The physical examination should begin with a visual inspection of the patient's gait and limb alignment. With the patient placed supine, the examiner can commence with a closer inspection of the knee joint and comparison with the uninjured side, focusing on the area of the chief complaint. Range of motion (ROM) and ligamentous stability should be noted using standard maneuvers. Presence of effusion should be noted, and the patellofemoral joint should be assessed for alignment, baja or alta position, mobility, grind, tracking, tilt, and signs of apprehension. It is particularly useful to palpate the femoral condyles and other accessible articular surfaces because focal tenderness at the site of cartilage lesions is an important physical finding. Symptomatic trochlear or patellar lesions can be stressed with a bounce test or by applying prepatellar pressure during the grind test, whereas condylar lesions often become painful when loaded with a valgus or varus stress test or during a McMurray maneuver. Accordingly, joint line pain and other complaints caused by meniscal or synovial symptoms or originating from extraarticular structures such as bursae or the iliotibial band should be distinguished from chondral pathology.

Patients who are considered for an osteochondral grafting procedure should optimally be fully imaged, including a complete radiologic series and magnetic resonance imaging (MRI) studies with cartilage-specific sequencing, if available. Depending on the type and location of cartilage injury being suspected, this should include at least standing anteroposterior (AP) weight-bearing and flexed knee lateral radiographs. Many chondral lesions and their subchondral sequelae are detectable on the AP views (Fig. 32-1), which also give an indication of possible secondary changes such as joint space narrowing and osteophytes. Imaging both knees side by side allows for a built-in comparison view. Of note, OCD presents with bilateral lesions in about a third of the cases that are often easily detected on an x-ray in their typical location on the lateral aspect of the medial femoral condyle toward the intercondylar notch. The lateral flexed view is an important supplementary tool to help assess lesion size, triangulate locations, and identify patient's morphology such as patella alta or baja and trochlear groove topography. Additional views that can be obtained include standing posteroanterior 45-degree flexed knee (Rosenberg) views and supine flexed knee (Merchant) views. The Rosenberg view brings the posterior condyles into view, which helps assess the posterior joint space during loading. Merchant views are standard for the evaluation of the patellofemoral articulation. Long-leg (hip to ankle) standing AP weight-bearing radiographs should be obtained if axial alignment is deemed contributory to the patient's symptomatology and are essential for preoperative planning if a realignment procedure is being considered.

MRI remains as an import tool for assessing the status of the articular cartilage and associated structures of the knee (Fig. 32-2).[61] The

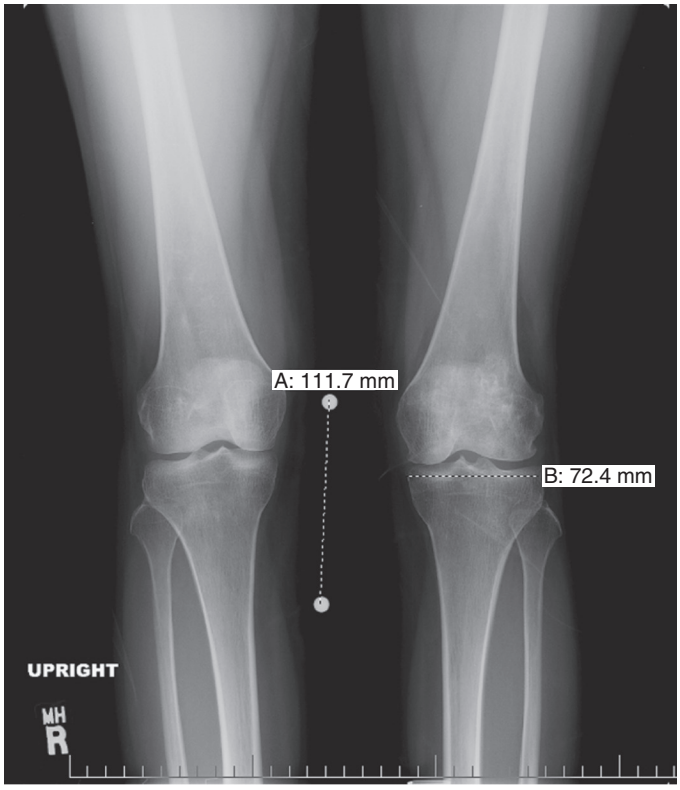

FIG 32-1 Anteroposterior radiograph of bilateral knees in a 44-year-old patient with osteonecrotic changes to her left lateral femoral condyle, displaying a tibial measurement and a radiographic magnification marker for allograft sizing.

FIG 32-2 T2 sequence magnetic resonance imaging of the left knee of an 18-year-old woman demonstrates an osteochondritis dissecans lesion in typical location on the lateral aspect of the left medial femoral condyle.

most common MRI sequences for cartilage assessment of cartilage repair require cartilage that are fat-suppressed 3-dimensional gradient echo (3D-GRE) and proton-density (PD) and T2-weighted (dual) fast spin echo (FSE) techniques with or without fat suppression. In general, 3D-GRE sequences with fat suppression allow analysis of the thickness and surface of cartilage, whereas dual FSE sequences outline the internal structure of hyaline cartilage.[7,8,31,34] Although not widely used on clinical scanners, recent advancements in specific sequences of MRI such as delayed gadolinium enhanced MRI of cartilage (dGEMRIC), T1 rho, T2 mapping and diffusion weighted imaging can assess biochemical details of cartilage tissue.[68] Additionally, with the widespread deployment and subsequent validation of novel qualitative and quantitative MRI sequences, imaging may play a larger role in the postoperative evaluation of cartilage repair techniques. This includes ultrashort echo time sequences that allow qualitative and quantitative evaluation of the calcified layer of cartilage, which play an important role in the overall function of the osteochondral unit. In an exploratory subgroup analysis, preserving the calcified cartilage layer was particularly useful in predicting biomechanic properties of osteochondral allografts.

Early degenerative ICRS grade I or II changes (softening, fibrillation) and associated surface irregularities often present as subtle alterations in contour morphology and thickness on MRI. Decreases in thickness can indicate cartilage volume loss, although increases in thickness can signal intrasubstance collagen degeneration and free water accumulation. Advanced degenerative grade III or IV lesions are usually more overt on MRI, manifesting as poorly marginated substance defects often associated with corresponding signal-intensive subchondral edema or cysts, apposing joint surface changes, localized synovitis, or general joint effusion. In contrast, acute, traumatic defects routinely present as focal chondral or osteochondral lesions with distinct margins, often with underlying bone signal changes.

PREOPERATIVE PLANNING

If the patient has had prior surgery, the corresponding operative reports and arthroscopic photographs (if available) are usually helpful not only in assessing the index lesion but also in gauging the overall disease burden and suitability for autologous graft harvest, if applicable. Obviously, results of any modalities and examinations described previously will also factor into the decision and any surgical planning.

Common to all fresh allografting procedures is matching the donor with the recipient. It should be noted that in current practice, small-fragment fresh osteochondral allografts are not human leukocyte antigen (HLA) or blood type matched between donor and recipient and that no immunosuppression is used. The allografts are matched to recipients on size alone. In the knee, an AP radiograph with a magnification marker is used (see Fig. 32-1), and a measurement of the mediolateral dimension of the tibia, just below the joint surface, is made and corrected for magnification of the radiograph. This corrected measurement is used, and the tissue bank makes a direct measurement on the donor tibial plateau. Alternatively, a measurement of the affected condyle can be performed. A match is considered acceptable at ±2 mm; however, it should be noted that there is a significant variability in anatomy, which is not reflected in size measurements. In particular, in treating OCD, the pathologic condyle is typically larger, wider, and flatter; therefore a larger donor generally should be used.

Lastly, when considering realigning osteotomy on the same articulating side of an osteochondral graft, staging the procedure is advised to not jeopardize the microvascularity of the recipient bone bed.

INTRAOPERATIVE PLANNING

The patient is positioned in a supine fashion to allow for full flexion of the knee. A tourniquet is recommended to assist with intraoperative visualization. A leg or foot holder can help to position and maintain the leg between 70 and 100 degrees of flexion during open procedures.

Autografting

Historically, the intercondylar notch and lateral trochlea were presumed to be non–load bearing and thus recommended as donor sites for autologous osteochondral grafting. More recent reports have demonstrated that these areas do bear significant weight, which can theoretically contribute to increased donor site morbidity. The lateral trochlea appears to be the most involved in loading followed by the intercondylar notch and the distal medial trochlea.[1] Because the lateral trochlea is wider than the medial side, the medial trochlea may best be suited for smaller donor plugs (<5 mm).[20] Larger plugs can be taken from the lateral trochlea, starting proximal to the sulcus terminalis, where the lowest contact pressures of the lateral trochlea were measured. Owing to its load-bearing demands, the lateral trochlea appears to have thicker articular cartilage, making it the favorite graft source of most surgeons. Plugs taken from the far medial and lateral margins of the femoral trochlea, just proximal to the sulcus terminalis, also appear to provide the most accurate reconstruction of the surface anatomy of central lesions in the weight-bearing portion of either femoral condyle.[5]

Smaller grafts (4 or 6 mm) from the lateral intercondylar notch can also provide precise matches to similar lesions; however, significant inaccuracies are noted when the lateral intercondylar notch grafts are increased in size (8 mm). Although all traditional donor sites have less cartilage thickness than common recipient sites, this discrepancy is most profound between the lateral intercondylar notch and the weight-bearing portion of the femoral condyles.[67] In addition, the concave central intercondylar notch grafts do not match the topography of the convex femoral condyles,[1] and their harvest jeopardizes the integrity of the trochlear subchondral bone, which might be responsible for the increased incidence of anterior knee pain in some studies.

In general, matching articular geometry becomes more difficult, and the potential for donor site morbidity increases with larger dowels.

Allografting

Usually, patients have undergone prior surgery or are at least fully imaged; otherwise, a diagnostic arthroscopy is performed before the allografting procedure to confirm the extent of the lesion and thus adequacy of the available graft. It is the surgeon's responsibility to inspect the graft and to confirm the adequacy of the size match and quality of the tissue before surgery.

OPERATIVE TECHNIQUE

Autografting

The technique can be performed through a standard arthrotomy, miniarthrotomy, or arthroscopically. Even in arthroscopic approaches, graft harvest from the trochlea almost always necessitates a mini-incision, and the surgeon should be prepared to convert to a standard arthrotomy because certain locations (e.g., the posterior femoral condyle) may be difficult to access with less invasive approaches and perpendicularity in graft harvest, and placement might be difficult to achieve.

After the entire knee joint has been inspected and tissue adequacy of the potential donor sites validated, the lesion to treat is accessed, probed, and measured, and a corresponding graft match is established. In current practice, available donor plug sizes vary from 4 to 10 mm depending on the technique and instrumentation system used and on the size of the chondral lesion treated. For reasons outlined previously, we advocate medium-sized trochlear plugs, optimally harvested through the same ipsilateral incision. The procedure should begin with the graft harvest to ensure availability of a suitable graft before creating a recipient tunnel or to at least have a fallback option available, such as bone void filler.

Proprietary instrument systems generally use a hollow-core instrument for the graft harvest. An appropriately sized T-handled recipient harvester is tapped perpendicular to the articular surface of the far ipsilateral margin of the trochlea, just proximal to the sulcus terminalis. The depth should be a minimum of 8 mm or more, depending on subchondral involvement of the lesion to treat. It is paramount to check the perpendicularity of the harvesting device from several angles after introduction and before advancing it further. Once tapped, the harvester chisel is then removed by rotating the driver to amputate the graft. The functional length of the graft is measured, and efforts should be made to fashion the recipient socket so that it provides a secure press-fit circumferentially and has enough depth to accommodate the plug easily lengthwise.

Biomechanic studies have confirmed that optimally sized, level-seated plugs face nearly normal joint contact pressures in situ.[40] Results also show that slightly countersunk grafts and angled grafts with the highest edge placed flush to neighboring cartilage demonstrate fairly normal contact pressures. Conversely, elevated angled grafts increase contact pressures as much as 40%, making them biomechanically disadvantageous.[39] The consensus is that it is more favorable to leave a graft slightly countersunk than elevated with respect to the neighboring cartilage.[55] Therefore we advise slightly lengthening the recipient tunnel to avoid leaving the graft proud or subjecting it to undue insertion forces in an effort to bury an oversized graft.

Depending on the instrument systems, the recipient socket can be prepared using either a core or a drill. The traditional osteochondral autograft system uses a tubular coring device. Using the same technique described previously with a slightly smaller circumference T-handled harvester and maintaining strict perpendicularity, the recipient socket is created. Again, it is advisable to not oversize the recipient tunnel; rather, it should be of equal or greater depth than the donor plug's length. Drilling the recipient site might produce a more precise socket depth. In either event, the recipient socket should be measured for accuracy. The bony portion of the plug can be rasped down to the desired depth measurement, if necessary. After the donor graft's length is verified, it is then transplanted into the recipient site using the donor insertion guide, which dilates the cartilage layer with its beveled edge creating a tight press fit. The last 1 mm of impaction should be performed by lightly tapping a bone tamp over the cartilaginous cap. The bone tamp should be oversized or placed offset to avoid countersinking a slightly shorter graft.

If required, the process can be repeated until a reasonable tissue fill is achieved in the lesion, but careful spacing of the plugs is essential. A 2-mm bone bridge between recipient sockets is recommended to help achieve and maintain a secure press fit. The resulting margins on the articular surface should fill with fibrocartilage. To avoid premature amputation of the graft, the osseous portions should not intersect with one another. This can be most problematic with longer grafts obtained in areas of the knee where there is high curvature, such as the posterior femoral condyle. Finally, to prevent recipient tunnel wall fracture, each plug transfer should be completed before proceeding with additional recipient sockets.

The surgeon may choose to retrofill the created defects to minimize donor site morbidity. Using the plugs removed from the recipient

sockets carries the risk of displacement owing to their undersized nature relative to the donor voids. However, osteobiologic plugs that correspond to the diameters of commercial coring devices are available for this purpose and are optional. After the graft process, surface congruity is confirmed, and the joint is put through a ROM to ensure graft stability and lack of impingement. The knee is closed in a standard fashion over a drain after irrigation of the joint and inspection for loose bodies.

Allografting

The technique of fresh osteochondral allografting generally relies on an open arthrotomy of variable size, depending on the position and dimension of the lesion. For most femoral condyle lesions, eversion of the patella is not necessary. A standard midline incision is made from the center of the patella to the tip of the tibial tubercle and elevated subcutaneously. Depending on the location of the lesion (either medial or lateral), the joint is entered by incising the fat pad, taking care not to disrupt the anterior horn of the meniscus or to damage the articular surface. In some cases in which the lesion is posterior or very large, the ipsilateral meniscus must be detached and reflected. Generally, this can be done safely, leaving a small cuff of tissue adjacent to the anterior insertion of the meniscus for reattachment during closure. Once the joint capsule and synovium have been incised and retractors carefully placed, the knee is brought to a degree of flexion that presents the lesion into the arthrotomy site. The lesion is then inspected and palpated with a probe to determine the extent, stable margins, and maximum size.

The two commonly used techniques for the preparation and implantation of osteochondral allografts include the press-fit plug technique and the shell-graft technique. Each technique has advantages and disadvantages. The press-fit plug technique is similar in principle to the autologous osteochondral transfer systems described previously. This technique is optimal for contained condylar lesions between 15 and 35 mm in diameter (Fig. 32-3). Fixation is generally not required owing to the stability achieved with the press fit unless the lesion falls into the intercondylar notch. Disadvantages include the fact that very posterior femoral and trochlear lesions are not conducive to the use of a circular coring system and may be more amenable to shell allografts. In addition, the more ovoid shape of a lesion, the greater amount of normal cartilage that needs to be sacrificed at the recipient site to accommodate the circular donor plug. Shell grafts are technically more difficult to perform and typically require fixation. However, depending on the technique employed, less native host cartilage may need to be sacrificed.

Dowel Allograft

As with autologous dowels, several proprietary instrumentation systems are currently available (Fig. 32-4) for the preparation and implantation of press-fit dowel allografts up to 35 mm in diameter, and surgical techniques are similar.

After a size determination is made, a guidewire is driven into the center of the lesion, perpendicular to the curvature of the articular surface. The size of the graft is then determined using sizing dowels, remembering that overlapping dowels (in a "master card" or "snowman" configuration) can possibly deliver the best area fit. The remaining articular cartilage is scored to subchondral bone, and a core reamer is used to remove the articular cartilage remnants and at least 3 to 4 mm of subchondral bone (Fig. 32-5). Because it merely serves as an osteoconductive scaffold for healing to the host by creeping substitution,

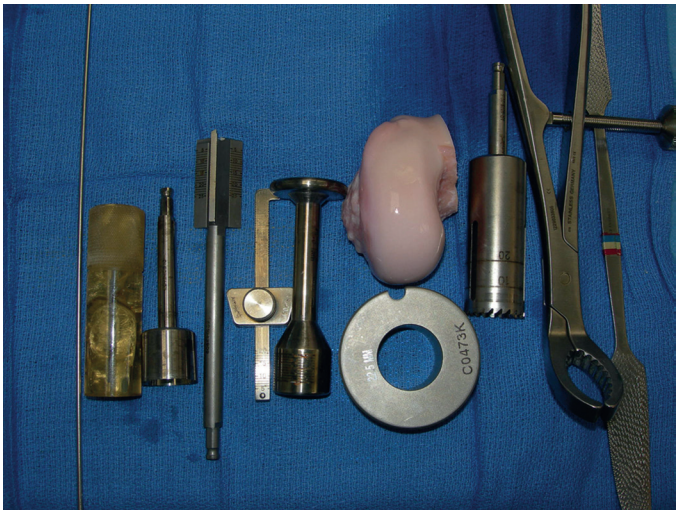

FIG 32-4 Common proprietary instrumentation used for dowel allograft preparation.

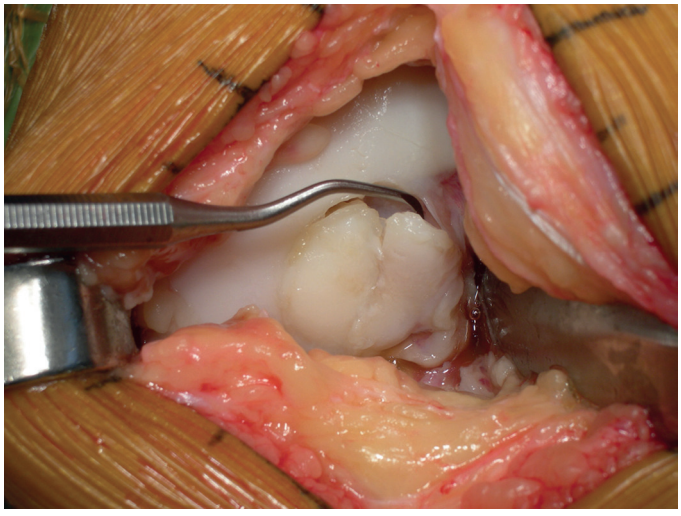

FIG 32-3 Intraoperative appearance of an osteochondritis dissecans lesion in the typical location on the left medial femoral condyle of an 18-year-old woman. (Same patient as shown in Figure 32-2.)

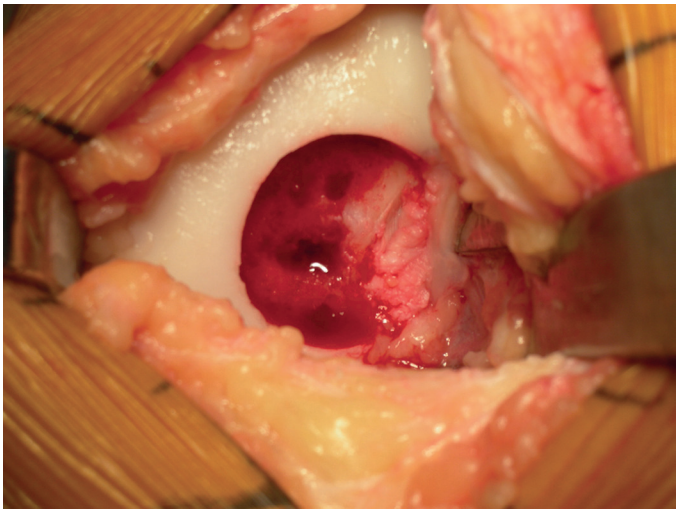

FIG 32-5 Intraoperative view after preparation of the graft bed via core reaming of the osteochondral defect and debridement down to bleeding bone.

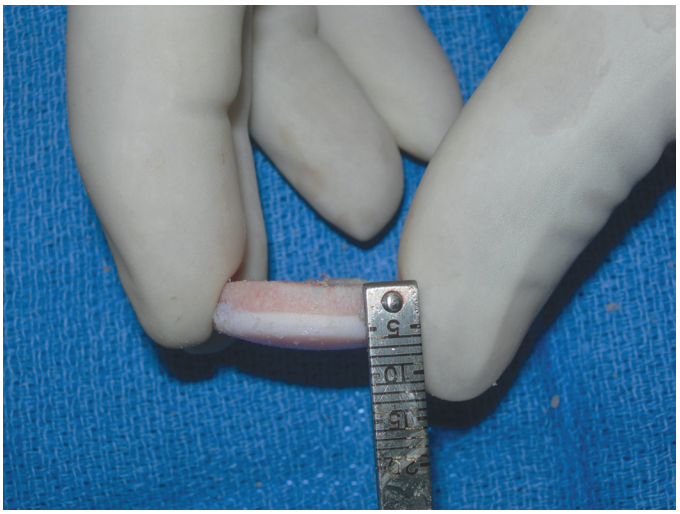

FIG 32-6 Side view of prepared dowel allograft before implantation displays the thickness of the articular cartilage in relationship to the subchondral bone portion.

FIG 32-7 Subchondral portion of the allograft dowel is being thoroughly pulse lavaged to remove potentially antigenic marrow elements and debris.

which is a rate-limited process, the portion of transplanted bone should be minimized wherever possible, without compromising the stability of the graft as warranted by the clinical situation (Fig. 32-6). This will also minimize the potential antigenic burden of marrow elements possibly remaining in the transplanted spongiosa.[18] In deeper lesions, fibrous and sclerotic bone is removed to a healthy, bleeding osseous base that does not exceed 10 mm in depth. Lesions below this depth should be curetted manually, and packed morselized autologous bone graft should be used to fill any deeper or more extensive osseous defects. Circumferential depth measurements are made of the prepared recipient site after the guide pin has been removed.

The graft is then placed into a graft holder or held manually with bone-holding forceps. The correspondent anatomic location is identified on the graft, and after a circular saw guide has been placed in the position, again perpendicular to the articular surface, an appropriate-sized tube saw is used to core out the graft. Recently, we reported an excellent OCA surface match with medial femoral condyle (MFC) donors or lateral femoral condyle (LFC) donor graft into the common MFC recipient site, suggesting that nonorthotopic LFC OCAs are also acceptable graft options for MFC defects.[53] Before removing the graft from the condyle, identifying marks are made to ensure proper orientation. Once the dowel is removed, the recipient's depth measurements are transferred to the graft. This graft is then cut with an oscillating saw and is trimmed with a rasp to the precise thickness in all four quadrants. The deep edges of the bone plug can be further chamfered with a rongeur and bone rasp to ease insertion.

The graft is then irrigated copiously with a high-pressure lavage (Fig. 32-7) to remove all marrow elements possible, and the recipient site is dilated using a slightly oversized tamp. This may ease the insertion of the graft to prevent excessive impact loading of the articular surface when the graft is inserted, while compacting the subchondral bone to prevent subsidence of the graft. At this time, any remaining osseous defects are bone grafted to a level base. The allograft is then inserted by hand in the appropriate rotation and is gently tamped into place until it is flush, again minimizing mechanical insult to the articular surface of both the graft and the surrounding native tissue. Alternatively, the graft can be seated by gently ranging the knee using the apposing joint surface as a fulcrum.

After the graft is seated, additional fixation with absorbable polydioxanone pins may be added, if necessary, particularly if the graft is large or has an exposed edge within the notch (Fig. 32-8). The knee is then brought through a complete ROM to confirm that the graft is stable and that no catching or soft tissue obstruction is noted. The wound is then copiously irrigated, and routine closure is performed.

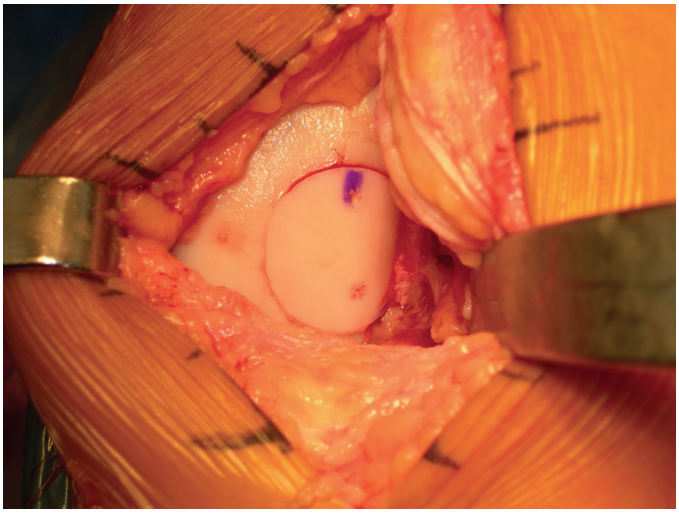

FIG 32-8 Osteochondral dowel plug in place and secured by several absorbable polydioxanone pins. Note the flush fit with the surrounding joint surface and the ink marks ensuring orthotopic orientation of the graft.

Shell Allograft

The defect is identified through the previously described arthrotomy, and the dimensions of the lesion are marked with a surgical pen. Minimizing the sacrifice of normal cartilage, a geometric shape is created that is amenable to handcrafting a shell graft (Figs. 32-9 and 32-10). A No. 15 scalpel blade is used to demarcate the lesion, and sharp ring curettes are used to remove all tissue inside this mark. Using motorized burrs and sharp curettes, the lesion is debrided down to a depth of 4 to 5 mm (Fig. 32-11). The shape is transferred to the graft, which is molded in a freehand fashion (Fig. 32-12), initially slightly oversizing the graft and carefully removing excess bone and cartilage from the template as necessary through multiple trial fittings. If there is deeper

FIG 32-12 Comparison of the removed collapsed native condyle on the right and the shell allograft on the left.

bone loss in the defect, more bone can be left on the graft, and the defect can be grafted with cancellous bone before graft insertion. The graft and host bed are then copiously irrigated and the graft placed flush with the articular surface. The need for fixation is based on the degree of inherent stability. Bioabsorbable pins, as described previously, are typically used when fixation is required (Fig. 32-13), but countersunk compression screws may be used as an alternative, optimally avoiding the weight-bearing portion. After cycling the knee through a full ROM and irrigating the joint, standard closure is performed.

Postoperative Management

The use of continuous passive motion during early postoperative management is optional. Patients are generally allowed full ROM unless the graft involves the patellofemoral joint or there are other additional reconstructive procedures, such as meniscal repair, anterior cruciate ligament (ACL) reconstruction, or osteotomy, which would alter the rehabilitation plan. Typically, braces are not used postoperatively except for patellofemoral grafts in which flexion is limited to less than 45 degrees for the first 4 to 6 weeks and in cases of bipolar tibial femoral grafts in which an unloader or ROM brace is used to prevent excessive stress on the grafted compartment.

Patients are begun on early ROM exercises and quadriceps strengthening (e.g., straight-leg raises) and are maintained in a toe touch only weight-bearing status for a period of at least 8 weeks, and often 12 weeks, depending on the size and containment of the graft, type of fixation, and ultimately, radiographic evidence of incorporation. At 4 weeks, patients are allowed closed-chain exercises such as cycling. Progressive weight bearing as tolerated is usually allowed at 3 months, and if functional rehabilitation is complete, the patient is allowed to return to recreation and sports at approximately 6 months. Patients are generally cautioned about excessive impact loading of the allograft, particularly in the first year. As with any cartilage replacement procedure, long-term outcomes in osteochondral allografting are directly and inversely related to the time to treatment and overall burden of disease in the affected joint. In a young patient with a focal lesion (traumatic or OCD), it is not unrealistic to expect him or her to go back to normal impact-loading activities after 12 months and to return to preinjury function, whereas the goals in a salvage situation are usually to delay or even eliminate the need for prosthetic replacement by reducing pain and allowing a return to functional activities of daily living as well as low-impact recreational activities.

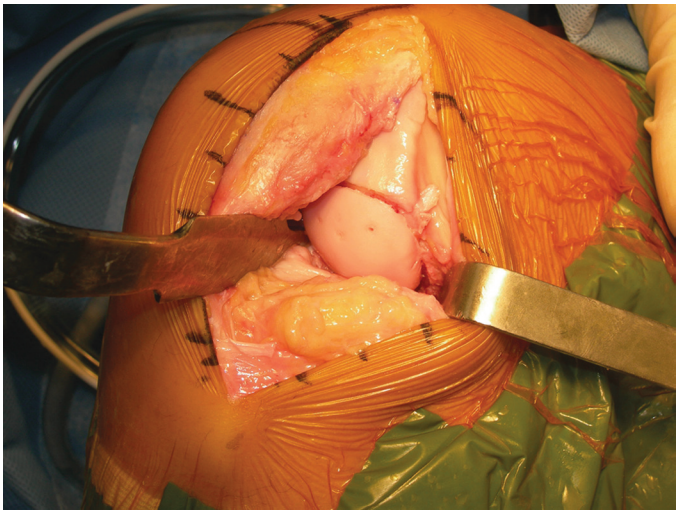

FIG 32-13 Osteochondral shell graft in place shows restoration of the condylar topography and weight-bearing portion of the articular cartilage in the lateral femoral condyle.

OUR CLINICAL OUTCOMES

We believe that osteochondral allografting is an excellent treatment option for advanced OCD lesions. We previously published the results of 66 knees in 64 patients with OCD of the femoral condyle, treated with fresh osteochondral allografts, implanted within 5 days of graft recovery.[17] Patients were evaluated preoperatively and postoperatively using an 18-point scale, which measures function, ROM, and absence of pain, allotting 1 to 6 points each, for a maximum of 18 points (Table 32-1).

There were 45 males and 19 females, with a mean age of 28.6 years (range, 15-54 years). All lesions were ICRS grade III-IV OCD; 40 involved the medial femoral condyle and 25 the lateral femoral condyle. All patients had undergone an average of 1.6 previous operations. The average allograft size was 7.5 cm^2. The mean follow-up was 7.7 years (range, 2-22 years); one patient was lost to follow-up. Overall, 47 of 65 knees (72%) were rated good or excellent, scoring 15 points or above on the 18-point scale. Seven (11%) were rated fair, and one (2%) was rated poor. The average clinical score improved from 12.9 points preoperatively to 16.1 points postoperatively ($P < .01$).

Preoperative, immediate postoperative, and most recent follow-up AP and lateral radiographs were available for 32 of 66 knees, with a mean follow-up of 3.1 years. In these, evidence of graft union, collapse, resorption, and the presence of degenerative changes were recorded by a musculoskeletal radiologist. Twenty-four of the grafts (75%) demonstrated healing; 26 (81%) were intact. Subchondral cysts were present in five (16%) knees. Sclerosis was found in six (19%) cases. Ten patients had reoperations on the allograft, with a mean time to reoperation of 56 months, including three patients who went on to arthroplasty. Subjective knee function improved from a mean of 3.4 to 8.4 points ($P < .01$) on a 10-point scale for the 59 patients who completed questionnaires. With greater than 70% good or excellent results, fresh osteochondral allograft transplantation has proved to be a successful surgical treatment for OCD of the femoral condyle in multiple-operated knees. In our experience, results are even more favorable for osteochondral allografts as a primary treatment measure in native OCD lesions.

Although OCD remains a perfect indication for osteochondral allografting, focal lesions of diverse etiologies are amenable to this application; the results were presented of 43 knees with isolated chondral lesions of the femoral condyle.[54] A total of 39 patients (43 knees) underwent fresh osteochondral allograft transplantation for treatment of chondral and osteochondral lesions. Twenty-six male and 17 female knees with a mean age of 16.4 years (range, 11-17.9 years) at index surgery were followed-up at a mean of 8.4 years (range, 1.7-27.1 years). Thirty-four knees (79%) had at least one previous surgery. The most common underlying causes of the lesions were osteochondritis dissecans (61%), avascular necrosis (16%), and traumatic chondral injury (14%). Mean allograft size was 8.4 cm^2. The most common allograft location was the medial femoral condyle (41.9%) followed by the lateral femoral condyle (35%). Each patient was evaluated with the International Knee Documentation Committee (IKDC) pain, function, and total scores; a modified Merle d'Aubigné-Postel (18-point) scale; and Knee Society function score. Failure was defined as revision osteochondral allograft or conversion to arthroplasty. Five knees experienced clinical failure at a median of 2.7 years (range, 1.0-14.7 years). Four failures were salvaged successfully with another osteochondral allograft transplant. One patient underwent prosthetic arthroplasty 8.6 years after revision allograft. Graft survivorship was 90% at 10 years. Of the knees whose grafts were in situ at latest follow-up, 88% were rated good or excellent (18-point scale). The mean IKDC scores improved from 42 preoperatively to 75 postoperatively, and the Knee Society function (KS-F) score improved from 69 to 89 (both $P < .05$). Eighty-nine percent of patients reported "extremely satisfied" or "satisfied." With 88% good or excellent results and 80% salvage rate of clinical failures with an additional allograft, osteochondral allograft transplantation is a useful treatment option in pediatric and adolescent patients.

We studied osteochondral allografts transplantation to treat isolated femoral condyle lesions.[43] There were 122 patients (129 knees) who underwent osteochondral allograft transplantation of the femoral condyle. The mean age was 33 years, and 53% were male. Clinical evaluation included the 18-point scale, IKDC, and KS-F scores. Graft

TABLE 32-1 18-Point Scale

Points	Pain	Criteria
1	Severe	Not relieved by rest and analgesics
2	Severe	Relieved by rest and analgesics
3	Moderate	Regular analgesics needed
4	Mild	Occasional analgesics needed
5	Minimum	Occasional ache
6	None	

Points	Function
1	Bedridden or household walker with two canes or crutches
2	Time and distance outside limited; walks with external aids
3	Walks <0.8 km with external aids; stair climbing limited
4	Walks >0.8 km with external aids; stair climbing not limited
5	No external aids; limps
6	Unlimited walking without a limp

Points	Range of Motion
1	<60 degrees of flexion
2	15-90 degrees of flexion
3	0-90 degrees of flexion
4	>90 degrees of flexion; ≤15 degrees contracture
5	>90 degrees of flexion without contracture
6	≥130 degrees of flexion without contracture

failure was defined as revision osteochondral allografting or conversion to arthroplasty. A determination was made of whether or not patients' characteristics or attributes of the graft influenced failure. Minimum follow-up was 2.4 years (median, 13.5 years); 91% had more than 10 years of follow-up. The 18-point scale improved from a mean of 12.1 to 16, the IKDC pain score improved from a mean of 7.0 to 3.8, the IKDC function score improved from a mean of 3.4 to 7.2; the KS-F score from a mean of 65.6 to 82.5. Sixty-one knees (47%) underwent reoperations. Thirty-one knees (24%) failed at a mean of 7.2 years. Survivorship was 82% at 10 years, 74% at 15 years, and 66% at 20 years. Age older than 30 years at time of surgery and having two or more previous surgeries for the operated knee were associated with allograft failure. Follow-up of femoral condyle osteochondral allografting demonstrated durable improvement in pain and function, with graft survivorship of 82% at 10 years.

Osteonecrosis of the knee is a serious potential complication of corticosteroid therapy with limited treatment options. Osteochondral allografting is a salvage alternative in patients who are of an age and activity level not ideally suited for arthroplasty. We reported the clinical outcomes of fresh osteochondral allografting in individuals with steroid-induced modified Association Research Circulation Osseous (ARCO) stage 3 to 4 osteonecrosis of the femoral condyles.[27] Clinical evaluation was performed using the modified D'Aubigné and Postel (18-point) scale. Subjective outcome measures included a patient questionnaire evaluating pain, function, and satisfaction. Of 24 patients who underwent osteochondral allografting for osteonecrosis between 1984 and 2005, 17 (12 females and 5 males) fulfilled inclusion criteria with minimum 2-year follow-up (mean follow-up, 65 months; range, 24-236 months). The 17 patients had a mean age of 28.8 years (range, 16-68 years). Five had bilateral surgery, for a total of 22 knees. Of these knees, 16 had unicondylar lesions (12 lateral, 4 medial) and six had bicompartmental involvement. Fifty-six percent of knees had previous surgery (average, 1.5; range, 1-5 surgeries). The mean graft surface area was 11.0 cm^2 (range, 5.3-19.0 cm^2). Twelve of 22 (54.5%) required additional bone grafting. Seventeen of 22 (77%) were considered successful (score, ≥15 points). The mean score improved from 11.1 to 15.9 points ($P < .0001$). Two patients had further surgery: one underwent arthroscopic debridement, and another underwent total knee arthroplasty 76 months after the index surgery. Fourteen patients completed questionnaires; all reported statistically significant higher ($P < .0001$) pain relief, improved function, and overall satisfaction with their outcome. Fresh osteochondral allografting was successful in 77% of these relatively young patients and resulted in significant improvement in function and pain with high patient satisfaction, leading us to consider osteochondral allografting as a reasonable salvage option for patients with avascular necrosis of the knee joint.

Recently, we reported the outcomes of osteochondral allografting in 28 knees with patellar cartilage injuries.[29] All patients had minimum 2 years of follow-up. The mean age of the patients was 33.6 years (range, 14-64 years); 54% were female. Twenty-six (92.9%) knees had previous surgery (mean, 3.2 procedures; range 1-10). The mean allograft area was 10.1 cm^2 (range, 4.0-18.0 cm^2). Any reoperation resulting in removal of the allograft was considered a failure of the OCA transplantation. Patients were evaluated preoperatively and postoperatively using the 18-point scale, the IKDC pain and function scores, and the KS-F score. Seventeen of the 28 knees (60.7%) had further surgery following the OCA transplantation. Eight of the 28 knees (28.6%) were considered OCA failures (four conversions to total knee arthroplasty, two conversions to patellofemoral knee arthroplasty, one revision OCA, 1 patellectomy). Patellar allografting survivorship was 78.1% at 5 and 10 years; 55.8% at 15 years. Among the 20 knees (71%) with grafts in situ, the mean follow-up duration was 9.7 years (range, 1.8-30.1 years). Pain and function improved from the preoperative visit to latest follow-up. Eighty-nine percent of patients were extremely satisfied or satisfied with the results of the OCA transplantation. We concluded that the treatment of patellar cartilage injuries remains a difficult clinical challenge regardless of the surgical intervention chosen, with relatively high reoperation and revision rates; however, patellar allografting is a useful salvage treatment option for patellar cartilage injuries.

Lately, a major concern has been raised because of the conflicting results of autologous chondrocyte implantation (ACI) after a failed previous cartilage repair. ACI after previous treatment with subchondral marrow stimulation interventions were proven to fail at a rate of three to five times higher than primary ACI.[51,56] We postulated that OCA transplantation is fundamentally different than ACI. In a recent study, we identified 46 knees that had OCA transplantation performed as a primary treatment (group 1) and 46 knees that underwent OCA transplantation after failure of previous cartilage repair (group 2).[28] All patients had a minimum of 2 years of follow-up. Patients in each group were matched for age (±5 years), diagnosis (osteochondral lesion, degenerative chondral lesion, traumatic chondral injury), and graft size (small <5 cm^2; medium, 5-10 cm^2, large >10 cm^2). The groups had similar body mass indexes, gender distributions, and graft locations (femoral condyle, patella and trochlea); failure was defined as any reoperation resulting in removal of the graft. On review, 91.3% of knees in group 1 and 95.7% in group 2 were located in femoral condyle. Functional outcomes were evaluated using the 18-point scale, IKDC subjective knee evaluation form, Knee Osteoarthritis and Injury Outcomes Scores (KOOS) scale, and KS-F scale. Patient satisfaction using a 5-point scale from "extremely satisfied" to "dissatisfied" was recorded at latest follow-up. Eleven of 46 knees (24%) in group 1 had reoperations compared with 20 of 46 knees (44%) in group 2 ($P = .04$). The OCA was classified as a failure in five knees (11%) in group 1 and seven knees (15%) in group 2 ($P = .53$). At 10 years of follow-up, survivorship of the graft were 87.4% and 86% in groups 1 and group 2, respectively. Both groups showed improvement in pain and function on all subjective scores from preoperatively to latest follow-up (all $P < .001$). Eighty-seven percent of patients in group 1 and 97% in group 2 were "satisfied" or "extremely satisfied" with the OCA transplantation. Favorable results were shown in both groups with significant improvement of functional scores and excellent survivorship. Despite the higher reoperation rate in the previously treated group, previous cartilage surgery did not adversely affect the survivorship and functional outcome of OCA transplantation.

Recently, we reported that revision osteochondral allograft transplantation of the knee demonstrated acceptable clinical outcomes, although they were inferior to primary allograft transplantation procedures.[32] Thirty three patients (33 knees) who underwent revision osteochondral allograft transplantation between 1983 and 2012 were at least 2 years out from surgery and had a minimum 2-year follow-up. Failure of the revision allograft was defined as conversion to partial or total knee arthroplasty. The mean follow-up after revision osteochondral allograft transplantation was 10 years, with 75% of patients having more than 5 years of follow-up. Thirteen patients (39%) had failed results after revision osteochondral allograft transplantation, with a mean time to failure of 5.5 years. The remaining 20 patients (61%) had surviving revision allografts, with a mean graft survival of 10 years. Mean pain and function scores at the last follow-up were improved. Survivorship of the revision allograft was 61% at 10 years.

Treatment options also remain limited in younger, active individuals with impeding knee arthrosis. We reported the results of osteochondral allografting in 37 knees with multifocal chondral lesions and arthritic changes.[58] All patients demonstrated radiographic evidence of

arthrosis. Assessment was performed with the modified D'Aubigné and Postel (18-point) scale and IKDC score. Radiographs were evaluated by modified Fairbanks/Ahlbäck criteria. Again, subjective outcome measures included a patient questionnaire evaluating pain, function, and satisfaction. The 37 patients (25 males, 12 females) had a mean age of 42 years (range, 15-67 years) and an activity level not ideally suited for arthroplasty. The mean follow-up was 36 months (range, 24-84 months). Three patients were lost to follow-up. Nineteen of the allografts were unipolar, 10 involved bipolar/kissing lesions, and 5 multiple surfaces. The mean allograft area was 10.5 cm^2. Twenty-six of 34 (76%) were considered successful (score, ≥15 points), and eight (24%) were unsuccessful (3 converted to total knee arthroplasty, 2 underwent repeat allografting declined further surgery but were considered failures owing to fair or poor postoperative scores). The average 18-point scores improved from 11.5 to 16.2 points, whereas IKDC scores improved from 33.0 to 64.7 points ($P < .01$).

Nineteen of 31 preoperative radiographs (61%) were grade 3 (>50% joint space narrowing), and 12 of 31 (39%) were grade 1 to 2 (<50% narrowing). Postoperatively, 13 of 31 radiographs (42%) were grade 3, and 18 of 31 (58%) were grade 1 to 2. Eighteen of 34 patients (53%) were extremely satisfied, 15 (44%) were satisfied, 1 (3%) was somewhat satisfied, and none were dissatisfied. Overall, clinical success of fresh allografting for knee arthrosis was 76%. Objective and subjective improvements were statistically significant. Success may be challenged with longer follow-up. Treatment options for knee arthritis in the young, active patient are currently extremely limited, and fresh osteochondral allografting is an emergent bioorthologic alternative in this growing and challenging segment of the population.

We recently reported outcomes of 48 knees with reciprocal bipolar cartilage lesions.[50] Twenty-one males and 25 females averaged 40 years of age (range, 15-66 years). Thirty-four lesions were tibiofemoral and 14 patellofemoral. Forty-two patients (88%) had an average of 3.4 previous surgeries (range, 1-8). Mean allograft area was 19.2 cm^2. Clinical evaluation included the 18-point scale, IKDC pain and function, and KS-F scores. Further surgeries on the operative joint were documented. Survivorship of the bipolar OCA was 64.1% at 5 years. Thirty knees had further surgery; 22 knees (46%) were considered failures (3 OCA revisions, 14 total knee arthroplasties, 2 unicondylar arthroplasties, 2 arthrodesis, and 1 patellectomy). Among patients whose OCA was still in situ at follow-up, the mean follow-up was 7 years (range, 2-19.7 years). The mean 18-point score improved from 12.1 to 16.1; 88% (23 of 26 knees) of surviving allografts scored higher or greater than 15. The mean IKDC pain score improved from 7.5 to 4.7, and the mean IKDC function score improved from 3.4 to 7.0. The mean KS-F score improved from 70.5 to 84.1. We conclude that OCA transplantation is a useful salvage treatment option for reciprocal bipolar cartilage lesions of the knee. High reoperation and failure rates were observed, but patients with surviving allografts had significant clinical improvement.

CLINICAL OUTCOMES FROM OTHER AUTHORS

Autografts

Hangody and Fules[31] reported their 10-year clinical experience with autologous osteochondral mosaicplasty (Table 32-2). These investigators performed 831 mosaicplasties involving 597 femoral condyles, 118 patellofemoral (patella and/or trochlea) joints, 76 talar domes, 25 tibial condyles, 6 capitulum humeri, 6 femoral heads, and 3 humeral heads. Concomitant surgery (ACL reconstruction, realignment procedures, and meniscal surgeries) was performed in 85% of the patients. Good to excellent results were reported in 92% of the patients who had femoral condyle grafts, 87% of those who had tibial grafts, and 79% of those who had patellar grafts. Long-term donor site morbidity was found in 3% of the patients.

Marcacci and coworkers[46] reported on 37 athletes younger than 50 years of age with at least a 2-year follow-up. In this study, 23 of 37 patients (62%) underwent an associated procedure with arthroscopic mosaicplasty of the femoral condyle. The data revealed that 78% of the patients had good to excellent results. Twenty-seven patients returned to sports at the same level, five patients returned at a lower level, and five were unable to return to sports. Medial femoral condyle lesions statistically did not fare as well as lateral condyle lesions. Donor site morbidity was not an identifiable problem in this case series.

The same group prospectively evaluated 30 patients with full-thickness chondral lesions (<2.5 cm^2) of the knee treated with arthroscopic autologous osteochondral transplantation.[45] The ICRS objective evaluation showed 76.7% of patients had good or excellent results at 7-year follow-up, and IKDC subjective score significantly improved from preoperative (34.8 points) to 7-year follow-up (71.8 points). The Tegner score showed a significant improvement after the surgery at 2- and 7-year follow-up (from 2.9 to 6.2 and 5.6 points, respectively); however, sports participation declined from 2- to 7-year follow-up. MRI evaluation showed good integration of the graft in the host bone and complete maintenance of the grafted cartilage in more than 60% of cases.

In a study by Jakob and associates,[34] 92% of patients (48 of 52) demonstrated improved knee function at the latest follow-up (average, 37 months) from open knee mosaicplasty. In 30 of 52 patients (58%), a concomitant procedure was performed. Four patients required reoperation because of graft failure.

With a mean follow-up of 45.1 months, Chow and colleagues[11] reported on 30 patients who had undergone arthroscopic autologous

TABLE 32-2 Selected Outcomes of Osteochondral Autografting in the Knee

Study	Site of Lesion	Knees (*n*)	Follow-up (yr)	Outcome (%)
Hangody & Fules[31] (2003)	Femur	597	1-10	92 Good/excellent
	Patellofemoral	118		87 Good/excellent
	Tibia	25		79 Good/excellent
Marcacci et al[46] (2005)	Femur	37	2.0	78 Good/excellent
Marcacci et al[45] (2007)	Femur	30	7.0	77 Good/excellent
Jakob et al[34] (2002)	Femur	52	3.1	92 Improved
Chow et al[11] (2004)	Femur	30	3.8	83 Good/excellent
Outerbridge et al[57] (2000)	Femur	18	7.6	81 High functional level
Karataglis et al[38] (2006)	Femur and patellofemoral	37	3.1	87 High functional level

osteochondral transplantation to the femoral condyle. Good to excellent results were reported in 83% (25 of 30) of patients. Lysholm scores increased from an average of 43.6 points preoperatively to a mean of 87.5 points postoperatively. Two patients (7%) had poor results and later underwent total knee arthroplasty.

Outerbridge and coworkers[57] followed 18 knees for an average of 7.6 years after osteochondral autografting of the femoral condyle using the ipsilateral lateral patellar facet as the donor graft. These investigators reported an increase in Cincinnati knee scores from an average preoperative score of 37 points to an average final follow-up score of 85 points. Eighty-one percent (13 of 16) of the patients returned to a high functional level. Twelve percent (2 of 16) experienced moderate patellofemoral joint symptoms. Nevertheless, all patients were satisfied with the procedural results and, given the choice, would have the same surgery done again for an identical lesion on the contralateral knee.

Karataglis and associates[38] reported on their mid- and long-term functional outcomes of 36 patients (37 knees) who underwent the osteochondral autograft transplantation technique with an average follow-up of 36.9 months. The lesions were located on the femoral condyle in 26 cases, on the trochlea in seven cases, and on the patella in four cases. Thirty-two of 37 patients (86.5%) reported significant improvement of their preoperative symptoms. All but five patients returned to previous daily and work activities. Eighteen patients returned to sports. Nine patients required second-look arthroscopies because of swelling, pain, or clicking. In two of those cases, the grafts were found to be loose and required revision. Symptoms improved significantly in four of those nine patients after repeat arthroscopy. Donor site morbidity was not seen in this series.

Allografts

Garrett[21] reported on the experience with fresh osteochondral allografts used as both a press-fit plug and a large shell graft in the treatment of 17 patients with OCD, all of whom had undergone previous surgery. Sixteen patients (94%) reported relief of symptoms at 2- to 9-year follow-up. This work is remarkable for the first reported use of dowel grafts in the literature.

Chu and colleagues[12] reported on 55 consecutive knees undergoing osteochondral allografting for diagnosis such as traumatic chondral injury, avascular necrosis, OCD, and patellofemoral disease. The mean age was 35.6 years, with follow-up averaging 75 months (range, 11-147 months). Of the 55 knees, 43 were unipolar replacements, and 12 were bipolar resurfacing replacements. On the 18-point scale, 45 of 55 of these knees (76%) were rated good to excellent and three as fair. Of note, 36 of the 43 knees (84%) that underwent unipolar femoral grafts were rated good to excellent compared with only six of the 12 knees (50%) with bipolar grafts.

McDermott and coworkers[49] reported on 100 patients treated with fresh osteochondral grafts implanted within 24 hours of recovery. Fifty patients had a unifocal traumatic defect of the tibial plateau or femoral condyle, 38 of which (76%) were considered successful at an average follow-up of 3.8 years. Patients with osteoarthritis and osteonecrosis had poorer results.

Ghazavi and associates[22] reported on 126 knees in 123 patients with an average follow-up of 7.5 years. One hundred and five of 123 patients (85%) were rated as successful; the remaining 18 failed. Advanced age (>50 years), bipolar defects, malalignment, and Workers' Compensation cases were considered main factors related to failure.

Beaver and colleagues[6] performed a survivorship study on 92 knees allografted for posttraumatic cartilage lesions with failure defined as the need for a revision operation or the persistence of symptoms. There was a 75% success rate at 5 years, 64% at 10 years, and 63% at 14 years. Advanced age (>60 years) and bipolar defects were again identified as factors for failure.

Aubin and coworkers[3] later followed 60 patients, 41 of whom (68%) had undergone simultaneous realignment osteotomy and 10 (15%) concomitant meniscal transplantation. Kaplan-Meier survivorship analysis that showed 51 grafts (85%) survived at 10 years and 44 (74%) at 15 years.

McCulloch and associates[48] presented the results of 25 consecutive patients who underwent prolonged fresh osteochondral allograft transplantation for defects in the femoral condyle. The average patient age was 35 years (range, 17-49 years). The average length of follow-up was 35 months (range, 24-67 months). Statistically significant improvements ($P < .05$) were reported for the Lysholm (39-67 points), IKDC scores (29-58 points), all five components of the KOOS, and the Short Form-12 physical component score (36 to 40 points). Overall, patients reported 84% satisfaction (range, 25%-100%) with their results and believed that the knee functioned at 79% of their unaffected knee (range, 35%-100%). Radiographically, 22 of the grafts (88%) were incorporated into host bone.

Williams and colleagues[71] prospectively followed 19 patients with symptomatic chondral and osteochondral lesions of the knee who were treated with fresh osteochondral allografts, with a mean preimplantation storage time of 30 days (range, 17-42 days). The mean age at the time of surgery was 34 years. The mean lesion size was 602 mm^2. MRI was used to evaluate the morphologic characteristics of the implanted grafts. The mean duration of clinical follow-up was 48 months (range, 21-68 months). The mean score (and standard deviation) on the Activities of Daily Living Scale increased from a baseline of 56 ± 24 to 70 ± 22 points at the time of the final follow-up ($P < .05$). The mean Short Form-36 (SF-36) score increased from a baseline of 51 ± 23 to 66 ± 24 points at the time of final follow-up ($P < .005$). At a mean follow-up interval of 25 months, cartilage-sensitive MRI demonstrated that the normal articular cartilage thickness was preserved in 18 implanted grafts, and allograft cartilage signal properties were isointense relative to normal articular cartilage in 8 of the 18 grafts. Osseous trabecular incorporation of the allograft was complete or partial in 14 patients and poor in 4 patients. Complete or partial trabecular incorporation positively correlated with SF-36 scores at the time of follow-up ($R = .487$; $P < .05$).

Recently, Raz and associates[62] reported outcomes of osteochondral allograft transplantation for posttraumatic osteochondral and osteochondritis dissecans defects in the distal aspect of the femur. Sixty-three patients underwent osteochondral allograft transplantation to the distal aspect of the femur. Fifty-eight patients aged 11 to 48 years at the time of surgery (mean age, 28 years) were followed for a mean of 21.8 years (range, 15-32 years). Thirteen of the 58 patients required further surgery; three underwent graft removal, nine were converted to total knee arthroplasty, and one underwent multiple debridements followed by above-the-knee amputation. A Kaplan-Meier analysis of graft survival showed rates of 91%, 84%, 69%, and 59% at 10, 15, 20, and 25 years, respectively. Patients with surviving grafts had good function, with a mean modified Hospital for Special Surgery (HSS) score of 86 at 15 years or more following the allograft transplant surgery. Late osteoarthritic degeneration on radiographs was associated with lower HSS scores and poorer clinical outcomes. Fresh osteochondral allograft was found to provide a long-term solution for large articular cartilage defects in the distal aspect of the femur in young, active patients.

Several therapeutic case series studies reported the functional outcome of osteochondral allograft transplantation in the knee. Besides the high heterogeneity of the studies reported, they are summarized in the Table 32-3.

TABLE 32-3 Functional Outcomes of Osteochondral Allografting in the Knee

COMPLICATIONS

The unique issue regarding possible postoperative complications with fresh allografts relates to transmission of disease from the graft. Infection after the implantation of a fresh osteochondral allograft is rare, but its consequences can be devastating. Generally, all grafts are currently harvested and tested in accordance with American Association of Tissue Banks standards. However, allograft-associated bacterial infections have been reported. Death in the immediate postoperative period has even occurred as a result of implantation of a contaminated fresh osteochondral graft. As with most procedures, infection may become apparent any time from days to weeks after surgery. Deep infection needs to be distinguished from a superficial infection with the use of physical examination findings and joint aspiration. Deep infection involving the allograft should be addressed immediately with removal of the allograft because of the risk that the fresh tissue is the source of the infection or a nidus for a recurrence. Patients need to be informed of this risk preoperatively and again counseled to look for signs of infection before and after discharge from the hospital.

Failure of the allograft procedure can occur owing to nonunion or late fragmentation and graft collapse. Disease progression (arthritis) may also lead to inferior clinical outcome. Although healing of the graft-host interface reliably occurs, particularly with smaller grafts, the degree of revascularization appears to be variable. Fragmentation and collapse typically occur in areas of unvascularized allograft bone. Patients typically present with new-onset pain or mechanical symptoms. Radiographs may show joint space narrowing, cysts, or sclerotic regions. MRI can help rule out contributory concomitant joint pathology in the differential diagnosis of postoperative symptoms. In the event of mechanical allograft failure, MRI will often show areas of graft collapse. However, care must be taken in the interpretation of MRI because even normal, well-functioning grafts demonstrate signal abnormalities. Depending on the status of the knee joint, the treatment options include observation, removal of the fragmented portion of the graft, repeat allografting, or conversion to arthroplasty.

INTRODUCTION

Articular cartilage defects of the knee appear to be an increasing cause of pain and functional disability in orthopedics and sports medicine. This pathology creates a significant challenge to the health care team, especially the physician who must decide on the appropriate treatment plan (see Chapter 31).[23,24,70,72] The avascular nature of articular cartilage predisposes the individual to progressive symptoms and degeneration owing to the extremely slow and frequent inability to heal. Nonoperative rehabilitation and palliative care are frequently unsuccessful, especially as the size of the lesion increases, and further treatment is required to alleviate symptoms. This presents a significant challenge for patients, particularly young and more active individuals.

Traditional methods of treating these lesions have led to unfavorable results, stimulating the need for newer surgical procedures designed to facilitate the repair or transplantation of autogenous cartilage tissue. Postoperative rehabilitation programs vary greatly among physicians and should be individualized based on specifics of the lesion (size, depth, location, containment, quality of tissue), patient (age, activities, goals, quality of tissue, lower extremity alignment, body mass index [BMI], general health, and nutrition), and surgery (exact procedure, tissue involvement, and concomitant surgeries). Thus the development of an appropriate rehabilitation program is challenging and must be highly individualized to ensure successful outcomes.

The programs described in this chapter are designed according to the knowledge of basic science, anatomy, and biomechanics of articular cartilage as well as the biologic course of healing after surgery. The goal is to restore full function in each patient as quickly as possible without overloading the healing articular cartilage. In this chapter, the essential principles of rehabilitation after articular cartilage repair procedures are discussed as well as specific rehabilitation guidelines for debridement, abrasion chondroplasty, microfracture, osteochondral autograft transplantation (OAT), and autologous chondrocyte implantation (ACI).

PRINCIPLES OF ARTICULAR CARTILAGE REHABILITATION

Several principles exist that must be considered when designing a rehabilitation program after articular cartilage repair procedures (Table 33-1). These key principles have been designed based on our understanding of the basic science and mechanics of articular cartilage. These principles include individualization, creating a healing environment, understanding the biomechanics of the knee, reducing pain and effusion, restoring soft tissue balance, restoring muscle function, restoring proprioception and neuromuscular control, controlling the application of loads, and team communication. These principles

CRITICAL POINTS Principles of Articular Cartilage Rehabilitation

Individualization

- Develop the program based on specifics regarding the patient (demands of activities of daily living, work, and sport activities, body mass index), lesion (location, size), and operative procedure.
- Age, obesity, poor nutrition, history of repetitive impact loading may slow down the rehabilitation process.
- Younger patients with isolated defects and relatively healthy surrounding articular cartilage will progress more rapidly than older individuals with degenerative changes.

Create a Healing Environment

- Biologic phases of maturation have been identified.
- Controlled weight bearing and range of motion are essential to facilitate healing and prevent degeneration: stimulate matrix production, improve the tissue's mechanical properties, and nourish the articular cartilage.
- Reduce weight bearing with the use of a pool and force platforms in early phases.

Biomechanics of the Knee

- Articulation between the femoral condyle and the tibial plateau is constant throughout knee range of motion.
- Area of contact between the patella and the trochlea gradually increases as the knee is flexed.
- Rate of weight bearing, passive range of motion, and exercise progression is based on the exact location of the lesion.
- Exercises are altered based on the biomechanics of the knee to avoid excessive compressive or shearing forces.
- Open kinetic chain exercises are typically performed from 90 to 40 degrees of flexion.
- Closed kinetic chain exercises are performed initially from 0 to 30 degrees and then progressed to 0 to 60 degrees.

Reduce Pain and Effusion

- Look for a progressive decrease in volitional quadriceps activity with knee pain, distention.
- Any increase in intraarticular joint temperature stimulates proteolytic enzyme activity, detrimental to articular cartilage.
- Reduction in knee pain and swelling is crucial to minimize reflexive inhibition and restore normal quadriceps activity.

Restore Soft Tissue Balance

- Avoid arthrofibrosis by restoring full passive knee extension, patellar mobility, and soft tissue flexibility of the knee and entire lower extremity.
- Achieve at least 0 degree of extension within the first few days after surgery.

Restore Muscle Function

- Use electrical muscle stimulation and biofeedback with exercises to facilitate active contraction and volitional control of the quadriceps musculature.
- Machine weights and closed kinetic chain exercises are included as the patient progresses. Emphasize total leg strength rather than concentrating solely on the quadriceps.
- Train core, hip, and ankle.

Enhance Proprioception and Neuromuscular Control

- Proprioceptive and neuromuscular control drills of both lower extremities are included to restore dynamic stabilization of the knee.

Control the Application of Loads

- Gradually increase the amount of stress applied to the injured knee as the patient returns to functional activities.
- Monitor pain and effusion as signs of overloading.
- Consider orthotics, insoles, and bracing to alter the applied loads on the articular cartilage during functional activities.

Team Communication

- Communication among surgeon, physical therapist, and patient before and after surgery is essential.

Rehabilitation Philosophy

- All members of the health care team should convey the same rehabilitation message.
- Slower is better for healing and maturation of articular cartilage.
- Medical team is more interested in long-term results rather than outcome 6 months after surgery.

TABLE 33-1 Key Principles to Consider When Designing Rehabilitation Programs after Articular Cartilage Repair Procedures

1. Individualize the program.
2. Create a healing environment.
3. Avoid overloading healing tissue.
4. Understand the arthrokinematics of the knee.
5. Understand the biomechanics of exercises.
6. Reduce pain and effusion.
7. Restore soft tissue balance.
8. Restore muscle function.
9. Enhance proprioception and neuromuscular control.
10. Control the application of loads.
11. Promote team communication.
12. Rehabilitation philosophical approach:
    Gradual progressive loading.
    "Slower functional progression is better."
    Think long-term functional results.

are briefly described as they relate to the rehabilitation program after articular cartilage repair procedures.

Individualization

One of the most important principles involving rehabilitation after articular cartilage repair procedures is the need for an individualized approach for each patient. Several variables must be considered when developing a unique rehabilitation progression for each patient. These include specifics regarding the patient, lesion, and surgery (Table 33-2).

The quality of each individual's articular cartilage is the result of several factors including age, BMI, general health, nutrition, history of previous injuries, and genetics. The composition of articular cartilage undergoes a gradual degeneration over time that results in a breakdown of tissue matrix and a reduction in the load-bearing capacity of the cartilage.[14] The specific factors that contribute to this deterioration remain controversial, but it appears that age, obesity, BMI, poor nutrition, and a history of repetitive impact loading (through work or sport activities) may result in osteoarthritic changes.[14] Thus younger patients with isolated defects and relatively healthy surrounding articular cartilage will progress more rapidly than older individuals with more

TABLE 33-2 Specific Variables That Must be Considered When Designing Postoperative Rehabilitation Protocols After Articular Cartilage Procedures

degenerative changes and less dense cartilage structure. Furthermore, the patient's motivation and previous activity levels must be considered when determining the rehabilitation approach to ensure that the goals of each patient are addressed. However, the nature of articular cartilage lesions will limit the rate of progression for even highly motivated and elite-level athletes. The rehabilitation program should be individualized to the specific demands of each patient's activities of daily living, work, and sport activities.

Several variables must be considered in regard to the lesion that may have a dramatic effect on the rehabilitation process. Most important are the exact location and size of the lesion. Lesions on a weight-bearing surface of a femoral condyle must avoid deleterious compressive forces and will require a different rehabilitation approach than those located within the trochlea or undersurface of the patella, where shear forces should be avoided. Furthermore, the size, depth, and containment of each lesion must be considered. Lesions that are large or deep or that have poor containment with healthy surrounding articular cartilage may require a slightly slower rehabilitation progression to ensure that the repair tissue or graft has an adequate amount of time to heal. In addition, the patient's lower extremity alignment must be carefully considered and often treated. For example, a patient's knee in a genu varum alignment with a medial compartment lesion may also require a high tibial osteotomy[3,7,17] or an osteoarthritis unloader brace.

BMI is another factor to consider. Mithoefer and coworkers[48] reported a correlation between BMI and outcomes after microfracture because the greater the BMI, the more likely the clinical outcome would be less favorable.

Lastly, the specifics of each surgical procedure will vary the rehabilitation process. Arthroscopic procedures such as chondroplasty or microfracture may progress at a different pace than those with larger incisions and greater tissue involvement, such as OAT or ACI, which require a slower rehabilitation process to protect the healing structures. Each specific surgical procedure has different biologic healing responses postoperatively, which are discussed in detail later in this chapter. Furthermore, any concomitant procedures to address alignment, stability, or meniscal function may also alter the rehabilitation program because of the need to protect other healing tissues. The importance of communication between the surgical team and the rehabilitation team cannot be overemphasized. Appropriate information regarding the specifics of each surgical procedure must be shared to ensure the highest quality of care for each individual.

Create a Healing Environment

The next principle of articular cartilage rehabilitation involves creating an environment that facilitates the healing process while avoiding potentially deleterious forces to the repair site. This involves a thorough knowledge of the physiologic repair process after surgery. Through animal studies, as well as closely monitoring the maturation of repair tissue in human patients via arthroscopic examination, the biologic phases of maturation have been identified after several articular cartilage repair procedures.[10,11,28,55,57] Knowledge of the healing and maturation process after these procedures will ensure that the repair tissue is gradually loaded and that excessive forces are not introduced too early in the healing process. These are discussed in detail in regard to each specific surgical procedure.

Two of the most important modes of rehabilitation of articular cartilage procedures are weight-bearing restrictions and range of motion (ROM) limitations. Unloading and immobilization have been shown to be deleterious to healing articular cartilage, resulting in proteoglycan loss and gradual weakening.[4,29,71] Therefore controlled weight bearing and ROM are essential to facilitate healing and prevent degeneration. This gradual progression has been shown to stimulate matrix production and improve the tissue's mechanical properties.[12,13,73]

Controlled compression and decompression forces observed during weight bearing may nourish the articular cartilage and provide the necessary signals to the repair tissue to produce a matrix that will match the environmental forces.[4,29,71] A progression of partial weight bearing with crutches is used to gradually increase the amount of load applied to the weight-bearing surfaces of the joint. The use of a pool or aquatic therapy may also be beneficial to initiate gait training and lower extremity weight-bearing exercises (see Chapter 34). The buoyancy of the water has been shown to decrease the amount of weight-bearing forces to approximately 25% of the individual's body weight when submerged to the level of the axilla and 50% of the individual's body weight when submerged to the level of the waist.[34] Commercially available devices to unload the patient's body weight during treadmill ambulation may also be useful.

A force platform is another useful tool during the early phases of rehabilitation when weight bearing is limited. This can be used to monitor the percentage of weight bearing on each extremity during closed kinetic chain (CKC) exercises such as weight shifts, minisquats, and leg press (Fig. 33-1).

The pool and force platforms may be used during early phases of rehabilitation to perform limited weight-bearing activities designed to facilitate a normal gait pattern and enhance strength, proprioception, and balance. The goal of these techniques is to initiate weight-bearing activities during the early protective phases of rehabilitation rather than remain strictly non–weight bearing and immobilized. Our opinion is that beginning controlled weight-bearing activities is a critical component to the overall successful outcome of the procedure. Although the return to functional activities will differ for each patient, early initiation of controlled exercise enables the individual to return to functional activities sooner than those who are immobilized and non–weight bearing. This may have a positive effect on patient satisfaction.

FIG 33-1 Exercises such as a weight shift **(A)** and leg press **(B)** performed on a force platform (Balance Trainer) that can measure the amount of weight distribution between each extremity **(C)**.

Passive range of motion (PROM) activities, such as continuous passive motion (CPM) machines or manual PROM, performed by a rehabilitation specialist are also begun immediately after surgery in a limited ROM to nourish the healing articular cartilage and prevent the formation of adhesions. Motion exercises may assist in creating a smooth low-frictional surface by sliding against the joint's articular surface and may be an essential component in cartilage repair.[64,65] Our opinion is that PROM is a safe and effective exercise to perform immediately postoperatively, with minimal disadvantageous shear or compressive forces, if done with patient's relaxation. This ensures that muscular contraction does not create deleterious compressive or shearing forces. Furthermore, the use of CPM has been shown to enhance cartilage healing and long-term outcomes after articular cartilage procedures.[61,62] In a study comparing the outcomes of patients after microfracture procedures, Rodrigo and associates[61] reported an 85% satisfactory outcome in patients who used a CPM machine for 6 to 8 hours per day for 8 weeks compared with a 55% satisfactory outcome in patients who did not use a CPM machine. Thus CPM or PROM using the contralateral leg should be performed for several hours during the day (some advocate 6 to 8 hours each day). PROM may also be performed on an isokinetic device (Biodex Corporation) in the passive mode or with a bike with adjustable pedals that can alter the available ROM (Unicam Corporation, Fig. 33-2). We advocate low-intensity (light-resistance) bicycling for long duration to stimulate articular cartilage regeneration.

Biomechanics of the Knee

The next rehabilitation principle involves the biomechanics of the tibiofemoral and patellofemoral joints during normal joint articulation. Articulation between the femoral condyle and the tibial plateau is constant throughout knee ROM. The anterior surface of each femoral condyle is in articulation with the middle aspect of the tibial plateau near full knee extension. With weight bearing, as the knee moves into greater degrees of knee flexion, the femoral condyles

FIG 33-2 Bicycle riding on a Unicam machine **(A)** that can adjust the pedal axis **(B)** to alter the range of motion performed.

progressively roll posteriorly and slide anteriorly, causing the articulation to shift posteriorly on the femoral condyle and tibial plateaus.[38,44]

The articulation between the inferior margin of the patella and the trochlea begins at approximately 10 to 20 degrees of knee flexion depending on the size of the patella and the length of the patella tendon.[16,37] As the knee proceeds into greater degrees of flexion, the contact area of the patellofemoral joint moves proximally along the patella. At 30 degrees, the area of patellofemoral contact (inferior facets) is 2 cm^2 approximately.[37] The area of contact gradually increases as the knee is flexed. Borotikar and associates[8] measured the in vivo contact area between the femur and patella using dynamic MRI during knee flexion-extension and reported a mean of 125 mm^2 at 10 degrees of flexion, which increased to 229 mm^2 at 40 degrees of flexion. At 60 degrees of knee flexion, the middle facets of the patella articulate with the trochlea. At 90 degrees of knee flexion, the contact area increases up to 6 cm^2, and the superior facets articulate.[37]

Using this knowledge of joint arthrokinematics, the rate of weight bearing, PROM, and exercise progression may be based on the exact location of the lesion (Fig. 33-3).[6,20,26,27] For example, a patient with a lesion on the anterior aspect of the femoral condyle may perform exercises into deeper degrees of knee flexion without causing articulation at the repair site. Conversely, lesions on the posterior condyle may require the avoidance of exercise in deep knee flexion owing to the rolling and sliding component of the articulation during deeper knee flexion. Furthermore, the rehabilitation program for lesions on a non-weight-bearing surface, such as the trochlea, may include immediate partial weight bearing with a brace locked in full knee extension without causing excessive compression on the repair site.

Rehabilitation exercises are altered based on the biomechanics of the knee to avoid excessive compressive or shearing forces. Although the exact ROM in which articulation of the lesion occurs is the most important factor to consider when designing the rehabilitation program, the amount of compressive and shear forces observed at the joint also vary throughout the ROM. Open kinetic chain (OKC) exercises, such as knee extension, are commonly performed from 90 to 40 degrees of knee flexion. This ROM provides the lowest amount of patellofemoral joint reaction forces while exhibiting the greatest amount of patellofemoral contact area,[36,37,69] thus distributing the force along a greater surface area. CKC exercises such as the leg press, vertical squats, lateral step ups, and wall squats are performed initially from 0 to 30 degrees and then progressed to 0 to 60 degrees where tibiofemoral and patellofemoral joint reaction forces are lowered.[36,37,69] Clinically, these exercises are begun using a leg press machine rather than the vertical minisquat owing to the ability to control the amount of weight applied to the lower extremities in the horizontal position in comparison with the vertical squat. As the repair site heals and symptoms subside, the ROM in which exercises are performed is progressed to allow greater muscle strengthening in a larger arc of motion. Exercises are progressed based on the patient's symptoms and the clinical assessment of swelling and crepitation.

Reduce Pain and Effusion

Numerous authors have studied the effect of pain and joint effusion on muscle inhibition. A progressive decrease in volitional quadriceps activity has been noted as the knee exhibits increased pain and distention.[68] Therefore the reduction in knee joint pain and swelling is crucial to minimize this reflexive inhibition and restore normal quadriceps activity. Furthermore, any increase in intraarticular joint temperature has been shown to stimulate proteolytic enzyme activity, which has a detrimental effect on articular cartilage.[35,53]

Treatment options for swelling reduction include cryotherapy, elevation, laser therapy, high-voltage stimulation, and joint compression through the use of a knee sleeve or compression wrap (Fig. 33-4). Patients presenting with chronic joint effusion may also benefit from a knee sleeve or compression wrap to apply constant pressure while

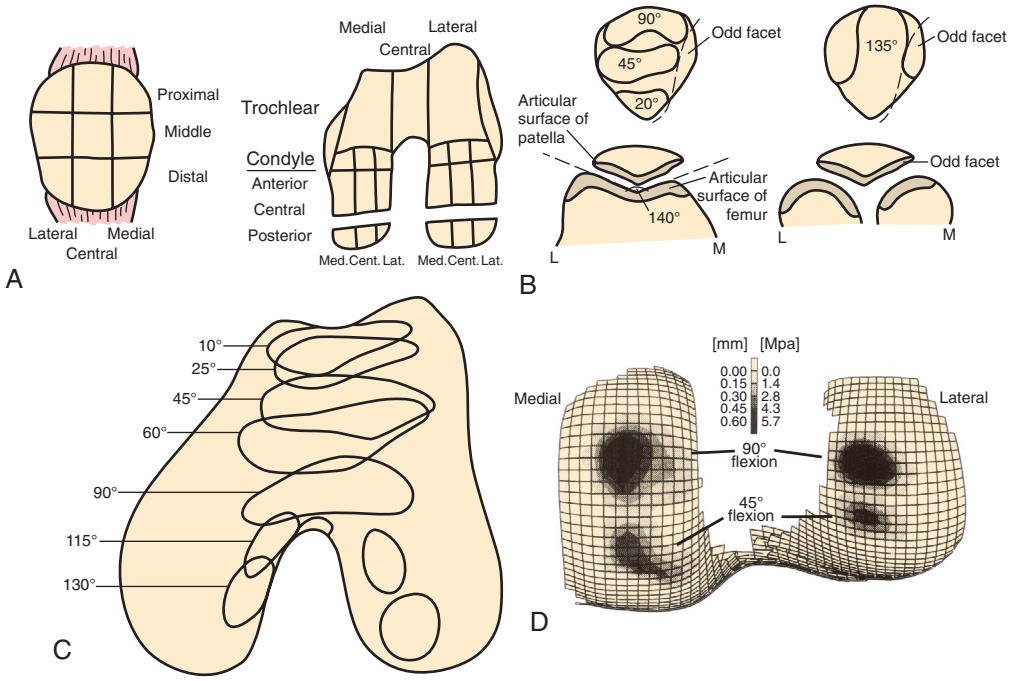

FIG 33-3 **A,** The lesion location diagram from the International Knee Documentation Committee evaluation form used to document the location of articular cartilage lesions on the patella, trochlea, and femoral condyles. This form may be used to correlate with the exact location of lesion articulation with the patella **(B),** trochlea **(C),** and femoral condyles **(D).** The diagrams represent the point of articulation of the patellofemoral and tibiofemoral joints at various degrees of knee range of motion. Surface displacements (mm) and surface stresses (MPa) at 45 and 90 degrees of knee flexion are depicted on **D.** (**A,** From the International Knee Documentation Committee. **B** and **C,** From McConnell J, Fulkerson J. performing everyday activities in an attempt to minimize the development of further effusion (Fig. 33-5).

Pain can be reduced passively through the use of cryotherapy, transcutaneous electrical nerve stimulation, and analgesic medication. Immediately after injury or surgery, the use of a commercial cold wrap can be extremely beneficial. PROM may also provide neuromodulation of pain during acute or exacerbated conditions.[63]

Restore Soft Tissue Balance

One of the most important aspects of articular cartilage rehabilitation involves the avoidance of arthrofibrosis, particularly with the OAT and ACI procedures, owing to the large open incision and extensive soft tissue trauma. This is achieved through the restoration of full passive knee extension, patellar mobility, and soft tissue flexibility of the knee and entire lower extremity. The inability to fully extend the knee results in abnormal joint arthrokinematics and subsequent increases in patellofemoral and tibiofemoral joint contact pressure, increased strain on the quadriceps muscle, and muscular fatigue.[54] Therefore a drop-lock postoperative knee brace locked into 0 degree of extension is used during ambulation, and PROM out of the brace is performed immediately after surgery.

The goal is to achieve at least 0 degrees of knee extension within the first few days after surgery. Specific exercises include manual PROM exercises performed by the rehabilitation specialist, supine hamstring stretches with a wedge under the heel, and gastrocnemius stretching with a towel. Overpressure of 6 to 12 lb may be used for a low-load long-duration stretch as needed to achieve full extension (Fig. 33-6). Patients are instructed to perform low, long-duration stretches for 10 to 12 minutes several times each day (usually five to six times per day). Modalities such as moist heat and ultrasound may also be applied to facilitate greater ROM improvements before and/or during these stretching techniques.[39,60]

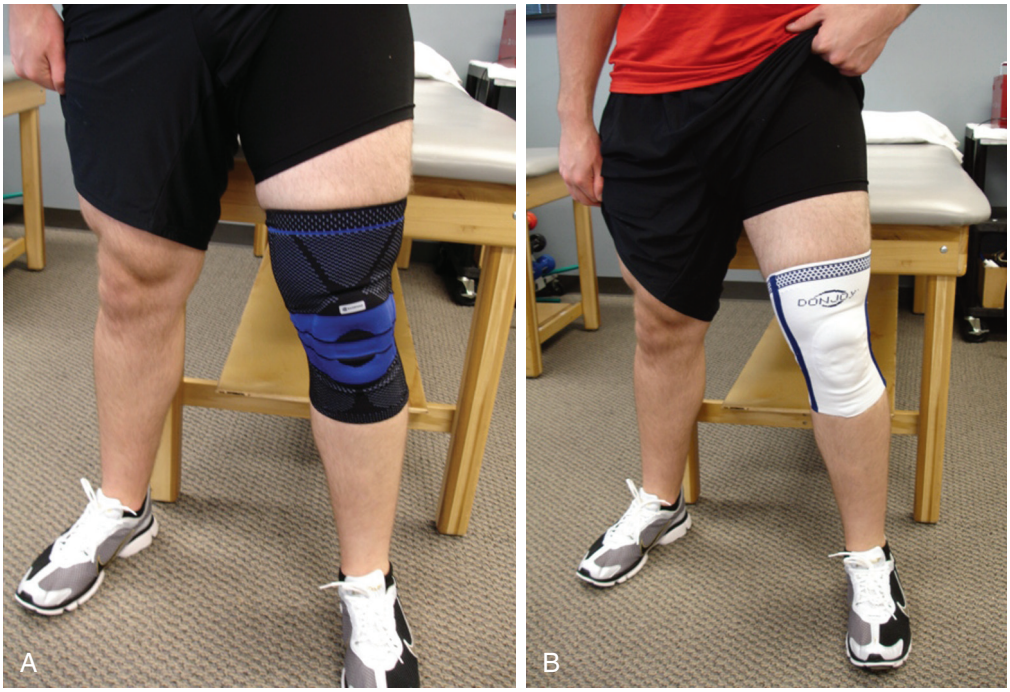

FIG 33-5 **A,** Knee compression sleeve (Bauerfeind Corp). **B,** Compression sleeve (DJ Orthopaedics).

FIG 33-6 Low-load long-duration stretching into knee extension using 8 to 10 pounds of overpressure. A wedge is applied under the heel to facilitate full extension (ERMI device, Get Motion Corporation).

The loss of patellar mobility after surgery may be caused by various reasons, including excessive scar tissue adhesions from the incision anteriorly as well as along the medial and lateral gutters. The loss of patellar mobility may result in ROM complications and difficulty in recruiting a quadriceps contraction. Patellar mobilizations in the medial-lateral and superior-inferior directions are performed by the rehabilitation specialist and independently by the patient during his or her home exercise program.

Soft tissue flexibility and pliability are also important for the entire lower extremity. Soft tissue mobilization and scar management are performed to prevent the development of adhesions around the anterior, medial, and lateral aspects of the knee. In addition, flexibility exercises are performed for the entire lower extremity, including the hamstrings, hip, and calf musculature. As ROM improves and the lesion begins to heal, quadriceps stretching may be performed as tolerated by the patient.

Restore Muscle Function

The next principle involves restoring muscle function of the lower extremity. As previously stated, inhibition of the quadriceps muscle is a common clinical enigma in the presence of pain and effusion during the acute phases of rehabilitation. Electrical muscle stimulation (EMS) and biofeedback are often incorporated with therapeutic exercises to facilitate the active contraction of the quadriceps musculature (Fig. 33-7, *A*).

EMS and biofeedback on the quadriceps musculature appear to facilitate the return of muscle activation and may be valuable additions to therapeutic exercises.[15,66] Clinically, EMS is begun immediately after surgery while the patient performs isometric and isotonic exercises such as quadriceps sets, straight leg raises, hip adduction and abduction, and knee extensions (see Fig. 33-7, *B*). EMS is used before biofeedback when the patient presents acutely with the inability to activate the quadriceps musculature. EMS is useful to attempt to recruit a maximum amount of muscle fibers during active contraction and may be used throughout the rehabilitation process. Once independent muscle activation is present, biofeedback may also be incorporated to facilitate further neuromuscular activation of the quadriceps. The patient must concentrate on neuromuscular control to independently activate the quadriceps during rehabilitation. The quadriceps and the hip/core muscles are emphasized to assist in dissipating ground reaction forces.

Exercises that strengthen the entire lower extremity, such as machine weights and CKC exercises, may be included as the patient progresses to more advanced phases of rehabilitation. It is important that total leg strength be emphasized rather than concentrating solely on the

FIG 33-7 Neuromuscular electrical stimulation (300PV, Empi Corporation) applied to the quadriceps muscle **(A)** during exercises such as knee extension **(B).**

quadriceps. Furthermore, the importance of incorporating core stability exercises cannot be overlooked. Training of the core, hip, and ankle located proximally and distally along the kinetic chain is emphasized to assist in controlling the production and dissipation of forces in the knee. In addition, the hip and ankle assist in controlling abduction and adduction moments at the knee joint. Often issues with alignment and muscle imbalances in the lumbopelvic region will place disadvantageous stress on the knee.

Enhance Proprioception and Neuromuscular Control

Proprioceptive and neuromuscular control drills of the lower extremities should be included to restore dynamic stabilization of the knee joint postoperatively. Proprioceptive deficits have been noted in the injured and postoperative knee.[18,59] Specific drills initially include weight shifting side to side, weight shifting diagonally, minisquats, and minisquats on an unstable surface such as a tilt board (Fig. 33-8). The use of kinesiotaping and other taping may enhance proprioception in patients during rehabilitation, especially if they exhibit poor proprioception. Additionally, perturbations can be added to challenge the neuromuscular system as well as additional exercises including lunges, step-ups, and balance onto unstable surfaces (Figs. 33-9 and 33-10).

Control the Application of Loads

The next principle of rehabilitation involves gradually increasing the amount of stress applied to the injured knee as the patient returns to functional activities. The rehabilitation process involves a progressive application of therapeutic exercises designed to gradually increase function in the postoperative knee. This progression is used to provide a healthy stimulus for healing tissues while ensuring that forces are gradually applied without causing damage. Common clinical signs that a patient may be progressing too quickly and overloading the healing tissue are joint line pain and effusion. This should be monitored throughout the rehabilitation process.

In addition, patients may benefit from the use of orthotics, insoles, and unloading braces to alter the applied loads on the articular cartilage during functional activities. These devices are used to avoid excessive forces by unloading the area of the knee where the lesion is located. Unloading braces are often used for patients with subtle uncorrected abnormal alignments (genu varum) or large or uncontained lesions or who had concomitant osteotomies and meniscal allografts (Fig. 33-11).

Team Communication

The next principle, and maybe the most important principle of rehabilitation involves communication among the surgeon, the physical therapist, and the patient. Communication between the surgeon and the rehabilitation team is essential to determine the accurate rate of progression based on the location and size of the lesion, tissue quality, and concomitant surgical procedures. In addition, communication between the medical team and the patient is essential to provide the patient with education regarding the avoidance of deleterious forces as well as improving compliance with precautions. Frequently, a preoperative physical therapy evaluation may be useful to mentally and physically prepare the patient for the articular cartilage procedure and postoperative rehabilitation.

Rehabilitation Philosophy

It is important that all members of the health care team (e.g., physician, physical therapist, athletic trainer, nurses) convey the same rehabilitation message. We advocate gradual progressive loading of healing articular cartilage. The purpose of this concept is to recondition the articular cartilage. Another message is "slower is better." It takes a long period of time for articular cartilage to heal, mature, and return to weight-bearing activities. One last philosophical point is "faster is not better, even if you feel pain free." Patients are instructed that the medical team is more interested in long-term results than outcome 6 months after surgery.

FIG 33-8 Minisquats on an unstable surface such as a tiltboard. The patient is instructed to squat while preventing movement of the board.

FIG 33-9 Single-leg balance on an unstable surface such as foam. The patient may use a weighted ball while performing reciprocal movement patterns with the uninvolved upper and lower extremities to alter the center of gravity throughout the exercise.

REHABILITATION AFTER ARTICULAR CARTILAGE REPAIR PROCEDURES

The rehabilitation progression is designed based on the four biologic phases of cartilage maturation: proliferation, transitional, remodeling, and maturation.[10,11,19,28,32,51,55,57] The length of each phase will vary depending on the lesion, patient's age and general health, and surgical specifics discussed previously; however, the concepts of each phase are consistent. The following sections overview the generalized rehabilitation process during each of the four phases.

Phase I: Early Protection Phase

The first phase of cartilage healing is the *proliferation phase*, which typically involves the first 4 to 6 postoperative weeks. During this phase, the initial healing process begins. It is imperative to decrease swelling, gradually restore PROM, and enhance volitional control of the quadriceps during this period of rehabilitation.

Controlled active ROM and PROM and a gradual weight-bearing progression are critical components to the rehabilitation process. As previously discussed, PROM and controlled partial weight bearing will help promote the nurturing of the cartilage through diffusion of synovial fluid as well as provide the proper stimulus for the cells to produce specific matrix markers. Individuals begin with partial weight-bearing activities using crutches. Progressive loading exercises using the pool and force platforms are gradually implemented to increase the amount of load applied to the weight-bearing surfaces of the joint. The use of a pool or aquatic therapy may be beneficial to begin gait training and lower extremity exercises once the incisions are well healed.

PROM activities, such as manual PROM performed by a rehabilitation specialist and CPM machines, are also begun immediately after surgery to nourish the healing articular cartilage and prevent the formation of adhesions. The use of a CPM typically begins 6 to 8 hours after surgery and is performed for at least 2 to 3 weeks, with recommended use up to 6 to 8 weeks. It is recommended that the CPM be used throughout the day for up to 6 to 8 hours. The patient is instructed to also perform active-assisted ROM frequently throughout the day. Patella mobilization, soft tissue mobilization, and soft tissue flexibility exercises are also performed to minimize scar tissue formation and avoid loss of motion. Low-intensity stationary cycling may be implemented in this phase.

FIG 33-10 Lateral step-up exercises performed while standing on an unstable surface such as a piece of foam. This exercise requires eccentric control of the lower extremity to perform the step-up exercise as well as to balance throughout the movement.

FIG 33-11 An osteoarthritis unloading brace (OA Defiance, Don Joy Corporation) using a four-point leverage system to unload the medial compartment of the knee by providing a mild valgus stress to the knee.

Early strengthening exercises are performed to restore volitional quadriceps control and neuromuscular control through the use of concomitant EMS. Exercises performed during this phase are limited based on the specific weight-bearing status of each patient and typically include quadriceps sets, straight-leg raises, and early baseline proprioception exercises such as weight shifting.

Exercises for areas elsewhere in the kinetic chain can be implemented in this phase as tolerated. These include strengthening exercises of the hip and baseline core stabilization exercises. During this phase it is essential to strengthen the hip abductors, external rotators, and extensors to control a valgus collapse to the knee joint. Manual therapy to restore hip and ankle mobility as well as lumbopelvic alignment are also important in this phase and are unique to each individual. Creating this foundation will allow a more progressive rehabilitation approach once the postoperative restrictions are removed later in the process.

Phase II: Transition Phase

The second phase is the *transitional phase*, which typically includes postoperative weeks 4 through 12. The repair tissue at this point is gaining strength, which will allow for the progression of rehabilitation exercises. During this phase, the patient progresses from partial to full weight bearing, while full ROM and soft tissue flexibility are achieved. Continued maturation of the repair tissue is fostered through higher-level functional and ROM exercises. It is during this phase that patients typically resume most normal activities of daily living. The rehabilitation program will gradually progress strengthening activities to include machine weights and CKC exercises, such as leg press, front lunges, wall slides, and lateral step ups, as the patient's weight-bearing status returns to normal.

At this time, the rehabilitation process involves the progressive application of therapeutic exercises designed to gradually increase function in the postoperative knee. The progression of weight-bearing activities and restoration of ROM, as previously discussed, involves the gradual advancement of activities to ensure that complications do not arise while facilitating healing. A principle of gradual progressive loading is implemented during this phase. Once weight bearing is initiated, the clinician may consider an osteoarthritis unloader brace. Common complications include motion restrictions and scar tissue formation. Furthermore, an overaggressive approach early within the

rehabilitation program may result in increased pain, inflammation, or effusion as well as graft damage. This simple concept may be applied to the progression of strengthening exercises, proprioception training, neuromuscular control drills, and functional drills. For example, exercises such as weight shifts and lunges are progressed from straight-plane anterior-posterior or medial-lateral directions to involve multi-plane and rotational movements. Exercises using two legs, such as leg press and balance activities, are progressed to single-leg exercises. Thus the progression through the postoperative rehabilitation program involves a gradual progression of applied and functional stresses. This progression is used to provide a healthy stimulus for healing tissues while ensuring that forces are gradually applied without causing damage.

Phase III: Remodeling Phase

The third phase, known as the *remodeling phase*, generally occurs from 3 to 6 months postoperatively. During this phase, there is a continuous remodeling of tissue into a more organized structure. The tissue continues to increase in strength and durability. As the tissue becomes more firm and integrated, more functional training activities may be performed. At this point, the patient typically notes improvement of symptoms and has normal ROM. The patient is encouraged to continue with her or his rehabilitation program independently to maximize strength and flexibility. Low- to moderate-impact activities such as bicycle riding, golfing, and recreational walking may often be gradually incorporated. The senior author's (K.E.W.) experience has shown that during this phase when overzealous patients are "feeling good," they may overexert their program, which may compromise the repair site.

Phase IV: Maturation Phase

The final phase is known as the *maturation phase*, which typically begins in a range of 4 to 6 months and can last up to 15 to 18 months. This depends on the type of surgery, size, and location of the lesion. During this phase, the repair tissue reaches its full maturation. The duration of this phase varies based on several factors such as lesion size and location and the specific surgical procedure performed. The patient will gradually return to full premorbid activities as tolerated. Impact-loading activities are gradually introduced. Although such procedures as OAT and ACI are designed to restore function rather than to facilitate return to high-impact athletic activities, a return to athletic activities is determined based on the unique presentation of each patient. A return to competitive athletics has been documented after microfracture,[50] OAT,[31] and ACI[47,58] procedures.

SPECIFIC POSTOPERATIVE GUIDELINES

Debridement and Chondroplasty

Rehabilitation after an arthroscopic debridement or chondroplasty is fairly simple owing to the nature and goal of the procedure to facilitate tissue healing rather than create repair tissue. Initial weight bearing is limited for the first 3 to 5 days using axillary crutches, although weight bearing is permitted as tolerated. PROM exercises are progressed as tolerated immediately with no postoperative limitations in motion. Full passive motion is typically achieved within 2 to 3 weeks. OKC exercises are performed initially, although CKC strengthening exercises and bicycle riding are normally incorporated by the end of the first week. The patient is allowed to return to full functional activities and progress to moderate-impact activities, such as light jogging and sports, beginning at week 4. The progression of impact loading may be delayed if significant degenerative changes are present within the knee or if symptoms of pain or effusion persist. The rate of progression is highly variable and should be based on the extent of the procedure and unique situation of each patient.

Microfracture

The operative procedure referred to as a microfracture to the knee joint is the most common procedure performed to the knee to treat focal articular cartilage lesions. Rehabilitation after a microfracture procedure progresses more cautiously than that of a debridement or chondroplasty (Table 33-3). The program is based on size, location, number of areas treated, and concomitant procedures. The early protection phase begins immediately after surgery and lasts until the fourth week postoperatively. During this time, defects begin to fill with a fibrin clot, although no fibrocartilage is present.[19] A period of non–weight bearing is applied for the first 2 to 6 weeks postoperatively for most lesions. Marder and colleagues[43] compared the results of patients with small focal lesions of less than 2.0 cm^2 using two postoperative rehabilitation programs. Group I used touch-down weight bearing and a CPM machine for 6 to 8 hours a day for 6 weeks. Group II was allowed weight bearing as tolerated immediately after surgery and used active-assisted heel-slides for ROM (without the use of a CPM). These authors reported significant improvements in both groups and no significant differences in the subjective or objective outcomes between groups a minimum of 2 years postoperatively. Thus it appears that it may be possible to begin early controlled weight bearing for small, focal lesions without applying deleterious forces to the repair site. The emphasis here is that early weight bearing should be initiated in patients with small focal lesions. If the rehabilitation specialist is unsure of the surgical details, a more conservative approach must by implemented.

Initial controlled touch-down weight bearing is begun for lesions that are localized and smaller than 2.0 cm^2 in patients with good tissue quality. For patients with patellofemoral lesions, immediate weight bearing is performed owing to the lack of lesion articulation during weight bearing; however, a drop-locked knee brace is worn to avoid deleterious sheer forces to the healing repair site.

Owing to the arthroscopic nature of the procedure, PROM is performed immediately without restrictions. Full PROM of at least 0 to 125 degrees is achieved between weeks 3 and 4, often with little difficulty.

The transition phase begins at week 4 and progresses to week 8. During this phase, the patient may progress to full weight bearing and more functional CKC exercises by the end. At 6 weeks postoperatively, a thin layer of tissue covers the base of the lesion.[21] Although the repair is still incomplete, fibrocartilaginous tissue is present, and by 8 weeks, some tissue with hyalinelike characteristics has been detected.[19] By 12 weeks, the defect is completely filled and the quality of cartilaginous tissue improves significantly.[21] Thus gentle CKC exercises may begin by week 8 but should not be advanced significantly until week 12.

Weight bearing is thus progressed to full at week 8 for most lesions when the strength of the repair tissue is increasing. However, the progression to more advanced exercises, including impact loading, is delayed until the end of the remodeling phase when the defect is completely filled. The patient may gradually begin to return to former activities during the maturation phase between months 4 to 6; however, larger lesions may need to delay the progression to high-impact activities for up to 8 months.

Clinical outcome studies indicate that a significant number of patients will be able to return to sports after a microfracture procedure.[22,40,50] Mithoefer and coworkers[50] reported on 32 patients who routinely participated in high-impact and pivoting sports. At a minimum 2-year follow-up, 66% had good to excellent results, and 44% had returned to high-impact sports. However, after initial improvement, scores decreased in 47% of athletes. Return to sports

TABLE 33-3 Rehabilitation After Microfracture Procedure

Phase I: Early Protection Phase (Weeks 0-4)

Goals
- Protect healing tissue from load and shear forces
- Decrease pain and effusion
- Restore full passive knee extension
- Gradually restore knee flexion
- Regain quadriceps control

Brace
- No brace; may use elastic wrap to control swelling

Weight Bearing
- Weight-bearing status varies based on lesion location, size.
- For medium to large femoral condyle lesions (>2.0 cm^2): non–weight bearing for 2 weeks, begin toe-touch weight bearing (~20-30 lb) at week 3; progress to partial weight bearing (~25% body weight) at week 4.
- For small femoral condyle lesions (<2.0 cm^2): immediate toe-touch weight bearing (per physician) (~20-30 lb) at weeks 0-2; progress to 50% weight bearing at week 3; 75% weight bearing at week 4.
- For patellofemoral lesions: immediate toe-touch weight bearing of ~25% body weight with brace locked in full extension; progress to 50% weight bearing at week 2, 75% weight bearing at week 3 with brace locked in full extension, full weight bearing at week 4.

Range of Motion
- Immediate motion exercise on day 1
- Full passive knee extension immediately
- Initiate continuous passive motion day 1 for total of 8-12 hr/day (0-60 degrees; if patellofemoral lesion >6.0 cm^2, 0-40 degrees)
- Progress continuous passive motion range of motion as tolerated 5-10 degrees/day
- May continue continuous passive motion for total of 6-8 hr/day for up to 6 wk
- Patellar mobilization (4-6 times/day)
- Motion exercises throughout the day
- Passive knee flexion range of motion at least 2-3 times/day
- Progress passive knee range of motion as tolerated, no restrictions
- Minimum range of motion goals: 0-90 degrees at week 1; 0-105 degrees at week 2; 0-115 degrees at week 3; and 0-125 at degrees week 4
- Stretch hamstrings and calf

Strengthening Program
- Ankle pumps with rubber tubing
- Quadriceps setting
- Multiangle isometrics (cocontractions quadriceps/hamstring)
- Active knee extension 90-40 degrees for femoral condyle lesions (no resistance), avoid for patellofemoral patients
- Straight-leg raises (four directions)
- Stationary bicycle when range of motion allows; low resistance
- EMS and/or biofeedback during quadriceps exercises
- Initiate weight shifting exercises with knee in extension at weeks 1-2 for patellofemoral lesions and small femoral condyle lesions and at week 3 for larger femoral condyle lesions
- Leg press 0-60 degrees at week 3 for small femoral condyle lesions and patellofemoral lesions; progress to 0-90 degrees at week 4
- Toe-calf raises at week 4 for small femoral condyle and patellofemoral lesions
- Use of pool for gait training and exercises at weeks 3-4 (when incision is fully healed)
- Stationary bike at weeks 3-4, low resistance
- *No* active knee extension exercises for patellofemoral lesions

Functional Activities
- Gradual return to daily activities
- If symptoms occur, reduce activities to reduce pain and inflammation

Swelling Control
- Ice, elevation, compression, and effusion modalities as needed

Criteria to Progress to Phase II
- Full passive knee extension
- Knee flexion to 125 degrees
- Minimal pain and swelling
- Voluntary quadriceps activity

Phase II: Transition Phase (Weeks 4-8)

Goals
- Gradually improve quadriceps strength and endurance.
- Gradual increase in functional activities.

Weight Bearing
- Progress as tolerated
- Large femoral condyle lesions: 50% weight bearing with crutches at week 6; 75% weight bearing at week 7, full weight bearing at week 8, discontinue crutches

Range of Motion
- Gradual increase in range of motion
- Maintain full passive knee extension
- Progress knee flexion to 135 degrees or more by week 8
- Continue patellar mobilization and soft tissue mobilization, as needed
- Continue stretching program

Strengthening Exercises
- Progress to closed kinetic chain exercises
- Initiate leg press for large femoral condyle lesions at week 6
- Minisquats 0-45 degrees at week 7
- Toe-calf-raises at week 8 for femoral condyle lesions
- Progress to balance and proprioception drills
- Initiate front lunges, wall squats, front and lateral step-ups at week 5 for small femoral condyle and patellofemoral lesions and at week 8 for large femoral condyle lesions
- For femoral condyle lesions, progress to open kinetic chain knee extension, 1 lb/wk
- For patellofemoral lesion, may begin open kinetic chain knee extension without resistance in a range of motion that does not allow for articulation of the lesion
- Continue stationary bicycle, low resistance (gradually increase time)
- Continue use of EMS and/or biofeedback as needed
- Continue use of pool for gait training and exercise

Functional Activities
- As pain and swelling (symptoms) diminish, gradually increase functional activities
- Gradually increase standing and walking

Criteria to Progress to Phase III
- Full range of motion
- Acceptable strength levels:
  - Hamstrings within 20% of contralateral leg
  - Quadriceps within 30% of contralateral leg
- Balance testing within 30% of contralateral leg
- Able to bike for 30 min

Continued

TABLE 33-3 Rehabilitation After Microfracture Procedure—cont'd

Phase III: Remodeling Phase (Weeks 8-16)

Goals

- Improve muscular strength and endurance
- Increase functional activities

Range of Motion

- Patient should exhibit 125-135 degrees + flexion

Exercise Program

- Leg press (0-90 degrees)
- Bilateral squats (0-60 degrees)
- Unilateral step-ups progressing from 2 to 8 inches
- Forward lunges
- Walking program at week 10
- Progress to open kinetic chain extension (0-90 degrees); for patellofemoral lesions, may begin at week 12, perform from 90-40 degrees or avoid angle where lesion articulates; progress 1 lb every 2 weeks beginning at week 20 if no pain or crepitus; must monitor symptoms
- Continue progressing balance and proprioception
- Bicycle
- Stair-climbing machine
- Swimming
- Ski or elliptical machine

Functional Activities

- As patient improves, increase walking (e.g., distance, cadence, incline)

Maintenance Program

- Initiate at weeks 12-16
- Bicycle: low resistance, increase time
- Progressive walking program
- Pool exercises for entire lower extremity
- Straight-leg raises
- Leg press
- Wall squats
- Hip abduction/adduction
- Front lunges
- Step-ups
- Stretch quadriceps, hamstrings, calf

Criteria to Progress to Phase IV

- Full nonpainful range of motion
- Strength within 80%-90% of contralateral extremity
- Balance and/or stability within 75%-80% of contralateral extremity
- No pain, inflammation, or swelling

Phase IV: Maturation Phase (Weeks 16-26)

Goals

- Gradual return to full unrestricted functional activities

Exercises

- Continue maintenance program progression 3-4 times/wk
- Progress resistance as tolerated
- Emphasis on entire lower extremity strength and flexibility
- Progress agility and balance drills
- Impact-loading program specialized to patient demands
- Progress sport programs depending on patient variables

Functional Activities

- Patient may return to various sport activities as progression in rehabilitation and cartilage healing allow. In general, low-impact sports such as swimming, skating, rollerblading, and cycling are permitted at about 2 months for small femoral condyle and patellofemoral lesions and at 3 months for large femoral condyle lesions. Higher-impact sports such as jogging, running, and aerobics may be performed at 4 months for small lesions or 5 months for larger lesions. High-impact sports such as tennis, basketball, football, and baseball are allowed at 6-8 months.

was significantly higher in athletes younger than 40 years of age, patients with a lesion size less than 200 mm^2, those with preoperative symptoms less than 12 months' duration, and patients who had no prior surgical intervention. In a separate report, Mithoefer and associates[49] described the results of microfracture for isolated femoral chondral lesions. They reported that 67% of patients had a good to excellent result; 25%, a fair result; and 8%, a poor result. The investigators were able to obtain follow-up magnetic resonance imaging (MRI) on 50% of the patients. MRI revealed good tissue healing and filling in 54%, moderate tissue filling in 29%, and poor healing result in 17%. Successful outcomes correlated to a low BMI, good healing or lesion filling, and short duration of symptoms. The worst results were seen in patients with a BMI of 30 kg/m. Kreuz and colleagues[42] compared the results of microfracture in patients older than 40 years of age with those younger than 40 years of age. These authors reported superior outcomes in patients 40 years or younger. Between 18 and 36 months postoperatively, the investigators found a deterioration in International Cartilage Repair Society (ICRS) scores, which was significantly pronounced in older patients. Furthermore, MRI performed at 36 months after surgery indicated better fill in patients younger than 40 years.

Osteochondral Autograft Transplantation Procedure

Rehabilitation after OAT procedures requires the avoidance of early deleterious forces to avoid disrupting the healing transplanted bone plugs (Table 33-4). Currently, the pace of the rehabilitation program after OAT procedures is based not only on the size of the lesion but also on the amount of transplanted bone plugs and location. The program is progressed more cautiously when numerous bone plugs are used owing to the potential for a less congruent surface. The early protection phase lasts until the eighth week postoperatively. During this phase, an initial 44% reduction in the push-in and pull-out strength of the transplanted bone plugs has been observed (at 1 week postoperatively),[74] emphasizing the need for strict non–weight bearing postoperatively. Partial weight bearing is usually initiated 2 to 4 weeks after surgery based on the size of the lesion and the number of transplanted bone plugs. Although the original hyaline cartilage remains intact and viable,[51] the strength of the bone plugs is the limiting factor when designing the postoperative rehabilitation program.

By 4 weeks, the cancellous bone plugs have united,[32] and by 6 weeks, there is full subchondral integration and 29% of grafts show bonding between the articular cartilage of the bone plugs and the surrounding articular cartilage.[51] Although integration has occurred, a 63% decrease in graft stiffness is still observed at 6 weeks postoperative.[51] During this time, weight bearing is gradually progressed as the strength of the repair increases. At 8 weeks postoperative, fibrocartilage has been observed to grow to the surface and seal the recipient and donor site hyaline cartilage, and weight bearing is progressed to full. Immediate

TABLE 33-4 Rehabilitation After Osteochondral Autograft Transplantation

Phase I: Early Protection Phase (Weeks 0-6)

Goals
- Protect healing tissue from load and shear forces
- Decrease pain and effusion
- Restore full passive knee extension
- Gradual improvement of knee flexion
- Regain quadriceps control

Brace
- Locked at 0 degrees during weight-bearing activities
- Sleep in locked brace for 2-4 weeks

Weight Bearing
- Weight-bearing status varies based on lesion location and size
- For femoral condyle lesions: non–weight bearing for 2-4 weeks (physician direction); if large lesion (>5 cm^2) may need to delay weight bearing up to 4 weeks, progress to toe-touch weight bearing (~20-30 lb) at weeks 3-4 and partial weight bearing (~25%-50% body weight) at week 6
- For patellofemoral lesions: immediate toe-touch weight bearing 25% body weight with brace locked in full extension; progress to 50% weight bearing at week 2-3 in brace and 75% at week 4-5 in brace

Range of Motion
- Immediate motion exercise on day 1
- Immediate full passive knee extension
- Initiate continuous passive motion on day 1 for total of 8-12 hr/day (0-60 degrees; if patellofemoral lesion >6.0 cm^2, 0-40 degrees)
- Progress continuous passive motion range of motion as tolerated 5-10 degrees/day
- May continue continuous passive motion for total of 6-8 hr/day for up to 6 weeks
- Patellar mobilization (4-6 times/day)
- Motion exercises throughout the day
- Passive knee flexion range of motion at least 2-3 times/day
- Passive knee range of motion as tolerated
- For femoral condyle lesions, minimum knee flexion range of motion goal is 90 degrees by 1-2 weeks, 105 degrees at week 3, 115 degrees at week 4, and 120-125 degrees by week 6
- For patellofemoral lesions, minimum knee flexion range of motion goal is 90 degrees by weeks 2-3, 105 degrees by 3-4 weeks, and 120 degrees by week 6
- Stretch hamstrings and calf

Strengthening Program
- Ankle pump using rubber tubing
- Quadriceps setting
- Multiangle isometrics (cocontractions quadriceps/hamstring)
- Straight-leg raises (four directions)
- Active knee extension 90-40 degrees for femoral condyle lesions if no articulation at week 4 (no resistance)
- EMS and/or biofeedback during quadriceps exercises
- Stationary bicycle when range of motion allows; low resistance
- Isometric leg press at week 4 (multiangle)
- Use of pool for gait training and exercises at week 6
- Initiate weight-shifting exercises with knee in extension at week 3-4 for patellofemoral lesions
- *No* active knee extension exercises for patellofemoral lesions
- *No* closed kinetic chain exercises for femoral condyle lesions

Functional Activities
- Gradual return to daily activities
- If symptoms occur, reduce activities to reduce pain and inflammation
- Avoid extended standing

Swelling Control
- Ice, elevation, compression, and edema modalities as needed to decrease swelling

Criteria to Progress to Phase II
- Full passive knee extension
- Knee flexion to 120 degrees
- Minimal pain and swelling

Phase II: Transition Phase (Weeks 6-12)

Goals
- Gradually increase range of motion and weight bearing to full
- Gradually improve quadriceps strength/endurance
- Gradually increase functional activities

Brace
- Discontinue brace at 6 weeks, consider unloading brace for femoral condyle lesions

Weight Bearing
- Progress weight bearing as tolerated
- For femoral condyle lesions: 75% body weight with crutches at 6-7 weeks, progress to full weight bearing at 8-10 weeks; may need to delay full weight bearing up to 14 weeks if large lesion; discontinue crutches at 8-10 weeks
- For patellofemoral lesions, progress to full weight bearing and discharge crutches at 6-8 weeks

Range of Motion
- Gradually increase range of motion
- Maintain full passive knee extension
- Progress knee flexion to 125-135 degrees by week 8-10
- Continue patellar mobilization and soft tissue mobilization, as needed
- Continue stretching program

Strengthening Exercises
- Initiate weight shifts at week 6-8 for femoral condyle lesions
- Initiate minisquats 0-45 degrees at week 6-8 for patellofemoral lesions
- Closed kinetic chain exercises (leg press) at weeks 8-10 for femoral condyle lesions: minisquats 0-45 degrees, front lunges, step-ups, wall squats; may need to delay closed kinetic chain up to 14 weeks if large lesion
- Leg press at week 8-10 (0-90 degrees for femoral condyle, 0-60 degrees for patellofemoral, progressing to 0-90 degrees as tolerated)
- Toe-calf raises at week 10-12
- Progress to active knee extension: begin resistance with femoral condyle lesions progressing 1 lb every 10-14 days; for patellofemoral lesions, begin with 0-30 degrees at week 12 and progress to deeper angles as tolerated
- Stationary bicycle (gradually increase time)
- Balance and proprioception drills
- EMS and biofeedback as needed
- Use of pool for gait training and exercise

Continued

TABLE 33-4 Rehabilitation After Osteochondral Autograft Transplantation—cont'd

Functional Activities
- As pain and swelling (symptoms) diminish, the patient may gradually increase functional activities
- Gradually increase standing and walking

Criteria to Progress to Phase III
- Full range of motion
- Acceptable strength levels:
  - Hamstrings within 20% of contralateral leg
  - Quadriceps within 30% of contralateral leg
- Balance testing within 30% of contralateral leg
- Able to bike for 30 minutes

Phase III: Remodeling Phase (Weeks 12-26)

Goals
- Improve muscular strength and endurance
- Increase functional activities

Range of Motion
- Patient should exhibit 125-135 degrees of flexion; no restrictions

Exercise Program
- Continue progressing exercises
- Leg press 0-90 degrees
- Bilateral squats (0-60 degrees)
- Unilateral step-ups progressing from 2 to 8 inches
- Forward lunges
- Begin walking program on treadmill
- Open kinetic chain knee extension (0-90 degrees) as tolerated, do not progress to heavy resistance with patellofemoral lesions; must monitor symptoms of pain and crepitus
- Bicycle
- Stair-climbing machine
- Swimming
- Ski or elliptical machine

Functional Activities
- As patient improves, increase walking (e.g., distance, cadence, incline)

Maintenance Program
- Initiate at weeks 16-20
- Bicycle, low resistance
- Progressive walking program
- Pool exercises for entire lower extremity
- Straight-leg raises into flexion
- Leg press
- Wall squats
- Hip abduction/adduction
- Front lunges
- Stretch quadriceps, hamstrings, gastrocnemius

Criteria to Progress to Phase IV
- Full nonpainful range of motion
- Strength within 80%-90% of contralateral extremity
- Balance and/or stability within 75%-80% of contralateral extremity
- No pain, inflammation, or swelling

Phase IV: Maturation Phase (Weeks 26-52)

Goals
- Gradual return to full unrestricted functional activities

Exercises
- Continue maintenance program progression 3-4 times/wk
- Progress resistance as tolerated
- Emphasis on entire lower extremity strength and flexibility
- Progress agility and balance drills
- Impact-loading program specialized to patient demands
- Progress sport programs depending on patient variables

Functional Activities
- Patient may return to various sport activities as progression in rehabilitation and cartilage healing allows. In general, low-impact sports such as skating, rollerblading, and cycling are permitted at about 6-8 months. Higher-impact sports such as jogging, running, and aerobics may be performed at 8-10 months. High-impact sports such as tennis, basketball, and baseball are allowed at 12-18 months.

weight bearing is initiated for patellofemoral lesions with a drop-lock knee brace and progressed to full without the brace at approximately 6 to 8 weeks postoperative.

ROM during the early protective phase is gradually progressed to ensure that adhesion formation and loss of motion is avoided. Owing to the large incision and invasive nature of the procedure, motion is progressed gradually to minimize effusion formation.

Exercises are progressed from non-weight-bearing, such as quadriceps sets and multiangle straight leg raises, to gentle weight bearing in a restricted weight tolerance after week 6.

During the transition phase, full ROM and weight bearing are achieved typically between weeks 8 to 10, although larger lesions may need to further delay the progress to full weight bearing for up to 12 to 14 weeks. At this point, the strengthening program is progressed to include weight-bearing CKC and machine exercises. Again, during this phase, patients return to low-impact functional activities.

During the remodeling and maturation phases, strength, proprioception, and neuromuscular control are enhanced while impact-loading stresses are gradually applied as tolerated without an increase in symptoms. Patients may return to various sport activities as progression in rehabilitation and cartilage healing allows, although this is more delayed than the previously discussed rehabilitation progressions. Generally, low-impact sports such as golf, swimming, cycling, and walking for exercise are permitted at 4 to 5 months postoperatively. Moderate-impact sports such as tennis and hiking are permitted at 6 to 8 months (depending on size and location of the lesion). The return to high-impact sports is controversial, although some clinicians allow sports such as jogging, running, and aerobics at 8 to 10 months and tennis, basketball, and baseball at 12 to 18 months. There are too few studies to indicate the long-term success in allowing the return to strenuous activities, which may risk deterioration of the reparative cartilage.

Clinical outcome results after OAT indicate good results.[1,30,52] Hangody and Fules[31] followed 831 patients and reported a good to excellent result in 92% of those who exhibited a lesion of the femoral condyle, and the same in 87% with a tibial plateau lesion. Lesions of the patella rendered the lowest outcomes, with only 79% exhibiting a good to excellent result. Furthermore, these authors reported a 3% rate of donor site morbidity. Lastly, 36 patients exhibited a painful postoperative hemarthroses. Bartha and coworkers[2] reported on 89 patients

who underwent second-look arthroscopy, 77% of whom exhibited congruent surfaces and healing of the lesion.

Autologous Chondrocyte Implantation Procedure

The rehabilitation program after ACI, and the newer matrix-induced ACI procedures,[9,41] is vital to the success and long-term outcomes of patients (Table 33-5). Early controlled ROM and weight bearing are necessary to stimulate chondrocyte development, although caution is placed on overaggressive activities that may result in cell damage or graft delamination.

Knowledge of the biologic healing response is vital for the development of appropriate rehabilitation guidelines. Rehabilitation may begin as early as the recovery room in the form of CPM. At this time, the chondrocytes are aligned and attached to the underlying surface.[67] It is imperative that the patient be appropriately positioned to allow for the effect of gravity to evenly distribute the chondrocytes on the base of the defect during these first 4 hours as the cells adhere to the surface. A study by Sohn and associates[67] showed that the defect orientation during these first 4 hours can be an important factor in the uniformity of cell distribution in the ACI procedure. These authors advanced the hypothesis, which has not yet been proved clinically, that the effects of gravity within the first few hours of cell implantation could lead to localization of induced cells in one area of the graft but not in other areas, which may affect healing of the defects. This suggests two possibilities. First, the position of the patient with a patellar defect in the prone position would contraindicate CPM because it

TABLE 33-5 Rehabilitation After Autologous Chondrocyte Implantation

Phase I: Early Protection Phase (Weeks 0-6)

Goals

- Protect healing tissue from load and shear forces
- Decrease pain and effusion
- Restore full passive knee extension
- Gradually improve knee flexion
- Regain quadriceps control

Brace

- Locked at 0 degrees during weight-bearing activities
- Sleep in locked brace for 2-4 weeks

Weight Bearing

- Weight-bearing status varies based on lesion location and size
- For femoral condyle lesions: non–weight bearing for 1-2 weeks, may begin toe-touch weight bearing immediately per physician if lesion <2.0 cm^2; begin toe-touch weight bearing (~20-30 lb) at weeks 2-3; progress to partial weight bearing (~25% body weight) at weeks 4-5
- For patellofemoral lesions: immediate toe-touch weight bearing of ~25% body weight with brace locked in full extension; progress to 50% weight bearing at week 2 and 75% weight bearing at weeks 3-4 with brace locked in full extension

Range of Motion

- Immediate motion exercise on day 1
- Immediate full passive knee extension
- Initiate continuous passive motion day 1 for total of 8-12 hr/day (0-60 degrees; if patellofemoral lesion >6.0 cm^2, 0-40 degrees)
- Progress continuous passive motion range of motion as tolerated 5-10 degrees/day
- May continue continuous passive motion for total of 6-8 hr/day for up to 6 weeks
- Patellar mobilization (4-6 times/day)
- Motion exercises throughout the day
- Passive knee flexion range of motion at least 2-3 times/day
- Passive knee range of motion as tolerated
- For femoral condyle lesions, knee flexion range of motion goal is 90 degrees by 1-2 weeks, 105 degrees at week 3, 115 degrees at week 4, and 120-125 degrees by week 6
- For patellofemoral lesions, knee flexion range of motion goal is 90 degrees by weeks 2-3, 105 degrees by 3-4 weeks, and 120 degrees by week 6
- Stretch hamstrings and calf

Strengthening Program

- Ankle pump using rubber tubing
- Quadriceps setting
- Multiangle isometrics (cocontractions quadriceps/hamstring)
- Active knee extension 90-40 degrees for femoral condyle lesions (no resistance)
- Straight-leg raises (four directions)
- Stationary bicycle when range of motion allows; low resistance
- EMS and/or biofeedback during quadriceps exercises
- Isometric leg press at week 4 (multiangle)
- Use of pool for gait training and exercises at week 4
- Initiate weight shifting exercises with knee in extension at weeks 2-3 for patellofemoral lesions
- *No* active knee extension exercises for patellofemoral lesions

Functional Activities

- Gradual return to daily activities
- If symptoms occur, reduce activities to reduce pain and inflammation
- Avoid extended standing

Swelling Control

- Ice, elevation, compression, and edema modalities as needed

Criteria to Progress to Phase II

- Full passive knee extension
- Knee flexion to 120 degrees
- Minimal pain and swelling
- Voluntary quadriceps activity

Phase II: Transition Phase (Weeks 6-12)

Goals

- Gradually increase range of motion
- Gradually improve quadriceps strength/endurance
- Gradual increase in functional activities

Brace

- Discontinue brace at week 6
- Consider unloading knee brace for femoral condyle lesions

Weight Bearing

- Progress weight bearing as tolerated
- For femoral condyle lesions: 50% body weight with crutches at 6 weeks; progress to full weight bearing at 8-9 weeks, discontinue crutches
- For patellofemoral lesions: progress to full weight bearing at weeks 6-8, discontinue crutches

Continued

TABLE 33-5 Rehabilitation After Autologous Chondrocyte Implantation—cont'd

Range of Motion
- Gradual increase in range of motion
- Maintain full passive knee extension
- Progress knee flexion to 125-135 degrees by week 8
- Continue patellar mobilization and soft tissue mobilization, as needed
- Continue stretching program

Strengthening Exercises
- Progress to closed kinetic chain exercises
- Initiate weight shifts at week 6 for femoral condyle lesions
- Leg press at weeks 7-8
- Minisquats 0-45 degrees at week 8
- Toe-calf-raises at week 6 for patellofemoral lesions, week 8 for femoral condyle lesions
- Progress to balance and proprioception drills
- Initiate front lunges, wall-squats, front and lateral step-ups at weeks 8-10
- For femoral condyle lesions, progress open kinetic chain knee extension, 1 lb/wk
- For patellofemoral lesions, may begin open kinetic chain knee extension without resistance in a range of motion that does not allow for articulation of the lesion
- Stationary bicycle, low resistance (gradually increase time)
- Treadmill walking program at week 10-12
- EMS and/or biofeedback as needed
- Pool for gait training and exercise

Functional Activities
- As pain and swelling (symptoms) diminish, the patient may gradually increase functional activities
- Gradually increase standing and walking

Criteria to Progress to Phase III
- Full range of motion
- Acceptable strength level:
  - Hamstrings within 20% of contralateral leg
  - Quadriceps within 30% of contralateral leg
- Balance testing within 30% of contralateral leg
- Able to walk 1-2 miles or bike for 30 min

Phase III: Remodeling Phase (Weeks 12-26)
Goals
- Improve muscular strength and endurance
- Increase functional activities

Range of Motion
- Patient should exhibit 125-135 degrees of flexion

Exercise Program
- Leg press (0-90 degrees)
- Bilateral squats (0-60 degrees)
- Unilateral step-ups progressing from 2 to 8 inches
- Forward lunges
- Walking program
- Progress to open kinetic chain extension (0-90 degrees), for patellofemoral lesions perform from 90-40 degrees or avoid angle where lesion articulates; progress 1 lb every 2 weeks beginning week 20 if no pain or crepitus; must monitor symptoms
- Continue progressing balance and proprioception
- Bicycle
- Stair-climbing machine
- Swimming
- Ski or elliptical machine

Functional Activities
- As patient improves, increase walking (e.g., distance, cadence, incline)

Maintenance Program
- Initiate at weeks 16-20
- Bicycle; low resistance, increase time
- Progressive walking program
- Pool exercises for entire lower extremity
- Straight-leg raises
- Leg press
- Wall squats
- Hip abduction/adduction
- Front lunges
- Step-ups
- Stretch quadriceps, hamstrings, calf

Criteria to Progress to Phase IV
- Full nonpainful range of motion
- Strength within 80%-90% of contralateral extremity
- Balance and/or stability within 75%-80% of contralateral extremity
- No pain, inflammation, or swelling

Phase IV: Maturation Phase (Weeks 26-52)
Goals
- Gradual return to full unrestricted functional activities

Exercises
- Continue maintenance program progression 3-4 times/wk
- Progress resistance as tolerated
- Emphasis on entire lower extremity strength and flexibility
- Progress agility and balance drills
- Impact-loading program specialized to patient demands
- Progress to sport programs depending on patient variables

Functional Activities
- Patient may return to various sport activities as progression in rehabilitation and cartilage healing allows. In general, low-impact sports such as swimming, skating, rollerblading, and cycling are permitted at about 6 months. Higher-impact sports such as jogging, running, and aerobics may be performed at 8-9 months for small lesions or 9-12 months for larger lesions. High-impact sports such as tennis, basketball, football, and baseball are allowed at 12-18 months.

would produce an abnormal gravity effect. Second, the use of CPM immediately after surgery is warranted to produce a "more even distribution of implanted cells within the defect." At present, no in vivo or clinical studies have been published to support this hypothesis.

Proliferation of the chondrocytes occurs in the first 6 weeks after cell implantation. During the first 24 hours after cell implantation, the cells line the base of the lesion and multiply several times to produce a matrix that will fill the defect with a soft repair tissue up to the level of the periosteal cover.[28,57] At this time, PROM and controlled partial weight bearing will help to promote cellular nutrition through synovial fluid diffusion as well as provide the proper stimulus for the cells to produce specific matrix markers. During this initial phase, controlled PROM and a gradual weight-bearing progression are two of the most important components of the rehabilitation process.

Immediate toe touch weight bearing is performed in knees with smaller lesions, progressing to 25% body weight at weeks 2 to 4, 50% body weight at weeks 5 to 6, and full weight bearing at week 8. This progression may be delayed approximately 2 weeks, with 2 weeks of non–weight bearing, if the lesion is large, deep, or uncontained. For lesions within the patella or trochlea, the patient is allowed to bear weight as tolerated immediately after surgery with a brace locked in full extension. ROM is progressed cautiously to avoid swelling similar to the OAT procedure, with at least 90 degrees of flexion at week 1, 105 degrees at weeks 2 to 3, 115 degrees at week 4, and 125 degrees at week 6. Early strength and proprioceptive exercises are performed within the patient's weight-bearing status.

During the transition phase, which includes weeks 7 through 12, the repair tissue is spongy and compressible with little resistance. Upon arthroscopic examination, the tissue may in fact have a wavelike motion when a probe is slid over the tissue.[28,57] During this phase, the patient achieves full ROM and progresses from partial to full weight bearing. Continued maturation of the repair tissue is fostered through higher level functional and motion exercises. CKC exercises, such as front lunges, step-ups, and wall-squats are performed as well as machine exercises for the entire lower extremity. Again, caution should be placed on exercises that produce sheer forces in patients with patellofemoral lesions.

The remodeling phase occurs from 12 weeks through 32 weeks postoperatively. During this phase, there is a continuous production of matrix with further remodeling into a more organized structural tissue. The tissue at this point has the consistency of soft plastic upon probing.[28,57] As the tissue becomes more firm and integrated, it allows for more functional training activities to be performed as well as elliptical, bicycle, and a gradual walking program.

The final maturation phase can last up to 15 to 18 months depending on the size and location of the lesion. During this phase, the repair tissue reaches its full maturation. The stiffness of the cartilage resembles that of the surrounding tissue.[28,57] The duration of this phase varies based on several factors such as lesion size and location.

Basic science studies have shown that it may take up to 6 months for the graft site to become firm and at least 9 months to become as durable as the surrounding healthy articular cartilage.[28,57] Thus, low-impact activities (such as golf, swimming, cycling, and walking) are initiated by months 5 to 6 and progressed to moderate-impact activities (such as tennis, hiking, skating) from months 7 to 9 as tolerated. Usually, high-impact activities such as running and skiing are permitted with a gradual return beginning at 11 to 12 months postoperative.

The results of clinical outcomes after ACI are encouraging.[5,25,33,40,45,46] Mithofer and colleagues[47] reported a 72% good to excellent result and return to play in competitive soccer players, with 80% returning back to the same level of play. Peterson and coworkers[56] reported a 90% good to excellent result using ACI on osteochondritis dissecans lesions of the knee in patients with a mean age of 26.4 years (range, 14-52 years).

CONCLUSION

The rehabilitation process after articular cartilage repair procedures is vital to the long-term success and functional outcome of the patient. The rehabilitation programs discussed are performed based on current understanding of articular cartilage and the natural healing response observed after articular cartilage repair procedures. Rehabilitation is based on several key principles designed to facilitate the repair process by creating a healing environment while avoiding deleterious forces that may overload the healing tissue. It is imperative that these principles be incorporated into the rehabilitation process along with the knowledge of the basic science and maturation process of each specific repair procedure. The medical team should consider the long-term results of the patients and functional outcomes at 1, 2, and 5 years after the surgical procedure. It is not important how quickly you may return a patient to running or sports; in fact it may be detrimental in many cases. It is more important that the procedure withstands the test of time. The basic principles outlined in this chapter may be applied and integrated as the understanding and clinical use of the next generation of procedures continue to evolve. Long-term clinical studies are needed to determine the effectiveness for each of the surgical techniques and postoperative rehabilitation programs discussed in this chapter.

INTRODUCTION

Water has been used for healing, spiritual, and religious purposes since at least 2400 BC.[17] Water was used by the people of Asia to combat fevers as early as 1500 BC. Hippocrates (460-375 BC) used water for relief of muscle spasms and joint pain.[25] For many years, water exercise was dismissed as a medical intervention and considered to be purely recreational. The advent of spas in Europe and around the world moved water-based interventions into the leisure and recreation category, making reimbursement for water-based medical interventions difficult.

Despite a history spanning over 4000 years, a resurgence of aquatics as an intervention has occurred in the past quarter century. Throughout this history, many different terms have been used to describe rehabilitation that takes place in water. Some of these terms include *hydrotherapy, aquatic therapy, spa therapy, water therapy, water gymnastics, balneotherapy* and *pool therapy*. The term *balneotherapy* is distinguished from other forms of hydrotherapy. Balneotherapy refers to the use of hot-water or thermal treatments to decrease pain and stiffness and promote muscle relaxation. Balneotherapy often uses minerals, salts, or sulfur treatments, mud packs, and water jets to achieve these goals. *Hydrotherapy* is a general term covering any type of water intervention, which might include balneotherapy or exercise. For the purposes of this chapter, the focus remains on the use of exercise in water for the treatment of knee arthritis. For further information on balneotherapy, the reader is referred to Verhagen and coworkers.[45]

Physical therapy for patients with knee arthritis focuses on decreasing pain while improving mobility, muscle performance, motor control, and function. This is often achieved through stretching, strengthening, and balance exercises. However, many patients are unable to perform these exercises on land owing to pain, comorbidities, or other limitations. These patients often do well in an unweighted environment where they are able to perform full range of exercises directed at improved function.[44] Preferably, exercises are not confined to a single environment but represent a comprehensive program of both land-based and water-based rehabilitation. It is not suggested that aquatic rehabilitation results in superior outcomes compared with land-based rehabilitation. Rather, the pool provides an effective, safe alternative for those who cannot tolerate a comprehensive rehabilitation program on land.

The purpose of this chapter is to discuss the scientific basis for rehabilitative exercise in the water, and then apply this information to the treatment of patients with knee arthritis. Understanding the physical properties of water is critical for building a successful rehabilitation program in water. This understanding is both cognitive and kinesthetic. The reader is encouraged to experiment with these properties to fully understand how the body responds differently to exercises in water compared with land.

SCIENTIFIC FOUNDATION

The scientific foundation for aquatic rehabilitation in patients with arthritic knees is found in two major areas. The first is the basis in aqua physics in which two key forces are critical for treatment planning. The first force is that of buoyancy. Buoyancy is used to unweight an arthritic extremity, normalize gait, and increase pain-free exercise. Buoyancy can also be used as resistance depending on equipment choices and patient positioning. The second force is that of viscosity. Viscosity is used to provide resistance for strengthening muscles from the core to the foot and to provide postural challenges that improve balance. The second major scientific foundational area is that of clinical research in which aquatic rehabilitation has been shown to increase measures of physical performance and to improve patient outcomes.

CRITICAL POINTS Scientific Basis

- Buoyancy can unweight an arthritic joint while permitting rehabilitation activities to continue.
- The precise amount of weight bearing at any given depth is unknown and is related to the individual's body composition and speed of movement.
- Buoyancy can assist, support, or resist a movement depending on how the individual is oriented in the water.
- Viscosity can always override buoyancy as resistance if the surface area and speed are great enough.
- Hydrostatic pressure can minimize swelling and edema in the lower limb that can occur with land-based exercise.
- Hydrostatic pressure causes a centralization of peripheral blood flow with subsequent changes in the pulmonary and heart blood volumes.
- Heart rates for exercise while immersed to the neck will be approximately 20 beats/min lower than comparable land-based exercise owing to hydrostatic pressure.

FIG 34-1 Standing hip extension from 0 to 15 degrees of extension. This is a buoyancy-assisted exercise with a short moment arm, making it a less effective exercise for gluteal muscle strengthening.

Aqua Physics

The principles supporting the use of water in rehabilitation are based in physics. Several physical properties of water are key to understanding how water is a useful exercise mode for people with arthritis of the knee. Capitalizing on these properties can increase the opportunity for a successful outcome for these patients with complicated problems. Failure to recognize or understand how these principles work in harmony or in opposition can lead to poor outcomes. The key properties include buoyancy, hydrostatic pressure, and viscosity.

Buoyancy

Buoyancy is the upward thrust experienced during immersion that is in direct opposition to gravity. Buoyancy is used to unload the lower extremity from the effects of gravity, making it a useful tool for those with knee arthritis. Archimedes' principle states that an immersed body, at rest, experiences an upward thrust equal to the weight of the same fluid volume it displaces.[6]

Buoyancy is related to a person's specific gravity (SG), which varies with body composition. Any object with an SG of less than 1.0 g/cm^2 will float, whereas any object with an SG greater than 1.0 g/cm^2 will sink. This property forms the basis of underwater weighing to determine body composition. Because lean body mass is heavier than fat mass, those with high lean body mass tend to sink, and those with greater fat mass float. This fact makes it difficult to know precisely how much weight bearing any given individual is achieving at a given water depth. Harrison and Bulstrode[22] performed studies on percentage weight bearing during static standing in various water depths ranging from the hips to the neck. The authors found considerable variability in the amount of weight bearing with immersion at various depths. This variation might have been partly caused by using a fixed-depth pool and only nine subjects. However, the disparity may also be the result of differences in body composition and body fat distribution among individual study subjects, suggesting that weight-bearing prescription is difficult in this medium. A follow-up study by Harrison and associates[23] showed that compared with static standing, fast walking increased weight-bearing forces up to 76%. Understanding Archimedes' principle highlights the difficulties in assigning a specific percentage of weight bearing at any given depth; the weight on the limb will vary with body composition and speed of movement.

The moment of buoyancy is also important in exercise prescription. As with moments of gravity on land, the moment of buoyancy increases with increasing lever arm length and nearer the parallel. If the movement is in an upward direction, the same direction as the force of buoyancy, the activity is considered to be *buoyancy assisted*. If the movement in toward the pool bottom in opposition to buoyancy, it is considered to be *buoyancy resisted*. Movements parallel to the bottom that are neither assisted nor resisted by buoyancy are considered *buoyancy-supported* exercises. For example, in a standing position, a straight-leg lift forward would be assisted by buoyancy, whereas the return motion back to the neutral position would be buoyancy resisted. In a supine position, hip abduction and adduction would be buoyancy-supported activities. An important application of this information is strengthening hip extensor muscles. In a standing position, the motion of hip extension from neutral to 15 degrees extension (the normal range of hip extension) occurs through such a small range of motion (ROM), with a short moment arm, and is buoyancy assisted, making the exercise a little more than a gluteal isometric exercise (Fig. 34-1). However, the motion from 90 degrees of hip flexion returning to neutral is also hip extension but is now moving through a larger range with a longer moment arm against the upward force of buoyancy, making this an effective hip extensor muscle-strengthening exercise (Fig. 34-2).

Hydrostatic Pressure

Pascal's law states that a fluid exerts pressure equally on an object at a given depth.[6] Hydrostatic pressure increases with a greater depth of immersion owing to the weight of the volume of fluid overhead. The increased hydrostatic pressure close to the bottom of the pool assists venous return to the heart and prevents fluid accumulation in the lower extremities. This is useful for people with knee or ankle arthritis, who tend to experience swelling with exercise. The increased venous return to the heart also affects the cardiorespiratory system. The hydrostatic pressure when the body is immersed to the neck produces an increase in heart volume, intrapulmonary blood volume, right atrial pressure, left ventricular end-diastolic volume, stroke volume, and cardiac output.[1,11] Heart rate is unchanged or decreased compared with similar land-based activities.[1] Peripheral circulation and vital capacity are decreased.[11] This cardiopulmonary response is significant for people with cardiorespiratory conditions and for those who are trying to achieve training heart rates in deep-water exercise.[21] These changes have been noted in people both with and without cardiac disease.[12,13] Aerobic exercise in neck-deep water will result in heart rates that are

FIG 34-2 Hip extension from 90 degrees of flexion to neutral is a buoyancy-resisted exercise with a longer moment arm, making it a more effective gluteal muscle-strengthening exercise.

FIG 34-3 Note the area of high pressure anteriorly and the area of low pressure evidenced by eddies formed in the wake.

approximately 17 to 20 beats/min lower than comparable land-based exercise.[2,20,38,42]

Viscosity and Hydrodynamics: Using Speed and Surface Area

The *viscosity* of a fluid is its resistance to adjacent fluid layers sliding freely by one another.[6] Viscosity causes a resistance to flow when a body is moving through the water. As such, viscosity is clinically insignificant when a body is stationary. The viscous quality of water allows it to be used effectively for resistance because of its *hydrodynamic properties*, or fluid mechanics. The key hydrodynamic properties are turbulence and drag.[40] Turbulent flow occurs when the speed of movement of an object (or person or body part) reaches a critical velocity or when the flow of water encounters an object (or person or body part).[3] In turbulent flow, resistance is proportional to the velocity squared, and increasing the speed of movement significantly increases the resistance.[32] Eddies are formed in the wake behind the moving body, creating drag that is greater in the unstreamlined object than in a streamlined object (Fig. 34-3).

When moving through the water, the body experiences a frontal resistance proportional to the presenting surface area. Resistance can be increased by enlarging the surface area (Fig. 34-4). For example, walking forward or backward will produce greater drag in most people than walking sideways because of the greater surface area. Increasing the surface area or otherwise increasing drag increases the resistance to movement. The clinician has two variables to alter resistance produced by viscosity: the velocity of movement and the surface area or streamlined nature of the object.

Several areas of research provide evidence for examining the impact of surface area and speed on force production. Law and Smidt[27] used Hydrotone bells (Hydro-Tone Fitness Systems, Inc.) at different speeds and angles to assess the impact on force production. Results showed a 50% increase in force production at fast speeds. Force also increased at fast speeds when the bells were oriented at 45 degrees compared with 0 degrees. Orientation had no impact on force production when performed at slow speeds. Therefore both speed and surface area influence force production when using viscosity.

Similar increases in drag were noted when using the Hydrotone boots compared with a barefoot condition.[33] In a series of studies, Poyhonen and coworkers[32-34] found that increasing the surface area of the lower leg significantly increased the level of water resistance. Interestingly, electromyographic (EMG) activity of the knee flexors and extensors was similar between barefoot and increased surface area conditions despite the increased drag caused by the boot. This EMG finding was the result of self-selected speed changes by the subjects. Speed was uncontrolled in the study, and subjects performed the exercise faster in the barefoot condition. This reinforces how similar muscle activation can be obtained by manipulating speed and/or surface area when using viscosity as the primary resistance. Both strategies will overload the muscle, allowing the exercise prescription to be specific to each patient's needs.

FIG 34-4 Adding the plow increases the surface area and creates additional drag.

Electromyographic data has also been used to examine the relationship between muscle activation and speed in the shoulder musculature. Data from the deltoid and rotator cuff musculature were captured during arm elevation at three different speeds (30, 45, and 90 degrees/sec) on land and in the water.[26] The percent maximum voluntary contraction was consistently higher on land at the two slowest speeds but higher in the water at 90 degrees/sec, highlighting the positive relationship among viscosity, speed, and force generation.

Research in the cardiopulmonary effects of speed on exertion measures also supports the positive relationship between speed and work in the water. Whitley and Schoene[47] examined walking on land and in the water at four different speeds. Heart rates were significantly higher after water-walking versus treadmill walking at all four speeds. In addition, heart rates rose significantly with each increasing speed in water-walking, suggesting increasing cardiopulmonary workloads at increasing speeds. Cassady and Nielsen[10] measured oxygen consumption during calisthenic arm and leg exercises at three different speeds on land and in the water. They also found increasing heart rate with increasing speed of exercise in the water. The higher metabolic cost of exercises at a faster speed supports the theory of increased work at faster speeds in the water.

CLINICAL RESEARCH

Clinical research has supported the effectiveness of aquatic rehabilitation for persons with knee arthritis. A study examining outcomes following a water-based program for patients with lower limb osteoarthritis found that group-based water exercise classes over 1 year produced significant reductions in pain and improvements in function.[14] A randomized, controlled trial (RCT) compared the effects of a water-based resistance program with a land-based program on function and strength in patients with osteoarthritis of the hip or knee.[18] The authors found improvements in strength and function in both the land- and the water-based groups as compared with the control group. Compliance rates were 84% for water therapy and 75% for land therapy. In a similar study, Wyatt and coworkers[48] examined change in function following a land-based or an aquatic exercise program in patients with knee osteoarthritis. Both groups showed significant improvements in measures of ROM, thigh girth, pain scales, and 1-mile walk test. However, the aquatic group had significantly lower pain levels than the land group. These results reinforce that patients can improve strength and function effectively in either a land or aquatic environment.[48,39] The key is the ability to provide a comprehensive and sustainable program, whether on land, in the water, or some combination of both. Ongoing exercise at the conclusion of formal rehabilitation is essential to prevent symptom recurrences.

Addressing the issue of compliance with a rehabilitation program, Hinman and colleagues[24] performed an RCT randomly assigned 71 participants with hip or knee osteoarthritis to 6 weeks of aquatic physical therapy or no physical therapy. Patients in the aquatic physical therapy program had less pain and joint stiffness and greater physical function, quality of life, and hip muscle strength than the control group. Nearly 75% of participants reported improvements in pain and function compared with 17% in the control group. More important, 84% of participants continued the aquatic program independently at the conclusion of the study. The chronic nature of osteoarthritis requires ongoing participation in an exercise program at the conclusion of formal rehabilitation.[7]

Although the previous study compared aquatic physical therapy with no physical therapy, Fransen and coworkers[19] compared hydrotherapy with ai chi or a control group in an RCT of 152 patients with hip or knee osteoarthritis. Results showed that both hydrotherapy and ai chi participants improved in the pain and physical function subscales of the Western Ontario and McMaster Osteoarthritis Index (WOMAC), but only the hydrotherapy group achieved significant improvements in the physical performance measures of the Short-Form-12 item questionnaire (SF-12). In addition, compliance with the hydrotherapy classes was higher than compliance with ai chi.

Pools are expensive to maintain and operate. An RCT examined the cost-effectiveness of water-based therapy for lower limb osteoarthritis. A group of 312 patients with hip or knee osteoarthritis was randomized into control and water exercise groups. The control group received usual care, and the intervention group received aquatic exercise for 1 year with follow-up for an additional 6 months. Results showed a favorable cost/benefit ratio as measured by a reduction in WOMAC pain as the measure of benefit.

Structured aquatic physical therapy for patients with knee arthritis is gaining momentum, with evidence supporting the clinical and cost-effectiveness of this intervention in this population. Outcomes following aquatic physical therapy appear to be similar to land-based rehabilitation, making the pool a viable alternative for those who are unable to rehabilitate on land or who have a preference for aquatic based exercise.[4,5,16,35]

APPLICATIONS

Although patients with knee arthritis have individualized problems and differing comorbidities, some generalizations about preferred applications in this population can be made based on the pathology and commonly associated limitations. A thorough examination is the foundation for determining the appropriate exercise intervention. Awareness of the interrelationships among lower extremity joints and the spine can ensure proper positioning and targeting of the tissue of interest. Altering the position of the hip or foot can significantly affect the loads across the knee. The following discussion is meant to provide examples of how the physical properties of water can be exploited to improve function in patients with knee osteoarthritis.

Mobility

Many activities typically performed on land can be modified, adapted, and used in the pool. *Mobility* has both a static component and dynamic. Functional mobility requires both appropriate soft tissue extensibility, achieved through stretching exercises, and dynamic mobility, achieved through a combination of stretching, strengthening, balance, and neuromuscular retraining.

Soft tissue stretching exercises are readily and easily performed in the pool. Many patients with arthritis have difficulty stretching on land owing to the positions or postures required. For example, some individuals are unable to get up and down off the floor or lack a sufficient supportive surface to perform the exercises appropriately. Some stretches require bending, twisting, reaching, or have weight-bearing components that patients are unable to accomplish on land. For

CRITICAL POINTS Applications

- Stretching is readily performed in the pool because positioning is simple and gravity is minimized.
- Stretching can be performed in functional upright positions using buoyant equipment or stationary features of the pool.
- Static stretching should be combined with dynamic mobility exercises for functional mobility.
- Buoyancy, viscosity, or the water's hydrodynamic principles can be used for improving muscle performance.
- Rapid direction changes can be used to challenge buoyancy and elicit eccentric muscle contractions.
- A variety of arm and trunk movements can be used to challenge dynamic balance.
- The water- and land-based programs can be progressed in tandem, with an eye to the long-term medium that will best support a lifetime of exercise.

example, hamstring or quadriceps muscle stretches often require balancing on a single leg or getting up and down off the floor. Many of these exercises are easily performed in the pool with stationary or buoyant equipment. The water's warmth and support from buoyancy make it easier and more relaxing to achieve a successful stretch.

As on land, muscles crossing both the hip and knee or both the knee and ankle are stretched together. Thus the position of the adjacent joint becomes important. Because many of the stretches use buoyancy, it is easy to adjust the stretch to decrease stress on the joints and emphasize the soft tissue component.

Key muscles to be stretched in patients with knee arthritis include the gastrocnemius and soleus muscles as well as the quadriceps, hamstring, lateral hip (iliotibial band), and gluteal/buttock muscles (Figs. 34-5 to 34-7). As with stretching exercises on land, the intensity should be subjectively between "low" and "medium" and should be pain free. The patient should feel stretching in the muscle of interest and not in the joint itself. The patient should be able to hold the stretch for 60 seconds without an increase in pain.[3] Repeat the stretches for two to three repetitions.

FIG 34-5 Hamstring stretching using a noodle. Other stationary equipment in the pool can also be used for stretching.

Dynamic mobility is easily accomplished in the pool. Dynamic mobility has been advocated as an appropriate means to increase functional mobility because it requires not only static flexibility but also strength, balance, and neuromotor coordination.[29] Dynamic mobility activities in the pool take place in a gravity-lessened environment, which decreases joint-loading forces. The water's viscosity also slows movement and increases the reaction time for patients with balance difficulties. This property makes the pool a safe environment for such individuals.

Dynamic mobility activities can easily replicate similar activities performed on land. Walking forward with varying speed and step length can be modified to emphasize lower extremity mobility. Cue the patient for increased knee flexion and extension during the swing phase of gait. Ankle or hip mobility can be similarly cued to increase sagittal plane mobility. Backward walking is useful for increasing dynamic knee flexion because increased knee flexion is required to clear the ground during walking this direction. Frontal plane mobility is emphasized by walking sideways.

Other dynamic mobility activities include marching in place and marching across the pool. Vary the amount of hip and knee flexion based on the patient's needs. Marching does not need to proceed in a straight line but can be on a diagonal to encourage more functional movement patterns. Proprioceptive neuromuscular facilitation (PNF) patterns also encourage functional movement patterns in the lower extremity. Cueing the patient appropriately can emphasize motion at the knee joint when tolerated. For closed-chain dynamic mobility, perform squats for hip, knee, and ankle mobility in shallow water or fully flex the hips and knees by flexing and extending these joints at a ladder (Fig. 34-8). These closed-chain activities can be progressed by asking the patient to lunge during ambulation.

Dynamic mobility of other joints in the kinetic chain such as the hip and low back is necessary to accommodate potential motion losses at the knee. Motions out of the straight plane such as figure-of-eights or other movement patterns can enhance mobility at these joints. Ai chi exercise stresses balance, stability, and mobility throughout the kinetic chain (Figs. 34-9 and 34-10).

Dynamic mobility can also be performed non–weight bearing. Bicycling or running with a belt or a noodle is a good way to perform repeated hip and knee flexion and extension. The range of movement can be modified as needed for any given patient. Similarly, deep-water

FIG 34-6 Lateral hip stretching. Start in the hamstring stretch position, then horizontally adduct approximately 15 degrees and internally rotate.

FIG 34-7 Quadriceps muscle stretching with a noodle.

FIG 34-8 Knee-to-chest stretching on a ladder.

FIG 34-9 Ai chi balancing pattern of hip extension with bilateral shoulder flexion.

FIG 34-10 Ai chi balancing pattern of hip flexion with bilateral shoulder extension.

cross-country skiing requires repeated non–weight-bearing sagittal plane mobility, with greater hip motion and less knee motion. These repeated movements provide lubrication via mobility, but lack the weight-bearing component necessary for articular cartilage lubrication (Table 34-1).[46]

Muscle Performance

Clinicians can use buoyancy, viscosity, or hydrodynamics as tools to increase lower extremity and core strength in individuals with arthritis. A variety of activities using all components will produce a well-rounded rehabilitation program. The starting point is established during the patient's examination when the strength of surrounding muscles and the irritability of the joint are determined. For example, in a patient with an irritable knee and decreased strength, buoyancy might be used to assist the exercise, whereas in a patient with a less irritable joint and greater strength, buoyancy may be used as resistance. Whether using buoyancy or viscosity, exercises can be performed in an open chain, a closed chain, or some combination of both.

Exercise Using Buoyancy

For patients needing buoyancy assistance, squats, step-ups, or step-downs in deeper water will provide the necessary assistance in both the eccentric and concentric phases of the exercise. Specially designed boxes can be submerged in water of any depth to find the appropriate amount of assistance/resistance for a given patient. A box submerged in 4 to 4.5 feet of water is a good place to start for the average adult. Remember that the amount of assistance provided by buoyancy will vary with body type. Thus the exercise prescription must be specific to the individual. As the patient improves, progress the buoyancy-assisted exercises by moving the exercise to more shallow water. This will increase the forces of gravity and lessen the assistance by buoyancy. Exercises can also be progressed to positions such as the lunge position, which is more challenging. Lunges can be performed in place or moving forward (Fig. 34-11), backward, or sideways.

Strengthening exercises can also use buoyancy as resistance. Adding buoyant equipment to the foot or ankle will increase the challenge of these exercises. Straight-leg lifts in the sagittal or frontal planes will result in concentric and eccentric contractions of the muscle groups positioned in opposition to buoyancy. For example, lifting the leg forward and back down will result in eccentric and concentric contractions of the hip extensor muscles if sufficient buoyant equipment is used. If the amount of buoyant equipment is inadequate or the speed not high enough, the muscle contractions become alternating concentric contractions of the hip flexor muscles and hip extensor muscles. Therefore the relative amounts of muscle strength and buoyant equipment will determine which muscle groups are working and in what type of muscle contraction. These straight-leg lifts strengthen the core hip muscles isotonically while challenging the muscles at the knee isometrically. To challenge these muscles directly, perform buoyancy-resisted hamstring curls in a standing position with the hip flexed to 90 degrees (Fig. 34-12). Buoyancy-resisted quadriceps exercises are performed in a standing position with the knee moving from extension to flexion (Fig. 34-13). Realize that while the moving limb is working in an open chain, the opposite limb is working in a closed chain to stabilize the body against the hydrodynamic forces created by the moving limb. This principle is one of the strengths of working in the aquatic medium.

Functional movement patterns can be trained using buoyant equipment. The same PNF patterns used for mobility can be used for strengthening using buoyant equipment. For example, place a Wet Vest strap (Hydro-Fit, Inc.) around the ankle and perform PNF diagonals, alphabet writing, or other functional movement patterns with the leg

TABLE 34-1 Exercises for Mobility

Level 1 Exercise	Level 2 Exercise	Level 3 Exercise	Additional Challenge
Passive knee extension with noodle under midcalf	Noodle under ankle	Foot on rigid object	Provide downward pressure on knee
Passive knee flexion with noodle under midshin	Noodle under ankle	Foot on rigid object	Provide overpressure into flexion
March in place	March across pool	Emphasize gait components such as knee flexion or extension, vary step length	Add stop to provide additional balance challenge
Standing knee flexion/extension with support	Increase range of motion	Add buoyant equipment	Remove support
Bicycle in stable, supported position	Bicycle on noodle or with vest	Increase range of motion, speed	Vary activity to emphasize flexion or extension or both
Squats at railing	Increase depth of squat	Progress to hip and knee flexion on ladder	Bring knees closer to chest as tolerated
Stationary lunges	Increase stride length	Increase depth of lunge	Progress to forward-moving lunges
Hip mobility through single plane with support	Hip flexion/extension, abduction/adduction, figure-eights	Increase range of motion, remove support	Add carioca walking, walking with direction changes and varying step length

Progress exercises from one level to the next after successful completion of the previous level.

FIG 34-11 Lunge walking.

FIG 34-12 Hamstring curls with buoyant equipment.

FIG 34-13 Standing quadriceps strengthening with buoyant equipment.

straight. This type of movement provides resistive exercise to muscles throughout the entire leg. Place a noodle under the bottom of a foot and press down as in a leg press for a buoyancy-resisted leg press activity (Fig. 34-14). Exercises using buoyancy as the primary resistance are increased by adding more buoyancy, as in adding more weight on land.

Exercise Using Viscosity

Open- or closed-chain exercises using viscosity provide an opportunity to strengthen lower extremity muscles isotonically. It is important to consider *how* the exercises are performed to ensure that the structures of interest are being challenged. Exercises using viscosity as the primary resistance are increased by increasing the exercise speed, the surface area, or both. A study of the hydrodynamic responses to viscosity-resisted single and repeated knee flexion and extension in water found high levels of antagonist activity with the repeated activity and lower levels with the single repetition activity.[34] This is an important issue for those wanting to provide both concentric and eccentric muscle

FIG 34-14 Buoyancy-resisted leg press performed with a noodle.

contractions during aquatic rehabilitation. Although concentric and eccentric contractions of a single muscle group can be achieved using buoyancy-resisted exercise (such as standing knee extension with buoyant equipment, Fig. 34-15, *A* and *B*), this same exercise using viscosity (such as standing knee extension with a resistive fin) produces reciprocal concentric contractions (see Fig. 34-15, *C* and *D*). However, research by Poyhonen and associates[33] suggested that the muscle activity is influenced by the surface area, speed, and limb orientation. During both the flexion and extension phases of a knee flexion and extension activity in water, the agonist EMG activity decreased with a concurrent increase in the antagonist EMG during the final portion of ROM. This finding suggests that the moment of the moving water produces lift that tends to "carry" the limb through the final ROM, requiring antagonist activation to decelerate the limb at end ROM. This is more evident in extension phase of seated knee extension than in the knee flexion phase owing to the additional lift from buoyancy. Therefore the quadriceps muscles will be activated through a greater ROM if performed in standing and the hip in neutral than in a seated or standing position with the hip at 90 degrees. Similarly, if the goal is to facilitate hamstring muscle activation and minimize quadriceps muscle activation near full knee extension (as in anterior cruciate ligament injuries), then the 90 degrees of hip flexion position would be preferable (Fig. 34-16).

Progress activities using viscosity as resistance by increasing the speed and/or surface area of the exercise. Flippers or fins are good choices for increasing the surface area. Flippers tend to work best in the sagittal plane, whereas Aquafins (Hygenic Corporation) can be placed in any plane, providing resistance in the sagittal plane, frontal plane, or on any diagonal in between. Other resistive equipment, such as a Hydro Boot (Hydro-Tone Fitness Systems, Inc.), provides a larger surface area for greater resistance.[34] Leg kicks, knee exercises, or walking activities can be performed with resistive fins around the ankle. Different components of the activity can be emphasized depending on how the exercise is cued. For example, during backward walking, emphasizing the knee flexion component will challenge the hamstring and gastrocnemius muscles whereas stressing the hip extension component will challenge the hamstring and gluteal muscles. Generate more resistance by positioning the arms with increased surface area. For example, walk forward with the arms held at 90 degrees abduction or increase the challenge by walking forward while simultaneously horizontally adducting the shoulders. Be aware of the additional stress this will place on the shoulders (Table 34-2).

Finally, resistance bands typically used on land can be applied in the water. Resistive hip, knee, and ankle exercises, as well as resistive walking patterns, can be successful in water because of the resistance applied to the musculature without the weigh-bearing effects of gravity (Fig. 34-17).

Balance, Stabilization, and Gait

The hydrodynamic forces of water provide excellent opportunities for activities to challenge the core muscles and balance. A study of balance training on land and in water found both mediums resulted in improvements in the center of pressure variables,[37] although outcomes research looking at the 8-foot up-and-go test found greater improvement in an aquatic-exercise group compared with a land-exercise group.[8] An 8-week program of aquatic exercise in older adults demonstrated improvements in measures of gait stability.[28] Exercise training on an aquatic treadmill led to improvements in joint angular velocity and pain in patients with knee osteoarthritis.[36] Exercises can be stationary or moving and can be challenged in a variety of ways. Although strength is important, it is only one component of a program to enhance balance. Muscle activation patterns and knowledge of position in space also contribute to good balance.

Patients can use their arms to create forces that are resisted by their trunk and core muscles. Reciprocal shoulder flexion and extension produce rotational forces that are resisted by the core muscles. Turning the palms to the direction of movement increases surface area and increases the challenge. Likewise, symmetrical, bilateral shoulder internal and external rotation also creates rotational forces resisted by the trunk. Anterior-posterior sway is produced with any bilateral anterior-posterior movement of the arms such as flexion/extension or horizontal abduction/adduction. Increase the challenge of these exercises by increasing the exercise speed or surface area or by decreasing the base of support by bringing the feet closer together. Further increase the challenge by removing the bilateral symmetry. For example, performing shoulder horizontal abduction/adduction with a single arm minimizes the anterior-posterior sway and produces trunk rotation (Fig. 34-18).

Progress the narrow base of support to exercise on a single foot as appropriate. Rotational activities will be difficult on a single foot and may not be appropriate for all patients with complex knee problems. Other sagittal or frontal plane activities may be appropriate on a single leg and challenge balance. Simple hip flexion/extension or hip abduction/adduction on a single leg will challenge balance if no external support is provided. For people with chronic knee problems, continuous standing for several repetitions on a single leg may be inappropriate. Consider alternating legs every repetition or every few repetitions for these patients.

Other dynamic activities can capitalize on the physical properties of water. Continuous moving in one direction is not particularly challenging to the core muscles other than the generalized strengthening that occurs with walking against resistance. Once an individual begins moving through the water, the momentum of the water produces lift, carrying the body along through the water. The real challenge to balance and strength occurs with stopping and changing direction once this momentum is achieved. A beginning activity is simply stepping forward onto one foot and balancing followed by a step backwards and balancing again. Increase the challenge by taking three or four steps forward, stop and balance, followed by three or four steps backwards, stop and balance. A few steps one direction is enough to get the water moving along with the patient. Stopping and balancing,

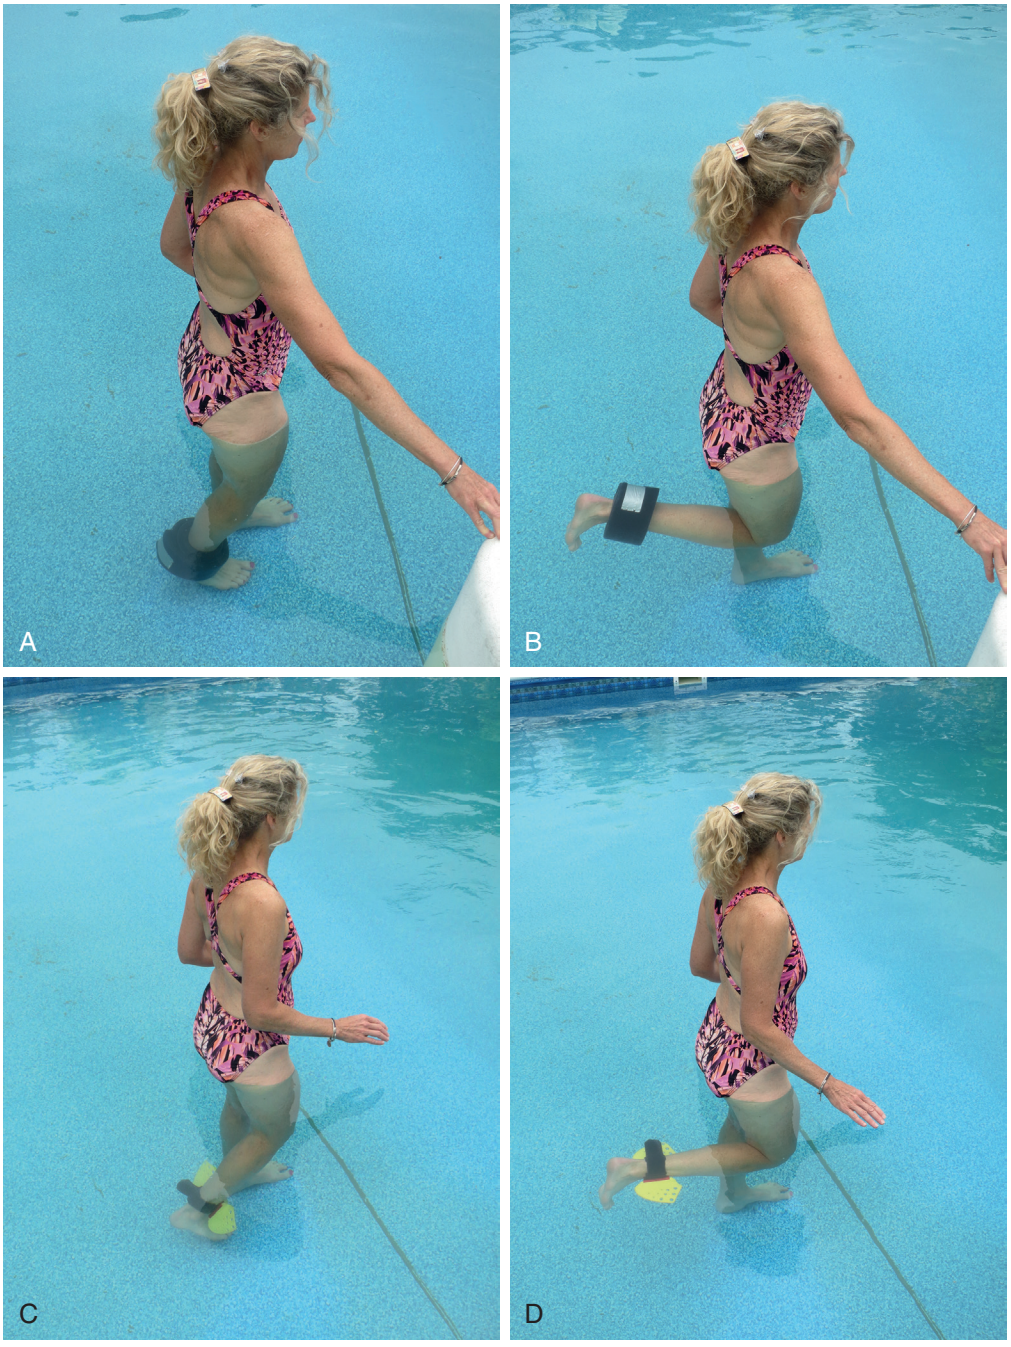

FIG 34-15 **A** and **B**, Standing knee extension using buoyant equipment with the hip in neutral results in eccentric and concentric quadriceps muscle contractions. **C** and **D,** Standing knee extension and flexion using surface area-increasing equipment results in reciprocal concentric quadriceps and hamstring muscle activation. The hip position does not change this activation pattern.

then changing direction produces significant balance challenges. This same pattern can be repeated moving in different directions. Further increase the challenge of the activity by increasing the speed of walking, decreasing arm assistance by placing the arms across the chest and/or decreasing visual input by closing the eyes. Finally, tip or turn the head to include the vestibular component.

Other balance exercises use movements of the arms or opposite leg while stabilizing on a single leg. A stepping motion with a concurrent pushing and pulling motion with resistive equipment makes an excellent core strengthening and balance exercise. In single-leg stance, pushing a ball down works on stability of the entire lower extremity. To increase the challenge, these exercises can be performed on an unstable base such as Therafoam (Hygenic Corporation) submerged in the water (Table 34-3).

Cardiopulmonary

Regular aerobic exercise is an important component of general fitness and weight loss. The American College of Sports Medicine[41] and the American Heart Association recommend performing moderately intense cardiopulmonary activity 30 minutes a day, 5 days a week, or

FIG 34-16 Standing knee flexion and extension with the hip at 90 degrees of flexion facilitates hamstring activation near full extension because these muscle work to decelerate the extending knee.

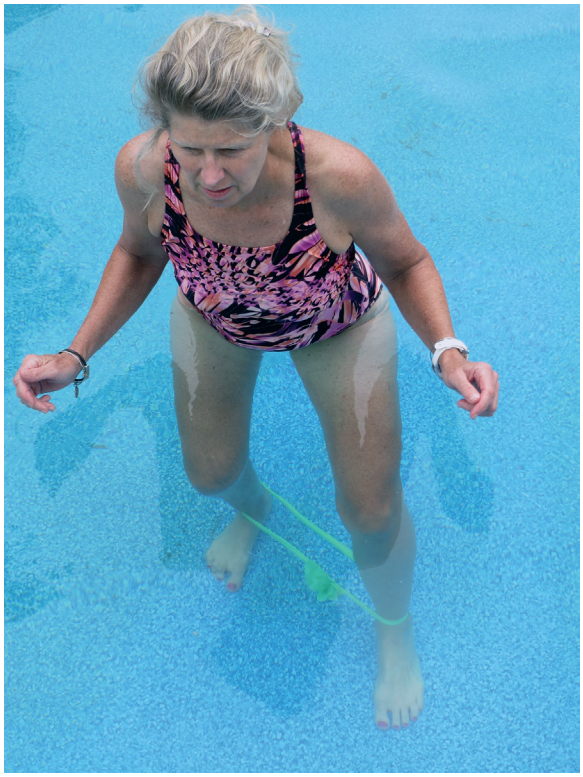

FIG 34-17 Monster walks with resistive band around ankles. The band can also be placed above the knees for less resistance across the knee joint.

TABLE 34-2 Aquatic Strengthening Activities

Level 1 Exercise	Level 2 Exercise	Level 3 Exercise	Level 4 Exercise	Comments
Standing hip flexion/extension	Add fins or buoyant equipment	Increase speed in a controlled fashion	Progress to unsupported will further challenge balance	Buoyant equipment will emphasize hip extensors; fins will equally emphasize flexors and extensors
Standing hip abduction/adduction	Add fins or buoyant equipment	Increase speed in a controlled fashion	Progress to unsupported will further challenge balance	Buoyant equipment will emphasize hip adductors; fins will equally emphasize adductors and abductors
Standing knee flexion/extension	Add fins or buoyant equipment	Increase speed in a controlled fashion	Progress to unsupported will further challenge balance	Buoyant equipment will emphasize knee flexors with hip at 90 degrees, extensors with hip in neutral; fins will equally emphasize flexors and extensors
Wall-sits	Progress to single leg	Add arm and/or contralateral leg movement to perturb	Decrease depth to increase weight bearing	
Squats with arm support	Progress to single leg	Bilateral squat without support	Decrease depth to increase weight bearing	Can add toe-raise to increase calf muscle work
Lunge	Stationary lunge with support	Stationary lunge without support	Lunge walk across pool	Can be performed in any direction
Noodle depression activities	Noodle leg press with foot kept close, more knee flexion	Noodle figure-of-eights or alphabet writing; foot further away, knee more extended	Increase depth and/or buoyancy to increase resistance	Remove support to add balance challenge
Stepping activities	Step-ups on box	Decrease depth to increase weight bearing	Perform in a variety of directions	Decrease depth to increase challenge
Resistive band exercises	Walking with band at knees	Walking with band at ankles	Standing single leg activities with support	Standing single leg activities without support
Deep-water activities	Bicycling, cross country skiing, running, vertical or supine kicking	Add fins	Increase speed or add interval training	

Progress to higher levels upon successful completion of prior levels.

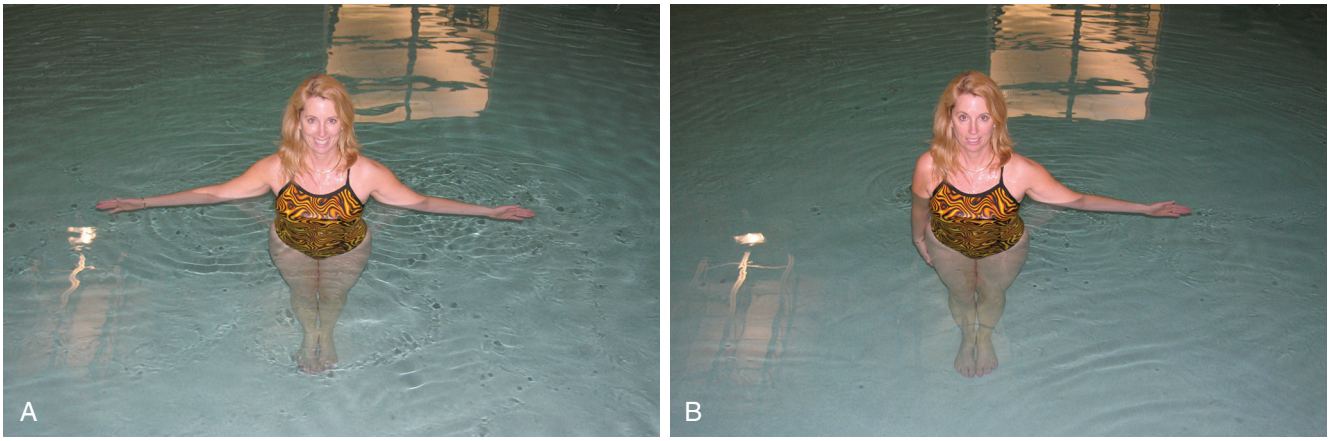

FIG 34-18 Balance exercise that performs shoulder horizontal abduction and adduction bilaterally. **A,** This position creates anterior-posterior sway. **B,** Single-arm position creates transverse plane rotation.

TABLE 34-3 Aquatic Balance Activities

Level 1 Exercise	Level 2 Exercise	Level 3 Exercise	Level 4 Exercise	Comments
Bilateral shoulder flexion/extension	Narrow base of support	Single foot	On unstable surface, such as immersible foam	Close eyes, add head movement to increase balance challenge; can also add gloves to increase resistance, or to single arm to emphasize core
Bilateral horizontal abduction/adduction	Narrow base of support	Single foot	On unstable surface, such as immersible foam	Close eyes, add head movement to increase balance challenge; can also add gloves to increase resistance, or to single arm to emphasize core
Reciprocal shoulder internal/external rotation	Narrow base of support	Single foot	On unstable surface, such as immersible foam	Close eyes, add head movement to increase balance challenge; can also add gloves to increase resistance
Stepping exercises	Step and hold forward and backward, with then without, arm balance	Three-step stop, with then without, arm balance	Stepping push-pull with resistive equipment	Close eyes, increase speed; perform in any direction
Single-leg activities, unsupported	Hip flexion/extension, abduction/adduction	Standing knee flexion/extension	Arms across chest	Close eyes, add unstable surface
Hop in place, with stable balance in between	Hop forward/back, side-to-side	Hop on diagonal	Arms across chest, close eyes	Perform 2-2, 2-1, 1-2, 1-1 footed with emphasis on stability upon landing

Progress to higher levels upon successful completion of the previous level.

performing vigorously intense cardiopulmonary activity 20 minutes a day, 3 days a week. These organizations also recommend regular strength-training exercises. For people with arthritis or complex problems at the knee, many of the traditional cardiopulmonary training activities are too painful. Most of these activities involve some weight bearing through the knee. Walking, running, elliptical trainers, stair steppers, and ski machines all require weight bearing through the knee. Bicycling places less weight-bearing loads across the knee than other cardiopulmonary training activities, but still places large demands on this joint.

The water is an excellent alternative to cardiopulmonary training on land. Patients do not need to be skilled swimmers to achieve a training effect in the pool. Alternative non-weight-bearing activities include deep-water bicycling, cross-country skiing or deep-water running. Vertical kicking or deep-water aerobics classes also provide a good training stimulus. For some individuals, walking in chest-deep water at a steady pace is sufficient cardiopulmonary training. One study found that walking backward in chest-deep water elicited greater physiological and perceptual responses than walking forward at the same speed.[30] Another investigation reported that muscle activity, cardiorespiratory responses, and rate of perceived exertion were all greater in elderly patients who walked in water compared with those who walked on land.[31]

For those who like to swim, traditional swim strokes can be modified to improve their efficiency. Adding a mask and snorkel decreases the amount of neck and trunk rotation necessary during the crawl stroke and the amount of extension necessary during breaststroke. This may increase the efficiency of the stroke and decrease stresses on the spine, allowing individuals to swim continuously enough to obtain the desired cardiopulmonary results. Adding flippers increases the torque production of the leg muscles and may decrease loads on the knees caused by inefficient kicking techniques. Simple flutter kicking with flippers is a good cardiopulmonary exercise. However, the frog or whip kick usually associated with breaststroke swimming places additional torque on the medial knee and may be painful for many people with knee arthritis.

Circuit training or interval-training techniques can also be incorporated into the cardiopulmonary program. Speed play is a simple technique to increase the musculoskeletal and cardiorespiratory demands of an activity. For example, when walking the length of the pool, begin at the usual pace, gradually build in speed to midway across the pool, and then gradually slow back to the usual pace by the time the other end of the pool is reached. This type of training can be incorporated into any of the cardiorespiratory activities, using time or repetitions as the metric for adjusting the speed. A circuit training strategy is often necessary for patients with osteoarthritis because any continuous repetitive activity can flare one or more arthritic joints. A combination program of lap swimming activities alternated with deep water running, cycling, vertical kicking, and/or cross-country skiing can provide a sufficiently varied cardiorespiratory workout without overstressing any single joint.

Research has shown that subjects exercising in the water can achieve a sufficient training stimulus.[9,15,43] D'Aquisto and colleagues[15] and Campbell and coworkers[9] found that controlling the frequency, intensity, and duration of shallow water exercise resulted in a training response sufficient to meet the American College of Sports Medicine's guidelines in younger and older women. Takeshima and associates[43] found that exercising three times per week for 12 weeks resulted in an increase in peak volume of oxygen consumption. Improvements in muscle strength, power, flexibility, agility, and subcutaneous fat were also found. All of these changes are positive for people who have complex knee problems.

Training parameters in the water are basically the same as land. Manipulating the frequency, intensity, and duration to meet the American College of Sports Medicine's guidelines follows the same thought process as those on land. One important issue is skill level in the water. Unskilled deep-water exercisers report higher rates of perceived exertion and have higher lactate levels than skilled deep-water runners. As patients become skilled and comfortable with the new techniques, the exertion levels and heart rate will decrease. Exercise in deep water will result in a heart rate approximately 20 beats/min lower than comparable land-based exercise because of the effects of hydrostatic pressure.[42]

TRANSITION TO LAND

Transition to land-based activities should be a part of the patient's treatment program. The balance between land-based and aquatic-based activities will vary from one patient to the next. Several issues must be considered when determining this balance. The patient's tolerance for land-based activities is a key consideration. If the patient is unable to achieve a sufficient training stimulus on land because of pain, swelling, or other mechanical symptoms, then the majority of the rehabilitation and maintenance program will likely contain an aquatic component. This can be achieved through an independent rehabilitation and exercise program at a local pool, or a community aquatic exercise class. In contrast, some patients may not tolerate regular aquatic exercise caused by reactions to pool chemicals. These individuals may need more land-based activities or find an alternative pool with fewer chemicals such as a salt-water system pool. Other considerations are pool availability and the patient's preferences.

The transition to land occurs similarly to other transitions in rehabilitation. Frequently, patients begin with programs that are primarily in the water, with the addition of a few land-based exercises that they tolerate and can complement the water activities. As the patient tolerates this program and healing progresses, the land-based component is gradually increased and the aquatic component is maintained or increased in parallel, as the patient tolerates. The long-term progression and outcome is dependent on the patient's long-term goals and whether these are best met with an aquatic program, a land program, or some combination of both. The ultimate goal should be the design of a program that the patient can easily maintain because of its ease, effectiveness, and enjoyment. This requires a partnership and communication between the therapist and patient.

SUMMARY

The water is an excellent exercise, training, and rehabilitation medium for patients with arthritis. The water's buoyancy unweights painful joints, allowing greater ease of movement and the ability to train and strengthen without high joint compressive forces. The unweighting reduces pain and allows more active participation in the rehabilitation process. The hydrostatic pressure controls lower extremity swelling that may accompany exercise in people with arthritis. Finally, the water's viscosity provides resistance for strengthening and support against falls caused by poor balance. Research into the efficacy of water-based exercise is ongoing. As with all interventions, exercise in the water is not for everyone. However, for those who tolerate or enjoy the water, this environment can provide opportunities to rehabilitate and exercise across the lifespan. More importantly, research has shown strong compliance with aquatic programs with continued participation at the conclusion of the structured program. For patients with knee osteoarthritis, ongoing, regular exercise, whether on land or water or both, is critical for preventing a progressive decline in function.

INDICATIONS

Disorders of the extensor mechanism, including the patellofemoral joint, are some of the most common causes of anterior knee pain related to inflammation of the parapatellar soft tissues, articular cartilage damage, and instability (subluxation, dislocation). Although the majority of patients respond favorably to conservative measures, surgical treatment is required for recalcitrant cases with distinct anatomic abnormalities that require correction. The key to the indications for surgical treatment is the diagnosis of the specific anatomic defects that cause the patient's symptoms. This underscores the importance of the history and physical examination discussed later in this chapter.

The terminology used to describe patellofemoral disorders in the literature can be confusing. *Patellar malalignment* may be defined as a translational or rotational deviation of the patella relative to any axis. It is caused by an abnormal relationship among the patella, the soft tissues surrounding the patella, and the femoral and tibial osseous structures. The source of such abnormal patellar kinematics may be peripatellar tissue tightness or laxity; osteochondral dysplasias, such as a shallow or convex trochlear groove; bony abnormalities of the patella; rotational malalignment of the femur and tibia proximal and distal to the knee joint; an excessive proximal or distal position of the patella relative to the trochlea (patella alta and patella baja); and inflexibility or weakness of the quadriceps, hamstrings, and iliotibial band (ITB).

Many surgical procedures have been described for realignment of the patellofemoral mechanism, including proximal realignment procedures, distal realignment procedures, or a combination of both. Proximal realignment procedures alter the medial-lateral position of the patella through balancing of soft tissue restraints proximal to its inferior pole. Included in this category are lateral retinacular release, medial retinacular capsular and medial patellomeniscal (MPML) plication, vastus medialis obliquus (VMO) advancement, and medial patellofemoral ligament (MPFL) repair or reconstruction. Distal realignment procedures modify the medial-lateral, anterior-posterior, rotations, and proximal-distal positions of the patella by transfer of the tibial tubercle. Included in this category are anterior (Maquet[100]), medial (Elmslie-Trillat[168]) and anteromedial (Fulkerson[65]) transfer of the tibial tubercle. Literally hundreds of articles have been written on these operative procedures regarding their indications, technique, and clinical outcome, and the reader is referred to review articles for further information.[4,18,30,57,61,81,102,107,142,153,155,174]

The purpose of this chapter is to provide an algorithm of the surgical treatment of specific patellofemoral disorders. Because this is an evolving surgical field, we recognize that there are many approaches and strategies to the treatment of these problems published in the review articles cited previously. In this chapter, the technique of a proximal and distal patellar realignment, a modification of

CRITICAL POINTS

Indications

- Majority of patients with patellofemoral disorders respond favorably to conservative measures.
- Surgery required for recalcitrant cases with specific anatomic abnormalities that require correction.
- Patellar malalignment: a translational or rotational deviation of the patella relative to any axis.
- Proximal realignment procedures alter the medial-lateral position of the patella through balancing of soft tissue restraints proximal to its inferior pole.
- Distal realignment procedures modify the medial-lateral, anterior-posterior, external rotation, and proximal-distal positions of the patella by transfer of the tibial tubercle.
- Operative procedures to be described:
  - Modification of Elmslie-Trillat procedure: arthroscopic lateral release if a contracted lateral retinaculum is present, a modified VMO advancement, and a modified medial transfer of the tibial tubercle.
  - MPFL reconstruction using the quadriceps tendon based on the proximal patella, combined with a distal realignment procedure when indicated.
  - Correction patella alta.
  - ITB lengthening.
- Types of extensor mechanism problems:
  - Diffuse anterior knee pain without distinct anatomic abnormalities in alignment, subluxation, or joint damage: treated conservatively.
  - Anterior knee pain with mild to moderate abnormalities: treated conservatively.
  - Patellofemoral pain with definite anatomic signs of an extensor mechanism malalignment: candidates for surgery.
- First-time patella dislocation treatment categories:
  - Anatomic abnormalities (congenital laxity MPFL, increased Q-angle, trochlear dysplasia): treated conservatively; candidates for surgery if symptomatic.
  - ± Underlying anatomic abnormalities, major joint hemarthrosis, MRI evidence of patellar or femoral osteochondral fracture: surgery, fixation fracture, MPFL repair.
  - Conservative treatment; reevaluate stability after acute injury.

Elmslie-Trillat procedure, is described. It includes an arthroscopic lateral release if a contracted lateral retinaculum is present, soft tissue balancing of medial restraints, and a modified medial transfer of the tibial tubercle when necessary. The goals of these procedures are to release abnormal lateral tethering tissues when present, provide a balanced medial tissue–ligament complex, and realign the quadriceps-patella–tibial tubercle relationship. The procedures are performed using cosmetically appealing incisions with rapid rehabilitation, immediate knee motion, early weight bearing, and early return to function.

The second operative procedure described in detail is a MPFL reconstruction using the quadriceps tendon (QT) based on the proximal patella. This procedure is performed through a limited cosmetic incision and avoids harvesting the semitendinosus tendon, use of an allograft, and bony fixation at the patella or medial femoral attachment. This procedure has proven to be useful in revision cases that failed after a proximal realignment in which an inadequate MPFL was not addressed. The operative procedure is combined with a distal realignment when indicated, as is discussed. Other operative procedures the senior author (F.R.N.) has found useful for correcting patella alta and ITB lengthening are also described. Surgical procedures for rotational malalignment of excessive femoral anteversion and external tibial torsion are discussed in Chapter 36 and are not repeated here.

The majority of patients with patellofemoral malalignment respond favorably to conservative treatment programs, covered in detail in other publications.[2,26,36,81,90] In general, three types of extensor mechanism problems present for treatment. The first group of patients have diffuse anterior knee pain without distinct anatomic abnormalities in alignment, subluxation, or joint damage that can be identified. Commonly, these are younger athletes who are involved in multiple sports, and frequently, the only finding is the presence of tenderness of peripatellar soft tissues and the anterior fat pad tissues. On occasion, a mild joint effusion may be present. Authors have stressed that these symptoms frequently represent an overuse condition from excessive participation in athletics.[26,138] Treatment consists of allowing the soft tissues time to heal and inflammation to recede by modification of athletics followed by appropriate strengthening and stretching of the muscle groups. Specific factors that may contribute to the symptomatic state include excessive conditioning, type of sport, and duration and frequency of athletic participation. Recurrence of symptoms is not an indication for surgical treatment because distinct anatomic abnormalities of the extensor mechanism are not present. A cartilage-sensitive magnetic resonance imaging (MRI) may be helpful in recurrent symptomatic knees to determine the status of the patellofemoral joint and presence of early articular cartilage damage that is aggravated by vigorous athletic activities.

There is a second group of patients with anterior knee pain that are similar in all aspects to the first group described previously, except that mild to moderate abnormalities are detected on the physical examination. For example, there may be a lateral subluxation (lateral glide) up to 50% of the patellar width and a mild to moderate increase in the Q-angle. There may be a physiologic posterolateral ligament laxity allowing increased external tibial rotation during activities (dynamic Q-angle). These patients are also treated conservatively and are not candidates for extensor mechanism realignment surgery.

The third group consists of patients who demonstrate definite anatomic signs of an extensor mechanism malalignment who are candidates for surgery. An example is patients with symptomatic lateral patellofemoral subluxation events who do not respond to conservative treatment and have a deficient MPFL. Included in this group are patients who have had a prior patellofemoral dislocation and remain symptomatic, either with recurrence of lateral patellofemoral subluxation or a repeat dislocation event.

Nonoperative treatment of first-time patella dislocations has a redislocation rate that ranges from 14% to 57% in adult populations[151,154] and from 36% to 71% in pediatric populations.[81,131] Stefancin and Parker[158] conducted a systematic review of 70 articles that focused on the management of traumatic first-time patellar dislocations and concluded that conservative treatment was indicated initially except in specific circumstances. These included the finding of an osteochondral fracture, a substantial disruption of the MPFL, a laterally subluxated patella with normal alignment of the contralateral knee, or after failed conservative treatment or recurrent dislocations. In a study that analyzed factors associated with patellar dislocations in 40,544 injured knees in the United States, Waterman and colleagues[179] reported that the peak incidence of injury occurred between 15 and 19 years of age, and 52% occurred during athletics.

Patients with an acute lateral first-time dislocation are separated into three categories:

1. Dislocation with underlying anatomic abnormalities such as congenital laxity of the MPFL, increased Q-angle, and trochlear

dysplasia, with similar abnormalities present in the opposite extremity. These patients undergo conservative treatment and are candidates for surgery if symptoms occur in the future. These patients require an MPFL reconstruction because the hyperlaxity indicates deficiency of the medial soft tissue stabilizers. This surgery is not indicated in an acute knee injury situation and may be performed on an elective basis after the patient has recovered muscle function and conditions are more ideal for surgery.

2. Dislocation with or without underlying anatomic abnormalities, as detailed previously, in which there is a major joint hemarthrosis and MRI evidence of a well-defined or probable patellar or femoral osteochondral fracture. These patients require arthroscopic examination, removal of loose bodies, and fixation of a large osteochondral fracture when present (rare). Only under rare conditions is an MPFL repair performed, when MRI helps define the location of the tear at the patellar attachment. The majority of MPFL tears represent an interstitial disruption throughout its substance or demonstrate a combination of tears at attachment sites and are not amendable to acute repair.[66,122,141]
3. Dislocation without distinct trochlear or patellar tendon insertion abnormalities in which the primary defect is an acute disruption of the medial retinacular restraints and the MPFL. In an athletic patient desiring an early return to athletics, an MPFL repair of a well-defined patella or femoral attachment tear has been advocated in some studies. Less clear are indications for acute repair of MPFL tears that are interstitial without a patella or femoral attachment tear. These interstitial tears have the ability to heal by conservative treatment and may not require further surgery.[131,151,158] Accordingly, the senior author refers to treat these dislocations initially in a conservative manner without surgical MPFL repair.

In a majority of chronic knees with recurrent bilateral patellar subluxation or dislocation, patient education is essential to explain the goals of the operative procedure. Patients are advised that any associated articular cartilage damage will likely cause future symptoms that limit athletic participation even though the recurrent patellar instability has been successfully treated.

CONTRAINDICATIONS

The primary contraindication for extensor mechanism malalignment surgery is the absence of a distinct anatomic defect because the goal of surgery is to restore as well as possible normal alignment of the extensor mechanism. The presence of chronic recurrent anterior knee pain is not an indication for surgery when the specific etiology of the pain symptoms cannot be determined. This point is worthy of emphasis because many patients present with anterior knee pain in which the specific diagnosis is not apparent despite a thorough and careful examination and evaluation. It is probable that there are pain generation factors related to early patellofemoral cartilage deterioration that are in the initial stage of the disease course. Alternatively, peripatellar and intraarticular soft tissues may be an explainable source of pain.[51,64] A common cause of unexplained pain is a subtle infrapatellar neuroma or neuritis of the sensory nerves about the knee joint, discussed in Chapters 39 and 40.

A specific contraindications to extensor mechanism surgery is the presence of excessive hip anteversion or abnormal external tibial torsion as discussed in Chapter 36. An MRI or computed tomography (CT) scan for axial rotation of the lower extremity from the hip to the ankle is required. The measurements obtained include femoral anteversion, tibial tubercle offset, trochlear groove, and external tibial torsion as are described. The anterior knee pain is caused by excessive lateral patellofemoral forces induced by external tibial torsion or increased femoral anteversion (Fig. 35-1). In these patients, a femoral or tibial derotation osteotomy may be indicated and not a proximal or distal patellofemoral procedure.[139,164]

A distal realignment is contraindicated in the skeletally immature patient. However, a proximal realignment that may include a QT autograft (for deficient, thin MPFL and retinaculum) may be performed because there is no drilling of osseous tunnels. In cases of recurrent dislocation in a skeletally immature patient, even with an abnormal lateral patellar tendon insertion offset (increased Q-angle), the MPFL reconstruction is usually very successful in providing patellar stability.[116] After growth is complete, the need for correction of the lateral patellar tendon tibial tubercle attachment may be assessed, which is frequently not required in our experience.

A relative contraindication is the presence of patellofemoral arthritis; however, in select knees, a realignment procedure may be performed with a cartilage restoration procedure.[55,67,72,77,85,99,110,136,137,150,173]

Often, patients with chronic extensor mechanism malalignment disorders have limited their activity, gained excessive body weight and have articular cartilage damage that limits rehabilitation. These problems cause muscle atrophy of the entire lower extremity. These patients require a comprehensive evaluation and team approach involving nutrition counseling, weight reduction to normal indices, prolonged rehabilitation, occupational rating and modification, and management of patellofemoral pain before any consideration of surgery. An abnormal body mass index in a patient with symptomatic patellofemoral cartilage damage contraindicates extensor mechanism surgery.

CRITICAL POINTS

Contraindications

- Primary contraindication surgery: absence of a distinct anatomic defect.
- Excessive hip anteversion or abnormal external tibial torsion.
- Distal realignment contraindicated in skeletally immature patients.
- Patellofemoral arthritis is a relative contraindication; however, in select knees, a realignment procedure is indicated along with a cartilage restoration procedure.
- Severe lower limb muscle atrophy.
- Obesity.

BIOMECHANICS OF MEDIAL AND LATERAL PATELLOFEMORAL RESTRAINTS

Multiple factors influence patellar stability, including articular geometry, dynamic muscle actions, and passive soft tissue restraints.[4,57] The

CRITICAL POINTS

Biomechanics of Medial and Lateral Patellofemoral Restraints

- Factors influencing patellar stability: geometry trochlear groove, dynamic muscle actions, passive soft tissue restraints, angle knee flexion.
- Methods to measure patellar mobility: manual, instrumented, radiographic
- Patella most unstable at 0-30 degrees of knee flexion.
- Shallow or dysplastic trochlear groove allows patella to displace more easily.
- Patella alta results in a loss of the trochlea geometric restraint until 30-40 degrees of flexion.
- MPFL primary restraint to lateral patellar translation, providing 53%-67% restraint up to 30 degrees of knee flexion.
- Mean failure load of the MPFL 208 N.

FIG 35-1 **A** to **C,** A classic case of increased femoral anteversion, external tibial torsion, and "squinting" patella requiring femoral rotational osteotomy and possible tibial rotational osteotomy, but proximal-distal realignment. **A** and **B,** Supine external-internal hip rotation abnormality. **C,** Standing rotational malalignment shows "squinting patella" and the "miserable malalignment syndrome." **D** to **J,** Physical examination parameters are demonstrated. **D,** Lateral tibial patellar tendon attachment full extension. **E** and **F,** Q-angle increase with external tibial rotation 30 degrees of flexion. **G,** Q-angle returns to 0 with internal tibial rotation 30 degrees of flexion. **H,** Normal lateral glide 30 degrees of flexion. **I** and **J,** Manual medial glide 0 and 30 degrees of flexion. Palpation of all parapatellar soft tissues, fat pad, patellar tendon, and plica area is also performed. (**A** to **C,** Courtesy Robert Teitge, MD.)

geometry of the trochlear groove,[4] the height and slope of the lateral femoral condyle, and the angle of knee flexion all affect lateral patellar translation. Amis[4] described objective patellar stability in terms of two factors: the amount of force required to displace the patella on a given linear distance from its equilibrium position (translation) or the turning moment required to induce a rotation, such as a lateral tilt. Methods used to determine patellar mobility include manual measurement, instrumented quantitative measurement, and radiographic measurement. Kolowich and coworkers[89] measured patellar glide by dividing the patella into four quadrants and describing medial and lateral mobility as a fraction of patellar width. Normal subjects had less than two quadrants of translation with the knee flexed 30 degrees. Teitge and associates[165] developed a stress radiographic method to measure patellar medial-lateral stability. Knees of normal subjects and symptomatic patients were tested between 30 and 40 degrees of flexion with 71 N of force applied. Wide variation was noted in the normal knees because lateral displacement ranged from 1 to 32 mm, and medial displacement ranged from 2 to 22 mm. The mean difference in lateral displacement between the right and left knees was 1.3 ± 1.1 mm, and the mean difference in medial displacement was 1.2 ± 1.08 mm. The investigators determined that a difference between knees in lateral displacement of 3.7 mm, or a difference in medial displacement of 3.5 mm, was abnormal.

Hautamaa and colleagues[79] developed an instrumented measurement device to determine patellar medial-lateral translation in the coronal plane. In 17 cadaver knees, with the knee flexed 30 ± 5 degrees, 5 lb of laterally directed force produced an average of 9.3 ± 0.9 mm of lateral translation. Instrumented measurement of medial-lateral patellar translation was also conducted by Fithian and coworkers[62] in normal and symptomatic patients. Right versus left knee comparisons revealed small mean differences in the control subjects for medial and lateral patellar translation (30 degrees of flexion, 2.5-lb force, 0.1 ± 1.9 mm, and 0.2 ± 1.0 mm, respectively). Significant differences were found between the control and the symptomatic subjects in the mean differences in lateral translation ($P < .01$).

It is well appreciated that the patella is most unstable in the range of 0 to 30 degrees of flexion. When the knee is near full extension, the Q-angle is maximized because of the external rotation of the tibia. In addition, with the quadriceps muscle relaxed, the patella is not engaged in the trochlear groove and thus is easily mobilized in a medial-lateral direction. As the knee is flexed, patellar stability is increased owing to the combined tensions of the quadriceps muscles and the patellar tendon that pull the patella into the trochlear groove. A shallow or dysplastic trochlear groove allows the patella to displace more easily.[146] A patella alta condition results in a loss of the trochlea geometric restraint until 30 to 40 degrees of flexion when patellotrochlear contact finally occurs.

In regard to passive soft tissue restraints, the MPFL is the primary restraint to lateral patellar translation, providing 53% to 67% restraint up to 30 degrees of flexion.[18,31,38,47,79,132] Desio and associates[47] examined nine cadaver knees (mean age, 57 years; range, 43-70 years) at 20 degrees of flexion and reported that the MPFL provided a mean of 60% of the restraining force to lateral patellar translation. The MPML provided a mean of 13% of the restraining force; the lateral retinaculum, 10%; and the medial retinaculum and medial patellotibial ligament, 3% each. Conlan and colleagues[38] reported similar findings from 25 cadaver specimens (Fig. 35-2); the MPFL provided an average of 53% of the total restraining force followed by the MPML (22% contribution), the medial retinaculum (11% contribution), and the medial patellotibial ligament (5% contribution). Sectioning of the MPFL decreased the restraining force significantly; the average stiffness decreased from 225 N/cm in the intact specimens to 104.6 N/cm ($P = .001$).

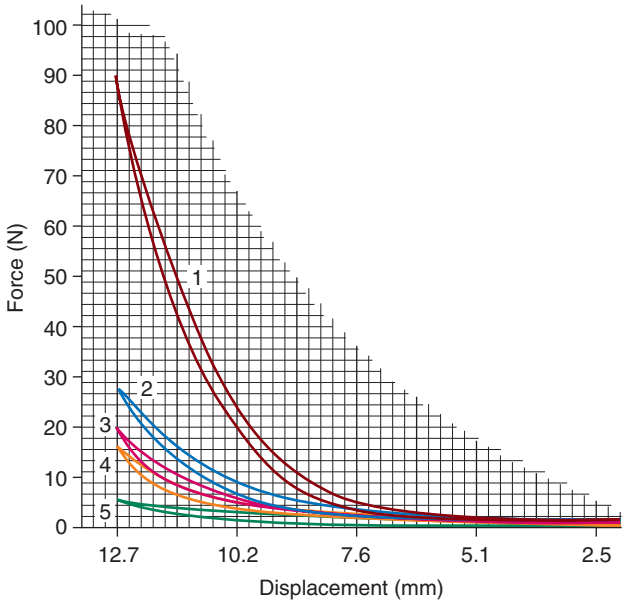

FIG 35-2 Superimposed force-displacement curves, recorded during the sixteenth testing cycle for one specimen. The medial patellofemoral ligament (MPFL) provided 67% of the medial soft tissue restraint to lateral patellar displacement (13% more than average), and the medial patellomeniscal ligament provided 12% (14% less than average). Curve 1 represents the intact ligaments, and curves 2, 3, 4, and 5 represent the MPFL, medial retinaculum, medial patellotibial ligament, and medial patellomeniscal ligament, respectively, after sectioning. (From Conlon T, Garth WP Jr, Lemons JE. Evaluation of the medial soft-tissue restraints of the extensor mechanism of the knee. *J Bone Joint Surg Am.* 1993;75:682-693.)

Nomura and coworkers[123] measured the lateral patellar translation in 10 cadaver knees (aged 45 to 60 years) with the quadriceps tensed to 10 N and a lateral force of 10 N applied before and after sectioning of the MPFL. Isolated sectioning of the MPFL significantly increased the lateral patellar translation from 20 to 90 degrees of flexion ($P < .05$).

Amis and associates[5] reported a mean failure load of the MPFL of 208 N from 10 cadaveric specimens. However, age effects may bias the results because the mean age was 70 years. These investigators reported the contribution of the MPFL in restraining lateral patellar translation was greatest with the knee at 0 degree extension. Significant increases in lateral translation occurred from 0 to 20 degrees after the MPFL was sectioned (*P* value not provided; Fig. 35-3).

PREOPERATIVE PLANNING

The physical examination is crucial in preoperative planning for patellar realignment surgery. The examination should be performed with the patient in the standing, sitting, and supine positions (see Fig. 35-1, *D* to *J*). Palpation of parapatellar soft tissues and the fat pad are performed for swelling and elicitation of pain. The examiner should look for evidence of lateralization of the extensor mechanism and tilt. The patellar compression test should be performed with flexion and extension of the knee to evaluate for articular crepitus or pain. Passive patellar tilt and tightness of the lateral retinaculum should be noted. Patellar subluxation tests (patellar glide at 0 and 30 degrees of flexion) should be performed in medial and lateral directions and patellar mobility noted. Other sources of pain such as neuroma, patellar tendonitis, synovial plica, synovitis, meniscus tears, osteochondritis dissecans, complex regional pain syndrome, and advanced tibiofemoral arthritis should be excluded.

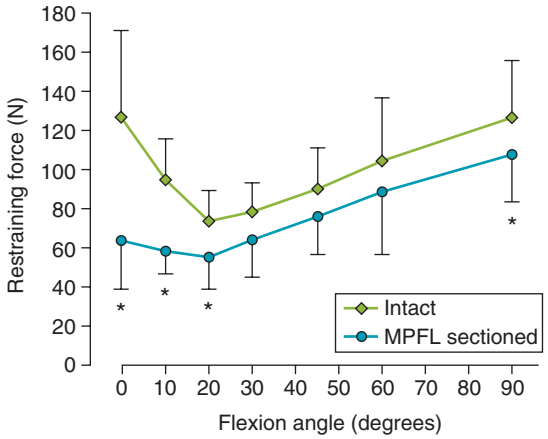

FIG 35-3 Patellar lateral displacing force at 10 mm displacement, for an intact knee with 175-N quadriceps tension, and after transection of the medial patellofemoral ligament (MPFL). The drop between the two curves shows that the contribution of the MPFL was greatest in the extended knee. Asterisks denote significant difference (*P* value not provided). (From Amis AA, Firer P, Mountney J et al. Anatomy and biomechanics of the medial patellofemoral ligament. *Knee.* 2003; 10:215-220.)

CRITICAL POINTS

Preoperative Planning

- Physical examination:
  - Palpation of parapatellar soft tissues.
  - Patellar compression test with knee flexion-extension.
  - Patellar subluxation, 0 and 30 degrees of flexion, medial-lateral.
  - Rule out other sources of pain
- Lower limb rotational alignment: femoral anteversion, tibial torsion, Q-angle 0 and 30 degrees of flexion.
- CT, MRI: trochlear dysplasia, TT/TG distance, femoral anteversion, tibial torsion.

Lower limb rotational alignment, including femoral anteversion and tibial torsion, is measured. The Q-angle is the angle formed between one line connecting the anterior superior iliac spine to the center of the patella and a second line connecting the center of the patella to the tibial tubercle. The Q-angle is measured with the knee in 0 and 30 degrees of flexion. The Q-angle arc is measured at 30 degrees with internal and external tibial rotation. Patients with a physiological laxity of the posterolateral ligament structures have an increased lateral patellar tendon deviation by virtue of the increased external tibial rotation. The clinical measurement of the Q-angle can be inaccurate for a number of reasons. If the patella is subluxed laterally, then the central reference point of measurement is also lateral, with a decrease in the Q-angle measurement unless the patella is carefully positioned within the center of the femoral groove. The Q-angle will vary depending on the amount of knee flexion and foot position; it increases with foot pronation and external tibial rotation. The proximal line to the anterior superior iliac spine is only an approximation.

Conventional radiographic techniques are often inadequate for the assessment of patellofemoral malalignment. The most commonly used Merchant technique requires 30 to 45 degrees of knee flexion. The difficulty with this technique and others is that images are not obtained near full extension where the trochlea is most shallow. As the knee flexes, the trochlear groove deepens, and the patella undergoes medialization and becomes more congruent with the femoral sulcus. The extent of trochlear dysplasia and patellar subluxation or tilt may be underestimated on the axial view owing to the amount of flexion required to obtain the image. A lateral radiograph in 30 degrees of flexion may be used to evaluate patellar height, patellar tendon length, and trochlear dysplasia. However, a true lateral radiograph, in which the distal and posterior aspects of the femoral condyles are perfectly superimposed, is required to evaluate trochlear depth, which is measured more accurately on an axial MRI.

Dejour and associates[46] analyzed the radiographs and CT scans of 143 knees with symptomatic patellar instability and 67 contralateral asymptomatic knees to determine the factors affecting patellar instability. These authors reported that trochlear dysplasia was present in 96% of unstable patellas. Dejour and colleagues[45] described a qualitative classification system of four types of trochlear dysplasia: type A, trochlear morphology preserved with a fairly shallow trochlea; type B, flat or convex trochlea; type C, asymmetry of trochlear facets with convex lateral facet and hypoplastic medial facet; and type D, asymmetry of trochlear facets and cliff pattern. Many years later, Nelitz and coworkers[117] evaluated MRI criteria of 80 knees with symptomatic patellofemoral instability to determine whether specific measurements of the femoral trochlea could be assigned to Dejour's classification system. Given the marked variation in trochlear morphology, none of the quantitative MRI measurements could be assigned to this system. A similar conclusion was reached in a study by Lippacher and associates,[96] who also noted that lateral radiographs underestimated the severity of trochlear dysplasia compared with axial MRI.

Nelitz and coworkers[117] reported median values of eight trochlear indices that distinguished Dejour type A (low-grade dysplasia) from the higher grade dysplasia categories (B-D) and, based on their findings, recommended that a two-grade system be used instead of a four-grade system. The cut-off values between low- and high-grade dysplasia were 2 mm for depth of the trochlear groove, 48% for trochlear facet asymmetry, and 11 degrees for lateral trochlear inclination.

CT and MRI have been used to assess lower limb rotational alignment and are important tests for a complete diagnosis of the anatomic abnormalities that may be present.[134] These studies obtain axial images of the patellofemoral joint at or near full extension to evaluate trochlear dysplasia and the tibial tubercle/trochlear groove (TT/TG) distance. Various investigators have studied this distance and found that it may be increased in patients with patellofemoral pain and instability.[44,88,147]

Femoral anteversion has been measured by a variety of techniques by many authors. Yoshioka and Cooke[180] measured anteversion from the bone in 32 femora and reported a mean of 13.1 ± 8 degrees (range, −11 to +22 degrees) in both males and females when the distal measurement was the tangent across the femoral condyles and a mean of 7.4 degrees when measured across the epicondyles. These authors conducted a review of the literature on this measurement and found that normal values were between 8 and 16 degrees in 12 different investigations. Teitge and associates[165] arbitrarily selected 13 degrees as the goal for correction (see Chapter 36).

The technique for measuring tibial torsion by CT has not been standardized, and wide variation exists in the literature regarding normal values. Yoshioka and colleagues[181] reported a mean lateral tibial torsion of 21 ± 4.9 degrees in males and 27 ± 11.0 degrees in females, a significant difference ($P < .05$). Eckhoff and coworkers[52] reported mean tibial "version" of 37.0 ± 1.7 degrees in control knees and 32.8 ± 1.7 degrees in a group of symptomatic knees. Turner[170] measured a mean of 19 ± 4.8 degrees in a control group compared with a mean of 24.5 ± 6.3 degrees in a group with unstable patellas. Sayli and associates[143] reported an average of tibial torsion in females of 31.07 degrees for the right side and 30.02 degrees for the left. For males, the averages were 32.7 and 35.26 degrees for the right and left sides, respectively.

Tamari and colleagues[163] conducted a reliability study that examined different methods of measuring tibial torsion. The results showed that clinical methods currently available do not accurately measure true torsion of the femur and tibia. The authors stressed that, even so, these methods may be useful for screening and descriptive purposes as indices of true torsion, and use of different reference axes could improve their reliability.

MRI has some advantages over CT, including improved ability to image cartilaginous structures, better anatomic approximation of the trochlear articular cartilage groove, and avoidance of radiation exposure. MRI also provides meaningful information about all of the soft tissue structures about the knee joint. The MRI is obtained in standard fashion, with images obtained of the hip parallel to the femoral neck and axial images obtained of the knee and ankle (Fig. 35-4). These individual images are then measured based on the techniques described by Murphy and coworkers[114] and Guenther and associates[74] (Figs. 35-5 and 35-6).

The angle between the femoral neck and the horizontal line is subtracted from the positive angle of the posterior portion of the distal femoral condyle. In rare cases, the rotation of the femoral neck and posterior femoral condyle are in opposite directions, which necessitates addition for the true femoral anteversion. The version of the knee is measured by adding or subtracting the posterior femoral angle (to the horizontal) from the proximal tibial angle (angle between the posterior aspect of the proximal tibia and the horizontal line). The tibial torsion is the difference between the proximal tibial angle and the anterior talus from the horizontal line. Chapter 36 provides a comprehensive analysis of the different anatomic landmarks and normal values that have been measured to define tibiofemoral rotational alignment and their important effects on the patellofemoral joint.

TT/TG is measured using the trochlear groove–patellar tendon insertion distance. TT/TG is measured in millimeters and is the difference from the center of the deepest point of the femoral groove to the center of the patellar tendon attachment to the tibial tubercle. This is done by superimposing the line perpendicular to these points and measuring the distance between the two lines, adjusting for magnification. Dejour and Walch[46] reported a mean TT/TG distance of 12.7 ± 3.4 mm in a group of asymptomatic knees. In a group of knees with patellar instability, the mean TT/TG distance significantly increased to 19.8 ± 1.6 mm ($P < .001$). The authors concluded that the pathologic threshold is 20 mm, which has been agreed upon by others.[164] In some knees with trochlear dysplasia, it is difficult to determine the true center point for the measurement, rendering the TT/TG offset to be inaccurate. In these knees, this measurement cannot be used as an evaluation measurement of the desired operative correction.

The TT/TG plays a role in estimating the amount of correction required at the time of the tibial tubercle realignment procedure. Intraoperatively, it is easier to accomplish linear corrections (in millimeters) than to assess angular relationships (in degrees), as in the Q-angle measurement. Importantly, this helps to prevent excessive medial translation of the tibial tubercle. The TT/TG measurement may not reflect the lateral deviation of the patellar tendon attachment with knee flexion and external tibial rotation and therefore the MRI measurements must be correlated with the physical examination. The tibial tubercle abnormality may also involve both a lateral translation and outward (external rotation) orientation.

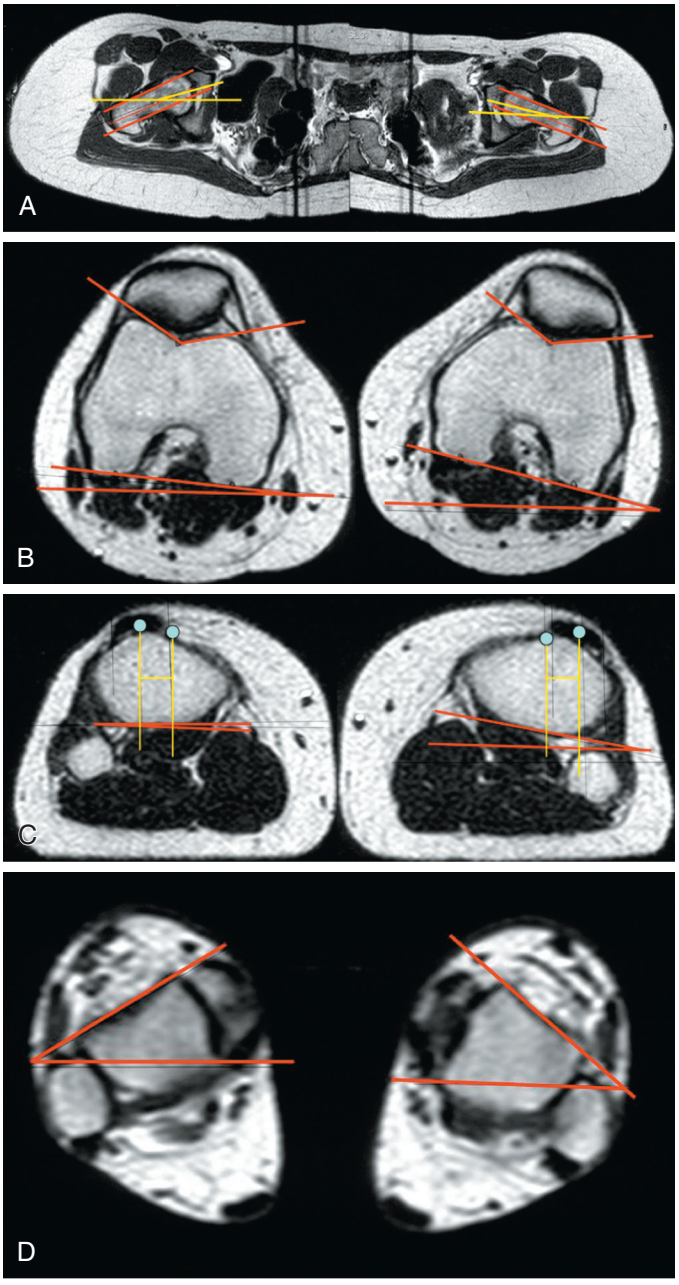

FIG 35-4 A patient's lower limb rotational magnetic resonance imaging profile. **A** and **B,** The femoral anteversion for the right knee was 16 degrees on the left and 3 degrees on the right. **B** and **C,** The knee version was 3 degrees on the right and 0 degrees on the left. The tibial tubercle/trochlear groove was 14 mm on the right and 12 mm on the left. **C** and **D,** External tibial torsion was 30 degrees on the right and 33 degrees on the left. An increased signal alternation is shown for the lateral patellar facet, which is related to the patient's primary abnormality of a bilateral external tibial torsion.

SURGICAL TECHNIQUES

The operative extremity is signed by the patient and surgeon with nursing personnel present. A time-out is performed with the patient's name, procedure, allergies, preoperative antibiotics, special precautions given and agreed upon by the surgeon, anesthetist, and nursing personnel.

The patient is positioned supine on the operating table. Under anesthesia, the peripatellar retinaculum, patellofemoral crepitation, patellar tilt, passive medial-lateral patellar glide (at 0, 30 degrees of knee flexion), and Q-angle are assessed and compared with preoperative measurements. A sterile thigh tourniquet is applied as proximal as possible, so that an intraoperative assessment of the Q-angle can be

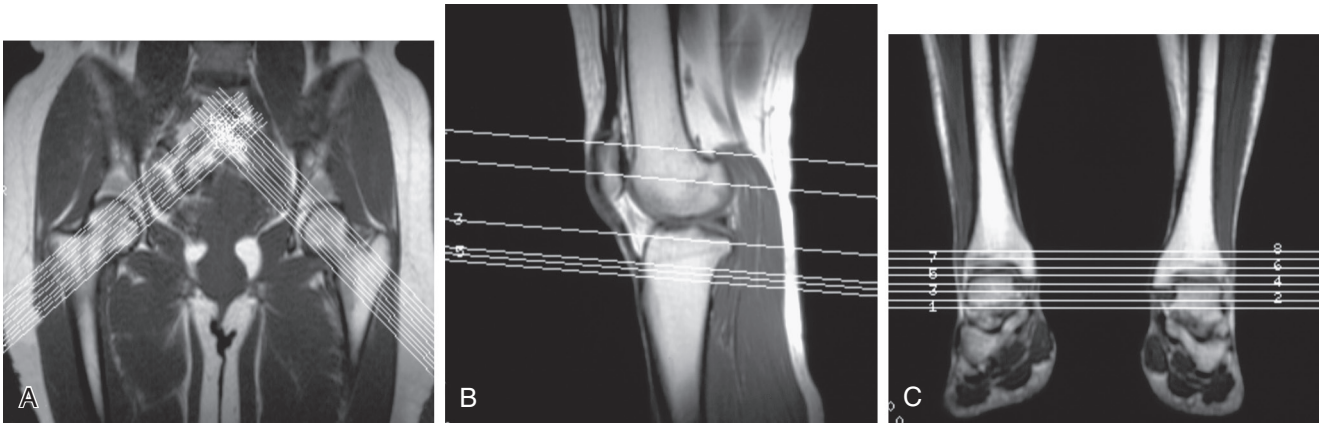

FIG 35-5 T1 Magnetic resonance imaging images obtained at the hip (**A**), knee (**B**), and ankle (**C**). This allows selection of the proper images for the measurements shown in Figure 35-6. (From Parik, SN, Noyes FR, Albright J. Proximal and distal extensor mechanism realignment: the surgical technique. *Tech Knee Surg.* 2006;5:27-38.)

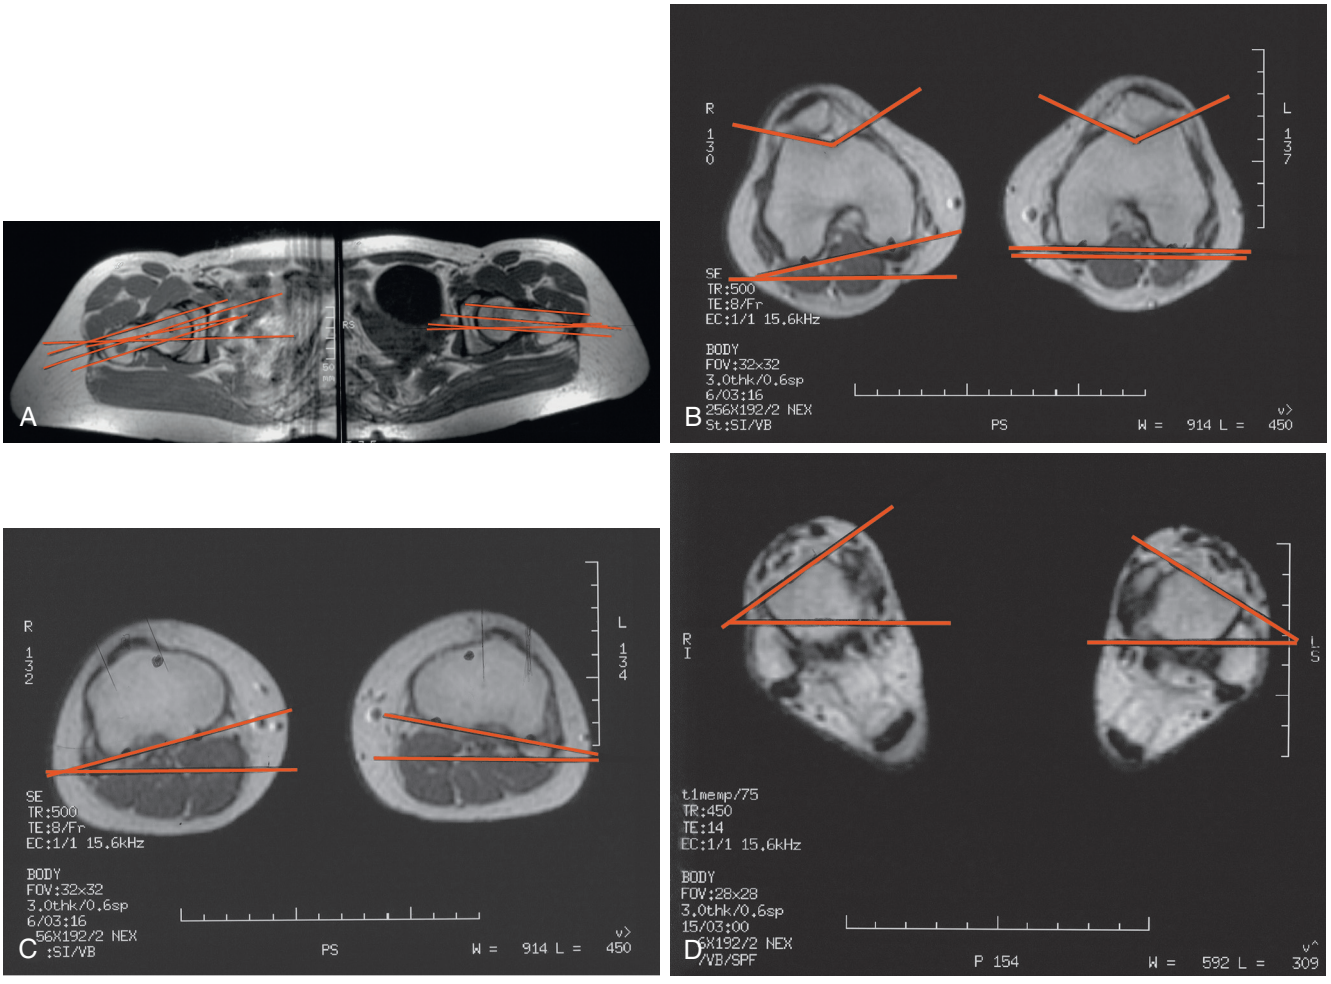

FIG 35-6 **A,** Axial view of the hip taken through the center of the femoral neck. **B,** The femoral view is taken at the proximal aspect of the femoral trochlea. **C,** The proximal tibia view is taken at the proximal insertion of the patellar tendon on the tubercle. The center of the patellar tendon is taken for the tibial tubercle/trochlear groove ratio. **D,** The axial ankle view is taken at the level of the flat edge of the talar dome (often at the same level and angle as the medial and lateral malleoli). (From Parik, SN, Noyes FR, Albright J. Proximal and distal extensor mechanism realignment: the surgical technique. *Tech Knee Surg.* 2006;5:27-38.)

CRITICAL POINTS

Surgical Technique

- Operative extremity signed by patient and surgeon with nursing personnel present.
- Patient's name, procedure, allergies, preoperative antibiotics, special precautions given and agreed upon by the surgeon, anesthetist, and nursing personnel.
- Under anesthesia, the peripatellar retinaculum, patellofemoral crepitation, patellar tilt, passive medial-lateral patellar glide (0, 30 degrees of flexion), Q-angle assessed.
- Articular cartilage lesions evaluated; loose flaps debrided.
- Lateral retinacular release
  - Only performed if patellar medial subluxation test is abnormal (patellar medial subluxation ≤8 mm on manual medial translation test, knee at 30 degrees of flexion).
  - Subcutaneous pouch created with a scissor from the anterolateral portal.
  - Arthroscopic retinacular release performed with commercial radiofrequency wand through anterolateral portal.
  - Initiated from 9 o'clock position (right knee); continued distally to 1 cm below inferior pole of patella with the knee in full extension.
  - Patellar medial subluxation test performed at 30 degrees of flexion.
  - If the release is inadequate, it is extended proximally to a 10 o'clock position.
  - Determine that there is no abnormal restraint to lateral patellar glide at 20-30 degrees of flexion, confirm absence of tight lateral tissues at 90 degrees.
- Proximal realignment
  - 3-cm vertical skin incision made along medial aspect of the patella.
  - Medial parapatellar incision made through medial retinaculum.
  - Superficial and deep retinaculum MPFL incised, 2-3 cm of VMO insertion into patella detached.
  - Quality of MPFL and medial retinaculum inspected.
  - Extensor mechanism reconstructed with medial plication of VMO and MPFL so that the VMO advancement is in line with its fibers and prior insertion.
  - VMO tissue sleeve is translated laterally and imbricated in a vest-over-pants fashion.
  - Suture placed at 1 o'clock position (right knee) so that the distal part of the VMO is brought laterally in the line of its attachment to restore normal tension at 30 degrees of flexion.
  - Suture placed at 2 o'clock position through MPFL and medial patellar insertion.
  - Suture placed at 4 to 5 o'clock position through MPML and medial retinaculum to plicate these structures in line with their normal patellar attachment.
  - Final tensioning of sutures 30 degrees of knee flexion, patella centered within trochlea.
  - Knee is taken through 0-135 degrees to observe normal tracking of the patella.
- MPFL reconstruction
  - See Table 35-1.
- Distal realignment
  - 3-cm vertical skin incision placed lateral to tibial tubercle.
  - Longitudinal incision made over periosteum along lateral border of patellar tendon.
  - Planned tibial tubercle osteotomy 15 mm wide, 8 mm thick, and 35 mm in length.
  - Hole drilled through tibial cortex; four to five holes drilled on anterolateral tibial cortex.
  - Axial 90 degrees cut made just proximal to patellar tendon insertion.
  - Drill holes along anterolateral surface of tibia connected using a 1/2-inch osteotome.
  - Osteotome carried through medial cortex directly adjacent to tibial tubercle.
  - Bone fragment mobilized and translated medially 8-10 mm based on measurements.
  - Tibial tubercle secured with a 3.2-mm drill bit.
  - When a proximal advancement is also performed, medial plication and reconstruction completed.
  - Patellar glide, tracking assessed, Q-angle measured 0 and 30 degrees of flexion.
  - Final fixation tibial tubercle three 4-mm cancellous screws
- Lateral patellofemoral (iliopatellar tract) reconstruction
  - Indicated symptomatic medial patellar subluxation, manual medial glide at 30 degrees of flexion grossly positive.
  - Goal restore lateral muscle function by reattachment of the VLO if possible and reconstruct lateral soft tissue restraints.
  - Dissect VLO attachment to the quadriceps tendon and patella.
  - Reattach VLO to lateral border of the quadriceps tendon.
  - Dissect distal VLO tendon proximally, reattach VLO as distally as possible to restore normal anatomy.
  - Knee flexed 135 degrees.
  - Semitendinosus tendon autograft used to reconstruct lateral soft tissue restraints when deficient
  - Tendon placed through a lateral patellar tunnel (10 mm) which enters and exits at the one third and two thirds junction points along the vertical height of the patella.
  - Tendon ends sutured, length 25 mm.
  - Incision made junction of iliopatellar tract and iliotibial band.
  - Usual site for graft is posterior just above the lateral intermuscular septum and proximal to the lateral epicondyle; isometric position, checked by suture at two attachment sites during 0-135 degrees of knee flexion.
  - Drill hole placed; Beath pin used to pass the two ends of the tendon into the tunnel.
  - Graft lightly tensioned with knee at 30 degrees of flexion; allow a normal 10-12 mm manual medial glide.
  - Soft tissue interference screw used for fixation.
- Patella alta correction
  - See Table 35-3.

made. Routine diagnostic arthroscopy is performed, and any intraarticular pathology is evaluated and treated. Particular attention is paid to patellar position, mobility, tracking and articular surface. Approximately one fourth of the patella should establish trochlear contact at 0 to 5 degrees of knee flexion. The medial and lateral translation of the patella is assessed at 0 and 30 degrees of knee flexion (Fig. 35-7). This is an important test because a lateral translation of the patella greater than 50% of its width indicates incompetency of the MPFL. The medial translation of the patella tests for lateral retinacular tightness, and a normal lateral translation of 10 to 12 mm should be obtained with the knee at 30 degrees of flexion. The patella and femoral groove are assessed for articular cartilage pathology or dysplasia. Articular cartilage lesions are evaluated for nature, location, and depth. The finding of loose flaps of articular cartilage requires a careful debridement; otherwise, fibrillated cartilage is left alone as it is possible to produce further damage by the debridement procedure.

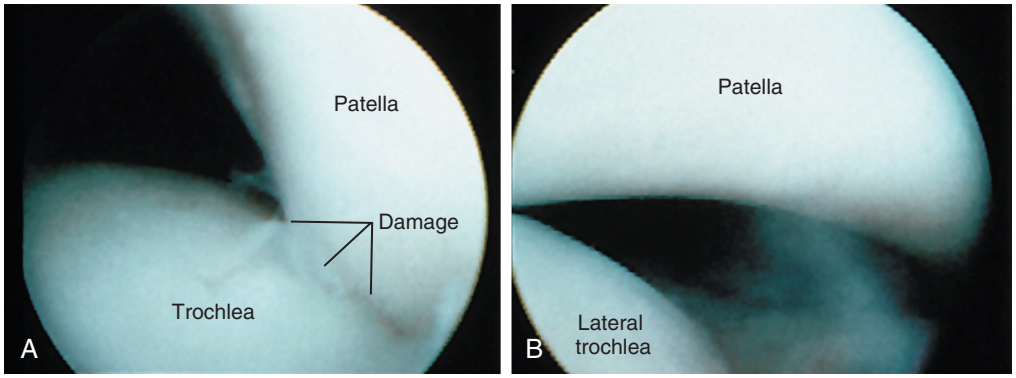

FIG 35-7 Arthroscopic medial-lateral translation manual test at 30 degrees of knee flexion shows third quadrant lateral subluxation with cartilage deterioration (**A**) and lateral subluxation viewed through the anterolateral portal (**B**).

Radiofrequency cartilage debridement devices are never used, because excessive cartilage damage occurs. Most important at the time of arthroscopy is the critical assessment of whether the realignment procedure will transfer the loading from soft or fragmented articular surface to an intact or less involved cartilage surface. The articular cartilage is graded by the classification system described in Chapter 44.[127]

Lateral Retinacular Release

A lateral retinacular release is performed only if the patellar medial subluxation test result is abnormal (the patellar medial subluxation is ≤5 mm on the manual medial translation test at 30 degrees of flexion). The goal is to perform a lateral release only when abnormally tight lateral structures and loss of normal lateral translation are demonstrated under direct visualization at arthroscopy, and not to weaken the vastus lateralis obliquus (VLO). A subcutaneous pouch is created with a scissor from the anterolateral portal over the site of the anticipated lateral release, which keeps the skin from being damaged by the intraarticular procedure. An arthroscopic retinacular release is performed using a commercial radiofrequency wand through the anterolateral portal. The lateral release is performed in two stages, from proximal to distal. The release is initiated from the 9 o'clock position (right knee) and continued distally to 1 cm below the inferior pole of the patella with the knee in full extension. The patellar medial subluxation test is then performed at 30 degrees of flexion to check for the adequacy of the release and restoration of a normal manual medial translation test. In a majority of knees, no further release is required. If the release is inadequate, it is extended proximally to a 10 o'clock position. The depth of the release involves division of the retinaculum, with care taken to avoid cutting the vastus lateralis insertion. The goal is not to perform a complete release of all lateral soft tissue restraints, which would allow the patella to be everted or have an abnormal medial translation. In select knees, there may exist excessive tightness of the VLO with marked contracture of lateral soft tissues and a tilted patella, warranting a Z-plasty lengthening through a limited lateral incision to preserve VLO function. Upon completion of the procedure, complete hemostasis is achieved by coagulation of all sources of bleeding, especially the superior lateral geniculate artery at the superolateral border of the patella.

In addition to determining that there is no abnormal restraint to lateral patellar glide at 20 to 30 degrees of flexion as already described, it is also important at 90 degrees to confirm the absence of tight lateral tissues. This is difficult to do, because lateral patellar tilting cannot be measured at high flexion angles. A measure of excessive lateral tissues can be qualitatively estimated by placing a thin-blade scissor (Metzenbaum) beneath the lateral retinaculum and observing, with knee flexion, if there is a bowstringing effect with excessive tension in the lateral soft tissues. The surgeon should always be able to gently lift and anteriorly displace the lateral soft tissues away from the lateral femoral condyle.

Proximal Realignment

The patient positioning and arthroscopic examination are performed as already described. The knee is fully flexed before inflation of the tourniquet to lengthen the quadriceps muscle. A 3-cm vertical skin incision is made along the medial aspect of the patella. The subcutaneous tissues are undermined sufficiently to create a skin flap that will allow the skin incision to be moved in proximal-distal and medial-lateral directions using four vein retractors. This decreases the length of the skin incision and allows for a cosmetic approach. The proximal retraction exposes the distal quadriceps tendon, superomedial border of the patella, and VMO insertion. The distal retraction exposes the medial border of patella, medial retinaculum, and distal retinaculum fibers referred to as the MPML. A medial parapatellar incision is then made through the medial retinaculum, extending from approximately 2 cm proximal to the superomedial aspect of the patella to the medial border of patella and progressing distally to the patella. The superficial and deep retinaculum MPFL is incised, taking care to avoid cutting through the muscle or underlying synovium. The proximal extent of the incision extends in the QT, thus detaching 2 to 3 cm of the VMO insertion into the patella. The free medial edge of the retinaculum is grasped, and the underlying synovium is dissected free. This allows the VMO, MPFL, and MPML tissue sleeve and medial retinacular tissues to be mobilized for later tensioning and advancement as required. The joint is not entered, and the synovium over the femoral condyle and medial pouch is protected to lessen postoperative scar formation at this location.

The quality of the MPFL and medial retinaculum is inspected, and a decision is made whether a MPFL reconstruction is necessary. The medial tissues should be 3 to 4 mm in thickness. A thin, abnormal medial retinaculum and MPFL indicates that a MPFL graft is required, to be described later. A mistake often made is to accept marginal MPFL tissue because it is relatively easy at this point to augment the surgery with a MPFL graft. If there is adequate MPFL tissue by visual inspection, proximal realignment is commenced. The closure procedure to be described next is performed if no distal realignment is planned; otherwise, the proximal closure is performed after the distal realignment described.

The extensor mechanism surgery involves medial plication of the VMO and MPFL so that the VMO advancement is in line with its fibers and prior insertion. The VMO tissue sleeve is translated laterally and imbricated in a vest-over-pants fashion. Three No. 1 nonabsorbable sutures are used. Three Ellis clamps are placed at the VMO center, MPFL, and MPML medial anatomic sites to reestablish a normal tension. The first suture is placed at the 1 o'clock position (right knee) so that the distal part of the VMO is brought laterally in the line of its attachment, overlapping the superior medial border of the patella and QT by 5 to 10 mm to restore normal tension at 30 degrees of flexion. The second suture is placed at the 2 o'clock position through the MPFL and medial patellar insertion. The third suture is placed at the 4 to 5 o'clock position through the MPML and medial retinaculum to plicate these structures in line with their normal patellar attachment. It is important that the final tensioning of the sutures be performed with the knee at 30 degrees of flexion with the patella held centered within the trochlea. The mistake is to adjust the tension with the knee at extension. The tightening procedure at 30 degrees of flexion allows for a normal slackness of the medial tissues and the MPFL and for a normal lateral glide of 10 to 12 mm (~25% patella width). The mistake is to apply too much tension that limits normal lateral translation, which restricts postoperative knee motion and potentially results in medial facet cartilage damage from excessive pressure. The lateral subluxation of the patella is also assessed at 0 degrees to ensure that a normal medial restraint exists, preventing abnormal lateral patellar subluxation at knee extension. The knee is taken through a range of motion of 0 to 135 degrees to observe normal tracking of the patella. If the sutures disrupt, this is an indication that the medial advancement was excessive and the suture placement and tensioning procedure is repeated.

FIG 35-8 Demonstration of complete dislocation of patella at the time of surgery after multiple prior operative procedures. A reconstruction of the medial patellofemoral ligament was required. (From Parik, SN, Noyes FR, Albright J. Proximal and distal extensor mechanism realignment: the surgical technique. *Tech Knee Surg.* 2006;5:27-38.)

Medial Patellofemoral Ligament Reconstruction

MPFL deficiency is diagnosed when the patella translates greater than 50% of its width from the center of the sulcus. Symptomatic patients with chronic dislocations or subluxations will frequently demonstrate patellar translation of 75% to 100% (of its width) under manual pressure at both 0 and 30 degrees of flexion (Fig. 35-8). An MPFL reconstruction is always indicated in revision surgery when a prior proximal realignment procedure has failed and a residual lateral patellar subluxation exists. The intraoperative examination includes the lateral subluxation test at 0 and 30 degrees of flexion. The balancing of the medial soft tissue restraints requires that tension be restored at both knee positions to guide the patella into the trochlear and resist lateral patellar subluxation at full extension and with knee flexion. The operative procedure includes a balancing of three structures, namely, the MPFL, VMO, and medial retinacular fibers, including the MPML. Preoperative radiographs and MRI define whether a patella alta or lateral patellar tendon offset exists, requiring distal tibial tubercle correction.

The patient is placed in a supine position on the operating table with the foot of the bed flexed 20 to 30 degrees. A high-thigh tourniquet is placed (sterile or nonsterile) so that the entire lower extremity is draped and provides an estimate of patellofemoral alignment. A diagnostic arthroscopy is performed as already described and the condition of the patellofemoral articular cartilage documented. Medial-lateral glide tests are performed at 30 degrees of flexion to determine the resisting function of the medial and lateral soft tissue restraints. The leg is elevated, exsanguinated, and the tourniquet inflated.

The operative steps of MPFL reconstruction are shown in Figure 35-9 and summarized in Table 35-1. A 5- to 6-cm incision is made at the medial border of the patella and extended 1 to 2 cm proximally (see Fig. 35-9, *A*). A dissection of the skin flaps is carefully performed beneath the fascia layer to preserve the skin blood supply. This allows the incision to be mobilized in a proximal-distal direction, providing a cosmetic incision one half the usual length. The dissection is carried over the medial aspect of the knee and medial epicondyle to the adductor tendon. A head light and careful dissection technique is used at this point to avoid the infrapatellar nerve branches, which can result in injury and a painful neuroma. The medial nerves are highly variable in their course as shown in Chapter 1. The skin flaps are further developed in all directions to be able to reach the proximal aspect of the QT, a distance of 6 to 7 cm from the patellar insertion for the planned turn-down of the medial QT graft.

A medial incision through the medial retinaculum is made 5 mm from the medial border of the patella from the inferior to superior pole. The medial incision is extended distally to the level of the joint. This is an incision similar to that used for a proximal realignment procedure already described, which is performed in conjunction with the MPFL reconstruction.

Using an Army/Navy retractor, the insertion of the VMO into the QT is identified. A ruler is used to measure the MPFL attachment length from the medial border of the patella, past the epicondyle to the adductor tubercle and tendon. This provides the length of the QT graft to be harvested (see Fig. 35-9, *B*). A ruler is used to mark the medial QT to harvest a graft 8 mm wide, 6 mm thick, and usually 60 mm in length. A partial- or full-thickness medial QT graft is harvested 5 mm from the medial border of the VMO to allow for VMO tendon-to-tendon suturing after harvest. The proximal graft never extends into the proximal QT-muscle junction because this would weaken the attachment. Two incisions are made into the medial QT at the marked graft site, avoiding penetration into the capsule. The incision connects to the prior medial patellar retinaculum incision. The medial QT graft

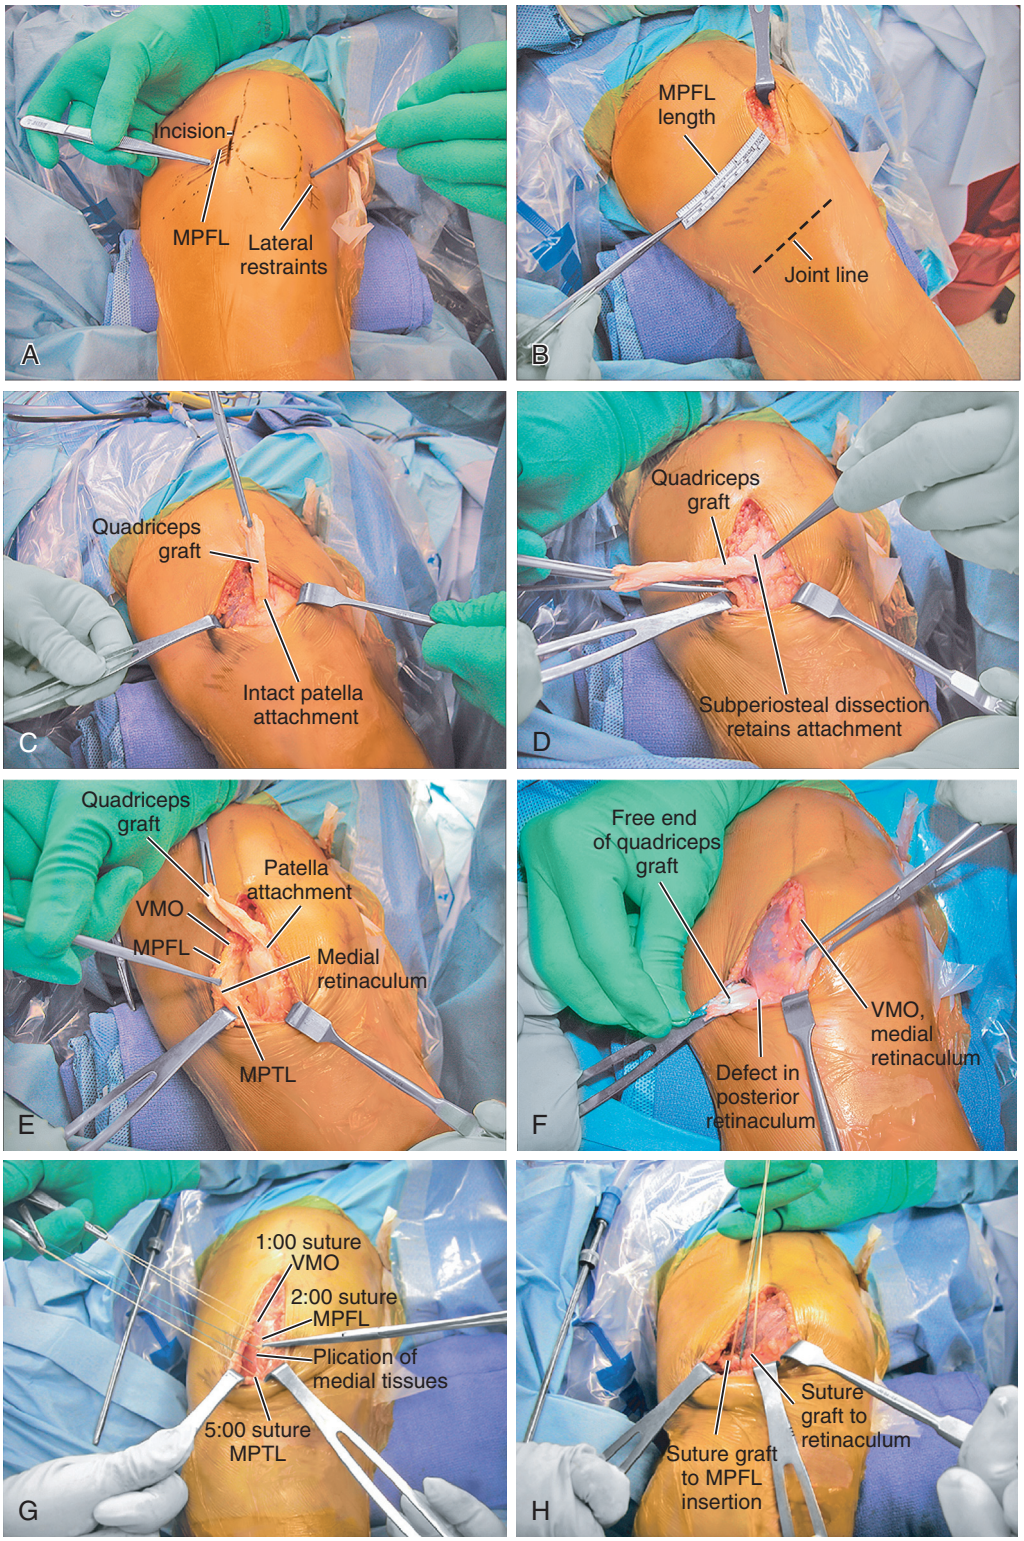

FIG 35-9 Medial patellofemoral ligament (MPFL) reconstruction with quadriceps tendon. **A,** After arthroscopic evaluation, the planned surgical incision (*thick black line*) along the medial aspect of the patella is shown. **B,** Measurement of length of graft needed (60 mm); limited cosmetic incision is shown. **C,** A medial full-thickness quadriceps tendon graft, 60 mm × 8 mm wide (measured to the superior edge of the patella) is harvested with the patellar attachment retained. In some knees, a partial-thickness autograft provides a suitably sized graft. Two to 3 mm of remaining quadriceps tendon is left attached to the vastus medialis obliquus (VMO) for later closure. **D,** Completed 60-mm quadriceps tendon graft after dissection from the superior-medial patella down to the normal anatomic attachment site of the MPFL. **E,** Dissection deep to the medial retinaculum and above synovial pouch and MPFL, medial patellomeniscal ligament (MPML). **F,** Puncture of the medial retinaculum, posterior to the medial femoral epicondyle at the native MPFL attachment just anterior to the adductor tendon, with passage of graft beneath retinaculum. Setting of the normal tension of the medial soft tissues (see text). **G,** Imbrication of the VMO, medial retinaculum, MPFL, and MPML. **H,** Suturing of the quadriceps graft to the MPFL native femoral attachment, with a backup suture to the adductor tendon. The graft and medial tissues are not overtensioned and should allow a normal lateral translation (glide) of 25% patellar width. (From Noyes FR, Albright J. Reconstruction of the medial patellofemoral ligament with autologous quadriceps tendon. *Arthroscopy.* 2006;22:904e1-904e7.)

TABLE 35-1 Key Points to Successful Medial Patellofemoral Ligament Reconstruction

Preoperative

1. Complete rehabilitation for muscle and motion deficits.
2. Comprehensive evaluation of patellar soft tissue restraints, Q-angle (0 and 30 degrees of flexion) and with internal-external rotation, standing rotational alignment, and gait (see text).
3. Complete radiographic and MRI evaluation, femoral anteversion, hip rotation, trochlear dysplasia, trochlear groove, patellar height, patella-trochlear contact at 0 degrees, lateral tibial tubercle offset, external tibial torsion.

Operative Steps

1. Confirm preoperative examination under anesthesia, medial-lateral translation tests, lateral translation >50% patellar width 0 and 30 degrees of knee flexion, measure resting Q-angle at 0 degrees and Q translation arc with internal-external tibial rotation at 30 degrees.
2. Arthroscopic procedure defines patellofemoral abnormalities, confirms medial-lateral translation 30 degrees, and need for proximal realignment. Limited arthroscopic lateral release only with contracted lateral tissues and absence of normal medial glide (see text).
3. High thigh tourniquet to view entire lower extremity and patellofemoral tracking.
4. Cosmetic limited medial incision, medial to patellar border and 1-2 cm proximal to patella; undermine incision for skin mobilization.
5. Careful subcutaneous dissection medially to adductor magnus tendon, avoiding infrapatellar nerves and proximally along medial VMO and quadriceps tendon.
6. Incise medial retinaculum adjacent to patella to the joint line, confirm thin medial tissues, insufficient MPFL requiring graft reconstruction.
7. Harvest full-thickness medial quadriceps graft 60 mm long, 8 mm wide, and 6 mm thick, leaving 5 mm medial VMO tendon for closure. Connect medial quadriceps tendon incision to prior medial retinaculum incision.
8. Careful subperiosteal dissection quadriceps graft attachment proximal and medial aspect patella to native MPFL attachment.
9. At the posterior junction of the medial retinaculum, preserve medial synovial pouch, penetrate retinaculum just above adductor tendon, rotate graft 90 degrees at patella. Pass free end of graft beneath retinaculum to exit through retinaculum hole overlying native MPFL attachment and adductor tendon.
10. Perform proximal realignment advancing the entire medial retinaculum sleeve and VMO, carefully setting tension to allow normal 25% patellar width lateral glide at 30 degrees of flexion (see text). Perform knee flexion-extension to observe normal patellofemoral tracking.
11. Determine graft tension with knee flexion 0-120 degrees. Graft should not piston or be tight with increasing knee flexion. Quadriceps graft sutured to native MPFL attachment posterior to femoral epicondyle and just anterior to adductor tendon under minimal graft tension to avoid overconstraining normal lateral patellar glide. Perform medial-lateral glides tests again and full flexion to confirm normal medial restraint and patellar stability restored. Closure of remaining quadriceps tendon incision.
12. Additional sutures to reinforce quadriceps graft at medial patellar attachment may be required.

MPFL, Medial patellofemoral ligament; *MRI*, magnetic resonance imaging; *VMO*, vastus medialis obliquus.

is transected proximally, preserving its attachment to the superomedial border of the patella (see Fig. 35-9, *C*). The three tendon components of the QT (rectus, confluent VMO-VLO, intermedius) are carefully identified, and the proximal end of the graft is sutured with a baseball-type stitch (No. 1 nonabsorbable suture).

With care taken not to transect the graft, subperiosteal dissection of the patellar attachment of the graft is performed to a point approximately 30% of the proximal height of the patella at the normal MPFL attachment (see Fig. 35-9, *D*). Later in the procedure, appropriate sutures are placed to secure the proximal patellar attachment of the QT graft to adjacent tissues. Preserving the medial synovial pouch and avoiding penetration of the joint, the medial retinaculum is bluntly dissected off the capsule past the medial epicondyle to the adductor tendon (see Fig. 35-9, *E*). At the junction immediately anterior to the adductor, distal to the insertion of the VMO, and posterior to the medial epicondyle, a hole is punctured in the retinaculum with a right-angle hemostat (see Fig. 35-9, *F*). The graft is turned 90 degrees and folded over on itself at the proximal medial portion of the patella. The free end of the QT graft is passed beneath the retinaculum, adjacent to the VMO attachment, and through the created retinaculum hole to exit and lay over the native MPFL attachment just posterior to the femoral epicondyle and anterior and slightly distal to the adductor tendon attachment (Fig. 35-10).

The final proximal realignment tensioning procedure is then performed following the steps previously outlined (and after the distal realignment when added to the overall realignment surgery). With the knee flexed 30 degrees and the patella located within the trochlea, the medial plication procedure is performed, including closure of the QT

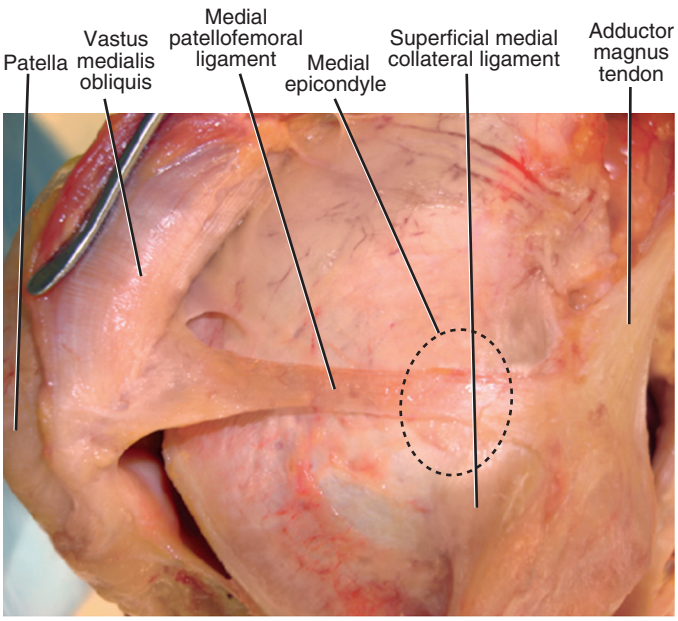

FIG 35-10 Medial patellofemoral ligament inserts into a depression behind the medial epicondyle and blends with fibers of the superficial medial collateral ligament.

graft harvest site. The entire medial soft tissue and VMO is grasped with an Ellis clamp placed at the 1 o'clock (VMO), 2 o'clock (MPFL), and 4 o'clock (retinaculum, MPML) areas and gently brought in line of its attachments to determine the amount of plication and overlap for suturing. Three sutures are placed at these respective sites with care taken not to overtension the repair. It is emphasized that there must always be a normal lateral glide of 25% of the width of the patella at 0 and 30 degrees of flexion under manual pressure to avoid limiting normal patellar mobility. The imbrication procedure restores the patella to its reduced position (see Fig. 35-9, *G*).

The final portion of the procedure consists of suturing the MPFL-QT graft to the native femoral MPFL attachment. The end of the graft is held with the clamp at the MPFL attachment, and the knee is flexed from 0 to 120 degrees to confirm that the graft is isometric and not too proximal or distal. Two nonabsorbable sutures are placed into the soft tissue of the native MPFL attachment and sutured to the graft with minimal to no tension on the graft. If the tissues are not substantial, then a suture anchor is used. The remaining graft lays over the distal adductor tendon, and a third suture of the graft to the adductor tendon is used as a back-up. The sutures avoid penetrating the medial geniculate artery at the posterior border of the VMO and the medial infrapatellar nerve when present (see Chapter 1). Again, emphasis is made that no tension is applied to the graft, which simply lies in the native MPFL attachment location, because the tension in the medial soft tissue restraints has already been set by the medial retinaculum suturing just described. Again, the lateral glide test is performed to make sure the graft is not under any resting tension and that the combined medial soft tissue imbrication and MPFL reconstruction is initially lax and allows the patella to be displaced 25% of its width, restoring the normal length of the medial soft tissues. After suturing is complete, the knee should be ranged from 0 to 135 degrees, restoring normal patellofemoral tracking. An additional two to three absorbable sutures are then placed in a figure-eight fashion, reinforcing the fixation of the graft to the medial border of the patella (see Fig. 35-9, *H*).

The advantage of this procedure is that no bone tunnels are placed into the patella or medial femoral condyle, as described in other MPFL reconstructions. The graft is sutured along the path of the native MPFL by pliable soft tissue fixation, reproducing patella and femoral attachments. It is not necessary to add a harvest of a medial hamstring tendon. Another advantage is the entire medial retinaculum and remaining MPFL and MPML tissues are restored to a normal tension. The disadvantage of the procedure is related to the medial QT graft harvest because this adds additional postoperative pain in comparison with a hamstring autograft. In knees with previous dislocations or revision cases, the restoration of the normal proximal VMO tension is performed with closure of the proximal harvest site. It is important that MPFL reconstruction be performed in the majority of knees with a prior dislocation because the medial retinacular restraints are usually thin with no identifiable competent MPFL structure. The resultant cosmetic appearance of the incision and restoration of full knee flexion are demonstrated in Figure 35-11.

The senior author has noted in the 2 to 4 postoperative week time period, the occurrence of pain with knee flexion along the MPFL reconstruction that reflects soft tissue graft and retinaculum irritation from the immediate motion program. There is a balance to be established with gentle range of motion of 0 to 90 degrees to prevent adhesions and allow tissue edema and healing. Antiinflammatory medications and cryotherapy are important. A local injection of an anesthetic into the medial retinaculum can be used in select cases to allow the therapist to mobilize knee flexion. In some cases, a gentle range of motion under chemical analgesia is necessary where only light pressure is required to restore full range of knee motion. This allows the patient to immediately regain knee motion and the relief of pain is somewhat dramatic. The surgeon should be aware of this problem, inherent in all MPFL reconstructions and necessity to restore early normal knee flexion.

Distal Realignment

A lateral radiograph is used to confirm that a normal patellar tendon length and patellar height exist, as described in Chapter 38. A 3-cm vertical skin incision is placed lateral to the tibial tubercle (Fig. 35-12). The subcutaneous tissues are undermined sufficiently to create a skin flap that allow the skin incision to be moved in all directions and maintain a small cosmetic incision. The patellar tendon insertion is identified and a retractor placed behind it to identify its insertion site on the tibial tubercle. A longitudinal incision is made into the periosteum along the lateral border of the tibial tubercle patellar tendon insertion. Subperiosteal dissection is carefully performed to expose the anterolateral aspect of the tibia, reflecting the periosteum and the muscular origin of the anterior compartment. Care is taken in the dissection not to enter into the muscle tissues to decrease postoperative pain and swelling. The planned tibial tubercle osteotomy is 15 to 20 mm in width, 8 mm thick, and 35 mm in length. At the distal extent of the osteotomy, a hole is drilled through the tibial cortex, using a 3.2-mm drill bit and drill guide. This is to prevent the osteotomy from extending distally. The drill hole is placed beneath the anterior tibial periosteum, which is preserved to maintain the normal

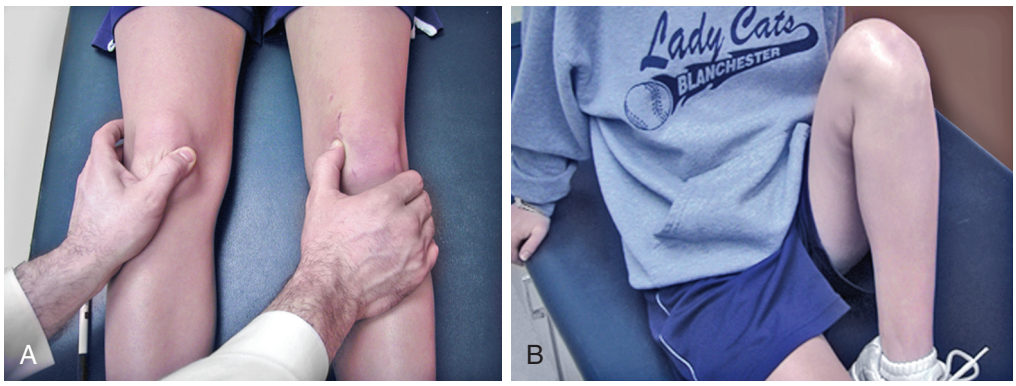

FIG 35-11 Three-month postoperative case demonstrating excellent healing and function of reconstructed medial patellofemoral ligament in resisting lateral patellar translation (**A**), and full flexion of the knee (**B**). proximal to distal position of the tibial tubercle. Similarly, four to five holes are drilled on the anterolateral tibial cortex along the line of the planned osteotomy; the angle of the osteotomy is oblique by 15 to 20 degrees from a posterolateral-to-anteromedial direction. An axial 90-degree cut is made just proximal to the patellar tendon insertion to mark the proximal extent of the osteotomy. This step-cut produces a bony buttress to prevent proximal migration of the tibial tubercle. The drill holes along the anterolateral surface of the tibia are then connected using a half-inch osteotome. The osteotome is carried through the medial cortex directly adjacent to the tibial tubercle, while the distal periosteal hinge remains intact. The bone fragment is carefully mobilized and translated medially, according to a predetermined amount based on TT/TG distance correction. This distance is usually 8 to 10 mm. The tibial tubercle is secured with a 3.2-mm drill bit.

The tourniquet is deflated so that there is no pressure on the quadriceps muscle during assessment of quadriceps function. When a proximal advancement is also performed, it is at this point that the medial plication and reconstruction are completed as already described. The ability to glide the patella medially and laterally by one quadrant, with the knee in 30 degrees of flexion, is verified. The patellofemoral tracking is next assessed by taking the knee through a range of motion. The patella should remain centralized within the femoral sulcus, with no medial or lateral tilt or subluxation in flexion or extension. The Q-angle is assessed using a goniometer, with the knee at 0 and 30

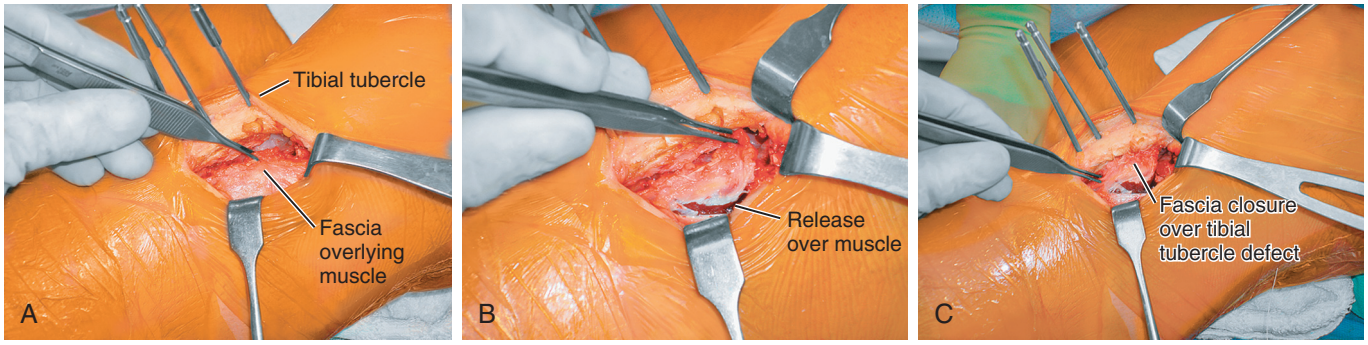

FIG 35-13 Technique for cosmetic closure of lateral tibial tubercle defect after medial displacement. **A,** The gap between the lateral soft tissues and tibial tubercle is shown. **B,** Incision 15 mm lateral to the defect and at the proximal extend of the soft tissue flap. **C,** Rotation of soft tissue flap into defect with closure to the soft tissues along the lateral border of the tibial tubercle. This simple transposition of adjacent soft tissues prevents the lateral indentation commonly visible after tibial tubercle medialization.

degrees of flexion in neutral, internal, and external rotation. The Q-angle should always be positive, even with maximum internal tibial rotation. The correction based on preoperative TT/TG distance and the preoperative measurements is confirmed. These measurements are only approximations, and the goal is to restore as closely as possible a normal lateral patellar tendon attachment. Once the ideal position is determined, the final fixation of the tibial tubercle is done with three 4-mm cancellous screws. A compression technique with overdrilling the tibial tubercle is performed, and the screw head is countersunk to prevent prominence under the skin. If the bone quality is questionable, cortical screws can be used for bicortical fixation. The screws should be tightened gently to avoid fracturing the tibial tubercle.

At this point, hemostasis is achieved, followed by the closure of the wound in layers. There is a lateral tibial tubercle defect after the medial displacement that requires a simple shifting of the anterolateral fascial tissues (Fig. 35-13), which closes the defect and prevents a cosmetic unappealing indentation and concavity in this area after healing of the incision. The skin is closed using subcuticular stitches. A Hemovac drain is not used. A double-cotton, double-Ace compression dressing is applied, and the lower extremity is placed in a brace. Cryotherapy is instituted immediately after surgery in the operating room.

Lateral Patellofemoral (Iliopatellar Tract) Reconstruction

The anatomy of the lateral iliopatellar tract is presented in detail in Chapter 1. The iliopatellar tract is divided into the superficial oblique retinaculum and a second layer termed the *deep transverse fibers*. The attachment of the vastus lateralis to the superolateral aspect of the patellae is shown in Chapter 1.

As previously discussed, a lateral release should only be performed when there is an abnormal contracture of these tissues, with an inability to perform a manual lateral translation (glide) at 30 degrees of flexion. This condition may occur with joint arthrofibrosis or from a developmental standpoint referred to as *lateral patellar compression syndrome* that may be associated with a bipartite patella. In the 1970s and 1980s, some authors recommended a lateral release that included resection of the VLO attachment for lateral patellar subluxation.[104-106] It is now appreciated that the appropriate treatment of a lateral patellar subluxation is restoration of the MPFL and not weakening the VLO. There remain descriptions of the lateral release of soft tissues and VLO to the extent that the patella can be everted, which should be avoided.

The syndrome of a medial subluxation after a release of the lateral restraining structures and VLO has been identified by numerous authors.[19,83,86,125,149] Nonweiler and DeLee[125] reported on a series of five patients who presented with medial subluxation, pain, swelling, and giving way following isolated lateral release. All underwent reconstruction of the lateral retinaculum. An average of 3.3 years postoperatively, four of the five had no symptoms of instability, and the patellar stability was similar to the contralateral limb. Hughston and Deese[83] described a series of 60 knees treated after failure of a lateral release to improve symptoms. Thirty knees had developed medial subluxation of the patella, 17 of whom underwent an isolated lateral release and 13 of whom underwent a concomitant proximal or distal realignment. Twenty-seven of these 30 knees had disabling symptoms postoperatively, and all demonstrated marked quadriceps atrophy and retraction of the VLO. Biedert and Friederich[21] described 41 cases of patients who had pain after a lateral release; 32 also had medial subluxation of the patella.

Christoforakis and colleagues[35] measured the effects of lateral release on the lateral stability of the patella in cadaveric specimens (aged 65-82 years). The patella was displaced 10 mm laterally while measuring the required force, with 175 N of quadriceps tension. Patellar force-displacement behavior was measured from 0 to 60 degrees of knee flexion in intact knees and then after lateral release, which extended from the proximal limit of the lateral retinaculum to Gerdy's tubercle. At 0, 10, and 20 degrees of flexion, the mean force required to displace the patella (10 mm laterally) was significantly reduced after lateral release by 16 to 19% ($P = .002$ to $.001$). The investigators concluded that the procedure decreased the lateral stability of the patella in normal elderly knees.

The diagnosis of a symptomatic medial patellar subluxation is not difficult. The patient complains of medial subluxation events that produce partial giving way and pain that commonly occurs with normal activities of daily living. The patient can usually distinguish the medial subluxation position of the patella from a lateral subluxation. The manual medial glide at 30 degrees of flexion is usually grossly positive, producing patient apprehension. The defect in the VLO attachment is palpable, and the patella can be everted. There is often extensive muscle atrophy that requires months of physical therapy before surgery.

The goal of surgical treatment is to restore lateral muscle function by reattachment of the VLO if possible and to reconstruct the lateral soft tissue restraints. The skin incision for the surgical approach depends on the placement of incisions from prior surgery and either a medial or lateral parapatellar incision provides exposure. It is necessary to dissect the VLO attachment to the QT and patella. It is usually

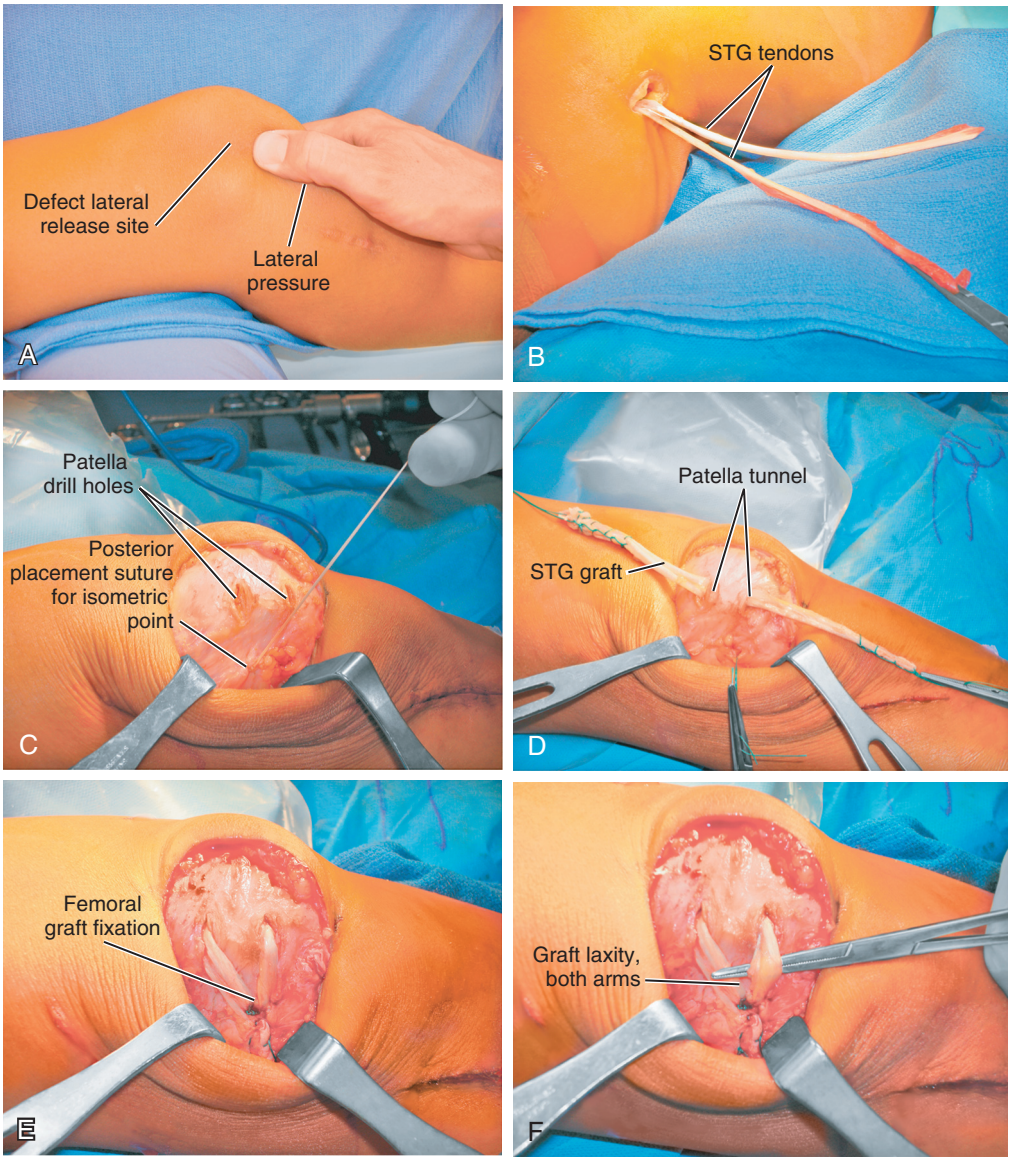

FIG 35-14 Surgical demonstration of semitendinosus-gracilis (STG) autograft lateral reconstruction for symptomatic medial subluxation after a prior proximal realignment involving complete release of the lateral soft tissue restraints. **A,** A positive manual medial glide test shows obvious medial subluxation. **B,** Harvest of STG autograft through limited medial incision. **C,** Placement of two drill holes on the lateral border of the patella avoids a tunnel into the anterior cortex, which would weaken the patella. A suture is placed to identify the location of the lateral femoral tunnel for the STG graft. The previously transected and scarred lateral retinaculum is not disturbed. In this case, the vastus lateralis obliquus insertion is shown to be intact. If it was previously released, it would be dissected and reattached. **D,** Passage of the two arms of the STG graft through the lateral patellar tunnel. **E,** Final STG graft fixation. **F,** Demonstration that the graft is under no tension with the patella at 30 degrees of knee flexion; however, the graft is adjusted to resist a 10-mm medial patellar glide (see text).

possible to reattach the VLO to the lateral border of the QT. Often, a layer of scar tissue at the site of the prior release is identified, and it is a simple matter to excise the scar and reattach the VLO. It may also be possible to reattach a portion of the VLO to the superior lateral border of the patella; however, frequently a contracture and shortening of the VLO have occurred. The distal VLO tendon is dissected proximally and an attempt made to reattach the VLO as distally as possible to restore normal anatomy. The knee is flexed to 135 degrees to ensure the distal attachment of the VLO does not limit flexion or that the sutures pull out from a shortened VLO muscle.

The reconstruction of the lateral soft tissue restraints is accomplished with a semitendinosus tendon autograft, which is preferred over an allograft to avoid delayed remodeling (Fig. 35-14). If the semitendinosus tendon is small in diameter, the gracilis tendon is also incorporated into the construct. The tendon is placed through a lateral patellar tunnel, which enters and exits at the one third and two thirds junction points along the vertical height of the patella and avoids a tunnel in the anterior patellar cortex which has been associated in some cases with fractures. The lateral patella tunnel for the graft is approximately 10 mm in length, with a diameter matching that of the

tendon. Each end of the tendon is sutured with a baseball-type stitch and the length adjusted so that 25 mm of tendon will pass into the femoral tunnel used for the posterior attachment of the graft.

An incision is made at the junction of the iliopatellar tract and the ITB to expose the lateral aspect of the femoral condyle and lateral intramuscular septum. The isometric point for the femoral tunnel on the lateral femoral condyle is identified by using a suture fixed to the lateral patellar tunnel site and a guidewire placed at the lateral femur with full extension-flexion produced. The usual site for the graft is posterior just above the lateral intermuscular septum and proximal to the lateral epicondyle. A drill hole is placed at this site and a Beath pin used to pass the two ends of the tendon into the tunnel. A soft tissue interference screw is used for fixation. The tension in the graft before fixation is adjusted by placing the knee at 30 degrees of flexion and allowing a normal 10- to 12-mm manual medial glide. The graft should be under no tension in its resting state and only under tension to resist the manual medial patellar displacement test previously described. It is important not to overtension the graft and produce a lateral soft tissue contracture, which would potentially lead to articular cartilage damage (iatrogenic lateral patellar compression syndrome). Following tensioning, the knee is taken through a full range of motion. The wound closure is routine, and a drain is not necessary. The rehabilitation program is the same as that described for an MPFL reconstruction.

Patella Alta Correction

Patella alta represents a congenital abnormality of an increased vertical position of the patella attributable to an elongated patellar tendon, resulting in the patella not engaging within the trochlea until the mid-flexion range of motion. Patients typically present with significant complaints related to lateral patellar subluxation or dislocation that can affect all activities of daily living. Ward and coworkers[178] studied patients with patella alta with MRI under partial weight-bearing loads that induced quadriceps tension at various knee flexion angles and reported increased lateral displacement and lateral tilt at 0 degree of knee flexion (Fig. 35-15). There was a decrease in patellofemoral joint contact area in subjects with patella alta at all knee flexion angles. The data did not explain the basis for anterior knee pain in symptomatic patella alta patients, and the authors recommended the need for further studies. In most patients, the patella alta abnormality does not occur in isolation, and other abnormalities of the extensor mechanism are usually present. Some patients with patella alta and anterior knee pain and joint swelling have signs of patellofemoral crepitus and arthritis (usually in the distal third of the patella) but do not experience subluxation symptoms.

The major factors for patellar instability include patella alta, MPFL deficiency, trochlear dysplasia, and patellar tendon tibial tubercle lateral offset, as already discussed. Associated increased femoral anteversion and increased external tibial torsion add to the predisposition for lateral patellar instability. The decision to correct an abnormal patellar tendon length to allow the patella to engage within the trochlea would only address one aspect of the problem in cases of lateral patellar subluxation or dislocation. Additional correction of an MPFL deficiency and lateral patellar offset may be required. At surgery, the tibial tubercle is advanced distally to restore a normal patellotrochlear relationship. In this corrected position, the medial-lateral manual translation tests determine the new tension relationship of the MPFL and lateral restraints and the need for rebalancing the tension by surgical correction.

There are differences in the methods used for measurement of patellar height regarding the anatomic points selected and the values used for the classification of an alta, normal, or infera position of the patella. Seil and colleagues[145] compared five different patellar height ratio techniques in 21 patients and reported that the classification of alta, normal, and infera depended on the normative data chosen for each technique. The normal values for patellar height and those selected to determine the presence of patella alta and patella infera are shown in Table 35-2. Noyes and colleagues[128] conducted a study to determine normal right to left patellar vertical height ratios within the same individual in a group of 51 patients (102 knees). The difference in the vertical height ratio of the patella between these two methods ranged from 0% to 9%, with an average difference of 3%. Large variations existed in the ratios among individual patients (range, 0.75-1.46).

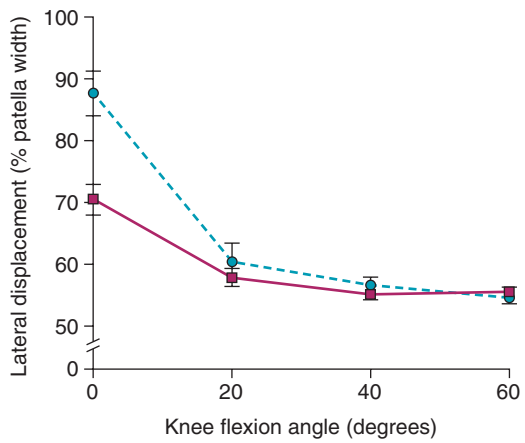

FIG 35-15 Lateral patellar displacement as a function of knee flexion angle in controls (*solid line*) and subjects with patella alta (*dashed line*). Error bars indicate one standard error. The difference between the patella alta group and the control group at 0 degrees of knee flexion was significant ($P < .05$). (From Ward SR, Terk MR, Powers CM. Patella alta: association with patellofemoral alignment and changes in contact area during weight bearing. *J Bone Joint Surg Am.* 2007;89:1749-1755.)

SD, Standard deviation.

Shabshin and coworkers[148] reported patellar tendon length to patellar length on MRI in 245 patients using the Insall-Salvati method. The results of the measurement are shown in Figure 35-16. The patients were not selected out as to diagnosis and were referred for orthopedic evaluation for a number of disorders; thus it is not known how many patients had a clinical diagnosis of a patellar subluxation or dislocation, which is an unaccounted variable in the study. In addition, the measurements were made with the knee in full extension with the possibility of an inaccurate length for the patellar tendon in a resting position.

Biedert and Albrecht[20] described an MRI method to measure the true articular cartilage sagittal patellotrochlear relationship at 0 degree extension. The ratio of the patellar to trochlear cartilage contact was described as a percentage and the mean index was 32 ± 12%. An index value greater than 50% indicated a patella infera and less than 12.5%, a patella alta (Fig. 35-17). This is a useful index in surgical cases of patella alta in determining at surgery the distal displacement of the tibial tubercle to establish a normal patellotrochlear relationship. The authors believe this index is useful along with other published indices (e.g., Blackburn-Peel,[23] Linclau,[95] and Caton and colleagues[33]). The potential problem with the patellotrochlear index method is the inability to obtain a quadriceps contraction during the MRI to define that the patella is at a maximum proximal relationship. In the absence of a quadriceps contraction, the patella may appear to be lower and the maximum patellar height will not be measured.

In Figure 35-18, radiographs of a 16-year-old male who had multiple recurrent lateral patellar dislocations are shown that demonstrate

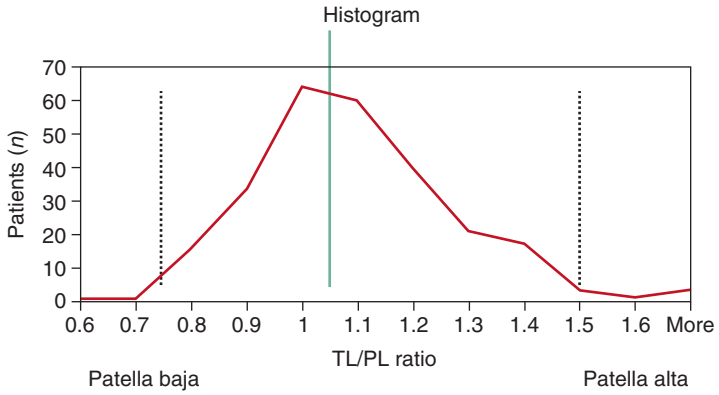

FIG 35-16 Histogram demonstrates the distribution of the Insall-Salvati Index (ISI) applied to the study population. Note the asymmetric curve, which is skewed toward the higher ratios. The *green line* shows the mean (1.05), and the *dashed lines* represent the proposed normal range, which is defined by calculating the extreme 2.5% of the ratio at each end of the curve. *PL*, Patellar length; *TL*, patellar tendon length. (From Shabshin N, Schweitzer ME, Morrison WB, Parker L. MRI criteria for patella alta and baja. *Skeletal Radiol.* 2004;33:445-450.)

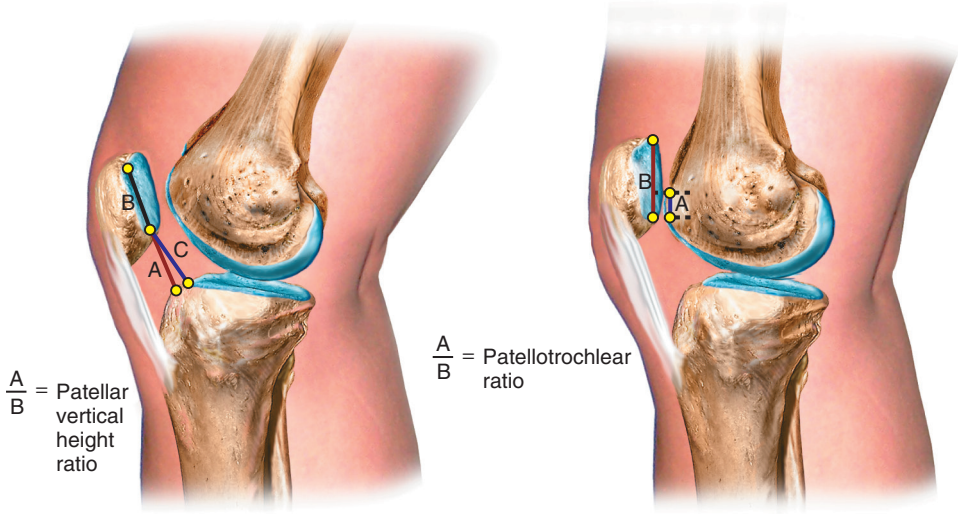

FIG 35-17 **Left,** Method used to determine patellar vertical height ratio on lateral radiograph with a quadriceps contraction to show the maximum elevated position of the patella. The numerator, *line segment A*, is the distance between the most ventral (anterosuperior) rim of the tibial plateau and the lowest end of the patellar articular surface. The denominator, *line segment B*, is the maximum length of the patellar articular surface. An alternative numerator, *line segment C*, locates the tibial reference point on the middle of the tibial plateau. The patellar vertical-height ratio equals A/B or C/B. **Right,** Alternative patellotrochlear ratio measurement. The mean ratio is 32 ± 12%; >50% indicates patella infera, and <12% indicates patella alta.

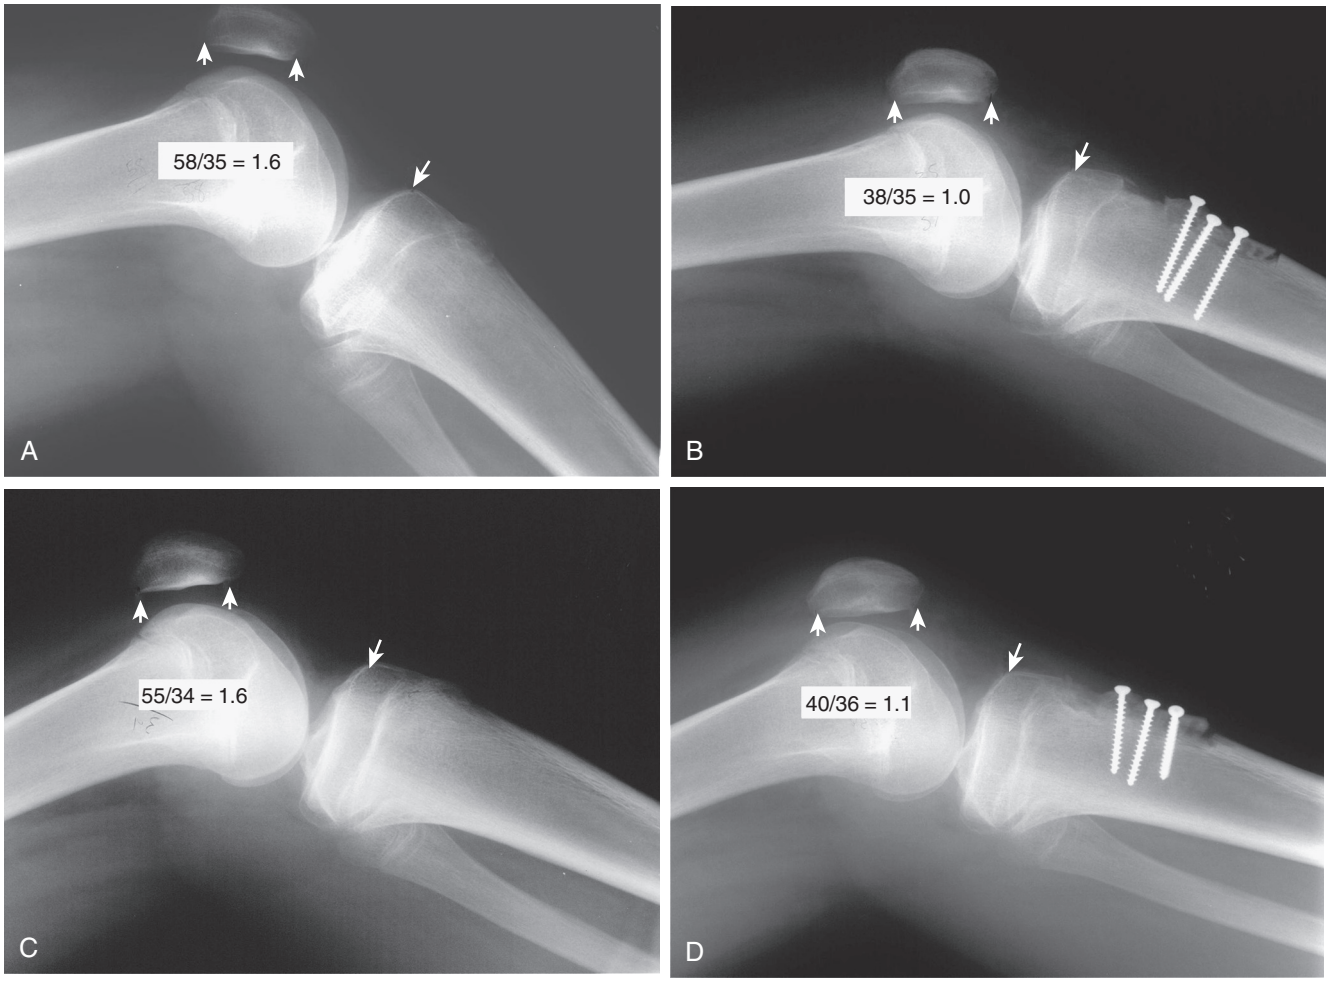

FIG 35-18 Demonstration of a symptomatic bilateral patella alta with multiple recurrent dislocations. **A** and **B,** Preoperative and postoperative radiographs of the left knee. **C** and **D,** Preoperative and postoperative radiographs of the right knee. A medial patellofemoral ligament reconstruction was performed with a quadriceps tendon autograft as previously described on both knees. The right knee was initially performed, followed 4 months later by the left knee reconstruction. The patient's growth was complete and the tibial tubercle physes closed. The patient had an uneventful successful recovery without further patellar dislocations and participates in athletic activities.

bilateral patella alta. The Linclau ratio was 1.6, and the patellotrochlear index demonstrated no patellar contact at full extension. The corrective bilateral operative procedures had to be delayed 2 years to allow for completion of growth. A distal transfer of the tibial tubercle was performed to restore these two indices to normal values. Lateral radiographs taken at surgery are required to measure that a normal patellar height ratio has been restored and to prevent too distal a transfer and a patella infera condition. A concurrent MPFL reconstruction was also performed.

Neyret and colleagues[119] measured the patellar tendon length on lateral radiographs and MRI in 42 knees with patellar dislocation and 51 control knees. These investigators reported that the patellar tendon was 8 mm longer in the former group (mean length, 52 ± 6 m, and range, 39 to 61 mm; and 44 ± 7 mm and range, 32 to 62 mm, respectively, $P < .0001$). The wide range in patellar length shows the marked variation in patellar length from patient to patient even in the dislocation group. The Caton-Deschamps index was abnormal (>1.20) in 48% of the dislocation group and 12% of controls, and the values for the MRI were 60% and 12%, respectively. There was no difference in the distance of the tendon insertion on the tibia compared with the tibial plateau. The authors suggested that when a distal transfer of the patellar tendon in patella alta cases is performed, a tenodesis of the tendon at the tibial insertion site would restore normal tendon length and decrease side-to-side patellar mobility, given the high percentage of associated trochlear dysplasia. The senior author has no experience with this operative technique and this technique is avoided because a concern exists of tilting the inferior pole of the patella in a posterior direction.

Lancourt and Cristini[93] used the Insall-Salvati method; however, these authors used the patellar tendon length as the denominator and the patellar length as the numerator, which is the reverse of the original description of this method. They reported that the Insall-Salvati index was 1.0 in normal patients, 0.80 in dislocating patella (alta), and 0.86 (infera) in chondromalacia (patella grating, crepitus), with the differences statistically significant ($P < .05$). The authors believed that patella alta results in patellotrochlear incongruity and risk for early patellofemoral arthritis. Marks and Bentley[101] used a similar Insall-Salvati method in 51 patients with patellar chondromalacia graded at arthroscopy and reported no definite relationship to patella alta, suggesting that recurrent dislocation provided a stronger relationship.

Al-Sayyad and Cameron[3] reported short-term improvements in patellofemoral scores (1-4 years postoperatively) in 25 patients with painful patella alta and no history of patellar dislocation who underwent distal transfer of the tibial tubercle. The authors did not provide a system for computing the measurement of the millimeters of distal transfer of the tibial tubercle. A patient satisfaction rate of 88% was reported. Patients with a normal-appearing trochlea had higher scores compared with those with trochlear articular cartilage damage. The study reported that cartilage lesions typically involved the inferolateral portion of the lateral patellar facet, with possible involvement of the lateral region of the trochlea. The authors stressed that patella alta may be a source of anterior knee pain not responsive to nonoperative treatment as well as leading to the development of patellofemoral arthritis.

The indications for correcting patella alta are recurrent dislocations and symptomatic anterior knee pain (and an obvious patella alta) that have not responded to conservative treatment. Commonly, associated patellar crepitus and articular cartilage degeneration are present, and the patient is advised that symptoms of anterior knee pain related to the arthritis will continue. It is thus preferable to correct a symptomatic patella alta condition early before the development of cartilage deterioration. At the time of a proximal or distal realignment, a patella alta results in the distal patella articular cartilage not engaging the trochlea but lying in a more cephalad position. It is at this point that lateral subluxation or dislocation events occur, particularly with a dysplastic shallow trochlea. In addition to correcting the patella alta, a functional MPFL is required because there is a loss of the normal geometric restraint provided by the trochlear groove. There are no established clinically proven rules regarding when correction of an abnormal patellar height is required or the amount of correction to be obtained at surgery. The goal is to restore a normal patellar height index for the index chosen and to confirm that patellotrochlear contact (~30% of the inferior patellar articular cartilage) has engaged the trochlear at full extension. These rules are empiric; however, they do provide the surgeon with guidelines to follow during the surgical technique. The operative steps for the correction of a patella alta are shown in Table 35-3.

TABLE 35-3 Operative Steps in the Technique to Correct Patella Alta

1. Determine abnormal patellar height indices shown in Figure 35-17. Determine millimeters of distal tibial tubercle transfer necessary to restore patellar height indices to normal values.
2. Determine whether any other abnormality present requiring correction: MPFL, lateral restraints, patellar tendon offset (TT/TG ratio).
3. Supine position operating table, lower limb draped with high thigh tourniquet.
4. Arthroscopic procedure performed, determine articular cartilage condition of patellofemoral joint, patellotrochlear dysplasia. Medial-lateral manual glide at 30 degrees of knee flexion to confirm function MPFL, medial and lateral restraints.
5. Skin incision 4 cm just lateral to tibial tubercle, excise lateral and medial patellar tendon retinaculum, preserve blood supply fat pad and patellar tendon. Subperiosteal limited dissection medial and lateral to tibial tubercle 35 mm.
6. Osteotomize tibial tubercle 8 mm depth × 35 mm length × 15-20 mm width. Leave the tibia section proximal to the tibial tubercle which is not included in the osteotomy as described for distal realignment technique. Remove the anterior tibial cortex just distal to the tibial tubercle the calculated distance to allow distal tibial tubercle displacement. Displace the tibial tubercle distally, avoiding recession, and correcting abnormal lateral tibial tubercle offset when present. Temporary fixation by single 2.7-mm drill bit.
7. Lateral radiograph or fluoroscopy at 0 and 30 degrees of knee flexion, measure patellar height indices and adjust tibial tubercle position to restore normal index indices. Patella should engage trochlea at 0 degrees of knee flexion (~ 30% patellar cartilage length).
8. Internal fixation tibial tubercle at new distal position, three cancellous 4.0-mm lagged screws or cortical screws as required.
9. Repeat medial-lateral manual translation (glide) tests at 0 and 30 degrees of knee flexion. Majority of knees will require MPFL reconstruction through limited medial parapatellar incision (steps already described). Lateral restraints usually do not require tensioning or release.

MPFL, Medial patellofemoral ligament; *TT/TG*, tibial tubercle/trochlear groove.

Trochleoplasty

In knees with recurrent patellar dislocation and severe trochlear dysplasia, trochleoplasty has been performed in several studies with the goal of creating a more congruent joint with improved bony stability and containment of the patella.[8,24,42,48,63,115,129,144,166,171,175,176] Currently, indications include repeat patellar dislocations (more than three episodes), type B or D trochlear dysplasia (Dejour[43]), abnormal patellar tracking with a J-sign, TT-TG distance greater than 10 to 20 mm, lateral patellar subluxation of 75% or more, and a dome-shaped trochlea on a perfect lateral radiograph.[27,37,49,130,156] Many patient candidates will have undergone prior unsuccessful patellofemoral procedures. The articular cartilage in the trochlea should be normal or nearly normal (ICRS grade 1 or 2). The most common risks of this operation include damage to the articular cartilage in the patellofemoral compartment, modification of the congruency in the joint, alterations of joint kinematics, and arthrofibrosis, all of which may lead to early arthritis.[130]

The most common open trochleoplasty techniques are the Dejour sulcus-deepening procedure,[45] the Bereiter distal femoral subchondral bone deepening technique,[176] and the Goutallier recession-wedge osteotomy procedure.[10] In the Dejour technique, subchondral cancellous bone under trochlea is removed with a high-speed burr until it is flush with the anterior femoral cortex. The trochlea is osteotomized over the position of the desired new groove, lateralized according to the preoperative TT-TG value. The trochlear facets are pushed posteriorly until they are flush with the femoral cortex, and then they are fixed with anchors and sutures. Dejour and coworkers perform concomitant soft tissue procedures as required for extensor mechanism abnormalities.[42,129]

The Bereiter technique involves removal of a 3- to 5-mm trochlear cartilage flap. The underlying cancellous bone is burred and deepened until the groove is flush with the anterior femoral cortex. A V-shaped groove is fashioned on the cancellous bone. The osteochondral flap is fixed on the newly shaped bone with tape and anchors. This technique was modified to be performed arthroscopically by Blond and Schottle.[25] Several investigators have performed this technique concurrently with an MPFL graft reconstruction.[8,24,115]

In the Goutallier procedure, the prominent groove is removed to the level of the anterior femoral cortex; no deepening of the groove is performed. The bone wedge is removed, pressure is applied on the trochlea posteriorly, and fixation is accomplished with cancellous screws. This procedure is designed to be simpler and less invasive than the others previously described because the trochlea is not violated.

In our opinion, although it would be ideal to correct a trochlear dysplasia, the problem remains that the patella is still flattened and dysplastic, and it is therefore not possible to restore a normal patellofemoral contact pattern by surgically deepening the trochlear groove. Abnormally high patellofemoral contact pressures may occur after

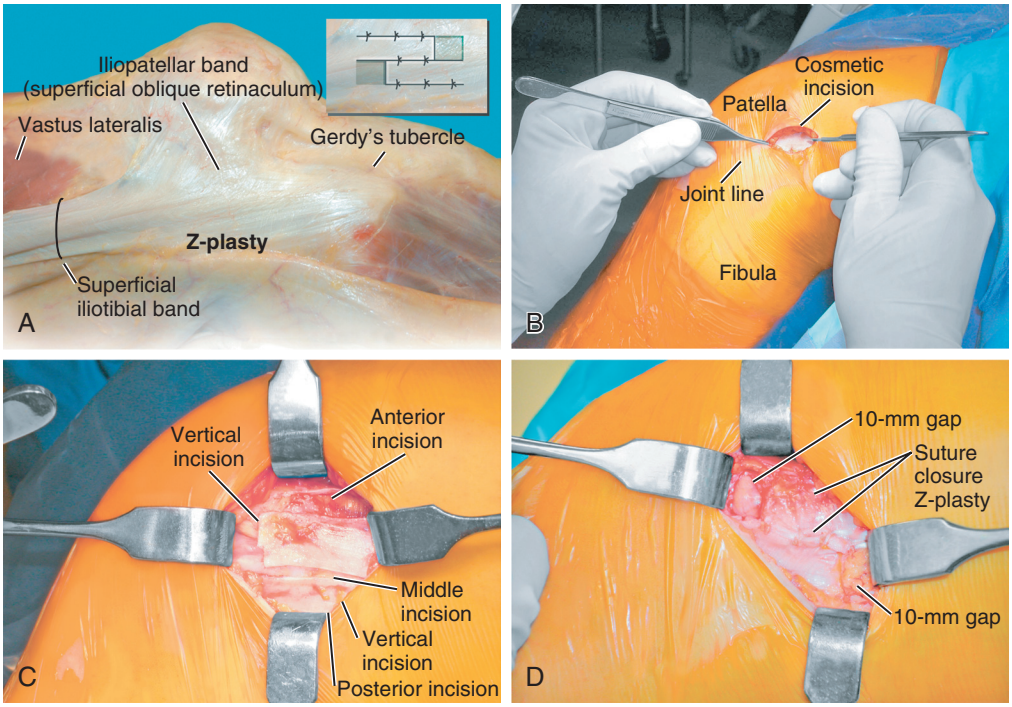

FIG 35-19 **A,** The Z-plasty iliotibial band (ITB) procedure for lengthening and preserving function. **B,** Cosmetic incision. **C,** Z-plasty incision of the ITB. Note the three longitudinal incisions and two vertical incisions. **D,** Final appearance of Z-plasty after closure. The bursae underlying the ITB is excised. The closure is under low tension and preserves ITB function.

trochleoplasty procedures, which may lead to short-term cartilage deterioration. Our approach is to restore a normal patellotrochlear contact and MPFL function and correct an abnormal lateral patellar offset when present. The exception may be a supratrochlear "bump" or prominence that may be recessed. The question of whether trochleoplasty leads to superior outcomes compared with MPFL reconstruction for recurrent patellar instability remains unanswered. To date, no randomized or comparative studies between these operations have been performed in the United States or abroad. In addition, the follow-up time periods for the modern trochleoplasty studies is short, and the long-term outcomes in regard to patellofemoral articular cartilage deterioration are unknown.

Iliotibial Band Z-Plasty Release for Contracture

The technique for a Z-plasty release of a tight ITB is demonstrated in Figure 35-19. After conservative treatment measures have failed, including one or two local cortical steroid injections, ITB stretching exercises over 4 to 6 months, and symptoms return, an ITB release may be indicated. The goal of the procedure is to restore the normal length of the ITB and the normal tension in both arms of the released ITB. The alternative technique that has been described is to remove a window of the ITB, which has the disadvantage of essentially removing the function of the ITB. In addition, there may be remaining anterior and posterior portions of the ITB that still require release. The Z-plasty release has the advantage of restoring normal anatomy. It is important to explore the soft tissues beneath the ITB for abnormal bursae tissue and a sensory nerve that represent sources of lateral pain.

POSTOPERATIVE MANAGEMENT

The postoperative rehabilitation protocol is summarized in Table 35-4. This protocol was developed for patients undergoing proximal and distal extensor mechanism realignment procedures, including MPFL reconstruction. Patients are placed into a postoperative long-leg brace for the first 4 weeks. Range of knee motion exercises and patellar mobilization in superior-inferior and medial-lateral directions are begun immediately after surgery to prevent parapatellar contractures. The goal for the first week is to obtain 0 to 90 degrees of motion. Knee flexion is gradually increased to 110 degrees by the fourth week, and then full motion of at least 135 degrees is allowed by the eighth week. This limitation of flexion in the first 4 weeks is designed to protect the suture lines and the repair when a proximal realignment procedure is performed. The therapist should be aware of the potential for a knee motion complication and, if 0 to 110 degrees is not obtained by the end of the fourth week, the patient should undergo a local anesthetic nerve block or a gentle range of motion under anesthesia as previously discussed. The early treatment and avoidance of an arthrofibrotic response to surgery is critical in these cases (see Chapter 38).

Patients are allowed to bear 50% of their body weight for 2 weeks; full weight bearing is allowed by fourth week. When a distal realignment osteotomy has been performed, full weight bearing by 4 to 6 weeks is allowed based on patient control and muscle strength parameters.

CRITICAL POINTS

Postoperative Management

- See Table 35-4
- Postoperative long-leg brace first 4 weeks
- Patellar mobilization begun immediately postoperative
- 0-90 degrees first week, full by eighth week
- Return to strenuous activities dependent on appearance of articular cartilage in the patellofemoral joint

TABLE 35-4 Postoperative Rehabilitation Protocol

	1-4 Weeks	5-8 Weeks	9-12 Weeks	4-6 Months	7-12 Months
Brace:

Radiographs are taken on the first and the fourth postoperative weeks to ensure adequate position and healing of the osteotomy. Weight bearing may be delayed if problems are detected in bony healing or in quadriceps control. Flexibility exercises, including stretching of the hamstrings, gastrocnemius-soleus, quadriceps, and ITB, are started in the first week. The strengthening program for quadriceps mechanism is begun during the first week and gradually progressed. Straight-leg raises are allowed after the third week. Open kinetic chain exercises are begun between fourth and sixth weeks because there is usually rapid healing of the osteotomy. To initiate a running program, the patient must demonstrate at least 70% of the strength of the noninvolved limb for quadriceps and hamstrings on isometric testing, be at least 3 months postoperative, and have normal articular cartilage surfaces. The return to strenuous activities is markedly dependent on the appearance of the articular cartilage in the patellofemoral joint. Unfortunately, the majority of patients already have deterioration from chronic patellofemoral malalignment. In these patients, the goal of surgery is to return to light, low-impact activities only.

COMPLICATIONS

The common pitfalls related to lateral retinacular release are improper patient selection, incomplete release, excessive or inappropriate release, and inadequate hemostasis. Sectioning of the VLO tendon will cause it to retract, with resultant weakness of quadriceps muscles and patellofemoral imbalance. The ability to evert the patella even at 30 degrees, and certainly at 90 degrees, indicates excessive release of lateral restraints and the VLO tendon insertion and should be avoided to

CRITICAL POINTS

Complications

- Lateral retinacular release pitfalls: improper patient selection, incomplete release, excessive or inappropriate release, inadequate hemostasis
- Proximal realignment: fail if MPFL incompetent, medial plication overtensioned
- Distal realignment: loss of patellar tendon fixation, delayed union or nonunion of the tibial tubercle, fracture of the bony fragment, inadequate correction, overcorrection with iatrogenic medial subluxation, prominent hardware
- Other rare complications: infection, compartment syndrome, neurovascular injury, deep venous thrombosis, pulmonary embolism, hemarthrosis, subcutaneous hematoma, arthrofibrosis, patella baja, complex regional pain syndrome

prevent medial patellar subluxation. A lateral release should also be avoided in a patient with hypermobile patella.

Potential complications related to distal realignment surgery include loss of patellar tendon fixation, delayed union or nonunion of the tibial tubercle, fracture of the bony fragment, inadequate correction, overcorrection with iatrogenic medial subluxation, and prominent hardware. Rapid healing of the tibial tubercle occurs owing to the inherent stability of the step-cut osteotomy and intact medial tissues. If the osteotomy is too superficial through the tibial tubercle, resulting in a thin cortical bony fragment, the potential for fractures, delayed union, or nonunion is increased. At the distal extent of the osteotomy, a hole is drilled through the tibial cortex to prevent the osteotomy from extending distally. Two to three smaller diameter screws are used for tibial tubercle fixation to control rotation of the osteotomized bony fragment. These screws often require removal in the future through a minimal approach.

During the proximal realignment procedure, the three primary sutures should be tied with the knee in 30 degrees of flexion followed by knee flexion-extension to ensure a full range of motion and normal patellofemoral tracking. The MPFL may be incompetent from repeat dislocations or prior surgery. A proximal plication of a thin attenuated MPFL is likely to stretch and fail[6] and should be reconstructed using a QT graft or other tendon graft. Overtensioning of the medial plication or MPFL may produce abnormal patellofemoral contact forces and cartilage deterioration, pain, and limitation of knee flexion.

Parikh and coworkers[135] reviewed complications after MPFL reconstruction in 179 knees in 154 patients aged 6 to 21 years in a single pediatric hospital. The complications included recurrent patellar instability episodes or instability and an osteochondral fracture. A hamstring autograft was looped through bone tunnels in the patella, and the free ends were passed between the medial retinaculum and capsule and then placed in the femoral tunnel and fixed with an interference screw. Eighteen complications were related to improper technique, including recurrent patellar instability or pain (12 knees) or patellar fractures (six knees). In addition, knee motion flexion deficits occurred in eight knees that required a manipulation under anesthesia. Female gender was significantly associated with complications (relative risk, 5.54; $P < .001$). The authors provided several recommendations for resolving the technical problems during surgery, including a single patellar tunnel, radiographic confirmation of an anatomic position of the femoral tunnel, using a gracilis autograft to minimize the size of the patellar tunnel, and checking patellar mobility in extension to avoid overtensioning the graft. It should be noted that suture "docking" of the MPFL tendon graft to the medial patellar MPFL attachment avoids the necessity of patellar tunnels and possibility of a fracture.

Nelitz and associates[118] determined the causes of failure of MPFL reconstruction in 19 patients before revision reconstruction. The primary MPFL procedure had been done with a free gracilis or semitendinosus graft, femoral fixation with an interference screw, and patellar fixation through one or two tunnels. The common causes of failure were severe trochlear dysplasia, increased femoral anteversion that was not corrected, malpositioning of the femoral tunnel, and overtensioning of the graft. Four patients were deemed inappropriate candidates because they did not experience any patellar instability before the operation.

Stephen and colleagues[161] assessed the effect of nonanatomic MPFL reconstructions on patellar tracking and patellofemoral joint contact mechanics in cadaveric knees (aged 46-88 years). The femoral tunnels were placed either at the MPFL anatomic site or 5 mm proximal or distal and tensioned at 2, 10, or 30 N. The investigators reported that anatomically oriented reconstructions with 2-N tension fixed at either 30 or 60 degrees of flexion restored joint contact pressures and tracking to within normal limits. Femoral graft tunnels positioned proximal or distal resulted in significant increases in peak and mean medial pressures and medial patellar tilt ($P < .05$). Grafts tensioned at 10 or 30 N caused significant increases in medial pressure and tilt. These authors previously determined the most isometric femoral attachment site of the MPFL to be (taking the anterior-posterior medial femoral condyle diameter to be 100%) 40% from the posterior, 50% from the distal, and 60% from the anterior border of the medial femoral condyle.[162] Femoral tunnel locations that were 5 mm proximal or distal to this site caused significant changes in lengthening (mean, 6.4 mm; $P = .005$) and shortening (mean, 9.1 mm; $P = .001$), respectively.

Arendt and coworkers[6] evaluated the outcome of MPFL repair and reattachment at its femoral origin in a group of 55 knees in 48 patients with chronic, multiple lateral patellofemoral dislocations. There were 35 women and 13 men whose average age at surgery was 18 years (range, 12-42 years). None of the patients had patella alta or trochlear dysplasia. At 2 years postoperative, 46% had sustained a redislocation injury. In a similar study, Camp and associates[32] reported a 28% failure rate of repair of MPFL tissues in a series of 29 knees that received the operation for chronic recurrent lateral patellar dislocations. The results of these studies highlight the necessity to use an anatomic graft to replace chronically deficient MPFL tissues.

Other postoperative complications should be very rare and include infection, compartment syndrome, neurovascular injury, deep venous thrombosis, pulmonary embolism, hemarthrosis, subcutaneous hematoma, arthrofibrosis, patella baja, and complex regional pain syndrome. The patient should also be informed about the risk of worsening of patellofemoral arthritis symptoms.

CLINICAL STUDIES

Medial Patellofemoral Ligament Reconstruction

A summary of recently published clinical studies on MPFL graft reconstructions is shown in Tables 35-5 and 35-6.[159] A variety of grafts have been used, including the gracilis and semitendinosus tendons, the QT, the patellar tendon, allografts, the adductor magnus, and artificial ligaments, along with different fixation methods. In the majority of studies, the prevention of recurrent dislocation or subluxation episodes was used as a primary outcome factor, along with rating activities of daily living. Typically, fewer than 5% of patients had dislocation or subluxation episodes postoperatively. The most widely used outcome rating instrument was the Kujala score[92] (0-100 points; see Chapter 45), which was designed to rate patellofemoral disorders by measuring the following factors: limp, support, walking, stairs, squatting, running, jumping, prolonged sitting with knees flexed, pain, swelling, knee

subluxation, thigh atrophy, and flexion deficiency. Nearly all of the studies reviewed reported statistically significant improvement in this score postoperatively.

Various techniques were used to ascertain patellar stability, including physical examination and stress radiographs.[40,41,108,109] Because most of the study cohorts were followed in the short term postoperatively (mean, <5 years), the percent of patients in whom progression of patellofemoral arthritis occurred after this operation and the survival rate of the procedure in preventing long-term future patellar dislocations or subluxations are unknown.

Two systematic reviews had been published at the time of writing that attempted to determine postoperative activity levels after MPFL procedures. In 2010, Fisher and colleagues[61] reviewed 21 studies (488 patients) and were unable to formulate conclusions regarding return to athletics postoperatively. This was because of the failure of the studies to use outcome measures that assessed sports activity levels or the effect of the knee condition on the ability to return to athletics. More recently, in 2014, Matic and associates[102] assessed 10 articles (402 patients) that included Tegner activity scores. Because only preoperative and follow-up mean scores were reported, the percent of patients who returned to athletics and the levels that were achieved were not provided in six studies. The time to return to sports, provided in three studies, ranged from 4 to 6 months. These investigators found a higher recurrent dislocation rate in patients who underwent MPFL repair compared with reconstruction (27% and 16%, respectively; $P < .0001$).

Bitar and associates[22] conducted a randomized controlled trial of nonoperative versus MPFL reconstruction for acute primary patellar dislocations. Twenty patients (aged 18-38 years) were assigned physical therapy only and 21 patients (aged 12-37 years) underwent MPFL reconstruction with the patellar tendon. The patients were followed from 2 to 5.1 years postoperatively. The mean Kujala score was significantly lower in the nonoperative group compared with the reconstruction group (71 and 89 points, respectively; $P = .001$). The nonoperative group had a 35% rate of recurrent patellar dislocation/subluxation, whereas the reconstruction group had no reports of recurrences.

The effect of femoral tunnel enlargement after MPFL reconstruction was assessed by Berard and colleagues.[15] A gracilis tendon autograft was harvested and folded in half, placed through a femoral tunnel, and secured with a bioabsorbable interference screw. The free ends of the graft were passed through two patellar tunnels. In 55 knees followed a mean of 3 years (range, 1-6 years), tunnel enlargement was noted in 23 (42%) that had a mean cross-sectional area of 105 ± 20 mm^2 compared with 58 ± 11 mm^2 in the other 32 knees. There were no differences between the two groups in patient's age, body mass index, prevalence of trochlear dysplasia, tunnel malposition, recurrent dislocations, or subjective International Knee Documentations Committee (IKDC) scores. However, the mean patellar height was significantly higher in the enlarged tunnel group (1.17 and 1.80; respectively; $P = .03$). The authors concluded that although femoral tunnel enlargement after MPFL reconstruction was common, it did not affect the risk of recurrent instability.

The effect of femoral tunnel placement and trochlear dysplasia on the outcome of hamstring MPFL reconstruction was determined by Hopper and associates in a group of 72 knees.[82] The extent of trochlear dysplasia was rated as grade A or B (low grade) in 89% and grade C or D (high grade) in 11%. All patients in the high-grade group had recurrent dislocations and significantly lower Kujala, Lysholm, and Tegner scores. When these patients were excluded, there were fewer recurrent dislocations and higher clinical scores in knees with anatomically placed femoral tunnels (<10 mm mean distance from anatomic insertion of MPFL to center of femoral tunnel) compared with those of knees with nonanatomically placed tunnels. Recurrent dislocations were associated with increased grade of trochlear dysplasia ($P < .001$) and nonanatomic femoral tunnel placement ($P = .02$). Four knees had postoperative patellar fractures and two had tibial tuberosity avulsion fractures caused by technical errors at surgery. Similar

findings were reported by Larson and coworkers[94] with respect to the deleterious effects of nonanatomic femoral tunnel placement on clinical outcomes.

We are currently following patients who received the quadriceps tendon autograft MPFL reconstruction previously described. From our database of 80 patients, there exists a subgroup of 43 patients (44 knees) in whom the patellofemoral joint cartilage was intact at surgery. This subgroup is composed of 30 women and 13 men whose mean patient age at surgery was 20; 77% were less than 20 years old. All of these patients have been followed a mean of 6 years (range, 2-10 years) postoperatively. Before surgery, all patients had either suffered a dislocation injury or had recurrent subluxation episodes and had pain with daily activities. At follow-up, statistically significant improvements were noted in mean Cincinnati Knee Rating scores for pain ($P < .01$), swelling ($P < .01$), partial giving-way ($P < .0001$), full giving-way ($P < .05$), walking ($P < .01$), squatting ($P < .01$), and the patient perception of the knee condition ($P < .0001$). In 41 out of 43 knees (95%), a competent MPFL was present, preventing subluxation and dislocation. Two knees required revisions because of recurrent dislocation episodes. As was discussed previously, this simplified MPFL reconstruction has the advantages of using an autograft rather than an allograft, does not require harvesting a hamstring tendon, and avoids potential complications from patellar drill holes of pain or fracture. Importantly, the soft tissue fixation to the MPFL femoral attachment by sutures with immediate knee motion prevents an abnormally tight medial constraint. The procedure also involves soft tissue balancing and tensioning of the entire medial retinaculum, including the MPFL and MPML tissues.

Outcomes of Procedures for Patellofemoral Articular Cartilage Lesions

Autologous Chondrocyte Implantation

Several clinical outcome studies (Table 35-7)[9,12] and systematic reviews (Table 35-8)[28,50,70,112,113] have been published regarding the use of autologous chondrocyte implantation (ACI) for patellar and trochlear lesions The majority of studies used first generation ACI, implanted as originally described by Brittberg and associates[29] with varying results. Mandelbaum and colleagues[99] followed 40 patients a mean of 4.9 years postoperatively, 28% of whom had a concomitant lateral release or Fulkerson procedure. The investigators reported significant improvement in Cincinnati pain and overall knee condition scores. However, nearly one third of the patients required further surgery for problems related to the ACI and 22% failed. Minas and coworkers[111] reported survivorship rates and outcomes of ACI grafts in 210 patients. The number of patellofemoral ACI grafts was not provided; however, the failure rate was higher for patellofemoral grafts compared with tibiofemoral grafts (70% and 79% at 10 years, respectively). Biant and colleagues[17] reported 10 year outcomes of 36 patellar ACI. Nine grafts (25%) failed, all of whom required further operations.

ACI, Autologous chondrocyte implantation; *F/U*, follow-up; *ICRS*, International Cartilage Repair Society; *IKDC*, International Knee Documentations Committee; *KOOS*, Knee Injury and Osteoarthritis Outcome Score; *MRI*, magnetic resonance imaging; *MACI*, matrix-assisted chondrocyte implantation; *WOMAC*, Western Ontario and McMaster Universities.

Gillogly and Arnold[68] followed 25 knees a mean of 7.6 years after ACI for isolated patellar defects. Significant improvements were noted for IKDC, Cincinnati, and Lysholm scores. However, 40% required a reoperation, mostly because of periosteal hypertrophy. The authors have modified their surgical technique by using an absorbable collagen membrane in place of the periosteal graft.

Gobbi and colleagues[69] followed 34 patients who received a second-generation ACI Hyalogaft-C (Fidia Advanced Biopolymers), a tissue-engineered graft composed of autologous chondrocytes grown on a hyaluronan-based 3-dimensional scaffold, for isolated defects in the patellofemoral joint. Ten patients also underwent a patellar realignment. At follow-up, a mean of 6.3 years postoperatively, significant improvement was noted in the mean IKDC subjective score ($P < .001$). On the IKDC objective knee evaluation, 91% were rated as normal or nearly normal. However, patients who underwent concomitant realignment procedures had lower scores and a deterioration in scores between the 2- and 5-year evaluations.

Filardo and colleagues[60] reported on 49 patients who underwent implantation of autologous chondrocytes seeded on a hyaluronan-based 3-dimensional scaffold (Hyalograft C, Fidia Advanced Biopolymers Laboratories). Thirteen patients also had a lateral release, and six had a realignment procedure. Five years later, significant improvements were found in mean IKDC subjective and Kujala scores. Patients who had trochlear lesions had better outcomes than those with patellar lesions; the latter underwent more combined procedures (lateral release, tibial tubercle osteotomy).

Other investigators reported that patients who had combined ACI-realignment procedures had results that were either superior or comparable with those who underwent ACI alone.[55,80,173] For example, Vasiliadis and colleagues[173] followed 92 patients that underwent ACI, of whom 38 had some type of realignment procedure. At a mean of 12.6 years postoperatively, the group demonstrated improvements in Lysholm rating, and 93% indicated they would undergo the operation again. The clinical rating results in patients who underwent realignment procedures were not significantly different than those who had an isolated ACI. In addition, realignment procedures were associated with a decreased incidence of periosteal hypertrophy compared with isolated ACI (16% and 39%, respectively; $P = .01$). However, realignment procedures resulted in a higher incidence of complications compared with isolated ACI (29% and 13%, respectively; $P = .05$), such as arthrofibrosis and delamination.

Trinh and associates[169] conducted a systematic review to determine if a difference existed in outcomes between combined ACI and realignment procedures compared with ACI alone. Eleven studies were included comprising 366 subjects, 84 (23%) of whom also underwent concomitant tibial tubercle osteotomy. Both first- and second-generation ACI studies were included. The authors reported significant improvements in clinical outcomes (IKDC subjective, Cincinnati, Lysholm, Knee and Osteoarthritis Outcome Score [KOOS], Tegner, Short Form Health Survey [SF-36]) for both groups, with a higher level of improvement noted in patients who had combined procedures from three studies that directly compared these groups. The overall complication rate was 15.2%; the majority were related to periosteal patch hypertrophy or extrusion. Ten of the eleven studies in this review were level III or IV, and there was noteworthy heterogeneity in the lesions, subjects, prior surgery performed, and length of follow-up.

The use of particulated juvenile articular cartilage allografts (Denovo NT Natural Tissue Graft; Zimmer) for patellar defects in a small case series was described by Tompkins and associates.[167] Fifteen knees were followed for a mean of 28.8 ± 10.2 months, 10 of whom underwent various concomitant extensor mechanism procedures. MRI at follow-up revealed normal or nearly normal ICRS cartilage repair score in 11 knees, and all but three showed 90% or greater fill of the defect surface area. Five patients returned to their presymptomatic activity levels; however, seven reported anterior knee pain with stair climbing or prolonged sitting. Three patients required subsequent surgery for graft problems. Farr and colleagues[56] also performed this procedure in 11 knees with trochlear defects along with 18 other knees that had femoral condylar defects. The results were presented for all knees combined and therefore the outcomes of this operation for trochlear defects is unknown.

Osteochondral Autograft Transfer

Few data have been published regarding osteochondral autograft transfer for patellofemoral defects.[7,13,59,76-78,120] Hangody and colleagues[78] summarized the results of 1097 osteochondral autograft transfer procedures, 137 of which were done for lesions located in the patellofemoral joint. The majority of patients (percentage unknown) underwent concomitant patellar realignment procedures. The results were assessed with a variety of scoring systems (modified Hospital for Special Surgery, modified Cincinnati, Lysholm) from 1 to 10 years postoperatively. The clinical scores demonstrated "good to excellent" results in 74% of this subset of patients, which were the only data reported. Hangody and associates[76] also reviewed the outcome of this operation in 383 professional athletes. Twenty-six patients received the procedure for patellar or trochlear defects. The only data reported specifically for patellofemoral procedures were mean Hospital for Special Surgery scores, which were not significantly improved compared with the preoperative condition.

Astur and associates[7] evaluated 33 patients who had an osteochondral autograft transfer for full-thickness patellar lesions 1 to 2.5 cm in diameter. Twenty-eight knees had one plug, and five knees required two plugs. At a mean of 2.5 years postoperatively, significant improvements were reported in Lysholm, Fulkerson, Kujala, and SF-36 scores ($P < .05$). MRI performed 6 months after surgery showed that 83% of the plugs had complete osseous integration, which increased to 100% at 1 year. Three patients had arthrofibrosis postoperatively that was successfully treated with an arthroscopic release.

Nho and colleagues[120] assessed clinical and MRI outcomes of osteochondral autograft transfer procedures for patellar lesions in 22 patients a mean of 2.4 years (range, 1.5-4.8 years) postoperatively. There were 12 men and 10 women whose mean age at surgery was 30 years (range, 15-57 years). The mean number of plugs used was 1.8 (range, 1-7); 20 patients had 1 to 2 plugs implanted. Nine patients underwent a concomitant distal realignment. The mean IKDC score improved from 47 ± 14 before surgery to 74 ± 12 at follow-up ($P < .05$), and the mean Activities of Daily Living score improved from 60 ± 17 before surgery to 85 ± 8 at follow-up ($P < .05$). MRI demonstrated 67% to 100% repair fill and 64% had fissures smaller than 2 mm at the articular cartilage interface. There was one failure in a patient who required four plugs.

Figueroa and associates[59] reported their results of this operation in 10 men aged 15 to 38 years who were followed a mean of 3.1 years postoperatively. Additional procedures to treat patellar instability and malalignment were required in each patient. The investigators reported improvements in the Lysholm score and a mean postoperative IKDC subjective score of 93.6 (range, 92-96). MRI obtained 6 to 10 months postoperatively demonstrated ICRS normal or nearly normal ratings in the graft and peripheral chondral tissue.

Our Studies of Procedures for Patellofemoral Articular Cartilage Lesions

We have prospectively followed all patients in whom a patellar osteochondral autograft transfer procedure was performed at our center.

Between July 1996 and February 2010, a total of 53 osteochondral autograft transfer procedures were done in 43 knees for isolated patellar lesions. Twenty-three of these had failed at the time of writing, leaving 30 procedures that have been followed a mean of 5.6 years (range, 2.3-10.1 years). The 23 procedures that failed occurred in 18 women and five men whose mean age at the time of surgery was 35.5 years (range, 26-50 years). The average time from surgery to the failure (defined as a revision osteochondral autograft transfer, total knee arthroplasty, patellectomy, patella allograft, or patient designated as requiring any of these procedures) was 3 years (range, 0.4-10 years). All but six of these patients had sustained an injury to their knee—during daily activities in eight, during work activities in six, and during sports in three. An average of 9 years had elapsed (range, 0.2-27 years) between the injury or onset of symptoms and the osteochondral autograft transfer procedure.

The 30 patellar osteochondral autograft transfer procedures that had survived at the time of writing were performed in 23 females and seven males. The mean age at the time of the procedure was 33 years (range, 14-45 years). Sixteen patients sustained an injury, and 14 patients had a gradual onset of symptoms without an injury. The mean time from the injury or onset of symptoms to the operation was 7.7 years (range, 0.6-23.6 years). At the most recent follow-up (data available for 25 patients a mean of 5.6 years [range, 2.3-10.1 years]), 11 patients rated their knee condition as very good, 8 as good, 4 as fair, and 2 as poor. Eighteen patients were able to participate in low-impact athletic activities without problems. Three patients were able to perform daily activities without problems, and four patients had moderate problems with daily activities. Seven of these patients received a functional rating as failed because their pain score had not improved compared with the preoperative rating.

We conducted a systematic review to determine the outcomes of operations performed for large (≥4 cm^2), symptomatic lesions in the patellofemoral joint in patients aged 50 years or younger.[126] Eighteen articles encompassing 840 knees were included. There were 613 knees that underwent ACI, 193 knees that had patellofemoral arthroplasty, and 34 knees that underwent osteochondral allografting. Long-term follow-up was only available in four studies, and 21 different outcome instruments were used to determine knee function. When taking into account knees that either failed or had fair or poor function, the percent of patients who failed to achieve a benefit averaged 22% after patellofemoral arthroplasty, 33% after osteochondral allografting, and ranged from 8% to 60% after ACI (Fig. 35-20). The results of this review demonstrated that in younger patients with large patellofemoral lesions, all three procedures had unpredictable results. Accordingly, patients with patellofemoral cartilage damage undergoing cartilage restoration procedures are advised that these procedures may or may not relieve arthritis-related symptoms. In middle-aged patients, there is increase use of a patellofemoral arthroplasty as described in Chapter 37.

Outcomes of Trochleoplasty Procedures

A recent systematic review of 11 studies encompassing 339 knees that underwent trocheoplasty procedures found significant improvements in clinical rating scales (Kujala, IKDC, KOOS) and an overall complication rate of 13.4%.[156] Problems related to increased pain were reported in 29 knees, loss of knee motion in 12 knees, and redislocated patella in 3 knees.

Blond and Haugegaard[24] followed 37 knees in 31 patients for 1 to 4.7 years after their modified arthroscopic Breiter trochleoplasty procedure and MPFL reconstruction (Table 35-9). These investigators reported that 87% had acceptable results with no further surgery required, and none had a recurrent patellar dislocation. These authors hypothesized that this combined procedure would reduce joint forces, pain, and subsequent cartilage wear compared with an MPFL reconstruction alone; however, the study was unable to address this theory.

Outcomes of the Dejour technique were assessed in a group of 31 knees a mean of 7 years postoperatively.[129] All patients underwent additional procedures as required such as tibial tuberosity distalization or medialization. No patient had a subsequent patellar dislocation, and patellar tracking was normal in all cases at follow-up. There was no

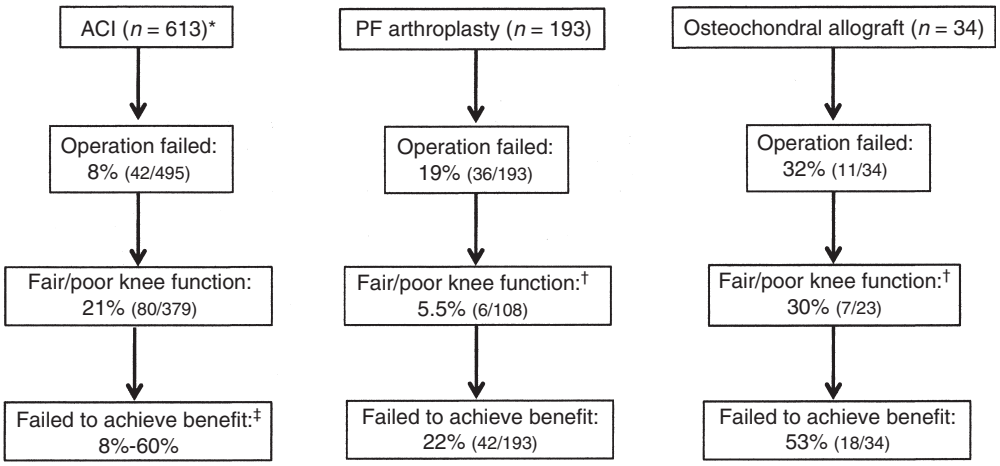

FIG 35-20 Rates of patients who failed to achieve a benefit from their operation. *For ACI, the rate of failure was not provided in one study, and fair or poor knee function could not be determined in three studies. †For PFA, fair or poor knee function could not be determined in one study. ‡An average value for this rate could not be accurately calculated in some studies because it was unclear whether patients in whom the operation failed were also included in the fair and poor knee function categories. For all other PFA studies and all allograft studies, fair or poor knee function was determined in patients in whom the prosthesis or allograft had survived. *ACI*, Autologous chondrocyte implantation; *PFA*, patellofemoral arthroplasty. (From Noyes FR, Barber-Westin SD. Advanced patellofemoral cartilage lesions in patients younger than 50 years of age: is there an ideal operative option? *Arthroscopy*. 2013;29:1423-1436.)

TABLE 35-9 Clinical Outcomes of Trochleoplasty for Severe Trochlear Dysplasia

	SUBJECTS						OUTCOMES			
Study	No. Knees/ Patients	Follow-up (yr)	Prior PF Procedures	Age (Range) (yr)	F:M	Operative Procedure	Complications	Redislocation Rate (%)	Rating Scales (2014)	Satisfaction, Return to Activity Rates
Blond & Haugegaard[24] (2014)	37/31	1-4.7	16 prior PF surgery	19 (12-39)	21:10	Modified Bereiter (arthroscopic); MPFL reconstructed with gracilis tendon	Two subsequent tibial tubercle medialization, three lateral release	0	Kujala preoperative 64 (range, 12-90), F/U 95 (range, 47-100) KOOS pain preoperative 86 (range, 42-97), F/U 94 (range, 53-100) KOOS sports preoperative 40 (range, 0-95), F/U 85 (range, 20-100)	93% satisfied; 55% resumed sports/maximal activities
Banke et al[8] (2014)	18:17	2-3.3	4 prior PF surgery	22 ± 5	11:6	Bereiter; MPFL reconstructed with gracilis tendon	Two arthroscopic lysis adhesions, one overtight MPFL revised	0	Kujala preoperative 51 (range, 7-86), F/U 88 (range, 59-103) IKDC preoperative 49 (range, 11-82), F/U 82 (range, 49-99)	94% satisfied
Ntagiopoulos et al[129] (2013)	31:27	2-9	No prior PF surgery	21 (14-47)	13:14	Dejour; all had combined procedures	Two removal broken staples, one DVT	0	Kujala preoperative 59 (range, 28-81), F/U 87 (range, 49-100) IKDC preoperative 41 (range, 25-80), F/U 82 (range, 40-100)	94% satisfied; 87% returned to prior activity level
Dejour et al[42] (2013)	24:22	2-15.9	All prior PF surgery	23 (14-33)	1:33	Dejour; all had combined procedures	One removal of broken staples	0	Kujala preoperative 44 (range, 25-73), F/U 82 (range, 61-100) IKDC preoperative 51 (range, 23-75), F/U 77 (range, 53-100)	All patients satisfied; 95% returned to prior activity level
Nelitz et al[115] (2013)	26:23	2-3.5	13 prior PF surgery	19 (15-23)	9:14	Bereiter; MPFL reconstructed with gracilis tendon	None	0	Kujala preoperative 79 (range, 21-100), F/U 96 (range 74-100) IKDC preoperative 74 (range, 32-95), F/U 90 (range, 65-98)	All returned to sports, 6 at a lower level; 10 very satisfied, 12 satisfied with results

Fucentese et al[63] (2011)	44:38	2-7.8	13 prior PF surgery	18 (14-40)	28:10	Bereiter	Two subsequent stabilization procedures, one transient femoral nerve palsy, one wound-healing problem, one CRPS	2	Kujala preoperative 68 (range, 29-84), F/U 90 (range, 42-100)	6 instability with daily activities, 7 would not have surgery again; authors now perform concurrent MPFL reconstruction
Thaunat et al[166] (2011)	19:17	1-5.9	7 prior PF surgery	23 (18-45)	9:8	Goutallier; all had additional procedures	One lysis adhesions, two procedures for tibial tubercle pseudarthrosis, eight removal anterior tibial screws, one dislocation traumatic injury	5; two patients failed, treated conservatively	Kujala F/U 80 (range, 33-98) KOOS F/U 70 (range, 23-96) IKDC F/U 67 (range, 21-92)	31% very satisfied, 63% satisfied with outcome
Utting et al[171] (2008)	42:40	1-4.8	16 prior PF surgery	21 (14-33)	NA	Bereiter; associated procedures in 29 knees	One manipulation, one dislocation traumatic injury	0	Kujala preoperative 62 (range, 29-92), F/U 76 (range, 26-100) IKDC preoperative 54 (range, 26-89), F/U 72 (range, 23-100)	93% satisfied; 67% resumed sports/maximal activities
Donell et al[48] (2006)	17:15	1-9	6 prior PF surgery	25 (15-47)	12:3	Dejour	Five lysis adhesions, one patellar chondroplasty, one remedial reefing, one removal loose screw; six marked painful crepitus	0	Kujala preoperative 48 (range, 13-75), F/U 75 (range, 51-98)	41% very satisfied, 41% satisfied, 18% disappointed
von Knoch et al[176] (2006)	45:38	4-14	15 prior PF surgery	22 (15-31)	22:16	Bereiter	One distal realignment, one patella infera; pain increased in 33%	0	Kujala F/U 95 (range, 80-100)	100% satisfied; all but one returned to higher sport levels
Verdonk et al[175] (2005)	13:12	0.7-2.8	19 prior PF surgery	27 (14-39)	9:3	Dejour	Five arthrofibrosis, two persistent pain, one total knee arthroplasty	0	Larsen-Lauridsen: 3 good, 3 fair, 7 poor	77% satisfied
Schottle et al[144] (2005)	19:16	2-4	5 prior PF surgery	22 (17-40)	13:3	Bereiter	Four persistent apprehension, five medial parapatellar tenderness, two increased pain	0	Kujala preoperative 56 (range, 27-67), F/U 80 (range, 43-99) Drez subjective score: 10 excellent, 6 good, 1 fair, 2 poor	NA

evidence of patellofemoral arthritis on axial radiographs. None of the patients in this series had undergone previous patellofemoral surgery, the mean age was 21 years, and 90% had ICRS cartilage grades of I or II (normal or nearly normal) on the trochlea.

In another series of 24 knees that had undergone prior failed patellofemoral procedures, Dejour and colleagues[42] reported no major complications and a 100% satisfaction rate a mean of 5.5 years postoperatively. However, a positive apprehension sign was still present in 25%, and pain remained unchanged or increased in 28%.

The outcome of the Bereiter technique, combined with a gracilis tendon MPFL reconstruction, was examined by Banke and colleagues[8] in a cohort of 17 patients (18 knees) whose mean age was 22 ± 5 years. At a mean of 2.5 years postoperatively, all patients but one were satisfied, and no recurrent patellar dislocations had occurred. None of these patients had degenerative changes in the patellofemoral compartment at surgery, and none had undergone prior major operative procedures. Two patients required an arthroscopic lysis of adhesions for early arthrofibrosis and one patient required a revision MPFL reconstruction.

Poorer results were reported after the Bereiter technique by Fucestese and associates,[63] who did not perform a concurrent MPFL reconstruction. In a group of 44 knees followed a mean of 4 years, two patients required further stabilization procedures and 6 others had a sensation of instability with daily activities. Deterioration of cartilage on the lateral trochlear facet was noted on MRI in 16 knees. These authors now perform MPFL reconstructions with this trochleoplasty technique.

ILLUSTRATIVE CASE

Acute Patellar Tendon Rupture. A demonstration of the surgical technique for an acute patellar tendon rupture is shown in Figure 35-21. In Figure 35-21, *A*, the preoperative photograph shows subcutaneous hemorrhage along the anterior aspect of the knee in a patient who sustained a fall and acute rupture of the patellar tendon. The preoperative MRI showed extensive disruption throughout the entire patellar tendon. In Figure 35-21, *B*, the initial exploration shows a "mop-end" appearance to the midsubstance patellar tendon rupture. Figure 35-21, *C* and *D* show the method of repair with interrupted baseball locking sutures from the distal tendon to the proximal tendon or through the patellar tunnel based on the site of the tendon rupture. In this case, a tendon-to-tendon repair was performed. Two wire sutures were placed through the tibial tubercle and distal one third of the patella. One wire suture was placed through the tibial tubercle and distal quadriceps patellar attachment to function as a tension band. The use of wire fixation does involve the need for later removal; however, it provides a firm fixation of low cross-sectional area, which is an advantage over synthetic tape. The length of the repaired patellar tendon is adjusted at surgery and verified by fluoroscopy to be equal to the opposite lateral knee preoperative radiograph. It is important that the immediate range of motion from 0 to 90 degrees be initiated within the first 2 weeks after surgery, along with quadriceps muscle exercises to prevent a patella infera. The wire fixation allows initial weight bearing with the knee in extension. A semitendinosus-gracilis graft augmentation was not required in this case but may be indicated if the patellar tendon is severely disrupted, preventing primary tendon suture. This patient had a successful result and was weaned from crutches at 8 weeks postoperatively, regained a normal range of knee motion, and had a normal patellar height equal to the opposite knee. He was cautioned to avoid full weight bearing on the operative limb in ascending and descending stairs until 20 weeks from surgery and to not participate in sporting activities until 6 months after surgery.

INTRODUCTION

What is Rotational Malalignment?

The geometry of bones is normally viewed in the three cardinal planes: frontal (coronal), sagittal, and transverse (horizontal, Fig. 36-1). The mechanical axis of the lower extremity from the femoral head center to the talus center (sometimes referred to as the hip-knee-ankle [HKA] axis) needs to be viewed in each of the three planes to define alignment. In the frontal plane, angular deviations from the normal straight line are referred to as varus-valgus, in the sagittal plane as flexion-extension, and in the horizontal plane as anteversion-retroversion (or antetorsion-retrotorsion). Just as varus or valgus deformity observed in the frontal plane causes abnormal joint loading, excess anteversion or retroversion observed in the horizontal plane causes abnormal joint loading.

Anterior knee pain, patellar instability, and patellar arthritis/chondromalacia are three different conditions that may be causally related to an abnormal limb alignment in the transverse plane. This chapter reviews the concept of torsional malalignment of the lower limb and its effect on the patellofemoral (PF) joint.

Limb alignment determines where and in what direction the tibiofemoral joint and patellofemoral joint (PFJ) are loaded. The geometry of the skeleton determines the direction of the load application on the PFJ. The PF ligaments acting against the patella in the trochlea are responsible for stability. Articular cartilage reduces friction to conserve energy and to transmit the force generated by a combination of body mass, momentum, gravity, and muscles. The musculotendinous units move the skeleton, stop it from moving, or hold it against gravity but are not normally responsible for preventing joint dislocation or subluxation. The total load depends on a variety of variables, including body mass, muscle activity, gravity, lever arm length, rate and direction of body motion, and so on. Femoral and tibial torsion both alter the position of the trochlea in space, thus where PF forces are centered. These forces may be changed by rotational osteotomy of the femur or tibia.

"Does Lower Limb Torsion Matter?" was the title of a keynote address at the 2012 European Society of Sports Traumatology, Knee Surgery and Arthroscopy (ESSKA) meeting. The question importantly opens the door to a multitude of related queries. What is torsion? What is rotation? How is torsion measured? Is there validity to the torsion measurement? What is normal torsion? What is the mechanical effect of altered torsion? Does abnormal torsion cause symptoms? Does abnormal torsion cause pathology? Where is abnormal torsion located? Are femoral and tibial torsions equally important? Are femoral and tibial torsions compensatory? Can abnormal torsion be corrected? Are femoral and tibial torsions the only causes of abnormal limb torsion? Is corrective osteotomy beneficial? There are an endless variety of additional questions, none of which has been adequately studied.

Maquet, in his masterpiece *Biomechanics of the Knee*,[29] drew a strong relationship between the location of the resultant vector sum of all of the forces that produce knee joint loading and the location of the mechanical axis. Although he is often remembered for his anterior displacement osteotomy of the tibial tuberosity, Maquet emphasized an understanding of limb alignment in the coronal plan. Missing from the complete picture has been a similar analysis of the forces as seen in the transverse or horizontal plane.

The term *miserable malalignment* was apparently first introduced by Stan James.[15] His classic description of limb maltorsion is highly recommended reading.

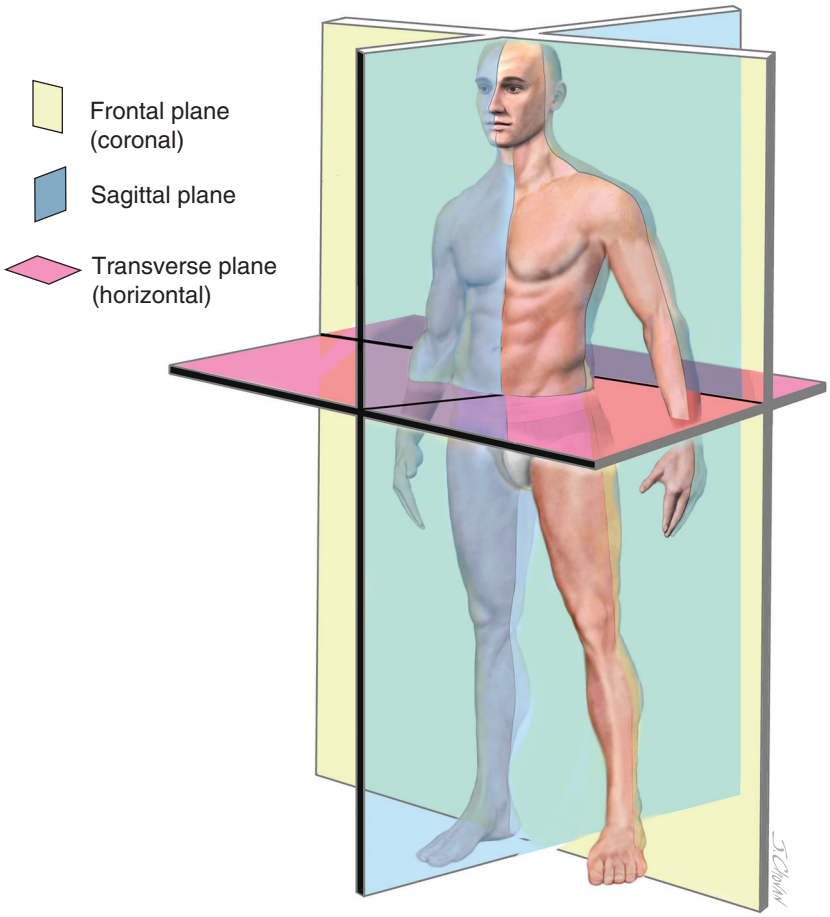

FIG 36-1 The geometry of bones is normally viewed in the three cardinal planes: frontal (coronal), sagittal, and transverse (horizontal).

The essence of this chapter is that during normal gait, the knee joint axis moves forward in the direction the body is moving. When the knee joint axis is twisted away from the direction the body is moving, the loading vectors are directed obliquely, resulting in abnormal PFJ shear forces. This is common with abnormal torsion of either the femur or the tibia. For example, a patella dislocates when the combined stabilizing elements of trochlear geometry and PF ligaments are overcome by an excessive dislocating force. The excessive dislocating force is often caused by a knee joint pointing inward because of abnormal femoral anteversion or abnormal increase in external tibial torsion. Corrective osteotomy has no effect on the trochlear geometry or the integrity of the PF ligaments, but it does change the displacement force.

Normal alignment is presumed to be normal because it is the optimal limb geometry for the transfer of the body mass to the ground. Abnormal geometry results in unusual force transmissions through the PF joint during gait. It is rare to see published PF clinical studies that have reviewed limb alignment adequately. The precise variation from the normal skeleton is generally not specified, ranges of motion of all joints in all planes of the lower extremity have not been adequately recorded, and ligamentous stability is not measured.

The literature on patellar malalignment is quite confusing because many terms are commonly interchanged and not precisely defined. John Insall in 1976 defined *patellar malalignment* as being either an increased Q-angle or a high-riding patella.[13] No other options were considered. In addition, he observed that "an increased Q-angle is usually associated with increased femoral anteversion and external tibial torsion. In the presence of these abnormalities, when the hip and ankle joints are normally aligned, the patella faces inward and motion of the knee occurs about an axis that is rotated medially compared with the axes of the hip and ankle joints." He then recommended a medial tibial tubercle transfer or "patellar realignment" to treat this torsional malalignment, and it is no surprise that he reported that 61% of the patients remained symptomatic. Clearly the underlying pathoanatomy had not been measured nor addressed. Subsequent biomechanic studies suggest the recommended treatment is inappropriate. Tibial tubercle transfer has been shown to cause external rotation of the tibia on the femur rather than pull the patella medially into the trochlea[17] and has been shown to increase medial compartment loading[20] and medial facet loading. I believe the terms *patellar malalignment* and *patellar realignment* lack precise definition and therefore should never be used. The term *malalignment* should refer only to a limb that deviates from a neutral (normal) mechanical axis, and the deviation must be defined in each plane. Skeletal alignment is a direct result of the shape of the bones in the limb, but limb malalignment may also be caused by a joint with acquired cartilage or ligament loss.

More than 50 different factors have been associated with anterior knee pain, chondromalacia patellae, patellar instability, or patellar malalignment (Table 36-1). Although these factors may be very important, objective measurement tools are lacking. No study has ever tried

TABLE 36-1 Cited Contributions to Patellofemoral Dysfunction

Genu valgum	Genu varum
Femoral anteversion	Femoral retroversion
Excess external tibial torsion	Excessive internal tibial torsion
Outerbridge ridge	Trochlear dysplasia
Shallow trochlea	Short lateral trochlea
Increased Q-angle	Decreased Q-angle
Excessive lateral quadriceps pull	Insufficient vastus medialis obliquus
Decreased patellar surface contact area	Abnormal patellar spin
Patellar dysplasia	Patella alta
Patella baja (infera)	Meniscectomy
Laxity of ACL, PCL, MCL, or FCL	Rotatory instability
Iliotibial band contracture	Quadriceps contracture
Achilles contracture	Retinacular contracture
Retinacular laxity	Hyperpronation
Pes planus	Tibial tubercle–trochlear groove distance (TT/TG)
Patellar malalignment	Patellar instability
Patellar subluxation	Medial patellar dislocation
Lateral patellar dislocation	Chondral softening
Genu recurvatum	Patellar tilt
Patellar shift	Abnormal (mal) tracking
VMO dysplasia	J sign
A sign	Bayonet sign
Crossing sign	Trochlear bump
Patellar thickness	Knee flexion contracture
Infrapatellar contracture	VMO/VLO ratio
Rearfoot varus	Patellar glide
Quadriceps tendon width	Flexor hallucis longus tendon entrapment
Flexor hallucis dysfunction	Increased lumbosacral instability
Hip flexion contracture	Abdominal oblique: rectus femoris + psoas imbalance
Quadriceps atrophy	Pelvic abductor weakness
Increased thoracolumbar extension	Inward pointing knee
Female gender	

ACL, Anterior cruciate ligament; *FCL*, fibular collateral ligament; *MCL*, medial collateral ligament; *PCL*, posterior cruciate ligament; *VLO*, vastus lateralis obliquus; *VMO*, vastus medialis obliquus.

to assess all of these variables in a single cohort of patients, and even if this were undertaken, the lack of objective measurement techniques would make the study invalid. If these variables are indeed important, then any study would need to incorporate accurate measurements of each. The relative importance of each needs to be developed. Without this, clinicians are left with a realization that data do not exist to guide in the knowledge of pathomechanics, diagnosis, and treatment and that we depend only on unrelated clinical observations and some very basic laboratory studies. Thus, the complete validation of the importance of limb torsion in contributing to PF pain and dysfunction may always be challenged.

Anterior Knee Pain, Patellar Instability, and Patellar Chondropathy

All three of these disorders are often the result of excessive mechanical force. This excessive force is often the result of a twisting of the knee out of normal alignment. These three disorders may or may not be related and may coexist. It is useful in the evaluation of PF symptoms to consider each independently.

Anterior knee pain may have many causes as suggested in Table 36-1. Abnormal soft tissue strain caused by twisting of the knee out of normal plane is a likely contributing cause. No studies linking the prevalence of abnormal femoral or tibial torsion with anterior knee pain have been published.

Patellar instability results from a loss of the patellar stabilizers when subjected to an excess of displacement forces. The patellar stabilizers are the trochlear groove and both the medial and lateral PF ligaments and the medial and lateral meniscopatellar ligaments. As early as 1964, Brattström[2] demonstrated that in recurrent dislocation of the patella, a flattening or dysplasia of the trochlear groove is nearly always present. Dejour and colleagues[6] demonstrated that this dysplasia is often in the proximal portion of the trochlea not seen on an axial PF radiograph but measureable on a true lateral knee radiograph by recognizing the floor of the groove and the anterior projections of the medial and lateral condyles. For lateral patellar dislocation to occur, the medial patellofemoral ligaments (MPFLs) must have been injured. A number of authors, including Christoforakis and colleagues[4] and Desio and associates,[8] have demonstrated in the laboratory that the lateral retinaculum provides up to 19% of the resistance against lateral displacement; thus the patella is usually more unstable after lateral retinacular release. Medial dislocation is a distinct possibility, and I reported 70 cases confirmed with stress radiography at the annual meeting of the American Association of Orthopaedic Surgeons in 1990. The diagnosis of instability requires a force and displacement examination, and stress radiography[46] may provide documentation as shown in Figures 36-2 and 36-3, in which unstressed radiographs were normal but stress application demonstrates obvious excessive displacement.

A necessary contributing cause of patellar dislocation is the existence of an abnormally high displacement force. This most often occurs when the direction of the lateral quadriceps vector is increased and commonly occurs when the femur twists medially out from under the patella. This is usually caused by some torsional abnormality of the lower limb (Fig. 36-4). In the face of such excess displacement forces, a PF ligament reconstruction may fail. No studies accurately correlating femoral and tibial torsion with the incidence of patellar instability have been published.

Arthrosis or chondromalacia exists when articular cartilage fails as the force per unit area exceeds biological tolerance. For acute fractures of articular cartilage, this may be in the range of 20 MPa. Chronic overload caused by a too small articular surface area or too much body weight, muscle loading, or long lever arms with chronic pressure exceeding 5 MPa may lead to arthrosis. Articular cartilage fractures exist nearly 100% of the time after acute patellar dislocation.[32] Although magnetic resonance imaging (MRI) is often used to demonstrate articular cartilage lesions, its sensitivity is still limited. Double-contrast computed tomography (CT) arthrography is seldom used but may offer increased resolution as seen in Figure 36-5. No studies correlating specific articular cartilage lesions with limb torsion have been completed.

HOW DOES LONG BONE TORSION AFFECT THE PATELLOFEMORAL JOINT?

The knee joint axis moves straight forward during gait with a small (<10 degrees) turning inward and outward.[27] The foot also tends to move in a fairly constant direction (foot progression angle).[28,38] The geometry of the lower extremity skeleton largely determines the direction of load application at the PF joint, with the amount of load depending on the body mass, the length of the lever arms, the surface

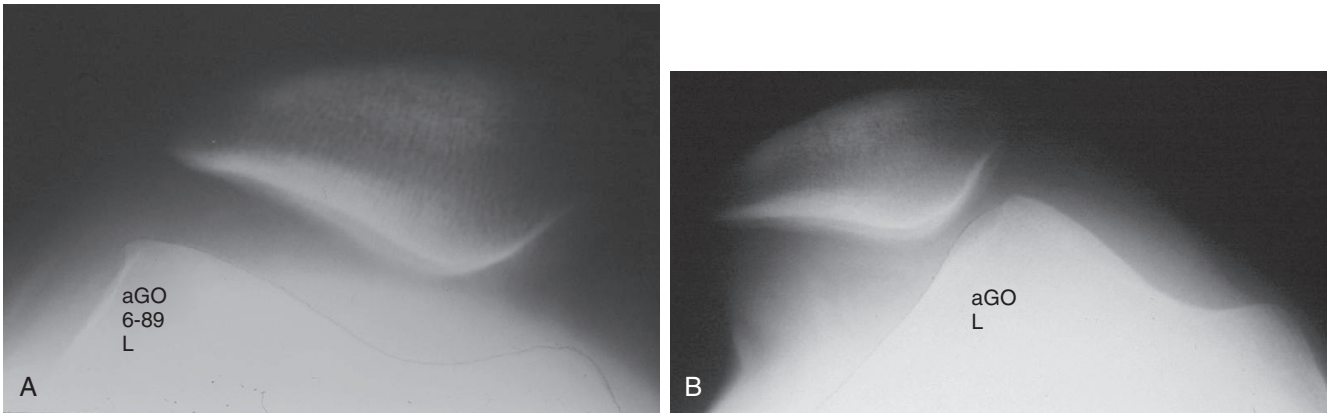

FIG 36-2 **A,** An 18-year-old patient complained of anterior knee pain and giving way, without a history of dislocation. Radiographic parameters are normal. **B,** Stress application was necessary to demonstrate dislocation.

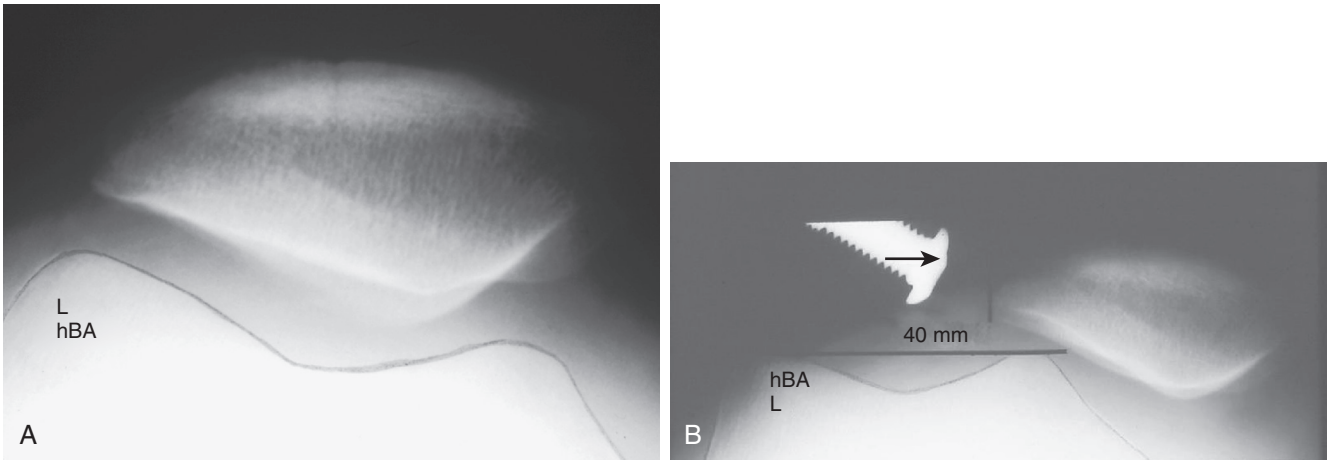

FIG 36-3 **A,** Radiograph of a 38-year-old woman with anterior knee pain after a dashboard injury. Symptoms worsened after a lateral retinacular release. Radiographic parameters were normal. **B,** Stress radiographs demonstrated medial dislocation.

area of the PFJ, and the velocity of the moving system. If the knee joint axis is twisted out of its normal plane of flexion and extension while the quadriceps is contracting, a side-directed force is created that acts on the patella, attempting to displace it. This causes an increased strain on the PF ligaments and retinaculum and an imbalanced direction of force on the PF articular surface.

If these side-directed vectors exceed biological tolerance, either instability or arthrosis may result. For example, an inward pointing of the knee increases the lateral direction of pull of the quadriceps. Therefore the pull on the MPFL (and medial retinaculum and medial meniscopatellar ligament) is increased and the direction of pressure on the patella is altered, creating an increase on the lateral facet and a decrease on the medial facet (Fig. 36-6). The radiographic appearance of subchondral density under the patellar facets is a useful clue to the mechanical environment (Fig. 36-7).

Maximum energy conservation during gait is caused by precise anatomy and joint kinematics.[35] Abnormalities in normal bony anatomy or joint motions distort the normal force vectors needed to transfer the body mass to the ground. Deviations in normal limb alignment may result in the knee joint flexion-extension axis advancing sideways while the body moves forward. Causes of a knee joint axis pointing out of the direction include weakness of hip musculature, femoral anteversion or retroversion, excess internal or external tibial torsion, genu valgum or varus, foot hyperpronation, and Achilles contracture.

The *foot progression angle* (FPA) is generally defined as the angle between the long axis of the foot and the direction of body progression and averages between 10 to 15 degrees.[28,38] It has been shown that the FPA remains similar despite differences in the torsion of the tibia or femur.[38] It is likely that this is because proper ankle dorsiflexion cannot occur during gait if the ankle joint axis is not aligned with the direction of forward movement or because this presents the most stable position of the foot on the ground. Hip rotation must vary if there are changes in the torsion of the long bones and the FPA stays constant. Alterations in both femoral and tibial torsion changes the effective lever arm of the hip stabilizers[1] and may account for the frequency of soft tissue complaints around the hip and pelvis, as well as the increased pelvic tilt and lumbar lordosis seen in these patients. Examples of the change

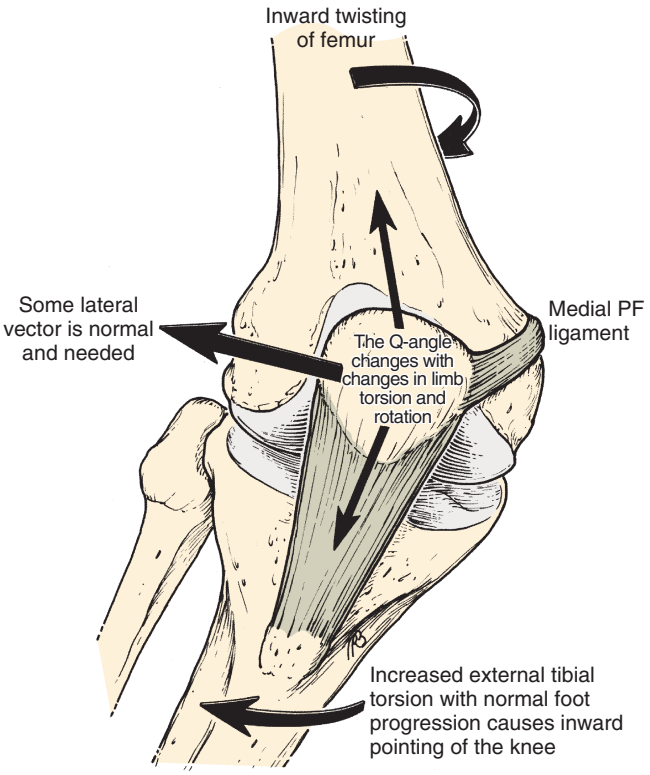

FIG 36-4 If the knee joint twists inward because the femur twists inward, the lateral pull on the quadriceps is increased, the lateral displacement pull on the patella is increased, the strain on the medial patellofemoral (PF) ligament is increased, the compression on the lateral patellar facet is increased, and the compression on the medial patellar facet is decreased. The treatment must be to decrease the inward twist on the knee joint, not to move the tubercle medially. A similar increase of inward pointing of the knee joint occurs in the presence of excess external tibial torsion when the foot is pointed forward.

in the position of the hip and knee with a constant foot progression angle and changes in femoral and tibial torsion are seen in Figures 36-8 to 36-12.

Figures 36-8 to 36-12 are drawn with a foot progression angle of 13 degrees (Seber average) for a normal male torsional alignment (Fig. 36-8), a normal female torsional alignment (Fig. 36-9), a female with 30 degrees of excess external tibial torsion (Fig. 36-10), a female with 30 degrees of excess femoral anteversion (Fig. 36-11), and a female with both 30 degrees of excess tibial external torsion and 30 degrees of excess femoral anteversion (Fig. 36-12). One may study the variations in knee joint progression with these common abnormal patterns. Yoshioka and associates[50-52] found identical femoral anteversion and genu valgus in both males and females but an increase in external tibial torsion and an increase in foot external rotation in females over males. This increase in external foot rotation may account for the apparent increased genu valgus in females, for the increased incidence in PF symptoms in females, and even for the increased incidence of anterior cruciate ligament (ACL) tears in females.

BIOMECHANIC EVIDENCE RELATING LIMB TORSION WITH PATELLOFEMORAL INSTABILITY AND PAIN

A change in PF contact areas and pressures were noted after alteration of femoral or tibial torsion or rotation by Lee and coworkers,[22-24] Hefzy and associates,[12] and vanKampen and Huiskes.[48] Kiljowski and colleagues[18] (unpublished data) placed lower limbs (femoral head to foot) in a frame with a clamp, attaching the femoral head to a vertical post that allowed the knee flexion to be altered by sliding the femoral head up and down the post. The foot was held in a position of normal FPA and an osteotomy was performed in the shaft of the femur, allowing rotation. PF contact pressures and MPFL strain were measured while the osteotomy changed the femoral torsion 15 degrees and 30 degrees, both inward and outward. At 30 degrees of knee flexion, lateral facet pressure increased an average of 30%, with a 30 degrees increase in

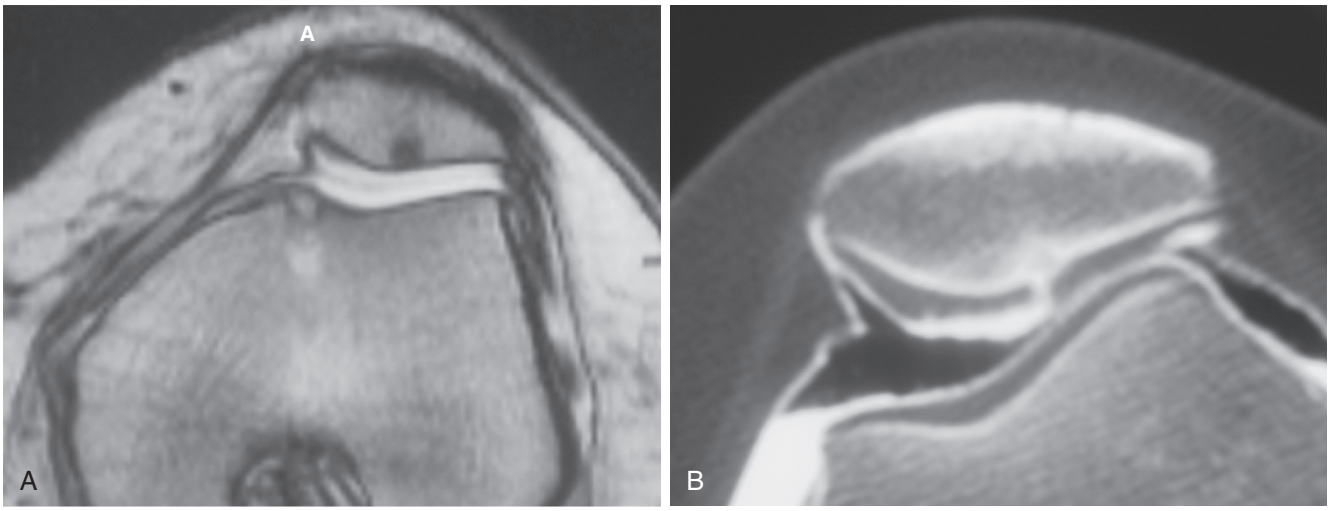

FIG 36-5 **A,** Magnetic resonance imaging read as focal osteonecrosis. **B,** Contrast computed tomography arthrogram clearly shows a split in the articular cartilage extending down to the cystic lesion with damaged articular cartilage medial to the cartilage split. Most likely, there was an acute subluxation episode that compressed the articular cartilage until it failed with a split relieving ligament tension, with further lateral subluxation damaging the medial articular cartilage into which the contrast dye now moves. *A,* Anterior.

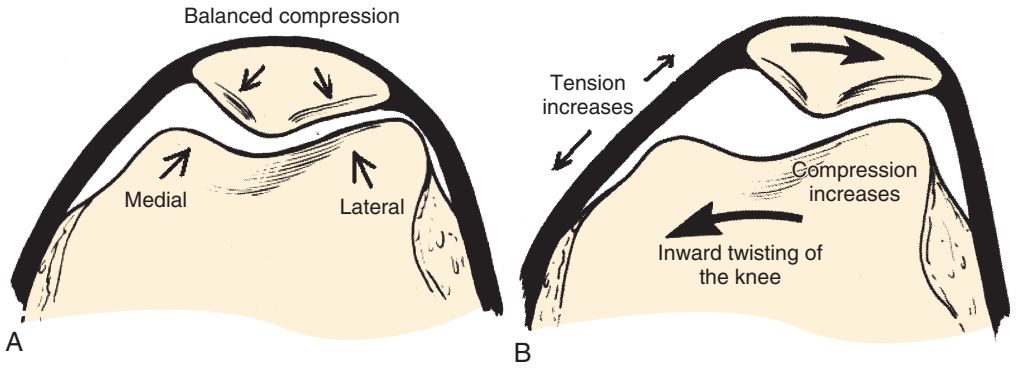

FIG 36-6 A, If the knee joint moves forward, the compression on the patellofemoral joint and ligaments tensioned are balanced. **B,** If the knee joint twists inward from beneath the patella, the medial patellofemoral ligament is placed under increased tension, the compression beneath the lateral facet increases, and the compression beneath the medial facet decreases.

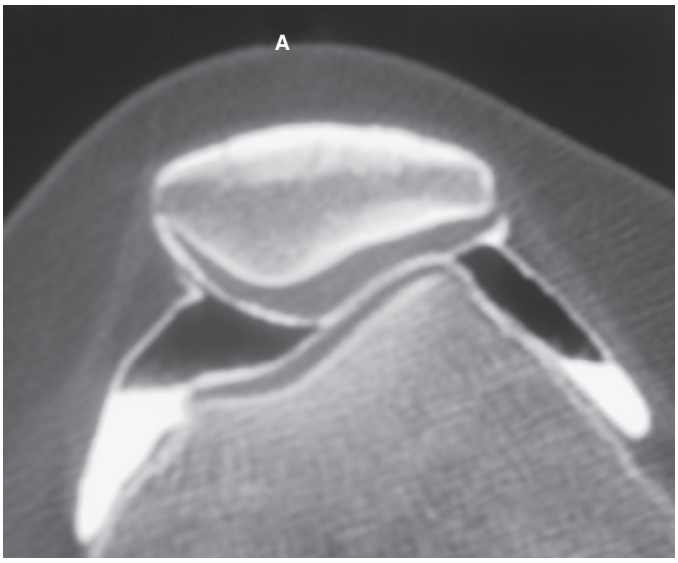

FIG 36-7 As the femur rotates internally beneath the patella, the lateral patellar articular cartilage is compressed. The increased crescentric density in the lateral patellar subchondral bone is indicative of chronic localized pressure. *A,* Anterior.

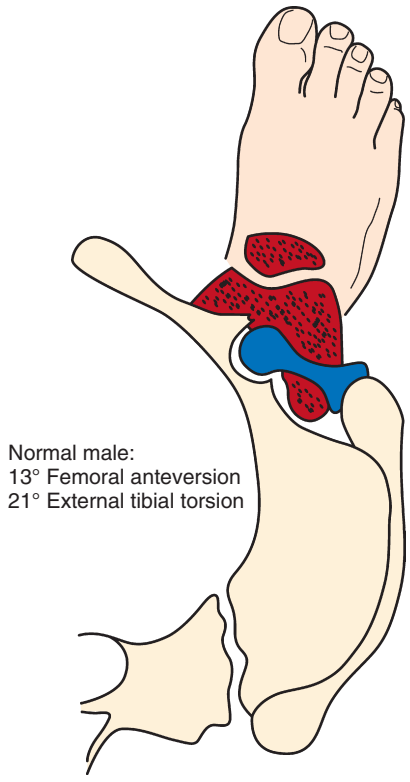

FIG 36-8 Normal male with femoral anteversion of 13 degrees and external tibial torsion of 21 degrees. Note that with a foot progression angle of 13 degrees, the knee joint faces slightly outward.

femoral anteversion, while medial facet pressures were decreased. Strain in the MPFL increased 57% after a 30 degrees increase of internal femoral torsion. Fujikawa and coworkers[11] in a biomechanic study measuring PF contact pressures concluded that if an angular deformity and a torsional deformity coexist, the rotatory component causes the greater PF changes. These authors also noted that when a varus deformity was created, the greater the varus deformity, the less the PF congruence.

CLINICAL EVIDENCE RELATING LIMB TORSION TO PATELLOFEMORAL INSTABILITY AND PAIN

Brattström[2] in 1964 measured trochlear depth in a group of patients with recurrent dislocation of the patella and confirmed that a shallow trochlea was always present. Brattström also defined the Q-angle and pointed out the change in Q-angle as a result of changes in limb rotation. Brattström reviewed the literature on the rotational femoral osteotomy as described by Graser (1904), Fürmeier (1953), Kiesselbach (1956), and Vinditti and Forcella (1958) and concluded that "femoral osteotomy is a big operation that demands prolonged after treatment. I have not encountered any instance of recurrent dislocation of the patella that justified my suggesting an operation of this nature to the patient." Takai and associates[42] measured femoral and tibial torsion in patients with unicompartmental arthrosis in either the medial, lateral, or PF compartment and found the highest correlation to be that of PF arthrosis with increased femoral anteversion (23 degrees of anteversion in the osteoarthritis group versus 9 degrees of anteversion in the control group). Janssen[16] found a high correlation between patellar dislocation and an increase in *internal femoral torsion* and speculated that *internal femoral torsion* was also responsible for the development

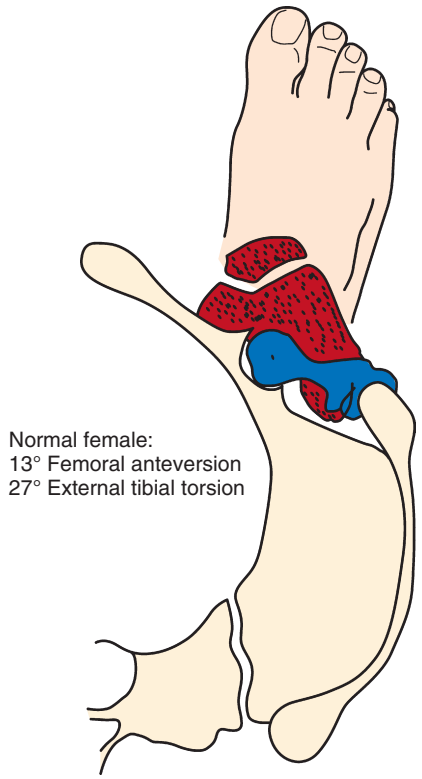

FIG 36-9 Normal female with femoral anteversion of 13 degrees and external tibial torsion of 27 degrees. Note that the knee joint is pointing slightly more inward and the greater trochanter is slightly more anterior than the normal male.

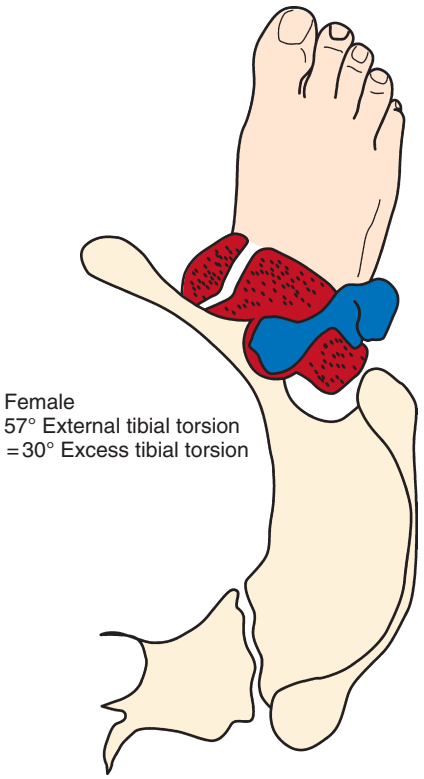

FIG 36-10 Female with a 30 degrees of increase in tibial torsion. To keep the foot progression angle normal, the knee joint axis points inward nearly 30 degrees, causing increased strain on the knee. The hip appears markedly internally rotated with the greater trochanter pointing somewhat anteriorly.

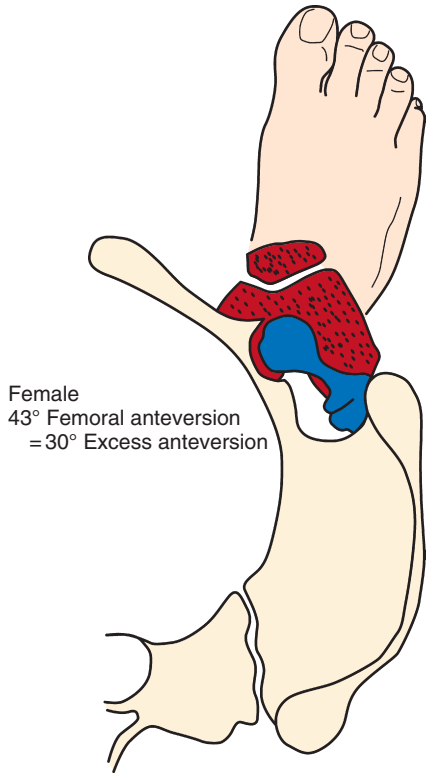

FIG 36-11 Female with 30 degrees of increase in femoral anteversion. The knee joint points in the same direction, slightly inward, as in the normal female, but the greater trochanter points posteriorly, giving a poor mechanical advantage. At some point, the hip cannot externally rotate enough to keep the knee joint pointed forward. With fatigue of the hip abductors, the knee points more inward to compensate for hip collapse, placing greater stress on the knee.

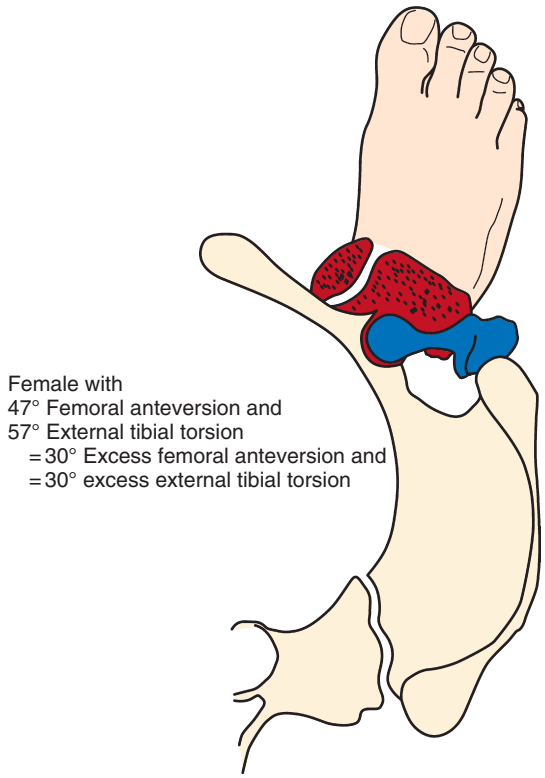

FIG 36-12 Female with a 30 degrees of increase in both femoral anteversion and external tibial torsion. Note the trochanter is pointed more anterior than normal, and with the foot progression angle normal, the knee joint axis points markedly inward.

of trochlear dysplasia. Lerat and colleagues[25,26] noted a significantly increased association of *internal femoral torsion* with both patellar instability ($P < .0001$) and patellar chondropathy ($P < .001$). Stroud and coworkers[41] followed 92 patients who, at age 5 years, showed 30 degrees greater *internal* hip rotation (measured in extension) than *external* rotation. At age 24 years, PF pain was noted by 30% in the increased *internal* rotation group compared with only 8% in the control group ($P < .001$). Winson and associates[49] found that 70% of adolescents undergoing arthroscopy for anterior knee pain had an increased *internal femoral torsion* compared with only 33% or those undergoing arthroscopy for a meniscal or cruciate injury. Turner[47] noted increased *external tibial torsion* in patients with PF instability (25 degrees vs. 19 degrees). Of perhaps great significance to those who believe that muscle strengthening is the key to treating PF symptoms, Nyland and colleagues[33] found a significant decrease in vastus medialis and gluteus medius electromyogram amplitude in athletes with clinically increased *internal femoral torsion*. Arnold and coworkers[1] noted that an increase in femoral anteversion of 30 to 40 degrees and decreased abduction moment arm strength by 40% to 50%, was enough to impair normal walking. Therefore those individuals required turning the knee inward to keep the hip from collapsing. This inward pointing of the knee creates high shearing force on the PFJ.

FEMORAL AND TIBIAL TORSION MEASUREMENTS LACK STANDARDS

Femoral anteversion has been measured by a variety of techniques by many authors[50,51] (Fig. 36-13). To measure limb alignment in the horizontal (transverse) plane, a CT rotational study is obtained. This is a CT scan that overlaps cuts from the femoral head, base of the femoral neck or lesser trochanter, the knee joint (either tangent to the posterior condyles or between the medial and lateral epicondyles), the proximal tibia at the joint, the tibial tuberosity, and the ankle joint (Fig. 36-14). These cuts allow measurement of femoral torsion, tibial torsion, knee torsion, and the tibial tubercle-trochlear groove (TT/TG) distance. CT also allows for the observation of trochlear depth or dysplasia, the position of the patella in the trochlea (unstressed), patellar tilt and shift, and the density of the subchondral trabeculae. Axial MRI with overlapped images may provide similar measurements, but no standards have yet been established.

To measure torsion of the femur, the recommendations of Murphy and coworkers[31] and Yoshioka and Cooke[50] are followed; these superimpose the CT cuts through the center of the femoral head and the base of the femoral neck where the circular nature of the femoral shaft becomes apparent (see Fig. 36-14, *A* to *C*). A line drawn through the center of these two proximal femoral locations becomes the proximal sreference line. A CT cut through the distal femur, where the anteroposterior (AP) dimension of the medial and lateral condyles is greatest allows a line to be drawn tangent to the posterior condylar surface. A second line can be drawn through the medial and lateral epicondyles. Yoshioka and Cooke[50] measured femoral torsion (anteversion) directly from the bone in a series of 32 femora and noted an average anteversion of 13.1 degrees in both males and females when the distal measurement was the tangent across the posterior femoral condyles and 7.4 degrees when measured across the epicondyles (standard deviation [SD], 8 degrees; range, –11 to +22 degrees). It is useful to measure both epicondylar axes and posterior condylar axes to help avoid an error if dysplasia of the lateral femoral condyle with a short AP distance is present. Yoshioka and Cooke[50] reviewed the literature that measured femoral anteversion using a variety of different techniques and noted that 12 of the 18 reviewed papers reported normal values between 8 and 16 degrees. I have arbitrarily chosen Yoshioka's 13 degrees as the goal for surgical correction. Kuo and colleagues[19] examined various measurement techniques and concluded that CT was accurate but

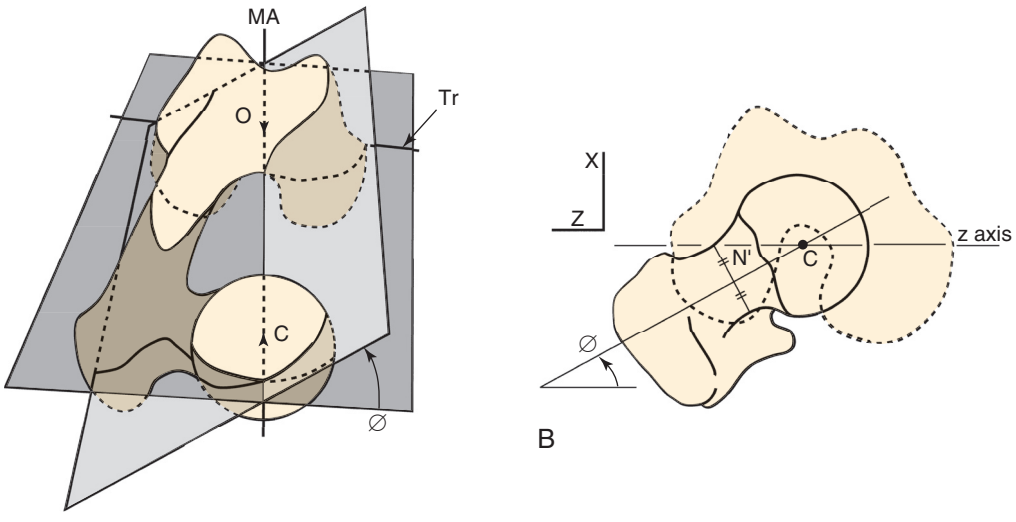

FIG 36-13 **A,** Femoral anteversion or antetorsion (angle Ø) may be measured along the center of the femoral neck from the center of the femoral head to the center of the femoral shaft at the base of the neck and distally either along the transepicondylar axis 7.4 degrees or the tangent of the posterior femoral condyles 13.1 degrees. These differ by about 6 degrees, with a range of 11 degrees retroversion to 22 degrees of anteversion. **B,** This measurement by Yoshioka and Cooke[50] is taken directly off the bone. Murphy and coworkers validated a computed tomographic measurement along these same lines. *C,* center of hip; *MA,* mechanical axis; *O,* origin of coordinate system, the attachment of the posterior cruciate ligament; *Tr,* transverse axis. (***A,*** From Yoshioka Y, Cooke TDV. Femoral anteversion: assessment based on function axes. *J Orthop Res* 1987;5:86-91. ***B,*** From Yoshioka Y, Siu D, Cooke TDV. The anatomy and functional axes of the femur. *J Bone Joint Surg Am* 1987;69:873-80.)

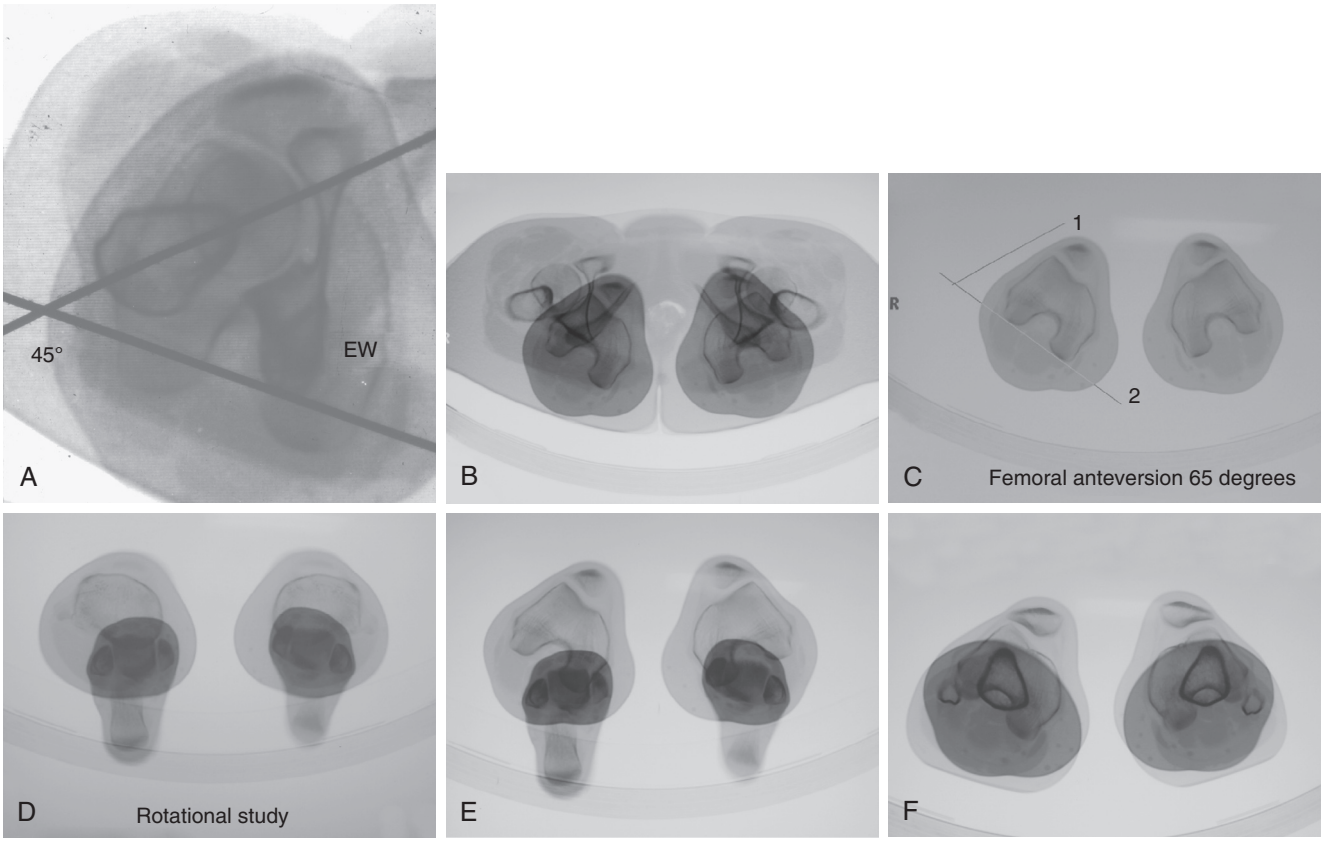

FIG 36-14 **A,** For measuring femoral torsion (anteversion), computed tomographic slices taken through the femoral head, the inferior greater trochanter, and the knee joint are superimposed. One line is drawn from the center of the femoral head through the greater trochanter and a second is tangent to the posterior femoral condyles at the knee joint. **B,** Hip and knee overlapped, allowing references lines seen in **C** to be drawn. **C,** *Reference line* 1 is taken from the center of the femoral head to the center of the femur at the level of the lower greater trochanter. *Reference line* 2 is a tangent to the posterior surface of the femoral condyles. The epicondyles are also readily seen and can be used as a second reference. There is generally a 6-degree difference between these two choices of reference. **D,** Tibial torsion can be measured between the axis of the tibial plateau and the ankle joint axis. **E,** The angle between the epicondylar axis of the femur and the ankle joint axis can be used as a measure of tibial torsion. **F,** The distance between the tibial tubercle and the center of the trochlear groove is also provided in the rotational study. Dejour and colleagues[6] stated that a distance greater than 20 mm is abnormal and correlates with objective patellar instability.

plane radiographic techniques were not. It is often stated that a patient with increased femoral anteversion has a compensatory external tibial torsion. Pasciak and coworkers[34] found this not to be the case and reported no relation between femoral anteversion and tibial torsion. In a review of over 300 CT rotational studies, we found that with increased femoral anteversion, tibial torsion may be normal, increased external, or increased internal.

The measurement of tibial torsion by CT has not been standardized. Jakob and coworkers[14] described a common sense method superimposing cuts across the proximal tibia and distal ankle joint. I have attempted to use the anatomic measurements of the tibia described by Yoshioka and colleagues[52] as a basis for measuring the proximal tibial reference line (Fig. 36-15). Blinded repeat measurements made by an orthopedic radiologist produced a measurement variation of less than 1 degree, indicating that reproducible measurements are possible. Yoshioka and colleagues'[52] anatomic study reported a lateral torsion of 21 degrees in males and 27 degrees in females, a significant difference. This was the only difference in geometry noted between males and females in both the tibia and the femur. In addition, these authors noticed a difference of 16 degrees between the transverse axis across the tibial plateau and the center of the foot. If this observation is confirmed, it is of major importance because it may explain the widely quoted difference between men and women in the frequency of PF disorders. It may also explain the reported increased incidence of ACL tears in women. Le Damany[21] reported 23.7 degrees to be normal tibial torsion. Seber and associates[38] calculated external tibial torsion to be 30 degrees (range, 16 to 50 degrees) in a group of 50 "normal" (asymptomatic) men, but their measurement technique was unique in selecting the location for drawing the proximal tibial reference. Eckhoff and coworkers[9] noted variations between 15 and 30 degrees. Turner[47] found 19 degrees (SD, 4.8 degrees) in a control group and 24.5 degrees (SD, 6.3 degrees) in a group with unstable patella. The CT measurements of Sayli and coworkers[36] averaged 30 to 35 degrees. Siston compared the selection of the transverse axis across the top of the tibial plateau by 11 different knee surgeons and reported a range of 90 degrees from 44 degrees of internal rotation to 46 degrees of external rotation and a standard deviation of 28.1 degrees.[53] This wide variation in selecting the location of a critical axis suggests that a more accurate and reproducible method is needed before we can answer important questions. Tamari and associates[43] demonstrated a lack of reliability

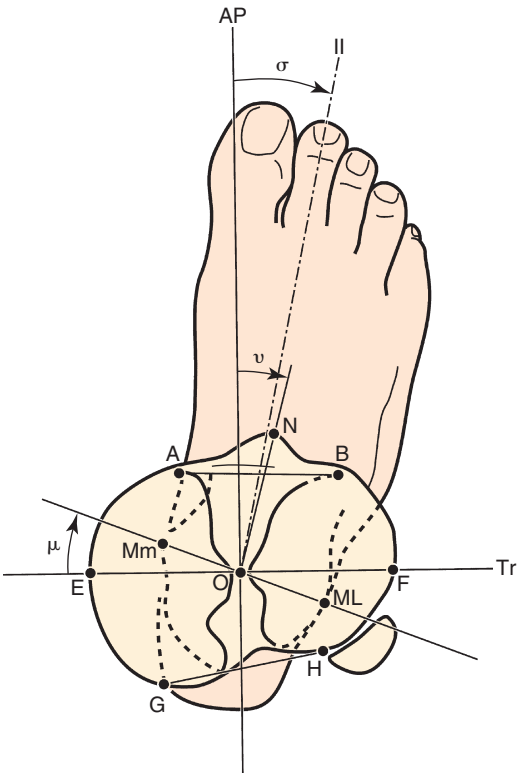

FIG 36-15 The tibial torsion may be measured as the angle μ, which is between the widest distance on the tibial plateau (E-F) and the line connecting the malleoli (Mm-ML). Males = 21 degrees, females = 27 degrees. Angle σ is the "foot rotation," the outward deviation of the foot in reference to the tibial plateau transverse axis (E-F). Males = –5 degrees, females = +11 degrees. *A,* Anterior margin of articular cartilage medial tibial plateau; *AP,* anterior-posterior axis; *B,* anterior margin of articular cartilage lateral tibial plateau; *N,* anterior point of tibial tuberosity; *ML,* tip of lateral malleolus; *Mm,* tip of medial malleolus. (From Yoshioka Y, Siu DW, Scudamore RA, Cooke TDV. Tibial anatomy and functional axes. *J Orthop Res.* 1989;7:132-137.)

among measurement methods and this remains a major stumbling block in answering the question of how much of an influence altered tibial torsion plays in PF instability and when osteotomy may be useful.

In addition to using the tangent to the posterior tibial cortex, Cobb's axis, and Yoshioka's anatomic measurements, I also use the femoral epicondylar axis as the proximal reference for tibial torsion. This is because of the interest in the relationship of the knee joint axis to the ankle joint axis and the problem incurred in selecting a line across an ovalshaped tibial plateau. A rotation of the tibia on the femur must not be present if a distal femoral axis compared with the angle joint axis is used as to measure tibial torsion.

INDICATIONS

Any variation from optimal skeletal alignment may increase the vector forces acting on the PF joint, causing either PF ligament failure with subsequent subluxation or cartilage failure as in chondromalacia or arthrosis or both ligament and cartilage failure. Anterior knee pain may result from these abnormal forces or their consequences (Fig. 36-16).

An inward-pointing knee attributable to any cause will increase the lateral displacement force on the patella (Figs. 36-17 to 36-19). If this force is great or if the trochlear support is reduced from dysplasia or

FIG 36-16 Miserable malalignment. The patient often presents with medial parapatellar pain with no localizing findings or images indicating pathology. Later instability or arthrosis may develop.

fracture, the medial ligaments may fail, resulting in lateral patellar instability. The converse is also true. Pain in the medial retinaculum is a common symptom caused by this increased stress. If the trochlear support is normal, the ligament may not fail, but the articular load may increase, causing arthrosis. This increased force may be the result of abnormal femoral torsion, abnormal tibial torsion, genu valgum, hyperpronation, Achilles contracture, or other conditions. The choice for surgery depends on the relative size of the deformity and the relative surgical risk and morbidity.

The MPFL is a rather small structure. This is because a large ligament is not needed to restrain the patella from leaving the center of the trochlea if the limb is straight, the knee joint axis points forward, the quadriceps vector is in the frontal plane, and the trochlea is normal. If the trochlea is dysplastic (shallow), the ligament may not be strong enough to withstand the normal lateral pull of the quadriceps. If there is an abnormal limb torsion (so the knee joint does not move forward in the direction the body is moving), the side-displacing force is increased, and the ligament is more likely to be overcome, leading to patellar instability. An MPFL reconstruction may be useful to restore patellar restraint, but in the face of continued increased displacement forces caused by a torsional limb malalignment, such a reconstruction may fail. Conversely, in the face of normal limb torsion, the side-directed force may not be sufficient to displace the patella even with insufficient ligaments. The clinical presentation may be pain, instability, arthrosis, or a combination of these problems.

SURGICAL STRATEGY

The goal of operative treatment is to normalize the biomechanics through restitution of normal anatomy.[44,45] The morbidity of surgery may dictate otherwise. When multiple anatomic abnormalities exist, it is not known which may be more important. If a patient has recurrent

FIG 36-17 A 17-year-old student with rapid onset of pain and abnormal gait. It is likely that progressive overload caused by torsional malalignment resulted in progressive increased foot pronation with loss of foot and ankle stability and secondary weakness of the lateral hip musculature. **A,** When standing anteroposterior, the squinting patella on the right is well seen. Both femurs have 50 degrees greater than normal anteversion. **B,** What the patient sees looking down her legs. **C,** If the knee faces forward, the foot turns out. **D,** The dynamic picture is much worse because the anteversion puts the greater trochanter pointing posteriorly so there is no hip abduction power, and the pelvis collapses. In an attempt to increase hip power and put the foot forward, the knee joint must point inward, even more when there is an increase in hyperpronation.

patellar lateral subluxation, articular cartilage damage, trochlear dysplasia, patella alta, an Achilles contracture, a femoral anteversion of 45 degrees, an external tibial torsion of 55 degrees, and a genu valgum of 10 degrees, is it best to perform a varus, external rotational femoral osteotomy, a distalization of the tibial tuberosity, a reconstruction of the MPFL, a trochlear osteotomy, an internal rotation osteotomy of the tibia, or an Achilles lengthening? These abnormal findings are often quite subtle, but combinations are surprisingly common. The surgical approach to correct all abnormalities may be quite logical from a biomechanic view but excessive from a surgical morbidity standpoint. A biomechanic solution with osteotomy may mean that the ligament reconstruction is not necessary because the displacing forces are reduced. A cartilage restoration is not necessary because the compressive forces are reduced and changed in direction. As yet, no biomechanic studies indicate which surgery alters biomechanics the most.

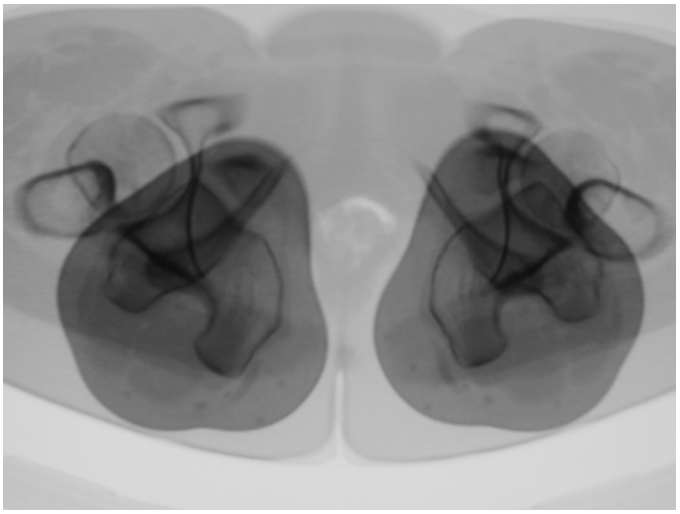

FIG 36-18 Computed tomography rotation study of the same patient yields anteversion of 67 degrees. The hip cannot be rotated externally enough for the knee joint to face forward.

FIG 36-19 Six weeks postoperative, the patient shows 50 degrees of external rotational intertrochanteric osteotomy on the right hip. The right foot is less pronated than the left foot, and the left knee joint is pointed slightly more inward than the right. Gait has already improved, and knee pain diminished immediately after surgery.

Experience suggests surgery is indicated for most cases with torsion of the femur or tibia exceeding 30 degrees from normal. For cases with torsion exceeding 20 degrees from normal, surgery is thought to be beneficial. For cases with abnormality less than 20 degrees, the accuracy of surgery or the morbidity may not justify surgery for small biomechanical changes. Turner's [47] data found 19 degrees average external torsion in a control group and 24.5 degrees in a patellar instability group. Takai and associates[42] found 9 degrees average femoral anteversion in a control group and 23 degrees average in a PF arthrosis group. Therefore it is possible that small limb torsional differences are significant.

FIG 36-20 Postoperative radiograph of a femoral rotational osteotomy produced with an intramedullary saw. Rotation changes the anterior bow of the femur to a corkscrew shape that does not allow the nail to pass congruently, resulting in splitting of the distal fragment.

SURGICAL TECHNIQUE

To correct an excess of internal femoral torsion that is not associated with a genu varus or valgus, an intertrochanteric osteotomy has been used since the late 1980s. Before that, I used the technique of closed intramedullary saw and fixation with an intramedullary nail. This technique is generally good for treating fracture malunion. However, with congenital maltorsion the normal antecurvatum of the femoral shaft is destroyed when the femur is cut in mid-diaphysis. The two antecurved fragments are rotated, and commonly a curved intramedullary nail can split the distal fragment (Fig. 36-20). In my original series of patients, osteotomizing the femur with an intramedullary saw and using an intramedullary nail for fixation resulted in poorer bone stability compared with rigid internal plate fixation. There were more postoperative pain, blood loss, and delayed union, and one death resulted from an apparent fat embolism. Consequently, the technique was abandoned, and I currently prefer rigid fixation with an AO 95-degree condylar blade plate (Figs. 36-21 and 36-22). The intertrochanteric location was chosen to minimize damage to the quadriceps, avoid scaring that may occur between the distal quadriceps and the supracondylar femur, and theoretically reduce the abrupt angular change the quadriceps would make with a supracondylar location. It should be noted these decisions are without scientific evidence. If a genu varum or genu valgum is associated with a torsional abnormality and the tibiofemoral angle is abnormal, this deformity must be corrected in the supracondylar region.

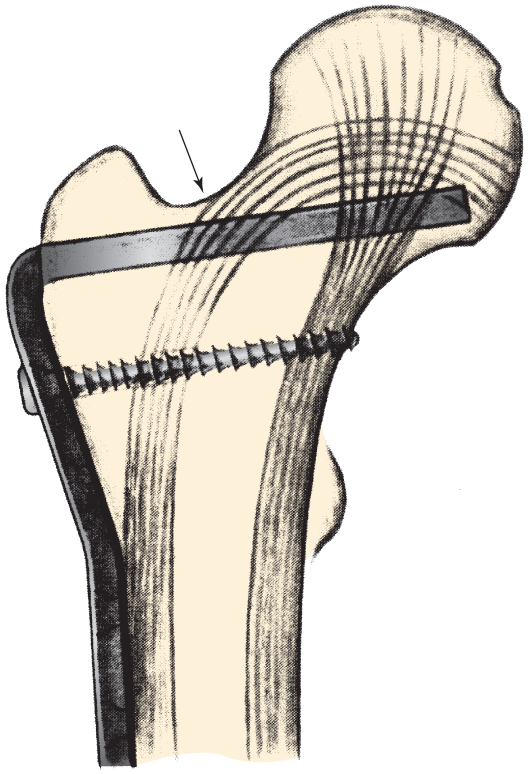

FIG 36-21 The 95-degree condylar blade plate is designed for fixation of the proximal femur. The U-shaped blade is inserted into the center of the neck and the inferior half of the head of the femur. (From Müller ME, Allgöwer M, Schneider R, Willenegger H. *Manual of Internal Fixation,* ed 2, New York: Springer-Verlag; 1979.)

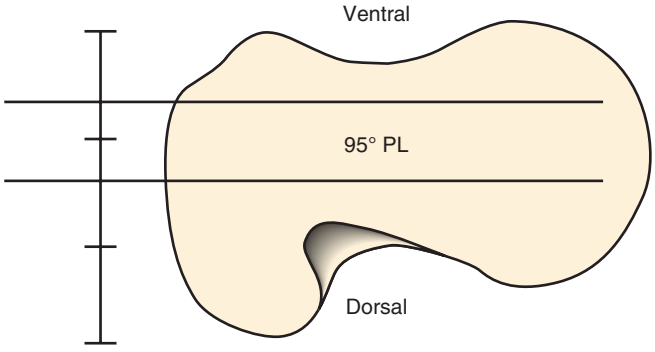

FIG 36-22 The blade is inserted into the center of the femoral neck and head. *PL,* Plate. (From Müller ME, Allgöwer M, Schneider R, Willenegger H. *Manual of Internal Fixation,* ed 2, New York: Springer-Verlag; 1979.)

The standard AO/ASIF (Arbeitsgemainshaft für osteosynthesefragen/Association for the Study of Internal Fixation) technique for hip osteotomy is used. This has been well described and is well known. The ability to solidly compress the two osteotomy fragments insures stability and reduces pain. This compression remains a major advantage of the classical approach. The osteotomy is placed at the level of the proximal third of the lesser trochanter to increase the osteotomy surface contact area and to leave sufficient purchase for the 95-degree condylar blade plate in the proximal fragment. The blade plate is a tool that controls the correction. One needs to ensure only that the seating chisel for the blade plate enters the femoral neck at the proper height and orientation and to attach the side plate to the shaft fragment. The goal is for the blade of the blade plate to be centered in the femoral neck at such an angle that the side plate will sit on the lateral cortex of the femur without altering either flexion-extension or varus-valgus. The standard AO tools aid in this goal (Fig. 36-23).

A standard lateral approach to the hip is altered so the iliotibial track (fascia lata) is entered more anterior than usual to ensure that the trochanter or the shoulder of the plate will not put pressure on the repaired facial incision, causing a dehiscence.

After exposure of the lateral shaft of the femur by elevating the vastus lateralis anteriorly, the condylar plate guide, a mirror image of the 95-degree condylar plate, is placed along the lateral shaft of the femur. It is moved proximally and distally until an extension along its proximal flat surface lines up just below the center of the femoral head, as seen with x-ray image intensification (Fig. 36-24). A 2.5-mm hole is drilled into the femoral neck parallel to the top of the condylar plate guide and centered in the femoral neck. This hole is placed proximal enough to leave room below it to insert a seating chisel on top of the condylar plate guide. It is convenient to slide a 2.0-mm Kirschner wire (K-wire) into the 2.5-mm drill hole and use a frog-leg lateral x-ray to judge its orientation in the femoral neck. With excess femoral anteversion, the femoral neck is often angled quite anteriorly relative to the knee joint and is not exposed; therefore image intensification is used to locate its center. Positioning the limb for a frog-leg lateral x-ray usually results in bending of the K-wire against the iliotibial band, but the position within the femoral neck will indicate if the direction is appropriate. It is common to need to change these bent K-wires after obtaining the frog-leg lateral x-ray, and the ability to slide the 2.0-mm wire in and out of the 2.5-mm hole easily is useful.

Once the proper position of the K-wire is obtained, the seating chisel for the angled blade plate is inserted. A thin chisel may be used to cut into the lateral femoral cortex at the top of the properly positioned condylar plate guide. This cut in the cortex will allow the seating chisel of the blade to be advanced without sliding proximally or distally. A window in the lateral cortex of the greater trochanter for the seating chisel may also be started with drills (Fig. 36-25). The thickness of the 95-degree condylar blade is 4.5 mm, allowing a 4.5-mm drill to be used. A triple drill guide is available to attach to the top of the condylar plate guide to ensure the correct drill direction (Fig. 36-26). This is usually not necessary and predrilling with three parallel 4.5-mm drills leaves a looser fit of the blade within the femoral neck.

As the seating chisel is passed into the femoral neck, it is necessary to hold either the condylar plate guide or the seating chisel guide parallel to the femoral shaft to ensure the side plate will align with the lateral femoral shaft and not create a change in flexion or extension of the femoral shaft (Fig. 36-27). Because of the anterior bow of the femur, the proper position is not parallel to the floor. The condylar plate guide is used repeatedly to check that both the varus-valgus angulation and the flexion-extension angle will not be changed (Fig. 36-28). The seating chisel is advanced slowly until it approaches the center of the femoral head. It is backed out after advancing every 5 mm or so as not to become incarcerated. The slotted hammer is used to prevent twisting of the seating chisel into flexion or extension as it is advanced (Fig. 36-29). The depth of insertion is read off the marks etched on the seating chisel. A chisel is used to remove a small sliver of bone from the inferior edge of the entry site for the blade. This allows the shoulder of the plate to be advanced into the proximal fragment (Fig. 36-30).

When the seating chisel is removed, a 2.0-mm K-wire may be inserted into the chisel track that will slide into the U corner made by the seating chisel (Fig. 36-31 and 36-32). This guarantees that

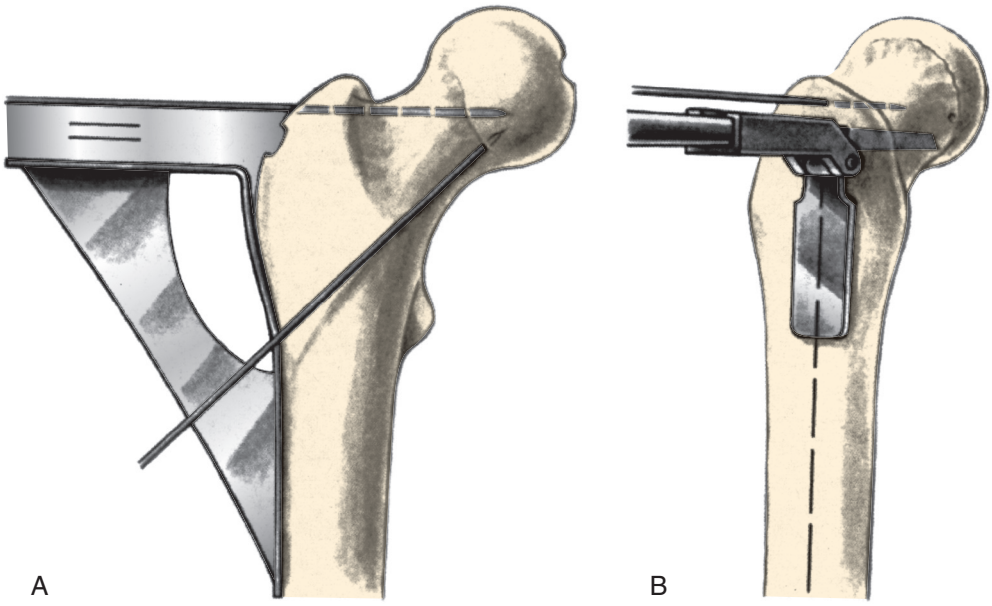

FIG 36-23 **A,** When a 95-degree condylar blade plate is to be used for fixation of a proximal femoral osteotomy, the site of insertion can be located with the aid of the condylar plate guide, which is a mirror image of the condylar blade plate. A K-wire inserted parallel to the top of the condylar plate guide will guide the insertion of the seating chisel. The direction of the femoral neck can be approximated with a K-wire placed along its anterior cortex. The neck must be seen for this to be precise and radiographic control with the image intensifier may be easier than opening the hip capsule. **B,** The seating guide placed in line with the axis of the femur will ensure there is no change in flexion or extension of the hip. (From Müller ME, Allgöwer M, Schneider R, Willenegger H. *Manual of Internal Fixation,* ed 2, New York: Springer-Verlag; 1979.)

FIG 36-24 The condylar plate guide is placed along the lateral femoral shaft. It is moved proximal or distal until a line extending medially parallel to the top of the guide is located just below the center of the femoral head. A K-wire is inserted above and parallel to this line; this K-wire position is checked on the lateral radiograph to ensure it is in the center of the femoral neck. Once proper positioning of the K-wire is obtained, the seating chisel for the blade of the blade plate is inserted into the femoral neck and head parallel to the K-wire and to the top of the condylar plate guide.

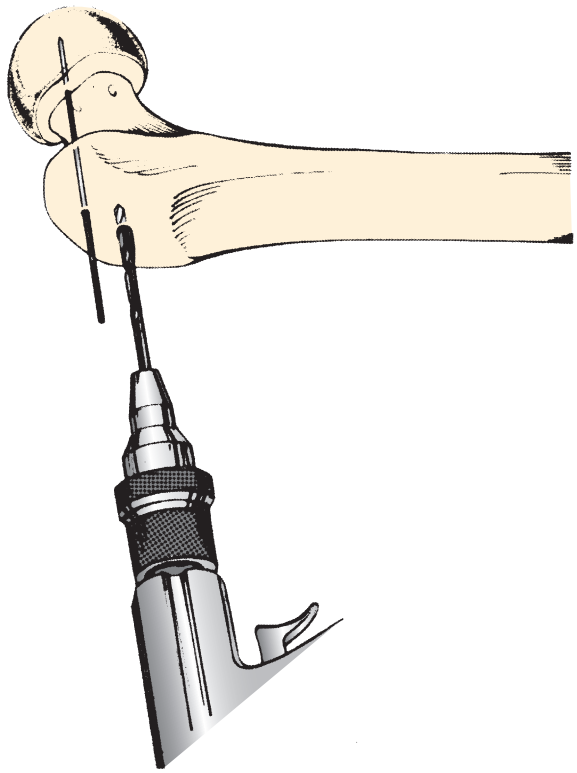

FIG 36-25 The window for the seating chisel may be created in the lateral cortex of the greater trochanter with a 4.5-mm drill. A triple drill guide (4.5 mm) may be attached to the top of the condylar plate guide. (From Schauwecker F. *Practice of Osteosynthesis,* 2nd rev ed., New York: Thieme-Stratton, 1982; p. 187.)

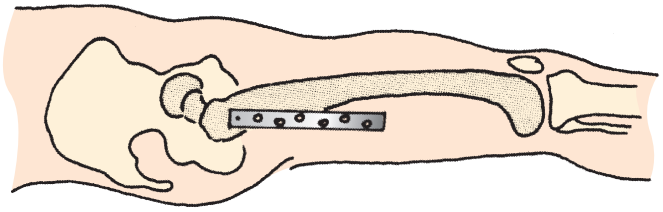

FIG 36-26 A triple drill guide is attached to the top of the condylar plate guide and 2 × 4.5 mm drill bits used to start the window for the seating chisel in the lateral cortex of the greater trochanter. A thin chisel is used to cut the cortex to begin the entry point for the seating chisel.

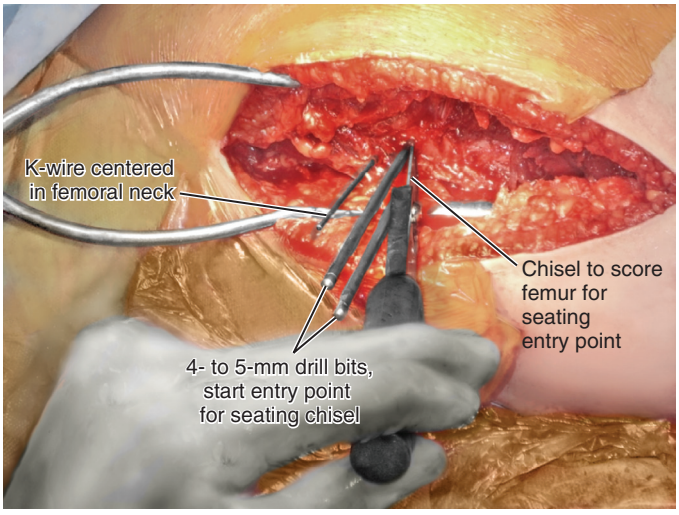

FIG 36-27 The seating chisel guide and condylar plate guide must be placed parallel to the shaft of the femur to avoid causing a flexion or extension change. The tendency is for the plate to be inserted horizontally (shown here), forgetting the anterior curve to the femur, thus causing an increased hip extension. (From Schauwecker F. *Practice of Osteosynthesis,* ed 2, New York: Thieme-Stratton; 1982.)

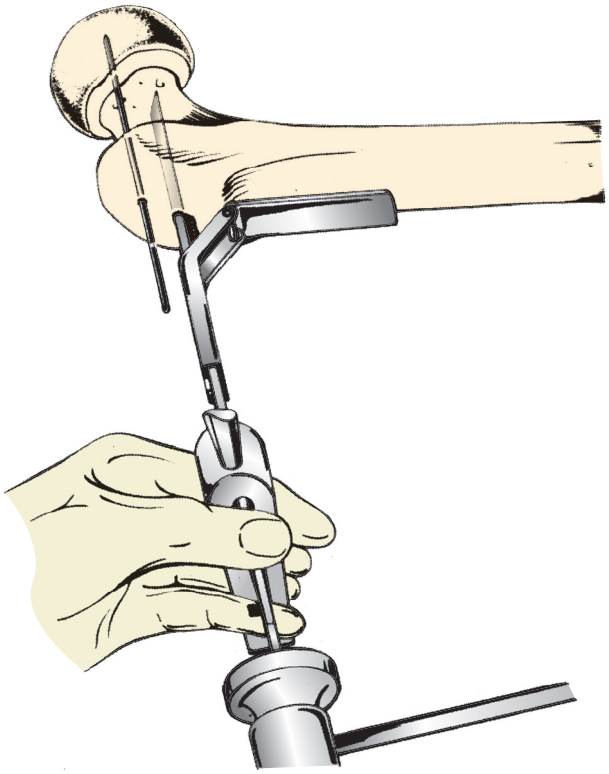

FIG 36-28 The seating chisel is driven into the femoral neck, parallel to the K-wire previously placed. The seating chisel guide is used to ensure the plate will lie centered on the lateral shaft of the femur. This flexion and extension is controlled by the slotted hammer. (From Schauwecker F. *Practice of Osteosynthesis,* ed 2, New York: Thieme-Stratton; 1982.)

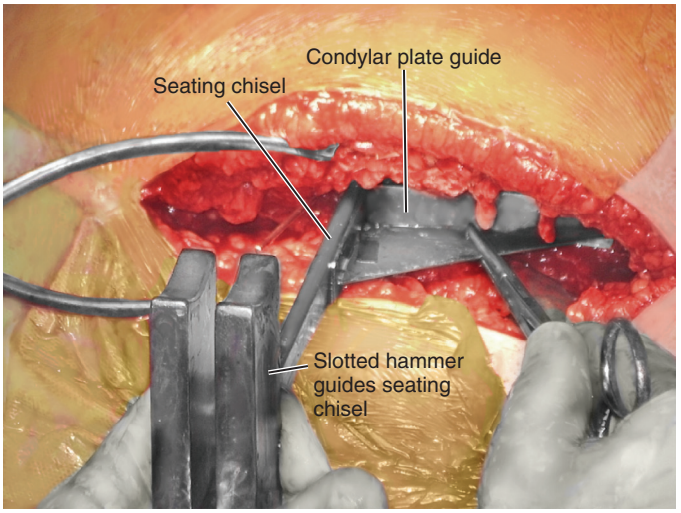

FIG 36-29 The condylar plate guide is placed parallel and touching the lateral femoral cortex, and the seating chisel is kept flush and parallel with the top of the guide. The slotted hammer allows control of the twist of the seating chisel; thus it controls flexion and extension of the osteotomy.

the direction for the blade will not be lost while the osteotomy is completed.

A 2.5-mm drill hole is placed at the location for the osteotomy, usually at the upper third of the lesser trochanter, and drilled from lateral to medial and perpendicular to the femoral shaft coronal plane axis. A 2.5-mm K-wire, which will be used to guide the saw, is inserted into this hole.

Two anterior to posterior K-wires, which are set at the desired angle of correction, are placed in the femur, one proximal and one distal to the selected site for osteotomy (Figs. 36-33 and 36-34). A 2.5-mm drill is used to create the holes for these two K-wires. These are the markers to indicate the torsional correction. For excess femoral anteversion, the need is to externally rotate the distal fragment. The proximal pin is placed first, far enough anterior and medial that it will not come into conflict with the angled blade plate that will be inserted into the proximal fragment. The distal pin is angled from medial to lateral the desired correction amount, usually indicated according to known triangles. Commercially provided triangles of various angles are available to be placed along the proximal K-wire to guide the distal reference 2.5-mm K-wire.

Once these reference pins are in place, the osteotomy is completed with a thin saw (Fig. 36-35). The saw blade is kept perpendicular to the axis of the femur, and the image helps ensure the orientation is proper (Fig. 36-36). Elevators are placed anterior and posterior to the bone to protect the soft tissues, and the image is used to judge the medial depth of the cut. Once the cut is completed, the soft tissues adjacent to the cut are stretched by placing a lamina spreader within

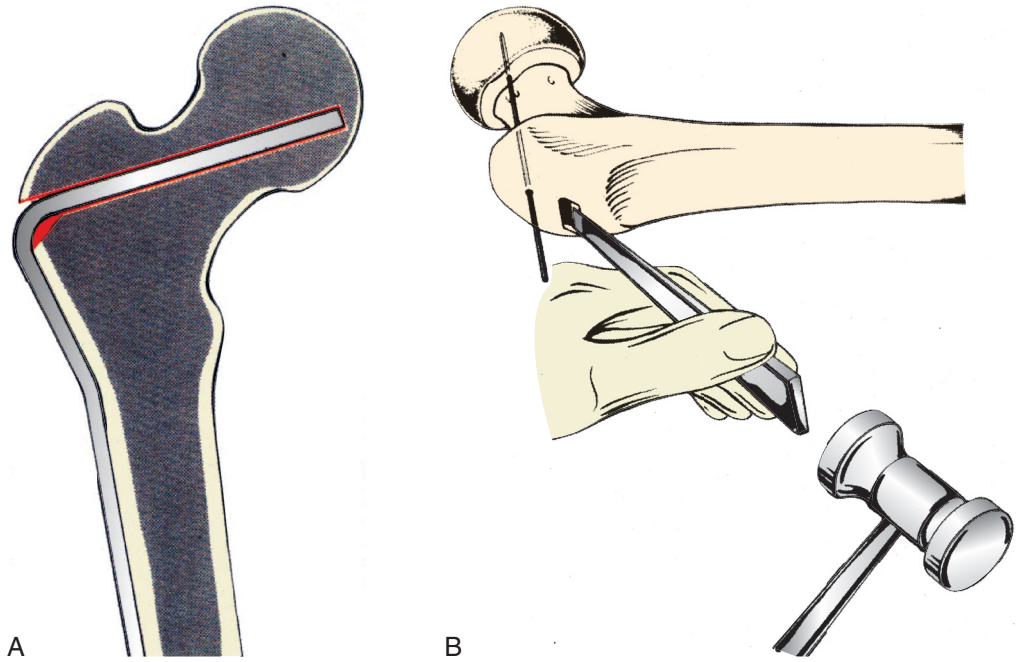

FIG 36-30 A, The shoulder of the condylar blade plate will prevent the plate from seating all the way into the proximal fragment. **B,** A chisel is used to remove the lower edge of the window for the blade plate so it does not block full insertion. (From Schauwecker F. *Practice of Osteosynthesis,* ed 2, New York: Thieme-Stratton; 1982.)

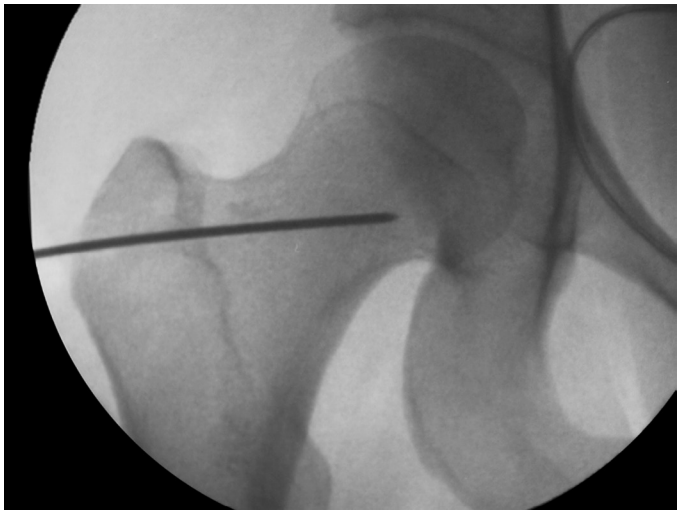

FIG 36-31 A 2-mm-diameter K-wire is inserted in the corner of the U-shaped chisel track so it can be located later when the osteotomy is complete and the blade is ready for insertion.

FIG 36-32 Once the seating chisel has been inserted, it is removed and a 2-mm K-wire is placed into the seating chisel track. A 2.5-mm wire is to be placed in the top half of the lesser trochanter and perpendicular to the femoral shaft.

the osteotomy (Fig. 36-37). This makes it easier to adjust rotation. Next, the blade plate is inserted into the proximal fragment (Fig. 36-38). The previously placed 2.0-mm K-wire in the seating chisel track makes the direction easier to follow. If the blade is properly in line with the track, it can often be pushed in by hand. After it is correctly placed in the femoral neck and head, it is necessary to impact the blade tightly into the proximal fragment (Fig. 36-39). Usually, a five-hole length side plate is sufficient. A longer-length side plate provides greater leverage but requires a longer incision and surgical approach.

The distal fragment is now externally rotated until the two torsional reference K-wires are parallel and the cortices of the osteotomy surface are well aligned circumferentially (Fig. 36-40). If the blade is not driven sufficiently far into the proximal fragment, it may allow the distal fragment to translate more laterally than the proximal fragment such that the surfaces of the osteotomy do not line up. This can be corrected by removing a small amount of bone from beneath the shoulder of the plate and impacting the plate farther into the proximal fragment. Hohmann retractors or clamps may be useful to help align the axis of both proximal and distal shaft fragments while maintaining the desired

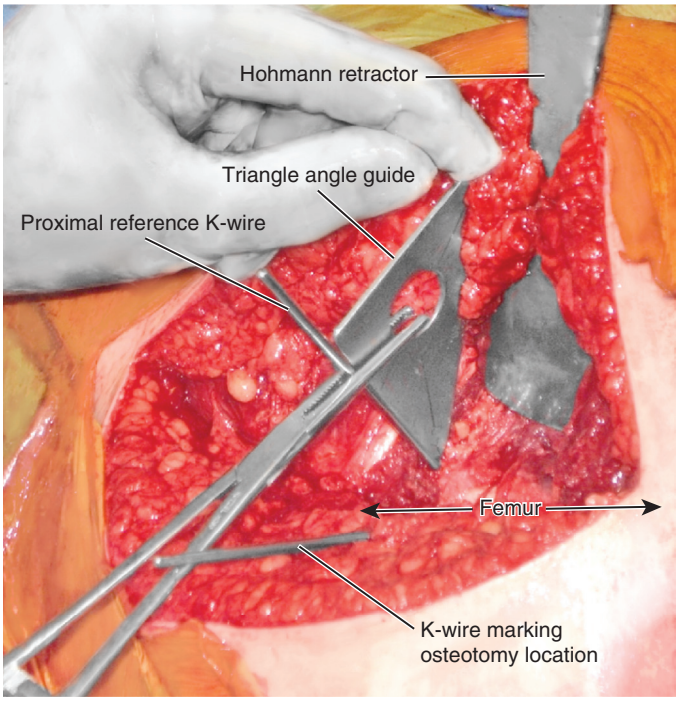

FIGURE 36-33 After the level of osteotomy is selected and marked with a K-wire, K-wires are needed as rotational markers. The first is placed proximal to the level of osteotomy and anterior to the location for the blade plate. For a 50-degree correction, one side of a 50-degree triangle is placed along the vertical K-wire, and a second K-wire will be placed distal to the osteotomy level (bottom K-wire) and parallel to the medial edge of the 50-degree triangle.

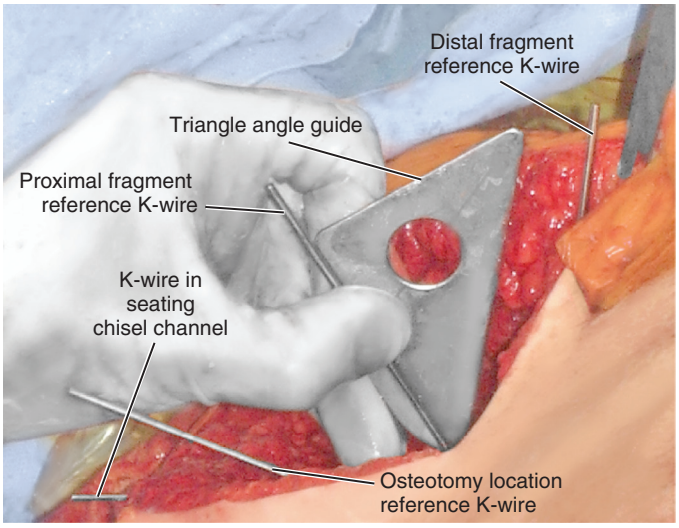

FIG 36-34 The K-wires (*right*) to indicate the angle of correction are seen to subtend an angle of 50 degrees. To the *left* are the K-wires in the osteotomy site and in the seating chisel tract.

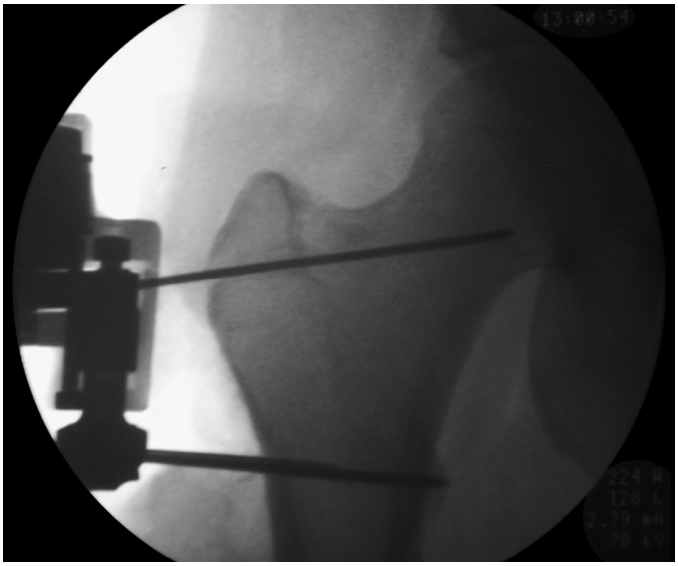

FIG 36-35 The saw cut is started in the lateral cortex, and the saw blade is perpendicular to the shaft in both the anteroposterior and lateral radiographic projections. The K-wires indicate that rotation must be placed before completing the osteotomy and should be placed now.

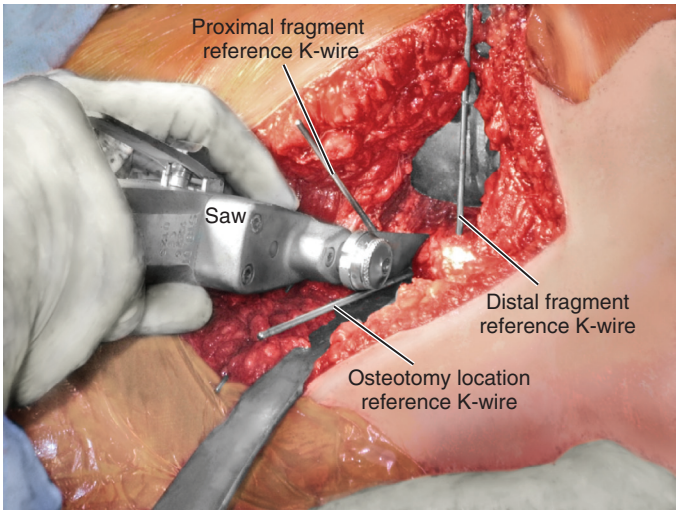

FIG 36-36 An oscillating saw is used to cut the femur transversely. The two rotation wires (*right*) subtend the desired angle of correction, and the lower K-wire is a guide for the saw at the osteotomy level.

rotational correction. Once this position is reached, the articular tension device is attached to the femur distal to the plate (Fig. 36-41). This must be in line with the plate, or the rotation will be changed as tension is applied to the plate.

A tension device placed anterior to the plate will cause external rotation of the distal fragment when tension is applied, and a tension device placed posterior to the plate will cause internal rotation of the distal fragment to be introduced. The articular tension device is color coded, with the red indicating 120 kPa. Using the spanning wrench, an attempt is made to always exceed the 120-kPa indicator (Fig. 36-42). If the screw attaching the tension device to the femoral shaft is bent, I am confident that satisfactory compression of the osteotomy surfaces has been reached. If the blade is not tightly seated in the proximal fragment, it may begin to pull out as tension in placed in the plate. A screw through the proximal plate into the proximal fragment is often necessary to prevent the blade from backing out with subsequent loss of osteotomy compression (Figs. 36-43 and 36-44). I have not found proximal femoral nails or locked plates providing the degree of compression that can be obtained with the angled plates and the articulated tension device.

Rotational osteotomy of the tibia should be performed below the level of the tibial tuberosity. The Q-angle or TT/TG distance is an

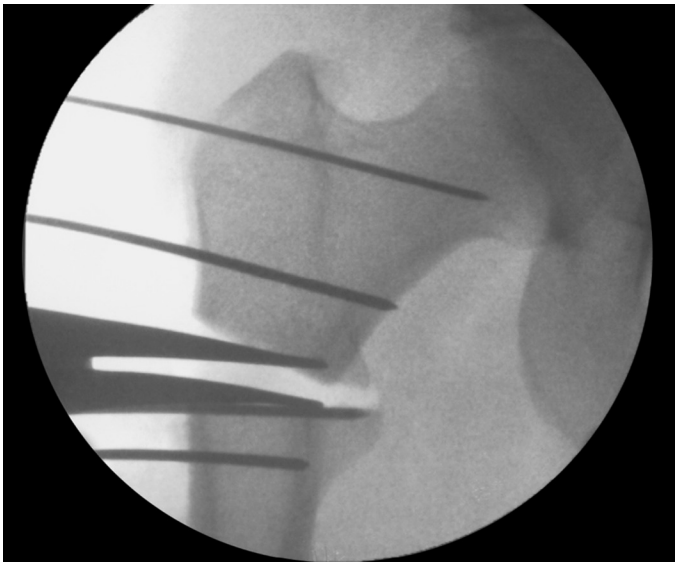

FIG 36-37 When the osteotomy is complete, it is useful to stretch the soft tissue with a lamina spreader. Four K-wires are shown: a 2-mm diameter in the track of the seating chisel, 2 × 2.5 mm diameter rotational wires above and below the osteotomy placed for rotational reference, and the fourth between to serve as a guide for the saw.

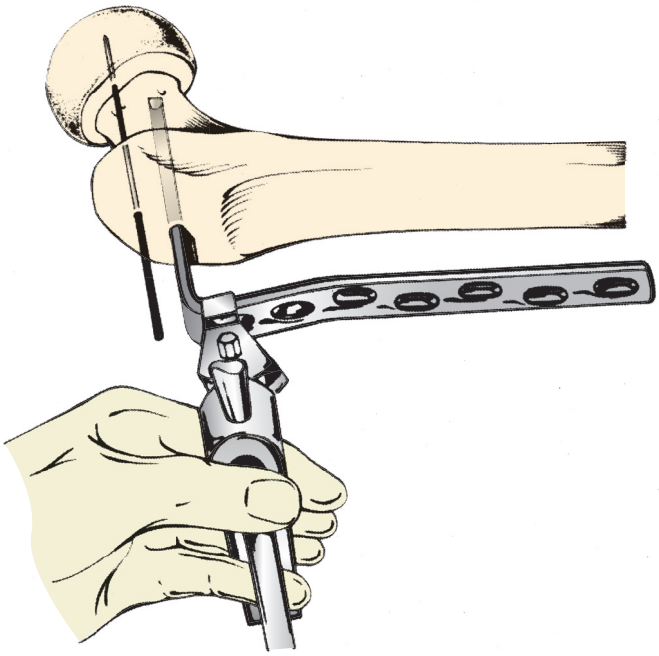

FIG 36-38 The blade can often be inserted by hand. The inserter handle is set so it is parallel to the blade and the insertion is parallel to the orientation K-wire. (From Schauwecker F. *Practice of Osteosynthesis,* ed 2, New York: Thieme-Stratton; 1982.)

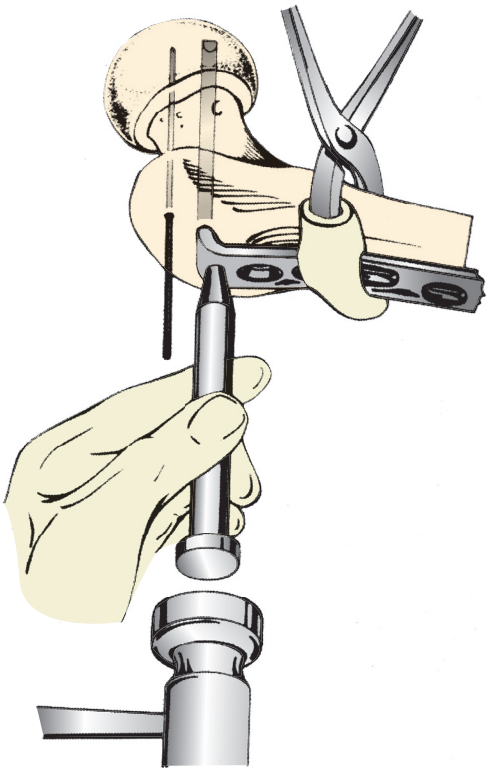

FIG 36-39 The impactor is used to seat the plate fully into the proximal fragment. (From Schauwecker F. *Practice of Osteosynthesis,* ed 2, New York: Thieme-Stratton; 1982.)

FIG 36-40 The desired cortical alignment. The oblique lag screw prevents the plate from backing out and contributes extra compression across the osteotomy. The holes for attachment of the articulated tension device are seen distal to the plate.

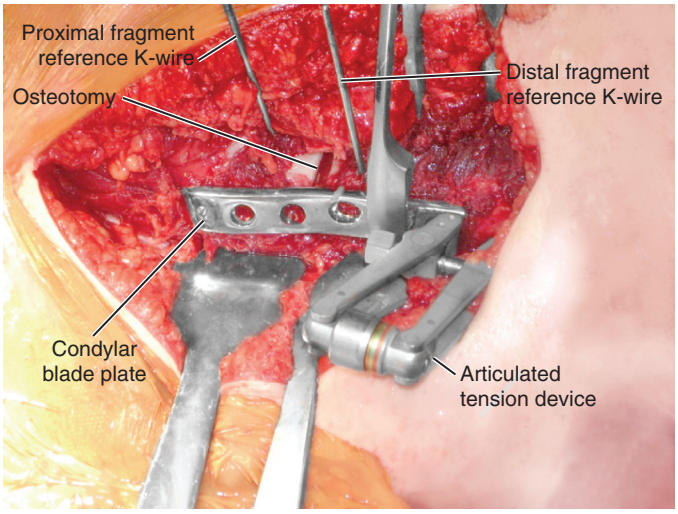

FIG 36-41 The distal fragment has been externally rotated so the rotational wires are parallel, and the gap at the osteotomy is seen between the two K-wires. The articulated tension device has been screwed onto the femur distally. Applying tension to the plate will compress the osteotomy surfaces, providing stability.

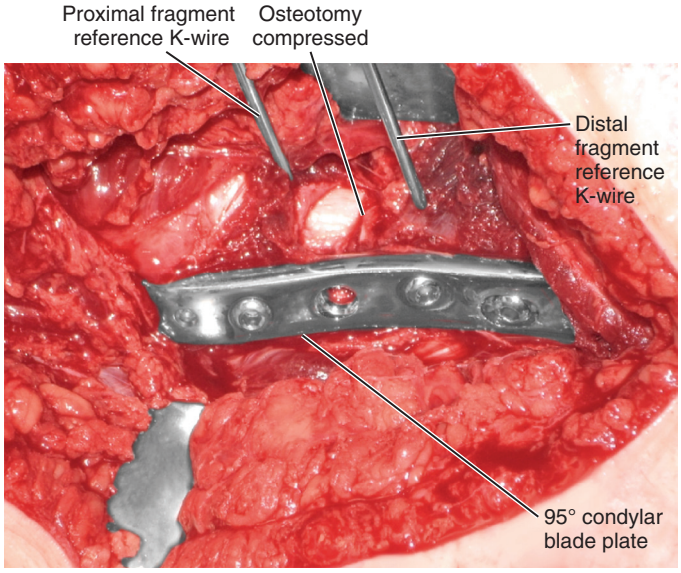

FIG 36-42 The osteotomy is compressed; the two rotational K-wires are parallel.

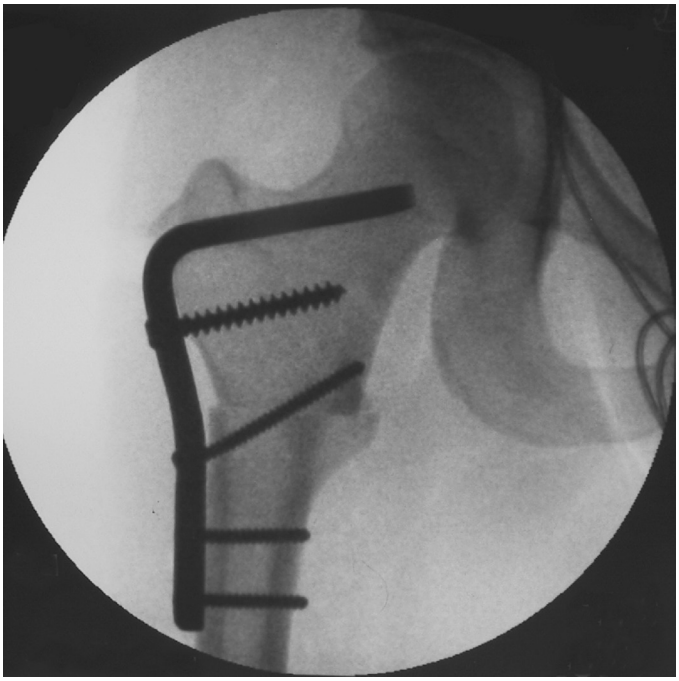

FIG 36-43 The blade has been inserted and the tensioning of the plate complete and screws inserted. The top cancellous screw is used to keep the plate from backing out of the proximal fragment as it is pulled distally with the tensioning device. The distal two screws hold the plate in tension by preventing the plate from proximal migration. The second screw from the top is both an interfragmentary lag screw and adds additional rotational support. For perfect cortical contact without the medial translation of the proximal fragment, bone under the shoulder of the plate could have been removed so it would not prevent the further advancement of the blade into the proximal fragment. The surgeon believed this would have little or no effect on the limb alignment and advised against taking down the fixation at this point.

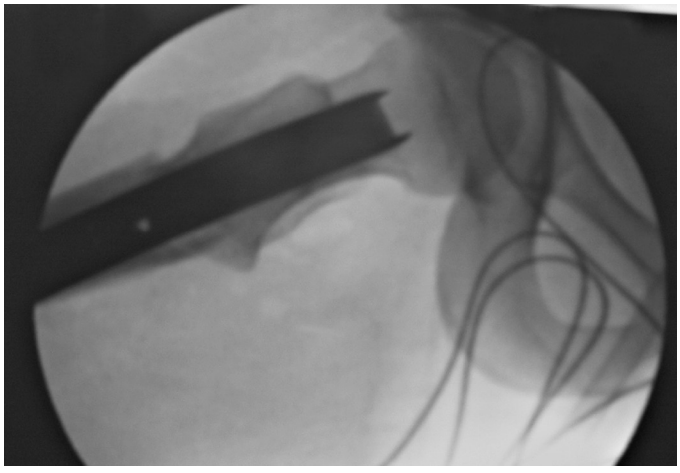

FIG 36-44 The blade is centered in the femoral neck, as seen on the frog-leg lateral view.

important biomechanical arrangement that should not be changed. It makes little difference where the osteotomy is performed because the goal is to realign the knee joint axis with the ankle joint axis in the transverse plane, leaving the trochlear-tubercle relationship normal (Fig. 36-45). I generally place the osteotomy in the proximal tibia below the tubercle and prefer to use the angled blade plate for compression; however, the geometry of the proximal tibia makes the blade insertion site a problem. With a lateral approach, the side plate will come to lie along the two flat surfaces of the proximal lateral tibia so the angle the blade takes into the proximal fragment will determine rotation. The eccentric loading of the plate with the tension device on the lateral tibia may introduce a valgus deformity that must be corrected.

The locking plate allows greater ease of rotational control but still allows a distortion of varus-valgus correction when a compression is applied to the osteotomy. Tensioning of a locked plate that is fixed in the proximal fragment may also result in the distal plate sitting well off the bone, producing an unsatisfactory prominence that can tent the anterior compartment muscle laterally or the sparse subcutaneous tissue medially. Locking plates allow easier adjustment of position, but

FIG 36-45 Excess external tibial torsion is corrected by an internal rotation osteotomy below the level of the tibial tubercle.

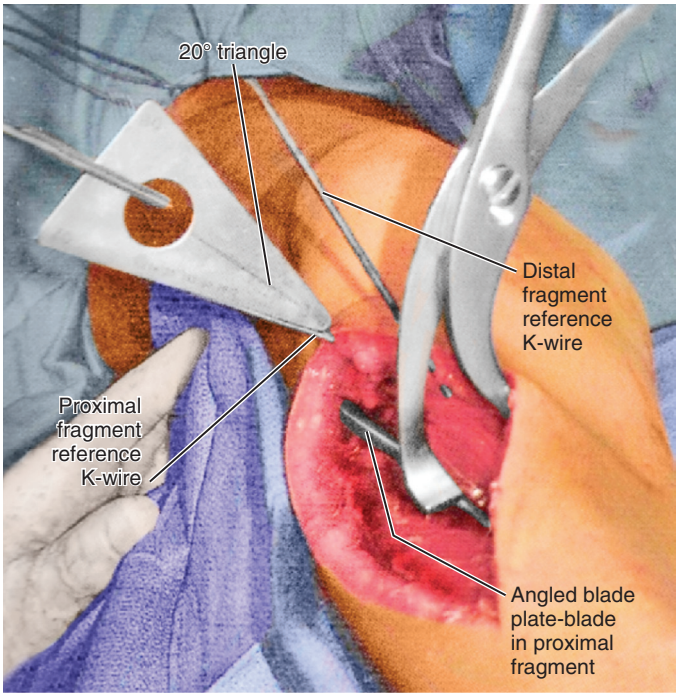

FIG 36-46 A blade of a blade plate has been inserted into the proximal tibial fragment in a direction to prevent changes in varus or valgus, flexion or extension. It is inserted 30 degrees in a posteromedial direction relative to the flat surface on the lateral tibial diaphysis. Two K-wires that were placed parallel before the osteotomy now are changed to an angle of 30 degrees with the distal wire in the distal or shaft fragment having been rotated internally 30 degrees. A clamp is holding the side plate to the lateral tibial cortex while the tension device will be applied.

are often not easily adapted for use of the tension device. This lack of high compression of the osteotomy fragments definitely results in slower union time and more postoperative discomfort than the tight compression that is possible with an angled blade plate. Two 2.5-mm K-wires are placed from anterior to posterior in the tibia, one proximal and one distal to the planned level of osteotomy. These wires may be parallel or subtend the desired angle of correction in the transverse plane. If they are parallel, then the angle between the two after manipulation of the osteotomy fragments indicates the correction angle (Fig. 36-46). If they have been placed at the desired correction angle, then the pins are brought parallel. It is important to have these as reference points before the osteotomy is made. Currently, I use a navigation system (Praxim) that indicates the changed alignment in all three planes (transverse, coronal, and sagittal; Fig. 36-47). It is impressive that small changes in all three planes are usually present, and the manipulation of the fragments to a realignment precise in all three planes is difficult to obtain and difficult to hold while fixation is applied. In my experience, the precision and confidence are greatly improved while using navigation, but the time and effort to obtain the correction is also increased. If a blade plate is used and the blade is inserted at the correct angle, the osteotomy fixation is easier to obtain but more difficult to change if an error is made. Unfortunately, there are no imageless navigation systems for use in the proximal femur.

COMPLICATIONS

As with all major surgery, complications are possible and include malunion with overcorrection, undercorrection or the addition of a varus or valgus deformity, a flexion-extension deformity, nonunion, muscle adhesions, compartment syndrome, vascular or neurological injury, painful trochanter, and painful implants. Implant removal is generally necessary. Generalized complications are the usual expected and are not listed here.

RESULTS OF TORSIONAL REALIGNMENT

Meister and James[30] reviewed seven patients who had undergone tibial rotational osteotomy for anterior knee pain at an average of 10 years previously and rated one patient excellent, five good, and one fair. Bruce and Stevens[3] reviewed 14 patients with anterior knee pain caused by miserable malalignment treated with combined external femoral rotational osteotomy and internal rotational tibial osteotomy at an average of 5 years and reported that all were satisfied. Cooke and colleagues[5] reported on seven patients with anterior knee pain associated with varus and excessive external tibial torsion treated with valgus internal rotation osteotomy in which five were rated as excellent. Delgado and coworkers[7] reported on nine patients with anterior knee pain and 13 osteotomies of the femur or tibia or both, with marked improvement seen at over 2 years. Server and associates[39] reported on 25 patients undergoing internal rotational tibial osteotomy for excessive external tibial torsion and symptoms suggesting patellar subluxation, with 23 of 25 satisfied, including some athletes. Ficat and Hungerford[10] reported one case of recurrent patellar subluxation that responded to osteotomy of both the femur and tibia.

Ruesch in 1995 (unpublished paper) reviewed a series of 35 femoral external rotational osteotomies performed for anterior knee pain and/or instability in 31 patients. Five patients were not located, but 26 (84%) were seen an average of 5.3 years postoperatively. Eighty-eight percent of the group presented with failed PF surgery, with 23 averaging more than two prior surgeries. Only three patients had not had prior surgery. Six osteotomies were diaphysis fixed with intramedullary nails, and 29 were intertrochanteric fixed with 95-degree condylar

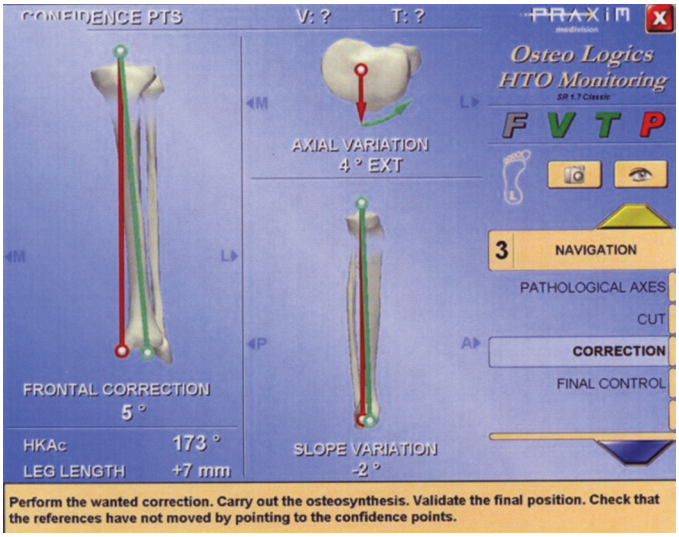

FIG 36-47 Computer screen from a navigation system that allows a direct and accurate reading of the change in position of fragments. This system uses infrared reflectors placed into the femur, the tibia above the osteotomy, and the tibia below the osteotomy. Three planes are represented with the correction in each plane. *Left,* the frontal correction, the sample shows 5 degrees of valgus has been introduced with current hip-knee-ankle line measuring 173 degrees and with an increase in leg length of 7 mm. *Upper central figure,* the horizontal plane correction, an example of 4 degrees of increased external rotation. *Lower central figure,* the sagittal plane change, an example of 2 degrees of recurvatum or extension. The *green V and T* in this program indicate which markers are being visualized by the camera and utilized by the computer. The *red P* is not being seen by the camera. *V* and *T:* are reference points on the metaphyseal and diaphyseal reflectors that are used as a test to ensure there has been no loss of position of these reflectors. (Courtesy OMNI.)

blade plates. Two PF rating scores were used. The average Schwartz and colleagues[37] score was 24.6 points (of 29 points), with 15 patients excellent, 6 good, 5 fair, and 9 poor. The average Shea and Fulkerson[40] score was 82.5 points (of 100 points), with 20 excellent, 6 good, 1 fair, and 8 poor. The poor results mostly reflected significant preexisting arthrosis that was not improved. However, subjectively, 77% indicated a decrease in the amount of pain, 86% less giving way, 80% improved quality of life, and 42% reduced retropatellar crepitation. Of the three patients without prior surgery, the Shea and Fulkerson score was 100 points, and the Schwartz score was 28.7 points.

Latteier (my series; unpublished data) reviewed 72 intertrochanteric external rotational osteotomies in 53 patients presenting with PF dysfunction. The mean follow-up was 9.7 years (range, 2 to 17 years), with a minimum of 2 years. At follow-up, mean Kujala scores had improved from 53 to 86, mean Lysholm scores had improved from 49 to 89, and mean Tegner activity scores had improved from 2.2 to 4.0.

Each patient presents with different combinations of anatomic pathology; thus outcome measures fail to reveal the complete patient profile. Pain in the absence of instability or chondral disease is the most common early presentation. The only objective measurement may be that of abnormal limb torsion. After surgery, patients have reported returning to painless cross-country running after not being able to walk to classes before correction, the loss of bunions, the loss of radiating pain down the lateral side of the limb from pelvis to lateral ankle after 40 years without relief, the loss of retropatellar crepitation on stairs, the first ability to ride a bicycle and ski without pain, and a feeling of increased stability in landing after a jump in basketball. Such observations are not part of any PF scores, and these improvements would therefore be missed. Exercise that constrains the pelvis and feet such as bicycling, classic cross-country skiing, or elliptical machines is a particular problem for these patients because there is no escape for the inward-pointing knee. Strong hip abduction is a benefit for patients with femoral anteversion because it may allow the patient to be active with a knee that points forward, thus relieving knee pain. However, because the hip abductor is working at a mechanical disadvantage, it will often fatigue, and the knee joint must point medially to gain mechanical leverage at the hip. This inward limb rotation forces an increased pronation at the foot such that medial arch strain, posterior tibial tendon strain, and bunions are more common. This chronic foot pronation may allow an increase in equinuus ankle contracture, which then accentuates the increase in internal limb rotation. Excess external tibial torsion with normal femoral torsion presents a different problem. The knee points inward because this is necessary for proper ankle dorsiflexion during gait. The medial knee pain is common because the quadriceps increases the lateral vector on the patella when the foot is pointing forward. The hip abductors, however, are working at near normal mechanical advantage, so pelvic strengthening is less likely to be useful.

CONCLUSIONS

1. Miserable malalignment as described by James[15] exists and must be recognized in the patient with PF pain, instability, or arthrosis.
2. Torsional limb malalignment may present with only pain or may coexist with patellar instability and/or patellar chondrosis, and it may be a biomechanic contributor to the etiology of both instability and arthrosis, but all three conditions must be assessed independently.
3. Restoration of normal limb alignment in all three planes is thought to restore the normal direction of the force vectors that cross the knee joint.
4. The transverse (horizontal) plane is frequently overlooked and is best evaluated with a CT scan or MRI that allows the axis of the hip, knee, and ankle to be measured relative to each other.
5. Realignment of the femur and tibia by rotational osteotomy may not only be appropriate but also necessary. It is the only reasonable surgical treatment for PF symptoms because of skeletal malalignment in the transverse plane.
6. Surgery for instability or for cartilage restoration is more likely to fail in the mechanical environment of persistent lower limb maltorsion.
7. Surgical morbidity must not be underestimated.

INDICATIONS

Patellofemoral arthroplasty (PFA) is a viable option for symptomatic patients in whom severe joint damage and loss of joint space are present in the patellofemoral (PF) compartment but not the tibiofemoral compartments. Although early reports of this procedure were disappointing, improvements in product materials, design, and robotic technology, as well as a better understanding of patient indications, have improved the expected outcome.

Indications for PFA include symptomatic secondary PF arthritis that is associated with congenital trochlear dysplasia or after joint dislocation or chronic subluxations that are unresponsive to nonoperative and operative measures.[19,22,28,30,31,54] Secondary PF osteoarthritis from trauma or fracture are other frequent indications. Although primary isolated PF osteoarthritis is an indication for PFA, it is important to note that some studies reported that patients with this diagnosis were more likely to have progression of tibiofemoral arthritis than patients with posttraumatic arthritis or dysplasia.[5]

Patient candidates typically have severe anterior knee pain, swelling, and stiffness that limits daily activities. A lengthy course of nonoperative treatment that includes nonsteroidal antiinflammatory medication, steroid injections, physical therapy, and weight control fails to alleviate the anterior patellar pain. In our opinion, the patient should be younger than 60 years, although consideration may be made for those older than 60 years, if no contraindications exist, and the tibiofemoral compartments are not arthritic or symptomatic.

Many patient candidates for PFA will have undergone multiple prior failed surgical procedures such as lateral release, arthroscopic

CRITICAL POINTS Indications

- Symptomatic patients who have severe joint damage and loss of joint space in the PF compartment but not in the tibiofemoral compartments
- Symptomatic secondary PF arthritis associated with congenital trochlear dysplasia or PF arthritis after joint dislocation or chronic subluxations
- Secondary PF osteoarthritis from trauma or fracture
- Failed lengthy course of nonoperative treatment measures

debridement and chondroplasty, extensor mechanism realignment, medial patellofemoral ligament (MPFL) reconstruction, or an articular cartilage procedure such as autologous chondrocyte implantation (ACI) or osteochondral autograft transfer. In our prospective study, 76% of patients who underwent PFA had undergone these types of prior PF procedures that subsequently failed. It is important that the patient has realistic expectations regarding what this operation may and may not accomplish. At our center, most patients are able to walk without support within approximately 2 to 3 weeks postoperatively, and the majority return to daily activities within 4 to 6 weeks. Light, low-impact activities such as walking, swimming, golfing, light hiking, and bicycling can often be performed by 3 months. However, running and high-impact athletics or occupational activities are not advised and, in fact, should be avoided; it is essential that the patient understands and accepts these limitations of the procedure. High flexion-repetitive activities may induce a mild effusion because the patella polyethylene replacement articulates with the tibiofemoral articular cartilage.

CONTRAINDICATIONS

The principal contraindication to PFA is tibiofemoral joint arthritis (articular cartilage deterioration and/or joint space narrowing on standing posteroanterior [PA] radiographs) owing to the evidence that this is the leading cause of failure requiring total knee arthroplasty (TKA). In addition, uncorrected excessive varus or valgus malalignment (greater than 3 degrees), uncorrected PF malalignment, knee ligament instability, inflammatory arthritis, and prior or active infection are contraindications. Patients with patella alta may require distalization of the tibial tubercle. Patients with complex regional pain syndrome, diabetes, knee arthrofibrosis (excessive extension or flexion contracture), chondrocalcinosis, or rheumatoid arthritis are not considered candidates. Patients older than 60 years of age or those who are obese (body mass index [BMI] >31) are also usually not candidates for PFA. Osteopenia (bone mineral density T score between −1.0 and −2.5 standard deviations below normal) and osteoporosis (T score less than −2.5) are contraindications for this operation. Other contraindications include failure to treat the patient with all conservative measures, a history of meniscectomy that is associated with tibiofemoral compartment joint damage or narrowing, noncompliance with rehabilitation, and unrealistic expectations for future activity levels. Magnetic resonance imaging (MRI) is frequently obtained to rule out associated tibiofemoral compartment osteoarthritis that would decrease the success rate. It is realized in younger patients that PFA is a temporary procedure to buy time before TKA, which can later be successfully performed. Younger patients who undergo corrective tibial or femoral osteotomy for varus or valgus malalignment could then be future PFA candidates.

CRITICAL POINTS Contraindications

- Tibiofemoral joint arthritis
- Uncorrected varus or valgus malalignment >3 degrees
- Uncorrected patellofemoral malalignment
- Uncorrected knee ligament deficiency
- Inflammatory arthritis, rheumatoid arthritis
- Complex regional pain syndrome, knee arthrofibrosis, chondrocalcinosis
- Age ≥60 years
- Body mass index >31
- Osteopenia or osteoporosis

IMPLANT DESIGN

There are two main types of PFA implants based on the trochlear preparation method.[30] So-called *first-generation* implants replace worn cartilage without altering the shape of the subchondral bone (Table 37-1). The trochlear implants are placed using an inlay or onlay technique, and their positioning is dependent on the patient's trochlear anatomy. These designs generally have a narrow, excessively deep trochlear component that is too constraining and causes many problems related to patellar catching, poor tracking, and continued anterior knee pain.[7,10,34,46,49,53]

Second-generation PFA implants replace the trochlea based on the femoral trochlear groove of TKA implants.* The shape of the trochlear groove varies greatly between models; from deep, highly constrained models to open, unconstrained models. The patellar component may be shaped as a dome, have facets, or be asymmetrical in design.

The term *third-generation* describes PFA systems that are implanted using 3-dimensional models of the patient's anatomy obtained from computed tomography (CT) scans in which either a custom prosthesis is created (KineMatch PatelloFemoral Replacement[43-45]; Custom Performa Knee Patellofemoral Arthroplast, Biomet Orthopedics[8]) or robotic technology (our preferred technique) is used for implant sizing and orientation and bone resection (MAKOplasty Partial Knee Resurfacing, Stryker Orthopaedics).

CLINICAL EXAMINATION

A thorough history is required including documentation of prior surgical procedures and conservative treatment measures, patellar dislocation or subluxation episodes, and other knee joint injuries. Symptoms typically occur in the anterior or retropatellar regions and are worsened with stair climbing, walking on uneven ground, kneeling, squatting, and prolonged sitting.

The comprehensive physical examination includes a complete PF examination, discussed in detail in Chapter 35, to assess patellar tilt, subluxation, mobility, Q-angle, and lower limb rotational alignment (femoral internal torsion, tibial external torsion). The integrity of the MPFL and medial soft tissue stabilizers is assessed by the amount of lateral patellar displacement (glide), which normally is 1 quadrant of patellar width (at 0 and 20 degrees of flexion). The presence of an active lateral patellar subluxation with knee extension (J sign) indicates deficient medial stabilizers and, often, patella alta. A lack of normal medial translation (<10 mm, 20 degrees of flexion) indicates excessive tightness of the lateral retinacular tissues and often an excessive lateral patellar compression syndrome, requiring Z-plasty lengthening and soft tissue balancing at surgery (to be discussed). The patella and all surrounding tissues are palpated to localize pain. The medial and lateral joint lines are also inspected for any tenderness, indicative of tibiofemoral joint involvement that may contraindicate PFA.

All knee ligament tests are conducted as described in Chapters 7 and 17.

The patient's gait, range of knee motion, lower extremity and hip muscle strength, and neurovascular status are evaluated.

Radiographs taken during the initial examination include standing anteroposterior (AP) at 0 degrees, lateral at 30 degrees of knee flexion, weight-bearing PA at 45 degrees of knee flexion, and PF axial views. A true lateral radiograph in which the distal and posterior

CT, Computed tomography; *PFA*, patellofemoral arthroplasty.

aspects of the femoral condyles are perfectly superimposed should be obtained to evaluate trochlear depth. Measurements of patellar height and patellar trochlear contact are made on lateral radiographs (Fig. 37-1). Double-stance full-standing radiographs of both lower extremities, from the femoral heads to the ankle joints, are obtained in knees in which varus or valgus lower extremity alignment is detected on clinical examination. MRI is required to determine the cartilage status of the entire knee joint, along with all other soft tissue structures.

PREOPERATIVE PLANNING

The PFA operative technique described in this chapter that the senior author (F.R.N.) has used since 2008 uses a cemented implant (RESTORIS MCK [Multicompartmental Knee] PF implant system, Stryker Orthopaedics) that is positioned using 3-dimensional modeling and computer-assisted robotic surgical navigation (Robotic Arm Interactive Orthopedic System [RIO], Stryker Orthopaedics). Before surgery, customized CT scans (CT Scanning Protocol Knee Arthroplasty PN 200004) are obtained with the patient lying supine with a motion rod attached to the operative leg. The CT scans are saved in DICOM 3 format and transferred to software that processes the hip, knee, and ankle data to create 3-dimensional bone models of the femur and tibia. Calculations made for implant sizing, orientation, and alignment are based on the patient's bone anatomy. Fine tuning of the component position and orientation based on patient-specific anatomy and cartilage thickness is completed intraoperatively. The primary preoperative planning steps for the trochlear implant are summarized in Figure 37-2 (see MAKOplasty Partial Knee Application User Guide 206388 Rev 01 and Surgical Technique and Planning Guide #201844, Stryker). The recommended positioning limits are:

1. Trochlear internal/external rotation: 4 degrees internal to 0 degree (ideal, 0 degree rotation), which is considered acceptable for the implant to be recessed into an abnormal prominent lateral trochlea to avoid internal rotation of the implant. Every degree of internal rotation medializes the trochlear groove approximately 0.5 mm and raises the patellar jump height approximately 0.3 mm. External rotation of the trochlear component is not recommended because it will decrease the lateral patellar jump height and increase the risk of lateral patellar subluxation.
2. The largest size trochlear implant is selected that will not overhang. There should be 0 to 2 mm of inset from the medial and lateral ridges and there should be no interference with the anterior cruciate ligament (ACL).
3. Alignment is set between 3 degrees varus and 2 degrees valgus (ideal, 0 to 2 degrees varus). Every degree of varus/valgus rotation translates the trochlear groove entrance by approximately 0.6 mm. The trochlear component should not be placed in more than 2 degrees of valgus because this will align the trochlear groove away from the anatomic axis of the femur and increase the risk of lateral patellar subluxation. The PF component trochlear groove pathway is curved proximally 6 degrees to align with the anatomic axis when the implant is planned at 0 degrees of varus-valgus.

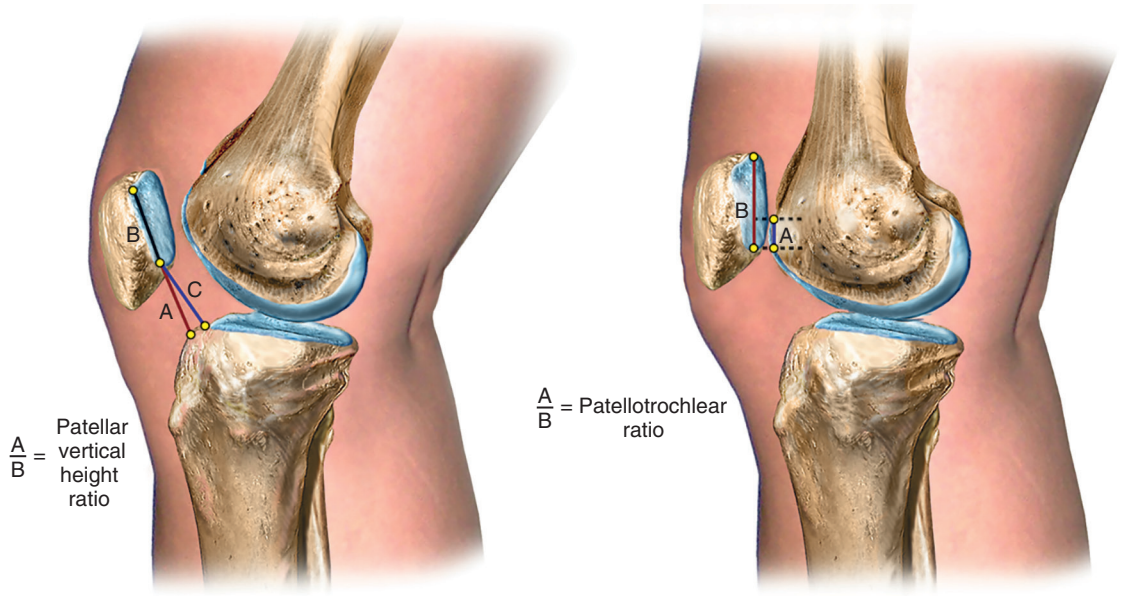

FIG 37-1 **Left,** Method used to determine patellar vertical height ratio on lateral radiograph with a quadriceps contraction to show the maximum elevated position of the patella. The numerator, *line segment A*, is the distance between the most ventral (anterosuperior) rim of the tibial plateau and the lowest end of the patellar articular surface. The denominator, *line segment B*, is the maximum length of the patellar articular surface. An alternative numerator, *line segment C*, locates the tibial reference point on the middle of the tibial plateau. The patellar vertical-height ratio equals A/B or C/B. **Right,** Alternative patellotrochlear ratio measurement. The mean ratio is 32 ± 12%; >50% indicates patella infera; <12% indicates patella alta.

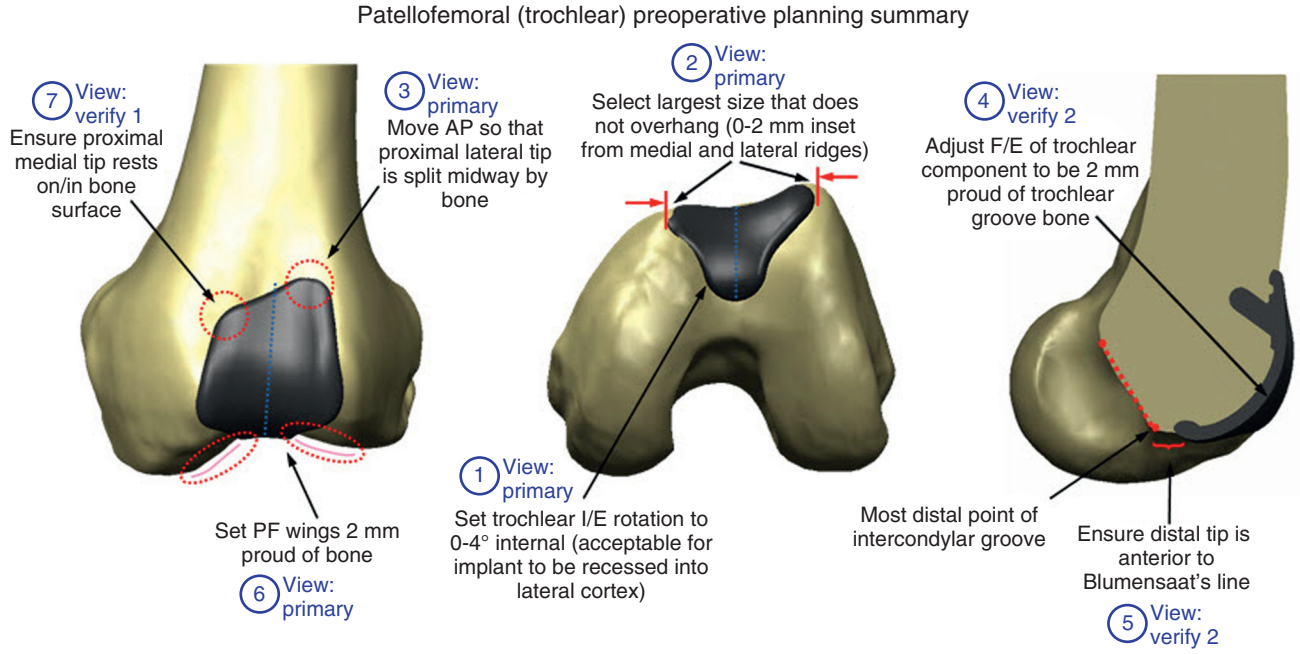

FIG 37-2 The preoperative planning steps for the precise location of the trochlear implant. *AP*, Anteroposterior; *F/E*, finite-element; *I/E*, internal/external; *PF*, patellofemoral.

4. The flexion-extension of the trochlear component is adjusted to be approximately 2 mm proud of the trochlear groove bone. This should be set between 5 degrees of flexion and 5 degrees of extension. Verification should be made that the distal tongue does not violate the intercondylar notch and cause ACL impingement. The PF distal tip should be anterior to Blumensaat's line.

SURGICAL TECHNIQUE

The reader is referred to the MAKOplasty Partial Knee Application User Guide 206388 Rev 01 and Surgical Technique and Planning Guide #201844, Stryker Orthopaedics, for the Robotic RIO PFA, which are summarized in this chapter.

The surgical positioning of the lower limb, along with the robotic arm instrumentation, is shown in Figure 37-3. A femoral array has been placed 8 cm above the patella. The surgeon views the operative resection of the trochlea on the screen (not shown). The leg is positioned in a leg holder that allows easy adjustment of knee flexion and controls rotation. There are multiple steps required in the registration of the lower limb and trochlear anatomy of the patient that are summarized in the user and planning guides.

Incision

With the knee flexed to 30 degrees, an anteromedial skin incision is made adjacent to the medial border of the patella, extending from the superior border of the patella to the top of the tibial plateau. The incision is extended proximally or distally as required for adequate visualization. The subcutaneous tissues are undermined and retractors placed to expose the medial retinaculum. An incision in the quadriceps tendon 3 cm above the patella (senior author's choice) or a medial subvastus or midvastus arthrotomy is created through the medial retinaculum, capsule, and synovium. The length of the incision and arthrotomy must be sufficient enough to enable patellar retraction for insertion of the trochlear implant and femoral registration. All compartments and cruciate ligaments are inspected to confirm the indications for PFA. The fat pad is partially removed as required and any synovium above the trochlea for exposure. The patella is reflected laterally to expose the PF joint space.

FIG 37-3 The operative positioning of the lower limb, along with the Robotic Arm Interactive Orthopedic System (Stryker Orthopaedics).

Registration

The techniques for registration are followed as specified in the surgical technical guide. Patient landmarks are collected and registered to verify femoral and tibial checkpoints. Bone registration is performed, but osteophytes are not removed. The cartilage in the trochlear groove and distal femur is mapped to ensure smooth transition from the implant to the femoral condyles and femoral component. The RIO is placed in the operative field and registration and verification performed of the position of the robotic arm and cutting tool tip.

Implantation of Trochlear Component

The intraoperative real-time fine tuning steps of the component position and orientation are summarized in Figure 37-4. Before bone resection, an assessment of ligament tension and visualization of implant articulation throughout the range of knee motion are performed. RIO provides tactile feedback and 3-dimensional visualization to facilitate the planned bone resection. Real-time virtual visualization is used during bone resection to confirm proper implant alignment and positioning. The surgeon controls the robotic arm, removing a precise amount of trochlea cartilage and bone based on the preoperative planning.

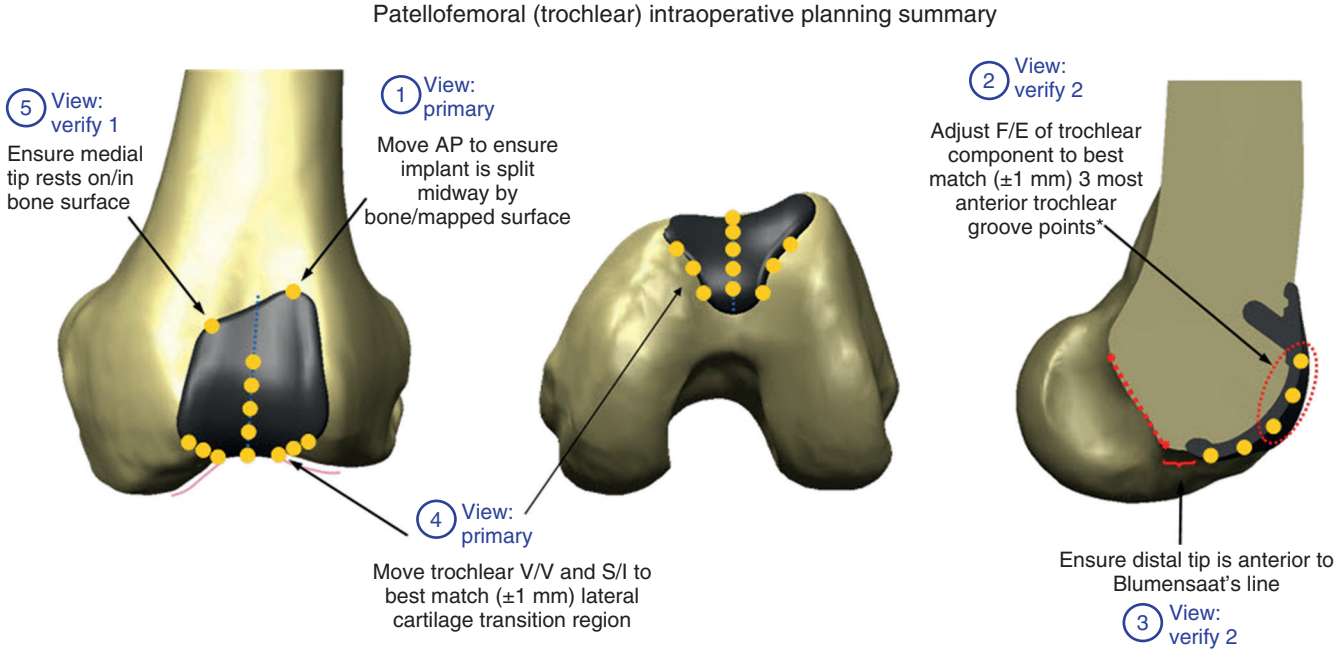

FIG 37-4 The intraoperative planning steps for the precise placement of the trochlear implant. *If the mapped points like on arthritic bone and not cartilage, adjust finite-element to be approximately 2 mm proud of bone surface.

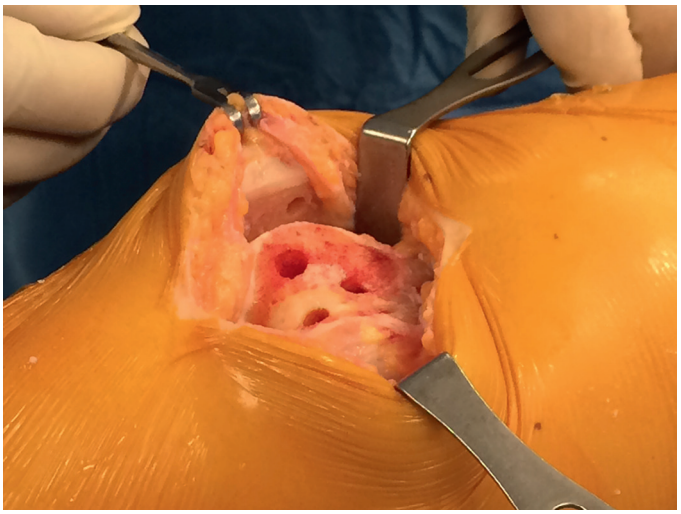

FIG 37-5 The resected bone for the trochlear and patellar components.

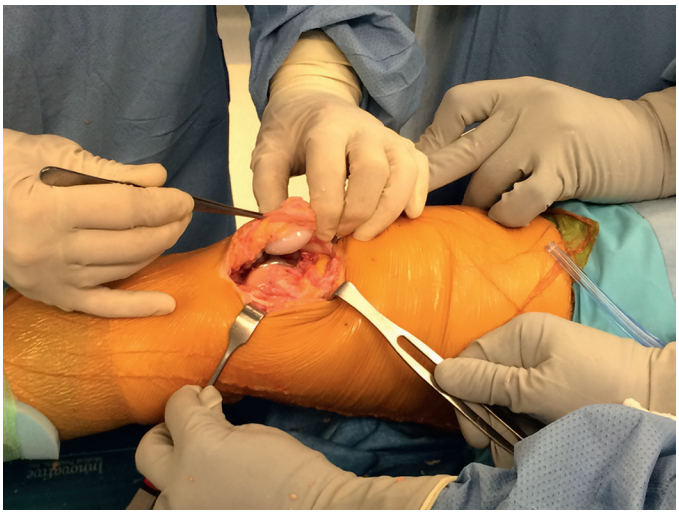

FIG 37-6 The final position and alignment of the patellofemoral implants, just before soft tissue balancing of the medial retinacular tissues and medial patellofemoral ligament.

As previously described, ensure that the trochlear implant is not in external rotation or valgus to decrease the risk of lateral patellar subluxation. The MAKO recommendations for the trochlear implant is 0 degree external rotation, 0 to 2 degrees varus, and 0 to 5 degrees of flexion. The proximal edge of the trochlear component is flush with the bone. It is important to map the articular cartilage-trochlear outline to verify the computer selected placement of the prosthesis. With the initial use of the burr, the depth is carefully observed again as a check on the selected trochlear positioning. The intraoperative placement of the patella and trochlear components are shown in Figure 37-5.

The implantation of the trochlear component begins with the insertion of the selected trochlear implant trial, which is impacted. Any proud cartilage and bone is resected with a rongeur and smooth patellar transitioning is confirmed. The trial implant is removed and fatty deposits from cancellous porous structures are removed.

Patellar Resection and Component Placement

The patella is measured with the leg in full extension with calipers that have a ±0.5 mm degree of accuracy. The patellar size is estimated by measuring the superior-inferior height of the patellar articular surface. The proper resection thickness is calculated based on patellar size and facet arthrosis. A saw guide is used to resect the articular surface of the patella, maintaining a residual patellar height of 14 to 15 mm.

With the knee in full extension, the patella sizing/drill guides are used to select the appropriate size patellar implant of 26, 29, 32, 35, 38, or 41 mm in diameter. There should be no overhang of the bone superiorly or inferiorly. The patella sizing drill guide should be aligned with the former patellar ridge (i.e., medialized on the patellar bone) to lateralize the remaining patellar bone. Caution is warranted in that centering the patella sizing drill guide will medialize the remaining patellar bone, which can overtighten the lateral soft tissue restraints. Three peg holes are drilled. A trial patellar implant is placed onto the resected patella and calipers are used to measure the patellar thickness. If the overall thickness is greater than the original patellar bone, additional bone may be shaved to avoid overstuffing the PF joint. The knee should be taken through a range of motion to ensure proper patellar tracking and transitioning.

Final Cement Technique

Cement is applied to the trochlear implant, ensuring that cement fully covers the back side of the implant, including the distal "tongue." Cement is applied to the resected cavity and firmly packed into the bone. The trochlear implant is placed onto the femur and impacted. The surgeon confirms that the implant is fully seated and carefully removes any excess extruded cement.

Cement is applied to the resected patellar surface, drilled peg holes, and implant and the patellar component is placed onto the resurfaced patella. Adequate clamping force is used to ensure the patellar implant is fully seated onto the patellar bone. Excess cement is removed as required. Once the cement has dried, patellar central tracking and range of motion are again checked before wound closure (Fig. 37-6). Checkpoints, bone pins, and arrays are removed and the extensor mechanism is closed as described later.

SURGICAL DECISION MAKING FOR SPECIAL PROBLEMS

Correction of Trochlear Dysplasia

Dejour and colleagues[15] described a qualitative classification system of four types of trochlear dysplasia: type A, trochlear morphology preserved with a fairly shallow trochlea; type B, flat or convex trochlea; type C, asymmetry of trochlear facets with convex lateral facet and hypoplastic medial facet; and type D, asymmetry of trochlear facets and cliff pattern. Many years later, Nelitz and coworkers[37] evaluated MRI criteria of 80 knees with symptomatic PF instability to determine whether specific measurements of the femoral trochlea could be assigned to Dejour's classification system. Given the marked variation in trochlear morphology, none of the quantitative MRI measurements could be assigned to this system. A similar conclusion was reached in a study by Lippacher and associates[26] who also noted that lateral radiographs underestimated the severity of trochlear dysplasia compared with axial MRI.

Nelitz and coworkers[37] reported median values of eight trochlear indices that distinguished Dejour type A (low-grade dysplasia) from the higher-grade dysplasia categories (B-D) and, based on their findings, recommended that a two-grade system be used instead of a four-grade system. The cut-off values between low- and high-grade dysplasia

CRITICAL POINTS Surgical Decision Making for Special Problems

- There is a high frequently of trochlear dysplasia that is corrected to a normal anatomic profile involving depth, sulcus angle, and proximal-distal and rotational alignment of the implant. Abnormal trochlear morphology frequently involves excessive lateral trochlear height, absent central groove, and medial trochlear hypoplasia. The potential problem of an onlay prosthetic design involves elevation of the trochlea and excessive soft tissue tensions that require added releases.
- Abnormal lateral position of the tibial tubercle, with increased TT-TG values, should be diagnosed preoperatively. In most cases, the TT-TG alignment is corrected by reestablishing a normal trochlear groove with prosthesis placement. Marked increased TT-TG values require correction with tibial tubercle medialization.
- Prior lateral dislocations resulting in attenuated and insufficient medial soft tissue restraints requires concurrent MPFL reconstruction to provide medial stability. A partial quadriceps tendon graft turndown that avoids patellar tunnels is recommended. For primary and secondary osteoarthritis, correcting trochlear morphology along with soft tissue balancing of existing medial structures provides stability.
- Avoid overtightening MPFL and medial retinacular tissues in soft tissue balancing by always allowing for a normal 1 quadrant lateral glide at 20 and 0 degrees of knee flexion.
- Lateral retinacular release indications are absence of a normal passive medial glide, patellar tilting, and failure to track centrally with knee flexion. Lateral soft tissue balancing is performed using Z-plasty lengthening and closure to restore normal lateral tension. Normal patellar tracking is always tested and restored at surgery.
- Infrapatellar contracture with abnormal scarred tissues and fat pad scar is frequent and should be removed at surgery.
- Patella alta is measured and, in most cases, distal transfer of the tibial tubercle is not required because the patella articulates with the lengthened proximal extent of the trochlear prosthesis. Distal tibial tubercle displacement is reserved for markedly abnormal patella alta conditions, with complete lack of patellar dome and trochlear contact at the beginning of knee flexion.

were 2 mm for depth of the trochlear groove, 48% for trochlear facet asymmetry, and 11 degrees for lateral trochlear inclination.

In the senior author's experience, there is a high frequency of abnormal trochlear morphology at the time of PFA that is corrected by the trochlear implant. The most common abnormality is excessive height of the lateral trochlea that is corrected at surgery. The mistake is to not correct this abnormal height because it would allow excessive internal rotation of the trochlear implant. In these cases, there is frequently hypoplasia of the medial trochlea. A complete reshaping of the dysplastic trochlea is performed to restore the normal trochlear depth and position that is based on the selected design of the trochlear prosthesis. It is necessary to cut into the abnormal lateral trochlear groove, maintain the center of the trochlear groove, and avoid medialization of the groove. The MAKO robotic technique has the distinct advantage in that the trochlear reshaping is performed using 3-dimensional computer adjustments, which is then transferred to the patient. The trochlea is shaped to afford a retained lateral buttress for patellar stability as previously described. The prosthesis has only a moderate trochlear depth, thereby avoiding other patellar implant designs that have an accentuated trochlea containment. There are specific recommendations for implant planning and intraoperative placement that the reader is referred to in the operative guide. Some custom onlay trochlea designs do not correct abnormal trochlear morphology and potentially produce overstuffing of the PF joint. Note is made that lateral release procedures and other soft tissue balancing procedures are commonly necessary as previously described.

Correction of Increased Tibial Tubercle-Trochlear Groove Distance

The preoperative examination already discussed involves measurement of PF-tibial tubercle alignment by Q-angle, CT, and, when abnormal, rotational MRI (see Chapter 35). In instances of trochlear dysplasia, an abnormal tibial TT-TG offset is frequently correctable at surgery by reestablishing a more normal lateral trochlear position in the placement of the trochlear prosthesis. Any excessive medial placement of the trochlear prosthesis will increase the TT-TG distance. There are select cases in which a highly abnormal TT-TG ratio requires a concurrent tibial tubercle medialization owing to persistent lateral tracking demonstrated at surgery. No specific rules have been established regarding TT-TG limits that require correction, and judgment at surgery is therefore required. For tibial tubercle medialization, the findings are usually a TT-TG ratio of 20 mm or greater and an obvious Q-angle of 20 degrees or greater that can be increased to 35 to 40 degrees with external tibial rotation (physiologic posterolateral laxity allows excessive tibial rotation). The goal of surgery in cases of extensor mechanism malalignment is to correct abnormal alignment and instability with added soft tissue balancing to ensure a successful long-term result.

Valgus-Aligned Lower Extremity with Excessive Body Mass Index

Of concern is the patient with an abnormal valgus malalignment of the lower extremity and an abnormal TT-TG ratio. There exists in these cases high lateral PF pressures of the patella dome and trochlear prosthesis. The problem is further compounded by the occurrence, in most of these patients, of excessive BMI. This represents a contraindication to PFA, and the patient is advised to obtain nutritional counseling and demonstrate weight loss to normal indices before PFA is considered. The patient is expected to do his or her part to decrease PF loading. These patients also have the potential for early lateral tibiofemoral compartment arthrosis and future necessity to perform a TKA. It is recognized that lack of patient compliance with weight loss may frequently occur, and therefore this patient profile usually represents a contraindication to PFA.

In select younger patients in whom a corrective femoral osteotomy has been performed, the goal of the PFA is to buy time before TKA. There should still exist greater than 50% lateral joint space on 45 degrees weight-bearing radiographs to warrant the PFA. A similar recommendation applies to varus-aligned knees already discussed. A prior meniscectomy to the affected compartment further amplifies the contraindication to PFA in these knees.

Prior Lateral Dislocations, Insufficient Medial Patellofemoral Ligament

The diagnosis of an insufficient MPFL and medial retinaculum structures, with preoperative symptomatic PF instability, should be established by both the history and physical examination of increased lateral patellar translation of 75% or greater patellar width at 0 and 20 degrees of knee flexion. At surgery, it is important to determine the integrity of the remaining MPFL and medial retinacular restraints. Although many MPFL reconstructions have been published, it is important to avoid any MPFL fixation tunnels into the patella. The senior author has described a quadriceps tendon turndown procedure to reconstruct the MPFL and adjust the tension in the remaining

medial retinaculum structures (see Chapter 35).[39] This procedure involves suture fixation without patellar or femoral tunnels. It should be noted that in most cases of prior PF dislocation, there are adequate medial soft tissues and a simpler pants-over-vest plication procedure of the MPFL and medial retinaculum restores medial stability. In addition, correction of trochlear dysplasia adds to extensor mechanism stability.

Excessive Medial Soft Tissue Tightening (Medial Patellofemoral Ligament and Medial Retinaculum)

The condition of excessive tightness of the MPFL and medial retinaculum suture closure at surgery must be closely monitored because this represents one of the most common factors that produces medial pain and limitation of knee flexion postoperatively. With the limited medial parapatellar incision that extends 2 cm above the patella, it is not necessary in most knees to excessively tighten or reef at the time of suture closure. Three nonabsorbable sutures are placed in the VMO, MPFL, and MPML structures and tensioned to restore normal medial stability that allows for a 1 quadrant or normal 10-mm lateral glide at 0 and 20 degrees of knee flexion. With the knee flexed to 120 degrees, there should be no disruption of the sutures. This technique ensures that a medial overpressure syndrome is not produced that will limit knee flexion and produce medial pain. Specific details of the MPFL and medial retinaculum tensioning are discussed in Chapter 35. The importance of performing patellar mobilization postoperatively to maintain normal patellar glide is discussed later.

Lateral Retinacular Release

The tension in the lateral retinacular structures is determined at the time of the PFA, with verification that there is normal tracking without tilting of the patellar prosthesis throughout knee flexion. The amount of medial patellar translation on the glide test performed at 20 degrees of knee flexion determines the amount of resting tension, and it should be possible to translate the patella at least 10 mm in the medial direction. When present, contracted lateral retinacular tissues resist medial patellar translation, and obvious tilting of the patella is observed with knee flexion. When necessary, the senior author prefers to perform a Z-plasty lengthening of the lateral retinaculum, termed a mini-release. In more contracted lateral soft tissue conditions, the vastus lateralis tendon requires a Z-plasty lengthening. These conditions represent an excessive lateral patellar compression syndrome, with complete absence of a normal medial patellar glide. The diagnosis should be made by performing these tests before surgery. All of the lengthened structures are closed under normal tension with sutures and soft tissue balancing to affect joint closure and prevent a medial patellar subluxation syndrome that has been recognized after excessive lateral release procedures.

Infrapatellar Contracture

The presence of an infrapatellar contracture should always be identified at surgery (Fig. 37-7). This represents a plate of scar tissue often 5 mm thick that extends from the inferior patellar pole to the anterior aspect of the tibia, just posterior to the patellar tendon. This band will limit normal patellar mobility and requires resection. The finding of a prominent fat pad with excessive lobule formation that may impinge postoperatively requires subtotal fat pad resection. A thickened medial plica is also resected when present. Recurrent PF disease of any type (frequently along with prior surgical procedures) usually results in abnormal and scarred infrapatellar tissues requiring attention at surgery. Care is taken at tourniquet deflation to be meticulous in electrocoagulation of fat pad bleeding and other soft tissue bleeding points.

FIG 37-7 Coronal T1 magnetic resonance imaging of infrapatellar scar contracture, which extends from the inferior pole of the patella, posterior to the fat pad, onto the anterior ventral tibial surface. These contractures, commonly found in multiple-operated knees, limit patellar mobility and require surgical excision at the time of patellofemoral arthroplasty.

Patella Alta

The presence of a patella alta requires diagnosis preoperatively and measurement of the patella height indices illustrated and discussed in detail along with the operative technique in Chapter 35. It is rare to have to perform a distal displacement of the tibial tubercle because the trochlear groove of the implant extends farther proximal than the native trochlea. This allows the patella to be guided into the trochlea and corrects the lateral extension subluxation (J-sign) that is present preoperatively, along with medial soft tissue balancing. There are rare instances in which the patella alta is so highly abnormal (>1.6 Linclau ratio) that the patellar dome does not engage into the prosthetic trochlea at 0 to 20 degrees of knee flexion. This will be obvious at surgery and requires distal displacement of the tibial tubercle. In these cases, it is necessary to restore a normal tension to the MPFL and medial retinaculum, and in some instances, determine that excessive tightness is not present in the lateral retinaculum. The test is to place the knee at 20 degrees of flexion and perform medial and lateral patellar displacement (glide) to determine the resting tension of these structures. The test is also repeated at 0 degrees of knee extension to ensure the medial structures have a normal resting tension that allows the patella to guide into the trochlear groove.

POSTOPERATIVE MANAGEMENT

The postoperative rehabilitation protocol is shown in Table 37-2. Patients begin immediate range of knee motion (ROM), patellar

PHASE 1: WEEKS 1-2

General Observation

Full weight bearing with crutches/walker when:
- Pain controlled
- Hemarthrosis controlled
- Voluntary quadriceps contraction achieved

Factors Evaluated (Goal)

Pain (controlled)
Hemarthrosis (mild)
Patellar mobility (good)
ROM (0-110 degrees)
Quadriceps contraction and patellar migration (good)
Soft tissue contracture (none)

Activity	Frequency	Duration
ROM		
ROM (0-110 degrees), hang 10-20 lb of weight if <0 degrees	6 ×/day, 10 min	
Patellar mobilization		
Ankle pumps (plantar flexion with resistance band)		
Hamstring, gastrocnemius-soleus stretches		5 reps × 30 sec
Strengthening	3 ×/day, 15 min	
Straight-leg raises (flexion, extension, abduction, adduction)		3 sets × 10 reps
Active quadriceps isometrics		10 reps
Knee extension quadriceps, active/active-assisted (range as tolerated)		3 sets × 10 reps
Multihip machine (flexion, extension, abduction, adduction)		3 sets × 10 reps

TABLE 37-2 Noyes Knee Institute Rehabilitation for Patellofemoral Arthroplasty—cont'd

PHASE 1: WEEKS 1-2

Activity	Frequency	Duration
Balance Training	3 ×/day, 5 min	
Weight shift side-side and forward-backward		5 sets × 10 reps
Balance board/two legged		
Cup walking		
Single-leg stance		
Aerobic Conditioning	2 ×/day, 10 min	
UBC		
Modalities	As required	
EMS		20 min
Cryotherapy		20 min
Goals	• ROM 0-110 degrees • Adequate quadriceps contraction • Control inflammation and effusion	

PHASE 2: WEEKS 3-4

General Observation	Full weight bearing without assistive devices when gait pattern normal and: • Pain controlled • Hemarthrosis controlled • Voluntary quadriceps contraction, full extension achieved
Factors Evaluated (Goal)	Pain (controlled) Effusion (mild) Patellar mobility (good) ROM, minimum (0-135 degrees) Quadriceps contraction and patellar migration (good) Soft tissue contracture (none)

Activity	Frequency	Duration
ROM	3 ×/day, 15 min	
Passive, 0-135 degrees, hang 10-20 lb weight if <0 degrees; flexion overpressure: stool rolls, wall-slides if <90 degrees		
Patellar mobilization		
Ankle pumps (plantar flexion with resistance band)		
Hamstring, gastrocnemius-soleus stretches		5 reps × 30 sec
Strengthening	2-3 ×/day, 20 min	
Straight-leg raises (flexion, extension, abduction, adduction)		3 sets × 10 reps
Isometric training: multiangle (0, 60 degrees)		1 sets × 10 reps
Knee extension quadriceps (resistance, 90-30 degrees)		3 sets × 10 reps
Closed-chain: wall-sits (0-45 degrees)		30-60 sec ×5
Knee flexion hamstring curls (0-90 degrees)		3 sets × 10 reps
Multihip machine (flexion, extension, abduction, adduction)		3 sets × 10 reps
Leg press (70-10 degrees)		3 sets × 10 reps
Balance Training	3 ×/day, 5 min	
Weight shift side-side and forward-backward		5 sets × 10 reps
Balance board/two legged		5 reps
Cup walking		
Single-leg stance

PHASE 2: WEEKS 3-4

Activity	Frequency	Duration
Aerobic Conditioning	2 ×/day, 10 min	
UBC		
Stationary bicycling (high seat, low resistance)		
Modalities	As required	
EMS		20 min
Cryotherapy		20 min
Goals	• Muscle control • ROM 0-135 degrees • Control inflammation and effusion	

PHASE 3: WEEKS 5-6

General Observation	• Independent ambulation • Pain controlled without narcotics • Hemarthrosis controlled • ROM 0-135 degrees • Muscle control throughout ROM
Factors Evaluated (Goal)	Pain (mild/no CRPS) Effusion (minimal) Patellar mobility (good) ROM (0-135 degrees) Muscle control (3+/5) Inflammatory response (none)

Activity	Frequency	Duration
ROM	3 ×/day, 10 min	
Passive, 0-135 degrees; continue overpressure program if <0-100 degrees		6 ×/day
Patellar mobilization		
Hamstring, gastrocnemius-soleus stretches		5 reps × 30 sec
Strengthening	2 ×/day, 20 min	
Straight-leg raises (ankle weight 2.5-10 lb)		3 sets × 10 reps
Heel raise/toe raise		3 sets × 20 reps
Knee extension (resistance, 90-30 degrees)		3 sets × 10 reps
Knee flexion (active, 0-90 degrees)		3 sets × 10 reps
Leg press (70-10 degrees)		3 sets × 10 reps
Multihip machine (flexion, extension, abduction, adduction)		3 sets × 10 reps
Closed-chain: wall-sits (0-45 degrees)		5 reps
Balance Training	2 ×/day, 5 min	
Balance board/two legged		
Cup walking		
Single-leg stance		
Aerobic Conditioning	1-2 ×/day, 10 min	
UBC		
Stationary bicycling (high seat, low resistance)		
Water walking (water thigh to waist high)

Cryotherapy		20 min
Goals	• Increase strength and endurance • Increase balance and coordination • ROM 0-135 degrees	

*After postoperative week 12, patient continues strengthening and conditioning program as desired.
BAPS, Biomechanical Ankle Platform System (Patterson Medical); *BBS*, Biodex Balance System; *CRPS*, complex regional pain syndrome; *EMS*, electrical muscle stimulation; *ITB*, iliotibial band; *ROM*, range of motion; *RSD*, reflex sympathetic dystrophy; *UBC*, upper body cycle.

mobilization, quadriceps strengthening, and balance training with partial weight bearing allowed. A continuous passive motion machine is not required or routinely used by us. Patients perform passive and active ROM exercises in a seated position for 10 minutes a session, approximately six times per day. Full passive knee extension must be obtained immediately to avoid excessive scarring. If the patient has difficulty regaining at least 0 degree by the seventh postoperative day, he or she begins an overpressure program. The foot and ankle are propped on a towel or other device to elevate the hamstrings and gastrocnemius that allows the knee to drop into full extension. This position is maintained for 10 minutes and repeated four to six times per day. A 10- to 20-lb weight may be added to the distal thigh and knee to provide overpressure to stretch the posterior capsule. Knee flexion is gradually increased to 110 degrees by the second postoperative week and 135 degrees by the third to fourth postoperative week. Passive knee flexion exercises are performed initially in the traditional seated position, using the opposite lower extremity to provide overpressure. Other methods to assist in achieving flexion greater than 90 degrees include chair rolling, wall slides, knee flexion devices, and passive quadriceps stretching exercises (see Chapter 11).

Patients use a walker or crutches with full weight bearing allowed as tolerated. Full weight bearing without crutches is permitted when the patient demonstrates a normal gait pattern, which is usually by the third to fourth postoperative week. Balance, proprioception, and strengthening exercises are gradually increased as supervised by the therapist and shown in Table 37-2 through approximately the 12th postoperative week. At that time, the patient is encouraged to continue the strengthening and aerobic conditioning program as desired.

COMPLICATIONS AND FACTORS LEADING TO FAILURE

First-generation PFA studies reported frequent problems related to patellar maltracking or subluxation, anterior knee pain, and improper positioning of the implant.[4,7,27,31,34,46,49] Fortunately, these problems have been markedly reduced with second- and third-generation implant design, improved operative techniques, and selection of patient candidates. Currently, the progression of tibiofemoral arthritis is one of the most common causes of failure or unsatisfactory results.[2,5,9,13,21,24,27,31,38,40,52,53,55] Therefore it is essential that the preoperative evaluation rules out patients with existing articular cartilage damage or joint space narrowing in either tibiofemoral compartment.

Problems with regaining normal knee motion have been reported that required arthroscopic lysis of adhesions in 9% in two series[8,35] and manipulation under anesthesia in 1% to 18% in other studies.[2,12,14,21,23,41,52] The majority of studies have not reported the final amount of knee motion achieved[2,3,8,23,35,38,48] or only provided means and standard deviations of the operative and contralateral knees.[11,40,42]

The need for additional operations (except revisions) after PFA varies among studies. van Jonbergen and colleagues[52] performed "arthrotomy, arthroscopy, or other" operative procedures in 51 of 181 knees (28%) after PFA with the Richards II implant. Lateral retinacular release was done in 2% to 11% in five studies.[5,9,10,12,42] Other complications such as infection and deep venous thrombosis appear to be extremely rare after PFA.

Prosthesis-related bone loss (postoperative decrease in bone mineral density) reported after TKA[25,47] has been believed to be related to strain shielding. Strain shielding may promote reduction of bone density and bone resorption, although overload promotes excessive formation of bone that causes an increase in bone density and may induce fatigue damage.[16] Loss of bone may lead to periprosthetic fracture or weakening of the implant fixation, resulting in loosening and implant failure.[32,47] In a study involving five synthetic femur models, Meireles and colleagues[32] experimentally determined the strain shielding effect of PFA (Journey, Smith & Nephew) during level walking, stair climbing, and deep squatting. The study found that, during deep squatting to 90 degrees, PFA reduced strains in the medial and distal regions of the femur compared with the preoperative condition (−72% and −67.5%, respectively) and increased strain in the anterior region (182%). There were no major strain reductions during level walking or stair-climbing conditions. No clinical studies have assessed bone mineral density after PFA.

CLINICAL STUDIES

The survivorship rates reported after first-generation PFA are shown in Table 37-3 and the clinical outcomes are shown in Table 37-4. High revision rates because of problems previously discussed lead to the discontinuation of most of these implants. Outcomes for second-generation implants are shown in Tables 37-5 and 37-6. The Avon PFA

NA, Not available.

is the most widely studied of these implants to date, with midterm survival rates (5 to 7 years) of 323 knees ranging from 82% to 100%. Inconsistent results have been reported 2 to 3 years after the Femoro Patella Vialli (Wright Medical Technology); survivor rates range from 65% to 97%.

Only two small series have been reported regarding mid- to long-term outcomes of third-generation PFA implants (Tables 37-7 and 37-8).[8,43,45] No revisions were required in 25 patients who received a KineMatch implant (Kinamed Inc.) followed a mean of 11 years postoperatively.[45] In 22 patients who received a Custom Performa Knee (Biomet Orthopedics), five had problems with the patellar button; one was revised because of poor sizing, three had worn, and one broke.[8] There were no problems with the trochlear components.

Lonner[27] retrospectively compared his early outcomes of the first-generation Lubinus with those of the Avon and reported incidence rates of fair and poor results (from PF dysfunction, subluxation, catching, substantial pain) of 17% and 4%, respectively. This investigator and coworkers[20] revised 14 Lubinus failures in 11 patients to the Avon implant for component malalignment and patellar subluxation, wear and synovitis, and component malposition. The PFA revisions were performed a mean of 5.6 years (range, 0.6-10.7 years) postoperatively. Only three patients were younger than 60 years at the time of the revision. At a mean of 5 years postrevision, two knees had undergone TKA, and three had poorer function compared with the preoperative condition. The remaining six knees had improved pain and knee function. The authors commented that PFA revision should only be considered in cases where the bone stock in the trochlear region is adequate to allow implantation of a new implant and if the tibiofemoral compartments are normal and do not produce symptoms. If these conditions do not exist, then conversion to TKA is the appropriate procedure.

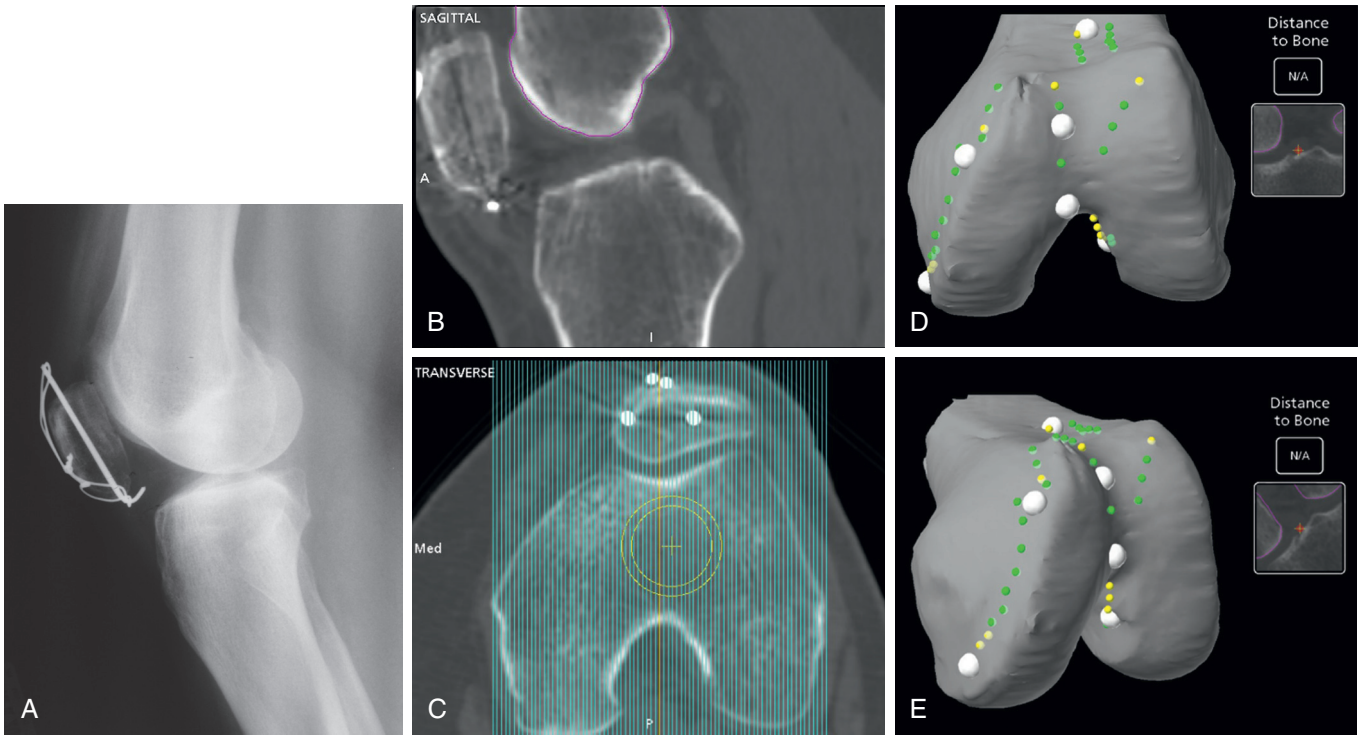
TABLE 37-8 Clinical Outcomes of Third-Generation Patellofemoral Arthroplasty

Study	Prosthesis	Knees (*n*)	Mean Age (Range) (yr)	Mean Follow-up (Range) (yr)	Knees With Outcome Data (*n*)	Knee Rating Scores (Mean)	Other Outcomes
Sisto & Sarin[45] (2010)	KineMatch	25	45 (23-51)	11.3 (7.8-14.9)	25	None	All patients very satisfied with results, would have procedure again; no revisions
Sisto & Sarin[43] (2006)	KineMatch	25	45 (23-51)	6.1 (2.7-9.9)	25	AKS Knee score, 91 (range, 82-96); Function score, 89 (range, 81-94); significant improvement	No problems normal walking; no revisions
Butler & Shannon[8] (2009)	Custom Performa Knee Patellofemoral Arthroplast	22	48 (35-63)	5	22	WOMAC overall 28; pain 5.5, stiffness 2.4, function 20.6 (all significantly better scores compared with preoperative)	5% revised patellar button

AKS, American Knee Society; *WOMAC*, Western Ontario and McMaster Universities Osteoarthritis Index.

ILLUSTRATIVE CASES

Case 1. A 35-year-old woman sustained a patellar fracture and underwent an open reduction and internal fixation and subsequently developed a patella infera (Fig. 37-8, *A*). Because of severe PF symptoms that were unresponsive to conservative treatment, she underwent a PF arthroplasty 3 years later. The preoperative sagittal CT segment is shown in Figure 37-8, *B*, and the preoperative axial CT segment is shown in Figure 37-8, *C*. The demonstration of the required anatomic landmarks for the trochlear implant is shown in Figures 37-8, *D* and *E*. The intraoperative verification of the trochlear implant placement is shown in Figure 37-8, *F*. The postoperative anteroposterior (Fig. 37-8, *G*) and lateral (Fig. 37-8, *H*) radiographs show the residual patella infera, which is expected to cause increased



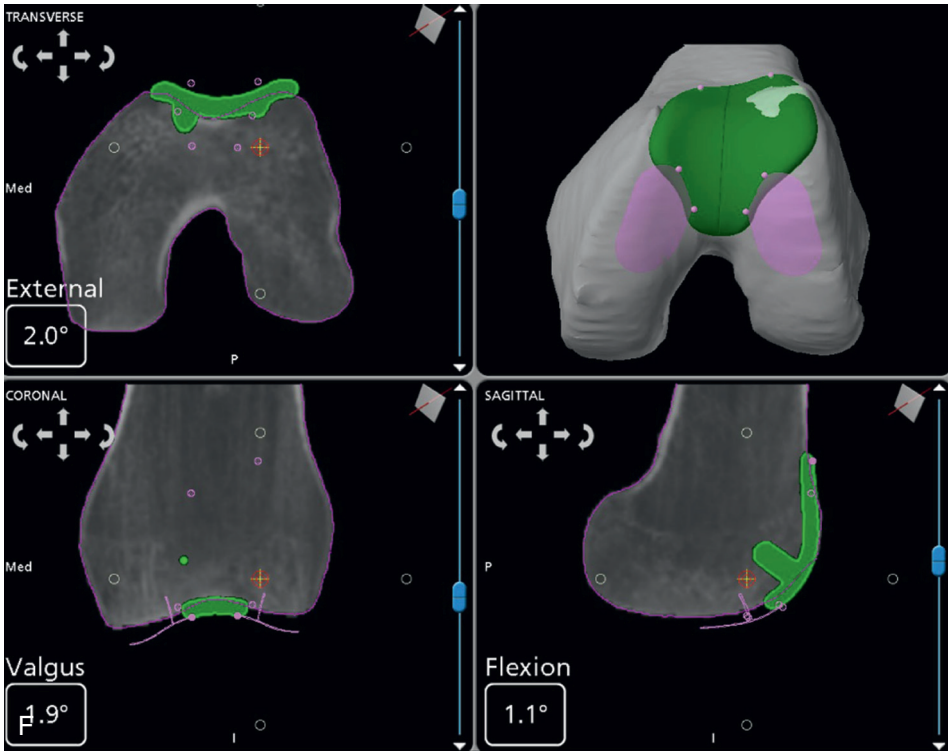


FIG 37-8 Case 1.

Continued

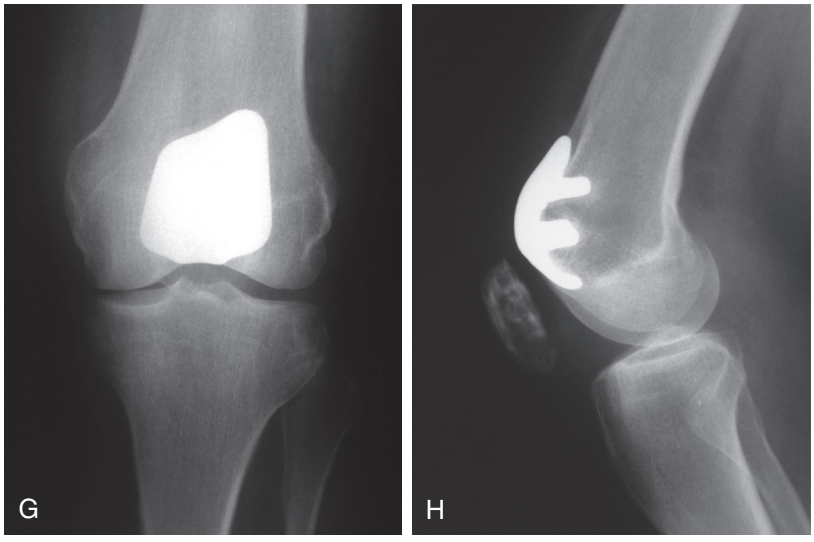

FIG 37-8, cont'd

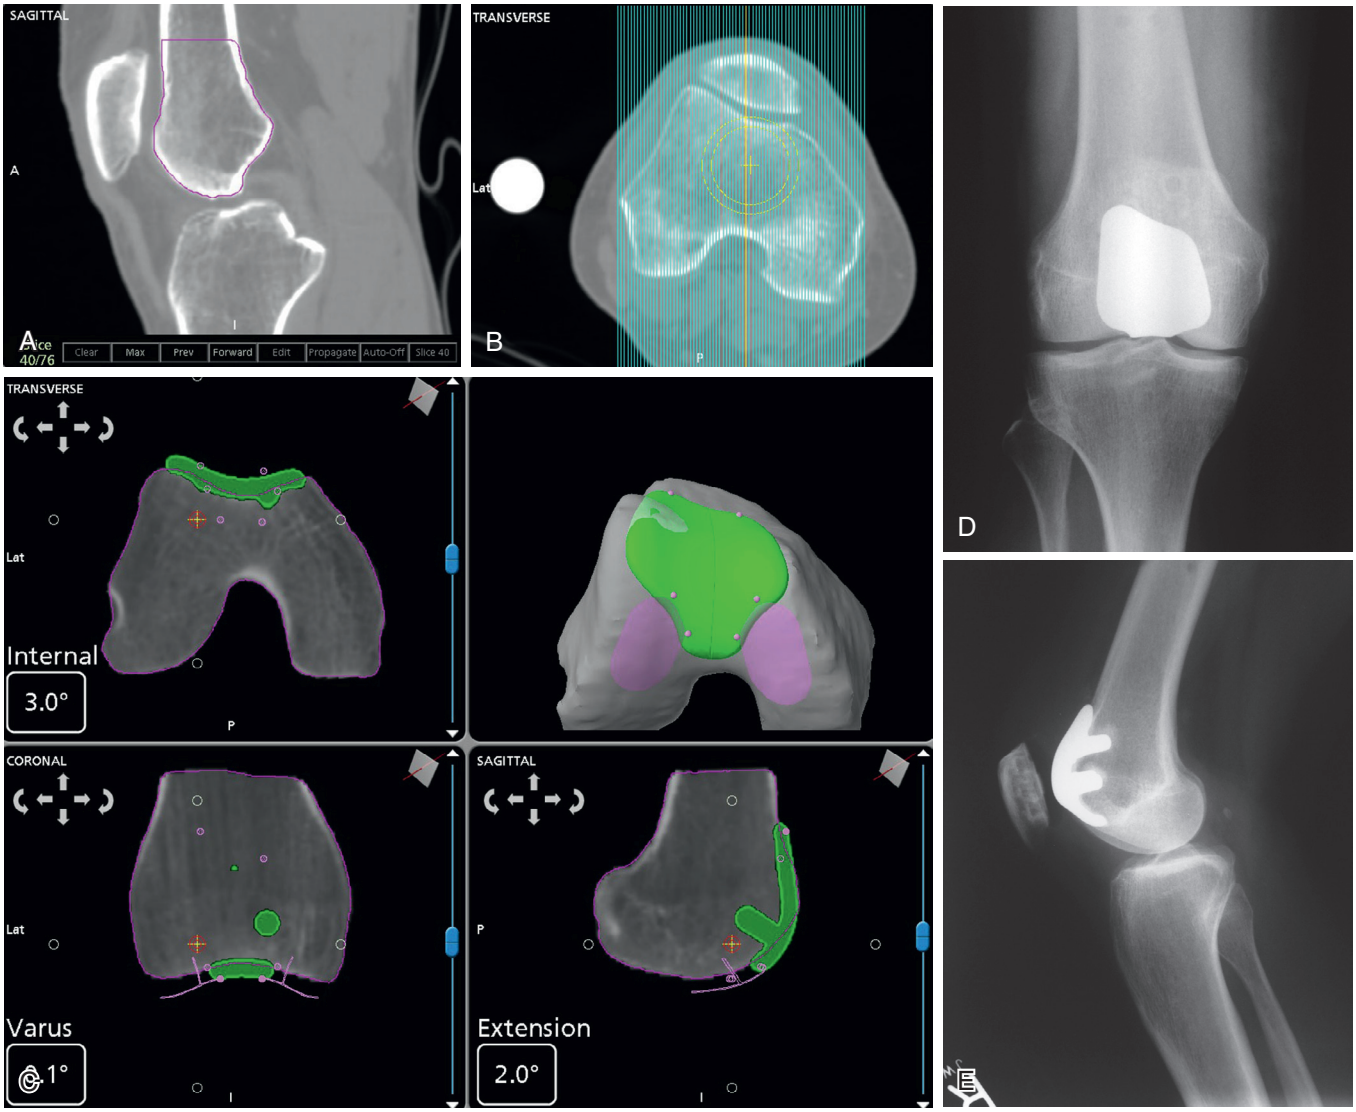

FIG 37-9 Case 2.

proximal patellar component pressures. Even so, the patient is asymptomatic with daily activities and markedly improved from her preoperative state.

Case 2. A 50-year-old woman with advanced PF arthritis and underlying trochlear dysplasia presented after failure of nonoperative treatment with marked disability with daily activities. The preoperative coronal CT segment (Fig. 37-9, *A*) and axial CT segment (Fig. 37-9, *B*) images show trochlear dysplasia and hypoplasia of the medial aspect of the trochlea. Figure 37-9, *C* shows the intraoperative placement of the trochlear implant and the resection required of the lateral trochlea for proper placement of the implant. Postoperative anterior (Fig. 37-9, *D*) and lateral (Fig. 37-9, *E*) radiographs demonstrate correct positioning of the PF arthroplasty. At 2 years postoperative, the patient is asymptomatic with daily activities.

Case 3. A 55-year-old woman underwent PF arthroplasty for advanced PF arthritis. Figure 37-10, *A* shows an obvious patella alta (Linclau ratio 1.30). The preoperative axial CT segment (Fig. 37-10, *B*) shows a prominent lateral trochlea. Figure 37-10, *C* shows the intraoperative placement of the trochlear component with verification of the proximal trochlear component that provided suitable contact with the patellar component in view of the patella alta condition. A distal advancement of the tibial tubercle was not required. Appropriate soft tissue balancing was required. The intraoperative photographs of this patient are shown in Figures 37-5 and 37-6.

INTRODUCTION

Loss of a normal range of knee motion following an injury or ligament reconstruction is a potentially devastating complication. Many investigations and publications have appeared since the early 1990s regarding this problem, and it continues to be one of the most frequently reported complications after surgical procedures such as autologous chondrocyte implantation (ACI), knee ligament reconstructions, and total knee arthroplasty (TKA).[37,52,66,93,98,154,176] Although the definition and use of the term *arthrofibrosis* varies among authors, it implies a loss of knee flexion, extension, or both compared with the contralateral normal knee. Stephenson and associates[176] estimated that the number of patients who undergo major knee surgery in the United States that are subsequently affected by arthrofibrosis is at least 85,000 a year. Of these, 21,000 are at risk of requiring additional surgery, and 54,000 may have an unsuccessful outcome of treatment for this complication.

Primary arthrofibrosis is caused by an exaggerated inflammatory response to an injury or surgical procedure, followed by the production of fibroblastic cells and an increase in the deposition of extracellular matrix proteins.[182] Proliferative scar tissue or fibrous adhesions form within the joint, which can result in either localized or diffuse involvement of all of the compartments of the knee and the extra-articular soft tissues (Fig. 38-1). In the most severe cases, dense scar tissue obliterates the normal peripatellar recesses, suprapatellar pouch, intercondylar notch, and articular surfaces. Formation of dense scar tissue in the infrapatellar region may result in a patella infera and permanent limitation of normal knee flexion and extension. The consequent pain and restricted knee motion resulting from arthrofibrosis may lead to disabling events, including severe quadriceps atrophy, loss of patellar mobility, patellar tendon adaptive shortening, patella infera, and articular cartilage deterioration.[129,130]

The incidence of arthrofibrosis after knee ligament reconstructive surgery varies according to several factors. In our experience, two of the most commonly noted factors are knee dislocations and major

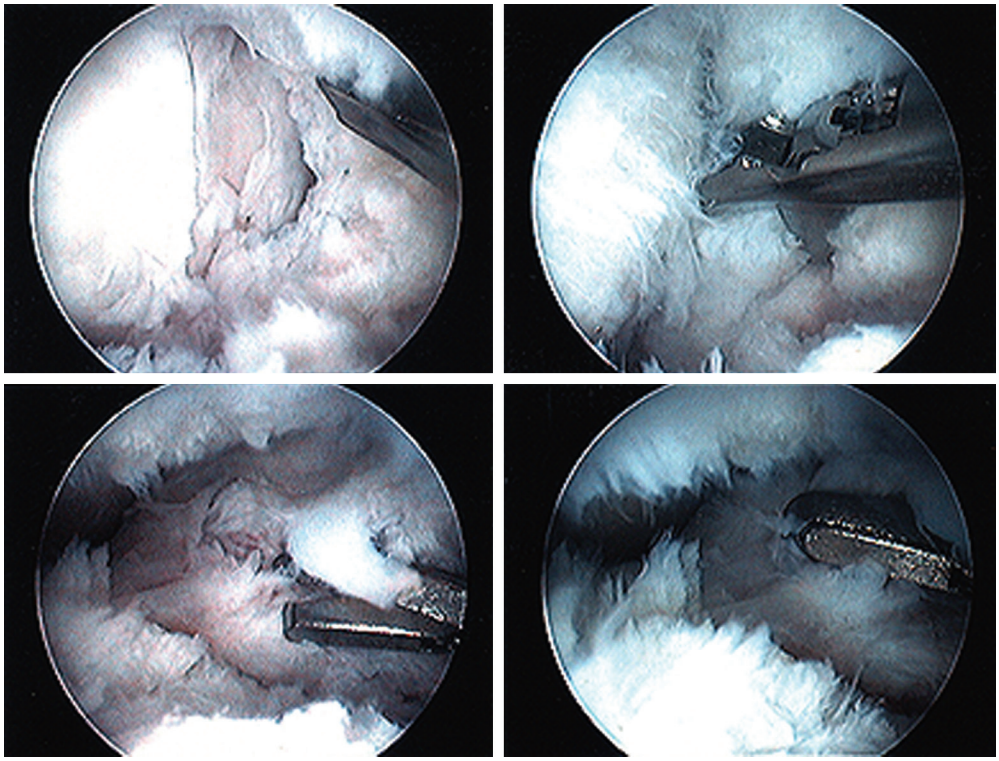

FIG 38-1 Proliferative formation of scar tissue requiring arthroscopic debridement and lysis of adhesions. A contracture of medial and lateral parapatellar soft tissues is shown, along with patella and trochlear cartilage deterioration.

CRITICAL POINTS Introduction

- Arthrofibrosis implies a loss of knee flexion, extension, or both compared with the contralateral normal knee.
- Primary arthrofibrosis is caused by an exaggerated inflammatory response to an injury or surgical procedure followed by the production of fibroblastic cells and an increase in the deposition of extracellular matrix proteins. Proliferative scar tissue or fibrous adhesions form within the joint, which can be either localized or diffuse.
- Incidence of arthrofibrosis following ligament reconstructive surgery varies.
- Wide disparity exists among authors regarding the treatment of this problem.
- Limitations in knee motion may occur owing to reasons other than arthrofibrosis:
  - Mechanical block from a displaced bucket-handle meniscus tear.
  - Impinged or improperly placed ACL graft.
  - Cyclops lesion.
  - Improper ACL graft tensioning.
  - Contracture of posterior capsular structures.
- If not resolved, these problems may result in the development of secondary arthrofibrosis.
- Most individuals have some amount of hyperextension to allow the normal "screw-home" mechanism to occur: knee stabilized in extension during the stance phase, with the quadriceps muscle relaxed.
- Normal knee flexion averages 140 degrees in men and 143 degrees in women.
- Patients not involved in athletics tolerate small flexion deficits. Significant flexion deficits <90 degrees cause problems with squatting, stair-climbing, and sitting.
- Loss of just 5 degrees of extension may produce a flexed-knee gait, fatigue the quadriceps muscle, and cause patellofemoral pain.
- Prevention of knee arthrofibrosis is paramount and preferred over the current treatment options for this complication.

concurrent operative procedures (Table 38-1).[12,113-127] Studies show wide disparity among authors regarding the treatment of this problem, especially the postoperative time that intervention is warranted and what type of treatment should be implemented for losses of knee extension and flexion and patella mobility.

Note that limitations in knee flexion and extension may occur because of reasons other than arthrofibrosis. Any acute injury causing pain and swelling may cause a short-term loss of knee motion, which usually resolves as symptoms subside. Other factors influencing the restoration of knee motion include a mechanical block from a displaced bucket-handle meniscus tear, an impinged or improperly placed anterior cruciate ligament (ACL) graft, a cyclops lesion,[80] improper graft tensioning that constrains normal knee joint motion,[30] and graft fixation at 30 degrees or more of extension.[7] In addition, contracture of the posterior capsular structures may limit knee extension. If not resolved, these problems may result in the development of what is termed *secondary arthrofibrosis*, complicating the course of treatment.

Normal knee motion varies, but most individuals have some amount of hyperextension, which averages 5 degrees in men and 6 degrees in women.[41,42,93] This degree of hyperextension is required so that the normal "screw-home" mechanism that allows the knee to be

stabilized in extension during the stance phase may occur, with the quadriceps muscle relaxed. Soucie and colleagues[172] provided the following ranges of knee motion, according to gender and age from a sample of 674 healthy subjects: (1) ages 9 to 19 years: 2.4 to 142.3 degrees for girls and 1.8 to 142.2 degrees for boys, (2) ages 20 to 44 years: 1.6 to 141.9 degrees for women and 1.0 to 137.7 degrees for men, and (3) ages 45 to 69 years: 1.2 to 137.8 degrees for women and 0.5 to 132.9 degrees for men.

It is generally assumed that at least 125 degrees of knee flexion is required for activities of daily living.[42,93] Rowe and coworkers[146] measured knee kinematics during functional activities in a group of 20 subjects aged 49 to 80 years and reported that 90 degrees of flexion is required for gait and slopes, 90 to 120 degrees for stairs and sitting, and 135 degrees for bathing. Patients not involved in athletics tolerate small flexion deficits. Significant flexion deficits of less than 90 degrees cause problems with squatting, stair climbing, and sitting. Athletes have a poorer tolerance for even minor losses of flexion, which affect running and jumping. Cosgarea and associates[34] reported that deficits of 10 degrees or more of flexion were associated with decreased running speed.

All patients, regardless of their activity level, have greater problems with loss of knee extension. A loss of just 5 degrees of extension may produce a flexed-knee gait, fatigue the quadriceps muscles, and cause patellofemoral pain.[78,81,108,111,149] Limitation of more than 20 degrees may cause a functional limb-length discrepancy.[34] Many years ago, Perry and colleagues[141] demonstrated the effect of a loss of extension on joint contact pressures, quadriceps muscle activity, and fatigue. These investigators measured the extensor forces required to stabilize the flexed knee during simulated weight bearing in cadaver specimens. The quadriceps force required to stabilize the knee was 75% of the load on the head of the femur at 15 degrees of flexion, which increased to 210% at 30 degrees of flexion and to 410% at 60 degrees of flexion. The quadriceps force was equal to 20% of average maximum quadriceps strength at 15 degrees of flexion but increased to 50% at 30

degrees of flexion. Surface pressure in the tibiofemoral and patellofemoral joints also increased with greater amounts of knee flexion.

It has become evident that the prevention of knee arthrofibrosis is paramount and preferred over using the currently available treatment options for this complication. This chapter discusses the risk factors and preventive measures for loss of knee motion after knee injury and surgery. In addition, conservative medical and therapeutic treatment intervention strategies are discussed that are usually successful in resolving a transient limitation of knee motion if initiated early postoperatively. Surgical procedures for severe cases of restriction of knee motion are presented. Our clinical studies involving 650 ACL-reconstructed knees are included to provide support for treatment recommendations.

TERMINOLOGY AND CLASSIFICATION SYSTEMS

A variety of terms have been used to describe, define, or classify a limitation of knee flexion and extension, including arthrofibrosis, flexion contracture, ankylosis, infrapatellar contracture syndrome, and motion loss. Some of the terms indicate a specific process, but others simply imply a limitation of motion compared with the contralateral normal knee. *Ankylosis* is one such generic term that indicates stiffness of joints that occurs for any reason and may represent loss of knee flexion, extension, or both. The term *motion loss* is another general phrase used to describe deviations from the amount of flexion and extension compared with the contralateral normal knee. Conversely, *arthrofibrosis* describes a specific cause for a limitation of knee motion, which is the formation of diffuse scar tissue or fibrous adhesions within a joint.[78,137,142] *Flexion contracture* indicates a loss of extension attributable to any cause and is accompanied by a relative shortening of the posterior soft tissues (in either the capsule or muscles). Petsche and Hutchinson[142] state that *arthrofibrosis* and *flexion contracture* are general terms, and it is necessary to indicate a specific cause for loss of motion.

Classification systems have been proposed by various authors to describe limitations in knee motion, based either on the anatomic location of scar tissue and adhesions or on the amount of knee motion in the affected joint (Table 38-2).[18,44,137,163,174] Sprague and coworkers[174] first introduced a system based on the arthroscopically observed location of scar tissues and adhesions in 24 patients who had a severe limitation of knee motion. Paulos and associates[137] described three stages of knee motion restrictions caused by infrapatellar contracture syndrome. Del Pizzo and colleagues[44] and Shelbourne and coworkers[163] developed classification systems based on the deviation of knee motion compared with the opposite knee. Blauth and Jaeger[18] described a system based on the total arc of motion in the affected knee.

CRITICAL POINTS Terminology and Classification Systems

- Terms used to describe limitation knee motion: *arthrofibrosis, flexion contracture, ankylosis, infrapatellar contracture syndrome, motion loss.*
- The term *arthrofibrosis* describes a specific cause for a limitation of knee motion, which is the formation of diffuse scar tissue or fibrous adhesions within a joint.
- Classification systems describe limitations in knee motion, based either on the anatomic location of scar tissue and adhesions, or on the amount of knee motion in the affected joint.
- Our classification system is based on the anatomic sites where scar tissue, adhesions, and adaptive shortening of soft tissues occur.

We have developed a classification system based on the anatomic sites at which scar tissue, adhesions, and adaptive shortening of soft tissues occur (Fig. 38-2 and Table 38-3). This system is advantageous because it highlights the areas that must be addressed surgically, as is discussed.

RISK FACTORS AFTER KNEE LIGAMENT RECONSTRUCTION

A variety of factors appear to influence the requirement for treatment intervention for knee motion limitations (Table 38-4) and the final amount of knee flexion and extension gained after ligament reconstruction. These factors are related to the severity of the injury, the timing of surgery, preoperative treatment, technical aspects of the ligament reconstruction, and the postoperative course and rehabilitation.

TABLE 38-2 Classification Systems of Arthrofibrosis

Study	Classification System
Sprague et al[174] (1982)	I: Discreet bands or a single sheet of adhesions traversing the suprapatellar pouch II: Near-complete obliteration of suprapatellar pouch and peripatellar gutters with masses of adhesions III: Multiple bands of adhesions or complete obliteration of suprapatellar pouch with extracapsular involvement
Del Pizzo et al[44] (1985)	Based on deviation from full extension and amount of flexion present: Mild: <5 extension, >110 flexion Moderate: 5-10 extension, 90-100 flexion Severe: >10 extension, <90 flexion
Paulos et al[137] (1987)	Three stages of infrapatellar contracture syndrome: I: Prodromal stage (2-8 wk postoperative) hardened synovium, fat pad, retinaculum marked by painful motion, restricted patellar mobility, quadriceps muscle lag II: Active stage (6-20 wk postoperative) peripatellar swelling, severely restricted patellar motion, hardening anterior tissues, step-off between patellar tendon and tibial tuberosity III: Residual stage (>8 mo postoperative) fat pad atrophy, patellofemoral crepitus and arthrosis, patella infera, quadriceps atrophy
Blauth & Jaeger[18] (1990)	Based on total arc of motion: I (mild): >120 II (moderate): 80-120 III (severe): 40-80 IV (extreme): <40
Shelbourne et al[163] (1996)	Based on deviation from full flexion and extension of opposite, normal knee: I: <10 extension, normal flexion II: >10 extension, normal flexion III: >10 extension, >25 loss of flexion IV: >10 extension, >30 loss of flexion, patella infera

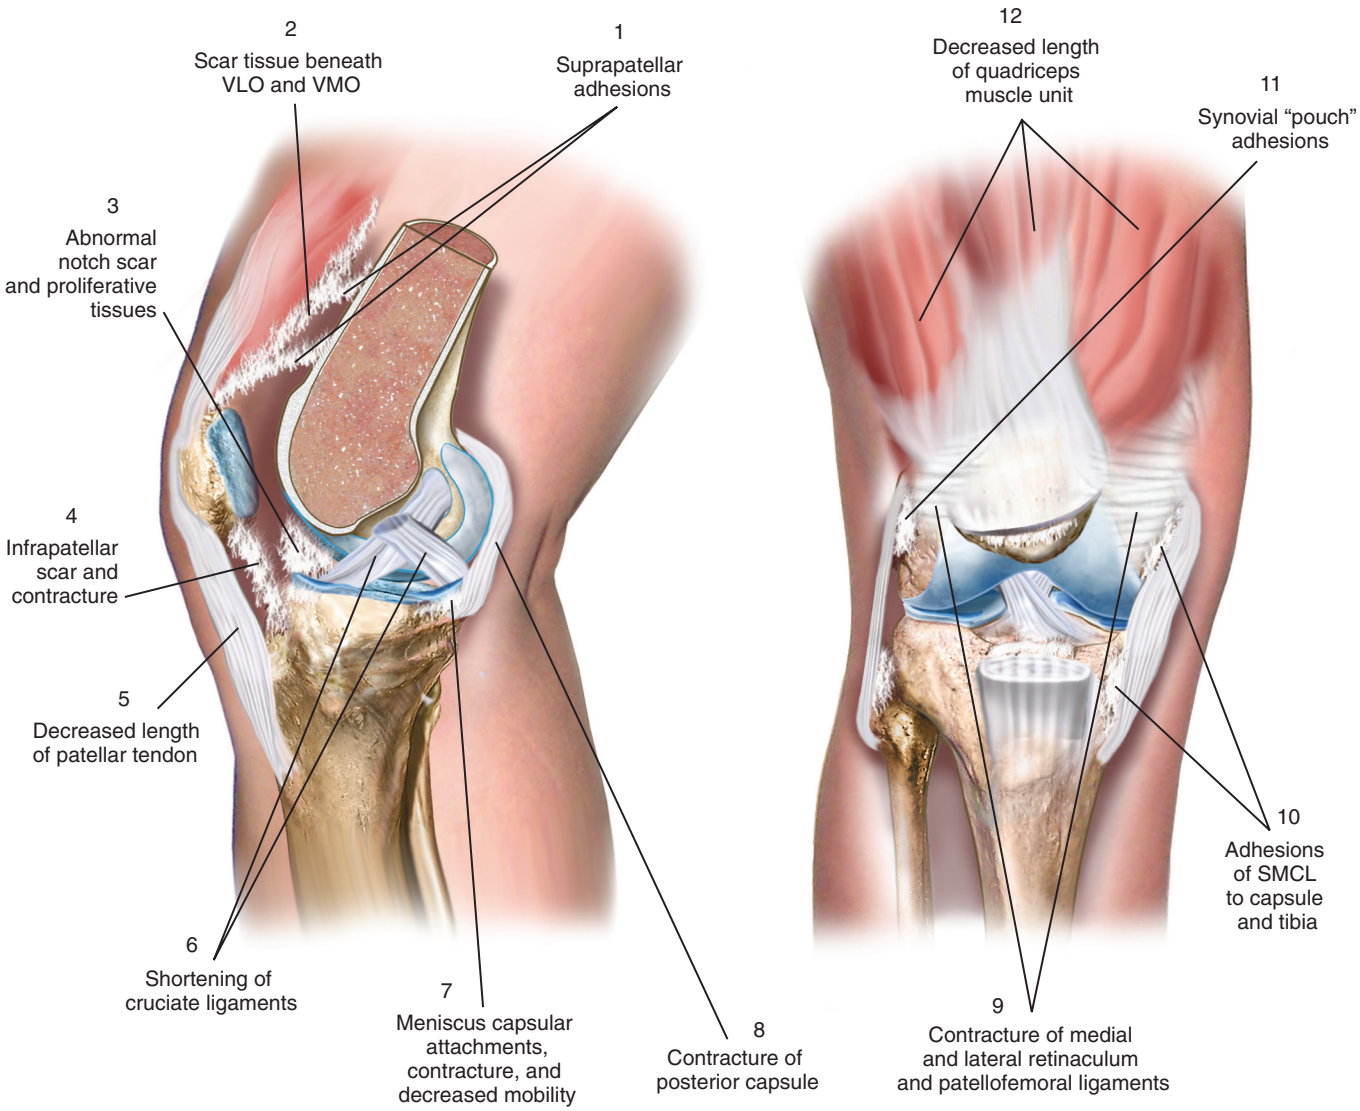

FIG 38-2 Multiple areas of soft tissue contracture, adhesions, and scar tissue formation with knee arthrofibrosis. *SMCL*, Superficial medial collateral ligament; *VLO*, vastus lateralis oblique; *VMO*, vastus medialis obliquus.

Although it remains uncertain why some knees are more likely to form an abnormal scar response to trauma and surgery than others, knowledge of these factors may help reduce this problem.

Severity of the Injury

Patients who sustain knee dislocations are at increased risk for developing motion complications (Fig. 38-3).[33,46,105,119,158,167] These injuries frequently occur from high-energy accidents that produce extreme soft tissue swelling and edema, hematomas, muscle damage, and other multiple trauma that must be resolved before consideration of knee soft tissue reconstructions. Early operative intervention when possible is advised for multiple ligament injuries that involve the lateral and posterolateral structures where acute repair and augmentation procedures are performed (see Chapter 17). For all other dislocations, surgery is delayed with the limb immobilized in a posterior plaster splint or bivalved cast with a posterior pad to prevent posterior tibial subluxation. Even in these severe knee injuries, it is possible to start immediate range of motion and prevent scar tissue formation that may compromise the outcome of a subsequent ligament reconstruction. Too often, these serious knee joint injuries are not treated with an early motion and function program. When surgical treatment is elected, the reconstructive and repair procedures of torn ligaments, capsular structures, and menisci are performed in a manner that allows immediate knee motion to be instituted postoperatively.[119]

Preoperative Issues

Performing anterior cruciate ligament (ACL) and other knee ligament reconstruction within a few weeks of the injury or before the resolution of swelling, pain, quadriceps muscle atrophy, abnormal gait mechanics, and motion limitations has been noted by many authors to correlate with postoperative knee motion problems.[35,100,108,160,161,165,178,189] Shelbourne and associates[165] noted an increased rate of arthrofibrosis in patients who underwent acute ACL reconstruction (within 1 week of the injury) compared with those in whom the reconstruction was delayed for at least 21 days. Similar findings were reported by Wasilewski and colleagues,[189] who noted that arthrofibrosis was found in 22% of

TABLE 38-3 Our Anatomic Classification System of Arthrofibrosis

Loss of Flexion

Quadriceps Muscle

- Shortens because of scar tissue and intramuscular changes, limiting normal muscle lengthening

Suprapatellar Pouch

- Scar tissue may form underneath quadriceps VMO, VLO, limiting muscle extensibility.
- Scar tissue from the superior pole of the patella produces patellar clunk, may extend as a band just above the femoral trochlea.
- Scar tissue and adhesions obliterate the suprapatellar pouch. Medial and lateral capsular pouches.

Medial and Lateral Capsular Pouches

- Scar down and become adhesive to the medial and lateral side of the femur

Patellar Retinaculum and Associated Ligaments

- Scar tissue forms with thickening, shortening, limiting patellar mobility

Patellar Tendon

- Tendon shortens or may adhere to the tibia.
- Infrapatellar scar tissue inferior pole to tibia just anterior to fat pad.

Medial and Lateral Extraarticular Ligament Structures

- Scar tissue, adhesions, adaptive shortening.

Loss of Extension

Posterior Capsule

- Scar tissue, adhesions, shortening of structures

Femoral Notch

- In-growth scar tissue, cyclops lesion

Hamstrings Muscle

- Shortening of musculotendinous unit

Cruciate Ligaments

- ACL, PCL adaptive shortening

ACL, Anterior cruciate ligament; *PCL*, posterior cruciate ligament; *VLO*, vastus lateralis oblique; *VMO*, vastus medialis obliquus.

TABLE 38-4 Risk Factors for the Development of Knee Arthrofibrosis

Magnitude of the injury: dislocation, multiple ligament injury
Normal or nearly normal knee motion not restored before surgery
Acute ligament reconstruction in swollen, painful knee
Technical errors in ACL graft placement, fixation, tensioning
Concurrent MCL repair or reconstruction
Infection
Immobilization
Chronic joint effusion
Quadriceps atrophy, shutdown
Poor rehabilitation, noncompliant patient
Cyclops lesion
Complex regional pain syndrome, reflex sympathetic dystrophy

ACL, Anterior cruciate ligament; *MCL*, medial collateral ligament.

FIG 38-3 Acute knee dislocation leads to severe disruption of soft tissues, swelling, hemorrhage, and muscle damage always resulting in motion problems and risk of arthrofibrosis.

CRITICAL POINTS Risk Factors after Knee Ligament Reconstruction

- Severity of injury: knee dislocations increase risk for developing motion complications. Surgery is delayed in all cases except those with ruptures to the posterolateral structures.
- Preoperative issues: performing knee ligament reconstruction within a few weeks of the injury or before the resolution of swelling, pain, quadriceps muscle atrophy, abnormal gait mechanics, and motion limitations correlates with postoperative knee motion problems.
- Technical factors at surgery: improper ACL graft placement, overtensioning graft at surgery, performing concurrent MCL repair with ACL reconstruction.
- Postoperative course and rehabilitation: immobilization is detrimental to all of the knee joint structures and may result in a permanent limitation of knee motion, prolonged muscle atrophy, patella infera, and articular cartilage deterioration. Begin knee motion, patellar mobilization, muscle-strengthening exercises the day after surgery. Treat joint effusion immediately.
- Postoperative infection, complex regional pain syndromes, and reflex sympathetic dystrophy may cause knee motion problems.

acutely reconstructed knees versus 12.5% of knees reconstructed with chronic ACL deficiency. Mohtadi and coworkers[108] found that ACL reconstructions performed less than 6 weeks postinjury had a higher rate of knee stiffness than those done more than 6 weeks post-injury (11% and 4%, respectively).

Mauro and associates[100] followed 229 patients who underwent ACL reconstruction to determine the incidence of loss of knee extension at 4 weeks after surgery. Fifty-eight patients (25%) had not regained full extension equal to the contralateral knee. When compared with the group of patients who had regained full extension, the group that had

a limitation were noted to have had a shorter mean time from injury to surgery (60 days and 93 days, respectively; $P < .05$), a greater preoperative loss of extension (4 and 1 degrees, respectively; $P < .05$), and a greater percentage that underwent autograft reconstruction than allograft reconstruction (28.5% and 14%, respectively; $P < .05$).

Although Bach and colleagues[8] did not observe a significant difference in knee motion complications between acute and chronic ACL-reconstructed knees, these authors stressed the need to delay surgery until patients achieved 120 degrees of knee motion and swelling had resolved. The authors found "no advantage to performing urgent acute ACL reconstruction."[8] Sterett and coworkers[177] found no association between surgical timing and postoperative motion problems. However, in their series, all patients had achieved at least 0 to 120 degrees, had good quadriceps control, and could perform a straight-leg raise without an extensor lag before undergoing surgery. Eight percent of the patients in this investigation's acute subgroup required arthroscopic debridement of scar tissue. Meighan and associates[103] also found no advantage in performing early ACL reconstruction and noted an increased rate of complications in patients who underwent surgery within 2 weeks of the injury compared with those who had surgery between 8 and 12 weeks postinjury. The delayed group had a faster return of knee motion and quadriceps strength.

Other authors have not found a higher rate of postoperative motion problems after acute ACL reconstruction.[4,25,86,171] However, it appears that delaying surgery until knee motion is regained, swelling is resolved, and a good quadriceps contraction is demonstrated is advantageous for decreasing the risk of postoperative arthrofibrosis. The inflammatory response to the initial injury varies among patients. Although some have little effusion and swelling, others have an exaggerated inflammatory response characterized by pain, soft tissue edema, and redness and increased warmth to tissues surrounding the knee. These knees are placed into an initial conservative treatment program to resolve these problems first and are also carefully monitored after ACL reconstruction for a similar exaggerated inflammatory reaction postoperatively. Knees with isolated ACL ruptures that have little swelling and demonstrate normal motion early after injury may be considered for earlier reconstruction. In addition, knees with multiple ligament ruptures that include the posterolateral structures are also candidates for early surgical repair, as discussed in Chapter 17.

Technical Factors at Surgery

Improper ACL graft placement has been frequently noted to cause loss of knee motion.[14,54,76,78,81,91,97,107,145,162,166,193] On the tibia, grafts placed anterior to the native ACL insertion result in impingement on the roof of the intercondylar notch when the knee is extended.[74,75,99] Yaru and colleagues[193] recommended that, with passive extension, there should be a 3-mm clearance between the anterior portion of the intercondylar notch and the graft to prevent impingement. Grafts placed lateral to the insertion site impinge on the lateral wall of the notch. In addition, Romano and coworkers[145] found that ACL grafts placed too far anteriorly in the tibial tunnel can cause knee extension deficits, and grafts placed too far medially in the tibial tunnel can cause knee flexion deficits. On the femur, an excessive anterior graft placement causes deleterious forces on the graft, leading to limitations in flexion and potential graft failure (Fig. 38-4).

Overtensioning ACL grafts may lead to abnormal knee kinematics.[106,142] In addition, the degree of knee extension during graft tensioning and fixation may affect postoperative motion.[7,30,59,104,111] Austin and associates[7] noted in a cadaver study that the amount of graft tension (44 N or 89 N) did not effect knee extension; however, tensioning the graft in knee flexion was associated with extension deficits. The authors reported that grafts tensioned and fixed at 30 degrees of flexion had more than a 12 degree increase in knee flexion after ACL reconstruction compared with those tensioned and fixed at 0 degrees of flexion. From a two-part biomechanic and clinical study, Nabors and colleagues[111] suggested that grafts tensioned in full extension result in a low incidence of knee motion loss. In their series of 57 patients who underwent patellar tendon autograft ACL reconstruction, only one patient had a mild (5 degrees) loss of extension.

FIG 38-4 Lateral radiographs show excessive anterior placement of the femoral tunnel limiting knee flexion and the anterior tibial tunnel limiting knee extension. The graft failed as motion was regained postoperatively.

Concurrent medial collateral ligament (MCL) repair with ACL reconstruction has been associated with an increased risk of knee arthrofibrosis.[65,117,159] Harner and associates[65] postulated that concurrent MCL primary repair may cause a limitation of knee motion attributable to the disruption of the medial capsule because the procedure does not restore the normal tissue planes, resulting in scar formation and a heightened pain response. Our studies[117] and the studies of Shelbourne and coworkers[159,164] led to the recommendation many years ago to treat the majority of combined ACL/MCL ruptures conservatively. This allows healing of the medial-side injury followed by ACL reconstruction in appropriately indicated patients (see Chapter 19). There are exceptions to this rule, and any surgical procedure on the medial side of the knee joint should be carefully observed postoperatively for a limitation of motion or, in acute knee injuries, the development of heterotopic soft tissue ossification requiring treatment.[157,186]

Postoperative Course and Rehabilitation

There is consensus in the literature that immobilization is detrimental to all of the knee joint structures and may result in a permanent limitation of knee motion, prolonged muscle atrophy, patella infera, and articular cartilage deterioration.[35,128-130,138,151] Early knee joint motion decreases pain and postoperative joint effusions, aids in the prevention of scar tissue formation and capsular contractions that can limit

normal knee flexion and extension, decreases muscle disuse effects, maintains articular cartilage nutrition, and benefits the healing ACL graft.[3,35,36,43,49,62,71,133,140,152,170] Modern rehabilitation programs incorporate immediate knee motion and muscle-strengthening exercises the day after surgery, both of which have been shown to be safe and not deleterious to healing grafts (see Chapters 10, 11, and 12). Importantly, the immediate motion program must include patellar mobilization (inferior, superior, medial, and lateral directions) to avoid an infrapatellar contracture.

Patient compliance with postoperative rehabilitation is essential in recovering full knee motion. In our experience, the small percentage of patients who have permanent restrictions in extension or flexion have often been unwilling to perform the required motion, strengthening, and patellar mobilization exercises postoperatively. In addition, in instances in which an early postoperative limitation of motion has been recognized, these patients are also unwilling to undergo treatment recommendations such as overpressure exercises, extension casts, and other modalities that are usually effective in resolving these problems.[125,126] Thus in a majority of cases, the inflammatory and fibrotic response that follows surgery and initially limits knee motion is treatable if no delay occurs in instituting a gentle motion and overpressure program along with appropriate antiinflammatory medications. There is a distinct group of patients, in the range of 1% to 2%, who demonstrate a pathologic exaggerated fibrous tissue proliferative response most likely from a genetic basis, in which the treatment is prolonged and may not be successful. This unique group of patients is discussed in a later section of this chapter.

Significant lower extremity muscle atrophy represents an unresolved problem after ACL reconstruction because the magnitude of quadriceps atrophy and strength loss may exceed 20% to 30% in the first few months postoperatively.[40,67,77,83,136,155,179] Prolonged quadriceps atrophy may affect the ability to regain normal knee motion and maintain knee extension. Chronic swelling may also cause a limitation of knee motion by inhibiting the function of the quadriceps muscle.[135,173,180,181] It is important that a knee joint effusion be treated to lessen its deleterious effect on quadriceps function.

Other Risk Factors

Infection may result in loss of knee motion after ACL reconstruction. The rule followed in our clinical practice is to always consider first that an exaggerated inflammatory response with joint swelling, synovitis, and early limitation of joint motion is caused by a joint infection until proved otherwise. Even when an infectious process appears to have been excluded, a knee joint that does not respond to the gentle modalities to regain knee motion or that has continued pain or lack of patellar mobility should undergo repeat aspiration, cell count, culture, and diagnostic studies. In our experience, the most severe cases of arthrofibrosis that initially were presumed to be caused by a genetic abnormality were subsequently proven to have an occult unrecognized infectious etiology. In patients with an established infectious process, the principles of treatment have been discussed (see Chapter 7), and it is important that gentle motion and overpressure programs continue to maintain the joint motion. Even in knees with swelling of soft tissues and the initial host response to an infection, it is possible within days after arthroscopic lavage, debridement, and appropriate antibiotics to initiate motion exercises and prevent a flexion contracture or patella infera. Although aggressive management of this complication usually leads to resolution of the infection, studies report permanent loss of extension and flexion in the majority of patients treated which may be avoidable.[102,156,183,191]

Recent reports by Csintalan and associates[38] and Nwachukwu and coworkers[131] identified female gender as a significant risk factor for the development of arthrofibrosis after ACL reconstruction. Csintalan and associates[38] studied a cohort of 14,522 primary ACL reconstructions and reported a hazard ratio (HR) for reoperations related to arthrofibrosis of 2.48 for women compared with men (P <.001). In addition, these authors reported any prior surgery was also a significant risk factor (HR, 3.02; P = .005). Nwachukwu and coworkers[131] studied 933 consecutive ACL reconstructions performed in patients aged 7 to 17 years and reported an overall arthrofibrosis rate of 8.3%. Statistically significant risk factors were female gender (P = .0001), patient aged 16 to 18 years (P = .007), patellar tendon autograft (P = .03), and concomitant meniscal repair (P = .007).

Complex regional pain syndromes and reflex sympathetic dystrophy may cause knee motion problems as a result of quadriceps atrophy, chronic swelling, and an increased sensitivity to pain.[61,132] These issues are discussed in detail in Chapter 40. Appropriate management using a variety of medical specialists is essential to diagnose and treat these problems.

PATHOPHYSIOLOGY AND EXPERIMENTAL PREVENTION STUDIES

In 1972, Enneking and Horowitz[48] published one of the first studies on the pathophysiology of a joint contracture after immobilization in humans. The investigators described in a series of case reports the presence of fibrofatty connective tissue in the infrapatellar fat pad, suprapatellar pouch, and posterior recesses of the knee joint with eventual obliteration of the joint cavity. Over time, this tissue was replaced with mature fibrous connective tissue.

Tissue homeostasis is maintained by the normal level of cell growth and proliferation along with the production and turnover of the extracellular matrix.[20,22] Polypeptides known as cytokines or growth factors are responsible for the constant signaling that occurs both between local cells (paracrine) and within cells (autocrine). Cytokines exist as

CRITICAL POINTS Pathophysiology and Experimental Prevention Studies

- Cytokines or growth factors responsible for constant signaling occurring both between local cells and within cells.
- TGF-β is a key cytokine that initiates and ends process of tissue repair. Its actions enhance the deposition of extracellular matrix and regulate the actions of other cytokines.
- Overexpression of TGF-β1 results in progressive accumulation of matrix in tissues and an elevated number of myofibroblasts, leading to fibrosis.
- Specific ASMA-expressing myofibroblasts generate tissue contraction, are responsible for collagen overproduction during fibrotic diseases. TGF-β is capable of upregulating ASMA and collagen in fibroblasts.
- ASMA is involved in scar formation and scar tissue contraction during the course of primary arthrofibrosis.
- Collagen type VI could play a contributory role in the deposition of extracellular matrix that leads to arthrofibrosis.
- Primary arthrofibrosis may be the result of an immune response.
- The effectiveness of various agents such as decorin, hyaluronic acid, chitosan, mitomycin C, and various IL-1 receptor antagonists (anakinra), as well as low-dose irradiation, in high-level human studies for early or later-stage arthrofibrosis has not been investigated to date.
- It is hopeful that chemical agents will become available to treat fibrotic response to injury by controlling elevated levels of myofibroblast up regulators and fibrogenic growth factors.

small proteins that signal cells in response to injury and infection. One cytokine, interleukin-1 (IL-1), has been found to stimulate platelets and macrophages to release a variety of growth factors, including transforming growth factor-β (TGF-β). TGF-β is thought to be one of the factors (among others[26,82,153]) mediating Dupuytren's contracture.[2] Cytokines regulate all aspects of tissue remodeling and may act positively or negatively on tissue damage. This variability results in a wide range of potential responses to injury among patients.

TGF-β, released by platelets, tendon fibroblasts,[168,169] and the joint capsule,[63,64] has been identified as a key cytokine that both initiates and ends the process of tissue repair. Although other growth factors are involved in tissue remodeling, TGF-β is unique in its actions that enhance the deposition of extracellular matrix and regulate the actions of other cytokines.[144,169] An overexpression of TGF-β_1 results in progressive accumulation of matrix in tissues and an elevated number of myofibroblasts, leading to fibrosis.[20,22,63,64,72,73,84,109,190] Border and Noble[20] believe that repeated injury or trauma may also cause autoinduction of TGF-β beyond normal levels, creating a "chronic, vicious circle of TGF-β overproduction" resulting in tissue fibrosis that may also occur in organ systems such as the kidney, liver, and lung. Investigators have documented that elevated levels of myofibroblasts and TGF-β occur rapidly, within 2 weeks following injury in experimental models, and that these changes are similar to those observed in humans with chronic elbow joint contractures.[63,72,73]

Zeichen and coworkers[194] compared tissue samples of 13 patients with arthrofibrosis obtained a mean of 16 months after the inciting knee ligament surgery with those of 8 patients undergoing primary ACL surgery. Histologic examination from the patients with arthrofibrosis showed marked synovial hyperplasia, infiltration of inflammatory cells, and vascular proliferation with an increased level of collagen types VI and III. None of the control subjects demonstrated these findings. These authors noted that this confirmed the observations of Murakami and associates[110] regarding the association between an inflammatory process and proliferation of fibroblasts. The suggestion was made that collagen type VI could play a contributory role in the deposition of extracellular matrix that leads to arthrofibrosis.

There is evidence that during the exaggerated fibrotic response that occurs in knee arthrofibrosis, a certain amount of tissue contraction or shrinkage occurs.[23,137,162] Specific α-smooth muscle actin (ASMA)-expressing myofibroblasts generate tissue contraction during wound healing and are responsible for collagen overproduction during fibrotic diseases.[39,45,50,58] TGF-β is capable of up regulating ASMA and collagen in fibroblasts.

Unterhauser and associates[182] measured the amount of ASMA-containing fibroblastic cells in arthrofibrotic tissue to determine whether the number of these cells was increased over that found in normal tissue. Tissue biopsies were obtained from 9 patients who underwent surgery for arthrofibrosis that had developed after ACL reconstruction. The patients all had primary arthrofibrosis and underwent the debridement procedure between 4 and 12 months after the ACL reconstruction. Tissue samples were also taken from 5 patients who underwent ACL reconstruction for chronic ligament deficiency and from 8 patients who had follow-up arthroscopy after ACL reconstruction for meniscus pathology; all 13 of these control patients showed no signs of arthrofibrosis. Significantly higher expressions of ASMA-positive fibroblastic cells were found in the collagen bundles and remaining fatty tissue in the study group compared with both control groups (23.4% of the total cell count vs 2.3% and 10.8%, respectively; $P < .001$). These authors concluded that this cell type is involved in scar formation and scar tissue contraction during the course of primary arthrofibrosis. They speculated that the expression of ASMA is most likely variable according to the time from the onset of the disease to tissue biopsy and probably decreases as the disease progresses.

Unterhauser and associates[182] also reported that the fatty tissues in the arthrofibrotic knees were replaced by a dense collageneous network with parallel fiber orientation. A significantly higher total cell count and lower vessel density were measured in the arthrofibrotic knees compared with the control group that underwent ACL reconstruction. Similar findings were noted by Mariani and colleagues[96] who biopsied 17 knees with arthrofibrosis that occurred after a variety of surgical procedures. The tissue samples were obtained less than 6 months from the onset of stiffness in 9 patients, from 6 to 12 months in 5 patients, and more than 12 months in 4 patients. The histological evaluations demonstrated collagen-producing fibroblastic tissue with differing amounts of cellularity and vascularization. This study supports the hypothesis that arthrofibrotic tissue undergoes progressive remodeling and acquires the characteristics of mature collagen, all within the first 6 months after the onset of joint stiffness. There was no association between the amount of knee motion and time from surgery or the degree of tissue maturation. The severity of loss of motion was associated only with the location and amount of adhesive tissue in the knee joint.

Many investigations have suggested that antifibrotic agents may be of potential use in preventing or combating arthrofibrosis because they inhibit the TGF-β signaling pathway.[1,13,28,56,57,85,89,182,195] However, the effectiveness of various agents such as decorin, hyaluronic acid, chitosan, mitomycin C, and various IL-1 receptor antagonists in high-level human studies for early or later-stage arthrofibrosis has not been investigated to date.

The use of powerful antiinflammatory medications, typically used for rheumatoid arthritis, may be useful in the future in patients who do not respond to high doses of oral corticosteroids. Magnussen and coworkers[94] reported a series of four patients who were treated with an intraarticular injection of Kineret (anakinra), an IL-1 receptor antagonist, to treat persistent postoperative inflammation and scarring after ACL reconstruction. The injections were performed on postoperative days 36, 38, 41, and 97. The patients regained normal or nearly normal knee motion; three did not undergo other procedures but one did require debridement of scar tissue from the anterior compartment. Brown and associates[27] also used intraarticular anakinra injections in eight patients, four of whom had chronic refractory arthrofibrosis and four of whom had "limited" arthrofibrosis with varying results. There was no control group or validated rating system used, and range of motion and joint effusion were based on "clinician estimate." With so few data published to date, no recommendation can be made regarding the use of Kineret for knee arthrofibrosis at present.

Decorin is a human proteoglycan that has been shown in many experimental models to inactivate the effects of TGF-β and have a beneficial effect in arthrofibrotic tissues. Several years ago, Fukushima and coworkers[57] reported that injection of decorin improved both the muscle structure and function of lacerated muscle to near-complete recovery in mice. More recently, Zhang and associates[195] found that decorin reduced the effect of TGF-β in regard to intrinsic cell expansion in cultured synovial fluid explants from osteoarthritic knees. Abdel and colleagues[1] assessed the effects of four intraarticular injections of decorin that were performed 8 weeks after an operation that was done to induce a knee joint contracture in rabbits. There was no significant effect on improving the flexion contractures. However, genetic analysis showed a significant alteration in several fibrotic genes that were likely associated in the arthrofibrosis process. These authors suggested that earlier injection might produce better results in terms of preventing joint contractures. Several other experimental models have demonstrated the effectiveness of decorin in inhibiting adhesion

formation in intraarticular adhesions,[55] skeletal muscle injury,[87,196] kidneys,[21,79] and lungs.[60] There are no current human trials on the use of decorin for the prevention or treatment of knee arthrofibrosis.

Emami and coworkers[47] investigated the effects of bevacizumab (Avastin), an agent that inhibits vascular endothelial growth factor, on preventing arthrofibrosis after surgery in a rabbit model. Given in either one or two injections, these authors reported reduced joint fibrosis, with better clinical and histological findings in the two-injection group. This was especially evident in the statistically significant reduced number of fibroblasts ($P = .002$), inflammatory cells ($P = .01$), vascularity ($P < .05$), and collagenous matrix deposition ($P < .05$).

Liang and colleagues[89] applied topical hydroxycamptothecin, a chemotherapeutic drug, to rabbit knees in an attempt to prevent intraarticular adhesions after surgery in which cortical bone was removed from the femoral condyles. After 4 weeks, there was a significant reduction of adhesions in knees that received 1.0 mg/mL or 2.0 mg/mL compared with lower doses and controls ($P<.05$). Another well-known chemotherapeutic agent, mitomycin C, was investigated by Yan and coworkers[192] in the rabbit model. The agent was applied following removal of cortical bone from the femoral condyle and the effects evaluated 4 weeks later. There was a dose-dependent significant effect on suppression of the formation of adhesions, with 0.1 mg/mL required to reduce the adhesion score, the hydroxyproline content, and the fibroblast number compared with controls.

Wang and associates[188] studied the effects of weekly intraarticular injections of 0.3 mL hyaluronic acid in immobilized rabbit knees performed for 8 weeks. Compared with the control group, the experimental group had significantly greater range of motion ($P = .002$), a lower mean adhesion score ($P = .01$), and lower mean collagen content ($P = .001$).

In a small animal model, Bedair and associates[13] showed that an angiotensin II systemic receptor blocker decreased fibrosis and enhanced muscle regeneration in acutely injured skeletal muscle and hypothesized that the blocker modulated TGF-β_1. Hagiwara and colleagues[64] reported that the joint capsule has the potential to produce TGF-β_1 and connective tissue growth factor, both of which play a role in causing fibrosis.

Two small case series used a single dose of low-level irradiation (700 to 800 rads) before repeat revision TKA in patients with long-standing arthrofibrosis.[9,51] The idea was derived from the established use of low-dose irradiation for the prevention of heterotopic ossification before total hip arthroplasty in high-risk patients,[10,139,185] and the potential effects of irradiation in preventing the differentiation of mesenchymal stem cells into osteoblastic precursors.[11] Farid and associates[51] employed this treatment method in 14 patients with severe idiopathic arthrofibrosis in an effort to suppress fibroblastic and fibroosseous proliferation postoperatively. Major improvements in knee motion and function were experienced in all but one patient, and there were no complications related to the irradiation therapy. Baier and colleagues[9] described three patients who had similar treatment and marked improvements in knee flexion. However, these authors cautioned that the influence of radioactivity on soft tissues has not been investigated, and bony nonunion may occur. Both series were retrospective, and no control group or randomization procedures were performed.

Bosch and colleagues[24] advanced the hypothesis that primary arthrofibrosis is the result of an immune response. Tissue samples obtained from 18 patients between 4 and 48 months from the triggering event to surgical debridement demonstrated synovial hyperplasia with fibrotic enlargement of the subintima and infiltration of inflammatory cells. These authors believed their findings supported an immune response as the cause of capsulitis leading to formation of diffuse scar tissue. The clinical implication was to avoid further surgery or aggressive manipulation while patients have acute capsulitis and to wait 3 to 6 months for the inflammatory response to resolve before debridement is considered. As is discussed, too often, there is a delay in treatment that results in a permanent limitation of knee motion. Unfortunately, even though a delay in treatment may allow tissues to "quiet down," the resulting fibrotic tissue that forms becomes well organized and dense and treatment is thus more difficult. It is anticipated that in the future, chemical agents will become available to treat fibrotic response to injury by controlling elevated levels of myofibroblast upregulators and fibrogenic growth factors.[1,13,32,47,53,57,63,72,73,88,112,195]

PREVENTION

Preoperative

Following an acute ACL tear and before reconstruction, the surgeon-therapist team must manage pain, effusion, quadriceps weakness, knee motion limitations, and gait abnormalities. Knee joint effusion and hemarthrosis are treated with appropriate nonsteroidal antiinflammatory medications (NSAIDs), cryotherapy, compression, and limb elevation. Patients are taught safe and effective muscle strengthening exercises (such as straight-leg raises, bicycling, minisquats, wall sits, calf raises, and knee extensions from 90 to 30 degrees) and must demonstrate good quadriceps control without an extensor lag before consideration is made for surgery. Regaining normal or nearly normal knee motion is essential and may take several weeks after an ACL rupture. The exceptions are knees with a mechanical block to motion, such as a displaced meniscus tear, in which early surgical intervention is warranted to preserve and repair the meniscus. A decision regarding future ACL reconstruction is based on the patient's activity goals and other factors (see Chapter 7). Other exceptions are knees with concomitant posterolateral ligament ruptures who are candidates for surgical intervention within 7 to 10 days of the injury (see Chapter 17). Knees with concomitant MCL tears are treated conservatively for at

CRITICAL POINTS Prevention

Preoperative

- After ACL injury, surgeon-therapist team manages pain, effusion, quadriceps weakness, knee motion limitations, gait abnormalities, other knee ligament injuries before ACL reconstruction.

Intraoperative

- Principles of correct graft placement, tensioning, and fixation are paramount to avoid a limitation of knee motion postoperatively.
- ACL graft placed within the femoral and tibial footprint, occupying the central two thirds or more, Limited notchplasty usually required.
- Femoral tunnel: anteromedial portal or a two-incision procedure favored.
- ACL graft conditioning: approximately 44-N tension placed on the distal graft sutures, knee flexed from 0 to 120 degrees for 30 flexion-extension cycles. Arthroscope verifies ideal graft position, no impingement against the lateral femoral condyle or notch with full hyperextension.

Postoperative

- First weeks: control knee joint pain and swelling, regain adequate quadriceps muscle contraction, initiate immediate knee motion exercises, and maintain adequate limb elevation.
- Goal: achieve 0 to 90 degrees of knee motion by the seventh postoperative day. Begin overpressure program immediately if goal not obtained.

least 4 to 8 weeks to allow the medial-side structures to heal and regain motion and muscle strength before proceeding to ACL reconstruction (see Chapter 19).

Intraoperative

The principles of correct graft placement, tensioning, and fixation are paramount to avoid a limitation of knee motion postoperatively (see Chapter 7). The ACL graft is placed within the femoral and tibial footprint, occupying the central two thirds or more of the footprint, to achieve an anatomic position that allows the graft to control the pivot shift and anterior tibial translation. To achieve an anatomic graft placement in the center of the tibial attachment frequently requires a limited notchplasty to avoid a limitation of knee extension. For the femoral tunnel, an anteromedial portal drilling technique or a two-incision procedure is favored to obtain a central anatomic femoral footprint placement. An endoscopic transtibial drilling technique is not recommended.[70,95] In nearly all chronic ACL-deficient knees, there is an overgrowth of cartilage and spur formation in the femoral notch, which necessitates a notchplasty to prevent ACL graft impingement.

The ACL graft is conditioned after femoral fixation by placing approximately 44-N tension on the distal graft sutures and flexing the knee from 0 to 120 degrees for 30 flexion-extension cycles. The arthroscope is used to verify that the graft position is ideal and there is no impingement against the lateral femoral condyle or notch with full hyperextension. The knee is placed at 20-degree flexion, and the tension on the graft is reduced to approximately 10 to 15 N to avoid overconstraining anteroposterior (AP) tibial translation. Alternatively, the graft can be tensioned to a higher load with knee extension. After graft fixation, a Lachman test is performed and anterior tibial translation of 2 to 3 mm should be elicited, indicating that the graft has not been over-tightened. If the graft has a "bow-string," tight appearance with no anterior tibial translation on testing, the distal tensioning and fixation procedure is repeated with less tension placed on the graft.

In knees that undergo concomitant meniscus repair, the sutures are tied with the knee at 30 degrees of flexion to prevent capsular shortening or increased pain with postoperative extension exercises. If an associated medial or lateral ligament reconstruction is required, care is taken to avoid overtensioning the tissues and grafts and to place a graft in the correct position on the femur (with the isometric point determined at surgery) to allow restoration of normal knee flexion (see Chapter 7). Posteromedial and posterolateral capsular plication procedures are performed in a manner that will not result in a limitation of knee extension, which is tested at the operative table.

Postoperative

The first week following ACL or other knee ligament reconstruction represents a critical time period for patients to control knee joint pain and swelling, regain adequate quadriceps muscle contraction, initiate immediate knee motion exercises, and maintain adequate limb elevation (see Chapter 11). A bulky compression dressing (cotton-Ace elastic bandage) is used for 48 hours followed by antiembolic compression stockings and a supplemental Ace bandage. Cryotherapy is begun in the recovery room after surgery. NSAIDs are used for 5 days along with pain medication to allow the immediate exercise protocol to be successfully implemented. Electrogalvanic stimulation or high-volt electrical muscle stimulation may be used along with ice, compression, and elevation to control swelling.[134]

Beginning on the first postoperative day, patients perform passive and active range of motion exercises in a seated position for 10 minutes a session, approximately four to six times per day. This is accompanied by patellar glides (mobilization), which are performed in all four planes (superior, inferior, medial, and lateral) with sustained pressure applied to the appropriate patellar border for at least 10 seconds (Fig. 38-5). The goal is to achieve 0 to 90 degrees of knee motion by the seventh postoperative day. Patients who are unable to achieve this amount of extension and flexion are immediately placed into an overpressure motion program, described in detail later in this chapter. In our experience, the exercises and modalities in the overpressure program resolve the majority of knee motion limitations when initiated early postoperatively. In 650 knees that underwent ACL reconstruction described elsewhere in this chapter, only 18 (3%) required a gentle manipulation under anesthesia, and 6 (<1%) underwent surgical debridement and lysis of adhesions after the overpressure program failed to resolve knee motion limitations.

FIG 38-5 Patellar mobilization is performed by the therapist during physical therapy visits and at home by the patient or family member several times daily.

Hamstring and gastrocnemius-soleus flexibility exercises are begun immediately, as are straight-leg raises in all four planes of hip movement. With a semitendinosus-gracilis tendon harvest, hamstring strengthening is delayed for 4 weeks. Partial weight bearing is permitted as long as pain and swelling are controlled and a voluntary quadriceps contraction demonstrated. Isometric quadriceps contractions are also begun the first postoperative day and are performed on an hourly basis following the repetition rules of 10-second holds, 10 repetitions, 10 times per day. The remainder of the rehabilitation program is detailed in Chapter 11.

DIAGNOSIS AND CLINICAL PRESENTATION

The early detection of a limitation of knee motion after ACL reconstruction is paramount for resolving the problem and preventing permanent arthrofibrosis. The establishment of specific knee flexion and extension goals according to the amount of time that has elapsed postoperatively and concurrent major operative procedures performed is required. In all knees, full passive knee extension must be obtained immediately to avoid excessive fibrous tissue proliferation in the intercondylar notch and posterior capsular contracture. In patients with physiologic bilateral knee hyperextension, we recommend the gradual return of 3 to 5 degrees of hyperextension in the reconstructed knee and not more than 5 degrees of hyperextension owing to potentially deleterious forces on the healing graft. Specific range of knee motion goals after ACL reconstruction (Table 38-5) are communicated to the patient before surgery and during postoperative assessments. Knee motion is carefully documented by the therapist in a closely supervised

TABLE 38-5 Our Goals for Restoration of Knee Motion After Anterior Cruciate Ligament Reconstruction

Operative Procedure Details	Weeks Postoperative	Range of Knee Motion Goal (Degrees)*
ACL B-PT-B autograft reconstruction, isolated or with meniscus repair, patient desires to return to strenuous athletics as soon as possible	1-2	0-110
	3-4	0-120
	5-6	0-135
ACL revision reconstruction (any graft source) or ACL primary reconstruction (with allograft or semitendinosus autograft) or complex reconstructions with concomitant operative procedures, or knees with noteworthy articular cartilage lesions	1-4	0-90
	5-6	0-120
	7-8	0-135
ACL reconstruction with posterior cruciate ligament reconstruction (see Chapter 16)	1-2	0-90
	3-4	0-110
	5-6	0-120
	7-8	0-135
ACL reconstruction with posterolateral procedure (see Chapter 17)	1-4	0-90
	5-6	0-110
	7-8	0-120
	9-12	0-135

*In patients with physiologic bilateral knee hyperextension, we recommend the gradual return of 3-5 degrees of hyperextension in the reconstructed knee. Greater than 5 degrees of hyperextension is not recommended owing to potentially deleterious forces placed on the healing graft.

ACL, Anterior cruciate ligament; *B-PT-B*, bone-patellar tendon-bone.

CRITICAL POINTS Diagnosis and Clinical Presentation

- Early detection limitation of knee motion after ACL reconstruction is paramount for resolving the problem.
- Full passive knee extension is obtained immediately to avoid excessive fibrous tissue proliferation in the intercondylar notch, posterior capsular contracture.
- Joint aspiration with cell analysis and culture for any indication of joint redness, warmth, limitation of knee motion.
- Initial phase primary arthrofibrosis (transient) occurs within first few weeks after surgery. Limitations in knee motion usually resolve with conservative measures with compliant patient.
- If not treated, condition becomes more established, requires operative management. Findings:
  - Shortening of the posteromedial and posterolateral capsule, ACL graft, quadriceps muscles
  - Significant ingrowth fibroproliferative tissue into intercondylar notch
- Comprehensive debridement and lysis of adhesions, inpatient epidural and physical therapy program, and weeks of outpatient therapy may be successful in achieving significant gains in knee motion.
- Final phase of arthrofibrosis (established) involves patellar infera and articular cartilage damage. Requires comprehensive evaluation, appropriate radiographs, bone scans, and MRI. Determine patellar vertical height, location grafts, and presence cyclops lesion.

postoperative rehabilitation program so that detection of a knee motion problem occurs in a timely manner. Failure to meet these goals prompts entering the patient in an overpressure program using appropriate medical and therapeutic measures to be described.

Joint aspiration with cell analysis and culture is important with any indication of joint redness, warmth, and limitation of knee motion. A serum sedimentation rate is usually not reliable after surgery because it is elevated for a number of weeks. After this time period, repeat studies for sedimentation rate, C-reactive protein, and other inflammatory mediates may be required. If surgery is required, multiple tissue specimens are sent for culture and microscopic evaluation. As already discussed, an occult infectious process is not excluded by a single negative joint aspirate, and repeat joint aspirations, culture, and blood studies are required.

The initial phase of primary arthrofibrosis occurs within the first few weeks after surgery. The condition at this time period is transient because limitations in knee flexion and extension are usually resolved with conservative measures as long as the patient complies with the recommended program. However, if knee motion deficits are left untreated for a few weeks, the condition becomes more established and eventually requires operative management. Findings include shortening of the posteromedial and posterolateral capsule blocking extension, significant ingrowth of fibroproliferative tissue into the intercondylar notch, shortening of the ACL graft preventing normal anterior tibial translation with extension, obliteration of the suprapatellar pouch, and shortening of the quadriceps muscles limiting flexion. A comprehensive debridement and lysis of adhesions, followed by an inpatient epidural and physical therapy program and many weeks of continued outpatient therapy, may still be successful in achieving significant gains in knee motion. The final phase of arthrofibrosis involves patellar infera and articular cartilage damage, which are exceedingly difficult to treat and the loss of knee motion is usually permanent.

Patients who present with an established arthrofibrosis condition require a comprehensive evaluation, including appropriate radiographs (Fig. 38-6), bone scans, and magnetic resonance imaging (MRI) to determine whether the condition is primary or secondary, as previously discussed. The examination may demonstrate diffuse edema, increased warmth, constant pain, limited patellar mobility (Fig. 38-7), contracture of peripatellar and infrapatellar soft tissues, tenderness in the fat pad, and limits in both extension and flexion compared with the contralateral normal knee (Fig. 38-8). Anterior knee pain, stiffness, pain with attempted knee motion, a flexed-knee gait, and severe quadriceps atrophy are common findings.

Patellar vertical height is determined using the radiographic method described by Caton and coworkers[31] and Linclau.[90] The left side of Figure 38-9 shows that the patellar vertical-height ratio is calculated by dividing line segment A, the distance between the most ventral rim of the tibial plateau and the lowest end of the patellar articular surface, by line segment B, the maximum length of the patellar articular surface. An alternative method described by Blackburne and Peel[17] locates the tibial reference point at an anterior central location on the tibial plateau (shown in Fig. 38-9 as line segment C). Using this method, the patellar vertical-height ratio equals C/B. The senior author (F.R.N.) conducted a study to determine normal right to left patellar vertical-height ratios within the same individual in a group of 51 patients (102 knees).[130] The difference in the vertical-height ratio of

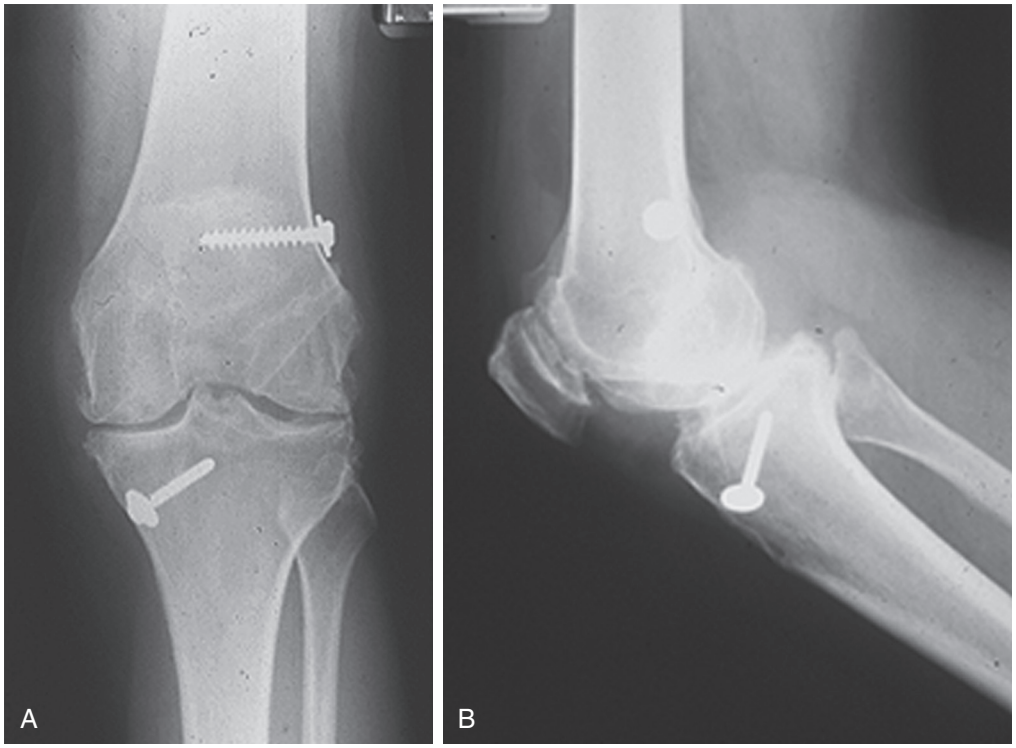

FIG 38-6 Anteroposterior (**A**) and lateral (**B**) radiographs of a knee with a severe flexion contracture and development of advanced joint arthritis after anterior cruciate ligament reconstruction. The patient was not a candidate for surgical soft tissue releases and subsequently underwent total knee arthroplasty.

FIG 38-7 Limited patellar mobility is demonstrated in this patient, referred after undergoing anterior cruciate ligament reconstruction elsewhere. The normal patellar medial glide allows at least 10 to 15 mm medial translation with the knee at 20 degrees of flexion. A normal lateral glide of up to 10 to 15 mm is possible. A loss of either medial or lateral translation occurs with contracture of peripatellar tissues. There is usually a limitation of proximal-distal glide because of an infrapatellar contracture.

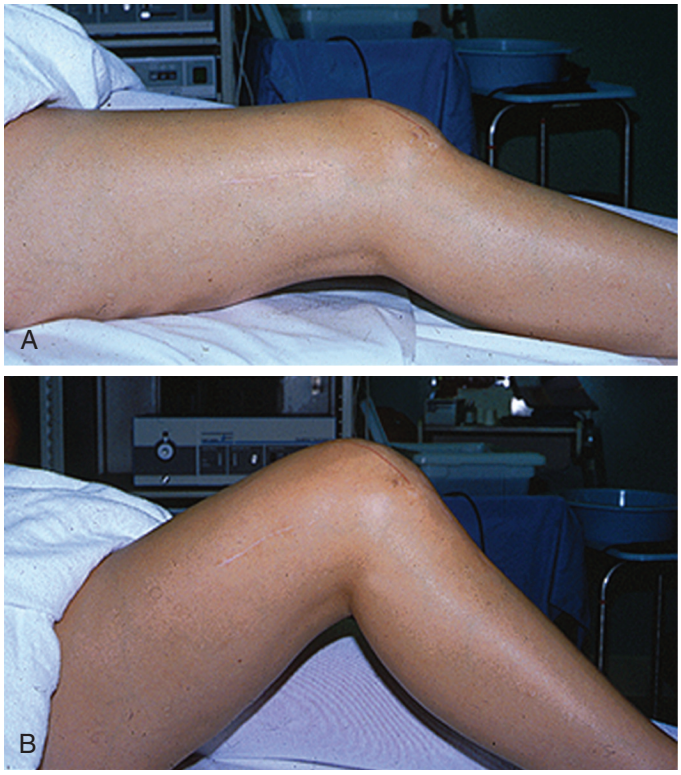

FIG 38-8 A severe limitation of knee extension (**A**) and flexion (**B**) demonstrated after anterior cruciate ligament (ACL) reconstruction in a patient referred for treatment 10 weeks after surgery. An arthroscopic debridement, lysis of adhesions, and posteromedial and capsular releases were required. Unfortunately, the motion deficits were not resolved in the first few weeks after ACL surgery.

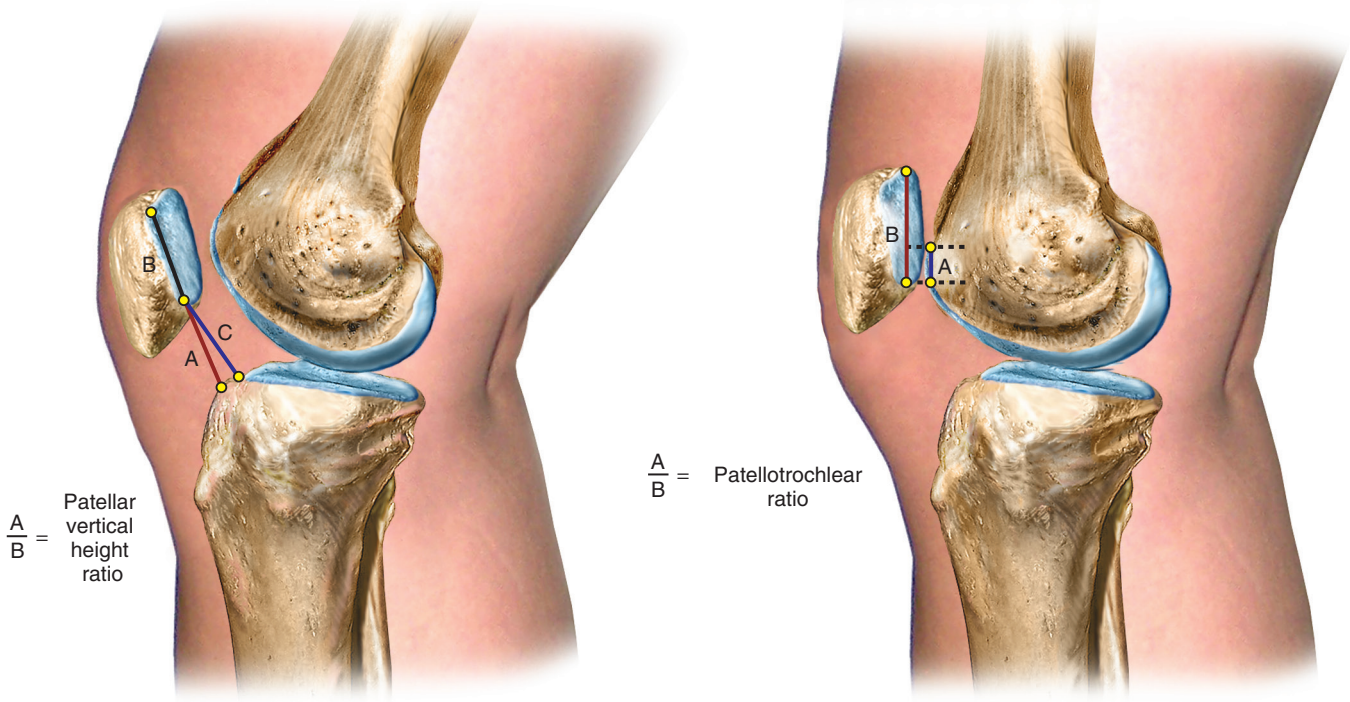

FIG 38-9 Methods used to determine patellar vertical-height ratio on a lateral radiograph. **Left,** The numerator (*line A, Linclau-Caton*) is the distance between the most ventral (anterosuperior) rim of the tibial plateau and the lowest end of the patellar articular surface. The denominator (*line B*) is the maximum length of the patellar articular surface. An alternative numerator (*line C, Blackburne-Peel*) locates the tibial reference point on the middle of the tibial plateau. The patellar vertical-height ratio equals A/B or C/B. **Right,** The numerator (*A*) is the superior-most aspect of the trochlear cartilage that is in contact with *line B*. The denominator (*line B*) is the maximum length of the articular patellar surface. Using this method, the mean index is 32% ± 12%, more than 50% is a patellar infera, and less than 12% is a patella alta.[15]

the patella between these two methods ranged from 0% to 9%, with an average difference of 3%. Large variations existed in the ratios among individual patients (range, 0.75-1.46). Therefore, the diagnosis of patellar infera requires comparison of patellar height ratios compared with those of the opposite knee and subsequent radiographs compared with the same knee at different time periods (Fig. 38-10). A decrease in the vertical height ratio of 14% to 15%, depending on the method used (Table 38-6), indicates a patella infera condition because this amount of difference is greater than 2 standard deviations of the normal difference between knees. An alternative method for the calculation of patellar height is the patellotrochlear index,[15] expressed as a percentage at knee extension (see Fig. 38-9).

MRI is useful in assessing the extent and location of scar tissue formation (Fig. 38-11). The infrapatellar band of scar tissue frequently found in the patellar infera state is just anterior to the fat pad and attaches from the inferior patellar pole to the anterior aspect of the tibia. Obliteration of the fat pad, with the patellar tendon attaching directly to the anterior tibia, is a poor prognostic sign because the patella may adhere to the proximal tibia, which markedly restricts medial-to-lateral mobility. Thick peripatellar tissues are frequently observed. The location of prior ACL or posterior cruciate ligament grafts must be determined. Important signs of an infectious process or unexplained edema and fluid in soft tissues or bone or about fixation implants are specifically evaluated to exclude an infectious etiology.

Patients who present with arthrofibrosis secondary to a cyclops lesion (fibrous fatty notch reactive tissues) or an impinged or improperly placed ACL graft require surgical debridement of the lesion or graft and scar tissue, followed by several months of physical therapy to regain normal knee motion and muscle function. The decision may then be made regarding the necessity for revision ACL reconstruction. In addition, patients with established primary arthrofibrosis require surgical management of the condition, described in detail elsewhere. These two groups of patients will not be successfully managed with conservative treatment measures. However, patients who fail to meet the knee motion goals established after ACL reconstruction (see Table 38-5) and in whom the arthrofibrosis is in the early, transient stage may usually be effectively treated with the exercises and modalities described later. The key is the early detection of the limitation of knee motion, as soon as the seventh postoperative day if 0 to 90 degrees is not demonstrated.

CONSERVATIVE MANAGMENT OF LIMITATION OF KNEE EXTENSION

If the patient has not achieved at least 0 degrees by the seventh postoperative day, she or he is placed into an overpressure extension program. The goal is to produce a gradual stretching of posterior capsular tissues, but not to induce soft tissue tearing and further injury because this could lead to an inflammatory response and worsen the condition. One effective exercise involves hanging weights, in which the foot and ankle are propped on a towel or other device to elevate the hamstrings and gastrocnemius, which allows the knee to drop into

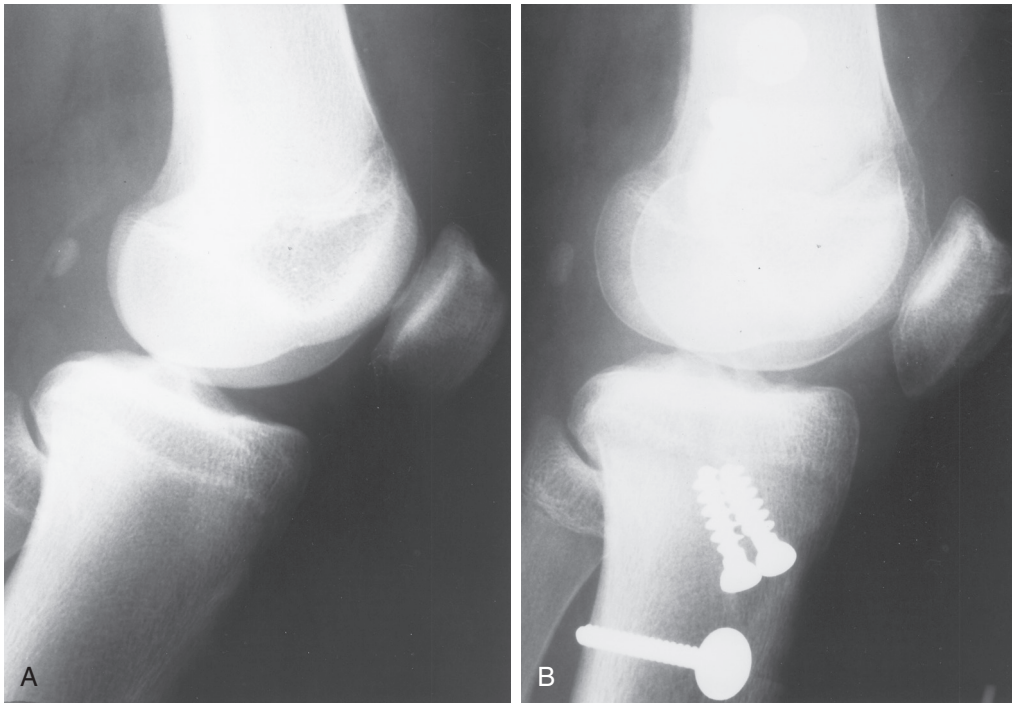

FIG 38-10 Lateral radiographs document a 22% decrease in patellar vertical-height ratio after a combined anterior cruciate ligament reconstruction and medial meniscus repair in a 14-year-old female gymnast. **A,** The injured knee before the reconstruction. **B,** Four weeks postoperative, the patient was referred to our center with significant quadriceps atrophy, difficulty performing knee motion exercises, and limited patellar mobility. The patient was treated with daily physical therapy and required an arthroscopic debridement, peripatellar release, lysis of adhesions, and removal of infrapatellar scar tissue. Nine months postoperative, the patient had regained full knee motion, had no pain symptoms, and had returned to recreational activities. However, the patellar infera remained unchanged. The patient is being followed for signs of patellofemoral arthritis and need for further treatment. (From Noyes FR, Wojtys EM, Marshall MT. The early diagnosis and treatment of developmental patella infera syndrome. *Clin Orthop.* 1991;265:241-52.)

TABLE 38-6 Differences among Three Radiographic Methods of Computing Patellar Vertical Height Ratios

Method	Pairs (*n*)	Knee	Patellar Ligament Length (Range)	Patellar Length (Range)	Ratio (Range)	Difference Right/Left Ratios (Range)	Difference Within 2 SDs (95% of Population)
Linclau[90]	51	Right	3.65 ± 0.46 (2.70-4.70)	3.54 ± 0.37 (2.80-4.20)	1.04 ± 0.13 (0.75-1.36)	–0.0200 ± 0.070 (–0.2100 to 0.135)	15%
		Left	3.69 ± 0.46 (2.90-4.70)	3.51 ± 0.33 (2.70-4.20)	1.06 ± 0.15 (0.80-1.46)

SD, Standard deviation.

full extension (Fig. 38-12, *A*). This position is maintained for 10 to 15 minutes and repeated at least eight times per day. Initially a 10-lb weight is used, which may be progressed up to 25 lb to the distal thigh and knee to provide overpressure to stretch the posterior contracted tissues. Full knee extension is usually obtained by the second to third postoperative week. A commercial extension appliance (see Fig. 38-12, *B*) is also an option.

If these treatment measures are not effective, a drop-out (bivalved) cast (see Fig. 38-12, *C*) is implemented for continuous extension overpressure. The advantage of this technique is that the patient is in control of the process and can apply or remove wedge material as tolerated and may bathe. A hyperextension splint may be used in the same manner; however, we believe that the bivalved cast offers superior benefits. Casting is not recommended in knees that have greater than

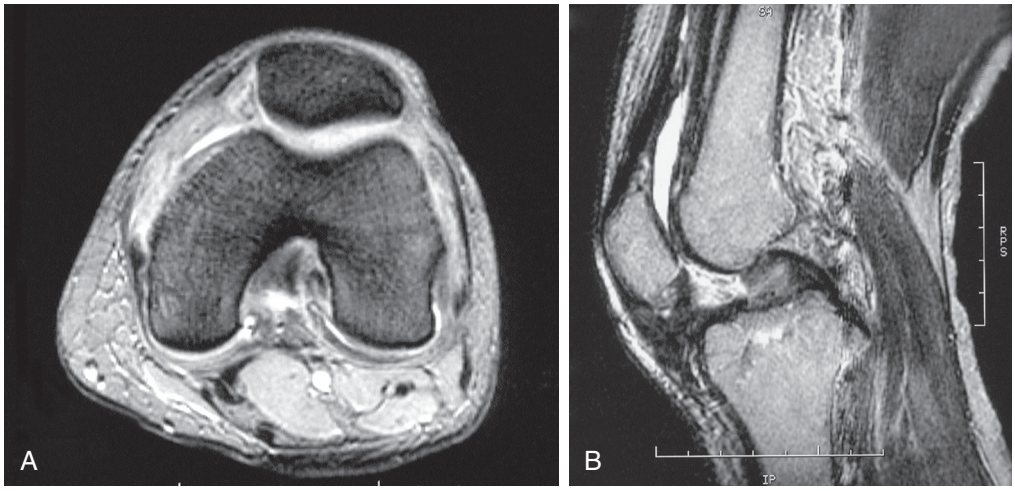

FIG 38-11 Magnetic resonance imaging of a knee with patella infera. **A,** Thickening of the medial and lateral peripatellar tissues. **B,** Note the infrapatellar tissues are replaced with dense fibrotic connective tissue. There is loss of the normal patellar tendon outline because the tendon is encased with scar tissue and attached to the proximal tibia. The infrapatellar scar extends from the inferior pole to the anterior tibia. This patient required arthroscopic debridement of the suprapatellar pouch, followed by open debridement of infrapatellar scar tissue and Z-plasty lengthening of the medial and lateral parapatellar tissues. The decrease in patellar tendon length is permanent.

CRITICAL POINTS Conservative Management of Limitation of Knee Extension

- If at least 0 degrees not achieved by the seventh postoperative day, the patient is placed into an overpressure extension program. Goal is to produce gradual stretching of posterior capsular tissues but not induce soft tissue tearing and further injury because this could lead to an inflammatory response and worsen the condition.
- Hanging weights: foot and ankle propped on a towel to elevate the hamstrings and gastrocnemius allows the knee to drop into full extension; use 10-25 lb weight on distal thigh.
- Bivalved cast (within first 4 weeks) if hanging weight is ineffective. Not used in knees that have more than –12 degrees extension deficit with a hard block to terminal extension or in knees with proliferative ingrowth of fibrous tissue in the femoral notch. These knees require posterior capsulotomy through a limited medial and lateral approach.
- Cylinder cast, if bivalved cast ineffective. Applied at 36-48 hours; anterior wedges used. Convert to night splint for 7-10 days.

a –12 degree extension deficit with a hard block to terminal extension. These knees are usually 3 or more months postoperative, and dense scar tissue has formed posteriorly with posterior capsular contracture requiring surgical releases and debridement. In knees with a rigid block to extension, extension casts have the potential to produce high tibiofemoral compressive forces and articular cartilage damage. Extension casts are also not effective when there is proliferative ingrowth of fibrous tissue in the femoral notch. These cases require arthroscopic debridement.

When indicated, the cast is used within the first 4 weeks for cases resistant to the other overpressure extension modalities. The goal is to resolve all extension problems by 4 weeks postoperatively. In select knees, the extension deficit may return and, accordingly, the drop-out cast is repeated. On occasion, the drop-out cast will not be effective and it is necessary to use a cylinder cast and serial wedges to gain extension. The cast is well padded to prevent skin breakdown. An anterior wedge is used every 12 to 24 hours to gradually achieve extension. The cast is applied for 36 to 48 hours and then removed to resume knee flexion and extension motion exercises. Once extension is regained, the cast is converted into a posterior night splint, which is used for an additional 7 to 10 days. In some knees, full extension is regained but then gradually lost over the course of several weeks. In these cases, a repeat cast application may resolve the problem.

The treatment algorithm for limitations of knee extension is shown in Figure 38-13. The goal is to resolve the loss of knee extension by 4 weeks using the modalities outlined. Frequently, it is necessary to repeat steps in the treatment protocol because the return in a knee extension deficit may occur. It is rare that manipulation or continuous epidural is necessary when the program is followed; however, these steps are provided for the most resistant cases. The most difficult problem is the knee joint that does not respond and, despite the overpressure program, continues to show a lack of full extension. If the lack of knee extension is 10 degrees or less, the overpressure program will usually be successful. However, it is important to identify the knee in which there is a rigid hard block to extension and the deficit is greater than 10 degrees. In these knees, it is better to proceed with a posterior capsulotomy through a limited medial and lateral approach, to be described.

CONSERVATIVE MANAGEMENT OF LIMITATION OF KNEE FLEXION

Because full knee flexion is present at the end of the ACL reconstruction, any limitation in the early postoperative period is because of intraarticular adhesions and contracture of peripatellar tissues and muscle spasm or pain. The early detection of a limitation of flexion (<90 degrees by the seventh postoperative day) necessitates an

FIG 38-12 **A,** Hanging weights. **B,** Extension board. **C,** Drop-out cast.

overpressure flexion program. A rolling stool exercise (Fig. 38-14, *A*) may be done in which the patient sits on a small stool close to the ground, the knee is flexed to the maximum position possible and held in that position for approximately 1 minute or as long as the patient is able to tolerate mild discomfort. Then the patient rolls the stool forward without moving the foot position on the floor to achieve a few more degrees of flexion. The procedure is performed for 10 to 12 minutes and repeated six to eight times a day. Wall slides are another effective exercise to achieve flexion. The patient lies on his or her back and places the foot of the reconstructed knee on a wall as shown in Figure 38-14, *B*. The foot of the opposite leg is used to gently slide the opposite foot and flex the reconstructed knee in a gradual manner. Commercial knee flexion devices (see Fig. 38-14, *C* and *D*) may also

CRITICAL POINTS Conservative Management of Limitation of Knee Flexion

- Overpressure program indicated <90 degrees flexion by seventh postoperative day.
- Rolling stool exercise, wall-slides, commercial knee flexion devices, figure-four exercise usually effective.
- Patients who have <90 degrees by 3-4 weeks require a gentle ranging of the knee under anesthesia (not a forceful manipulation) in which full flexion is easily obtained with only light loads applied.
- Associated peripatellar contracture must be immediately treated to prevent patella infera.
- Knees with no patellar mobility: operative release of tight contracture peripatellar tissues indicated.
- Chronic cases of arthrofibrosis and retinacular contracture usually require open medial and lateral Z-plasty release.

be used as available to further promote overpressure. In addition, a figure-four overpressure exercise is effective (Fig. 38-14, *E*). A 4-inch tubular stocking is used, double wrapped around the foot and ankle, which allows the patient under his or her own power to flex the knee. The patient shown in Figure 38-14, *E* had 90 degrees of flexion, and an arthroscopic release was successful in achieving 135 degrees. After the debridement and placement of an epidural, the surgeon sets a mark on the thigh by gentle pressure to establish the flexion goal for that day. The mark on the thigh in the photograph demonstrates the 135-degree flexion position, which is the overall goal. The mark on the distal portion of the patella in the photograph demonstrates the starting position, which in this case was 90 degrees. The goal of these exercises and modalities is to gradually and passively stretch tissues in a controlled manner while not inducing pain or tearing of tissues. Patients who have difficulty achieving 90 degrees by the third to fourth week require a gentle ranging of the knee under anesthesia (not a forceful manipulation) in which full flexion is easily obtained with only light loads applied. This stretches out early joint adhesions, markedly reduces postoperative pain, and allows the patient to regain motion.

The treatment algorithm for a limitation of knee flexion is shown in Figure 38-15. The first step is to determine whether there is associated contracture of patellar tissues, which makes the treatment more difficult. The loss of knee flexion when there is no peripatellar contracture is more easily resolved. With the treatment protocol shown, it is rare to progress to the necessity for an arthroscopic debridement and release of peripatellar tissues. When there is an associated peripatellar contracture, it is important that the condition be immediately treated because this can result in a patella infera. A conservative patellar mobilization program with oral steroids is performed for 1 week. If the limitation of motion and peripatellar contracture persists, a gentle manipulation under anesthesia is performed; however, no more than "two to three fingers of pressure" is placed at the distal tibia to achieve knee flexion. If more force is necessary, it indicates that the peripatellar contracture is composed of more dense, resistant scar that requires arthroscopic debridement. An aggressive manipulation under higher forces risks damaging the patellofemoral articular cartilage because the tight contracted tissues increase patellofemoral contact forces with knee flexion. Knee flexion is gained but at the expense of possibly damaging the patellofemoral joint. This is also true for pushing knee flexion in the clinic when there is no patellar mobility. Again, an operative release of tight contracture peripatellar tissues is indicated instead of overzealous flexion exercises or a knee manipulation under high flexion loads.

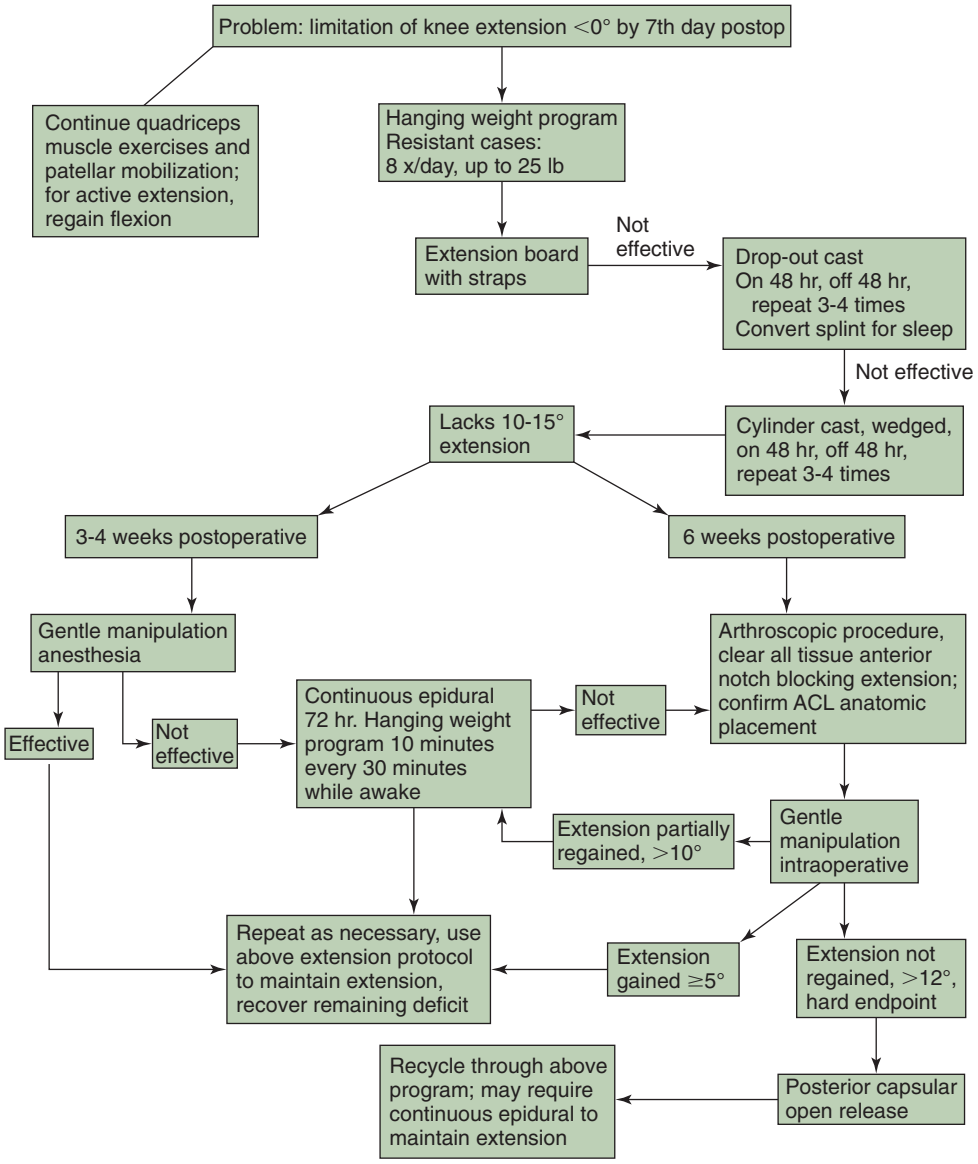

FIG 38-13 Treatment algorithm for limitations of knee extension. *ACL,* Anterior cruciate ligament.

It should be noted that there are select knees, most commonly chronic cases of arthrofibrosis, in which the peripatellar scar tissue is thick and contracted and an attempted arthroscopic release would result in too extensive a release on both the medial and lateral peripatellar tissues. If a major release is necessary, extending to the proximal aspect of the patella, the senior author recommends an open medial Z-plasty release in which the more normal tissue laxity is restored and the abnormal scar tissue is excised. The Z-plasty frequently involves contracted vastus medialis obliquus (VMO) and vastus lateralist obliquus (VLO) tissues. In addition, the Z-plasty procedure prevents the occurrence of a major capsular defect with joint communication to subcutaneous tissues, which is a complication of an extensive medial or lateral arthroscopic release.

ROLE OF ORAL CORTICOSTEROIDS

There is a subset of patients who develop an exaggerated postoperative inflammatory soft tissue response with excessive pain, joint stiffness,

CRITICAL POINTS Role of Oral Corticosteroids

- Indications: knees with exaggerated inflammatory soft tissue response with excessive pain, joint stiffness, soft tissue edema, warmth, and redness about the joint.
- Inflammation not resolved by cryotherapy, antiinflammatory medications, elevation, and compression.
- A 6-day 4-mg Medrol Dosepak is effective if used early. Avoid forceful and aggressive physical therapy.
- Consider oral corticosteroids at elevated doses for 4 weeks if the inflammatory symptoms return or are more severe.
- In cases of severe arthrofibrosis, oral corticosteroids may be required for 2 to 3 months in an effort to avoid repeat surgery.

FIG 38-14 **A,** Rolling stool exercise. **B,** Wall-slides. **C,** Flexion seat. **D,** Knee flexion overpressure device. **E,** Figure-four knee flexion overpressure exercise.

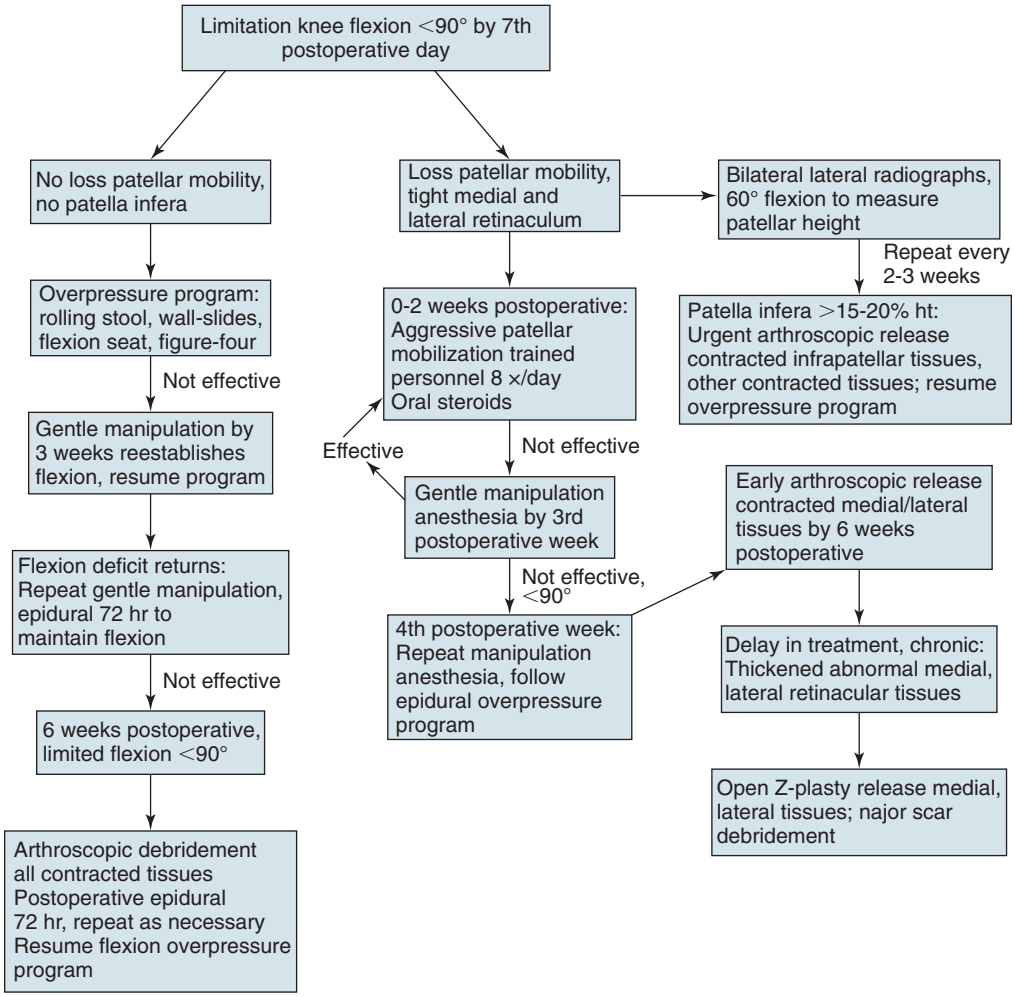

FIG 38-15 Treatment algorithm for a limitation of knee flexion.

soft tissue edema, warmth, and redness about the knee. The inflammation is not resolved by the standard treatment methods of cryotherapy, antiinflammatory medications, elevation, and compression. It is first recommended to use a maximum dose of NSAID for 1 week. If this is not successful, a trial of oral steroids is indicated. It is important that before and during the treatment of these resistant cases, an occult infectious process is ruled out, with appropriate serial diagnostic tests (aspiration, serum inflammatory tests) performed as necessary.

A 6-day 4-mg Medrol Dosepak (methylprednisolone) is effective if used early in the phase. Six tablets are taken on the first day of treatment, five on the second, four on the third, three on the fourth, two on the fifth, and one on the sixth. During this treatment period, forceful and aggressive physical therapy is avoided. Gentle knee motion and lighter overpressure exercises are performed. In select cases, the 6-day dose pack may be repeated.

Another option is to use elevated doses of oral corticosteroids for 4 weeks if the inflammatory symptoms return or are more severe. The usual daily dose is 30 mg in the first week (two tablets taken three times a day), 15 mg in the second (one tablet taken three times a day), 10 mg in the third (one tablet taken two times a day), and 5 mg in the fourth. In cases of severe arthrofibrosis, oral corticosteroids may be required for 2 to 3 months in an effort to avoid repeat surgery. Complications that may arise from prolonged corticosteroid intake include pituitary adrenal suppression, fluid and electrolyte disturbance, hyperglycemia, peptic ulcers, and avascular necrosis. In the most resistant cases, it is necessary to repeat oral steroid cycling on the off days to NSAIDs, which are prescribed at their maximum dosage.

GENTLE MANIPULATION UNDER ANESTHESIA

As already described, a forceful manipulation of a knee with extensive scar tissue is harmful and ineffective in treating the limitation of knee

CRITICAL POINTS Gentle Manipulation Under Antesthsia

- Forceful manipulation of a knee with extensive scar tissue is harmful and ineffective in treating the limitation of motion.
- Patients with a hard stop to knee motion (joint contracture) are treated with arthroscopic debridement, lysis of adhesions.
- A gentle manipulation under anesthesia, done with only mild pressure exerted on the distal leg, is effective if performed within 3-4 weeks postoperatively.
- Supervised physical therapy program required to maintain the knee motion achieved by the manipulation.

motion. A forced manipulation may tear intraarticular and extraarticular tissues and cause excessive tibiofemoral and patellofemoral compression with the risk of fracture, damage to the articular cartilage, rupture of the patellar tendon, and even femoral fracture.[91] Therefore any patient who has a hard stop to knee motion (which represents a joint contracture) is treated with an arthroscopic debridement and lysis of adhesions.

A gentle manipulation under anesthesia, done with only mild pressure exerted on the distal leg, is effective if performed early after ligament surgery, within 3 to 4 postoperative weeks. Even at 6 weeks, there may exist dense scar tissue proliferation in joint soft tissues, and the window of opportunity has been lost to perform an early ranging of motion under general anesthesia. Adequate patellar mobilization must be established before flexing the knee during the procedure to prevent damage to the patellofemoral articular surface. A supervised physical therapy program is required to maintain the knee motion achieved by the manipulation as detailed in the treatment algorithm.

OPERATIVE MANAGEMENT OF SEVERE RESTRICTION OF KNEE MOTION

Arthroscopic Soft Tissue Releases

A demonstration of an arthroscopic technique for debridement of contracted tissues in a knee with arthrofibrosis is shown in Figure 38-16. In this patient, there was a restriction in medial-to-lateral translation (glide) of the patellofemoral joint, with a contracture of the medial and lateral retinaculum. However, approximately 50% of normal patellar mobility was still present, indicating that an arthroscopic technique could be used and an open extensive technique was not necessary. There were limitations of motion at 0/5/90 degrees. The procedure was performed after tourniquet inflation.

Open Z-Plasty, Medial-Lateral Retinacular Tissues

Figure 38-17 demonstrates the operative technique for an open Z-plasty release of the medial and lateral retinacular tissues. An arthroscopic release alone is contraindicated in this case because the release is so extensive (extending above the proximal patella and releasing all medial and lateral soft tissues) that there would be open communication of the joint into the subcutaneous tissues. The principal shown is to preserve the function of the medial and lateral retinacular soft tissues and, as well, debride the tissues to a normal thickness. The Z-plasty open release allows an arthrotomy to thoroughly debride infrapatellar contracted tissues, protect the patellar tendon, and lengthen contracted medial and lateral patellar tissues.

Posterior Medial-Lateral Capsulotomy

The technique for a posterior medial-lateral capsulotomy involves the same exposure as that used for a medial or lateral meniscus repair (Fig. 38-18). On the medial side, the posterior capsule is sectioned at its femoral attachment proximally. On the lateral side, the capsule is sectioned in its proximal aspect just below the attachment of the lateral gastrocnemius to the posterior capsule. The dissection and posterior capsule excision are carried directly over the posterior femoral condyles and not into the posterior intercondylar region because scar tissue may extend to the neurovascular structures. It is often impressive how dense the posterior capsular structures are, and with their release, further gains in knee extension are possible on the operating table. The remaining posterior intercondylar tissues are easily stretched with the overpressure program. The posterior capsule releases are also accompanied with an arthroscopic procedure to remove any tissue that has grown into the notch producing an anterior impingement that would also block extension.

INPATIENT PHYSICAL THERAPY PROGRAM

An inpatient physical therapy program supplemented with a continuous epidural anesthetic, a femoral nerve block, or appropriate analgesics may be used for 3 to 4 days in resistant cases that do not respond to other interventions or in whom limitations of knee motion return after manipulation or arthroscopic debridement. The epidural is regulated to block pain and sensory input, with the goal to retain muscle motor control to allow active knee motion and the overpressure program. The block requires close supervision by an anesthesiologist for levels and medication dosage. The catheter is replaced under fluoroscopy control if the patient expresses insufficient pain relief. If the repeat block fails, pain relief is obtained with a femoral nerve block and analgesics. A skin care and protection program is performed by nursing personnel. The block is maintained for a minimum of 72 hours to allow a gradual overpressure program to stretch contracted soft tissues.

The following measures are taken to avoid deep venous thrombosis and pulmonary embolism. First, a careful analysis is done to detect patients at increased risk, including diabetics; obese individuals; those with venous insufficiency; and patients with a family history or personal history of phlebitis, venous clots, or embolism. These patients are not appropriate candidates for the epidural program owing to the associated inactivity and bedrest. When the epidural is in place, the patient remains mobile and is encouraged to be out of the bed intermittently throughout the day. Antiembolism stockings are worn, and ankle pumps are done for 5 to 10 minutes hourly. The extremity is monitored daily, and a calf venous compression device is used. Aspirin (600 mg daily) is prescribed. The patient is monitored for calf tenderness or leg edema, and an ultrasound examination of both lower extremities is obtained if any suggestion of a deep venous thrombosis exists.

The inpatient overpressure program is contraindicated in patients with open growth plates or disuse osteopenia owing to the increased risk of a fracture. The patient is taught before the epidural how to perform the program and uses the amount of tension applied to the foot-calf stocking to achieve gains in knee flexion. It is important that other individuals such as the family not assist in the overpressure

Text continued on p. 1086

CRITICAL POINTS Inpatient Physical Therapy Program

- An inpatient physical therapy program supplemented with either a continuous epidural anesthetic, femoral nerve block, or appropriate analgesics may be used for 3-4 days in resistant cases who do not respond to other interventions or in whom limitations of knee motion return after manipulation or arthroscopic debridement.
- Contraindicated in patients with open growth plates or disuse osteopenia owing to the increased risk of a fracture.
- Block maintained at least 72 hours to allow a gradual overpressure program to stretch contracted soft tissues.
- Take appropriate measures to avoid deep venous thrombosis.
- Patient is taught before the epidural how to perform the overpressure program.
- Recommend active range of motion program by the patient; continuous passive motion machine rarely required.
- Leg lifts, isometric exercises performed while in the hospital.
- Exercises must be continued after discharge at home 8 times a day, along with supervised therapy program.

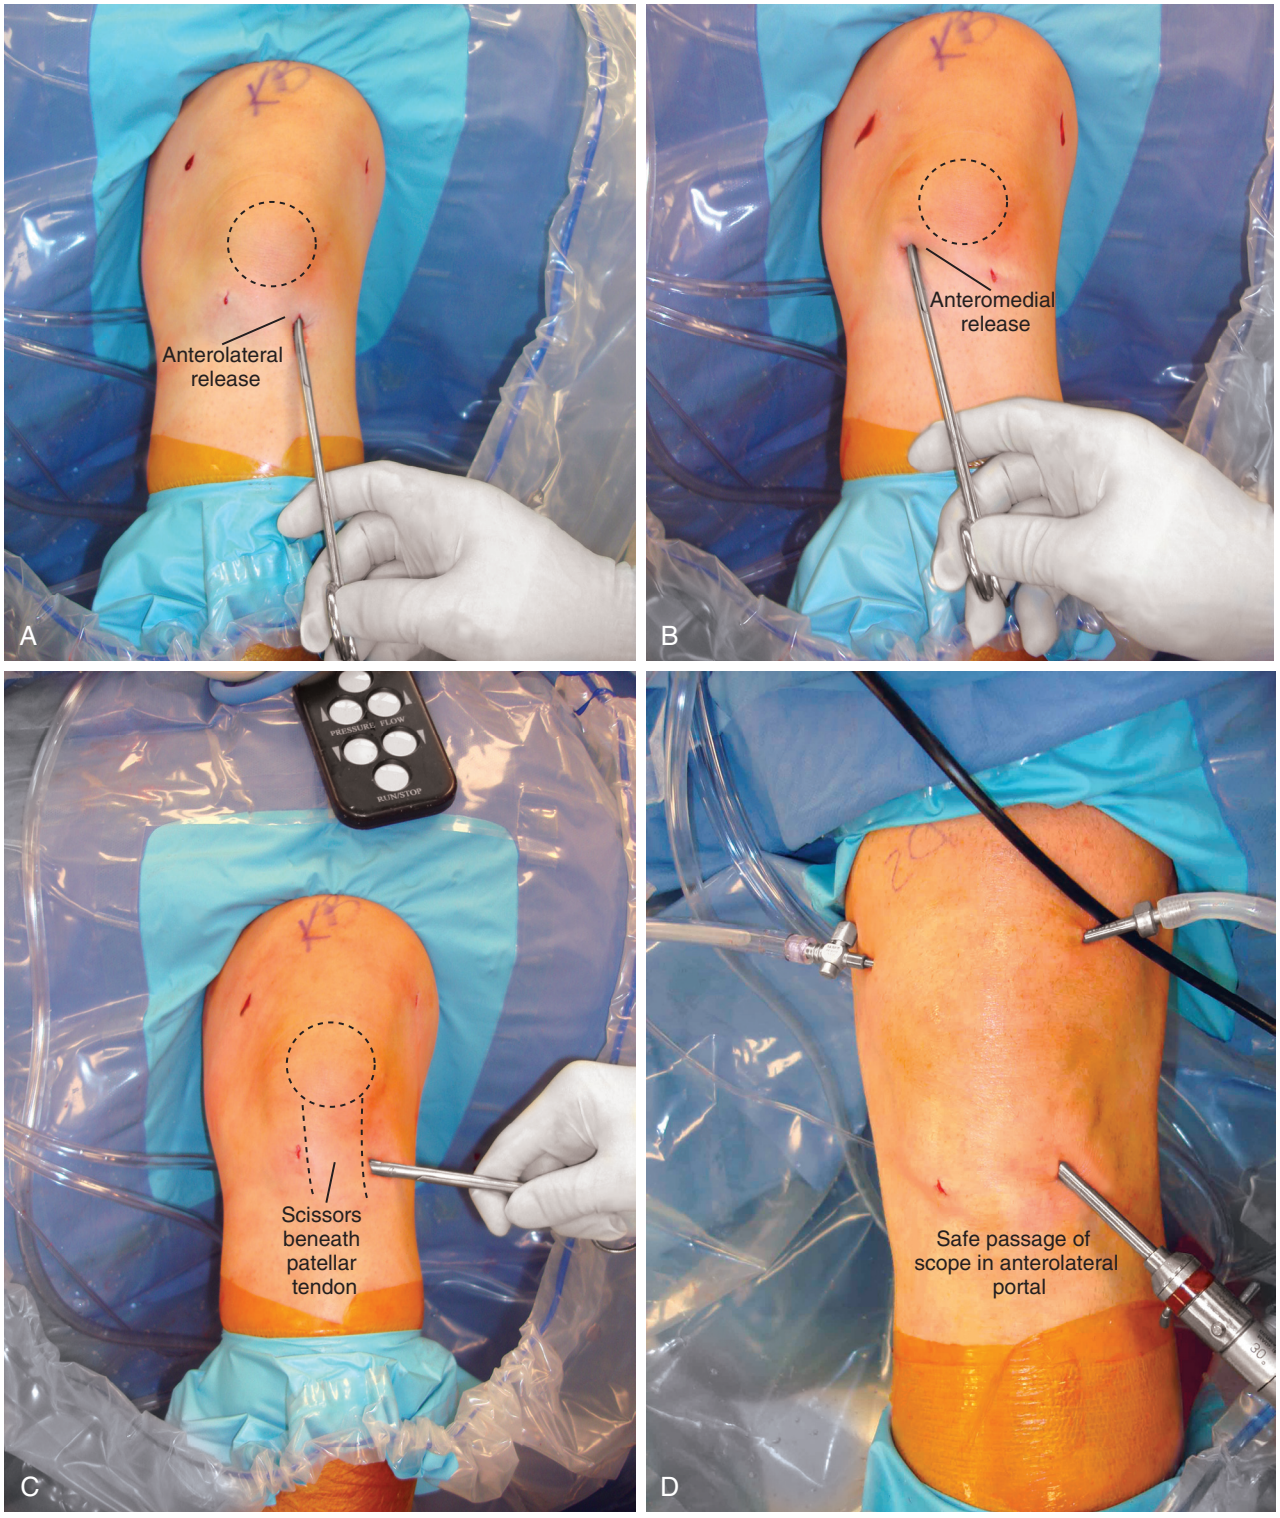

FIG 38-16 **A,** The anterolateral portal is used to transect the lateral retinaculum 15 mm. **B,** The anteromedial portal is used to transect the medial retinaculum 15 mm. **C,** The anterolateral portal is used to place a Metzenbaum scissor beneath the patellar tendon and palpate for an infrapatellar patella–tibial band of scar tissue. The scissor is bluntly pushed posterior to the patellar tendon and through the infrapatellar band to allow fluid to pass into the fatty space behind the patellar tendon. This maneuver protects the patellar tendon during removal of the infrapatellar band, to be described. If a safe plane cannot be established and verified arthroscopically, an open debridement procedure is indicated. **D,** There is now sufficient patellar mobility to pass an arthroscope beneath the patella safely without damaging the patellofemoral cartilage surfaces. If this is not possible, additional medial and lateral releases are performed. The releases at this point are conservative.

FIG 38-16, cont'd **E,** A blunt obturator or shaver is placed into the suprapatellar pouch and translated in a superior and inferior plane to reestablish a space sufficient for the initial arthroscopic debridement. A band of scar extends from the superior patella to the trochlea, and dense suprapatellar adhesions are present. Debridement of suprapatellar scar tissues is performed using an electrocuting device. **F,** The soft tissues and synovium over the anterior femur are not removed to leave a gliding soft tissue surface. **G,** A resection of scar tissue beneath the vastus medialis obliquus and vastus lateralis obliquus may be required because this scar can limit muscle mobility. **H,** The scope is placed in the superolateral portal to view the infrapatellar region and debride an infrapatellar contracture.

Continued

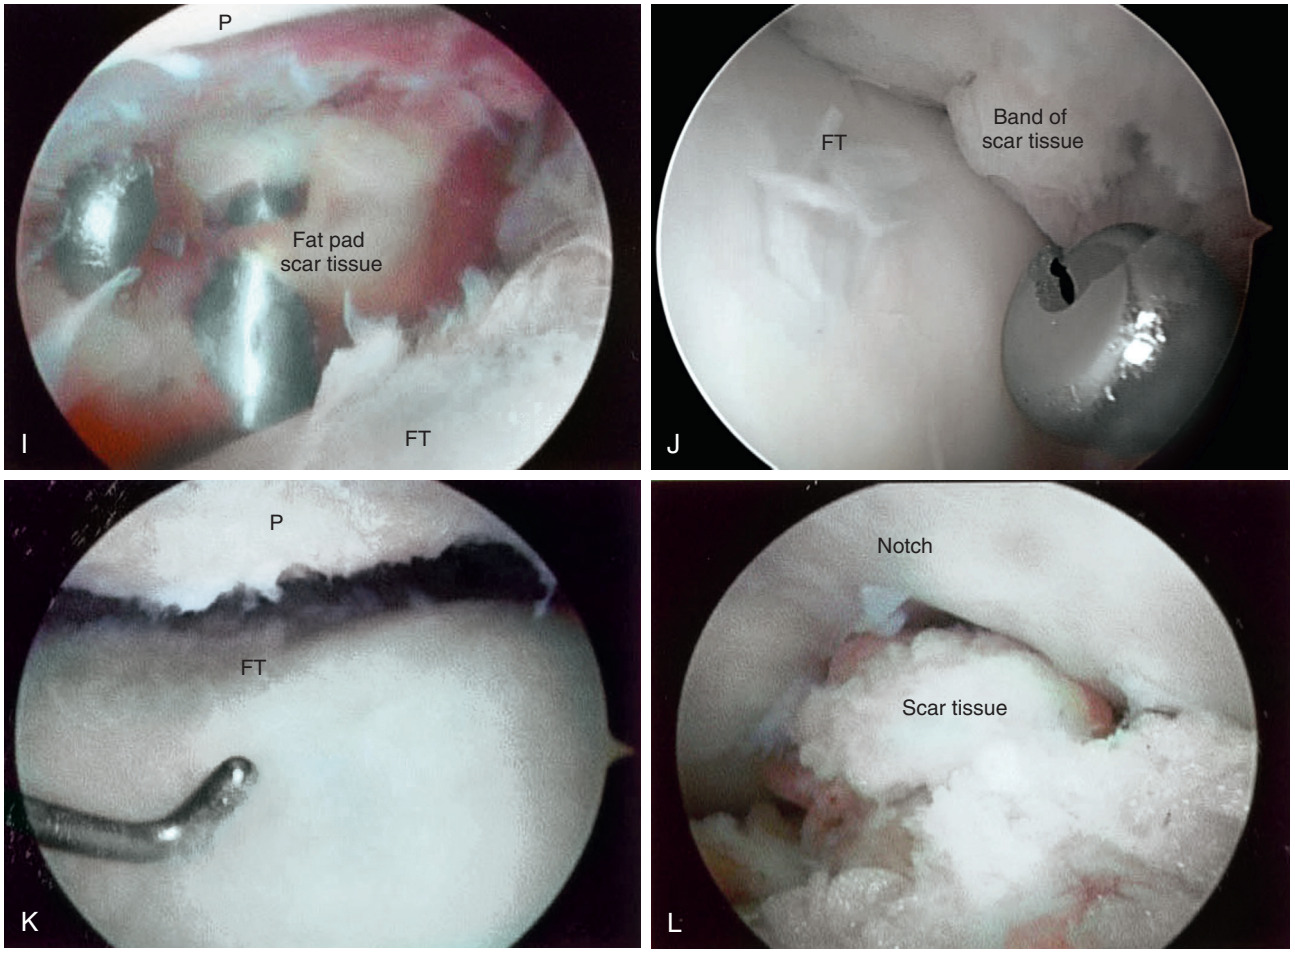

FIG 38-16, cont'd **I,** An arthroscopic view through the superolateral portal shows the fat pad and instruments to remove infrapatellar scar tissue. Care is taken to not transect the anterior medial and lateral meniscus attachments. **J,** With the scope placed alternatively in the anteromedial and anterolateral portals, extensive synovium and scar are removed from the medial and lateral recesses and intercondylar notch. Scar tissue proliferation may block extension on the anterior aspect of the medial and lateral meniscus; this requires removal. **K,** The knee is placed at 30 degrees flexion and sufficient medial and lateral parapatellar contracted tissue and retinaculum are removed to allow for a normal medial-lateral glide. This release rarely extends above the midportion of the patella. In this knee, moderate patellofemoral damage is observed. **L,** Notch ingrowth of tissue removed that may block extension. After completion of the arthroscopic procedure, and verification that no scar tissue remains, the tourniquet is deflated, and meticulous electrocoagulation of bleeding points is performed. The decision to use a drain is based on the ability to control intraarticular bleeding. A gentle ranging of the knee with the patient under anesthesia is performed that is not aggressive in terms of the loads applied. The knee is placed into a bulky compression (cotton-Ace-cotton-Ace) dressing with an ice bladder incorporated into the dressing. *FT,* Fibrous tissue; *P,* patella.

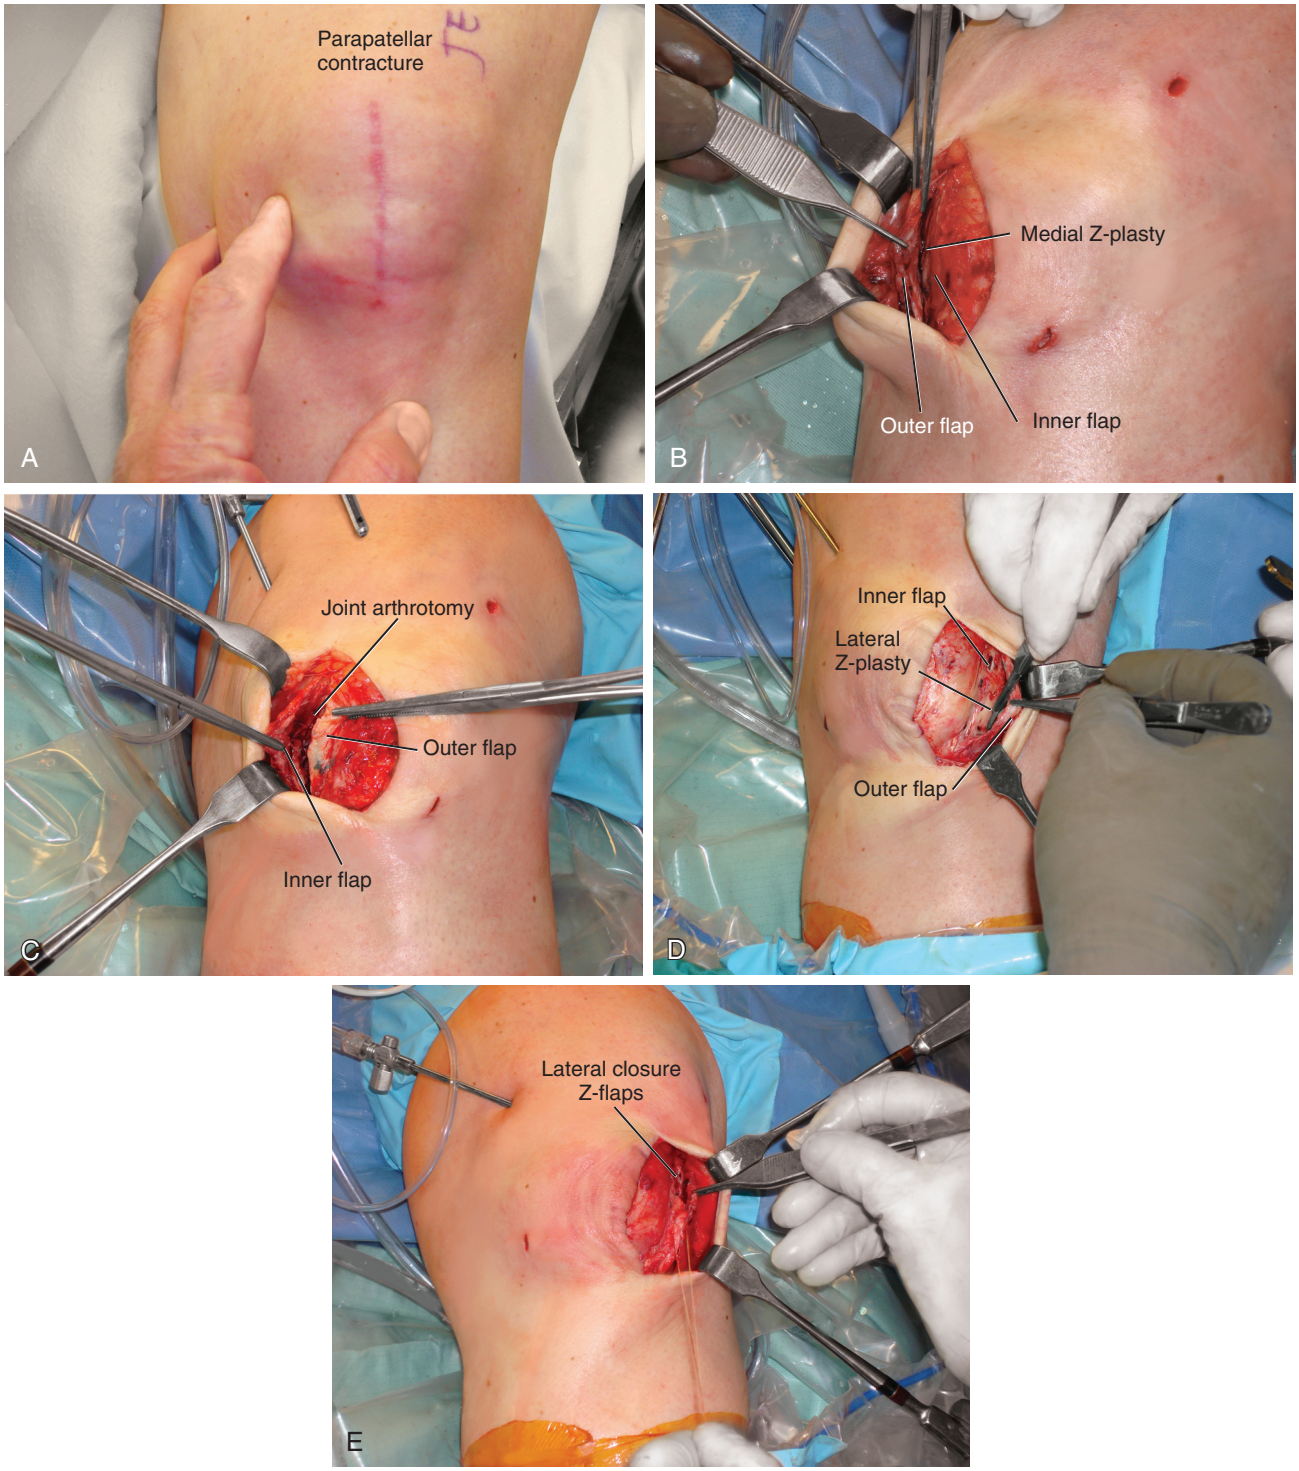

FIG 38-17 Z-plasty operative technique for contracted medial and lateral peripatellar tissues. **A,** Preoperative examination under anesthesia of a patient with established arthrofibrosis discloses a complete lack of patellar mobility, absent medial and lateral glide and an obvious patella infera with shortening of the patellar tendon. The patient's range of motion was 0/0/80 degrees. **B,** Open medial Z-plasty approach. The medial retinaculum and soft tissues are split in a Z-plasty fashion to allow a loose closure and restore a normal medial patellar glide. An arthroscopic procedure was performed just before the open procedure to reestablish the suprapatellar pouch, remove intraarticular adhesions within the suprapatellar pouch and medial and lateral tibiofemoral gutters, and document the condition of the joint. **C,** Completion of medial Z-plasty release shows the medial soft tissue flaps that have been developed. A debridement of infrapatellar scar tissue was performed under direct visualization. **D,** A lateral Z-plasty release of contracted lateral retinacular tissues is performed in a similar fashion. **E,** The loose closure of the lateral Z-plasty release allows restoration of a normal medial glide. A medial and lateral Z-plasty release for contracted soft tissues represents a real key for the successful management of this type of contracture. There is restoration of normal patellar mobility, and most important, the joint soft tissues can be closed.

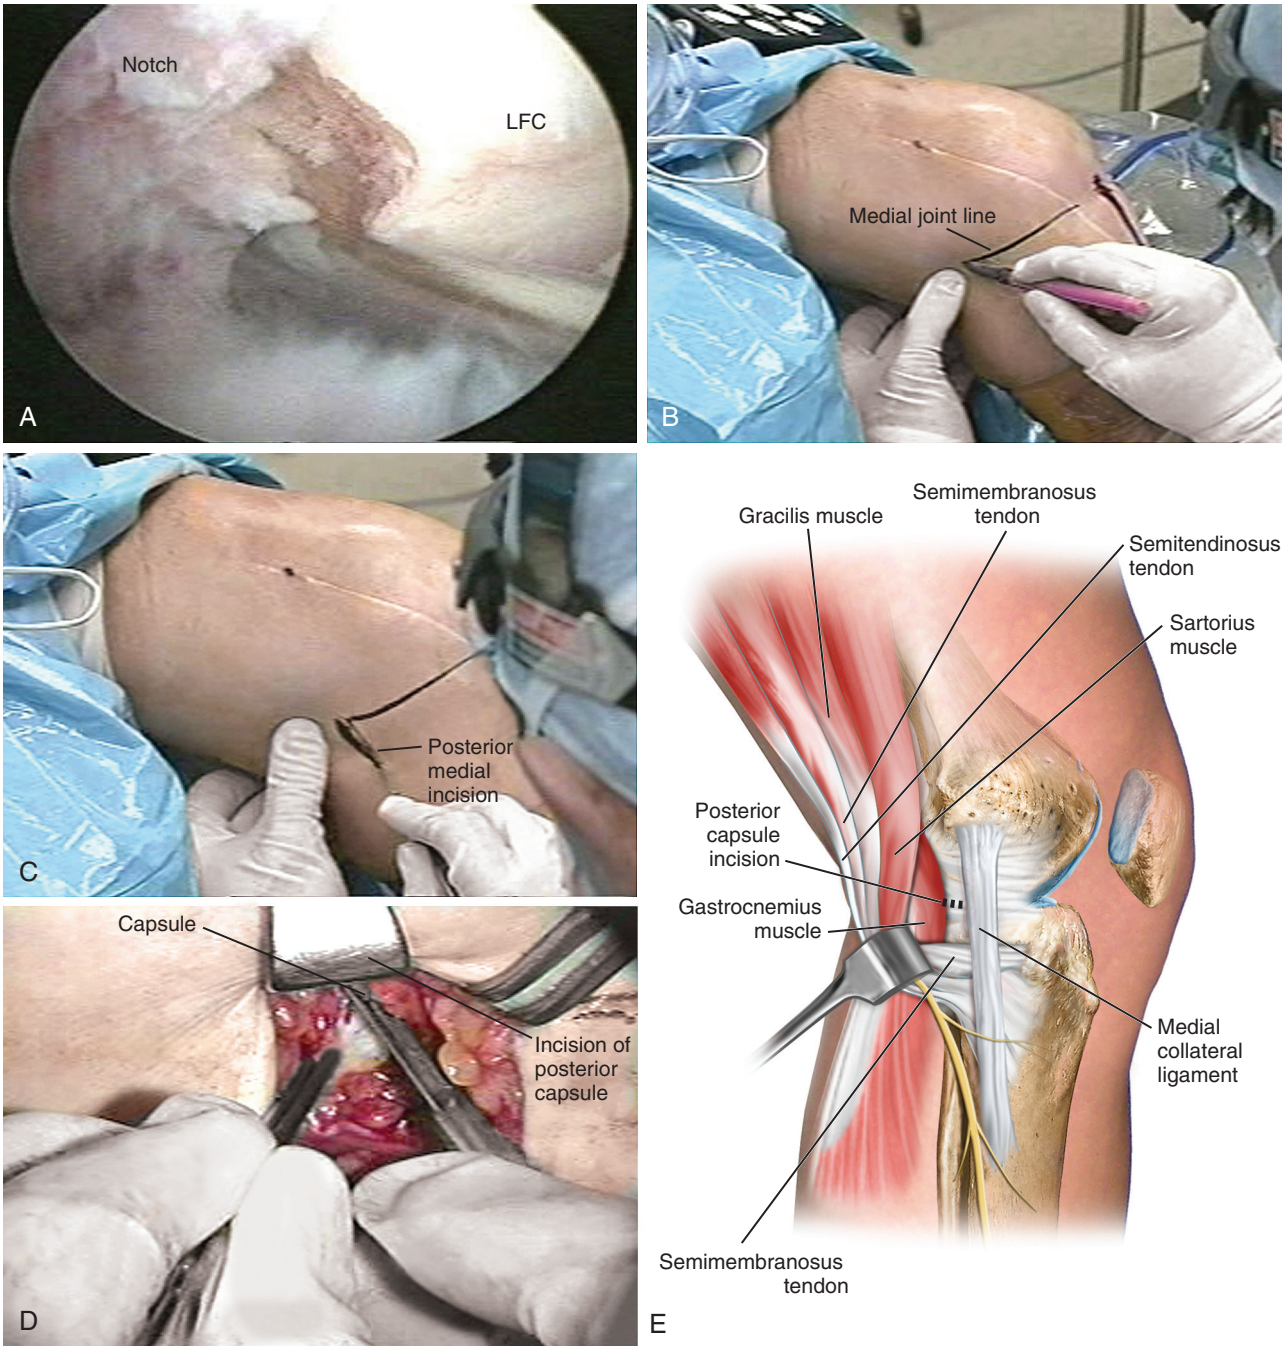

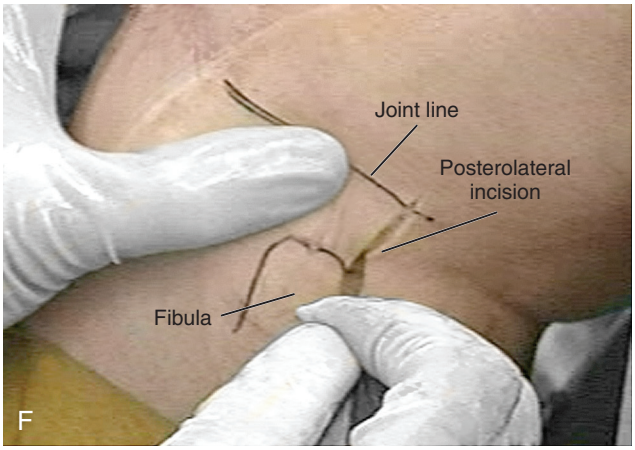

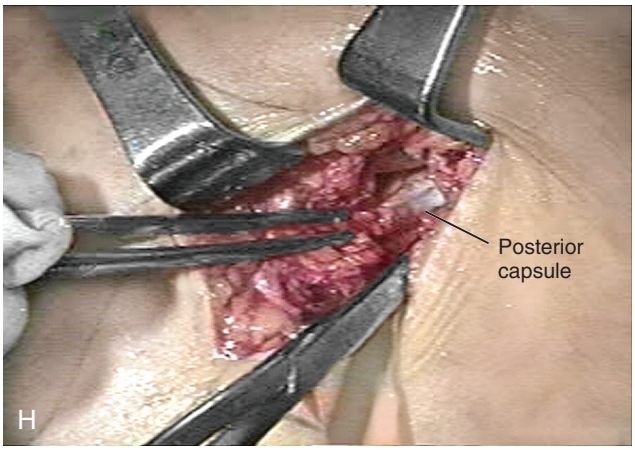

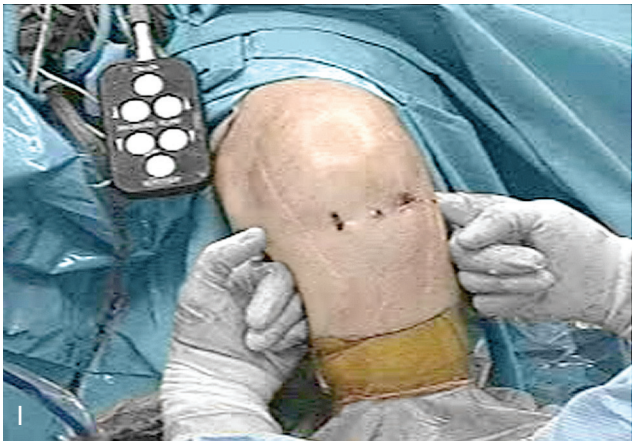

FIG 38-18 Operative photographs of a patient with arthrofibrosis (0/15/80 degrees) requiring an arthroscopic lysis of adhesions, parapatellar releases, and posterior medial and lateral capsulotomy for the 15 degrees flexion contracture. **A,** An arthroscopic lysis of adhesions, removal of scar tissue, and parapatellar releases is performed, as already described. All scar tissue from the notch region is removed and a notchplasty performed as required so that these tissues do not block extension. **B,** The medial joint line is marked. **C,** A posteromedial incision is made. **D,** The approach reflecting the sartorius is used as described for an inside-out medial meniscus repair (see Chapter 23). **E,** A vertical posteromedial capsulotomy is made directly behind the superficial medial collateral ligament. Operative photograph: The surgeon uses a headlamp and the femoral insertion of the posteromedial capsule is identified and transected millimeter by millimeter to the edge of the medial femoral condyle, but not beyond to avoid the neurovascular structures.

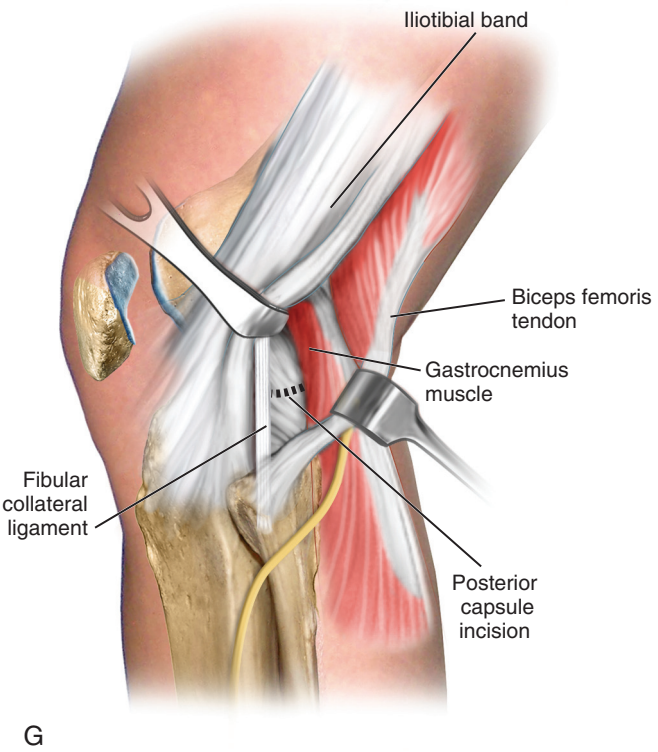

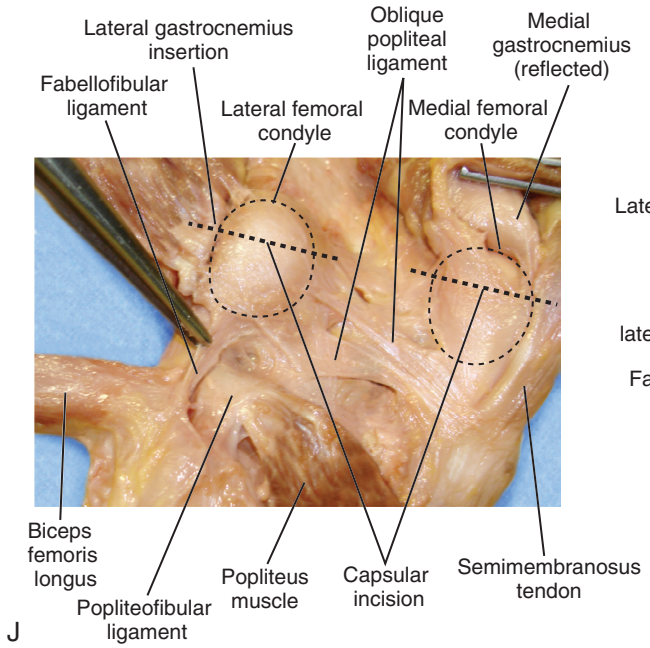

FIG 38-18, cont'd **F,** The posterolateral approach for a capsular release uses the same approach as that for a lateral meniscus repair (see Chapter 23) with a skin incision just distal to the joint line as shown. **G,** The posterolateral capsule anterior to the gastrocnemius tendon is identified. **H,** The posterolateral capsule is carefully incised under direct visualization to the edge of the lateral femoral condyle, avoiding the neurovascular structures. **I,** A finger is placed into the posteromedial and posterolateral incisions, and the central neurovascular structures can be palpated. The central posterior capsule anterior to the neurovascular structures is not released. The finger palpation confirms that the capsule directly posterior to the medial and lateral femoral condyles has been incised, removing this block to extension as the knee is extended.

Continued

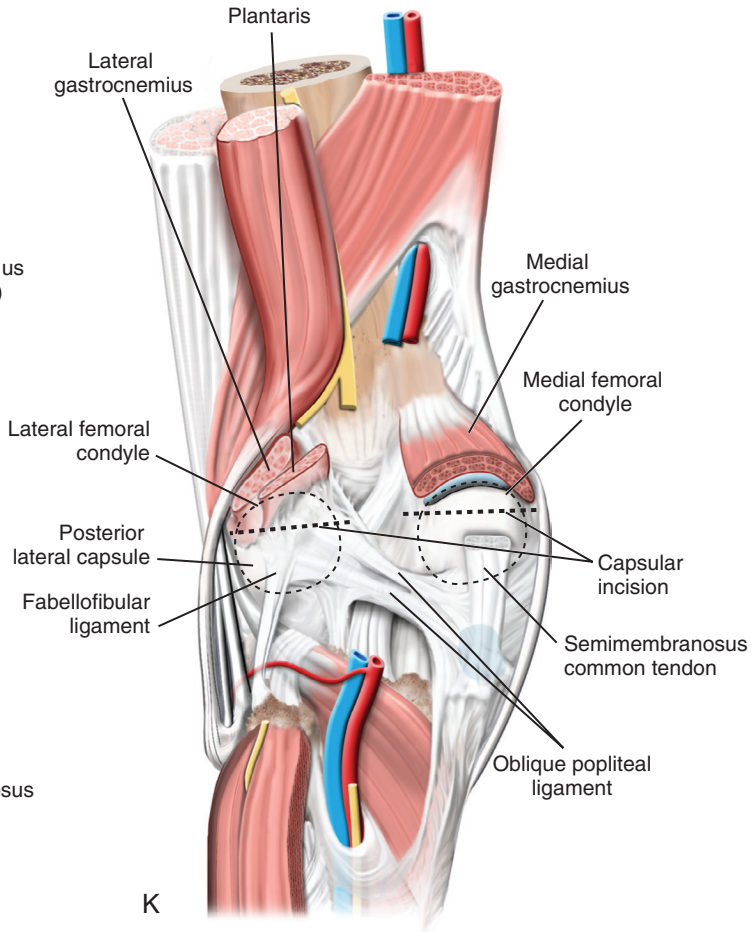

FIG 38-18, cont'd **J** and **K,** The posterior capsular releases. The remaining posterior capsular tissues are gently stretched with the overpressure program to achieve extension. This is a limited cosmetic approach that does not disturb other posterior soft tissues and removes only the contracted posterior capsule as shown by the *dotted line*. *LFC,* Lateral femoral condyle.

flexion, because this would involve a flexion manipulation by untrained personnel.

The overpressure extension (Fig. 38-19) and flexion (Fig. 38-20) exercises are described in Table 38-7. We recommend an active range of motion program performed by the patient instead of use of a continuous passive motion machine. As well, the patient should continue with leg lifts and isometric exercises while in the hospital. It is imperative to control soft tissue inflammation and avoid a hemarthrosis. If soft tissue swelling persists, or thigh muscle pain occurs owing to excessive stretching, a NSAID or steroidal dose pack should be considered. After the epidural, it is routine to obtain a venous ultrasound to exclude venous clot disease.

Upon completion of the inpatient program, the exercises must be continued at home eight times a day. Close supervision by the physical therapist is required because the gains in knee flexion and extension may be reduced rapidly if the regimen is not maintained or if pain and swelling prohibit the patient's ability to perform the exercises.

EXTENDED EPIDURAL FOR PAIN MANAGEMENT

The use of a tunneled epidural catheter in patients who require extended pain management has been described for a variety of diagnoses, including cancer, human immunodeficiency virus, complex regional pain syndrome (CRPS), and TKA.[5,6,29,68,69,148,175] Buvanedran and associates[29] demonstrated the efficacy and safety of placing a tunneled epidural catheter for an average of 49 ± 3 days in 47 patients who underwent knee procedures that were considered high risk for developing a knee motion complication. The procedures were TKA revision, arthroscopy to treat arthrofibrosis, or knee manipulation for arthrofibrosis after TKA. The fluoroscopic-placed catheters were used along with rigorous rehabilitation. There were significant improvements in pain and knee motion following the treatment program, and these improvements remained after removal of the epidural. There only two complications (leaks and disconnects) and no major side effects.

Hartman and coworkers[68] described the use of a tunneled epidural catheter in 9 of 35 patients who underwent revision TKA because of symptomatic knee joint arthrofibrosis that had extended neuraxial pain. Although these authors reported significant improvements in knee motion and the mean Knee Society score for the entire cohort, the results of these 9 patients were not provided separately. All patients except one improved both flexion and extension; however, 34% required additional procedures after the TKA because of continuing arthrofibrosis. The amount of time the catheters were used was not provided. Stanton-Hicks and associates[175] empirically noted that a tunneled epidural catheter was of value in children with CRPS and recommended a period of 4 to 6 weeks of usage along with physical therapy.

The most common complication with tunneled epidural catheters is infection; however, rates appear to vary according to diagnosis.

FIG 38-19 Inpatient extension overpressure exercises include hamstring stretching (**A**) and hanging weights (**B**).

TABLE 38-7 Inpatient Overpressure Extension and Flexion Program Exercises

Extension (Perform First, Before Flexion)

1. Determine weight to be used and pain limits before epidural is begun.
2. Use 15-20-25 lb of weight over the knee with the foot and ankle supported. Progress as tolerated.
3. Use lowest amount of weight to achieve 3 degrees of hyperextension at the third day.

Flexion

1. Perform release of contracted tissues that produce a hard stop to flexion before the overpressure program; protect patellofemoral joint. Expect soft stop to gradually release over 72 hours, producing significant gains in flexion.
2. Mark the affected heel height on the opposite thigh before the epidural is begun to determine the extent of contracture and starting point.
3. Limit the amount of flexion gained over the first 24 hours to prevent muscle and tissue tearing.
4. Perform patellar mobilizations to avoid patella overpressure with knee flexion.
5. Figure-four position in bed; place and hold strap or towel using approximately 15-20 lb of pull on the ankle. Monitor heel-thigh mark on the opposite thigh to determine the gain in flexion.
6. Perform flexion overpressure program every 30 min for 5 min while awake. Goal is to achieve heel height above patella.
7. Physician performs flexion overpressure test to determine whether soft or hard resistance is present and measures knee flexion angle daily.
8. Continue the overpressure program after discharge at home, eight times every 24 hours, using pain control to achieve flexion gained under the epidural.

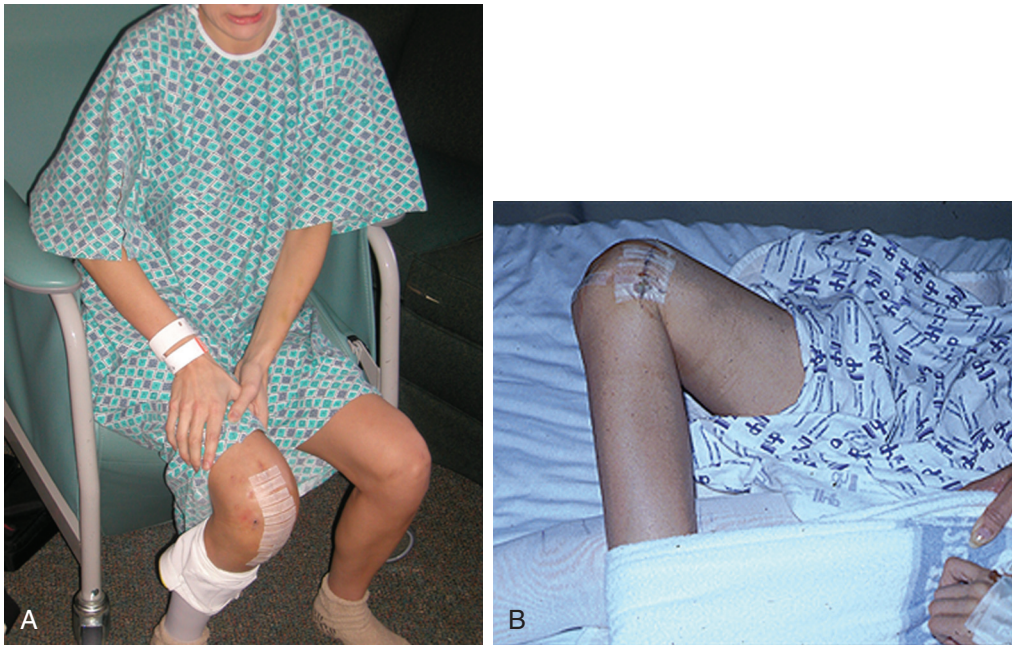

FIG 38-20 In-patient flexion overpressure exercises include rolling stool (**A**) and figure-four with a towel or strap in which the heel is brought up to a predetermined mark on the anterior thigh of the opposite extremity (**B**).

Ruppen and associates[148] conducted a metaanalysis of 12 studies (published between 1983 and 1998) that encompassed 4628 patients who had a catheter in place for at least 7 days. Data pooled from nine studies that focused on cancer patients produced a 2.8% rate of deep infection compared with a rate of 0.48% from three studies of noncancer or both noncancer and cancer (mixed) cohorts. Hayek and colleagues[69] reported on the use of 260 tunneled epidural catheters in 218 patients who had chronic noncancer regional pain, the majority of whom had CRPS. There were 24 epidural space infections; 22 of these patients had CRPS. The epidurals had been used between 11 and 130 days. In addition, 34 others had to be discontinued because of superficial infection or suspicion of infection. These authors reported a significantly increased incidence of infection in patients with neuropathic pain and somatic pain (most of which was adhesive capsulitis of the shoulder) of 24.4% and 6.7%, respectively ($P = .03$). Other potential side effects include numbness or weakness in the lower extremities, dizziness, and discomfort at the insertion site.

DEVELOPMENTAL PATELLA INFERA

The senior author has reported on the complication of developmental patella infera (Fig. 38-21) that occurs after major knee injury or surgery, secondary to contracture of peripatellar and infrapatellar scar tissues and quadriceps weakness.[129,130] This condition may result in permanent shortening of the patellar tendon, patellofemoral arthritis, and severe functional limitations. To prevent this problem, the steps previously described to prevent arthrofibrosis are taken before and after surgery. In addition, the patient is instructed preoperatively on the importance of achieving a voluntary quadriceps contraction as soon as possible after surgery, which is expected to occur by the second postoperative day. Patellar mobility is assessed weekly by the therapist to detect any early contracture. Serial lateral radiographs are taken to detect any decrease in patellar height for patients demonstrating limited patellar mobility or in whom an early arthrofibrotic response is detected (Fig. 38-22). The differences in criteria for determining the presence of patella infera according to published techniques are shown in Table 38-8.

For patients who present with an established patella infera, the treatment algorithm is shown in Figure 38-23. The first principle of treatment is the preoperative preparation of the patient to establish quadriceps muscle function, rehabilitation, and training to avoid a quadriceps shutdown after the surgical procedure. Second, to remove the contracted and scarred tissues either by arthroscopic or open surgery, as already discussed. A number of months of intensive therapy

is then required. The final functional limitations are based on residual motion deficits and joint arthritis that are present. A majority of patients with established patella infera have functional limitations.[130] These patients do not desire any further surgery and are willing to live with these limitations, understanding that an eventual arthroplasty procedure may be required. A small percentage of patients with a remaining patella infera and minimal patellofemoral arthritis who have symptoms of anterior knee pain and stiffness may be candidates for restoration of a normal patellotrochlear relationship.

CRITICAL POINTS Developmental Patella Infera

- Occurs secondary to contracture of peripatellar and infrapatellar scar tissues and quadriceps weakness
- May result in permanent shortening of the patellar tendon, patellofemoral arthritis, and severe functional limitations
- Prevention: voluntary quadriceps contraction by second postoperative day, knee motion, patellar mobilization
- Serial lateral radiographs to measure patellar height in patients with limited patellar mobility; early arthrofibrotic response detected
- Treatment established patella infera: preoperative muscle strengthening, rehabilitation. Operative removal contracted and scarred tissues.
- Final functional limitations based on residual motion deficits, joint arthritis

OUR CLINICAL STUDIES

Two studies were conducted to determine the effectiveness of the postoperative rehabilitation program and early diagnosis and treatment of knee motion limitations after ACL reconstruction in preventing arthrofibrosis. In the first study,[126] a group of 207 knees that underwent an ACL bone-patellar tendon-bone (B-PT-B) allograft reconstruction were followed for at least 1 year postoperatively to determine the final amount of knee flexion and extension obtained and document the necessity of treatment interventions. Sixty-nine patients received the operation for an acute ACL rupture and 138 for chronic ACL deficiency. Of the 207 knees, 90 had the ACL reconstruction alone, 52 had a concurrent iliotibial band extra-articular procedure, 52 had a concurrent meniscus repair, and 13 had a concurrent MCL repair.

The investigation found that 189 of the knees (91%) regained normal motion without requiring additional treatment intervention. The remaining 18 required extension casting, gentle manipulation under anesthesia, or (in only three knees) arthroscopic debridement and lysis of adhesions (Table 38-9). There was a correlation among

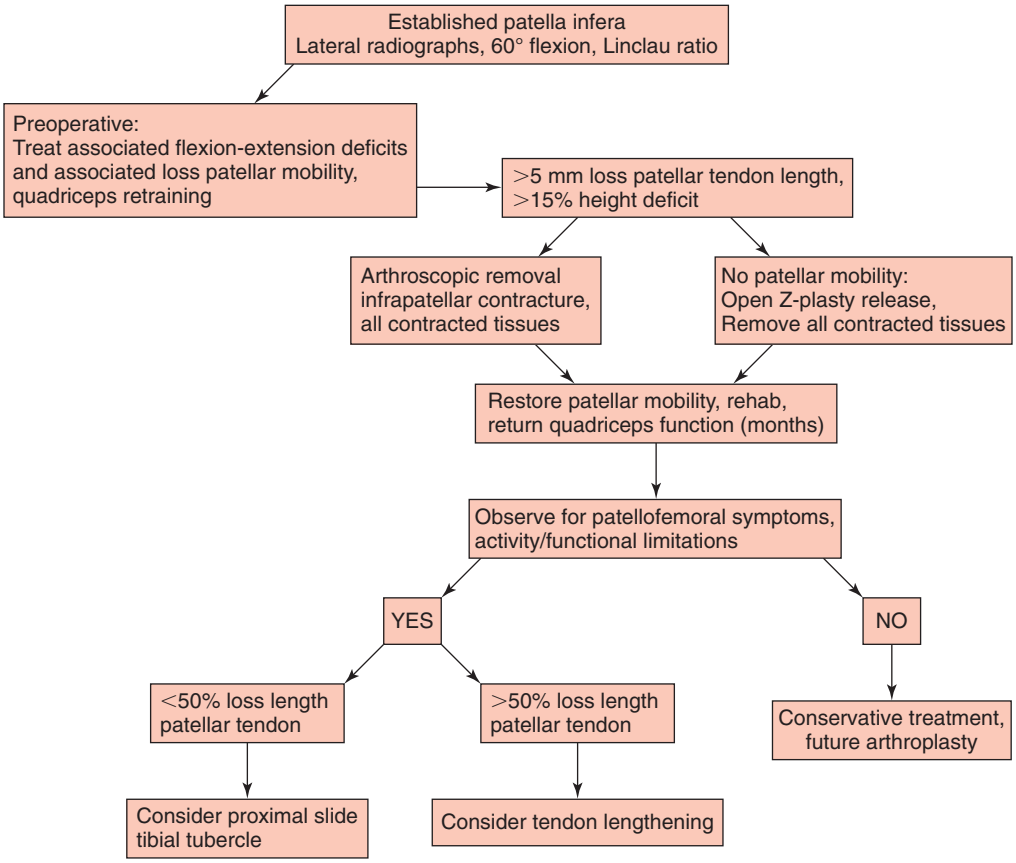

FIG 38-23 Treatment algorithm for established patella infera.

concurrent procedures and the incidence of patients requiring additional treatment because 4% in the ACL alone subgroup, 10% in the iliotibial band extraarticular subgroup, 12% in the meniscus repair subgroup, and 23% in the MCL subgroup required intervention. The timing of surgery had no effect on the necessity for treatment intervention.

Extension casts were applied to 6 knees between 4 and 12 weeks postoperatively, and all regained normal extension. A gentle manipulation under anesthesia was performed in 9 knees between 3 and 13 weeks postoperatively. All achieved full flexion, and all but two achieved full extension; two knees lacked 5 degrees of extension at follow-up. Arthroscopic debridement was done in three knees; the details and results are shown in Table 38-10. At follow-up, full knee motion was present in 98%, 1% had a 5 degree limitation of extension, and 1% had a permanent contracture.

We conducted a second study[125] comprising 443 knees that underwent ACL B-PT-B autograft reconstruction. The operations were performed for acute/subacute ACL ruptures in 161 patients and for chronic ruptures in 283 patients. All were followed for an average of 2.1 years (range, 1-7.2 years) postoperatively. Concurrent procedures done in 224 knees included meniscus repairs in 194 knees, proximal advancement of the posterolateral structures in 32 knees, an autograft reconstruction of the fibular collateral ligament (FCL) in 4 knees, a repair or reconstruction of the MCL in 9 knees, and a proximal patellar realignment in 17 knees.

No correlation existed between concurrent procedures and the incidence of patients requiring addition treatment in this study. The percentages of patients requiring additional treatment intervention were 6% in the ACL alone subgroup, 5% in the FCL reconstruction/posterolateral advancement subgroup, 8% in the meniscus repair subgroup, 18% in the proximal patellar realignment subgroup, and 22% in the MCL subgroup. The timing of surgery had no effect on the necessity for treatment intervention.

The investigation found that 98% of the knees regained normal motion, and 2% had mild losses of extension of 5 degrees. In 23 knees, treatment intervention was required (Table 38-11), which was successful in treating the limitation of knee flexion or extension (Table 38-12). The 2% (seven knees) that had mild losses of extension refused treatment intervention.

Extension casts were applied to nine knees an average of 13 weeks postoperatively. All of these knees regained normal extension. A gentle manipulation under anesthesia was performed in nine knees a mean of 6.4 weeks postoperatively, and all achieved full knee flexion. Arthroscopic debridement was done in three knees, which also successfully restored normal knee motion. There was no statistically significant increased risk for knee motion problems for six variables studied, including gender, injury chronicity, condition of the articular cartilage at reconstruction, location of physical therapy, whether or not prior surgery had been performed, and whether or not a prior ACL reconstruction had been performed.

CRITICAL POINTS Our Clinical Studies

Study 1

- *n* = 207 knees ACL B-PT-B allograft reconstruction followed at least 1 year postoperatively.
- 189 (91%) regained normal motion without additional treatment intervention:
  - 6 extension casting
  - 9 gentle manipulation under anesthesia
  - 3 arthroscopic debridement and lysis of adhesions
- Correlation concurrent procedures and incidence of patients requiring treatment:
  - 4% ACL alone
  - 10% ACL + iliotibial band extra-articular
  - 12% ACL + meniscus repair
  - 23% ACL + MCL
- At follow-up, full knee motion was present in 98%, 1% had a 5 degrees limitation of extension, 1% had a permanent contracture.

Study 2

- *n* = 443 knees ACL B-PT-B autograft reconstruction followed mean 2.1 years (range, 1-7.2 years) postoperatively.
- Treatment intervention required 23 knees, all successfully resolved.
- Concurrent procedures and incidence of patients requiring treatment:
  - 6% ACL alone
  - 5% ACL + FCL reconstruction/posterolateral advancement
  - 8% ACL + meniscus repair
  - 18% ACL + proximal patellar realignment
  - 22% ACL + MCL
- 98% regained normal motion, and 2% (refused additional treatment) had mild losses of extension of 5 degrees.

†Equal to the opposite normal knee.
‡Not available, patient lived out of town, but full at the 2-yr follow-up evaluation.
NA, Not available; *ROM,* range of motion.

The data from the two investigations on 650 knees showed that 6% of the patients required and agreed to treatment intervention for a knee motion problem. At the final follow-up evaluation, 2% lacked normal knee motion (nine knees lacked 5 degrees of extension and two had permanent contractures). An extension cast was applied in 2%, gentle manipulation under anesthesia was done in 3%, and arthroscopic debridement was performed in fewer than 1%. The percentages of all 650 knees requiring additional treatment intervention were 5% in the ACL alone subgroup, 5% in the FCL reconstruction/posterolateral advancement subgroup, 10% in the meniscus repair subgroup, 10% in the extraarticular subgroup, 18% in the proximal patellar realignment subgroup, and 23% in the MCL subgroup.

OTHER AUTHORS' CLINICAL STUDIES

Several authors have reported on the outcome of the treatment of arthrofibrosis following ACL reconstruction, as well as other procedures and injuries (Table 38-13). These studies help identify risk factors for a limitation of knee motion discussed previously, including a delay in initiating treatment, performing acute knee ligament reconstruction or multiple ligament reconstructions, and use of immobilization after surgery. Although authors usually reported that significant gains were obtained in knee motion, most found that the many patients had permanent losses of flexion and/or extension and had more complaints of pain and limitations compared with patients who did not have this complication.

ILLUSTRATIVE CASES

Case 1 A 42-year-old woman presented 7 months after an open reduction internal fixation of a patellar fracture and 4 weeks of immobilization with a severe patella infera, marked by a Linclau ratio of 60% of the left knee (compared with 97% on the opposite knee, Fig. 38-24, *A*). She complained of muscle weakness, pain, and limitations with activities of daily living. She had a range of motion of 0/10/95 degrees and a significant decrease in patellar mobility in both medial-lateral and superior-inferior directions. Physical examination showed an obvious patella infera, with mild patellofemoral crepitus. An isokinetic evaluation revealed a 75% deficit in quadriceps peak torque compared with the contralateral side. She underwent 2 months of rehabilitation because of this severe quadriceps muscle weakness.

The patient was then treated with an open release of scar tissue, which completely obliterated the suprapatellar pouch. Dense scar was

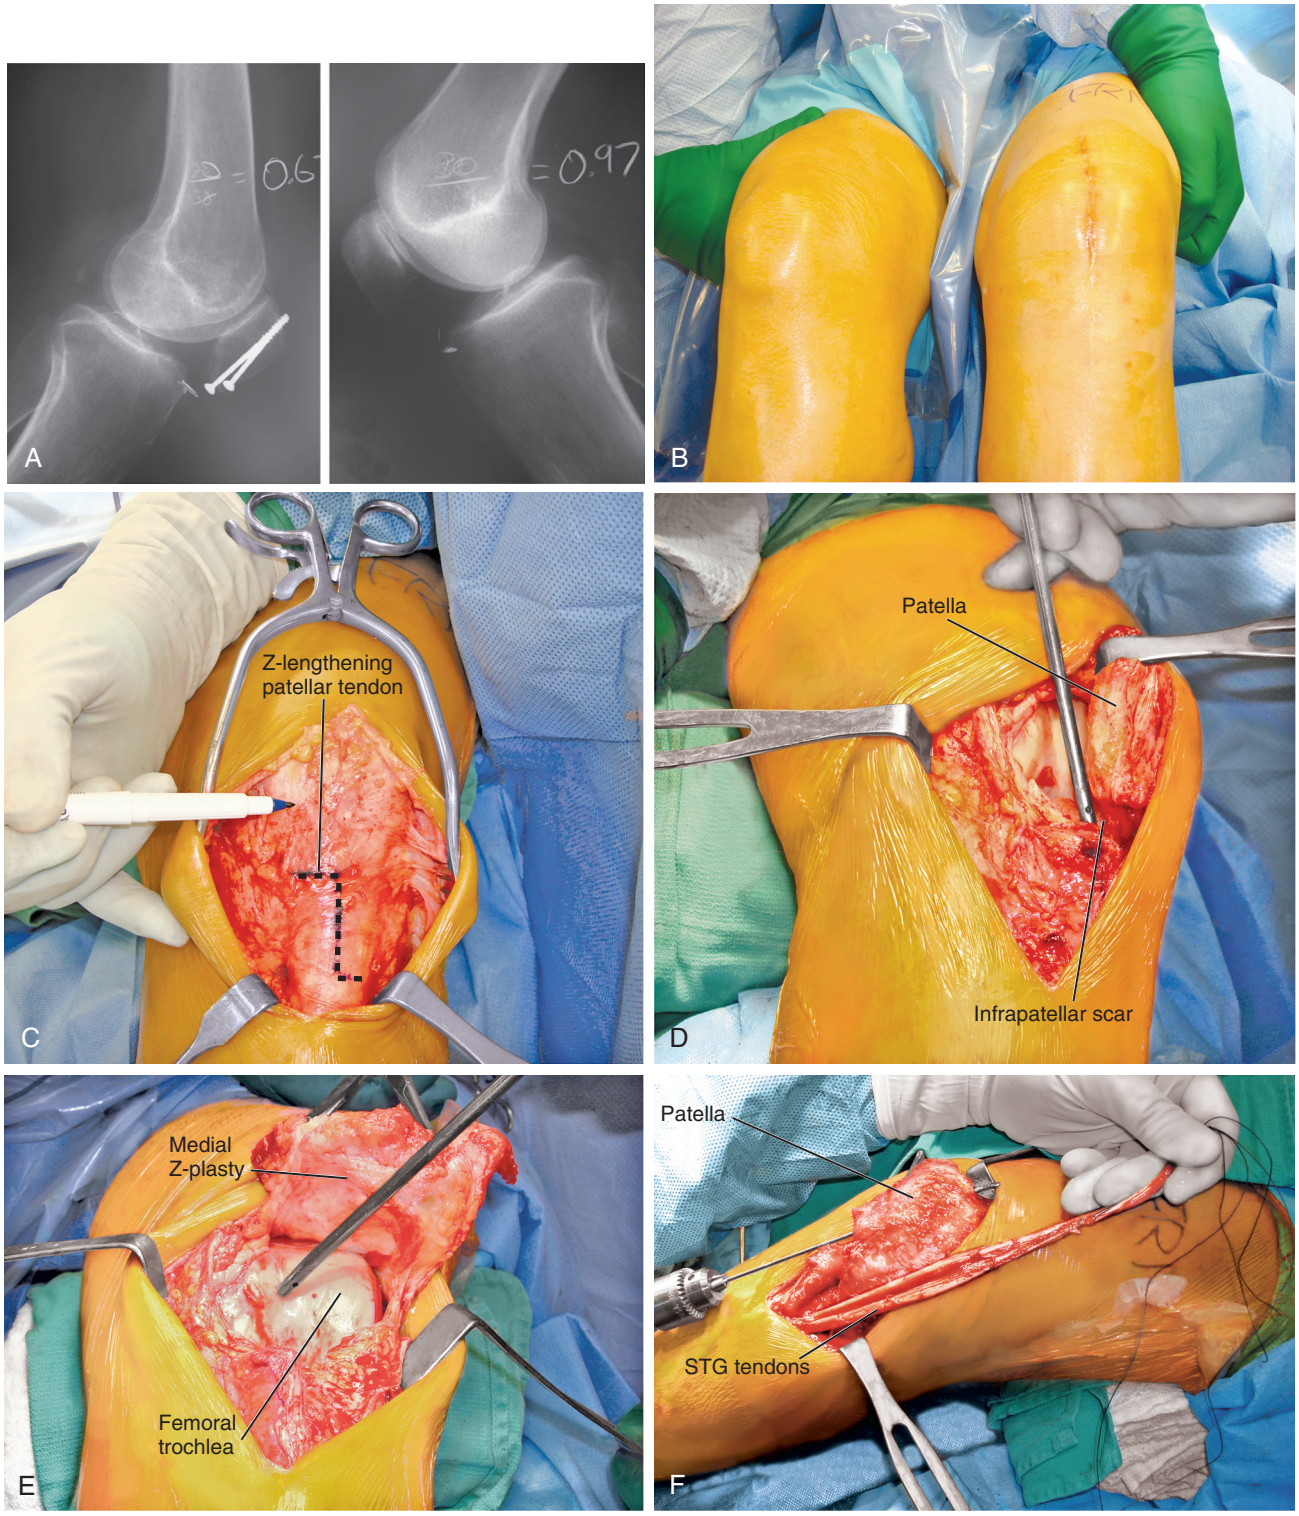

FIG 38-24 Case 1. **A,** Preoperative lateral radiographs demonstrate patella infera. **B,** Preoperative appearance of the left knee. The skin mobility was sufficient and did not contraindicate surgery. **C,** The line for the incision of the Z-plasty lengthening of the patient's patellar tendon. **D,** Extensive resection of infrapatellar scar tissue was required. **E,** Appearance of the femoral trochlea shows intact articular cartilage. An extensive medial Z-plasty release was performed. **F,** Placement of a central patellar tunnel for later passage of semitendinosus and gracilis (STG) tendons from a distal-to-proximal direction. *Continued*

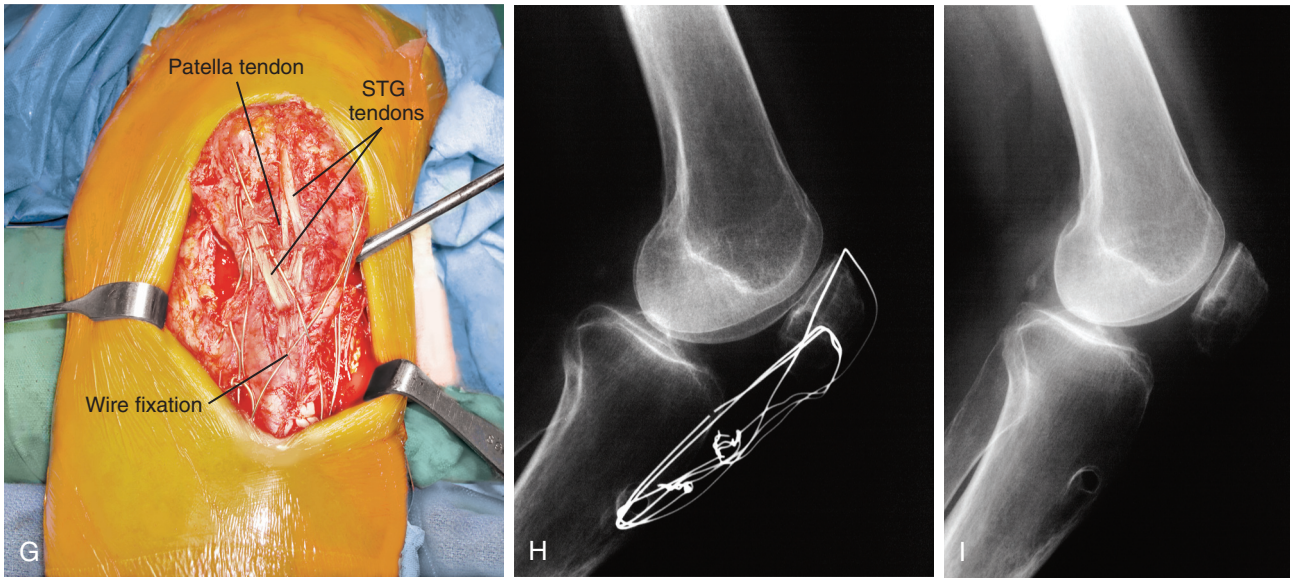

FIG 38-24, cont'd **G,** Final appearance of patellar tendon reconstruction. The patient's patellar tendon was reapproximated after the Z-plasty lengthening. The STG tendons were passed from the inferior to the superior pole and brought distally along the medial retinaculum to further augment the medial portion of the patellar tendon. In this case, the advantage of using the patient's own patellar tendon added significant soft tissues so that further augmentation was not required. **H,** Postoperative radiograph shows three internal fixation wires that provide stabilization and allow immediate range of motion. **I,** Radiograph shows restoration of normal patellar height after removal of internal fixation wires. The patient was asymptomatic with activities of daily living and able to perform light recreational activities. The final range of motion was normal (0/0/135 degrees).

present in the medial and lateral gutters, the medial and lateral joint lines, and intercondylar notch. After the procedure, the patient underwent 3 days of inpatient physical therapy on the epidural overpressure program described previously. Her knee motion improved to 0/0/100 degrees.

Two months later, the patient continued to have symptoms and minimal improvement. Therefore, the decision was reached to perform a patellar lengthening procedure. Figures 38-24, *B* to *G* demonstrate the tendon lengthening. A Z-plasty lengthening of the patient's patellar tendon was performed along with an augmentation using a four-strand semitendinosus-gracilis autograft. Internal fixation with wire was used to initiate immediate knee motion. The procedure was successful in restoring a normal patellar height (Fig. 38-24, *H* and *I*). The goal was to buy time until the patient eventually requires a patellofemoral arthroplasty, which is possible with normal patellar height.

Case 2 A 33-year-old woman presented with severe patellar infera (Linclau ratio, 29%) 4 months after resection of a ganglion cyst, which was growing under her patellar tendon. A portion of the patellar tendon was damaged in the procedure, and the patient was treated with 5 weeks of plaster immobilization, which resulted in severe quadriceps atrophy and severely contracted peripatellar and joint soft tissues. This represented a salvage knee condition because the patient had significant loss of function of the lower extremity. The range of motion was 0/10/75 degrees. She underwent 6 weeks of intense preoperative rehabilitation for muscle strengthening and then a skin expansion procedure (Fig. 38-25, *A* and *B*). Because this patient had no remaining patellar tendon to use in a Z-plasty fashion to incorporate into the reconstruction, she underwent a combined allograft-autograft patellar tendon lengthening procedure (see Fig. 38-25, *C* to *G*). The patient required intensive rehabilitation for 6 months.

At the most recent follow-up evaluation, 2 years postoperatively, the patient had equal Linclau ratios of 85% (see Fig. 38-25, *H* and *I*) and a range of motion of 0 to 120 degrees. She has no symptoms with activities of daily living or swimming and, although pleased with her condition, realizes that in the future a patellofemoral arthroplasty may be required.

Our comments: The salvage procedure of lengthening the patellar tendon was performed in this young patient to buy time before an anticipated total knee replacement. The benefit of reestablishing the normal patellar height (see Fig. 38-25, *H* and *I*) allowed a return of moderate lower limb function, with the added benefit at the time of the total joint procedure of retaining patellofemoral joint function.

Case 3 A 42-year-old woman sustained an acute anterior cruciate ligament rupture to the right knee, which was treated 4 weeks later with an anterior tibialis allograft reconstruction. Before surgery, the patient had achieved 0/0/100 degrees of knee motion. Postoperatively, she experienced significant problems with quadriceps muscle atrophy and failed to gain more than 100 degrees of knee flexion. A manipulation under anesthesia was performed 2 months postoperatively in which 0/0/120 degrees was achieved; however, the patient gradually reverted back to 0/0/90 degrees of motion.

The patient presented to our center 5 months after surgery with complaints of stiffness, tightness, failure to achieve more than 90 degrees knee flexion, and a flexed knee gait. On physical examination, she had a stable knee with negative Lachman and pivot shift test results. There was significant muscle atrophy, and the patient was unable to actively perform an isometric quadriceps contraction. She ambulated with limited knee flexion. The patellofemoral joint was markedly restricted, with no medial or lateral glide and an obvious patella infra position.

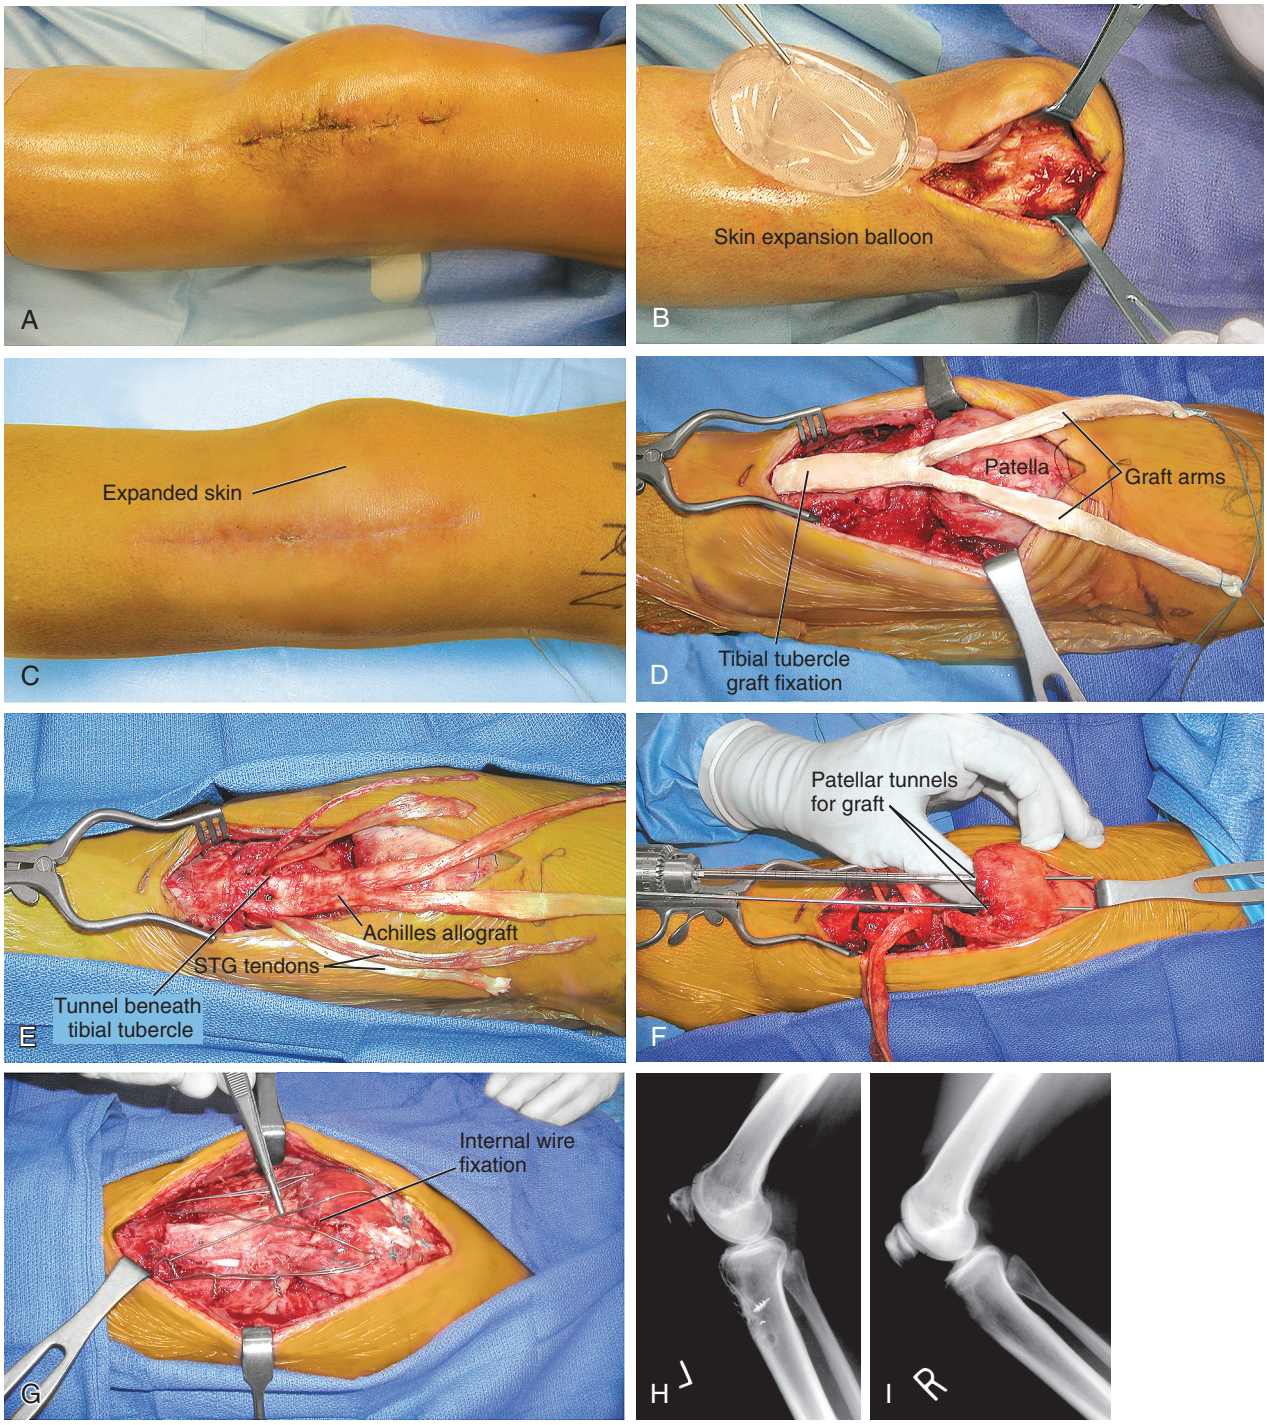

FIG 38-25 Case 2. **A,** Preoperative appearance of skin contracture. It is necessary to obtain more normal skin and soft tissue before the patellar tendon–lengthening procedure. Otherwise, there would be an increased risk of a complication of skin breakdown and infection. **B,** Placement of the skin expansion system at surgery. The expansion system may be placed either through the prior incision or through limited medial and lateral incisions using two balloons to avoid the primary incision. **C,** Appearance of expanded skin over the anterior aspect of the knee joint after 4 weeks of skin expansion. The balloon was removed through a small incision before the operative procedure. Extra redundant skin and subcutaneous tissue is shown, and a scar revision was performed. **D,** Operative photograph shows an Achilles tendon allograft for reconstruction of the patellar tendon. The bone portion of the graft is fixated at the tibial tubercle. The two arms of the graft are placed through separate patellar tunnels and sewn into the quadriceps tendon proximally. **E,** A semitendinosus and gracilis autograft harvest is performed. The tendons are passed beneath the tibial tubercle and the Achilles tendon–bone allograft. **F,** Placement of two patellar tunnels. **G,** Final tendon-lengthening construct. The Achilles tendon has been secured both proximally and distally. The semitendinosus-gracilis autograft tendons are placed through the proximal tibia adjacent to the tibial tubercle. Both tendon arms are passed medially and laterally and secured to the peripatellar tissues to augment the allograft tendon reconstruction. Two wire loops are placed through the tibial tubercle to the midpoint of the patella. A third wire is crossed from the tibial tubercle over the superior portion of the patella and passed beneath the quadriceps tendon patella insertion as a tension band. The height of the patella is adjusted to the normal opposite side using intraoperative fluoroscopy. **H** and **I,** Postoperative lateral radiographs of both knees show retention of the normal height of the patella in the left knee (**H**) compared with the right knee (**I**).

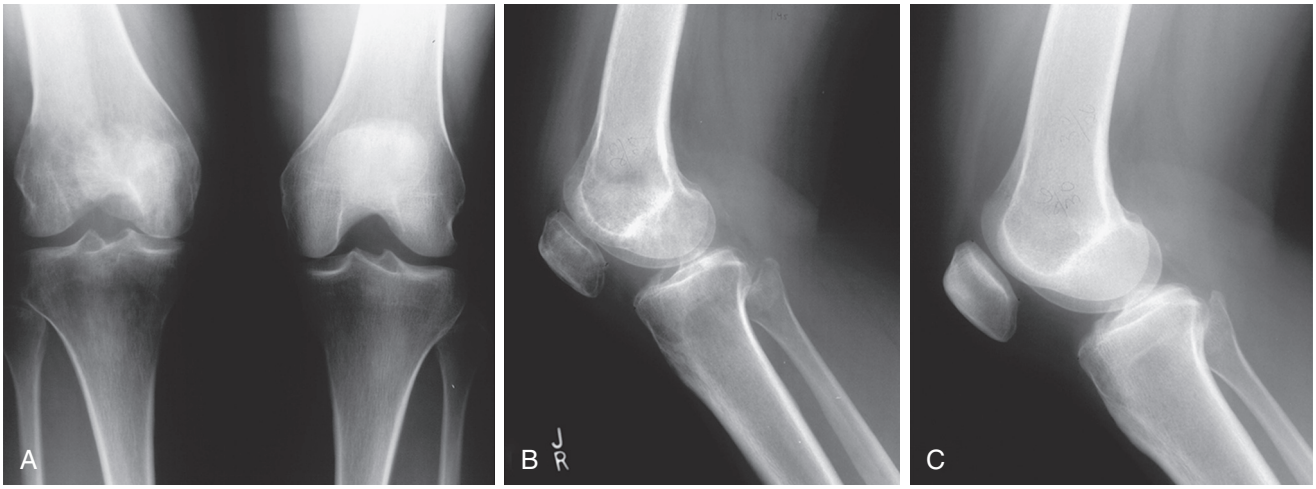

FIG 38-26 Case 3.

Standing posteroanterior radiographs showed a decrease in the height of the patella and osteopenia (Fig. 38-26, *A*). Lateral radiographs with the knee flexed showed an obvious patella infra, with a 68% Linclau ratio on the involved side see (Fig. 38-26, *B*) compared with the opposite side of 87% (see Fig. 38-26, *C*). The patient underwent Z-plasty lengthening of the medial and lateral retinacular structures to restore patellar mobility, an arthroscopic suprapatellar debridement to open the synovial pouch, and removal of infrapatellar contracture. The patellar tendon shortening was permanent. The patient underwent 3 months of intensive rehabilitation, muscle strengthening, and gait retraining and achieved 0/0/125 degrees of motion, with restoration of patellar mobility.

Our comments: This case demonstrates the importance of maintaining normal patellar mobility postoperatively. Any limitation of patellar mobility should be treated by 3 weeks postoperatively using the programs discussed in this chapter. The lack of motion after surgery, with inadequate rehabilitation, contributed to the postoperative problem. It is not advisable to perform a manipulation at 8 postoperative weeks in a knee where the joint contracture is well established. Arthroscopic debridement and appropriate lysis of adhesions are instead indicated. Overpressure flexion exercises are contraindicated until release procedures are performed to restore patellar mobility; otherwise, high patellofemoral forces exist with forced flexion and possible articular cartilage damage. If treated early, loss of patellar tendon length and patella infra and associated patellofemoral cartilage damage could possibly have been avoided in this knee. The contracture of the medial and lateral parapatellar tissues was so severe that an open Z-plasty release was required.

Video 1-1 The Key to the Knee: A Layer-by-Layer Demonstration of Medial and Anterior Knee Anatomy

INTRODUCTION

Nerves related to the knee include not only those that go in the skin about the surface of the knee joint but also mixed (motor and sensory) nerves that pass the knee on the way to their targets distal to this joint. In addition to these well-known nerves are those that innervate the knee joint. Each is at risk of injury when there is (1) blunt force directed at the knee, (2) a stretch/traction injury to the musculoskeletal system of the knee joint, or (3) an inversion sprain to the ankle or when (4) open or arthroscopic knee surgery has been performed. Although it is intuitively clear that a joint is innervated, the exact pathways of this innervation are curiously omitted from the classic and even the newer anatomy texts. For the human knee, the innervation pattern was not found to be described until 1994, during my search for an etiology of knee pain unrelated to musculoskeletal dysfunction.[25] The approach to knee pain described in this chapter closely follows the approach developed for wrist pain,[8,16,20] which preceded my interest in knee pain. This led to a subsequent similar approach to shoulder pain[1,3] and ankle pain.[6,13,29]

CRITICAL POINTS Introduction

Nerves are at risk of injury from:
- Blunt force directed at the knee
- Stretch/traction injury of the knee joint
- Inversion sprain to the ankle
- Open or arthroscopic knee surgery

Approach: knee pain that exists after musculoskeletal treatment is of neural origin.
- Decide whether pain is coming from direct damage to the cutaneous nerves about the knee or from an injury to one of the nerves arising within the knee joint structures themselves.
- Partial joint denervation is an approach in which the joint afferents that transmit a pain message are interrupted.

The approach described in this chapter considers knee pain that exists after musculoskeletal treatment to be of neural origin. The physician caring for these patients must consider whether the pain is coming from direct damage to the cutaneous nerves about the knee, such as a neuroma of the infrapatellar branch of the saphenous nerve, or from an injury to one of the nerves arising within the knee joint structures themselves. A further source of knee pain caused by nerve injury is an injury to a nerve far away from the knee, such as the lateral femoral

cutaneous nerve, or a nerve that is simply going past the knee on its way to some other distal target. The concept of partial joint denervation is presented as an approach in which those joint afferents that transmit a pain message are interrupted, thereby stopping the pain and preserving the musculoskeletal components of the joint. A Charcot-type joint is not created because the deafferentation is partial instead of total.

PERIPHERAL NERVE ANATOMY RELATED TO THE KNEE

Innervation of the Human Knee Joint

The innervation of the human knee joint is remarkably constant.[25] On the medial aspect (Fig. 39-1), the femoral nerve branch that innervates the vastus medialis continues past its motor point and exits deep and distal to the muscle. At this point, it lies deep within the medial retinaculum and becomes related to the medial recurrent geniculate artery and vein. This structure is termed the *medial retinacular nerve*. Both nerve and vessels continue directly adjacent to the vastus medialis and superficial to the synovium to enter the ligamentous structures of the medial aspect of the knee. These fibers also continue toward the midline of the knee to innervate the undersurface of the patella (see Fig. 39-1).

On the lateral aspect of the knee (Fig. 39-2), a branch of the sciatic nerve leaves the popliteal fossa, travels laterally and anteriorly, emerges deep within the biceps tendon and enters the space beneath the lateral retinaculum. In this location, the nerve is adjacent to the superior lateral geniculate artery and vein. This structure is termed the *lateral retinacular nerve*. Both structures, the nerve and vessels, are immediately distal to the vastus lateralis and superficial to the synovium. The nerve enters the ligamentous structures of the lateral aspect of the knee (which have not yet been further defined histologically) and travels to the midline to innervate the undersurface of the patella.

Anteriorly, another source of innervation is derived from the femoral nerve innervation of the vastus intermedius. This nerve continues on the surface of the periosteum to innervate the tissues around the prepatellar bursa. Finally, posteriorly, branches from the sciatic nerve enter the posterior knee joint capsule to provide innervation (see Fig. 39-2).

Innervation of the Proximal Tibiofibular Joint

Although many patients complain of "knee pain," they may be pointing or referring to the region distal and lateral to the knee, which is the articulation between the fibular head and the tibia. This joint space is likely to be injured from fractures of the fibula or lateral tibial plateau or from high tibial osteotomy or a Maquet operative procedure. It is innervated by the common peroneal nerve (see Fig. 39-2). As the common peroneal nerve travels from the popliteal fossa to the fibular head, it gives off a small (~1 mm in diameter) nerve that may enter

CRITICAL POINTS Peripheral Nerve Anatomy Related to the Knee

- Innervation of human knee joint
- Innervation of proximal tibiofibular joint
- Common peroneal nerve
- Deep peroneal nerve
- Superficial peroneal nerve
- Proximal tibial nerve
- Lateral femoral cutaneous nerve
- Saphenous nerve

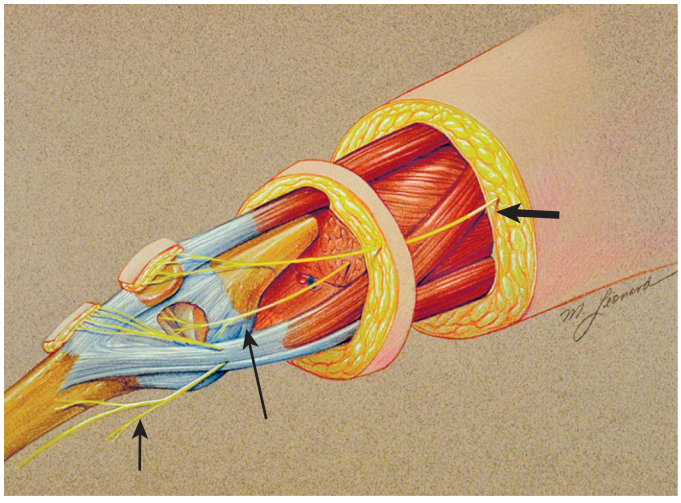

FIG 39-1 Medial view of the innervation of the knee. The skin overlying the patella is innervated by the medial cutaneous nerve of the thigh, a branch of the saphenous nerve (*thick arrow*). The medial joint structures are innervated by a branch of the femoral nerve, the medial retinacular nerve, which, after innervating the vastus medialis, continues distal and then anterior to this muscle to enter the ligamentous structures of the knee joint (*long thin arrow*). This nerve lies superficial to the synovium and deep to the medial retinaculum. The saphenous nerve's infrapatellar and distal branches are shown in their most common variation (*short thin arrow*). (Courtesy Dellon.com.)

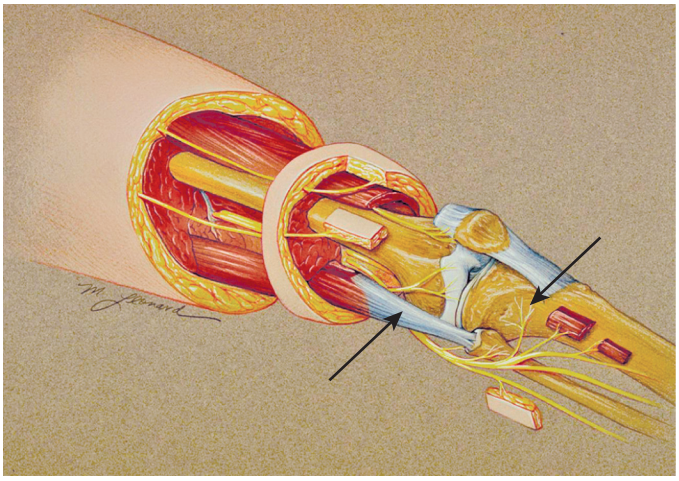

FIG 39-2 Lateral view of the innervation of the knee. The innervation of the skin in this area represents the terminal branches of the lateral femoral cutaneous nerve. The lateral joint structures are innervated by a branch of the sciatic nerve that comes from the popliteal fossa, goes deep to the biceps tendon to enter the joint, termed the *lateral retinacular nerve* (*bottom arrow*). The nerve passes just distal to the vastus lateralis and then lies superficial to the synovium and deep to the lateral retinaculum as it enters the joint. The branches of the sciatic nerve to the posterior knee joint capsule are shown next to the femur posteriorly. The branch to the prepatellar bursa is shown on the anterior surface of the femur as it exists the vastus intermedius. The innervation of the proximal tibiofibular joint is shown as branches proximal and distal to the fibular head, arising from the common peroneal nerve (*top arrow*). (Courtesy Dellon.com.)

the space posterior to the fibular head. The common peroneal nerve gives off a second innervating branch immediately as it curves anterior to the fibular head at the junction with the fibular neck. This branch is also approximately 1 mm in diameter. The next branch of the common peroneal nerve goes to the tibialis anterior, which is a critical motor branch. In the operating room, the only way to identify the branch to the joint is to stimulate it electrically. No motor function will be elicited when the branch is stimulated. This is a critical step. This small branch often looks like epineurium.

Common Peroneal Nerve

The common peroneal nerve is the lateral branch of the sciatic nerve. It can most often be identified as a distinct branch even to the sciatic notch. Therefore, in the thigh, there is clearly a common peroneal nerve even though it may be referred to as the sciatic nerve. In the distal thigh, the common peroneal nerve courses laterally, approaches the fibular head, and continues anteriorly to cross the fibular neck and enter the leg. As the common peroneal nerve approaches the fibular neck, it clearly divides into the superficial and the deep peroneal nerve, increasing in size as increased epineurium is required to ensheath these two branches (Fig. 39-3). The critical anatomic sites that can cause compression have long been appreciated to occur where the common peroneal nerve crosses the fibular neck, requiring division of the fascia of the peroneus longus fascia.[35] With increasing experience, it has become evident that three other anatomic factors must be considered. A fibrous band exists beneath the peroneus longus in 20% of cadavers, but this band is present (and ranges from 5 to 15 mm in width) in 80%

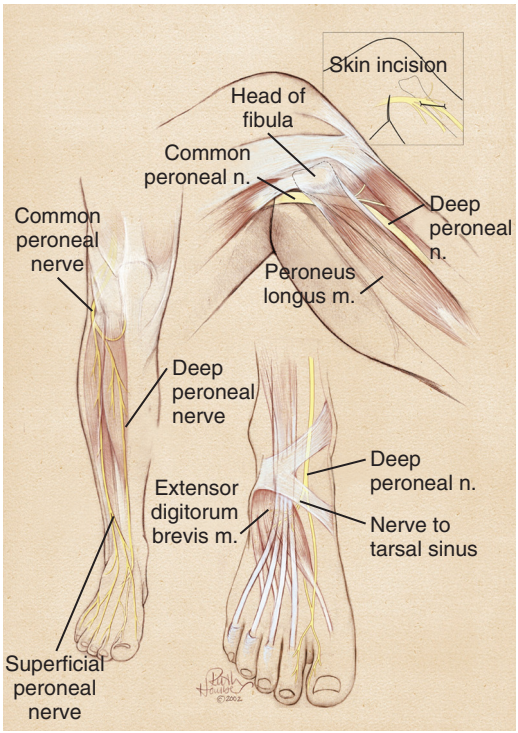

FIG 39-3 Common peroneal nerve enters the leg at the fibular head and divides into the deep and superficial peroneal nerves. *Inset,* The typical incision for the decompression of the common peroneal nerve. The superficial peroneal nerve entrapment site as it exits from the deep fascia is noted laterally, and the deep peroneal nerve entrapment site is illustrated beneath the extensor hallucis brevis tendon. (Courtesy Dellon.com.)

of patients requiring neurolysis.[14] The surgeon must identify the common peroneal nerve by elevating it from the fibular neck; determine whether or not fibrous thickening in the lateral gastrocnemius muscle fascia is present; and finally, be certain that the overall entrance into the anterior and lateral compartments is sufficiently large.

Deep Peroneal Nerve

The deep peroneal nerve arises over the fibular neck as a discrete fascicle. It can be dissected proximally by microtechnique if necessary. Immediately after crossing the fibular neck, it gives off tiny branches to the tibialis anterior and the toe extensor muscles. In so doing, the deep peroneal nerve effectively tethers the common peroneal and its distal branches from having too much excursion. This predisposes the common peroneal nerve and its branches to stretch/traction injuries. The entrapment site for the deep peroneal nerve is at the ankle, the "anterior tarsal tunnel," which is a rare site for compression unless there has been a direct injury at this location. A more common site for compression is over the dorsum of the foot where the tendon of the extensor hallucis brevis represents the anatomic structure causing the compression. A portion of the tendon of the extensor hallucis brevis is excised in the region of the deep peroneal nerve (see Fig. 39-3).[5]

Superficial Peroneal Nerve

The superficial peroneal nerve arises over the fibular neck from the common peroneal nerve. It can be dissected proximally by microdissection if required. The motor innervation to the foot everters arises within the first 1 to 2 cm distal to the neck of the fibula. The known site of entrapment for this nerve is the region where it transitions from deep fascia into the subcutaneous tissues in the distal third of the leg. The typical division into its dorsomedial and dorsolateral branches occurs just proximal to the ankle in approximately 75% of patients (see Fig. 39-3). In my experience, it is now clear that in at least 25% of cadavers and patients coming to surgery, this division can occur in the proximal third of the leg.[2,39] This creates the situation in which the superficial peroneal nerve may be found in both the anterior and its most usually described location, the lateral compartment. Indeed, the superficial peroneal nerve may be present in just the anterior compartment or within the septum between the two compartments.[40] The anatomic variability means that any surgical approach to this nerve must open both the anterior and the lateral compartments.

Proximal Tibial Nerve

Although the tibial nerve (like the common peroneal nerve) arises at the sciatic notch as the medial component of the sciatic nerve and is often clearly a distinct nerve in the thigh, the only well-described site for tibial nerve compression was at the medial ankle in the tarsal tunnel.[31] It is now evident that the tibial nerve can be compressed in a site more proximal than the tarsal tunnel, and this site (just distal to the knee) is best described as the proximal tibial nerve, to distinguish it from the tarsal tunnel region. Tibial nerve compression in the popliteal fossa has been described related to the presence of compartment syndrome or space-occupying masses, such as a popliteal artery or a Baker cyst.[26,34] Although anatomy texts clearly depict a fibrous arch or soleal sling from which the soleus muscle arises, only recently has there been an anatomic study describing the relationship of this sling to the proximal tibial nerve (unpublished data). This sling lies at a mean distance of 9.3 cm (range, 7-13 cm) from the middle of the popliteal fossa and causes a visible narrowing of the tibial nerve over a length of 1.5 cm in 55% of the cadavers, with a severe constriction being found in 2% of the specimens. With injury to the knee, especially one

associated with postoperative bleeding into the popliteal fossa, tibial nerve compression at this proximal site must be considered as a source of symptoms of numbness in the plantar aspect of the foot, with proximal referral to the knee region.

Lateral Femoral Cutaneous Nerve

The lateral femoral cutaneous nerve has a great deal of anatomic variability related both to its location at the anterior superior iliac crest[2] and to its innervated skin territory. If the location is within the inguinal ligament instead of inferior to it, the lateral femoral cutaneous nerve is at risk for compression or stretch/traction injury during falls, while wearing tight belts, during a seatbelt injury, or during manipulation of the knee with the patient on the operating room table. From Figure 39-4, it can be noted that compression of the lateral femoral cutaneous nerve can produce symptoms that include numbness or pain about the lateral aspect of the knee.[37] This nerve, or the femoral nerve itself, can be injured during regional anesthesia given for knee surgery.[22]

Saphenous Nerve

The saphenous nerve is a branch that arises from the femoral nerve in the proximal thigh. Its cutaneous branches to the skin below the knee are well described and lie in a position to be injured directly from either a medial ankle arthroscopy portal or the midline incisions used for many surgical approaches to the knee. These branches can be directly injured by blunt trauma as well. Less well recognized is the nerve to the skin overlying the patellar itself. This is a branch of the femoral nerve, which may include sensory contribution from the obturator nerve joining within Hunter's canal. The medial cutaneous nerve of the thigh (see Fig. 39-1) approaches from the medial aspect of the knee compared with the vertical approach taken by the anterior femoral cutaneous nerves.[1] Even less well appreciated is that the saphenous nerve can be compressed in the distal thigh within Hunter's canal. This is called *adductor canal syndrome*, which is rare in the absence of direct trauma to the region. Entrapment of the saphenous nerve in this location can present as medial knee pain.[36]

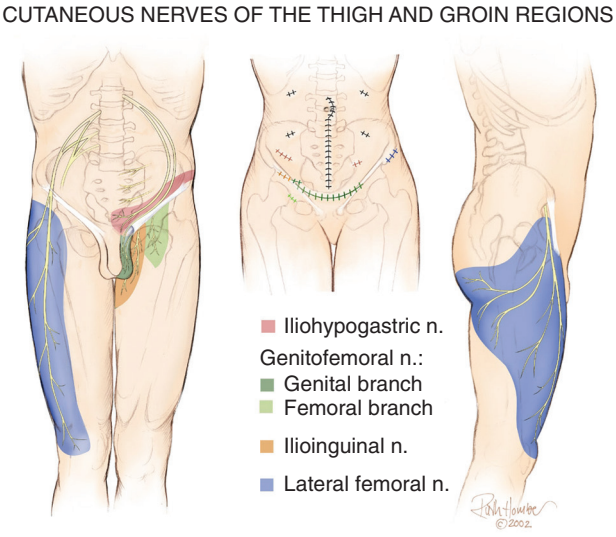

FIG 39-4 Skin territory innervated by different nerves related to the groin. The lateral femoral cutaneous nerve territory is shown in *blue* and extends distally to the knee. Compression or stretch/traction injury of this nerve can be perceived as knee pain. (Courtesy Dellon.com.)

CLINICAL EVALUATION OF KNEE PAIN OF NEURAL ORIGIN

It is critical to obtain the history of knee pain. Knee pain does not arise de novo but because of a history of some type of sports event, overuse activity, new activity, or actual direct injury to the knee. The knee injury may be blunt or open. Surgery should also be considered as a source of trauma. Many patients with knee pain caused by musculoskeletal problems awake from their reconstructive knee surgery to have a different pain or paralysis. These are known complications of knee surgery that should be recognized as such and referred for appropriate treatment in a timely manner. The determination of whether or not the pain is made worse by certain positions of the body or leg or by certain activities is important for a correct diagnosis. Certainly, most knee pain unrelated to structural impairment will be relieved by nonoperative treatment. But when pain persists beyond a reasonable timeframe of 3 to 6 months, the diagnosis is most consistent with pain of neural origin.

The physical examination is directed at identifying one or more sources of neural origin of the pain. First, the clinician should try to distinguish whether any skin territories are dysesthetic or painful when touched lightly. If so, these areas should be outlined. The most common distribution is that of the infrapatellar branch of the saphenous nerve; the second most common is the skin over the patella itself. These areas might be numb, indicating loss of sensation (Fig. 39-5). Once the pattern is identified, examine proximally along the course of the given nerve, observing for a trigger spot, which is either a true end-bulb neuroma or an in-continuity nerve lesion. The hypothesis is made that this nerve or these nerves are the source of the cutaneous pain; a diagnostic nerve block will be required to confirm this hypothesis.

The physical examination is then directed to the joint afferents. Palpation is done deeply on the spot located just distal to the vastus medialis muscle, through the medial retinaculum to elicit pain from the medial retinacular nerve. Next, palpation is repeated on the area located just

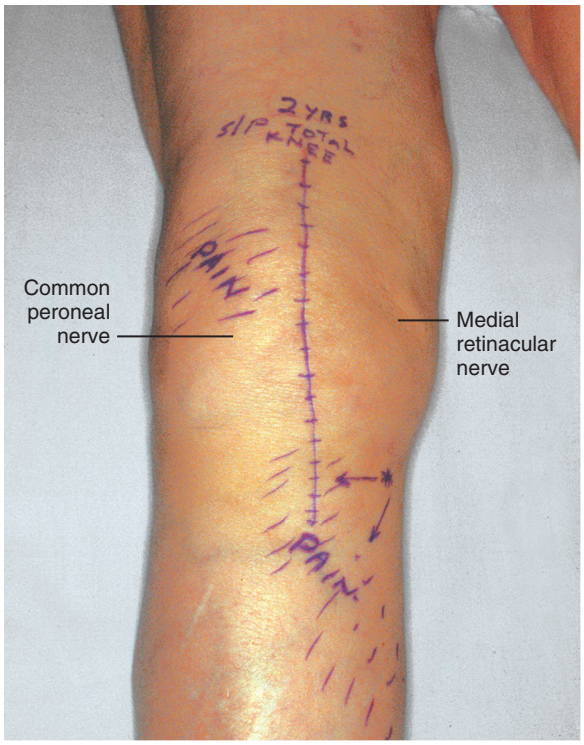

FIG 39-5 Demonstration of the sites to palpate a tender medial and lateral retinacular nerve in a patient with joint pain.

CRITICAL POINTS Clinical Evaluation of Knee Pain of Neural Origin

- History is critical.
- Determine whether pain is made worse by certain positions of the body or leg or by certain activities.
- If pain persists beyond a reasonable timeframe of 3 to 6 months, diagnosis is most consistent with pain of neural origin.
- Distinguish whether any skin territories are dysesthetic; observe for trigger spot.
- Joint afferents: palpate medial and lateral retinacular nerves. To determine whether knee pain is because of an injury to one or both of the joint afferents, conduct diagnostic nerve block. Determine whether effective.
- If block is not effective, look for more rare sources of nerve pain: anterior femoral cutaneous nerve, another branch of the infrapatellar saphenous nerve, Tinel's sign over lateral femoral cutaneous nerve, or motor function of the common peroneal nerve.

distal to the vastus lateralis muscle, through the lateral retinaculum, to elicit pain from the lateral retinacular nerve (Fig. 39-5). The hypothesis is made that the knee joint pain is caused by an injury to one or both of the joint afferents; a diagnostic nerve block will be required to confirm this hypothesis. The medial cutaneous nerve to the thigh and the medial retinacular nerve can be blocked at the same area. Ten minutes after the nerve blocks, the patient is instructed to walk in the hallway, climb and descend a few steps, and even kneel on a padded chair (Fig. 39-6). A reduction of 5 points on a visual analog scale, for example, from 10 to 5, where 10 represents the worst pain, is confirmation that sufficient relief of pain has occurred to permit surgery for partial knee denervation and resection of cutaneous neuromas.

If the nerve blocks just described have not reduced the pain level to less than 5 points or the blocks were not effective, the physical examination should proceed to include other more rare sources for the nerve pain. In a patient with a knee replacement, the remaining pain may stem from an anterior femoral cutaneous nerve found in the proximal portions of the incision or another branch of the infrapatellar saphenous nerve, which can have many branches, including more distal branches.

Finally, the groin should be examined to search for Tinel's sign over the lateral femoral cutaneous nerve. The patient will be noted to sit with the lower extremity extended at the hip joint (Fig. 39-7). The midthigh should be examined to search for Tinel's sign over Hunter's adductor canal. This is most effectively done with the patient supine and the affected leg externally rotated at the hip, leaving the knee bent. This stretches the adductor muscle group over the saphenous nerve. Then gentle palpation over the canal produces a distal radiating painful response (Fig. 39-8).

If the pain is below the knee joint and located laterally, examine for tenderness in the proximal tibiofibular joint space. If this is present, a nerve block can be done directly into this space without blocking the common peroneal nerve.

If pain is accompanied by complaints of the leg "giving out," the foot dragging, or a "footdrop," the motor function of the common peroneal nerve must be evaluated by manual muscle testing. The common peroneal nerve must be palpated or percussed at the fibular neck, with tenderness (even without distal radiation) considered a positive sign for nerve entrapment.

INDICATIONS FOR PARTIAL KNEE DENERVATION

Knee pain that persists for more than 6 months despite musculoskeletal nonoperative and operative treatment is considered chronic. By definition, patients with chronic pain require appropriate management. The diagnosis of knee pain of neural origin should be considered before sending a patient for pain management or, at the least, be considered and evaluated with nerve blocks by a pain-management physician. Certainly, before any consideration is given for a peripheral nerve or spinal stimulator for pain relief, the physician should contemplate treating the peripheral nerve pain generators directly by resection or decompression, as described in this chapter.

CRITICAL POINTS Indications for Partial Knee Denervation

- Knee pain more than 6 months.
- Persistent knee pain in athletes after ligamentous repair or knee arthroscopy.
- Persistent pain after knee reconstruction related to other disorders.
- Patient who has severe degenerative knee pain, but who is "too young" for a hemi- or total knee replacement.
- Patient with persistent knee pain after total knee arthroplasty, in the absence of loosening, malalignment, or infection.

In the athlete, persistent knee pain after ligamentous repair or knee arthroscopy is an indication to determine whether the pain is caused by a traction injury to the nerves that innervate the knee joint, a stress/traction injury, or compression of nerves that cross the knee. Medial knee pain can be related to a groin pull if the contracted adductor muscles create an adductor canal syndrome.

In the patient who has had knee reconstruction related to other disorders, persistent pain must be considered as related to a cutaneous neuroma or an injury to the joint afferents.

In the patient who has severe degenerative knee pain, but who is "too young" for a hemireplacement or total knee replacement, consideration should be given to diagnostic nerve blocks. Although partial joint denervation will not change the underlying osteoarthritic process, it may provide the patient some degree of relief until she or he ages sufficiently to enter the age bracket considered appropriate for an arthroplasty.

In the patient with persistent knee pain after total knee arthroplasty (TKA), in the absence of loosening, malalignment, or infection, pain of neural origin clearly must be evaluated, as described in this chapter.

PREOPERATIVE PLANNING

The first consideration is to make the correct diagnosis. The pain must be identified as coming from either an injured joint afferent as proven by a successful nerve block, an injured cutaneous nerve as proven by a successful nerve block, or a nerve entrapment as demonstrated by the history and physical examination.

The second consideration is that all structural musculoskeletal problems have been treated either nonoperatively, operatively, or both as documented in the referring letter from the orthopaedic surgeon.

The third consideration is the presence of lumbosacral disk disease. Appropriate imaging, electrodiagnostic studies, and subspecialty referral must be completed before peripheral nerve surgery is conducted.

The fourth consideration is the existence of a neuropathy, either diabetic or idiopathic. If the patient has complaints related to the feet, the presence of neuropathy should be evaluated. In addition to the history and physical examination, my preferred approach is to obtain

FIG 39-6 Demonstration of the use of local anesthesia to block the suspected joint and cutaneous afferents in the patient with knee pain. A mixture of 0.5% bupivacaine (Marcaine) and 1% lidocaine (Xylocaine), each without epinephrine (*upper left*), is used to conduct the local block at the two sites indicated in Figure 39-5 to block the joint afferents most likely to be the source of joint pain. Additional blocks would also be done of cutaneous afferents. After the block, the patient should be able to climb stairs and kneel without the previous pain (as shown). There should be a reduction of at least 5 on the 10-point Likert scale in order for this block to be considered successful enough to recommend a partial knee denervation. If there is significant residual pain after the block, additional nerves causing this pain should be identified.

CRITICAL POINTS Preoperative Planning

- Identify pain as coming from either an injured joint afferent, an injured cutaneous nerve, or a nerve entrapment.
- All structural musculoskeletal problems have been treated either nonoperatively, operatively, or both.
- Treat lumbosacral disk disease if present first.
- Determine whether neuropathy exists.
- Consider general health condition of patient, vascular status of limb.
- Educate patient regarding postoperative pain, success rate, and therapy required.

nonpainful and noninvasive neurosensory testing with the Pressure-Specified Sensory Device (PSSD) (Sensory Management Services, LLC).[4,7,38] The PSSD documents the presence of a neuropathy and a nerve entrapment, providing a basis for decompression of the common or superficial peroneal nerve or both (dorsomedial and dorsolateral foot sensibility sites). This device also documents the presence of tibial nerve dysfunction by evaluating the medial calcaneal and medial plantar nerves (heel and hallux pulp skin test sites). This is especially helpful in a patient with postarthroplasty palsy, in whom the PSSD evaluation can document whether the involved nerves demonstrate a nerve regeneration pattern and warrant further observation or, in the absence of that pattern, whether or not neurolysis is indicated at the 3-month timeframe.[9]

The fifth consideration is the medical condition of the patient with regard to the risks of general anesthesia.

The sixth consideration is the vascular status of the limb. The peripheral nerve surgery is done with the use of a tourniquet. Currently, it is not recommended to use a tourniquet in the presence of a leg that has had a bypass grafting procedure.[21]

The seventh consideration is to inform the patient that after a denervation procedure, a neurectomy of a peripheral nerve, or a decompression, there may be unusual and sometimes painful postoperative sensations. These are because of either nerve regeneration in

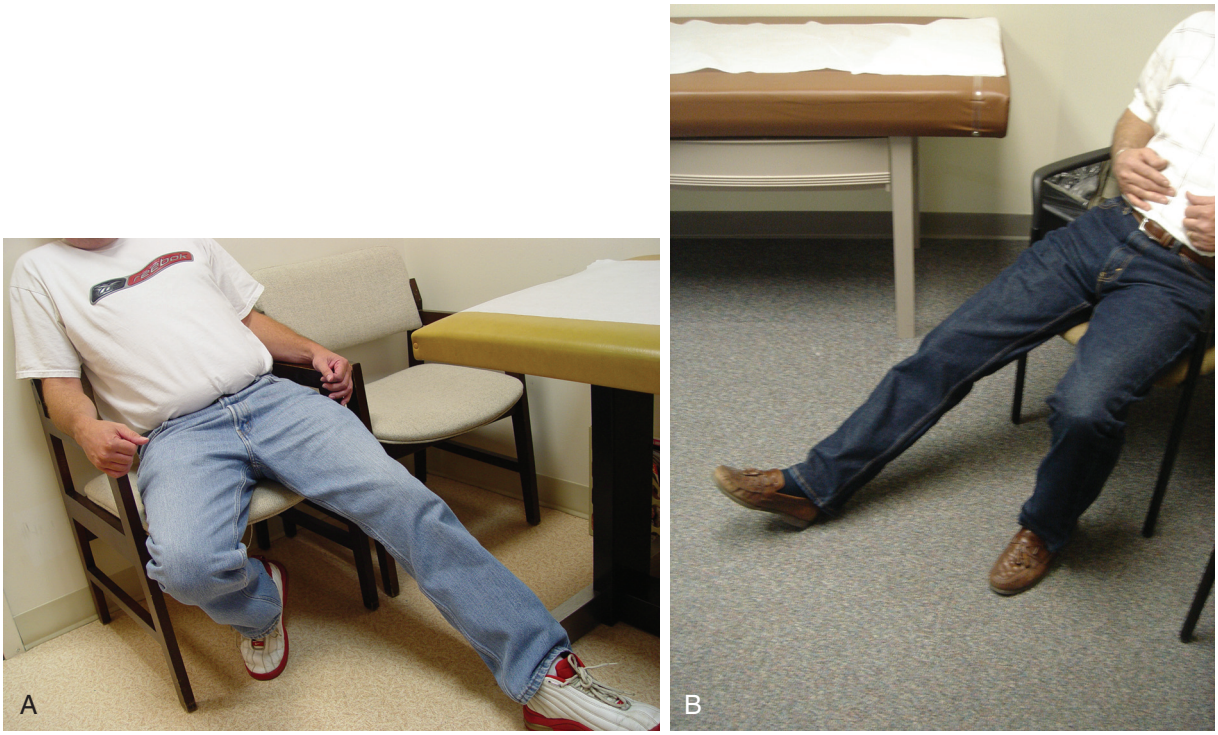

FIG 39-7 Clinical sign of compression of the lateral femoral cutaneous nerve (meralgia paresthetica). Two examples are shown. The patient can be observed to be sitting with the lower extremity on the painful side extended at the hip. Hip flexion increases pressure on the lateral femoral cutaneous nerve as it exits through the site of compression. Shown are a left (**A**) and a right (**B**) lateral femoral cutaneous nerve compression.

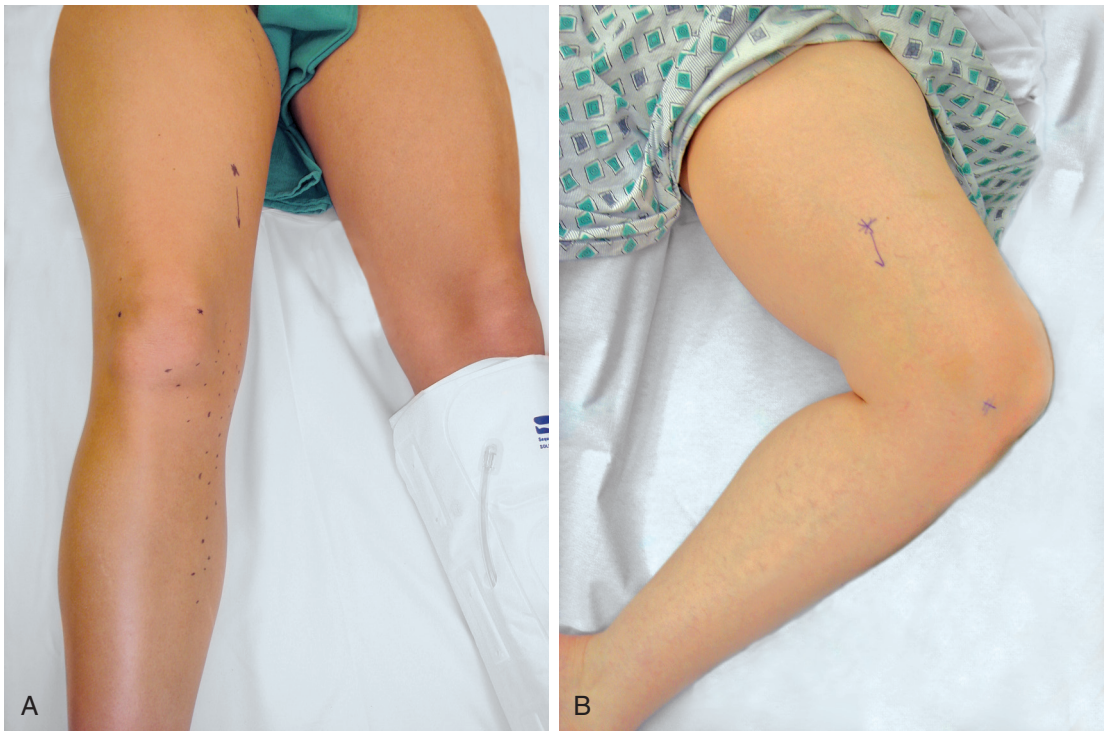

FIG 39-8 Location of the distally radiating Tinel's sign in the patient with compression of the saphenous nerve in Hunter's canal. **A**, Site in a right thigh. **B**, Site in a left thigh. Tinel's sign is marked, and distal radiation into saphenous skin territory is noted.

the case of a nerve decompression or collateral sprouting in the case of a resection of a cutaneous nerve. Some patients perceive that the knee area is swollen, although no visible effusion is present. Postoperatively, the patient should be prepared to participate in aquatic therapy pool sessions two to three times a week for 3 weeks and perform water walking to desensitize the skin and help reorganize the cortical maps.[10]

The eighth consideration is to inform the patient that not all of the original knee pain may be resolved. Small nerves have many anatomic variations, and although in some patients the preoperative block suggests that all pain has been relieved, there may still be a small branch (e.g., the infrapatellar branch of the saphenous nerve) that will require a second operation to remove. A second operation may be necessary in approximately 10% of patients.

With regard to postoperative care, the patient ambulates immediately. This facilitates gliding of any nerves that have been decompressed and minimizes the risk of venous thrombosis. Once the sutures are removed, the patient begins water therapy. With regard to postoperative wound healing, in an obese individual, the lipid substances may come out of the fat cells into the subcutaneous tissue. The biologic process to absorb this often results in a firm, warm area in the fat that may appear to be cellulitis. This responds to topical warmth and antiinflammatory medication. If it is difficult to distinguish this from a bacterial problem, a course of antibiotics may be necessary.

Finally, the patient must be told that peripheral nerve surgery will not alter the stiffness present in the knee joint. Once pain has been relieved, the patient's range of motion (ROM) and strength can again be addressed by the orthopedic surgeon and the physical therapist.

OPERATIVE TECHNIQUES

The operative techniques for partial knee denervation described later have been previously published.[17-19] For each patient, a tourniquet is used and set at a pressure of 300 mg Hg. If the leg is quite large or exceptionally muscular, this pressure can be increased to 325 mm Hg. It is critical to note that the leg is *not* completely exsanguinated. Deliberately, some venous blood is left in the region around the knee by not wrapping the Ace bandage tightly. The small amount of blood left in all the recurrent geniculate artery and veins is helpful in identifying the small joint afferents that lie next to these structures and the larger nerves, such as the infrapatellar branch of the saphenous nerve. A bipolar coagulator and Loupe magnification (×3.5) are used. Intravenous antibiotic prophylaxis is given before inflating the tourniquet. A femoral nerve block is *not* done owing to the risk of injury to the femoral nerve, but rather bupivacaine (Marcaine) 0.5% is infiltrated into the skin edges of the incisions at the end of the surgical procedure. The dressing consists of Xeroform gauze over the incision followed by sterile 4 × 4 inch gauze, which is held in place with Kling and covered with a stockinette. Then an Ace wrap is applied firmly and left in place for 30 minutes to counteract the reactive hyperemia attendant to use of the tourniquet.

Finally, the concept of minimizing the risk of recurrent neuroma pain must be understood. Because the sensory nerves remain alive once divided owing to their intact nucleus in the dorsal root ganglion, nerve regeneration will occur in every joint afferent or cutaneous afferent that is divided. Alteration of the microenvironment of the nerve by implanting the proximal end of a divided sensory nerve into an innervated motor environment results in the absence of formation of a true neuroma.[32] Implanting a sensory nerve into an innervated muscle after resecting the painful neuroma or after interruption of that nerve function by division of that nerve results in predictable pain relief without recurrent neuroma for upper[15,30] and lower extremity[12,28,29] peripheral nerves. The location chosen to place the divided nerve is explained for each operation described later.

CRITICAL POINTS Operative Techniques

- Intravenous antibiotic prophylaxis
- Tourniquet used, leg not completely exsanguinated
- Femoral nerve block not done owing to risk of injury to femoral nerve.
- Bupivacaine (Marcaine) 0.5% is infiltrated into skin edges of incisions at end of surgical procedure
- Dressing: Xeroform gauze over incision followed by sterile 4 × 4 inch gauze held in place with Kling and covered with a stockinette; Ace wrap applied firmly, left in place for 30 minutes
- Operative procedures
- Lateral denervation of knee joint
- Medial denervation of knee joint
- Resection of infrapatellar branch of saphenous nerve
- Resection of medial cutaneous nerve of thigh
- Neurolysis of common peroneal nerve
- Denervation of proximal tibiofibular joint
- Neurolysis of superficial peroneal nerve
- Neurolysis of proximal tibial nerve
- Neurolysis of lateral femoral cutaneous nerve
- Neurolysis of saphenous nerve in Hunter's canal

Lateral Denervation of the Knee Joint

An incision is outlined lateral to the patella, beginning over the distal muscle belly of the vastus lateralis. This muscle sometimes has a slight distal split, and the surgeon must be sure to remain distal to the most distal portion of the vastus lateralis muscle. The iliotibial band (lateral retinaculum) is divided longitudinally for approximately 1.5 cm. Immediately adjacent to the muscle belly are small recurrent vessels and a 1- to 1.5-mm nerve that go from beneath the biceps tendon and the iliotibial band and across the synovium into the lateral joint and infrapatellar structures. This nerve is infiltrated with bupivacaine 0.5% down beneath the iliotibial band and the nerve and vessels are cauterized toward the patella to prevent bleeding and placed under traction. Subsequently, they are cauterized deep beneath the iliotibial band to prevent further bleeding. The portion between the two cauterized sites is sent to pathology. The iliotibial band (lateral retinaculum) is repaired with two figure-eight sutures of 2-0 braided nonabsorbable material (Fig. 39-9).

Medial Denervation of the Knee Joint

An incision is outlined medial to the patella beginning over the distal muscle belly of the vastus medialis. The thin medial retinaculum is divided longitudinally for approximately 1.5 cm. Immediately adjacent to the muscle belly are the small recurrent vessels and a 1- to 1.5-mm nerve that goes from beneath the vastus medialis and across the synovium into the medial joint and infrapatellar structures. This nerve is dissected proximally beneath the retinaculum until it exits from beneath the muscle. It is infiltrated with bupivacaine 0.5% down beneath the vastus medialis and the nerve and vessels are cauterized toward the patella to prevent bleeding and placed under traction, then cauterized deep beneath the vastus medialis to prevent further bleeding. The portion between the two cauterized sites is sent to pathology. The medial retinaculum is repaired with two figure-eight sutures of 3-0 braided nonabsorbable material (Fig. 39-10).

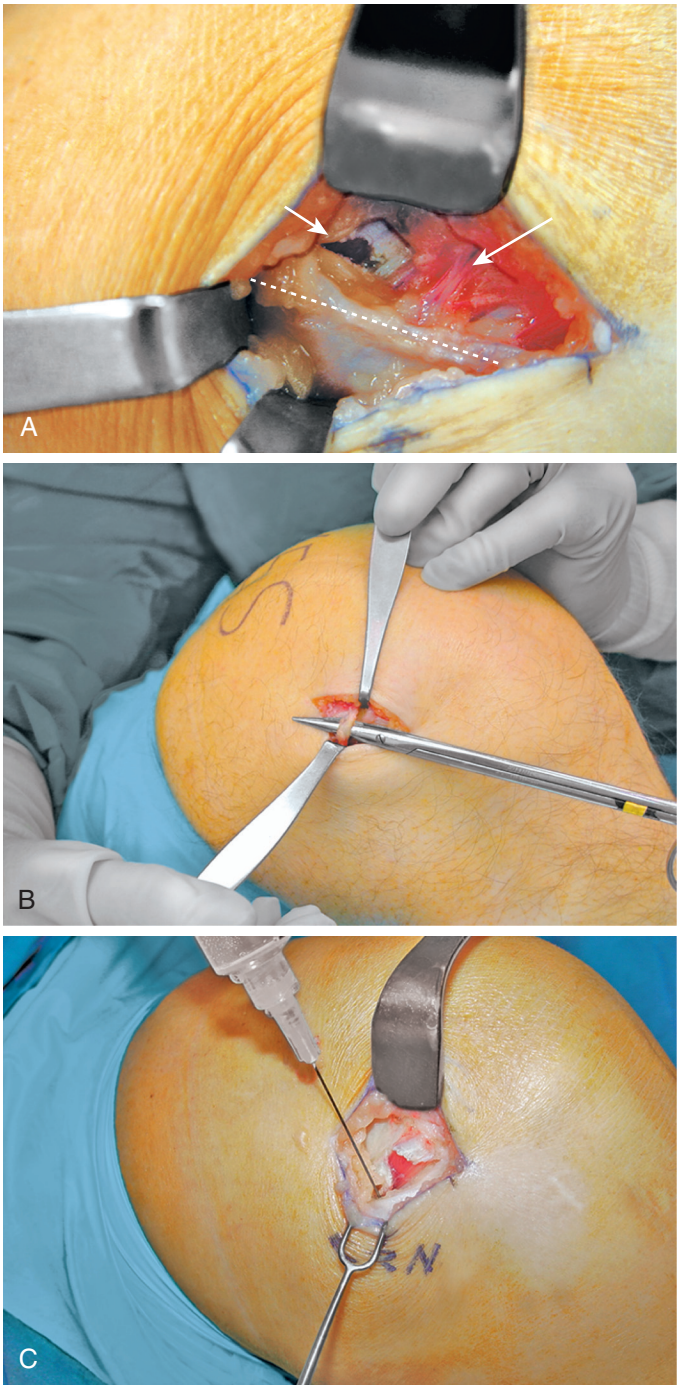

FIG 39-9 Lateral knee denervation. **A**, Incision is shown, lateral to the patella, centered over the tender site shown in Figure 39-5. The *short arrow* indicates the vastus lateralis. The iliotibial tract is incised (*dotted line*) to demonstrate the lateral retinacular nerve (*long arrow*) adjacent to the superior lateral geniculate vessels. **B**, The lateral retinacular nerve. **C**, The nerve is first infiltrated with local anesthetic, cauterized distally and proximally, and then divided proximally below the level of the iliotibial band so that the nerve drops into the popliteal fossa.

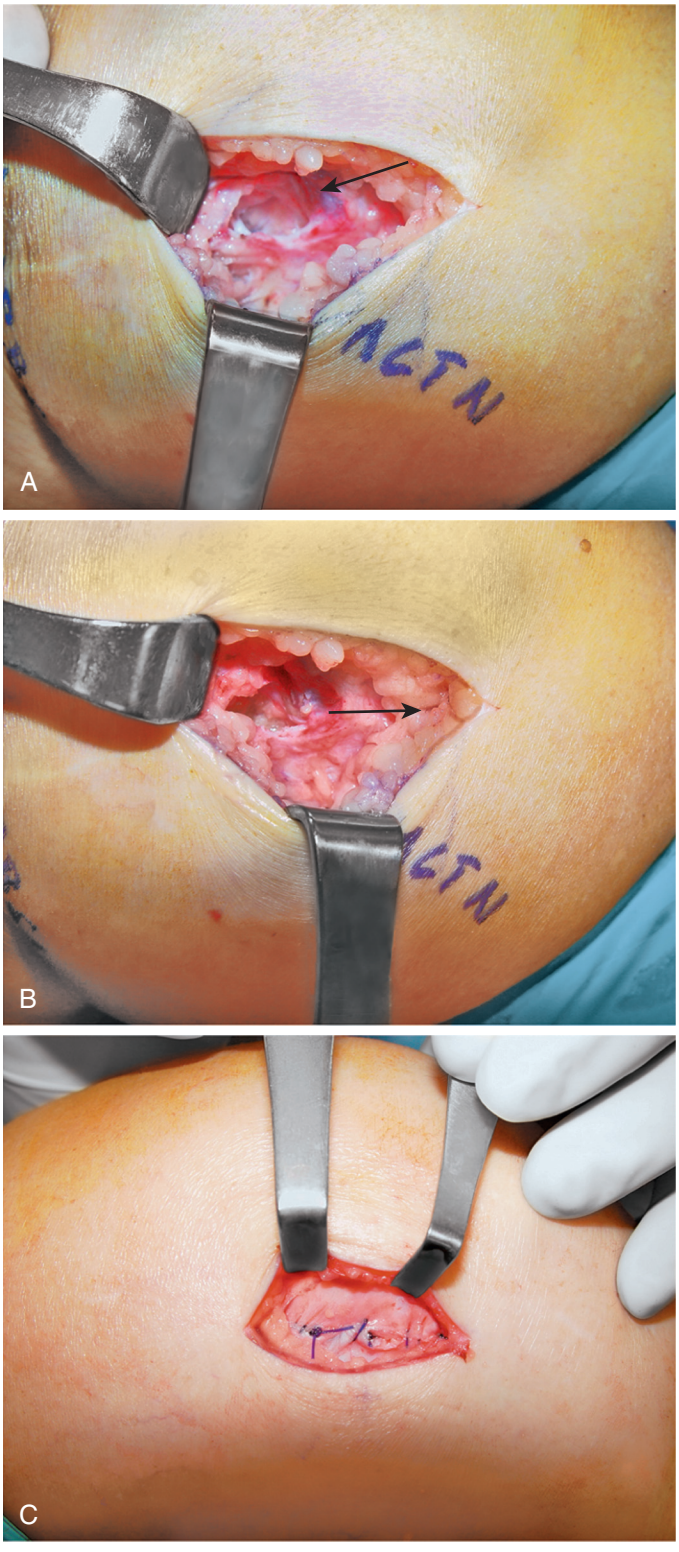

FIG 39-10 Medial knee denervation. **A**, Incision is shown, medial to the patella, centered over the tender site shown in Figure 39-5. The medial retinaculum is opened. The *arrow* points to the medial retinacular nerve adjacent to the recurrent medial recurrent geniculate vessels. **B**, The nerve has been resected. The *arrow* points to the direction in which, beneath the medial retinaculum, the nerve has been implanted into the vastus medialis muscle. **C**, Closure of the medial retinaculum.

Resection of the Infrapatellar Branch of the Saphenous Nerve

The saphenous nerve exits Hunter's canal in the distal thigh to become the medial cutaneous nerve of the thigh, the infrapatellar branch of the saphenous nerve, and the distal saphenous nerve. The infrapatellar branch crosses the insertion of the adductor tendons into Gerdy's tubercle beneath the deep fascia. There may already be two branches at this level. Ultimately, several terminal branches cross from medial to lateral across the region of the tibial tuberosity to innervate the lateral knee skin. The skin proximal to this laterally is the terminal zone of innervation of the lateral femoral cutaneous nerve. Although the numbness is lateral, the damage to the nerve usually occurs in the axial line of the knee from an incision or medially from a scope portal. The site of Tinel's sign medially is around Gerdy's tubercle. An incision is made longitudinally across Tinel's sign. The dissection is carried deep into the fascia where one or more branches are noted by the blood in the vein that accompanies the nerve branch. A thorough proximal and distal search must be done to identify more than one branch. This is the most common location for a missed remaining painful nerve. The nerve is infiltrated with bupivacaine 0.5% proximally, the distal end cauterized to minimize bleeding, a segment resected for pathology, and the proximal end dissected. There is usually a clear tunnel where this nerve has transversed along or through the sartorius or other adductor muscle or tendon. The proximal end of the divided nerve, after cauterization to prevent bleeding, is turned blindly into these muscles and implanted there, proximal to the popliteal crease (Fig. 39-11).

Resection of the Medial Cutaneous Nerve of the Thigh

The medial cutaneous nerve goes to the skin overlying the patella. This skin is traditionally shown as being innervated by an anterior femoral cutaneous nerve coming vertically down the leg. However, the skin is actually innervated by a branch of the saphenous, which approaches this region medially. Indeed, the same tender location for the medial retinacular nerve is the location of this nerve. The clinical clue is that the skin of the patella is dysesthetic. The medial nerve block will block both of these nerves. An incision is used to approach the medial retinacular nerve. There will be blood in the immediate subcutaneous tissue from the small vein that accompanies this nerve. The nerve is cauterized distally, and the proximal end is dissected medially across the surface of the vastus medialis. The nerve is injected with bupivacaine 0.5% proximally. A small window is opened into the fascia of the vastus medialis. The proximal end of the nerve is implanted loosely into this muscle (Fig. 39-12).

Neurolysis of the Common Peroneal Nerve

An oblique incision is made going from the location of the popliteal fossa distally across the fibular neck overlying the palpable and tender common peroneal nerve. In the immediate subcutaneous tissue, the surgeon should be aware that the lateral cutaneous nerve of the calf can be present as a branch of the common peroneal nerve. Injury to this nerve will cause a postoperative painful incision. In addition, this nerve can become adherent to the biceps tendon, which also causes postoperative pain beneath the incision proximally.

The deep fascia is opened. In patients who do not have a neuropathy but who sustained trauma, this fascia will be adherent to the common peroneal nerve, which will be white with an area of inflammation and swelling as the peroneus longus muscle is approached. In patients with neuropathy, particularly those with glucose intolerance or actual diabetes, the common peroneal nerve will be yellow and resemble a neuroma. Be aware of these cases and handle the fat beneath the fascia with great care because it is usually the nerve. The dissection must release the nerve into the popliteal fossa, especially in the case of trauma or joint replacement. The usual compression site, however, is beneath the peroneus muscles. As the surgeon evaluates the common peroneal nerve approaching the fibular head and crossing the fibular neck, two or more tiny branches that go around the fibular head to innervate the proximal tibiofibular joint will be observed. Because the peroneus fascia is the main site of compression, divide the peroneus longus fascia transversely and from the fibula head distally, cauterizing the edges. If there is a septum between muscle groups, divide this septum, being careful on its deep surface. Retract the muscle; dividing the muscle is not necessary. In 20% of cadavers, but in 80% of patients, there will be another band of varying width and thickness deep into the muscle and overlying the nerve across the fibular neck.[12] This is the site of compression, and this band is resected. Next, look beneath the nerve for fibrous bands on the lateral gastrocnemius muscle; if they are present, cauterize and resect them. Check the passageway of the common peroneal nerve beneath the muscles and into the leg. If this is tight, divide the fascial origins of the muscle at the fibula by cautery. This completes the neurolysis of the common peroneal nerve (Fig. 39-13).

Denervation of the Proximal Tibiofibular Joint

In the preceding section, the small branches to the proximal tibiofibular joint were observed. The safest way to denervate this joint is to perform a complete neurolysis of the common peroneal nerve. Then, using a disposable nerve stimulator, stimulate the deep and the superficial peroneal nerves to demonstrate a "positive control." Stimulate the small branches purported to go the proximal tibiofibular joint. If no muscle twitches, these are indeed the correct nerves, and they may be resected back to the common peroneal nerve and submitted to pathology. Do not inject bupivacaine into these nerves because this is likely to create a motor block and cause worry in the recovery room until it wears off (Fig. 39-14).

Neurolysis of the Superficial Peroneal Nerve

Symptoms related to compression of the superficial peroneal nerve are numbness, tingling, or pain radiating from the midlateral lower leg to the top of the foot.

The most important concept here is that the superficial peroneal nerve in at least 25% of patients will have a branch in the anterior compartment.[2,39] Therefore, in addition to opening the lateral compartment, the anterior compartment must be opened. The incision is made approximately 4 cm long, centered on the site of the positive Tinel's sign. The most common location for the incision is 10 to 15 cm proximal to the lateral malleolus. In the subcutaneous tissue, look for a small bulge in the fascia or fat protruding from the fascia because this may be the transit site of the superficial peroneal nerve from deep to superficial to the fascia. There may be a small branch to the skin right at this point that must be preserved. Create a longitudinal opening in the lateral compartment. Even if a nerve is found, a longitudinal opening in the anterior compartment must be made. In addition, transversely cut the fascia to visualize all the way anteriorly. The fascial edges must be cauterized because they are well vascularized and can be a source of postoperative bleeding. The septum between the two compartments is another site in which a branch or the entire superficial peroneal nerve may be located. Do not just simply cut across this region.[40] The goal is to leave the superficial peroneal nerves surrounded only by muscle because

FIG 39-11 Resection of the infrapatellar branch of the saphenous nerve. **A**, A woman 9 years after total knee arthroplasty whose knee is shown from medial aspect demonstrating sites of pain over the anterior femoral cutaneous nerve (proximally), over the medial cutaneous nerve of the thigh (and medial retinacular nerve), and over the infrapatellar branch of the saphenous nerve. **B**, The infrapatellar branch is noted at the medial aspect of the knee, near the tibial tuberosity, at which site it is usually painful to touch. The nerve is infiltrated with local anesthetic prior (**C**) and then cauterized and divided (**D**). **E**, The proximal end of the nerve is dissected and implanted into an adductor muscle medially (location denoted by the finger at the popliteal fossa). **F**, A search must be made proximally for other infrapatellar branches. One is shown here in the incision used to resect the medial cutaneous nerve of the thigh and the medial retinacular nerves.

FIG 39-12 Resection of the medial cutaneous nerve of the thigh. A 23-year-old with a direct injury to the knee resulting in pain over the patellar region. **A**, Site of Tinel's sign and nerve block that eliminated the pain. **B**, Medial cutaneous nerve of the thigh demonstrated by the scissors' tips in the subcutaneous plane. **C**, This is superficial to the medial retinaculum. **D**, The nerve has been divided distally and dissected proximally and is held by a clamp. **E**, A window is made in the fascia over the vastus medialis into which the proximal end of the nerve will be implanted.

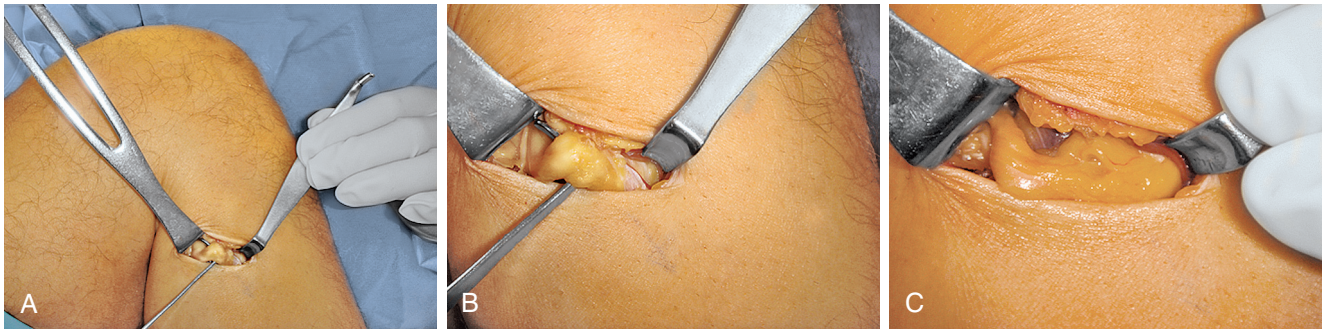

FIG 39-13 Decompression of the common peroneal nerve. **A**, The incision is noted on a right knee, overlying the fibular head and angling toward the popliteal fossa. **B**, The peroneus fascia has been released superficially and the muscles retracted anteriorly. The common peroneal nerve is infiltrated by fat in this patient with diabetes and is compressed by the fibrous band deep to the retracted muscle. **C**, The fibrous band has been excised. The nerve is noted to be indented at the site and to have lost its fascicular markings, consistent with severe compression.

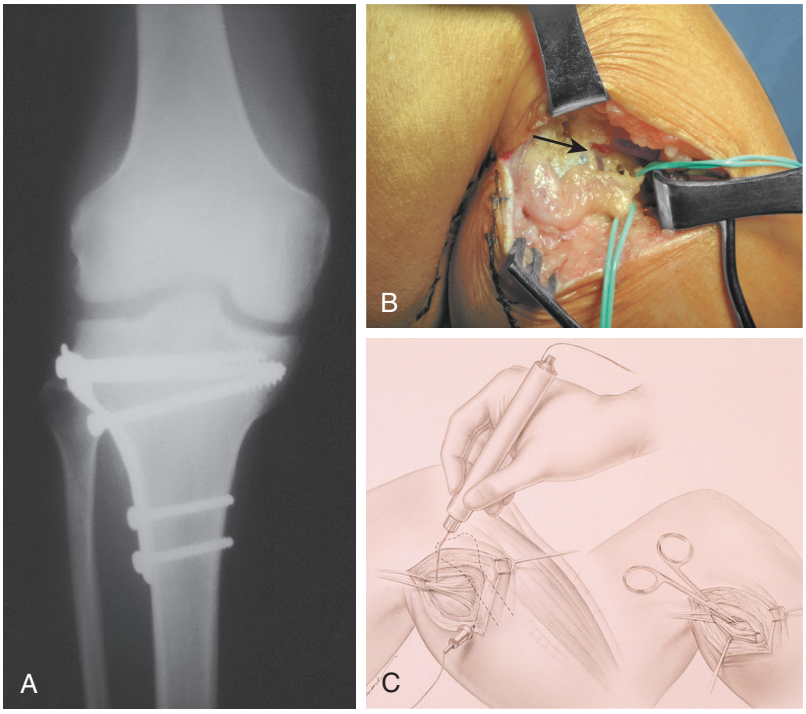

FIG 39-14 Denervation of the proximal tibiofibular joint. **A**, Example of surgery in the region of the proximal tibiofibular joint that can cause pain in this region, typically after a high tibial osteotomy or tibial plateau fracture. **B**, The common peroneal nerve has been decompressed, with the normal common peroneal nerve proximally, and a vessel loop is placed about its major branches, the deep and superficial peroneal nerves. The *arrow* marks a branch that innervates the proximal tibiofibular joint. **C**, Electrical stimulation will give no motor response, and this small branch can be resected. There may be a more proximal branch as well.

this guides the proximal and distal extent of the fascial releases (Fig. 39-15).

Neurolysis of the Proximal Tibial Nerve

An incision approximately 12 cm long is made medially in the calf just anterior to the medial head of the gastrocnemius muscle. The center of the incision is made at the level of the tender proximal tibial nerve, approximately 9 cm distal to the popliteal crease. The deep fascia is opened and the medial gastrocnemius muscle is dissected bluntly from the soleus muscle. The plantaris tendon and the popliteus muscle will be seen. The tibial nerve and the popliteal vein will be observed to pass anterior to the fascial origin or arch or sling of the soleus muscle. A large clamp placed deep to this arch demonstrates the tight area. The soleus muscle fibers may require dissection to reveal the fibrous arch.

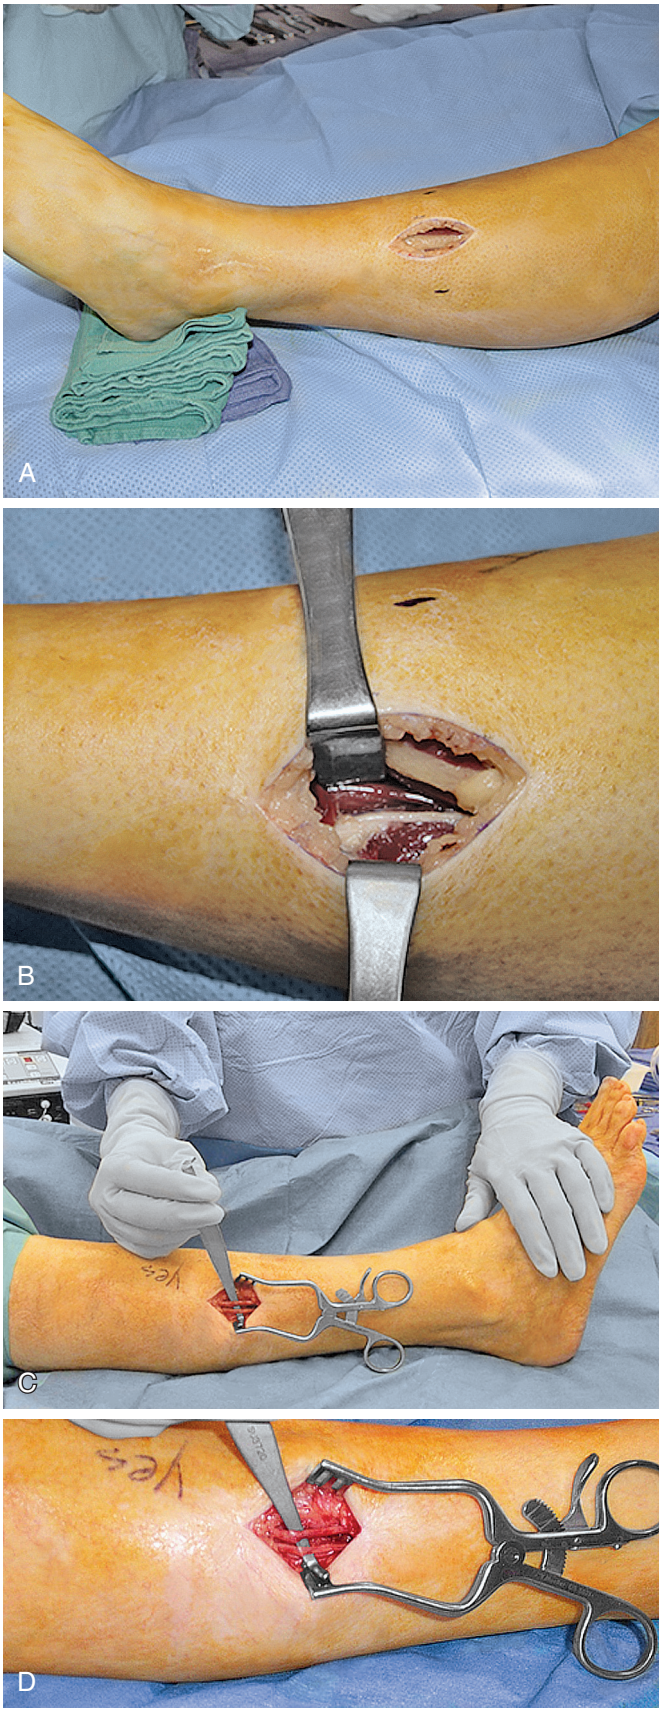

FIG 39-15 Neurolysis of the superficial peroneal nerve. An incision is made over the lateral aspect of the leg at the site of Tinel's sign. Whereas the superficial peroneal nerve is in the lateral compartment in 75% of patients, it can be in just the anterior compartment (**A** and **B**) or in both the anterior and the lateral compartments (**C** and **D**). For this reason, a fasciotomy of both compartments must be done for each patient. The neurolysis is continued until the nerve is distally in the subcutaneous tissue and is proximally surrounded by muscle. In some patients, a portion of the septum between the two compartments must be excised.

If there has been bleeding in this area, this dissection can be difficult. The soleal arch must be completely divided. Usually, a notch in the tibial nerve will be identified (Fig. 39-16).

Neurolysis of the Lateral Femoral Cutaneous Nerve

A tender spot exists just anterior to the anterior superior iliac crest. An incision approximately 4 cm long is made just cephalad to this area and deepened into the subcutaneous tissue. The inguinal ligament is identified and carefully divided, millimeter by millimeter, adjacent to the anterior superior iliac crest while the surgeon looks for the compressed lateral femoral cutaneous nerve. The nerve is narrowed, yellow, and inflamed and often does not look like a nerve. The nerve must be released into the thigh and then proximally until it enters the pelvis. Proximally, this entails dividing portions of the internal oblique fascia. Where this dissection stops, the surgeon should take care not to divide the deep circumflex iliac artery and vein. If the lateral femoral cutaneous nerve is too badly damaged by the compression, it may need to be resected with the proximal end allowed to lie within the pelvis (Fig. 39-17).

Neurolysis of the Saphenous Nerve in Hunter's Canal

A 6 cm incision is made longitudinally at the site of Tinel's sign of the saphenous nerve in the adductor canal. The dissection goes deep until the fascia connecting the vastus medialis to the adductor longus is identified. The length of this tunnel is between 6 and 8 cm. Small nerves will be in this vicinity. They need to be stimulated, because some are not saphenous branches but motor branches. Once the fascia is released, the saphenous nerve will be present as one or more branches. Deep within them will be the superficial femoral artery (Fig. 39-18).

OUR CLINICAL STUDIES

If a patient obtains relief of knee pain after a block of any combination of joint or cutaneous afferents, there is a 90% chance that he or she should also obtain good to excellent relief of his or her knee pain postoperatively.[17-19] Patients who achieve less than a satisfactory result either have another nerve that requires removal or have confounding problems such as a central mechanism for their chronic pain, drug addiction, or legal issues related to work or an accident.

The first group of patients selected for partial knee denervation were chosen from a group who had undergone a TKA but had persistent pain for greater than 6 months that was unrelated to loosening, malalignment, or infection.[19] In this study, the orthopedic surgeons completed a preoperative Knee Society Function Score, ROM, and pain assessment in 15 patients. The author independently performed the partial knee denervation, whereas the orthopedic surgeons conducted the postoperative assessment. To be selected for surgery, each patient had to achieve a reduction of 5 points on a visual analog scale for pain after undergoing selective nerve blocks. A total of 45 nerves were

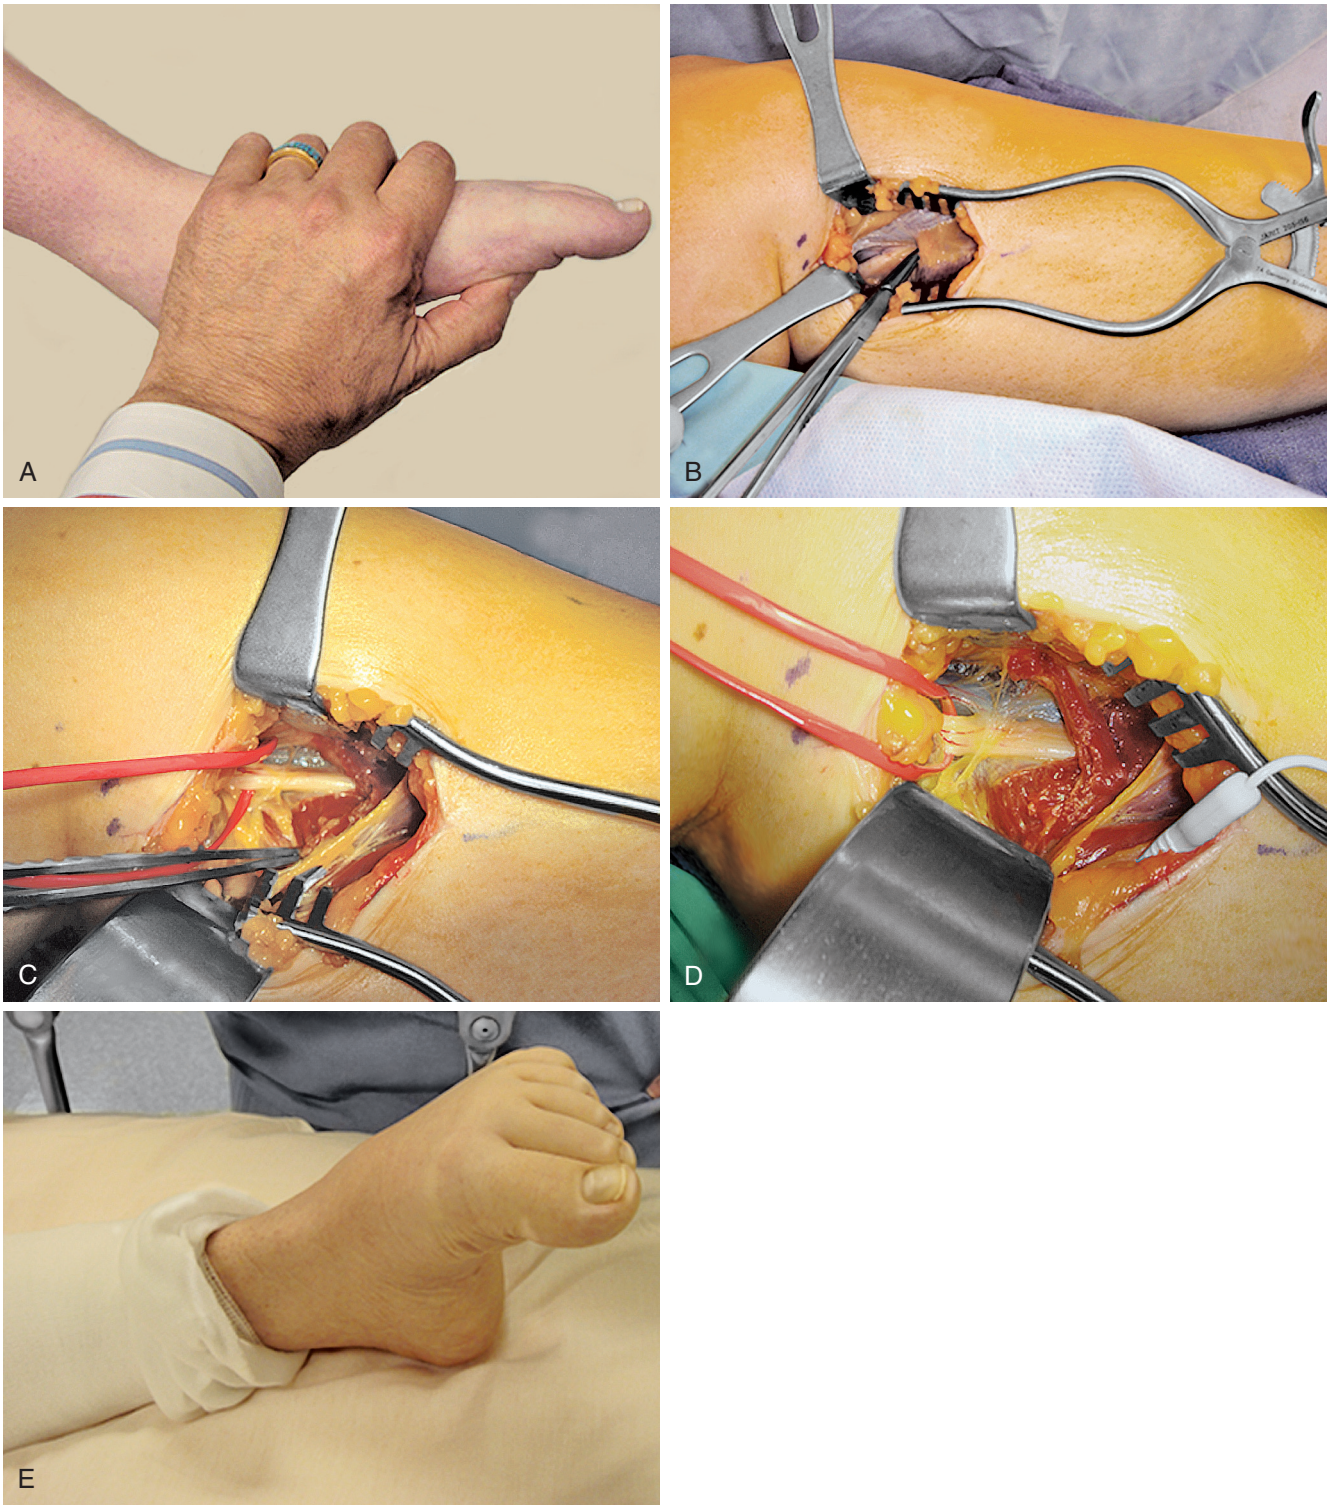

FIG 39-16 Neurolysis of the proximal tibial nerve. Compression of the tibial nerve proximally or distally will decrease sensibility in the plantar aspect of the foot. **A**, However, with a proximal compression versus a tarsal tunnel syndrome, the patient may lose the ability to flex the big toe. **B**, The medial incision is used to expose the space between the medial gastrocnemius muscle and the soleus. **C**, The clamp identifies the compression site of the tibial nerve by the fibrous arch of the soleus muscle. **D**, The nerve has been decompressed, and a difference in appearance of the nerve at this site is noted. **E**, In the recovery room, the patient regained the ability to flex the big toe.

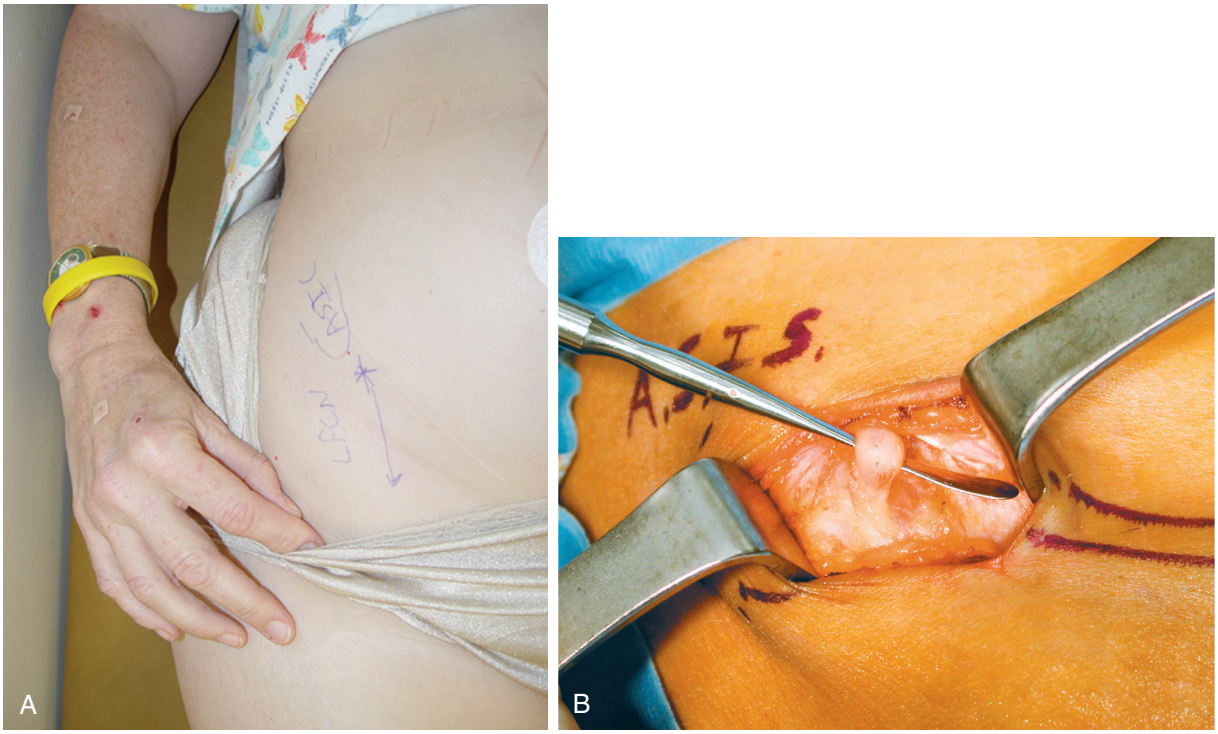

FIG 39-17 Neurolysis of the lateral femoral cutaneous nerve. **A**, Typical site of tenderness of the lateral femoral cutaneous nerve, just medial to the anterior superior iliac crest. **B**, A decompressed right lateral femoral cutaneous nerve is elevated by the instrument after division of the inguinal ligament from above and below. Additional neurolysis is required more proximally for the internal oblique fascia.

CRITICAL POINTS Our Clinical Studies

Study 1

- 45 nerves resected in 15 patients after total knee arthroplasty
- All patients subjective improvement immediately postoperative, maintained 6 to 16 months.

Study 2

- 70 patients after total knee arthroplasty, knee trauma, tibial osteotomy
- 86% satisfied with results
- Knee Society score: preoperative mean, 51 points (range, 40-62 points); follow-up mean, 82 points (range, 15-100 points)

Study 3

- 344 patients after total knee arthroplasty, knee trauma
- All had multiple nerves resected.
- 70% excellent (no remaining pain), 20% good (some pain remained, but no medication was required), 5% some improvement (surgery helped, but pain medication still required), and 5% no improvement.

resected in the 15 patients including (in each patient) both the medial and the lateral retinacular nerve and the infrapatellar branch of the saphenous nerve. All patients reported subjective improvement in the immediate postoperative period, which was maintained at a mean follow-up of 12 months (range, 6-16 months). It was concluded that selective knee denervation is indicated in the management of intractable knee pain of neuroma origin after TKA.

The next series reported consisted 70 patients.[18] Some of these patients had persistent knee pain after TKA, but the indications were extended to include those with chronic pain after knee trauma or tibial osteotomy. In patients with TKA, aseptic loosening, sepsis, ligamentous instability, malalignment, and polyethylene wear were systematically ruled out as the source of pain by the orthopedic surgeons. In patients with non-TKA pain, arthrosis, synovitis, ligamentous instability, and meniscal derangement were excluded as a source of pain. All candidates for the procedure had a successful selective nerve block. Sixty of the 70 patients (86%) were satisfied with the denervation procedure as judged by direct questioning and a reduction in their preoperative pain visual analog score of 5 or more points. The average Knee Society Score improved from a preoperative mean of 51 points (range, 40-62 points) to a follow-up mean of 82 points (range, 15-100 points). Forty-nine patients (70%) had final Knee Society objective scores greater than 80 points. There was no difference in patient satisfaction whether the follow-up period was less than 2 years or more than 2 years. Selective knee denervation is indicated in the management of intractable knee pain after exhaustion of traditional approaches to any structural or infectious etiologies and after successful selective nerve block.

In 2000, a series of 344 patients reviewed.[17] Of these, 255 had a previous TKA, and 89 had knee trauma. Most patients had several nerves removed; none had only one nerve resected. All required removal of the medial and the lateral retinacular nerves, and the majority also required removal of the medial cutaneous nerve of the thigh and the infrapatellar branch of the saphenous nerve. The nerves least often removed were the anterior femoral cutaneous and the distal saphenous nerve. Approximately half of the patients, especially those who had sustained knee trauma, required a neurolysis of the common peroneal nerve. The proximal tibiofibular joint required denervation in patients with fractures of the fibula or tibial plateau and who had undergone a Maquet procedure or a high tibial osteotomy. The results for the entire series were 70% excellent (no remaining pain), 20% good

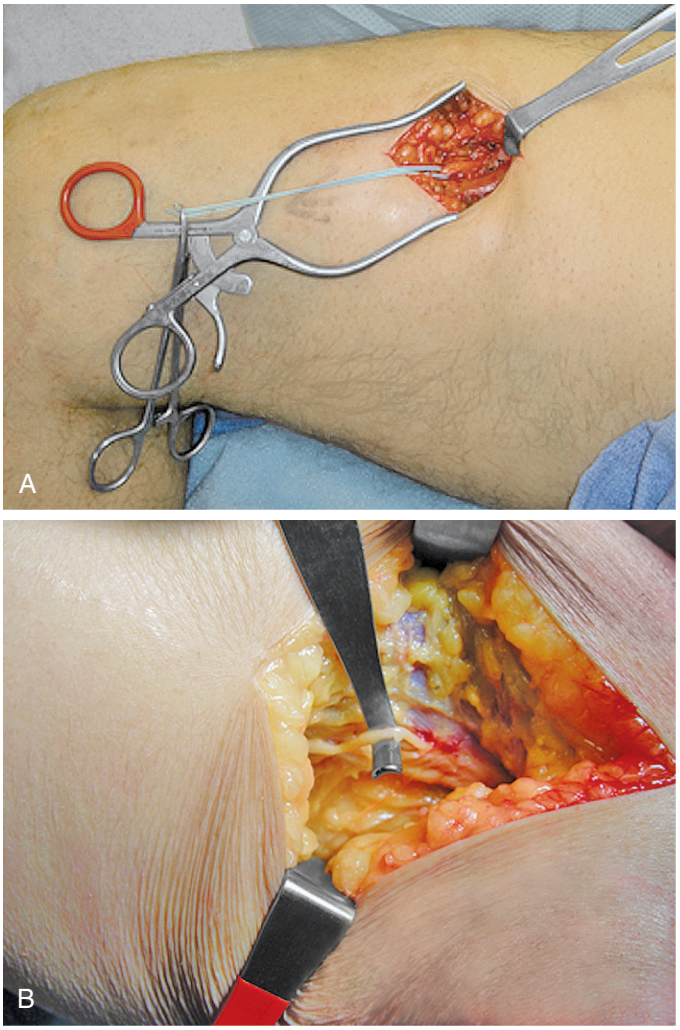

FIG 39-18 Neurolysis of the saphenous nerve in Hunter's canal. **A**, The location of the incision is clear. The entire fascial band from the vastus medialis to the adductor magnus has been released. The large single saphenous nerve is noted. **B**, In this view, a single small saphenous nerve branch is seen emerging from the fascia of Hunter's canal before its release.

(some pain remained, but no medication was required), 5% some improvement (surgery helped, but pain medication still required), and 5% no improvement. No patient was neurologically downgraded or made worse. No knee implant or hardware was exposed. No patient had to be hospitalized to treat infection. The abnormal sensibility, which is usually decreased sensibility, remained to some degree in everyone after a cutaneous nerve was removed.

A review of knee denervation patients on our office computer from January of 2000 through December of 2006 included 405 patients. Although this large group of patients had not been reviewed at this time, the overall experience with the diagnosis, intraoperative management, and postoperative outcomes remained the same as those obtained in our 2000 review data.[16]

OTHER AUTHORS' CLINICAL STUDIES

In contrast to the vast literature on relief of acute knee pain with femoral, obturator, or even lateral femoral cutaneous nerve blocks (more than 120 references cited in PubMed between 2006 and 2008), with the exception of one surgeon in Germany,[23,24] there have been no reported studies of partial knee denervation. Between May 1995 and June 1999, Fromberg and Hempfling[24] performed partial denervation using the "Dellon technique" described in this chapter in 45 knees. The investigations of Fromberg and Hempfling included patients with direct knee injury as well as those who had knee joint replacement. Thirty-four patients were followed, 11 with bilateral knee pain, whose ages ranged from 25 to 86 years (mean, 34 years). At follow-up 6 to 18 months postoperatively, 70% of the patients reported "a reduction in pain," and after 4 years, 50% "still confirmed a positive result." Complications included 1 hematoma and 2 seromas, which resolved with conservative management.

A recent study evaluated the innervation of the patella in 30 knees of 15 formaldehyde-fixed cadavers.[33] A nerve from the vastus medialis (which is the nerve described previously[1]) entering the patella "superomedially" and a nerve "from the vastus lateralis entering the patella superolaterally" were identified. The origin of these nerves was not described. The superolateral nerve "from the vastus lateralis" was most likely the nerve described previously that originates from the sciatic nerve and crosses in front of the vastus lateralis.[25] This anatomic study in fixed cadavers confirms the author's observations reported in 1994.[25] Maralcan and coworkers[33] confirmed that these nerves were patellar pain afferents by performing a local anesthesia block in 32 knees of 20 patients with patellofemoral pain. They observed a significant difference between the visual analog scale scores before and after local anesthetic injections ($P < .01$). Their observations appear to confirm that knee pain can be of neural origin from the medial and the lateral retinacular nerves, as described previously.[17-19,25]

CRITICAL POINTS Other Authors' Clinical Studies

***Fromberg and Hempfling*[24]**

- $n = 45$
- 70% reported "a reduction in pain" 6 to 18 months postoperative
- After 4 years, 50% "still confirmed a positive result"

***Maralcan et al.*[33]**

- Local anesthesia block in 32 knees of 20 patients with patellofemoral pain
- Significant difference between the visual analog scale scores before and after local anesthetic injections
- Confirmed that knee pain can be of neural origin from the medial and the lateral retinacular nerves

REFLEX SYMPATHETIC DYSTROPHY OF THE KNEE

In 1986, Katz and associates[27] defined reflex sympathetic dystrophy of the knee as diffuse pain, often accompanied with skin color changes, in patients who did not allow their knee to be touched and exhibited all the characteristics of what today is termed *complex regional pain syndrome*. These authors reported on 5 patients from a series of 662 primary total knee arthroplasties (0.8%) who demonstrated, in addition to pain, marked limitation of flexion. They stated that the traditional bone scan and osteopenia that were used as criteria for diagnosing reflex sympathetic dystrophy in the hand were difficult to aid in diagnosing this disease in patients who had TKA (Fig. 39-19). A lumbar sympathetic block was believed to be more helpful in making the diagnosis.

With the vision of hindsight, I now maintain that this condition is related to the combination of joint and cutaneous neuromas. However,

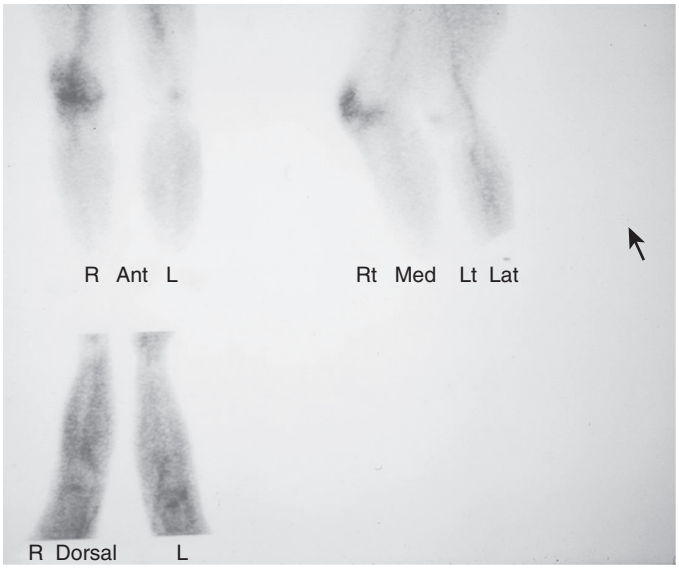

FIG 39-19 Reflex sympathetic dystrophy of the knee. A bone scan illustrates the increased uptake about the prosthesis after a total knee arthroplasty in a patient with chronic severe knee pain. This bone scan was interpreted as being consistent with reflex sympathetic dystrophy.

CRITICAL POINTS **Reflex Sympathetic Dystrophy of the Knee**

- Condition related to the combination of joint and cutaneous neuromas
- Preferred treatment is to interrupt the pain stimuli from entering the dorsal columns of the spinal cord.
- *n* = 40 upper and 30 lower extremity patients with complex regional pain syndrome followed a mean of 15 mo postoperative

Outcome

- Upper extremity patients: 55% excellent, 35% good, 10% failed
- Lower extremity patients: 66% excellent, 30% good, 4% failed

instead of attempting to treat this problem by blocking the sympathetic outflow, my preferred treatment is to interrupt the pain stimuli from entering the dorsal columns of the spinal cord using the techniques described previously. My experience with this approach was reviewed in 40 upper and 30 lower extremity patients with complex regional pain syndrome.[11] At a mean postoperative time interval of 15 months, and based on decreased pain medication usage, recovery of function, repeat history, and physical examination, outcome in the upper extremity patients was excellent in 55%, good in 35%, and failed in 10%. Outcome in the lower extremity patients was similar: excellent in 66%, good in 30%, and failed in 4%.

INTRODUCTION

Complex regional pain syndrome (CRPS) is the term that refers to a painful and disabling disorder that was first described during the United States Civil War.[195] Nomenclature relating to CRPS has varied over the years and has included Sudeck's atrophy, reflex sympathetic dystrophy (RSD), posttraumatic dystrophy, and causalgia. CRPS has a variable presentation, and no single test exists to confirm the diagnosis. The disorder usually follows tissue injury or surgery to a limb (although it may have a spontaneous onset[320]) that may be associated with sensory, vasomotor, sudomotor, motor, and dystrophic changes (Table 40-1).[301] The pain is distinct in that it is out of proportion to the inciting event and may be accompanied by discoloration of skin (Fig. 40-1), change in skin temperature, abnormal sweating, edema, and loss of the normal range of motion of the affected limb.

In 1994, the International Association for the Study of Pain (IASP) established a definition of CRPS to accommodate the various presentations, hypothesized pathophysiology, and anatomical structures involved.[194] The diagnostic criteria for CRPS recommended by the IASP involved four factors:

1. The presence of an initiating noxious event, or a cause of immobilization
2. Continuing pain, allodynia, or hyperalgesia in which the pain is disproportionate to any known inciting event
3. Evidence at some time of edema, changes in skin blood flow, or abnormal sudomotor activity in the region of pain (can be sign or symptom)
4. This diagnosis is excluded by the existence of other conditions that would otherwise account for the degree of pain and dysfunction.

In addition, the physician was instructed to diagnose CRPS-I if the criteria existed without "major" nerve damage and to diagnose CRPS-II if the criteria were found in the presence of major nerve damage. In this respect, the region of disproportionate pain was believed to originate initially within a dermatome.[194] As the disease progressed, it could spread beyond a single dermatome.

Although the standardized, internationally recognized terms of CRPS-I and CRPS-II were made available more than 3 decades ago, there continued to be inconsistencies in the literature that focused on this disorder. These were mainly believed to be caused by the poor specificity that existed for the IASP criteria, which lead to a high rate of false-positive diagnoses.[117] In response to this problem, an international consensus conference was held in Budapest in 2003 with the goal of improving the IASP criteria.[119] The resulting diagnostic criteria for CRPS, known as the "Budapest Criteria", were found to have excellent sensitivity and specificity (Table 40-2).[118] The Committee for Classification of Chronic Pain of the IASP approved these criteria and will use them in upcoming revisions of their formal classification and diagnostic criteria for pain states.[121]

TABLE 40-1 Terms Relevant to Complex Regional Pain Syndrome

Adrenergic: synapses in which the neurotransmitter epinephrine is used.
Abnormal sudomotor activity: excessive or spontaneous sweating.
Afferent neurons (sensory neurons): transmit sensory signals from receptors or sense organs to the central nervous system.
Allodynia: pain caused by a stimulus that normally does not produce pain (i.e., light touch, clothing, bed sheet).
Apraxia: loss of the ability to execute or perform learned skilled motor movements.
Bradykinesia: extreme slowness of movements and reflexes.
Dermatome: an area of skin that is innervated by sensory fibers from a single spinal nerve.
Dorsal root ganglions: transmits somatosensory information from afferent sensory nerve fibers (representing pain, pressure, and temperature) to the spinal cord.
Dystrophic changes: changes in the sympathetic nervous system which may include pain, sweating, edema.
Dystonia: sustained involuntary muscle contractions and spasms, cause twisting and repetitive movements or abnormal postures.
Efferent neurons (motor neurons): transmit signals from the central nervous system to effectors in the body such as muscles and glands.
Ephapses: abnormal synapses that occur between nerve fibers in the dorsal-root ganglion after a peripheral injury.
Hyperalgesia: increased sensitivity to painful stimuli.
Hyperreflexia: involuntary overactive or exaggerated reflexes.
Hyperhidrosis: excessive sweating.
Hypoalgesia: reduced sensitivity of painful stimuli.
Hypoesthesia: diminished or partial loss of sensation.
Hypohidrosis: diminished sweating.
Kinesiophobia: fear of movement.
Myoclonus: involuntary brief twitching of a muscle or group of muscles.
Neurogenic inflammation: inflammation that arises from the local release of inflammatory mediators (neuropeptides) from nociceptive C-fibers such as the substance P, calcitonin gene-related peptide, and bradykinin; evokes vasodilation in acute complex regional pain syndrome and may cause edema, sweating, elevated skin temperature, erythema, and hair growth.
Neurotransmitters, excitatory: increase the likelihood that a neuron will fire an action potential (i.e., epinephrine and norepinephrine).
Neurotransmitters, inhibitory: decrease the chance of a neuron firing an action potential (i.e., serotonin and gamma-aminobutyric acid).
Noradrenergic: synapses in which the neurotransmitter norepinephrine is used.
Paravertebral ganglia (sympathetic chain or trunk): a series of paired chains of ganglia which lie parallel to the vertebral bodies of the spinal column.
Preganglionic neurons: arise in the central nervous system and run to a ganglion in the body.
Postganglionic neurons: originate in the peripheral nervous system within a ganglion, synapse with preganglionic neurons, and then run to an effector organ.

Much debate continues regarding the etiology and pathophysiology of CRPS.[60,69,97,182,216,310] There are potential peripheral, afferent, efferent, and central mechanisms. The pain generator in CRPS has historically been described as being either sympathetically maintained pain (SMP) or sympathetically independent pain (SIP), depending on whether or not the sympathetic nervous system is involved.[296] A sympathetic nerve block has been recommended to determine how much of the patient's pain is "SMP" and how much is "SIP." The pain relieved by the block has been hypothesized to be SMP, although the remaining pain represents SIP.[294] However, recent research has questioned this explanation of pain and other signs and symptoms of CRPS, which appear to be more centrally involved, as will be discussed later.[60,138,216]

FIG 40-1 Dark discoloration of the limb upon initial presentation.

Despite the complexity of the definition of CRPS, the hallmark of this disease is pain usually starting in an arm or leg that is out of proportion to the inciting event of trauma or surgery. Recent research has shown that, despite prior beliefs, CRPS is not significantly associated with a history or presence of psychological problems.[13,14] The early diagnosis and treatment of this disorder is crucial because early management yields a more favorable outcome.[141,222,230,231] If not successfully managed, CRPS patients have a major loss of quality of life[275] and will most likely experience psychological consequences of their chronic pain.[59,315] This chapter covers basic relevant anatomy, proposed etiology and pathophysiology, clinical presentation, diagnosis, and treatment options for CRPS. It is important to note that controversy and a lack of consensus exists within the medical community regarding these issues.

ANATOMY

To understand the basis of the proposed etiology and pathophysiology of CRPS, the clinician must have an understanding of the human nervous system anatomy and function. Detailed knowledge of the innervation of the knee joint and lower limb is also required because in many instances, this disorder begins from obvious peripheral nerve injury[64] or minimal injury or degeneration of small distal nerves.[215,217]

Nervous System: Review of Basic Concepts

The human nervous system is divided into the *central nervous system* (CNS, the brain, spinal cord) and the *peripheral nervous system* (PNS, composed of cranial nerves, spinal nerves, and peripheral nerves with their motor and sensory endings). The PNS has sensory neurons that run from stimulus receptors to the CNS and motor neurons that relay information from the CNS to the muscles and glands. The PNS is subdivided into the *somatic* and *autonomic* nervous systems.

TABLE 40-2 Budapest Clinical Diagnostic Criteria for Complex Regional Pain Syndrome

General Definition:

CRPS describes an array of painful conditions that are characterized by a continuing (spontaneous and/or evoked) regional pain that is seemingly disproportionate in time or degree to the usual course of any known trauma or other lesion. The pain is regional (not in specific nerve territory or dermatome) and usually has a distal predominance of abnormal sensory, motor, sudomotor, vasomotor, and/or trophic findings. The syndrome shows variable progression over time.

To Make the Clinical Diagnosis of CRPS, the Following Criteria Must Be Met:

1. Continuing pain, which is disproportionate to any inciting event
2. Must report at least one symptom in *three of the four* following categories:
   - **Sensory:** Reports of hyperesthesia and/or allodynia
   - **Vasomotor:** Reports of temperature asymmetry and/or skin color changes and/or skin color asymmetry
   - **Sudomotor/edema:** Reports of edema and/or sweating changes and/or sweating asymmetry
   - **Motor/trophic:** Reports of decreased range of motion and/or motor dysfunction (weakness, tremor, dystonia) and/or trophic changes (hair, nail, skin)
3. Must display at least one sign at time of evaluation in *two or more* of the following categories:
   - **Sensory:** Evidence of hyperalgesia (to pinprick) and/or allodynia (to light touch and/or deep somatic pressure and/or joint movement)
   - **Vasomotor:** Evidence of temperature asymmetry (>1° C) and/or skin color changes and/or asymmetry
   - **Sudomotor/edema:** Evidence of edema and/or sweating changes and/or sweating asymmetry
   - **Motor/trophic:** Evidence of decreased range of motion and/or motor dysfunction (weakness, tremor, dystonia) and/or trophic changes (hair, nail, skin)
4. There is no other diagnosis that better explains the signs and symptoms

From Harden RN, Bruehl S, Stanton-Hicks M, et al. Proposed new diagnostic criteria for complex regional pain syndrome. *Pain Med.* 2007;8:325-331.

The somatic nervous system consists of cranial nerves (12 pairs), spinal nerves (31 pairs) (Fig. 40-2), and association nerves. It is the consciously controlled part of the PNS. Functions of this system include smell, vision, movement (stimulation of skeletal muscles), facial and mouth sensation, chewing, taste, swallowing, hearing, and balance.

The autonomic system controls the subconscious actions of cardiac muscle, smooth muscle, and glands. This system uses a two-neuron pathway from the CNS to the peripheral organ, known as the *sympathetic* and *parasympathetic nervous systems* that are described in detail later. There are two nerve fibers in this pathway termed *preganglionic* and *postganglionic*. The preganglionic neurons arise in the CNS and run to a ganglion in the body. They then synapse with postganglionic neurons, which run to the effector organ. Various neurotransmitters are frequently involved with this process, as we will describe later. For instance, postganglionic parasympathetic neurons release acetylcholine, while postganglionic sympathetic nerve fibers release norepinephrine.

CRITICAL POINTS Anatomy

- Review of nervous systems, autonomic system uses two-neuron pathway from central nervous system to peripheral organ, called sympathetic and parasympathetic nervous systems.
- Postganglionic parasympathetic neurons release acetylcholine, postganglionic sympathetic nerve fibers release norepinephrine, neurotransmitters involved with CRPS.
- Review afferent, efferent neurons, dorsal root ganglions, synapses.
- Sympathetic nervous system responsible for the fight-or-flight response, mediated by catecholamines epinephrine and norepinephrine, substance P.
- Catecholamine neurotransmitters stimulate α and β receptors. Stimulation α receptors: elevated heart rate and blood pressure, piloerection, and skin vasoconstriction. Stimulation β receptors: increased heart rate, muscle vasodilation, and bronchial dilation.
- Stellate ganglion supplies majority of sympathetic innervation to upper extremities, lumbar paravertebral ganglia supplies lower extremities.
- Nerves around knee and lower limb: femoral, obturator, common peroneal, tibial, saphenous, medial retinacular.

Neurons

Neurons process and communicate information within the body by transmitting electrical and also frequently electrochemical signals to other neurons or effector cells. A typical neuron contains a cell body, dendrites, and an axon (Fig. 40-3). Many axons are covered with a myelin sheath, which is an expanded plasma membrane of an accessory Schwann cell. There are areas where space exists between the sheath of Schwann cells, known as the node of Ranvier. These areas contain voltage-gated sodium channels, whereby depolarization sweeps along the cell. When depolarization reaches threshold, an action potential is generated. This in turn triggers the release of neurotransmitter chemicals, which will be discussed later.

Information is usually processed from the axon of one neuron to a dendrite of another, although there are exceptions to this rule. Dendrites frequently branch profusely and the axon may extend for a great distance, giving rise of hundreds of branches. There are three types of neurons:

- *Afferent neurons* (sensory neurons) transmit sensory signals from receptors or sense organs to the CNS. These neurons have an axon that extends to the periphery and another axon that extends into the CNS via the dorsal root. The cell body of these neurons is located in the dorsal root ganglion or a sensory ganglion of sensory cranial nerves (Fig. 40-4). The ventral and dorsal rootlets join together to form the root of a peripheral nerve. Specialized somatic sensory nerve endings known as nociceptors, mechanoreceptors, and thermoreceptors perceive pain stimuli, pressure stimuli, and temperature stimuli.
- *Efferent neurons* (motor neurons) transmit signals from the CNS to effectors in the body such as muscles and glands. They project their axons outside the CNS to directly or indirectly to control muscles. These include somatic and visceral motor neurons.
- *Interneurons* form complex networks within the CNS to integrate information between sensory and motor neurons.

Ganglions

Ganglions represent a group or nodule of cell bodies of sensory nerves (neurons) that are usually located outside the brain and spinal cord. There are two major types of ganglions: dorsal root (spinal) and autonomic.

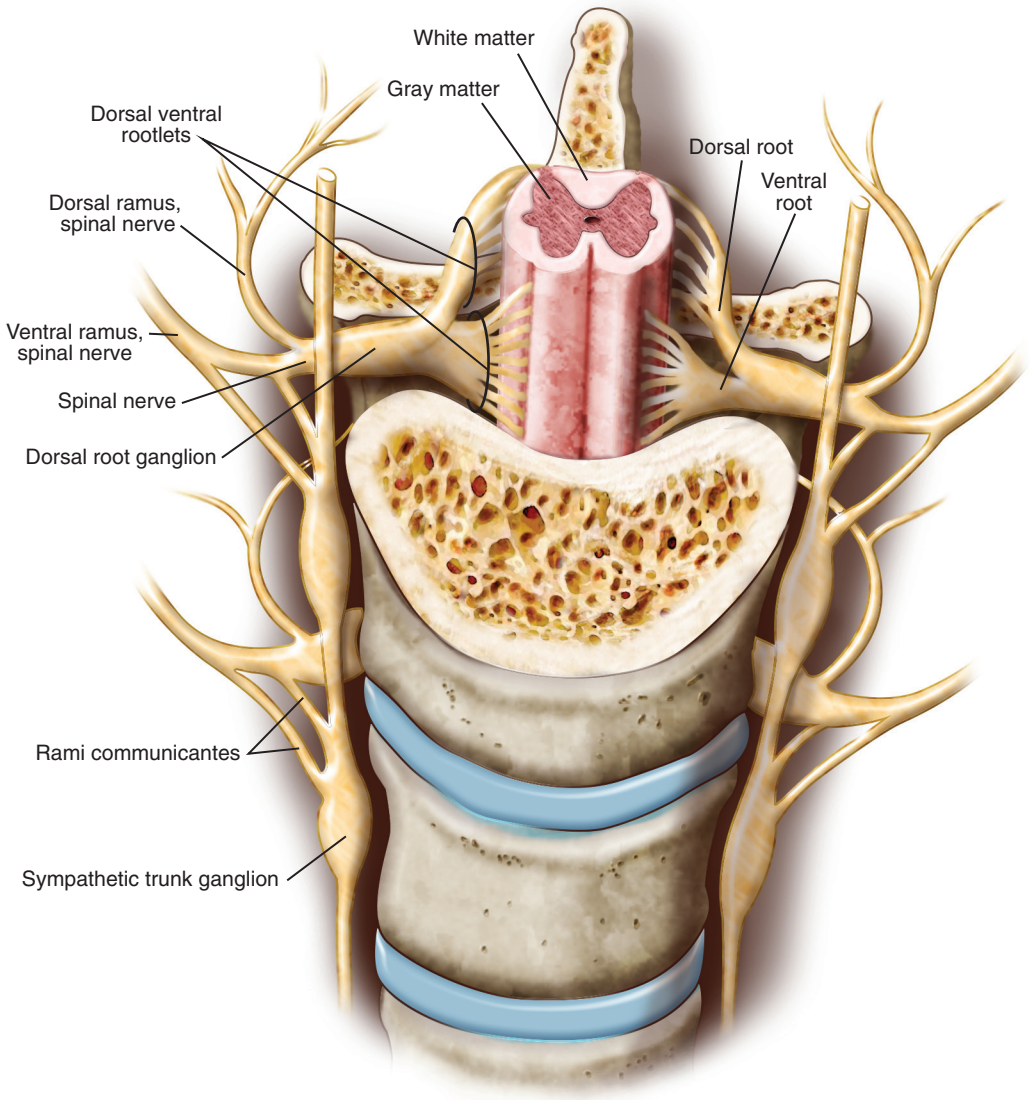

FIG 40-2 Major elements of a spinal nerve.

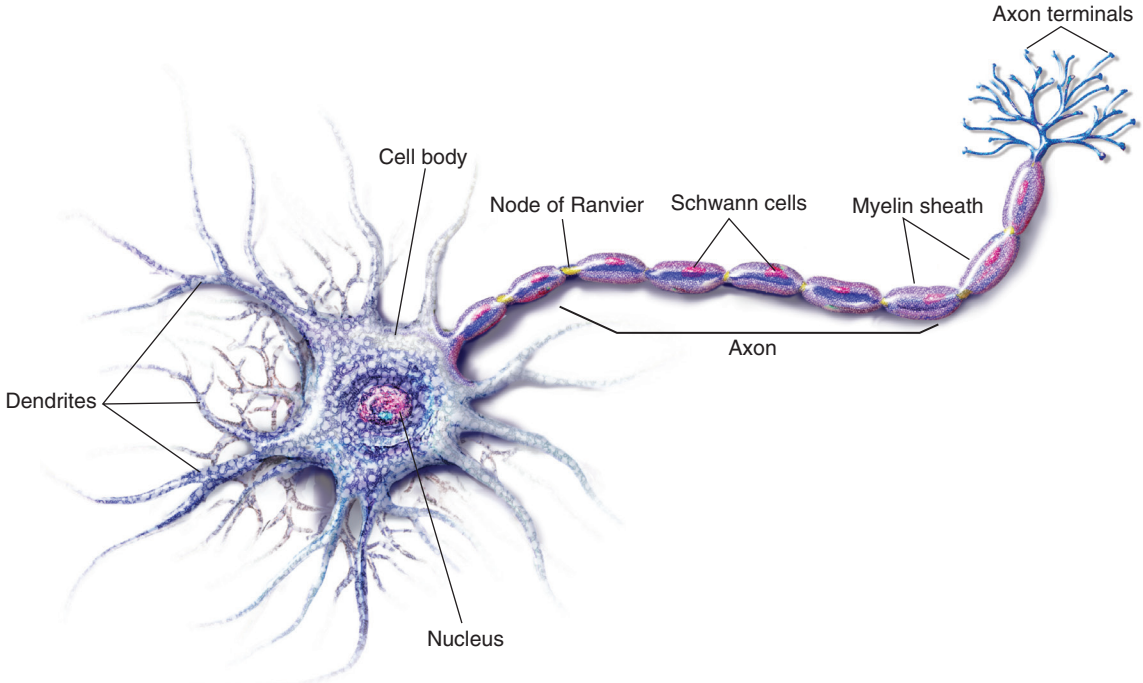

FIG 40-3 Basic components of a neuron.

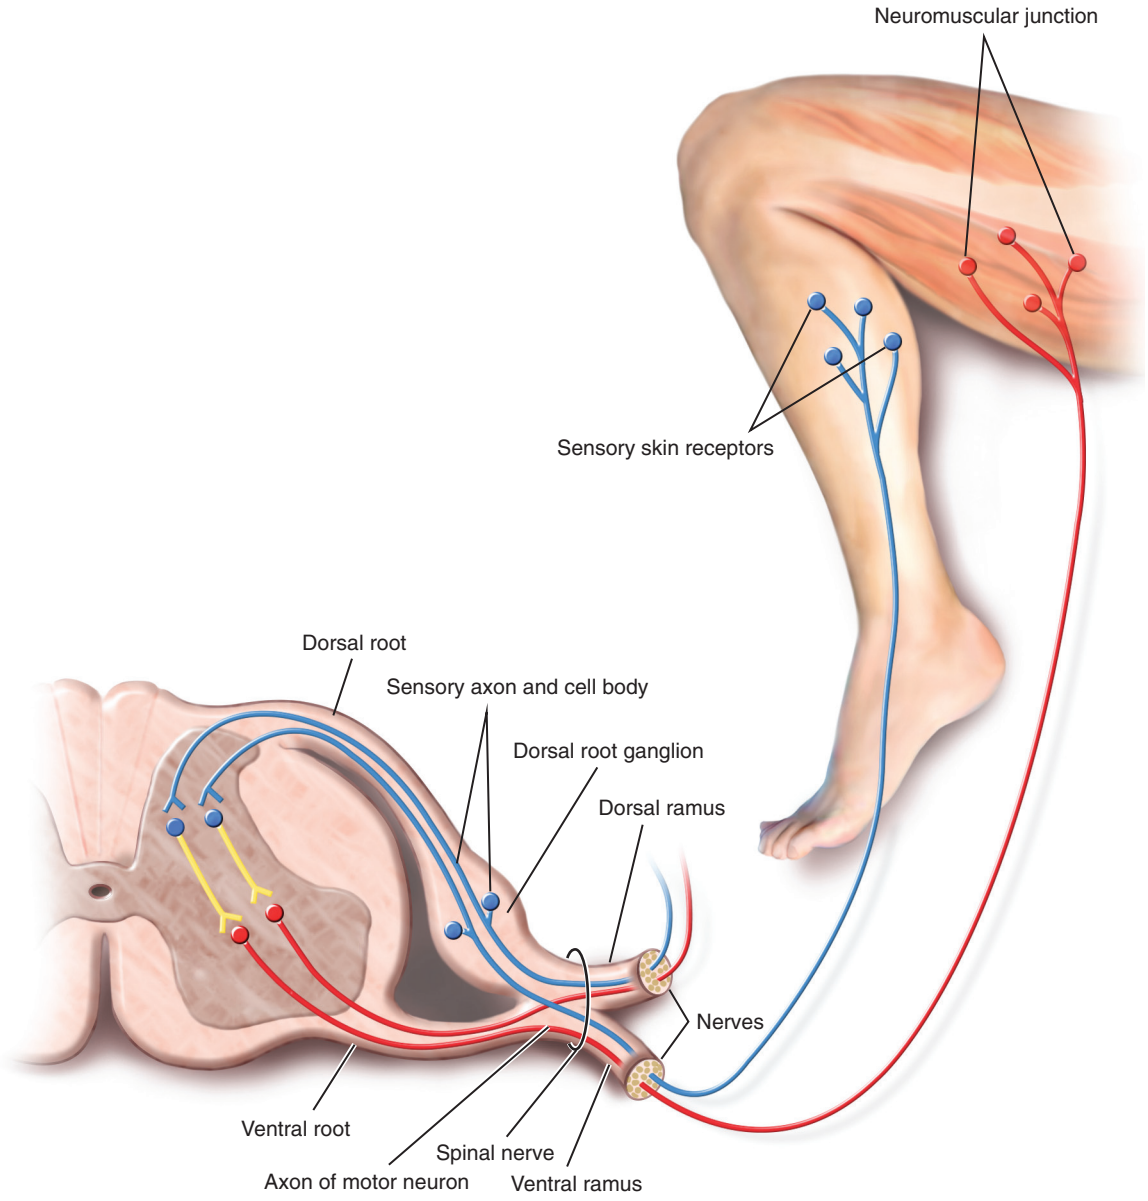

FIG 40-4 Path of afferent sensory skin receptor (blue line), which eventually causes contraction of the biceps muscle via efferent neurons (red line).

Dorsal root ganglions are located on dorsal roots along the vertebral column of the spine (Fig. 40-5).[107] It is through dorsal root ganglions that somatasesensory information from afferent sensory nerve fibers are transmitted (representing pain, pressure, and temperature) to the spinal cord.[284] Each sensory neuron in the dorsal root ganglion has a long axon which relays information to the spinal cord and ultimately to the brain in the parietal cortex.

Autonomic ganglions are part of the autonomic nervous system and are located along the sympathetic trunks, on the peripheral plexuses, and within the walls of organs.

Synapses

A synapse is the gap between a neuron and another cell (Fig. 40-6). Synapses may form between two neurons or between a neuron and an effector cell. In a typical synapse, contact occurs between the axon of one neuron and a dendrite or cell body of another.

Electrical synapses take place between two apposed neurons. The nerve transmission occurs by the passage of ions from one neuron to the other through gap junction channels. Electrical synapses occur much faster than electrochemical synapses.

An *electrochemical synapse* represents a junction that occurs between neurons or between a neuron and an effector cell via release of neurotransmitters that result in physiologic reactions.

Neurotransmitters are either *excitatory*, whereby they increase the likelihood that a neuron will fire an action potential, or *inhibitory*, in which they decrease the chance of a neuron firing an action potential. Major excitatory neurotransmitters include epinephrine and norepinephrine and some inhibitory neurotransmitters are serotonin and gamma-aminobutyric acid. Acetylocholine and dopamine may be either excitatory or inhibitory, depending upon the type of receptors that are present. Other neurotransmitters include various endorphins, enkephalins, and neuropeptides such as substance P.

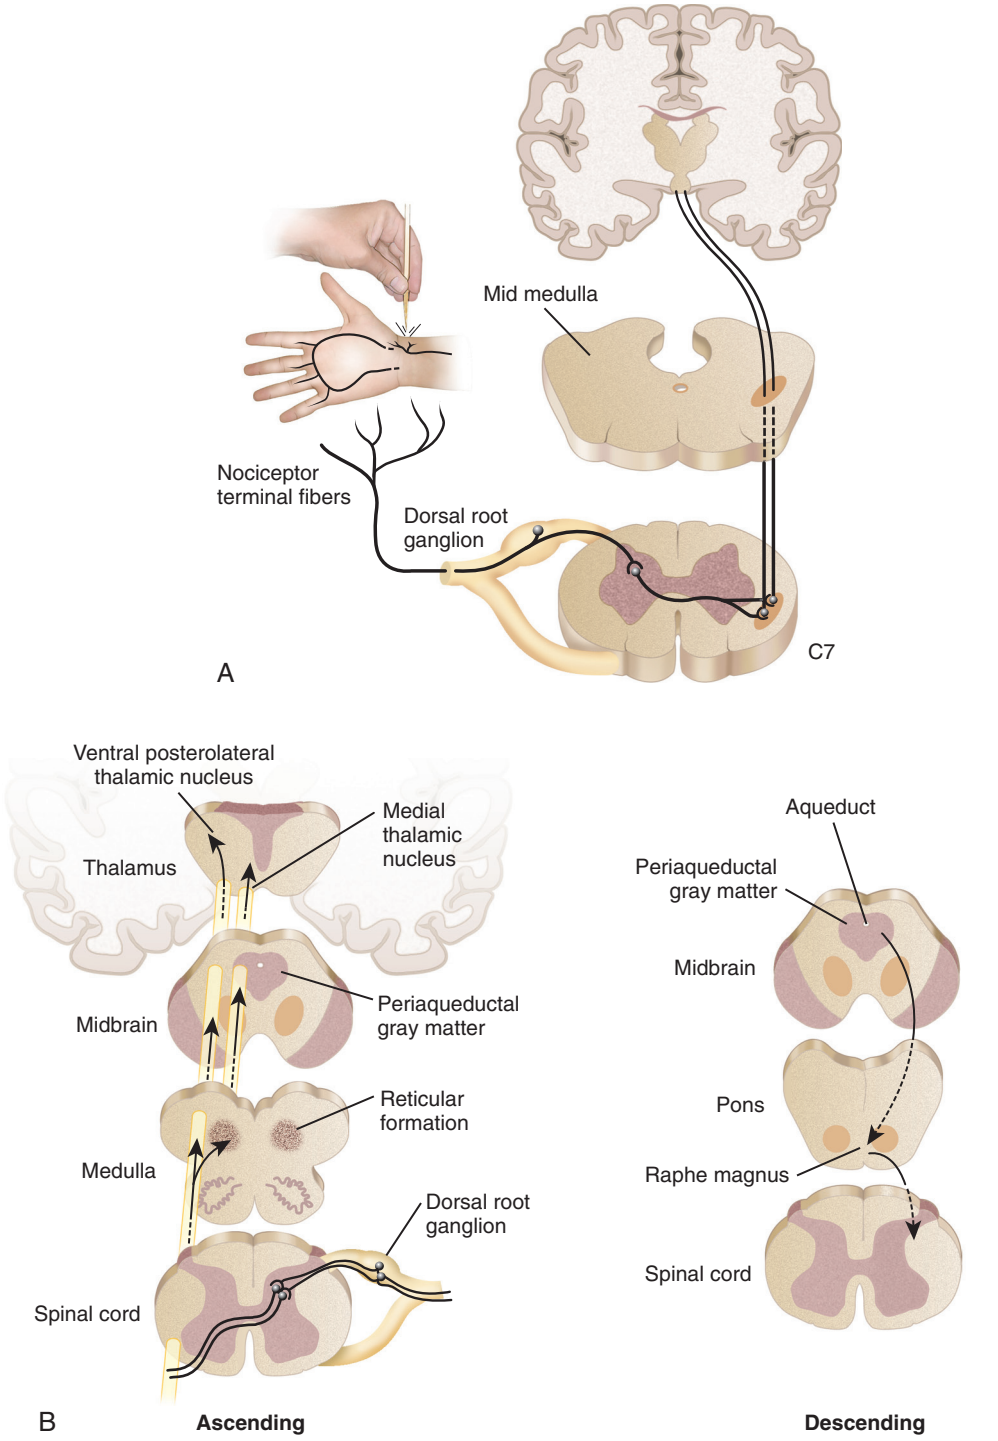

FIG 40-5 **A,** How peripheral nociceptive information is relayed by the peripheral nerve through the dorsal root ganglia to the dorsal horn of the spinal cord and then via contralateral ascending spinal tracks to the brainstem and cortex. **B,** How pain signals are modulated by descending pathways after processing in the core.

Acetylcholine is widely used at synapses in the neuromuscular junction; including motor neurons activating skeletal muscle, preganglionic neurons of the autonomic nervous system, and postganglionic neurons of the parasympathetic branch of the autonomic nervous system. Epinephrine (adrenaline) is considered a crucial component of the fight-or-flight response of the sympathetic nervous system and is released in substantial quantities when the body is under stress. Noradrenaline (norepinephrine) is released by postganglionic neurons of the parasympathetic branch of the autonomic nervous system.

At the end of a neuron's axon is an enlarged area known as the axon terminal, which is separated from the next cell by the synaptic cleft. Neurotransmitters release their contents by exocytosis into this cleft. The chemicals are received by receptor sites in the dendrites of the receiving neuron. When enough receptor sites have been filled, the

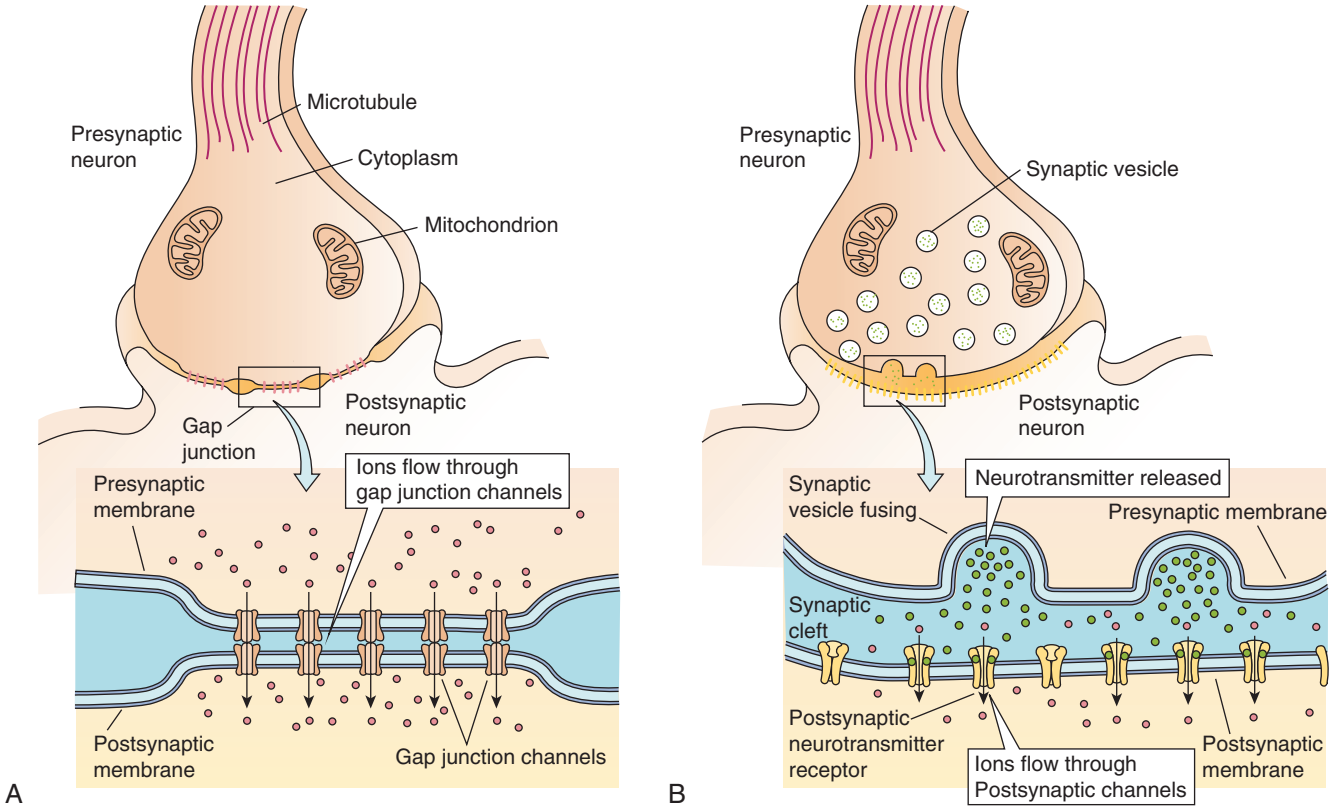

FIG 40-6 An electrical synapse **(A)** and an electrochemical synapse **(B)**. (Illustration licensed under a Creative Commons Attribution Share-Alike 3.0 License. From http://kin450-neurophysiology.wikispaces.com/file/detail/Chemical_vs_Electrical.jpg.)

receiving neuron sends the neuron impulse down its axon to its terminal fibers. The neurotransmitter is immediately inactivated by an enzyme.

In summary, before a sensory signal can be relayed to the nervous system, it must be transduced into an electrical signal in a nerve fiber. This involves a process of opening ion channels in the membrane in response to mechanical deformation; temperature; or, in the case of nociceptive fibers, signals released from damaged tissue. Many receptors become less sensitive with continued stimuli, termed adaptation. The adaptation may be rapid or slow, with rapidly adapting receptors being specialized for detecting changing signals.

There are encapsulated and nonencapsulated receptors in the skin. The nonencapsulated endings include free nerve endings, the peripheral end of the sensory axon. These mostly respond to noxious (pain) and thermal stimuli. Injuries to peripheral nerves may affect sensation and strength, resulting in severe weakness and muscle atrophy over time.

Sympathetic Nervous System

The sympathetic nervous system is responsible for the fight-or-flight response. This reaction is mediated by catecholamines, including epinephrine and norepinephrine. The term *adrenergic* refers to synapses in which epinephrine is used, although *noradrenergic* refers to synapses in which norepinephrine is used. Another neurotransmitter important for the sympathetic nervous system and CRPS is substance P, which is responsible for transmission of pain from certain sensory neurons to the CNS and aids in controlling relaxation of the vasculature and lowering blood pressure.

These catecholamine neurotransmitters stimulate α and β receptors. The stimulation of α receptors results in elevated heart rate and blood pressure, piloerection, and skin vasoconstriction. The stimulation of β receptors results in increased heart rate, muscle vasodilation, and bronchial dilation.[172]

Sympathetic nerve fibers originate inside the vertebral column at the first thoracic segment and extend to the third lumbar segment. Because the cells begin in both the thoracic and lumbar regions of the spinal cord, the sympathetic nervous system has a thoracolumbar outflow. Axons of these nerves leave the spinal cord and pass near the spinal ganglion.

The *paravertebral ganglia*, also termed the sympathetic chain or trunk, are a series of paired chains of ganglia that lie parallel to the vertebral bodies of the spinal column. The ganglia are interconnected to each other by nerve fibers and extend from the base of the skull down to the coccyx. There are three sympathetic chain ganglia located at the cervical level. The most inferior of these is the *stellate ganglion* which is believed to the supply the majority of the sympathetic innervation to the upper extremities. In the lower extremities, the sympathetic innervation is carried through *lumbar paravertebral ganglia*.[107]

All preganglionic motor neurons originate within the spinal cord and postganglionic fibers always originate in the PNS within a ganglion. There are 22 to 23 pairs of sympathetic chain ganglia. The interaction of nerve fibers begins at the spinal cord where they arise at the thoracolumbar region (T1-L2) and emerge via the ventral nerve root. They enter the sympathetic chain through the white rami communicans.

There are three options available to the preganglionic neurons in the sympathetic ganglion: (1) synapse with postganglionic neurons,

(2) pass up and down the sympathetic chain, and (3) leave the ganglion using a cord that leads to a special ganglia in the viscera. It is this ability to move superiorly and inferiorly along the chain that results in the mass response to the sympathetic nervous system. A preganglionic fiber may synapse to 15 to 20 postganglionic fibers. Sympathetic postganglionics from the chain enter the gray rami communicans and go back to the spinal nerves to be distributed to somatic tissues of the limbs and body walls.

The sympathetic nervous system innervates all vascular smooth muscle (vasomotor function for blood pressure control and distribution control), all sweat glands (sudomotor control: core temperature control), and all arrector pili smooth muscle of hair follicles (pilomotor function: temperature control). Stimulation of the sympathetic nervous system results in:

- Dilation of pupils
- Stimulation of sweat glands
- Accelerated heart rate
- Increased blood pressure
- Increased blood glucose levels
- Relaxed bronchial muscles
- Reduction of saliva and mucus
- Reduction digestive activity, urine secretion

There is a dual innervation of most organs of the body by the sympathetic and parasympathetic divisions. In these cases, one will inhibit and the other will excite, providing the opposite effect such as speeding or slowing of heart rate.

Parasympathetic Nervous System

The parasympathetic nervous system is composed mainly of the cranial and sacral spinal nerves. The preganglionic neurons, arising from either the brain or sacral spinal cord, synapse with just a few postganglionic neurons which are located in or near the effector organ (muscle or gland). The parasympathetic nervous system is responsible for the body's rest and digestion response when the body is relaxed, resting, or feeding. It basically undoes the work of sympathetic division after a stressful situation. The parasympathetic nervous system decreases respiration and heart rate and increases digestion. Stimulation of the parasympathetic nervous system results in:

- Construction of pupils
- Decreased heart rate and blood pressure
- Constriction of bronchial muscles
- Increase in digestion
- Increased production of saliva and mucus
- Increase in urine secretion

Nerves Around the Knee and Lower Limb

The major nerves around the knee and lower limb are shown in Figure 40-7. The two plexi that contribute to the innervation of the lower limb are the lumbar plexus and sacral plexus. The lumbar plexus (L2-4) gives rise to the *femoral* and *obturator nerves*. The obturator nerve innervates obturator externus, adductor brevis, adductor longus, adductor magnus, and gracilis. The femoral nerve innervates the iliacus, pectineus, all four heads of quadriceps, and sartorius. The terminal cutaneous branch of the femoral nerve is the saphenous nerve, which will be discussed in detail.

The sacral plexus (L4-5, S1-S3) forms the sciatic nerve, which passes deep to biceps femoris and divides into the *common peroneal nerve (common fibular nerve)* and the *tibial nerve* at the popliteal fossa. The tibial nerve innervates the popliteus, gastrocnemius, soleus, and plantaris. The common peroneal nerve innervates the peroneus longus, peroneus brevis, and short head of the biceps femoris muscles. The tibial nerve is the larger of the two divisions of the sciatic nerve. It runs vertically through the popliteal fossa directly underneath the fascia and is the most superficial of the neurovascular structures behind the knee. The common peroneal nerve separates from the tibial portion of the sciatic nerve at the apex of the popliteal fossa and then follows the tendon of the biceps femoris along the upper lateral margin of the popliteal fossa to the back of the head of the fibula. The nerve then winds round the neck of the fibula and passes deep to the peroneus

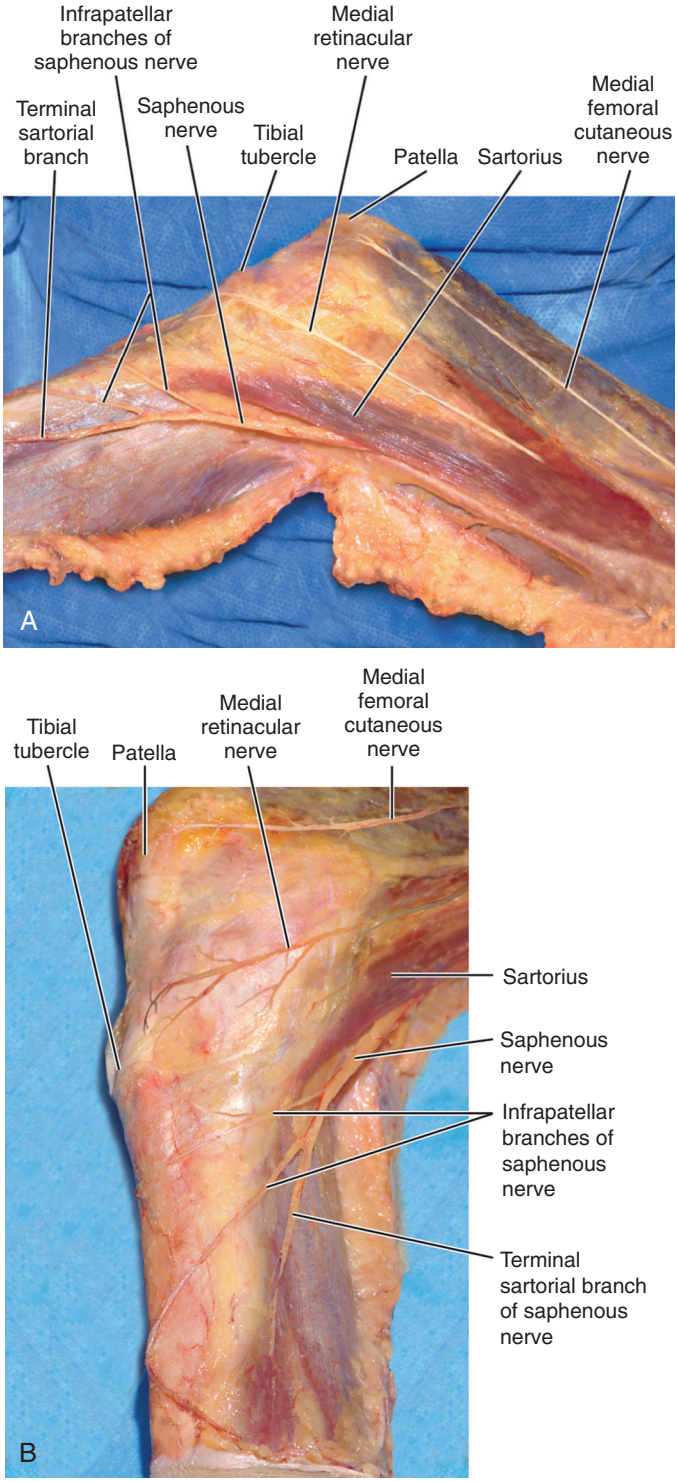

FIG 40-7 A, Anteromedial view of the superficial nerves. **B,** Medial view of the superficial nerves.

longus muscles and divides into the superficial and deep peroneal nerves.

On the medial side of the knee lies the *saphenous nerve* with its sartorial and infrapatellar branches, the medial femoral cutaneous nerve, and the medial retinacular nerve. The infrapatellar branch may follow four different courses at the medial joint line, which are described according to the nerve's relationship to the sartorius muscle. The medial femoral cutaneous nerve may travel superficially to the sartorius muscle, but is often found in Hunter's canal where it perforates the sartorius or exits deep to the sartorius. The medial retinacular nerve resides near the vastus medialis. A more detailed description of the innervation of the knee joint may be found in Chapter 39.

In the senior author's (F.R.N.) experience, many cases of knee CRPS-II are related or most likely directly caused by injury to the saphenous nerve or its branches. Injury may occur by direct trauma or contusions, or by surgical procedures on the medial side of the knee. Formation of a neuroma may result from direct injury by the scalpel during arthroscopic anteromedial portal placement. Techniques for avoiding injury to these structures include careful dissection through a 1-cm incision with identification of the nerve, transillumination with use of the arthroscope, and use of a 2-cm posteromedial incision with posterior retraction to deflect the needles anteriorly during inside-out medial meniscal repair.[252]

ETIOLOGY, PATHOPHYSIOLOGY

Several theories have been devised to explain the etiology and pathophysiology of CRPS. This chapter provides a summary of the more recent systematic reviews regarding these topics,[14,60,97,182,216,279,310] most of which discuss CRPS in general and not specifically as it relates to the knee joint.[69] Investigators typically agree that this disorder involves the central, autonomic, and somatic nervous systems; may be influenced by neurogenic inflammation and an immunologic response; creates central sensitization; and may induce cortical reorganization. In the chronic state, tissue ischemia/hypoxia may result from endothelial dysfunction and impaired circulation, and severe psychological distress and neuropsychological impairment may occur.

Etiology: Known and Speculated Risk Factors

It is known that surgery as benign as knee arthroscopy can injure nerve structures and precipitate CRPS-II, although the reported incidence has been less than 0.1%. Historically, a survey study conducted by the Arthroscopy Association of North America (AANA) of member orthopaedic surgeons in 1986 reported that 229 nerve injuries occurred during 375,069 arthroscopic knee procedures.[292] These included 97 saphenous nerve injuries, 11 peroneal nerve injuries, 7 femoral nerve injuries, 6 sciatic nerve injuries, and 108 tourniquet related or unspecified injuries. A more recent study reported 3 peripheral nerve injuries occurred in 12,271 patients who underwent knee arthroscopy.[189]

In historic outcome studies, knee surgery was frequently reported as the trigger for RSD, although whether this represented CRPS-I or CRPS-II cannot be determined with certainty. O'Brien and coworkers[214] described 60 patients referred for RSD of the knee. Of these, 40 had developed symptoms after knee surgery (24 arthroscopic and 12 arthroplasty procedures). One patient in this cohort had a neuroma identified as the potential trigger. Katz and Hungerford[144] reported the results of 36 patients treated for RSD of the knee, on whom 15 had knee surgery (6 arthroscopies, 5 total knee replacements, 1 patellectomy, 1 high tibial osteotomy, 1 medial arthrotomy, 1 Maquet tibial tubercle osteotomy). Six patients in this study had nerve injuries, two involving the peroneal nerve and four involving neuroma formation at the infrapatellar branch of the saphenous nerve. In 1988, Poehling and associates[230] described a series of 35 patients who developed RSD following injury to the infrapatellar branch of the saphenous nerve. These authors noted avoidance of trauma to this nerve during surgery was paramount, as was the early detection and initiation of treatment of RSD signs and symptoms.

In many instances, CRPS begins from obvious peripheral nerve injury,[63,64] and the diagnosis of CRPS-II is definitive; however, it may also stem from a minimal (occult) injury or degeneration of small distal nerves where the diagnosis of CRPS-I is made but may not be correct.[215,217] Knee pain may originate from direct damage to cutaneous nerves, such as the infrapatellar branch of the saphenous nerve, or from injury to a nerve far away from the knee, such as the lateral femoral cutaneous nerve.[63]

An injured or compressed peripheral nerve creates painful dorsal column input. A direct nerve injury may cause abnormal signaling, which may overstimulate sensory nerves or cause an imbalance in the normal release of transmitters resulting in an abnormal response.[69] There may also be formation of abnormal synapses (also termed *ephapses*) between nerve fibers in the dorsal-root ganglion after a peripheral injury that cause a type of short-circuit to occur. The signals being sent from the CNS to the PNS to control heart rate and other factors are short circuited to sensory fibers and misinterpreted as pain signals being sent from the PNS to the CNS.[131] The sympathetic nervous system drives the pain and, as a result, increased anxiety (which would normally increase blood pressure and heart rate) amplifies pain.

A neuroma may form as a result of a nerve injury. Within this neuroma, the transected sensory nerve endings develop a catecholamine sensitivity through the upregulation of α receptors (which respond to epinephrine from the autonomic nervous system).[236] In this manner, when the sympathetic nervous system sends signals to increase heart rate, the increased density of α receptors in the sensory nerve endings of the neuroma are stimulated and transmit the pathologic pain signal back to the CNS.[11] There is also a theory in which a similar upregulation of α receptors occurs in the dorsal root ganglion.

Whether the upregulation of α receptors occurs in the dorsal root ganglion or a peripheral nerve neuroma, it helps to explain the increased pain patients have in physical therapy or in the clinic because they anticipate the pain associated with an examination or treatment. This anxiety stimulates the fight-or-flight response. The catecholamines released from the sympathetic nervous system stimulate the intended targets of heart and blood vessels. However, because of the upregulation of α receptors, they also stimulate the sensory nervous system and produce pain.

CRITICAL POINTS Etiology, Pathophysiology

- CRPS involves central, autonomic, and somatic nervous systems.
- CRPS may be influenced by neurogenic inflammation and an immunologic response.
- CRPS may create central sensitization and induce cortical reorganization.
- Chronic CRPS may result in tissue ischemia/hypoxia from endothelial dysfunction and impaired circulation, severe psychological distress, and neuropsychological impairment.
- CRPS-II results either from obvious nerve injury/neuroma or minimal injury/compression/degeneration of small distal nerves.
- CRPS may be caused by abnormal increase in sympathetic nervous system activity after a stimulus (injury or surgery). However, role of sympathetic dysfunction questionable as the disorder progresses over time.

Small nerve fiber damage may cause edema, sweating, and vasodysregulation. In this case, CRPS represents a neuropathic pain syndrome initiated by limb trauma or its treatment. Small-fiber polyneuropathy has the same signs and symptoms as CRPS (abnormalities in limb color and temperature, sweating, and hair growth). Some neurosurgeons believe nearly all CRPS is initiated or explained by nerve injury or dysfunction and that treatment should be directed toward resolving this problem surgically.[64,215] Oaklander suggested that the terms CRPS-I and CRPS-II be abandoned and replaced with neuropathic pain syndrome.[215]

There is no association between preexisting psychological disturbances and the development of CRPS; however, studies have reported a relationship between stressful life events and the ensuing development of this disorder.[21,88,89] Immobilization of an injured limb may be a risk factor, especially following a fracture.[188] Fractures, especially those of the upper extremity, are the most common precipitating event of CRPS.[60] There is a potential genetic predisposition to this disorder, but further studies are required.

Autonomic Dysfunction

Some investigators have suggested that CRPS occurs because of an abnormal increase in sympathetic nervous system activity after a stimulus (injury or surgery).[6,130,140,172] Pain may be provoked by sympathetic outflow via sympathetic-afferent coupling in which adrenergic receptors are expressed on primary afferent nerve endings.[12,265] There may be reduced sensory input from the affected limb, an increase in peripheral catecholamine receptor sensitivity (adrenergic supersensitivity), or injury-mediated hypersensitivity at target organs to sympathetic discharge.[69]

In the early stage of the disorder, a red and warm affected extremity is frequently present, which may stem from neurogenic inflammation and/or inhibition of sympathetic vasoconstrictor neurons (from a decreased centrally mediated sympathetic outflow) and subsequent vasodilation.[182] In the chronic stage, decreased limb temperature and vasoconstriction may occur. Supersensitivity of innervated vascular structures may exist in the affected limb from decreased sympathetic activity or release of norepinephrine by the sympathetic nerve fibers.

Some investigators have questioned the role of sympathetic dysfunction because the disorder progresses over time, especially in patients who still experience pain after (apparently) successful sympathetic blocks[60,97,188] and in those with chronic CRPS. Some patients initially present with a bluish, cold affected extremity, which may be caused by reactive adrenoceptor upregulation and/or supersensitivity rather than a dysregulation of the sympathetic outflow.[70] Permanent cold temperature in chronic cases may be caused by endothelial rather than sympathetic dysfunction.[266] The percentage of pain that depends on sympathetic activity declines over the course of CRPS, as indicated by failure of sympathetic blocks in patients 24 months or more from the onset of the disorder.[144,222,299]

Sweating and trophic disturbances are not predominant features of CRPS and may be attributed to neuropeptide effects. SMP may be caused by failure of spinal inhibitory mechanisms to suppress nociceptive input by normal (instead of increased) sympathetic stimulation.[60] Inflammation or nerve injury may precipitate sprouting of new sympathetic nerves centrally in the dorsal horn or peripherally in the upper dermis.[330]

Investigations have demonstrated that the warmer affected extremity in acute CRPS is caused by inhibition of cutaneous sympathetic vasoconstrictor activity that leads to cutaneous vasodilation.[111,327,329] Several studies detected decreases in sympathetic neurotransmitters (noradrenaline, neuropeptide Y) from postganglionic sympathetic vasoconstrictor fibers on affected extremities.[71,120,325,327,329] The loss of vasoconstrictor responses and increase in skin temperature are not believed by some to be caused by a peripheral lesion of sympathetic fibers.[325] Symmetrical, normal sympathetic innervation has been measured in CRPS patients by positron emission tomography scanning[104] and histochemical evaluation of skin biopsies.[72] Conclusions have been made that a "profound central inhibition is the underlying mechanism of disturbed sympathetic vasoconstriction in the acute stage of CRPS" (Fig. 40-8).[325]

Neurogenic Inflammation

An exaggerated inflammatory response to injury or surgery in patients diagnosed with CRPS has been noted for many years.[297] Classic

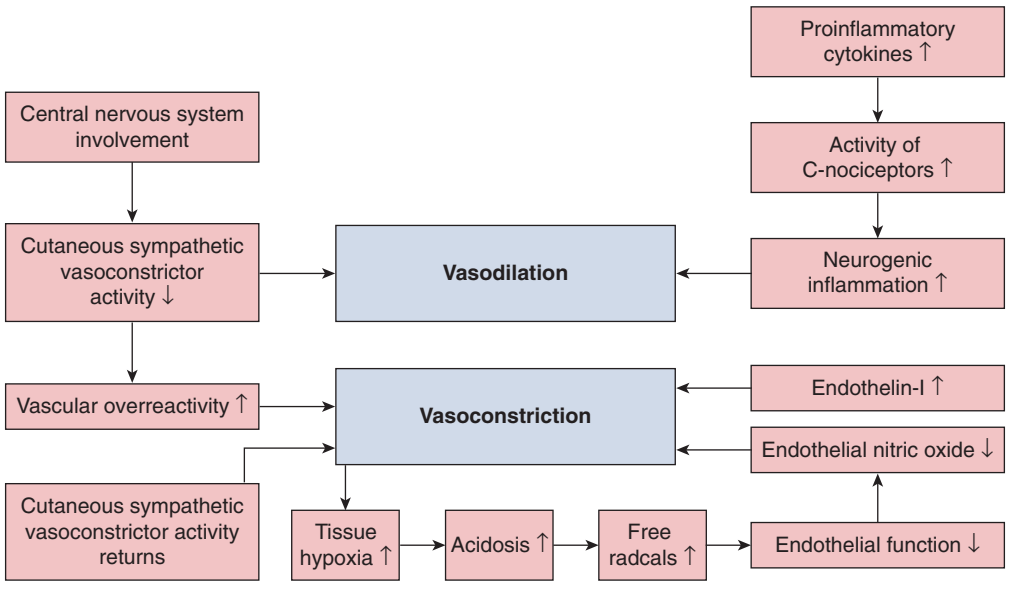

FIG 40-8 Mechanisms involved in vasomotor disturbances in complex regional pain syndrome. (From Wasner G. Vasomotor disturbances in complex regional pain syndrome—a review. *Pain Med.* 2010;11:1267-1273.)

inflammation is marked by immune cells such as lymphocytes, phagocytes, and mast cells that secrete proinflammatory cytokines. Recent studies have shown that inflammatory mediators are elevated in CRP-affected limbs, including interleukin-6 and tumor necrosis factor α (TNF α),[16,108,133,205,269] as well as activated monocytes and macrophages.[127] However, systematic parameters of classic inflammation, including white blood cell count and C-reactive protein, are normal in CRPS patients. It therefore appears that a neurogenic inflammatory process may instead occur, which may explain many of the signs and symptoms of CRPS.

Trauma causes the release of nerve growth factor and proinflammatory cytokines, both of which can activate and sensitize peripheral nociceptors. Neurogenic inflammation arises from the local release of inflammatory mediators (neuropeptides) from nociceptive C-fibers such as the substance P, calcitonin gene-related peptide (CGRP), and bradykinin.[60,182,188] These neuropeptides have been shown to be elevated in CRPS patients.[22,25,268] They evoke vasodilation in acute CRPS and may cause edema, sweating, elevated skin temperature, erythema, and hair growth. Also, aberrant neuropeptide signaling may cause decreased limb temperature and trophic changes.

Central Sensitization

Central sensitization is a process in which the excitability of neurons in the spinal cord is increased. In the *Raja model,*[235] pain receptors (nociceptors) upregulate their α receptors. Because the body is constantly sending sympathetic signals, these nociceptors are being constantly stimulated, which reduces the CNS threshold for perceiving pain.[247] Changes occur in the dorsal root ganglion.[115] The mechanoreceptors responsible for light touch sensation and thermoreceptors responsible for cold sensation instead produce an abnormal painful response when they stimulate the sensitized central pain neurons. The term central sensitization may be used to explain the clinical findings of allodynia and hyperalgesia.

In the Raja model, treatment by sympathetic blockade is effective by the production of a temporary inhibition of norepinephrine release. By temporarily blocking the release of catacholamines, the sympathetic block relieves pain. By allowing the CNS to experience relief from pain, the central pain neurons may be desensitized (downregulation of α receptors), resulting in a long-term improvement in the painful response to light touch.[11]

The change in regulation of α receptors also explains the change in appearance of the limb over time. Initially, an increase in α receptors causes excess stimulation, which presents as a red, warm, and swollen limb (increased sympathetic function). Later, as the body adjusts and downregulates the expression of α receptors, the same limb will take on a blue, cool, and contracted appearance.[11] Secondary psychological problems such as pain-related fear and movement anxiety have been associated with central sensitization.[310] Changes in somatosensory processing have been shown to occur at the cortical level in CRPS-I[319] of the upper extremity.

Central Nervous System Alterations, Cortical Reorganization

Many studies have stressed the important role of the CNS in the disease process of CRPS.[9,90,140,178,182,191,276,312] The question of whether the changes that occur in the CNS do so as a direct response to the initiating event or subsequently over time remains unanswered. There are changes in central sympathetic, somatosensory, and motor systems that many believe imply alterations occur in the CNS. Many patients develop muscle paresis in the affected limb, which results in restrictions in active range of motion.[276] Studies have reported that 9% to 49% of patients with CRPS develop movement disorders such as loss of voluntary control, bradykinesia, myoclonus, dystonia, and tremor.[312] Central sensitization occurs as a result of functional and structural changes in the CNS. The pattern of sensory disturbances is usually not limited to the area of a single peripheral nerve but are rather in a wider area detected as brush-evoked allodynia.[70,182] Hemisensory deficits have been reported, with sensory disturbances detected in the contralateral normal limb.[253,254] Thermoregulatory reflexes are disturbed in the distal areas of the affected limbs, which investigators attributed to alterations in cutaneous vasoconstrictor neurons.[329] In addition, up to 50% of patients with chronic CRPS-I develop hypoesthesia on the affected side of the body, which is believed to be caused by changes in central processing of tactile stimuli at the thalamic or cortical level.[253,254]

Alterations in the CNS are manifest in CRPS studies that have demonstrated impaired perceptual learning,[177] global cognitive impairment,[171] altered brain activation patterns,[66,85,162,176,279] changes in cerebral blood flow, and body perception disturbances (Fig. 40-9).[60] *Cortical reorganization* is a potential consequence of this disorder, with functional magnetic resonance imaging (MRI) studies providing evidence of alterations in the primary somatosensory cortex (S1) contralateral to the CRPS affected side.[179,180] Changes have also been detected in the motor cortex during finger tapping tests.[176] Altered central opioidergic neurotransmission was reported in one study from ligand positron emission tomography studies.[155] Abnormal thalamocortical activity (spontaneous abnormal low frequency rhythmic magnetoencephalographic activity) was detected in another study of CRPS patients.[324] Patients may abnormally activate the dorsolateral and ventromedial prefrontal cortex, regions important for perceptual learning and emotional decision making.[171]

The sensory representation of the CRPS-affected limb is frequently altered in that the limb feels disfigured and out of place.[97] From a psychophysical standpoint, studies have reported that high percentages of patients (54%-84%) have cognitive and/or motor neglect–like symptoms in which the affected limb may feel foreign, and directed mental and visual attention are required to move the limb.[84,86,87] Patients may perceive the affected limb to be larger than it actually is[201] or that the limb is altered in shape and appearance.[170] In one study, patients with long-standing CRPS expressed strong negative feelings about the affected limb, and many wanted it amputated.[170] Libon and associates[171] noted that significant neuropsychological deficits were present in 65% of 137 patients with chronic CRPS. These included reduced performance on tests that assessed working memory/mental search and problems on tests of naming and memory. These impairments were not associated with spread of CRPS to other limbs, duration of symptoms, or medication use. These authors concluded that the data was consistent with recent MRI studies suggesting the disorder involves the CNS and involves a large amount of cortical and subcortical areas.

Limb Ischemia/Hypoxia

The concept that limb ischemia or hypoxia occurs in CRPS-affected limbs is associated with the inflammatory hypothesis.[97] There is the possibility that the abnormal inflammation leads to a compartment-syndrome scenario that results in oxygen–free radical–induced microvascular damage. This in turn leads to further tissue ischemia and nociceptor excitation. The presence of ischemia, with decreased capillary oxygenation, has been shown in superficial skin layers in CRPS-affected limbs and may also be present in deeper tissues.[157,306] In muscle, nuclear magnetic resonance spectroscopy showed signs of acidosis and impaired high-energy phosphate metabolism in amputated specimens from patients with chronic CRPS.[306] Hypoxia and its associated acidosis and free radical formation can trigger primary afferents to cause severe pain. It has been proposed to be caused by extreme

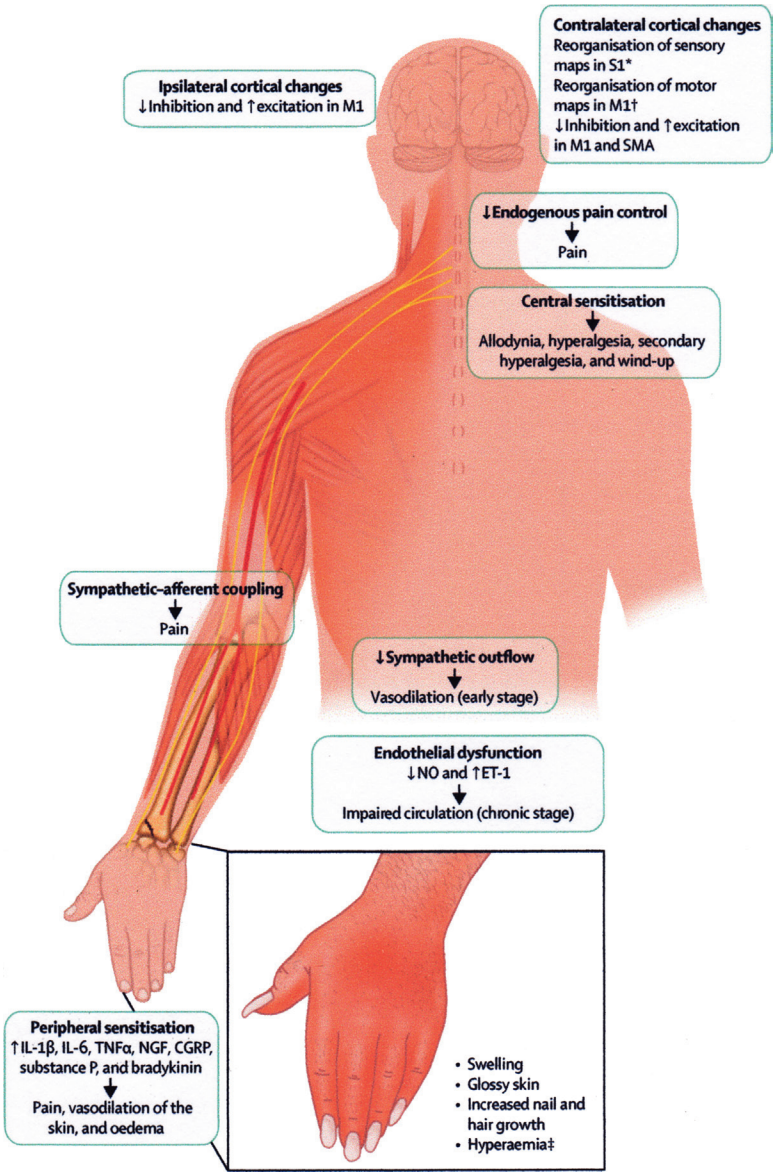

FIG 40-9 Clinical features and proposed pathophysiologic mechanisms of complex regional pain syndrome (CRPS). Although these pathophysiologic mechanisms have all been identified in CRPS, they might occur independently of each other. The absence of such fixed relations explains the clinical heterogeneity that is often encountered in this condition. *Reorganization of contralateral S1 is associated with spontaneous CRPS pain and mechanical hyperalgesia. This reorganization might also explain altered sensations (e.g., perceptual disturbances and referred sensations). †Reorganization of contralateral M1 is associated with motor dysfunction (i.e., tapping). However, these changes might be secondary to the symptoms rather than being a cause of the symptoms. ‡Decreased sympathetic outflow might also be responsible. *CGRP*, Calcitonin-gene-related peptide; *ET*, endothelin; *IL*, interleukin; *M1*, primary motor cortex; *NGF*, nerve growth factor; *NO*, nitric oxide; *S1*, primary somatosensory cortex; *SMA*, supplementary motor cortex; *SP*, substance P; *TNF*, tumor necrosis factor. vasoconstriction or from a local imbalance between endothelial factors.[108, 266]

Psychological Factors

The association between psychological factors and CRPS-I is controversial because of the lack of high quality studies.[14] Historically, many believed that preexisting psychological disorders played a role in the development of this disorder.[4,313] However, a recent systematic review encompassing 31 studies conducted by Beerthuizen and associates[14] refuted this bias. This investigation found no evidence for a relationship between CRPS-I and depression, anxiety, neuroticism, anger, obsessive-compulsive behavior, comatization, hostility/anger, interpersonal sensitivity, extraversion/introversion, or paranoia. There did appear to be a relationship between stressful life events that were soon followed by the development of this disorder.[21,88,89] This association has been hypothesized to be caused by a repeatedly triggered sympathetic

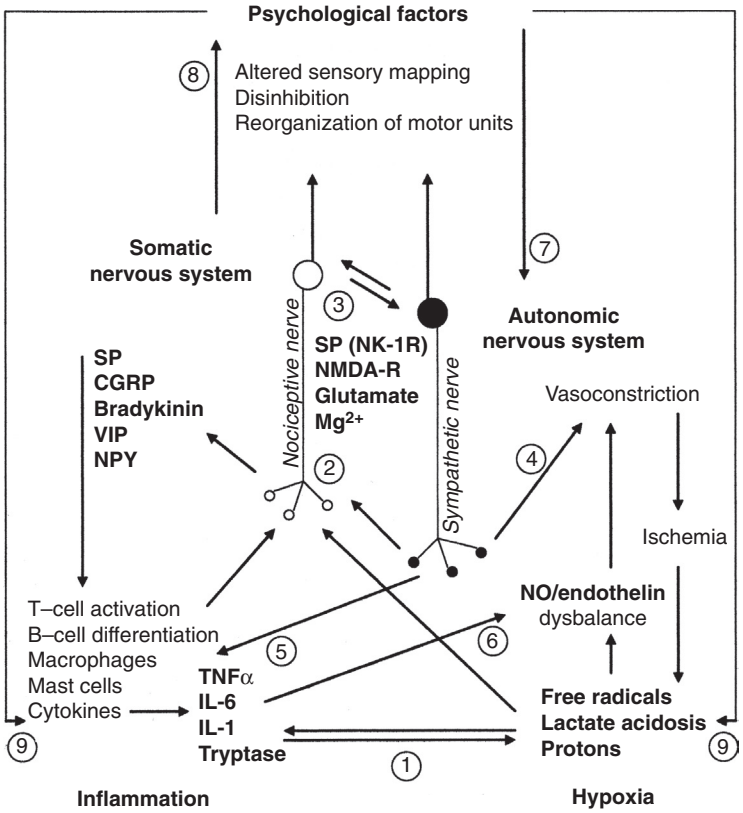

FIG 40-10 Possible paths for interaction among proposed pathogenic mechanisms of complex regional pain syndrome. 1. Hypoxia may trigger inflammatory response *(Interaction: hypoxia inflammation [classic and neurogenic])*. 2. Continuous nociceptive input by hypoxia, inflammation, or sympathetic stimulation may lead to sensitization and alterations in cortical organization of sensory and motor units. *(Interaction: hypoxia, inflammation, and autonomic dysfunction somatic neuronal dysfunction [sensitization and cortical reorganization])*. 3. Neuropeptides (substance P [SP]) released in dorsal horn may facilitate sensitization through interaction with NK-1 and NMDA) receptors. *(Interaction: inflammation [neurogenic] somatic neuronal dysfunction [sensitization])*. 4. Sympathetic dysfunction (either central sympathetic hyperactivity or increased peripheral adrenergic receptor hypersensitivity) may cause hypoxia because of impaired nutritive blood flow. *(Interaction: autonomic dysfunction hypoxia)*. 5. Adrenergic receptors can be expressed on immune cells, and catecholamines can modulate cellular immunity, and it also has been speculated that inflammation may change sensitivity or expression of α-adrenergic receptors on nociceptive fibers. *(Interaction: autonomic dysfunction inflammation [classic])*. 6. Cytokines influence the balance of nitric oxide (NO) to endothelin (ET). *(Interaction: [classic] inflammation hypoxia)*. 7. Psychological distress may influence sympathetic outflow and levels of catecholamines. *(Interaction: psychopathology autonomic dysfunction)*. 8. Severe chronic pain and disability may cause psychological distress. *(Interaction: somatic neuronal dysfunction [sensitization] psychopathology)*. 9. Fear of movement may result in the accumulation of inflammatory mediators and free radicals and prevent desensitization. *(Interaction: psychopathology inflammation and hypoxia and somatic neuronal dysfunction)*. *CGRP*, Calcitonin gene-related protein; *IL*, interleukin; *Mg^2*, magnesium ions; *NK-1R*, neurokinin-1 receptor; *NMDA-R*, N-methyl-D-aspartate receptor; *NPY*, neuropeptide Y; *SP*, substance P; *TNF α,* tumor necrosis factor α; *VIP*, vasoactive intestinal pain. (From de Mos M, Sturkenboom MD, Huygen FJ. Current understandings on complex regional pain syndrome. *Pain Practice* 2009;9:86-99.)

system (from the stressful event), which develops an altered local catecholamine responsiveness, resulting in prolonged increased autonomic arousal.[14] A recent prospective study found a positive association between the development of CRPS-I after a distal radius fracture and patients with an "anxious personality," or a high level of general anxiety.[67] However, there was no significant relationship between a history of psychiatric disorder and the development of CRPS-I.

There is a relevant question of the contribution of longstanding CRPS to the development of psychological disturbances. There are psychophysiological mechanisms that we previously discussed that may lead to changes in personality and management of anger. In chronic cases, extreme fear of pain may lead to disuse of the affected extremity resulting in prolonged immobilization that leads to decreased active range of motion, diminished nutritive blood flow, and trophic alterations (Fig. 40-10).[60]

Autoimmune Disorder

Studies have shown evidence of antineuronal autoantibodies in 30% to 90% of CRPS patients.[23,100,159] A randomized controlled trial reported that low-dose intravenous immunoglobulin reduced pain in chronic CRPS, considered circumstantial evidence for an autoimmune etiology.[97] Several case reports have been published that report the onset of CRPS in patients with an autoimmune disease.[60] A recent investigation suggested that antigens for the autoantibodies found in CRPS patients

might be α adrenoceptors and muscarinergic acetylcholine receptors.[188] The question of autoimmune mechanism involvement in the pathophysiology of CRPS requires further study.

DIAGNOSIS

Differential Diagnosis

The diagnosis of CRPS-I and CRPS-II is based mostly on clinical findings. Other diseases and disorders such as infection, inflammatory disorder, metabolic disorders, vascular insufficiency, neoplasms, stress fractures, and missed intraarticular disorders should be ruled out. Pelvic disorders and occult hip osteoarthritis should also be excluded in patients with knee symptoms. Neuropathy (such as diabetic polyneuropathy) and unilateral arterial or venous occlusive diseases may present with similar symptoms and must be ruled out.

The full blood count, erythrocyte sedimentation rate, fasting blood sugar, and serum calcium levels should be determined along with thyroid function to exclude systemic causes of pain. There is no laboratory marker for CRPS. Increased white blood count, erythrocyte sedimentation rate, and C-reactive protein can indicate a generalized inflammatory process, but these findings are nonspecific. However, these tests along with others such as rheumatoid factor and antinuclear antibody tests assist in identifying other possible diagnoses (Table 40-3).

The diagnosis for CRPS is based on criteria obtained from the patient's medical history, clinical presentation, and comprehensive diagnostic tests to be described. The Budapest clinical diagnostic criteria should be used as described in Table 40-2.[119] The presence of at least three of the symptoms and two of the signs shown in Table 40-2 has a diagnostic sensitivity of 0.85 and specificity of 0.69.[119] The inclusion of all four of the symptom and sign components increases the diagnostic sensitivity to 0.95 and specificity to 0.81.[118]

CRPS-II indicates nerve injury, entrapment, or compression or the formation of a neuroma. In the knee, this frequently involves the saphenous nerve and/or its branches and, therefore, the detection of this problem is paramount. Electromyography (EMG) and nerve conduction studies are helpful to determine the presence of a nerve injury, nerve root avulsion, entrapment, or a painful neuropathy attributed to diabetes. Documentation of a pain source with a successful diagnostic nerve block is indicative of CRPS-II.[64] However, it is important to realize that sympathetic hypersensitivity and denervation do not account for all the abnormalities in CRPS-II because the symptoms often spread beyond the dermatome of the damaged nerve.

CRITICAL POINTS Diagnosis

- Diagnosis CRPS-I and CRPS-II based mostly on clinical findings, Budapest clinical diagnostic criteria. No laboratory marker available. Early diagnosis highly important.
- Women have a higher incidence.
- Usual trigger is trauma, surgery, immobilization.
- Rule out all other possible diseases and disorders.
- EGM studies, diagnostic nerve blocks indicate CRPS-II.
- Most common finding is pain disproportionate to the inciting event: burning and shooting, or as deep, constant, and aching.
- Changes in skin temperature and color, extraarticular and painful swelling, frequent findings.
- Hyperalgesia and/or allodynia usually present, hypoalgesia may also exist.
- Motor abnormalities: decreased active range of motion, action tremors, myoclonus, hyperreflexia, muscle spasm, voluntary guarding.
- Tests: x-rays, MRI, bone scan, diagnostic nerve block, skin surface temperature.

Clinical Presentation

The clinical presentation of CRPS has diverse signs and symptoms, but one of the most common findings is pain disproportionate to the inciting event. Women have a higher incidence of developing this disorder, with reported female/male ratios varying from 2:1 to 4:1.[21,58,261,275] The average age of onset ranged from 41.8 years to 50.4 years in three investigations,[3,21,261] and in a more recent investigation of 656 patients, 37.8 ± 12.3 years for males and 36.7 ± 12.1 years for females.[275] The usual trigger is trauma to an extremity from an injury that is frequently treated with immobilization. Surgery is another initiating event. Approximately 3% to 11% of cases are of spontaneous onset.[62]

The percent of CRPS-I patients in one investigation who experienced specific symptoms and signs of the disorder according to the Budapest criteria is shown in Table 40-4.[121] The most commonly self-reported symptoms were asymmetry in skin color, hyperesthesia (allodynia, hyperpathia), asymmetric edema, and motor changes. The most frequent signs observed on physical examination were skin color

TABLE 40-3 Differential Diagnoses for Complex Regional Pain Syndrome

Problem	Potential Diagnoses
Bone or soft tissue injury	Stress reaction, stress fracture, ligament damage, meniscus tear
Neuropathic pain	Peripheral (poly) neuropathy, nerve entrapment, neuroma, radiculopathy, postherpetic neuralgia, deafferentation pain after cerebrovascular accident (stroke), plexopathy, motor neuron disease, metabolic (diabetes), neoplastic
Infection	Bone, joint, soft tissue, skin
Inflammation	Erysipelas, inflammation nitric oxide synthase, bursitis, seronegative arthritis, rheumatologic diseases, Lyme disease
Compartment syndrome	
Arterial insufficiency, vascular disease	Thrombosis, acrocyanosis, atherosclerosis, thromboangitis obliterans (Burger's disease), Raynaud's disease, erythromelalgia, phlebothrombosis
Movement disorders	
Lymphatic or venous obstruction	
Central nervous system	Stroke, neoplasm, encephalitis, spinal cord trauma or transverse myelitis, multiple sclerosis, poliomyelitis
Myofascial pain	Overuse, disuse, tennis elbow, repetitive strain injury, fibromyalgia
Thoracic outlet syndrome	Nerve compression or vascular compression
Gardner-Diamond syndrome	
Psychiatric problems	Self-harm, somatoform pain disorders (malingering), Munchhausen syndrome

TABLE 40-4 Statistically Significant Differences in Diagnostic Signs and Symptoms of CRPS-I Patients vs. Non-CRPS Patients with Neuropathic Pain

Variable	CRPS-I (n = 113)	Non-CRPS (n = 47)	P Value
Self-reported symptoms (% yes):			
Skin color asymmetry	91.1	27.7	<.01
Hyperesthesia (allodynia, hyperpathia)	90.2	63.8	<.01
Asymmetric edema	89.2	40.4	<.01
Motor changes	88.3	46.7	<.01
Temperature asymmetry	86.6	38.3	<.01
Trophic changes	75.0	38.3	<.01
Sweating asymmetry	62.5	15.2	<.01
Hypoesthesia (localized numbness)	38.5	65.0	<.01
Signs observed on physical examination (% yes):			
Skin color asymmetry	83.9	36.2	<.01
Hyperalgesia to pinprick	81.5	43.5	<.01
Decreased active range of motion	80.0	37.8	<.01
Motor changes (any)	79.3	40.0	<.01
Allodynia (any stimulus)	70.5	29.8	<.01
Temperature asymmetry by palpation	69.4	14.9	<.01
Trophic changes (any)	68.5	29.8	<.01
Allodynia to cold	63.5	10.5	<.01
Asymmetric edema	63.5	24.2	<.01
Allodynia to deep joint pressure	67.6	26.7	<.01
Hypoesthesia to light touch	57.7	77.5	<.05
Altered reflexes in affected area	50.8	86.7	<.05
Sweating asymmetry	43.8	10.6	<.05
Allodynia to vibration	40.0	10.5	<.05
Tremor	30.1	5.6	<.05
Dystonia	26.5	5.6	<.05
Mean asymmetry by infrared thermometry (°C)	–0.62 ± 1.97	0.11 ± 1.04	<.01

asymmetry, hyperalgesia to pinprick, decreased active range of motion, and any motor changes. A natural history study of 656 patients treated between 1 and 46 years following the onset of CRPS-I and CRPS-II had similar findings in terms of self-reported symptoms (Table 40-5) but also reported a vast array of "other" problems that occurred over the course of the disease (Table 40-6).[275]

Disproportionate Pain to Inciting Event

The hallmark finding of CRPS is pain disproportionate to the inciting event. The disproportionate response includes pain more intense than expected, lasting longer than expected, and expanding beyond the dermatomal region of the extremity. Pain is the body's response to impending or ongoing cell death. With CRPS, the pain may be generated in the absence of cellular insult.[160] Within hours to days after the inciting event, the pain becomes diffuse and expands beyond the site of the injury and dermatomal area in a stocking or glove pattern, with a preference for distal limb involvement. Patients describe the pain as burning and shooting or as deep, constant, and aching. A classic finding is allodynia, which is found during the physical exam and described by the patient as the inability to tolerate pressure from bed sheets at night, clothing, and even air currents. The pain may fluctuate in intensity in response to many influencing factors. Pain may worsen with aggressive physical therapy, weather changes (becoming colder), physical activity, and fear or agitation.

Vasomotor Abnormalities

Changes in skin temperature and color are frequent findings. In most patients, the limb will initially appear red, warm, and dry and progress over time to a mottled, bluish, cool and moist condition. However, some affected limbs will be blue and cooler than the opposite extremity after the initial onset of the disorder.

Sudomotor/Edema Abnormalities

Patients frequently report extraarticular and painful swelling. This is a prominent finding early in the course of the disease that decreases over time. Initially, the skin is edematous but gradually is replaced by skin that is tight, shiny, and lacking in normal skin creases.[75] Excessive or diminished sweating or sweating asymmetry is also frequently noted. The sudomotor function may be opposite of what is normally expected. A red and swollen limb will normally be moist, and a bluish and cool limb will normally be dry.

Sensory Abnormalities

There is usually evidence of hyperalgesia and/or allodynia, but there may also exist hypoalgesia. Of particular interest is an unusual

TABLE 40-6 Other Symptoms and Problems in 656 Patients with CRPS Followed From 1 to >20 Years After Onset

Symptom	% Affected	Correlation With Progression of CRPS (*P* Value)
Pain interfered with quality of life	>97	NS

intolerance to cold, which is often first encountered in physical therapy when cryotherapy is used to control swelling and elicits a significant painful response.[172] In the office, the clinician may conduct an ice cube test (Fig. 40-11) in which ice is applied to the sensitive region and the patient's evoked sensations are determined. The abnormal response the clinician seeks is a description of intolerable, burning pain. Early after the onset of CRPS, the patient may describe the sensation evoked from the ice cube test as decreased cold sensation compared with the contralateral limb. In a similar manner, cold weather can precipitate a painful flare.[172]

Motor Abnormalities

Some form of motor impairment is usually present. The abnormalities range from decreased active range of motion to hyperfunction, manifested as action tremors, myoclonus, hyperreflexia, muscle spasm, and voluntary guarding.[270] Even when motor abnormalities are grossly evident, EMG test results may be normal. This finding suggests that the motor response of CRPS is centrally mediated, most likely at the spinal cord level.[326] Initially, weakness may be attributed to disuse and expected muscle atrophy. Some patients develop pseudoparalysis, which may extend to limb neglect. In long-standing illness, dystonia, apraxia, lack of coordination, and impaired proprioception may be present.[9,10,92,326]

Trophic Changes

Common trophic changes are abnormal nail growth, increased or decreased skin hair growth, fibrosis, thin and glossy skin, and osteoporosis.

Psychological Issues

Historically, a bias toward patients with CRPS and their disproportionate pain existed in terms of belief of fictitious disorders or other psychiatric overtones. However, as with other chronic pain syndromes, comorbid psychiatric disease either develops as a result of the pain syndrome or it promotes the pain syndrome.[36,218] It is uncertain whether or not this is a cause or effect of CRPS, but in daily diaries kept by patients with chronic pain, investigators found that a depressed mood one day contributed to increased pain the next day.[80] In addition, pain one day contributed to depression, anxiety, and anger the next day. It is likely that the emotional and behavioral disturbances are the

result of chronic pain and loss of function. These psychological disturbances have been shown to resolve when the pain resolves.[187,198]

Stages and Natural History of Complex Regional Pain Syndrome

Historically, three progressive stages of CRPS have been cited, but their existence has since been disproven.[33,121,199] A patient with CRPS may present with some or all of the well-known signs and symptoms but may also present only with disproportionate pain. In addition, the natural history of CRPS does not appear to have progressive stages.[275] The largest natural history study published to date encompassed 656 patients, 485 of whom were followed from 1 to 9 years and 171 of whom were followed 10 to 46 years after the onset of the disorder.[275] The authors noted that after 1 year, most of the signs and symptoms were well developed and did not change greatly thereafter (see Table 40-5). None of the patients demonstrated a spontaneous remission of symptoms. The data were collected via a patient questionnaire between 1995 and 2006, so many patients did not have access to the latest treatment options which could have affected the course of the disorder.

Objective Tests

CRPS is primarily a clinical diagnosis. There are no laboratory tests or imaging studies that can absolutely confirm this diagnosis; however, many are useful for lending additional credibility to clinical suspicions and ruling out other possible diagnoses.[199,272]

Radiographs

Radiographs of the affected knee should be taken to rule out concomitant pathology. In the acute phase of CRPS, no change in radiographic appearance will be found. As the disorder progresses, films will reveal decreased cortical density of the affected extremity when compared with the contralateral limb. The classic radiographic finding for CRPS is a patchy periarticular osteoporosis, with osteopenia of the patella and medial femoral condyle.[130,291] In late stages, profound bone demineralization occurs.[49]

Magnetic Resonance Imaging

MRI should be performed to exclude other possible causes of pain and allow the clinician to narrow the differential diagnosis. MRI may identify a possible focus for the pathology that triggered the disease, such as a meniscus tear. It may also detect bone marrow edema, stress reaction, stress fractures, soft tissue changes, and occult fractures. MRI findings of CRPS include thickening of the skin, intraarticular effusions, soft tissue and muscle edema, interstitial edema, and vascular hyperpermeability.[212,278] Chronic changes are muscle atrophy, fibrosis or fatty infiltration of the affected muscle, and thinning of the skin.[212,278]

Triple-Phase Bone Scintigraphy

The diagnosis of CRPS based on results of triple-phase bone scintigraphy (TPBS) is controversial.[129,156,199,340] The TPBS has three phases: arterial, soft tissue and bone. Historically, wide ranges of sensitivity (19%-97%) and specificity (56%-97%) have been reported in the ability of this test to diagnose CRPS.[272] Note that many studies did not use the current standardized criteria for the diagnosis of CRPS, and most focused on upper extremity disease involvement. Fluctuations in sensitivity and specificity have been hypothesized to be attributed to the use of phases I and II of the bone scan, qualitative or quantitative image analysis, and the time that elapsed between the onset of CRPS symptoms and when the scan was performed.[335] Some studies reported increased uptake in CRPS in the second and third phase of the scan.[225,270] A recent investigation found that the TPBS was highly specific in diagnosing CRPS of the upper limb when only phase 3 of the test was considered and when the test was done within 5 months of the onset of the disorder.[335]

A recent investigation of 69 patients diagnosed using the Budapest criteria with either upper or lower extremity involvement reported sensitivity of TPBS for the diagnosis of CRPS of 40.6% and specificity of 76.6%.[199] The odds ratio of TPBS for diagnosing CRPS was 2.24 (95% CI, 0.98-5.12). Although a positive TPBS result was related to skin color changes and edema, the diagnostic performance of the test was low. The authors reported no differences in findings based on the chronicity of the disorder and believed their findings support the absence of pure clinical stages of CRPS.

Few studies have evaluated the diagnostic ability of TPBS for lower extremity CRPS. Wuppenhorst and associates[335] empirically noted several technical limitations of this test that occur at the feet. For example, the tracer uptake in phase 3 is smaller than that noted in the hands, leading to a weaker demarcation of the joints. In addition, regions of interest can currently only be localized over the metatarsophalangeal joints.

Successful treatment of CRPS may result in a paradoxical increase in tracer uptake as the blood flow improves to the affected limb.[129,183] Thus increased uptake to a limb can indicate CRPS in the initial phase or successful treatment of the disorder (Fig. 40-12). This tendency for change in bone scan results over time is also why this test should not be used to track the course of the disease or the success of treatment.[129,341]

Diagnostic Blocks

In patients with suspected nerve injuries or neuromas, a diagnostic nerve block is indicated. In the knee, this usually involves the infrapatellar branch of the saphenous nerve and may also involve the medial retinacular nerve, the medial cutaneous nerve, and the lateral retinacular nerve. Dellon[64] recommends a 50:50 mixture of 1% xylocaine and 0.5% bupivacaine, each without epinephrine. Each nerve block contains 5 cc of this mixture that is injected into the region of the known joint afferent and not into the nerve itself or suspected cutaneous neuroma. Ten minutes after the block, the patient is asked to walk on level ground, climb and descend stairs, and kneel on a padded chair. A reduction of 5 points on a visual analogue scale confirms sufficient relief and a diagnosis of CRPS-II.

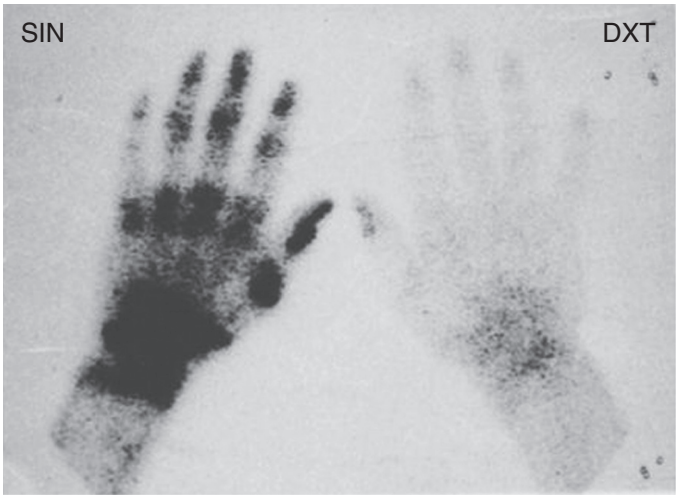

FIG 40-12 The left hand represents either an acute-phase complex regional pain syndrome (CRPS) or successful treatment of CRPS. The right hand represents either a normal examination or a dystrophic/atrophic-phase CRPS.

A lumbar sympathetic ganglion block is one tool used for both diagnosing and treating CRPS-I, although its use is controversial.[125,172,233] The patient is injected with a local anesthetic under fluoroscopic control. Successful block of the ganglion is monitored by documenting vasomotor and sudomotor changes in the extremity. van Eijs and associates[308] recently defined a successful block as one in which there is radioscopic confirmation of adequate craniocaudal contrast dye outline over the prevertebral sympathetic chain at the L3-L4-L5 level for the lower limb and at the C6-C7-T1 level for the upper limb.

The patient may be examined while the block provides relief to determine if a specific focus for the pain exists. Before the procedure, the patient may complain of diffuse pain about the knee. Following a successful block, the patient may be able to localize the pain (for instance, to the medial aspect of the knee), and the clinician may be able to localize clinical findings to a specific disorder (such as saphenous neuritis). We recommend that a MRI be done before a lumbar block to detect other possible triggers for pain such as a meniscus tear to avoid the necessity of this test. It is important to note that there are many potential side effects of a sympathetic block. A recent study[308] found that 79% of 27 patients with lower extremity (Table 40-7) and 90% of 22 patients with upper extremity CRPS-I had side effects following the procedure. In addition, a potential placebo effect may ensue following sympathetic blocks.[218,271,293] Horner's syndrome (partial ptosis, miosis, and anhidrosis) may occur after a stellate block.

Spinal or epidural blocks may be used for diagnosis of CRPS because the nerve fibers respond to varying concentrations of local anesthetic differently. The lowest concentrations of local anesthetic penetrate the least myelinated sympathetic nerve fibers. At increasing concentrations, the sensory nervous system is blocked, and even higher concentrations block the motor system. When used to test for CRPS, the initial injection is often saline to detect a placebo response. Unfortunately, even at low concentrations, some sensory blockade that may lead to false-positive results occurs.[172]

Vasomotor Measurement

Skin surface temperature measurements may be done by the clinician using a variety of commercially available devices. Handheld infrared thermometers measure skin temperature in the periphery of the hands and feet.[34,118,145,199,211,219,221,224,328,332] There is also a noninvasive clinical thermal test that assesses the function of small nerve fibers and their central connections. An investigation of 37 hands and 48 feet in patients with tonic dystonia showed cold and warmth hypesthesia without increased heat pain sensitivity with this device.[207] Thermography is another technique available for detecting temperature differences.[43,211] However, this test requires extensive setup and monitoring and is not useful clinically if only for cost reasons. One problem with all of the available skin surface temperature devices is that there is no agreement on the amount of temperature difference which constitutes a positive test for CRPS.

Sudomotor Measurement

The quantitative sudomotor axon reflex test (QSART) is one method of measuring sweat output. In this test, acetylcholine is administered to the extremities, and the sweat output of each extremity is measured and compared.[20,174,262] One criticism of this test is based on the theory that sudomotor dysfunction is centrally mediated and this test has its mechanism of action at the postganglionic sympathetic neuron. Therefore, the results of this test may not reflect CRPS sympathetic hyperactivity.[20]

TABLE 40-7 Side Effects After Lumbar Sympathetic Ganglion Blockade in 28 Patients

Side Effect	*n* (%) Patients	Median Time (Range) (Days)
Back pain	17 (60.7)	2 (0-7)
Increased pain	10 (35.7)	3 (0-11)
Headache	8 (28.6)	2 (0-3)
Groin pain	5 (17.9)	2.5 (0-3)
Nausea/vomiting	5 (17.9)	2 (1-3)
Hoarseness	2 (7.1)	3 (2-4)
Hematoma	2 (7.1)	3 (2-4)
Dysphagia	1 (3.6)	1 (0-1)
None	6 (21.4)

TREATMENT

Many treatment options have been proposed for CRPS, but few are supported by high-level clinical trials. This is especially true for CRPS related to the knee or lower extremity. Even so, agreement exists in the literature that multiple disciplines should be involved in providing patient care, including orthopedists, neurologists, pain specialists, anesthesiologists, physical therapists, occupational therapists, psychologists, and primary care physicians.[121,172,182,295]

The treatment options presented in this section should begin as soon as possible following a definitive diagnosis. Identification and appropriate management of nerve injuries in CRPS-II patients should be performed without delay. In CRPS-I patients, all attempts should be made to identify any triggers responsible for the abnormal

CRITICAL POINTS Treatment

- Multiple disciplines should be involved, including orthopedists, neurologists, pain specialists, anesthesiologists, physical therapists, occupational therapists, psychologists, and primary care physicians.
- Few treatment options are supported by high-level studies for lower extremity CRPS.
- Educate patient; ensure he or she is actively involved in treatment options.
- Identify, treat nerve injuries immediately.
- Look for hidden triggers in CRPS-I.
- Begin physical therapy, occupational therapy immediately. Include graded exposure to activities/movements/light touch, desensitization activities, active range of motion and flexibility, water therapy, graded motor imagery and mirror visual feedback, coping/relaxation techniques, tissue massage. Work hardening, vocational rehabilitation required to return to normal function.
- Use psychotherapy as required in patients with chronic CRPS.
- Medications: few tested in high-level studies. Treat comorbidities as required. Options include corticosteroids, nonsteroidal anti-inflammatories, free radical scavengers, bisphosphonates, anticonvulsants, calcium channel blockers.
- Stronger interventions: IV ketamine, sympathetic block, epidural infusion, surgical sympathectomy, neurostimulation, surgery.
- Authors disagree with amputation, high percentage recurrence symptoms, phantom pain.

pain response (such as a meniscus tear). Although surgery may be poorly tolerated in some patients, it may be done in a manner that minimizes the chance of exacerbating the condition.[172] In most cases, it is worth the risk of worsening the condition to eliminate the primary cause of the pain symptoms. There is a general consensus that physical and occupational therapy is paramount in the treatment of CRPS, although high level data regarding the specific components and modalities (along with other medical and psychological intervention) that successfully restore normal function are currently not available.[68,121]

Regardless of the lack of high-level investigations, protocols and practical guidelines for the treatment of CRPS have emerged from consensus conferences, metaanalyses, systematic literature reviews, and extensive clinical experience. In 2013, Harden and associates[121,310] described the necessity for specific treatments that included physical therapy, occupational therapy, vocational rehabilitation, medications, psychotherapy, and if required, interventions (nerve blocks, drug infusions, implantable pain treatment devices) to regain *functional restoration*. Functional restoration is based on the principle of gradual and steady progression from activation of presensorimotor cortices (graded motor imagery) to gentle active movements to weight-bearing activities. An increase in function corresponds with desensitization to increasing sensory stimuli. A gradual increase in normalized sensation is believed to reset some of the complex, higher central changes previously described, such as central sensitization. These investigators introduce pharmaceutical and other interventions if the patient fails to progress in a reasonable time frame, to be discussed later.

Occupational and Physical Therapy

Occupational and physical therapy are considered essential in the treatment of CRPS.[21,53,68,202,220,244] In fact, many drug regimens are intended to relieve symptoms so patients can tolerate effective therapy measures. Several guiding principles[53] have been developed for therapy of CRPS patients (Fig. 40-13), including:

- Patient education
- Graded exposure to activities, movements, light touch
- Sensorimotor treatment: desensitization activities
- Exercises: flexibility, active range of motion, water therapy, stress loading
- Graded motor imagery and mirror visual feedback
- Pain management: coping/relaxation techniques, tissue massage

A successful patient-therapist alliance with strong communication is paramount. The therapist must be an advocate for the patient, gaining trust and lending credibility to the treatment regimen. Slow response to treatment and frequent setbacks may occur, but confrontations between the patient and therapist are always counterproductive.[295] The rehabilitation program should not be overly aggressive because this may trigger more pain, edema, distress, and fatigue that only exacerbate the inflammation and sympathetic symptoms of CRPS. Cryotherapy should be avoided.

In patients with a recent onset of CRPS, when pain is experienced at rest, therapy should consist of careful and gentle active and active-assisted mobilization. Exercises on the contralateral extremity may be performed. In patients with long-standing CRPS, therapy should initially focus on correcting the "mismatch between the motor and sensory systems and the sustained attention to the painful limb."[190] A program that combines graded motor imagery and mirror visual feedback[30,79,168,190,263] is becoming popular.[121] *Graded motor imagery* (Table 40-8) attempts to sequentially activate the premotor and primary motor cortices through limb laterality recognition, motor imagery (imagination), and mirror therapy (small movements performed by the opposite extremity that are watched in a mirror while the affected extremity is hidden from view). Moseley in 2004[200] described a three-stage program that was found to effectively alleviate pain in chronic CRPS-I patients with upper extremity involvement.[200] A recent metaanalysis found that this program had large (beneficial) effects compared with standard physical therapy alone in patients with chronic pain syndromes.[30] Although the mechanisms of the effect of this program remain unclear, the hypothesis is that this type of training forces attention to the affected extremity, decreases kinesiophobia, and provides corrective sensory feedback into a system when a discrepancy exists between motor output and sensory feedback.[190]

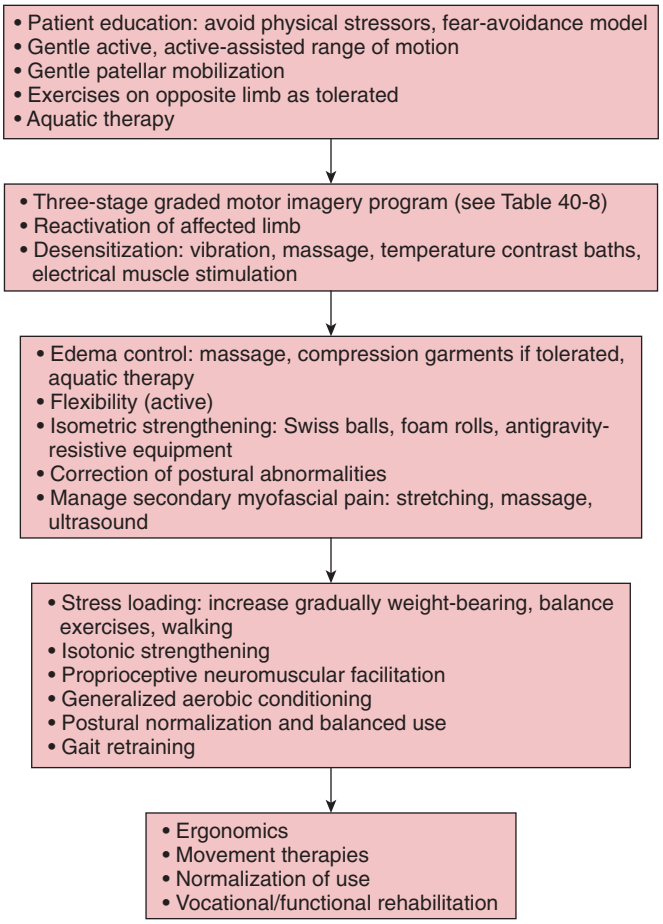

FIG 40-13 Physical therapy algorithm to regain functional restoration for complex regional pain syndrome (CRPS). Conduct the program within bounds of patient tolerance. Do not use when the patient is insensate (after a block) or a patient with pronounced hypoesthesia. Aggressive therapy, range of motion devices, cryotherapy, and inactivity may aggravate CRPS. (From Harden RN, Oaklander AL, Buron AW, et al. Complex regional pain syndrome: practical diagnostic and treatment guidelines, ed 4. *Pain Med.* 2013;14:180-229.)

Patients with chronic CPRS have pain with any movement of the affected limb and will guard by voluntarily restricting its range of motion. These movement phobias must be overcome before long-term sequelae develop. Active and active-assisted range of motion exercises are preferred over passive motion. Forced passive motion is too aggressive, painful, and counterproductive to treatment.[122] Gentle patellar mobilization should also be performed. Minimizing edema may be done using active motion, elevation, massage, and compression with special garments if tolerated. Myofascial pain, which is a common finding in patients with longstanding CRPS, should be treated with stretching, massage, and ultrasound on the trigger points. Normalizing

TABLE 40-8 Graded Motor Imagery Program for Chronic Knee-Related Complex Regional Pain Syndrome

Stage 1: Recognition of Laterality (2 Weeks)

Using web-accessible software (Recognise, Noigroup*), the patient is shown photographs of normal right and left knees in a variety of positions in random order. The patient is asked to identify as quickly as possible which knee (right or left) he or she sees. Emphasis is on speed and accuracy. Normal guidelines: ≥80% accuracy, similar results for left and right knees, response time 2 ± 0.5 sec, consistent for ≥1 week.

Stage 2: Imagined Movement (2 Weeks)

Pictures of a knee are shown in random order to the patient, who is asked to imagine moving his or her own knee to adopt the posture shown in the picture. Emphasis is on accuracy, not speed. The patient does not actually move the knee during this phase.

Stage 3: Mirror Therapy (2 Weeks)

With the patient sitting on an examination table, a high vertical mirror is positioned so that the affected knee is concealed from the patient. The patient begins by watching the unaffected knee (which is in a comfortable position) in the mirror. Then the patient is shown pictures of a knee doing simple movements or asked to do simple movements by the therapist. The patient slowly tries to perform the movements simultaneously with both knees. The affected knee is kept concealed at all times, and emphasis is on watching the reflection of their unaffected knee in the mirror. Movements should be very easy initially and gradually increase in difficulty as tolerated. The therapist should check behind the mirror to ensure the limbs are moving together and that the affected limb does not stop. Emphasis is on full concentration; sequence should not be done for more than 5 min at a time.

*www.noigroup.com/recognise and www.gradedmotorimagery.com/.

sensation is accomplished through vibration, massage, temperature contrast baths, and electrical muscle stimulation. Initially, light touch will be painful, but as treatment progresses, patients will gradually be able to tolerate greater amounts of stimulation.

Aquatic therapy is an excellent approach for lower extremity CRPS, especially in patients in whom weight bearing cannot be tolerated because any land-based exercise may be initially done in the water. Walking is begun when the patient is able to tolerate weight on the leg. Loads are increased with verbal cues or by having the patient carry a weighted object on the affected side. Activities that promote weight shifting and balance (e.g., ball toss) are encouraged.

When the patient is ready, strengthening exercises are performed isometrically to minimize painful motion with devices such as Swiss balls, foam rolls, and antigravity-resistive equipment.[121] Over time, the patient is advanced to isotonic strengthening. Loads are gradually increased from water exercises to full weight-bearing activities. Gait retraining may be required as patients progress to full weight bearing.[295] Proprioceptive neuromuscular facilitation patterns are useful to facilitate strength and balance.

Another approach that has been briefly described for chronic CPRS patients in whom previous treatments have failed is *graded pain exposure therapy*.[57,77,304] This program consists initially of patient education regarding the fear-avoidance model and development of the willingness to engage in activities previously avoided. It is based on the assumption that behavioral and psychological factors can exacerbate pain and dysfunction, which may in turn maintain CRPS in some patients. An individualized program is designed by the therapist that includes active and active-assisted joint motion, passive stretching, and friction massage. Use of the affected extremity is encouraged, with gradual progression of exercises and loading. Unlike most other therapeutic programs, pain severity is not used as a guideline to increase or reduce activities. Patients are encouraged to perceive pain as a false warning sign of the nervous system that should be ignored. Family members and partners are involved and educated to provide the correct support as the patient initially goes through an increase in pain.

Returning the patient to normal function is accomplished through work-hardening and vocational-rehabilitation programs. Future rehabilitation studies are required that use the Budapest diagnostic criteria and appropriate outcome measures for pain and function. Randomized controlled trials should be performed on some of the measures described here that appear promising, such as graded motor imagery and graded pain exposure therapy.

Psychotherapy

A recent systematic review of 31 articles found that despite prior beliefs, the onset and maintenance of CRPS is not significantly associated with a history or presence of psychological problems.[13,14] However, as this chronic pain condition persists, patients may develop some degree of emotional distress, increased anxiety, and depression. Investigators agree that all CRPS patients and their families, regardless of the duration of the disorder, should be educated about the negative effects of disuse, the pathophysiology of the syndrome, the possible interactions with psychological/behavioral factors, the importance of reactivation, and the need for an active self-management approach to treatment.[32,121] Chronic CRPS patients should undergo a thorough psychological evaluation, followed by appropriate treatment that might include relaxation training and cognitive-behavioral interventions. Relaxation training with biofeedback can help increase the patient's ability to control his or her pain and decrease emotional arousal. This includes breathing-focused relaxation, progressive muscle relaxation, relaxing imagery, and autogenic training. Cognitive-behavioral intervention aims to reframe the patient's role as that of an active participant in the treatment process rather than a passive recipient. Correcting misconceptions that the patient may have regarding the disorder and treatment options is essential. Changing the patient's focus from completely negative thoughts to more positive, constructive ones is stressed. The combination of psychotherapy and physical therapy is advocated when techniques such as graded exposure therapy, autogenic relaxation techniques, mirror therapy, and hypnotic imagery are available.[121]

Medications

Many medications have been tested for efficacy in chronic pain conditions such as peripheral neuropathy, but few have been tested in high-level studies (double-blind, randomized, placebo-controlled studies) to treat CRPS (Table 40-9).[121,175,182,255] Because CRPS may involve central sensitization, motor abnormalities, and sympathetic efferent features that differ among patients, no one medication can be expected to treat this disorder.[121] In addition, there may be the need to treat comorbidities such as depression and insomnia; therefore the decision on prescribed medication must take into account the entire patient presentation.

Corticosteroids and Nonsteroidal Antiinflammatories

Corticosteroids are potentially effective if begun early in the course of CRPS.[18,45,109,142,161,206] In a small randomized controlled trial,

TABLE 40-9 Pharmacology Treatment Options for Complex Regional Pain Syndrome

Study, Country	Level	Subjects (*n*)	Type and Location Pain	Drug	Results/Complications
Kozin et al[161] (1981), U.S.	Open label	17 "definite," 9 "probable," 5 "possible"	RSD, upper and lower extremities	**Corticosteroid**: oral prednisone, tapered	Good/excellent pain relief in 82% of "definite" group, 66% of "probable" group, 0% of "possible" group.
Christensen et al[45] (1982), Denmark	RCT	23	RSD, upper extremity	**Corticosteroid**: oral prednisone, 30 mg daily vs. placebo for 12 wk	All 13 patients in prednisone group had >75% clinical improvement compared with 2/10 patients in placebo group. No side effects.
Grundberg[109] (1996), U.S.	Open label	69	RSD, upper extremity	**Corticosteroid**: IM long-acting methylprednisolone	At 1 year, 47 patients significantly improved pain and ROM. Mild side effects in 8 patients, all resolved.
Kalita et al[142] (2006), India	RCT	60	CRPS-I upper extremity after stroke	**Corticosteroid**: oral prednisone 40 mg or piroxicam 20 mg daily for 1 mo	25 (83%) patients in prednisone group improved compared with 5 (17%) in piroxicam group. Five patients had mild gastritis, 2 had upper respiratory tract infection; all resolved.
Bianchi et al[18] (2006), Italy	Open label	31	CRPS hand (25), foot (4), knee (2)	**Corticosteroid**: oral prednisone, tapered + therapy; 4 patients required 2 cycles of Rx, 2 patients also had ganglion blocks	Significant improvement short term and at 1-yr follow-up in clinical CRPS severity score. No side effects.
Munts et al[206] (2010), The Netherlands	DB RCT	21	CRPS-I, upper and lower extremities (chronic)	**Corticosteroid**: single intrathecal dose 60 mg methylprednisolone vs. placebo	No improvement at 6 wk, trial stopped prematurely. Minor side effects in 10 Rx patients and 11 placebo patients.
Rico et al[245] (1987), Belgium	Nonrandomized	26	RSD, lower extremity	**NSAID**: oral naproxen 1000 mg daily vs. IM calcitonin	At 3 mo, calcitonin group had significant decrease in bone/soft tissue uptake index on bone scan; naproxen group had increase in index. No side effects.
Goris et al[105] (1987), The Netherlands	Crossover	20	RSD, upper and lower extremities	**Free radical scavenger**: all patients 50% DMSO cream 1 wk, placebo 1 wk	DMSO more effective for improving ROM and symptoms. No side effects.
Geertzen et al[88] (1994), The Netherlands	RCT	26	RSD, 3-mo duration, upper extremity	**Free radical scavenger**: DMSO vs. regional IV Ismelin block	At 9 weeks: better result in DMSO group. DMSO had onion-garlic–like taste and smell but no side effects.
Zuurmond et al[339] (1996), The Netherlands	DB RCT	32	RSD, acute, upper and lower extremity	**Free radical scavenger**: 50% DMSO cream vs. placebo + therapy	At 2 mo, DMSO had group significantly better results; 13 DMSO patients and 3 placebo patients had mild scaling of skin.
Perez et al[229] (2003) The Netherlands	DB RCT	145	CRPS-I, 105 upper extremity, 41 lower extremity	**Free radical scavenger**: 50% DMSO cream vs. oral N-acetylcysteine (NAC) 1800 mg	Both interventions equally effective at 1 yr; 3 patients on DMSO and 5 patients on NAC had severe stomach complaints and dropped out of study.
Perez et al[227] (2008), The Netherlands	DB RCT	41	CRPS-I	**Free radical scavenger**: IV mannitol vs. placebo 4 hr, 5 consecutive days + therapy	At 9 wk, no difference between groups. Mild side effects in 16 patients on Rx, 13 patients on placebo; all resolved.
Gobelet et al[95] (1986), Switzerland	RCT	24	RSD, stage I	**Calcitonin:** 100 IU injection daily 3 wk + therapy vs therapy only	Significant pain improvement in calcitonin group after 1 wk.
Bickerstaff & Kanis[19] (1991), United Kingdom	DB RCT	40	Algodystrophy, posttraumatic	**Calcitonin:** 400 IU nasal daily 4 wk vs. placebo	No improvement in clinical or skeletal progression of disorder.

TABLE 40-9 Pharmacology Treatment Options for Complex Regional Pain Syndrome—cont'd

Study, Country	Level	Subjects (*n*)	Type and Location Pain	Drug	Results/Complications
Gobelet et al[96] (1992), Switzerland	DB RCT	66	RSD	**Calcitonin:** 300 IU nasal daily 3 wk + therapy vs. placebo + therapy	At 8 wk, significant improvement in pain and range of motion in calcitonin group. Effect not equally observed for other parameters. Two patients in each group had nasal pruritus, 3 patients on Rx had headache, 6 patients on placebo had nausea and fatigue; all resolved.
Maillefert et al[184] (1995), France	Open label	11	RSD, chronic; 5 feet, 2 hand, 2 upper limb, 1 knee, 1 lower limb	**Bisphosphonate/IV pamidronate:** 30 mg 3 consecutive days	At 3 mo, significant reduction in pain, physician-noted improvement in 7 patients. Two patients had transient fever, 2 had asymptomatic hypocalcaemia, 1 had symptomatic hypocalcaemia; all resolved.
Adami et al[1] (1997), Italy	DB RCT	20	RSD; 8 feet, 12 hands	**Bisphosphonate/IV alendronate:** 7.5 mg 3 consecutive days vs. placebo; then 14 days later, all received open IV alendronate 7.5 mg/day for 3 days	At 2 wk, Rx group had significantly better results in pain, tenderness, swelling, and motion than placebo. All patients responded to open alendronate therapy. Three Rx patients had fever after first injection that resolved.
Cortet et al[52] (1997), France	Open label	26	RSD; 17 foot/ankle, 3 hand, 2 hip, 2 knee, 1 shoulder	**Bisphosphonate/IV pamidronate:** 1 mg/kg/day for 3 consecutive days (14), 2 days (7 because of adverse events), 1 day (2 because of adverse events)	At 30, 60, 90 days, significant decrease in pain. Six patients had transient fever, 3 hypocalcaemia, 2 venous irritation, 1 patients each nausea, transient hypertension, and leucopenia with neutropenia. All resolved.
Varenna et al[317] (2000), Italy	DB RCT	32	RSD	**Bisphosphonate/IV clodronate:** 300 mg daily for 10 consecutive days or placebo, then 40 days later, placebo group received clodronate	After 40 days, Rx group had significantly better results in pain, clinical global assessment scores. At 180 days, significant improvement seen in entire group for pain.
Kubalek et al[163] (2001), France	Open label	29	RSD, upper and lower limb	**Bisphosphonate/IV pamidronate:** 60 mg/day for 3 days	At day 45, pain resolved in 86%, functional improvement seen in 70%. Six patients had fever, 5 shivers, 3 diarrhea.
Manicourt et al[187] (2004), Belgium	DB RCT	40	CRPS-I, lower extremity (30 foot/ankle, 10 knee)	**Bisphosphonate/oral alendronate:** 40 mg/day for 8 wk vs. placebo; then 4 wk no therapy, then 8 wk voluntary (open) use of alendronate	Rx group had "marked and sustained" improvement in levels of spontaneous pain, pressure tolerance, joint mobility at weeks 4, 8, 12; 24 patients volunteered for 8-week open trial, all had positive response. One Rx patient dropped out because of upper gastrointestinal intolerance. One placebo patient had nausea for 1 hr, resolved.
Robinson et al[249] (2004), New Zealand	DB RCT	27	CRPS-I, upper and lower limb	**Bisphosphonate/IV pamidronate:** 60 mg/day 1 dose vs. placebo	At 3 months, pain, global assessment, SF-36 scores significantly better for Rx group. Five patients in Rx group and 2 in control group had minor influenza-type symptoms, 2 in Rx group had mild infusion site reactions; all resolved.

Continued

TABLE 40-9 Pharmacology Treatment Options for Complex Regional Pain Syndrome—cont'd

Study, Country	Level	Subjects (*n*)	Type and Location Pain	Drug	Results/Complications
Breuer et al[31] (2008), U.S.	Open label	10	CRPS	**Bisphosphonate/IV ibandronate:** 6 mg for 3 days	At 4 wk, improvements observed in average and "worst" pain ratings; 8 patients had transitory flulike symptoms.
Varenna et al[316] (2013), Italy	DB RCT	82	CRPS-I hand, foot, <4 mo onset symptoms	**Bisphosphonate/IV neridronate:** 100 mg 4 times over 10 days vs. placebo; after 50 days, placebo group open trial neridronate available	At 20 days, Rx group had significantly better results in pain that continued for next 20 days. Significant improvements in Rx group for several SF-36 indexes vs. placebo; 21 patients in Rx group, 12 in placebo group had minor adverse events. 14 patients had open trial phase (39%) minor adverse events.
Prough et al[234] (1985), U.S.	Open label	13	RSD, 10 upper extremity, 3 lower extremity, acute and chronic	**Calcium channel blocker/oral nifedipine:** 10-30 mg tid	7 patients' pain resolved, 2 patients' pain partially resolved, 3 withdrew for side effects (severe headache); 1 failed.
Muizelaar et al[204] (1997), U.S.	Retrospective chart review	59	CRPS-I (41), CRPS-II (18), 80% upper extremity, 20% lower extremity, 12 early stage, 47 chronic	**Calcium channel blocker/oral nifedipine** or **α-sympathetic blocker/oral phenoxybenzamine:** dosages varied, 8-12 wk	92% early-stage symptoms resolved, majority treated with phenoxybenzamine. 40% chronic stage symptoms resolved, majority treated with nifedipine. One third of patients on nifedipine had mild headaches. Phenoxybenzamine dizziness, orthostatic hypotension symptoms, impotence in men in majority; 7 patients dropped out because of these side effects.
Mellick and Mellick[193] (1997), U.S.	Open label	6	RSD, 4 upper extremity, 2 lower extremity	**Calcium channel blocker/oral gabapentin:** 300-800 mg tid	Verbal pain scale, reduction of pain, 85%-100% in 5 patients, 60% in 1.
van de Vusse et al[305] (2004), The Netherlands	DB RCT	58	CRPS-I, chronic, upper and lower extremity	**Calcium channel blocker/oral gabapentin:** 600 mg days 1-2, 1200 mg days 3-4, 1800 mg days 5-21 vs placebo; two 3-wk Rx periods; gabapentin or placebo, then washout	Pain relief found in favor of gabapentin in first study period. Sensory deficits reversed compared with placebo. Therapy less effective in second period, no effect when both periods combined. Mild side effects (dizziness, somnolence, lethargy) in 95% of gabapentin group and 58% placebo in first Rx period.
Tan et al[298] (2007), Turkey	Open label	22	RSD, acute (<6 mo onset); 15 hand, 5 foot, 1 elbow, 1 knee	**Calcium channel blocker/oral gabapentin:** 600 mg/day, increased every 3 days by 300 mg until satisfactory pain relief obtained; done for 3 wk, then 6 wk at maintenance dosages	At 6 wk, significant improvements in pain, motion; 5 patients had complete resolution of pain. Mild dizziness in 3 patients, headache in 2, turning in tongue in 1; all resolved.

CRPS, Complex regional pain syndrome; *DB*, double-blind; *DMSO*, dimethyl sulfoxide; *IM*, intramuscular; *IV*, intravenous; *RCT*, randomized controlled trial; *Rx*, treatment; *RSD*, reflex sympathetic dystrophy.

Christensen and associates[45] found that 30 mg per day of prednisone was significantly better in terms of clinical improvement than a placebo. A second study compared the use of 40 mg prednisolone per day combined with piroxicam in CRPS-I following stroke and reported improvements in symptoms and signs after 1 month of treatment.[142]

A course of cortisone may be indicated in the initial period after onset of CRPS. Maihofner and colleagues[182] empirically recommended methylprednisolone 100 mg/day, which is reduced to 25 mg every 4 days. The senior author has found a Medrol Dosepak, or other equivalent steroid dosage, is also useful early in the course of the disease process. If the patient has a positive but incomplete response to an initial course of oral steroids, a second course may be beneficial.

Although very little clinical data exist,[245] NSAIDS are commonly used to treat CRPS especially early after the onset of the disorder if the limb has an inflamed appearance.[175,264,295] The mechanism of action of these agents is inhibition of cyclooxygenase which decreases the production of prostaglandins. However, the problem is that inflammation in CRPS is now regarded to be neurogenic in nature and no drugs have been studied for this type of inflammation.[121] In addition, there is a real danger of overdose from prescription combination products containing acetaminophen.

Free Radical Scavengers

The use of free radical scavengers to combat CRPS is based on the proposed inflammatory response theory in which an excessive production of inflammatory mediators and oxygen radicals harms healthy tissue. A randomized controlled trial in 32 patients with acute RSD reported that topically applied 50% dimethyl sulfoxide (DMSO) was superior to placebo and led to improved pain and inflammatory signs.[339] Two other studies reported positive effects of DMSO in CRPS-1 patients.[88,105] Oral N-acetylcysteine was found to be equally effective as DMSO in a high-level trial involving 146 CRPS-I patients.[229] It appeared from this study that 50% DMSO cream was more effective in primary "warm" CRPS-1 patients, although N-acetylcysteine was more effective in primary "cold" CRPS-I patients.

Zollinger and associates[337] found vitamin C, taken at 500 mg per day for 50 days, to be effective in reducing the prevalence of CRPS in wrist fractures. This is the only CRPS medication prevention trial conducted to date.

Calcitonin, Bisphosphonates

One problem in select CRPS patients is rapid and painful bone reabsorption (identified with MRI or a three-phase bone scan). Inhibiting osteoclast activity and bone reabsorption is important not only for pain reduction but also for preservation of bone mass in the affected extremity. Calcitonin, used commonly for osteoporosis in women, has been studied in just three randomized controlled trials for "posttraumatic algodystrophy" and RSD with conflicting results in terms of pain relief.[19,95,96]

More extensive work has been conducted with various oral and intravenous (IV) bisphosphonates in CRPS patients.[1,31,52,163,184,187,249,316,317] However, most of the trials are older and used first- and second-generation drugs. One such study revealed that IV alendronate was successful in improving function and increasing the bone density in the affected limb.[1] The bone density in the unaffected limb remained unchanged. A double-blind placebo controlled trial of oral alendronate[187] in 40 patients reported improvement 4 weeks after alendronate was initiated which continued after the medication was stopped. All patients exhibited improved pain levels, pressure tolerance, and joint mobility.

A small, open-label trial of a third-generation bisphosphonate, ibandronate (6 mg infusion, 3 consecutive days) showed encouraging results 4 weeks posttreatment.[31] Eight of 10 participants had flulike symptoms, which resolved. The investigators concluded that a future randomized, double-blind, placebo-controlled trial was justified.

In 2013, Varenna and associates[316] published the results of IV-infused neridronate compared with placebo in 82 patients with acute (<4 months' duration) CRPS-I in the upper and lower extremities. The placebo patients were offered open-label neridronate treatment after 50 days. Significant improvements were found between the treatment and placebo group for pain and a number of quality of life indices. The improvements were also found in the patients who participated in the open-label phase of the trial. One year later, none of the patients complained of CRPS-related symptoms. The authors concluded their results "provide conclusive evidence that the use of bisphosphonates, at appropriate doses, is the treatment of choice for CRPS-I" in patients diagnosed after recent onset of the disorder.

Anticonvulsants and Calcium Channel Blockers

Drugs that block entry of sodium or calcium into neurons, used as anticonvulsants and antiepileptics, may play a role in CRPS, although high-level study evidence remains lacking.[121,175] The mechanisms of action are not well understood for these medications in regard to neuropathic pain. The main hypothesis is that peripheral nerve injury alters the distribution and expression of subtypes of sodium channels on axonal membrances.[255] This in turn induces upregulation of primary nociceptive afferent fibers and small dorsal root ganglia pain transmission neurons. Blocking sodium channels should reduce the action potentials of these neurons.[121]

Nifedipine (Procardia) decreased pain and improved signs of sympathetic dysfunction in two small studies[204,234] but has not been investigated for CRPS for many years. Gabapentin (Neurontin) has received considerable attention in both neuropathic pain[93,281] and CRPS trials.[193,298,305] Gabapentin has been reported to be effective in decreasing both allodynia and hyperalgesia.[44,305] Start with smaller doses such as 300 mg three times a day and gradually increase the dosage, observing for side effects. A newer antiepileptic drug, pregabalin (Lyrica), may also be considered because it has a similar mechanism of action as gabapentin. To date, pregabalin has not been studied in CRPS patients.[121]

Antidotal recommendations have been made for usage of carbamazepine[124] (or preferably oxcarbazepine) in CRPS-II.[175,255] Oxcarbazepine may be a better alternative because it has fewer side effects and drug-drug interactions,[121] but this medication has not been studied in CRPS patients.

Alpha-Adrenergic Antagonists

Alpha-adrenergic antagonists, or α-sympathetic blockers, have been used clinically for CRPS, but they have significant side effects, and no high-level evidence exists to support their efficacy.[154,175,204,255] Typical adverse effects include sedation, dizziness, headache, nausea, and hypotension. Clonidine was used several years ago in two small series of patients topically ($n = 6$)[55] and epidurally ($n = 19$)[242] to treat CRPS. Phenoxybenzamine (Dibenzyline) was tested in four small studies for causalgia (orally, $n = 40$)[91], RSD (orally, $n = 35$[204] and intravenously, $n = 5$[185]), and CRPS (orally, $n = 4$).[137] Inchiosa and coworkers[137] recommended oral phenoxybenzamine for refractory cases of CRPS before consideration of more invasive treatment, but this advice was based on the results of treatment in just four patients.

Topical Lidocaine and Capsaicin

Topical medications that remain local and do not cause systematic side effects offer an alternative medication option for CRPS patients,

although high-level study evidence of their efficacy for this disorder does not currently exist. Investigators have empirically recommended consideration for use of the 5% lidocaine patch (Lidoderm).[121] This patch is approved in the United States for treating postherpetic neuralgia.[54,256] One open-label study that included six CRPS patients (5 CRPS-I and 1 CRPS-II) reported that all patients experienced pain relief after wearing the patch an average of 6.2 weeks.[65]

Many years ago, a preliminary study was performed on high-dose topical capsaicin delivered with regional anesthesia in 10 patients with refractory CRPS.[246] All but one patient experienced some pain relief that lasted from 1 to 18 weeks. This medication is approved in the United States (8% capsaicin patch, Qutenza) for postherpetic neuralgia and has been found to be effective in peripheral neuropathic pain.[285,286] The problem is that capsaicin causes a painful burning sensation at the site of application, which Harden and associations found to be "intolerably painful, messy, and unacceptable to most patients."[121]

Antidepressants

To date, no high-level evidence exists regarding the use of various antidepressant medications for CRPS.[121,228] In neuropathic pain, tricyclic and heterocyclic drugs have been found to be advantageous for both pain relief and antidepressant effects.[48,192,289] These medications include peripheral sodium-channel blockade, which may also add to their efficacy.[334] For example, amitriptyline (Elavil) has been shown to provide relief from burning pain. In addition, this medication treats mood and anxiety disorders that may develop in patients with a chronic pain condition. Amitriptyline has sedating properties, which can relieve insomnia. The problem with tricyclic antidepressants is their toxicity in an intentional overdose situation.

Selective serotonin reuptake inhibitors have been ineffective in providing analgesic effects.[121] However, combined serotonin-norepinephrine reuptake inhibitors, such as duloxetine (Cymbalta) and venlafaxine (Effexor), are approved in the United States for several chronic pain diagnoses and have been found to be effective for neuropathic pain.[226,240,241,288] There is a tremendous need for high-level studies on the potential effectiveness and safety of antidepressants for CRPS.

Opioids

The use of opioids such as morphine, oxycodone, and tramadol for the treatment of CRPS (or any chronic pain condition not related to cancer) is controversial. Many studies have demonstrated the effectiveness of these medications in controlling pain and improving the quality of life in patients with chronic peripheral neuropathic pain[7,73,94,257,331] and knee osteoarthritis.[213] Combining an opioid with another drug (e.g., a tricyclic antidepressant or gabapentin) may have an even greater effect on neuropathic pain.[41] Side effects with opioids are common and, with high doses, include nausea, vomiting, constipation, cognitive impairment, respiratory depression, and addiction. Long-term use may lead to tolerance, hyperalgesia, decreased libido, suppression of the immune system, and overdose leading to death.[74,175] As a matter of course, orthopedists in most cases should avoid using opioids in chronic pain conditions and explain the disadvantages to patients. However, there are times when it may be necessary to use these drugs, especially for patients in pain crisis,[116] and in those instances it is best to provide a pain management referral and have only one physician dispensing the opioid. Tramadol is an option because it blocks serotonin/norepinephrine reuptake and has been proven clinically useful in randomized controlled trials to decrease pain associated with peripheral neuropathy[73,113] and osteoarthritis.[39] Methadone has a theoretical usefulness because it also acts as an N-methyl-D-aspartate (NMDA) antagonistic (see "Interventions" below) and is low in cost.[121]

Pharmacotherapy for Movement Disorders

A common movement disorder in patients with chronic CRPS is dystonia, which may be limited to small areas or may encompass larger regions such as the fingers, wrist, and feet where a fixed flexion posture occurs.[312] There is also a tendency for dystonia to spread to other extremities. Intramuscular botulinum toxin injections have been suggested for pain relief in chronic neuropathic pain[38,239,336] and treatment of pain and dystonia in chronic CRPS.[5,148,259,260] The most widely known action of botulinum toxin is its relaxing effect on skeletal muscles; however, recent studies indicate that it appears to have an early antinociceptive action that may be beneficial in CRPS.[38] Harden and associates[121] suggested these injections are most useful for focal dystonia limited to small areas.

Baclofen has been suggested for dystonia in CRPS because of its stimulation of presynaptic and postsynaptic gamma-aminobutyric acid B receptors that enhance central inhibitory activity.[307] Investigators reported mixed results in terms of partial or complete resolution of focal dystonia from oral[276] and intrathecal pump[307,311,338] administration of baclofen. Intrathecal administration has a high complication rate, including infections, catheter and pump system failures, postdural puncture headache, and the formation of intrathecal granulomas, which have the potential to produce spinal cord compression.[310] High-level studies on the efficacy of botulinum toxin injections and baclofen on the treatment of dystonia in CRPS patients are lacking.

Interventions

N-Methyl-D-Aspartate Receptor Antagonists: Intravenous Ketamine

NMDA receptor antagonists are a class of anesthetics that work to inhibit the action of the N-methyl-D-aspartate receptor. This receptor allows for the transfer of electric signals between neurons in the brain and in the spinal column. The receptor must be open for the signals to pass and, therefore, chemicals that deactivate the NMDA receptor are termed antagonists. Common antagonists include ketamine, amantadine, dextromethorphan, and memantine. Only memantine,[110] magnesium,[47] and ketamine have been studied in CRPS patients, with recent extensive attention given to ketamine (Table 40-10).[51,101-103,158,258] However, high-level trials (double-blinded, randomized, placebo-controlled) with adequate numbers of patients receiving this treatment for CRPS are lacking.[15,46]

Initial case reports appeared in 2002 on the topical application (0.25%-1.5%) of ketamine in CRPS-I and CRPS-II patients with allodynia or hyperalgesia.[302] Pain relief and reduction in swelling were observed 1 to 2 weeks later in CRPS-I subjects. A more recent study found that a single-dose topical application of ketamine did not lead to pain reduction, but did reduce allodynia in a group of 20 patients with CRPS-I.[81]

Most case reports[78,114,149,152,153,208,282] and studies[51,101,102,150,151,158,267,273,283] have involved IV infusion of ketamine of varying dosage levels. Koffler and associates[158] used a high dosage (anesthetic) of ketamine in nine refractory CRPS patients, producing a medically induced coma for 4.5 days, and reported no problems with cognitive function 6 weeks later. Lower, subanesthetic doses were reported effective in reducing pain in other studies.[102,273,283] Schilder and colleagues[267] recently studied the effects of continuous, low-dose IV infused ketamine and placebo (for 4 days) on motor function in 29 CRPS-I patients. Motor function was determined by measuring a finger tapping task. Over a period of 12 weeks following treatment, a direct correlation was found between pain intensity and motor function, irrespective of receipt of ketamine or placebo. This study leads credence to the belief that achieving pain relief is an important goal in the management of motor problems and in rehabilitating patients with CRPS.

TABLE 40-10 Investigations on N-Methyl-D-Aspartate Receptor Antagonist Ketamine

Study, Country	Level	Subjects (*n*)	Type and Location of CRPS	Drug	Results/Complications
Correll et al[51] (2004), Australia	Open-label, retrospective review	33	CRPS-I in 31, CRPS-II in 2, upper and lower extremities	Continuous IV infusion of 10 mg/hr, increased as tolerated Cycles stopped after 12-24 hr complete pain relief, 24 hr after partial pain relief with no further improvement, after 48 hr of no pain relief. 12 patients had 2 courses of therapy, 2 patients had 3 courses of therapy.	After one course, complete pain relief in 25 (65%), partial relief in 6 (18%), and no relief in 2 (6%). After repeat therapy, all had complete relief. Duration of pain relief: 9 mo after one course, 25 mo after 2-3 courses. Side effects: inebriation, dizziness, blurred vision, nausea. Hallucinations in 6 patients.
Goldberg et al[101] (2005), U.S.	Open label	40	CRPS-I, CRPS-II, chronic	IV infusion, outpatient, 40 mg and increased over 10-day period to 80 mg	Day 10: significant reductions in pain intensity, percentage of overall pain relief, improvements in motion, some reduction in skin color changes. Side effects minimal: 4 patients had headaches, 5 restlessness.
Koffler et al[158] (2007), Germany	Open label	9	CRPS-I, chronic	Continuous IV infusion high dose (anesthetic), medically induced coma 4.5 days	At 6 weeks, significant reduction in acute and overall pain. Brief attention and processing speed improved, all other cognitive domains remained stable, slight decline in motor strength. Side effects: muscle weakness, dizziness, fatigue, hyperhidrosis, anxiety; 2 patients had flashbacks.
Kiefer et al[151] (2008), Germany	Open label pilot	4	CRPS, chronic	Continuous IV, gradually titrated from 50 mg/day to 500 mg/day (subanesthetic) over 10-day period	No improvement in pain, no relevant side effects. Lack of therapeutic response led to termination of study.
Kiefer et al[150] (2008), Germany	Open label phase II	20	CRPS, chronic, severe	Continuous IV infusion high dose (anesthetic), patients intubated, mechanically ventilated 5 days	Significant reduction in pain intensity at 1 wk and 1, 3, and 6 mo. Complete remission at 1 mo in all patients, 3 mo in 17, 6 mo in 16.
Finch et al[81] (2009), Australia	DB RCT	20	CRPS-I in 18, CRPS-II in 2, 12 upper extremity, 8 lower extremity	Topical, 10%, 0.5 mL vs. placebo cream; one-time application, both extremities	At 7 days, allodynia and punctate hyperalgesia significantly reduced affected side, slightly reduced opposite side. No change in pain.
Schwartzman et al[273] (2009), U.S.	DB RCT	19	CRPS, chronic, upper and lower extremity	IV infusion, outpatient, over 10-day period, ketamine vs. placebo. Max rate 100 mg over 4-hr period. First day 50% of max dosage, second day, 75% of max, 3-10 days max.	At 1 mo, ketamine group had significant reduction in pain; placebo group had no treatment effect. Side effects: nausea, headache, tiredness, or hysphoria (4 with ketamine, 2 with placebo).

TABLE 40-10 Investigations on N-Methyl-D-Aspartate Receptor Antagonist Ketamine—cont'd

Study, Country	Level	Subjects (*n*)	Type and Location of CRPS	Drug	Results/Complications
Sigtermans et al[283] (2009), The Netherlands	DB RCT	60	CRPS-I, chronic, upper and lower extremity	Continuous IV infusion 4 days, low-dose ketamine vs. placebo. Dosage individualized based on effect, side effects.	For 11 wk, pain score in ketamine group significantly lower, but treatment effect lost at week 12. No effect on function. Most ketamine patients had side effects: 92% inebriation, 63% nausea, 93% psychometric, 37% headache.
Goldberg et al[102] (2010), U.S.	Open label	16	CRPS-I and CRPS-II	Continuous IV infusion 5 days, begun at 10 mg/hr and titrated to 40 mg/hr (subanesthetic)	Significant reduction in pain scores by days 3, 4, 5 compared with baseline and day 1.
Schilder et al[267] (2013), The Netherlands	DB RCT	29	CRPS-I, chronic, upper extremity	Continuous IV infusion 4 days, low-dose ketamine vs. placebo. Dosage individualized based on effect, side effects.	Over 12 wk, direct correlation of pain intensity and motor function, irrespective of ketamine or placebo. Ketamine had no direct effect on motor function.

CRPS, Complex regional pain syndrome; *DB RCT*, double-blind randomized controlled trial; *IV*, intravenous; *NMDA*, N-methyl-D-aspartate.

Intravenous Immunoglobulin and Tumor Necrosis Factor-α Inhibitors

The use of IV immunoglobulin (IVIG) or anti-TNF antibodies has generated some interest as evidence of immune system involvement in CRPS has become available.[24,133,181,303] Only two small studies have appeared to date in which IVIG was used in CRPS patients. Goebel and associates[99] demonstrated some pain relief in a group of 12 patients 28 days after receiving 9 to 18 g of IVIG. More recently, Goebel and coworkers[98] assessed the effectiveness of low-dose IVIG (0.5 g/kg) in 12 CRPS patients. Pain intensity was reduced in eight patients; however, the patients were only followed for 19 days after treatment.

A few case reports have observed reduced cytokine levels and pain after the use of IV regional block with low-dose administration of infliximab, a TNF-α inhibitor.[17,134] Thalidomide, a TNF-α and interleukins 1 and 6 inhibitor, has also shown promise in case reports and small trials.[42,237,274]

Sympathetic Block

Blockade of the sympathetic nervous system is typically performed with a local anesthetic at the stellate ganglion for upper extremity involvement and at the lumbar L2-L4 levels for lower extremity involvement. There are other sympatholytic procedures available such as IV phentolamine, IV regional anesthesia, and epidural infusion. The literature regarding sympathetic blocks for CRPS has been reviewed extensively and recently by others.[40,56,121,293,310] The common conclusion is that high-level study evidence demonstrating the efficacy of these blocks in reducing pain and improving function is not available. There are problems identifying a clinically successful block, and the potential exists for a high rate of partial or incomplete sympathetic blockade.[186] Even so, many investigators include these blocks in their treatment algorithms (Fig. 40-14) because of their clinical importance in terms of decreasing pain and increasing function in some patients, thereby allowing participation in physical therapy.[121] The senior author has empirically found that, when it is necessary to operate on a limb with CRPS, a perioperative sympathetic ganglion block can reduce the recurrence rate of CRPS.

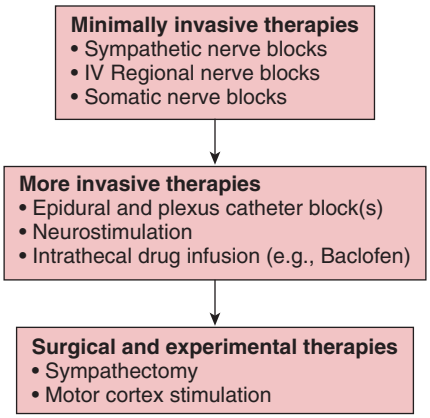

FIG 40-14 Interventional pain treatment algorithm for complex regional pain syndrome. (From Harden RN, Oaklander AL, Buron AW, et al. Complex regional pain syndrome: practical diagnostic and treatment guidelines, ed 4. *Pain Med.* 2013;14:180-229.)

Many studies have investigated the effect of IV regional blockade with a variety of sympatholytic, anesthetic, or antiinflammatory medications for CRPS.* These blocks are performed mostly with guanethidine, and to a lesser extent, lidocaine, clonidine, reserpine, methylprednisolone, and phentolamine. Unfortunately, several good quality investigations failed to find a beneficial effect from this therapy.[121,154,227,228,300] IV regional blockade offers placement of medication directly into the affected extremity, which is potentially

*References 26, 28, 76, 88, 128, 132, 139, 143, 173, 209, 210, 238, 243, 251, 318, 323.

advantageous if a suitable agent or combination of agents is eventually found.

Phentolamine and lidocaine have been intravenously infused in patients with CRPS in just a few studies with disappointing results. Verdugo and Ochoa[322] failed to find any differences with respect to pain, sensory testing, regional blood flow, or hyperalgesia between placebo, phentolamine, and phenylephrine infusions in 100 patients with RSD or causalgia. Wallace and associates[323] found that IV infused lidocaine had no effect on cool, warm, or cold pain thresholds, spontaneous pain scores, and mechanical allodynia in 16 patients with CRPS-I and CRPS-II. The treatment did decrease pain response to cold stimuli. Lack of efficacy precludes recommendation of these treatment options.[121]

Epidural Infusion

Continuous epidural infusion may be used to treat CRPS,[50,203,242] and some authors believe this is the anesthesia of choice when operating on a CRPS limb (discussed later).[167] The drug concentration may be titrated to allow motor function to remain intact although still blocking sympathetic and sensory input. This treatment option may be combined with other medications such as clonidine with or without bupivacaine.[50,242] The use of tunneled epidural catheters for extended periods of time is discussed in detail in Chapter 38. There is a risk of infection that does increase with long-term use.[242]

Surgical Sympathectomy

Surgical sympathectomy involves removal of the sympathetic chain and ganglia from the lower third of the stellate ganglia to T3 or removal of the sympathetic chain and ganglia from L2 to L4. The procedure is done endoscopically when feasible and has been successfully used to treat CRPS-I and CRPS-II.[29,197,248,277,290] Singh and associates[290] found better results in patients with upper extremity CRPS-II who were treated with thoracoscopic sympathectomy compared with an open procedure and in patients treated within 3 months of the onset of symptoms compared with those treated more than 3 months from onset of symptoms. Schwartzman and coworkers[277] reported better outcomes in CRPS-I patients treated within 12 months of onset of symptoms (100% permanent symptom relief) than those treated within 24 months (69% symptom relief) and those treated more than 24 months (44% symptom relief). This series included 8 patients with knee-related CRPS.

Initial pain relief may be significant, but symptoms may recur 6 months to 24 months later, requiring additional treatment.[8,223] This is believed to happen because of incomplete surgical removal of all sympathetic innervation to the extremity. Reinnervation and contralateral innervation may also occur. Harden and associates[121] recommended against surgical ablative sympathectomy because of the potential of long-term postoperative problems.

Neurostimulation

Neurostimulation refers to spinal cord stimulation (SCS) and peripheral nerve stimulation. The treatment methods are believed to be effective by blocking the transmission of pain nerve fibers or causing the release of endogenous opioids.[270] SCS (also called dorsal column stimulation) has been used in chronic pain conditions since 1967.[250] Electrodes are implanted in the epidural space in either the cervical or lumbar region. Several studies and reviews have shown favorable results in patients with CRPS in both regions.[83,106,123,135,146,164,165,232,280,287,294] However, even if SCS is entirely successful, the patient will require repeat surgery for battery or electrode replacement.[166] There is also the possibility of infection or electrode displacement/breakage. The effect of a permanent SCS on pain may gradually decrease over time.[147] Kemler and associates[147] reported no difference in outcome in a randomized study between CRPS-I patients who received a SCS and physical therapy and those who underwent 6 months of physical therapy alone when assessed 5 years later. van Eijs and colleagues[309] reported that brush-evoked allodynia predicted poor outcomes of a permanent implant in a study of 36 CRPS-I patients. Patient age, duration of symptoms, localization of the disorder, pain intensity, and the presence of mechanical hypoesthesia did not predict success of SCS.

It is possible to disrupt the sympathetic chain ganglion with caustic chemicals (such as alcohol) or peripheral nerve stimulation, but few reports exist to support these treatment options.[35,37,126,196,250,333] Pulsed radiofrequency for ablation of the saphenous nerve is another option; however, to date, there are few data available and future high-level studies are necessary to evaluate this treatment option.[2,112,136]

Surgery

Operating on a limb with active or quiescent CRPS should normally be avoided. Patellofemoral surgery is associated with a high rate of painful CRPS flares.[82] Lankford and Thompson[169] recommended that sympathetic blocks be performed and the CRPS process be allowed to "cool down" for 1 year before considering other surgical procedures. Katz and Hungerford[144] recommended in postarthroplasty patients with CRPS that surgery to correct mechanical dysfunction (aseptic loosening, ligament imbalance, component malalignment) be delayed until the CRPS symptoms are under control. These authors also recommended that patients undergo a series of sympathetic blocks before the anticipated surgery.

However, if the painful focus can be identified, appropriate surgical intervention to eliminate this focus is advocated.[49] Without this intervention, resolution of the CRPS is unlikely to occur. Tourniquets should be avoided because they can cause a painful flare.[321] Exacerbation of CRPS symptoms has been reported to occur in patients when appropriate perioperative pain management has not been accomplished.[144,321] The likelihood of a painful flare response may be decreased with a sympathetic block during and after the procedure.

A continuous epidural infusion for 2 to 5 days after surgery can help minimize the chance of CRPS recurrence.[167] Regional anesthesia has proven to be more effective in our experience in blocking painful flares than general anesthesia. The block is gradually reduced until it is discontinued. If the patient begins to experience pain during this weaning period, the dosage is increased until the pain is relieved and weaning begins again the following day. During this treatment phase, it is critical to protect the patient from decubitus ulcers. The patient should log roll every 2 hours, use heel cushions, be placed on an air mattress, and be helped out of bed frequently during the day. Sequential compression devices and antiembolism stockings are required to prevent deep vein thrombosis. Anticoagulant medications are contraindicated in patients with indwelling epidural catheters. A Foley catheter may be required if the patient is unable to void. A history of peripheral venous disease, blood clots, or high-risk factors (diabetes, obesity) contraindicate this form of treatment. Lower extremity ultrasound for venous clots is used as indicated, and the patient is examined every day for signs of a lower extremity venous clot condition (tibial edema, calf or inner thigh compression pain, Homan's test). In our experience, no exacerbation of CRPS symptoms has occurred as long as a sympathetic blockade and other appropriate pain management is used in the perioperative period.

Patients with chronic, unremitting pain may demand an amputation, which, in our opinion, should not be performed. Bodde and associates[27] systematically assessed the results of 111 amputations in 107 CRPS-I patients. Recurrence of CRPS symptoms in the stump occurred in 48%, and phantom pain occurred in 41% of the patients.

Conclusions

Many treatment options have been proposed for CRPS, but few are supported by high level clinical trials. This is especially true for CRPS related to the knee or lower extremity. Even so, agreement exists in the literature that multiple disciplines should be involved in providing patient care, including orthopedists, neurologists, pain specialists, anesthesiologists, physical therapists, occupational therapists, psychologists, and primary care physicians.

It is important to take all complaints seriously in a patient with suspected CRPS before discounting his or her comments as indicative of a personality disorder or drug-seeking behavior. By maintaining a high degree of clinical suspicion, the likelihood of early diagnosis of CRPS is greatest. A careful examination and use of other tests (MRI, TPBS) may be necessary to assist in identifying any triggers responsible for the abnormal pain response (such as a meniscus tear).

At the time of the initial CRPS diagnosis, it is important for the patient to be educated and become a participant in their recovery. In regard to the appropriate medications to prescribe, several have been tested for efficacy in other chronic pain conditions, but few have been investigated in high-level studies in CRPS patients. As such, there does not exist a consensus on which medications to use during the initial onset and subsequent course of the disease. The senior author empirically initiates a Medrol Dosepak or a short course of prednisone and prescribes physical therapy for desensitization and active and active assisted range of motion exercises. Neurotin (Gabepentin) is considered. The patient is referred early in the course of symptoms to an anesthesiologist skilled with administering paravertebral ganglion blocks. It is important to begin the treatment protocol within the first weeks of the onset of CRPS and not delay progressive treatment strategies if relief is not obtained.

The senior author does not refer CRPS patients to general pain management centers because they do not perform paravertebral sympathetic blocks. Patients are referred only to physicians skilled and experienced in treating CRPS who are able to perform the paravertebral blocks necessary (along with the use of other medications) to help resolve the condition. Multiple blocks may be required over several weeks. If the condition is refractory to treatment at this point, other medications are required (Table 40-11) and should be provided by a pain management specialist knowledgeable in the treatment of CRPS at either a local center or a major national treatment center. A comprehensive review of available treatment strategies, physical therapy options, and indications for various medications and blocks was recently published by Harden and associates.[121]

TABLE 40-11 Pharmacotherapy Guide

Problem	Intervention
Mild to moderate pain	Simple analgesics and/or blocks
Excruciating, intractable pain	Opioids (short-term) and/or blocks or later, more experimental interventions
Inflammation/swelling and edema	Steroids, systemic or targeted (acutely) or NSAIDs (chronically); immune modulators
Depression, anxiety, insomnia	Sedatives, analgesic antidepressant/anxiolytics and/or psychotherapy
Significant allodynia/hyperalgesia	Anticonvulsants and/or other sodium channel blockers and/or NMDA receptor antagonists
Significant osteopenia, immobility, trophic changes*	Calcitonin or bisphosphonates
Profound vasomotor disturbance	Calcium channel blockers, sympatholytics, and/or blocks

From Harden RN, Oaklander AL, Burton AW, et al. Complex regional pain syndrome: practical diagnostic and treatment guidelines, ed 4. *Pain Med.* 2013;14:180-229.

The following strategies are suggested for patients who have been diagnosed with complex regional pain syndrome who cannot begin or progress in the functional restoration algorithm (see Fig. 40-13). Remember that these suggestions are overruled by individual patient presentation.

*Certain drugs, such as calcitonin, may be associated with analgesia as well as the more primary action.

NMDA, N-methyl-D-aspartate; *NSAID*, nonsteroidal anti-inflammatory drug.

ILLUSTRATIVE CASE REPORTS

Case 1. A 25-year-old female U.S. Army sergeant injured her left knee during combat training. She sustained a complete PCL rupture from an anterior blow to the anteromedial tibia. Her chief complaint was a feeling of instability going down stairs. She had unexplained aching pain along the anteromedial aspect of her leg, which was especially noticeable at night and which interfered with her sleep for more than 2 years. She did not have normal sensation along this aspect of her leg. She had been seen by multiple physicians, who were unable to provide a diagnosis of her severe pain.

Upon examination, a careful palpation of the tissues about the knee joint was performed to find the exact areas producing this patient's pain. In Figure 40-15, the patient points to the two areas that were exquisitely sensitive, in which any pressure produced marked pain. The first area is in the infrapatellar nerve region, and the second is along the saphenous nerve. This represented a classical presentation of CRPS type II in which the anterior blow produced a nerve contusion and injury. A PCL reconstruction could not be performed until the infrapatellar nerve branch was ablated and her symptoms resolved. Any surgery would carry the risk of exacerbating the CRPS II symptoms.

Case 2. A 47-year-old woman presented 2 years after a total knee arthroplasty that was performed for degenerative joint disease of the left knee. Her postoperative course was complicated by a failure to achieve a normal range of knee motion owing to aching pain to the medial and anterior aspect of knee that was present during the day and even more so at night. She also had hypersensitivity of the skin to touch and a burning sensation along the anteromedial aspect of her knee (Fig. 40-16). For two years, her pain symptoms were treated with standard medication, with the burning sensation and severe aching not appreciated to represent symptoms of CRPS. She had no color changes or coolness to her skin.

Unfortunately, as a result of the pain, this patient developed arthrofibrosis with complete entrapment of the patella, no medial or lateral patellar mobility, a patellar infera, and knee flexion limited to 80 degrees. As a result, she had a limping gait and a feeling of stiffness in

the knee and was incapacitated for daily activities. Other physicians were consulted and the diagnosis of arthrofibrosis was made but not the underlying CRPS. She presented to us with multiple questions regarding what had occurred with her knee, believing her pain symptoms were psychological, and was in a depressed state.

FIG 40-15 Patient described in Case 1 pointing to the painful areas along the regions of the infrapatellar nerve and the saphenous nerve.

Treatment immediately initiated by a pain management specialist involved multiple sympathetic nerve blocks and medications. The extensive release of soft tissues required to regain knee motion must unfortunately await control of the CRPS symptoms.

Our comments: This case emphasizes that CRPS symptoms may only present as aching and burning, with a hypersensitivity component that may not be recognized without careful questioning.

Case 3. A 47-year-old woman underwent arthroscopy for persistent medial knee pain, locking, and clicking in her knee after MRI had suggested a medial meniscal tear. The patient had a history of saphenous neuritis; however, her symptoms were quiescent at the time of surgery. At arthroscopy, an intact medial meniscus was found along with scaring of the anteromedial infrapatellar fat pad, which was debrided. One month later, the patient had a recurrence of mild saphenous nerve tenderness, which was treated with oral prednisone with no relief. Five weeks postoperatively, she had temperature sensitivity and light touch sensitivity (hyperesthesia and allodynia) and was referred to a pain management specialist for a sympathetic nerve block. The block produced complete relief of the hypersensitivity and a significant improvement in pain. Based on this response, the patient was scheduled for a series of epidural sympathetic blocks and medications. After a series of seven blocks performed over 2 months, the hypersensitivity to light touch was resolved, but the patient remained exquisitely tender to palpation about the knee.

The duration of relief became shorter and shorter between blocks, and the patient was admitted for an inpatient 7-day epidural blockade. Her pain was relieved initially but only partially resolved at follow-up. A repeat series of six epidural blocks was ineffective, and referral was made for a surgical sympathectomy which was performed 9 months after the index arthroscopic procedure. This entirely relieved her symptoms for 4 months, but the recurrence of pain after this treatment was more severe than that experienced before surgical sympathectomy.

FIG 40-16 **A** and **B**, Patient described in Case 2 indicating site of skin hypersensitivity to touch and a burning sensation on the anteromedial aspect of her knee.

At approximately 1 year from the index operation, the patient began to manifest CRPS symptoms in the contralateral leg. She ultimately underwent paravertebral ganglion blocks and had a nerve stimulator implanted, which was later removed for hardware failure. For this patient, all treatments provided initial relief, only to be followed with later relapses. At the time of writing, she still had pain and was seeking another pain management specialist.

Our comments: This patient demonstrates the long-term treatment aspects that some patients with CRPS will undergo. Often, these treatment aspects are only partially successful, and, unfortunately, these patients must live with a painful debilitating condition.

Case 4. A 28-year-old woman presented for evaluation of left lower extremity pain. She had an acute onset of left-sided weakness, numbness, tingling, and blurred vision of the left eye, which were attributed to transverse myelitis. She had previously been seen by neurologists and pain-management specialists. On evaluation, there were dark discoloration of the limb (see Fig. 40-1) and increased sensitivity to light touch from the knee to the foot. A 30-degree flexion contracture of the knee and ankle equinus was noted. The patient was unable to sleep under sheets owing to the inability to tolerate the pain from foot contact with the sheets. Additionally, pulses could not be palpated owing to her inability to tolerate the pressure required. The patient had been previously diagnosed with reflex sympathetic dystrophy and underwent three sympathetic blocks and implantation of a spinal cord stimulator. She was taking Neurontin, Lyrica, Morphine, and Vicodin.

The patient was advised to stop smoking. Paroxetine (Paxil) was prescribed, and although consideration was given for the addition of alendronate, its benefit was believed to be limited because the patient had a normal dual-energy x-ray absorptiometry (DEXA) scan. Physical therapy was continued but was ineffective, and referral was made to an outside facility specializing in CRPS. Eight weeks of treatment included elimination of narcotics and desensitization training with a device that swirled cornhusks around the leg at levels of intensity controlled by the patient. On her return, the patient had an erythematous appearance (improved from the dark discoloration previously) and had made great improvement in her ability to tolerate light touch. The patient continued physical therapy and her medications and was able to ambulate without pain.

Case 5. An 18-year-old female student was diagnosed with bilateral patellofemoral pain and medial patellofemoral ligament insufficiency. She was sent to physical therapy for quadriceps strengthening and stretching. Celebrex 200 mg daily was initiated and the patient advised to restrain from aggravating activities. Eight weeks later, the right knee pain had improved, but the left knee pain persisted. MRI detected no operative lesions, but the patient exhibited pain with light touch medially and laterally from the knee to midtibia. The pain was described as burning, and an ice cube test showed decreased temperature sensation in the affected region. There was no discoloration, but her skin felt cooler to touch. The diagnosis was made of early CRPS, and the patient was referred to physical therapy for desensitization training and provided a Medrol Dosepak. Her symptoms improved but were not eliminated, and a second Medrol Dosepak was prescribed. The patient's CRPS symptoms entirely resolved and she resumed her treatment for patellofemoral pain.

Our comments: In our experience, many patients with anterior knee pain are diagnosed with patellofemoral chondrosis without the appreciation of an associated CRPS that requires treatment first.

Case 6. This series of three cases is presented because it is the only familial representation of CRPS we have encountered. A possible genetic association between CRPS and the human leukocyte antigen (HLA) system has been previously described.[61,314] However, when the following patients were tested for HLA-specific antigens, none related to CRPS were detected. The following cases represent a mother and her two daughters, each of whom developed CRPS.

The primary case, a 43-year-old mother, was diagnosed with bilateral patellofemoral malalignment and severe trochlear dysplasia at the age of 13 years. The patient had repeated injuries (bilateral meniscal tears, bilateral patellar subluxations, and right patellar chondral injury) while playing tennis and softball. These injuries resulted in multiple surgical procedures (seven on the left knee, four on the right knee) to address her patellofemoral malalignment, meniscal injuries, and patellofemoral arthritis. At the age of 26 years, bilateral, staged patellectomies were performed for severe patellofemoral arthritis. She had brief relief of pain; however, 2 months after the right patellectomy, she experienced increasing pain that was generalized around the knee and along the leg. The pain was described as "severe and burning," even with the light touch of her clothing. The skin over the leg was shiny and edematous. Her family history was not significant except for a brother with diabetes mellitus and a sister with rheumatoid arthritis. There was no history of smoking. There were no lawsuit or workers' compensation claims involved. She was initially treated with multiple medications, physical therapy, and transcutaneous electrical nerve stimulation (TENS). The medications included combinations of anti-inflammatories, analgesics, anxiolytics, oral steroids, and gabapentin. Later that year, four sympathetic lumbar blocks were performed that provided only temporary relief. A surgical sympathectomy was performed. One month later, most of her symptoms had resolved, though she continued to have occasional episodes of hyperesthesia over the medial aspect of her knee. This patient was treated before the development of modern spinal stimulators that would not likely be offered today.

This patient's 13-year-old daughter was diagnosed with idiopathic toe walking at the age of 8 years. She developed tendoachilles contracture on the left side, which was treated using sequential below-knee casts in maximal dorsiflexion. After removal of the second cast, she refused to bear weight on the involved side and complained of burning pain around her ankle and foot. The skin over the foot was shiny, edematous, and cooler compared with the contralateral side. Prompt treatment was instituted in the form of multiple medications, physical therapy, and TENS. Six months later, there was no improvement in her symptoms, and she was admitted for continuous epidural sympathetic blockade for 5 days. The patient had complete relief of symptoms with the epidural blockade, only to have a recurrence of all her symptoms 1 month later, after a great toe injury on the same side. Again, treatment was instituted with medications, physical therapy, and hydrotherapy. The symptoms gradually diminished over a period of 3 months. She developed a normal heel-toe gait pattern during this time frame.

The mother's 15-year old daughter sustained an ankle sprain at the age of 11 years. She was treated with a soft ankle support brace, crutches, and partial weight bearing. Three weeks later, she developed hyperesthesia, burning sensation, and temperature changes along her ankle and foot. She had increased swelling and shiny skin over the involved area. The pain was not resolved with antiinflammatories, rest, and elevation and was worse with ice application. The family members promptly recognized the symptoms consistent with CRPS owing to their prior experiences and sought immediate medical attention. Treatment consisted of multiple medications, TENS, physical therapy, and hydrotherapy. The symptoms gradually resolved over a period of 6 months.

Case 7. A 38-year-old woman sustained a fall at work and dislocated her left patella. She underwent initial conservative treatment. Within 3 months, the patient was diagnosed with CRPS owing to a burning sensation and had developed arthrofibrosis. Ice to the affected area created burning pain. She had no recurrent instability episodes. The range of motion was 5 to 110 degrees, and severe quadriceps atrophy was noted. She was referred to pain management and placed on venlafaxine hydrochloride (Effexor) and Baclofen. As well, she continued physical therapy for knee motion and strengthening exercises. Over several months, she consistently improved but had a gradual return of her hypersensitivity 1.5 years later. She was placed on Neurontin and Depakote, and her symptoms abated within 1 month.

Case 8. A 26-year-old woman diagnosed with a medial meniscus tear by MRI was referred for extreme pain. The patient was taking oxycodone and acetaminophen (Percocet) and celecoxib (Celebrex). Her medial knee and tibia were exquisitely tender to palpation. She held her leg flexed 30 degrees and would not allow physical examination secondary to extreme pain with light touch. She had a mild effusion with no color changes, but her limb was cool to the touch. She reported being unable to tolerate the pressure of her bed sheets on her knee. She was prescribed Neurontin and referred for paraspinal ganglion blocks. Although the Neurontin helped her pain, the patient was prescribed tramadol because she could not tolerate the sedating effects. She underwent 10 blocks, which relieved her pain. She is currently in remission and being treated conservatively for patellar malalignment syndrome. She never underwent arthroscopy at our institution. This case demonstrates the importance of an immediate diagnosis because the pain could have been mistakenly attributed to the medial meniscus tear.

INTRODUCTION

The assessment of outcome following the treatment of knee injuries and disorders has received tremendous attention in the orthopaedic literature. In regard to rating the outcome of anterior cruciate ligament (ACL) reconstructions, early scoring scales and systems were introduced into the medical community without undergoing an assessment of the psychometric properties of reliability, validity, and responsiveness.[25,31,52,55,63,90,98,107] There was a lack of consensus regarding which variables to include in the measurement of patient outcome. As a result, studies conducted in the 1990s comparing the results of ACL reconstruction using different rating systems showed distinct differences in results and conclusions.[11,35,83,91]

However, many knee-specific scales and rating systems have been published in the past decade with acceptable psychometric properties for a variety of diagnoses (Table 41-1).[102] It is important to understand the difference between *scales* that rate specific activities and *rating systems* that are more encompassing in terms of assessing the entire knee condition. For instance, scales have been designed to quantitate athletic activity levels,[5,19,59,90,98] problems with activities of daily living (ADLs),[9,40,52] or both,[62,84] all from the patient's perspective. We agree with Zarins[106] that although the subjective assessment of symptoms and functional limitations is important, the final outcome of a specific treatment must also take into account objective measures that are appropriate for the diagnosis or injury under study. The determination of patient outcome according to subjective questionnaire-based data only[93] does not provide a complete understanding of the ability of the treatment protocol to restore normal knee function. For instance, knee rating scales exist in which a patient may be rated as "excellent" even though an ACL reconstruction failed to restore normal or nearly normal knee stability, which is a major goal of the operation.[98] It is well known for this injury that in the short term, patients may do well without a functional ACL, but over time, the knee joint deteriorates, and problems increase to eventually affect daily activities.[3,7,15,77]

In contrast to scales, rating systems provide a comprehensive analysis of the knee condition and its impact on activity and function. Clinical investigators have suggested that such systems should measure a variety of symptoms, sports and daily activity functions, patient satisfaction, and objective physical findings.[2,91,106] Only three knee rating systems are currently available that have established reliability, validity, and responsiveness: the Cincinnati Knee Rating System (CKRS),[6,67] the International Knee Documentation Committee (IKDC) Knee Evaluation system,[37-39,89] and the new Knee Society Scoring System.[66,88] The CKRS and IKDC Knee Evaluation measure pain, swelling, giving way, functions of sports and daily activities, sports activity levels, patient perception of the knee condition, range of knee motion, joint effusion, tibiofemoral and patellofemoral crepitus, knee ligament subluxations, compartment narrowing on radiographs, and lower limb symmetry during single-leg hop tests. The CKRS has been validated for a variety of knee problems[6,58] and the IKDC has been validated for ACL reconstruction,[89] patellar dislocation,[80] and meniscus procedures.[18] The IKDC system is discussed in detail in Chapter 42. The new Knee Society Scoring system is discussed in detail in Chapter 45.

General health outcome instruments are also available that determine general health and other indicators such as the psychological and social aspects of the patient's life (Table 41-2).[56] The most widely used of these types of scales for knee research appears to the be Short Form 36 (SF-36) Health Survey,[99] although a recent study[100] indicated the Short Form 12 Health Survey may also be appropriate for ACL reconstruction studies. Generic health questionnaires have limited usefulness in studies comprised of patients with a specific diagnosis and therefore should be used in addition to disease-specific rating

CRITICAL POINTS Introduction

- Many knee-specific scales and rating systems have been published in the last decade with acceptable psychometric properties for a variety of diagnoses.
- Scales rate specific activities, such as sports or daily functions.
- Rating systems provide a comprehensive analysis of the knee condition and its impact on activity and function after the treatment protocol under study.
- Only three knee rating systems are currently available that have established reliability, validity, and responsiveness: Cincinnati Knee Rating System, International Knee Documentation Committee Knee Evaluation system, and Knee Society Scoring System.
- The Cincinnati Knee Rating System is one of the most commonly used instruments in the orthopaedic literature to measure the results of ACL reconstruction, and has been considered a gold standard in the development and content and criterion validity analyses of other knee rating scales.

systems.[29,80] Finally, global outcome instruments that are extremity specific (upper or lower) or disease specific (e.g., osteoarthritis) are widely used to determine the outcome of a many types of knee injuries and disorders. The most commonly used assessments are discussed in Chapter 43.

The CKRS was first published in concert with the largest ACL natural history study conducted during that time period.[77] In the early 1980s, the dilemma of the appropriate treatment for complete ACL ruptures stemmed in part from limited knowledge of the functional limitations caused by the injury and the lack of a rigorous rating system which graded symptoms and limitations according to the specific type of activity during which they occurred. Over the next decade, additional scales and modifications were developed for the CKRS to provide a comprehensive assessment of the knee condition.[6,67,69,76] An overall rating scheme was devised to provide a final rating, which is available in either in a numeric or categorical manner, as is discussed later. The major components of the CKRS are shown in Table 41-3. This system is one of the most commonly used instruments in the orthopedic literature to measure the results of ACL reconstruction and has been considered a gold standard in the development and content and criterion validity analyses of other knee rating scales.[29,34,37,39,59] The CKRS was initially designed and validated in athletically active populations; however, it is also useful for patients who have undergone other operative procedures such as articular cartilage restorative procedures,[29] meniscus repairs or transplants, osteotomies, or patellofemoral procedures. This chapter describes the rationale and methodology for the major components of the CKRS.

MEASUREMENT OF PSYCHOMETRIC PROPERTIES OF OUTCOME INSTRUMENTS

Outcome instruments and scales must have strong psychometric properties to be useful in evaluating the results of treatment. These properties—(reliability, validity, and responsiveness)—are determined in a variety of methods.

Reliability is the extent to which scores on an instrument are reproducible and is measured either between subjects (test-retest) or between observers (interobserver). Patients complete questionnaires at separate time periods; a minimum 1-week interval was recommended by Deyo and coworkers[21] to elapse between questionnaire administration. Reliability is measured with product-moment correlations and intraclass correlation coefficients (ICCs). ICC is the most commonly used statistic in modern studies and is calculated by

$$(A^2 + B^2 - C^2)/A^2 + B^2 + D^2 - C^2/n$$

where A is the standard deviation (SD) from all values in trial number 1, B is the SD from all values in trial number 2, C is the SD of the difference in all values between trials number 1 and number 2, D is the mean of the difference between trials number 1 and number 2, and n is the total number of patients.

Correlations among test-retest data should be greater than 0.70, which is considered the standard for adequate reliability for questionnaires.[79] The use of ICC rather than the more common Pearson correlation coefficient was suggested by Deyo and coworkers[21] and Lin[49] to provide a more sensitive assessment of variability within data. The problem that can occur with the Pearson correlation coefficient is that duplicate measurements may be systematically different yet correlate

CRITICAL POINTS Review of Analyses Used to Measure Psychometric Properties of Outcome Instruments

- Reliability is the extent to which scores on an instrument are reproducible and is measured either between subjects (test-retest) or among observers (interobserver).
- Internal consistency represents the concept that the consistency with which a patient answers from one question to the next can be used to provide an estimate of reliability for the total test score.
- Construct validity is the extent to which a measure corresponds to expected theoretical concepts or hypotheses regarding the diagnosis.
- Item-discriminant (or -divergent) validity is present when variables which are hypothesized to be dissimilar are proven so.
- Criterion (or concurrent) validity is assessed by correlating scores on the instrument under study with other criteria known or believed to adequately measure the function or symptom.
- Responsiveness is the ability of an instrument to detect clinically important change.

highly and, as a result, be falsely interpreted. For example, if every patient scored exactly 5 points lower on a scale on the second administration, the test-retest correlation would be a perfect 1.0, despite the fact that every patient had a lower score. The ICC handles this problem because it not only assesses the strength of the correlation but also determines whether or not the slope and intercept in the regression line of test-retest data vary from those expected with duplicate results. In our example, the ICC would correspondingly be reduced to demonstrate the systematic difference among the test-retest data.

Internal consistency is determined by a coefficient α greater than 0.60.[42] The underlying concept of this measure is that the consistency with which a patient answers from one question to the next can be used to provide an estimate of reliability for the total test score.[65] A high coefficient α indicates that the items in a questionnaire are consistently measured or are homogeneous with regard to the measurement of the underlying diagnosis or attribute.[44]

Several measures have been described to determine the validity of an instrument, including content, construct, item discriminant, convergent, and criterion. In general, *validity* is the psychometric criterion in which an instrument is tested to determine its ability to actually measure what it claims to measure.[41] *Content validity* is the extent to which a question or instrument represents the area of interest and has been described in various manners. Face validity, one example of content validity, is determined by consulting both patients and experienced medical professionals regarding the development of a scale's questions and their relevance to the diagnosis under study.[26] For instance, for ACL reconstruction investigations, a questionnaire with good face validity would be believed by patients, surgeons, and therapists to measure the common problems caused by this injury, such as pain and instability. This represents a subjective analysis that is not statistically analyzed. Another method to determine content validity is to calculate floor (worst result) and ceiling (best result) effects.[60,96] Scales in which the majority of patients score either the highest level or the lowest level do not allow for an assessment of deterioration or improvement over time. Floor and ceiling effects are present when greater than 30% of the population marks either the best possible or worst possible scores on a scale.[42]

Construct validity is the extent to which a measure corresponds to expected theoretical concepts or hypotheses regarding the diagnosis. An instrument will accurately differentiate patients whose outcome is expected to vary with regard to certain characteristics known to the disease process.[24,95] Researchers develop hypotheses based on prior research and clinical experience in which the questionnaire scores are expected to be significantly different among selected patient groups. The hypotheses are confirmed using the F and T-test at the level of $P < .01$. In addition, construct validity is determined by conducting Pearson product-moment correlation coefficients between scale items and either previously validated instruments or physician and patient assessments. A moderately strong coefficient is proven at $R > .60$.

Item-discriminant (or *item-divergent*) *validity* is present when variables which are hypothesized to be dissimilar (such as patient age and anteroposterior [AP] knee displacements) are indeed found to be statistically unrelated.[24,61] Pearson correlations are performed to detect statistical dissimilarities, proven at $R = 0.28$ or less. In the opposite manner, convergent validity is present when variables which are believed to be similar within the questionnaire are indeed found to be statistically similar.

Criterion (or *concurrent*) *validity* is assessed by correlating scores on the instrument under study with other criteria known or believed to adequately measure the function or symptom. This determines how a new instrument compares with an accepted gold standard instrument. The Pearson product-moment correlation coefficient is used to determine this property, with moderately strong findings indicated by $R > 0.60$.

Responsiveness, or the ability of an instrument to detect clinically important change, is determined by calculating standardized response means (SRM) and effect sizes (ES) of the selected instrument categories. The magnitude of the SRM (mean change in score from preoperative to follow up/SD of change in score)[30] and the ES (mean change in score from preoperative to follow up/SD of preoperative score)[43] are interpreted using the Cohen standard of greater than 0.20 for small effects, greater than 0.50 for moderate effects, and greater than 0.80 for large effects.[17] This analysis provides a more precise indication of the change in results over time from those obtained by the standard Student t-test. An instrument's sensitivity simply denotes its ability to measure any change, which by definition does not necessarily indicate one that is clinically meaningful.[41]

COMPONENTS OF THE CKRS

Rating of Symptoms

Pain, swelling, partial giving way, and full giving way are the major knee symptoms assessed in ACL investigations. Pain and swelling are also symptoms that may occur in all other types of knee injuries and disorders, and instability is a problem with other knee ligament ruptures and certain patellofemoral disorders. Authors have proposed a variety of methods for measuring symptoms, from a binary system ("yes" or "no"[31,55]), to visual analogue scales,[28,34,62] to a severity rating (such as mild, moderate, severe), which can be done either alone[52] or in combination with activities (such as "slight after strenuous sports").[25,52,84,107]

In 1983, Noyes and associates[77] proposed that knee symptoms should be rated according to the activity during which they occurred: strenuous sports, recreational sports, or walking. This rationale provided an understanding of the impact of a chronic ACL-deficient knee because 30% of 103 patients reported pain with walking alone, 47% with recreational sports, and 69% with strenuous sports in the authors' natural history study.

The assessment of symptoms was later refined and the scale increased to a six-level gradient shown in Figure 41-1.[67,69,75] Points are awarded for the highest activity level in which the patient is able to participate without incurring the symptom (Appendix A). If the

DIRECTIONS: Using the key below, circle the appropriate boxes on the four scales which indicates the highest level you can reach WITHOUT having symptoms.

Scale	Description
10	Normal knee, able to do strenuous work/sports with jumping, hard pivoting
8	Able to do moderate work/sports with running, turning, twisting; symptoms with strenuous work/sports.
6	Able to do light work/sports with no running, twisting, jumping; symptoms with moderate work/sports
4	Able to do activities of daily living alone; symptoms with light work/sports
2	Moderate symptoms (frequent, limiting) with activities of daily living
0	Severe symptoms (constant, not relieved) with activities of daily living.

1. PAIN

10 — 8 — 6 — 4 — 2 — 0

2. SWELLING (actual fluid in the knee, obvious puffiness)

10 — 8 — 6 — 4 — 2 — 0

3. PARTIAL GIVING WAY (partial knee collapse, no fall to the ground

10 — 8 — 6 — 4 — 2 — 0

4. FULL GIVING WAY (knee collapse occurs with actual falling to the ground)

10 — 8 — 6 — 4 — 2 — 0

FIG 41-1 Symptom Rating Scale.

CRITICAL POINTS Rating of Symptoms and Patient Satisfaction

Rating of Symptoms

- Pain, swelling, partial giving way and full giving way are major symptoms assessed in knee injuries and disorders.
- Symptoms are rated according to the highest activity level possible without incurring the symptoms.
- Six-level scale

Rating of Patient Perception of the Knee Condition

- Patients rate the overall condition of the knee by circling a number on a scale from 1 to 10.
- Descriptors are provided to assist the patient in understanding the meaning of the numerical scale.
- Most subjective of all factors, not correlated with other outcome measures

symptom is present with ADL, it is rated as either moderate (frequent, limiting) or severe (constant, not relieved). Definitions are provided for terms that might otherwise be ambiguous to patients, such as "moderate" sports (running, turning twisting) and "strenuous" sports (jumping, hard pivoting).

When reporting symptoms before and after surgery, a distribution of the percent of patients in each of the six levels should be shown (along with a mean and SD) for both time periods. An example is shown in Figure 41-2 for a group of patients who received a meniscus transplant.[73] The data were also expressed in the body of the text as "the mean preoperative Cincinnati Knee Rating Scale pain score of 2.5 points (range, 0-6 points) improved to a mean of 5.8 points (range, 0-10 points) at follow up (P <.0001). Before the meniscus allograft, thirty patients (79%) had moderate to severe pain with daily activities but at follow up, only four patients (11%) had pain with daily activities."[73]

One problem may occur in the rating of symptoms when patients have not attempted to return to strenuous sports activities. In these situations, a potential bias may occur if the patient or clinician attempts to project the correct symptom level based on a hypothetical answer. For instance, if a patient returned to bicycling or swimming and had no pain with those activities, then the pain score awarded would be a level 6 (see Fig. 41-1). However, if the patient is asked whether she or he believes pain would occur with level 8 activities (running, twisting, turning) and she or he responds that it probably would not occur, a bias would occur if this score was assigned without further verification that this was indeed true. This is often the case with the symptom of giving way, because patients frequently return asymptomatically to level 6 or 8 activities postoperatively but state that they participated a few times at level 10 activities (jumping, hard pivoting) without problems. Points are awarded only with a reasonable basis for the assessment and not speculated by the patient as to the level that may be possible.

This potential bias is a particular problem with populations of chronic knee injuries with compounding problems of advanced articular cartilage deterioration, multiple ligament reconstructive procedures, or varus osseous malalignment, which is corrected with a high tibial osteotomy (HTO) in addition to ACL reconstruction. This problem has two solutions. First, the clinician may ask the patient to

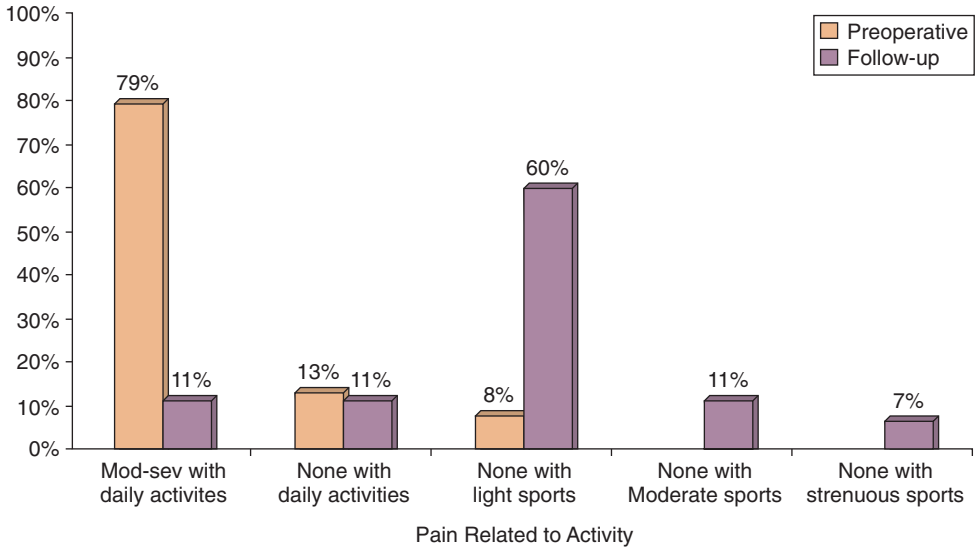

FIG 41-2 The pain scale shows the highest level of activity possible without the patient experiencing knee pain. This example was taken from a clinical study on meniscus transplantation. The difference between the preoperative and follow-up visit was statistically significant ($P < .0001$). *Mod-sev,* Moderate to severe. (From Noyes FR, Barber-Westin SD, Rankin M. Meniscal transplantation in symptomatic patients less than fifty years old. *J Bone Joint Surg Am.* 2004;86A:1392-1404.)

DIRECTIONS: Using the key below, circle the appropriate boxes on the four scales which indicates the highest level you can reach WITHOUT having symptoms.

Scale	Description
6	Able to do light /moderate/strenuous work/sports without symptoms
4	Able to do activities of daily living alone; symptoms with light work/sports
2	Moderate symptoms (frequent, limiting) with activities of daily living
0	Severe symptoms (constant, not relieved) with activities of daily living

1. PAIN

6 — 4 — 2 — 0

2. SWELLING (actual fluid in the knee, obvious puffiness)

6 — 4 — 2 — 0

3. PARTIAL GIVING WAY (partial knee collapse, no fall to the ground)

6 — 4 — 2 — 0

4. FULL GIVING WAY (knee collapse occurs with actual falling to the ground)

6 — 4 — 2 — 0

FIG 41-3 Modified Symptom Rating Scale.

test the knee at higher levels of activities if both patient and physician believe this is a reasonable request. Then, the patient can be contacted later for a symptom rating after he or she has participated in strenuous activities several times.

Second, the clinician may use the modified symptom rating scale (Fig. 41-3) that was first introduced in an investigation of patients with varus osseous malalignment and ACL deficiency who were treated with multiple operative procedures.[70] This modified scale consists of a four-level gradient. The levels of 0, 2, and 4 are the same as the original scale shown in Figure 41-1. The fourth and highest level (level 6) indicates that some type of sports participation is possible without the symptom. This modified scale is intended for studies in which the majority of patients do not return to moderate or strenuous athletics indicated in levels 8 and 10. The reliability of this modified scale was previously

shown to be adequate for patients and normal subjects.[6] However, clinicians should be aware that the modified scales may have reduced sensitivity, especially if the results of a study that used the modified scale are compared with another study that used the original scale. This pertains only to the individual symptom results. The effect of the modified scale on the overall rating score, described later in this chapter, is small and only has a negligible impact when comparing the data of the overall scores among different populations.

Even though there is always the potential for a bias to exist regarding the scoring of subjective symptoms, the CKRS format allows for an accurate assessment of the activity levels patients return to on a routine basis. The scale was designed to not award points if a patient participates at a high activity level but has symptoms, thereby fulfilling the criteria of the "knee abuser."[77]

Rating of Patient Perception of the Knee Condition

Modern knee rating systems incorporate some form of patient satisfaction, or rating of the patient's perception of the knee condition, into the assessment of clinical outcome.[6,37] In the CKRS, patients are asked to rate the overall condition of the knee by circling a number on a scale from 1 to 10 (Fig. 41-4). Four descriptors are provided to assist the patient in understanding the meaning of the numerical scale. Under the number 2 is the term "poor," defined as "I have significant limitations that affect activities of daily living," whereas under the number 10 are the terms "normal/excellent," defined as "I am able to do whatever I wish (any sport) with no problems" (see Appendix A). For data reporting purposes, a distribution of responses is shown in a five-level gradient. Responses under numbers 1 and 2 are termed "poor," those under numbers 3 and 4, "fair"; those under numbers 5 and 6, "good"; those under numbers 7 and 8, "very good"; and those under numbers 9 and 10, "normal."

An example is shown in Figure 41-5 for a group of patients who received a meniscus transplant.[73] The data were also expressed in the body of the text as "the mean preoperative patient perception score of 3.2 points (range, 1-6 points) improved to a mean of 6.2 points (range, 1-9 points) at follow up ($P = .0001$). Two patients rated the knee condition as the same, and two as worse."

Clinicians and researchers should realize that inconsistencies may arise from the responses to the patient perception scale and those in other scales of the CKRS. An example is an 18-year-old patient who successfully returned to competitive soccer without problems or symptoms rated the overall knee condition as a 7 because he felt "slower than before the injury." Conversely, a 45-year-old patient with a triple varus knee who required an HTO, ACL reconstruction, and posterolateral reconstruction and was only able to return to low-impact activities, also rated her knee condition as a 7. She indicated that she was exceptionally pleased that her constant pain with daily activities had resolved and that she was able to swim and bicycle without problems. Because this portion of the CKRS is perhaps the most subjective of all of the assessment factors, it is not correlated with other outcome

Rate the overall condition of your knee at the present time. Circle one number below.

1	2	3	4	5	6	7	8	9	10
	poor		fair		good				normal

Poor - I have significant limitations that affect activities of daily living.
Fair - I have moderate limitations that affect activities of daily living, no sports possible.
Good - I have some limitations with sports but I can participate; I compensate.
Normal/excellent - I am able to do whatever I wish (any sport) with no problems.

FIG 41-4 Patient Perception of the Knee Condition.

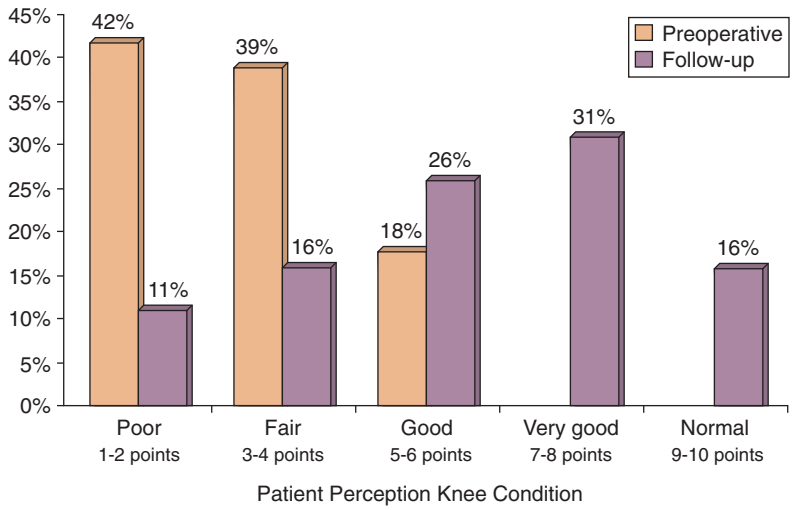

FIG 41-5 Distribution of patient perception of the overall knee condition from a clinical study on meniscus transplantation. The difference between preoperative and follow up was statistically significant ($P < .0001$). (From Noyes FR, Barber-Westin SD, Rankin M: Meniscal transplantation in symptomatic patients less than fifty years old. *J Bone Joint Surg Am.* 2004;86A:1392-1404.)

measures. This underscores the inconsistencies in reporting of patient outcome when only a patient perception rating is used to determine the results of an operation.

Rating of Sports and Daily Activities

In the sports medicine literature, the accurate assessment of sports activity levels and participation is crucial in the determination of the result of an operation or treatment of any knee problem. This is true for many situations. For instance, if a competitive athlete chooses an ACL reconstruction after an acute rupture to be able to return to a high activity level, the outcome instrument must be able to precisely define the level of sports participation before and after surgery. Or, if a sedentary individual with moderate arthrosis and giving-way symptoms chooses ACL reconstruction to reduce limitations with daily activities and adopt a more active lifestyle, the instrument must be able to detect a more subtle change (increase) in activity. An instrument must also be able to detect the knee abuser, or the patient who returns to athletics and experiences symptoms that may be harmful to the knee joint over the long term.[77] These individuals should be sorted from others who returned to athletics without problems. Therefore the accurate assessment of sports participation must span many levels of athletics, intensity, and frequency of participation; be able to sort populations according to changes in athletic levels or lifestyle; and identify patients who experience symptoms during athletic activities.

The CKRS Sports Activity Scale was first introduced in 1989 after an analysis of existing scales at that time period detected multiple biases and potential sources of error in reporting outcome of ACL reconstruction.[69] The problems identified included (1) the failure to precisely define sports activity levels according to specific sport and intensity of participation; (2) the failure to sort populations according to overall intensity of athletic participation before and after treatment; (3) the failure to detect and sort from the population patients who return to sports and experience significant symptoms; (4) the combination of work and sports activities into the same scale; and (5) the failure to detect alterations in athletics because of changes in lifestyle and non–knee-related factors.

The goal in the development of the Sports Activity Scale was to distinguish among categories of athletic activities in a manner that allowed investigators to apply the rating in a uniform manner to any type of athletic activity. Two criteria were selected to determine this rating. First, the frequency of participation was determined using a four-level gradient that assigned patients to a subgroup depending upon the number of days in a week (or month) of sports participation (Fig. 41-6). Second, the knee functions that occurred during various sports activities were determined and sorted into three subgroups. The first subgroup consisted of sports that involved the most difficult knee motions: jumping, hard pivoting, and cutting. The second subgroup included sports that involved running, twisting, and turning. The third subgroup consisted of sports that did not involve running, twisting, or jumping (e.g., swimming and cycling).

This sorting of sports activities according to frequency and intensity eliminates the ambiguous classification of athletes into categories such as recreational or competitive. Note that collegiate, professional, and adolescent athletes can be placed in the same category on this scale. Although some examples of sports are listed under the various subgroups, any athletic activity may be placed into the scale according to the knee functions that occur during that particular activity. The investigator may analyze the sports activity scale data according to either the frequency subgrouping or the intensity subgrouping categories. In addition, the sports scale incorporates a three-level gradient for patients who do not participate in athletics. This allows a determination of the overall severity of symptoms with ADLs.

The reporting of the patient responses to the Sports Activity Scale may be shown as a distribution according to either frequency or intensity of activities. An example is shown in Table 41-4 from a study on posterior cruciate ligament (PCL) reconstruction.[71] An average score should not be calculated from this scale, because the data are categorical in nature.

A second component of the assessment of sports activities is the change that occurs in activity levels between treatment periods, the most common being that which occurs between the preoperative and most recent follow-up evaluations (Fig. 41-7). The format is designed to determine changes in sports activities because of either knee-related or non–knee-related reasons and to detect knee abusers. The data from this analysis are usually displayed in publications in the same table as the Sports Activity Level data (see Table 41-4).

The third component of the assessment of sports activities is the rating of six individual functions that place varying loads on the knee joint (Fig. 41-8). Functions of sports are analyzed separately from those of daily activities to assess limitations in all patients, not just those participating in athletics. Even in cases in which the knee joint is markedly affected, patients are able to indicate the problems encountered with these types of activities. Each function is determined using a four-level gradient whose terminology was selected to decrease the subjective component inherent in this type of analysis. The data obtained for each of the six functions is reported individually using means, SD, and the distribution of responses in each of the four levels.

Rating of Occupational Activities

Little attention has been given in the sports medicine literature on the effect of ACL reconstruction on work activities. The results of knee

CRITICAL POINTS Rating of Sports and Daily Function and Activities

Accurate assessment of sports participation must span many levels of athletics, intensity, and frequency of participation; be able to sort populations according to changes in athletic levels or lifestyle; and identify patients who experience symptoms during athletic activities.

Biases and Potential Sources of Error in Other Rating Systems

- Failure to precisely define sports activity levels according to specific sport and intensity of participation
- Failure to sort populations according to overall intensity of athletic participation before and after treatment
- Failure to detect and sort from the population patients who return to sports and experience significant symptoms
- Combining work and sports activities into the same scale
- Failure to detect alterations in athletics because of changes in lifestyle and non-knee-related factors

Two Criteria to Determine Sports Rating, Allows All Sports to be Rated

- Frequency of participation
- Knee functions incurred during activity

Assess Change in Sports Activities Between Treatment Periods

- Determine whether change is because of knee-related or non–knee-related reasons.
- Detect knee abusers.
- Also rate individual functions of sports, daily activities.

Circle the number that describes your level of sports activity at this time.

Level I (participates 4-7 days/week)

100 Jumping, hard pivoting, cutting (basketball, volleyball, football, gymnastics, soccer)
95 Running, twisting, turning (tennis, racquetball, handball, ice hockey, field hockey, skiing, wrestling)
90 No running, twisting, jumping (cycling, swimming)

Level II (participates 1-3 days/week)

85 Jumping, hard pivoting, cutting (basketball, volleyball, football, gymnastics, soccer)
80 Running, twisting, turning (tennis, racquetball, handball, ice hockey, field hockey, skiing, wrestling)
75 No running, twisting, jumping (cycling, swimming)

Level III (participates 1-3 times/month)

65 Jumping, hard pivoting, cutting (basketball, volleyball, football, gymnastics, soccer)
60 Running, twisting, turning (tennis, racquetball, handball, ice hockey, field hockey, skiing, wrestling)
55 No running, twisting, jumping (cycling, swimming)

Level IV (no sports)

40 I perform activites of daily living without problems
20 I have moderate problems with activities of daily living
0 I have severe problems with activities of daily living; on crutches, full disability

FIG 41-6 Sports Activity Scale.

TABLE 41-4 Example of Sports Activity Levels Before and After Posterior Cruciate Ligament Reconstruction

Type of Sport	Preoperative (*n* Patients)	Follow-up (*n* Patients)
Jumping, hard pivoting, cutting	0	2
Running, twisting, turning	1	2
Swimming, bicycling	7	11
None	11	4
Change in sports activities:		
Increased level, no symptoms		8
Same level, no symptoms		4
Decreased level, no symptoms		1
Playing with symptoms		2
No sports, knee-related reasons		3
No sports, non–knee-related reasons		1

CRITICAL POINTS Rating of Occupational Activities

- Occupational activities should be rated separately from sports activities.
- Seven factors are graded to provide a general intensity rating of work conditions.
- 0-100 point scale:
  - Disabled (0 points)
  - Very light (1-20 points)
  - Light (21-40 points)
  - Moderate (41-60 points)
  - Heavy (61-80 points)
  - Very heavy (>80 points)
- Determine change in work activities in same manner as sports activities.
- Reliability of the Occupational Rating Scale is adequate for patients with ACL ruptures, chronic patellofemoral disorders, degenerative meniscal tears, and degenerative joint arthritis.

operations and treatment programs should be determined by assessing both occupational and sports activities, especially if patients are not involved in athletics because of lack of interest, time, ability, or other factors. In these cases, the ability of an operation or treatment program to successfully return patients to their occupation is a primary determinant of the program's effectiveness. This determination can only be made with a rating scale for work activities, which is separate from that of sports activities. Scales that combine work and sports into one activity rating do not allow for this analysis to be performed.[98]

A study was conducted on published occupational rating systems in which several bias and potential sources of error were detected when reporting outcomes of treatment programs.[76] One problem was the lack of a scale that sufficiently evaluated the amount of stress placed on the knee at work or whether the knee condition was limiting work activities. Ambiguous terminology, such as light, moderate, and heavy, was frequently encountered to describe occupations. No published scale incorporated a method to detect a change in work status because of factors not related to the knee condition. Based on this study, an Occupational Rating Scale (Fig. 41-9) was created. This was composed of seven factors that place varying amounts of load on the lower extremity (see Appendix A). Each factor was graded according to intensity, frequency, and duration of the task required on a daily basis. The factors chosen were commonly used to assess the condition of the knee joint in workers' compensation evaluations. This scale was found to be more effective and valid in assessing demands of occupations on the lower extremities than scales that used job titles or arbitrary numeric scales.[76]

The factor of "standing/walking" was selected because of the harmful effect prolonged weight bearing has on patients with certain knee disorders, including patellofemoral and tibiofemoral arthrosis.

Check the box that best describes the change you have had in sports activities since your injury or surgery. My sports activities have:

Not changed
- ☐ I have no/slight problems
- ☐ I have moderate/significant problems

Increased
- ☐ I have no/slight problems
- ☐ I have moderate/significant problems

Decreased
- ☐ I have no/slight problems
- ☐ I have moderate/significant problems
- ☐ For reasons not related to my knee

Stopped, given up all sports
- ☐ I have moderate/significant problems when I play sports
- ☐ For reasons not related to my knee

FIG 41-7 Change in sports activities.

Check the problems you have during:

1. Walking
check one box:
- ☐ Normal, unlimited (40)
- ☐ Some limitations (30)
- ☐ Only 3-4 blocks possible (20)
- ☐ Less than 1 block; cane, crutch (0)

2. Stairs
check one box:
- ☐ Normal, unlimited (40)
- ☐ Some limitations (30)
- ☐ Only 11-30 steps possible (20)
- ☐ Only 1-10 steps possible (0)

3. Squatting/kneeling
check one box:
- ☐ Normal, unlimited (40)
- ☐ Some limitations (30)
- ☐ Only 6-10 possible (20)
- ☐ Only 0-5 possible (0)

4. Straight running
check one box:
- ☐ Fully competitive (100)
- ☐ Some limitations, guarding (80)
- ☐ Definite limitations, 1/2 speed (60)
- ☐ Not able to do (40)

5. Jumping/landing
check one box:
- ☐ Fully competitive (100)
- ☐ Some limitations, guarding (80)
- ☐ Definite limitations, 1/2 speed (60)
- ☐ Not able to do (40)

6. Hard twists/cuts/pivots
check one box:
- ☐ Fully competitive (100)
- ☐ Some limitations, guarding (80)
- ☐ Definite limitations, 1/2 speed (60)
- ☐ Not able to do (40)

FIG 41-8 Activities of Daily Living and Sports Function Scales.

"Climbing" and "squatting" assess the ability of the knee to function under repetitive loading conditions. The factor "walking on uneven ground" is important for assessing joint instability in knees after a ligament injury or reconstruction. The factors "lifting/carrying" and "pounds carried" are helpful in assessing the general ability of the knee to tolerate specific loading conditions. The number of factors assessed was limited for the sake of brevity and simplicity, even though many others could have been included. These factors were not chosen to relate to one diagnosis or condition. Rather, they provide a general intensity rating of the work conditions on the lower extremity.

Each factor is graded according to one of two numeric scales: five factors are assigned a possible total of 10 points, and two factors are assigned a possible total of 5 points. In terms of rating loads placed on the knee joint, the numbers assigned to rate the work intensity of one factor do not necessarily equal the same numbers assigned to rate the work intensity of other factors. The actual loads placed on the knee joint are a function of multiple intrinsic and extrinsic factors that would require actual measurement. The scores for each factor are totaled, providing a numerical score for data reporting purposes. Occupations may then be categorized based on the total number of points as either disabled (0 points), very light (1-20 points), light (21-41 points), moderate (41-60 points), heavy (61-80 points), or very heavy (>80 points). The data may be expressed as means and SD for the population under study or through the distribution of patients in the six occupational categories before and after treatment.

The second major component in the assessment of work activities is the change that occurs in these activities between treatment periods, the most common occurring between preoperative and most recent follow-up evaluations. The format and terminology are the same as those used in the assessment of the change in sports activities between treatment periods, previously described in Figure 41-7. Importantly, the determination is made if changes in work activities are caused by knee-related or non–knee-related reasons and if patient is experiencing symptoms in her or his occupation.

The reliability of the Occupational Rating scale was demonstrated to be adequate in patients with ACL ruptures, chronic patellofemoral disorders, degenerative meniscal tears, and degenerative knee joint arthritis.[6] This scale is useful in the clinic to rate and categorize the occupational status of workers' compensation patients and in the

development of disability ratings. In addition, the Occupational Rating Scale has been used to assess the effect of insurance plans (private vs. workers' compensation) on the outcome of ACL reconstruction.[72,101]

Patient History

For research purposes, a specific data collection format was developed to ensure that accurate and consistent information is obtained for the patient history (Fig. 41-10). For instance, the coding of major reinjuries and prior surgical procedures to the involved knee is necessary to determine whether or not the patient meets the established criteria for a particular study. For example, an acute prospective study would include only patients who have sustained one major injury to the knee and no prior surgical intervention. In such an investigation, patients who had additional injuries or previous surgical procedures to the involved knee would be excluded. In addition, the condition of the noninvolved knee must be taken into consideration. Patients who have problems with the noninvolved knee are sorted into a separate subgroup to determine whether this factor affects the treatment outcome.

Only information related to orthopaedic conditions is included in the history portion of the CKRS. Patients are screened for additional medical problems, but these findings are usually not included unless they alter the treatment outcome. General demographic data are documented for identification and description purposes. The history of prior knee surgeries is coded by major operative categories to provide the basic information necessary for reporting prior treatment.

Knee Examination

The knee examination portion of the physical evaluation is designed to document all parameters of the knee condition (Fig. 41-11). The contents are divided into five sections. The general examination section includes joint effusion and range of motion. Joint effusion is rated as normal, mild (<25 mL of fluid), moderate (26-60 mL of fluid), or severe (>60 mL of fluid). Knee flexion and extension are measured with a goniometer; the heel-height method is also used to determine differences in extension between knees.

The tibiofemoral assessment includes joint line pain, crepitus, and compression pain. Pain is rated as none, mild, moderate, or severe. Crepitus is graded as none, mild, moderate, or severe. Moderate crepitus indicates that a cartilage abnormality (definite fibrillation) exists within 25 to 50 degrees of knee motion. Severe crepitus indicates that the abnormality is present in an arc greater than 50 degrees of knee motion. The patellofemoral exam includes crepitus, compression pain, lateral subluxation at 20 degrees, medial subluxation at 20 degrees, soft tissue pain, and soft tissue swelling. Crepitus and pain are rated as described for the tibiofemoral assessment. Lateral patellar subluxation at 20 degrees of flexion is rated as normal if the patella can be moved within 25% of its width; mild, 26% to 50%; moderate, 51% to 75%; and severe, greater than 75%. Medial patellar subluxation at 20 degrees of knee flexion is rated as normal if the patella can be moved 15 mm or less; mild, 11 to 15 mm; moderate, 6 to 10 mm; and severe, less than 6 mm.

The radiographic section assesses the three knee compartments as normal (no joint space narrowing), mild, moderate (narrowing <50% of the total joint space), or severe (narrowing >50% of the total joint space) using standing 45-degree posteroanterior and 30-degree axial patellofemoral radiographs. Studies regarding lower limb malalignment also require standing radiographs of the hip-knee-ankle to document the weight-bearing line and mechanical axis.[22]

The ligament subluxation section documents the results of the pivot shift test (scale, 0 to 3) and other knee ligament subluxation tests (see Fig. 41-11). The pivot shift test is recorded on a scale of 0 to 3, with a grade of 0 indicating no pivot shift; grade 1, a slip or glide; grade 2, a jerk with gross subluxation or clunk; and grade 3, gross subluxation with impingement of the posterior aspect of the lateral side of the tibial plateau against the femoral condyle. The posterior drawer test (palpation of the medial tibiofemoral step-off) is done at 90

degrees of flexion, and the difference in posterior tibial translation between the reconstructed knee and the contralateral knee is recorded. The clinical tests for lateral and medial joint opening are based on the varus and valgus stress tests performed at 0 and 30 degrees of flexion. The examiner estimates the amount (in millimeters) of joint opening from the initial closed contact position of each tibiofemoral compartment to the maximal opened position, comparing the injured with the opposite normal knee. The tibiofemoral rotation test is used to detect posterior tibial subluxations in a qualitative manner at 30 and 90 degrees of knee flexion.[74]

Objective Testing

Objective testing of the lower extremity is performed to determine ligamentous, muscular, and limb symmetry deficits (Fig. 41-12). The KT-2000 knee arthrometer test is performed at 20 degrees of flexion at 134 N for ACL investigations. Total AP displacement is measured because this is more accurate than attempting to set a neutral point between anterior and posterior tibial displacement. The difference in the measurements between the reconstructed and contralateral knee is recorded. Any knee that has an ACL or PCL rupture on the

contralateral knee is excluded from KT-2000 testing. The manual maximum arthrometer examination is not used because the magnitude of the force applied is highly variable and not defined or measured. This problem results in inconsistent results among examiners and studies.

Posterior stress radiographs are done with an 89-N force applied to the proximal tibia in knees with PCL ruptures.[33] A lateral radiograph is taken of each knee at 90 degrees of flexion. The limb is placed in neutral rotation with the tibia unconstrained and the quadriceps relaxed. The difference in posterior tibial displacement between the reconstructed knee and the contralateral knee is recorded. More than 8 mm of increase in posterior tibial translation on stress testing indicates a complete PCL rupture. The knee arthrometer is the device most frequently used by investigators to measure posterior tibial translation after PCL reconstruction. However, this device underestimates the true amount of residual posterior translation in PCL-injured and reconstructed knees and, in our opinion, is unreliable for determining the results of PCL surgical procedures at high flexion angles.[33,54,94] Lateral stress radiographs are performed in knees with deficiency of the posterolateral structures. Both knees are radiographed at 20 degrees of flexion, neutral tibial rotation, and 67 N of varus force, and a comparison is made of the millimeters of lateral tibiofemoral compartment opening.

Muscular weaknesses or imbalances are assessed with isokinetic testing at either slow (60 degrees/sec) or fast (300 degrees/sec) speeds or in an isometric mode for patients with patellofemoral pain or symptomatic crepitus. Single-legged function hop tests are performed as previously described.[4,68] Patients perform any two of the hop tests shown in Figure 41-12 to determine functional limitations after ACL reconstruction and to continue the functional progression for return to sports activities.

Operative Procedures and Articular Cartilage Surfaces

Documentation of the operative procedures performed and the condition of all ligamentous structures, menisci, and articular cartilage in the patellofemoral and tibiofemoral compartments is essential (Fig. 41-13). The operative procedures and findings may be used as final exclusionary or inclusionary criteria as determined by the study protocol.

A classification system for the rating of articular cartilage has been described previously.[78] This system separates the description of the surface appearance of the cartilage from the extent or depth of the defect. Three surface grades are rated: (1) closed chondromalacia (surface intact), (2) open lesions of fibrillation and fragmentation (surface disrupted), and (3) bone exposed. Subtypes (a) and (b) then make a distinction regarding the depth of the lesion as described. The location and millimeters of surface involvement are recorded. Chapter 44 further details this and other articular cartilage rating systems. In addition, treatment of articular surfaces such as debridement, drilling/abrasion arthroplasty, osteochondral autograft transfer, or autologous chondrocyte implantation is also documented.

Postoperative Complications

Complications from surgical procedures or rehabilitation programs are documented on a prospective basis (Fig. 41-14). In addition, senior researchers or surgeons who did not participate in the care of the patient conduct a chart review to ensure complete and accurate reporting of complications and results of treatment.

Ligament Findings and Procedures

Anterior Cruciate Ligament _____

Overall Rating Assessment

An overall rating assessment is performed that is based on the ratings from 20 factors, including symptoms, functional limitations, knee examination, stability, radiographs, and function testing (Appendix B). In patients in whom the ACL reconstruction is done for an acute injury (within 12 weeks of the original injury), the analysis of the overall rating is performed in a different manner from that for patients with chronic injuries, who often have compounding problems such as articular cartilage damage, prior meniscal loss, loss of secondary restraints, and associated ligamentous instabilities.

Patients with acute knee injuries are expected to have more favorable results, especially in the symptom and functional limitations analyses, and therefore a categorical analysis is used (along with a point scale) to determine the outcome of these patients. With this method, patients receive an overall rating grade of "excellent," "good," "fair," or "poor" from the 20 factors shown in Appendix B. To receive a rating of "excellent," all but one score must be in that category, with the remaining score being in the "good" category. A "good" result is given when all scores are in the "excellent," and "good" categories and none are in the "fair" or "poor" categories. A "fair" result is assigned when any 1 score is "fair," and a "poor" result, when any 1 score is "poor." In short, a knee can only be as good as the worst rating in any 1 of the 20 categories. This rationale was developed to solve the problem incurred with other systems that only use point scores to determine results and then arbitrarily assign categories for a certain number of point ("excellent" for 91-100 points, "good" for 81-90 points, and so on). In these systems, an ACL reconstruction that failed according to knee arthrometer testing could still receive an "excellent" or "good" rating if all other parameters score high numbers. Using this rationale, the CKRS is one of the strictest in terms of reporting results for acute knee injury studies.

The overall rating of knees with chronic injuries is not determined in the same categorical manner as that used for acute injuries because many of these individuals have preexisting problems that cannot be corrected with ACL reconstruction. In these instances, patients may be negatively biased into the "fair" or "poor" categories. For instance, a knee with preoperative moderate joint space narrowing on radiographs would not be expected to show improvement in this factor after an ACL reconstruction. This knee would, therefore, not have a chance of improving from the preoperative overall rating of "fair" to one of "good" or "excellent." Because of these problems, the results for chronic knees are determined in the following manner. First, special emphasis is placed on the results of the individual components that make up the overall rating categories such as symptoms, knee range of motion, arthrometer testing, and functional testing. These data are presented in separate tables and graphs to allow comparisons of these important parameters among investigations. Second, the overall point total is calculated before and after treatment, including the change in points between evaluations. A distribution of the change in points is provided to allow assessment of slight change (<10 points), moderate change (between 10 and 20 points), and significant change (>20 points) between evaluations.

RELIABILITY, VALIDITY, AND RESPONSIVENESS TESTING: OUR STUDY

Reliability testing of the scales and overall rating score of the CKRS was conducted on two groups of individuals.[6] The first group consisted of 50 patients who had a variety of chronic knee injuries and disorders, including meniscal tears, knee ligament tears, patellofemoral complaints, and degenerative joint disease. The second group consisted of 50 volunteers who had no current knee pathology and no history of prior knee operations. The questionnaires were given to these 100 individuals by an interviewer who was available to explain the instructions if required, but a formal interview was not accomplished. The questionnaires were completed an average of 7 days (range, 4-13 days) after the baseline evaluation.

Validity (construct, content, and item discriminant) and responsiveness testing of the CKRS were conducted on a group of 250 patients who were prospectively followed after ACL bone-patellar tendon-bone autogenous reconstruction a mean of 27 months (range, 23-74 months) postoperatively. The patients completed the questionnaires preoperatively and at the most recent follow-up evaluation.

All volunteers and patients completed 13 scales: (1) the four Symptom Rating Scales for pain, swelling, partial giving way, and full giving way; (2) the Patient Perception Scale; (3) the Activities of Daily Living Scales for walking, stair climbing, and squatting; (4) the Sports Activities Function Scales for running, jumping, and hard twisting/cutting/pivoting; (5) the Sports Activity Scale; and (6) the Occupational Rating Scale. The overall rating score was calculated before surgery and at the most recent follow-up evaluation for the ACL-reconstructed patients.

The 13 scales all demonstrated adequate test-retest reliability (Table 41-5, R >0.70). In the normal population, the ICCs ranged from 0.71 (jumping) to 1.0 (walking, full giving way). In the patient population, the ICCs ranged from 0.75 (squatting/kneeling) to 0.98 (Sports Activity Scale).

In the analysis of content validity, the CKRS overall rating score had no floor or ceiling effects preoperatively in the 250 patients (Table 41-6). At follow up, no floor scores were found, and limited ceiling effects were calculated (22 patients [9%]). Good construct validity was demonstrated because eight of the nine clinical hypotheses were confirmed using the overall rating score (Table 41-7). Item-discriminant validity was found for 59 of the 63 (94%) comparisons between the CKRS categories and the other variables shown in Table 41-8).

The CKRS was highly responsive to detecting changes from the preoperative to the follow-up evaluations. Seven of the eight

CRITICAL POINTS Reliability, Validity, and Responsiveness Testing: Our Study

- Reliability testing of the scales and overall rating score:
  - 50 patients with chronic knee injuries and disorders, including meniscal tears, knee ligament tears, patellofemoral complaints, and degenerative joint disease.
  - 50 volunteers with no current knee pathology and no history of prior knee operations.
- The questionnaires were completed an average of 7 days (range, 4-13 days) after the baseline evaluation.
- Validity (construct, content, and item-discriminant) and responsiveness testing in 250 patients prospectively followed after reconstruction a mean of 27 mo (range, 23-74 mo) postoperatively.
- 13 scales demonstrated adequate test-retest reliability.
- Content validity: overall rating score had no floor or ceiling effects preoperatively. At follow up, no floor scores were found, and limited ceiling effects were calculated in 9%.
- Construct validity: 8/9 clinical hypotheses were confirmed.
- Item-discriminant validity: 94% comparisons.
- Highly responsive in detecting change between evaluations.

categories showed large effects ranging from 1.07 to 2.48, and the remaining category (ADL average score) showed a moderate effect of 0.72 (Table 41-9).

ASSESSMENT OF THE CKRS BY INDEPENDENT INSTITUTIONS

Marx and colleagues[58] conducted reliability, validity, and responsiveness testing of the CKRS Symptom Rating Scale and the Sports and Daily Activity functional scales in 42 patients with a wide variety of knee disorders. These investigators found that these components had adequate reliability (ICC, >0.80), face and content validity, and

CRITICAL POINTS Assessment of Cincinnati Knee Rating by Independent Institutions

- CRKS has adequate psychometric properties.
- CKRS is highly sensitive to detecting significant changes over time in contrast to the Lysholm, IKDC, and visual analogue scales.
- CKRS score provides more effective estimate of disability than Lysholm.
- CKRS defines most precisely the outcome of anterior cruciate ligament reconstruction in athletically active patients.
- "Modified" CKRS scales should not be used because they do not represent the instruments developed that have undergone rigorous statistical testing and may not provide the data that was intended by the authors of the CKRS.

responsiveness (standardized response mean, 0.8). The authors found that the Lysholm scale, the American Academy of Orthopaedic Surgeons sports knee-rating scale, and the Activities of Daily Living Scale of the Knee Outcome Survey also had adequate reliability, validity, and responsiveness.

Risberg and coworkers[83] assessed the responsiveness of the CKRS Symptom Rating and the Sports and Daily Activity functional scales in 109 patients after ACL reconstruction. The patients completed the questionnaires 3, 6, 12, and 24 months postoperatively. The authors reported that the CKRS was highly sensitive to detecting significant changes over time in contrast to the Lysholm, IKDC, and visual analogue scales, which were not found to be effective in detecting such changes.

Borsa and colleagues[11] evaluated 29 patients with an ACL-deficient knee to determine if performance-based measures or patient-reported measures of function were more effective in estimating disability. Patients completed the CKRS Sports Activity Scale, Symptom Rating

Scale, Patient Perception of the Knee Condition questions, and Sports Activity Function questions. Patient also completed the Lysholm questionnaire and were taken through proprioception, balance, single-leg hop, and isokinetic strength testing. Stepwise regression analysis demonstrated that the CKRS score was the most effective estimate of disability ($R^2 = 0.56$). The addition of the Lysholm score into the model only increased R^2 to .58 and the addition of the hop test index score only slightly improved the adjusted R^2 to 0.60. The authors concluded that the inclusion of the Lysholm score and hop index did not significantly improve the ability to estimate disability induced by ACL deficiency.

Sgaglione and coworkers[91] used four separate knee rating outcome instruments to determine the outcome of 65 patients who underwent ACL reconstruction. The patients were evaluated a mean of 35 months (range, 24-58 months) postoperatively. The CKRS in its entirety was used in this investigation. The results demonstrated that the CKRS individual scaled scores were lower than the Hospital for Special Surgery (HSS) and Lysholm questionnaire scores. The investigators concluded that the CKRS defined most precisely the outcome of ACL reconstruction in athletically active patients. The conclusion was related to the fact that the CKRS incorporated physical findings and avoided combining raw scores into categoric score data (e.g., excellent = 90-100 points). According to the investigators, the Lysholm and HSS scores tended to inflate the outcome of the operation.

Anderson and associates[2] evaluated 70 patients a minimum of 5 years following ACL reconstruction with the HSS, Feagin and Blake, CKRS, Lysholm, and Zarins rating scales. The authors reported that the CKRS had a large number of measurements which reflected high precision in the analysis of subjective symptoms, subjective function, and objective examination. Substantial differences were noted among the results of the six scales evaluated. The conclusion was reached that future rating scales should provide a balance among subjective symptoms, subjective function, and objective findings.

Agel and LaPrade[1] collected "modified" CKRS and IKDC subjective questionnaires from 130 patients with a variety of complex knee disorders both before surgery and at intervals postoperatively (4-8 months, 9-15 months, 16-24 months, >24 months). The overall total scores for both questionnaires were equivalent in the analysis of the entire population at all time intervals. There were no differences between the questionnaires for ceiling and floor effects. There were differences when the individual patient scores were assessed and, across time intervals, between 9% and 21% of the population exhibited individual patient score differences of more than 10 points. The authors concluded that the decision of which questionnaire to use should be based on the specific diagnosis of the population under study, with careful consideration given to the individual questions contained in each system.

Greco and colleagues[29] compared reliability and responsiveness of the IKDC Subjective Knee Form to the "modified" CKRS, the Western Ontario and McMaster Universities Osteoarthritis Index (WOMAC), and the SF-36 in patients with full-thickness articular cartilage defects treated with a variety of cartilage restoration procedures. The ICCs of three of the instruments were comparable (IKDC, 0.91; CKRS, 0.91; WOMAC, 0.81-0.93), as were the ES and SRM 12 months after surgery. The SF-36 subscales failed to show adequate reliability (across all ten scales) and responsiveness.

MODIFIED CKRS SCALES

We express concern and caution regarding the use of so-called modified CKRS scales. Although some authors who implement these scales in their investigations[1,12,92] provide the actual portion of the CKRS used along with the modifications, the reasons for changing the original scales are usually not provided. The interpretation of data is difficult and cannot be compared with studies that use unedited CKRS scales. In our opinion, modified CKRS scales should not be used because they do not represent the instruments developed, which have undergone rigorous statistical testing, and may not provide the data that was intended by the authors of the CKRS.

APPENDIX A: SPORTS ACTIVITY AND FUNCTION FORM, SYMPTOM RATING FORM, OCCUPATIONAL RATING FORM

Patient Name	Involved Knee	Date of Visit
	Right____ Left____	mo____ day____ yr____

Sports Activity Scale

Check the box which describes your level of sports activity before your original knee injury. Then, check the box which describes your level of sports activity at this time

BEFORE INJURY		CURRENT LEVEL
☐	100	☐
☐	95	☐
☐	90	☐
☐	85	☐
☐	80	☐
☐	75	☐
☐	65	☐
☐	60	☐
☐	55	☐
☐	40	☐
☐	20	☐
☐	0	☐

Level I (participates 4-7 days/week)
Jumping, hard pivoting, cutting (basketball, volleyball, football, gymnastics, soccer)
Running, twisting, turning (tennis, racquetball, handball, ice hockey, field hockey, skiing, wrestling)
No running, twisting, jumping (cycling, swimming)

Level II (participates 1-3 days/week)
Jumping, hard pivoting, cutting (basketball, volleyball, football, gymnastics, soccer)
Running, twisting, turning (tennis, racquetball, handball, ice hockey, field hockey, skiing, wrestling)
No running, twisting, jumping (cycling, swimming)

Level III (participates 1-3 times/month)
Jumping, hard pivoting, cutting (basketball, volleyball, football, gymnastics, soccer)
Running, twisting, turning (tennis, racquetball, handball, ice hockey, field hockey, skiing, wrestling)
No running, twisting, jumping (cycling, swimming)

Level IV (no sports)
I perform activities of daily living without problems
I have moderate problems with activities of daily living
I have severe problems with activities of daily living; on crutches, full disability

Highest Level (before injury) ___/100
Highest Level (current) ___/100

Change in Sports Activities

Check the box which best describes any change you have had in sports activities since your injury / surgery.
My sports activities have:

Not Changed
If yes, check one box below:
☐ I have no / slight problems (*c*)
☐ I have moderate / significant problems (*d*)

Decreased
If yes, check one box below:
☐ I now have no / slight problems (*e*)
☐ I now have moderate / significant problems (*d*)
☐ For reasons not related to my knee (*g*)

Stopped -- given up all sports
If yes, check one box below:
☐ I have moderate / significant problems when I play sports (*f*)
☐ For reasons not related to my knee (*g*)

Level_____

Function ADL

Check the problems you have during:

1. Walking
check one box:
40 ☐ normal, unlimited
30 ☐ some limitations
20 ☐ only 3-4 blocks possible
0 ☐ less than 1 block; cane, crutch

2. Stairs
check one box:
40 ☐ normal, unlimited
30 ☐ some limitations
20 ☐ only 11-30 steps possible
0 ☐ only 1-10 steps possible

3. Squatting / kneeling
check one box:
40 ☐ normal, unlimited
30 ☐ some limitations
20 ☐ only 6-10 possible
0 ☐ only 0-5 possible

Level_____/ 3 =_____

Function Sports

Check the problems you have during:

1. Straight running
check one box:
100 ☐ fully competitive
80 ☐ some limitations, guarding
60 ☐ definite limitations, half speed
40 ☐ not able to do

2. Jumping / landing on affected leg
check one box:
100 ☐ fully competitive
80 ☐ some limitations, guarding
60 ☐ definite limitations, half speed
40 ☐ not able to do

3. Hard twists / cuts / pivots
check one box:
100 ☐ fully competitive
80 ☐ some limitations, guarding
60 ☐ definite limitations, half speed
40 ☐ not able to do

Level_____/ 3 =_____

Problems with Sports

Describe the problems you would have with your knee after participating for one hour without guarding or limitations in each of the three sports categories below. (___ check here if you are using a brace.)

Strenuous Sport
(soccer, football, basketball, volleyball)
check one box:
100 ☐ no problems
☐ moderate problems during or after game
☐ severe problems; cannot participate

Moderate Sport
(tennis, racquetball)
check one box:
80 ☐ no problems
☐ moderate problems during or after game
☐ severe problems; cannot participate

Light Sport
(golf, bowling, hiking)
check one box:
60 ☐ no problems
50 ☐ moderate problems during or after game
30 ☐ severe problems; cannot participate

Total Points_____

SPORTS ACTIVITY AND FUNCTION FORM — **CINCINNATI KNEE RATING SYSTEM (F07A)**

Patient Name	Date of Visit	Involved knee ☐right ☐left	Date of original injury

DIRECTIONS:

Using the KEY (at right), check the appropriate boxes on the four scales below which indicate the highest level you can reach WITHOUT having symptoms.

KEY:

Scale Description

10 Normal Knee, able to do strenuous work/sports with jumping, hard pivoting
8 Able to do moderate work/sports with running, turning and twisting; symptoms with strenuous work/sports
6 Able to do light work/sports with no running, twisting or jumping; symptoms with moderate work/sports
4 Able to do activities of daily living alone; symptoms with light work/sports
2 Moderate symptoms (frequent, limiting) with activities of daily living
0 Severe symptoms (constant, not relieved) with activities of daily living

1. PAIN _____/ 10

10 — 8 — 6 — 4 — 2 — 0

2. SWELLING (actual fluid in the knee, obvious puffiness) _____/ 10

10 — 8 — 6 — 4 — 2 — 0

3. PARTIAL GIVING-WAY (partial knee collapse, no fall to the ground) _____/ 10

10 — 8 — 6 — 4 — 2 — 0

4. FULL GIVING-WAY (knee collapse occurs with actual falling to the ground) _____/ 10

10 — 8 — 6 — 4 — 2 — 0

Pain	**Location of pain**	☐ inner side	☐ outer side	☐ front / kneecap	☐ back of knee	☐ all over
	Type of pain	☐ sharp	☐ aching	☐ throbbing	☐ burning	
	Pain occurs on	☐ sitting	☐ standing	☐ stairs	☐ squatting	☐ running / jumping
	Pain relieved	☐ by not doing sports	☐ by limiting daily activities		☐ by rest / medications	☐ pain not relieved
	Kneecap grinding? ☐ yes ☐ no		Knee stiffness? ☐ yes ☐ no			
Catching/ Locking	1. Check one box: ☐ yes ☐ no My knee **catches** -- it does not move for a few seconds but works out. 2. Check one box: ☐ yes ☐ no My knee **locks** -- it does not move for five or more minutes at a time.					
Work Activity	My job title is:		Work status: ☐ full time ☐ part time		☐ full duty ☐ light duty ☐ not working	
	When I work, I experience: ☐ no limitations ☐ mild limitations ☐ moderate limitations ☐ severe limitations					
Exercise Program	In my exercise program, I am: ☐ making good progress ☐ slow progress, but better ☐ some problems with exercise ☐ exercise causes pain, problems ☐ doesn't apply					
Follow-up Progress	Following my last visit, I am: ☐ making good progress ☐ slow progress, but better ☐ staying the same ☐ symptoms worse ☐ doesn't apply					
Patient Grade	***Rate the overall condition of your knee at the present time. Circle one number below.*** 1 — 2 poor — 3 — 4 fair — 5 — 6 good — 7 — 8 — 9 — 10 normal **poor** -- I have significant limitations that affect activities of daily living. **fair** -- I have moderate limitations that affect activities of daily living, no sports possible. **good** -- I have some limitations with sports but I can participate; I compensate. **normal/excellent** -- I am able to do whatever I wish (any sport) with no problems.					
Average	Pain (x2)_____ + swelling_____ + partial giving way_____ + full giving way_____				Subtotal = _____ / 5 = _____	

SYMPTOM RATING FORM

CINCINNATI KNEE RATING SYSTEM F02

Patient name	Date of Visit	Involved Knee ☐ right ☐ left	Date of Original Injury
Occupation	Current Work Status ☐ full-time ☐ part-time		

How soon after your injury/surgery/knee problem were you able to return to work activities?

☐ 0-3 months ☐ 4-6 months ☐ 7-12 months ☐ unable to return

Occupational Rating Scale

Check the response which best describes what you actually do at work. Check only one response per column.

Factor 1 sitting	Factor 2 standing/ walking	Factor 3 walking on un-even ground	Factor 4 squatting	Factor 5 climbing	Factor 6 lifting/carrying	Factor 7 pounds carried
0 ☐ 8-10 hrs/day	0 ☐ 0 hr/day	0 ☐ 0 hr/day	0 ☐ 0 times/day	0 ☐ 0 times/day	0 ☐ 0 times/day	0 ☐ 0-5 lbs
1 ☐ 6-7 hrs/day	1 ☐ 1 hr/day	1 ☐ 1 hr/day	1 ☐ 1-5 times/day	1 ☐ 1 flight, 2 times/day	1 ☐ 1-5 times/day	1 ☐ 6-10 lbs

INTRODUCTION

To provide a comprehensive analysis of the knee condition and the effect of a treatment protocol on a knee injury or disorder, authors[2,4,29,30,37] have suggested that rating systems measure a variety of symptoms, sports and daily activity functions, and objective findings. To our knowledge, only three knee-specific rating systems are available that measure all of these factors and have established psychometric properties of reliability, validity and responsiveness: the Cincinnati Knee Rating System (CKRS),[4,19] the International Knee Documentation Committee (IKDC) Knee Evaluation system,[14,29] and the new Knee Society Scoring System.[18,27] The CKRS (see Chapter 41) and IKDC Knee Evaluation measure pain, swelling, giving way, functions of sports and daily activities, sports activity levels, patient perception of the knee condition, range of knee motion, joint effusion, tibiofemoral and patellofemoral crepitus, knee ligament subluxations, compartment narrowing on radiographs, and lower limb symmetry during single leg hop tests. The new Knee Society Scoring system (see Chapter 45) is designed specifically for arthroplasty research investigations. It includes an objective knee score completed by the physician (measuring alignment, instability, and joint motion) and multiple scales completed by the patient that assess symptoms, satisfaction, and daily and athletic functions and limitations.

The IKDC is one of the most commonly used instruments to determine the results of anterior cruciate ligament (ACL) reconstruction and other knee operations and injuries. This chapter describes the history, development, initial forms, and revisions of the IKDC system. Investigations which provided reliability, validity, and responsiveness data are summarized. The major sections of the current knee forms are described.

HISTORY OF THE IKDC

As early as 1983, some authors[7] expressed concern that comparing results of different methods of treatment of ACL ruptures was not possible without a standardized method of evaluation. At that time, a multitude of scoring systems had been proposed to quantify symptoms and functional limitations caused by ACL injuries and to evaluate the results of operative and conservative treatment. None of these systems were accepted internationally. One major problem was that the majority assigned numerical values to factors that were not quantifiable, weighted certain factors over others, and then added these scores together to provide either an excellent, good, fair, or poor overall outcome grade. Because the content and relative weight given to each component varied greatly from one system to another, individuals rated as excellent or good on one instrument could be rated as fair or poor on another.[30]

To develop a worldwide, standardized knee ligament rating system, a group of knee surgeons from Europe (European Society of Sports Traumatology, Knee Surgery and Arthroscopy [ESKA]) and America (American Orthopaedic Society for Sports Medicine [AOSSM]) founded the IKDC in 1987 (Table 42-1). Common terminology to describe knee motion and function were agreed upon by the committee members.[22] A set of measurements to determine knee motion limits was validated in formal investigations.[6,21,22] Methods to quantify knee function, activity levels, and symptoms were evaluated. A single-page Knee Ligament Standard Evaluation Form was then created (Fig. 42-1).[10,14] The goals of the evaluation form were to measure the essential criteria judged at that time to be necessary to determine the results of treatment and to be simple enough to complete so that research personnel were not required. The committee anticipated that a more

comprehensive system would eventually be developed. The form evaluated sports activity levels and eight domains, including patient's assessment of knee function, symptoms, range of knee motion, ligament evaluation, compartment findings, harvest site pathology, radiographic findings, and single-leg hop function testing.

The 1995 IKDC evaluation form adopted the philosophy of Noyes and coworkers (contained in the CKRS[20,23]) in the assessment of symptoms that were graded at the highest activity level possible without incurring pain, swelling, or giving way. Two questions determined the patient's assessment of knee function and its effect on activity level. A total of 24 factors were rated as normal, nearly normal, abnormal, or severely abnormal as shown in Figure 42-1. Four domains (patient's subjective assessment, symptoms, range of motion, and ligament evaluation) received a final rating, and an overall evaluation result was derived, also using the same philosophy as the CKRS.[4,19] In this manner, the lowest-graded factor determined the overall grade for each individual domain and the final evaluation. For example, a knee that had a positive pivot shift test and 6 mm of increased anteroposterior displacement on KT-2000 testing would receive an abnormal rating, even if all of the other categories were rated as normal or nearly normal. The form also rated sports activities according to a four-level gradient of strenuous, moderate, light, or sedentary.

Irrgang and associates[14] evaluated the construct and concurrent validity of the 1995 IKDC evaluation form in 133 patients who were 1 to 5 years post-ACL reconstruction. These authors reported that the form was useful for reporting outcome after ACL reconstruction. The scoring system clearly distinguished patients whose outcomes were normal or nearly normal from those who were abnormal or severely abnormal, thus preventing a positively biased result when a significant problem in the knee persisted postoperatively. All of the domains contributed to the final rating; however, symptoms and knee ligament evaluation accounted for 62% of the variance in the final rating. The authors did not conduct reliability or responsiveness testing in this investigation.

Paxton and colleagues[24] reported the reliability and internal consistency of the 1995 IKDC evaluation form in 153 patients who had sustained patellar dislocations. The patients completed the form 2 to 5 years after their injury. Adequate reliability and internal consistency (correlation coefficients, 0.82 and 0.84, respectively) were reported. However, high ceiling effects were noted that indicated poor content validity for this group of patients.

CRITICAL POINTS History

- The IKDC is one of the most commonly used instruments to determine the results of anterior cruciate ligament reconstructions and other knee operations and injuries.
- To develop a worldwide, standardized knee ligament rating system, a group of knee surgeons founded the IKDC in 1987.
- Committee members agreed on:
  - Common terminology to describe knee motion and function
  - Set of measurements to determine knee motion limits
  - Methods to quantify knee function, activity levels, and symptoms
- A single-page Knee Ligament Standard Evaluation Form was created.
- The 1995 IKDC Evaluation Form evaluated sports activity levels and eight domains, including patient assessment of knee function, symptoms, range of knee motion, ligament evaluation, compartment findings, harvest site pathology, x-ray findings, and functional testing.
- Symptoms are graded at the highest activity level possible without incurring pain, swelling, or giving way.
- Worst-graded factor determined the overall grade for each individual domain and the final evaluation.
- Scoring system clearly distinguished patients whose outcomes were normal or nearly normal from those who were abnormal or severely abnormal, thus preventing a positively biased result when a significant problem in the knee persisted postoperatively.
- Adequate reliability and internal consistency but high ceiling effects were reported.

COMPONENTS OF THE IKDC KNEE SCORING SYSTEM

The IKDC Knee Scoring System currently includes six forms for research investigations. The IKDC is copyrighted by the AOSSM and

CRITICAL POINTS Components of the International Knee Documentation Committee System

- 2000 IKDC Subjective Knee Evaluation Form
  - Focus of the second IKDC committee: create a general (knee problem) instrument for a variety of knee injuries and disorders.
  - 18 questions in the domains of symptoms, functions of daily and sports activities, current function of the knee, and participation in work and sports.
  - Form has acceptable psychometric properties.
  - Normative data obtained in a random sample of 5246 knees, used to compare a patient's score to those of age- and gender-matched normal subjects.
- 2000 IKDC Knee Examination Form
  - Markedly similar to the original 1995 IKDC Knee Ligament Standard Evaluation form.
  - Should be completed along with Subjective Knee Evaluation Form for research studies.
- IKDC Demographic Form
  - MODEMS-compatible questionnaire.
- IKDC Current Health Assessment Form
  - Composed of 35/36 questions from the Medical Outcomes Study Short Form-36 (SF-36) Health Survey.
- 2000 IKDC Knee History and Surgical Documentation Forms
  - Includes the articular cartilage classification system of the International Cartilage Repair Society.

****FINAL EVALUATION**					❑	❑	❑	❑

*Group Grade: The lowest grade within a group determines the group grade. **Final Evaluation: The worst group grade determines the final evaluation for acute and subacute patients. For chronic patients compare preoperative and postoperative evaluations. In a final evaluation, only the first 4 groups are evaluated but all groups must be documented.

△ Difference in involved knee compared to normal or what is assumed to be normal.

IKDC – INTERNATIONAL KNEE DOCUMENTATION COMMITTEE, Members of the Committee:

AOSSM: Anderson, AF, Clancy, WG, Daniel, D, DeHaven, KE, Fowler, PJ, Feagin, J, Grood, ES, Noyes, FR, Terry, GC, Torzilli, P, Warren, RF.

ESSKA: Chambat, P, Eriksson, E, Gillquist, J, Hefti, F, Huiskes, R, Jakob, RP, Moyen, B, Muller, W, Staeubli, H, vanKampen, A.

FIG 42-1 The 1995 International Knee Documentation Committee (IKDC) Knee Ligament Standard Evaluation Form. *ADL,* Activities of daily living; *AP,* anteroposterior. (Courtesy the American Orthopaedic Society for Sports Medicine.)

all of the forms are available on the website of the AOSSM at www.sportsmed.org. The forms have been translated into Portuguese, Chinese, French, German, Greek, Italian, Japanese, Korean, Spanish, and Swedish.

1. 2000 IKDC Subjective Knee Evaluation Form
2. 2000 IKDC Knee Examination Form
3. IKDC Demographic Form (Musculoskeletal Outcomes Data Evaluation and Management System [MODEMS] demographic form)
4. IKDC Current Health Assessment Form (Medical Outcomes Study 36-Item Short Form Health Survey [SF-36] form)
5. 2000 IKDC Knee History Form
6. 2000 IKDC Surgical Documentation Form

An online IKDC Scoring worksheet is also available on the website of the AOSSM. The patient's responses to each question are entered and the worksheet calculates a raw (overall) score and a percentile rank (relative to age- and gender-based norms). Also available on this website is the modified IKDC Subjective Knee Form (Pedi-IKDC), developed for children and adolescents who are between 10 and 18 years of age. This form was found to have adequate validity and internal consistency in a group of 673 patients.[26] However, its reliability and responsiveness have not been published.

2000 International Knee Documentation Committee Subjective Knee Evaluation Form

In 1997, the AOSSM elected to revise the IKDC rating system to broaden its application. The focus of the new committee (Table 42-2) shifted from designing and implementing a disease-specific (knee ligament) instrument to creating and testing a general (generic) knee problem instrument. Thus the 2000 IKDC Subjective Knee Evaluation Form (Fig. 42-2) was devised to rate symptoms and functional limitations for a variety of knee disorders and operations, including ligament and meniscus tears, patellofemoral problems, and articular cartilage lesions. This form comprises 18 questions in the domains of symptoms, functions of daily and sports activities, current function of the knee, and participation in work and sports. An overall score is calculated on the sum of the questions answered (at least 90% of the questions must be answered) divided by the maximum possible score, as shown in Figure 42-2. This form does not analyze findings from a physical examination, radiographs, knee arthrometer tests, function tests, or other objective tests.

The 2000 IKDC Subjective Knee Evaluation Form underwent reliability and validity testing in 533 patients[12] and responsiveness testing in 207 patients who had a wide variety of knee problems.[13] The overall score (scale, 0-100 points) had acceptable reliability (intraclass correlation coefficient, 0.94); convergent validity with the SF-36 scales of physical function and bodily pain and the physical component summary score (Pearson correlation coefficients, 0.63, 0.64, and 0.66, respectively); and discriminates validity with the SF-36 subscales of mental health, role limitations because of mental problems, general health, and the mental components summary score. Adequate responsiveness, with a large effect size of 1.13 and a large standard response mean of 0.94, was reported. An additional evaluation of responsiveness was determined by ascertaining the change in the overall score (between treatment evaluations) that best distinguished patients who improved from those who did not. A change of 20.5 points had the greatest specificity in making this distinction, whereas a change of less than 12 points was not considered clinically relevant for indicating improvement. Subsequently, Crawford and colleagues[5] reported acceptable reliability, validity, and responsiveness properties of the IKDC Subjective Knee Evaluation Form in patients with meniscus pathology.

Anderson and coworkers[3] reported normative data obtained in a random sample of 5246 knees. The data collected allow comparison of a patient's score to those of age- and gender-matched normal subjects. This investigation also demonstrated adequate construct validity of this form because the overall score was able to identify patients who had knee symptoms and low levels of function.

In 2008, Slobogean and associates[32] reported normative data obtained with the IKDC Subjective Knee Evaluation Form in a small random sample of 125 children aged 12 to 14 years. The mean score for this population (89.4 points) was similar to that of the young adulthood data published by Anderson and coworkers.[3] Subsequently, a modified IKDC Subjective Knee Form (Pedi-IKDC) was developed for children and adolescents between the ages of 10 and 18 years of age. This form was found to have adequate validity and internal consistency in a group of 673 patients.[26] However, its reliability and responsiveness have not been published.

2000 International Knee Documentation Committee Knee Examination Form

Because the 2000 IKDC Subjective Knee Evaluation Form does not incorporate data from the physical examination, radiographs, knee arthrometer tests, function tests, or other objective tests, researchers are encouraged to also complete the 2000 IKDC Knee Examination Form (Fig. 42-3) to provide comprehensive data for publication. The 2000 IKDC Knee Examination Form is markedly similar to the original 1995 IKDC Knee Ligament Standard Evaluation form, except the original categories of patient's subjective assessment and symptoms were eliminated and a rating of knee effusion was added to produce a total of seven domains. In addition, the original Sports Activity Scale was removed and inserted into the 2000 IKDC Subjective Knee Form.

International Knee Documentation Committee Demographic Form

The IKDC Demographic Form (Fig. 42-4) is a MODEMS-compatible questionnaire. The MODEMS project, developed by the American Academy of Orthopaedic Surgeons in 1995, was terminated in 2000. The system was expected to be the premier program for the collection and analysis of functional outcomes information on a variety of musculoskeletal conditions. The program was terminated because of lack of subscribers and interest to maintain financial viability.

2000 IKDC SUBJECTIVE KNEE EVALUATION FORM

Your Full Name_____

Today's Date: _____ /_____ /_____ (Day / Month / Year)

Date of Injury: _____ /_____ /_____ (Day / Month / Year)

SYMPTOMS*:

*Grade symptoms at the highest activity level at which you think you could function without significant symptoms, even if you are not actually performing activities at this level.

1. What is the highest level of activity that you can perform without significant knee pain?

   4 ❑ Very strenuous activities like jumping or pivoting as in basketball or soccer
   3 ❑ Strenuous activities like heavy physical work, skiing or tennis
   2 ❑ Moderate activities like moderate physical work, running or jogging
   1 ❑ Light activities like walking, housework or yard work
   0 ❑ Unable to perform any of the above activities due to knee

2. During the past 4 weeks, or since your injury, how often have you had pain?

	10	9	8	7	6	5	4	3	2	1	0	
Never	❑	❑	❑	❑	❑	❑	❑	❑	❑	❑	❑	Constant

3. If you have pain, how severe is it?

	10	9	8	7	6	5	4	3	2	1	0	
No pain	❑	❑	❑	❑	❑	❑	❑	❑	❑	❑	❑	Worst pain imaginable

4. During the past 4 weeks, or since your injury, how stiff or swollen was your knee?

   4 ❑ Not at all
   3 ❑ Mildly
   2 ❑ Moderately
   1 ❑ Very
   0 ❑ Extremely

5. What is the highest level of activity you can perform without significant swelling in your knee?

   4 ❑ Very strenuous activities like jumping or pivoting as in basketball or soccer
   3 ❑ Strenuous activities like heavy physical work, skiing or tennis
   2 ❑ Moderate activities like moderate physical work, running or jogging
   1 ❑ Light activities like walking, housework, or yard work
   0 ❑ Unable to perform any of the above activities due to knee swelling

6. During the past 4 weeks, or since your injury, did your knee lock or catch?

   0 ❑ Yes 1 ❑ No

7. What is the highest level of activity you can perform without significant giving way in your knee?

   4 ❑ Very strenuous activities like jumping or pivoting as in basketball or soccer
   3 ❑ Strenuous activities like heavy physical work, skiing or tennis
   2 ❑ Moderate activities like moderate physical work, running or jogging
   1 ❑ Light activities like walking, housework, or yard work
   0 ❑ Unable to perform any of the above activities due to giving way of the knee

FIG 42-2 The 2000 International Knee Documentation Committee (IKDC) Subjective Knee Evaluation Form. (Courtesy the American Orthopaedic Society for Sports Medicine.)

SPORTS ACTIVITIES:

8. What is the highest level of activity you can participate in on a regular basis?

- 4 ❑ Very strenuous activities like jumping or pivoting as in basketball or soccer
- 3 ❑ Strenuous activities like heavy physical work, skiing or tennis
- 2 ❑ Moderate activities like moderate physical work, running or jogging
- 1 ❑ Light activities like walking, housework or yard work
- 0 ❑ Unable to perform any of the above activities due to knee pain

9. How does your knee affect your ability to:

		Not difficult at all	Minimally difficult	Moderately difficult	Extremely difficult	Unable to do
a.	Go up stairs	4 ❑	3 ❑	2 ❑	1 ❑	0 ❑
b.	Go down stairs	4 ❑	3 ❑	2 ❑	1 ❑	0 ❑
c.	Kneel on the front of your knee	4 ❑	3 ❑	2 ❑	1 ❑	0 ❑
d.	Squat	4 ❑	3 ❑	2 ❑	1 ❑	0 ❑
e.	Sit with your knee bent	4 ❑	3 ❑	2 ❑	1 ❑	0 ❑
f.	Rise from a chair	4 ❑	3 ❑	2 ❑	1 ❑	0 ❑
g.	Run straight ahead	4 ❑	3 ❑	2 ❑	1 ❑	0 ❑
h.	Jump and land on your involved leg	4 ❑	3 ❑	2 ❑	1 ❑	0 ❑
i.	Stop and start quickly	4 ❑	3 ❑	2 ❑	1 ❑	0 ❑

FUNCTION:

10. How would you rate the function of your knee on a scale of 0 to 10 with 10 being normal, excellent function and 0 being the inability to perform any of your usual daily activities which may include sports?

FUNCTION PRIOR TO YOUR KNEE INJURY:

	0	1	2	3	4	5	6	7	8	9	10	
Couldn't perform daily activities	❑	❑	❑	❑	❑	❑	❑	❑	❑	❑	❑	No limitation in daily activities

CURRENT FUNCTION OF YOUR KNEE:

	0	1	2	3	4	5	6	7	8	9	10	
Cannot perform daily activities	❑	❑	❑	❑	❑	❑	❑	❑	❑	❑	❑	No limitation in daily activities

Scoring Instructions for the 2000 IKDC Subjective Knee Evaluation Form

Several methods of scoring the IKDC Subjective Knee Evaluation Form were investigated. The results indicated that summing the scores for each item performed as well as more sophisticated scoring methods.

The responses to each item are scored using an ordinal method such that a score of 0 is given to responses that represent the lowest level of function or highest level of symptoms. For example, item 1, which is related to the highest level of activity without significant pain is scored by assigning a score of 0 to the response "Unable to perform any of the above activities due to knee pain" and a score of 4 to the response "Very strenuous activities like jumping or pivoting as in basketball or soccer". For item 2, which is related to the frequency of pain over the past 4 weeks, the response "Constant" is assigned a score of 0 and "Never" is assigned a score of 10. **Note:** Previous versions of the form had a minimum item score of 1 (for example, ranging from 1 to 11). In the most recent version, all items now have a minimum score of 0 (for example, 0 to 10). To score these prior versions, you would need to transform each item to the scaling for the current version.

The IKDC Subjective Knee Evaluation Form is scored by summing the scores for the individual items and then transforming the score to a scale that ranges from 0 to 100. **Note:** The response to item 10a "Function Prior to Knee Injury" is not included in the overall score. To score the current form of the IKDC, simply add the score for each item (the small number by each item checked) and divide by the maximum possible score, which is 87:

$$\text{IKDC Score} = \left[\frac{\text{Sum of Items}}{\text{Maximum Possible Score}} \right] \times 100$$

Thus, for the current version, if the sum of scores for the 18 items is 45, and the patient responded to all the items, the IKDC Score would be calculated as follows:

$$\text{IKDC Score} = \left[\frac{45}{87} \right] \times 100$$

$$\text{IKDC Score} = 51.7$$

The transformed score is interpreted as a measure of function such that higher scores represent higher levels of function and lower levels of symptoms. A score of 100 is interpreted to mean no limitation with activities of daily living or sports activities and the absence of symptoms.

The IKDC Subjective Knee Form score can be calculated when there are responses to at least 90% of the items (i.e., when responses have been provided for at least 16 items). In the original scoring instructions for the IKDC Subjective Knee Form, missing values are replaced by the average score of the items that have been answered. However, this method could slightly over- or under-estimate the score depending on the maximum value of the missing item(s) (2, 5 or 11 points). Therefore, in the revised scoring procedure for the current version of a form with up to two missing values, the IKDC Subjective Knee Form Score is calculated as (sum of the completed items) / (maximum possible sum of the completed items) * 100. This method of scoring the IKDC Subjective Knee Form is more accurate than the original scoring method.

A scoring spreadsheet is also available at: www.sportsmed.org/research/index.asp This spreadsheet uses the current form scores and the revised scoring method for calculating scores with missing values.

1. Do you smoke cigarettes?

❑Yes
❑No, I quit in the last six months.
❑No, I quit more than six months ago.
❑No, I have never smoked.

2. Your height ❑centimeters ❑inches

3. Your weight ❑kilograms ❑pounds

4. Your race (indicate all that apply)

❑White ❑Black or African-American ❑Hispanic

❑Asian or Pacific Islander ❑ Native American Indian ❑Other

5. How much school have you completed?

❑Less than high school ❑Graduated from high school ❑Some college

❑Graduated from college ❑Postgraduate school or degree

6. Activity level

❑Are you a high competitive sports person?

❑Are you well-trained and frequently sporting?

❑Sporting sometimes

❑Non-sporting

FIG 42-4, cont'd

International Knee Documentation Committee Current Health Assessment Form

The IKDC Current Health Assessment Form (Fig. 42-5) consists of 35 of the 36 questions from the SF-36. The reliability and validity of the SF-36 as a generic, patient-based health status instrument have been well documented.[17,35,36] Shapiro and colleagues[31] reported that the SF-36 was useful in showing significant changes with treatment for ACL ruptures treated either conservatively or surgically. These authors recommended including this outcome measure along with other disease-specific measures such as the IKDC Knee Examination Form when reporting outcome following ACL reconstruction.

2000 International Knee Documentation Committee Knee History and Surgical Documentation Forms

The 2000 IKDC Knee History Form (Fig. 42-6) allows documentation of injury history, previous knee surgery, and imaging studies. The 2000 IKDC Surgical Documentation Form (Fig. 42-7) includes the articular cartilage classification system of the International Cartilage Repair Society (ICRS),[10] described in further detail in Chapter 44. The size, location, and grade (normal; ICRS grade 1, nearly normal; ICRS grade 2, abnormal; ICRS grade 3, severely abnormal; ICRS grade 4, severely abnormal) of articular cartilage lesions are recorded. This form also documents surgical procedures for articular cartilage lesions and meniscus and ligament damage. However, the form does not record other surgical procedures such as extensor mechanism realignment or osteotomy.

COMPARISON OF IKDC OUTCOMES WITH THOSE OF OTHER KNEE RATING SYSTEMS

Investigators have compared the psychometric properties and outcome scores of the 1995 IKDC evaluation form with other knee rating scales and systems. Risberg and coworkers[25] compared the responsiveness of the IKDC, Cincinnati, and Lysholm knee scores in 109 patients who were evaluated 3, 6, 12, and 24 months after ACL reconstruction. The IKDC domains analyzed were patient's subjective assessment (IKDC-1), symptoms (IKDC-2), range of motion (IKDC-3), ligament examination (IKDC-4), and the final grade (IKDC-F). The IKDC-1 and IKDC-2 results changed significantly only between 12 and 24 months postoperatively. The IKDC-3 and IKDC-F changed only from 3 to 6 months but not thereafter. IKDC-4 did not change significantly postoperatively. In comparison, the Cincinnati score demonstrated significant changes throughout the follow-up period. The Lysholm score increased significantly only between 3 and 6 months postoperatively. High correlations were found between IKDC-1 and IKDC-2 and the

IKDC CURRENT HEALTH ASSESSMENT FORM*

Your Full Name_____

Your Date of Birth_____/_____/_____
Day Month Year

Today's Date _____/_____/_____
Day Month Year

1. In general, would you say your health is: ❑Excellent ❑Very Good ❑Good ❑Fair ❑Poor

2. Compared to one year ago, how would you rate your health in general now?

❑Much better now than 1 year ago ❑Somewhat better now than 1 year ago ❑About the same as 1 year ago

❑Somewhat worse now than 1 year ago ❑Much worse now than 1 year ago

3. The following items are about activities you might do during a typical day. Does your health now limit you in these activities? If so, how much?

		Yes, Limited A Lot	Yes, Limited A Little	No, Not Limited At All
a.	Vigorous activities, such as running, lifting heavy objects, participating in strenuous sports	❑	❑	❑
b.	Moderate activities, such as moving a table, pushing a vacuum cleaner, bowling, or playing golf	❑	❑	❑
c.	Lifting or carrying groceries	❑	❑	❑
d.	Climbing several flights of stairs	❑	❑	❑
e.	Climbing one flight of stairs	❑	❑	❑
f.	Bending, kneeling or stooping	❑	❑	❑
g.	Walking more than a mile	❑	❑	❑
h.	Walking several blocks	❑	❑	❑
i.	Walking one block	❑	❑	❑
j.	Bathing or dressing yourself	❑	❑	❑

4. During the past 4 weeks, have you had any of the following problems with your work or other regular daily activities as a result of your physical health?

		YES	NO
a.	Cut down on the amount of time you spent on work or other activities	❑	❑
b.	Accomplished less than you would like	❑	❑
c.	Were limited in the kind of work or other activities	❑	❑
d.	Had difficulty performing the work or other activities (for example, it took extra effort)	❑	❑

5. During the past 4 weeks, have you had any of the following problems with your work or other regular daily activities as a result of any emotional problems (such as feeling depressed or anxious)?

		YES	NO
a.	Cut down on the amount of time you spent on work or other activities	❑	❑
b.	Accomplished less than you would like	❑	❑
c.	Didn't do work or other activities as carefully as usual	❑	❑

FIG 42-5 The International Knee Documentation Committee (IKDC) Current Health Assessment Form. (Courtesy the American Orthopaedic Society for Sports Medicine.)

6. During the past 4 weeks, to what extent has your physical health or emotional problems interfered with your normal social activities with family, friends, neighbors, or groups?

❑Not At All ❑Slightly ❑Moderately ❑Quite a Bit ❑Extremely

7. How much bodily pain have you had during the past 4 weeks?

❑None ❑Very Mild ❑Mild ❑Moderate ❑Severe ❑Very Severe

8. During the past 4 weeks, how much did pain interfere with your normal work (including both work outside the home and housework)?

❑Not at All ❑A Little Bit ❑Moderately ❑Quite a Bit ❑Extremely

9. These questions are about how you feel and how things have been with you during the past 4 weeks. For each question, please give the one answer that comes closest to the way you have been feeling. How much of the time during the past 4 weeks...

	All of the time	Most of the time	A good bit of the time	Some of the time	A little of the time	None of the time
a. Did you feel full of pep?	❑	❑	❑	❑	❑	❑
b. Have you been very nervous?	❑	❑	❑	❑	❑	❑
c. Have you felt calm and peaceful?	❑	❑	❑	❑	❑	❑
d. Did you have a lot of energy?	❑	❑	❑	❑	❑	❑
e. Have you felt down-hearted and blue?	❑	❑	❑	❑	❑	❑
f. Did you feel worn out?	❑	❑	❑	❑	❑	❑
g. Have you been a happy person	❑	❑	❑	❑	❑	❑
h. Did you feel tired?	❑	❑	❑	❑	❑	❑

10. During the past 4 weeks, how much of the time has your physical health or emotional problems interfered with your social activities (like visiting with friends, relatives, etc.)?

❑All of the time ❑Most of the time ❑Some of the time ❑A little of the time ❑None of the time

11. How TRUE or FALSE is each of the following statements for you?

	Definitely True	Mostly True	Don't Know	Mostly False	Definitely False
a. I seem to get sick a little easier than other people	❑	❑	❑	❑	❑
b. I am as healthy as anybody I know	❑	❑	❑	❑	❑
c. I expect my health to get worse	❑	❑	❑	❑	❑
d. My health is excellent	❑	❑	❑	❑	❑

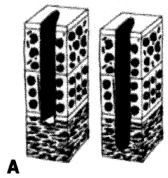

FIG 42-7, cont'd

Cincinnati knee score, and moderate correlations were detected between IKDC-2 and the Lysholm score. IKDC1-4 showed high criterion validity with the Cincinnati score and KT-1000 manual maximum testing.

Hrubesch and associates[11] failed to find significant correlations among the IKDC rating and the Cincinnati, Lysholm, Feagin and Blake, Zarins and Rowe, and Marshall scores. However, these authors did not use the entire Cincinnati Knee Rating System, which incorporates variables similar to the IKDC knee examination form. This was the reason that superior results were found using the Cincinnati score compared with the IKDC overall grade.

Kocher and colleagues[16] conducted a study to identify the determinants of patient satisfaction of the outcome of ACL reconstruction. Patient satisfaction was significantly associated with the IKDC-1 to IKDC-3 (subjective assessment, symptoms, range of motion) and IKDC-F. There was no association between IKDC-4 (ligament examination) and patient satisfaction.

The IKDC Subjective Evaluation Form was compared with the "modified" Cincinnati Knee Rating System by Agel and LaPrade.[1] These investigators collected "modified" CKRS and IKDC subjective questionnaires from 130 patients with a variety of complex knee disorders both before surgery and at intervals postoperatively (4-8 months, 9-15 months, 16-24 months, >24 months). The overall total scores for both questionnaires were equivalent in the analysis of the entire population at all time intervals. There were no differences between the questionnaires for ceiling and floor effects. There were differences when the individual patient's scores were assessed and, across time intervals, between 9% and 21% of the population exhibited individual patient's score differences of more than 10 points. The authors concluded that the decision of which questionnaire to use should be based on the specific diagnosis of the population under study, with careful consideration given to the individual questions contained in each system.

Greco and colleagues[8] compared reliability and responsiveness of the IKDC Subjective Knee Form to the "modified" CKRS, the Western Ontario and McMaster Universities Osteoarthritis Index (WOMAC), and the SF-36 in patients with full-thickness articular cartilage defects treated with a variety of cartilage restoration procedures. The interclass correlation coefficients of three of the instruments were comparable (IKDC, 0.91; CKRS, 0.91; WOMAC, 0.81-0.93), as were the effect sizes and standardized response means 12 months after surgery. The SF-36 subscales failed to show adequate reliability (across all ten scales) and responsiveness.

To determine which questions were considered most important to patients that had undergone ACL reconstruction, Hambly and Griva[9] compared patients' responses on the IKDC Subjective Evaluation Form with those collected on the Knee Injury and Osteoarthritis Outcome Score (KOOS) form. These investigators reported that 78% of the items from the IKDC were experienced by more than half of the patients compared with 57% from the KOOS. However, items from the Function in Sports/Recreation and Quality of Life KOOS subscales were also very important to this cohort. In an investigation with a similar purpose, Tanner and associates[33] found that the IKDC Subjective Evaluation Form was one of the top general knee instruments (among five instruments evaluated) because it contained many questions on symptoms and limitations considered important to patients. This investigation assessed 153 patients who had ACL tears, meniscus tears, or mild/moderate knee osteoarthritis.

OUR COMMENTS

Clinical researchers must select a knee rating instrument composed of the essential variables required to study hypotheses and assess other variables that may potentially bias the study outcome. Researchers should understand the major differences that exist between available knee rating instruments that could affect the conclusions of studies. In our opinion, clinical studies must measure and report not only symptoms and functional limitations with athletic and daily activities but objective physical findings as well. Factors such as range of knee motion, joint effusion, tibiofemoral and patellofemoral crepitus, knee ligament subluxations, radiographic findings, and functional testing should be included in the results of investigations. Therefore, if the IKDC is chosen as the outcome instrument for a study, both the 2000 IKDC Subjective Knee Form and the 2000 IKDC Knee Examination Form should be completed and incorporated into the publication.

It is important to realize the limitations of the 2000 IKDC Subjective Knee Form. First, this form is, by intended design, a generic knee questionnaire. We believe that investigators should use instruments as sensitive to the condition under study as possible. Second, this form combines data from 18 questions that rate symptoms, functions of daily and sports activities, current function of the knee, and participation in work and sports into one numerical value. The IKDC to date has not recommended that researchers separately assess specific symptoms, functional limitations, or sports activity levels before and after treatment, even though the questionnaire format allows for such an assessment. Therefore given the current committee recommendations, the ability to detect specific limitations, such as pain or giving way during various activities, is not possible. Investigators and readers

CRITICAL POINTS Comparison of IKDC Outcomes with Those of Other Knee Rating Systems

- Not all IKDC domains are responsive to detecting change over time after anterior cruciate ligament (ACL) reconstruction.
- No difference in functional outcome reported between "modified" CKRS and IKDC Subjective questionnaires.
- No difference in reliability and responsiveness between the IKDC Subjective Knee Form, the "modified" CKRS, WOMAC, and SF-36 in patients with full-thickness articular cartilage defects treated with a variety of cartilage restoration procedures.
- IKDC Subjective Evaluation Form one of the top general knee instruments in determining which questions were considered most important to patients that had undergone ACL reconstruction.

CRITICAL POINTS Our Comments

- Clinical studies must measure and report symptoms and functional limitations with athletic and daily activities and objective physical findings.
- Limitations of the IKDC Subjective Knee Evaluation Form:
  - Combines symptoms and functions of work, sports, and daily activities into one score.
  - Sensitivity for detecting specific limitations is greatly reduced.
  - Cannot detect knee abusers, activity level, or changes in activity level from total score.
  - Researchers should analyze data from individual questions as well as total score.
  - Age- and gender-matched percentiles generated by the online scoring system are more useful than the total score.

cannot ascertain from a single numeric value if an individual is participating in athletics, and if so, whether problems are incurred. Changes in sports activity levels are not determined, nor are limitations in individual knee functions such as walking, running, and pivoting. We believe that it is important in athletically active populations to provide a specific analysis of the sports levels preoperatively and postoperatively, which may be easily done by reporting the distribution of patients in the five levels provided in question 8. It is equally important to report the percent of patients who returned to athletics without symptoms versus those who experienced problems and were considered knee abusers.[23]

We recommend that investigators provide pretreatment and posttreatment data from individual questions on the 2000 IKDC Subjective Knee Evaluation Form and not just the overall score. Investigators may choose the specific questions that are considered the most important according to the knee injury or disorder under study. For example, a study of the results of ACL reconstruction should separately analyze data from question 7, which ascertains whether giving way of the knee occurs with varying activity levels. In addition, the overall function of the knee determined by question 10 should be individually profiled by providing not only the mean values before and after treatment but a distribution of responses along the scale. Investigators should realize that this question measures daily activity function only because a score of 0 equals "cannot perform daily activities," and a score of 10 equals "no limitation in daily activities." Therefore this question (as it currently appears on the questionnaire) does not take into account the patients' ability to perform sports activities.

In our opinion, the age- and gender-matched percentiles generated by the AOSSM online scoring system for the 2000 IKDC Subjective Knee Evaluation Form are more useful than the total score. For instance, a 46-year-old woman who experiences only mild, occasional symptoms with strenuous activities could score an 87, which initially appears to be a good result and would compare favorably with scores of other systems such as the Lysholm[34] or Activities of Daily Living Scale of the Knee Outcome Survey.[15] However, this total score places this patient into only the 50th percentile according to the IKDC normative database. Therefore researchers should consider incorporating the age- and gender-matched percentiles in the results section of published studies, such as is commonly done with SF-36 data. An example of this type of analysis with SF-36 data may be found in the investigation of Sekiya and coworkers[28] who described the short-term (average, 2.8 years postoperative) outcome of combined meniscus transplantation and ACL reconstruction in 28 patients. The mean absolute scores were provided for the individual domains of the SF-36 questionnaire, along with scores standardized to age- and sex-matched U.S. population norms for each individual patient.

INTRODUCTION

This chapter reviews commonly used scales and outcome instruments that rate athletic and daily functional activities for a variety of knee injuries and disorders in younger active patients. The instruments are analyzed according to their strengths and potential biases as well as their measured reliability, validity, and responsiveness properties. Scales from the Cincinnati Knee Rating System (CKRS) and the International Documentation Committee Rating (IKDC) System are not included because they are described in detail in Chapters 41 and 42, respectively. Outcome measures typically used in older or sedentary populations with osteoarthritis, patients who undergo total knee arthroplasty (TKA), and individuals with patellofemoral pain are described in Chapter 45.[1,36,41] Generic health status instruments, such as the Short Form-36 Health Survey (SF-36) and the Musculoskeletal Function Assessment,[22] are also available but these are not discussed in this chapter.

It is important to stress that, in our opinion, clinical research studies should include the assessment of symptoms and athletic and daily functional activities, as well as objective physical findings. The determination of patient's outcome using subjective questionnaire data only does not provide an accurate understanding of the ability of the treatment protocol to restore normal knee function. Factors such as range of knee motion, joint effusion, tibiofemoral and patellofemoral crepitus, knee ligament subluxations, radiographic findings, and limb symmetry on functional testing should be included as required according to the diagnosis under study.

SPORTS ACTIVITY SCALES

Tegner Activity Scale

Tegner and Lysholm[42] developed one of the first rating scales to quantify activity levels in patients with anterior cruciate ligament (ACL) ruptures (Table 43-1). The Tegner Activity Scale classifies both sports and work activities into one questionnaire using an 11-level gradient. Competitive sports make up the top three levels (levels 10-8), competitive and recreational sports categories both appear in level 7, and "other recreational sports" make up level 6 (Table 43-2). Levels 5 through 1 combine work and sports together, and level 0 indicates sick leave or disability because of the knee condition. The original publication did not provide reliability, validity, or responsiveness data of this scale.

Several problems are incurred with this activity rating instrument. First, work activities are rated within the same scale as sports activities. Patients who work in heavy-labor occupations are only awarded a level 5 (out of a possible 10), but the analysis of the stress on the lower limb in some of these occupations would probably show that these knees are functioning at a level equivalent to those of competitive athletes. They should not be awarded a lower level simply because they are not athletes or did not return to highly competitive sports. Athletics and occupational activities should be measured on separate rating scales (see Chapter 41).

Second, this scale does not separate various sports levels according to frequency of participation or the intensity of the sport, which is determined by accounting for the forces placed on the lower extremity. For instance, only national and international elite soccer players are

CRITICAL POINTS Sports Activity Scales

- Tegner Activity Scale
  - Classifies both sports and work activities into one questionnaire using an 11-level gradient.
  - Does not separate sports levels according to frequency of participation or intensity of sport.
  - Cannot determine change in athletic participation between time periods owing to a change in lifestyle.
  - Does not detect knee abusers.
  - Adequate psychometric properties for meniscus injuries, acute patellar dislocations.
  - Less responsive to change after articular cartilage restorative procedures in comparison with the Knee Injury and Osteoarthritis Outcome Score subscales of sport/recreation and quality of life.
  - Unable to discriminate among patients sufficiently active and those insufficiently active after total knee arthroplasty.
- Hospital for Special Surgery Sports Scale
  - Sports levels sorted according to four stress categories.
  - Ambiguous terms are used to define sports categories.
  - Cannot determine change in athletic participation between time periods owing to a change in lifestyle.
  - Psychometric properties not evaluated.
- Seto Sports Participation Survey
  - Sports activity level and participation rated.
  - Allows analysis of athletic participation according to frequency of play and the detection of changes in levels between evaluations.
  - Psychometric properties not evaluated.
- Straub and Hunter's Sports Performance Index
  - Sports index based on rating of participation and intensity levels.
  - Sports not included in the rating cannot be placed on scale because the rationale for the classification of activities into the various categories is unknown.
  - Frequency and duration of activities not included.
  - Knee abusers cannot be detected.
  - Psychometric properties not evaluated.
- Daniel Sports Level Rating
  - Sports activity rated according to frequency of participation (number of hours played per year) and intensity. Frequency assessed retrospectively.
  - Knee abusers cannot be detected.
  - Cannot determine change in athletic participation between time periods owing to a change in lifestyle.
  - Psychometric properties not evaluated.
- Marx Sports Activity Scale
  - Scale based on frequency of participation and intensity of activities.
  - Satisfactory reliability, validity.
  - Unable to discriminate between patients sufficiently active and those insufficiently active after total knee arthroplasty.

TABLE 43-1 Tegner Activity Score

Level	Descriptor	Examples of Activities
10	Competitive sports	Soccer: national and international elite
9	Competitive sports	Soccer: lower divisions; ice hockey, wrestling, gymnastics
8	Competitive sports	Bandy, squash or badminton, athletics (e.g., jumping), downhill skiing
7	Competitive sports	Tennis, athletics (running), motocross: speedway, handball, basketball
	Recreational sports	Soccer, bandy and ice hockey, squash, athletics (jumping), cross country, track and field, findings both recreational and competitive
6	Recreational sports	Tennis and badminton, handball, basketball, downhill skiing, jogging at least five times/wk
5	Work	Heavy labor (e.g., building, forestry)
	Competitive sports	Cycling Cross-country skiing
	Recreational sports	Jogging on uneven ground at least twice/wk
4	Work	Moderately heavy labor (e.g., truck driving, heavy domestic work)
	Recreational sports	Cycling, cross-country skiing, jogging on uneven ground at least twice/wk
3	Work	Light labor (e.g., nursing)
	Competitive and recreational sports	Swimming
	Walking in forest possible	
2	Work	Light labor
	Walking on uneven ground possible but impossible to walk in forest	
1	Work	Sedentary work
	Walking on even ground possible	
0	Sick leave or disability pension because of knee problems	

From Tegner,Y, Lysholm J. Rating systems in the evaluation of knee ligament injuries. Clin *Orthop Relat Res.* 1985;198:43-49.

listed on level 10, whereas basketball is listed on a level 7. In the United States, it could be argued that competitive high school, collegiate, or professional basketball players are asked to place similar demands on the knee joint and lower extremity as elite soccer players. For patients who play or return to sports not listed on the scale, problems are incurred in trying to determine exactly which level accurately defines their sport. Third, this scale does not allow an assessment of a change in athletic participation between time periods owing to a change in lifestyle (e.g., graduated from school and no longer participates in a league). In addition, one cannot detect knee abusers in either the sport or the work levels.

Independent investigations assessed the reliability, validity and responsiveness of the Tegner scale for a variety of knee injuries. Briggs and coworkers[6] determined its reliability, validity, and responsiveness in 122 patients with meniscus injuries. The scale was found to have adequate reliability (intraclass correlation coefficient [ICC], 0.817), content validity (no ceiling or floor effects), criterion validity with the Medical Outcomes Short Form-12 Health Survey (SF-12), and construct validity. However, only moderate effect sizes (ES) and standardized response mean (SRM) values were reported. The investigators concluded that the scale measures only moderate changes in activity

Table 43-2 Published Sports Activity Rating Scales

Scale, Year Published	Factors Rated	Reliability, Validity, Responsiveness Testing	Comments
Tegner, 1985	**11 levels:** Levels 8-10: competitive (lists of sports provided) Level 7: competitive and recreational (lists of sports provided) Level 6: recreational (lists of sports provided, jogging at least 5 times/wk) Level 5: work (heavy labor), competitive and recreational sports (cycling, cross-country skiing, jogging uneven ground at least twice/wk) Level 4: work (moderately heavy), recreational sports (cycling, cross-country skiing, jogging even ground at least twice/wk) Level 3: work (light), competitive and recreational sports (swimming), walking rough terrain Level 2: work (light), walking uneven ground Level 1: work (sedentary), walking even ground Level 0: sick leave, disability because of knee	ACL injuries/reconstructions: adequate reliability, content validity, criterion validity, construct validity, responsiveness Meniscus injuries: adequate reliability, content validity, criterion validity, construct validity; moderate responsiveness Acute patellar dislocations: adequate reliability, content validity Articular cartilage repairs: inadequate responsiveness Total knee arthroplasty: adequate reliability, validity	Developed to compare activity levels before and after treatment. Rationale for assignment of activities to each level unknown. Patients in United States may have difficulty completing scale; designed for European sports. Combines work and sports in 5 of the 11 levels.
Hospital for Special Surgery, 1987	**4 levels:** Very stressful (lists of sports provided) Moderately stressful (lists of sports provided) Mildly stressful (lists of sports provided) No sports	Not done	Frequency of participation not assessed
Seto Sport Participation Survey, 1988	13 sports, each assigned 0-4 points (see text). May assign points for activities not listed on scale. Each sport also rated according to frequency and duration of participation: assigned 1-3 points.	Not done	Allows detection of knee abusers, change in activity levels between evaluations. Reporting of data may be difficult if a population is composed of individuals who play a wide variety of sports because data are sorted according to each activity separately.
Straub & Hunter's Sport Performance Index, 1988	**Participation level score:** Professional (5 points) Intercollegiate (4 points) Intramural (college), varsity (high school), recreational (intense) (3 points) Recreational (casual) (2 points) Junior high school (1 point) No sports (0 points) Performance index score (intensity level): sport rated according to perceived stress on knee, levels 1-5 (lists of sports provided). Participation score added to intensity level score to calculate performance index.	Not done	Only certain sports listed on performance index scale. Sports not rated according to frequency and duration of participation. Rationale for classification of sports in levels 1-5 not given.

Table 43-2 Published Sports Activity Rating Scales—cont'd

Scale, Year Published	Factors Rated	Reliability, Validity, Responsiveness Testing	Comments
Daniel Sports Activity Rating, 1994	**4 levels:** I: jumping, pivoting, hard cutting II: lateral motion, less jumping or hard cutting than level I III: other sports IV: no sports Lists of sports provided for each level	Not done	Assessed frequency of participation; total hr/yr estimated retrospectively
Marx Sports Activity Scale, 2001	4 factors: running, cutting, decelerating, pivoting Each factor rated according to frequency of participation: <1 time/mo, 1 time/mo, 1 time/wk, 2-3 times/wk, >3 times/wk	Reliability ICC = 0.97. Validity: face, content, construct, divergent; acceptable, correlated with three other sports activity scales Responsiveness testing not done Scale showed inverse correlation with age	Tested in 40 normal subjects. No category available for low-impact activities (swimming, bicycling, low-impact aerobics).
High-Activity Arthroplasty Score, 2010	4 factors: walking, running, stair climbing, general activities; patient selects highest level of function in each domain, sum equals score	High internal consistency Validity: correlated with four other scales Reliability using ICC, responsiveness testing not done	Tested in 22 patients, pilot study

ACL, Anterior cruciate ligament; *ICC*, intraclass correlation coefficient.

levels, and noted that patients in the United States may have difficulty completing the scale because it was designed for sports commonly played in Europe.

Paxton and associates[28] assessed the reliability and validity of this scale in 153 patients followed 2 to 5 years after an acute patellar dislocation. The scale was found to have adequate reliability (ICC, 0.92) and content validity. Briggs and colleagues[7] found the Tegner scale had adequate reliability, validity, and responsiveness following ACL injury and reconstruction.

Ebert and associates[10] reported that the Tegner scale was less responsive to change following articular cartilage restorative procedures in comparison with the Knee Injury and Osteoarthritis Outcome Score (KOOS) subscales of sport/recreation and quality of life. There was no strong evidence that a change in the Tegner scale was associated with patient satisfaction of the outcome of the operation. A systematic review of the use of the Tegner scale following articular cartilage repair procedures[14] found that the majority of studies reported means values only, where nonparametric methods would be more relevant. The investigators concluded that if the instruments is used in a nonstandardized or inappropriate manner, its value as a clinical outcome measure will be compromised.

Naal and coworkers[26] compared data from three activity rating scales (Tegner, University of California, Los Angeles [UCLA],[48] and Marx Activity Rating Scale[24]) in patients who underwent total joint arthroplasty. Physical activity was assessed using the "last 7 days" version of the International Physical Activity Questionnaire (IPAQ).[8] The Tegner scale was found to be reliable and had acceptable validity in patients undergoing total knee arthroplasty (TKA). However, this scale had lower correlation coefficients and lower completion rates than the UCLA scale and was unable to discriminate between patients who were sufficiently active (moderate and vigorous activity levels according to IPAQ classification) and those who were insufficiently active.

Hospital for Special Surgery Sports Scale

Hanley and Warren[15] developed the Hospital for Special Surgery (HSS) knee assessment instrument for an investigation of 48 patients with ACL-deficient knees who underwent arthroscopic partial meniscectomy. The instrument includes a scale composed of four levels of various sports ranked "very stressful," "moderately stressful," "mildly stressful," and "no sports activities." Examples of sports are provided in categories A, B, and C to assist with the ratings. The advantages of this scale include the assessment of sports activities only (separately from occupations) and the attempt to sort sports participation according to the level of intensity. The problems with this scale are that ambiguous terms are used to rate the sports categories ("very stressful" may have different meanings to different patients), an assessment of reasons for change in athletics owing to non–knee-related reasons is not provided, and the detection of knee abusers is not possible. The authors did not conduct reliability, validity, or responsiveness testing of their outcome instrument.

Seto Sports Participation Survey

Seto and associates[37] developed a sports participation survey to determine activity levels in 19 patients who had undergone ACL reconstruction. In this survey, subjects rate their activity level for 13 sports, which are divided into cutting and noncutting categories. Each sports activity receives 0 to 4 points.[12]

4 = full activity with no significant signs or symptoms
3 = full activity with occasional or recurring mild episodes of pain, swelling, or instability
2 = limited activity because of moderate or severe episodes of pain, swelling, or instability
1 = does not participate in activity because of the injured knee
0 = does not participate in activity but not because of the injured knee

Patients also rate their sports participation according to frequency and duration as either competitive (6 to 7 times/week or regular participation in organized competition, 3 points), recreational (3 to 5 times/week, or 2 times/week and more than 2 hours/session, or seasonal sports 5 days or more/months, 2 points), or weekend (1 to 2 times/week for 1 hour or participation in seasonal sports ≤4 days/months, 1 point).

This scale allows the analysis of athletic participation according to frequency of play and the detection of changes in activity levels between evaluations. Knee abusers may be identified from the categories of "mild" or "moderate" symptoms occurring with activity. Because the activity level is rated per sport, reporting of data can be difficult if a population is composed of individuals who play a wide variety of sports. Reliability, validity, and responsiveness testing were not conducted on this survey.

Straub and Hunter's Sports Performance Index

Straub and Hunter[40] devised a sports performance index to determine the outcome of ACL reconstruction. The index is based on scores from two factors: a participation level rating and an intensity level rating. The participation level rating is accomplished on a six-level gradient that ranges from professional (5 points); intercollegiate (4 points); intramural (college), varsity (high school), or recreational (intense, 3 points); casual (2 points); junior high school (1 point); to no sports (0 points). The intensity rating scale sorts various sports into categories according to the authors' perception of the intensity of those activities on the lower extremity. The most intense activities receive 5 points, and the least intense receive 1 point. The two rating scores are summed up to produce a sports performance index.

This scale does not allow for the rating of sports that are not included in the intensity rating scale because the rationale for the classification of activities into the various categories is unknown. The frequency and duration of activities is not included in the sports level assessment. Knee abusers cannot be detected. The authors did not assess the reliability, validity, or responsiveness of this instrument.

Daniel Sports Activity Rating

Daniel and coworkers[9] described a sports rating scheme that was used to determine outcome in both ACL-deficient and ACL-reconstructed knees. The sports activity rating assessed frequency of participation (number of hours played per year) and intensity of the activities. Frequency of participation is determined in a retrospective manner; patients are asked to recall the two most frequent sports they played before their ACL rupture and to provide the number of weeks per year and the number of hours per week that they played each sport. The number of hours per year of participation in the two sports is summed up. A four-level intensity rating is also included in which level I comprises jumping, pivoting, and hard cutting activities; level II, lateral motion but less jumping or hard cutting than level I; level III, "other sports"; and level IV, no sports. A few examples of sports are provided for levels I, II, and III.

The retrospective analysis of hours of participation can be problematic, especially in long-term clinical studies where patients may be asked to recall hours of participation from many years ago. The scale does not allow for the detection of knee abusers or patients who decreased their activity level or stopped athletics owing to reasons not related to their knee condition. Reliability, validity, and responsiveness testing were not conducted by the investigators.

Marx Sports Activity Scale

Marx and associates[24] developed a sports activity rating scale to use as a general research tool to determine outcome for a variety of knee injuries and operations. This scale takes into account frequency of participation and intensity of the activity. Four separate activities are rated: running, cutting, decelerating, and pivoting. Frequency of participation for each activity is classified as "none," "1 time a month," "1 time a week," "2 or 3 times a week," and "4 or more times a week."

Reliability and construct validity were assessed in 40 volunteers with no history of knee problems. The scale showed acceptable reliability (ICC, 0.97) and correlated with the Tegner, Cincinnati, and Daniel sports activity scales. Responsiveness testing was not completed.

As previously described, Naal and coworkers[26] compared data from three activity rating scales (Tegner, UCLA,[48] and Marx Activity Rating Scale[24]) in patients who underwent total joint arthroplasty. The Marx Activity Rating Scale was found to be reliable and had acceptable validity in patients undergoing TKA. However, this scale had the weakest correlation coefficients with other scales, had large floor effects, and was unable to discriminate among patients who were sufficiently active (moderate and vigorous activity levels according to IPAQ classification) and those who were insufficiently active.

Although this scale is useful in rating activities that involve the specific motions selected by the authors, it cannot rate low-impact activities such as swimming, bicycling, or low-impact aerobics. If a patient swam or bicycled several times a week, he or she would receive 0 of a possible 16 points on this scale.

ACTIVITIES OF DAILY LIVING SCALES

Lysholm Knee Score

The Lysholm knee score, first introduced into the medical community in 1982[21] and modified in 1985[42] (Table 43-3), remains one of the most frequently used assessment tools for the results of ACL reconstruction even though it only measures activities of daily living (ADLs). Eight factors are rated to produce an overall score on a point scale of 0 to 100. Then an assignment is given as "excellent" for 95 to 100 points; "good" for 84 to 94 points, "fair" for 65 to 83 points, or "poor" for less than 65 points. The factors of limp, support, and locking are worth a potential of 23 points; pain and instability, 25 points each; swelling and stair climbing, 10 points each; and squatting, 5 points.

CRITICAL POINTS Activities of Daily Living Scales

- Lysholm Knee Score
  - Eight factors rated to produce an overall score on a point scale of 0 to 100
  - Symptoms of pain, swelling, and instability graded according to the activity in which they occur
  - Adequate reliability and responsiveness for ligament and meniscus injuries, patellofemoral pain, and degenerative joint disease
  - High ceiling effects for the domains of limp, instability, support, and locking found in patients with chondral lesion
  - High ceiling effects for the domains of limp, instability, support, and locking in patients with meniscus injuries
  - High ceiling effects and small-moderate effects sizes for the domains of support and locking in patients with anterior cruciate ligament reconstructions
- ADLS Scale of the Knee Outcome Survey
  - Seven symptoms and 10 functions rated
  - Acceptable psychometric properties for a variety of knee disorders
  - Ceiling effects possible in athletes

TABLE 43-3 Lysholm Knee Scoring Scale

Factor	Scale	Points
Limp	None	5
	Slight or periodic	3
	Severe and constant	0
Support	None	5
	Stick or crutch	2
	Weight-bearing impossible	0
Locking	No locking/catching sensations	15
	Catching sensation but no locking	10
	Locking: occasionally	6
	Locking: frequently	2
	Locked joint on examination	0
Instability	Never giving-way	25
	Rarely during athletics or other severe exertion	20
	Frequently during athletics or other severe exertion (or incapable of participation)	15
	Occasionally in daily activities	10
	Often in daily activities	5
	Every step	0
Pain	None	25
	Inconstant and slight during severe exertion	20
	Marked during severe exertion	15
	Marked on or after walking > 2 km	10
	Marked on or after walking < 2 km	5
	Constant	0
Swelling	None	10
	On severe exertion	6
	On ordinary exertion	2
	Constant	0
Stair-climbing	No problems	10
	Slightly impaired	6
	One step at a time	2
	Impossible	0
Squatting	No problems	5
	Slightly impaired	4
	Not beyond 90 degrees	2
	Impossible	0

The symptoms of pain, swelling, and instability are graded according to the activity in which they occur. For example, for the factor of instability, patients may receive 15 of a possible 25 points if they experience instability frequently during athletics or heavy exertion (or are unable to do these activities). Independent studies have demonstrated that the Lysholm system, "may inflate results, particularly if raw scores are combined to obtain an overall final rating"[38] and is "less sensitive for ACL patients…than three other diagnostic categories."[4] Risberg and colleagues[30] found poor sensitivity in detecting changes over time (responsiveness), and concluded that, "The Lysholm score was not sensitive to detect changes over time, and therefore it is not recommended as an outcome measurement after ACL reconstruction."[30]

Other authors have reported adequate reliability and responsiveness of this scale when tested in combined samples of patients with a variety of knee disorders including ligament and meniscus injuries, patellofemoral pain, and degenerative joint disease. Irrgang and coworkers[17] assessed internal consistency, criterion validity, and responsiveness of the Lysholm scale in a group of 397 patients who had a wide variety of knee disorders. Data collected at baseline and then 1, 4, and 8 weeks later were compared with those obtained with the authors' ADL Scale. The Lysholm scale demonstrated adequate criterion validity with the ADL scale (Pearson product-moment correlation coefficients ranged from $R = 0.78$ at baseline to $R = 0.86$ at 8 weeks after baseline) and with the patients' global rating of the overall knee condition. Large ES (> 0.80), indicating adequate responsiveness, were noted at 4 and 8 weeks after baseline testing. Internal consistency of the Lysholm scale was lower than that of the ADL scale, resulting in higher standard error of measurement for all time periods of data collection.

Marx and associates[23] determined reliability, validity, and responsiveness of the Lysholm scale along with the subjective components of the CKRS, the American Academy of Orthopaedic Surgeons (AAOS) sports knee-rating scale, and the ADL scale in a population of patients with a wide variety of knee disorders. All of the scales demonstrated high reliability (ICCs > 0.80), adequate face and content validity, and responsiveness (SRM > 0.80).

Paxton and associates[28] measured the reliability and validity of the Lysholm score in 153 patients followed 2 to 5 years after an acute patellar dislocation. The score demonstrated adequate reliability (ICC, 0.88), content validity, and construct validity. Kocher and colleagues[19] assessed the Lysholm scale in a population of 1657 patients with traumatic and degenerative chondral lesions. Adequate reliability was found for the overall score and all individual components of the scale except for pain and stair climbing. Adequate content validity was found for the overall score. However, unacceptably high ceiling effects were found for the domains of limp, instability, support, and locking and a high floor effect was found for the domain of squatting. Criterion validity was acceptable, with significant correlations between the overall score and SF-12 and the Western Ontario and McMaster Universities Osteoarthritis Index (WOMAC) scales. Construct validity was proven in the nine hypotheses generated by the investigators. Adequate responsiveness was found for the overall score and all of the individual components except for instability.

Briggs and coworkers[6] determined the reliability, validity, and responsiveness of the Lysholm scale in patients with meniscus injuries. Adequate reliability was reported for the overall score and all individual components except locking. Acceptable content validity was found for the overall score. However, high ceiling effects were reported for the domains of limp, instability, support, and locking and a high floor effect was found for the domain of squatting. Criterion validity was adequate, as the scale correlated with the physical component score of the SF-12. Acceptable construct validity was proven, with all eight hypotheses developed by the authors' found to be significant. The overall score had adequate responsiveness, with large ES and SRM. However, the individual domains of instability, locking, limping, support, and swelling had only small to moderate ES and SRM.

Briggs and colleagues[7] found that the Lysholm score had adequate reliability (ICC, 0.9), internal consistency, criterion validity, construct validity, and responsiveness in 1783 patients with ACL tears, 1071 of whom underwent reconstruction. High ceiling effects were found for the domains of support and locking. The domains of locking and support had small to moderate ES.

Ebert and associates[10] reported that the Lysholm score had high ES (1.22) and SRM (1.11) in a group of 81 patients analyzed before and 5 years after autologous chondrocyte implantation. However, there was no strong evidence that a change in the Lysholm was associated with patient satisfaction of the outcome of the operation.

Table 43-4 Activities of Daily Living Scale of the Knee Outcome Survey

Domain	Factors	Possible Responses	Points
Symptoms	1. Pain	I never have (factor) in my knee.	5
	2. Grinding/grating	I have (factor) in my knee, but it does not affect my daily activity.	4
	3. Stiffness	(Factor) affects activity slightly.	3
	4. Swelling	(Factor) affects activity moderately.	2
	5. Slipping	(Factor) affects activity severely.	1
	6. Buckling	(Factor) prevents from performing all daily activities.	0
	7. Lack of strength		
Functional Disability	8. Walk	My knee does not affect my ability to walk.	5
		I have pain in my knee when walking, but it does not affect my ability to walk.	4
		My knee prevents me from walking more than 1 mile.	3
		My knee prevents me from walking more than 1/2 mile.	2
		My knee prevents me from walking more than 1 block.	1
		My knee prevents me from walking.	0
	9. Walk with crutches or cane?	I can walk without crutches or a cane.	3
		My knee causes me to walk with 1 crutch or a cane.	2
		My knee causes me to walk with 2 crutches.	1
		Because of my knee, I cannot walk even with crutches.	0
	10. Limp while walking	I can walk without a limp.	2
		Sometimes my knee causes me to walk with a limp.	1
		Because of my knee, I cannot walk without a limp.	0
	11. Go up stairs	My knee does not affect my ability to go up stairs.	5
		I have pain in my knee when going up stairs, but it does not limit my ability to go up stairs.	4
		I am able to go up stairs normally, but I need to rely on use of a railing.	3
		I am able to go up stairs one step at a time with use of a railing.	2
		I have to use crutches or a cane to go up stairs.	1
		I cannot go up stairs.	0
	12. Go down stairs	My knee does not affect my ability to go down stairs.	5
		I have pain in my knee when going down stairs, but it does not limit my ability to go down stairs.	4
		I am able to go down stairs normally, but I need to rely on use of a railing.	3
		I am able to go down stairs one step at time with use of a railing.	2
		I have to use crutches or a cane to go down stairs.	1
		I cannot go down stairs.	0

From Irrgang JJ, Snyder-Mackler L, Wainner RS, Fu FH, Harner CD. Development of a patient-reported measure of function of the knee. *J Bone Joint Surg Am.* 1998;80: 1132-1145.

Instructions: The questionnaire is designed to determine the symptoms and limitations that you experience because of your knee while you perform your usual daily activities. Please answer each question by checking the statement that best describes you over the last 1 to 2 days. For a given question, more than one of the statements may describe you, but please mark ONLY the statement that best describes you during your usual daily activities.

Activities of Daily Living Scale of the Knee Outcome Survey

Irrgang and coworkers[17] developed the ADL Scale (Table 43-4) to measure limitations in patients with a variety of knee disorders including ligament ruptures, patellofemoral pain, meniscus tears, and articular cartilage damage. The scale rates seven symptoms and 10 functions. The responses to all 17 factors in the scale are summed up, divided by 80 (the total number of possible points), and multiplied by 100 to produce a final score that is expressed as a percentage. These investigators administered the scale to 397 patients at four treatment intervals (over an 8-week period) to determine its internal consistency, validity, and responsiveness. A subset of 52 patients completed the scale before and after one treatment session for reliability testing. The authors reported acceptable results for all psychometric properties. Because the reliability testing was accomplished during one treatment setting, the authors concluded that further analysis of this factor is required. In addition, ceiling effects may occur in athletes or patients involved with strenuous work activities.

Piva and associates[29] tested the responsiveness of the ADL scale in 60 patients with patellofemoral pain by administering the scale before and after 8 weeks of physical therapy. These authors reported a moderate ES (0.63). An increase of at least 7.1 percentage points was determined to represent clinically meaningful improvements in physical function. Williams and colleagues[46] compared the reliability and responsiveness of the ADL scale with the WOMAC and the Lower Extremity Functional Scale (LEFS) in patients with knee osteoarthritis. All three instruments had adequate reliability (ICCs ranged from 0.75 to 0.93). There were no differences in internal or external responsiveness, which tended to decrease over time. The authors concluded that all three outcome measures have similar psychometric properties in this particular patient population.

GLOBAL OUTCOME INSTRUMENTS

Western Ontario and McMaster Universities Osteoarthritis Index

In 1988, Bellamy and coworkers[3] first published the WOMAC, a 24-item, condition-specific questionnaire to be used for hip and knee osteoarthritis. Since its conception, the WOMAC has undergone several revisions and modifications, with the latest version (WOMAC 3.1) available in over 90 languages. The instrument is available in 5-point Likert, 100-mm visual analogue scale (VAS) and 11-box numerical rating scale formats by submitting a request to www.womac.org. It is one of the most widely used instruments in patients with knee or hip osteoarthritis and has proven psychometric properties.[13,20,31]

The WOMAC consists of three subscales: pain (five questions), stiffness (two questions), and physical function (17 questions). The subscale scores can vary, with pain ranging from 0 to 20 points; stiffness, 0 to 8 points; and physical function, 0 to 68 points. Higher scores represent worse pain, stiffness, and functional limitations. These investigators reported adequate face, content, and construct validity as well as responsiveness in patients with hip or knee osteoarthritis.

As described previously, Williams and colleagues[46] compared the reliability and responsiveness of the WOMAC with the ADL scale and the LEFS in patients with knee osteoarthritis. All three instruments had adequate reliability (ICCs ranged from 0.75 to 0.93). There were no differences in internal or external responsiveness. These three outcome measures had similar psychometric properties in this patient population.

Whitehouse and associates[45] introduced a reduced WOMAC function scale and reported acceptable reliability, convergent validity, and responsiveness in patients who underwent total joint arthroplasty. This scale retained the original pain and stiffness questions, but eliminated seven items from the physical function subscale. In a second study, Whitehouse and colleagues[44] found acceptable criterion validity and reliability in a similar group of patients.

Knee Injury and Osteoarthritis Outcome Score

Roos and coworkers[33] developed the Knee Injury and Osteoarthritis Outcome Score (KOOS) instrument to assess symptoms and functional limitations with activity for patients with a variety of knee problems. KOOS is composed of five subscales:

1. Pain (9 questions)
2. Symptoms (7 questions)
3. ADL Function (17 questions)
4. Sport/Recreation Function (5 questions)
5. Knee-related Quality of Life (4 questions)

The ADL questions are composed of the original 17 WOMAC Osteoarthritis Index Physical Function questions. Therefore, the score of the KOOS ADL dimension is equal to that of the WOMAC Osteoarthritis Index. The KOOS questionnaire, available at www.koos.nu, has been translated into many languages. Also available on the website are a user's guide, scoring instructions, and a scoring worksheet.

All questions are answered on a five-level frequency or severity gradient in which terms such as "none," "mild," "moderate," "severe," "extreme" or "always," "often," "sometimes," "rarely," and "never" are provided. Two questions assess frequency of pain and are answered as either "never," "monthly," "weekly," "daily," or "always."

In the first investigation on the psychometric properties of the KOOS in knees with ACL injury, meniscus injury, or posttraumatic osteoarthritis, Roos and associates [33] reported adequate reliability for all five subscales (ICC ≥0.75). Construct validity tested against the SF-36 subscales showed varying correlation coefficients. Responsiveness of the five subscales 6 months postoperatively was acceptable because all ES were 0.84 or greater. Later studies by Roos and associates[34] provided evidence of satisfactory reliability, validity, and responsiveness of the KOOS for patients who had total knee replacement, meniscectomy, or posttraumatic osteoarthritis.[32,34] Salavati and coworkers[35] found this instrument had adequate reliability, construct validity, and internal consistency after ACL reconstruction in a group of 57 athletes. Acceptable psychometric properties were also reported in a group of 40 patients after autologous chondrocyte implantation or microfracture.[2] Ebert and associates[10] found the KOOS subscales of sport/recreation and quality of life were the most responsive patient-reported outcome scales when compared with the Lysholm score, the Tegner scale, and the SF-36. These KOOS subscales also were the most predictive of patient satisfaction following autologous chondrocyte implantation. According to the KOOS User's Guide, August 2012, the questionnaire has been assessed in more than 20 studies worldwide.

The questionnaire format does not provide an analysis of the activity level in which symptoms occur, other than daily activities. Although the scales assess certain sports functions, an activity rating for athletics is not provided, and therefore, it is unknown what activities patients are actually participating in or whether a change in activity level occurred between evaluations. Ambiguous terminology to define gradient levels can be problematic because patients may interpret terms

CRITICAL POINTS Global Outcome Instruments

- WOMAC
  - 24-item, condition-specific questionnaire available in 5-point Likert, 100 mm VAS, and 11-box numerical rating scale formats.
  - Three subscales: pain (5 questions), stiffness (2 questions), and physical function (17 questions).
  - Acceptable psychometric properties for variety of knee injuries and disorders.
- Knee Injury and Osteoarthritis Outcome Score (KOOS)
  - Five subscales: pain (9 questions), symptoms (7 questions), activities of daily living (17 questions), sport/recreation (5 questions), knee-related quality of life (4 questions).
  - Acceptable psychometric properties for anterior cruciate ligament (ACL) injury and reconstruction, meniscus injury, posttraumatic osteoarthritis, total knee arthroplasty, autologous chondrocyte implantation.
  - Does not provide an analysis of the activity level in which symptoms occur, other than daily activities.
  - Activity rating for athletics is not provided.
- Lower Extremity Functional Scale
  - 20-item self-report measure
  - Acceptable psychometric properties for variety of knee injuries and disorders
- American Academy of Orthopaedic Surgeons Lower Limb Outcomes Questionnaire
  - Global instrument that combines seven items into three subscales: pain attributed to the lower limb, stiffness and swelling, and function.
  - Adequate construct validity, reliability, and responsiveness not tested.
- VAS for Quality of Life and Subjective Knee Symptoms
  - Mohtadi quality of life: 31 questions for ACL-deficient knees. Limited testing done of psychometric properties.
  - Subjective knee score: 28 questions for a variety of knee disorders. Limited testing done of psychometric properties.
  - Multiple problems with VAS questionnaires; not recommended.

such as "moderate," "severe," and "extreme" differently. Some may assign a grade according to the frequency of the problem, others may assign a grade according to the intensity of the problem, and still others may use a combination of frequency and intensity to assign a rating.

Lower Extremity Functional Scale

The LEFS was introduced by Binkley and coworkers[5] in an effort to provide a condition-specific measure that would be easy to administer and score and apply to a wide range of lower-extremity orthopedic conditions. It is a 20-item self-report measure in which each item is scored on a five-point gradient: 0, extreme difficulty or unable to perform activity; 1, quite a bit of difficulty; 2, moderate difficulty; 3, a little bit of difficulty; and 4, no difficulty. The total score may vary from 0 to 80 points, with higher scores indicating better levels of lower extremity function. The authors reported the scale had acceptable reliability and construct validity and had superior responsiveness than the SF-36 in a group of patients with a variety of lower-extremity injuries or disorders. Stratford and associates[39] found no difference in scores between the LEFS and WOMAC physical function subscale in patients who underwent total joint arthroplasty. Watson and colleagues[43] reported high reliability and responsiveness of this scale in patients with anterior knee pain treated with physical therapy. Yeung and associates[47] also reported adequate reliability, construct validity, and responsiveness of the LEFS in a sample of orthopedic inpatients treated for a variety of knee injuries and disorders. As described previously, Williams and colleagues[46] compared the reliability and responsiveness of the LEFS with the ADL scale and WOMAC in patients with knee osteoarthritis. All three instruments had adequate reliability (ICCs ranged from 0.75 to 0.93) and the conclusion was reached that all have similar psychometric properties in this cohort.

American Academy of Orthopaedic Surgeons Lower Limb Outcomes Questionnaire

The AAOS developed a Lower Limb Core Scale (now called the Lower Limb Outcomes Questionnaire), a global instrument that combines seven items into three subscales.[18] The subscales include pain attributed to the lower limb, stiffness and swelling, and function. The Lower Limb Outcomes Questionnaire, scoring algorithms, and description of normative data are available on the website of the AAOS (www.aaos.org).

Johanson and associates[18] administered this questionnaire to patients with ligament or meniscus injury or patellofemoral disorders. These investigators reported good construct validity, with adequate correlation coefficients of this scale to other instruments such as the SF-36 and the WOMAC. However, there were limitations to this study. Reliability was not assessed with ICC but rather with correlation coefficients that the authors expressed was a potential limitation. Responsiveness was not determined in a large sample size, and floor and ceiling effects were not calculated.

Visual Analogue Scales for Quality of Life and Subjective Knee Symptoms

Mohtadi devised a quality of life outcome instrument for ACL-deficient knees.[25] The questionnaire is composed of 31 questions in a VAS format and sorted into five domains. There are five items in the area of symptoms and physical complaints, four items in the area of work, 12 items in the area of sports, six items in the area of lifestyle, and five items in the area of social and emotion.

The instrument was tested for reliability and responsiveness in 25 patients with chronic ACL-deficient knees. Responsiveness was tested in 25 patients who completed the questionnaire 6 months apart and included patients with ACL-deficient or reconstructed knees. The author reported that the scale had adequate reliability using a paired *t* test (instead of ICC) and adequate responsiveness, although ES statistics were not provided. Face and construct validity was assessed in 50 patients with satisfactory results. Other validity measures such as content (floor and ceiling effects), criterion, and item-discriminant were not assessed.

A subjective knee score comprising 28 questions in a VAS format was originally described by Flandry and colleagues[11] and later by Hoher and coworkers.[16] The questionnaire combines symptoms and athletic and daily activity functions into one overall score. The instrument is weighted to an assessment of ADL because 12 questions (43%) refer to ADLs, but only 5 (18%) assess sports activities. The questionnaire's reliability was measured in 25 volunteers with normal knees and in 21 patients with a variety of knee disorders. The correlation coefficients of the score were 0.86 in the volunteers and 0.92 in the patients. Although the score was able to detect a significant difference between normal and injured subjects, only a highly competitive athlete could score the maximum of 100 points. Construct validity, tested against the Lysholm score and an older version of the CKRS,[27] showed adequate correlation coefficients. Other validity analysis were not conducted. Responsiveness effect size data were not provided.

There are problems with these global VAS questionnaires. VAS formats do not allow for an analysis of symptoms or functional limitations according to activity level. Therefore results of studies from different clinicians cannot be accurately compared with the knowledge of the percent of patients who have symptoms with strenuous, moderate, light sports activities or with ADL. Because these instruments combine a variety of factors including symptoms, work, athletics, social, and emotional issues into one final score, there is no effective manner to address these items separately. Mohtadi's final score[25] is weighted for sports, which is problematic for patients who do not return to sports for reasons not related to the knee condition. On the other hand, Hoher and coworker's[16] final score is weighted for ADLs and thereby loses sensitivity in defining functional limitations in athletic populations.

The VAS format does not allow for the detection of knee abusers, which can positively bias the final results and conclusions of the effectiveness of a specific treatment. These scales do not produce a measurable sports activity level according to frequency of participation and stress incurred to the lower extremity or allow the detection of a change in activity levels from one time period to another. In addition, overall patient satisfaction and perception of the knee condition are not addressed. These studies did not measure reliability, validity, or responsiveness of either the individual questions or domains.

INTRODUCTION

Many grading systems have been proposed to classify lesions of the articular cartilage in the knee joint at arthroscopy; however, only a few are commonly used in modern orthopedic literature (Table 44-1). The systems published in the 1960s and 1970s introduced grading schemes for lesions located only in the patellofemoral joint and documented the most frequent locations of damage in this compartment.[9,10,12,23] The first of these patellofemoral classification systems, proposed by Outerbridge,[23] remains one of the most commonly used schemes to grade lesions located in all three compartments of the knee (patellofemoral, medial tibiofemoral, and lateral tibiofemoral).[7] As arthroscopic and imaging techniques have evolved, a few investigators[11,22] and societies (French Society of Arthroscopy,[8] International Cartilage Repair Society [ICRS][3,4]) have proposed articular cartilage rating systems which are far greater in sophistication in classifying lesions (described later). These systems are useful for formal clinical investigations to determine the etiology and prognosis of partial and full-thickness cartilage injuries after various knee injuries[15] and to determine the indications and outcomes of cartilage resurfacing procedures such as mosaicplasty and autologous chondrocyte implantation (ACI).[5] This is especially true when practical and financial constraints limit or prohibit the use of advanced magnetic resonance imaging (MRI) or objective measurements done at surgery. These techniques are not discussed in this chapter, although we recognize their significance in this area.[24,28] This chapter focuses on the most commonly used arthroscopic articular cartilage rating systems today.

COMMONLY USED ARTICULAR CARTILAGE RATING SYSTEMS

Outerbridge

In 1961, Outerbridge[23] introduced a system for grading articular cartilage lesions in the patellofemoral joint. The four-gradient scale was based on the appearance of the cartilage and, in two of the levels, the size of the lesion. A *grade 1 lesion* was defined as softening and swelling of the cartilage. A *grade 2 lesion* involved fissuring and fragmentation in an area less than ½ inch in diameter. A *grade 3 lesion* involved fissuring and fragmentation in an area greater than ½ inch in diameter. In a *grade 4 lesion,* the cartilage was eroded down to subchondral bone. This rating system did not specify the location, depth, or exact size of the lesion.

Cincinnati Knee Rating System

In 1989, Noyes and Stabler[22] proposed an arthroscopic articular cartilage classification system that included four variables: the appearance of the cartilage, the depth of the lesion, the size (diameter) of the lesion, and the location of the lesion. A point scaling system was devised for research purposes to facilitate statistical analysis (Table 44-2).

The appearance of the cartilage is classified into one of three grades: *grade 1*, cartilage surface intact, closed lesion; *grade 2*, cartilage surface damaged, open lesion; or *grade 3*, subchondral bone exposed. Each grade is divided into subtypes *A* or *B*, depending upon the depth of involvement.

Grade 1A corresponds to a moderate degree of softening of the cartilage compared with its normal resilient appearance (Fig. 44-1, *A*). *Grade 1B* designates complete loss of resilience, resulting in full indentation of the surface when probed (see Fig. 44-1, *B*). This grade is reserved for lesions in which a severe softening of the cartilage exists without gross surface breakage. This description indicates the initial stage of cartilage deterioration characterized by diminished glycoproteins and early collagen fiber deterioration.[22] These lesions, which commonly involve the undersurface of the patella, have a high potential to progress to an open lesion.

A *grade 2A lesion* (Fig. 44-2, *A*) is an open disruption of the cartilage surface, including cracks, surface blisters, fissures, fibrillations, and fragmentations that extend less than one half of the thickness of the cartilage. *Grade 2B lesions* (Fig. 44-2, *B* and *C*) are similar in appearance but extend greater than one half of the thickness of the cartilage. Superficial lesions with fibrillation-type changes are usually easily distinguishable from deeper lesions that involve lacerations, clefts, and fragmentation down to bone. Chondrosclerosis is classified as a grade 2 lesion because the surface is abnormal. Lesions that have two or three deep lacerations that extend through the cartilage surrounded by otherwise normally appearing cartilage are graded as 2B.

TABLE 44-1 Commonly Used Articular Cartilage Rating Systems

Rating System	Surface Description of Articular Cartilage	Lesion Size (Diameter)	Location	Comments
Outerbridge	1 = Softening and swelling 2 = Fragmentation and fissuring 3 = Fragmentation and fissuring 4 = Bone exposed	1 = none 2 = ≤0.5 inch 3 = >0.5 inch 4 = none	Usually starts on medial facet of patella; later extends to lateral facet and then whole patella. Concomitant femoral condylar lesions usually not present; may have occasional "mirror" lesion on intercondylar area; erosion upper border medial femoral condyle.	Rating developed for patellar lesions only. Hypothesized majority initiated by pressure or friction of patella in high knee flexion angles.
Cincinnati Knee Rating System	1 = Cartilage surface intact 1A = Definite softening with some resilience remaining 1B = Extensive softening with loss of resilience (deformation) 2 = Cartilage surface damaged; cracks, surface blisters, fissures, fibrillations, fragmentations 2A = Less than half thickness 2B = Half thickness or greater 3 = Bone exposed 3A = Bone surface intact 3B = Bone surface cavitation	<10 mm, ≤15 mm ≤20 mm ≤25 mm >25 mm	Patella A = Proximal third B = Middle third C = Distal third Trochlea Medial and lateral femoral condyles A = Anterior third B = Middle third C = Posterior third Medial and lateral tibial plateaus A = Anterior third B = Middle third C = Posterior third	Also record degree of knee flexion where the lesion is in weight-bearing contact. Scoring system for lesions provided for research purposes (see Table 44-2).
International Cartilage Repair Society	Four grades for chondral defects, four types for osteochondral defects (see Table 44-5)	Record in mm	Mapping system (see Fig. 44-7) Medial, lateral femoral condyle Trochlea Medial, lateral tibial plateaus Patella Sagittal, frontal plane	Incorporated into IKDC rating system

IKDC, International Knee Documentations Committee.

CRITICAL POINTS Commonly Used Articular Cartilage Rating Systems

Outerbridge

- Four-gradient scale for grading articular cartilage lesions in patellofemoral joint based on the appearance of the cartilage and the size of the lesion

Cincinnati Knee Rating System

- Articular cartilage classification system based on four variables: the appearance of the cartilage, the depth of the lesion, the size (diameter) of the lesion, and the location of the lesion
- Point scaling system for research purposes
- Cartilage classified into one of three grades: grade 1, cartilage surface intact, closed lesion; grade 2, cartilage surface damaged, open lesion; or grade 3, subchondral bone exposed. Each grade is divided into subtypes A or B, depending upon the depth of involvement.

International Cartilage Repair Society

- Classification system of articular cartilage lesions according to the depth of lesion (graded from 0 to 4), the size of the lesion (in millimeters), and the area of damage (documented on a mapping system)
- Mapping system requires validation because it contains 46 zones that have minimal anatomic and functional referencing.

TABLE 44-2 Point Scaling System of the Cincinnati Articular Cartilage Classification System

Articular Cartilage Grade	Articular Cartilage Description	10-mm Lesion (Points)	15-mm Lesion (Points)
1. Closed lesion			
A	Softening	0	0
B	Softening, loss of resilience, indentation when probed	1	2
2. Open lesion			
A	Fissures, fragmentation extending less than half the depth of articular surface	2	4
B	Fissures, fragmentation extending more than half the depth of articular surface	3	6
3. Bone exposed			
A	Normal bony contour	5	10
B	Cavitation or erosion of bone surface	5	10

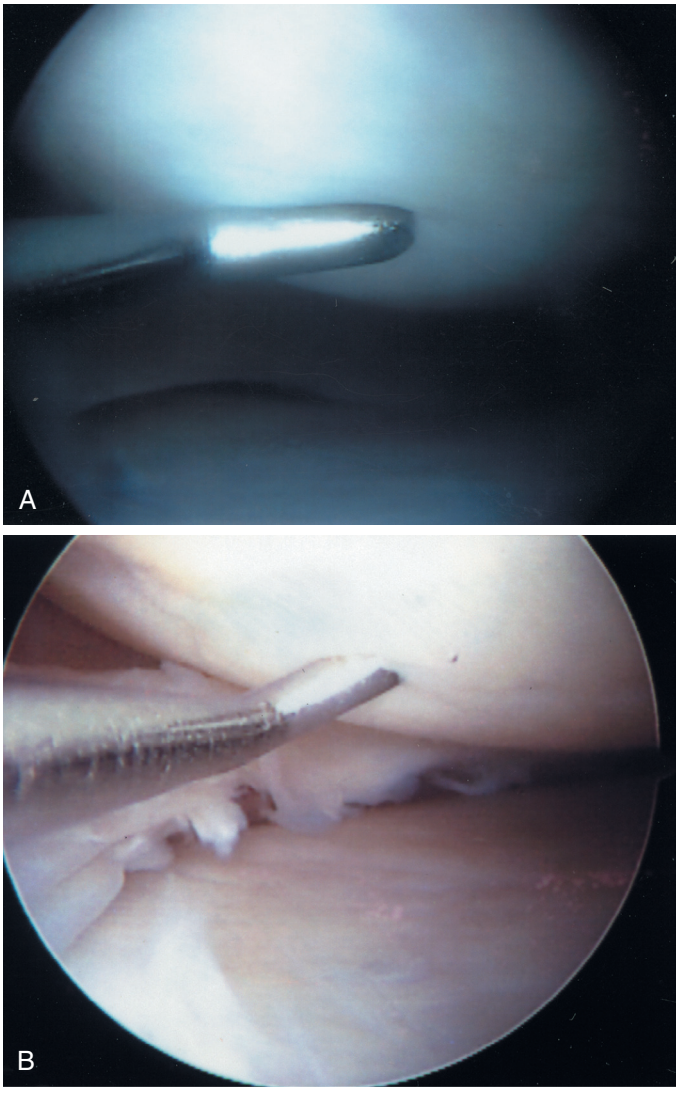

FIG 44-1 A, Arthroscopic image of a grade 1A articular cartilage lesion according to the Cincinnati Articular Cartilage Rating System. **B**, Arthroscopic image of a grade 1B articular cartilage lesion,

A *grade 3A lesion* (Fig. 44-3, *A*) indicates a surface with exposed bone in which the normal bony contour remains. The most severe lesion, *grade 3B* (Fig. 44-3, *B* and *C*), indicates cavitation or erosion of the bone surface. An example of a grade 3B lesion is an osteochondritis dissecans lesion where there is loss of the subchondral bone. Other examples are lesions in which grooving of the bony surface is visualized or those involving fractures that extend through the subchondral bone.

The size of all lesions is determined using a calibrated nerve hook probe. The size is recorded according to one of five categories ranging from less than 10 mm to greater than 25 mm (see Table 44-1). A schematic illustration of all grades is shown in Figure 44-3, *D*.

The anatomic location of the lesion is also recorded. The femoral articular surface is divided into the trochlea and anterior, middle, and posterior thirds of the femoral condyles and tibial condyles. The patella is anatomically classified in two ways: in a proximal-to-distal direction and according to facet (odd, medial, lateral). The range of degrees of knee flexion where patellofemoral and tibiofemoral lesions are in contact is documented. This information is provided to the physical therapist postoperatively so that modifications of exercises may be made to avoid placing forces on the affected area. Any lesion in contact

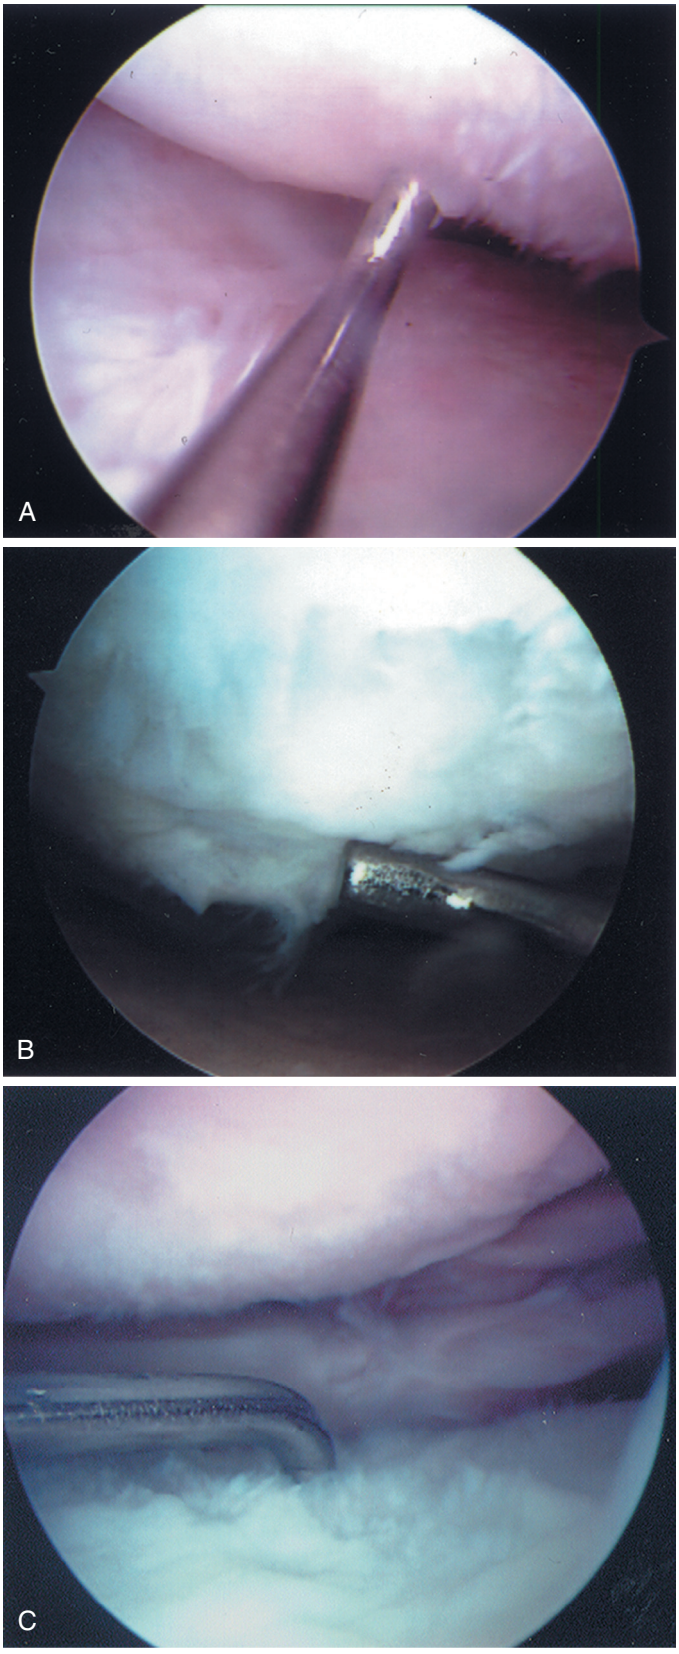

FIG 44-2 A, Arthroscopic image of a grade 2A articular cartilage lesion according to the Cincinnati Articular Cartilage Rating System. **B**, Arthroscopic image of a grade 2B articular cartilage lesion. **C**, A knee with a combined grade 2A lesion on the femoral condyle and a grade 2B lesion on the tibial plateau.

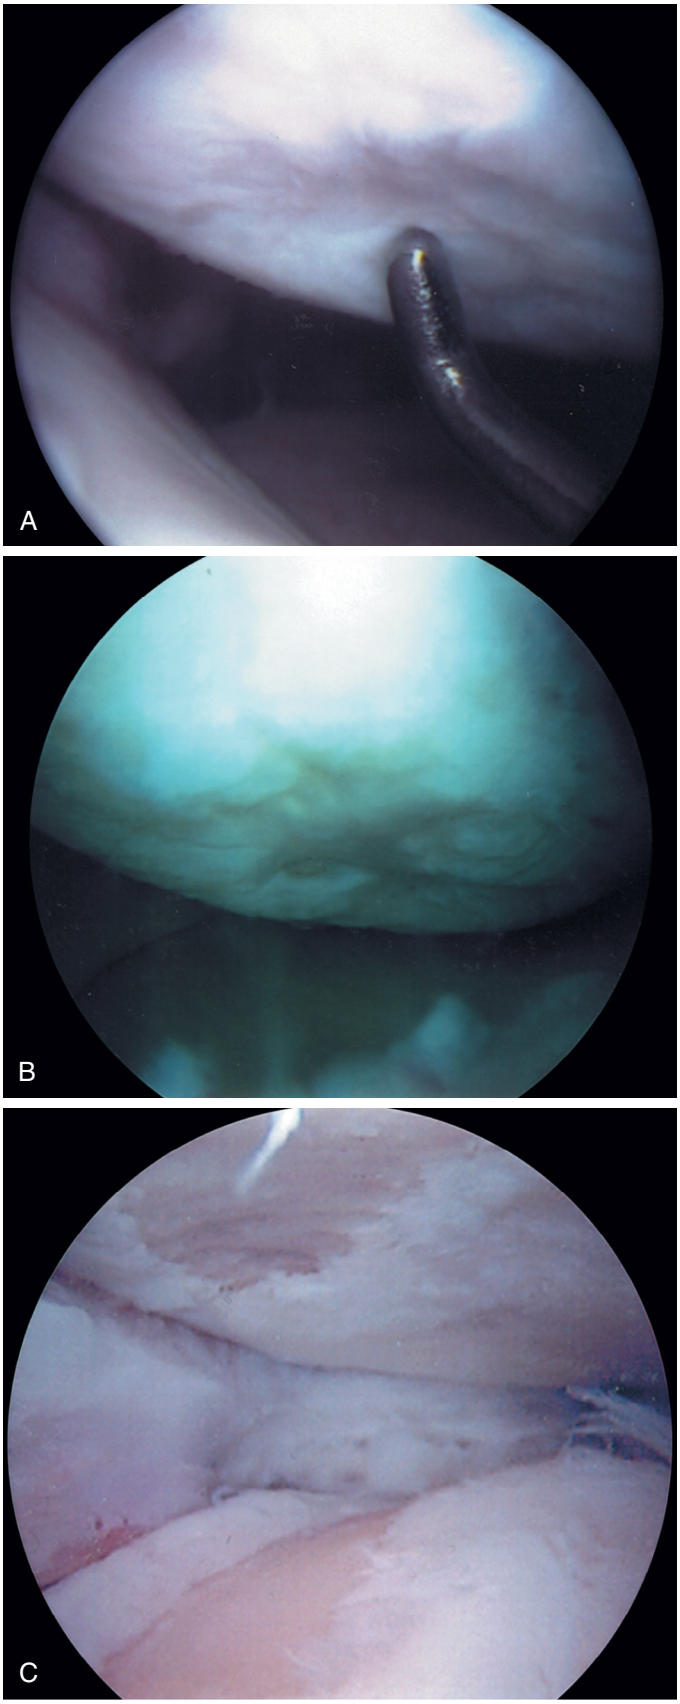

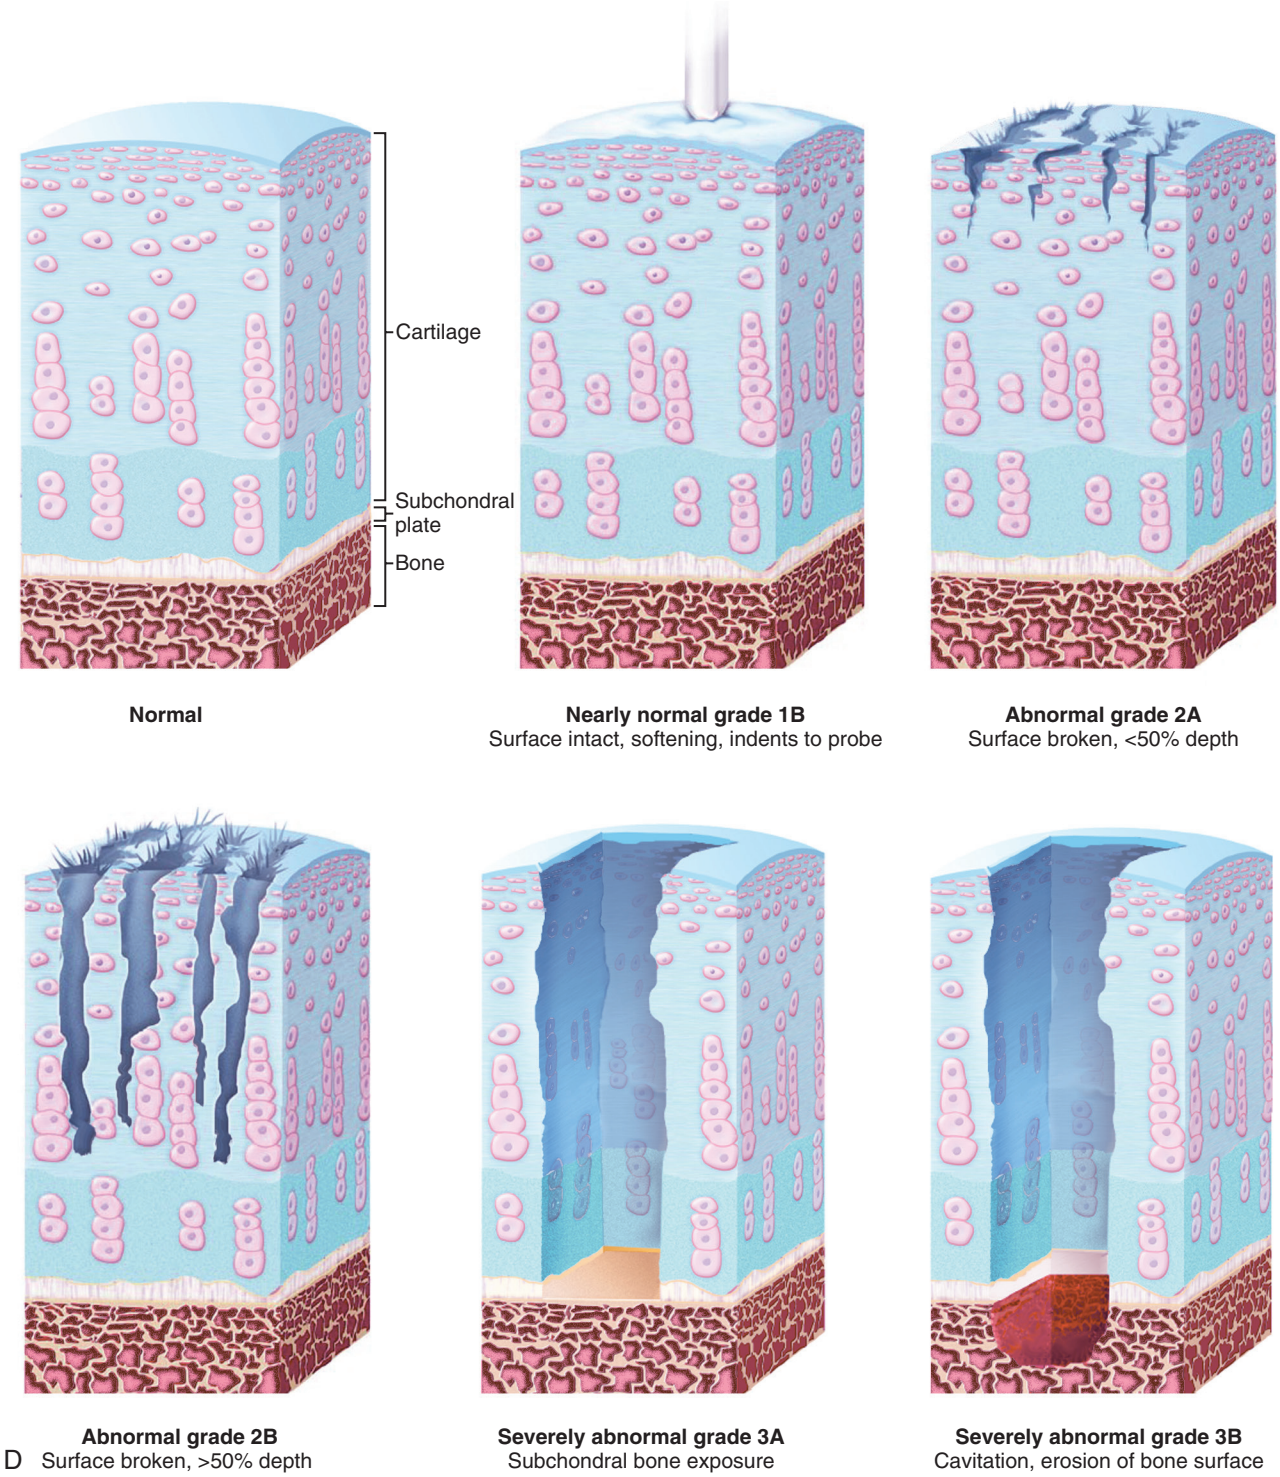

FIG 44-3 **A**, Arthroscopic image of a grade 3A articular cartilage lesion according to the Cincinnati Articular Cartilage Rating System. **B**, Arthroscopic image of a grade 3B articular cartilage lesion. **C**, A grade 3A lesion on both the femoral condyle and tibial plateau in a meniscectomized knee.

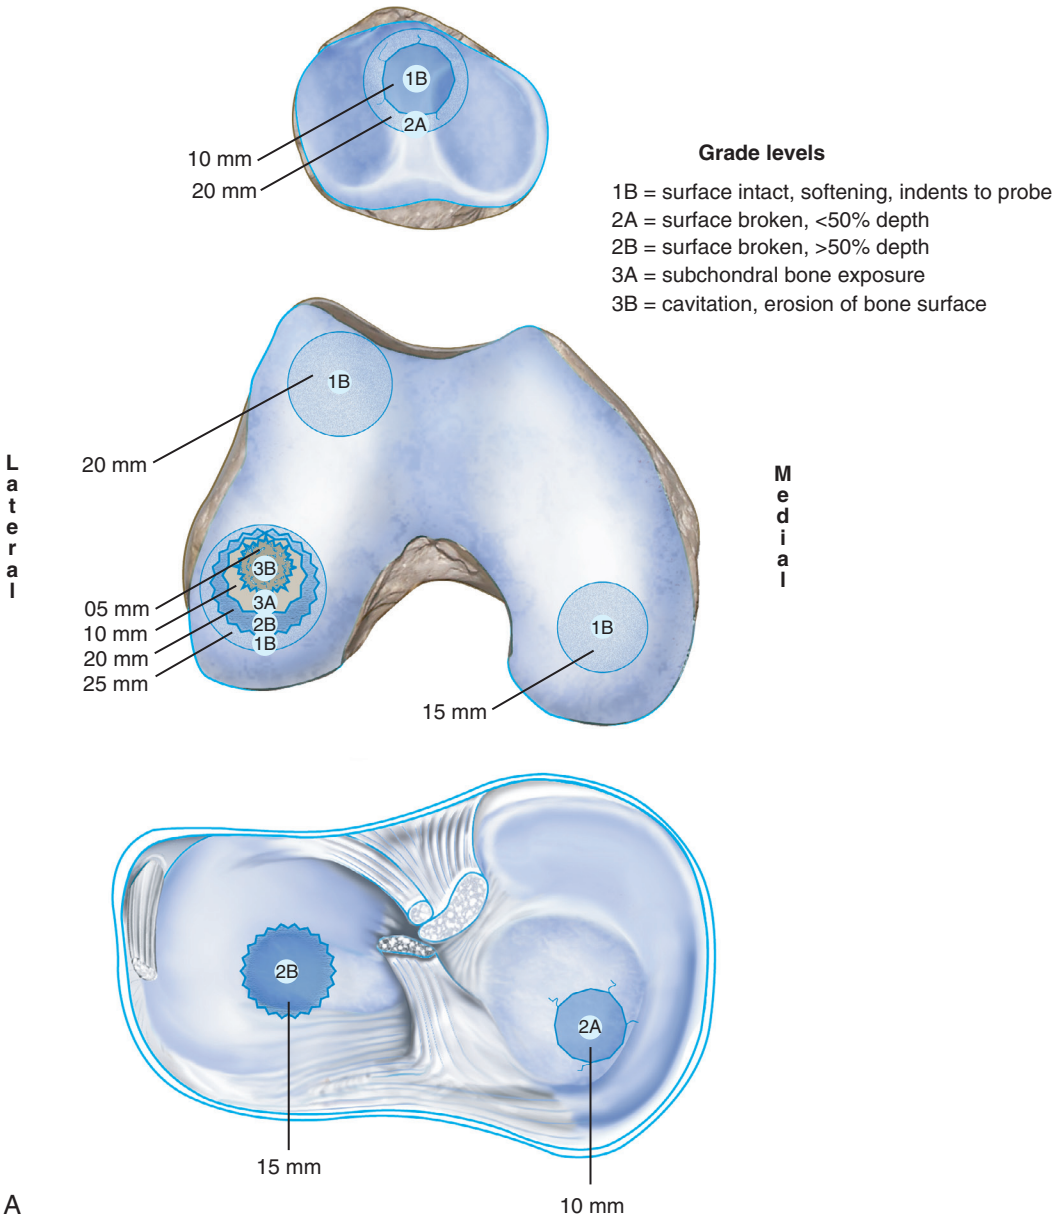

D

FIG 44-3, cont'd **D**, Schematic illustrations of grades according to the Cincinnati Knee Rating System.

from 0 to 45 degrees of flexion may affect normal walking activities and may have more implications than those that contact at greater degrees of knee flexion.

Figure 44-4, *A* illustrates how this classification system is used to record the visual appearance of articular cartilage lesions. The patella has a 10-mm grade 2A lesion that is surrounded by a larger closed area of softening (1B) that extends 20 mm in diameter. The trochlea has a large area of extensive softening as well, graded as a 1B that is 25 mm in diameter. The medial femoral condyle also has a large area of extensive softening, measuring 15 mm in diameter. A "kissing" lesion is found on the medial tibial plateau of a grade 2A lesion that is 10 mm in diameter. The lateral femoral condyle has a complex lesion; 10 mm of exposed bone (3A) is surrounded by an open lesion of fragmentation of 20 mm in diameter (2B), which is in turn surrounded by a closed lesion of soft cartilage that extends to 25 mm (1B). The lateral tibial plateau has a large 2B lesion,

A

Anatomic Location	Anatomic Location Score	Compartment Score	Compartment Percent*
Patella + Femoral sulcus	3 + 2	5	75%
Medial femur + Medial tibia	2 + 2	4	80%
Lateral femur + Lateral tibia	7 + 5	12	40%

B *To calculate percent: $\frac{(20 - \text{Score of compartment})}{20} \times 100$

FIG 44-4 **A**, An example of grading articular cartilage lesions found at arthroscopy. **B**, Scoring system for articular cartilage lesions (see Table 44-2).

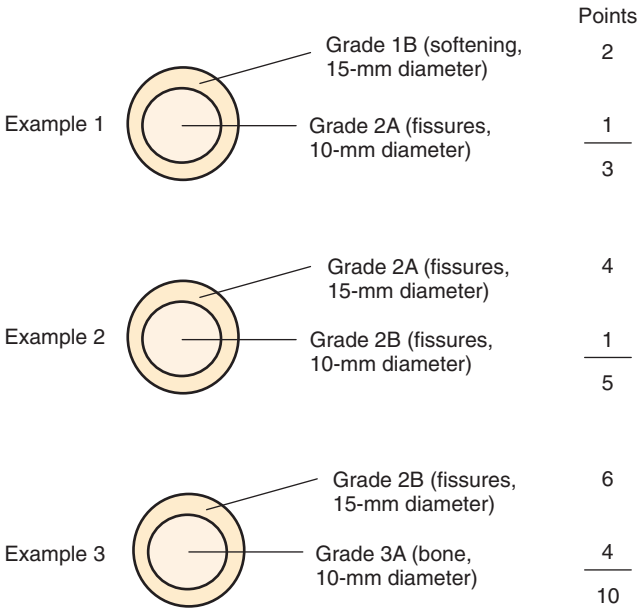

FIG 44-5 Three examples of scoring complex lesions (see Table 44-2 and text).

15 mm in diameter. For research purposes, the lesions may be quantified on a scaling system to allow statistical analysis (see Table 44-2). Any lesion that is less than 10 mm in diameter, or graded 1A, is not considered clinically significant and therefore no points are given. Figure 44-4, *B* illustrates the points awarded for the lesions noted in the example.

Occasionally, complex lesions are encountered such as a 2A circumferential fibrillation surrounding a 10-mm 2B lesion. For scoring purposes, additional points for complex lesions may be incorporated so that the total points to be subtracted are increased but still less than the corresponding 15-mm lesion. Examples for scoring complex lesions are shown in Figure 44-5.

This classification system allows clinical investigations to analyze results according to the condition of the articular cartilage and to determine the difference in outcome among patients with normal cartilage, noteworthy cartilage damage (grade 2B), and severe cartilage damage (grade 3).[18-20] For instance, in a study of 66 patients who had an anterior cruciate ligament (ACL) revision reconstruction,[21] we found that patients with grade 2B or 3A lesions had significantly poorer subjective and functional outcomes a mean of 42 months postoperatively compared with those with normal or grade 1 surfaces (Table 44-3). The factors included pain ($P = .03$), stair climbing ($P = .01$), kneeling ($P = .01$), running ($P = .001$), jumping ($P = .01$), twisting and turning ($P = .01$), and the overall Cincinnati Knee Rating Score (CKRS; $P = .0001$). Analysis of the preoperative data found significant differences among these subgroups as well for giving-way ($P = .004$), walking ($P = .04$), stair climbing ($P = .04$), kneeling ($P = .01$), running ($P = .004$), jumping ($P = .001$), twisting and turning ($P = .01$), and the overall CKRS ($P = .0001$). Differences were also noted in the sports activity levels patients resumed postoperatively (Table 44-4). The stratification of lesions according to the six compartments may be presented as shown in Figure 44-6. These findings allow appropriate patient counseling regarding the expected outcome of the operation according to, among other factors, the condition of the articular cartilage. Larger sample sizes would allow further analysis of the effect of not only the grade of lesions but their location as well.

TABLE 44-3 Effect of the Condition of the Articular Cartilage at the Index Operation on the Subjective Scores and Overall Rating at the Latest Follow-up Examination after Anterior Cruciate Ligament Revision Reconstruction

Cincinnati Knee Rating System	Point Scale	Patients Who Had Normal Articular Cartilage (Mean ± SD)	Patients Who Had Grade 2B or 3A Cartilage Lesions (Mean ± SD)	*P* Value
Pain	0-6	5.9 ± 0.5	4.6 ± 2.1	.03
Swelling	0-6	5.8 ± 0.6	5.2 ± 1.4	NS
Partial giving-way	0-6	5.9 ± 0.4	5.2 ± 1.5	NS
Full giving-way	0-6	6	5.5 ± 1.4	NS
Walking	0-40	38 ± 4	34 ± 8	NS
Stair climbing	0-40	36 ± 5	29 ± 11	.01
Kneeling	0-40	28 ± 14	21 ± 14	.01
Running	40-100	84 ± 18	61 ± 21	.001
Jumping	40-100	78 ± 21	57 ± 22	.01
Twisting, turning	40-100	73 ± 21	55 ± 20	.01
Overall rating	0-100	85 ± 9	71 ± 12	.0001

NS, Not significant; *SD,* standard deviation.

TABLE 44-4 Effect of the Condition of the Articular Cartilage at the Index Operation on the Sports Activity Level at the Latest Follow-up Examination after Anterior Cruciate Ligament Revision Reconstruction

Type of Sports Activity	Patients Who Had Normal Articular Cartilage (*n* = 28)	Patients Who Had Grade 2B or 3A Cartilage Lesions (*n* = 37)
Jumping, pivoting, cutting	8 (29%)	3 (8%)
Running, twisting, turning	7 (25%)	6 (16%)
Swimming, bicycling	9 (32%)	18 (49%)
No sports	4 (14%)	10 (27%)

International Cartilage Repair Society

The ICRS was founded in 1997 to develop a standardized system for the evaluation of articular cartilage injury and repair.[3,4] The ICRS Clinical Cartilage Injury Evaluation System-2000 was developed during a workshop held in 2000. The system consists of the ICRS Cartilage injury questionnaire, the Short Form-36 (SF-36) Health Survey, and the IKDC Subjective Knee Evaluation Form, all completed by the patient. The surgeon completes the ICRS Knee Surgery History Registration, the IKDC Knee Examination Form-2000, the ICRS articular cartilage injury mapping system, the ICRS articular cartilage injury classification, the ICRS osteochondritis dissecans classification (if required), and the ICRS macroscopic cartilage assessment score (if required). All of the forms are available on the society's website at www.cartilage.org/?pid=223.

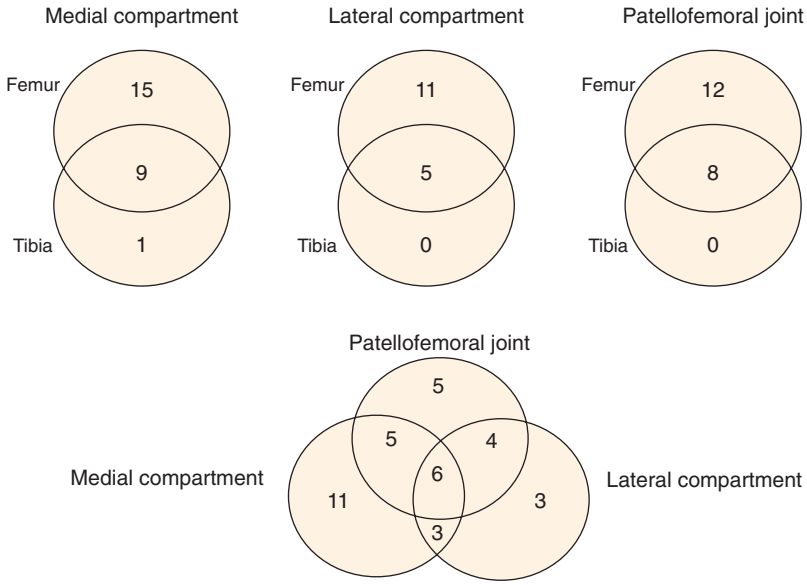

FIG 44-6 Venn diagrams of the number of patients who had an abnormal articular cartilage surface, according to each separate compartment. Thirty-seven patients (56%) had abnormal articular cartilage, defined as fissuring and fragmentation of more than half of the involved surface or any exposure of subchondral bone. (From Noyes FR, Barber-Westin SD, Roberts CS. Use of allografts after failed treatment of rupture of the anterior cruciate ligament. *J Bone Joint Surg Am.* 1994;76-A:1019-31.)

TABLE 44-5 International Cartilage Repair Society Cartilage Defect Description

Grade	Description
Chondral Defects	
Grade 0	Normal
Grade 1	Superficial lesions
Grade 1A	Soft indentation
Grade 1B	Superficial fissures and cracks
Grade 2	Cartilage lesions <50% of cartilage depth
Grade 3	Cartilage lesions >50% of cartilage depth
Grade 3A	Not extending down to calcified cartilage
Grade 3B	Down to calcified cartilage layer
Grade 3C	Down to but not through subchondral bone
Grade 3D	Down to subchondral bone with cartilage blisters
Grade 4	Defects penetrating subchondral bone
Grade 4A	Penetration of subchondral bone in part of the defect
Grade 4B	Subchondral bone penetration involving complete defect
Osteochondral Defects	
Type 1	Stable continuity, softened area covered by intact cartilage
Type 2	Partial discontinuity, stable on probing
Type 3	Complete discontinuity, "dead in situ," not dislocated
Type 4A	Dislocated fragment, loose within the bed or empty defect
Type 4B	Loose and dislocated fragment >10 mm in depth

The ICRS system focuses on the depth of lesions (Table 44-5), the size of the lesion (recorded in millimeters), and the area of damage (documented on a mapping system; Fig. 44-7).[5,17] The ICRS mapping system requires validation because it contains 46 zones that have minimal anatomic and functional referencing.[11] Brittberg and Winalski[5] expressed that "If the total joint involvement can be assessed with percentages and/or with such a scoring system, perhaps with the aid of a computer-based system, the progression or improvement of cartilage disease can be followed."[5]

The ICRS proposed and validated a scoring system for the assessment of cartilage resurfacing procedures such as mosaicplasty, osteochondral autograft transfer, and ACI. The assessment includes consideration of the volume of the defect that is filled with repair tissue, the integration of repair tissue with surrounding articular cartilage, and the macroscopic surface appearance (Table 44-6).[5,26,29] A grading system is incorporated that allows both statistical analysis of the total points obtained (scale, 1-12 points) and placement of patients into International Knee Documentations Committee (IKDC) rating system overall rating categories of normal, nearly normal, abnormal, or severely abnormal.

RELIABILITY AND VALIDATION STUDIES OF CARTILAGE RATING SYSTEMS

Only a select number of reliability and validation studies of various articular cartilage rating systems have been conducted to date.[1,2,6,15,16,25,29] Cameron and colleagues[6] used six cadaveric knees aged 50 to 79 years in their study in which standard arthroscopy was first performed followed by arthrotomy and measurement of lesions using calipers to assign the appropriate Outerbridge grade. Nine orthopedic surgeons reviewed each videotape twice during the same session and graded any lesions viewed. The results demonstrated moderate accuracy (68%) and agreement (kappa score, 0.602) of the observers in correctly grading the lesions from the arthroscopic videotapes compared with the grade assigned during the arthrotomy. The lower grade lesions were diagnosed with less accuracy than the higher grade lesions. The observers tended to grade lesions higher than that assigned during the arthrotomy. The authors concluded that orthopedic surgeons can "accurately grade chondral lesions" with the Outerbridge classification system. The number of years of orthopedic experience did not significantly influence the study findings.

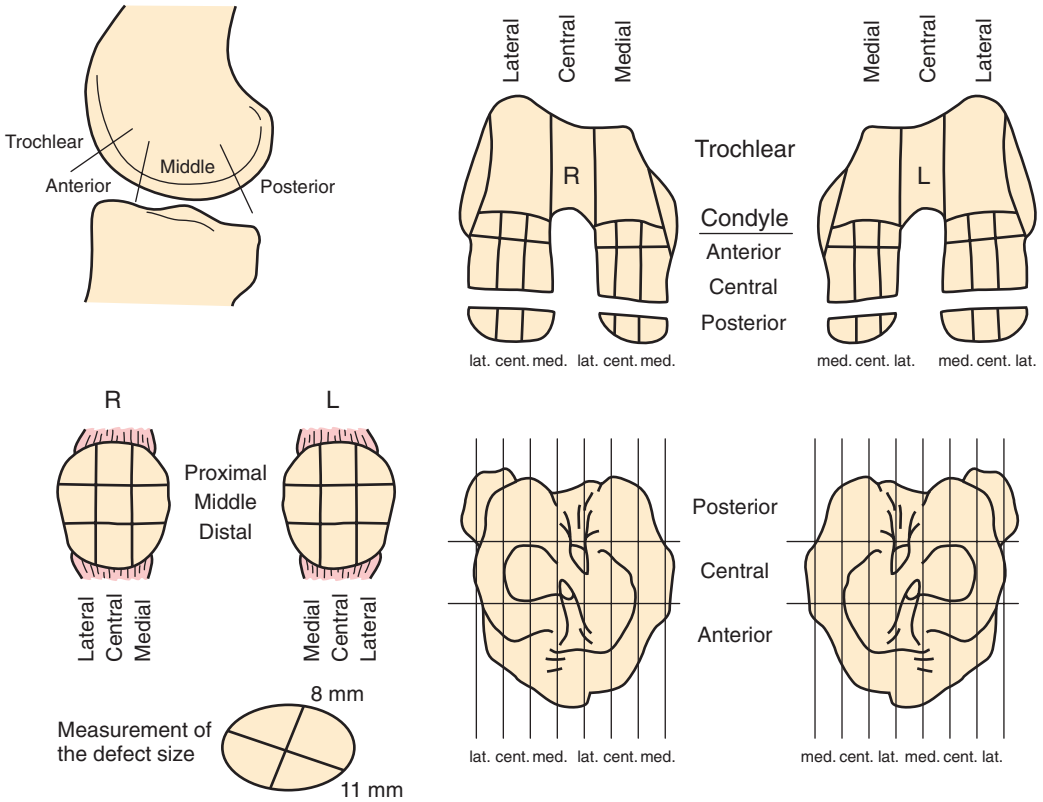

FIG 44-7 International Cartilage Repair Society knee cartilage mapping system. (Courtesy the International Cartilage Repair Society.)

TABLE 44-6 International Cartilage Repair Society Macroscopic Cartilage Assessment Score

Criteria	Findings	Points
1. Degree of defect repair: autologous chondrocyte implantation, periosteal or perichondrial transplantation, subchondral drilling, microfracturing, carbon fiber implants	Level with surrounding cartilage	4
	75% repair of defect depth	3
	50% repair of defect depth	2
	25% repair of defect depth	1
	0% repair of defect depth	0
1. Degree of defect repair: mosaicplasty, osteochondral autograft transfer, osteochondral allograft	100% survival of initially grafted surface	4
	75% survival of initially grafted surface	3
	50% survival of initially grafted surface	2
	25% survival of initially grafted surface	1
	0% survival of initially grafted surface	0
II. Integration	Complete integration with surrounding cartilage	4
	Demarcating border <1 mm	3
	75% integrated, 25% with notable border >1 mm	2
	50% integrated, 50% with notable border >1 mm	1
	0-25% integrated	0
III. Appearance	Intact smooth surface	4
	Fibrillated surface	3
	Small, scattered fissures or cracks	2
	Several, small or few but large fissures	1
	Total degeneration of grafted area	0
Overall Repair Assessment:	**Grade 1 (normal)**	**12 points**
	Grade 2 (nearly normal)	**8-11 points**
	Grade 3 (abnormal)	**4-7 points**
	Grade 4 (severely abnormal)	**1-3 points**

CRITICAL POINTS Reliability and Validation Studies of Cartilage Rating Systems

- Outerbridge classification system: moderate accuracy (68%) and agreement (kappa score, 0.602) of nine observers in correctly grading the lesions from arthroscopic videotapes compared with grades assigned during arthrotomy in cadavers.
- ICRS system: adequate reliability for test-retest data and interrater reliability, satisfactory internal consistency. Tested on articular cartilage repair operations.
- Investigation to determine the relationship between stages of articular cartilage deterioration, as rated macroscopically by the ICRS system, and changes in tissue mechanical properties. Correlation noted between increasing ICRS grade and reduction in stiffness. The relationship between cartilage stiffness and ICRS scoring predicted a 25% loss of stiffness for each ICRS grade.

Marx and coworkers[15] measured the interobserver variability in the grading of articular cartilage lesions using the Outerbridge system as observed on surgical videotapes. Six surgeons provided grades for each articular surface in 53 knees. In the first 31 knees, grades 2 and 3 were combined, whereas in the remaining 22 knees, these grades were not combined. Multirater kappa statistics demonstrated high interrater agreement for all joint surfaces except the medial and lateral tibial plateaus when grades 2 and 3 were combined. However, in the knees in which grades were not combined, only moderate interrater agreement was reported.

Smith and associates[26] tested the validity and reliability of the ICRS system and the previously unpublished Oswestry Arthroscopy Score (OAS), as used to rate repair of articular cartilage after procedures such as osteochondral autograft transfer and ACI. The OAS score showed five macroscopic parameters of graft level with surrounding cartilage, integration with surrounding cartilage, appearance of surface, color of graft, and stiffness on probing to reveal an overall point score from 0 to 10 points. Six orthopedic surgeons viewed five arthroscopic videotapes in patients who had undergone ACI and scored the chondral surfaces according to both rating systems two times, 6 weeks apart. The intraclass correlation coefficient (ICC) demonstrated adequate reliability for the test-retest data (0.94 for both rating systems) and interrater reliability (0.83 for ICRS; 0.76 for OAS). Both systems had satisfactory internal consistency for use in research investigations. The OAS score was slightly superior in terms of content validity because it measured stiffness and provided an indication of hypertrophy of a grafted area, whereas the ICRS score did not measure these parameters and could therefore induce a positively biased score.

van den Born and associates[29] tested the reliability and validity of the ICRS and OAS systems. Seven observers rated a total of 101 images (prints or videos) made during arthroscopy that was performed 12 months after cartilage repair surgery. There were 52 cases of microfracture and 49 cases of ACI. Good reliability was found for the ICRS and OAS systems (ICC, 0.073 and 0.65, respectively), as well as internal consistency. These investigators concluded that their large study demonstrated that both scoring systems may be used as research tools, although the ICRS system scored slightly higher and was the preferred method to determine the result of articular cartilage repair operations.

A study by Spahn and colleagues[27] revealed poor interobserver agreement for the ICRS grade determined by four orthopedic surgeons in 15 patients (60 difference cartilage areas). This study was unique in that all surgeons rated the cartilage appearance during an arthroscopic examination and not from prints or videotapes. Only six (10%) cartilage areas were scored the same by the four surgeons. The authors expressed concern that the real-time subjective grading of cartilage lesions using the ICRS system was unsatisfactory and that more precise objective measurement methods need to be developed. Moderate interrater reliability was observed by Reed and coworkers[25] in both the Outerbridge and ICRS rating systems (kappa scores, 0.54 and 0.41, respectively) in a study involving 96 articular surfaces evaluated by three surgeons.

Kleemann and colleagues[13] conducted an investigation to determine the relationship between various stages of articular cartilage deterioration, as rated macroscopically by the ICRS system (grades 0-4) and changes in tissue mechanical properties. Tibial plateaus were collected in 21 patients who underwent total knee arthroplasty and ICRS grades assigned by three surgeons. The specimens were examined biomechanically and histologically using a modified Mankin scoring system (Table 44-7).[14] The mechanical properties were measured with a custom-made material testing device which determined the Young modulus of the cartilage by unconfined compression. Histologic analysis used haematozylin and eosin staining and Safranin-O staining for the evaluation of the Mankin score. The results showed a correlation between increasing ICRS grade and reduction in stiffness (Young's modulus) ($R^2 = 0.69$, $P < .01$, Fig. 44-8). Progressive thinning of the cartilage was noted in specimens rated ICRS grade 3.

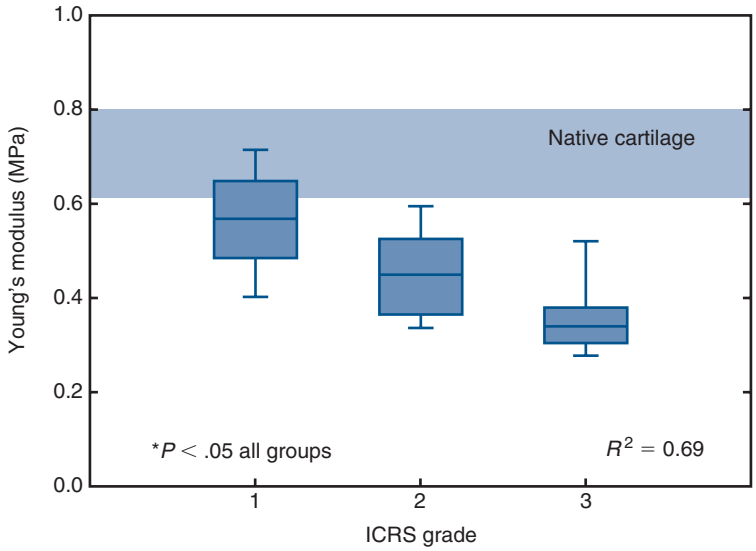

FIG 44-8 Stiffness reduction of degenerated cartilage (increasing International Cartilage Repair Society [ICRS] grade) related to Young's modulus; the band layer represents native human articular cartilage. Boxplots display median values and interquartile range. (From Kleemann RY, Krocker D, Cedraro A, Tuischer J, Duda GN. Altered cartilage mechanics and histology in knee osteoarthritis: relation to clinical assessment (ICRS Grade). *Osteoarthritis Cartilage*. 2005;13:958-963.)

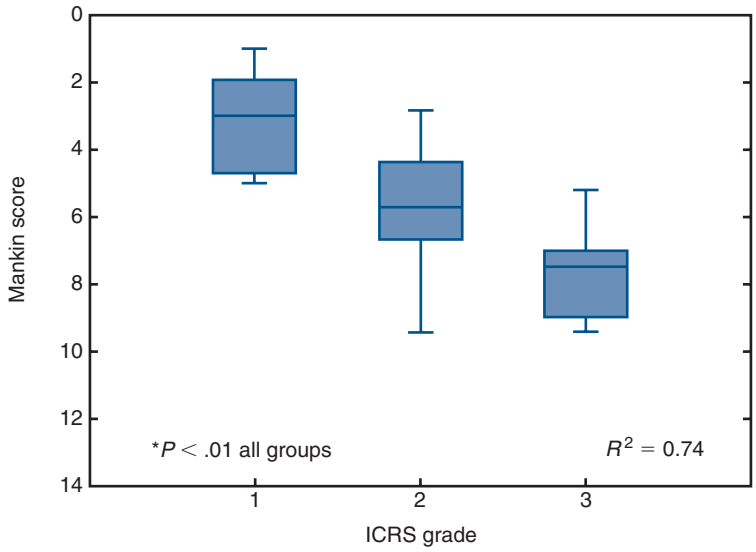

FIG 44-9 Stiffness reduction in degenerated cartilage (increasing International Cartilage Repair Society [ICRS] grade) related to histologic appearance (Mankin score). (From Kleemann RY, Krocker D, Cedraro A, Tuischer J, Duda GN. Altered cartilage mechanics and histology in knee osteoarthritis: relation to clinical assessment (ICRS Grade). *Osteoarthritis Cartilage*. 2005;13:958-963.)

Histologic analysis showed a significant correlation between Mankin scores and ICRS grades ($R^2 = 0.74$, $P < .01$, Figs. 44-9 and 44-10). Higher Mankin scores were obtained with increasing ICRS grades. The mean Mankin scores according to ICRS grades were 3.2 ± 1.5 points for grade 1, 5.7 ± 2.0 points for grade 2, and 7.6 ± 1.7 points for grade 3. A moderate correlation was found between the Mankin score and the Young modulus ($R^2 = 0.47$, $P < .02$). The authors reported that early stage of degenerative joint disease, ICRS grade 1, was very difficult to detect because of the "inconspicuous changes of the surface appearance between ICRS Grade 1 and native cartilage." The investigation found that the relationship between cartilage stiffness and ICRS scoring predicted a 25% loss of stiffness for each ICRS grade. The macroscopic or visual surface cartilage appearance gave an impression of the mechanical behavior of the tissue and was considered a reliable method for classifying degenerated articular cartilage.

A survey of orthopaedic surgeons in Germany was performed (in approximately 2007 to 2008) to determine which grading systems were preferred and the perception of the arthroscopists of the usefulness of these systems.[28] The Outerbridge classification system was by far the

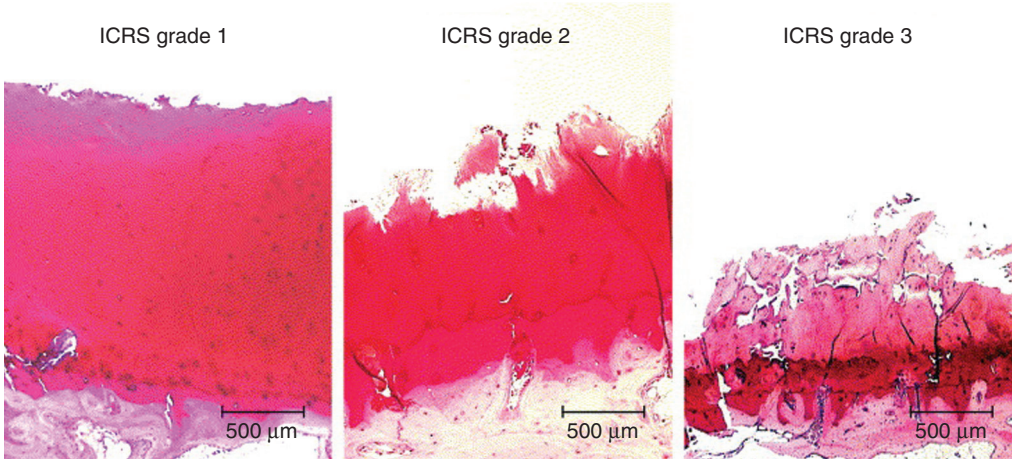

FIG 44-10 Histologic views of safranin-O-stained cartilage examples for International Cartilage Repair Society (ICRS) grade 1, including surface irregularities *(left)*, ICRS grade 2 showing thinning and clefts of cartilage *(middle)*, and ICRS grade 3 with complete disorganization of cartilage *(right)*. (From Kleemann RY, Krocker D, Cedraro A, Tuischer J, Duda GN. Altered cartilage mechanics and histology in knee osteoarthritis: relation to clinical assessment (ICRS Grade). *Osteoarthritis Cartilage*. 2005;13:958-963.)

most frequently used ($n = 87$ surgeons), followed by the ICRS ($n = 8$) and the Insall score ($n = 3$). The majority of surgeons indicated improvement was needed in the grading system they used to be able to differentiate between low-grade and high-grade cartilage lesions. A majority of participants indicated that they would use a practical tool (if available) to quantify cartilage lesions in "questionable cases". However, since 83% of the participating surgeons used the Outerbridge system, this study's conclusions can only be applied to this rating instrument.

CONCLUSION

Many surgeons and arthroscopic operative reports use inaccurate articular cartilage grading systems and language such as "the lesion was between a grade 2 and grade 3" without specifying the cartilage changes that were noted. Arthroscopic examination of the knee joint provides an opportunity to rate the articular cartilage according to the size, depth, and location of lesions, which have clinical significance both in the short and long term. In addition, the detailed rating of articular cartilage is important in clinical knee studies. We recommend the use of detailed systems, such as the Cincinnati Knee Rating or ICRS, to provide a sophisticated analysis of the condition of the articular cartilage. Clinical investigations should assess the effect of noteworthy cartilage damage on the subjective and functional outcome of various operative procedures. When feasible, advanced MRI or objective measuring instruments should be used to more accurately determine the status of articular cartilage.

TOTAL KNEE ARTHROPLASTY OUTCOME INSTRUMENTS

Introduction

Many outcome scales and systems have been used to assess the results of total knee arthroplasty (TKA). These include scales specifically designed for this operation, as well as general health measures and outcome instruments that were originally developed for a variety of knee diagnoses. Although some scales only rate levels of physical activity, others are more encompassing in terms of providing a detailed analysis of the knee condition and function. The American Knee Society Scoring System, the University of California Los Angeles (UCLA) Activity-Level Rating Score, and the Oxford Knee Score were devised specifically to determine the outcome of TKA and currently are the most frequently used instruments. The Short Form 36 (SF-36) Health Survey[26] is a common general health measure that is also used in many TKA studies. Disease-specific (osteoarthritis) instruments typically found in TKA investigations are the Western Ontario and McMaster Universities Osteoarthritis Index (WOMAC) and the Knee Injury and Osteoarthritis Outcome Score (KOOS).

A lack of consensus exists regarding which instrument or rating system should be selected to determine the results of TKA, caused in part by the moderate to poor quality of investigations that determined their psychometric properties.[1,32] One systematic review found that, of 28 instruments assessed, only three had been studied at length in regard to their measurement properties.[1] These were the WOMAC, the Oxford Knee Score, and the SF-36. Another review of instruments used in hip or knee osteoarthritis studies reported that none of the instruments received positive ratings for all psychometric properties.[32] It is important to note that these reviews were conducted before the publication of the two newest outcome instruments and scales for TKA, the new Knee Society Scoring System and the High-Activity Arthroplasty Score. Some of the more commonly used outcome measures are described below, presented in chronological order of publication. The WOMAC and KOOS outcome assessments are described in Chapter 43 and are not repeated in this chapter.

University of California Los Angeles Activity-Level Rating Score

In 1984, Amstutz and colleagues[2] introduced the UCLA activity rating scale for patients undergoing TKA. The scale has 10 activity levels ranging from "wholly inactive" to "regularly participate in impact sports" (Table 45-1). Subsequently, Zahiri and associates[37] compared this activity score with a quantitative assessment of the walking activity of 100 total joint replacement patients. These investigators found the UCLA score strongly correlated with average steps per day as recorded by a pedometer. The recommendation was made to adjust the score for frequency and intensity of activity to increase its accuracy. Naal and coworkers[21] compared the psychometric properties of the UCLA scale with the Tegner and Marx Sports Activity scales in 105 patients undergoing total hip arthroplasty and 100 patients undergoing TKA. The UCLA scale had the best reliability, the highest completion rate, and the strongest correlations with other measures and was the only scale that discriminated between active and sedentary patients. The score also had no floor effects. These investigators concluded that the UCLA scale appeared to be the most appropriate for assessment of physical activity levels following total joint arthroplasty.

American Knee Society Scoring System

In 1989, the Knee Society (of the American Academy of Orthopaedic Surgeons) published its scoring system, which was intended to quantify the results of TKA.[16] In 2011, an extensive update was performed, and a new system was published in 2012.[23,29] The goals of the updated version are to better characterize patient expectations and satisfaction of the operation and measure physical activities of younger individuals undergoing TKA. This system consists of an objective knee score completed by the physician (Table 45-2) and several scales completed by

the patient that assess satisfaction (Table 45-3), symptoms, expectations (Table 45-4), and knee function (Table 45-5). Noble and associates[23] reported adequate internal consistency, reliability, and construct and convergent validity for the four subscales: objective knee score, satisfaction score, expectation score, and functional activity score. The objective knee score consists of seven items; the satisfaction score, five items; the expectation score; three items; and the functional activity score, 19 items. The questionnaires are available by contacting the Knee Society at knee@aaos.org; further information, including the user manual, may be found at www.kneesociety.org/web/outcomes.html.

CRITICAL POINTS Total Knee Arthroplasty Outcome Instruments

- Lack of consensus exists regarding which instrument or rating system should be selected, due in part to the moderate to poor quality of investigations that determined their psychometric properties.
- UCLA activity rating scale: 10 levels ranging from wholly inactive and dependent on others to regular participation in impact sports. Superior to Tegner and Marx for reliability, completion rate, ability to discriminate varying activity levels.
- New Knee Society Scoring System: adequate internal consistency, reliability, and construct and convergent validity for four subscales.
- Oxford knee score: assesses knee-related pain and functional limitations with usual daily and work activities. Adequate reliability, internal consistency, and responsiveness. Adopted in the United Kingdom as a primary outcome measure for patients undergoing TKA as a part of the UK National Patient Reported Outcome Measures Program.
- High-Activity Arthroplasty Score: assesses functional abilities of younger active patients who undergo lower limb arthroplasty. Correlates with Oxford, Knee Society, reduced WOMAC scores; high internal consistency.

Oxford Knee Score

In 1998, Dawson and associates,[9] within the Public Health and Primary Health Care at the University of Oxford, developed a 12-item questionnaire to determine the outcome of TKA. The Oxford knee score (OKS) represents an assessment of knee-related pain and functional limitations with usual daily and work activities (Table 45-6). Each question has five possible responses, scored from 1 to 5, from least to most difficult. The OKS instrument has been translated into 17 languages. Information regarding the scoring system, user manual, and requests for a license may be obtained at www.isis-innovation.com/outcomes/orthopaedic/oks.html.

TABLE 45-1 University of California Los Angeles Activity-Level Rating

Activity	Level
Regularly participate in impact sports such as jogging, tennis, skiing, acrobatics, ballet, heavy labor, or backpacking	10
Sometimes participate in impact sports	9
Regularly participate in very active events, such as bowling or golf	8
Regularly participate in active events, such as bicycling	7
Regularly participate in moderate activities, such as swimming and unlimited housework or shopping	6
Sometimes participate in moderate activities	5
Regularly participate in mild activities, such as walking, limited housework, and limited shopping	4
Sometimes participate in mild activities	3
Mostly inactive: restricted to minimal activities of daily living	2
Wholly inactive: dependent on others, cannot leave residence	1

TABLE 45-2 Knee Society Objective Knee Score

Item	Measurement Method	Possible Responses	Points
1. Alignment	AP standing x-ray (anatomic alignment)	Neutral: 2-10 degrees valgus	25
		Varus: <2 degrees valgus	–10
		Valgus: >10 degrees valgus	–10
2. Medial/lateral instability	Measured at 0 degrees extension	None	15
		Little or <5 mm	10
		Moderate or 5 mm	5
		Severe or >5 mm	0
3. Anterior/posterior instability	Measured at 90 degrees	None	10
		Moderate <5 mm	5
		Severe >5 mm	0
4. Joint motion	Deductions		
	Flexion contracture	1-5 degrees	–2
		6-10 degrees	–5
		11-15 degrees	–10
		>15 degrees	–15
	Extension lag	<10 degrees	–5
		10-20 degrees	–10
		>20 degrees	–15
5. Pain with level walking	Patient's response	0-10 scale	10-score of patient's response
6. Pain with stairs or inclines	Patient's response	0-10 scale	10-score of patient's response
7. Does knee feel "normal" to patient	Patient's response	Always	5
		Sometimes	3
		Never	0

0-100 points.

TABLE 45-3 Knee Society Satisfaction Score

Patient Questions

Currently, how satisfied are you with the pain level of your knee while sitting?
Currently, how satisfied are you with the pain level of your knee while lying in bed?
Currently, how satisfied are you with your knee function while getting out of bed?
Currently, how satisfied are you with your knee function while performing light household duties?
Currently, how satisfied are you with your knee function while performing leisure recreational activities?

Response Options for Each Question

Very satisfied (8 points)
Satisfied (6 points)
Neutral (4 points)
Dissatisfied (2 points)
Very dissatisfied (0 points)

0-40 points.

TABLE 45-4 Knee Society Expectation Score

Patient Questions

My expectations for pain relief were…
My expectations for being able to do my normal activities of daily living were…
My expectations for being able to do my leisure, recreational or sports activities were…

Response Options for Each Question

Too high: "I'm a lot worse than I thought" (1 point)
Too high: "I'm somewhat worse than I thought" (2 points)
Just right: "My expectations were met" (3 points)
Too low: "I'm somewhat better than I thought" (4 points)
Too low: "I'm a lot better than I thought" (5 points)

15 points.

TABLE 45-5 Knee Society Functional Activity Score

Question	Response Options	Points
Walking and standing: Can you walk without any aids (e.g., cane, crutches, or wheelchair)?	Yes or no	0
If no, which of the following aid(s) to you use?	Wheelchair	–10
	Walker	–8
	Crutches	–8
	Two canes	–6
	One crutch	–4
	One cane	–4
	Knee sleeve/brace	–2
Do you use these aid(s) because of your knees?	Yes or no	0
For how long can you stand (with or without aid) before sitting because of knee discomfort?	Cannot stand	0
	0-5 minutes	3
	6-15 minutes	6
	16-30 minutes	9
	31-60 minutes	12
	More than an hour	15
For how long can you walk (with or without aid) before stopping because of knee discomfort?	Cannot walk	0
	0-5 minutes	3
	6-15 minutes	6
	16-30 minutes	9
	31-60 minutes	12
	More than an hour	15
Standard activities: How much does your knee bother you during each of the following activities?	I never do this	0
	Cannot do because of knee	0
1. Walking on an uneven surface	Very severe	1
2. Turning or pivoting on your leg	Severe	2
3. Climbing up or down a flight of stairs	Moderate	3
4. Getting up from a low couch or a chair without arms	Slight	4
5. Getting into or out of a car	No bother	5
6. Moving laterally (stepping to the side)		
Advanced activities: How much does your knee bother you during each of the following activities?	I never do this	0
	Cannot do because of knee	0
1. Climbing a ladder or step stool	Very severe	1
2. Carrying a shopping bag for a block	Severe	2
3. Squatting	Moderate	3
4. Kneeling	Slight	4
5. Running	No bother	5

Continued

TABLE 45-5 Knee Society Functional Activity Score—cont'd

Question	Response Options	Points
Discretionary knee activities: Check 3 of the activities below that you consider most important to you. How much does your knee bother you during each of these activities?		
Recreational activities: swimming, golfing (18 holes), road cycling (>30 min), gardening, bowling, racquet sports, distance walking, dancing/ballet, stretching exercises	Cannot do because of knee	0
	Very severe	1
	Severe	2
Workout and gym activities: weightlifting, leg extensions, stair-climbing machine, stationary biking/spinning, leg press, jogging, elliptical trainer, aerobic exercise	Moderate	3
	Slight	4
	No bother	5

0-100 points.

TABLE 45-6 Oxford Knee Score

Question	Possible Responses	Points
1. How would you describe the pain you usually have from your knee?	None	1
	Very mild	2
	Mild	3
	Moderate	4
	Severe	5
2. Have you had any trouble with washing and drying yourself (all over) because of your knee?	No trouble at all	1
	Very little trouble	2
	Moderate trouble	3
	Extreme trouble	4
	Impossible to do	5
3. Have you had any trouble getting in and out of a car or using public transport because of your knee (whichever you tend to use)?	No trouble at all	1
	Very little trouble	2
	Moderate trouble	3
	Extreme trouble	4
	Impossible to do	5
4. For how long have you been able to walk before the pain in your knee becomes severe (with or without a stick)?	No pain/>30 min	1
	16-30 min	2
	5-15 min	3
	Around the house only	4
	Not at all; severe on walking	5
5. After a meal (sitting at a table), how painful has it been for you to stand up from a chair because of your knee?	Not at all painful	1
	Slightly painful	2
	Moderately painful	3
	Very painful	4
	Unbearable	5
6. Have you been limping when walking because of your knee?	Rarely/never	1
	Sometimes or just at first	2
	Often, not just at first	3
	Most of the time	4
	All of the time	5
7. Could you kneel down and get back up again afterwards?	Yes, easily	1
	With little difficulty	2
	With moderate difficulty	3
	With extreme difficulty	4
	No, impossible	5
8. Have you been troubled by pain from your knee in bed at night?	No nights	1
	Only 1 or 2 nights	2
	Some nights	3
	Most nights	4
	Every night	5

TABLE 45-6 Oxford Knee Score—cont'd

Question	Possible Responses	Points
9. How much has pain from your knee interfered with your usual work (including housework)?	Not at all	1
	A little bit	2
	Moderately	3
	Greatly	4
	Totally	5
10. Have you felt that your knee might suddenly "give way" or let you down?	Rarely/never	1
	Sometimes or just at first	2
	Often, not just at first	3
	Most of the time	4
	All of the time	5
11. Could you do the household shopping on your own?	Yes, easily	1
	With little difficulty	2
	With moderate difficulty	3
	With extreme difficulty	4
	No, impossible	5
12. Could you walk down a flight of stairs?	Yes, easily	1
	With little difficulty	2
	With moderate difficulty	3
	With extreme difficulty	4
	No, impossible	5

Dawson and associates[9] found that TKA patients completed the OKS at a higher rate than the SF-36, the original American Knee Society score,[16] and the Stanford Health Assessment Questionnaire. These investigators reported the OKS had adequate reliability, internal consistency, and responsiveness for this patient cohort. Other authors have confirmed these findings.[13,17] The OKS is predictive of patient satisfaction postoperatively.[6] However, Whitehouse and coworkers[34] reported patients had problems with the questionnaire in terms of items left blank because of a lack of understanding or inability to answer with the responses provided. There is no allowance for comorbidities, which is a problem with many elderly patients undergoing TKA. Recommendations were made for consideration of reformulation of questions and response categories. Even so, in 2009, the OKS was adopted in the United Kingdom (UK) as a primary outcome measure for patients undergoing TKA as a part of the UK National Patient Reported Outcome Measures Program.

High-Activity Arthroplasty Score

In 2010, Talbot and associates[31] devised the High-Activity Arthroplasty Score to assess the functional abilities of younger and more active patients who undergo lower limb arthroplasty. This scale is markedly different from other general activity analysis previously published for this population.[2,11,27] The scale consists of four domains (walking, running, stair climbing, activity level) shown in Table 45-7. A pilot study composed of 22 patients (11 post–total hip arthroplasty, 11 post-TKA) showed the score correlated significantly with the Oxford,[9] Knee Society,[16] Harris Hip,[14] and reduced WOMAC[35,36] scores. Internal consistency was high. Reliability as determined by ICC and responsiveness were not assessed by the investigators.

PATELLOFEMORAL OUTCOME INSTRUMENTS

Introduction

Several disease-specific outcome instruments have been used to rate symptoms and function in patients with patellofemoral pain and disorders. No consensus exists regarding which instrument or rating system should be selected. One problem is that many studies use the generic term "patellofemoral pain syndrome" (PFPS) to describe the cohort under investigation. PFPS encompasses a multitude of potential (more specific) diagnoses such as extensor mechanism malalignment, infrapatellar fat pad syndrome, lateral patellar compression syndrome, patellar dislocation/subluxation, or an inflammatory condition such as bursitis. A recent systematic review of psychometric properties of self-reported questionnaires used for PFPS defined this term as "anterior or retropatellar knee pain or pain along the lateral and medial borders of the patella, which could be caused by anterior knee structures such as the infrapatellar fat pad, patellar subchondral bone, anterior synovium and medial or lateral retinaculae."[10]

A systematic review conducted by Esculier and associates[10] found several questionnaires with measured psychometric properties used to assess PFPS: the Activities of Daily Living Scale (ADLS), the Anterior Knee Pain Scale (AKPS, also known as the Kujala Scale), the International Knee Documentation Committee (IKDC) Subjective Knee scale,

CRITICAL POINTS Patellofemoral Outcome Instruments

- No consensus regarding which instrument or rating system should be used for patellofemoral pain, injuries, and disorders
- Functional Index Questionnaire: eight-item questionnaire assesses problems with daily and sports activities in patients with PFPS. Reliability varies, responsiveness low.
- AKPS or Kujala Scale: adequate psychometric properties, able to discriminate between knee conditions and levels of severity in patients with PFPS
- Samsung Medical Center Patellofemoral Scoring System: pain score (8 items) and function score (9 items). Acceptable reliability, internal consistency, content validity.
- Saltzman Patellofemoral Score: 3 sections, 0-100 points, includes self-reported questionnaire and objective and radiographic analyses. Psychometric properties not analyzed.

TABLE 45-7 High-Activity Arthroplasty Score

Domain	Levels	Points
Walking	Over rough ground >1 hr	5
	Unlimited on flat, rough ground with difficulty	4
	Unlimited on flat, no rough ground	3
	On flat at least 30 minutes	2
	Short distances unassisted (up to 20 m)	1
	Using walking aids for short distances or worse	0
Running	More than 5 km	4
	Jog slowly up to 5 km	3
	Run easily across the road	2
	Run a few steps to avoid traffic if necessary	1
	Cannot run	0
Stair-climbing	Climb stairs two at a time	3
	Climb without handrail	2
	Climb with hand rail or stick	1
	Cannot climb stairs	0
Activity level	Competitive sports (e.g., singles tennis, running >10 km, cycling >80 km)	6
	Social sports (e.g., doubles tennis, skiing, jogging <10 km, high-impact aerobics	5
	Vigorous recreational activities (e.g., hill-walking, low impact aerobics, heavy gardening or manual work/farming	4
	Moderate recreational activities (e.g., golf, light gardening, light working activities)	3
	Light recreational activities (e.g., short walks, lawn bowls)	2
	Required outdoor activities only (e.g., walk short distance to shop)	1
	Housebound without assistance	0

The patient selects the highest level of function in each of the four domains.

the Functional Index Questionnaire (FIQ), and the Lysholm Scale. These investigators recommended the ADLS, followed by the AKPS and the IKDC, to evaluate patients with PFPS. The IKDC is described in detail in Chapter 42, and the ADLS and Lysholm scales are discussed in Chapter 43 and therefore are not repeated in this chapter. It is important to note that it is unknown whether or not an outcome instrument or rating system exists that contains adequate psychometric properties for all patellofemoral-related injuries and disorders. Clinical investigations regarding specific patellofemoral diagnoses, injuries, and operations typically use several rating instruments to determine outcome. These include those described above, as well as general health questionnaires such as the SF-36 and osteoarthritis-specific instruments such as the WOMAC and KOOS.

Functional Index Questionnaire

The FIQ is a commonly used instrument to rate patellofemoral problems.[7,8,10,22,24,25] Published in 1989 by Chesworth and coworkers,[4] the eight-item questionnaire assesses problems with daily and sports activities in patients with PFPS. Items measured are walking, stair climbing, squatting, kneeling, and running. Responses are determined from a three-level gradient of "unable to do," "can do with problem," and "no problem." A modified version of this instrument provides a fourth level of "not appropriate."[30] Chesworth and coworkers[4] reported poor reliability (ICC, 0.48), but acceptable validity in detecting change after a mean of 11 weeks of physical therapy (determined with repeated-measures analysis of variance). However, Harrison and colleagues[15] and MacIntyre and associates[20] conducted more rigorous investigations of this instrument in patients with patellofemoral pain who underwent a program of physical therapy and found acceptable values for reliability, validity, and responsiveness. A high reliability ICC of 0.94 was also reported by Bennell and associates.[3] However, poor reliability (ICC, 0.49) was found by Crossley and coworkers.[8] In a systematic review of articles that measured the psychometric properties of PFPS outcome instruments, Esculier and colleagues[10] reported a weighted average (calculated from a total of 47 patients) ICC of 0.61. Because of the poor reliability and low responsiveness of the FIQ, these investigators did not recommend the use of this instrument in patients with PFPS.

Anterior Knee Pain Scale (Kujala Scale)

The Anterior Knee Pain Scale (AKPS), frequently referred to as the Kujala Scale,[18] is another commonly used instrument to determine function and outcome in PFPS.[5,7,8,10,12] First published in 1993, this scale consists of 13 factors (0-100 point scale) shown in Table 45-8. Watson and associates[33] found high reliability (ICC, 0.95) and moderate responsiveness of the AKPS in 30 patients treated with physical therapy for anterior knee pain. Excellent reliability of this instruments was also reported by others.[3,8,10] Esculier and colleagues[10] found adequate internal consistency, responsiveness, and validity. These investigators recommended use of the AKPS for PFPS studies because it had the highest weighted average ICC and responsiveness and the lowest measurement error among five scales assessed. Another advantage of the AKPS was its ability to discriminate between knee conditions and levels of severity in patients with PFPS.

Samsung Medical Center Patellofemoral Scoring System

Recently, Lee and associates[19] introduced the Samsung Medical Center (SMC) patellofemoral scoring system. The system is composed of two scores: a patellofemoral pain score (eight items) and a patellofemoral function score (nine items, Table 45-9). These investigators reported excellent reliability and internal consistency in a group of 179 patients. There were 123 patients with isolated anterior knee pain, 28 patients with knee pain in another location, and 28 healthy volunteers. Acceptable floor and ceiling effects (content validity) were found for all items except sitting down on a chair in the patellofemoral function score. The investigators concluded that their scoring system was unique because it was able to distinguish patients with anterior knee pain or patellofemoral dysfunction from patients with knee pain or problems arising from other diagnoses, and from individuals without knee pain or problems.

Saltzman Patellofemoral Score

A comprehensive rating system was devised by Saltzman and associates[28] to determine the outcome of treatment of displaced patellar fractures. The system comprised three sections: a self-reported patient questionnaire (five items, 45 points), an objective analysis (six items, 43 points), and a radiographic analysis (three items, 12 points). The subjective portion of the score was developed (based on the Cincinnati Knee Rating System) to determine the symptoms of pain, swelling, and giving-way according to activity levels (Table 45-10). The scores of all items are summed up to produce one final score, which is then categorized as "excellent" (90-100 points), "good" (80-89 points), "fair" (70-79 points), or "poor" (<70 points). This system's psychometric properties have not been evaluated. Even so, it is included here because it represents one of the few patellofemoral outcome instruments that assesses both subjective and objective factors.

TABLE 45-8 Anterior Knee Pain Scale

Question	Possible Responses	Points
1. Limp	None	5
	Slight or periodical	3
	Constant	0
2. Support	Full support without pain	5
	Painful	3
	Weight-bearing impossible	0
3. Walking	Unlimited	5
	More than 2 km	3
	1-2 km	2
	Unable	0
4. Stairs	No difficulty	10
	Slight pain when descending	8
	Pain both when descending and ascending	5
	Unable	0
5. Squatting	No difficulty	5
	Repeated squatting painful	4
	Painful each time	3
	Possible with partial weight-bearing	2
	Unable	0
6. Running	No difficulty	10
	Pain after more than 2 km	8
	Slight pain from start	6
	Severe pain	3
	Unable	0
7. Jumping	No difficulty	10
	Slight difficulty	7
	Constant pain	2
	Unable	0
8. Prolonged sitting with the knees flexed	No difficulty	10
	Pain after exercise	8
	Constant pain	6
	Pain forces to extend knees temporarily	4
	Unable	0
9. Pain	None	10
	Slight and occasional	8
	Interferes with sleep	6
	Occasionally severe	3
	Constant and severe	0
10. Swelling	None	10
	After severe exertion	8
	After daily activities	6
	Every evening	4
	Constant	0
11. Abnormal painful kneecap (patellar) movements (subluxations)	None	10
	Occasionally in sports activities	6
	Occasionally in daily activities	4
	At least one documented dislocation	2
	More than two dislocations	0
12. Atrophy of thigh	None	5
	Slight	3
	Severe	0
13. Flexion deficiency	None	5
	Slight	3
	Severe	0

Patients are asked to indicate the duration of their symptoms and, for each question, to circle the latest choice that corresponds to their knee symptoms.

TABLE 45-9 Samsung Medical Center Patellofemoral Scoring System

Factors	Scoring
Patellofemoral Pain Score	0 (no pain) to 10 (intractable pain) in increments of 1; the higher the number, the more painful. Subtotal score ranges from 0-80 points.
1. Climbing up stairs	
2. Walking down stairs	
3. Rising from floor	
4. Sitting down on floor	
5. Rising from a chair	
6. Rising from squatting position	
7. Squatting	
8. Sitting on a chair for 10 minutes	
Patellofemoral Function Score	0 = no difficulty
1. Climbing up stairs	2.5 = mild
2. Walking down stairs	5 = moderate
3. Rising from floor	7.5 = severe
4. Sitting down on floor	10 = extreme difficulty (unable to do)
5. Rising from a chair	Subtotal score ranges from 0-90 points.
6. Sitting down on a chair	
7. Rising from squatting position	
8. Squatting	
9. Sitting on a chair for 10 minutes	

TABLE 45-10 Saltzman Patellofemoral Score

Factor	Responses	Points
Pain	None	10
Do you have knee pain when you do strenuous sports or heavy work?	Yes, definite pain, moderate limitations	8
Do you have knee pain when you do recreational sports or moderate work?	Yes, definite pain, moderate limitations	6
	Yes, definite pain, mild limitations	4
Do you have knee pain when you do daily living activities (walking) or light work (office)?	Yes, definite pain, moderate limitations	2
	Constant pain, severe limitations	0
Swelling	None	5
Do you have knee swelling when you do strenuous sports or heavy work?	Yes, definite swelling, moderate limitations	4
Do you have knee swelling when you do recreational sports or moderate work?	Yes, definite swelling, moderate limitations	3
	Yes, definite swelling, mild limitations	2
Do you have knee swelling when you do daily living activities (walking) or light work (office)?	Yes, definite swelling, moderate limitations	1
	Constant swelling, severe limitations, relieved by rest	0
Giving way	None	5
Do you have giving-way when you do strenuous sports or heavy work?	Yes, definite giving way, moderate limitations	4
Do you have giving-way when you do recreational sports or moderate work?	Yes, definite giving way, moderate limitations	3
	Yes, giving-way, mild limitations	2
Do you have giving-way when you do daily living activities (walking) or light work (office)?	Giving-way, moderate limitations	1
	Giving-way, severe limitations	0
Movement	No pain or swelling	15
Sitting	Each factor rated as either yes or no; each pain factor rated as yes equals –2 points; each swelling factor rated as yes equals –1 point	
Standing/walking		
Climbing stairs		
Squatting		
Lifting/carrying		
Work	Work activities have not changed or have increased	10
	Work activities decreased because of problems with knee	5
	Unable to work because of problems with knee	0
Effusion	None	6
	Mild	4
	Moderate	2
	Severe	0

TABLE 45-10 Saltzman Patellofemoral Score—cont'd

Factor	Responses	Points
Active range of motion (involved/noninvolved)	>90%	12
	80%-90%	9
	70%-80%	6
	60%-70%	3
	<60%	0
Extensor lag	None	4
	–1 point for each 5 degrees of extensor lag	
Patellofemoral compression pain	None	3
	Mild	2
	Moderate	1
	Severe	0
Thigh atrophy (noninvolved-involved)	<12 mm	8
	12-25 mm	4
	>25 mm	0
Isokinetic quadriceps strength (noninvolved-involved); 60 degrees/sec	<10%	10
	10%-20%	8
	20%-30%	6
	30%-40%	4
	40%-50%	2
	>50%	0
Radiographs	None	12
Patellofemoral compartment Medial compartment Lateral compartment	–1 point if narrowing, sclerosis, cysts, osteophytes in any compartment; subtract 1 point for all that exist	

90-100 points = excellent; 80-89 points = good; 70-79 points = fair; <70 points = poor.

    medial unicompartmental knee arthroplasty, 894, 895*t*-898*t*
    unicompartmental knee arthroplasty *versus* high tibial osteotomy, 894-899, 899*t*
    unicompartmental knee arthroplasty *versus* total knee arthroplasty, 899-901, 900*t*
  complications and factors leading to failure of, 888-894, 894*t*
  contraindications of, 883
  versus high tibial osteotomy, 824
  illustrative cases of, 903, 904*f*-905*f*
  implant design in, 883, 883*t*-884*t*
  indications of, 882-883
  postoperative management of, 887-888, 889*t*-893*t*
  robotic technology of, 883-884, 885*t*
  surgical technique of, 884-887, 886*f*-888*f*
  for varus or valgus malalignment, 882-910
University of California Los Angeles (UCLA) Activity-Level Rating Score, 1235, 1236*t*
Unloading braces, types of, 873
Unstable platform, 310

V

Valgus knee, common characteristics of, 850*b*
Valgus malalignment, 848-857
  clinical biomechanics and, 849-850
  clinical evaluation of, 850
  clinical examination of, 884
  clinical outcomes of, 854-856
  clinical studies of, 894-901
    lateral unicompartmental knee arthroplasty, 901, 901*t*-903*t*
    medial unicompartmental knee arthroplasty, 894, 895*t*-898*t*
    unicompartmental knee arthroplasty *versus* high tibial osteotomy, 894-899, 899*t*
    unicompartmental knee arthroplasty *versus* total knee arthroplasty, 899-901, 900*t*
  complications and factors leading to failure of, 888-894, 894*t*
  complications of, 856
  contraindications of, 883
  distal femoral osteotomy contraindications and, 849, 849*b*
  distal femoral osteotomy indications and, 848-849, 849*b*
  history and physical examination of, 850
  illustrative cases of, 903, 904*f*-905*f*
  implant design in, 883, 883*t*-884*t*
  indications of, 882-883
  operative technique of, 851-854, 851*f*-854*f*
  postoperative management of, 887-888, 889*t*-893*t*
  postoperative regimen for, 853*b*
  preoperative planning and, 850-851, 850*f*
  radiographic evaluation of, 850, 850*b*
  robotic technology of, 883-884, 885*t*
  surgical technique of, 851*b*, 884-887, 886*f*-888*f*
  unicompartmental knee replacement for, 882-910
Valgus rotation, 66*f*
Valgus test, ligamentous restraints of knee joint in, 50*t*
Validity, 1165
  our study in, 1179-1180, 1179*b*, 1180*t*
Varus angulation, in ACL-deficient knees, 776*t*
Varus knee syndromes
  clinical algorithm for, 785*f*
  clinical evaluation of, 779-783, 780*b*
    diagnostic clinical tests in, 781
    physical examination in, 780-781
    radiographic assessment in, 783, 783*f*
    subjective and functional outcome of, 779
    tibiofemoral rotation test in, 781-783
  clinical studies, 812-825, 812*b*, 820*b*
  closing wedge tibial osteotomy, 805-809, 805*b*
  diagnosis of abnormalities in, 782*t*
  double varus, 776, 777*f*, 816-818, 817*b*, 817*f*-818*f*
  and dynamic muscle forces, 780*f*
  and external adducting moment, 781*f*
  intraoperative evaluation for, 797-798, 798*b*, 799*f*
  knee adduction moment and, 778*f*-779*f*, 781*f*
  and lower limb alignment, 776-778, 777*b*, 778*f*
    gait analysis in, 778-779, 779*b*
  manual knee tests for, 782*f*
  and opening wedge tibial osteotomy, 798-805, 799*b*
  preoperative planning for, 783-797, 784*b*
    and angular correction calculations, 783-787, 784*f*, 786*f*-787*f*
    coronal and slope alignment, final recommendations to obtain correct, 797
Varus knee syndromes (*Continued*)
    cruciate graft options in, 793
    opening *versus* closing wedge osteotomy in, 794
    and preservation of tibial slope, 794-797, 797*f*
    and tibial slope, 787-791, 788*t*, 789*f*-792*f*
    timing of procedures in, 791-793, 792*t*, 793*f*
  prevention and management of complications of, 825-839, 826*b*
    arterial injury, 827
    arthrofibrosis and patella infera, 828
    bony instability, 825-826
    deep vein thrombosis, 828-829
    delayed union or nonunion, 825-839
    iliac crest harvest site pain, 828
    inadequate or loss of axial correction, 826-827
    peroneal nerve injury or palsy, 827-828
    tibial plateau fracture, 827
  primary varus, 777, 777*f*
  and tibial and femoral osteotomy contraindications, 775-776, 775*b*
  and tibial and femoral osteotomy indications, 774-775, 774*b*
  triple varus, 777, 777*f*, 816-818, 817*b*, 817*f*-818*f*
  and varus angulation, 776*t*
Varus malalignment, 564*t*
  clinical examination of, 884
  clinical studies of, 894-901
    lateral unicompartmental knee arthroplasty, 901, 901*t*-903*t*
    medial unicompartmental knee arthroplasty, 894, 895*t*-898*t*
    unicompartmental knee arthroplasty *versus* high tibial osteotomy, 894-899, 899*t*
    unicompartmental knee arthroplasty *versus* total knee arthroplasty, 899-901, 900*t*
  complications and factors leading to failure of, 888-894, 894*t*
  contraindications of, 883
  illustrative cases of, 903, 904*f*-905*f*
  implant design in, 883, 883*t*-884*t*
  indications of, 882-883
  osseous
    and ACL reconstruction, 199
    in primary anterior cruciate ligament reconstruction clinical studies, 201*t*
  postoperative management of, 887-888, 889*t*-893*t*
  robotic technology of, 883-884, 885*t*
  surgical technique of, 884-887, 886*f*-888*f*
  unicompartmental knee replacement for, 882-910
Varus recurvatum, 535, 868, 879*f*
  severe, posterolateral capsule reconstruction for, 550-552, 553*b*, 553*f*-555*f*
Varus stress testing, 530*t*-534*t*
Varus test, ligamentous restraints of knee joint in, 50*t*
Vascular anatomy, posterior cruciate ligament, 458-460, 458*b*
Vascular injuries, 664-666, 664*b*, 666*f*
Vascularity modulation, tissue healing and, 117
Vascularized ACL grafts, 103-104, 103*b*, 104*f*
Vasomotor, complex regional pain syndrome (CRPS) and
  abnormalities, 1136
  measurement, 1139
Vasopneumatic devices, 295-304
