant adipocytes were shown to have an increased release of fatty acids. Subsequently, saturated fatty acids could activate toll-like receptor (TLR)-4/NF-κB pathways in adipose tissue macrophages, in a paracrine fashion. This then induces release of TNF-α which, in turn, stimulates TNF-receptors on the adipocytes. TNF-induced release of fatty acids can then provoke a vicious cycle of worsening inflammation and insulin resistance [59,60]. JNK is not only activated upon exposure to cytokines and fatty acids but also in response to internal cues such as ER stress [23]. Given the high prevalence of NAFLD in obesity and type 2 diabetes, it is also of interest that experimental activation of JNK in the liver appeared to be sufficient to induce systemic insulin resistance [61]. These data corroborate the view that the liver may be a major contributor to the induction of obesity-associated systemic insulin resistance. The proinflammatory effects of fatty acids appeared to be mainly restricted to the saturated fatty acids, while unsaturated and in particularly ω-3 fatty acids, in contrast, appeared to be anti-inflammatory [62,63].

47.4.2 Inflammation Causes β-cell Dysfunction

The endocrine pancreas is a key player in the maintenance of normoglycaemia. It does so via an increase in β-cell mass and subsequent hyperinsulinaemia [64]. Hyperinsulineaemia may subsequently enhance β-cell mass since insulin may act as a "β-cell growth factor" [65]. However, once the demand for insulin exceeds the production of the pancreas, hyperglycemia will develop (Figure 47.1). β-cell failure can result on the one hand from an intrinsic insulin secretion defect in existing β-cells and on the other hand from insufficient β-cells mass [66]. β-cell failure may be partly due to genetic and partly due to acquired factors. It is probable that genetic disposition may render some individuals more sensitive to those acquired factors than others. This may explain why some (obese) individuals will remain normoglycemic for a long period of time, while others more rapidly progress to hyperglycemia and type 2 diabetes.

In addition to their interference with insulin signaling (as described in Section 47.4.1), inflammatory cytokines may also contribute to β-cell dysfunction and, as such, to development of type 2 diabetes [49]. In addition, prolonged exposure of pancreatic β-cells to high levels of glucose and lipids, also known as glucotoxicity and lipotoxicity, may contribute to oxidative stress – potentially via effects on mitochondrial function – and to high rates of β-cell apoptosis in type 2 diabetes [67–69]. Moreover, impaired signaling via IRS may add to β-cell dysfunction [70,71].

In a state of insulin resistance without diabetes, when fasting normoglycaemia is maintained, there will already be higher than normal increases in circulating glucose concentration after consumption of food. These enhanced postprandial glucose excursions are particularly present in those who have impaired glucose

tolerance [72]. Hyperglycemia can induce the production of IL-1β by β-cells [66,73] and this proinflammatory cytokine was shown to be involved in β-cell deterioration in both type 1 and type 2 diabetes [74,75]. IL-1β may, via induction of specific signal transduction pathways that include Fas (CD95), initially induce β-cell proliferation, but with prolonged hyperglycemia switch to increased β-cell apoptosis [76]. Notably, leptin, which is increased in obesity, was shown to enhance the release of IL-1β by β-cells [77]. In addition to its effects on β-cells, IL-1β may also induce insulin resistance via direct effects in insulin signaling. For example, IL-1β can down-regulate IRS mRNA expression in adipocytes [78]. Clearly, the effects of IL-1β are not the only way through which β-cell mass and function are affected in the development of type 2 diabetes, but the IL-1β pathway is a relevant representative of the many (inflammatory) pathways that are involved in the generation of β-cell failure in response to obesity-associated low-grade inflammation and the concomitant increased insulin demand. Pancreatic lipotoxicity partly results from dyslipidaemia (high small dense LDL cholesterol, low HDL cholesterol, high non-esterified fatty acids (NEFA) and partly from accumulation of fat (triglycerides) in the pancreas as an ectopic fat depot. Increased concentrations of circulating NEFA, particularly saturated fatty acids, are considered harmful for β-cells. First, because saturated fatty acids may induce IL-1β [79] and, as such, trigger an inflammatory response in pancreatic islets [80]. Second, because fatty acids can induce local production of other IL-1-dependent proinflammatory cytokines such as IL-6 and IL-8 [80]. In addition to those effects via interleukins, palmitic acid could also activate JNK in pancreatic β-cells, which was followed by a decrease in insulin gene transcription [81]. In addition, a reduction in the pancreatic triglyceride content led to an improvement in insulin secretion capacity of the β-cells [82]. The effects of lipotoxicity may be enhanced in case of hyperglycemia [83]. The data presented above indicate that both glucotoxicity and lipotoxicity can induce local production of cytokines and inflammation in pancreatic islets. The extent to which circulating cytokines can directly affect β-cell survival as their systemic concentrations remains to be established. *In vitro* studies suggest that externally added cytokines can affect the secretory function of β-cells [84].

Other mechanisms that may enhance β-cell failure in obesity-associated type 2 diabetes include ER stress, oxidative stress, amyloid deposition, and autophagy [85]. Most of these mechanisms have also been implicated in inflammation, either because they induce a (local) inflammatory response or because they result from inflammation [86,87]. The detrimental effects of inflammation on β-cell function may be particularly relevant in situations of a sustained inflammatory response. This is probably the case in obesity and associated glucose and lipid overload [86], but may also contribute to increased prevalence of type 2 diabetes in other conditions that are characterized by a chronic inflammatory state such as endotoxaemia [88], and, possibly periodontitis [89]. Increased numbers of macrophages have been shown in pancreatic islets of patients with type 2 diabetes [80,90], most likely in response to increased islet expression of IL-1β and chemokines [80,91]. Besides, angiotensin II, which is increased in insulin resistance and type 2 diabetes [92], can induce β-cell dysfunction, independent of vasoconstrictor effects [93].

47.5 How Does Inflammation Cause Vascular Disease in Type 2 Diabetes?

The vascular system can be divided into large (macrovasculature) and small vessels (microvasculature). The main inflammation-associated pathology of the macrovasculature is the development of atherosclerotic plaques in the arteries, which may advance to unstable plaques that can rupture and result in occluded vessels and ischemic events [94]. The microvasculature comprises arterioles, capillaries, and venules. The microcirculation serves to control whole body and tissue metabolism, and blood pressure [95,96]. It does so via three main mechanisms. First, the microcirculation regulates the exchange of nutrients, oxygen, and hormones, second, it drastically dampens large fluctuations in hydrostatic pressure at the capillary level, and third it is an important determinant of the overall peripheral resistance. The latter is because the quantitatively most substantial drop in hydrostatic pressure occurs at the level of the microcirculation [97]. Microvascular dysfunction is defined as impairment in one or more of these functions. In type 2 diabetes, either type of vascular bed can be affected leading to macrovascular or microvascular disease, respectively, or both.

47.5.1 Inflammation Contributes to Macrovascular Disease

Cardiovascular disease is a major long-term complication of insulin resistance and diabetes. Various aspects of (obesity associated) inflammation and macrovascular disease have been extensively reviewed before [98–101]. In short, atherosclerosis, the main process underlying macrovascular disease, starts with activation of the endothelial cells that line the intima. This activation can be induced by, for example, lipids (including NEFA and cholesterol) or inflammatory cytokines [98–101]. Notably, adipose tissue depots in close proximity to the vasculature and the heart have been implicated in the development of vascular dysfunction [98] production of mediators that contribute to a local inflammatory response [102,103] and local insulin resistance, which may directly affect vascular function [104,105].

Endothelial activation is characterized by, among others, increased expression of leukocyte adhesion molecules on the endothelial cells and enhanced binding of leucocytes to the inner lining of the large blood vessels. These leucocytes migrate through the endothelial cell layer to the intima, where they can attract monocytes that transform into macrophages and ultimately into lipid-laden foam cells. Foam cell formation comprises an early event in the generation of atherosclerotic plaques. All these processes may be enhanced in obesity-associated insulin resistance and type 2 diabetes, for instance, because of the ongoing systemic inflammation, the presence of an atherogenic lipoprotein profile, including small dense LDL particles, [106] and the presence of monocytosis [107]. Further progression of the atheroma and generation of rupture-prone atherosclerotic plaques involves a complex interplay of immune cells and inflammatory mediators. Inflammatory pathways are also involved in thrombosis, the late complication of atherosclerosis that is responsible for most of the complications of

macrovascular disease [94,101]. Macrovascular disease is thus perceived to be a major consequence of obesity-induced inflammation, insulin resistance, and type 2 diabetes. Moreover, individuals with insulin resistance or type 2 diabetes appear to be more sensitive to the detrimental effects of endothelial dysfunction than those with normal glucose metabolism [108]. This will render them more prone to develop macro- and possibly also micro-vascular disease in response to deteriorating endothelial dysfunction.

47.5.2 Inflammation Contributes to Microvascular Disease

Microvascular dysfunction may also contribute to the vicious cycle of adipose tissue dysfunction and inflammation. Capillary recruitment, which has been shown to be necessary for normal insulin-mediated glucose uptake by skeletal muscle, is impaired in obese insulin-resistant humans and rats [109]. Increased systemic concentrations of NEFA and inflammatory cytokines, and decreased concentrations of adiponectin, as is present in obesity-associated inflammation, can induce endothelial insulin resistance and reduce local NO production. This may lead to a reduction in insulin-mediated glucose uptake in muscle, by as much as 40% and, as such, contribute to whole-body insulin resistance. A small but metabolically relevant ectopic fat depot, that is, perivascular fat, is located around resistance arterioles of muscle. Perivascular fat may directly affect the function of the microvessels. Indeed, it appeared that in lean mice perivascular fat had a beneficial effect to stimulate insulin-induced vasodilation due to local adiponectin production, which was lessened in obese mice [110].

Functional capillaries in the expanding adipose tissue are necessary to provide optimal blood flow and delivery of nutrients and oxygen to adipocytes. Thus, insufficient adipose tissue angiogenesis and capillarisation may lead to hypoxia and induction of an inflammatory response [111]. A relative reduction in the density of the capillary network combined with microvascular dysfunction may further aggravate the hypoxic and inflammatory processes in expanding adipose tissue and lead to deterioration of insulin resistance and metabolic homeostasis [112]. Adipose tissue is capable of producing all the factors of the renin-angiotensin-system (RAS) that are needed to produce angiotensin II, and RAS activity is enhanced in obesity [109,113]. In the expanding adipose tissue, microvascular dysfunction may therefore be aggravated via increased (local) production of angiotensin II. Moreover, cross-talk between the signaling pathways of insulin and angiotensin II as well as a disturbed balance in relative contributions of AT1R and AT2R activation in response to antiotensin II in insulin resistance appear to modulate endothelial function and contribute to endothelials dysfunction [114].

Microvascular dysfunction may additionally contribute to the development of type 2 diabetes via effects on β-cell function. For example, transient periods of (mild) hyperglycemia that coincide with insulin resistance as well as low-grade inflammation – possibly in combination with increased NEFA and dysregulation of adipokines – may lead to reduced islet perfusion and (mild) islet ischemia [115] and control the recruitment of inflammatory cells to the islets [116].

47.6 Master Regulators and Potential Novel Targets to Counteract Obesity-Associated Inflammation in Type 2 Diabetes

As described in the previous sections, the various pathways via which obesity, inflammation, insulin resistance, and β-cell function are interconnected form a complex and intricate system. Together they determine whether an (obese) individual will develop chronic, systemic inflammation and insulin resistance, and also whether he or she will progress to develop hyperglycemia and type 2 diabetes. Several major contributors have been identified. These include cellular components such as the metabolic master switch 5′ AMP-activated protein kinase (AMPK), PPAR-γ, the inflammasome, and NF-κB, and also extend to metabolic or regulatory systems such as the incretin pathway, carbonyl and/or oxidative stress, the innate immune system, including complement, the microbiome, endotoxaemia, epigenetic signatures, and many more. Several of these have over the years been proposed – and partly also implemented – as potential targets for control of inflammation and prevention of insulin resistance and type 2 diabetes. In this section, we will discuss a selection of these potential targets for intervention, that is, PPAR-γ, the inflammasome, the gut microbiome, the complement system, dicarbonyl compounds/AGEs, and lifestyle.

47.6.1 PPAR-γ and PPAR-γ Agonists

PPAR-γ is a member of the nuclear receptor superfamily and acts as a ligand-inducible transcription factor. PPAR-γ plays a key role in the regulation of metabolic homeostasis and inflammation. PPAR-γ is strongly expressed in adipose tissue but also in cells of the immune system [117]. The natural ligand of PPAR-γ has not yet been identified. Most endogenous ligands identified thus far are dietary metabolites, mostly fatty acid metabolites that generally have low affinity [118]. Enhanced PPAR-γ signaling generally has beneficial effects on insulin resistance and type 2 diabetes and it remains to be determined to what extent these effects are primarily related to the metabolic or to the anti-inflammatory effects of PPAR-γ agonism.

Thiazolidinediones (TZDs) are synthetic PPAR-γ agonists that act as insulin sensitizers and are used in treatment of type 2 diabetes (reviewed in [119,120]). TZDs increase insulin sensitivity, lower postprandial glucose, and fatty acid concentrations and have anti-inflammatory effects [120]. Several lines of evidence, mainly derived from animal studies, show that the insulin sensitizing effect of TZDs is primarily conferred via effects in adipose tissue [119]. The adipose effects of TZDs include improved expandability of white adipocytes leading to a reduction in ectopic fat, increased production of adiponectin, and induction of the polarization of adipose tissue macrophages toward the anti-inflammatory M2 phenotype [119]. The first TZDs entered clinical practice in the late 1990s. These compounds were efficient with respect to improvement of glycaemic control, but had side effects that have hampered their full implementation and development [119]. For instance, all PPAR-γ agonists promote weight gain due to fat

accumulation (albeit in the subcutaneous, rather than abdominal of ectopic depots), fluid retention, and bone fractures [120]. Moreover, the first PPAR-γ agonist that was approved for glycaemic control, that is, troglitazone, was removed from the marked in 2000 due to severe hepatotoxic effects [121,122]. In contrast, another PPAR-γ agonist, pioglitazone, is actually implicated in improvement of nonalcoholic steatohepatitis [119,120]. This effect may partly be attributable to improvement in (adipose tissue) insulin resistance, and partly to anti-inflammatory of immunomodulatory effects [119].

For future development of novel PPAR gamma regulators, lessons learned over the past 15 years from first-generation drugs are currently used to develop more efficient drugs with less side effects. Directions that are currently explored include dual-action PPAR-α/γ agonists and selective PPAR-γ modulators (SPPARMs), which are partial PPAR-γ agonists [118–120]. SPPARMs are non-TZD compounds that separate the insulin sensitizing effects of PPARγ agonists from the transcriptional activation of genes that result in unwanted side effects. One SPPARM (INT131) has by now progressed into clinical trials [123]. Interestingly, one particular angiotensin II type 1 receptor blocker telmisartan has been identified to have partial PPARγ agonist properties [124]. Finally, modulatory rather than agonistic interference with PPAR-γ activation may be a viable future perspective. This approach is taken in the development of compounds that block cyclin-dependent kinase 5 (Cdk5)-mediated phosphorylation of PPAR-γ, preferably without transcriptional agonism [125].

47.6.2 Inflammasome

Recently, inflammasomes have been proposed as central regulators of early adipose tissue inflammation. The inflammasome is an important cellular danger-sensing system. It consists of pattern-recognition receptors (PRRs) that assemble into high-molecular weight platforms that control maturation and secretion of proinflammatory interleukins, primarily IL-1β, which has a central role in inflammatory processes [126]. The NOD-like receptor family pyrin domain containing 3 (NLRP3) is one of the best characterized members of the inflammasome-family [127]. NLRP3 releases bioactive caspase-1, which can cleave procytokines, for example, pro-IL-1β, into their mature active forms, that is, active IL-1β [128]. The expression of inflammasome NLRP3 components is increased in obesity, while whole-body knockout of components of this complex in mice resulted in protection from obesity (due to higher energy expenditure), and from inflammation and insulin resistance [26]. Several endogenous stress signals, including glucose, palmitate, cholesterol crystals, islet amyloid peptides, and reactive oxygen species, have been suggested as potential *in vivo* inflammasome inducers, but their relevance in the etiology of human obesity and insulin resistance remains to be elucidated. Notably, the NLRP3 inflammasome may be causally involved in induction of obesity and insulin resistance [129,130], at least in mouse models. Moreover, the NLRP3 inflammasome was shown to be upregulated in immune cells of human type 2 diabetes patients, *ex vivo* [131], although the trigger for this upregulation has not yet been identified. Controlling

obesity-associated chronic inflammation via modulation of the NLRP3 inflammasome and control of IL-1β activity is an area of active research.

A possible angle for control of NLRP3 activity in the future is to apply endogeneous or exogeneous miRNAs that are negative regulators of NLRP3 [132]. Also several known small-molecule inhibitors of inflammation have been shown to affect NLRP3 inflammasome activity [133,134]. However, at this point in time, the best option to control the effect of inflammasome activation is to target the main product of the NLRP3 inflammasome, IL-1β [133]. Already a decade ago it was shown that in islet of patients with type 2 diabetes there was an increased expression of IL-1, while expression of IL-1Ra, that is, the natural IL-1 receptor antagonist, was decreased [77], which makes IL-1β a target with good prospective. IL-1β activity can be blocked via for example, IL-1 receptor antagonists, or anti IL-1β antibodies [135]. The relevance of IL-1β blockade in the control of human type 2 diabetes, and in particular β-cell function, has been shown in a placebo-controlled proof-of-concept study with anakinra, an IL-1 receptor antagonist [136,137].

47.6.3 Gut Microbiome

Another target for the treatment of insulin resistance and diabetes that is still in the experimental stage is the gut microbiome [138,139]. The composition of the gut microbiome contributes to the inflammatory response that is seen in insulin resistance and type 2 diabetes. Fecal transplantation, an innovative approach to manipulate the gut microbiome, has been applied in humans and resulted in improved insulin resistance [140]. More indirect intervention in the gut microbiome such as bariatric surgery [141] or dietary interventions [142] may also induce beneficiary alterations of the microbiome composition and better insulin sensitivity. Moreover, higher concentrations of gut-derived endotoxins were seen in obese than in nonobese [143]. This has been observed both in humans and in animal models. Experimental endotoxaemia can induce adipose tissue inflammation and insulin resistance in lean human subjects [144]. Even at relatively mild levels, endotoxaemia may trigger TLRs, for instance, in adipose tissue or on pancreatic β-cells, and as such contribute to insulin resistance and β-cell failure [145]. Besides, gut-derived endotoxaemia may via the portal vein also induce inflammation in steatotic livers. As such, endotoxaemia may comprise a risk factor for progression of simple steatosis toward nonalcoholic steatohepatitis [146].

47.6.4 Complement

The complement system is a complex protein network that was initially identified as part of the innate immune system. Nowadays, the complement system is, in addition to its well-known role in immunity, increasingly recognized as an essential regulator of cell and tissue homeostasis [147,148]. Notably, the central component of the complement system (C3) has been identified as an independent risk factor for type 2 diabetes [149,150].

The complement system consists of soluble and membrane-bound proteins that function in cascades of stepwise protease activation. Complement can be

activated via several pathways – the classical, the lectin, and the alternative – all of which converge on complement C3. Activation of C3 initiates the activation of the terminal complement pathway. Compelling evidence from experimental animal studies indicates that the complement system – and more specifically the alternative and terminal pathways of complement activation – is causally involved in the development of insulin resistance as well as glucose and lipid metabolism. Most importantly, C3a-receptor knock-out mice are protected from high-fat-diet-induced insulin resistance and have less macrophage infiltration in adipose tissue [151] and similar data were obtained in C5a-receptor knock-out mice [152]. These observations on C3a and C5a and their receptors suggest that complement activation in obesity, and in particular in hypertrophic, metabolically stressed adipocytes, may contribute to recruitment of immune cells from the circulation to the adipose tissue. Also, recently the terminal pathway of complement activation was implicated in activation of the NLRP3 inflammasome [153,154]. Additionally, complement activation in humans is strongly associated with systemic (low grade) inflammation [155–157]. There is also a growing body of data that complement activation leads to endothelial dysfunction [156–158], especially when protection of the endothelial cells is compromised due to decreased expression of complement inhibitors [159]. Since the microvasculature comprises approximately 98% of the total vascular surface area [160], complement activation will inevitably affect microvascular function and may, as such, further contribute to development of insulin resistance and type 2 diabetes.

47.6.5 Dicarbonyl Compounds and AGEs

Advanced glycation end products (AGEs) form a heterogeneous family of unavoidable by-products that are formed by, among others, reaction of intracellular or extracellular proteins with reactive dicarbonyl compounds [161]. Reactive dicarbonyl compounds are generated during metabolism of glucose, lipid, and amino acids [162]. The most potent glycation product, the reactive dicarbonyl compound methylglyoxal (MGO), is mainly generated during glycolysis [163] and is increased in humans with insulin resistance and type 2 diabetes [164]. In obesity, the combined effects of enhanced food consumption, low energy expenditure, hyperglycemia, hyperlipidemia, and increased oxidative stress may augment the formation of AGEs. Indeed, obese individuals were characterized by accumulation of AGEs in adipose tissues [165] that may contribute to low-grade inflammation in obesity [166]. AGEs are involved in the development of vascular disease in diabetes [167,168]. Besides, AGEs have also been implicated in the development of obesity and diabetes [169] and have been found to be associated with insulin resistance [170]. In addition to the effects in insulin resistance, increased levels of dicarbonyl compounds and AGEs have been shown to also induce β-cell dysfunction and apoptosis, at least partly via the AGE-RAGE axis [171] and via effects of MGO [172,173]. There are indications in the literature that the effects of RAGE and IL-1β in obesity and type 2 diabetes are intertwined and have the potential to enhance one another [174] but the exact details for this remain to be elucidated.

47.6.6 Nonpharmacological Management of Inflammation in Type 2 Diabetes

Substantial progress in the management of inflammation in diabetes may be found in improvement of the quality of the diet and exercise. Dietary improvements may be achieved via two approaches; first, by consumption of a healthy diet with general anti-inflammatory effects [175], and second by addition of functional food and/or nutraceuticals with anti-inflammatory properties [176]. Medium and high energy physical exercise has long been known to improve low-grade inflammation and insulin resistance in obese individuals [177]. However, progress can also be gained by fine-tuning of interventions in physical activity [178,179]. Moreover, it becomes increasingly clear that, in addition to regular exercise, breaking sedentary patterns will also contribute to improved control of metabolism [180,181].

47.7 Concluding Remarks

Taken together, the interrelations between obesity, inflammation, and type 2 diabetes are becoming increasingly clear. The main points of this chapter are summarized in Box 47.1. The details on exactly where and how inflammation is induced, the temporal order of the events that contribute to insulin resistance and the development of β-cell function, and the role of vascular dysfunction therein remain to be fully elucidated. More detailed knowledge of these events will help to pinpoint optimal targets for prevention and management of type 2 diabetes. We

Box 47.1: Inflammation and Type 2 Diabetes: Key points

- Visceral and ectopic fat are implicated in the adverse metabolic phenotype that often coincides with central obesity.
- In obesity and type 2 diabetes, it is primarily the metabolic pathway of insulin signaling (via IRS and PI3 kinase) that is affected.
- Glucotoxicity, lipotoxicity, ER stress, oxidative stress, and amyloid deposition may all contribute to β-cell failure in obesity-associated type 2 diabetes.
- Endothelial dysfunction is a shared factor underlying both micro- and macrovascular dysfunction.
- PPAR-γ is a major target for anti-inflammatory, insulin sensitizing therapy but there is a need for more specific drugs.
- Inflammasomes, particularly the NLRP3-inflammasome, were proposed as central regulators of early adipose tissue inflammation and are a novel target for anti-inflammatory therapy in type 2 diabetes.
- Complement activation may contribute to insulin resistance and type 2 diabetes via (local) inflammation and attraction of immune cells, and may also induce endothelial dysfunction.
- Advanced glycation end products (AGEs) in obesity may contribute to dysregulation of adipokine secretion and the induction of insulin resistance and β-cell dysfunction.

also discussed the growing range of established and emerging targets for pharmaceutical management of chronic inflammation in obesity-associated insulin resistance and type 2 diabetes. In addition to pharmaceutical targets, substantial progress in the management of inflammation in diabetes can be reached by improvement of the quality of the diet and nonexercise movement patterns.

48.1 Introduction

Neuroinflammation is a protective response of the central nervous system (CNS) in an attempt to remove offending materials or harmful stimuli and to initiate a healing process. It is achieved mainly by the activation of microglia (the resident immune cells in the CNS) under tight spatial and temporal regulation by a complex regulating system. As the first line of defense, microglia become readily activated whenever injury or disease occurs and secrete a variety of proinflammatory and potentially cytotoxic soluble factors [1–3]. Excessive amount of these factors can make inflammation neurodestructive. Neuroinflammation is an important contributor to neurodegenerative process. Here we summarized recent progress in understanding inflammation-mediated neurodegeneration from creation of inflammation-related models to exploration of cellular and molecular mechanisms and development of therapeutic interventions for neurodegenerative diseases.

48.2 Neuroinflammation Is a Double-Edged Sword in Neurodegenerative Diseases

Neuroinflammation is a complex cascade of self-defense response of the CNS to injurious stimuli. It eliminates harmful agents (e.g., pathogens, damaged cells/tissues, and autoimmunogens) and initiates tissue repair. Being different from peripheral organs, the CNS only has microglia as the resident immune cell, and it lacks leukocytic infiltration resulting from restriction of blood–brain barrier (BBB), a membrane structure that restricts passage of cells and many substances

from blood to brain. The CNS has been accepted to be immunologically specialized. We will review recent evidence showing that neuroinflammation plays critical roles in both maintaining brain function and participating in the pathogenesis of neurodegenerative diseases.

48.2.1 Neuroinflammation and Its Physiological Roles

Inflammation in the CNS (neuroinflammation) primarily involves the activity of two types of glial cells: microglia (the resident innate immune cells in the CNS) and astroglia. An acute insult to the CNS triggers rapid microglial activation, the principal component of neuroinflammation. During late embryonic and early postnatal brain remodeling and maturation, microglia participate in the programmed elimination of neural cells [2,4,5]. Microglia are distributed throughout the mature CNS and they constitute approximately 15% of the total CNS cells. In mature brains, resting microglia exhibit ramified morphology and conduct immune surveillance [4]. While the small cell bodies remain stationary, their long branches are constantly moving and surveying the surrounding area [5]. Microglia are very sensitive and sense a wide range of stimuli that disrupt physiological homeostasis, including trauma, ischemia, infection, toxic insult, and autoimmune injury in the CNS [3,4,6]. Activated microglia undergo dramatic morphologic changes (from a resting, ramified shape into an active, ameboid shape), upregulation of surface molecules (e.g., complement receptors and major histocompatibility complex molecules), phagocytosis, proliferation, and secretion of inflammatory/cytotoxic factors (e.g., eicosanoids, cytokines, chemokines, reactive free radicals, and proteases [1–3]. Phagocytic microglia (ameboid shape) migrate along a chemotactic gradient to reach the injury site, phagocytose cellular debris or foreign materials, release chemokines to attract more microglia, and secrete inflammatory factors to promote more microglia to proliferate [1–3]. These inflammatory mediators not only modulate immunological actions but also act on neurons to alter their function.

Astroglia also become activated in response to CNS injuries or immunologic challenges, but the proinflammatory function of astroglia is not as prominent as that of microglia [7,8]. Astroglia provide physical contact and nutrition to neurons, maintain ionic homeostasis, buffer excess neurotransmitters, modulate synaptic transmission, secrete neurotrophic factors, and serve as an important component of BBB [9,10]. The processes of astroglia enwrap synapses, the junctions between the axon terminals of a neuron and the receiving cell (a neuron, muscle cell, or gland cell). Astroglia express transporters (e.g., glutamate transporters) and participate in the reuptake and/or release of neurotransmitters including glutamate and GABA (gamma-aminobutyric acid), the principal excitatory and inhibitory neurotransmitter in the CNS, respectively [10]. When activated, astroglia upregulate the expression of cell-type-specific protein glial fibrillary acidic protein (GFAP) (GFAP), increase the secretion of neurotrophic factors, and release several proinflammatory cytokines [11,12]. Enlargement and increased proliferation of astroglia to fill up the left space after microglial phagocytosis of neural debris is thought to be a form of repair of CNS injuries [3]. Astrocytic scars (a dense glial scar formed by mature, hypertrophic astroglia)

prevent local infections/injuries from being widespread. Collectively, interactions among neurons, microglia, and astroglia are essential for maintaining the integrity and function of the CNS.

48.2.2 Association of Neuroinflammation and Neurodegenerative Diseases

Ample genetic, clinical, epidemiologic, and animal studies have demonstrated that inflammatory and immune responses play an important role in the pathogenesis of AD and PD, the two most prevalent neurodegenerative diseases. For instance, postmortem observation of brains of patients and animal models of AD revealed close association of amyloid plaques (the key pathological hallmark of AD) and activated microglia and astroglia [13]. Neuroradiological studies using positron emission tomography (PET) and the peripheral benzodiazepine ligand PK11195 detect activated microglia in the early stages of pathology of AD without cerebral atrophy [14]. Similarly, the substantia nigra of patients and animal models of PD revealed activated microglia and accumulation of inflammatory mediators [2,15]. These long-standing pathological observations uncover possible involvement of inflammation in neurodegenerative diseases but cannot distinguish whether inflammation initiates, exacerbates, or attenuates disease pathogenesis. Epidemiologic studies and case reports have suggested increased possibility of developing postencephalitic Parkinsonism several decades after early-life viral infections in people [16–20]. Experimental exposure of rodents to Japanese encephalitis virus, bacterial endotoxin lipopolysaccharide (LPS), and highly pathogenic H5N1 influenza virus can partially mimic PD-like neurodegeneration and gliosis in the substantia nigra as well as movement impairment [21–30]. Moreover, prospective studies suggest that higher plasma concentration of proinflammatory cytokine interleukin-6 correlates with an increased risk for PD [31]. The genetic studies from the past decade have identified several AD- or PD-associated genes functioning in inflammation and the immune system. DNA polymorphisms of several inflammatory cytokines might become risk factors for PD [32]. A recent genome-wide association study (GWAS) of 2000 PD patients and 1986 controls identifies an association of genetic variation in the HLA (human leukocyte antigen) with late-onset sporadic PD [33]. HLA contains a large number of genes related to immune function in humans. Additional GWASs have also implicated several AD susceptibility genes, such as *CR1*, *CD33*, *MS4A4A/MS4A4E/MS4A6E* cluster, *ABCA7*, *CD2AP,* and *EPHA1* [34–36]. Some evidence has indicated/implied that these genes are involved in the regulation of inflammation and the immune system [37]. Another GWAS of 59 AD candidate proteins has reported genetic associations with CSF levels of five proteins, of which chemokine (C–C motif) ligand 2 (CCL2), chemokine (C–C motif) ligand 4 (CCL4), and interleukin 6 receptor (IL6R) are important inflammatory mediators [38]. These hypothesis-free GWASs lend strong and independent support to an important role of inflammation in the pathogenesis of AD and PD, and more importantly, they pinpoint urgent investigations of potential causative involvement of these susceptibility genes in AD/PD etiology. Moreover, epidemiological studies and clinical trials suggest some beneficial effects of chronic use of nonsteroidal anti-inflammatory drugs

(NSAIDs) on the development of AD or PD, but there are some conflicting findings [39–46]. Altogether, the evidence summarized above has indicated that inflammation play an important role in neurodegenerative diseases.

48.2.3 Beneficial Effects of Neuroinflammation

A precisely controlled neuroinflammation will benefit the CNS by destructing pathogens (e.g., viruses or bacteria) or other foreign materials, removing cellular debris, eliminating toxic substances (e.g., aggregated amyloid and α-synuclein), preventing spread of infections and injuries, releasing neurotrophic factors, and promoting tissue repair and regrowth [12,47,48]. For example, in AD, microglia cluster around extracellular senile plaques in which they phagocytose and degrade amyloid-β (Aβ) deposits [49–51]. Activated microglia also secrete numerous cytotoxic factors, including reactive oxygen species (ROS), proteases, cytokines, and glutamate, to destroy infectious organisms and infected neurons [1–3].

Neuroinflammation also paves the way for repairing CNS-damaged tissue. During neuroinflammation, microglia and astroglia undergo several steps to promote regeneration of neural tissue. These include the secretion of anti-inflammatory cytokines, the recruitment of microglia and astroglia to the damaged site, and the release of neurotrophic factors. Indeed, glia-derived neurotrophic factor (GDNF) has been reported to promote neuronal survival and rescue injured dopamine neurons in several animal models of PD [52]. Microglia stimulate myelin repair and prevent neurodegeneration in chronic CNS diseases [47]. In addition, activated microglia physically remove the branches from neuronal perikarya near damaged tissue. This process is called synaptic stripping that facilitates regrowth and remapping of damaged neural circuitry [53]. Moreover, the localized production of chemoattractant molecules, the microglial chemotaxis, and the formation of astrocytic scars in the injury site prevent local lesions and infections from widely spreading.

Coordination among activated microglia, astroglia, and neurons plays a pivotal role in mediating tissue repair and fighting off the infection with minimal damage to the healthy CNS cells [5]. It seems that the beneficial effects of inflammation are apparently either inadequate or ineffective in neurodegenerative diseases. Thus, a reduction in generating these neuroprotective effects in response to CNS injuries might remove an important defense mechanism and consequently worsen the disease process.

48.2.4 Detrimental Effects of Neuroinflammation

As described earlier, a well-regulated neuroinflammatory process is essential for CNS homeostasis and proper function. However, excessive inflammatory response of microglia can become destructive. For example, although the initial aim of the secretion of various inflammatory factors from activated microglia is to destroy bacteria, viruses, and infected neurons, these inflammatory factors can also create considerable bystander damage to neighbor healthy tissue. In fact, ample evidence has demonstrated that in chronic inflammatory conditions,

microglia can be neurotoxic and play a major role in the pathogenesis of neurodegenerative diseases [1,54–56].

A restricted cell renewal and regenerative capacity of neural tissues renders the CNS extremely vulnerable to uncontrolled autodestructive immune and inflammatory processes. To date, a great amount of compelling data show inflammatory exacerbation of neurodegeneration in various neurodegenerative diseases. First, an excessive inflammatory response correlates with neuronal loss in various neurodegenerative diseases [13,55,57]. Second, epidemiological studies indicate a possible beneficial effect of long-term use of NSAIDs in both AD and PD [40–42]. Third, genetic studies reveal increased risk for AD and PD in individuals with DNA polymorphisms of several inflammatory cytokines [58,59]. Fourth and most important, experimental evidence shows that the suppression of inflammatory processes mitigates neuronal impairment in models of various neurodegenerative diseases [1,60–62]. Taken together, neuroinflammation displays neuroprotective and neurotoxic functions and is now increasingly accepted as a double-edged sword in neurodegenerative diseases [12]. The combined effects of individuals' vulnerability (e.g., genetic predisposition), level and period of insults (acute or persistent injurious stimuli), and concurrent events (e.g., stressors or existing diseases) with immune regulation eventually determine whether the immune reaction is a beneficial physiological one or a chronic neurodestructive one. With failed regulation of the immune reaction, uncontrolled sustained neuroinflammation, either as an initiator or as a secondary reaction to initial direct neuronal damages, could drive the chronic, progressive neurodegenerative process where detrimental effects of inflammation overcome its beneficial effects.

48.3 Inflammation-Related Models of Neurodegenerative Diseases

The most common features of various neurodegenerative diseases are the late onset, slow, progressive neurodegenerative process, and the prominent microglial activation in the diseased brain regions. The lack of animal models that recapitulate the delayed and progressive nature along with other key features of neurodegenerative diseases has impeded the progress in understanding the pathogenesis of these diseases and developing disease-modifying therapeutics. Several inflammation-associated models created in the last decade better mimicked the slow progression and other critical features of neurodegenerative diseases and provided an opportunity to explore the cellular and molecular mechanisms of the progressive nature of these diseases. Using PD as an example for a variety of neurodegenerative diseases, we summarize recently developed inflammation-associated models. PD, the second most common neurodegenerative diseases, is characterized by the progressive degeneration of the nigrostriatal dopaminergic pathway and consequent movement impairment. Intracranial or systemic administration of LPS or virus into rodents has been used to produce inflammation-associated PD model.

48.3.1 LPS-Induced PD Models

LPS, the active immunostimulant in the cell wall of Gram-negative bacteria, has been used as a representative inflammogen for direct immunological insults. Direct nigral injection of LPS causes robust microglial activation and acute loss of nigral dopamine neurons in rodents [22,24,63,64]. Because LPS has no direct effect on neurons, LPS-elicited neurotoxicity is entirely dependent on the activation of microglia. Chronic infusion of LPS for 2 weeks into the rat substantia nigra triggered a rapid activation of microglia, followed by a selective and gradual loss of nigral dopamine neurons that reached 70% by 10 weeks [25]. This is the first subacute PD model indicating that persistent microglial activation induced by chronic exposure to inflammogen was able to mimic the most fundamental pathological feature of PD, the delayed, progressive and selective degeneration of nigral dopamine neurons. Microglia-generated ROS play a critical role in dopaminergic neurotoxicity in this inflammation-mediated model of PD [25]. Next, a chronic inflammation-elicited PD was created by an intraperitoneal injection of LPS (5 mg/kg) in C57BL/6 mice. In this model, significant loss of nigral dopamine neurons was detected 7 months after the LPS injection and progressed further overtime [29]. Poor passage of peripheral LPS through the intact BBB [65] indicates the neuroinflammation and neurodegeneration induced by a systemic LPS injection is likely an indirect effect of LPS. Mice deficient in TNF receptors (TNF R1/R2$^{-/-}$) are protected from LPS-elicited chronic neuroinflammation and progressive dopaminergic neurotoxicity [29]. Thus, inflammatory cytokines such as TNFα played a critical role in transferring inflammation from the periphery to the CNS and mediating chronic progressive neurodegeneration in this chronic PD model [29]. Moreover, maternal exposure of developing rat fetuses to LPS was used to study how prenatal inflammation affects neurodevelopment of nigrostriatal dopaminergic system and subsequently alters the vulnerability of adults to inflammation-elicited neurotoxicity [26]. The neonates with *in utero* exposure to LPS displayed lesions of nigrostriatal dopaminergic system, which persists into adulthood [26]. Adult rats with prenatal exposure to LPS developed progressive dopaminergic neurodegeneration after chronic nigral LPS infusion in adulthood [27]. These findings together indicate that once reaching certain threshold, the inflammatory process is capable of initiating neurodegeneration. The higher density of microglia in the substantia nigra than other brain regions [23,66] may be partially responsible for the foremost loss of dopamine neurons in the inflammation-induced neurodegenerative process in PD models with systematic LPS exposure.

48.3.2 Virus-Associated Inflammatory PD Models

Epidemiologic studies and case reports have suggested an association between early-life viral infections and postencephalitic Parkinsonism [16–20]. People infected by highly pathogenic H5N1 influenza virus display acute neurological lesions ranging from mild encephalitis to motor disturbances to coma [67,68]. However, the long-term neurological manifestations of H5N1 infection in surviving hosts remain unknown. Whether viral infection can act as an initiating factor in human PD is unclear. Experimental administration of Japanese encephalitis virus or H5N1 influenza virus has been used to study whether virus-

associated inflammation can partially mimic PD-like pathological and behavior alteration in animals [21,30]. Exposure of neonatal Fisher 344 rats to Japanese encephalitis virus can induce degeneration of dopamine neurons and gliosis in the substantia nigra and movement impairments resembling human PD [21]. H5N1 virus administrated by intranasal inoculation in mice traveled into the CNS and induced microglial activation as well as α-synuclein phosphorylation and aggregation. Long after H5N1 virus became undetectable in the brain at 21 days after viral inoculation, microglial activation and α-synuclein pathological alterations persist and a significant loss of nigral dopamine neurons was observed [30]. This study provides important information on the role of virus-associated inflammation in potential long-term impairment to the CNS.

48.3.3 Inflammation-Associated Two-Hit PD Models

The etiology of various neurodegenerative diseases is unclear. Increasing evidence indicates that these diseases may be the final outcome of interactions, over decades of time, among multiple factors including genetic predisposition, exposure to environmental toxins, and the occurrence of neuroinflammation. In addition, most of the current animal models of various neurodegenerative diseases created by using a single environmental insult (e.g., toxin, heavy metals, physical injury, or stress) or a genetic lesion failed to reproduce the full spectrum of the diseases [69,70]. It suggests a combination of genetic vulnerability and an environmental trigger may be required for the development of neurodegenerative diseases. Thus, two-hit animal models are generated to test whether genetic deficiency increases vulnerability of neurons to potential environmental risk factors.

After the stereotaxic injection of LPS into the substantia nigra, transgenic mice overexpressing either wild-type or A53T mutant human α-synuclein, but not α-synuclein knockout mice, developed sustained microglial activation, accumulation of insoluble α-synuclein aggregates, and formation of Lewy body-like cytoplasmic inclusions in neurons, and death of dopamine neurons in the substantia nigra [71]. Furthermore, a two-hit, chronic, progressive model has been created by a single intraperitoneal injection of a relatively low dose of LPS (3×10^6 EU/kg) into 7-month-old transgenic mice overexpressing A53T mutant human α-synuclein [72]. This two-hit chronic PD model displays sustained low-grade neuroinflammation, α-synuclein accumulation and aggregation, Lewy body-like neuronal inclusions containing aggregated α-synuclein, and progressive dopaminergic neurodegeneration in the nigrostriatal pathway [72]. Compared with the previous LPS model [29], in which it took 7 months for LPS-injected mice to manifest PD-like dopaminergic neurodegeneration, this new two-hit model shows much earlier onset and more pronounced loss of nigral dopamine neurons [72]. The α-synuclein pathology, the pathological hallmark of PD, in the two-hit model has not been reproduced in the previous LPS model. This new two-hit model provides a better tool for studying mechanisms of interactions of chronic α-synuclein pathology and persistent neuroinflammation in chronic PD progression. Furthermore, loss-of-function mutations in the *parkin* gene cause early-onset familial PD. Deletion of *parkin* gene in mice failed to produce PD-like phenotypes. The intraperitoneal injection of low-dose of LPS (7.5×10^5 EU/kg)

twice a week into Parkin-deficient mice for 3–6 months resulted in persistent neuroinflammation, oxidative stress, and selective loss of dopamine neurons in the substantia nigra and subtle fine-motor deficits [73,74]. Thus, synergistic effects of low-grade neuroinflammation and dysfunction of α-synuclein or Parkin induce chronic PD neurodegeneration, while neither factor alone is sufficient to cause neuronal death.

Combination of LPS with neurotoxins was also used to mimic PD. Neurotoxin 1-methyl-4-phenyl- 1,2,3,6-tetrahydropyridine (MPTP), a by-product of synthetic heroin, causes Parkinsonism in both human and nonhuman primates. MPTP trigger direct lesion to dopamine neurons after its uptake by dopamine transporter. Neither MPTP nor its toxic product 1-methyl-4-phenylpyridinium (MPP^+) can directly activate microglia [75]. Mice with systemic injection of both MPTP and LPS, but not with either toxin, showed striatal dopamine depletion and reduced stride length at 4 months after the injection. Systemic injection of MPTP alone triggered an acute reduction in striatal dopamine, but the reduction was transient and recovered to normal levels 4 months after the injection [76]. Earlier studies by our group reported synergistic dopaminergic neurotoxicity of a combination of individually nontoxic concentrations of MPTP and LPS or PD-related pesticide rotenone and LPS in midbrain neuron-glia cultures [77,78].

The two-hit models mimic PD multifactorial etiology and recapitulate the key features of PD. They underscore synergistic effects of genetic predisposition and environmental exposure or multiple exposures to environmental risk factors in the development of PD. More importantly, the chronic progressive nature of dopaminergic neurodegeneration makes the chronic two-hit models invaluable for the study of mechanisms of PD progression and for the screening of disease-modifying therapeutics.

48.4 Inflammatory Mechanisms of the Progressive Neurodegeneration

It is well accepted that neuroinflammation loses its defensive nature and becomes destructive to CNS homeostasis once it escapes from the strict regulation and exceeds the threshold of CNS tolerability. The two key question to understand whether and how neuroinflammation determines the slow, progressive nature of neurodegenerative diseases is how neuroinflammation converts initial neuronal damage into chronic, progressive neurodegeneration and how chronic neuroinflammation is formed and maintained.

48.4.1 Dysregulated Neuroinflammation and Injured Neurons Form a Self-Perpetuating Vicious Cycle Driving Neurodegeneration Progression

Various insults to the CNS (e.g., trauma, environmental neurotoxins, or genetic deficiency) can directly trigger neuronal injuries. As a result, microglia become activated. The microglial response secondary to direct neuronal lesions is usually

termed reactive microgliosis, a process involving increased proliferation, recruitment, and activation of microglia. Activated microglia, either as a direct result of immunologic stimuli or as reactive microgliosis, can release a variety of neurotoxic factors to induce or exacerbate neuronal damages. It is well documented that the inflammatory response has a self-amplifying nature. Once microglia escape from the strict regulation normally imposed on them, they lose their defensive features and switch to producing neurotoxic effects [3]. Consequently, a vicious cycle between injured neurons and uncontrolled inflammation occurs inevitably and further contributes to the ongoing disease progression. Both neuroinflammation and neurodegeneration continue even after the initial offending factors are overcome. Long after MPTP has been cleared from the brain, the substantia nigra of MPTP-exposed patients and monkeys displays an active and sustained neuroinflammation as well as active neurodegeneration [15,79]. Similarly, in AD, the extracellular environment remains hostile to neurons even after the removal of amyloid plaques [80]. Collectively, regardless of the type of initial lesions–inflammation by immune stimuli or neurodegeneration by traumatic brain injury, once one event starts, the other event joins in, forming a self-perpetuating vicious cycle that drives the chronic progressive neurodegeneration.

48.4.2 Interactions between Neuron-Derived Self-Compounds and Microglial Mac1 Bridges Microgliosis and Chronic Neurodegeneration

Release of a variety of soluble factors from injured neurons, along with loss of cell–cell contact between neurons and glial cells, can stimulate reactive microgliosis [81–83]. Neurons negatively regulate the reactivity of glial cells through cell–cell contact involving the neural cell adhesion molecules expressed on the surface of both cell types [83] and the CD200 receptor–ligand interaction [84]. A spectrum of noxious self-compounds released into the extracellular milieu following neuronal injuries, such as membrane breakdown products; released/leaked cytosolic compounds (e.g., α-synuclein and neuromelanin); abnormally processed, modified, or aggregated proteins (e.g., α-synuclein and Aβ); altered molecules (e.g., the active form of matrix metalloproteinase-3); and imbalanced neurotransmitters (e.g., elevated glutamate) can serve as stimuli to induce reactive microgliosis [85–89]. Microglia respond to these aberrant endogenous compounds and invading microbes similarly [90].

The pattern recognition receptors (PRRs) rapidly detect and eliminate invading microorganisms and also respond to host-derived ligands to activate inflammatory signaling cascades. Membrane-bound PRRs, such as toll-like receptors (TLRs) and C-type lectin receptors (CLR) are broadly expressed on the surface of innate immune cells, including macrophages and microglia. Mac1 (macrophage antigen complex 1; also known as CD11b/CD18, complement receptor 3, $\alpha_M\beta_2$) is an adhesion molecule of the leukocyte-specific β2 integrin family and also functions as a PRR [91–95]. In the CNS, Mac1 exclusively expresses on microglia and is involved in microglial adhesion, chemotaxis, and phagocytosis [96]. The expression of Mac1 is elevated in numerous neurodegenerative diseases including AD and PD [97,98]. Microglial Mac1 is an important mediator, bridging inflammation and neurodegeneration

in neurodegenerative diseases [85,91,92,99]. A binding study followed by a flow cytometry analysis using Mac1-deficient or wild-type microglia revealed Mac1 might bind with α-synuclein and/or affect microglial phagocytosis of α-synuclein [92]. Mac1 mediated α-synuclein-elicited microglia-dependent neurotoxicity in neuron-glia cultures [92]. Mac1-deficient mice were more resistant to MPTP neurotoxicity [100]. Additionally, deficiency in microglial Mac1 greatly mitigated neuronal death induced by *in vitro* exposure to MPP^+ [100]. Since MPTP and MPP^+ cannot directly activate microglia, Mac1 may react to noxious endogenous substances released from the damaged neurons, thereby enhancing MPTP/MPP^+ neurotoxicity. HMGB1 (high-mobility group box 1, a nonhistone DNA-binding protein), released from inflamed microglia and/or degenerating neurons, acted on microglial Mac1 to mediate chronic neuroinflammation and progressive neurodegeneration [101]. Aβ25–35 has been reported to bind to Mac1 and mediate microglial release of nitric oxide [2,92]. Mac1 might also participate in mediating microglial activation via the interaction with fibrinogen, a blood-clotting factor, which gains access to the CNS after BBB disruption in multiple sclerosis (MS) [99,102]. Interestingly, our recent studies identified Mac1 as a novel surface receptor for extracellular dsRNA in regulating macrophage immune responses. Extracellular polyinosinic:polycytidylic acid (poly I:C; a synthetic dsRNA) activates Mac1 to enhance TLR3-dependent signaling and to trigger TLR3-independent, but Mac1–dependent, inflammatory oxidative signaling. Altogether, Mac1 might play a critical role in mediating microglial activation, especially reactive microgliosis, and subsequent neurodegeneration in various neurodegenerative diseases.

48.4.3 The Coupling of Microglial Mac1 Receptor and NADPH Oxidase

Mac1 reacts to diverse stress stimuli to activate NADPH oxidase leading to production of ROS in microglia [103–107]. NADPH oxidase, an activity-dependent enzyme complex, is widely expressed in various immune cells including microglia. It is a main superoxide-producing enzyme during inflammation. Overexpression of mutant superoxide dismutase 1 (SOD1) enhances activation of microglial NADPH oxidase and subsequent secretion of TNFα elicited by TLR2 stimulation [107]. Regulation of NADPH oxidases activation by TLR2, TLR4, and other TLRs identified in peripheral immune cells and nonimmune cells have not been fully investigated in microglia. However, recent evidence has indicated a critical participation of Mac1 in the activation of NADPH oxidase during inflammation [101,108–111]. ADPH oxidase-generated ROS are required for Mac1-mediated phagocytosis [108]. Mac1 recognizes LPS and some endogenous ligands (e.g., α-synuclein, Aβ, or HMGB1) to induce NADPH oxidase activation [103–106]. The activation of NADPH oxidase and consequent ROS production elicited by these ligands are blunted in Mac1-null microglia, which resulted in less neuronal impairment [103–106]. Thus, the coupling between Mac1 and NADPH oxidase might be an important mechanism underlying microglia-mediated NADPH oxidase-dependent oxidative insults to neurons in neurodegenerative diseases.

48.5 Modulation of Neuroinflammation May Become a Disease-Modifying Therapy for Neurodegenerative Diseases

In neurodegenerative diseases, the role of inflammation can be beneficial and detrimental and can change dynamically over time. The dynamic modulation of inflammatory processes aimed at preventing or interrupting the vicious cycle between damaged neurons and dysregulated inflammation hold promise to halt or slow down the disease progression. When the inflammatory reaction is beneficial but not sufficient, immunization in a well-controlled way may become a choice for neurodegenerative disease treatment. When inflammation becomes destructive, therapeutic interventions to either suppress inflammation or boost endogenous anti-inflammatory signals will become an urgent need. In the meantime, exogenous administration or inducible release of neurotrophic factors to promote neuronal survival and/or regeneration could also become a disease-modifying therapy for neurodegenerative diseases. Most likely, the combination of these therapies could offer best treatment for neurodegenerative diseases.

48.5.1 Novel Anti-Inflammatory Therapy for Neurodegenerative Diseases

With increasing awareness of the detrimental effects of uncontrolled inflammation in the progression of neurodegenerative diseases, pharmacological targeting of progressive neurodegeneration mediated by the uncontrolled inflammation could become a potential disease-modifying therapeutic approach. In fact, various inflammatory pathways, receptors, or enzymes have been tested as prime therapeutic targets for neurodegenerative diseases *in vivo* and *in vitro* models. Correlation of pharmacological inhibition of inflammation with attenuated neurodegeneration as shown by a plethora of *in vivo* and *in vitro* studies [1,13,27,60,61,112] indicates dampening excessive inflammation to controllable levels could become beneficial for neuronal survival.

48.5.2 Therapeutic Targeting NADPH Oxidase

Neuroinflammation and oxidative stress are two intertwined major pathologic factors in neurodegenerative diseases. Among a myriad of inflammatory and cytotoxic factors released from activated microglia, NADPH oxidase-derived ROS are a crucial player in chronic neurodegeneration [50,113,114]. Pathological examinations reveal upregulated microglial NADPH oxidase in diseased CNS regions of patients with AD, PD, or ALS [115,116]. Peroxynitrite (a reactive product of superoxide and nitric oxide) and H_2O_2 (nonradical oxidants) derived from activated microglial NADPH oxidase can enter neurons. They are highly reactive and their excessive production can damage proteins, lipids, DNA, or RNA, leading to cell dysfunction and eventual death [117–119]. Pharmacological inhibition of NADPH oxidase activity with its well-known inhibitors (e.g., apocynin and diphenylene iodonium) and several structurally and functionally different compounds correlates with less neurodegeneration in models of neurodegenerative diseases including AD, PD, ALS, and MS [120–134]. These compounds include sinomenine

(a natural dextrorotatory morphinan analog), squamosamide derivative FLZ, pituitary adenylate cyclase-activating polypeptides, TGF-β1 (transforming growth factor-β1; a known endogenous immune modulator), verapamil, and resveratrol (a nonflavonoid polyphenol with antioxidant and anti-inflammatory properties). All these compounds suppress inflammation, inhibit superoxide release from wild-type microglia, and provide neuroprotection but fail to do so in the absence of NOX2, the catalytic subunit of NADPH oxidase [135–140]. Moreover, the genetic ablation of NOX2 attenuates the neurodegeneration induced by *in vivo* and *in vitro* exposure to diverse challenges, including neurotoxins (e.g., MPTP, rotenone and paraquat), inflammogen (e.g., LPS), aggregated proteins (e.g., Aβ and α-synuclein), extracellular HMGB1, nanometer size diesel particles, and genetic overexpression of mutant SOD and APP in mice as a model of ALS and AD, respectively [57,60,75,92,100,122,141–147]. These multiple lines of evidence strongly implicated overactivated NADPH oxidase as a major mediator of inflammatory oxidative neurodegeneration in various neurodegenerative diseases. Thus, NADPH oxidase, especially its NOX2 subunit, could become a promising therapeutic target for neurodegenerative diseases.

Although preclinical evidence provides a strong rationale for pharmacological modulation of NADPH oxidase activity for neurodegenerative diseases, long-term targeting NADPH oxidase has potential drawbacks. NADPH oxidase is indispensable for host defense. People with mutations in genes encoding subunits of NADPH oxidase are more susceptible to bacterial and fungal infections and chronic granulomatous disease (CGD) [148]. More than two-thirds of CGD cases are X-linked recessive due to NOX2 gene mutations, the remaining CGD cases are autosomal recessive due to gene mutations in $p47^{phox}$, $p67^{phox}$, or $p22^{phox}$. Importantly, one copy of causative NOX2 mutations in females reduces NOX2 activity but does not cause CGD or other ROS-related illness. Only CGD patients whose phagocytic ROS generation lowers to more than two orders of magnitude of healthy controls develop severe illness and poor long-term survival [149]. Thus, it appears feasible to develop therapeutic compounds for neurodegenerative diseases to decrease – but not to abolish – the excessive activity of the NADPH oxidase without compromise of immune function.

The limitations of available NADPH oxidase inhibitors, such as lack of selectivity of diphenylene iodonium for NADPH oxidases, the pro-oxidant potential of apocynin, the irreversible off-target effect on serine proteases and the very low efficacy of 4-(2-aminoethyl)benzenesulfonyl fluoride (IC50 >1 mM), and the nonoral administration routes of NOX2ds-tat peptide limit their clinical translation. Interesting, posttreatment with an ultralow dose of diphenylene iodonium inhibited microglial activation, reduced the expression of proinflammatory factors, attenuated α-synuclein aggregation, mitigated progressive dopaminergic degeneration, and improved rotarod activity in multiple PD models [150]. **T**he action mechanism and the selectivity of other putative NADPH oxidase inhibitors remain to be investigated thoroughly [151–155]. In view of the limitation of existing NOX2 inhibitors in clinical translation and the potential drawbacks to targeting NOX2, more efforts should be devoted to develop novel BBB permeable NADPH oxidase inhibitors with improved specificity, efficacy, and pharmacokinetic profiles. Taken together, with increasing awareness of the

prime role of NADPH oxidases, especially NOX2, in inflammation-mediated chronic neurodegeneration, proper modulation of NADPH oxidases activity might present a promising therapeutic strategy to retard the progression of neurodegenerative diseases.

48.5.3 Targeting Cyclooxygenase (COX) Using NSAIDs

Most NSAIDs act as nonselective inhibitors of the COX enzyme, inhibiting both the COX-1 and COX-2. COX catalyzes the formation of prostaglandins and thromboxane from arachidonic acid. Prostaglandins are produced by almost all nucleated cells and act on diverse receptors to exert a wide variety of effects including regulating inflammation. While COX-1 is constitutively expressed and regulates many physiological processes, COX-2 is expressed upon stimulation in scenarios of inflammation and growth. About 20 epidemiological studies reveal association of chronic use of nonselective COX-1/COX-2 inhibitors (e.g., indomethacin or ibuprofen) with reduced risk for AD [156,157]. The nonselective COX-1/COX-2 inhibitor diclofenac combined with misoprostol (a synthetic prostaglandin E1 analog) led to an insignificant marginal decrease in AD deterioration compared with placebo [158]. In much larger clinical trials, COX-2 inhibitors celecoxib [159,160], nimesulide [161], and naproxen [159,160] failed to show effectiveness in AD patients.

A variety of NSAIDs provide neuroprotection in animal models of PD [162,163]. Most of epidemiological studies suggest reduced risk for PD after chronic use of non-aspirin NSAIDs [39,40,44,45,164–166], but one study reported an increased risk [167]. Regular use of aspirin has been associated with a decreased risk of PD [39,45,165] and either no effect or increased risk [40,164]. A nested case-control analysis in a large cohort of 22 007 male physicians aged 40–84 years did not find evidence that NSAIDs use reduces PD risk [46].

At present, the number of clinic trials concerning the effects of anti-inflammatory drugs on the natural progression of neurodegenerative diseases is too limited to draw a firm conclusion, although there is encouraging experimental evidence [1,13,27,60,61,112]. The low success rate of translating anti-inflammatory drugs from animal models to the human scenario highlights the need for better approaches to anti-inflammatory drug design and more appropriate animal models for preclinical drug screening. In this regard, chronic models are better suited to assessing the progressive nature and to screening the putative disease-modifying therapies.

48.6 Conclusions

In neurodegenerative diseases, neuroinflammation can be neuroprotective and detrimental and its role can change dynamically over time. Dysregulated, prolonged, and self-amplifying inflammatory processes may be a common mechanism underlying the self-propelling nature of numerous neurodegenerative diseases. Owing to its vital role in pathogenesis, inflammation is a prime

therapeutic target for neurodegenerative diseases. Ample preclinical evidence has underscored a pivotal role of overactivated NADPH oxidase in microglia-mediated chronic neuroinflammation and progressive neurodegeneration. Given such an important role and the feasibility of pharmacological modulation of its activity, NADPH oxidase can become a promising target for retarding progression and improving outcome of neurodegenerative diseases. Because of the vicious cycle between uncontrolled neuroinflammation and damaged neurons and the present failure of single drug treatment (anti-inflammation or neuroprotection), drugs with multiple actions and multidrug approaches directed at both inflammatory and noninflammatory mechanisms might represent the most promising therapeutic strategies for neurodegenerative diseases. Although clinical trials have not yet produced encouraging results, conceivably this can change in the near future as we learn more about inflammatory mechanisms of progressive neurodegeneration, development of better disease models, and improvement of trial design.

49.1 Introduction

Atherosclerosis is a major cause of cardiovascular disease and its clinical manifestations such as stroke or myocardial infarction are among the leading causes of death worldwide. The pathology is characterized by a chronic inflammatory condition that is driven by an overload of lipids, particularly cholesterol, and formation of fibrous and lipid-laden plaques in arterial walls [1]. Animal, epidemiological, and clinical studies have all established that high levels of low-density lipoprotein (LDL) and its major constituent, cholesterol, promote atherosclerosis development. Plaque formation is initiated upon endothelial dysfunction at sites of disturbed blood flow. Increased vascular permeability and alterations in composition of the extracellular matrix allow for retention of LDL at these disrupted sites in the subendothelial space [2]. Concurrently, an increase in leukocyte adhesion molecule expression and chemokine release by vascular cells results in immune cell infiltration (e.g. monocytes and T cells) [3]. LDL trapped in the intima is then prone to oxidation, which enhances its uptake by scavenger receptors expressed on macrophages. Macrophages are unable to clear the large amounts of LDL cholesterol they ingest and store them as cholesterol esters in lipid droplets. This gives the macrophages a lipid-laden appearance, hence their description as "foam cells" [3]. In addition, oxidized LDL (oxLDL) is a potent danger-associated molecular pattern (DAMP) and elicits an inflammatory response. As these foam cells accumulate in arterial walls, they recruit more immune cells, including T cells that further drive plaque development. With progression of disease, smooth muscle cells migrate into the intima of affected arteries and start secreting extracellular matrix components resulting in

Inflammation: From Molecular and Cellular Mechanisms to the Clinic, First Edition.

formation of a fibrous cap. Generally, atherosclerosis manifests clinically when the fibrous cap impairs blood flow or ruptures, which may cause myocardial infarction or stroke as a result of arterial occlusion [1].

49.2 Cholesterol Transport and Metabolism in Atherosclerosis

Cholesterol is a major constituent of membranes and is essential for their stability and function. However, excess cholesterol is highly toxic to cells and is therefore rapidly converted to cholesterol esters for storage in lipid droplets or secreted from the cell [4]. Cholesterol can either be synthesized *de novo* from acetyl-CoA or taken up from dietary sources. In the bloodstream it is bound to lipoproteins; the major ones being LDL and high-density lipoprotein (HDL). LDL is secreted from the liver and transports cholesterol to peripheral organs, where it is taken up via the LDL receptor [4]. Additionally, foam cells can take up modified forms of LDL via the scavenger receptors, Scavenger Receptor Class A (SR-A), and cluster of differentiation 36 (CD36) [3]. HDL, in contrast, mediates cholesterol transport from peripheral organs to the liver, a process also referred to as reverse cholesterol transport (RCT). Unlike other lipids, cholesterol cannot be broken down by mammalian cells and as such the only way for foam cells to deplete excess cholesterol is through excretion and subsequent transfer to HDL [5]. RCT is mediated by two members of the ATP-binding cassette transporters: (ABC) ABCA1 and ABCG1, which efflux cholesterol from the cell and transfer it to HDL. Cholesterol loaded in HDL is in turn taken up by the liver, from where it is either secreted directly or as a conjugate form as bile acids [6]. The balance between cholesterol uptake by scavenger receptors and excretion by ABCA1 and ABCG1 is a major determinant of foam cell formation and disease progression. As cholesterol cannot be broken down, RCT and subsequent secretion provides the only way for the body to eliminate excess cholesterol. Thus, understanding and targeting RCT is subject of intense investigation and could have important clinical implications [7].

49.3 Mouse Models of Atherosclerosis

Many crucial insights into the development and progression of atherosclerosis were gained using mouse models. However, due to major differences in lipid metabolism, wild-type mice, unlike humans, do not spontaneously develop atherosclerosis when fed a high-fat or high-cholesterol diet. Therefore, transgenic mouse models are commonly used [8]. Mice deficient in apolipoprotein E (ApoE) or the LDL receptor (LDLR) are the most common transgenic mouse models for studying atherosclerosis. ApoE is the protein component of LDL and mediates the interaction with the LDLR. Absence of either ApoE or LDLR causes defects in cholesterol clearance from the bloodstream and results in hypercholesterolemia. LDLR-deficient animals require a high-fat or high-cholesterol diet to develop

atherosclerosis. ApoE$^{-/-}$ mice spontaneously develop atherosclerosis, but both onset and progression of the disease are accelerated by a high-fat diet [8]. A lack of consistency in diet composition represents a significant limitation of these murine models of atherosclerosis; indeed, a whole spectrum of both control- and high-fat diets, which differ vastly in nutrient composition, especially in regards to fatty acid and cholesterol content, are used for studying atherosclerosis. Therefore, care needs to be taken when comparing mouse studies, and especially when extrapolating implications for human disease from mouse data [3]. Nevertheless, mouse models represent a valuable tool in understanding the mechanisms and identifying mediators of atherosclerosis [8].

49.4 Triggers and Receptors of Inflammation in Atherosclerosis

Over the years, studies in both mice and humans have established that atherogenesis – the process of atherosclerosis progression – is driven by inflammation. Many pattern-recognition receptors (PRRs), which are predominantly expressed on innate immune cells such as macrophages and play key roles in host defense, have been implicated in atherogenesis, including scavenger receptors, toll-like receptors (TLRs), and inflammasomes, some of which will be discussed in the following section [1].

49.4.1 Scavenger Receptors

Scavenger receptors recognize a wide range of ligands and have broad functions in homeostasis and inflammation. The most intensively studied scavenger receptors are SR-A and CD36, which were initially identified as receptors for modified lipoproteins [9], but they also mediate clearance of apoptotic cell debris or cooperate with other receptors to sense pathogens. For example, CD36 is required for recognition of lipoteichoic acid, a component derived from the cell wall of gram-positive bacteria, as part of a complex with TLR2 and TLR6 [9]. *In vitro* studies identified Scavenger Receptors Class A-I/II and CD36 as the major receptors for oxLDL uptake [10]. By mediating this uptake, they not only have a crucial role in foam cell loading, but they also activate a multitude of receptors and signaling pathways.

As already described, free cholesterol is highly toxic to cells and thus rapidly esterified and stored in lipid droplets. In macrophages, oxLDL-derived free cholesterol can activate the unfolded protein response and induce apoptosis [11]. CD36 also mediates uptake of 9-hydroxyoctadecadienoic acid (HODE) and 13-HODE: oxidation products of linoleic acid that are abundant in oxLDL. These molecules are potent activators of peroxisome proliferator-activated receptor (PPAR) γ and promote foam cell formation by sustaining CD36 expression [12].

CD36 also facilitates the activation of other PRRs by oxLDL, including TLRs and inflammasomes.

49.4.2 Toll-like Receptors

TLRs are the best studies class of PRRs. They recognize a wide range of molecules of microbial origin, but also respond to exogenous and endogenous danger signals [13]. Receptor ligation upon ligand binding initiates a downstream signaling cascade that results in activation of transcription factors such as NFκB and expression of target genes, including cytokines, inerferons, costimulatory molecules, or antimicrobial prptides [14]. In the context of atherosclerosis, TLRs are expressed by a multitude of cells, including monocytes, macrophages, T cells and parenchymal cells [15]. TLR4 was originally discovered as the LPS receptor, but was also implicated in atherogenesis from early on. ApoE/TLR4-double-deficient mice fed a high-cholesterol diet exhibit a moderate phenotype with regards to inflammation and plaque formation compared to ApoE-deficient control animals [16]. However, while in a more recent study, LDLR/TLR4-deficient animals fed a high-fat, high-sucrose diet showed a marked reduction in disease severity, they showed no changes in inflammatory parameters. These LDLR/TLR4-deficient mice displayed improved plasma cholesterol levels and a drastic reduction in lesion size of 75% [17]. Interestingly, TLR4 engagement with TLR6 and CD36 upon stimulation with oxLDL induces the expression of proinflammatory cytokines *in vitro*. Mechanistically, CD36 facilitates oxLDL binding, internalization, and recruitment of TLR4 and TLR6. TLR4 and TLR6 activation in turn leads to downstream signaling and transcription of proinflammatory mediators [18]. TLR2 was initially discovered as a receptor for bacterial lipopeptides [14] and its expression is increased in atherosclerostic lesions [19]. Mouse studies further support the relevance of TLR2 in atherogenesis as administration of the TLR2/TLR1 agonist Pam3CysK4 to $LDLR^{-/-}$ mice fed a high-fat diet results in disease aggravation [20]. Interestingly, pharmacological inhibition of TLR2 in human atheroma explants diminishes the expression of inflammatory chemokines and matrix metalloproteases [21]. Together, these data suggest a role for TLR2 in the recruitment of immune cells by the activated endothelium and in plaque progression. Another study addressed the role of TLR2 in the ApoE model fed normal chow. ApoE/TLR2-double deficient animals exhibited reduced plaque formation, macrophage recruitment, and production of the chemokine macrophage chemotactic protein-1 (MCP-1), also known as C–C motif ligand 2 (CCL2) [22] 1. In addition to microbial ligands, TLR2 also recognizes a number of endogenous ligands, including oxidized phospholipids and serum amyloid A (SAA) [23]. SAA is an acute phase protein that is secreted from the liver during inflammation. It is also elevated in patients with coronary artery disease and was shown to induce factors that are involved in neutrophil activation in human coronary artery endothelial cells [24]. TLR2 also triggers apoptosis of plaque macrophages. As already mentioned, free cholesterol can induce ER stress and plaque macrophages express proteins of the UPR response. In concert with CD36, TLR2 activated by oxidized LDL or oxidized phospholipids drives apoptosis of macrophages undergoing ER stress [25].

49.4.3 Inflammasomes

Inflammasomes are another group of PRRs that sense a cholesterol imbalance. The NLRP3 (nucleotide-binding domain leucine-rich repeat containing (NLR) family, pyrin domain containing 3) inflammasome is a multimeric protein complex that consists of the receptor NLRP3, the adaptor molecule Asc (apoptosis-associated speck-like protein), and the effector molecule caspase-1. Inflammasome assembly results in cleavage of procaspase-1 to its active form and subsequent cleavage and maturation of the proinflammatory cytokines IL-1β and IL-18 [26]. NLRP3 inflammasome activation requires two steps: a priming step that drives NLRP3 expression and a second stimulus that leads to NLRP3 activation. Priming can be accomplished by a multitude of PPRs that activate NFκB [27]. NLRP3 itself is then activated by a multitude of molecules ranging from adenosine triphosphate (ATP) to pore-forming toxins and crystalline material. A direct ligand has not been identified so far, but in general NLRP3 activation is triggered in response to a deviation from cellular homeostasis [26].

Cholesterol, which accumulates in artery walls over the course of atherogenesis, is very poorly soluble in aqueous solutions and tends to crystallize at very low concentrations. Indeed, crystal deposition was reported in human atherosclerotic lesions as they advance from fatty streaks to more complex plaques [28]. *In vitro* studies also described intracellular cholesterol crystal formation in foam cells [29,30].

Cholesterol crystals are also activators of the NLRP3 inflammasome [31–33]. They are present in early stages of plaque formation and colocalize with macrophages in human plaque samples [31,32]. *In vitro,* cholesterol crystals that are engulfed by macrophages appear to activate NLRP3 by eliciting lysosomal damage [31]. OxLDL is also capable of activating NLRP3. When fed to macrophages, oxLDL-derived cholesterol accumulates in lysosomes, where it falls out of solution [31]. The uptake and subsequent crystallization of oxLDL-derived cholesterol is CD36 dependent [34]. As oxLDL can also activate NFκB via CD36, TLR4 and TLR6, it can therefore provide both signal 1 and signal 2 and treatment of macrophages with oxLDL indeed results in IL-1β mRNA induction and also secretion [18,34]. Interestingly, while priming requires the heterotrimeric complex of CD36, TLR4 and TLR6, cholesterol nucleation only requires CD36 and still occurs in TLR4- and TLR6-deficient animals *in vivo* [18,34].

49.5 Mediators of Inflammation in Atherosclerosis

49.5.1 Cytokines

IL1α and IL-1β are proinflammatory cytokines that exert their biological activities by binding to the same receptor: the IL-1 receptor (IL-1R) [35]. Both cytokines are synthesized as preforms and as they lack signal peptides, even after maturation do not enter the canonical secretory pathway. IL-1β is synthesized *de novo* upon PRR ligation and requires inflammasome activation and subsequent cleavage by

caspase-1 for secretion. IL-1α is constitutively expressed in a variety of cell types and can also be subject to cleavage by proteases [35]. In contrast to IL-1β, the IL-1α precursor as well as the processed mature molecule is capable of activating the IL-1R [36]. Both molecules however are released via distinct routes: dying cells that lost cellular integrity passively release the unprocessed precursor, while active secretion of Il-1α from intact cells requires processing by calpain-like proteases [37].

Both IL-1α and IL-1β play roles in atherogenesis, which was confirmed in studies using IL-1R-deficient mice [38,39]. Of the two cytokines however, Il-1β is the far more characterized and indeed models of IL-1β deficiency as well as administration of an Il-1β neutralizing antibody show decreased plaque formation [40,41]. However, in a comparative study, while both IL-1α- and Il-1β-deficient mice exhibited a phenotype, intriguingly Il-1α deficiency was more effective in reducing atherosclerosis [42].

The NLRP3 inflammasome is crucial for IL-1β release, however many established NLRP3 activators also elicit Il-1α secretion from macrophages [37] and crystalline activators including cholesterol crystals are able to trigger IL-1α release via an NLRP3-independent mechanism [32]. Reconstitution of LDLR-/- mice with NLRP3-deficient bone marrow nonetheless confers the same protection against atherosclerosis as Il-1α/IL-1β double-knockout bone marrow reconstitution, which suggests that Il-1α from hematopoetic cells is released in a NLRP3-dependent manner [31]. A more recent study highlighted a role for oleic acid in driving atherosclerosis via triggering Il-1α secretion in an ApoE model [43]. Using mass spectrometry, the authors found that after 6 months of high-fat diet, oleic acid was the most abundant fatty acid in plaque samples [43]. While unsaturated fatty acids, such as oleate, generally protect against the deleterious effects of saturated fatty acids [44], at high concentrations they can cause mitochondrial uncoupling [45]. Uncoupling of oxidative phosphorylation by unsaturated fatty acids is a conserved protective mechanism to deplete free fatty acids, reduce lipotoxicity, and protect from apoptosis [45]. In macrophages, this pathway in addition leads to secretion of pro Il-1α [43].

IL-18 is another member of the IL-1 cytokine family. It is synthesized as a preform, requires cleavage by inflammasomes, but in contrast to IL-1β is expressed constitutively [35]. Together with IL-12, IL-18 is a potent inducer of Th1 cells and interferon gamma. On its own it has proinflammatory properties and drives inflammation in many diseases [46]. The IL-18 receptor (IL-18R) is a heterodimer consisting of the IL-18Rα and IL-18Rβ chain [46]. IL-18 expression as well as expression of its receptor is increased in atheroma samples from patients. While the receptors are expressed by macrophages, endothelial cells, and smooth muscle cells, IL-18 expression is confined to macrophages [47,48]. IL-18- deficiency or overexpression of IL-18 binding protein, which sequesters IL-18 and thereby limits its activity, protect from atherosclerosis [49,50]. Conversely, administration of recombinant IL-18 results in a more severe disease phenotype, including increased lesion size and recruitment of proinflammatory cells into plaques [51,52]. Unexpectedly, it was found that while IL-18 deficiency has an effect on atherosclerosis, IL-18R deficiency alone does not. A recent study identified the sodium chloride (NaCl) cotransporter (NCC), also known as Slc12a3, as an IL-18 coreceptor, which

together with the IL-18 receptor complex is essential for IL-18-mediated effects in atherosclerosis. NCC is expressed by macrophages, smooth muscle cells, and endothelial cells and interacts with the IL-18 receptor. Strikingly, only ApoE/IL-18R/NCC triple-deficient mice exhibit a reduced disease phenotype, while ApoE/IL-18R- or ApoE/NCC double-deficient mice do not. IL-18 treatment triggers signaling through the IL-18R as well as NCC, although it remains to be established whether they signal in a complex or if they engage distinct downstream pathways to mediate the overall effects of IL-18 [53].

IL-6 is a pleiotropic cytokine also involved in atherosclerosis that initiates the acute phase response and activates the adaptive immune system during an infection [54]. It is a major mediator of autoimmune diseases such as rheumatoid arthritis and Crohn's disease and blocking of IL-6 signaling in these diseases with antibodies against the IL-6 receptor (IL-6R) is highly therapeutic [54]. The role of IL-6 in atherosclerosis progression is however more complex. In murine models, IL-6/ApoE-deficient mice showed increased diet-induced atherosclerosis, suggesting a protective role for IL-6 in disease progression [55,56]. However, administration of recombinant IL-6 into $ApoE^{-/-}$ mice increased atherosclerotic burden [57]. Interestingly, in two elegant Mendelian randomization studies, single nucleotide polymorphisms in the IL-6 receptor causing defective IL-6 signaling were associated with lower CRP levels and lower incidence of cardiovascular disease (CVD) events [58,59]. While these studies suggest a role for IL-6 in atherogenesis, whether this is protective, harmful or negligible remains unclear. Some of this apparent discrepancy within mouse models of atherosclerosis could be further investigated by interrogating the effect of IL-6R deficiency in an ApoE or LDLR background on atherosclerosis progression, and thereby determining if IL-6 or another cytokine of the family that signals through the IL-6R, contributes to disease.

IL-12 is a 70 kDa heterodimeric cytokine consisting of subunits encoded by two separate genes: *IL12a* (IL-12p35) and *IL12b* (IL-12p40), and is essential for driving a Th1 adaptive immune response [60]. IL-12p40 can also form a homodimer (IL-12p80) as well as another heterodimer with IL-23p19 to form the related cytokine IL-23 [60]. IL-12p40 deficiency is protective in mouse models of atherosclerosis, suggesting a role for IL-12 in atherosclerosis progression [61]. TNF, a 17-kDa cytokine, can further amplify inflammation via NFκB signaling upon activation of the TNF receptor. Furthermore, elevated TNF is a risk factor for CVD [62] and TNF-deficient mice are protected from atherosclerosis development [63], indicating a likely role for TNF in atherosclerosis [64].

49.5.2 Interferons

Interferon (IFN) α and β are members of the class of type I interferons. They are typically released in response to viral infection and are essential for inducing an antiviral state, but are also released during bacterial infection. Their role in atherosclerosis was only discovered quite recently. IFNα is detectable in plaque samples from patients and its levels correlate with plaque instability [65]. In mouse studies, type I IFNs alter monocyte recruitment into the plaque and foam cell lipid metabolism, while myeloid deficiency of their cognate receptor, IFNα/β

receptor (IFNAR), decreases macrophage recruitment and lesion size. Signaling through IFNAR leads to production of the chemokine CCL5 and subsequent monocyte infiltration into the plaque. In agreement with this, IFNβ injection results in increased CCL5 levels, plaque size, and macrophage infiltration [66]. IFNβ can also promote foam cell formation by affecting lipid metabolism. Foam cells treated with IFNβ increase SR-A expression and decrease ABCA1 expression, thereby fostering lipid accumulation [67]. A recent study further emphasized the role of type I IFNs in atherosclerosis: Myeloid cells deficient in the gene *N*-acetylglucosamine *N*-deacetylase-*N*-sulfotransferase 1 (Ndst1) display defects in heparan sulfate proteoglycan biosynthesis and are more sensitive to type I IFN due to decreased IFN sequestration. As a result, they exhibit a more inflammatory phenotype that accelerates atherogenesis [68].

49.5.3 Chemokines

Finally, chemokines also contribute to early-stage atherosclerosis by recruiting monocytes and other immune cells. Endothelial cells that have been activated upon lipoprotein deposition express adhesion molecules and immobilize chemokines, which initiates the leukocyte adhesion cascade. In particular, the capture and rolling stage of leukocyte adhesion appears to be dependent on C-C motif ligand (CCL)-5 and CXC motif ligand (CXCL)1 immobilization, as well as an increase in P-selectin expression on the luminal side of endothelial cells [69]. The interaction of chemokines with their receptors expressed on monocytes is also required for the transmigration of monocytes into the subendothelial layer. Different monocyte subsets with different inflammatory capabilities express different chemokine receptors, but the key chemokine–receptor interactions in atherosclerosis as determined in murine models are CCL2–CCR2, CXCL1–CXCR1, and CCL5–CCR5 [69,70]. Combined inhibition of this chemokine axis resulted in reduced monocyte recruitment and reduction of atherosclerosis progression in ApoE-deficient mice [71]. These chemokines also modulate total circulating monocyte numbers by controlling their release from the bone marrow and their growth and survival [72,73]. Reducing or inhibiting chemokine, chemokine receptor or adhesion molecule activity represents a potential strategy for treating inflammation in atherosclerosis, and indeed a P-selectin blocking inhibitor has shown some promise in initial clinical trials [74].

49.6 Targeting Inflammation Atherosclerosis

Atherosclerosis and its clinical manifestation cardiovascular disease (CVD) are still the leading cause of death worldwide [1] and as such there is intense interest in improving existing therapies, but also education to promote healthier lifestyles.

49.6.1 Potential of Dietary Changes

Epidemiological studies have identified several risk factors for CVD, including lifestyle factors such as dietary intake, exercise, smoking, and alcohol consumption [75,76].

Recent investigations have highlighted the potential of simple dietary adaptations in preventing and alleviating CVD. Two extreme dietary classifications are commonly made: the Western diet, which is rich in dairy products, meat, refined grains, and sugars and is classified as unhealthy [77] and the mediterranean diet, consisting of whole grains, vegetables, legumes, and olive oil [78].

Western diet increases CVD risk [77]. It is typically characterized by high amounts of saturated fats, cholesterol, and refined sugars. In contrast, a Mediterranean diet, which is high in unsaturated fatty acids, fiber, antioxidants, and vitamins protects against CVD development [78,79]. These diets differ not only in their cholesterol content but also in a multitude of other potent bioactive molecules that may modulate atherogenesis by either fostering or dampening inflammation.

Lipids taken up from different dietary sources can vary dramatically in their fatty acid composition. Animal fats are particularly rich in saturated fatty acids, the most prominent of these being palmitic and stearic acid. Saturated fatty acids are sensed by macrophages and have also been implicated in atherogenesis. At high concentrations they can be cytotoxic [44] and induce ER stress [80], which can drive macrophage apoptosis and necrotic core formation in plaques [11]. Strikingly, desaturation of fatty acids reduces ER stress in macrophages and mitigates atherosclerosis development [80]. Saturated fatty acids can also directly activate PRRs such as TLR4 and NLRP3. Palmitate conjugated to BSA activates NFκB signaling and induces cytokine expression in macrophages in a TLR4-dependent manner [81]. Furthermore, TLR4-deficient mice are protected against fatty acid-induced inflammation [81]. A more recent study addressed the molecular mechanism and found that stearate complexed with the serum protein fetuin A is a potent TLR4 activator [82]. Interestingly, serum fetuin A levels are increased in obese patients, which further highlights the relevance of this pathway in the context of metabolic and cardiovascular disease [82]. Palmitate was also shown to activate NLRP3 via inhibition of adenosine monophosphate (AMP)-activated protein kinase AMPK and generation of mitochondrial reactive oxygen species [83]. ApoE-deficient mice fed a diet rich in saturated fatty acids exhibit higher plasma cholesterol levels and accumulate higher amounts of cholesterol-esters in atherosclerotic plaques [84]. Notably, LDLR/TLR4- double deficient mice fed a diet high in saturated fatty acids are protected from atherosclerosis, which suggests that activation of PRRs by saturated fatty acids might be highly relevant in the context of atherosclerosis [17].

Unsaturated fatty acids, in particular omega-3 fatty acids, have been shown to exert protective effects in atherosclerosis. They can be subdivided into three groups: omega-3, omega-6, and omega-9. Mammals can produce omega-9 fatty acids themselves, but acquire omega-3 and omega-6 fatty acids from dietary sources. Plant fats are rich in unsaturated fatty acids, for example, olive oil is rich in oleic acid and linseed oil is rich in the omega-3 fatty acid linoleic acid [78]. Omega-3 fatty acids exert a multitude of beneficial physiological effects, in part by acting on macrophages. For instance, they bind to the G-protein-coupled receptor GPR120 [85], which has a multitude of functions, but notably is also expressed by macrophages. Several studies have established that omega-3 fatty acids can act as potent anti-inflammatory agents via macrophage GPR120.

Signaling through GPR120 inhibits TLR signaling and subsequent production of proinflammatory cytokines and chemokines via the downstream effector β-arrestin2 [86]. Mice fed an omega-3 fatty acid-rich diet are protected against high-fat diet-induced inflammation, while GPR120 deficiency has the opposite effect [86]. Another study addressed the effect of omega-3 fatty acids on inflammasome activation. Indeed, activation of GPR120 and GPR40, another fatty acid sensing GPR, by omega-3 fatty acids, interferes with NLRP3 inflammasome assembly and IL1-β secretion [87]. While this effect is also partially mediated by β-arrestin [87], the effects of omega-3 fatty acids on NFκB activation and in particular the priming step of inflammasome activation is still controversial, as these two studies showed contradictory results. Omega-3 fatty acids are also protective in mouse models of atherosclerosis: Replacement of saturated fatty acids with omega-3 fatty acids in high-fat diet reduces plasma cholesterol levels, aortic macrophage accumulation, and overall lesion size [88]. However, whether these effects are macrophage GPR120 dependent remains to be established.

The gut microbiome also metabolizes food-derived molecules to bioactive molecules that can affect macrophage function and atherosclerosis. Trimethylamine-*N*-oxide (TMAO) and protocatechuic acid (PCA) are two prominent examples of how metabolites of animal or plant origin can be turned into bioactive compounds by the microbiome. TMAO is synthesized from carnitine, which plays an essential role in fatty acid import into mitochondria. It can be synthesized *de novo* but is also taken up from dietary sources, in particular red meat. Recent studies have shown that carnitine metabolism to TMAO by the microbiome has atherogenic effects. TMAO affects macrophage recruitment into plaques and foam cell formation resulting in increased atherosclerotic burden [89,90].

In contrast, anthocyanins ameliorate atherosclerosis in a microbiome-dependent manner. These are plant-derived molecules with antioxidant and anti-inflammatory properties, which affect macrophage cholesterol metabolism. In mouse models of atherosclerosis, they have a protective role. Mice fed with a diet rich in anthocyanins exhibit reduced plaques and systemic cholesterol levels [91]. Cyanidin-3-*O*-β-glucoside, an anthocyanin that is found in pigments of fruits and vegetables has potent anti-inflammatory and atheroprotective effects. In fact, it is PCA, a metabolite of cyanidin-3-*O*-β-glucoside produced by the microbiome that is the active component with antiatherogenic effects. PCA inhibits expression of adhesion molecules in aortic endothelial cells and subsequent monocyte adhesion. It also affects foam cell formation and RCT by increasing macrophage ABCA1 expression and circulating HDL levels [92,93].

49.6.2 Pharmacological Intervention

In addition to preventative lifestyle changes such as improved diet or exercise programs, patients with CVD can also be treated medically to lower circulating LDL-cholesterol (LDL-C) levels. LDL-C, which is thought to be both a strong biomarker for CVD risk and a causative agent in disease progression, can be lowered by a number of therapies.

Key among these LDL-C-lowering therapies are the statins drugs, which, as competitive HMG-CoA reductase inhibitors, block *de novo* cholesterol synthesis and thereby reduce total circulating LDL-C. Statin-based therapies have been the cornerstone of atherosclerosis treatment for the past 25 years and are effective at lowering LDL-C and reducing CVD events [94]. However, although there is consistent reduction in CVD events and mortality with statin therapy, CVD-related deaths still account for 31% of all global deaths, with 80% of these deaths coming from low- or middle-income countries [95]. An alternative route to statin-mediated lowering of LDL-C levels is by inhibiting proprotein convertase subtilisin-kexin type 9 (PCSK9), which degrades the LDLR. PCSK9 inhibition therefore increases LDLR expression and LDL-C clearance from the bloodstream, thereby reducing total circulating LDL-C levels. The potential of PCSK9 inhibitors for treating CVD is boosted by evidence that people carrying inactivating mutations in PCSK9 have decreased risk of CVD, and indeed monoclonal antibodies against PCSK9 (alirocumab and evolocumab) are currently available to lower LDL-C, but their efficacy in reducing CVD outcomes in large-scale clinical trials has yet to be elucidated [96].

In addition to the *in vitro* and animal studies, a further indication that inflammation plays an important role in atherosclerosis is that the acute-phase C-reactive protein (CRP) is as strong a predictive biomarker of CVD risk as LDL-C or HDL-C levels [97]. CRP is a pentameric protein that binds to phosphocholine present on invading bacteria or dying cells. CRP binding activates the complement system and targets the cells or bacteria for opsonization [98]. CRP is produced in the liver in response to systemic cytokine (especially IL-6) production [98]. The initial observation that CRP and inflammation predict CVD risk came from the Physician's Health Study (PHS), where it was also observed that the common anti-inflammatory drug aspirin was more likely to prevent first time myocardial infarction in patients with elevated CRP levels [99]. Further evidence that systemic inflammation may contribute to disease risk arose from CRP level evaluation during the statin clinical trials. Intriguingly, even patients with low LDL-C starting values were also protected against CVD risk [100]. This finding was then validated directly in the Justification for the Use of Statins in Prevention: an Intervention Trial Evaluating Rosuvastatin (JUPITER) trial, which showed that in apparently healthy patients without hyperlipidemia but with elevated CRP, rosuvastatin treatment reduced the risk of a first myocardial infarction [101]. While the cholesterol-lowering effects of statins are well understood, the molecular mechanisms behind the apparent anti-inflammatory actions of statins are less well characterized, though are speculated to involve inhibition of prenylation of inflammatory signaling molecules, which is likely required for their effective activation [102]. While CRP is an excellent predictor or CVD risk, it does not appear to be causally involved in the inflammation driving atherosclerosis, as seen in both mouse and human studies (reviewed in Ref. [103]). It is therefore not considered a promising target for therapeutic intervention.

IL-6 levels also correlate with disease risk, though it is not used as a biomarker due to limitations of clinical assay sensitivity and reliability [103]. Blocking cytokine action, such as IL-6 or TNF, is an effective treatment method in inflammatory diseases such as arthritis, but whether this is an effective approach

in CVD has not yet been directly tested. However, the MEASURE study, a clinical study assessing vascular risk in rheumatoid arthritis patients treated with the IL-6 inhibitor tocilizumab, showed that IL-6 inhibition may adversely affect lipid profiles in CVD, as significant increases in total cholesterol, LDL-C, and triglyceride levels in tocilizumab-treated patients compared to placebo were observed, though the ApoB/ApoA1 ratio remained constant [104]. Anti-TNF therapy (such as with the TNF blocker Etanercept) has little or no benefit on cardiovascular outcomes in patients treated for rheumatic or psoriatic arthritis [105]. The ENTRACTE clinical trial, which is currently underway, will compare the effect of targeting TNF (e.g., with etanercept) to targeting IL-6 (e.g., with tocilizumab) on cardiovascular outcomes in patients with rheumatoid arthritis (ClinicalTrials.gov Identifier: NCT01331837). The clear drawback of the ENTRACTE study is that there is no placebo group, as all patients enrolled require anti-inflammatory therapy [97]. However, considering the potential adverse effects on lipid profiles, as well as the inherent increased risk of infection when blocking TNF or IL-6, the drugs targeting these cytokines have not yet been tested in large-scale clinical trials specifically investigating CVD.

Two large-scale clinical trials are however currently underway that are directly testing whether targeting inflammation in atherosclerosis can reduce adverse cardiovascular events. The first trial, the Cardiovascular Inflammation Reduction Trial (CIRT), has enrolled 7000 patients and will assess the efficacy of low-dose methotrexate on reducing CVD events [106]. Low-dose (15–20 mg/week) methotrexate is currently used as an effective treatment in rheumatic and psoriatic arthritis, and observational evidence suggests that there are reduced CVD events in methotrexate-treated arthritis patients [106]. Low-dose methotrexate is proposed to function at a cellular level by stimulating extracellular adenosine release [107]. This results in increased activation of the adenosine receptors, which can have direct anti-inflammatory effects [108], and importantly for atherosclerosis may enhance RCT by increasing the expression of ABCA1 and 27-hydroxylase in macrophages [109]. The results of the CIRT trial are expected in 2018 (Figure 49.1).

The second major clinical trial is the Canakinumab Anti-inflammatory Thrombus Outcomes Study (CANTOS), which was launched in 2011. Canakinumab is an anti-IL-1β antibody, which similar to its counterparts Anakinra (an IL-1R antagonist) and Rilonocept (an IL-1 trap) is currently used clinically to block excessive IL-1 signaling in the cryopyrin-associated auto-inflammatory syndromes (CAPS). Promisingly, Canakinumab reduced circulating IL-6 and hsCRP levels in patients with rheumatoid arthritis, type II diabetes, or CAPS without affecting lipid levels [110]. Further justification for targeting IL-1β with Canakinumab in a chronic disease setting is that it does not appear to reactivate tuberculosis or HIV infection unlike other blockers of cytokine signaling, possibly because IL-1α signaling remains intact [110]. The CANTOS study will particularly assess whether targeting IL-1β signaling in patients with elevated hsCRP levels will provide additional benefit to statin-based treatments in terms of CVD outcomes [110]. This study has enrolled over 10 000 patients worldwide and the results are expected in 2017.

An alternative approach to lowering LDL-C or targeting inflammatory mediators directly is to raise functional HDL levels. An inverse correlation

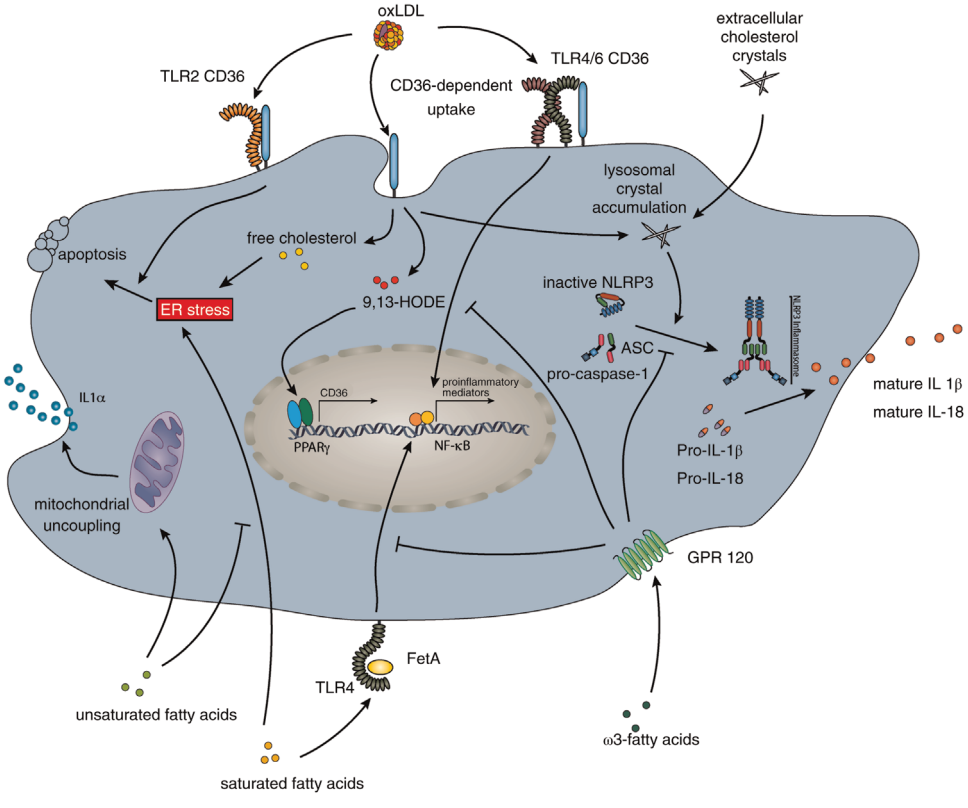

Figure 49.1 Macrophage inflammatory pathways in atherosclerosis. OxLDL engages multiple pathways. When recognized by a complex of TLR4 and TLR6, oxLDL triggers transcription of proinflammatory mediators [18]. oxLDL and/or oxidized phospholipids can trigger apoptosis in macrophages undergoing ER stress through TLR2 and CD36 [25]. CD36 also mediates macrophage oxLDL uptake [10] and subsequent particle breakdown and free cholesterol release, which can itself induce ER stress [11]. The linoleic acid-derived oxidation products, 9- and 13-HODE associated with oxLDL also activate PPARγ to sustain CD36 expression [12]. Cholesterol crystals are either taken up from the extracellular space via phagocytosis or precipitate from oxLDL-derived cholesterol in the lysosomal compartment [31]. Crystalline cholesterol activates the NLRP3 inflammasome by damaging the lysosome, which results in inflammasome formation and caspase-1-dependent maturation of IL-1β and IL-18 [31,32,33]. Saturated fatty acids alone induce ER stress but can also activate NFκB via TLR4 when complexed with fetuin A [44,82]. Unsaturated fatty acids protect from saturated fatty acid-induced ER stress [44], but cause mitochondrial uncoupling triggering IL-1α secretion [43]. Omega-3 fatty acids exert anti-inflammatory effects via GPR120 activation. GPR120 downstream signaling inhibits TLR-signaling [86] and interferes with NLRP3 inflammasome assembly [87]. oxLDL: oxidized low-density lipoprotein; TLR: toll-like receptor; CD: cluster of differentiation; HODE: hydroxyoctadecadienoic acid; PPAR: peroxisome proliferator-activated receptor; NLRP3: nucleotide-binding domain leucine-rich repeat containing (NLR) family, pyrin domain containing; ASC: apoptosis-associated speck-like protein; NFκB: nuclear factor "kappa-light-chain-enhancer" of activated B cells; GPR: G protein-coupled receptor; IL: interleukin; ER: endoplasmatic reticulum.

between HDL- associated cholesterol (HDL-C) levels and CVD risk was first reported over 50 years ago, and has been consistently reported since then in large-scale epidemiological studies such as the Norway Tromso study and the Framingham heart study [111,112]. However, to date, clinical trials

investigating the effect of raising HDL-C alone have shown no benefits in decreasing CVD risk, and indeed one trial showed significant harm [112]. Limitations to these clinical trials notwithstanding, these studies suggest that merely raising HDL-C levels does not lower CVD risk, and that HDL functionality may be a more pertinent factor in CVD protection. Accordingly, the HDL "flux" hypothesis, where HDL functionality is a better predictor of its protective effect in CVD than the amount of cholesterol associated with HDL, that is, HDL quantity, has also gained popularity [112]. A key study supporting this hypothesis showed in an *ex vivo* assay (measuring cholesterol efflux from lipid-laden macrophages to HDL isolated from patients) that HDL efflux capacity is indeed a better predictor of CVD risk than HDL-C levels alone [113]. This confirmed earlier studies in mice, where the rate of cholesterol efflux to HDL correlated with disease severity across a variety of genetic models and pharmacological interventions [5,112]. Besides, HDL is a complex lipoprotein with a myriad of functions beyond mediating RCT, including antioxidative, antithrombotic and anti-inflammatory functions [114–116]. Indeed, HDL can block cytokine, including IL-6, release from macrophages by modulating the activity of the transcriptional repressor activating transcription factor 3 (ATF3), which may contribute to its atheroprotective, anti-inflammatory effects [117]. Infusion of reconstituted HDL (i.e., purified human ApoA1 reconstituted *in vitro* with phosphatidylcholine) is currently being tested for efficacy in CVD: While one formulation (CSL-111) was discontinued due to liver toxicity, a second formulation (CSL-112) is currently in Phase IIa clinical trials (ClinicalTrials.gov Identifier: NCT02108262). Other formulations that are in development include ETC- 216, which is based on $ApoA1^{Milano}$, a naturally occurring antiatherogenic ApoA1 mutant, and CER-001, which contains sphingomyelin in its phospholipid shell [118]. The biology of HDL is however complex, and much remains to be discovered about HDL function and regulation before its full benefits can be clinically exploited.

49.7 Conclusion

Atherosclerosis can cause devastating pathologies leading to decreased lifespan. Evidence from population studies, intervention trials, and basic research has uncovered many different mechanisms that contribute to atherogenesis, yet two essential drivers have emerged: high LDL cholesterol levels and increased inflammation. Pharmacological interference to modulate cholesterol metabolism has proven to be a highly successful CVD therapy and now large studies testing anti-inflammatory therapeutic strategies are underway. Should the latter studies show therapeutic efficacy, further approaches targeting the individual innate receptors involved in the inflammatory response in the plaque could be developed. Finally, in recent years, numerous molecular insights have been gained that could explain how dietary factors can influence atherosclerosis in a positive or negative way. Life style modifications remain one of the most powerful strategies for preventing or halting atherosclerosis and therefore such approaches should be advertised in the general public.

50.1 Introduction

The systemic inflammatory response to infection, trauma, and surgery is a major trigger of acute kidney injury (AKI) [1]. Such inflammation-associated AKI is typically seen as part of injury or dysfunction in multiple organs and is an independent contributor to excess mortality in critically ill patients [2]. In addition, long-term consequences of AKI include progression to chronic kidney disease [3] and supporting the notion of a sustained inflammatory response beyond the acute phase. Unfortunately, as no effective AKI treatment or prevention exists, supportive renal replacement therapy remains the only option when severe AKI leads to pronounced accumulation of circulating waste products and/or when inadequate diuresis leads to fluid overload and tissue edema.

AKI is defined as a rapid (within days) increase in serum creatinine and/or sustained oliguria [4]. Several mechanisms triggering the activation of kidney endothelial, glomerular, and tubular cells during the systemic inflammatory response syndrome (SIRS) have recently been identified. Since such mechanisms appear to precede the decline in kidney function, they are potential targets for future prevention and treatment of AKI. Additionally, unfolding the complex interactions between systemic and renal circulatory changes during SIRS will likely contribute to improved hemodynamic management of patients with or at risk of AKI.

This chapter gives a brief overview of the normal kidney anatomy and physiology. In addition, the consequences of systemic inflammation on kidney vascular, glomerular, and tubular structure and functions will be discussed in detail. Sepsis, one of the most severe triggers of SIRS and at the same time one of the most common AKI triggers, will act as a model for inflammation in this chapter.

Inflammation: From Molecular and Cellular Mechanisms to the Clinic, First Edition.

50.2 Normal Kidney Anatomy and Physiology

Under normal conditions, the kidneys receive approximately 1 l or 20% of cardiac output every minute. Through the afferent arteriole, renal blood flow (RBF) reaches the glomerulus where, in healthy kidneys, approximately 125 ml/min of plasma-water is filtered. The remaining blood volume leaves the glomerulus via the efferent arteriole to enter the peritubular capillaries in the renal cortex. In addition, approximately 10% of the RBF circulates through the vasa recta in the renal medulla. The unique design of the vasa recta allows circulating osmolytes (sodium chloride and urea) and water to equilibrate with the kidney interstitium and the tubular lumen – referred to as the countercurrent mechanism – creating the corticomedullary osmotic gradient necessary for water and electrolyte homeostasis in humans. In addition to osmolytes and water, oxygen also equilibrates between the descending and ascending vasa recta. Together with high oxygen consumption from ATPase-dependent sodium pumps in that part of the nephron, a hypoxic environment (pO_2 ~1.5 kPa) is often maintained in the inner medulla. Finally, after reabsorption of most of the filtered plasma-water, blood flows from cortex and medulla to the renal vein and the inferior vena cava.

The glomerular filtration rate (GFR) of plasma-water and molecules is dependent on RBF, on the net filtration pressure (NFP) across the filtration barrier, and on the specific features of the filtration barrier itself [5].

NFP is created by the hydraulic pressure in glomerular capillaries (P_{GC}) and is opposed by plasma oncotic pressure (π_{GC}), mainly determined on the plasma albumin concentration, and by the hydraulic pressure in Bowman's space (P_B) according to the following relationship:

$$\text{NFP} = P_{GC} - \pi_{GC} - P_B.$$

As water is filtered (and albumin retained), the plasma albumin concentration and hence the π_{GC} will increase along the glomerular capillary until it equals P_{GC} and, consequently, NFP ceases (Figure 50.1). Thus, higher RBF (and thereby higher plasma-water flow) leads to lower relative concentration of plasma proteins, delayed increase in π_{GC}, higher mean NFP, and greater GFR.

The relative resistance in the afferent and efferent arteriole is a major determinant of NFP and hence GFR; vasoconstriction of the afferent arteriole and/or vasodilation of the efferent arteriole decreases GFR, whereas afferent vasodilation and/or efferent vasoconstriction has the opposite effect. Renal autoregulation maintains RBF and GFR during fluctuations within a wide range of mean arterial blood pressures. Such autoregulation is achieved via two important mechanisms. When increased blood pressure stretches the afferent arteriolar wall it contracts, thereby lowering RBF and blunting NFP and GFR – the myogenic reflex. Additionally, higher blood pressure will increase the filtered NaCl load, which activates the "NaCl-detecting" macula densa cells in the distal nephron. In response to macula densa activation, the afferent arteriole contracts, which lowers P_{GC}, NFP, and GFR, thereby attenuating NaCl filtration.

The glomerular filtration barrier consists of three major components: the fenestrated glycocalyx-rich endothelium, the basement membrane, and the slit diaphragm between podocytes (Figure 50.2). The filtration barrier is size and

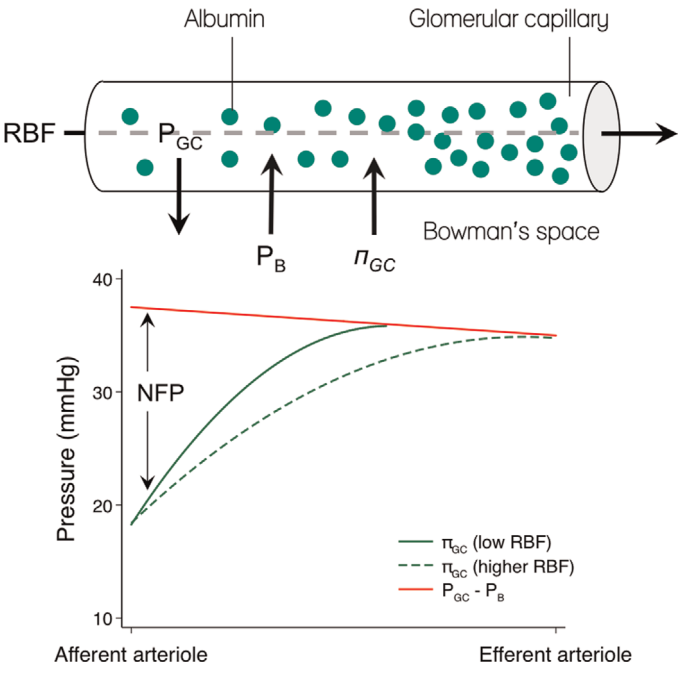

Figure 50.1 Hydraulic (red line) and oncotic pressure (green lines) changes along a glomerular capillary during lower (solid green line) and higher (dashed green line) renal blood flow (RBF).

charge selective [6]. Molecules up to 8 nm (80 Å) can theoretically pass the fenestrated endothelium. However, since the glycocalyx is negatively charged, filtration of negatively charged middle-sized molecules (7–60 kDa) is restricted. In fact, loss of negative charge of the filtration barrier is an important feature of

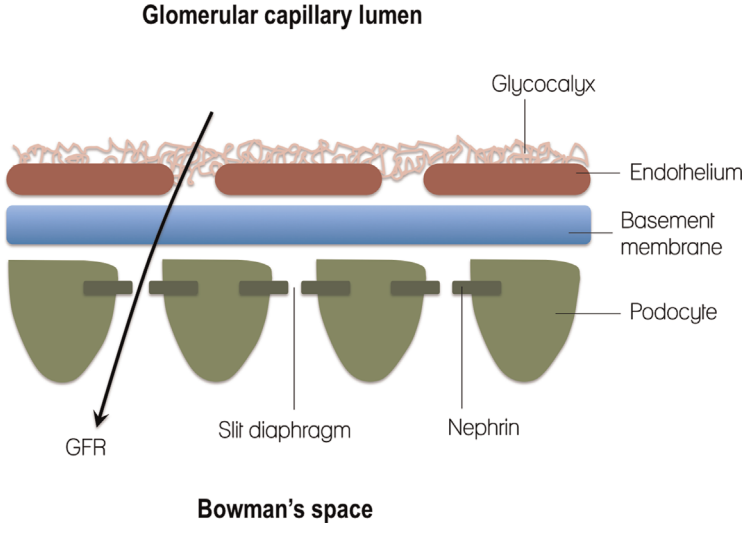

Figure 50.2 Glomerular filtration barrier.

some glomerular diseases and may partly explain the proteinuria that accompanies such conditions.

50.3 The Renal Response to Systemic Inflammation

Systemic inflammation causes stress or injury to kidney endothelial, tubular, and glomerular cells. The kidney tubular cells are particularly susceptible to circulating inflammatory mediators since they are continuously exposed to a filtrate derived from a large proportion of the circulating blood volume. Moreover, the majority of such mediators are amenable to filtration and can therefore injure cells facing the tubular lumen. In fact, several inflammatory mediators are being actively reabsorbed by the proximal tubule. An important clinical observation is that despite a sometimes complete shutdown of kidney function during severe inflammatory states such as sepsis, microscopic evidence of kidney parenchymal injury is scarce [7,8]. Recently, however, several cellular responses to inflammatory stimuli have been identified, which appear to have profound effects on kidney function (Figure 50.3).

50.3.1 Endothelial Activation

The vascular endothelial cells are part of the first line of defense during inflammation. However, systemic inflammation may activate endothelial cells distant from the primary injury, amplifying the systemic inflammatory response, and causing multiorgan injury and dysfunction. Endothelial activation is mediated by the recognition and binding of damage-associated molecular patterns (DAMPs) by so-called pattern recognition receptors (PRR), for example, toll-like

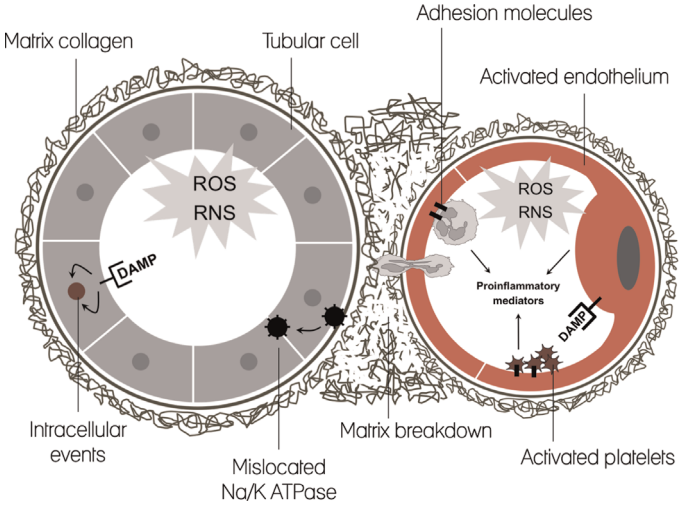

Figure 50.3 Inflammatory effects on kidney tubules and peritubular capillaries.

receptors, on the endothelial surface [9]. Such endothelial activation triggers the expression of adhesion molecules (e.g., P-selectin), which encourage recruitment, binding, and activation of platelets and neutrophils on the cell surface [10]. Upon their activation, platelets and neutrophils release hundreds of biologically active molecules, including cytokines, chemokines, reactive oxygen species (ROS), reactive nitrogen species (RNS), and coagulation factors. Consequently, a vicious circle is created, maintaining or even aggravating endothelial damage and surrounding tissue injury [11].

In their aggregate, these alterations contribute to degradation of endothelial glycocalyx and intercellular tight junctions, ultimately increasing vascular leak of water, proteins, enzymes, and inflammatory mediators and migration of activated immune cells into the interstitial compartment [12]. Interstitial accumulation of protein degrading enzymes (proteinases) causes matrix breakdown, further impairing vascular stability [13]. Finally, outburst of platelet granular contents shift the balance toward a procoagulant state with increased risk of microthrombosis in renal capillaries [14].

50.3.2 Glomerular Filtration Barrier Changes

Glomerular capillaries are similarly activated during inflammation. Additional important alterations in the structure and function of other components of the glomerular filtration barrier are seen. Glycocalyx breakdown leads to loss of anionic charges, whereby the ability to reflect negatively charged molecules such as albumin is lost and albuminuria occurs [15]. In addition, loss of glycocalyx contributes to loss of vascular tone, microthrombosis (less adhesion to antithrombin III), and accelerated inflammation (increased adhesion of leucocytes). The important role of glycocalyx in inflammation was supported by Nelson *et al.* who found an association between circulating glycocalyx contents and mortality in patients with septic shock [16].

Increased glomerular capillary leakiness exposes podocytes to circulating cytokines. Such cytokine exposure suppresses nephrin expression by podocytes in *in vitro* studies. This, in turn, causes disruption of the slit diaphragm and further increased permeability to albumin over the glomerular barrier [17,18]. Indeed, proteinuria is commonly seen in critically ill patients with sepsis, even without obvious features of AKI such as elevated serum creatinine or oliguria [19].

Mesangial cells are important for the structure and function of the glomerular filtration barrier [20]. They produce several components of the extracellular matrix (e.g., collagens) and glycocalyx (e.g., proteoglycans), which provide support for glomerular capillaries. In addition, several growth factors important for cell proliferation are secreted by the mesangium. Moreover, they are actively involved in the removal of apoptotic cells by phagocytosis. Finally, mesangial cells share features with smooth muscle cells and contracts upon stimulation, thereby reducing the glomerular filtration area and GFR. Dysregulation of the mesangium appear to be involved in the progress of several chronic kidney diseases. Whether contraction of these cells contributes to reduced GFR in AKI is, however, yet to be determined.

50.3.3 Tubular Injury

During severe systemic inflammation, tubular cells are exposed to filtered (from the tubular lumen) and circulating (via capillary leakage and migration of immune cells) cytokines, DAMPs, ROS, and RNS (Figure 50.3). In addition to the degree and duration of such inflammatory stress, adaptive cellular mechanisms will determine the fate of injured tubular cells. Such adaptive responses appear to effectively reduce energy-consuming cellular activities until inflammation has subsided.

Triggered by the interaction of DAMPs with PRR on the kidney tubular cell surface, cellular turnover increases via complex intracellular signaling pathways [21] (Figure 50.3). However, episodes of cell cycle arrest have also been observed during AKI in animal models of ischemia–reperfusion injury [22] and sepsis [23]. In addition, urinary excretion of proteins involved in cell cycle regulation has been observed in critically ill patients with AKI [24], which supports the role of cell cycle disruptions in human AKI as well. The purpose of cell cycle arrest is uncertain. Yet, tubular cells are the major source for replacing injured cells by accelerated mitosis [25]. Therefore, the prevailing idea that cell cycle interruptions prevent injured cells from proliferating and dedifferentiating into dysfunctional cells – which would most certainly lead to permanent damage – appears logical.

In addition to cell cycle arrest, other mechanisms contribute to reduce renal oxygen consumption during inflammatory stress. Sodium chloride reabsorption via Na/K ATPase located at the outer cell surface (facing peritubular capillaries) is the major energy-consuming process in the kidney. During tubular stress, however, the sodium chloride pumps are relocated to the intercellular border or to the surface facing the tubular lumen [26]. Relocation inactivates these pumps and thereby effectively reduces energy consumption. Consequently, more sodium chloride is delivered to and detected by the "salt-detecting" macula densa cells, the tubuloglomerular feedback mechanism is activated, and ultimately GFR is reduced. Moreover, this reduces the filtered sodium chloride load, which further lowers oxygen demand.

Filtered proteins are mainly reabsorbed via megalin receptor-mediated endocytosis in the proximal tubule. Additionally, the megalin receptor mediates reabsorption of filtered toxins and cytokines and may therefore contribute to AKI [27]. However, downregulation of the megalin receptor has been observed during experimental endotoxemia and inhibition of the receptor appears to attenuate AKI. Collectively, these findings support the notion that megalin receptor downregulation is yet another mechanism by which kidney tubular cells protect themselves against further injury. In addition to glomerular filtration barrier changes (described in the previous section), megalin receptor downregulation likely contributes to proteinuria during systemic inflammation and AKI. In fact, accumulation of urinary biomarker proteins known to be reabsorbed by the megalin receptor, such as cystatin C and neutrophil gelatinase-associated lipocalin (NGAL), is typically seen in patients with SIRS and AKI [28].

Regulated cell death is associated with organ damage in many inflammatory diseases, including AKI. Experimentally, common pathways regulating both

inflammation and apoptosis have been identified. For example, upregulation of small intracellular noncoding RNA molecules, so-called miRNAs, was recently demonstrated in mice with septic AKI [29,30]. Furthermore, pharmacological stimulation of miRNA-21 production inhibited apoptosis, mitigated the systemic inflammatory response, and attenuated AKI. These findings suggest that miRNA synthesis is another mechanism by which kidney cells protect themselves during extreme inflammatory stress.

Tubular cell apoptosis has been detected in human AKI by terminal deoxynucleotidyl transferase–mediated digoxigenindeoxyuridine nick-end labeling (TUNEL) and activated caspase 3 staining [8]. Cellular stress, resulting in mitochondrial permeability, leakage of apoptogenic factors to the cytoplasm, and caspase 3 activation trigger apoptosis. Additionally, cytokine activation of membrane receptors can activate intracellular apoptotic pathways. Caspase activation is responsible for degradation of intracellular contents and fragmentation of the dying cell into apoptotic bodies, which are cleared by phagocytosis. The exact role of apoptosis in AKI and why it predominantly occurs in the distal nephron is uncertain. Autocrine and paracrine "cross-talk" between apoptotic epithelium and adjacent segments may trigger repair mechanisms after inflammatory insults [31]. Pharmacological modulation of apoptotic mechanisms may therefore be part of future AKI preventive or therapeutic interventions [32].

Recently, the importance of other regulated cell death mechanisms, such as necroptosis, was highlighted [33]. Unlike apoptosis, caspase-dependent phagocytotic clearance of cell debris is not a feature of necroptosis. Instead, necroptosis is caspase independent and involves cell membrane rupture with a massive outburst of cellular contents, including DAMPs into the extracellular space. The likely rationale for necroptosis is to attract immune cells to the site of injury/infection and thereby actively contribute to tissue homeostasis. However, the massive release of DAMPs from necroptotic cells further amplifies the inflammatory response and hence contributes to tissue injury in AKI. Since the discovery of some of its regulating pathways, pharmacological interference with necroptosis to prevent or treat inflammatory injuries such as AKI is currently being considered [33].

50.3.4 Changes in Renal Hemodynamics

The early systemic inflammatory response is characterized by increased cardiac output in the setting of systemic vasodilation and hypotension. In animal models of hyperdynamic septic shock, a proportional increase in RBF is a ubiquitous finding [34,35]. Similarly, in humans with early hyperdynamic sepsis, a relative increase in RBF (RBF/cardiac output) has been demonstrated [36]. Importantly, despite such increases in RBF, marked reductions in GFR are commonly seen. This apparent disconnection between RBF and GFR can physiologically be explained by excessive vasodilation of the efferent arteriole, causing NFP and GFR to drop. Indeed, under such circumstances, increased RBF will not be sufficient to compensate for reduced NFP (see Figure 50.1).

In addition to renal vasodilation, sepsis-induced systemic hypotension reduces the driving pressure needed for GFR. However, worsening kidney function is a

common clinical finding during sepsis despite normalization of MAP with vasopressors. Therefore, additional factors must contribute to sustained AKI in the context of systemic inflammation. Intravenous fluids are commonly used to treat hypotension in patients with hyperdynamic circulation during sepsis, after trauma or after major surgery. While such therapy may transiently stabilize cardiovascular function, it contributes to elevated central and renal venous pressure and kidney interstitial edema around leaky peritubular capillaries.

Venous congestion attenuates the difference between MAP and renal venous pressure, and hence the hydraulic transrenal pressure gradient needed for RBF [37]. Together with fluid accumulation in the kidney interstitium, venous congestion will increase subcapsular kidney pressure and P_B, further counteracting GFR. In fact, even in healthy volunteers with expected normal endothelial barrier, increased overall extravascular fluid volume and renal volume was observed together with reduced renal cortical tissue perfusion after a 2 l crystalloid infusion [38]. In addition, in septic patients with moderate to severe AKI after initial resuscitation with fluids and vasopressors, consistently decreased RBF, quantified by cine phase-contrast magnetic resonance imaging, was observed [39]. Finally, recent studies have confirmed a strong and independent association between elevated CVP and worsening kidney function in septic patients [40,41] and in patients with cardiac diseases [42,43].

Although physiological changes in intrarenal blood flow distribution can affect GFR [5], the importance of microcirculatory changes during AKI is not well understood. Preserved cortical RBF but decreased medullary RBF and tissue oxygenation was observed in sheep with hyperdynamic sepsis and AKI [44]. However, such findings have not been consistently demonstrated in previous studies. Moreover, attempts to enhance RBF with renal vasodilators in cardiac surgery patients did not prevent severe AKI [45]. In contrast, targeting a higher MAP with vasopressors attenuated AKI in septic patients with chronic hypertension [46]. Therefore, while the effects of renal microvascular alterations in AKI patients are being untangled, it appears critical to avoid fluid overload, venous congestion, and major deviations from premorbid blood pressure in such patients.

50.4 Summary

Systemic inflammation triggers adaptive responses in kidney endothelial, glomerular, and tubular cells. The clinical consequences of such responses depend on the degree of inflammatory stress and may vary from mild proteinuria to loss of GFR, need for renal replacement therapy and substantially elevated short- and long-term mortality risks. While novel therapies, targeting inflammatory pathways, are explored, hemodynamic management remain important in the management of patients with inflammation-induced AKI. Avoiding fluid overload and venous congestion appear particularly important since both are independently associated with worsening kidney function. In addition, maintaining systemic blood pressures close to premorbid levels appear to attenuate further deteriorations in kidney function during inflammatory stress.

51.1 Introduction

The events of ischemia–reperfusion injury trigger a local and/or a systemic inflammatory response that leads to cellular damage and even organ failure [1,2]. Ischemia induces cell death and inflammation through oxygen deprivation. However, restoration of blood flow (reperfusion), which is necessary for the recovery of cellular function, may first worsen the lesions present in ischemia, aggravating irreversible damage and cellular demise [1,3].

Although there are some similarities in the biological responses among ischemic episodes, there are important differences between a systemic reduction in perfusion (e.g., successfully resuscitated cardiac arrest) compared with regional ischemia and reperfusion of single organ (e.g., myocardial infarction, stroke, or organ transplantation) [3].

51.2 Pathophysiology

51.2.1 Ischemia

Prolonged ischemia results in a variety of cellular metabolic and ultrastructural changes such as altered membrane potential, cellular swelling, leakage of lysosome enzymes, cytoskeleton disorganization, altered ion distribution, and finally intracellular acidosis [2,4]. Initially, ischemia induces a large decrease in cellular oxidative phosphorylation due to a switch from aerobic to anaerobic metabolism, which results in a failure to resynthesize energy-rich phosphate such as adenosine 5′-triphosphate (ATP) and phosphocreatine. This leads to a dysfunction in the ATP-dependent ionic pumps, subsequently resulting in the entry of calcium, sodium, and water into the cells. Ischemia also promotes expression of some

Inflammation: From Molecular and Cellular Mechanisms to the Clinic, First Edition.

proinflammatory genes, which increases the activation of proinflammatory state [2]. As a result, during the hypoxia phase, only exiguous amounts of radical oxygen species are produced because of the redox reduction of cytochromes, nitric oxide (NO) synthases, xanthine oxidase, and NADPH oxidase activations [5,6].

51.2.2 Reperfusion

Paradoxically, reperfusion, either spontaneously or through a clinical intervention, does not restore initial homeostasis, but rather further enhances damage after normalization of oxygen levels and extracellular pH. As a consequence, this results in a normalization of the above-mentioned enzymes, and induces a large production of reactive oxygen species (ROS), which subsequently contributes to increase membrane and cytoskeleton structures. ROS also contribute in increasing mitochondrial calcium content, which causes opening of the mitochondrial transition pore (mPTP). Opening of mPTP represents one of the pathways that leads to cell death [7].

Hypoxia occurs in the boundary zone around the ischemic area after a reperfusion, and induces local and systemic inflammation response mainly through the hypoxia-inducible factor (HIF) [8], which is specifically dealt with in another chapter.

51.2.3 Ischemia–Reperfusion Pathophysiology

Although ischemia–reperfusion shares many similarities with infection responses, it usually occurs in a sterile environment except in the case of bacterial translocation after intestinal injury [9]. Various biological processes have been fully studied and many interact with each other (e.g., infection or noninfection).

51.2.4 Cell Death

Two main types of cell death have been described as apoptosis and necrosis. Autophagy has been more recently proposed as a process of cell death during which cells generate energy and metabolites by digesting their own organelles and macromolecules. Similar to apoptosis, autophagy is genetically controlled (e.g., programmed) and thus considered as a less immune-stimulating process as opposed to necrosis, which is considered to be a more brutal method of cell death. However, this dichotomic approach may be too simplistic and needs further investigation [7]. For instance, in some circumstances, necrosis could also be initiated by programmed control mechanisms [10].

51.2.5 Microvascular Dysfunction

Microvascular dysfunction is associated with endothelial cell dysfunction and increased vascular permeability, which might explain, at least in part, of tissue edema occurrences (e.g., lung edema). Abnormalities in vascular tone have been described to occur due to the imbalance of vasoconstricting and vasodilating factors that explain an intense vasoconstriction during the reperfusion phase such as

increased thromboxan A_2, prostaglandin H_2, leukotrienes, and adenosine production and decreased prostacyclin or nitric oxide production [11]. In addition, crawling neutrophils as well as increased adherence of circulating erythrocytes and platelets play a role in mechanical obstruction of microvascularization [11–14]. As a result, reperfusion can result in a "no-reflow phenomenon," which has been most commonly described in instances of myocardial infarction. This phenomenon is characterized by an increase in the impedance of microvascular blood flow and a decrease in intramyocardial blood flow, despite a reperfusion of the culprit coronary artery [15,16]. Similarly, ischemia was shown to induce a sustained contraction of pericytes on microvessels despite a successful reopening of the middle cerebral artery in a mouse model of stroke [17].

51.2.6 Innate Immune System

During ischemia and reperfusion, both innate and adaptive immune systems are activated and they interplay between each other. There is an imbalance among vasodilating and vasoconstricting factors in addition to activation of coagulation and complement systems.

Polymorphonuclear neutrophils are among the first cells that appear at the site of inflammation as both adherents and diapedes [18–20]. They are activated by inflammation and, in turn, release a variety of factors that further increase the inflammatory processes. In recent times, molecular targets (rather than cellular), such as complement receptors, Toll-like receptorss (TLRs), and proinflammatory cytokines, have been particularly emphasized for their role in this process [19–22]. Neutrophils seem to play a key role, as they are the first to be activated. Neutrophils aid in blocking capillaries to prevent reperfusion of the tissue and in secreting proinflammatory cytokines and chemokines to create a positive feedback loop with activation and recruitment of more neutrophils [19]. The role of natural killer (NK) cells and macrophages/monocytes relating to ischemia–reperfusion are unclear as studies have shown conflicting results [18].

Innate system activation can be summarized as follows: First, the system is activated through the recognition receptors, intra- and extracellular TLRs, the intracellular NOD-like receptors, and retinoic acid-inducible gene 1 receptors. TLRs play a major role in recognizing damage- or pathogen-associated molecular proteins (DAMPs and PAMPs) and work to activate various kinases (IRAK, TBK1, and IKK) that recruit cytoplasm adapter molecules. TLRs then amplify and transmit the signal to various transcriptional factors (NF-κB, MAP3, and the interferon IFR3) that encode the genes involved in the inflammation process [3,18,20].

Ischemia–reperfusion triggers excessive platelet aggregation and the release of platelet-derived mediators partly through integrin-mediated endothelial interactions [12]. They can also aggregate on leukocytes' surface through an integrin-dependent platelet activation and aggregation, and then migrate across the epithelial barriers to the sites of inflammation to further aggravate tissue damage [23]. Platelets can also release inorganic polyphosphate, polymers of 60–100 phosphate residues, that can activate factor VII, thereby acting as

proinflammatory and procoagulant factors [24]. However, inflammation observed after an ischemia and reperfusion can also trigger natural anticoagulation such as antithrombin, tissue factor inhibitors, and protein C [25–28].

The complement system plays a key role, and is the very first line of defense against pathogens and inflammatory reaction after an ischemia–reperfusion. It acts as an immune surveillance system that can discriminate cellular debris, apoptotic cells, and foreign intruders to vary its response accordingly [29]. DAMPs can also activate all three of the complement pathways (classic, alternative, and lectin) to bind either C1q, or C3 or mannose–lectin [30]. C3, C5 convertase, and the membrane attack complex (MAC) are well-known landmarks of the complement attack complex, which is a well-known landmark of the complement cascade. The activation of these proteins by the three overlapping pathways leads to cell opsonization and recruitment of many different inflammatory cells, such as neutrophils and B cells, which eventually result in phagocytosis and cell death [31,32]. Recent data have shown that some products of the coagulation pathway are able to activate the complement cascade. Serine proteases from the coagulation pathway can target C3 and C5 complement factors and produce fully active C3a and C5a complement factors that are known to play a major role in the inflammatory response [33].

51.2.6.1 Adaptive Immune Activation

Adaptive immune response involves T lymphocytes, along with other T-cell types. Pathways involved are not fully understood, but recent data suggest that there is a large contribution of both antigen-specific and antigen-independent mechanisms of activation [34,35]. Studies with mice deficient in specific populations suggest that $CD4^+$ and $CD8^+$ T cells play a detrimental role in ischemia–reperfusion tissue injuries [36–38], whereas T_{reg} cells seem to have a protective role [39,40]. Interaction between T and B cells through specific receptors generates an alloimmune response.

Autoimmunity is usually associated with the adaptive immune system. However, there are now evidences of innate recognition proteins that can be self-reactive and can initiate inflammation after ischemia–reperfusion as observed in response to pathogen; this phenomenon is also described as “innate autoimmunity” [41]. This process is related to the presence of autoantibodies produced by B cells in the absence of deliberate immunization, mainly IgM and more scarcely IgG [42]. However, the mere presence of these autoantibodies does not lead directly to tissue damage. Ischemia leads to cells injury and subsequent expression of new surface antigens, which represent a self-target of readily circulating autoantibodies [42–44]. The complex then activates a complement cascade, generating a positive feedback loop in the inflammation process.

These effects are not only observed within the same tissue area but can also affect remote tissue organ either in the same organ or even in a remotely different organ, such as kidneys and lungs, and are likely mediated through the release of circulating mediators [45,46].

Remote ischemic preconditioning has added more interesting insight as the protective effect was able to be observed in remote tissues and was initially

described as "reconditioning at distance" in an *in vivo* canine heart model of an ischemia–reperfusion [47]. The application of four 5 min occlusion–reflow cycles to the circumflex coronary artery before 60 min transient occlusion of left descending coronary artery reduced the infarct area by 60%, suggesting that protective agents are able to transfer from one cardiac site to another one. This concept was subsequently extended in the protection mechanisms that were induced by cycles of ischemia–reperfusion in remote organs such as kidney, liver, and brain [45]. The underlying mechanisms remain elusive and are likely related to release transferable mediators from the reperfused tissue and neuronal reflexes. For instance, after lower limb ischemia–reperfusion, remote effects on oxidative capacities have been variably observed in liver, lung, or kidney tissues [46].

51.3 Clinical Diseases

Most common clinical setting outcomes were particularly studied after instances of myocardial infraction, a neurologic stroke that can be induced spontaneously or through a thrombolysis agent [15,48–51]. However, this phenomenon has been largely in organ transplantation, particularly in kidney [4,11] and liver transplantation, to avoid any further damage when the organ is harvested after a necessary ischemia-reperfusion from cadaveric or living donors (kidney). The consequences of depriving an organ of its blood supply have also long been recognized as a critical factor in systemic hypoperfusion, as observed in hemorrhagic shock [52,53], aortic cross-clamping [54], cardiopulmonary bypass, or successful resuscitation of cardiac arrest [55,56].

Interestingly, even local ischemia–reperfusion phenomenon may induce important systemic inflammatory responses that could extend the damage beyond the ischemic area to include injury to remote nonischemic organs [3,57]. This has been observed, for instance, as remote effects of lower limb ischemia–reperfusion [46] after organ transplantation or after cardiac arrest that may have induced multiple organ failure, acute kidney injury, or intestinal injury [3,57]. In a particular model of systemic ischemia–reperfusion that is represented by a successful resuscitated cardiac arrest, severe hyperoxia was independently associated with decreased survival rates to hospital discharge, suggesting that hyperoxia may further increase systemic and brain tissue damage [58]. Nevertheless, exposure to high concentrations of inspired oxygen has shown not to worsen lung injury after cardiac arrest [59]. Moreover, a systematic review, meta-analysis, and metaregression of cohort studies have shown that an association between arterial hyperoxia and poor outcome is present in a subset of critically ill patients [60]. The same team [61] has suggested that oxygen retains its life-saving importance in critical care, accumulating evidence that further illustrated the role of hyperoxia and consequent formation of reactive oxygen species in the pathogenesis of several life-threatening diseases. Actually in sepsis and multiple organ failure, refractory shock can lead to a decrease in blood perfusion and supply of oxygen to cells, combined with arterial and uniform vasoconstriction; edema can explain in part of the resulting mitochondrial dysfunction. Furthermore, under conditions

of stress, cells can adapt to maintain viability through a decrease in the consumption of O_2 energy use, ATP demand, and basal cellular functions, as well as an increase in the consumption of energy reserves (e.g., cellular hibernation) and the activation of the damage repair mechanism. Restoration of oxygen delivery through therapeutic intervention (fluid resuscitation, for instance), spontaneous improvement, or, more commonly, both may lead to a better oxygen delivery that can at least temporarily aggravate tissue damage [62,63]. This situation strongly mimics what is observed in clinical situations more classically admitted for ischemia–reperfusion [3].

51.4 Therapeutic Perspectives

Ischemia–reperfusion is very often involved in various clinical diseases, as previously described, which can lead to numerous research teams who investigate how to limit the phenomenon by studying how to restore oxygenation either spontaneously or mechanically (angioplasty transluminal, for instance) or by using thrombolytic agents without inducing further damage related to the ischemia itself.

51.4.1 Ischemic Conditioning (Pre-, Post-, and Remote Conditioning)

The ischemic preconditioning might be effective in reducing kidney injury according to a recent systematic review on kidney animal models [64], although without wide translating therapies into clinical renal transplantation as of now. Ischemic preconditioning of a transplant graft before a liver transplantation or before a major liver resection has shown some benefit but without the expected scope from various animal studies [47,65]. Although these studies have shown to have some benefit, they have not been able to reproduce the profound tissue-protective effects of ischemic preconditioning observed in these animal studies, perhaps because of the difficulty in determining the most effective preconditioning protocol for a clinical study [3].

Similar to ischemic preconditioning, short episodes of ischemia following a reperfusion are associated with a reduction in myocardial infarct size, which can be described as postconditioning [16]. A prospective, randomized, controlled, multicenter study investigated whether postconditioning in 30 patients protected the human heart from a coronary angioplasty after an instance of myocardial infarction had any potential beneficial effects [66]. After a reperfusion into the occluded coronary artery using a stent, a protocol of 1 min inflation interspersed with 1 min deflation of the angioplasty balloon was used to induce postconditioning. The study then observed a persistent infarct size reduction and improvements in long-term (1 year) functional recovery in patients with acute myocardial infarction [66]. However, a more recent and a larger study did not observe any benefits in 1 year clinical outcomes such as a composite of death, myocardial infarction, severe heart failure, or stent thrombosis in patients with ST-segment elevation myocardial infarction who were undergoing primary percutaneous coronary intervention (PCI) [67].

As previously mentioned, ischemic preconditioning was suggested as a potentially effective protection on other remote tissues. The discovery of ischemia–reperfusion cycles in skeletal muscle, elicited by application of simple, noninvasive tourniquet, seemed to provide a similar ischemic preconditioning cardioprotection as well as protection of other vital organs and potentially for the whole body. This discovery fostered a rapid clinical evaluation of this concept that showed some promising results in smaller, underpowered, single center studies on the effects of remote ischemic preconditioning being administered to patients undergoing cardiac surgery [45]. However, two very recent large-scale, prospective, randomized, sham-controlled trials studying remote ischemic preconditioning in cardiac surgeries that required cardiopulmonary bypasses were negative [68,69]. A commonly used study regimen of four 5 min cycles of ischemia in the arm interspersed with 5 min cycles of reperfusion was used in both studies. These negative results may be partially explained through various factors that interfered with remote ischemic preconditioning such as less effective mechanisms in infarct-remodeled hearts, diabetes and, in older patients, redundant use of cardioprotective bypass technics, and the use of medications, specifically anesthetics, which may interfere with remote ischemic preconditioning [45].

Remote ischemic postconditioning induced by repeated cycles of limb ischemia (four cycles of 5 min inflation and 5 min deflation) before hospital admission was found to be effective as an adjunct of angioplasty in myocardial salvage of 333 patients with acute myocardial infarction [70]. The beneficial effect seemed to persist in the long-term clinical outcomes (median follow-up: 3.8 years) of the same population study [71].

51.4.2 Therapeutic Gases

Several therapeutic gases have been in use for the treatment of ischemia–reperfusion, among which are hydrogen, nitric oxide, hydrogen sulfide, and carbon monoxide. Of these gases, the most extensively studied is nitric oxide because it is endogenously produced by endothelial NO synthase, and also plays a role in regulating basal vascular tone, endothelial function, and maintenance of blood oxygenation through hypoxic pulmonary vasoconstriction. Multiple studies have indicated that the endogenous production of NO or its therapeutic delivery had effect in attenuating the damages of ischemia–reperfusion [72]. In a small, randomized, and placebo-controlled clinical trial ($N = 10$/arms) that used inhaled NO for the treatment of graft ischemia–reperfusion after a liver transplantation, NO gas was found to improve the restoration of liver function and to lower instances of hepatocyte apoptosis [73]. However, in contrast, inhaled NO was shown to be relatively inefficient in acute cell crisis time resolution. Inhaled NO and H_2S have both been shown to be helpful in rodent model of ischemia–reperfusion, such as in resuscitation of cardiac arrest [74,75].

51.4.3 Antioxidant Therapy

The enzyme superoxide dismutase (SOD) scavenges for superoxide anions on free radicals produced during tissue injury, and catalyzes the dismutation of

superoxide into oxygen and hydrogen peroxide. This function of SOD has been evaluated as a promising treatment approach to limit tissue injury after ischemia–reperfusion [76]. Numerous agents with antioxidant properties have been evaluated, and among those SOD and *N*-acetylcysteine are most extensively studied, particularly after a renal transplantation with some potential interests [77,78]. For instance, when SOD was administered intravenously during transplantation, it significantly reduced acute rejection and improved long-term outcome [78]. However, despite numerous trials with many different compounds in various organ targets, it showed that the aforementioned results do not seem to be as stringent as we might expect [79–81]. Several trials testing antioxidant agents are still under way.

51.4.4 Inhibition of the Innate Inflammatory Response

Inhibition of complement has been more specifically tested in clinical trials within renal transplantation [82]. Renal damage due to complement activation occurs in two phases: first phase during reperfusion after restoration of blood circulation, and second phase during an acute rejection when innate and adaptive immune systems recognize the donor antigens. Eculizumad, a recombinant C1 inhibitor (C1-INH), and soluble complement receptor 1 mainly inhibit C5, an alternative pathway, and C3/C5 convertase, respectively [11]. Several inhibitors are still under investigation in larger clinical trials. Experimental studies suggest that inhibiting TLR2 and TLR4 in ischemia reperfusion syndrome after myocardial infarction or renal transplantation could have potentially interesting results. Preliminary studies are under way to investigate the safety and efficacy of antibodies anti-TLR2 (OPN-305) and anti-TLR4 (eritoran). In these studies, TLR4 inhibitors are being studied in context of either myocardial infarction or renal transplantation [83–85]. Suppressing dendritic cells using antimyocytes globulins have been suggested as another potential interesting therapy in ischemia–reperfusion syndrome [86,87].

51.4.5 Improving Ischemia Tolerance

During ischemic phase, the energy metabolism pathway is shown to change from fatty acid oxidation to glycolysis to protect the body from tissue injury. This change is controlled by hypoxia-inducible factor, whose stability is regulated by three oxygen-sensing prolyl hydroxylase domain isoform (PHDs) enzymes. Deficiency or inhibition of PHD1 decreases oxygen consumption in ischemic skeletal muscle by reprogramming glucose metabolism to a more anaerobic route of ATP production, which is through a peroxisome proliferator-activated receptor-α pathway [88]. Incidentally, pharmacological doses of PHD inhibitors have shown to increase tolerance to kidney ischemia [89] and to cardio protection, resembling what was observed in heart ischemic preconditioning [90]. Moreover, heterogeneous deficiency of PHD2 has shown to be able to restore tumor oxygenation and to inhibit metastasis through endothelial normalization [91]. Therefore, inhibition of PHD2 may also offer alternative therapeutic opportunities for anticancer therapy.

Although HIF target genes mainly encode erythropoietin (EPO), a major regulator of red blood cell formation whose production and secretion are mainly regulated by tissue oxygen levels, promising preclinical studies have suggested that erythropoietin could have beneficial effects in metabolic response, apoptosis inhibition, and angiogenesis [3]. However, clinical trial evaluating erythropoietin treatment showed that the result from a successful reperfusion following a myocardial infarction through a percutaneous intervention of 4 h was disappointing, with no reduction in infarction size and with association in higher rates of adverse cardiovascular events [92].

Currently, other therapies using recombinant annexin 5, recombinant P-selectin glycoprotein ligand Ig fusion protein, anticomplement therapies, and induction of heat shock protein 70 have been recently reviewed [93].

51.5 Conclusion

Although rapid reperfusion is necessary after an instance of ischemia, the reoxygenation process can adversely contribute to further the tissue injury and destruction. Many clinical trials have studied this phenomenon, and many have tried to dampen the damage lesion in relation to reoxygenation. Despite procedure improvements and numerous investigations, it remains a serious challenge to circumvent the adverse impacts of ischemia–reperfusion, particularly after an organ transplantation, stroke, or revascularization of myocardial infarction. Despite promising results in basic research and several small clinical trials, many larger clinical trials have failed to provide clear evidence of protective effects of various approaches. Continuing research on the activation of innate and adaptive immune systems will play a key role in the pathogenesis of ischemia–reperfusion syndrome. Currently, numerous novel therapies are under investigation to evaluate whether they affect the reoxygenation of the products released after ischemia. To further improve tissue preservation, agents such as antioxidants and *N*-acetyl cysteine that interfere with pathways involved in ischemia–reperfusion mechanisms should continue to be investigated in the future to improve tissue preservation.

Single-Nucleotide Polymorphisms and Inflammation

Evangelos J. Giamarellos-Bourboulis

National and Kapodistrian University of Athens, Medical School, 4th Department of Internal Medicine, ATTIKON University Hospital, 1 Rimini Street, 12462 Athens, Greece

52.1 The Principle

The concept that genetic predisposition may influence an inflammatory phenotype has been evolved by the clinical characteristics that many patients present with extreme phenotypes of an inflammatory disorder; for instance, some young and otherwise healthy patients develop severe sepsis, whereas other patients with several chronic comorbidities can survive severe sepsis despite their positive scoring for severity [1]. As such, most attention has been focused on how host DNA can encode the proteins involved in the inflammatory cascade. This was the driving force for conducting thousands of case–control studies with a common study design—to compare between cases suffering from the inflammatory conditions under investigation and controls well-matched for age, sex, and other probable confounding conditions for the frequency of one single-nucleotide polymorphism (SNP) of a gene encoding for one of these proteins. The end point of this comparison was the impact of the studied SNP on the susceptibility for the disease under investigation. Another end point was the impact of the SNP on the disease phenotype.

An SNP is the substitution of one nucleotide base for another, and this leads to functional change of the encoded protein (i.e., sense SNP) or it does not affect the function of the protein (i.e., missense SNP). The functional change may result by the amino acid change induced by the new nucleotide codon or by alternative splicing leading to different gene transcripts and altered protein production. People can be heterozygotes or homozygotes for the SNP. SNPs can be located at the exons or at the introns of a gene. For most genes, several SNPs have been described. This immediately generates the question: Which SNPs should be studied in one case–control study? In most studies this question remains unanswered. The selection of SNPs for a specific study design often relies on the presumed importance of the protein under study and on the frequency of the SNPs in the population. This is known as the candidate gene approach. For instance, some SNPs are so rare that the requested power of the study to

Inflammation: From Molecular and Cellular Mechanisms to the Clinic, First Edition.

document important associations should be extremely large. In some studies, patients are genotyped for SNPs located on the same chromosome, that is, for haplotypes.

With the advent of new technologies involving genome-wide association studies (GWAS) and next-generation sequencing (NXS), the need to select the candidate SNP is no longer required. In GWAS, chips with primers for a wide variety of SNPs are predesigned, whereas in NXS a full sequencing of the human exome is performed. The main limitations of these approaches are the huge cost and the need for bioinformatics analysis looking for associations at *p*-values of significance below 10^{-8}. At a next step, the elaborated association should be analyzed after adjusting for the clinical characteristics of the patients.

This analysis of the strengths and the limitations of the genetic workout of inflammatory conditions renders obvious why study results showing a genetic susceptibility by one SNP cannot have a universal value and why results may vary considerably from one publication to the next. This chapter provides an in-depth presentation of the most widely studied SNPs for which some association with either acute or chronic inflammatory disorders has been described in the last decade. To achieve this, a thorough MedLine search was conducted using the terms "SNPs," "genetic susceptibility," "GWAS," and "next-generation sequencing" for the disease entities that are analyzed in this chapter for the period 2005 until November 2015. Of the thousands of articles published, those who reported on GWAS, NXS, or meta-analysis of an SNP for a disease were finally included in the chapter.

52.2 SNPs and Functional Genomics

One of the major concerns is whether studied SNPs can modify the function of monocytes and lymphocytes. Some of the most broadly studied SNPs are those of *TLR4*; the first is rs4986790 leading to the substitution of aspartic acid by glycine at amino acid position 299 (Asp299Gly) and the second is rs4986791 leading to the substitution of threonine by isoleucine at amino acid position 399 (Thr399Ile). The emergence of these SNPs has evolved under natural pressure. People from Africa carry haplotypes with the rs4986790 SNP allele and with the rs4986791 wild-type allele. Their monocytes can overproduce tumor necrosis factor-alpha (TNFα) after stimulation with TLR4 ligands offering protection against *Plasmodium* spp. When people migrate from Africa to Europe, haplotypes with either both wild-type alleles or both SNP alleles emerge so that monocytes can no longer overproduce TNFα and be protected from sepsis [2]. In a similar way, the frequency of rs16910526 wild-type and SNP alleles of *Dectin-1* encoding for the receptor of β-D-glucan of *Candida albicans* does not differ between patients with candidemia and noninfected controls; however, carriage of minor frequency SNP alleles decreases the ability of TNFα and interleukin (IL)-1β production by circulating monocytes after stimulation with *C. albicans* [3].

Several studies have shown that carriage of the SNP rs1800629 A allele at the −308 position of the *TNF* gene modulates the capacity of circulating monocytes for the production of TNFα after *ex vivo* stimulation with bacterial endotoxin (LPS) compared with the carriage of only wild-type G alleles. This was shown in

Asian, Latin, and Caucasian populations [4–6]. Initial monocyte exposure to low LPS concentration impedes high cytokine production upon reexposure to high LPS concentration, a phenomenon known as LPS tolerance. One GWAS analysis indicated that the presence of rs522807, rs5745938, and rs625847 upstream of *TNFRSF1B* encoding for the receptor 2 of TNFα is probably associated with the expression of *TNFRSF1B* and mediates LPS tolerance [7].

52.3 Genetic Susceptibility for Acute Inflammatory Conditions

Severe sepsis is the prototype of acute inflammatory conditions. Available studies are characterized by great heterogeneity, and they have the limitations already analyzed in the first section of this chapter. However, these studies reflect the major limitation of the poor understanding of the pathogenesis of severe sepsis. More precisely, severe sepsis is the host reaction to an invading microorganism that is leading to acute organ dysfunction. This definition is very broad and introduces great heterogeneity because causative infections and responsible pathogens vary considerably from one patient to the other. This becomes far more complicated after considering that infection predisposition is severely affected by chronic coexisting illnesses and by the age and the ethnicity of the patient. As a consequence, how is it possible to identify specific SNPs responsible for predisposition to sepsis when adjusting for all this heterogeneity is mandatory? This is probably the reason why severe sepsis is considered the prototype of individualized medicine [8]. The following section provides some grouping of the available knowledge on the role of SNPs for severe sepsis. A synopsis is given in Table 52.1. The selection of SNPs to be included in this analysis was made by the following criteria: (a) studies conducted in the last decade; and (b) existing confirmation of the published evidence in other cohorts as this was coming from meta-analysis.

52.3.1 Genetic Susceptibility to Homogeneous Study Populations

Although homogeneous study populations in fact do not exist, some studies are characterized by relative homogeneity as this is expressed by the inclusion of patients with the same infection as the cause of sepsis or by the inclusion of patients with the same predisposing condition for sepsis acquisition.

52.3.1.1 Patients with the Same Underlying Infection

The only GWAS study in patients with sepsis was the multicenter GenOSept study of patients with community-acquired pneumonia (CAP) hospitalized in European Intensive Care Units (ICUs). To increase the power of analysis, patients of another three cohorts were analyzed together reaching a total of 3410 patients. Only one SNP was significantly below the set significance threshold of 5×10^{-7}; this was rs4957796 on chromosome 5 belonging to an intron region of *FER* that encodes for one Fps/Fes-related tyrosine kinase. Mortality after 28 days was 25.3% for patients with the TT genotype, 15.2% for patients with the TC genotype, and

Table 52.1 Synopsis of the most important single-nucleotide polymorphisms (SNPs) associated with susceptibility to the development of sepsis and with modulation of the physical course of sepsis.

SNP	Gene	Substitution and gene position	Encoded protein	Impact of minor frequency alleles
SNPs associated with susceptibility for sepsis				
rs1800629	*TNF*	−308 G/A	TNFα	Risk for severe sepsis in Asian populations; protection from leprosy in Brazilians
rs143634	*IL-1B*	+3594 C/T	IL-1β	TT genotype protects from sepsis
VNTR 86bp	*IL-1RN*	Intron 2 (1–6 VNTR alleles)	IL-1ra	Short sequence VNTRs increases susceptibility to septic shock
4G/4G genotype	*PAI-I*	−675 (4G/4G) homozygotes	Plasminogen activation inhibitor I	Increased risk for sepsis development
rs5743551	*TLR1*	−702 A/G	Promoter	OR = 2.56 for septic shock
rs6667605	*TNFRSF14*	Intron 4	Receptor for BTLA	Increased risk for infection by *Clostridium difficile* in UC patients
SNPs modulating the physical course of sepsis				
rs4957796	*FER*	Intron variant	Fps/Fes-related tyrosine kinase	OR = 0.56 for death with C allele carriage in CAP
rs1801274	*FCGR2A*	−167 C/T	Receptor for IgG2	OR = 2.90 for pneumococcal bacteremia in CAP
rs5743551, rs5743618, rs4833095	*TLR1*	−7202 A/G; −602 T/G; +743 A/G	TLR1	Increased risk for Gram-positive sepsis and sepsis-associated death after multiple injuries
rs1059703	*IRAK-1*	+532 C/T exon 12	IL-1 receptor associated kinase	Increased risk for MODS and death after multiple injuries
4G/5G genotype	*PAI-I*	−675 (4G/5G) heterozygotes	Plasminogen activation inhibitor I	Increased risk for death
SNPs modulating gene function				
rs1800629	*TNF*	−308 G/A	TNFα	Increased production of TNFα from circulating leukocytes after *ex vivo* stimulation

Ig, immunoglobulin; IL, interleukin; IRAK, IL-1 receptor associated kinase-1; MODS, multiple organ dysfunction syndrome; PAI, plasminogen activator inhibitor; UC, ulcerative colitis; TNFα, tumor necrosis factor alpha.

9.5% for patients with the CC genotype of this SNP. The combined protective odds ratio of the four cohorts was 0.56 with the carriage of C alleles [9].

Two studies are available in patients with bacteremia by *Staphylococcus aureus*: the first was a GWAS in 361 cases and 699 controls and failed to identify any SNP to be associated with susceptibility for bacteremia [10]; the second study in 127 cases compared SNPs of *MBL2* responsible for high, low, or absent production of mannose-binding lectin 2 (MBL2). Analysis revealed that SNPs responsible for low or absent production of MBL2 offered greater risk for persistent bacteremia (odds ratio 2.09, $p = 0.040$) [11].

The rs1801274 SNP of exon 4 of *FCGR2A* encodes for one arginine to histidine substitution at position 131 of the receptor FcγRIIA of the immunoglobulin IgG2. It is presumed that carriage of this SNP allele impedes adequate phagocytosis by neutrophils. The SNP was analyzed in 1262 patients with CAP and in 1244 controls. No differences in genotype distributions were found between patients and controls showing the lack of effect of the SNP on susceptibility for CAP. However, patients homozygous for this SNP had a greater risk for bacteremia by *Streptococcus pneumoniae* [12].

Using geographically different cohorts of patients with pneumonia from Germany and Greece, the rs2232613 SNP of LPS-binding protein (LBP) has been analyzed. The description of this SNP was largely based on differences in the crystallographic structure of LBP between patients. This SNP leads to the substitution of one cytosine to thymine at +988 position associated with 6.6 odds ratio for pneumonia by Gram-negative bacteria. Carriage of the SNP is also associated with lower production of TNFα by circulating monocytes compared with patients carrying only wild-type alleles [13].

52.3.1.2 Patients with the Same Predisposing Condition

Two large studies have recently been published exploring the role of candidate SNPs in patients with severe injuries. The first study enrolled 1498 patients of Caucasian origin analyzed for the carriage of three SNP alleles of *TLR1*: rs5743551 at the −720 promoter position, rs5743618 encoding one serine isoleucine transition at the 1804 position of the transmembrane domain of TLR1, and rs4833095 encoding one aspartate serine transition at the 742 position of the extracellular domain of TLR1. Patients homozygous for the SNP G allele rs5743551 and for the T allele rs5743618 had increased mortality due to sepsis contrary to patients who did not develop sepsis (odds ratios 3.16 and 2.48, respectively). Patients homozygous for the rs4833095 SNP allele had 4.13 odds ratio for sepsis by Gram-positive cocci ($p = 0.023$) [14]. These findings emerging in one homogeneous critically ill cohort of multiple injuries were confirmed in a nonhomogeneous cohort of 724 patients with sepsis admitted in the ICU. More precisely, patients homozygous for the G rs5743551 allele had 1.82 odds ratio for unfavorable outcome ($p = 0.028$); the odds ratio by carriage of this SNP allele was 2.56 for the development of septic shock. Furthermore, patients who were homozygotes for this SNP allele had increased prevalence of infections by Gram-positive cocci. This corroborates with the function of TLR1 that recognizes structures of the cell wall of the Gram-positive cocci. In the same study it was shown that

homozygosity of this SNP was associated with greater production of IL-6 after stimulation of leukocytes of healthy carriers with ligands of TLR1 [15].

The genetic variant rs1059703 of *IRAK-1* carried at the X chromosome, and encoding for the IL-1 receptor-associated kinase (IRAK-1) was genotyped in 321 patients admitted to one ICU for multiple injuries. Among patients homozygous for the wild-type haplotype, 4.7% developed multiple organ dysfunction (MODS) and 2.4% died; respective percentages were 11.1% and 10.3% for patients heterozygotes for the variant haplotype and 18.2% and 12.5% for patients homozygotes for the variant haplotype [16].

Although not always severe, it seems that the development of *Clostridium difficile* infection (CDI) is influenced by the genetic background of the host. As pathogenesis of CDI is characterized by marked heterogeneity regarding predisposing conditions, one recent publication focused only on the genetic make-up of patients with ulcerative colitis that is a common predisposing condition for CDI. Genetic analysis was done for the 163 SNPs that have been associated with susceptibility to ulcerative colitis. Seven of these SNPs (rs6667605, rs1363907, rs10051722, rs864745, rs4409764, rs1129555, rs17085007, and rs941823) were independently associated with the development of CDI. There was also a linear increase of the risk for CDI with the presence of each of these loci, so that each locus increased the risk for acquisition of CDI by threefold. Most susceptibility came from the TT genotype of rs6667605 influencing the activity of NF-κB [17].

52.3.2 Meta-Analysis Published

Since the beginning of case–control gene association studies, some SNPs have attracted much attention and they were thoroughly studied in multiple cohorts. The availability of studies allowed the publication of meta-analyses, although these cohorts were characterized by great heterogeneity. Available meta-analyses report on the role of SNPs of *TNF*, *IL-1*, and *PAI-I* for sepsis susceptibility and sepsis mortality.

Most case–control studies published so far involve the SNP rs1800629 of one guanine to adenine substitution at the −308 promoter region of *TNF*. One large meta-analysis published in 2010 [18] incorporated data from 25 studies conducted between 1996 and 2008; patients enrolled in these studies were of Caucasian origin, Asian origin, or mixed origin. The underlying condition predisposing to sepsis also varied considerably between these studies. Despite this heterogeneity, the meta-analysis indicated a pooled 2.15 odds ratio for sepsis development for carriers of the A SNP allele. This susceptibility was more pronounced in Asian populations (odds ratio 3.16 contrary to 1.94 in the Caucasians). Carriage of the A SNP allele was also associated with greater risk for death in Asian populations (odds ratio 10.75) but not in the Caucasian populations.

The results of this meta-analysis for the impact of the rs1800629 SNP in the Asiatic population were confirmed later in a cohort of 432 Chinese patients with severe sepsis who were compared with 624 Chinese healthy volunteers [4]. Carriage of the minor frequency A allele was associated with 1.92 odds ratio for the development of severe sepsis ($p = 0.00046$). We tried to follow up the

impact of carriage of SNP alleles of *TNF* in the physical course of Caucasian patients who were admitted in the ICU due to the need of ventilator support. These patients were uninfected on study enrollment, and the primary study end point was the time to the development of ventilator-associated pneumonia (VAP) as a result of exposure to intubation that is a well-known risk factor for VAP. Results revealed that wild-type haplotypes with major frequency G alleles for SNPs rs1800750 at −376 promoter region, rs1800629 at −308 promoter region, and rs361525 at −238 promoter region were associated with slower development of VAP compared with carriers of SNP haplotypes [5].

Meta-analyses for the role of the rs1800629 SNP involve not only sepsis risk but also the risk for leprosy. This later meta-analysis was conducted in case–control studies in Indian, Brazilian, Malawian, Thai, and Nepalese populations. Carriage of the minor frequency A allele was protective from leprosy, and this effect was more pronounced in the Brazilian populations. When whole blood of Brazilian patients was *ex vivo* stimulated, production of TNFα was greater than carriers of A alleles corroborating the findings coming from sepsis studies [6].

Meta-analysis has also been conducted on 18 case–control studies that explored the role of SNPs *IL-1A*, *IL1B*, and *IL-1RN* encoding for IL-1α, IL-1β, and IL1ra, respectively. Results showed that, among all analyzed SNPs, two conferred most susceptibility for sepsis. The first was the one SNP at the +3594 position of *IL-1B*; patients homozygous for the minor frequency T SNP allele were protected from sepsis (odds ratio 0.59, $p = 0.040$). The second was the presence of two alleles of tandem 86 bp repeats at intron 2 of *IL*-1RN that increased the risk of sepsis (odds ratio 1.85, $p = 0.020$); the effect on septic shock susceptibility was even more pronounced (odds ratio 10.00, $p = 0.040$) [19].

One of the meta-analyses involves genotyping for *PAI-I* encoding for the plasminogen activator inhibitor I that inhibits the activation of tissue plasminogen activator. Circulating concentrations of PAI-I are increased in severe sepsis. The published meta-analysis was done in 15 studies; 13 studies involved Caucasian populations and two studies involved Asiatic populations. Patients may carry one of 4G/4G, 4G/5G, or 5G/5G genotypes of *PAI-I* at the −675 position of the gene promoter. The 4G/4G genotype was associated with increased risk for sepsis acquisition (odds ratio 2.75, $p = 0.006$ for all the studies; odds ratio 1.23, $p = 0.03$ only for patients of Caucasian origin). However, higher risk for unfavorable outcome came from the 4G/5G genotype; the cumulative odds ratio for death for carriers of this genotype was 1.72 [20].

52.3.3 General Considerations

The above analysis generates doubts on which of the studied SNPs may really confer some genetic susceptibility to the host and modulate the physical course of severe infections or whether this is more or less confined to some ethnicities or even to individualized cases. One main reason for these doubts is the heterogeneity of the results. It may be argued that for a gene to affect the severe course of an infection, its implication should be shown in more than one disease states. One example is *CISH* encoding for cytokine-inducible Src homology-2 domain protein that belongs to the SOCS family. SOCS is the acronym for the suppressor of

cytokine signaling proteins that regulate cytokine production. Seven separate large cohorts of patients each suffering from one specific severe infection (bacteremia, tuberculosis, and malaria) were collected from different ethnicities and geographic regions from Gambia, Kenya, Malawi, and Hong Kong. Genetic analysis for the SNPs at positions −639, −292, −163, +1320, and +3415 of *CISH* was conducted, and results were compared with respective control cohorts of the same ethnicity and geographic region. Carriage of any of the five SNPs increased the likelihood for each of the studied infections, although most of the association signal came for the −292 SNP (pooled odds ratio 1.19 from the seven studied cohorts). The risk was more pronounced for patients carrying more than one SNP by at least 18%. Patients homozygous for the T allele of the −292 SNP had lower expression of *CISH* in their circulating mononuclear cells after *ex vivo* stimulation with IL-2 compared with patients homozygous for the A wild-type allele [21].

52.4 Genetic Predisposition for Chronic Inflammatory Disorders

Contrary to acute inflammatory conditions, evidence available for the role of genetic predisposition of the host for chronic inflammatory disorders is more robust due to the large number of available studies and to the nature of these studies. More precisely, the major study approach is the one of GWAS accompanied by confirmation of findings in independent cohorts. A summary of major findings is provided in this chapter.

52.4.1 Inflammatory Bowel Disease (IBD)

Large GWAS have been conducted for patients with both ulcerative colitis (UC) and Crohn's disease (CD). In most of these studies, findings are confirmed using a meta-analysis approach of published sequencing data or GWAS data (Table 52.2). One recent large GWAS involved 2693 patients and 6791 controls of European descent from the United States and Sweden; a replication cohort of 2009 patients and 1580 controls from Italy and The Netherlands was used for confirmation. Results identified 59 SNPs in 14 genetic loci that differed significantly between cases and controls. The most frequently implicated gene loci were *RNF186*, *OTUD3*, and *PLA2G2E* on chromosome 1 (rs3806308, rs1317209, and rs6426833); *IL23R* on chromosome 1 (rs2201841 and rs11209026); *FCGR2A* and *FCGR2C* on chromosome 1 (rs10800309); *IL10* and *IL19* on chromosome 1 (rs3024505); *REL*, *CCDC139*, and *PUS10* on chromosome 2 (rs6706689 and rs13003464); *MST1* on chromosome 3 (rs3197999); *CEP72* and *TPPP* on chromosome 5 (rs4957048); *C6orf10* and *BTNL2* on chromosome 6 (rs2395185); *DLD* and *LAMB1* on chromosome 7 (rs4598195); *CARD9* on chromosome 9 (rs4077515); *NKX2-3* on chromosome 10 (rs11190140); *IFNG* and *IL26* on chromosome12 (rs1558744 and rs971545); the *ORMDL3* region on chromosome 17 (rs2305480); and *PSMG1* on chromosome 21 (rs2836878) [22].

The implication of gene loci of *RNF186*, *IL23R*, and *CARD9* was confirmed in one GWAS of 200 UC patients of French Canadian ancestry [23]. One large

Table 52.2 Most common gene loci associated with susceptibility to ulcerative colitis as defined by genome-wide association studies [22–25].

SNP	Gene	Risk allele	Function	Odds ratio (95% CIs)
rs3806308	*RNF186*	G	E3 ubiquitin ligase for DSB repair	1.49 (1.17–1.90)
rs2858829	18 kb upstream of *FAM26F*	G	Increased *FAM26F* expression	1.12 (1.08–1.16)
rs11209026	*IL23R*	G	IL-23 receptor	1.74 (1.57–1.92)
rs1801274	*FCGR2A*	A	Immunoglobulin G Fc receptor II (low affinity receptor)	1.21 (1.16–1.26)
rs3024505	*IL10*, *IL19*	A	IL-10, IL-19	1.25 (1.19–1.32)
rs7608910	*PUS10*	G	Spliceosome biogenesis	1.19 (1.24-1.24)
rs7134599	*IFNG IL26*	A	IFNγ, IL-26	1.19 (1.14–1.24)
rs4077515	*CARD9*	C	Cardinal	0.39 (0.30–0.53)

CI, confidence interval; IL, interleukin.

meta-analysis of data collected from six UC GWAS confirmed the implication of these genes as well. This precise meta-analysis [24] comprised 6687 cases and 19 718 controls and added another new 29 gene loci associations with UC. This meta-analysis confirmed the importance of genetic variations of the previously reported genes such as *IL23R*, *FCGR2A*, *IL10*, *IL19*, *PUS10*, *IFNG*, *IL26*, and *CARD*9. Newly implicated genes were *TNFRSF8*, *TNFRSF9*, *TNFRSF14*, and *TNFRSF15* all encoding for receptors of the TNF superfamily; *IL1R2*, *IL7R*, and *IL8RA* encoding for receptors of IL-1, IL-7, and IL-8, respectively; *DAP* encoding for the death-associated protein of the apoptosis pathways; *PRDM1* encoding for a master transcriptional regulator in plasma cells and in T and B lymphocytes; and *IRF5* encoding for interferon regulatory factor 5 [24]. Another meta-analysis of 15 GWAS on UC and CD increased the number of implicated gene loci for predisposition to IBD in 193. This meta-analysis tried to provide the functional significance of the reported SNPs. It was found that SNPs associated with susceptibility to IBD are enriched either in the regulation of cytokine production pathways or in the activation of lymphocytes or in the JAK–STAT signaling pathways [26]. The enrichment of these pathways generated the hypothesis that selection of these gene SNPs is a process of natural pressure by the microbial gut flora.

Starting from new genotyping of 825 UC cases and 1527 controls from Spain and confirming the data with previous published GWAS data of the North-European ancestry, the rs2858829 located in chromosome 6q.22.1 was associated with significant risk for UC. This SNP is located 18 kb upstream of the *FAM26F* gene. Analyses of the microarrays from four studies in UC indicate that this SNP is associated with increased expression of *FAM26F* in the lamina propria of the colon mucosa [25].

GWAS for 19 799 coding SNPs was done in 735 German patients with CD. After bioanalysis, the G allele of rs2241880 of *ATG16L1* on chromosome 2 was associated with 1.45 odds ratio for susceptibility to CD. This was confirmed in sets of 498 German patients and 509 UK patients [27].

After capture and analysis of the whole exome from 42 CD patients from Germany, two missense SNPs of *PRDM1* on chromosome 6 were identified: rs106659789 as a risk variant for CD and rs106660076 as a protective variant for UC. Minor frequency C alleles of the rs106659789 risk variant were associated with greater potential of CD3 lymphocytes for replication and production of IFNγ. Moreover, carriage of C alleles of rs7746082 of *PRDM1* was associated with lower gene expression of *PRDM1* in T and B lymphocytes both in the gut lamina propria and in circulating lymphocytes [28].

52.4.2 Psoriasis Vulgaris and Psoriatic Arthritis

More than 30 studies have been published on the influence of carriage of A alleles of rs1800629 and rs361525 of the *TNF* promoter for susceptibility of psoriasis vulgaris and psoriatic arthritis. One meta-analysis of 26 studies has recently been published [29]. Results were homogeneous for patients of both Caucasian and Asiatic origin, and these showed an opposite effect of carriage of A alleles at −308 promoter region (rs1800629) and of A alleles at −238 promoter region (rs361525). More precisely, carriage of A alleles of rs1800629 was protective from psoriasis vulgaris (pooled odds ratio 0.574) but not from psoriatic arthritis, whereas carriage of A alleles of rs361525 increased susceptibility to both psoriasis vulgaris (pooled odds ratio 2.636) and psoriatic arthritis (pooled odds ratio 2.242).

A large genomic analysis of 9389 cases and 9477 controls pinpointed two important genetic elements predisposing to psoriasis vulgaris. The first is a 32.2 kb deletion of two *LCE* genes, known as *LCE3C_LCE3B-del* which is part of the epidermal differentiation complex. The second is one copy number variant offering the tag rs4112788 located 584 nucleotides downstream of *LCED*. The presence of the *LCE3C_LCE3B-del* offered overall odds ratio 1.21 for psoriasis at p-value 4.58×10^{-13}. This was also the case with the carriage of C alleles of rs4112788 associated with psoriasis with overall odds ratio 1.21 at p-value 1.42×10^{-12}. These associations were confirmed in populations of both European and Asiatic ancestry [30].

Most of the genetic susceptibility for psoriasis is coming from a region of 300 kb of *HLA-C* on chromosome 6p21 encoding in part for the major histocompatibility complex class I, also known as *PRORS1*. One large GWAS in 2622 cases and 5667 controls confirmed the implications of SNPs of *HLA-C* for predisposition to psoriasis with odds ratio 4.66. This chromosome encompasses four main genes, *TRAF3IP2*, *NFKBIA*, *REL*, and *TYK2*, involved in the activation of IκB, IL-17, and IFN signaling that are key molecules for the pathogenesis of psoriasis [31]. Another GWAS was conducted in 1831 cases and 2546 controls and a confirmation cohort of 4064 cases and 4685 controls. Authors validated three SNPs to be associated with psoriasis: rs4795067 of *NOS2* encoding for inducible nitric oxide synthase, rs10782001 involved in the activation of NF-κB, and rs12586317 also involved in the activation of NF-κB [32].

Table 52.3 Most common gene loci associated with susceptibility to systemic lupus erythematosus as defined by genome-wide association studies [33–36].

SNP	Gene	Risk allele	Function	Odds ratio (95% CIs)
rs7574865	*STAT4*	T	Intracellular signaling	1.55 (1.34–1.79)
rs13397	*TMEM187*	A	Yet unknown	1.41 (1.12–1.79)
rs4898475	TKTL1	A	Transketolase of pentose phosphate pathway (nonoxidative phase)	1.44 (1.15–1.82)
rs1059702	*IRAK1*	A	IL-1 receptor-associated kinase-1	1.18 (1.17–1.87)
rs2734647	*MECP2*	T	Repression of transcription from methylated gene promoters	1.42 (1.16–1.80)
rs2075596	*MECP2*	A	Repression of transcription from methylated gene promoters	1.45 (1.16–1.80)
rs1616369	*MECP2*	C	Repression of transcription from methylated gene promoters	1.50 (1.20–1.88)
rs7704116	*PPP2CA*	A	T lymphocyte proliferation	1.3 (1.1–1.3)
rs34933034	*CSK*	A	Expansion of late transitional B lymphocytes	1.32 (1.20–1.44)

CI, confidence interval; IL, interleukin.

52.4.3 Systemic Lupus Erythematosus (SLE)

SLE is the prototype of autoimmune disorders involving women in more than 90% of cases. Multiple large GWAS have been published for patients with SLE. Here, we report the results of studies published in the last decade with confirmation of the genetic evidence in European and several other ethnicities (Table 52.3). The first study highlighting the importance of individual SNPs used a candidate gene approach for SNPs of *STAT4* encoding for STAT4 that modulates intracellular signaling. Besides three independent cohorts, it was shown that carriers of the minor frequency T allele of rs7574865 have increased risk for SLE; the association was stronger for patients at a state of SNP homozygosity [33].

Often, presentation of SLE in women shed light on the importance of X chromosome for the genetic susceptibility for SLE. One large GWAS was performed for SNPs located in X chromosome in Americans of European Ancestry (3915 cases and 3462 controls). Identified SNPs below the threshold of significance of GWAS were confirmed in separate cohorts of African origin, Asian origin, and Hispanic origin. Data confirmed that 34 SNPs at the Xq28 locus are a risk factor for SLE. These SNPs are contained in the same haplotype, called haplotype H1, and they are located at the *IRAK1* and *MECP2* genes. The frequency of the H1 haplotype comprises 17.4% in cases and 13.3% in controls of European ancestry, 69.1% in cases and 64.2% in controls of Asian ancestry, 52.1% in cases and 40.1% in controls of Hispanic ancestry, and 63.3% in cases and 4.3% in controls of African ancestry. SNPs rs13397, rs4898375, rs1059702, rs2734647, rs2075596, and rs1616369 are the core of this haplotype. Of these

SNPs, carriage of rs1059702 was associated with lower expression of *MECP2* in circulating lymphocytes (Table 52.3). The significance of this biological association comes from the fact that IRAK-1 encoded by *IRAK-1* is implicated in the downstream activation of IκB and *MECP2* is implicated in the activation of the IFN signaling pathways [34]. Using the same cohorts of patients, it was found that the A allele of rs7704116 increases susceptibility for SLE in all ethnic groups and, in particular, for renal manifestations. This SNP is located in the *PP2CA* gene, and the A risk allele is associated with decreased gene expression of *PPC2CA* linked with defective proliferation of T lymphocytes. This is probably due to the significance of *PPP2CA* for the production of IL-2 [35].

Analysis of another three cohorts identified that patients homozygous for the minor frequency A rs34933034 allele of *CSK* have increased likelihood for SLE. This is associated with increased activation of gene expression of *CSK* accompanied by increased mobilization of calcium and expansion of late transitional B lymphocytes [36]. Other large genetic studies have shown that SNPs at the genetic region of *HLA* confer susceptibility for SLE and that they are associated with the phenotype of the disease. However, findings are limited in European populations and confirmation sets in other ethnic groups are not yet available [37,38].

52.4.4 Rheumatoid Arthritis (RA)

RA affects more than 1% of the general population worldwide, and genetic predisposition is a major component of pathogenesis in at least 20% of cases (Table 52.4). Using the candidate gene approach, SNPs located at *HLA-DRB14*

Table 52.4 Most common gene loci associated with susceptibility to rheumatoid arthritis as defined by genome-wide association studies [33,39–44].

SNP	Gene	Risk allele	Function	Odds ratio (95% CIs)
rs6457620	*HLA-DRB1*	C	HLA class II	2.55 (2.40–2.71)
rs6679677	*PTPN22*	A	Negative regulator of T-cell receptor (TCR)	1.79 (1.65–1.94)
rs7574865	*STAT4*	T	Intracellular signaling	1.14 (1.06–1.23)
rs3761847	*TRAF1-C5*	A	Negative regulator of TNF signaling pathway	1.32 (1.23–1.42)
rs44181354	*CD40*	T	CD40	0.91
rs6920220	*TNFAIP3*	A	Inhibition of NF-κB	1.32 (1.23–1.43)
rs10499194	*OLIG3*	—	Neuronal development	0.88 (0.83–0.93)
rs3890745	*TNFRSF14*	A	TNF receptor	1.13
rs2872507	*IKZF3*	A	B cell differentiation	0.90
rs10489629	*IL23R*	C	IL-23 receptor	1.15 (1.06–1.24)
rs7517847	*IL23R*	G	IL-23 receptor	1.18 (1.09–1.28)

CD, cluster of differentiation; CI, confidence interval; IL, interleukin; TNF, tumor necrosis factor.

and *PTPN22* were associated with increased likelihood for RA testing positive for the antibodies against cyclic citrullinated peptide (anti-CCP). The first large GWAS was conducted in 1522 RA cases testing positive for anti-CCP and 1850 well-matched controls. A confirmation of the results in 1053 cases and 1798 controls was done. Results identified gene loci at chromosome 6, where the *HLA-DRB1* is found, and at chromosome 9 to be associated with increased likelihood for RA. Loci of chromosome 9 referred mainly to nine SNPs of *TRAF1-C5*, of which rs3761847 was associated with an odds ratio of 1.32 for RA [39].

Another large GWAS was conducted by the Wellcome Trust Case Control Consortium (WTCCC) in 3714 cases and 5870 controls. Results were validated in another study of 9644 cases and 7390 controls, and indicated a profound role of rs6920220 located at chromosome 6p23 for susceptibility to RA. The effect was more pronounced for patients testing positive for anti-CCP (pooled odds ratio versus controls 1.32) and for patients testing positive for rheumatoid factor (pooled odds ratio versus controls 1.28) [40]. The significance of this SNP was also highlighted by another GWAS of 2680 cases and 4469 controls [41]. These results of the GWAS database of the WTCCC were confirmed in a new collection of 3929 RA patients testing positive for anti-CCP or for rheumatoid factor and 5807 matched controls. In this analysis, the SNP rs4810485 surpassed the level of significance; it is located in the gene encoding for CD40 and carriage of the minor frequency T allele is associated with protection from extensive joint involvement [42].

Trying to further validate the findings, genomic analysis in RA patients from five different countries used a new immunochip that was designed to comprise all known SNPs defined by the 1000 Genomes Project and all SNPs of the 186 loci defined to be involved in 12 autoimmune disorders. Results fully confirmed the implication of *HLA-DRB1*, *PTPN22*, *STAT4*, and *TNFAIP3* [43]. A multiethnic GWAS approach in 5505 RA cases and 22 603 controls followed by validation in 6768 cases and 8806 controls of European ancestry identified two more gene loci: rs3890745 of *TNFRSF14* located at chromosome 1 and rs2872507 of *IKZF3* located at chromosome 17q12; rs3890745 was associated with increased susceptibility for RA and rs2872507 with protection from RA [44].

In light of the conduct of the large GWAS, some meta-analysis of case–control studies of candidate genes managed to outscore the significance of some SNPs for RA acquisition and for the RA phenotype [45–47]. One meta-analysis was conducted for two SNPs of *IL23R* in populations of European origin coming from Australia, New Zealand, Norway, Spain, and the United Kingdom: rs10489629 and rs7518847. Analysis revealed that carriage of the C allele of rs10489629 and carriage of the G allele of rs7517847 were associated with increased likelihood for RA [45]. Another meta-analysis of 30 studies focused on the significance of two SNPs of *CTLA-4*: rs231775 and rs3087243. rs231775 is one adenine to guanine substitution at +49 position that increases the risk for RA in Asians (pooled odds ratio 1.27) and Americans (pooled odds ratio 1.87) but not in Europeans. rs3087243 is one guanine to adenine substitution at +60 position that decreases the risk of RA in Europeans (pooled odds ratio 0.89) without affecting other ethnicities [46]. Finally, one meta-analysis of 10 studies comprising 2053 patients revealed that the presence of A alleles of rs1800629 at −308 promoter of *TNF* was protective from erosions with 0.78 common odds ratio [47].

52.5 Conclusive Remarks

The current chapter rendered evident that genetic susceptibility for an acute or chronic inflammatory condition does not rely on single SNP but rather on a constellation of SNPs. This constellation may offer genetic susceptibility or modify disease phenotype. Existing evidence suggests that as genetic analysis goes on using the new high throughput techniques more susceptibility loci will be identified. The main question remains: Is this identification of clinical significance? The need for an answer becomes more demanding because some of these SNPs do not necessarily belong to genes directly implicated in the inflammatory process or to genes with known function. One recent example comes from an attempt to identify new genetic loci in patients with RA. To this end, a meta-analysis was conducted in data from 22 GWAS and then findings were replicated in two independent cohorts. The authors of this study followed such a thorough approach because they thought it was necessary to combine genetic data coming from patients with different ethnic backgrounds. Analysis managed to replicate the significance of already-reported SNPs in Table 52.4 associated with RA. Moreover, 42 new gene loci were identified to confer the susceptibility for RA. All identified SNPs, both the formerly acknowledged and the new described, were related with pathways of either immune regulation or hematologic cancer

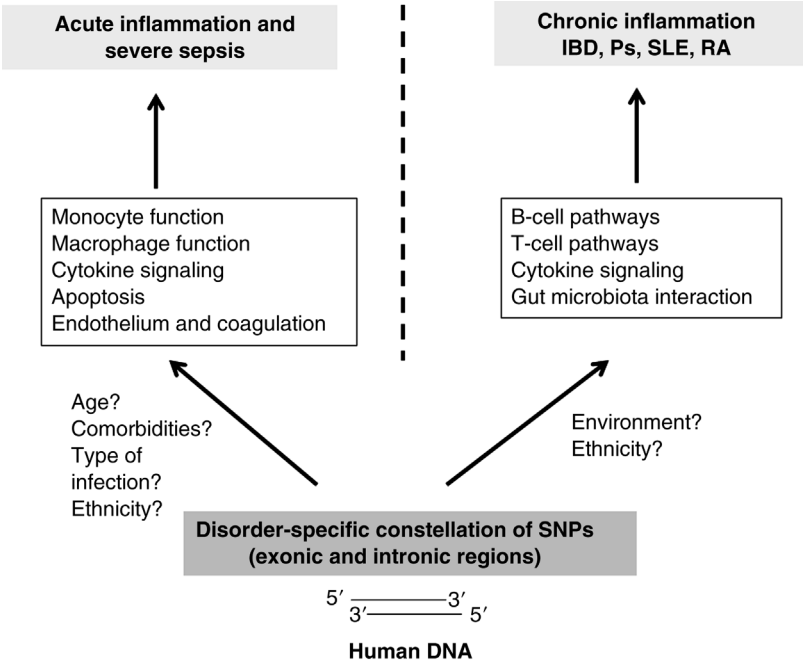

Figure 52.1 A simplistic representation of our current understanding of the impact of SNPs for acute and chronic inflammatory disorders. A specific for each disorder constellation of SNPs modulates pathways that dominate the development of acute and chronic inflammatory processes. Factors interfering as confounders to this modulation are marked with a question mark. IBD, inflammatory bowel disease; Ps, psoriasis; RA, rheumatoid arthritis; SLE, systemic lupus erythematosus; SNPs, single-nucleotide polymorphisms.

mutation. Those related to immune regulation were pathways of B-cells, T-cells, and cytokine signaling. One salient finding was that the described loci were related with functions targeted by many of the available biological disease-modifying agents for RA such as tocilizimab, tofacitinib, and abatacept [48].

Although the genetic predisposition provided by a constellation of SNPs for a chronic state of inflammation like in IBD, SLE, and RA seems clear-cut, the significance of a constellation of SNPs for susceptibility to severe sepsis seems far more complex and heterogeneous. This is probably a reflection of the disease process *per se* where both acquisition of severe infection and outcome are affected by a variety of factors. The intensity of the initial inflammatory reaction of the host to a microbial insult, the type of infection triggering septic phenomena, and the age and comorbidities of the host are the most important of these factors (Figure 52.1). It should also be underscored that part of the variability in findings is associated with the genetic background of different ethnicities. Heterogeneity of the genetic make-up between different ethnicities seems to largely affect predisposition for both acute and chronic inflammatory disorders.
