Hiraga and colleagues[40] reported the results of cyclic loading tests on four types of PCL reconstructions in cadaveric knees. The knee joints were cycled between 0 and 100 N for 1000 cycles. Increases in posterior tibial translation were attributed to slippage of the graft and/or permanent elongation of the graft construct. The knees were positioned at 90 degrees of flexion, and the cyclic loading involved repetitive AP displacements. This is in contrast to the study by Shearn and coworkers,[92] where the knees were cycled between 0 and 120 degrees of knee flexion. It is important that differences in cyclic loading techniques be understood because the cyclic loading under both posterior load and knee flexion-extension is more detrimental in terms of inducing graft elongation or failure than unidirectional loading. Hiraga and colleagues[40] reported that no grafts failed under the reduced loading of 100 N; however, there were increases in posterior tibial translation after only 100 cycles in all reconstruction groups. The greatest increase was found in semitendinosus-gracilis (STG) grafts fixated with an EndoButton (Smith & Nephew), which was less than an STG graft fixed with an interference screw and an EndoPearl device (ConMed Linvatec). There was no difference between B-PT-B tibial tunnel and B-PT-B tibial inlay reconstructions, with increases in residual posterior translation of approximately 3 mm reported for both tunnel and inlay grafts.

To the extent that these in vitro results apply to in vivo PCL graft constructs, the data indicate the potential need to protect PCL grafts in the initial postoperative period. The in vitro data represent the worst-case scenario for a PCL graft in that the PCL construct was loaded to 100 N and up to 120 degrees of knee flexion, which would be expected to induce graft tensile loads already reported of 200 to 300 N. In addition, a 5-mm B-PT-B graft was used, in contrast to larger-diameter grafts used in vivo, which would undoubtedly require greater number of cycles to ultimate failure. There are insufficient in vitro and in vivo biomechanic and clinical data on the effects of these variables to scientifically construct a rational treatment program. We stress that the surgeon needs to select empiric rules in terms of the postoperative treatment rehabilitation protocol.

FIG 16-1 Severe posterior tibial subluxation is shown in a chronic posterior cruciate ligament–deficient knee. There is loss of the normal anterior tibiofemoral step-off.

CRITICAL POINTS Indications

- Mechanism of injury, low versus high velocity.
- Complete PCL rupture usually associated with other ligament injuries.
- Isolated PCL rupture represents serious injury, chance of functional deterioration, arthritis over time.
- Indications for chronic isolated complete PCL rupture: pain and instability with athletics or other activities, swelling, ≥10 mm of increased posterior tibial translation (90 degrees of flexion).
- Results of PCL reconstruction in chronic knees less favorable as arthritic symptoms persist.

INDICATIONS

Complete ruptures to the posterior cruciate ligament (PCL) account for approximately 2% to 3% of all knee ligament injuries in the general population.[131,213] However, the reported incidence of PCL ruptures ranges between 1% and 44% of all acute knee ligament injuries.[192] These injuries are classified as either low-velocity, such as those that occur from contact with another player in sports, or high-velocity, such as a dashboard injury in a motor vehicle accident. The mechanism of PCL rupture in athletes is usually a fall on the flexed knee with a plantar-flexed foot or hyperflexion of the knee.[192,235] High-velocity injuries frequently involve dislocations with multiple ligament ruptures that require immediate medical attention. Traffic-related injuries appear to produce greater posterior tibial displacement values on stress radiography than sports-related injuries.[193] In this chapter, the different types of PCL reconstructive techniques are described in detail to allow the surgeon to select the procedure most suited for the specific knee injury. In addition, the initial diagnosis and management of acute PCL ruptures is addressed in the "Preoperative Planning" section.

The proper management of complete ruptures to the PCL requires thorough knowledge of anatomy, diagnosis, surgical reconstruction, and rehabilitation concepts. Some aspects of the treatment of complete isolated PCL ruptures are controversial owing to the surgical limitations in completely restoring knee stability and the unclear natural history regarding long-term symptoms, functional limitations, and risk of joint arthritis. Although some studies (that included large percentages of patients with partial PCL deficiency) reported that patients did well when treated conservatively,[177,199,200] other investigations described noteworthy symptoms and functional limitations after the injury.[11,19,41,43,97] Many knees with complete PCL ruptures develop articular cartilage deterioration over time that usually occurs on the medial femoral condyle and patellofemoral surfaces owing to increased joint pressures and altered tibiofemoral and patellofemoral kinematics.* Posterior tibial subluxation with activities after PCL rupture has a deleterious effect to the knee similar to that of a medial meniscectomy[57] because there is loss of medial meniscus function and increased joint contact stress. There is less of a deleterious effect on the lateral tibiofemoral compartment because the lateral meniscus retains load-bearing function. Posterior tibial subluxation with weight-bearing activities results in a loss of normal joint kinematics[64,218] and in coupled external tibial rotation with joint loading. Accordingly, a PCL rupture would be expected to have a more deleterious effect in a varus-angulated knee with associated loss of the medial meniscus and, in particular, larger-sized athletes who desire to return to strenuous athletics. All of these factors alone or together result in substantial medial tibiofemoral loads and risk of joint deterioration.

The indications for surgical reconstruction in knees with a chronic isolated complete PCL rupture are pain and instability with athletics or other activities, swelling, and 10 mm or more of increased posterior tibial translation at 90 degrees of flexion (Fig. 16-1). PCL reconstruction is most frequently performed in dislocated knees with gross instability owing to other ligament injuries to the anterior cruciate ligament (ACL), medial collateral ligament (MCL, see Chapter 19), or posterolateral structures (see Chapter 17). Indications for surgery in acute isolated PCL ruptures are discussed later in this chapter.

If symptomatic meniscal tears or early patellofemoral or tibiofemoral articular cartilage damage are present, early PCL reconstruction is recommended with the goal of decreasing joint deterioration over

*References 32, 60, 61, 64, 65, 73, 79, 106, 121, 172, 212, 217, 218, 222.

time. The results of PCL reconstruction in knees with chronic ruptures are not as favorable as those that undergo reconstruction for acute injuries. This is because patients with chronic ruptures frequently present with pain and swelling from joint deterioration that will often persist even though some benefit may be gained from improved knee stability from a reconstruction.[154]

CONTRAINDICATIONS

Contraindications to PCL reconstruction include acute partial and complete isolated tears that will heal and provide partial function with conservative treatment. Advanced symptomatic patellofemoral or tibiofemoral arthritis is a frequent contraindication. Unfortunately, many patients with chronic PCL deficiency present with severe associated joint arthritis. It is important to distinguish joint instability symptoms from symptomatic arthritis, in which case a ligament reconstruction would provide little to no benefit.

Patients with chronic PCL ruptures, varus angulation, and early medial tibiofemoral arthritis, or with increased lateral joint opening and associated posterolateral insufficiency, require high tibial osteotomy (HTO) before PCL reconstruction.

Dislocated knees require initial observation, vascular evaluation (ankle-brachial index), possible arteriography, early protected range of motion, and rehabilitation to restore muscle function before PCL reconstruction. We discourage the use of external fixators to initially stabilize the knee joint, because the use of these devices frequently results in arthrofibrosis and pin track infection and limits the ability to perform a ligament reconstruction. It is important to document with lateral radiographs that tibiofemoral reduction has been maintained and a residual posterior subluxation is not present.

In addition, patients with chronic PCL deficiency who have severe muscle atrophy, loss of knee motion, or hyperextension gait abnormalities require extensive rehabilitation and gait retraining before reconstruction (see Chapter 29).[165]

A select group of morbidly obese patients sustain serious knee dislocations with minimal trauma. The lack of protective muscle function and the abnormal body weight places excessive tensile loads on ligament reconstructions, and a high rate of failure of a PCL reconstruction is expected. The preferred treatment for these patients is short-term plaster immobilization (and occasionally external fixation) to allow healing of soft tissues, followed by rehabilitation to return muscle function and knee motion. In only exceptional circumstances would operative repair (acute or chronic) be warranted in these patients, although consideration for surgical reconstruction is warranted after appropriate weight reduction.

CRITICAL POINTS Contraindications

- Acute partial and complete isolated PCL tears that will heal and provide partial function.
- Advanced symptomatic patellofemoral or tibiofemoral arthrosis.
- Varus-angulated knees with early medial tibiofemoral arthrosis; osteotomy required before PCL reconstruction.
- Dislocated knee: vascular evaluation, protected range of knee motion, and return of muscle function before PCL reconstruction.
- Loss of knee motion, quadriceps weakness, and hyperextension gait abnormalities require extensive rehabilitation and gait retraining before PCL reconstruction.

POSTERIOR CRUCIATE LIGAMENT ANATOMY

The PCL attaches in a depression posterior to the intraarticular upper surface of the tibia and courses anteromedially behind the ACL to the lateral surface of the medial femoral condyle (see Chapter 2; Fig. 16-2). Illustrations by Anderson and colleagues[9]

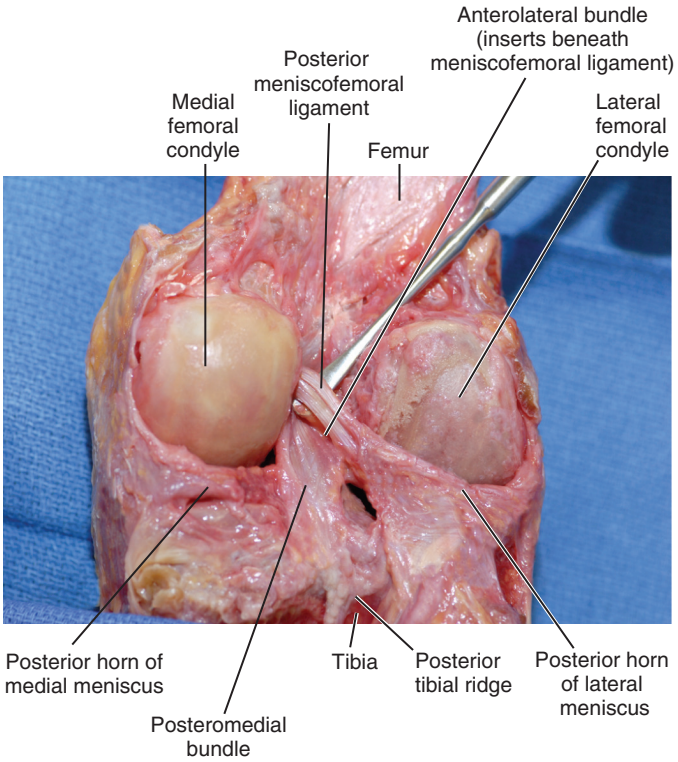

FIG 16-2 Posterior cruciate ligament femoral and tibial attachments. Note the prominent posterior meniscofemoral ligament and broad posterior tibial attachment.

CRITICAL POINTS PCL Anatomy

- PCL arises from a depression posterior to the intraarticular upper surface of the tibia, courses anteromedially behind ACL to lateral surface of medial femoral condyle.
- Contains type I, type II, type IV mechanoreceptors.
- 91% of knees have at least one meniscofemoral ligament.
- PCL complex anatomic structure composed of a continuum of fibers of different lengths and attachment characteristics.
- PCL attachment extends from high in the notch (11:30 to 5 o'clock, right knee).
- Anterior portion of PCL attachment follows articular cartilage within 2 to 3 mm of its edge.
- Posterior third of PCL is 5 mm from the articular margin.
- Proximal edge of PCL is straight or oval, with the attachment tapered in width along its posterior portion.
- PCL femoral attachment described using rule of thirds to define the proximal-middle-distal thirds (deep to shallow in the femoral notch) and anterior-middle-posterior thirds.
- Femoral attachment location strongly influences graft tension, ability of reconstruction to restore posterior stability.
- PCL fibers function from proximal-to-distal in length changes with knee flexion.

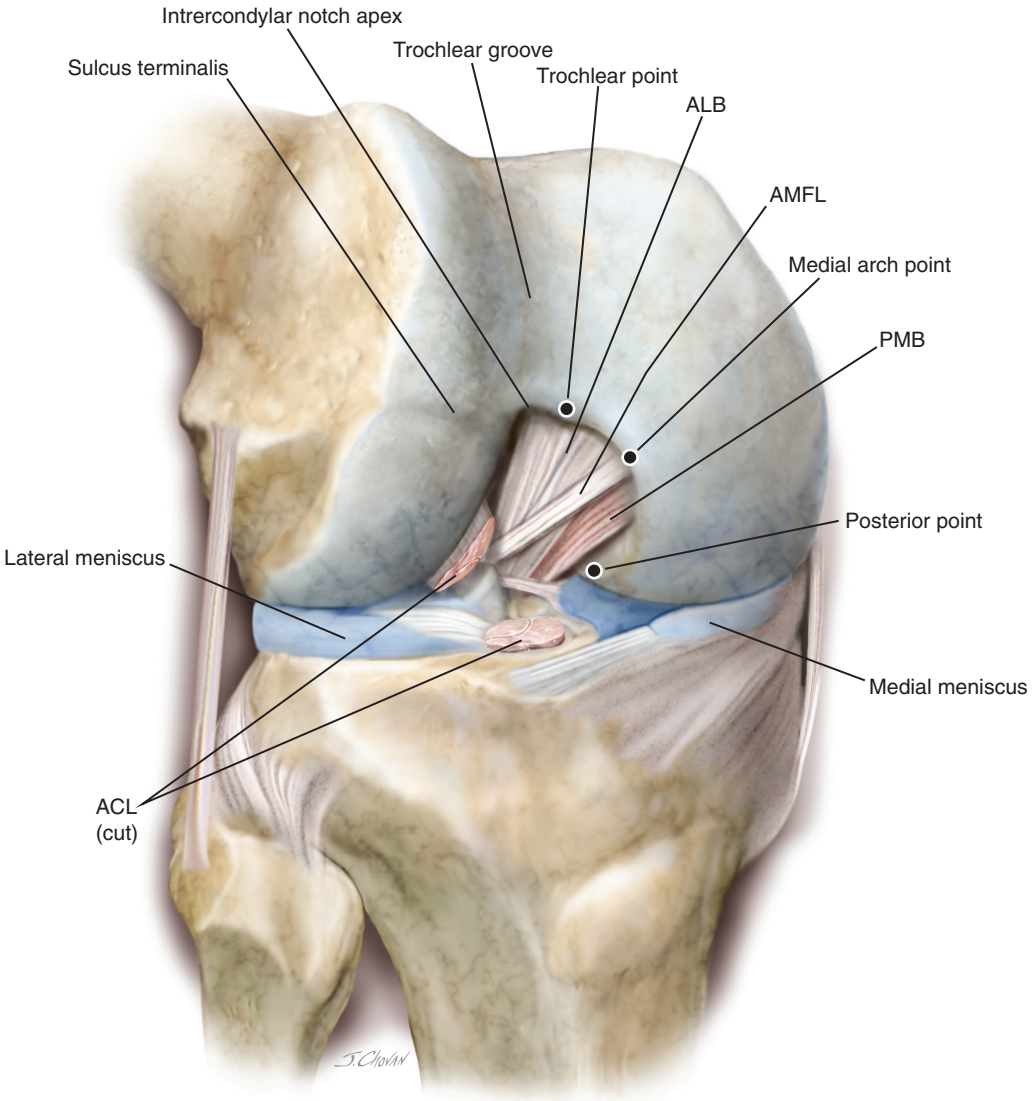

FIG 16-3 Anterior view of a right knee flexed to 90 degrees with the posterior cruciate ligament intact, demonstrating the characteristic morphology of the cartilage margin of the femoral intercondylar notch. The illustration also shows the trochlear, medial arch, and posterior points as well as the intercondylar notch apex and trochlear groove. *ACL*, Anterior cruciate ligament; *ALB*, anterolateral bundle; *aMFL*, anterior meniscofemoral ligament; *PMB*, posteromedial bundle. (Modified from Anderson CJ, Ziegler CG, Wijdicks CA, Engebretsen L, LaPrade RF. Arthroscopically pertinent anatomy of the anterolateral and posteromedial bundles of the posterior cruciate ligament. *J Bone Joint Surg Am.* 2012;94:1936-1945.)

show the anterior (Fig. 16-3) and posterior (Fig. 16-4) aspects of the PCL and its insertion characteristics. The PCL has an average length of 38 mm and an average width of 13 mm (Table 16-1).[63,220] The cross-sectional area of the PCL is variable and increases from its tibial to femoral insertions.[76] It is approximately 50% larger than the ACL at its femoral origin and 20% larger than the ACL at its tibial insertion.

Free nerve endings and mechanoreceptors have been identified in the femoral and tibial attachment sites and on the surface of the PCL.[96,191] The mechanoreceptors resemble Golgi tendon organs and are believed to have a proprioceptive function in the knee.[98]

In a histologic study of the PCL in cadaveric knees, Katonis and coworkers[96] reported a neural innervation similar to that of the ACL. Specifically, the PCL contains type I or Ruffini's corpuscles that have a slow threshold to pressure changes, type II (Vater-Pacini) corpuscles that are more rapid acting, and type IV (free nerve endings) corpuscles for pain reception. The mechanoreceptors are located at each ligament bony attachment and on the surface of the PCL.

The meniscofemoral ligaments are in close proximity to the PCL. They arise from the posterior horn of the lateral meniscus and insert near the PCL insertion site on the lateral aspect of the medial femoral condyle.[76] The anterior meniscofemoral ligament (ligament of Humphrey) courses anterior to the PCL, and the posterior meniscofemoral ligament (ligament of Wrisberg) runs obliquely behind the PCL. Frequently, the anterior meniscofemoral ligament interdigitates with the PCL fiber attachments on the medial femoral condyle

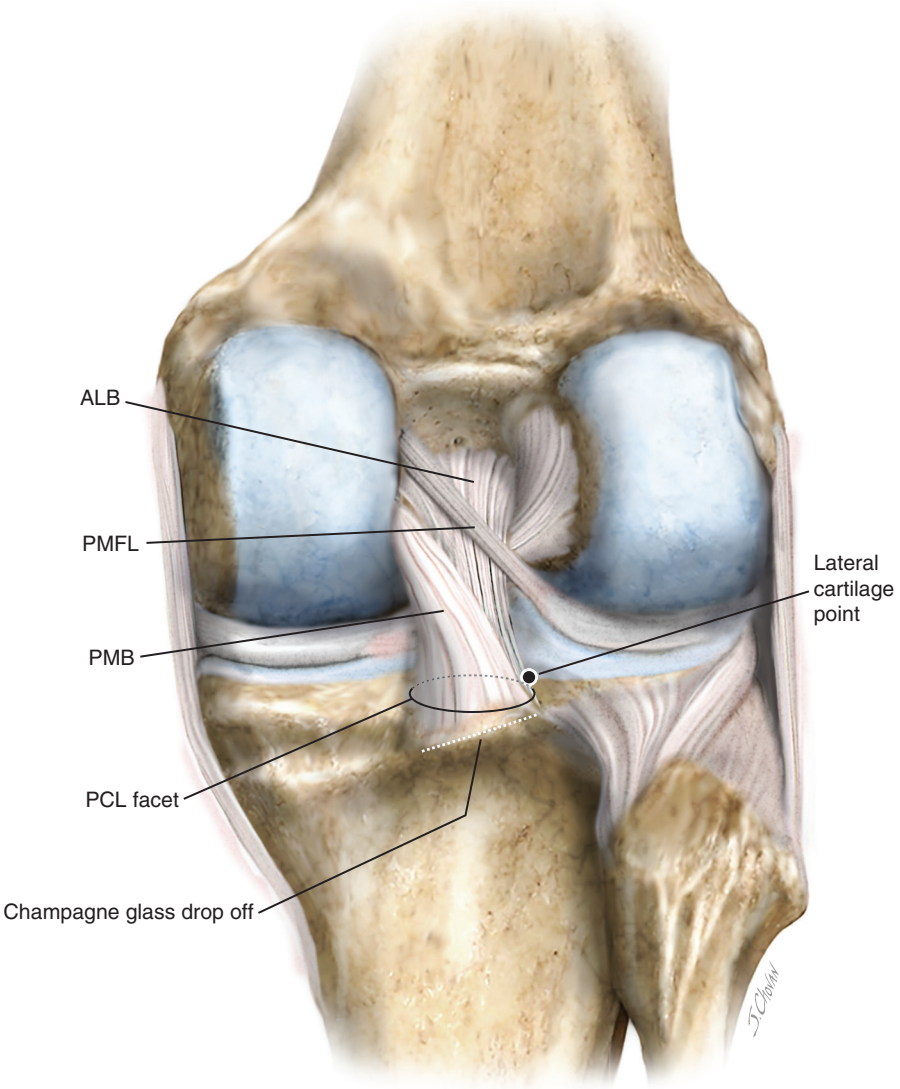

FIG 16-4 Illustration of the posterior aspect of a right knee with the posterior cruciate ligament (PCL) intact, demonstrating the fiber orientation. *ALB*, Anterolateral bundle; *PMB*, posteromedial bundle; *PMFL*, posterior meniscofemoral ligament. (Modified from Anderson CJ, Ziegler CG, Wijdicks CA, Engebretsen L, LaPrade RF. Arthroscopically pertinent anatomy of the anterolateral and posteromedial bundles of the posterior cruciate ligament. *J Bone Joint Surg Am.* 2012;94:1936-1945.)

(Fig. 16-5).[144] At least one of the meniscofemoral ligaments is present in 91% of knees, and both ligaments may be found in 50% of knees in young individuals.[72,76,144] The biomechanical function of the meniscofemoral ligaments is discussed in detail in Chapter 23.

The traditional division of the PCL into a separate anterolateral bundle (ALB) and posteromedial bundle (PMB) oversimplifies PCL fiber function. The PCL is a complex anatomic structure composed of a continuum of fibers of different lengths and attachment characteristics. The length-tension behaviors of the fibers that resist posterior tibial translation (with knee flexion) are controlled primarily by femoral attachment regions.[40,55,69,132,133,189,197,203] The distal fibers lengthen with increasing knee flexion and the proximal fibers shorten with knee flexion.[144,189] A detailed description of the length-tension behavior of the PCL appears in Chapter 15.

The anatomy of the PCL femoral attachment site has been studied extensively (see Table 16-1).[144,189] Variation exists between knees in the shape of this attachment, from the common elliptical shape to a more rounded and thicker shape (Fig. 16-6).[144] Different measurement systems have been proposed to describe the femoral attachment site. The most common method uses a clock reference position (Fig. 16-7), with measurement lines perpendicular to the articular cartilage edge and measurement lines parallel to the femoral shaft (Fig. 16-8). The clock method is a general guide and not highly accurate; therefore the entire PCL footprint and relationships to other structures described should be viewed.

In general, the PCL attachment extends from high in the notch (11:30 to 5 o'clock position on a right knee) along the medial femoral

TABLE 16-1 Posterior Cruciate Ligament Anatomy Studies

Study	Methods	Specimens	PCL Footprint, Attachment/Insertion Sites	Anatomic Landmarks	Conclusions
Narvy et al[149] (2014)	Systematic review of cadaveric and radiographic studies; 10 yr		*Radiographic parameters:* ALB center 40% and PLB 56% distance anterior surface femur. *Cadaveric data*: center of ALB 8 mm (27.5%) from cartilage edge, PLB 11.9 mm (42.5%) from anterior articular surface.	Blumensaat line, articular cartilage surface, medial intercondylar ridge	Review of 38 studies on PCL femoral footprint anatomy
Hatsushika et al[77] (2013)	ALB and PMB separated into ~20 small bundles (1 mm in diameter), attachment sites preserved; photographs, illustrations	$n = 12$, age unknown	Femoral attachment patterns similar; each small bundle ran in parallel towards tibial attachment in extension, crossed over each other in flexion. Tibial attachments showed two patterns: parabolic and transverse.	NA	First study to describe two patterns of ALB and PMB attachments in the tibia
Van Hoof et al[221] (2013)	3-D model from CT images. Concepts of best-fit cylinder and central axis given; illustrations	$n = 9$, 66-97 years	Mean footprint surface area: tibia 189.1 mm^2, femoral 293.3 mm^2. Mean diameter of best-fit cylinder, 10.5 mm. Mean coverage best-fit cylinder on tibial footprint 76.5%, femoral footprint 46.5%.	NA	Study confirmed large difference between tibial and femoral footprints. Best-fit 10-mm tunnel covers only 50% of femoral footprint; single-bundle PCL not able to be considered anatomic on femoral side.
Westermann et al[231] (2013)	3-D model from CT images; photographs, illustrations	$n = 7$, age unknown	Femoral footprint: center is 38% of the entire medial femoral condyle from anterior to posterior, parallel to Blumensaat's line on perfect lateral view and 25% of the condyle height from the notch roof on a perfect notch view.	NA	Provides standards of measurement for future studies that use advanced imaging for entire PCL insertion. Not applicable for location ALB or PMB.
Johannsen et al[89] (2013)	AP and lateral x-rays, attachment centers labeled with radiopaque spheres, attachment areas labeled with barium sulfate; illustrations	$n = 20$, 21-59 years	Lateral view: ALB center located 17.4 mm posteroproximal, PMB center located 23.9 mm posteroproximal to anterior cortex line of femoral condyles. ALB tibial center located 8.4 mm, PMB center located 2.5 mm superior, PCL center 5.5 mm superior to "champagne glass drop-off" of posteroproximal tibia.	Lateral view: Blumensaat line and anterior cortex line, champagne glass drop-off of posteroproximal tibia	Most important findings on lateral views. Femur: measurements to Blumensaat line and anterior cortex line. Tibia: PCL attachment center measurement to champagne glass drop-off. Size scaling percentages not incorporated in measurements. Radiographic landmarks differ from cartilage-based arthroscopic landmarks.

TABLE 16-1 Posterior Cruciate Ligament Anatomy Studies—cont'd

Study	Methods	Specimens	PCL Footprint, Attachment/Insertion Sites	Anatomic Landmarks	Conclusions
Anderson et al[9] (2012)	Electromagnetic tracking system used to outline structures, distances measured between center of fiber bundles and anatomic landmarks; photographs, illustrations, arthroscopic views	$n = 20$, 21-49 years	Femoral attachment: mean area PCL 192 mm^2, ALB 112 mm^2, PMB 60 mm^2, anterior MFL 35 mm^2, posterior MFL 31 mm^2. Tibial attachment: mean area PCL, 219 mm^2, PCL facet 291 mm^2, ALB 88 mm^2, PMB 105 mm^2.	Tibia: lateral plateau articular cartilage, medial meniscus attachment, osseous ridge separating anterolateral and posteromedial bundles.	Used two femoral tunnels, one tibial tunnel. Center of femoral AL tunnel should be triangulated on basis of the trochlear point, the medial arch point, and the medial bifurcate prominence. Distal edge should be placed adjacent to articular cartilage. Femoral PM tunnel should be placed equal distance from the posterior point and medial arch point and just distal to the medial intercondylar ridge (center a mean 8.6 mm proximal to articular cartilage margin). Center of tibial tunnel should be just anterosuperior to bundle ridge, on the medial side of the PCL facet, 9.8 mm from lateral cartilage point and 5 mm from medial groove.
Osti et al[173] (2012)	High-resolution digital images, two grid systems (16 rectangular zones), AP and lateral x-rays; photographs	$n = 15$, 82 ± 8 years	PCL tibial footprint mediolateral 10.37 mm, superoinferior 9.58 mm. ALB length 31.79 mm, femoral footprint mediolateral 7.85 mm, anteroposterior 8.51 mm, superoinferior 8.56 mm. PMB length 32.42 mm, femoral footprint mediolateral 6.84 mm, anteroposterior 8.82 mm, superoinferior 8.83 mm.	Cartilage borders, intercondylar roof, medial femoral condyle used in two measurement grid systems.	Provides femoral measurement grid system for arthroscopic views and x-ray images.
Greiner et al[66] (2011)	CT, insertions marked with plastic markers; photographs, CT images, illustrations	$n = 10$, 60-85 years	Femoral insertion mean surface area 232 mm^2. Tibial insertion trapezoidal shape, mean surface area 154.8 mm^2.	Mean distance center of femoral insertion to roof of notch 8.9 mm; to anterior articular cartilage surface 18.7 mm. Tibial insertion centered 9.1 mm from posterior border of tibia on retrospinal surface, 1.6 mm inferior to plane of articular cartilage.	Study documented native femoral and tibial attachments relative to CT-specific landmarks.

TABLE 16-1 Posterior Cruciate Ligament Anatomy Studies—cont'd

Study	Methods	Specimens	PCL Footprint, Attachment/Insertion Sites	Anatomic Landmarks	Conclusions
Lee et al[117] (2010)	Four corners of tibial footprint marked with drill tip, screws inserted at each corner and at 1-cm intervals in posterior cortex aligned with the tibial tunnel. AP and lateral x-rays, CT; photographs, x-ray, and CT images	$n = 10$, 34-61 years	Mean tibial insertion from joint line on AP x-ray 5.9 ± 1.1 mm to proximal aspect of PCL, 17.4 ± 2.4 mm to the distal aspect of PCL. Mean tibial insertion from joint line on lateral x-ray, 2.2 ± 1.2 mm to proximal aspect of PCL and 12.3 ± 1.5 mm to distal aspect of PCL.	PCL facet (fossa) consistent radiographic landmark for pin placement. PCL insertion was in posterior 48% of the area of the posterior intercondylar fossa, to the posterior cortex.	Mean tibial insertion of PCL from joint line was located higher on lateral x-ray than on AP x-ray. Identified posterior intercondylar fossa and posterior cortex that align with the tibial tunnel.
Jeong et al[88] (2010)	3-D CT-based knee joint model. Femoral attachment divided into four sectors, tibial attachment divided into six sections; 24 virtual PCL bundles; illustrations	$n = 10$ living subjects, healthy knees, scanned 0, 90, 135 degrees	At 0 and 90 degrees, bundle with least amount of length change was PMB inserting into most posterior femoral sector and most distal tibial sector. Change was not different compared with other bundles with tibial points attached to same femoral sector.		No isometric points in any virtual PCL bundle. Avoid high flexion during postoperative rehabilitation.
Tajima et al[214] (2009)	Macroscopic observation, 3-D laser photography; photographs, illustrations	$n = 21$, 42-93 years	Mean area PCL tibial attachment 243.9 mm^2, AL insertion 93 mm^2, PM insertion 150.8 mm^2.	Posterior intercondylar fossa: ALB attached to superolateral aspect (slope), PMB attached to inferomedial aspect (slope). Change of >10 degrees observed between AL and PM slopes.	Tibial insertion complex, shapes, and positions of insertion sites of AL and PM consistently located in different planes on fossa.
Lopes et al[127] (2008)	Macroscopic observation, 3-D laser photographs; photographs, illustrations	$n = 20$, 57-93 years	Mean area PCL femoral footprint 209 mm^2, mean ALB 118 mm^2, PMB 90 mm^2. AL center 7 ± 2 mm (10:20 o'clock), PM center 10 ± 3 mm (8:30 o'clock) from the articular cartilage.	Femoral footprint: osseous prominence proximal frequently seen (medial intercondylar ridge). Small osseous prominence between ALB and PMB in some knees.	Femoral footprint has medial intercondylar ridge usually present.
Moorman et al[147] (2008)	Observation, histology, lateral x-rays; photographs, x-rays	$n = 14$, age unknown	Mean PCL tibial insertion AP dimension 15.6 ± 1.1 mm. Center tibial insertion mean 7 mm anterior to the posterior cortex. Majority of fibers insert on posterior half of PCL facet.	PCL facet	Tunnel placement at the center of the PCL can be measured along the PCL facet as seen in a true lateral x-ray.
Edwards et al[47] (2007)	Observation, high-resolution digital photos; photographs, illustrations	$n = 39$, 60-80 years	Tibial attachment occupied posterior intercondylar fossa. Parallel femoral long axis: AL 9 to 12 o'clock (center, 10:20); 7 ± 2 mm (range, 4-12 mm) from cartilage edge. PMB 7:30 to 10:30 o'clock (center, 8:30), 10 ± 3 mm (range, 6-19 mm) from cartilage edge.	Posterior intercondylar fossa, Blumensaat's line, articular cartilage outlines	Tibial attachments consistent pattern in posterior intercondylar fossa. Femoral attachment required more than one measuring system.

ALB, anterolateral bundle; *AP*, anteroposterior; *CT*, computed tomography; *MFL*, meniscofemoral ligament; *NA*, not available; *PCL*, posterior cruciate ligament; *PMB*, posteromedial bundle.

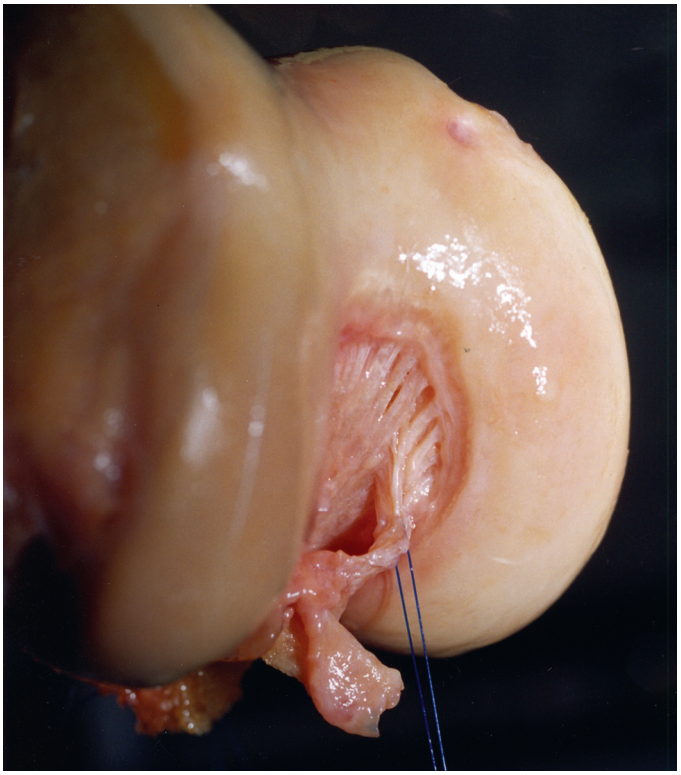

FIG 16-5 Anterior meniscofemoral ligament (ligament of Humphrey) attachment on the femur interdigitates with the posterior cruciate ligament distal fibers. (From Mejia EA, Noyes FR, Grood ES. Posterior cruciate ligament femoral insertion site characteristics. Importance for reconstructive procedures. *Am J Sports Med*. 2002;30:643-651.)

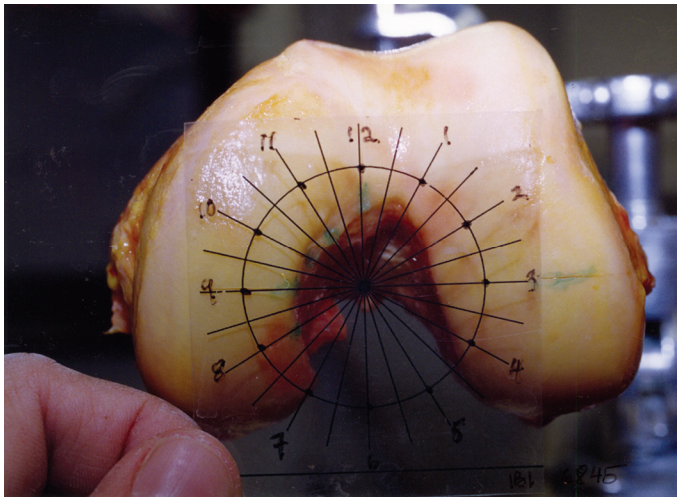

FIG 16-7 Clock-face markings on the medial femoral condyle as projected from a transparent sheet of acetate onto the notch viewed axially from a knee at 90 degrees of flexion. (From Mejia EA, Noyes FR, Grood ES. Posterior cruciate ligament femoral insertion site characteristics. Importance for reconstructive procedures. *Am J Sports Med*. 2002; 30:643-651.)

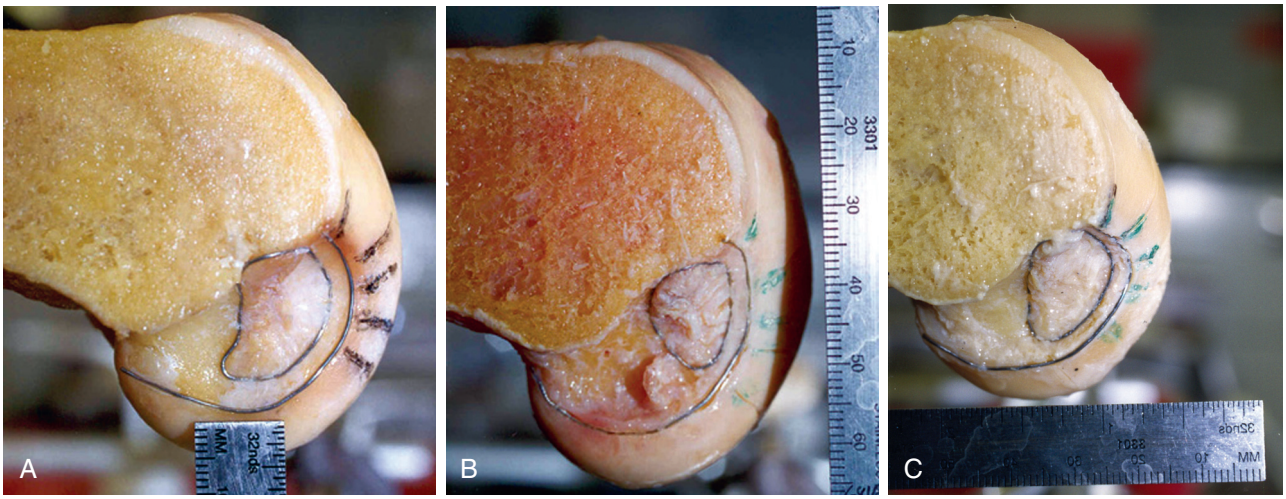

FIG 16-6 Composite of the shapes of different posterior cruciate ligament (PCL) insertion sites as seen on lateral views. Variability is noted among specimens from an oval to an elliptical PCL footprint configuration. Note the differences in anterior-to-posterior and proximal-to-distal dimensions in the PCL footprint. The most common shape of the PCL footprint is elliptical. **A,** Note that the fibers insert proximally to the intercondylar roof. The PCL footprint is smaller in its anteroposterior dimension. **B,** Note the prominent posterior meniscofemoral ligaments. **C,** A more oval PCL attachment with greater proximal-to-distal width. (From Mejia EA, Noyes FR, Grood ES. Posterior cruciate ligament femoral insertion site characteristics. Importance for reconstructive procedures. *Am J Sports Med*. 2002;30:643-651.)

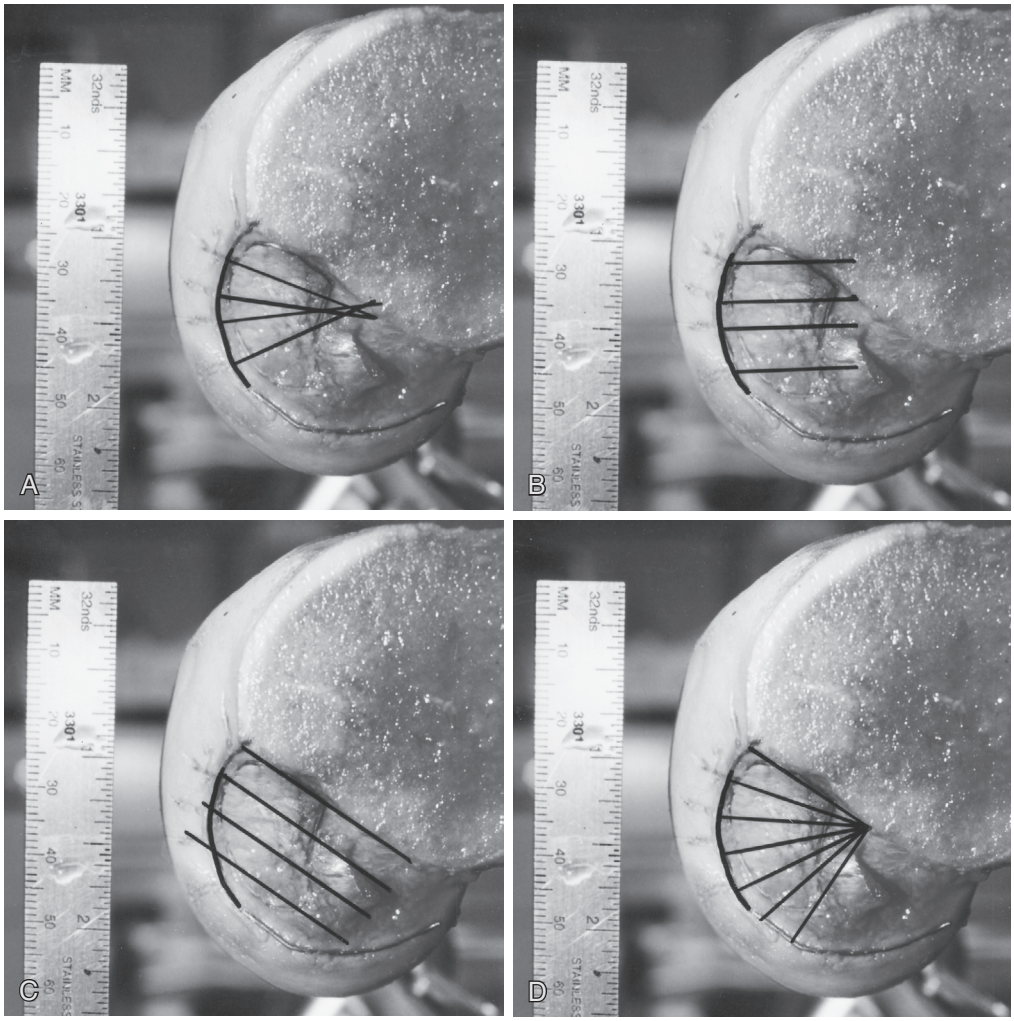

FIG 16-8 **A,** Measurement lines referenced from clock-face positions perpendicular to the cartilage edge. These reference lines represent the shortest distance to the distal margin of the posterior cruciate ligament (PCL) attachment. **B,** Measurement lines referenced from a clock-face position parallel to the femoral shaft. **C,** Measurement lines referenced from a clock-face position parallel to the intercondylar roof (5-mm increments). **D,** Measurement lines referenced radially from the intercondylar roof. These lines are directed from a center located at the most proximal extent of the PCL attachment onto the roof of the intercondylar notch. This point is, on average, located at approximately 60% of the roof depth. The line progresses from the 12 o'clock position (*top line*) to the 6 o'clock position (*bottom line*). (From Mejia EA, Noyes FR, Grood ES. Posterior cruciate ligament femoral insertion site characteristics. Importance for reconstructive procedures. *Am J Sports Med.* 2002;30:643-651.)

condyle notch. The anterior portion of the PCL attachment follows the articular cartilage within 2 to 3 mm of its edge and gradually recedes deeper within the notch until, at the 5 o'clock position, the posterior third is 5 mm from the articular margin. Therefore the distal boundary of the PCL femoral attachment does not parallel the articular margin as reported by others[63,219] but is farthest away from the cartilage margin posteriorly.

The distal and proximal measurements for the PCL femoral attachment are shown in Table 16-2 and measurements vary from one study to another depending on the method selected. The proximal edge of the PCL is usually straight or partially oval, with the attachment tapered in width along its posterior portion.

The PCL attachment measurements parallel to the intercondylar roof are shown in Table 16-3. The length of the radial measurement lines extending from the intercondylar roof are shown in Table 16-4. This method provides a means to measure the middle and lower portions of the PCL and provides information on the distance from the lowest cartilage margin to the most posterior portion of the PCL attachment.

The use of measurement lines perpendicular to the cartilage edge is preferred for describing the distal attachments of the PCL (see Fig. 16-8, *A*). The disadvantage of this system is that the 12 o'clock and usually the 1 o'clock measurements cannot be made parallel to the femoral shaft but must be done perpendicular to the cartilage (Fig. 16-9).

Therefore more than one measurement system is required to describe the anterior, middle, and posterior portions of the PCL femoral origin. Location of the center of the clock face midway in the

TABLE 16-2 Posterior Cruciate Ligament Femoral Attachment Measurements Made With the Femoral Condyle Articular Cartilage Clock System

Measurement	Distal (mm)	Proximal (mm)	Thickness (mm)
Perpendicular to the Cartilage			
12 o'clock	2.54 ± 1.0	12.92 ± 2.8	10.38 ± 2.8
1 o'clock	2.38 ± 0.7	14.33 ± 2.2	11.96 ± 2.0
2 o'clock	2.38 ± 0.5	14.79 ± 1.8	12.42 ± 1.7

notch is difficult but critical for identification of the landmarks required to map the PCL femoral attachment. This location should be identified with the knee at 90 degrees of flexion. Ideally, sagittal, anteroposterior (AP), and notch descriptions are required to anatomically represent the entire PCL attachment.

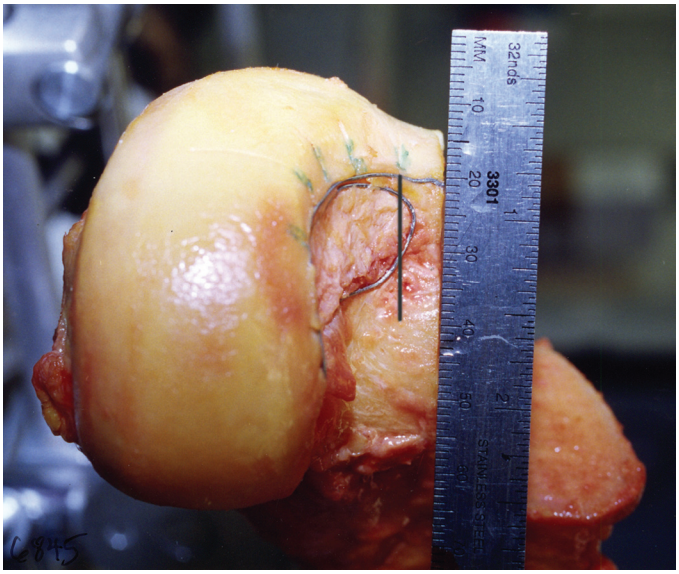

FIG 16-9 Reference line at the 12 o'clock position. The curved posterior cruciate ligament attachment is shown extending to the intercondylar roof. (From Mejia EA, Noyes FR, Grood ES. Posterior cruciate ligament femoral insertion site characteristics. Importance for reconstructive procedures. *Am J Sports Med.* 2002;30:643-651.)

A clear understanding of the anatomy of the native PCL is critical to determine what portion of the ligament will be reconstructed. The terms "high," "low," "shallow," and "deep" are only general descriptors. Because there may be considerable confusion regarding femoral graft tunnel placement during PCL reconstruction, the PCL femoral attachment is described using the rule of thirds (Fig. 16-10) to define the proximal-middle-distal thirds (deep to shallow in the femoral notch), and anterior-middle-posterior thirds (high to low), with a small posterior oblique portion in the sagittal plane.[144,151] This provides a grid for the identification of the tunnel locations for the graft strands and is preferred by the senior author (F.R.N.).

It is well appreciated that the PCL graft femoral attachment location strongly influences graft tension and the ability of the reconstruction to restore posterior stability.[12,56,189,197] Investigations by Grood and associates[68] and Sidles and colleagues[203] demonstrated that the femoral attachment location determines the graft tibiofemoral separation distance with knee flexion-extension, much more so than the tibial attachment location. The proximal-distal femoral location of a graft has a greater effect on the attachment separation distance than the AP femoral location, which is the basis for the rule of thirds (see Fig. 16-10, *B*). A graft placed in the distal and middle thirds elongates with knee flexion, whereas a graft placed in the proximal third elongates with knee extension. These concepts are used to select PCL graft attachment locations and tensioning described in the "Operative Techniques" section.

Anderson and colleagues[9] described, in 20 unpaired cadaveric knees, the PCL femoral and tibial attachments of the ALB and PMB to provide the surgeon with landmarks for the placement of PCL grafts. The femoral PCL attachment is illustrated in Figure 16-3 and the arthroscopic viewpoint is illustrated in Figure 16-11. The centers of the ALB and the PMB were a mean of 7.9 mm and 8.6 mm, respectively, from the articular cartilage edge, which is in close agreement with the data previously presented (see Table 16-1). It is understood that the variability among studies of a few millimeters reflect differences in both measurement techniques and cadaveric specimens. Even

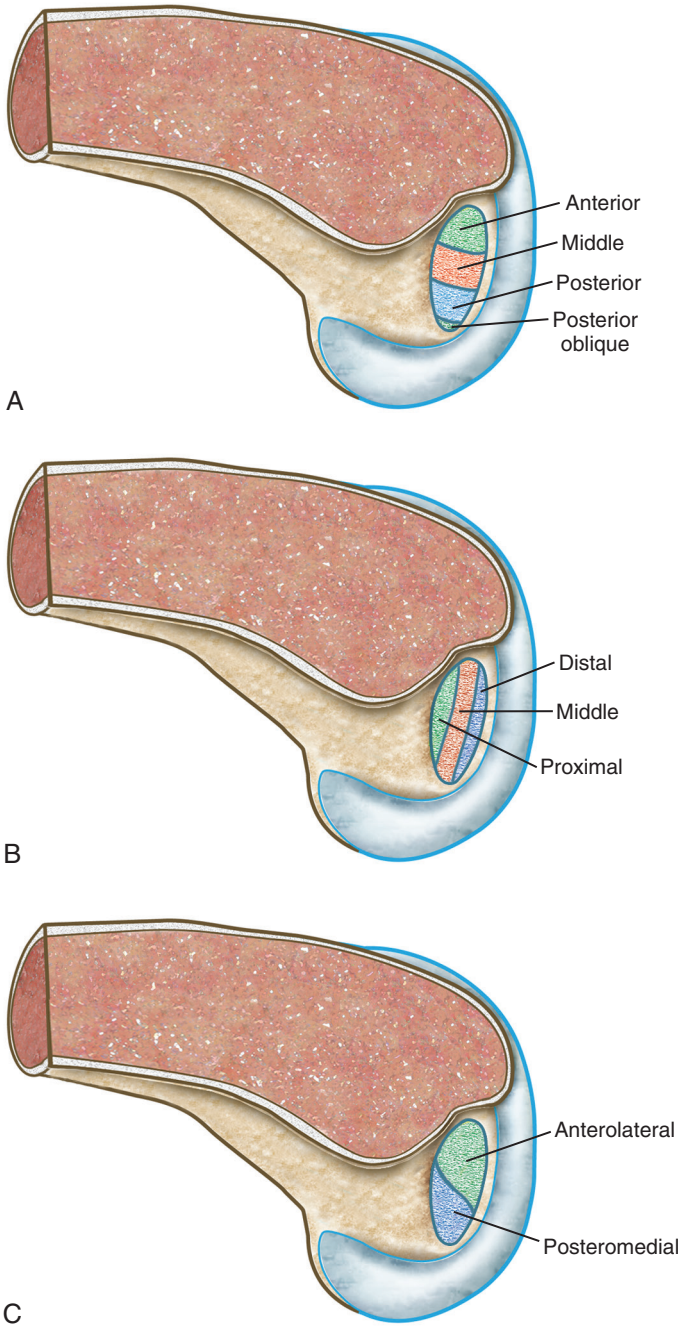

FIG 16-10 A, Rule of thirds: The posterior cruciate ligament (PCL) footprint is divided into anterior, middle, and posterior thirds. The anterior third extends past the midline (12:30, left knee) and the posterior region extends to 5 o'clock. The smaller posterior oblique portion of the PCL footprint is also represented. The PCL footprint is elliptical in most knees, but variations exist. **B,** Rule of thirds: The PCL footprint is further divided into the distal, middle, and proximal thirds. This allows for more exact referencing of graft strand placement during PCL reconstruction. The PCL fibers in the distal two-thirds lengthen with knee flexion while the proximal fibers shorten. The reverse occurs with knee extension. **C,** Classical division of anterolateral and posteromedial bundles provides a general description of PCL fiber length change of anterolateral fibers that lengthen and posteromedial fibers that shorten with knee flexion.

so, the data of these collective studies allow a reasonable definition of the PCL attachment sites at surgery. The AL portion extends distally to within approximately 2 mm of the femoral articular cartilage edge or margin, and the PM portion extends distally 4 to 6 mm from the femoral articular cartilage edge. This analysis allows for a more distal femoral placement of PCL grafts than has been historically recommended, as will be discussed.

An illustration of the posterior PCL tibial attachment is shown in Figure 16-4. The landmarks for the tibial attachment of the PCL are illustrated in Figure 16-12. The *shiny fibers* of the medial meniscus attachment are easily viewed at surgery. The posterior capsule attachment at the posterior tibial ridge is illustrated as an opening to show the proximity of the popliteus muscle. This posterior capsular attachment is always preserved and not violated at surgery.

VASCULAR ANATOMY AND VARIATIONS

The vascular supply to the cruciate ligaments is provided mostly by the middle genicular artery, which is a branch of the popliteal artery that penetrates the posterior capsule of the knee.[10,190] The PCL is covered with a well-vascularized synovial sleeve that contributes to its blood supply. The distal portion of the PCL also receives some vascular supply from capsular vessels originating from the inferior genicular arteries and the popliteal artery.

Detailed knowledge of posteromedial knee anatomy, especially the vascular structures, is required to avoid complications when using a posteromedial approach to a tibial inlay PCL reconstruction (see Chapter 2). The popliteal artery originates at the adductor hiatus and passes through the popliteal fossa. Before passing deep to the fibrous arch over the soleus muscle, it divides into the anterior and posterior tibial arteries at the distal aspect of the popliteus muscle.

Proximal to the knee joint, several muscular branches arise and supply the adductor magnus and hamstring muscles. At the level of the supracondylar ridge, the superomedial and superolateral genicular arteries are present.

At the level of the knee joint, four major arteries are distributed: the medial and lateral sural arteries, a cutaneous branch that travels with the small saphenous vein to supply superficial tissues, and the middle genicular artery. Finally, the medial and lateral inferior genicular arteries are present just distal to the knee joint.

Two branches deserve particular attention. The medial inferior genicular artery arises from the medial aspect of the distal portion of the popliteal artery and runs medially, deep to the medial head of the

CRITICAL POINTS Vascular Anatomy and Variations

- Vascular supply mostly provided by middle genicular artery.
- Popliteal artery originates at adductor hiatus, passes through popliteal fossa, and divides into anterior and posterior tibial arteries at the distal aspect of the popliteus muscle.
- Four major arteries at level of knee joint: medial and lateral sural arteries, a cutaneous branch that travels with the small saphenous vein to supply superficial tissues, middle genicular artery.
- Medial and lateral inferior genicular arteries given off just distal to knee joint.
- Normal vascular pattern 88% of knees, 5%-7% anatomic variation, anterior tibial artery passes anterior and proximal to popliteus muscle.
- Popliteal artery: anatomic variability possible, manifests as popliteal artery entrapment syndrome.
- Embryologic development explains abnormal vascular patterns.

gastrocnemius, and approximately 2 to 3 mm from the superior surface of the popliteus muscle. It continues around the medial aspect of the proximal tibia, deep to the superficial medial collateral ligament (SMCL). The middle genicular artery arises at the level of the femoral condyles proximal to the joint line and passes anteriorly to pierce the oblique popliteal ligament (OPL) and posterior joint capsule and supply the cruciate ligaments.

This "normal" vascular pattern has been reported to occur in approximately 88% of cases.[42,140] In approximately 5% to 7% of cases, the popliteal artery will divide at least 2 cm or more proximal to the popliteus muscle.[38,42,140] In slightly less than half of these cases, with a high division of the popliteal artery, the anterior tibial artery passes anterior, not posterior, to the popliteus muscle belly.[216] The number of variations of the anterior tibial artery according to Mauro and coworkers[140] is illustrated in Figure 16-13. Therefore with a tibial inlay approach, the dissection is always proximal to the popliteus muscle with a meticulous technique, because the anterior tibial artery is at risk for transection in approximately 3% to 4% of knees.

An unusual variation in the vascular pattern involves the popliteal artery passing medial and then beneath the medial head of the gastrocnemius. Various subtypes of this abnormal pattern have been described. An abnormal vascular pattern may manifest clinically as the popliteal artery entrapment syndrome, which is characterized by vascular claudication symptoms.[112,185,207] Arterial insufficiency occurs most commonly with entrapment of the artery deep to the medial gastrocnemius muscle, but can also occur when the artery is entrapped deep to the popliteus muscle (persistence of ventral component of artery) or deep to an abnormal accessory head of the gastrocnemius. A history of pain in the lower extremity with activity and disappearance with rest, particularly in a young patient, should alert the surgeon to the possibility that an abnormal vascular pattern may exist. Further evaluation with angiography may be warranted.[54,128]

Embryologic development helps to explain these abnormal vascular patterns. In the embryo, the lower extremity blood supply is derived from the sciatic or axial artery (a branch of the internal iliac artery) as well as the femoral artery (a branch of the external iliac artery). The proximal sciatic artery regresses, whereas the middle and distal sciatic artery persist to form the definitive popliteal and peroneal arteries.

The anterior tibial artery arises as a branch of the popliteal artery and initially courses anterior to the popliteus muscle. In humans, the early anterior tibial artery is replaced with the superficial popliteal artery and passes posterior to the popliteus muscle, which then gives rise to the anterior tibial artery. Furthermore, during embryonic life, the medial head of the gastrocnemius migrates medially and cranially. It is with this migration that the popliteal artery can be caught and swept medially with the muscle.[140,185]

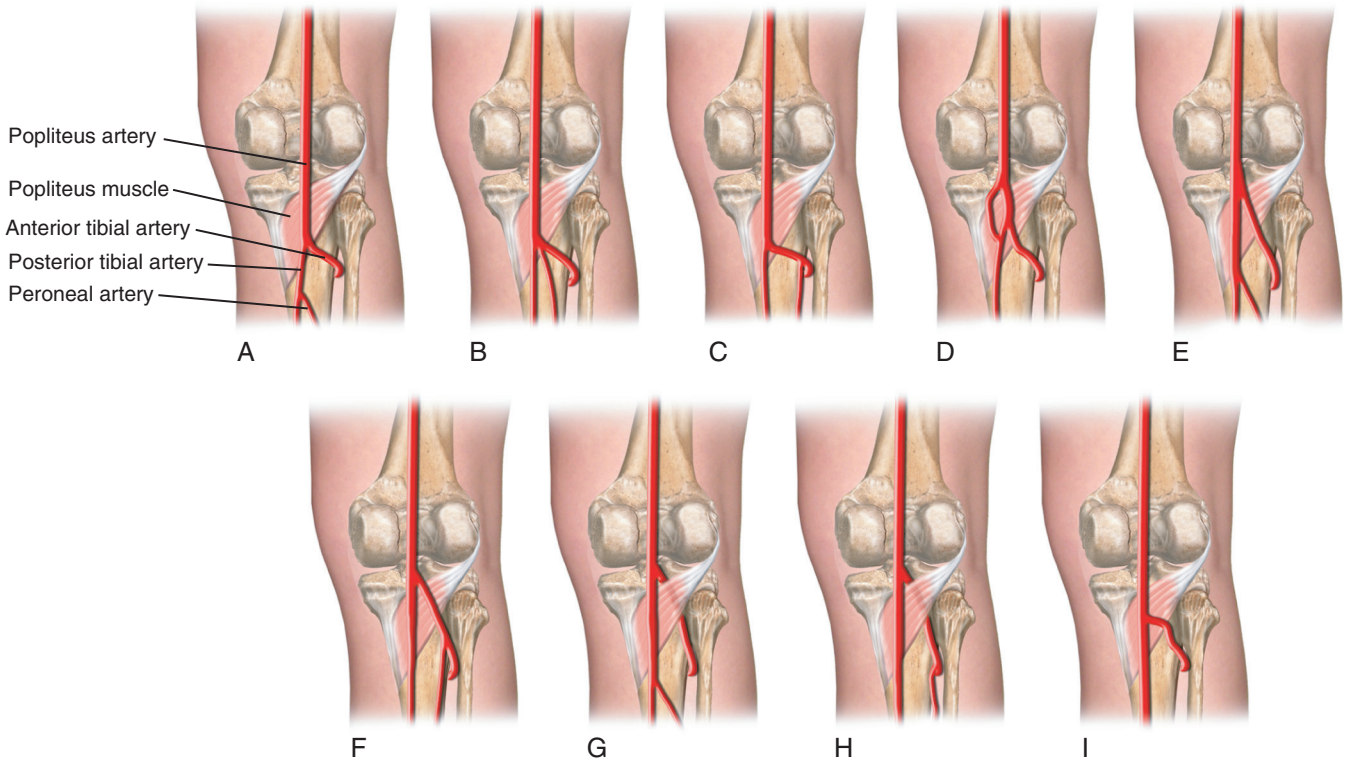

FIG 16-13 Anatomic variations of the popliteal artery and its branches. Diagrams represent posterior views of popliteal fossa and popliteus muscle. **A,** Normal. **B,** Trifurcating popliteal artery. **C,** Peroneal artery arising from low anterior tibial artery. **D,** "Island" popliteal artery (very rare). **E,** High anterior tibial origin passing superficial to popliteus muscle. **F,** Same as E with peroneal artery arising from anterior tibial artery. **G,** Same as E with anterior tibial artery passing deep to popliteus muscle. **H,** Same as F except anterior tibial artery passes deep to popliteus muscle. **I,** Absent posterior tibial artery. Note that the anterior tibial artery is at risk in the initial dissection proximal to the popliteus muscle in **D** through **H**. (From Mauro MA, Jacques PF, Moore M. The popliteal artery and its branches: embryologic basis of normal and variant anatomy. *AJR Am J Roentgenol.* 1988;150:435-437.)

CLINICAL EVALUATION

Physical Examination

A comprehensive examination of the knee joint is required to detect all abnormalities. This includes assessment of, first, the patellofemoral joint and patellar tendon-tibial tubercle alignment (Q angle), which may be increased owing to increased external tibial rotation when a posterolateral ligament injury accompanies the PCL rupture. Second, patellofemoral and tibiofemoral crepitus, is indicative of articular cartilage damage. Third, gait abnormalities (excessive hyperextension or varus thrust) are assessed during walking and jogging.[165] Finally, abnormal knee motion limits and subluxations are compared with those of the contralateral knee[167].

Experienced clinicians are aware that patients with chronic deficiency of the PCL and posterolateral structures may develop an abnormal gait pattern that is characterized by excessive knee hyperextension during the stance phase.[165] Subjective complaints of knee instability and giving-way during routine daily activities, along with severe quadriceps atrophy, often accompany this gait abnormality. Gait analysis and retraining are required in patients who demonstrate abnormal knee hyperextension patterns before proceeding with any ligament reconstruction (see Chapter 29).[165] The failure to do so may lead to failure of reconstructed ligaments if the abnormal gait pattern is resumed postoperatively.

Diagnostic Clinical Tests

The medial posterior tibiofemoral step-off on the posterior drawer test is performed at 90 degrees of flexion. The amount of posterior tibial translation will vary between knees with isolated PCL ruptures because of physiologic laxity or injury to the secondary posterolateral or medial soft tissue restraints. Posterior tibial translation progressively increases with injury to the secondary restraints. The importance of determining abnormal medial or lateral joint opening and increases in external-internal tibial rotation cannot be overemphasized, because the failure to correct these associated subluxations places PCL graft reconstructions under high in vivo forces postoperatively and risk of graft failure.[157] The diagnostic tests and their interpretation are discussed in Chapter 15.

The exact determination of the extent of a PCL tear (partial versus complete) can be difficult but is essential from a therapeutic standpoint. The clinical posterior drawer test can be highly subjective, with the forces applied too variable to allow accurate determination of the status of the PCL. Magnetic resonance imaging (MRI) is not always accurate in diagnosing partial PCL tears (Fig. 16-14). Frequently, this test may indicate that the ligament is completely ruptured; however, ligament continuity may still exist with some portions functioning to limit posterior tibial subluxation to only a few millimeters. Patten and associates[178] reported only a 67% sensitivity rate of the ability of MRI to distinguish complete from partial PCL tears by identifying focal areas of ligamentous discontinuity.

The quantitative measurement of posterior tibial subluxation in knees with PCL ruptures or reconstruction is therefore important.[80] The knee arthrometer is the most frequently used device to measure posterior tibial translation after PCL injury and reconstruction. However, the knee arthrometer underestimates the true amount of posterior translation in PCL-deficient and reconstructed knees, often by several millimeters.[80,134,208] Stress radiography is the most accurate and reproducible technique currently available.[46,80,134,181,193] We recommend that PCL clinical investigations incorporate stress radiography to provide a more valid measure of posterior tibial translation (Fig. 16-15). To correct for tibial rotation, which can produce errors in

CRITICAL POINTS Clinical Evaluation

Physical Examination
- Patellofemoral joint, extensor mechanism malalignment
- Patellofemoral and tibiofemoral crepitus
- Gait abnormalities
- Abnormal knee motion limits, subluxations

Diagnostic Clinical Tests
- Posterior drawer, 90 degrees of knee flexion
- Pivot shift, Lachman
- KT-2000, 20 degrees of knee flexion, 189 N of force (optional)
- Reverse pivot shift
- Medial tibiofemoral joint opening 0, 30 degrees of knee flexion
- Lateral tibiofemoral joint opening 0, 30 degrees of knee flexion
- Tibiofemoral rotation dial test, 30 and 90 degrees of knee flexion

Radiographic Assessment
- Anteroposterior
- Lateral, 30 degrees of knee flexion
- Posteroanterior, weight bearing, 45 degrees of knee flexion
- Patellofemoral axial
- Posterior stress, 90 degrees of flexion, 89 N posterior force on tibia
- Medial or lateral stress, neutral tibial rotation, tibia unconstrained, 89 N varus force
- Double-stance to measure mechanical axis and weight bearing line

Assessment of Symptoms and Functional Limitations With Activity: Use Cincinnati Knee Rating System
- Sports Activity and Function Form
- Occupational Rating Form
- Symptom Rating Form

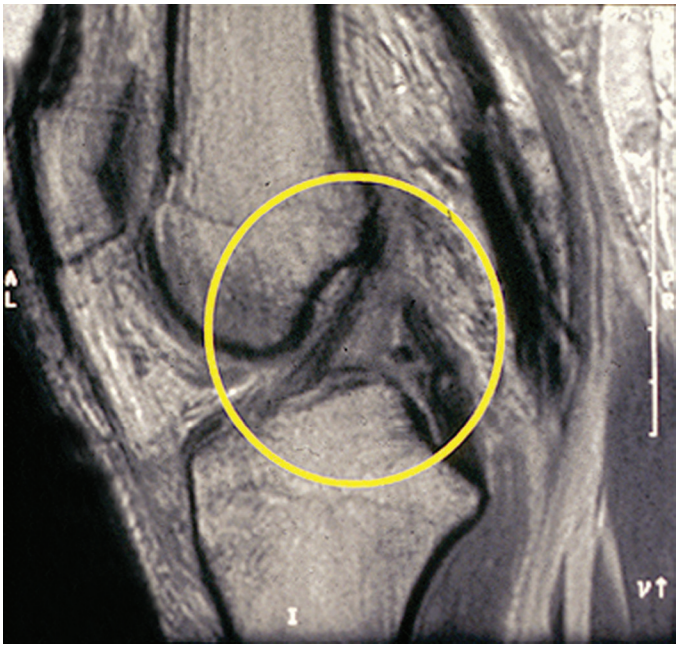

FIG 16-14 A partial posterior cruciate ligament (PCL) rupture is shown. Even though the magnetic resonance imaging suggests a complete rupture, there were remaining PCL fibers resisting posterior tibial subluxation.

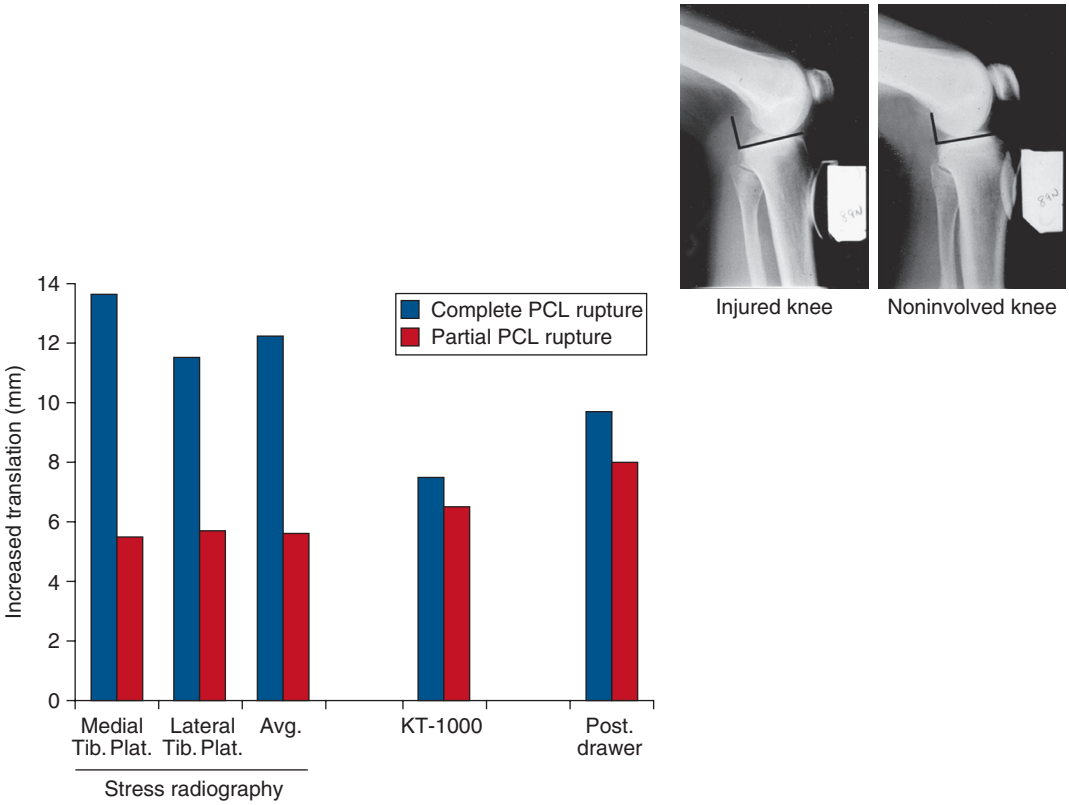

FIG 16-15 The results of lateral stress radiography on 20 patients with posterior cruciate ligament (PCL) deficiency (9 complete ruptures and 11 partial ruptures). The differences in the measurements between complete and partial PCL ruptures for the medial tibial plateau (Tib. Plat.), the lateral tibial plateau, and the average of both plateaus were statistically significant ($P < .01$). Differences in the KT-1000 and posterior (Post.) drawer measurements between complete and partial PCL ruptures were not significant. The KT-measurements at 70 degrees of flexion underestimated the magnitude of posterior tibial subluxation for complete PCL ruptures. (From Hewett TE, Noyes FR, Lee MD. Diagnosis of complete and partial posterior cruciate ligament ruptures. Stress radiography compared with KT-1000 arthrometer and posterior drawer testing. *Am J Sports Med.* 1997;25:648-655.)

measurement, the radiograph should be as close to a pure lateral as possible, with the two femoral condyles superimposed on themselves. A horizontal line is placed across the medial tibial plateau and a perpendicular line determines the posterior position of each femoral condyle. A similar measurement is made for the most posterior position of the medial and lateral tibial plateau. The amount of tibial translation is the average of both of these measurements. An alternative technique is to measure the posterior extent of the Blumensaat line and the proximal aspect of the PCL tibial fossa, which avoids the error of tibial rotation.[85]

The integrity of the ACL is determined by Lachman and pivot shift testing. The result of the pivot shift test is recorded on a scale of 0 to III, with a grade of 0 indicating no pivot shift; grade I, a slip or glide; grade II, a jerk with gross subluxation or clunk; and grade III, gross subluxation with impingement of the posterior aspect of the lateral side of the tibial plateau against the femoral condyle. A KT-2000 arthrometer test may be done at 20 degrees of flexion (134-N force) to quantify total AP displacement.

Medial and lateral ligament insufficiency are determined by varus and valgus stress testing at 0 and 30 degrees of knee flexion. The surgeon estimates the amount of joint opening (in millimeters) between the initial closed contact position of each tibiofemoral compartment, performed in a constrained manner avoiding internal or external tibial rotation, and the maximal opened position. The result is recorded according to the increase in the tibiofemoral compartment of the affected knee compared with that of the opposite normal knee.

The tibiofemoral rotation dial test at 30 and 90 degrees is done to determine whether increases in external tibial rotation exist with posterior subluxation of the lateral tibial plateau (see Chapter 17).[167]

The presence of a varus recurvatum in both the supine and standing positions is carefully assessed. The difference in results of these tests must be done between the injured and contralateral normal knee because of inherent physiologic looseness present in some individuals.

Radiographic Assessment

Radiographs taken during the initial examination include AP, lateral at 30 degrees of knee flexion, weight-bearing posteroanterior (PA) at 45 degrees of knee flexion, and patellofemoral axial views.

Posterior stress radiographs are done with an 89-N force applied to the proximal tibia.[80] A lateral radiograph is taken of each knee at 90 degrees of flexion. The limb is placed in neutral rotation with the tibia unconstrained and the quadriceps relaxed. The difference in posterior tibial displacement between the reconstructed knee and the contralateral knee is recorded. More than 8 mm of increase in posterior tibial translation on stress testing indicates a complete PCL rupture and

more than 12 mm of increase is indicative of probable injury to the posterolateral structures.[193]

Medial or lateral stress radiographs may be required of both knees. The patient is seated (20 degrees of knee flexion) in neutral tibial rotation with the tibia unconstrained. Approximately 89 N of varus or valgus force is applied and a comparison is made of the millimeters of medial or lateral tibiofemoral compartment opening between knees.

Full standing radiographs of both lower extremities, from the femoral heads to the ankle joints, are done in knees in which varus lower extremity alignment is detected on clinical examination. The mechanical axis and weight-bearing line are measured to determine whether HTO is indicated before PCL reconstruction (see Chapter 26).[45,163] If the varus malalignment is not corrected, there is a risk that either a PCL or ACL graft may fail owing to the varus thrusting forces and concurrent increased lateral joint opening producing high graft tension loads.[157]

Patients complete questionnaires and are interviewed for the assessment of symptoms, functional limitations, sports and occupational activity levels, and patient perception of the overall knee condition according to the Cincinnati Knee Rating System (CKRS).[13]

PREOPERATIVE PLANNING

Acute Ruptures of the Posterior Cruciate Ligament

Controversy exists in the treatment of isolated midsubstance complete PCL ruptures, primarily owing to the lack of a scientifically proven operative procedure that can predictably restore posterior stability and PCL function. In comparison, surgical procedures to reattach the native PCL in cases of bony avulsion injuries or peel-off injuries directly at the PCL attachment site have more predictable healing rates.[36,67,232,245] In cases of PCL rupture directly at the attachment site, there is usually sufficient ligament substance for a direct repair. In select situations, an augmentation using the semitendinosus tendon may facilitate PCL repair. Augmentation of partial PCL tears is controversial[6,44,92,93,103,114,115,239,241,248] and only indicated in high-grade tears. Posterior stress radiography plays an important role in determining whether an abnormal increase of 10 mm or more of posterior tibial translation exists, indicating loss of PCL function. Partial ligament tears are treated conservatively with an extension brace and posterior calf pad or bivalved cast to allow for potential PCL healing.

The treatment rationale for patients with acute PCL ruptures is shown in Figure 16-16. The algorithm is divided into three major sections based on the PCL tear (partial, complete, or combined with other ligament ruptures). The 10-mm division is somewhat arbitrary. As discussed, stress radiography is helpful in determining the exact increase in posterior tibial translation. The rules to treat partial or acute isolated PCL tears are used when the injury is seen within the first two weeks; after this time, the program is not instituted. The program rules are as follows:

1. Immobilize for 4 weeks in a full knee extension brace or bivalved cylinder cast to maintain tibiofemoral reduction.[4,87,95] Use quadriceps isometrics, electrical muscle stimulation, leg raises, and 25% weight bearing.
2. Obtain an AP and lateral radiograph to verify that no posterior tibial or lateral subluxation exists, which can occur in up to 50% of knees.
3. At 2 weeks, the therapist initiates 0 to 90 degrees of motion, maintaining an anterior tibial translation load. The patient must sleep in the brace and is not allowed unsupervised knee motion to prevent posterior tibial subluxation.
4. At 4 weeks, the patient is allowed to perform active quadriceps extension out of the brace, 50% weight bearing with crutch support, and maintains brace protection.
5. At 5 to 6 weeks, the patient is weaned from the brace and crutch support, full knee flexion is allowed, and the rehabilitation protocol (described in Chapter 18) is followed to protect the healing PCL fibers.

In our experience, 4 weeks of protection to allow initial healing of a complete PCL rupture will frequently restore partial PCL function, with less than 5 to 7 mm of posterior tibial subluxation remaining on examination. The initial PCL healing process involves a low tensile strength and an additional 4 to 6 weeks of protection is recommended, including avoiding athletics, running, walking on downhill grades,

CRITICAL POINTS Preoperative Planning

Acute Ruptures

- Reattach native PCL bony avulsion injuries, peel-off injuries directly at PCL attachment, predictable healing rates.
- Select knees, augmentation with semitendinosus tendon may facilitate PCL repair, add postoperative protection.
- Partial or acute isolated PCL tears
  - Immobilize 4 weeks in full knee extension brace or bivalved cylinder cast.
  - Lateral radiograph verifies no posterior tibial subluxation.
  - 2 weeks: 0-90 degrees of motion maintaining anterior tibial translation load. Patient sleeps in brace, no unsupervised knee motion.
  - 4 weeks: active quadriceps extension out of brace, 50% weight bearing, crutch support, maintain brace protection.
  - 5-6 weeks: wean from the brace and crutch support, rehabilitation.
- Acute PCL injuries with associated rupture to medial or posterolateral structures: delay reconstruction until neurovascular status and other injuries are resolved and major knee ligament surgery can be safely performed.
- Associated posterolateral ruptures: acute anatomic repair required within 14 days before scarring occurs.

PCL graft reconstruction in select athletes before secondary restraints stretch out with subsequent reinjury, arthritis.

PCL and Multiligament Injuries

- Acute disruption: delay reconstruction to resolve other injuries.
- Posterolateral injuries: perform anatomic repair within 14 days if possible.
- Displaced meniscus tear: repair as soon as possible, all-inside technique.
- Dislocated knees: majority treated in staged approach, surgery delayed, knee protected to prevent posterior tibial subluxation.
- MCL disruptions require cast 7 to 10 days that is then split into anterior and posterior shell to allow therapist-assisted range of motion.

Chronic Injuries

- Assess patient's symptoms, goals, athletic desires: may indicate PCL reconstruction required.
- Varus malalignment: osteotomy before PCL reconstruction.
- PCL plus medial or posterolateral ligament injury, complex instability pattern, usually surgical candidate.
- Severe arthrosis: not expected to benefit from PCL reconstruction.
- Nonoperative approach chronic PCL tears: warn that return to athletics carries uncertain prognosis, joint arthrosis may eventually ensue.
- Consider bone scan, MRI cartilage sequences.
- Initiate rehabilitation, patient's education, avoid high knee flexion activities.

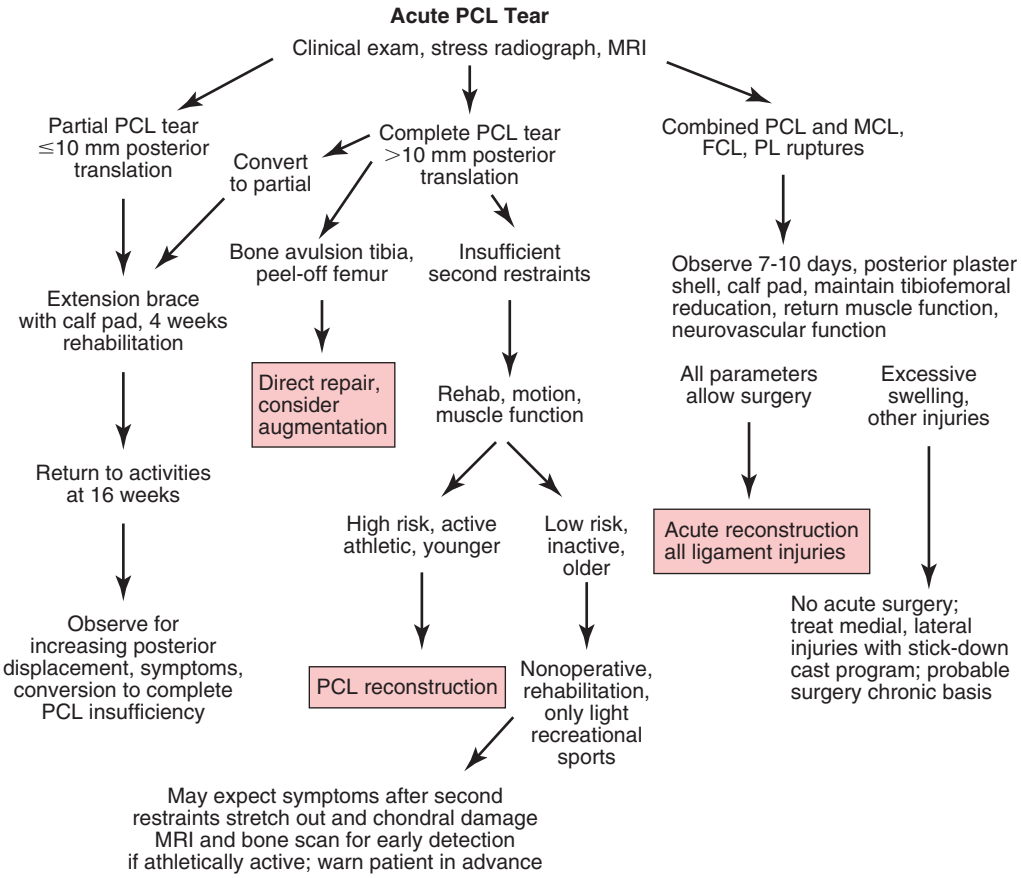

FIG 16-16 Treatment algorithm for acute posterior cruciate ligament (PCL) ruptures.

walking downstairs, or other high knee flexion activities that load the PCL. Even in knees with a complete PCL tear and more than 10 mm of increased posterior tibial displacement, healing of the disrupted PCL fibers may still occur, although a residual posterior tibial subluxation of a few millimeters (with a hard endpoint) will remain. These knees in which partial PCL function has been restored should be followed and repeat stress radiographs obtained at 6 months and over the next few years to determine PCL function. These partial PCL tears seldom require reconstruction. A repeat MRI with fast spin-echo cartilage sequences[182] helps determine the integrity of the articular cartilage and provides important information for counseling the patient on athletic activities to decrease the risk of future joint arthritis.

There are cases of complete isolated mid-substance PCL ruptures (>10 mm of increased posterior tibial displacement) in which the patient is seen late after the injury and the previously discussed program cannot be instituted. In athletes and patients involved in strenuous occupations, one treatment approach is PCL graft reconstruction before the secondary restraints stretch out with subsequent reinjury. We believe that PCL reconstructive procedures have advanced to the point where more predictable results can be expected to restore sufficient PCL function to prevent gross posterior tibial subluxation. Studies have demonstrated, at least in the short term, that the majority of patients with acute PCL ruptures treated with reconstruction are able to return to various levels of sports activities.[122,154] Additional factors to be weighed in the decision to perform early surgery on a complete isolated PCL rupture include athletic goals, body weight, medial meniscus damage, tibiofemoral joint damage, patellofemoral joint damage, and varus malalignment. These factors add to the effects of the residual posterior subluxation in increasing knee joint loads and subsequent joint deterioration. Future long-term clinical studies will confirm the importance of these factors in the operative decision of early restoration of PCL function in active younger individuals who subject their knee to high forces in sports or work activities. Sedentary patients with a complete PCL rupture and 10 mm of posterior translation (90 degrees of flexion) are not considered surgical candidates; however, they are followed as previously described.

Posterior Cruciate Ligament and Multiligament Injuries

Patients with a PCL disruption and other ligament injuries have an obvious posterior tibial dropback without a firm endpoint on posterior drawer testing (≥10 mm of posterior tibial subluxation). In almost all of these knees, some increase in medial or lateral joint opening or external tibial rotation can be detected, although the findings may be subtle. There may be physiologic laxity of other ligament structures without a true injury that allows for the gross posterior tibial subluxation (see Chapter 3).

In knees that present with acute disruption of the PCL and medial or posterolateral structures, reconstruction should be delayed until the neurovascular status and other injuries are evaluated and the decision reached that major knee ligament surgery can be safely performed. In knees that have associated posterolateral ruptures, acute anatomic repair is planned if possible within 14 days before scarring occurs and the ability to anatomically restore these structures is lost (see Chapter 17). A similar situation exists for the medial ligament structures; however, these tissues are easier to reconstruct later if surgery cannot be performed in the ideal time period for anatomic repair.

There may exist a displaced meniscus tear requiring early treatment. As a word of caution, a displaced meniscus should be reduced

into the tibiofemoral joint by 3 weeks to prevent meniscus shortening and scarring that compromise a future repair and result in loss of meniscus function. Even in knees that have marked soft tissue swelling and edema in which major ligament reconstruction is contraindicated, a meniscus repair using all-inside techniques can be performed to reduce the meniscus to a normal tibiofemoral position. The mistake is to wait until 6 weeks or later, expecting that the meniscus repair can be performed at that time.

Too frequently, major ligament surgery in dislocated knees performed under acute conditions results in joint arthrofibrosis, compromising the result. Patients should be carefully selected for acute multiligament repairs, realizing that there are proven techniques for reconstruction of the ruptured ligaments performed later under more ideal conditions. When surgery is performed on acute combined PCL and posterolateral ruptures, the procedure includes the use of appropriate grafts to restore lateral stability and allow an early protected range of knee motion program (see Chapter 17).

The majority of acute knee dislocations should be treated in a staged approach by first treating the acute injury and then determining if a ligament reconstruction should be performed either within the 10- to 14-day envelope or delayed. When early surgery is not advisable, the knee is protected for the first 4 weeks to prevent posterior tibial subluxation, as already described for acute isolated PCL ruptures. AP and lateral radiographs are obtained with the knee placed in a posterior plaster shell and a soft bolster positioned beneath the calf to prevent posterior tibial subluxation. The capsular tissues heal in 7 to 10 days to provide enough stability to prevent recurrence of dislocation.

If a nonoperative approach is selected with associated MCL and posteromedial capsular disruptions, the same program is followed with the lower limb placed in a cylinder cast to allow "stick-down" of the medial soft tissues. Plaster immobilization is required because a soft hinged brace, even if maintained at 0 degrees of extension, does not provide sufficient protection to maintain medial joint line closure to allow the disrupted medial tissues to heal. At 7 to 10 days, the cylinder cast is split into an anterior and posterior shell and the therapist assists the patient with range of motion from 0 to 90 degrees in a figure-four position with the hip joint externally rotated to protect the healing medial tissues. This program of "aggressive" nonoperative treatment of associated medial ligament injuries is described in further detail in Chapter 20.

In multiligament knee injuries, a deep venous thrombosis (DVT) program is instituted that involves assessment of risk factors such as family or personal history of DVT and use of estrogen products in women. A lower extremity ultrasound is obtained before surgery. Postoperative care includes initial use of compressive calf devices, ankle pumps, and early mobilization and ambulation to avoid unnecessary bed rest. In the absence of specific risk factors requiring chemical prophylaxis, we routinely use one aspirin (325 mg) twice daily and pay close attention for signs of a DVT.

Chronic Ruptures of the Posterior Cruciate Ligament

The algorithm for the treatment of chronic PCL ruptures is shown in Figure 16-17. The symptoms and clinical examination determine the functional limitations, particularly the component of symptoms because of medial tibiofemoral or patellofemoral arthritis because these problems are likely to persist after surgical stabilization. Knees with chronic PCL ruptures are arbitrarily divided into three categories: those with varus osseous malalignment (and rarely, valgus

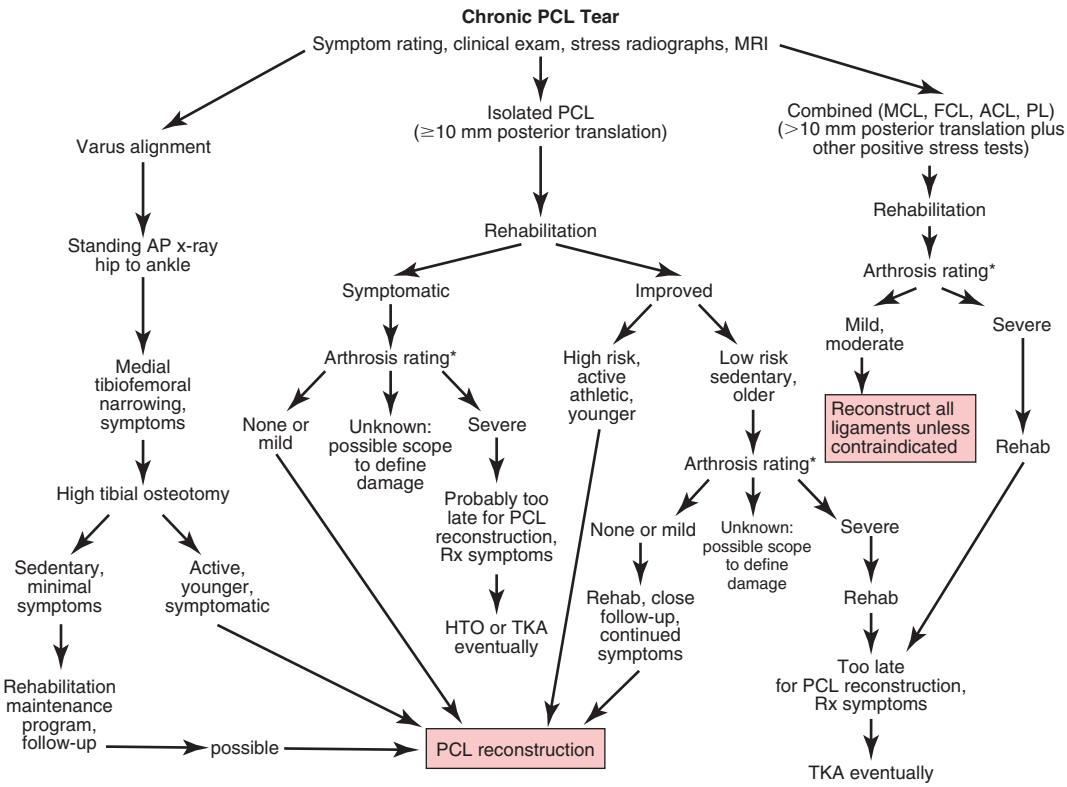

FIG 16-17 Treatment algorithm for chronic posterior cruciate ligament (PCL) ruptures. *Arthrosis rating: standing 45 degrees tibiofemoral and patellofemoral views or magnetic resonance imaging special cartilage sequences. *ACL*, Anterior cruciate ligament; *AP*, anteroposterior; *FCL*, fibular collateral ligament; *HTO*, high tibial osteotomy; *MCL*, medial collateral ligament; *PL*, posterolateral; *TKA*, total knee arthroplasty.

malalignment) in which an osteotomy must be considered, those with an isolated PCL rupture in which reconstruction may or may not be necessary, and those with significant combined ligament injuries that require reconstruction.

Patients are entered into a formal rehabilitation program to correct muscular weakness and gait-related problems (hyperextension) when required. The amount of joint arthritis must be determined with accuracy. Radiographs (merchant, standing PA at 45 degrees) and MRI articular cartilage fast spin-echo sequences provide valuable information.

In knees with no or only mild articular cartilage damage, an assessment of the patient's goals and athletic desires may indicate the need to proceed with PCL reconstruction. Combined ligament ruptures that produce complex instability patterns require careful clinical assessment to detect all of the joint subluxations and ligament deficiencies present.

Knees that have advanced arthritis are not expected to benefit from ligament reconstruction. In these knees, areas of exposed bone are frequently encountered in the medial tibiofemoral compartment, along with diffuse cartilage fragmentation in the patellofemoral joint. In these individuals, even mildly strenuous exercises aggravate the joint arthritis symptoms and cannot be performed. The patient's initial experience with rehabilitation, and the inability to perform the required exercises, provides important information regarding the amount of joint arthritis present and joint symptoms that are likely permanent.

If a nonoperative approach is elected, the clinician should warn the patient that the return to athletic activities may carry an uncertain prognosis, and that although sports may be resumed in the short term, some form of joint arthritis will eventually ensue. It is therefore important to follow the patient at regular intervals. A bone scan may be used to provide some indication of abnormal blood flow dynamics; however, it is our experience that the onset of pain and swelling usually indicates more advanced joint damage and a poor prognosis after PCL reconstruction. An MRI with fast spin-echo[182] sequences provides a baseline for repeated studies at 1- to 2-year intervals. The nonoperative treatment protocol for chronic PCL injuries involves educating the patient to avoid activities such as lunges and other high knee flexion activities that increase posterior tibial subluxation.[32,61,64]

INTRAOPERATIVE EVALUTION

The patient is instructed to use a chlorhexidine scrub of the body with emphasis on the operative limb ("toes to groin") 3 days before surgery and the evening before and the morning of surgery. Lower extremity hair is removed by clippers, not a shaver. Antibiotic infusion is begun 1 hour before surgery. A nonsteroidal antiinflammatory drug (NSAID) is given to the patient with a sip of water upon arising the morning of surgery (which is continued until the fifth postoperative day unless there are specific contraindications to the medicine). The use of an NSAID and a postoperative firm double-cotton, double-Ace compression dressing for 72 hours (cotton, Ace, cotton, Ace-layered dressing) has proven very effective in diminishing soft tissue swelling and is used in all knee surgery cases. In select knees that demonstrate soft tissue swelling before or after surgery, the judicious use of an intravenous corticosteroid for two to three days may be necessary. This is especially relevant in larger muscular patients in whom postoperative swelling of the entire lower extremity may occur. In complex multiligament surgery, the antibiotic is repeated at 4 hours and continued for 24 hours. A urinary indwelling catheter is not used unless there are specific indications. The patients' urinary output and total fluids are carefully monitored during the procedure and in the recovery room.

CRITICAL POINTS Intraoperative Evaluation

- Patient and staff identification of surgical procedure, "time-out," operative site signed by surgeon.
- Repeat all knee ligament subluxation tests under anesthesia.
- Rate all articular cartilage surfaces
  - Normal.
  - Grade 1, softening.
  - Grade 2 A, fissuring & fragmentation < ½ depth of the articular surface.
  - Grade 2 B, fissuring & fragmentation > ½ depth of the articular surface.
  - Grade 3, subchondral bone exposed.
- Medial and lateral gap test at arthroscopy
  - Knee 30 degrees of flexion.
  - Measure millimeters tibiofemoral compartment opening with calibrated nerve hook.

The knee skin area is initialized by the surgeon before entering the operating room, with a nurse observing the procedure. The identification process is repeated with all operative personnel with a "time out" before surgery to verify the patient's name and birth date, knee undergoing surgery, procedure, allergies, antibiotic infusion, and special precautions that apply. All personnel provide verbal agreement.

All knee ligament subluxation tests are performed after the induction of anesthesia in both the injured and contralateral limbs. The amount of increased anterior tibial translation, posterior tibial translation, lateral and medial joint opening, and external tibial rotation is documented. In acute knee injuries, arthroscopic pressure is maintained at a low setting with adequate outflow at all times to prevent fluid extravasation, which is carefully monitored during the procedures that follow. A thorough arthroscopic examination should be conducted, documenting articular cartilage surface abnormalities[170] and the condition of the menisci.

The medial and lateral tibiofemoral gap test is done during the arthroscopic examination (see Chapter 17).[161] The knee is flexed 30 degrees and a varus and valgus load of approximately 89 N applied. A calibrated nerve hook is used to measure the amount of lateral and medial tibiofemoral compartment opening. Twelve mm or more of joint opening at the periphery of the compartment indicates the need for a combined lateral or medial ligament reconstructive procedure to protect and unload the PCL reconstruction. The presence of 10 mm of opening is a gray zone that, in some instances, may require concurrent surgery. The goal is to restore the function of all ligament structures to normal or nearly normal and not leave a knee with a residual ligament insufficiency. This also applies to the ACL, which is reconstructed at the time of PCL surgery when deficient.

Appropriate arthroscopic procedures are performed as indicated including meniscus repairs or partial excision, debridement, and articular cartilage procedures.

OPERATIVE TECHNIQUES

PCL operative techniques continue to evolve and clinical outcome studies remain limited to allow precise decision making regarding the exact recommendations of one surgical procedure over another. This chapter describes the senior author's recommended surgical approach and relative advantages and disadvantages of each procedure, realizing that these are evolving treatment options (Table 16-5).

First, the surgical approach of the all-inside technique is chosen. The use of the open tibial inlay procedure has been completely replaced by most surgeons with modern all-inside arthroscopic techniques. The

TABLE 16-5 Recommended Surgical Approaches

All-Inside:

Single-Tibial Tunnel Approach

- Bone plug in tunnel at PCL attachment (same as inlay except tunnel)
- Avoids posterior dissection, operative time
- Projected results similar to tibial inlay

Two-Tunnel Femoral Approach

- Provides better anatomic positioning along oval PCL attachment
- Advantage of graft incorporation over single large-diameter graft
- Outside-in tunnel, graft interference screw with suture post
- Second option: single femoral tunnel for multiligament reconstruction where time and operative complexity warrant single tunnel

Tibial Inlay

- Reserved for revision knees to bypass misplaced tibial tunnel (staged bone graft may be required)

Graft Selection

Isolated PCL Rupture

- Quadriceps tendon-patellar bone autograft, ipsilateral (rarely contralateral)
- Bone-patellar tendon-bone allograft
- Achilles tendon-bone allograft

PCL Combined With Other Ligament Rupture

- Use allograft listed above
- Avoid large-diameter soft tissue allograft through tibial tunnel
- Bone plug placed at posterior tibial tunnel
- No autograft harvest same knee

CRITICAL POINTS Operative Techniques

- All-inside surgical approach.
- QT-PB or AT-B grafts provide more secure fixation, superior healing than soft tissue grafts.
- Place bone portion of graft at posterior tibial attachment.
- Select large-diameter graft that will fill majority of anatomic femoral and tibial footprints.
- Use two-tunnel technique at femoral attachment for larger patients.
- Graft fixation: use high-strength methods.
- Use QT-PB autograft in isolated PCL reconstruction in athletic patients.
- Use allografts in multiligament injuries.

tibial inlay procedure is described later for completeness and still has a role in PCL tibial avulsion fractures, in rare revision cases, or when arthroscopic techniques are not indicated.

The all-inside approach involves the decision regarding where to place the bone portion of the graft when a quadriceps tendon-patellar bone (QT-PB) or Achilles tendon-bone (AT-B) graft is used. We strongly advise use of a graft that has a tendon-bone construct owing to the predictable and prompt healing of the bone portion compared with delayed tendon-graft healing that occurs in bone tunnels. Our preferred technique places the bone portion of the PCL graft directly at the posterior tibial attachment, simulating the tibial inlay approach. This also allows the use of either one or two femoral tunnels for a single- or two-strand graft construct, as is discussed later.

In our experience, soft tissue grafts placed through a large tibial tunnel have an increased risk of failure owing to delayed graft incorporation that may lead to a revision procedure and necessity for staged bone grafting. A sclerotic line often forms in the bone tunnel about the graft periphery, with limited or often no bone ingrowth into the central regions of the graft. From an antidotal standpoint, an increased success rate of PCL reconstruction occurs when the bone portion of the graft is placed at the tibia, with one or two collagenous graft strands placed at the femoral site. Still, there are many publications that describe the historical technique of placing the bone plug at the femoral site (inside-out or outside-in tunnel) and the collagenous portion through a single tibial tunnel, most frequently using an AT-B allograft. This technique is perhaps the easiest to master and can be used when surgical time is an issue, because it is more difficult to pass the bone portion of the graft into the tibial tunnel.

Second, a large-diameter graft is selected that will fill the majority of the anatomic femoral and tibial footprints. At the femoral PCL attachment, a two-tunnel technique is preferred for larger patients; however, in smaller patients, a single large-diameter tunnel may also be used. It is probable that with either technique, only 75% of the femoral attachment site is covered. The mistake is to select a graft construct in which a smaller-diameter graft covers less of the footprint.

Third, an autograft or allograft construct is selected that, as already discussed, has a bone plug at one end for more secure fixation and superior healing compared with a soft tissue graft that does not contain bone plugs. It is important that high-strength graft fixation methods be used to withstand the large forces expected postoperatively. For example, the use of a single soft tissue interference screw to hold a PCL graft strand provides weak fixation strength and requires a back-up procedure with sutures for added graft fixation strength.

Fourth (the senior author's preference), an autogenous QT-PB graft is used in isolated PCL surgical procedures in athletic patients owing to a higher success rate and healing compared with allografts. It is now well appreciated in clinical outcome studies of ACL grafts that there is a 4 to 6 times higher failure rate of allografts and there is no apparent reason why this would not be applicable to PCL grafts. The exception would be an entirely sedentary patient who would not be loading the knee in athletic activities. In multiligament knee injuries, it is necessary to use allograft tissue, although an autogenous graft may be harvested from the contralateral side in rare select conditions. In combined ligament reconstructions, a QT-PT autograft is not removed from the same knee because this adds to the morbidity of the operative procedure.

Selection of Tibial Attachment Techniques: Arthroscopic All-Inside Versus Open Tibial Inlay Approach

The arthroscopic-assisted placement of the tibial tunnel or socket avoids the added operative time and complexity of the posteromedial tibial inlay approach. The surgeon must have extensive arthroscopic experience to safely perform an all-inside procedure to identify the PCL posterior tibial attachment site, avoid penetration into the posterior capsule and subsequent damage to the neurovascular structures, and place the tibial tunnel into the anatomic PCL tibial footprint. Specially designed instruments, drill guides with safety stops for guide pins, and drills are available to lessen the serious risk of inadvertent penetration of instruments posteriorly and damage to neurovascular structures.

The all-inside arthroscopic technique is particularly advantageous in knees with multiple ligament ruptures that require repair and reconstruction. In these knees, high-strength grafts are used to reconstruct the PCL and ACL, which are appropriately tensioned and fixed to reduce the tibiofemoral joint to its normal AP position. Medial or lateral operative approaches are used for concurrent medial and posterolateral ligament and soft tissue repairs or reconstructions. A combined ACL/PCL/MCL injury involves an all-arthroscopic approach for the ACL and PCL, followed by a limited medial dissection for repair of the medial tissues and meniscus attachments.

Combined ligament injuries, particularly those involving medial ligament and muscle tissues, have a high rate of postoperative motion problems and arthrofibrosis. In these knees, an open posterior tibial inlay procedure and popliteal dissection may be avoided by using the all-inside arthroscopic approach. One exception is a PCL avulsion fracture from the tibial attachment. Another exception is a PCL revision knee where a prior tibial tunnel was used and a tibial inlay graft is required to bypass this tunnel. In these cases, there may exist loss of the normal bony architecture about the posterior tibial PCL attachment and a tibial inlay bone graft is required. However, in PCL revision cases that have enlarged tibial tunnels, a staged bone graft procedure is more commonly used under arthroscopic control to remove the disrupted tibial tunnel graft and place a freeze-dried core allograft. An autogenous iliac crest graft is required only in exceptional cases, in which there is a large loss of bone (see Chapter 26).

From a historical standpoint, the open posteromedial tibial inlay technique did have the advantage of placing a tibial inlay graft securely into the posterior PCL tibial attachment site. This approach was often selected when only the PCL required reconstruction. The tibial inlay graft provides ideal graft fixation and early healing. A two-strand autogenous QT-PB graft with two femoral tunnels has been previously described and the clinical outcomes published.[152,153]

One theoretical disadvantage of the all-inside technique is the potential for the collagenous portion of the graft abrading against the angulated posterior tibial tunnel. There are operative techniques designed to diminish this problem. These include creating a more oblique tibial tunnel drilled through the anterolateral tibia and carefully chamfering the tunnel exit. Collagen grafts with a large cross-sectional area and diameter are favored over those with a smaller area and diameter, in which any abrasion compromises graft strength. To decrease soft tissue graft abrasion at the tibial tunnel, the bone portion of the graft may be placed in a tibial tunnel directly adjacent to the tunnel exit or placed in an all-inside tibial socket. The goal is to match the beneficial effect of the tibial inlay procedure to allow prompt osseous healing.

CRITICAL POINTS Selection of Tibial Attachment Techniques: Arthroscopic All-Inside Versus Open Tibial Inlay Approach

- Arthroscopic-assisted placement tibial tunnel preferred, requires extensive arthroscopic experience.
- All-inside arthroscopic technique advantageous in dislocations, multiple-ligament reconstructions.
- Combined ACL + PCL injury: all-arthroscopic approach ACL and PCL; limited dissection for medial or lateral repairs.
- PCL avulsion fracture or revision knee may require tibial inlay procedure.
- Techniques available to diminish problem of graft abrasion in posterior tibial tunnel, as well as femoral attachment site, in all-inside procedure.

Biomechanical studies of PCL reconstructions conducted at our facilities have shown the potential for graft abrasion and failure at the femoral attachment.[198] Operative techniques to protect against graft failure and abrasion are required at both tibial and femoral attachment sites, and repetitive knee motion in the early postoperative time period is limited, as will be described.

Selection of Posterior Cruciate Ligament Femoral Attachment Technique: Two-Tunnel Versus Single-Tunnel Options

It is not difficult from a technical standpoint to use two well-placed femoral tunnels within the PCL femoral footprint from outside-in, and this is a recommended preferred technique to master. The outside-in technique, with a limited anteromedial subvastus or muscle-splitting approach, allows graft tensioning, a long femoral tunnel for tendon graft incorporation, and graft fixation with an interference screw and suture post. The posteromedial graft is usually shorter by 15 mm than the anterolateral graft. The outside-in tunnel approach allows accurate tensioning, fixation, and visualization of the graft length change during knee flexion. This allows the surgeon to determine the ideal knee flexion position for graft fixation. This is our preferred technique with either an autograft or allograft.

When a single femoral graft is selected, the femoral tunnel may be drilled from inside-out or outside-in. There is an increased obliquity with the inside-out approach; however, in either case, the posterior or deep portion of the tunnel needs to be radicalized and smoothed to decrease graft abrasion effects. A FlipCutter (Arthrex) may be selected to create the femoral socket and TightRope (Arthrex) fixation may be used along with a soft tissue interference screw. This avoids a vastus medialis obliquus (VMO) incision, maintains the medial femoral cortex, and is less invasive.

In the alternative technique described in which the bone portion of the PCL graft is placed at the femoral site, a rectangular femoral slot technique has a theoretical advantage. The bone plug is fixed using an inside-out arthroscopic technique. The rectangular slot technique places the bone within the PCL femoral footprint and is more ideal than a single large-diameter tunnel, although either technique may be used. We advocate only one tibial tunnel for the collagenous portion of the graft. In a PCL revision procedure, there may exist a misplaced femoral tunnel in which the bone portion of the graft is required for adequate femoral graft placement and fixation instead of one or two soft tissue femoral graft tunnels.

A single femoral tunnel drilled from an inside-out anterolateral portal is more difficult because of the narrow intercondylar notch,

CRITICAL POINTS Selection of Posterior Cruciate Ligament Femoral Attachment Technique: Two-Tunnel Versus Single-Tunnel Options

- Two well-placed femoral tunnels within PCL femoral footprint from outside-in most ideal technique to master.
- Single femoral socket: FlipCutter may be used to create, TightRope fixation in addition to interference screw.
- Alternative technique: bone portion of graft placed at femoral site, rectangular femoral slot technique or circular tunnel (FlipCutter).
- Single femoral tunnel from inside-out approach more difficult because of narrow intercondylar notch, proximity of lateral femoral condyle.
- Advantageous to select graft fixation methods that provide for maximum tensile strength of graft construct.

proximity of the lateral femoral condyle, placement of the tunnel within the PCL footprint, and exact placement required to avoid portions of the graft located outside the PCL footprint. Accordingly the surgeon has the ability to select the most desired technique; however, the outside-in drilling approach or FlipCutter approach for a single large-diameter femoral graft tunnel is often more advantageous.[21]

Tables 16-6 and 16-7 provide a reference to studies on graft fixation and can be extrapolated to the fixation of the PCL bone portion of the graft. Techniques for fixation of soft tissue grafts at the femoral attachment site using interference screws alone provide a weaker fixation construct[82] and result in lower attachment strength. The outside-in approach allows graft sutures and a suture post to be incorporated (Tables 16-8 and 16-9), or TightRope fixation may be used that is similar to an EndoButton configuration. PCL reconstructions are under high in vivo loads and it is advantageous to select graft fixation methods that provide for a high tensile strength of the graft construct.[30,136,205]

Selection of Single-Strand Versus Two-Strand Posterior Cruciate Ligament Graft Constructs

The advantages and disadvantages of one- and two-strand PCL graft techniques are summarized in Table 16-10. The goal of adding a second strand is to place additional collagenous tissue within the PCL footprint to increase the cross-sectional area of the graft and more closely replicate the native PCL attachment. This theoretical advantage is sometimes referred to as the *mass action effect* of adding additional collagen within the PCL footprint. The improved stability and clinical success of a two-strand graft construct compared with a single-strand graft have not been proven from a clinical standpoint.[106] There are clinical studies that show patients who received a single-strand PCL graft reconstruction obtained results similar to those that underwent a two-strand PCL procedure.[49,101,104,122,202]

The incorporation of a second graft strand has the theoretical advantage of providing additional collagen tissue for load sharing that decreases stress in the collagen fibers, increases graft strength, and reduces cyclic fatigue of the graft construct.[198,233] The two graft strands are tensioned at surgery to share loads to decrease the loads compared with those of a single PCL graft construct. This has been shown in a majority of (but not all[135]) biomechanical studies that compared single- with two-strand graft constructs. Studies report that the two graft strands placed in the distal two-thirds of the PCL femoral footprint will function to resist posterior tibial translation with increasing knee flexion (see Chapter 15). Alternatively, when two graft strands are placed in a proximal and distal (deep and shallow) portion of the PCL footprint, graft loading occurs in a reciprocal manner and the graft strands are under higher loads, which is less ideal. As previously noted, the length and tension changes in grafts are governed for the most part by the femoral attachment and any graft fibers in the distal two-thirds are subjected to increasing tension and elongation with knee flexion.[68,203]

In Chapter 15, the function of single- and two-strand PCL grafts is described in detail. The usual description of a PMB that resists tension with knee extension and an ALB that resists tension with knee flexion represents an oversimplification of PCL fiber behaviors. In this chapter, the rule of thirds (see Fig. 16-10) is used to described PCL graft placement at surgery, as already discussed.[16,17,74,133,197]

A justification to add a second PCL strand is the observation in clinical studies of a residual posterior tibial subluxation at high knee

TABLE 16-6 Femoral Fixation Options for Bone Graft

Study	Construct	Failure (*n*)	Stiffness (N/mm)	Failure Mode
Martin et al[137] (2002)	Metal interference screw	710 ± 224	298 ± 36	Not reported
Pena et al[180] (1996)	Metal interference screw	640 ± 201	Not reported	Pull-out and bone block fracture
Steiner et al[210] (1994)	Endoscopic interference screw	588 ± 282	33 ± 14	Bone plug fractured, femoral screw pull-out, bone tendon rupture
Johnson et al[90] (1996)	Biodegradable interference screw	565	Not reported	Failure between the cortical and cancellous bone of the bone plug
Caborn et al[27] (1997)	Metal endoscopic interference screw	558 ± 68	Not reported	Femoral fixation failure, fracture of bone plug, tearing of graft
Brand et al[21] (2000)	EndoButton	554 ± 276	27 ± 13	Tibial bone block fracture or suture breakage, tibial side fixation failure
Caborn et al[27] (1997)	BioScrew endoscopic interference screw	552 ± 56	Not reported	Femoral fixation failure, fracture of bone plug, tearing of graft
Brand et al[21] (2000)	Mitek device	511 ± 350	18 ± 8	Patellar tendon failure, fracture tibial bone block, sutures tore through bone block
Johnson et al[90] (1996)	Metal interference screw	436	Not reported	Failure between the cortical and cancellous bone of the bone plug
Steiner et al[210] (1994)	Interference screw from outside-in	423 ± 175	46 ± 24	Pull-out around the screw
Pena et al[180] (1996)	BioScrew interference screw	418 ± 118	Not reported	Bone block pull-out
Brand et al[21] (2000)	Press-fit	350 ± 48	37 ± 16.3	Tibial bone plug pull-out, fracture tibial bone block, patellar tendon failed
Brown et al[23] (1993)	Endoscopic interference screw	256 ± 130	70 ± 29	Bone block pull-out, bone block fracture
Brown et al[23] (1993)	Interference screw outside-in	235 ± 124	83 ± 30	Bone block pull-out, bone block fracture

Cadaveric studies have varying results, particularly when older specimens are used, with osteopenia compromising fixation strength.

TABLE 16-10 Basis for Selection of Single- Versus Two-Strand Posterior Cruciate Ligament Reconstruction

	Single Strand	Two Strand
Greater area	–	+
Load-sharing (decreased tensile forces in each graft strand)	–	+
Operative complexity	+	–
Cyclic fatigue	–	+
Clinical results (residual posterior tibial translation)*	Unknown	Unknown

*Proven by objective measurements, including stress radiography at 90 degrees of knee flexion.
+, Relative advantage; –, relative disadvantage.

CRITICAL POINTS Selection of Single-Strand Versus Two-Strand Posterior Cruciate Ligament Graft Constructs

- Goal of second strand: place additional collagenous tissue within PCL footprint, increase cross-sectional area of graft, and more closely replicate native PCL attachment. Decreases stress in collagen fibers, increases graft strength, and reduces cyclic fatigue of graft construct.
- Second strand placed in distal two-thirds of footprint functions to resist posterior tibial translation with increasing knee flexion.
- Biomechanical studies justify two-strand reconstruction restores posterior tibial translation to normal values.
- Preferred technique:
  - QT-PB: bone plug placed tibial tunnel. Tendon placed femoral attachment and split into two strands, tensioned separately.
- Controversy exists between well-placed single-strand and two-strand grafts owing to inadequate clinical data.
- Our opinion: sound theoretical reasons exist to warrant two-strand PCL reconstruction when clinically feasible.
- Multiligament reconstructions require modification to single-strand PCL graft constructs.

flexion after single-strand PCL reconstructions.[106,154] Current PCL surgical procedures do not uniformly produce functional restoration of normal joint kinematics and stability postoperatively. This problem is discussed in detail in the Clinical Studies section of this chapter. The concern is that a residual posterior tibial displacement changes tibiofemoral contact positions (more anterior on the tibia), with altered and high cartilage pressures and decreased function of the medial meniscus.[126,179,204] Increases in patellofemoral contact pressures have also been reported.[60]

There are many different types of two-strand PCL graft constructs reported in the literature. One type consists of two separate grafts placed into two separate femoral and tibial tunnels, or two separate femoral tunnels with both graft strands through one tibial tunnel. For purposes of differential load sharing between two graft strands with knee flexion, it is assumed that two separate femoral attachments and a single tibial attachment obviates the necessity and operative complexity of two tibial tunnels.

When an AT-B allograft is selected, it is important that the graft be inspected to discard those that have a narrow tendon section just adjacent to the bone attachment. A QT-PB allograft is a more suitable PCL substitute because of the larger cross-sectional area of the tendon; however, this graft has to have sufficient length and is more difficult to obtain from tissue banks. It should be noted that, in some patients, the (autogenous) quadriceps tendon portion of the graft is not robust enough to produce two graft strands. In these cases, a single graft is used that represents a large-diameter graft.

Multicenter randomized controlled trials of one- and two-strand PCL reconstructions are required in the future to provide a more scientific basis for selection of one type of PCL reconstructive technique over another. The surgeon is currently faced with small clinical trials with level 4 evidence described later in this chapter. For this reason, more than one PCL technique is described, with recommendations made regarding the technical issues to maximize the clinical result. Our preferred PCL graft procedures are provided, along with the justification and rationale for these selections.

In summary, it does appear there are sound theoretical reasons to warrant a two-strand PCL reconstruction when clinically feasible (Table 16-10). These conditions include isolated PCL reconstructions when the added time required to perform a two-strand PCL graft does not represent a contraindication in terms of operative time and complexity. In multiligament reconstructions, the primary goal is to repair and reconstruct all ruptured ligaments. Adding a second femoral tunnel, and tensioning and securing two graft strands, is time-consuming to an already complex surgical reconstruction. Therefore the surgeon should be prepared, based on the operative findings, to modify the preoperative plan when required. In certain multiligament injured knees, a single-strand PCL graft construct may offer a reasonable opportunity to restore functional stability (Fig. 16-18).[135] Given the complex PCL fiber microgeometry, either a one- or two-strand graft construct still represents an imperfect substitution, providing only a check rein effect in controlling joint motions and subluxations.

Selection of Posterior Cruciate Ligament Grafts Based on Biomechanical Properties

The mechanical properties of grafts commonly used to reconstruct the PCL are shown in Table 16-11. The goal of PCL surgery is to select a graft that matches the structural properties of the PCL as closely as possible. The problem is that the PCL is a highly complex ligament composed of fibers of different lengths that are brought into the loading configuration based on the knee flexion and tibial rotation positions. The data show initial graft mechanical properties that are expected to decline after graft implantation and in vivo remodeling. It is therefore not possible to match the complex PCL microgeometry with any tendon substitute.

The cadaver age in the investigation by Race and Amis[184] ranges from 53 to 98 years. Previous investigations by the senior author[166] and others[237] documented significant reductions in strength and stiffness properties of ligament units with advancing age. For instance, one study[166] documented that, although ultimate failure of ACL-bone grafts occurred at a mean of 1730 N in young cadavers (aged 16 to 26 years), this value decreased to a mean of 734 N in older cadavers (aged 48 to 86 years). Race and Amis[184] estimated that a PCL reconstruction should be designed to match a native PCL with a strength of 4000 N, and not the approximate 2000 N shown in Table 16-11 (for both bundles combined).

Harner and associates,[76] in a study of 14 cadaveric PCL specimens (mean age, 52 years; range, 30-83 years), reported a mean ultimate load to failure of the ALB of approximately 1200 N and of the PMB of 400 N. This provides an ultimate failure load of the entire PCL in the 1600- to 1700-N range, well below that expected; this is most likely because of the advanced age of the cadaver specimens.

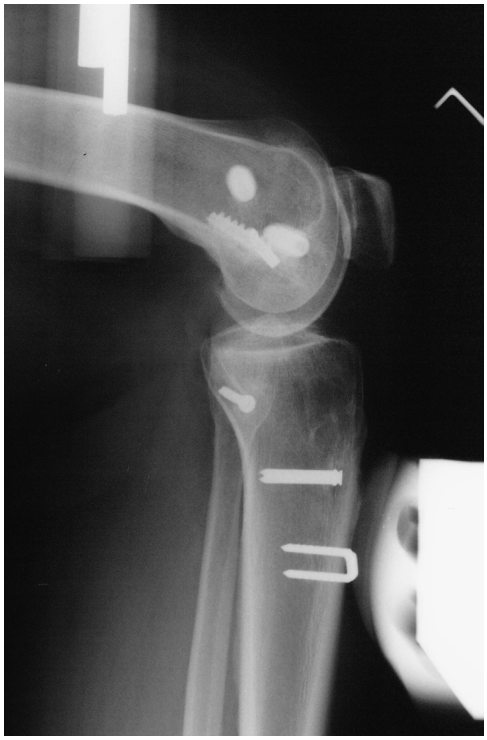

FIG 16-18 Posterior stress radiograph of a patient 2 years after a single-strand posterior cruciate ligament quadriceps tendon-patellar bone autograft shows only 2 mm of increased posterior tibial translation. The patient had sustained a knee dislocation and also underwent an anterior cruciate ligament bone-patellar tendon-bone allograft reconstruction, and an anatomic posterolateral reconstruction.

In a similar manner, there may exist large variations in reported strength and stiffness data based on the testing apparatus and manner in which soft tissues are grasped without inducing premature failure. For example, the strength of the quadriceps tendon construct shown in Table 16-11 is 2353 N; however, the mean cross-sectional area is 65 mm^2. There are different methods used to measure cross-sectional area that affect these values. The senior author previously described a method that induced a low level of compressive force to compress the soft tissues into a block of defined dimensions that provided an accurate cross-sectional measurement.[164] The data shown in Table 16-11 are derived from investigations that used different area measurement systems, making comparisons difficult.

Preparation of Quadriceps Tendon-Patellar Bone Autograft

A tourniquet is inflated to 275 mm Hg. This is usually the only time the tourniquet is used in the reconstructive procedure. An incision is made just medial to the superior pole of the patella and extended proximally 5 to 6 cm (Fig. 16-19). The incision allows access to the anteromedial aspect of the medial femoral condyle and VMO for subvastus placement of the femoral tunnels. A cosmetic approach is used, with subcutaneous dissection performed circumferentially about the incision to allow the skin to be mobilized superiorly and inferiorly for the graft harvest. With this technique, no incision is required over the patella.

The graft length and thickness is marked on the tendon and the proximal musculotendinous junction is avoided because it would weaken the extensor mechanism. The quadriceps tendon appears narrower proximally and it is important not to remove more than one third of the tendon. In rare instances, there is a shortened quadriceps tendon that is not suitable for harvest; the patient is advised preoperatively and provides consent for either an autograft or allograft approach. A suitable quadriceps tendon must be a minimum of 70 mm, not counting the 22- to 24-mm patellar bone plug. The full-thickness quadriceps tendon graft is taken from the central tendon and is 10 to 12 mm in width and thickness, respectively, depending on the overall size of the tendon. A general rule is to take approximately 30% of the tendon in the middle portion, realizing there may be some narrowing of the tendon proximally. The quadriceps tendon consists of three layers: rectus tendon, VMO-vastus lateralis oblique (VLO) combined tendon, and vastus intermedius tendon. A meticulous technique is followed to incise all three layers in a perpendicular fashion with a new blade. There is a tendency not to harvest the deep layer or to allow the blade to assume an oblique plane rather than a perpendicular plane. A curved instrument is placed behind the three tendon layers at the proximal aspect of the tendon harvest site to protect the underlying joint synovium. If the synovium is entered, it is closed along with the remaining quadriceps tendon closure to maintain joint distention for the arthroscopic procedure.

An Ellis clamp is placed about the three ends of the tendon to maintain tension. Care is taken at the quadriceps tendon attachment to the patella, because the tendon attachment is located at the proximal and anterior third of the proximal patella. There is a plane established at this point just behind the quadriceps tendon attachment to preserve the posterior underlying synovial attachment and adjacent soft tissues. These tissues provide a superior buttress for the bone grafting of the patella to close the defect and secure the bone graft.

The patellar bone block matches the quadriceps width. The bone block length is 22 to 24 mm and has a depth of 8 to 10 mm. A thin powered saw blade is marked with a Steri-Strip to a depth of 10 mm to prevent a deep penetration. The saw is kept perpendicular to the patellar anterior surface for all cuts. After the anterior bone cuts are made, the quadriceps tendon is lifted anteriorly at its attachment site. The posterior portion of the bone block is cut in a transverse plane beneath the quadriceps tendon attachment to a depth of 8 to 10 mm. This allows the bone block to be gently removed for graft preparation. The tourniquet is deflated and hemostasis obtained.

The graft is prepared based on whether the one-strand or two-strand technique is selected. The tendon portion must be 11 to 12 mm

CRITICAL POINTS Preparation of Quadriceps Tendon-Patellar Bone Autograft

- Incision just medial to superior pole of patella, extend proximally 5-6 cm.
- Cosmetic approach, subcutaneous dissection circumferentially about skin incision.
- Quadriceps tendon ≥70 mm plus 22-24 mm patellar bone plug for suitable graft.
- Graft is taken from central tendon, 10-12 mm in width and thickness.
- Incise prepatellar retinaculum in midline, dissect to width of graft, protected for later closure over bone-grafted patellar defect.
- Match patellar bone block width to quadriceps width. Bone block length 22-24 mm, full-thickness depth 8-10 mm.
- Graft prepared based on size and whether one- or two-strand technique is selected.
- Graft strands sutured in meticulous manner using 1-0 or 2-0 FiberLoop or FiberWire sutures.
- Close quadriceps tendon (Z-plasty technique) and synovium to provide a fluid tight closure, allows joint distention.
- Patellar bone defect later grafted with bone obtained by core reamer.

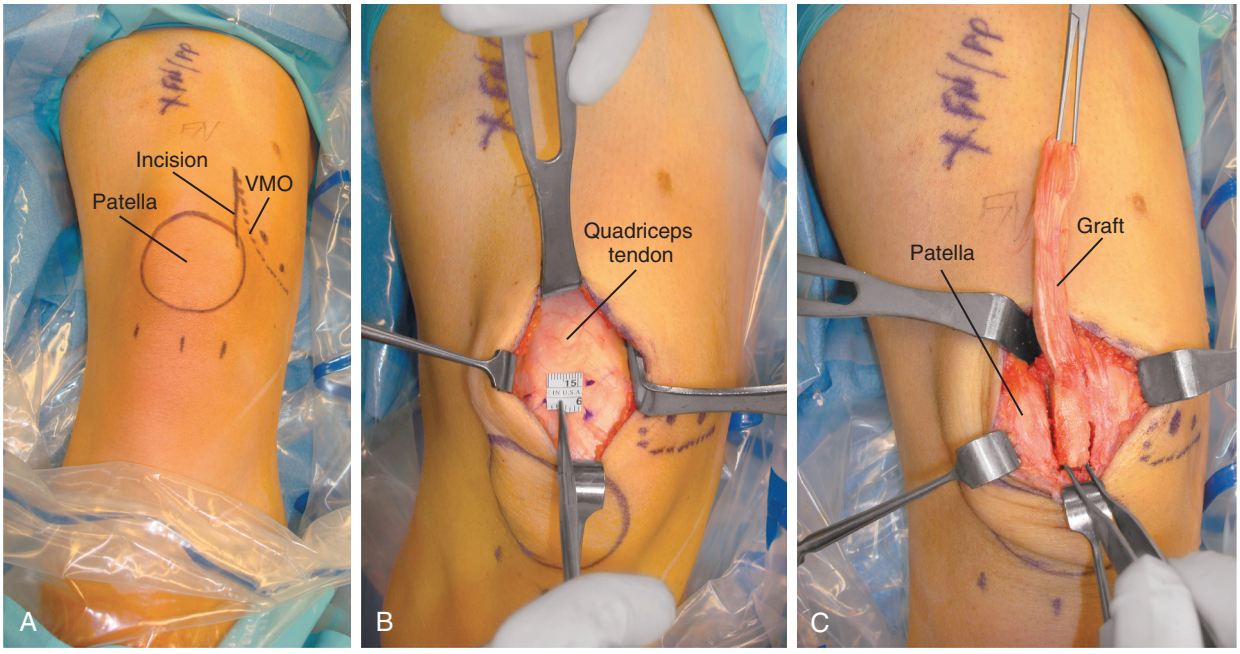
wide and thick to be able to fashion graft strands that are 7 to 8 mm in diameter. In smaller patients, a single 10-mm quadriceps tendon with a reduced thickness does not provide sufficient tendon for a robust two-strand graft; therefore a single-strand construct must be selected. The tendon graft strands are sutured in a meticulous manner using a 1-0 or 2-0 FiberLoop or FiberWire sutures (Arthrex). The graft diameter is sized for the appropriate tunnel to be drilled. Two 2-0 FiberWire sutures are passed in the distal end of the patellar bone. A blood-soaked sponge is wrapped around the graft to provide protection, keep the tissues moist, and potentially maintain some cell viability.



In the optional all-inside technique with the patellar bone block placed into the PCL femoral attachment, either a one-strand or two-strand technique may be selected for the graft strands placed through the tibial tunnel. There is a theoretical advantage of tensioning the two graft strands separately; however, insufficient clinical outcome data exist in this regard.

The quadriceps tendon and synovium are closed to provide a fluid tight closure, allowing joint distention. The quadriceps tendon defect is loosely closed with nonabsorbable zero sutures. The tendon is closed in a Z-plasty manner, in which portions of the quadriceps tendon layers are brought together to avoid the circumferential tight sutures placed through all three tendon layers. This technique decreases medial-to-lateral tension in the extensor mechanism.

The patellar bone defect is later bone grafted in a meticulous manner with bone obtained with a coring reamer during preparation of the femoral graft tunnels. It is important to obtain a bone graft that completely fills the defect, because bone shavings from the tunnel preparations are insufficient. Postoperatively, a bone defect that was meticulously grafted heals without a palpable patellar defect and decreases the incidence of graft harvest site pain.

Preparation of Achilles Tendon-Bone Allograft

The preparation of an AT-B allograft is performed in a manner similar to that of QT-PB already described and is the most commonly used single-strand construct. It is necessary to tube or roll the wide proximal fan-shaped portion of the tendon. In the optional technique described, the bone plug is placed into a rectangular femoral site for all-inside placement, or a 10- to 11-mm diameter graft for a single femoral

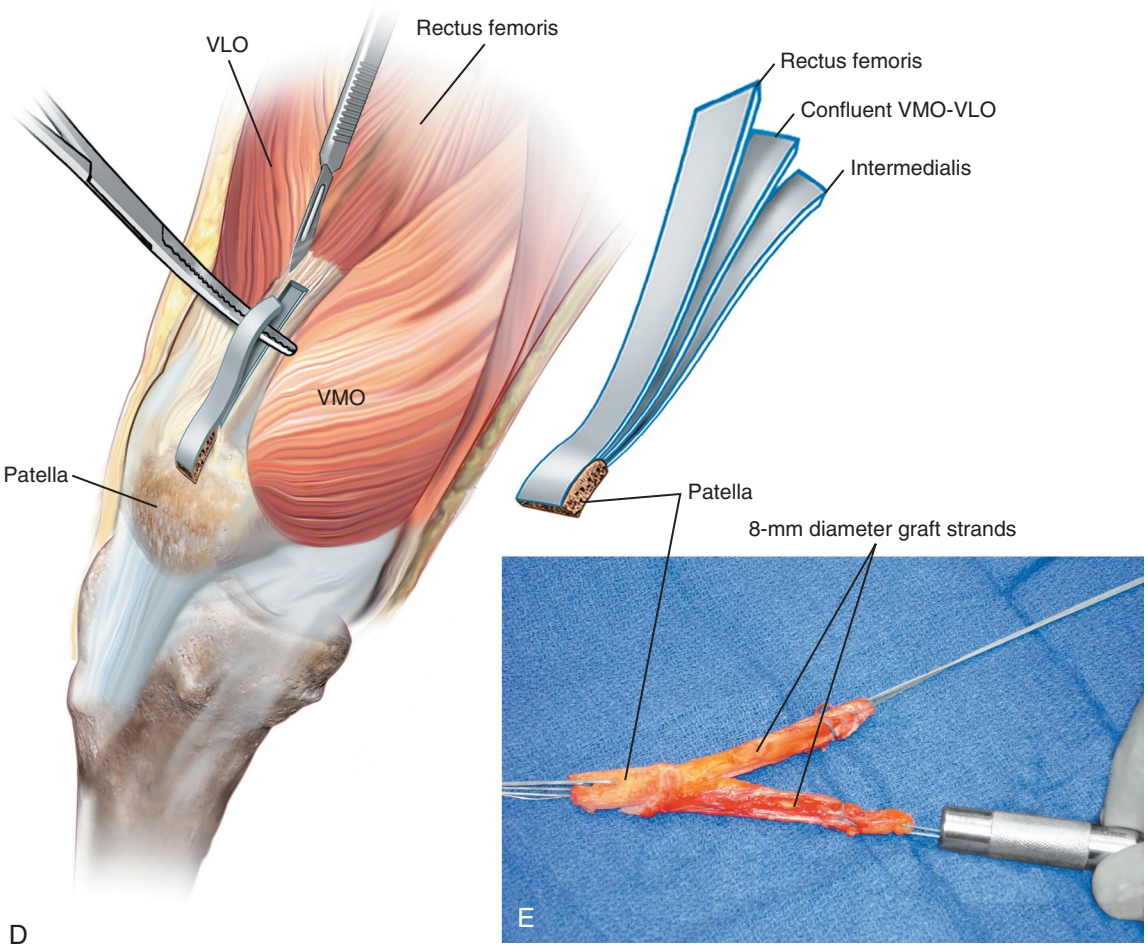


FIG 16-19 Quadriceps tendon-patellar bone autograft harvest. **A,** Medial incision. **B,** The quadriceps tendon is carefully marked to remove only 30% of its width and not extend to the musculotendinous junction. **C,** A central 11- to 12-mm wide full-thickness quadriceps tendon graft is harvested. The defect is later closed to maintain arthroscopic joint distention. **D,** Illustration of graft harvest. **E,** Two-strand 8-mm tendon graft with patellar bone is prepared. *VLO*, Vastus lateralis obliquus; *VMO,* vastus medialis obliquus.

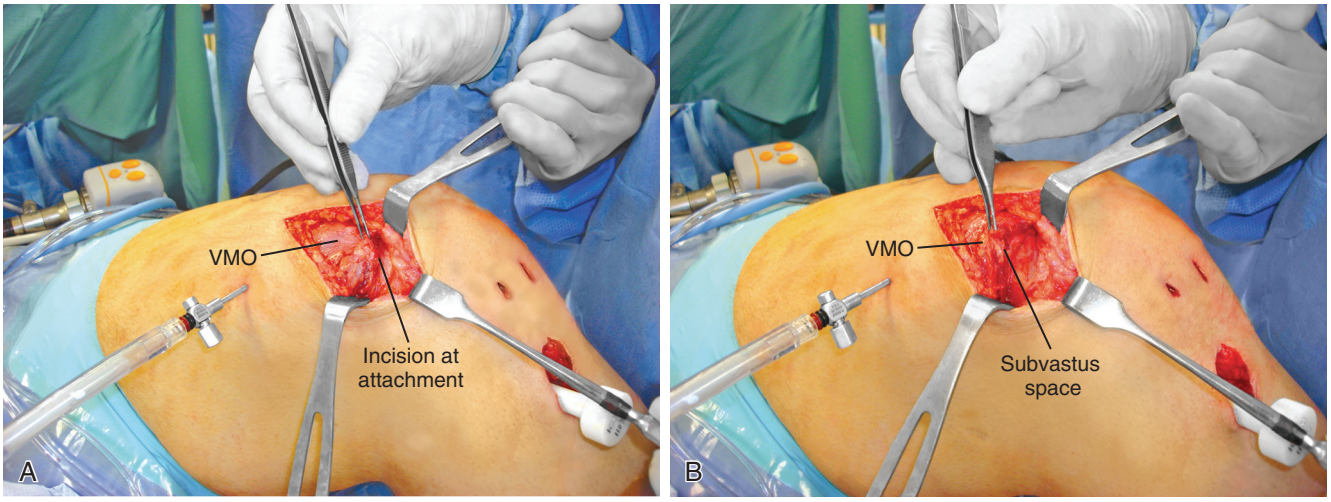

FIG 16-20 In this revision knee with a quadriceps autograft, the tendon harvest site is used to perform the subvastus approach. **A,** An incision is made at the vastus medialis obliquus (VMO)-retinacular attachment. **B,** The VMO is gently reflected proximally in an extracapsular blunt dissection. If a single femoral tunnel is selected, a smaller skin incision and muscle-splitting approach are used.

CRITICAL POINTS Preparation of Achilles Tendon-Bone Allograft

- Each portion of single or double-strand graft is tubed, Achilles tendon has a wide fan shape at its proximal aspect.
- AT-B graft used for single tibial or femoral tunnel applications.

tunnel is placed using an outside-in technique through a VMO muscle-splitting approach.

Surgical Technique for Anteromedial Approach and Outside-in Femoral Tunnels

This approach is selected when two femoral tunnels are used and is less traumatic than a muscle-splitting approach, in which the VMO is split for 5 to 6 cm for proper visualization. In addition, this approach allows for good visualization of the graft and suture post fixation. When a single femoral tunnel is selected, a limited muscle-splitting approach is performed. A vertical skin incision of 3 to 4 cm is made over the anteromedial vastus medialis proximal to the knee joint and just medial to the quadriceps tendon. When an ipsilateral QT-PB is harvested, the same skin incision is used (Fig. 16-20).

The key to the anteromedial approach is to identify the VMO anterior attachment to the medial retinaculum and dissect in this plane, thereby avoiding the muscle and achieving a subvastus elevation of the VMO. Note that no incision is made into the VMO attachment to the patella and the medial patellofemoral ligament is not incised. Only a limited subvastus exposure is required. The synovium beneath the VMO is protected and not entered. The VMO nerve innervation proximally is not disturbed. A branch of the superior genicular artery that traverses the inferior border of the VMO is protected.

The outside location of the 1 o'clock femoral tunnel entrance is identified with the drill guide. The guide pin is placed 12 mm proximal to the articular cartilage of the medial femoral condyle, and an equal distance medially from the medial trochlear border. The articular cartilage border is carefully palpated. The more distal femoral tunnel decreases graft tunnel angulation at the entrance within the joint. The tunnel should be in line with the obliquity of the PCL graft, but not located too far distally adjacent to the articular cartilage to prevent a

CRITICAL POINTS Surgical Technique for Anteromedial Approach and Outside-In Femoral Tunnels

- Less traumatic than muscle-splitting approach, selected when two femoral tunnels will be used.
- Single femoral tunnel, limited muscle-splitting approach or FlipCutter.
- Vertical skin incision, 3-4 cm.
- Key: identify VMO anterior attachment to medial retinaculum and dissect in this plane, avoids muscle and achieves subvastus elevation of VMO.
- Only limited subvastus exposure required.
- Outside location 1 o'clock graft femoral tunnel entrance identified with drill guide.
- Guide pin placed 12 mm proximal to articular cartilage of medial femoral condyle and an equal distance medially from posterior from medial trochlear border.
- Tunnel located in line with the obliquity of the PCL graft.
- 4 o'clock graft femoral tunnel located 12 mm from medial articular cartilage margin, just anterior to femoral epicondyle.

breakout of the tunnel into the distal femoral condyle. The location of the 4 o'clock femoral tunnel, to maintain an adequate bone bridge at both the entrance and exit of both tunnels, is also 12 mm from the medial articular cartilage margin and just anterior to the femoral epicondyle.

At the time of graft fixation, the surgeon uses a headlight to view the graft in the tunnels. The graft length is observed as the knee is flexed to determine the knee flexion angle at which the greatest graft length is produced. In addition, the headlight provides for adequate visualization for the placement of the interference screw and a graft suture post for added fixation. Routine closure is performed with absorbable sutures used for the VMO retinaculum attachment and subcutaneous tissues.

Recommendations for Surgeons on Selecting a Posterior Cruciate Ligament Operative Technique

The operative techniques available to the surgeon require experience and knowledge at an expert arthroscopic level. There is a building level

CRITICAL POINTS Recommendations for Surgeons on Selecting a Posterior Cruciate Ligament Operative Technique

- Levels of difficulty in PCL reconstruction options, marked variability among surgeons in techniques and grafts selected.
- Initial level: all soft tissue graft. Concern exists with allograft tissue in athletes; low strength fixation of interference screws. Low recommendation.
- Next level: graft with bone in one portion (AT-B allograft). Tendon portion placed in tibial tunnel, bone plug secured in femoral tunnel. Ease of tibial graft passage.
- Next level: placement of bone portion in tibial tunnel. Distinct advantage in revision cases. Added benefit secure graft fixation and healing.
- Next level: additional second femoral tunnel in larger patients with larger PCL footprint.
- Next level: harvest QT-PB autograft in athletic patients: one- or two-strand femoral tunnel, bone in tibial tunnel

of difficulty in PCL reconstructive techniques and the literature reflects marked variability among surgeons in surgical options and graft choices. Based on the senior author's experience, a few suggestions are provided for consideration of this selection process.

Starting from the initial level of surgical complexity, a soft tissue graft (without a bone portion) is the easiest to prepare, pass into the knee joint, and fixate in well-placed femoral and tibial tunnels. There are a variety of fixation methods available. The senior author expresses a level of concern with allograft tissue, particularly in an athletic patient, owing to delayed remodeling and lack of a beneficial graft hypertrophy after implantation that occurs with autografts. In addition, the use of soft tissue interference screws alone provides a relatively low strength attachment fixation.

The next level of complexity is a PCL graft that has bone attached on one end, such as an AT-B allograft. There is the opportunity for ease of passage, with the tendon portion placed in the tibial tunnel and secure fixation accomplished with an interference screw of the bone plug at the femoral tunnel. The tendon is passed first into the knee joint through an enlarged anterior portal, and then into the tibial tunnel. This allows the bone portion of the graft to be passed next into the joint and docked by a leading suture within the femoral tunnel and fixed with an interference screw. The tendon portion in the tibial tunnel allows double fixation with an interference screw and back-up suture post. This is a recommended graft construct for surgeons and probably one of the most frequently used graft constructs with either an AT-B or QT-PB graft.

The placement of the bone portion of an autograft or allograft within the tibial tunnel is an added level of difficulty because the bone portion is introduced into the knee joint through an enlarged portal and then guided by a leading suture (always at the end of the bone) and nerve hook into the tibial tunnel. This requires the bone plug to be angled close to a right angle to enter into the tibial tunnel entrance. The tibial tunnel is enlarged 2 mm greater than the bone portion of the graft. With experience, the gentle docking technique of the bone plug within the tibial tunnel is successful. After the bone plug is in the tibial tunnel, the tendon portion is brought into the joint and easily passed into the femoral tunnel. This allows the overall graft to be displaced proximal to distal for appropriate graft lengths in the tunnels and final fixation. The senior author believes the fixation of the bone plug within the tibial tunnel is a distinct advantage. The clinical experience at our center has shown (in revision cases) a relatively poor healing ability of large allografts within a large-diameter tibial tunnel. The bone plug is fixed with both an interference screw and back-up suture post. Accordingly, this represents the preferred technique recommended in this chapter. In addition, two tibial tunnels are not necessary to achieve successful results and therefore one well-placed tibial tunnel is selected in all PCL surgical cases.

The final level of complexity is adding a second femoral tunnel; the recommendations for the double-graft construct have already been presented. In summary, the primary indication is in larger patients with corresponding larger PCL femoral attachment sites where a single graft replaces 50% or less of the femoral attachment area. Future well-designed level 1 studies of sufficient numbers of patients are necessary to resolve these controversies; however, the recommendations discussed in this chapter appear warranted at this time.

Posterior Cruciate Ligament All-Inside Technique: One- and Two-Strand Graft Reconstructions Using Quadriceps Tendon-Patellar Bone Autograft (Preferred Technique for Athletic Patients)

Our graft preference for isolated PCL reconstruction using the all-inside technique is a QT-PB autograft, using a one- or two-strand femoral placement based on the size of the quadriceps tendon, as discussed. This approach is recommended for athletic patients. The bone plug is placed and fixated in a posterior tibial tunnel directly at the posterior entrance under fluoroscopic control (see Table 16-12). The goal is to match the results of the tibial inlay procedure, with the bone plug placed directly at the posterior PCL attachment using an oblique tunnel instead of a tibial inlay that requires an open posteromedial approach. In a sedentary patient or multiligament knee injury, an AT-B graft is selected with the bone plug placed in either the femoral or tibial tunnel. The operative steps for these techniques are described in the following sections. There are other PCL procedures and potential options for tibial and femoral placement and tunnels, based on the graft selected (see Table 16-13).

Patient Positioning and Setup

An examination under anesthesia is performed to confirm the diagnosis and carefully compare the injured knee with the opposite normal knee. It is important to palpate the medial tibiofemoral step-off at 90 degrees of flexion in both knees. At surgery, the PCL grafts will be tensioned in knee flexion and the medial tibiofemoral step-off used as verification that the abnormal posterior translation has been corrected.

The patient is placed supine on the operating table with appropriate padding (Fig. 16-21). The operating table is placed in a 15-degree reflexed position to prevent hyperextension of the spine and produce mild flexion of the hip to relieve undue tension on the right and left femoral nerves. The knee portion of the bed is flexed to 70 degrees. A thigh tourniquet is placed over cast padding. The opposite limb is positioned in a foam leg holder with the hip slightly flexed. A thigh-high compression hose is placed on the opposite extremity. After appropriate draping, a 4-inch flat padded bolster is placed underneath the operative thigh to protect the tissues and allow for knee flexion during the operative procedure. The operative procedure is performed with the knee flexed from 60 to 90 degrees; however, further knee flexion is possible by adjusting the operative table or using an additional thigh bolster. No undue pressure should be placed against the posterior thigh and sciatic nerve during the operative procedure. For this reason, an arthroscopic thigh holder is usually not used. In prolonged surgical cases, a rigid thigh holder may place abnormal

TABLE 16-12 All-Inside Posterior Cruciate Ligament Graft Options

	Two-Strand Grafts	Single-Strand Grafts
Preferred	QT-PB autograft 1. Single tibial tunnel: bone plug at posterior tunnel exit 2. Femur: two-strand, two tunnels or one-strand, one tunnel based on graft size	QT-PB autograft 1. Tibial tunnel: bone plug at posterior tunnel exit 2. Femoral tunnel: one-strand FlipCutter femoral socket TightRope plus interference screw
Alternatives	Femoral attachment, two tunnels QT-PB allograft AT-B allograft	QT-PB allograft AT-B allograft
Principles	Allografts have lower success rate, delayed healing Bone graft plug provides secure fixation, faster healing, and increased graft construct tensile strength compared with all soft tissue grafts. Rehabilitation, return to activity are delayed with allografts. Avoid single small-diameter B-PT-B autograft; second graft is required to achieve native PCL width. Graft selection rules are still empiric until randomized controlled clinical trials are performed.	Allograft provides acceptable results in multiligament reconstructions, dislocated knees when operative complexity and time warrant single-tunnel procedure. Preference for bone plug at posterior tibial tunnel to avoid large-diameter soft tissue graft through tibia with delayed graft incorporation.

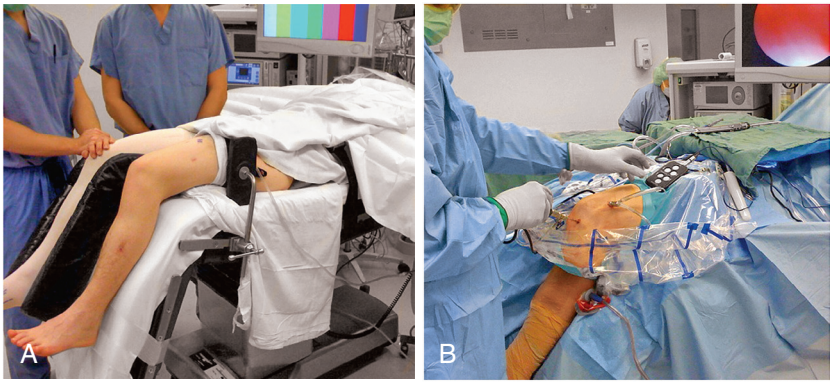

FIG 16-21 Patient position with the knee flexed to 70 degrees. Note the bed is flexed to maintain hip flexion. There is no pressure against the posterior popliteal space. The opposite leg is well padded. The knee flexion angle is adjusted as required.

pressures on the posterior thigh, which compromises the neurovascular structures. Posterior thigh muscle ischemia and peroneal tibial nerve damage are avoided by ensuring no undue posterior pressures occur.

When a meniscus repair is required, an arthroscopic thigh holder is initially used to allow for adequate joint opening for an inside-out meniscus repair using the patient and limb positioning described. The knee position of the bed is flexed as required. After the meniscus repair is performed, the thigh holder is removed and appropriate posterior thigh padding placed as necessary.

Arthroscopy of the knee begins with a pressure-regulated pump that is adjusted to provide mild joint distention and prevent fluid extravasation. The pump is required to maintain joint distention, particularly during the drilling of the tibial tunnel, so that the fluid expands the posterior capsule out of the operative field. Modern pressure- and volume-regulated pumps allow for a controlled inflow and outflow that maintain a safe pressure. In addition, sufficient fluid inflow is maintained so that a tourniquet is used only selectively during the operative procedure.

Routine arthroscopic anteromedial, anterolateral, and superolateral portals are created (Fig. 16-22). During the PCL reconstruction, a transpatellar central portal is required. Many surgeons recommend a posteromedial portal to debride the PCL tibial fibers and visualize the PCL tibial attachment. The senior author performs a technique in which the posteromedial portal, in most cases, is not required. The use of three anterior portals is advantageous because inadvertent fluid extravasation into the popliteal fossa is avoided, which may limit posterior capsule distention and visualization during drilling of the tibial tunnel.

A standard arthroscopic examination is performed. The gap test is used to assess lateral and medial joint opening at 20 degrees of knee flexion with a varus and valgus stress. Any meniscal repairs or partial resections, debridement, or other arthroscopic procedures are performed.

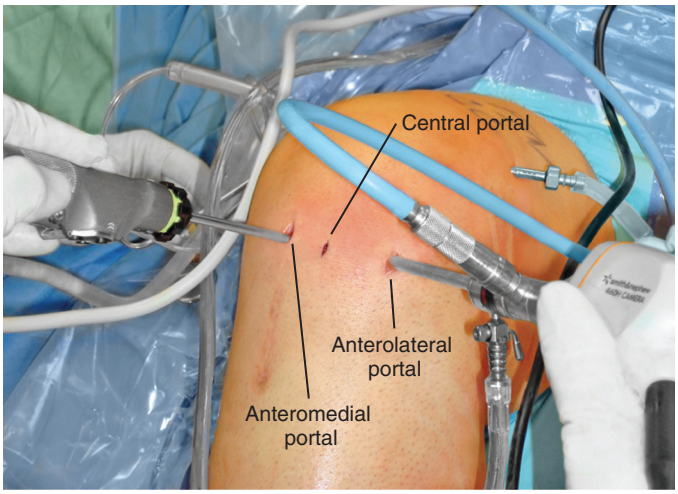

FIG 16-22 Arthroscopic preparation of the tibial and femoral posterior cruciate ligament graft sites through anteromedial, central, and anterolateral portals.

Tibial Tunnel Preparation

The most difficult part of the operative procedure is preparation of the tibial tunnel, (located in the distal PCL attachment position), without injuring the popliteal neurovascular structures. To maintain joint distention and allow full visualization, the tourniquet is inflated, a pressure-regulated arthroscopic pump is used, and the femoral tunnels and ipsilateral graft harvest are completed after preparation of the tibial tunnel.

The knee is positioned at 70 degrees of flexion to prevent pressure against the popliteal structures posteriorly and a proximal thigh pad is used to elevate the thigh. This allows the posterior neurovascular structures to drop away from the posterior aspect of the knee. Matava and coworkers[139] reported that the mean distance of the PCL from the popliteal artery from 0 to 100 degrees of flexion was 7.6 mm in the axial plane and 7.2 mm in the sagittal plane; however, there may be individual variation between knees. During the operative procedure, the surgeon is constantly aware of the joint pressure, fluid inflow and outflow, increased thigh tension, and any lack of joint distention. Intermittent palpation of the popliteal and calf region is performed during the operative procedure to detect fluid extravasation by an inadvertent puncture of the posterior capsule.[169]

The preparation of the tibial tunnel is more difficult when the ACL is intact. It is first necessary to identify residual PCL fibers adjacent to the ACL, which are removed with a shaver or basket through the anteromedial portal with the arthroscope in the anterolateral portal. The middle genicular artery enters into the proximal aspect of the PCL and requires electrocoagulation. Some PCL fibers are left on the

CRITICAL POINTS Posterior Cruciate Ligament All-Inside Technique: Patient Positioning and Setup

- Palpate medial tibiofemoral step-off (90 degrees of flexion) in both knees, will be used to verify correction of abnormal posterior translation at end of procedure.
- Operating table 15 degrees reflexed position, knee portion flexed to 70 degrees. A 4-inch flat padded bolster placed under operative thigh.
- Begin arthroscopy with pressure regulated pump: required to maintain joint distention.
- Routine arthroscopic anteromedial, anterolateral, and superolateral portals.
- Measure lateral and medial joint opening 20 degrees of flexion with gap test. Perform meniscus repair or resection, debridement, other arthroscopic procedures as required.
- Remove leg holder for PCL reconstruction, avoids prolonged posterior thigh pressure.

CRITICAL POINTS Posterior Cruciate Ligament All-Inside Technique: Tibial Tunnel Preparation

- Knee 70 degrees of flexion to protect neurovascular structures.
- Surgeon monitors joint pressure, fluid inflow and outflow, increased thigh tension, any lack of joint distention.
- Remove residual PCL fibers at femoral attachment, some fibers left for later identification and placement of the graft tunnels.
- 30-degree arthroscope placed into anteromedial portal, positioned high in notch adjacent to PCL femoral attachment.
- Pass curved elevator, gently free up capsular space behind remaining PCL fibers.
- Protect medial and lateral meniscus posterior tibial attachments adjacent to the PCL tibial fossa.
- Remove PCL stump.
- View entire posterior PCL tibial fossa to identify correct placement of tibial tunnel.
- Do not violate distal capsule attachment at tibial ridge.

femoral attachment for later identification and placement of the graft tunnels. The anterior meniscofemoral ligament (AMFL) and posterior meniscofemoral (PMFL) ligament are identified if present. It is usually possible to preserve the PMFL. If these structures impede visualization, they may be removed as long as the lateral meniscus has a confirmed posterior horn attachment to the posterior tibia and is not an anatomic variant, in which the posterior horn is attached by a meniscofemoral attachment.

The 30-degree arthroscope is next placed into the anteromedial portal and positioned high in the notch adjacent to the PCL femoral attachment. This allows the posterior capsular recess and remaining PCL stump at the tibial attachment to be viewed and instruments to be passed medial to the ACL.

A critical step is the passage of a curved Cobb elevator or commercially available curved Acufex (Smith & Nephew Endoscopy) PCL elevator (Fig. 16-23), which has a 90-degree curve and is used to gently free up the capsular space behind the remaining PCL fibers. In some knees, the posterior capsule becomes adherent to the PCL fibers. The PCL elevator is used to tease the capsule gently off of the PCL fibers and avoid rupture of the posterior capsule. This step requires a gentle approach to push the posterior capsule distally to the level of the distal PCL and capsule attachments, which are at the level of the posterior tibial step-off. Again, this step is emphasized as the key step to prevent damage to the neurovascular structures, because the posterior capsular pocket behind the PCL tibial attachment is restored. This allows the PCL elevator to be placed into this posterior position behind the tibial attachment during the tibial drilling.

If the posterior capsule is violated, a decrease in pump pressure is required and a large anterior fluid outflow portal is established. Close monitoring of any fluid extravasation into the popliteal space and calf is performed. It is usually safe to proceed under low pressure conditions; however, if there is any question of visualization and popliteal space distention, the operative procedure is postponed to allow for capsule healing.

The medial and lateral meniscus posterior tibial attachments adjacent to the PCL tibial fossa are viewed with the 30-degree arthroscope placed adjacent to the medial femoral condyle through the anteromedial portal. The shiny white attachment of the medial meniscus is well visualized and the adjacent lateral meniscus attachment is protected at all times during the preparation of the tibial tunnel. These meniscal

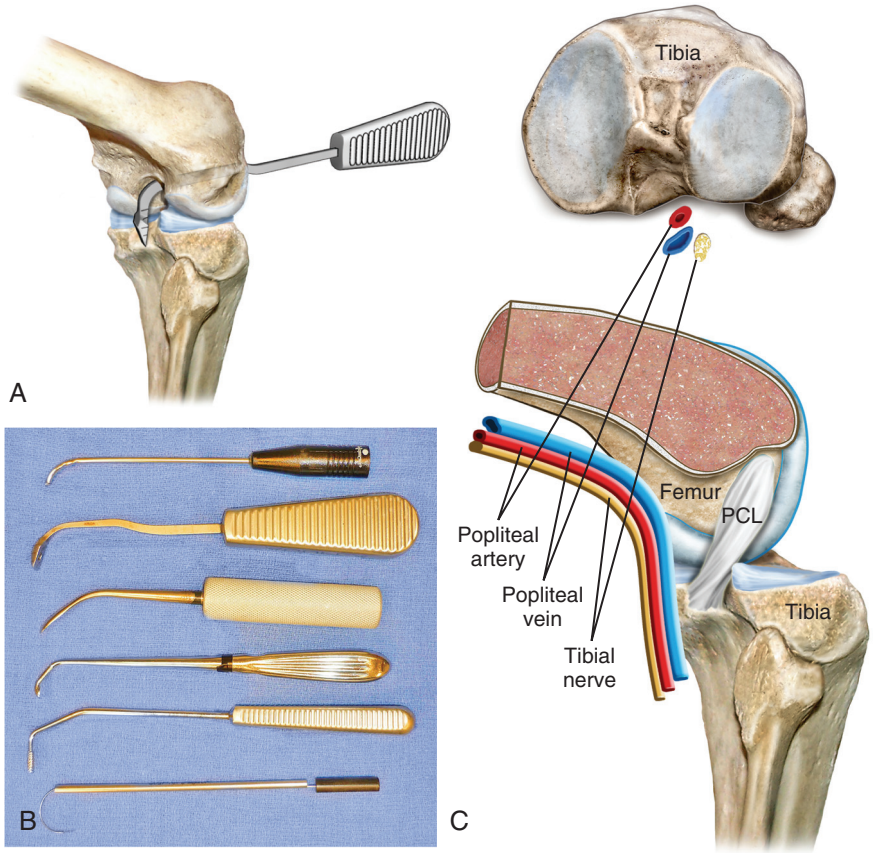

FIG 16-23 **A** and **B,** Tibial preparation. A 30-degree arthroscope is placed through the anteromedial portal. The scope is placed high in the notch adjacent to the medial condyle to view the posterior region of the joint. Instruments are placed through a central portal, medial to the anterior cruciate ligament, carefully protecting the ligament. **A,** The Acufex posterior cruciate ligament (PCL) elevator is inserted through the notch to carefully free the posterior capsule and recreate the normal capsular recess behind the PCL, because the capsule may be adherent to the ruptured PCL fibers. This step allows the capsule to displace posteriorly with fluid distention protecting the neurovascular structures. **B,** The tibial PCL stump is removed under direct visualization using curved shavers, baskets, Cobb elevators, and radiofrequency instruments. The posterior medial and lateral meniscus attachments are protected at all times. **C,** Anatomic illustration shows the close proximity of popliteal neurovascular structures.

attachments are located within a few millimeters of the PCL attachment and may be easily damaged during drilling of the tibial tunnel if it is too proximal or angled to the medial or lateral aspect of the PCL fossa.

The PCL stump is removed with arthroscopic instruments of the surgeon's preference. There are a variety of curved instruments, including baskets, shavers, and curettes, that are helpful. The senior author prefers an electrocoagulation cautery instrument that is manually bent to a 45-degree curve to initially cauterize the PCL fibers at the most proximal portion of the PCL fossa, immediately posterior to the ACL tibial attachment. This initiates a safe plane directly on cortical bone, which is then continued distally to the main PCL attachment. At times, there are remaining PCL fibers that are adherent to the posterior capsule. These fibers are left alone, or they may be easily displaced posteriorly while exposing the bony PCL fossa distally to the capsular attachment at the posterior tibial champagne glass step-off. The capsule attachment is not violated to prevent fluid extravasation into the popliteal space. At the conclusion of these steps, the entire posterior PCL tibial fossa (to the level of the posterior capsule attachment) is viewed for identification of the correct placement of the tibial tunnel.

Tibial Tunnel Drilling

A medial skin incision 3 to 4 cm is made 1 cm medially to the tibial tubercle. The tunnel entrance is medial or lateral to the tibial tubercle (Fig. 16-24). There may be a theoretical advantage for the tunnel to be started just lateral to the tibial tubercle to produce less posterior tunnel graft angulation. However, either tunnel location is acceptable. The senior author usually prefers an entrance medial to the tibial tubercle. When an ACL reconstruction is also performed with a medial tunnel, the PCL graft is placed through a tunnel lateral to the tibial tubercle.

The arthroscope is placed in the anteromedial portal and positioned high in the notch to view the posterior aspect of the tibial PCL attachment to the capsular attachment. In the majority of cases, the 30-degree arthroscope provides an excellent view. On occasion, a 70-degree arthroscope is required. As already discussed, an alternative approach is to place the arthroscope in a posteromedial portal and view the drill guide placed through the anteromedial portal; however, this is seldom required and avoids the potential for posterior fluid extravasation.

The drilling of the tibial tunnel is shown in Figure 16-25. The drill guide is placed through the central transpatellar tendon portal. The tip of the guide is placed so that the guide pin exits 6 mm proximal to the level of the posterior capsule insertion on the tibia, just before the posterior tibial step-off. This is a critical step because a guide pin placed directly at the bony tibial ridge would allow a large-diameter drill to enter distal to the capsular attachment into the popliteal space. At all times, the drill pin and drill are proximal to the distal capsular attachment of the PCL fossa. Another error is to place the guide pin too proximal in the PCL fossa, which produces a near-vertical PCL graft with limited ability to resist posterior tibial subluxation. The goal

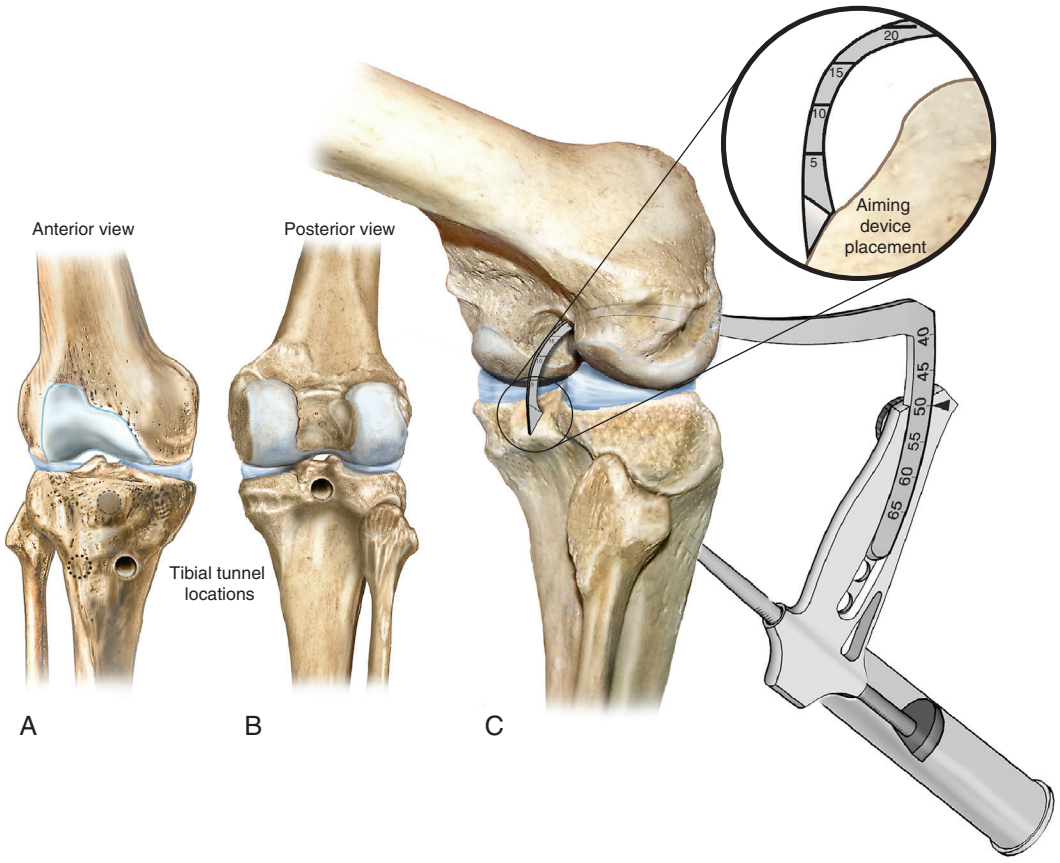

FIG 16-24 Location of tibial tunnel. **A,** Tunnel position may be medial or lateral (*dotted circle*) to the tibial tubercle 3-4 cm distal to the joint line. The tunnel position is at a 50-degree angle or greater to decrease the acute angulation at the posterior tibia. **B,** Posterior tibial tunnel at distal posterior cruciate ligament (PCL) attachment site. **C,** Acufex Director PCL Tibial Aimer is placed through the central portal with the tip of the guide resting on the posterior capsule insertion, with the target 5 mm proximal to the distal aspect of the PCL footprint. This allows sufficient tibial bone proximal to the tunnel to prevent anterior graft migration.

is to place the guide pin in the distal central portion of the PCL fossa, 20 to 25 mm from the proximal entrance of the PCL fossa. This leaves 15 mm of the posterior fossa to retain the posterior graft position and prevent a vertical PCL graft. This is a key step of the procedure. The drill guide is angled 50 to 55 degrees to produce an oblique tibial tunnel that will decrease graft angulation effects.

The next step involves use of the drill guide Safety Stop system (Acufex). This is a unique feature of this drill guide system. The guide pin is chucked to a fixed distance with the safety stop mounted on the drill guide. The safety stop controls the depth of guide pin penetration into the tibia, irrespective of the angle or position of the PCL tibial aimer, and prevents the guide pin from passing beyond the guide tip and damaging neurovascular structures.

The guide pin is drilled into the selected tibial tunnel location. The depth of the guide pin is measured and used during the drilling process to determine the depth of drill penetration. The final position of the guide pin is viewed and again confirmed that the guide pin is distal in the PCL fossa. Fluoroscopic confirmation of the guide pin position is recommended.

The tibial tunnel is drilled to the desired diameter using safety procedures to be described. A commercially available PCL guide pin protector (Acufex) has a wide shape, with a central recess 5 mm from its tip to engage the tibial guide pin before and during the drilling procedure. The tip of the pin is viewed at all times during the drilling process with the arthroscope. The instrument prevents posterior migration of the pin and drill bit. The drilling process involves use of a drill with a drill tip and not a drill twist extending the length of the drill. The drill tip only extends 10 mm with a smooth shank. The drill is advanced in a slow manner. The depth of drill penetration is measured by the calibrated drill and prior drill guide pin measurements. As the drill tip reaches the posterior cortex, there is a noticeable resistance. At this point, the drill is slowly advanced without sudden penetration. A second option is to remove the power and place a hand chuck over the drill bit to complete the tunnel through the posterior tibial cortex. In younger patients with a thick posterior tibial cortex at the PCL fossa, a two-stage drilling process is used, starting with an 8-mm drill and then progressing to an 11- or 12-mm drill.

When the FlipCutter (Arthrex) technique is selected, a 4-mm drill is initially used to establish the tibial tunnel. The FlipCutter is then advanced under arthroscopic visualization to exit the posterior tibial tunnel. The drill is flipped and held against the posterior tibial cortex and the tunnel is carefully drilled in a retrograde manner to the desired depth that is determined by the measured length of the FlipCutter. The PCL dilator remains in place posteriorly at all times to displace the posterior capsule away from the drilling procedure and prevent inadvertent capsule penetration. This technique requires practice and, importantly, requires an enlarged posterior capsular recess so the drill tip does not engage the capsular tissues when it is first engaged.

To summarize, there are specific safety procedures built into this technique to protect the neurovascular structures. First, use of the drill guide system with the Safety Stop and controlled depth of guide pin penetration, with the guide pin placed 5 mm proximal to the distal posterior capsule insertion. Second, placement of the guide pin protector and slow drill penetration, with direct viewing of the guide pin. Third, the final drill penetration of the posterior tibial cortex with complete protection posteriorly to prevent inadvertent deep drill penetration.

The proximal edge of the tibial tunnel is carefully chamfered with a rasp to limit graft abrasion effects (Fig. 16-26). Any remaining PCL fibers are removed so that the tibial tunnel entrance does not have soft tissue that would limit graft passage and to ensure the graft will lie flat against the PCL tibial fossa. Again, it is necessary to have 15 mm of the posterior tibial fossa and an intact posterior intraspinous area proximal to the tunnel. This maintains the angulation of the PCL graft from the tibial attachment to the femoral attachment to prevent a vertical graft and decrease graft tunnel enlargement (windshield-wiper effect). The most common technical mistake is to place the tibial tunnel at the proximal entrance of the PCL fossa, which is proximal to the native PCL tibial attachment.

Femoral Graft Technique

An important aspect of a successful PCL reconstruction is to have a clear understanding of PCL anatomy and changes in fiber-length and tension with knee flexion as already described. The anatomic "rule of thirds" to describe the PCL attachment assists the surgeon in defining the anterior-to-posterior plane and the proximal-to-distal plane of the native PCL (see Fig. 16-10, *A* and *B*).

As described previously, the PCL attachment is elliptical in shape, extending from high in the notch of the distal medial condyle from an approximate 11:30 to 5 o'clock position (left knee). The PCL footprint follows the articular cartilage, with the anterior portion within 2 to

CRITICAL POINTS Posterior Cruciate Ligament All-Inside Technique: Drilling of Tibial Tunnel

- Medial skin incision 3 to 4 cm, 1 cm medial or lateral to tibial tubercle.
- Place arthroscope in anteromedial portal, position high in notch to view posteriorly.
- Place drill guide through transpatellar portal.
- Do not place guide pin too proximal in PCL fossa, produces vertical PCL graft.
- Place guide pin in distal portion of PCL fossa 5-6 mm proximal to distal capsule attachment tibial ridge.
- Angle drill guide 50 to 55 degrees to produce oblique tibial tunnel.
- Chuck guide pin to fixed distance with safety stop mounted on drill guide.
- Measure depth of guide pin to determine depth of drill penetration, confirm with fluoroscopy.
- Drill tip only extends 10 mm with a smooth shank, advance slowly. As drill tip reaches the posterior cortex, advance slowly. In dense cortical bone, consider smaller-diameter drill.
- FlipCutter technique another option; however, requires added exposure and experience.
- Chamfer proximal edge tibial tunnel.

CRITICAL POINTS Posterior Cruciate Ligament All-Inside Technique: Posterior Cruciate Ligament Femoral Graft Technique

- Anatomic rule of thirds used to define the anterior-to-posterior and the proximal-to-distal planes of native PCL.
- PCL footprint follows articular cartilage, anterior portion within 2-3 mm of its edge.
- At 4 o'clock position, PCL attachment is 4-5 mm from articular cartilage edge.
- If anterior meniscofemoral ligament present, footprint appears to be 1-2 mm from cartilage edge.
- Anatomic variability in femoral attachment; map out using remaining PCL fibers to locate desired graft position.

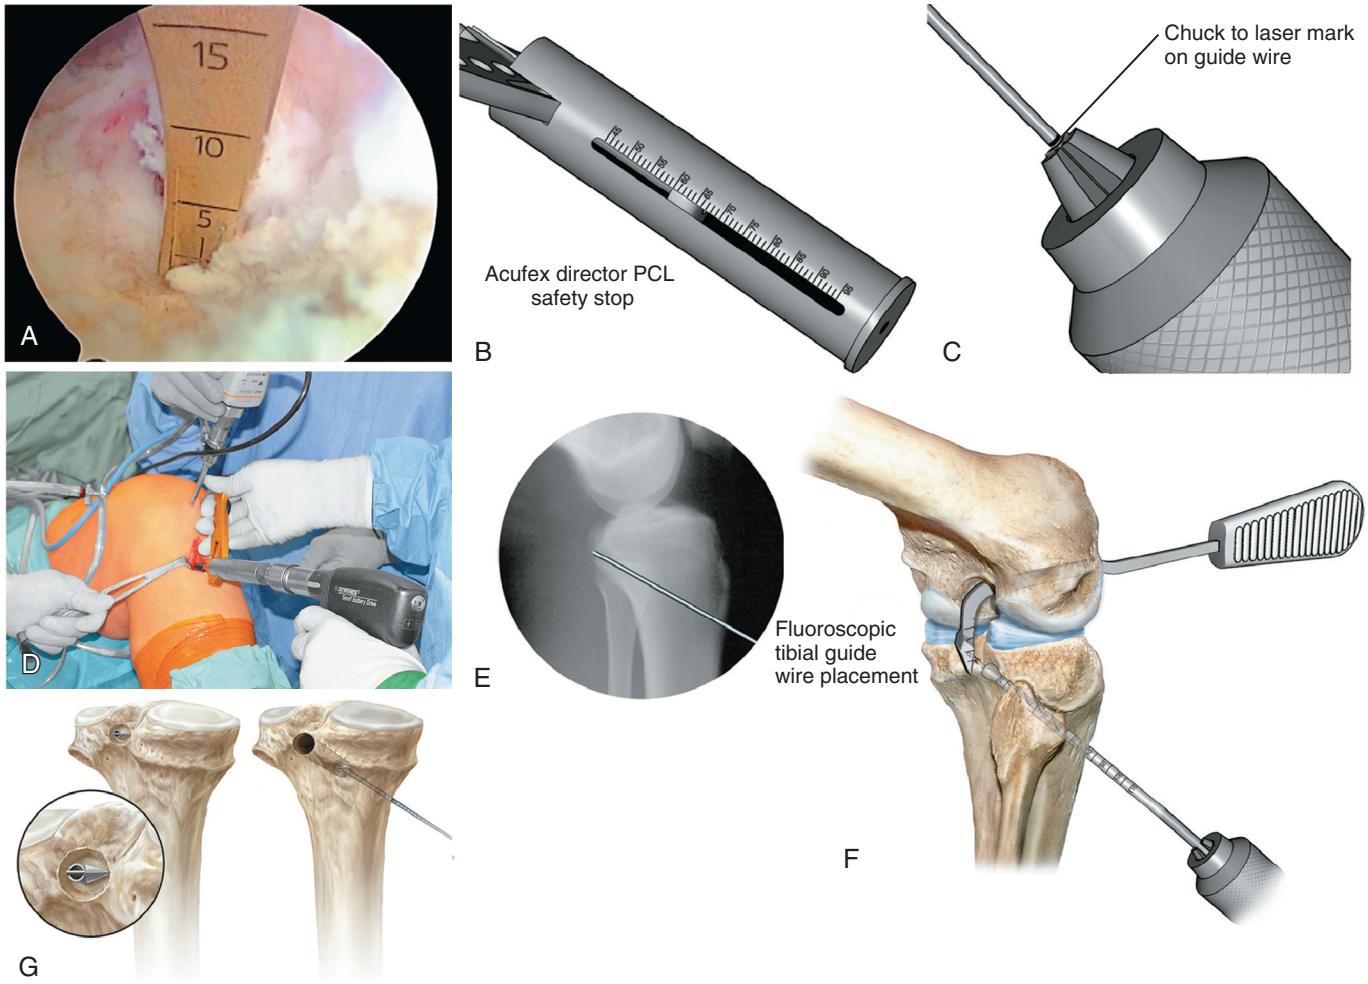

FIG 16-25 Drilling of tibial tunnel. **A,** Drill guide at the distal posterior cruciate ligament (PCL) attachment adjacent to the posterior capsule insertion. **B,** Acufex guide pin safety stop is attached to the drill guide. **C,** The guidewire is chucked on the power drill to the laser mark, which is the maximum length from the safety stop to the drill guide tip. This prevents the guidewire from being advanced beyond the drill guide after passing through the posterior cortex. **D,** Placement of guide pin using drill guide system at surgery. **E,** Fluoroscopy verifies guidewire placement. **F,** Tibial tunnel drilling with PCL elevator/wire catcher to protect posterior neurovascular structures. **G,** Alternative technique using a "flip-drill" to make a posterior tibial socket for the PCL graft bone plug. Four FiberWire sutures placed through the plug are passed to the anterior tibia for graft fixation.

3 mm of its edge, depending on the reference system used.[144] At the 4 o'clock position, the PCL attachment is approximately 4 to 5 mm from the articular cartilage edge.[189] However, if the AMFL is present, the footprint will appear to be 1 to 2 mm from the cartilage edge. There is anatomic variability in the normal proximal to distal width of the PCL, and in some knees a more oval appearance exists because of an increased width of the middle third of the PCL attachment. Because of anatomic variability in the PCL femoral attachment, it is necessary to map out the attachment using remaining PCL fibers to locate the desired graft position within the PCL attachment grid represented by the rule of thirds. The reference system axis used to describe the PCL attachment is distal to proximal and anterior to posterior with the knee in full extension. However, the surgeon views the PCL with the knee flexed and it is also helpful to communicate a graft position as deep or shallow and high or low in the femoral notch on the medial femoral condyle.

There are two main techniques used for PCL graft femoral placement and fixation. The first technique (our preference) incorporates two separate femoral tunnels with two separate graft strands. The second technique involves a single femoral tunnel when operative time and complexity of the surgery are factors, or if the graft does not allow two separate graft strands to be prepared.

Technique for Femoral Placement of One or Two Tunnels and Graft Passage

The technique for femoral placement of two tunnels and graft passage is shown in Figure 16-27. The PCL footprint is mapped with a calibrated probe and electrocoagulation. The 12, 1, and 4 o'clock position marks on the medial femoral condyle are made. The goal is to create two separate femoral tunnels in the distal two-thirds of the native PCL attachment. This places a graft with an approximate area of 100 mm^2 in cross section, occupying up to 75% or more of the PCL attachment.

If the PCL graft is placed too distal or shallow in the notch, it will be subjected to high tensile forces with knee flexion, resulting in constraining flexion and probable graft failure. If the graft is placed too

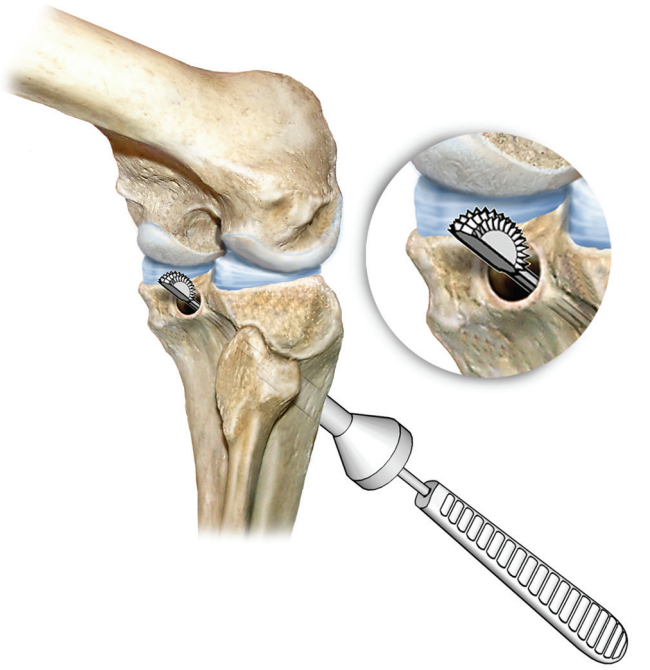

FIG 16-26 Chamfering of the tibial tunnel with a rasp to decrease graft abrasion effects. It is necessary to have 15 mm of bone retained in the posterior tibial fossa above the posterior cruciate ligament footprint to prevent the graft from migrating through the tibia.

CRITICAL POINTS Posterior Cruciate Ligament All-Inside Technique: Technique for Femoral Placement of Two Tunnels and Graft Passage

- Map PCL femoral footprint, mark 12, 1, and 4 o'clock positions.
- Two separate femoral tunnels in distal two-thirds native PCL attachment.
- Anterior tunnel centered 1 o'clock, 6 to 8 mm deep to articular cartilage.
- Posterior tunnel centered 4 o'clock, 8 mm proximal (deep) to articular cartilage edge.
- Tunnels placed anterior-to-posterior direction to allow for 2- to 3-mm bone bridge.
- Femoral tunnels drilled outside-in subvastus technique.
- Core reamer used for 1 o'clock tunnel (for bone graft patellar defect).
- 20-gauge wire passed through tibial tunnel, out anterolateral portal.
- 22-gauge wires passed through separate femoral tunnels, out anterolateral portal.
- Tibial bone plug passed in joint, assist with nerve hook to orient graft to enter tibial tunnel.
- Pass two femoral graft strands, confirm correct placement.
- Confirm placement of bone plug with fluoroscopy, arthroscope.
- Tie sutures to tibial suture post. Final interference screw fixation under fluoroscopic control.

proximal or deep in the notch, the graft will slacken with knee flexion and allow posterior tibial subluxation. The recommended placement within the PCL footprint is shown in Figure 16-27, in which the graft replaces the distal two-thirds of the PCL that functions in resisting posterior tibial subluxation with knee flexion.

The PCL guide is used for two separate femoral tunnels to prevent overlap. The anterior tunnel is centered at the 1 o'clock position, 6 to 8 mm deep to the articular cartilage based on the size of the graft and footprint that allows the graft tunnel to come within 1 to 2 mm of the articular cartilage edge. The posterior tunnel is centered at the 4 o'clock position, 8 mm proximal (deep) to the articular cartilage edge. A mark is made at the center position of each tunnel with cautery, and then defined with a curette or sharp awl passed from the anterolateral portal. The bone beneath the PCL attachment is dense and requires making a well-defined small entrance hole for the two drill guide pins. Following this technique, the first tunnel is located in the anterior half of the PCL attachment, and in the distal two-thirds in the proximal to distal direction. The second tunnel is located in the posterior half of the PCL attachment, also in the distal two-thirds. The tunnels are carefully placed in the anterior to posterior direction to allow for a 2- to 3-mm bone bridge between tunnels. This placement of the two tunnels ensures that both graft strands will resist posterior tibial translation with knee flexion, sharing the load and not placed too deeply in the notch.

The two femoral tunnels are drilled using the outside-in subvastus technique previously presented. The entrance of the 1 o'clock tunnel is 12 mm proximal to the femoral articular cartilage border and medial to the trochlea. The 4 o'clock tunnel entrance is also 12 mm proximal to the articular cartilage border and anterior to the femoral epicondyle. A core reamer is used for the 1 o'clock tunnel to obtain a bone graft for the patellar defect (QT-PB graft, Fig. 16-28). Careful chamfering of the tunnel edges is performed to decrease graft abrasion. A flexible ruler is passed through the tibial and femoral tunnels to measure the intraarticular length of the two graft strands.

The passage of the graft is performed in a stepwise fashion (Fig. 16-29). A 20-gauge wire is passed through the tibial tunnel and brought out the anterolateral portal which is enlarged sufficiently to accept the PCL graft. A 22-gauge wire is passed through each of the two femoral tunnels and a grasper or nerve hook is used to bring the two wires out of the same anterolateral portal. The 1 o'clock and 4 o'clock wires are marked.

The tibial tunnel bone plug is first passed into the knee joint with the arthroscope placed in the anteromedial portal. A nerve hook facilitates passage adjacent and medial to the ACL and into the tibial tunnel. It is important that all soft tissues have been removed about the tibial tunnel, which is 2 mm larger than the graft to facilitate passage. The nerve hook is used to angle the bone to facilitate the initial entrance into the tibial tunnel. The two femoral graft strands are then passed through the enlarged anterolateral portal and viewed through the anteromedial portal to have the correct orientation in the 1 and 4 o'clock tunnels. It is preferable to first pass the 4 o'clock, and then the 1 o'clock graft.

Fluoroscopy is used to confirm final placement of the bone plug in the tibial tunnel (Fig. 16-30). The graft is marked at the collagenous fiber-bone junction and is viewed arthroscopically to confirm that the bone plug is entirely within the tibial tunnel and placed directly at the posterior tibial tunnel entrance. The sutures are tied over a tibial suture post. An absorbable interference screw (1 mm smaller than the diameter of the tunnel) is used for bone plug fixation at the tibial tunnel, verified by fluoroscopy. The final tensioning of the graft at the femoral site is performed next.

With the selection of one single femoral tunnel, the technique is modified as follows. A FlipCutter is used for the femoral tunnel, the center of which is located at the 2 o'clock position to span the center two-thirds of the PCL attachment. This is located approximately 8 mm from the articular cartilage edge to produce a graft tunnel that comes to within 1 to 2 mm of the cartilage margin. A TightRope (Arthrex) fixation for the tendon portion of the graft is used. Three No. 2 FiberLoop (Arthrex) sutures are passed in a locking stitch at the end of the

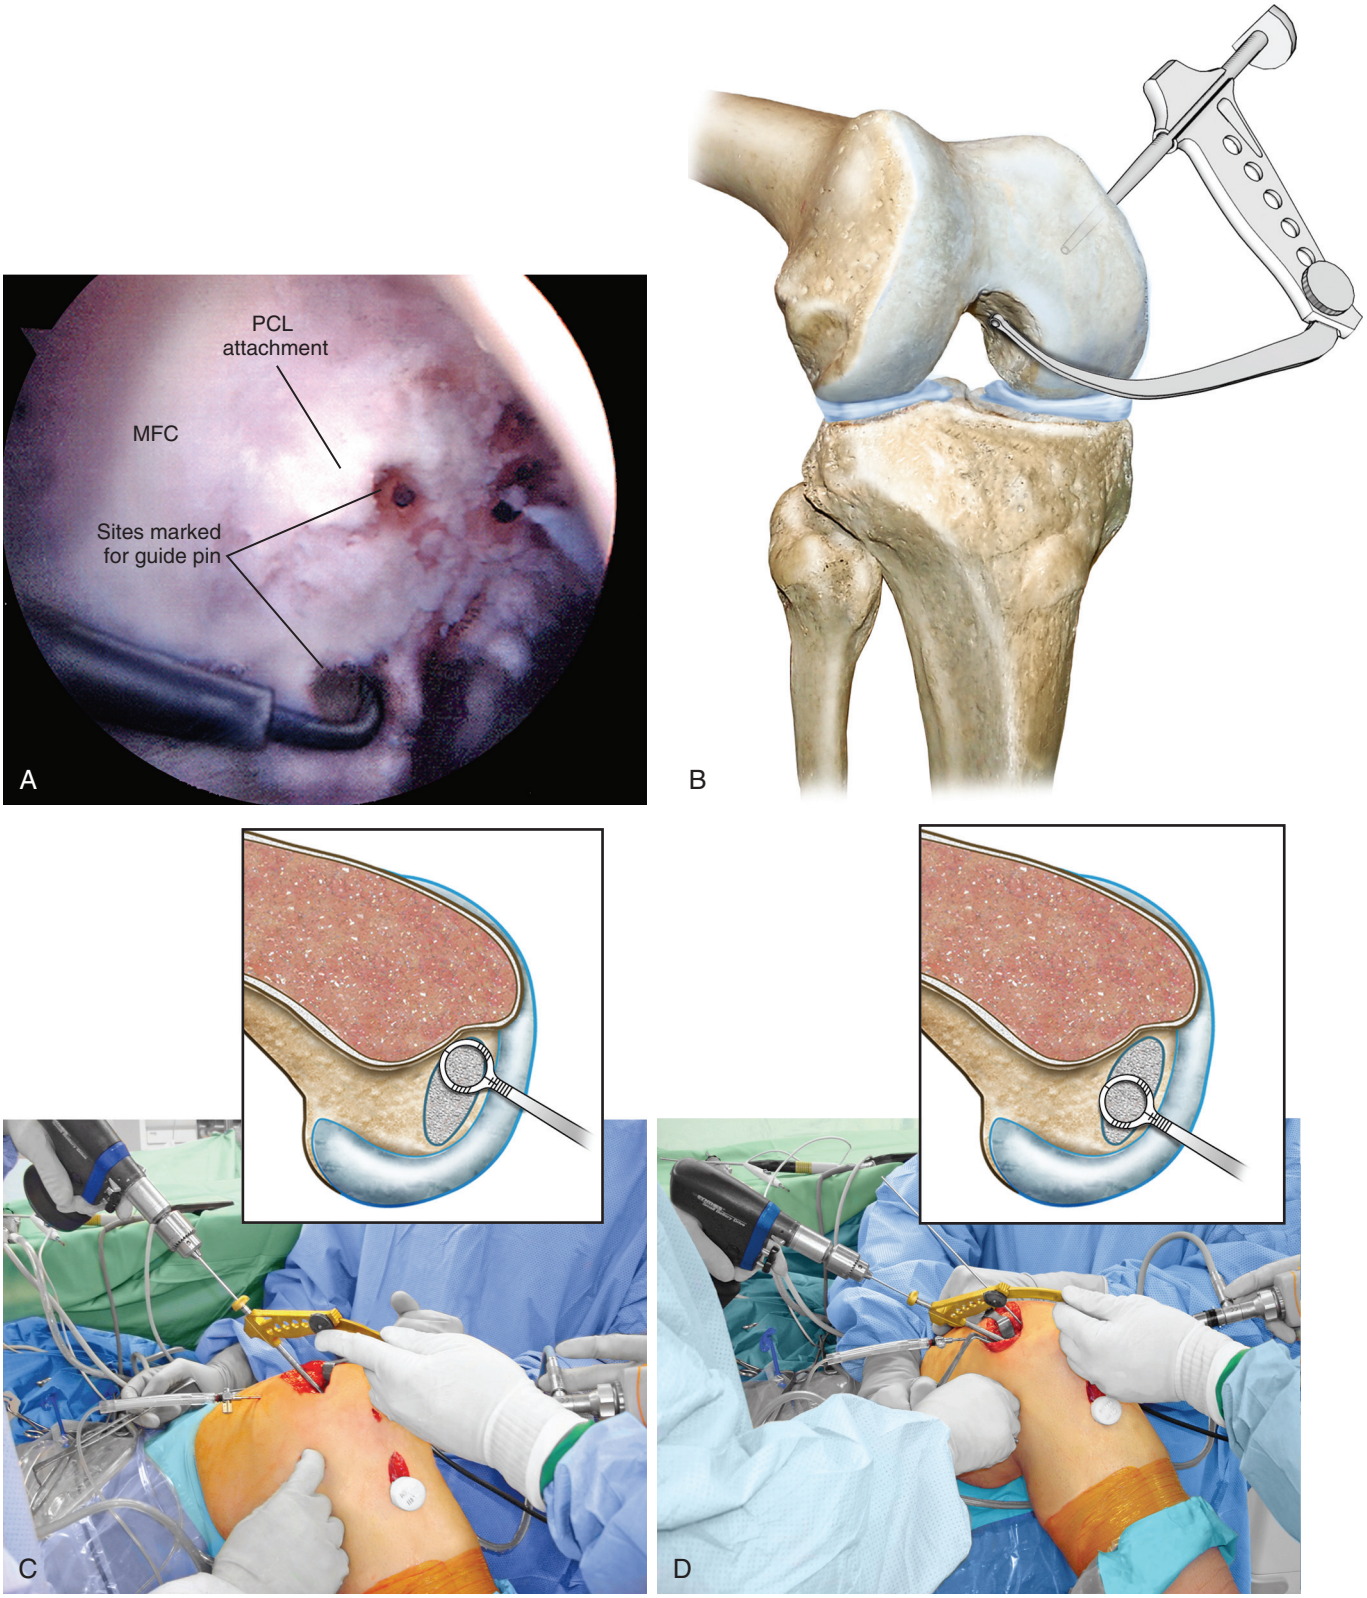

FIG 16-27 Placement of two femoral tunnels. **A,** Arthroscopic view of two posterior cruciate ligament (PCL) attachment shows 1 o'clock and 4 o'clock guide pin marks, 6 to 7 mm from the articular cartilage. **B,** PCL guide 15 mm proximal to the outside articular cartilage border. **C,** Placement of the 1 o'clock tunnel. **D,** Placement of the 4 o'clock tunnel. *MFC*, Medial femoral condyle.

FIG 16-30 Fluoroscopy confirms that the patellar bone plug is directly at the posterior tibial tunnel exit.

graft that is tied to the TightRope. The graft passage is the same as already described with the bone portion passed into the tibial tunnel and the TightRope sutures passed through the femoral tunnel.

Graft Tensioning and Fixation

The graft tensioning and fixation steps are the same for all grafts. For grafts with the bone block in the tibial tunnel, initial fixation is performed at the tibia (as already described) and final tensioning and fixation are performed at the femoral site. For bone blocks placed at the femoral site, fixation is first performed at the femoral site and final tensioning and fixation are performed at the tibial site (Fig. 16-31).

After the initial fixation of the graft at either the femoral or tibial site, the knee is taken through a full range of motion with an assistant displacing the tibia forward to correct for the weight of the leg and maintain joint reduction.

The knee flexion position for graft fixation is checked by determining the flexion angle at which the graft strand is the longest (functional zone) to ensure that the graft is not tensioned in its shortest position, which would overconstrain the joint and produce graft failure. A nonserrated hemostat is placed on each set of graft strand sutures exiting

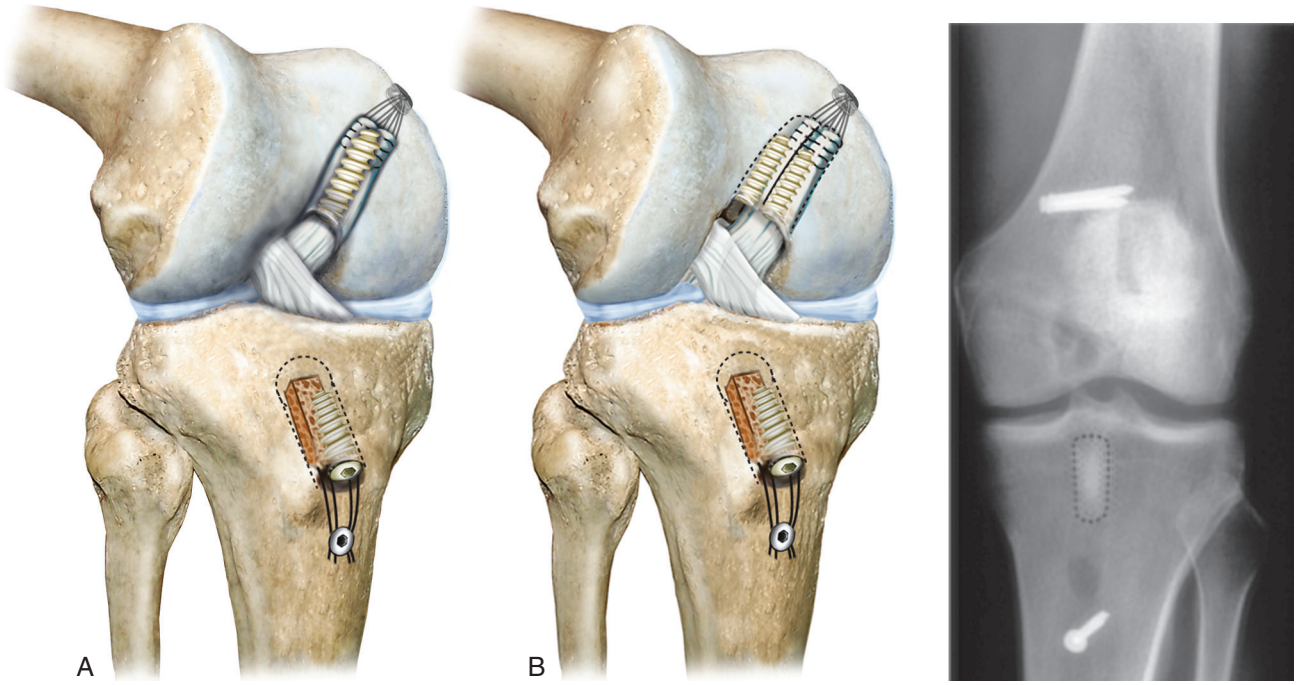

FIG 16-31 Two femoral techniques are shown and used based on surgeon preference of either a single tunnel **(A)** or two tunnels **(B)**; see text. **C,** Anteroposterior radiograph of a posterior cruciate ligament single tibial tunnel reconstruction; the bone plug (dotted line) is placed in the posterior tunnel exit and fixed with an absorbable interference screw and suture post.

CRITICAL POINTS Posterior Cruciate Ligament All-Inside Technique: Graft Tensioning and Fixation for All-Inside Grafts

- Bone plug in tibial tunnel: initial fixation at tibia, final tensioning and fixation at femoral site.
- Bone plug at femoral site: initial fixation at femoral site, final tensioning and fixation at tibial site.
- After initial fixation, at one end of graft, knee taken through full range of motion.
- Check knee flexion position for graft fixation by determining the flexion angle at which the graft strand is the longest.
- Condition graft 0-120 degrees of flexion.
- Verify normal medial tibiofemoral step-off at 90 degrees.
- Tie sutures for each graft stand over femoral or tibial post, verify final position of medial tibiofemoral joint. Absorbable interference screw added.
- Use arthroscopically placed nerve hook to confirm tension in PCL graft strands.
- With ACL reconstruction:
  - Tension PCL graft, avoid anterior tibial subluxation.
  - Verify tibiofemoral position at 0 and 90 degrees and graft tension with extension-flexion.
  - Confirm arthroscopic normal femoral condyle, anterior medial and lateral meniscus relationship.

from either the femoral or tibial tunnel(s) and circumferentially wound onto the clamp. The clamp is used to apply a 10 lb (44-N) load to each graft strand. The graft strands are conditioned by taking the knee joint through 0 to 120 degrees of flexion. The knee is placed at 90 degrees of flexion and a normal medial tibiofemoral step-off is palpated and confirmed. This is done with the assistant placing approximately 10 lb (44 N) of pressure against the calf to apply an anterior tibial force (assuming the ACL is intact). The knee is again taken through a full range of motion and the change in length of both graft strands noted. With increasing knee flexion, there will be increased tension and a pulling of the sutures and clamp into the tunnel of only 0 to 2 mm as the 90-degree position is reached.

The graft is longest at high knee flexion angles, which is the position selected for graft fixation. In most knees, the 70-degree flexion angle has the same graft length behavior as 90 degrees and this position is selected. There are commercially available graft-tensioning devices[53] (as used in ACL reconstructions) that provide measurable length-tension data and may be used for measurement of graft-tensioning loads. The sutures for each graft strand are tied over a femoral or tibial post, maintaining the 44 N of graft load and 44 N of anterior tibial load. These are empiric loading profiles.

The final position of the medial tibiofemoral joint is again verified. An absorbable interference screw is added to the fixation. The arthroscope is again placed and with a nerve hook, the tension in the PCL graft strand(s) is confirmed. The knee is taken through 0 to 110 degrees of flexion.

Although techniques have been described in the literature for the second posterior tunnel to be placed in a deeper, more proximal position, we recommend placing the tunnels in the middle and distal two-thirds of the PCL attachment as described. This allows both graft strands to share the loading and therefore tensioning is at the 70-degree flexion position for both grafts.

It should be noted that if one or both femoral tunnels are too proximal (deep in the notch), the graft strand length decreases with knee flexion (allowing posterior subluxation), because the graft strand is longest closer to full extension. In this situation, the final graft fixation is done at the more extended position. The more proximal graft strand will function in a reciprocal manner and the desired load sharing between grafts will not be achieved.

Alternatively, if the graft tibiofemoral attachment length is longer at 45 to 60 degrees of knee flexion, as the graft is pulled into the tunnel with knee flexion, then the femoral tunnels are too distal (shallow).

This is not an acceptable position and the femoral tunnel is reconfigured, removing 5 mm of the proximal aspect of the tunnel to allow the graft to assume a deeper position. The interference femoral screws are placed distal in the femoral tunnels to secure the grafts in a more proximal (deep) position. With the technique described in the placement of the femoral tunnels, it would be unusual for this graft tunnel adjustment to be performed.

In knees that undergo ACL reconstruction, it is important to determine as accurately as possible the neutral AP position of the medial and lateral tibiofemoral joints (without added internal or external tibial rotation). There is a tendency to displace the tibia into an abnormal anterior position by over tensioning the PCL graft. When the ACL is intact, the graft forces displace the tibia anteriorly, loading the ACL under low loads. When the ACL is insufficient, to prevent anterior tibial subluxation, the following steps are performed:

1. Place the knee at full extension with a 10-lb (44-N) force on each graft (or 20 lb for a single graft) and sufficient anterior loading on the calf to overcome gravity weight effects of the leg. This achieves a reduced tibiofemoral joint position when one or both of the medial or fibular collateral ligaments are present.
2. Flex the knee to 90 degrees, maintaining the same approximate graft load and anteriorly directed load on the calf. An anteriorly subluxated tibia at 90 degrees (compared with 0 degrees) will have abnormally increased tibiofemoral attachment site distances and the graft can be observed to piston into the tibial tunnel. In essence, the graft should be nearly similar in its tibial position at both 0 and 90 degrees of flexion.
3. Palpate for a normal tibiofemoral step-off and arthroscopically visualize a normal anterior relationship of the anterior portion of the medial and lateral meniscus in relationship to the respective femoral condyles. If there is any question, a lateral fluoroscopic or radiograph may be obtained intraoperatively. This is especially helpful in large limbs where the neutral AP position is difficult to determine with accuracy.

Femoral Placement of a Single Tunnel: Outside-In Technique

The drill guide is introduced into the anteromedial portal and the desired femoral tunnel position is located. The arthroscope is placed in the anterolateral portal. The goal is to place the tunnel into the middle two-thirds of the PCL attachment, avoiding too proximal a placement. The entrance of the guide pin is at the 2 o'clock position and approximately 8 mm from the articular cartilage edge. This should produce a tunnel that is 2 mm from the articular cartilage edge. A note of caution is that there is a tendency to place the drill tunnel too proximal (deep in femoral notch) and out of the PCL femoral footprint, producing a graft that only functions at low flexion angles. The ability to determine the native PCL footprint in the patient's knee carefully is important for correct tunnel placement. The preference is for a femoral tunnel of 11 to 12 mm in most knees. If the drill diameter is larger, portions of the graft will be too deep in the notch and outside of the normal PCL footprint.

The entrance position of the guide pin in the outside-in technique is midway between the femoral epicondyle and trochlea, at least 12 mm proximal to the articular cartilage edge. A more proximally placed guide pin would increase the tunnel angulation entering the joint and potentially increase graft abrasion effects.

A small skin incision and VMO muscle-splitting incision is made. A larger incision is not required because the bone block fixation is done with a cancellous screw without an added fixation device. The guide pin is overreamed or, alternatively, a coring reamer may be used to harvest a bone graft. The tunnel entrance into the knee joint is chamfered to limit graft abrasion effects.

CRITICAL POINTS Posterior Cruciate Ligament All-Inside Technique: Femoral Placement of a Single Tunnel: Outside-In Technique

- Drill guide in anteromedial portal, locate desired femoral tunnel position.
- Entrance of guide pin: 2 o'clock position, 8 mm from articular cartilage edge.
- Tunnel size: 11 to 12 mm.
- Small skin incision, VMO muscle-splitting approach or use FlipCutter placed from outside-in.
- Over-ream guide pin or use coring reamer to harvest bone graft.
- Chamfer tunnel entrance into knee joint.
- Graft passage: inside-out.
- Femoral graft fixation with TightRope adjustment of tension, interference screw placed through anterolateral portal.

A modification of this technique is used with a FlipCutter placed from outside-in instead of the guide pin and the femoral socket drilled from inside-out (Fig. 16-32). This is an easier technique than placing the femoral tunnel through the anterolateral portal. When a femoral or socket is placed with the FlipCutter, the technique involves overdrilling the socket depth so that graft positioning and tensioning are possible.

At the time of graft passage, either an inside-out passage (preferred; enlarged anterolateral portal used for graft passage into the knee) or an outside-in passage (retrograde guide wire from tibial tunnel out through femoral tunnel) is used. The process of graft positioning in the tunnels, graft conditioning, and fixation at the tibial tunnel is the same as described earlier. Femoral graft fixation is easily performed with the TightRope adjustment of tension, and an interference screw is also placed through the anterolateral portal (usually 8-mm diameter, 2 to 3 mm less than the tunnel diameter). With the VMO muscle-splitting approach, the final tension is the same except it is performed on the femoral side with an interference screw and added suture post. The surgeon uses a headlight and adequate exposure to advance an interference screw into the anterior aspect of the femoral tunnel for graft fixation. Arthroscopic examination confirms that the screw is not advanced into the knee joint.

There are publications that describe the all-inside drilling of a large single tunnel at the femoral attachment. However, the outside-in approach or inside-out FlipCutter is preferred for the femoral tunnel. From a technical standpoint, the drilling of a large-diameter tunnel is difficult owing to the proximity of the lateral condylar articular cartilage and the ACL, and the tendency exists to have a tunnel entrance that is markedly angled distally. In the senior author's experience, a more precise and less angulated tunnel is obtained with the outside-in approach.

Alternative Posterior Cruciate Ligament All-Inside Techniques

Femoral Placement of Rectangular (Oval) Tunnel for Bone Plug

An all-inside technique using the QT-PB autograft or allograft or AT-B allograft is described in which the bone plug is placed at the femoral site and the soft tissue graft is placed through a tibial tunnel. This procedure has the advantage of easy passage of the soft tissue graft through the posterior tibial tunnel. This is used in select knees in which operative time is a factor. In addition, in revision knees, there may be displaced femoral tunnels where the bone plug provides a more stable

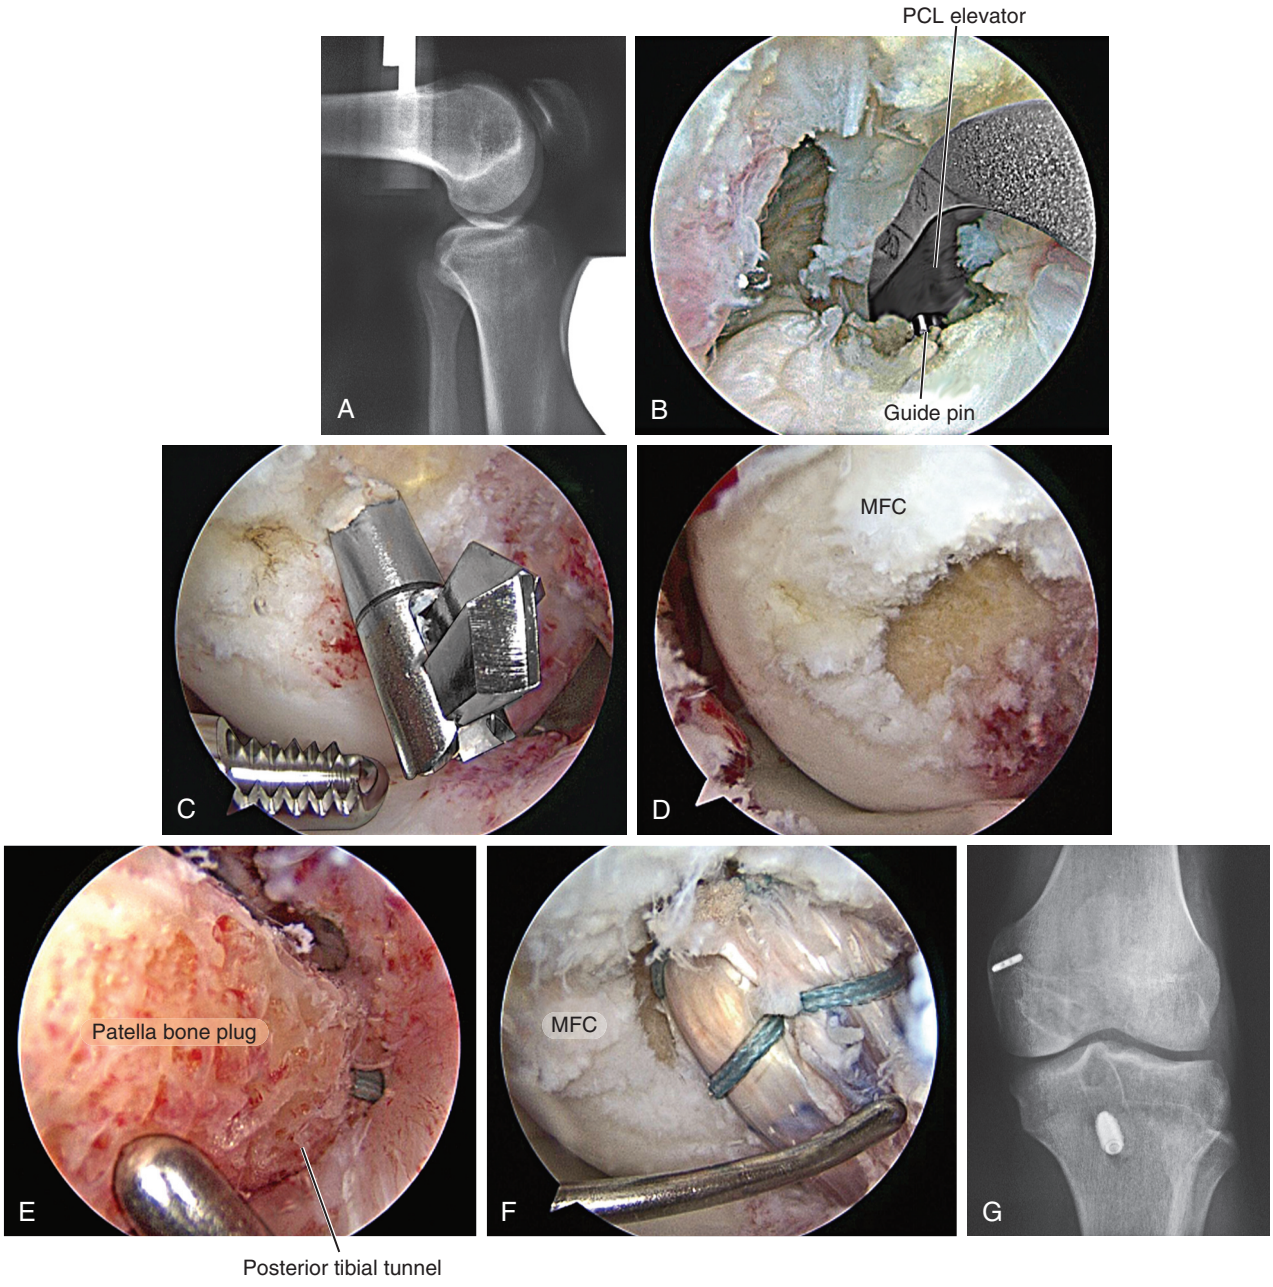

FIG 16-32 A 19-year-old male athlete presented with chronic posterior cruciate ligament (PCL) rupture and giving-way symptoms. An all-inside quadriceps tendon-patellar bone autograft was elected because of the athletic status of the patient. **A,** Stress radiograph shows abnormal posterior tibial subluxation. **B,** The arthroscope placed in the anteromedial portal views the PCL fossa. The PCL elevator rests on the posterior attachment of the capsule at the posterior tibial ridge. This shows that an excellent exposure can be obtained through the anteromedial portal, without requiring a posteromedial portal. The guide pin is shown exiting 5 mm above the posterior capsular attachment. **C,** The FlipCutter (Arthrex) is placed at the center of the PCL attachment on the femur for a single-tunnel construct (see text for description of placement). **D,** The femoral PCL tunnel occupies at least 75% of the PCL attachment. **E,** The bone plug is passed into the tibial tunnel through an enlarged anterolateral portal. **F,** The QT is passed into a 30-mm long femoral tunnel, using a TightRope suture construct. A soft tissue interference screw is also used for added fixation strength at the femoral site. **G,** Postoperative radiograph. *MFC,* Medial collateral ligament; *PCL*, posterior cruciate ligament.

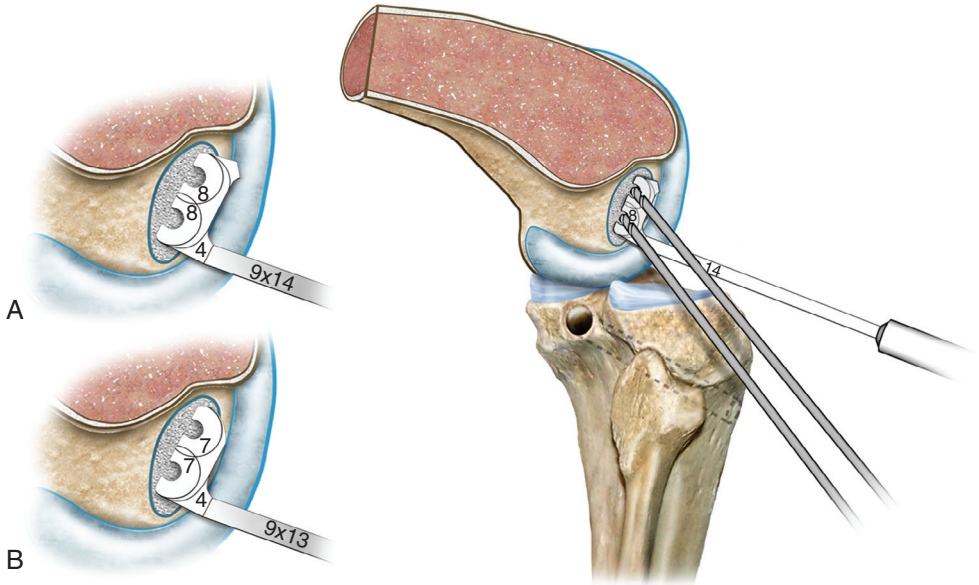

FIG 16-33 A and **B,** All-inside femoral tunnel. The PCL femoral template (Acufex) is placed through the anteromedial portal with the arthroscope in the central portal that defines the position of two overlapping 7- or 8-mm tunnels. The top edge of the template is placed 2 mm from the articular margin and the bottom edge is 4 mm from the articular margin. This places the center of the anterior tunnel 6 to7 mm from the articular cartilage margin and the center of the posterior tunnel 8 mm from the articular cartilage margin.

CRITICAL POINTS Alternative Posterior Cruciate Ligament All-Inside Techniques: Femoral Placement of Rectangular (Oval) Tunnel for Bone Plug

- Bone plug placed at femoral site using rectangular femoral slot or femoral tunnel, soft tissue graft placed through tibial tunnel.
- Use when operative time is a factor, revision knees.
- Goal: create 9 × 13 mm rectangular slot that extends from 1 to 4 o'clock in distal two-thirds of PCL attachment.
- Mark 12 o'clock, 4 o'clock positions on medial femoral condyle.
- 2.4-mm guide pin placed through anterolateral portal, knee flexed 90 degrees, and advanced through medial femoral condyle 25 mm in depth.
- Place second guide pin, overream with endoscopic drill.
- Avoid lateral femoral condyle articular cartilage as the drill is introduced into knee joint.
- Single femoral tunnel: consider FlipCutter.
- Chamfer and rasp distal aspect of femoral oval opening.
- Femoral fixation: interference screw.
- Tibial fixation: soft tissue interference screw and suture post.

fixation at the femoral site. As noted, the senior author prefers to reverse the graft with the bone plug at the posterior tibial tunnel.

The patient's positioning and initial surgical approach are similar to the all-inside technique described. The posterior PCL stump is removed and PCL tibial attachment is prepared for one tibial tunnel.

The technique for the femoral PCL graft attachment of the bone portion of the graft involves using a rectangular femoral slot or a femoral tunnel. The all-inside technique for the rectangular slot has a theoretical advantage of placing a greater portion of the graft within the PCL femoral footprint, in which approximately 75% of the footprint is occupied by the graft.

The goal is to create a 9 × 13 mm rectangular slot that extends from 1 to 4 o'clock in the distal two-thirds of the PCL footprint. The 12 and 4 o'clock marks are made on the medial femoral condyle. Again, the guide pin mark is 7 to 8 mm from the articular cartilage of the medial femoral condyle for the anterior and posterior tunnels (Fig. 16-33), verified by observing the PCL footprint and the two tunnels in the distal two-thirds of the footprint. A small curette or awl is used to penetrate and define the pilot hole for each tunnel. A 2.4-mm guide pin is placed through the anterolateral portal into the anterior tunnel location, the knee is flexed to 90 degrees, and the guide pin is advanced through the medial femoral condyle, approximately 25 mm deep, based on the patellar bone length.

The second guide pin is placed into the second marked position. The guide pins are overreamed with an endoscopic drill (Fig. 16-34) to form an oblong tunnel entrance to a depth that corresponds to the graft bone. Care is taken to avoid the lateral femoral condyle articular cartilage as the drill is introduced into the knee joint. The remaining central bone bridge is removed with a curette or burr.

The PCL Dilator (Fig. 16-35) produces an oval 9 × 13 mm shape that is approximately 1 mm larger than the bone portion of the graft. Care is taken to use low forces in dilating the rectangular slot to avoid fracture of the femoral condyle. In the senior author's experience, this has not been reported; however, it is worth a cautionary note. The PCL Dilator has a graft sizing slot on the handle for a 9 × 13 mm bone block that is used in preparation of the graft. The distal aspect of the femoral oval opening is chamfered and rasped to create a gentle slope to limit graft abrasion.

The passage of the graft (Fig. 16-36), conditioning, and final fixation are the same as already described. The femoral bone is fixed first with an interference screw and the tibia portion of the graft is fixed next with a soft tissue interference screw and suture post (Fig. 16-37). The option exists to use two graft strands that are tensioned separately in the tibial tunnel; however, there are no data to determine whether this is required.

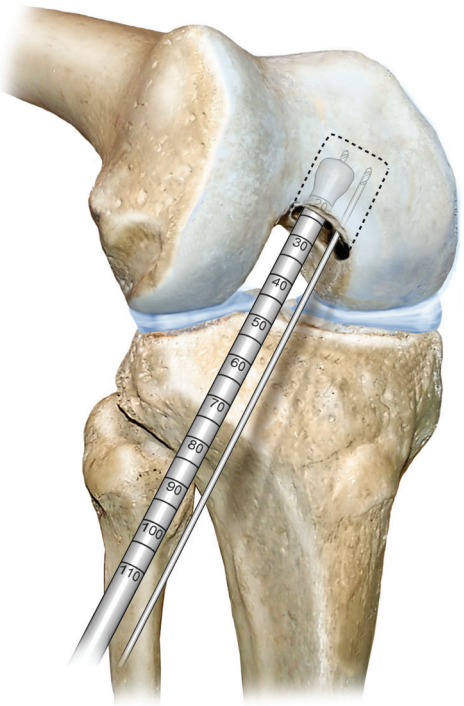

FIG 16-34 The guide pins are placed and then overreamed with an endoscopic drill to a depth of 25 mm, avoiding passage of the drill through the femoral cortex. The central bone bridge is removed with a curette and burr.

FIG 16-35 The PCL dilator (Acufex) is used to gently conform the femoral oval footprint to 9 × 13 mm and to an appropriate depth. There is a matching oval opening in the PCL dilator handle of 9 × 13 mm to size the bone block.

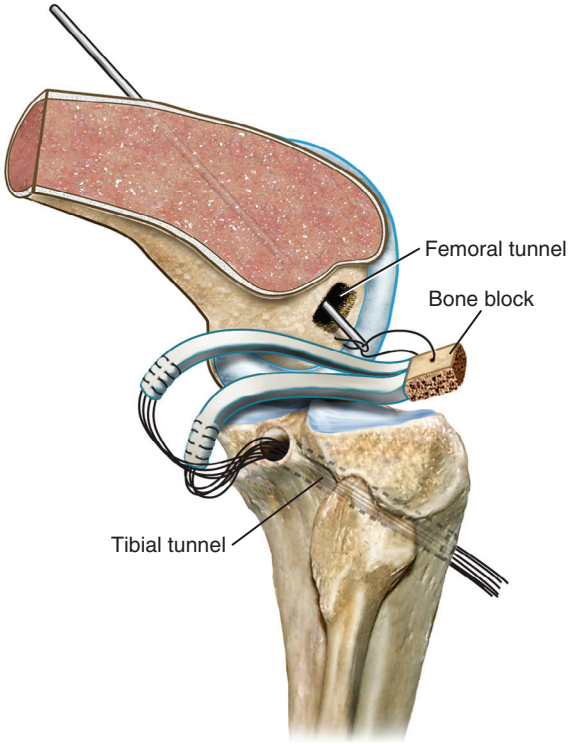

FIG 16-36 All-inside graft passage. A 20-gauge wire is passed through the tibial tunnel and grasped anteriorly through the anterolateral arthrotomy. The tibial portion of the graft is passed through the single tibial tunnel. The pin is then passed through the anterolateral portal into the femoral tunnel. The bone block is passed through the enlarged anterolateral portal and carefully oriented into the correct position with the cancellous bone surface oriented deep in the oval opening.

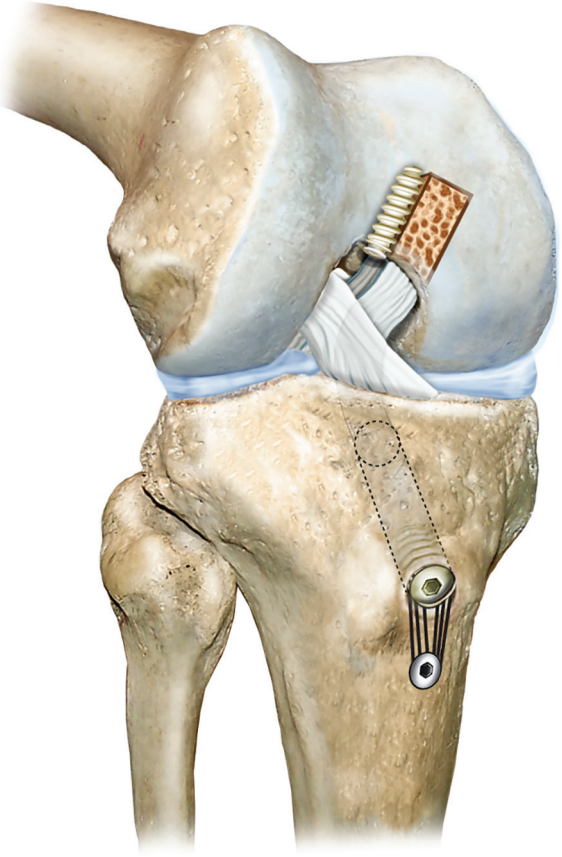

FIG 16-37 The final configuration of the single-tunnel technique.

FIG 16-38 Patient positioning. The patient is in a supine position with an inflatable beanbag, safety belt, and kidney rest (not shown) to secure the patient to the operating table.

Posterior Cruciate Ligament Arthroscopic-Assisted Open Tibial Inlay Technique

Patient Positioning and Setup

An examination under anesthesia of both knees is performed to confirm the preoperative diagnosis and detect any subtle instability. The medial tibiofemoral step-off at 90 degrees of flexion with a posterior tibial load is noted and the joint is reduced to normal and compared with the uninvolved knee. The reduced position and normal medial tibiofemoral step-off will later be reproduced with graft tensioning. Varus-valgus and tibial rotation tests for joint subluxation are performed as already described and compared between involved and uninvolved knees as concurrent ligament injuries, particularly to the posterolateral structures, are frequent and require reconstruction.

The patient is placed in a supine position on an inflatable beanbag (Fig. 16-38). The distal end of the beanbag is placed at the gluteal crease so it does not interfere with the tourniquet and the external rotation of the lower limb during the posteromedial tibial inlay approach. The beanbag is inflated and contoured to the patient's thorax and pelvis. A safety belt and kidney rest are placed to further secure the patient to the operating table when it is externally rotated (operative side down) during the posteromedial approach. A thigh tourniquet is placed over cast padding and only used intermittently for short periods during graft harvest and the posteromedial approach. The table is reflexed at its midpoint to decrease spine hyperextension, produce mild hip flexion, and prevent tension on the femoral nerve from a hip hyperextension position. The opposite extremity is placed in a thigh high compression hose and posterior padded leg support to avoid hip hyperextension or abnormal pressures on the posterior thigh during operative procedure.

The correct positioning of the operative extremity deserves special emphasis as described. During prolonged arthroscopic-assisted procedures, pressure on the posterior thigh may interfere with the vascular supply of the biceps muscle and peroneal nerve, and although rare, muscle necrosis and nerve injury have been reported. A leg holder is not used unless a meniscus repair is required, at which time the leg holder is used initially to allow adequate tibiofemoral joint opening, and is then removed for the remainder of the operative procedure.

CRITICAL POINTS Posterior Cruciate Ligament Arthroscopic-Assisted Open Tibial Inlay Technique

- Note medial tibiofemoral step-off 90 degrees of flexion with posterior tibial load, reduce joint to normal, compared with uninvolved knee.
- Patient supine position on beanbag, inflated and contoured to patient's thorax and pelvis.
- Use safety belt and kidney rest, table externally rotated (operative side down) during posteromedial approach.
- Thigh tourniquet used for short periods during graft harvest and posteromedial approach.
- Emphasis on correct positioning and padding, no leg holder used.
- Perform initial arthroscopic procedure, regulate pressure with inflow and outflow arthroscopic pump, and monitor joint distention continuously.
- Identify PCL femoral attachment, graft location as in all-inside technique.
- Use VMO approach for femoral tunnels with outside-in technique.
- Pass 22-gauge wire through femoral tunnels into the posterior aspect of the knee adjacent to PCL fossa for later graft passage.
- Patient supine, partial figure-four knee position (45 degrees of external hip rotation, 45 degrees of knee flexion).
- 7- to 8-cm longitudinal incision, 2 cm proximal to knee flexion crease, distally over medial head of gastrocnemius, posterior border of semitendinosus tendon.
- Protect saphenous nerve, posterior to the sartorious muscle and the infrapatellar branches crossing the sartorius superficially.
- Incise fascia along posterior border of semitendinosus tendon and medial border of the gastrocnemius.
- Dissect between semimembranosus muscle and gastrocnemius tendon.
- Maintain posterior exposure, avoid undue retraction forces on gastrocnemius and underlying neuromuscular structures.
- Subperiosteal dissection popliteus muscle at distal PCL fossa.
- Enter joint proximal and above semimembranosus tendon, avoiding medial meniscus attachments.
- Use Richardson retractor to retract medial gastrocnemius muscle. Replace with two Steinmann pins placed just lateral and distal to PCL fossa.
- Remove posterior tibial slot for inlay procedure.
- Placement, adjustment of position of PCL graft.
- Guide wires retrieved, strands passed beginning with 1 o'clock strand.
- Graft strands brought out respective femoral tunnels, positions adjusted proximal-distal direction.
- Tibial fixation graft bone with two 4.0-mm cannulated cancellous screws.
- Arthroscopically confirm proper placement both graft strands.
- Graft condition, tension, and confirmation isometric as described for all-inside technique.
- Tie each suture 44 N (10 lb) on each graft strand, 70 to 90 degrees of flexion, and 44-N (10-lb) anterior tibial load to produce a normal medial tibiofemoral step-off.
- Soft tissue interference screw added each tunnel.
- Arthroscopically confirm tension, fixation, and return of stability.
- Graft patellar defect.
- Soft hinged knee brace locked at 5 degrees of flexion with a 3-inch cotton roll behind proximal calf.

General anesthesia is used and a urinary catheter placed when multiple operative procedures will be performed and the anesthesia time prolonged. Even though all dislocated knees have vascular consultation and ankle-brachial index studies, if there is any question of diminished pulses or vascular supply, the foot is draped in a sterile plastic bag to allow palpation of pulses and observation of color during the operative procedure.

The initial arthroscopic procedure is performed to thoroughly examine the knee joint including patellofemoral tracking, articular cartilage lesions, and medial and lateral tibiofemoral joint opening "gap tests" to exclude associated ligament injuries. At this time, debridement or meniscus procedures are performed as required. A pressure regulated inflow and outflow arthroscopic pump is necessary and joint distention is monitored continuously by the surgeon. The arthroscopic pump is set to the lowest pressure and volume for visualization, which avoids the requirement of a tourniquet.

The autograft harvest procedure or preparation of the allograft is completed as described.

Identification of the Femoral Posterior Cruciate Ligament Attachment: Vastus Medialis Obliquus Approach

The identification of the femoral PCL attachment has been described in the previous all-inside two-tunnel technique section. The femoral tunnels are prepared as described using a VMO outside-in approach. Two 22-gauge wires are passed and placed by arthroscopic visualization adjacent to the PCL tibial attachment posteriorly to be later brought out through the posteromedial capsular incision.

Posteromedial Approach

With the patient in a supine position, the posteromedial aspect of the knee is viewed by rolling the table 25 degrees with the operative side in the down position.[151,160,168] The tourniquet is inflated. A partial figure-four knee position is assumed (45 degrees of external hip rotation, 45 degrees of knee flexion). The operative limb is elevated and the foot placed on a padded (pillow) Mayo stand to lift the knee away from the table. An assistant externally rotates the foot and controls the lower limb position on the Mayo stand during the procedure. The surgeon and assistant are seated at the side of the operative table directly viewing the entire posteromedial aspect of the knee. Operative headlights are used.

An alternative approach is for the surgeon to be seated between the patient's lower extremities by flexing the knee portion of the table and elevating the nonoperative limb into a flexed and abducted position. The senior author has not found it necessary to use this position. In either of the two limb positions, one person must be dedicated to maintain the operative limb in a safe elevated and externally rotated position supported by the padded Mayo stand.

Numerous surgical approaches that provide access to the popliteal fossa PCL tibial attachment have been described.[1,14,15,24,143,145,215] These approaches use either an S-shaped popliteal incision,[14] an L-shaped popliteal incision,[24,145] or a medial incision.[119,148] The senior author recommends a medial incision as described to avoid the popliteal neurovascular structures.

A 7- to 8-cm longitudinal incision, beginning approximately 2 cm proximal to the flexion crease of the knee, is carried distally over the medial head of the gastrocnemius and the posterior border of the semitendinosus tendon (Fig. 16-39). The straight posteromedial incision, compared with an S-shaped popliteal incision, avoids the horizontal popliteal skin crease with less skin retraction necessary and possible wound breakdown.[145]

Dissection is carried down sharply through the skin and subcutaneous tissues. Care is taken to protect the saphenous nerve posterior to the sartorius muscle and the infrapatellar branches that cross the sartorius superficially. The long saphenous vein and the saphenous branch of the descending genicular artery follow the course of the saphenous nerve and are protected as well. The gracilis and semitendinosus lie deep to the sartorius and are palpated.

The first key to the approach is to incise the fascia[228] along the posterior border of the semitendinosus tendon adjacent to the medial

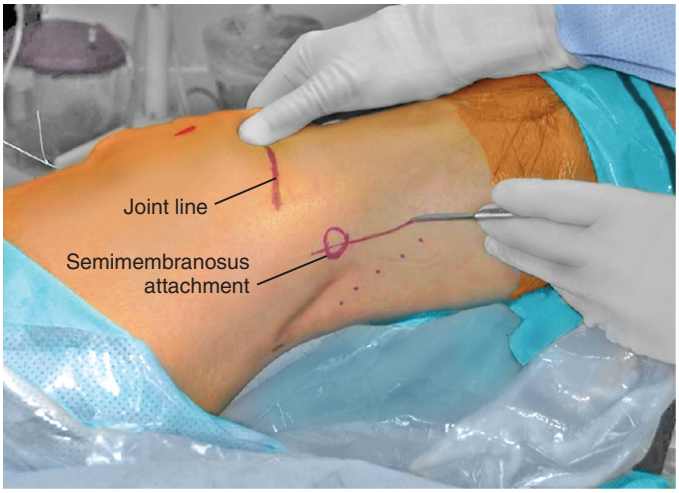

FIG 16-39 Intraoperative photograph of the left knee with the lower extremity in a figure-four position. The longitudinal incision begins approximately 2 cm proximal to the flexion crease of the knee. The incision is carried distally over the medial head of the gastrocnemius and the posterior border of the semitendinosus tendon. (From Noyes FR, Medvecky MJ, Bhargava M. Arthroscopically assisted quadriceps double-bundle tibial inlay posterior cruciate ligament reconstruction: an analysis of techniques and a safe operative approach to the popliteal fossa. *Arthroscopy*. 2003;19:894-905.)

border of the gastrocnemius muscle. The three pes tendons are then retracted anteriorly (taking the saphenous nerve) and the semimembranosus tendon is visualized (Fig. 16-40).

The second key to the procedure is the dissection between the semimembranosus muscle and the gastrocnemius tendon. Understanding the anatomy of the posteromedial corner of the knee and the semimembranosus is important to obtain good exposure by mobilization of the semimembranosus tendon for the next portion of the dissection. The dissection uses the interval between the medial border of the gastrocnemius and the posterior border of the common semimembranosus tendon. To mobilize the semimembranosus medially and improve exposure, the tendon sheath extensions are incised to allow full mobilization of the semimembranosus tendon (Fig. 16-41). Anterior to the semimembranosus, the posterior oblique ligament is partially incised from the attachment to the semimembranosus tendon to improve exposure. These capsular attachments are later repaired at the end of the procedure. With lateral retraction of the medial gastrocnemius, the inferolateral semimembranosus tendon sheath expansion to the popliteus is visualized and dissected from its attachment to the posterior border of the common semimembranosus tendon. In this way, the insertion of tendon directly onto the posteromedial tibia is exposed.

The third key is maintaining the posterior exposure and avoiding undue retraction forces on the gastrocnemius and underlying neuromuscular structures. An S-shaped retractor is placed extraarticularly between the semimembranosus tendon and the medial femoral condyle and levered anteriorly, allowing for anterior retraction of the semimembranosus and pes anserinus tendons and muscle bellies. The medial head of the gastrocnemius is carefully retracted laterally with a Richardson retractor, allowing for exposure of the popliteus muscle belly on the posterior tibia. Care must be exercised at this juncture in the procedure, as undue retraction can avulse branches off the popliteal artery.

The neurovascular structures are not visualized and remain medial to the gastrocnemius muscle (medial head). The anterior tibial artery

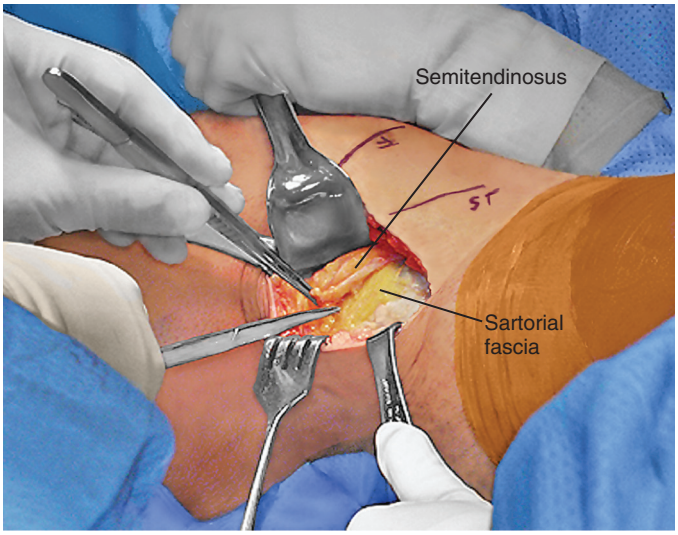

FIG 16-40 Surgical exposure of the left knee shows the development of the interval between the semitendinosus (ST) tendon and the gastrocnemius muscle belly. The sartorial fascia is incised along the posterior border of the ST tendon. The forceps is on the ST tendon. During the superficial dissection, care is taken to protect the main trunk as well as superficial branches of the saphenous nerve. The infrapatellar branch of the saphenous nerve is vulnerable as it superficially crosses the sartorius. (From Noyes FR, Medvecky MJ, Bhargava M. Arthroscopically assisted quadriceps double-bundle tibial inlay posterior cruciate ligament reconstruction: an analysis of techniques and a safe operative approach to the popliteal fossa. *Arthroscopy.* 2003;19:894-905.)

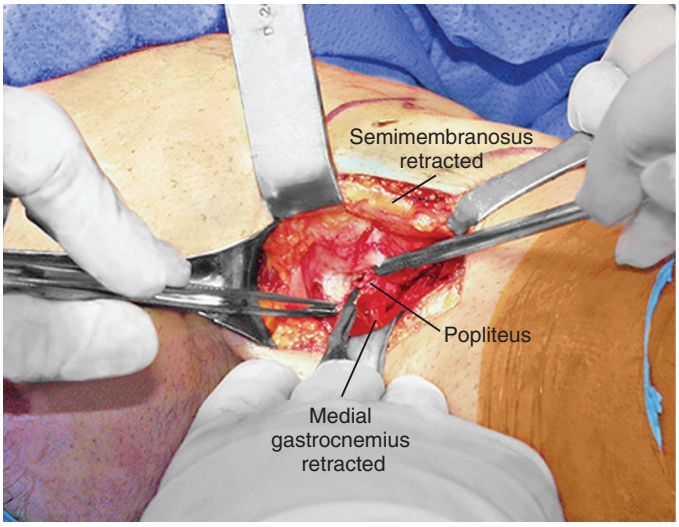

FIG 16-41 Surgical exposure shows the popliteus muscle exposure. The gastrocnemius muscle belly is retraced laterally and the pes tendons and the semimembranosus muscle are retracted by an S-shaped retractor away from the popliteal space, exposing the posterior cruciate ligament fossa. Caution must be exercised with the lateral retraction of the gastrocnemius muscle because the neurovascular structures are not fully protected and the retractor should not be placed deep to the gastrocnemius muscle belly. (From Noyes FR, Medvecky MJ, Bhargava M. Arthroscopically assisted quadriceps double-bundle tibial inlay posterior cruciate ligament reconstruction: an analysis of techniques and a safe operative approach to the popliteal fossa. *Arthroscopy.* 2003;19:894-905.)

may lie directly on the popliteal muscle over the PCL fossa, or pierce the popliteal muscle just distal to the PCL fossa as already described (see Fig. 16-13).

The fourth key to the procedure is the subperiosteal dissection of the popliteus muscle. Care is taken to gently dissect the popliteal muscle superior border in a distal direction to allow better subperiosteal exposure to the posterior tibia and PCL fossa for later placement of the tibial inlay graft. The inferior medial genicular artery and vein are at the superior border of the popliteus muscle and are easily identified and protected during this step, as the dissection is in a subperiosteal plane anterior and deep to the genicular artery.

Identification of Posterior Tibial Posterior Cruciate Ligament Attachment

The PCL tibial attachment site is palpated as a midline depression in the proximal tibial metaphysis, between the two tibial condyles. The width of the PCL is approximately 15 mm[63] and the distal extent of the PCL is marked by a small ridge (posterior tibial step-off) that coincides with the proximal border of the popliteus.[183]

The fifth key to the exposure is to enter the joint proximal and just behind the semimembranosus tendon, avoiding the medial meniscus attachments. The posterior slope of the proximal tibia and the PCL fossa are palpated and the posterior capsule and OPL are incised sharply, starting proximal and superior on the lateral aspect of the medial femoral condyle. The posterior portion of the medial femoral condyle is easily palpated. The posterior capsule just lateral to the medial femoral condyle is incised. The joint is entered directly over the inner aspect of the medial femoral condyle to establish from proximal-to-distal a safe plane of dissection (Fig. 16-42; see also Fig. 16-41). The dissection of the capsule is performed in the midline directly over the PCL fossa with care at the joint line to avoid injury to the posterior medial meniscus tibial attachment. This capsular incision is extended distally and connected to the popliteus subperiosteal exposure, which will be closed at the conclusion of the procedure. The entire PCL tibial attachment site is easily identified. The remaining PCL stump is removed.

The sixth key to the exposure involves the Richardson retractor, used to retract the medial gastrocnemius muscle that is replaced with two Steinmann pins placed under direct vision just lateral and distal to the PCL fossa. The pins allow for excellent exposure during the tibial inlay procedure and avoids undue lateral retraction and pressure against the neurovascular structures by the surgical assistant.

The seventh key is the removal of the posterior tibial slot for the inlay procedure. A 10-mm osteotome is used to cut a rectangular slot into the PCL fossa at the proximal tibia. The slot is started 1 cm distal to the normal PCL attachment, which allows for the proximal bone block and collagenous portion of the graft to assume a normal anatomic position and preserve the proximal 15 mm of the PCL fossa. The posterior interspinous tibial bone just proximal to the PCL fossa is preserved to prevent a vertical PCL graft orientation. The rectangular bone block of the graft is placed flush into the inlay, avoiding too deep of a slot, which would produce a vertical PCL graft.

The eighth key is the placement and adjustment of the position of the PCL graft. The previously positioned guide wires are retrieved from the posteromedial capsular recess within the joint. The two strands of the sagittally split graft are identified (lateral arm, 1 o'clock tunnel; medial arm, 3 o'clock tunnel) and are passed individually starting with the 1 o'clock graft strand (Fig. 16-43). Care is taken that there is no soft tissue or native PCL fibers so the graft strands lie directly against the posterior tibial PCL fossa in a normal anatomic position.

The two graft strands are brought out of their respective femoral tunnels and the position of the overall graft position is adjusted 5 to

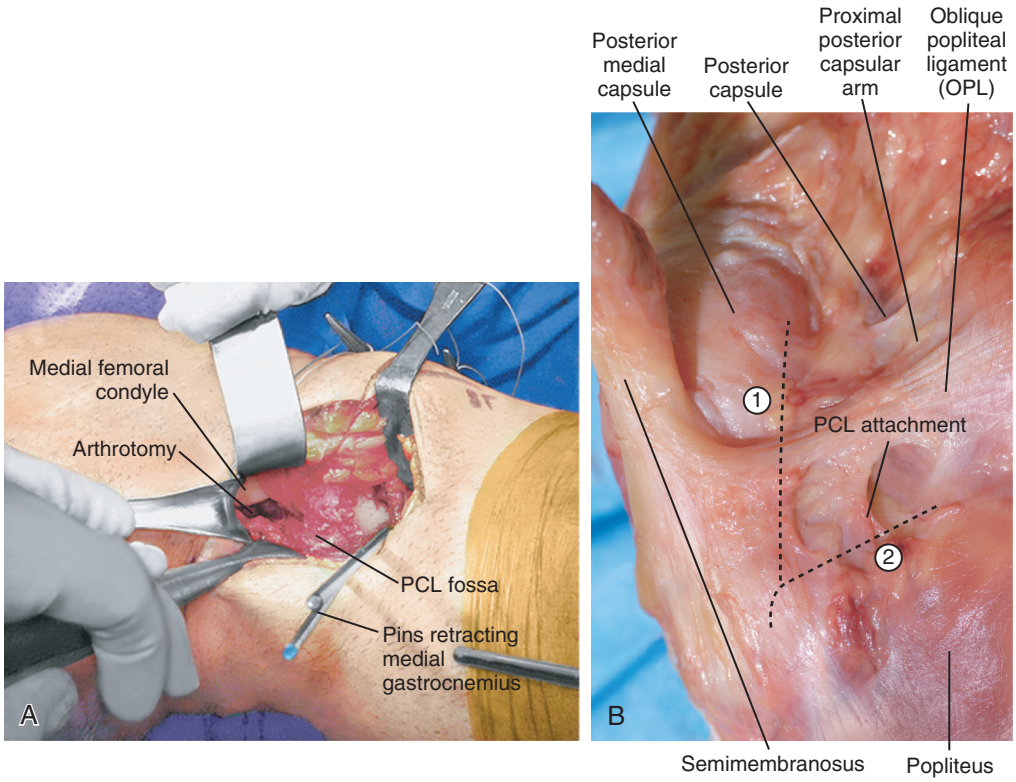

FIG 16-42 **A,** Surgical exposure shows the posterior arthrotomy over the inner aspect of the medial femoral condyle. The suture-passing wires are retrieved from within the joint. Care is taken during the arthrotomy to avoid injury to the medial meniscus. The subperiosteal dissection is carried to the lateral ridge of the posterior cruciate ligament (PCL) fossa to allow for creation of the tibial slot at the anatomic PCL attachment site. An S-shaped retractor assists in positioning the semimembranosus out of the operative field, allowing for better visualization of the PCL fossa. The creation of the subperiosteal popliteus flap adds an additional layer of protection and provides a safer exposure, because vascular anatomic variations may exist. Two Steinmann pins allow for retraction of the popliteus and gastrocnemius muscle. **B,** Anatomic specimen shows line of incision into posteromedial capsule and superior to popliteal muscle to expose PCL tibial attachment. (From Noyes FR, Medvecky MJ, Bhargava M. Arthroscopically assisted quadriceps double-bundle tibial inlay posterior cruciate ligament reconstruction: an analysis of techniques and a safe operative approach to the popliteal fossa. *Arthroscopy*. 2003;19:894-905.)

10 mm by observing the graft strand in the femoral tunnel (VMO approach). The graft position is adjusted in a proximal-distal direction to ensure the collagen graft strands have the appropriate length for the femoral tunnels. In the alternative procedure, when a bone-patella tendon-bone (B-PT-B) graft is used (rather than a QT-PB graft), too proximal a placement of the tibia inlay allows the bone plug to protrude from the femoral tunnel proximally, compromising interference screw fixation. If the placement of the tibial inlay is too distal, it may shorten the graft in the femoral tunnels, also compromising femoral graft fixation. Visualization of both strands of the graft with an outside-in femoral tunnel approach allows for proximal-to-distal graft positioning and final fixation.

Tibial fixation of the graft bone is achieved with two 4.0-mm cannulated cancellous screws. The guide wires for the cannulated drill bit are angled distally to avoid intraarticular penetration, especially as the knee is positioned in a flexed position. A lateral radiograph may be taken intraoperatively to confirm the position of the screws. The length of the screws is usually 30 to 35 mm for adequate purchase.

The capsulotomy is closed, the Steinmann pins removed and the posteromedial capsule incision and OPL repaired (Fig. 16-44). The tourniquet is deflated and hemostasis verified. Vascular clips are available should the inferior medial genicular artery or other bleeding sources be identified. The subcutaneous tissues and wound are not closed at this stage to allow for any extravasation of fluid during the final arthroscopic portion of the procedure. After graft fixation, the posteromedial wound is closed in a routine fashion.

Graft Conditioning, Tensioning, and Fixation

Arthroscopic visualization of the graft confirms proper placement of both strands before fixation. The graft tensioning and fixation steps have been previously described in detail in the all-inside technique. A staple post is placed proximal to the femoral tunnels. Fixation is accomplished by tying each suture with approximately 44 N (10 lb) on each graft strand, at 70 to 90 degrees of flexion, and a 44-N (10-lb) anterior tibial load to produce a normal medial tibiofemoral step-off, which is confirmed. A soft tissue absorbable interference screw is added for each tunnel (Fig. 16-45). Arthroscopic evaluation of the graft confirms tension, fixation, and return of stability.

The patellar defect is carefully grafted with bone from the core reamer as described. The anteromedial and posterolateral approaches are closed. The knee is carefully padded in a sterile compression

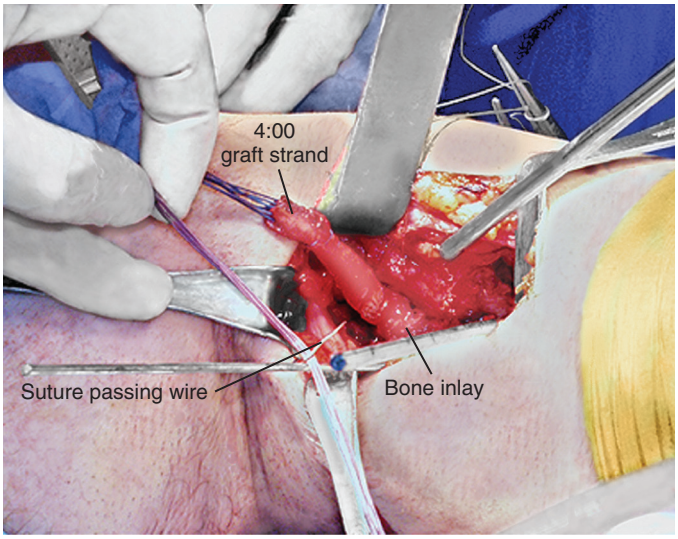

FIG 16-43 Surgical exposure shows placement of the quadriceps tendon autograft. The rectangular bone portion of the graft has been fixated to the proximal tibia with two 4.0-mm partially threaded cancellous screws. The sutures on the medial and lateral graft strands will be pulled intraarticularly with the suture-passing wires. The graft strands lay directly against the posterior tibia, recreating the normal anatomic posterior cruciate ligament tibial attachments. (From Noyes FR, Medvecky MJ, Bhargava M. Arthroscopically assisted quadriceps double-bundle tibial inlay posterior cruciate ligament reconstruction: an analysis of techniques and a safe operative approach to the popliteal fossa. *Arthroscopy.* 2003;19:894-905.)

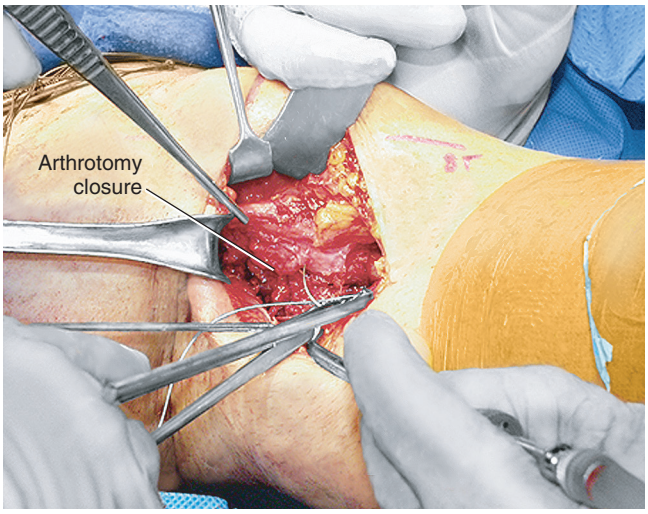

FIG 16-44 Surgical exposure shows the closure of the semimembranosus sheath and posterior arthrotomy. The skin incision is only partially closed at this point to allow for potential fluid extravasation during the final arthroscopic portion of the procedure. (From Noyes FR, Medvecky MJ, Bhargava M. Arthroscopically assisted quadriceps double-bundle tibial inlay posterior cruciate ligament reconstruction: an analysis of techniques and a safe operative approach to the popliteal fossa. *Arthroscopy.* 2003;19:894-905.)

dressing. The lower extremity is placed in a soft hinged knee brace locked at 5 degrees of flexion, with a 3-inch cotton roll placed behind the proximal calf to prevent posterior sagging of the tibia. The neurovascular status is confirmed to be normal before leaving the operating room.

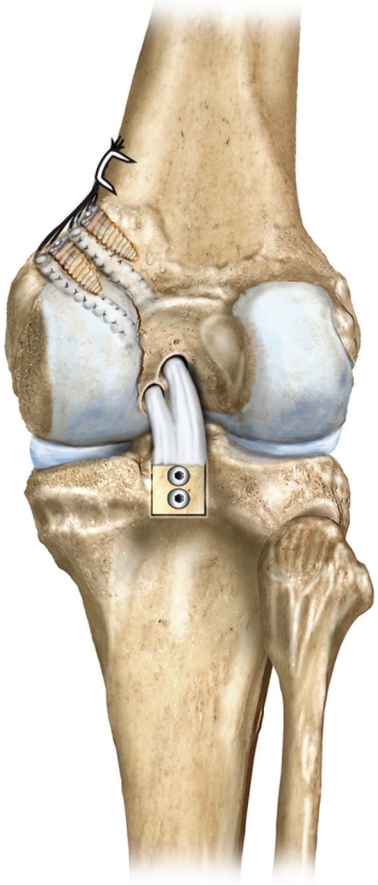

FIG 16-45 The final tibial and femoral fixation of the quadriceps tendon-patellar bone two-strand graft.

Posterior Cruciate Ligament Avulsion Fractures

Avulsion fractures of the PCL are rare, and treatment options depend on the type and size of the fracture, displacement, comminution, and orientation of the fragment.[67,234] These injuries typically occur at the tibial attachment and may involve a small area at the posterior region of the attachment or a large area that extends anteriorly and outside the PCL attachment. Griffith and colleagues[67] reported that the entire insertion area was avulsed in all 19 skeletally mature patients in their series of PCL avulsion fractures. The avulsion fracture is usually obvious on routine radiographs. Occasionally, a computerized tomography scan or MRI is required to define the extent of the facture pattern in major avulsion fractures extending into the joint.[28,67] Avulsion or peel-off PCL injuries at the femoral site have been reported in the literature, but are rare.[62,125,176,186,232]

Patients who have small, partial PCL avulsion fractures, with a negative posterior translation test at 90 degrees of knee flexion, are kept in a brace locked in full extension and remain partial weight bearing for 4 weeks to allow healing. The brace is removed for gentle range of motion (avoiding posterior tibial translation) and quadriceps exercises as described in Chapter 18. Overall, the prognosis for healing and PCL function is good to excellent in these cases.[246]

Complete avulsion of the PCL attachment at the tibia, and less frequently, at the femoral attachment (peel-off avulsion) with posterior tibial subluxation, is an indication for surgical repair. Authors have reported favorable clinical results with the open reduction and internal fixation of PCL avulsion fractures at the tibial insertion site.[8,84] For

CRITICAL POINTS Posterior Cruciate Ligament Avulsion Fractures

- Treatment based on type and size of the fracture, displacement, comminution, orientation of fragment.
- Small, partial avulsion fractures, negative posterior translation at 90 degrees of knee flexion: brace locked full extension, protected motion, partial weight bearing for 4 weeks to allow healing.
- Complete avulsion fractures: surgical repair. Use either arthroscopic or open technique based on experience.
- Large and medium avulsion fractures: arthroscopic approach, cannulated screw fixation.
- PCL tibial avulsions with small bony fragments: consider open posterior medial tibial approach.
- Peel-off PCL rupture from femoral attachment: repair PCL attachment with sutures passed through small drill holes, avoid physeal plate when still open.
- Our preferred technique: arthroscopic-assisted approach, repair PCL fibers to approximate broad elliptical femoral attachment.
- Postoperative protocol suture repair maximum protection, early motion by therapist.

instance, Inoue and associates[84] reported on 31 patients followed for 2 to 8 years and noted low side-to-side differences (<5 mm, KT-2000) after surgery. The majority of knees showed a mild residual posterior knee displacement (mean, 3.0 mm). Along with the tibial avulsion, an abnormal MRI signal intensity may be observed within the PCL fibers, indicating partial tearing.

More recently, several authors have described arthroscopic techniques for PCL tibial avulsion fractures.[28,36,70,81,105,201,225,240,246] Gui and associates[70] treated 28 patients using two posteromedial portals and a single tibial tunnel to facilitate suture passage and seating of the bony fragment. The knees were casted for 2 weeks unless a concomitant tibial plateau fracture was present, which necessitated 4 weeks of immobilization. The fractures healed a mean of 2.8 months postoperatively. At 1 year postoperative, four of 20 cases followed had arthrofibrosis, two of whom underwent arthroscopic release. The posterior drawer test was negative in all but one knee. International Knee Documentations Committee (IKDC) rating system[78] results were normal in 20 and nearly normal in four patients.

Zhao and colleagues[246] treated 29 patients with PCL tibial avulsion fractures. The PCL and bony fragment were arthroscopically fixed with sutures that were pulled out through Y-shaped bone tunnels and fixed on a titanium button. Immediate knee motion and partial weight bearing were allowed in a brace that was used for the first 4 weeks. Four patients required a manipulation 3 months after surgery for flexion limitations. At follow-up (>2 years postoperatively), all patients except one had a negative posterior drawer test, and all regained full knee motion except for two patients who had 5 degrees of flexion limitations. IKDC results were normal in 28 patients and nearly normal in one patient.

Zhang and associates[245] treated isolated PCL tibial avulsion fractures in 16 patients (mean age, 43 years) with a minimally invasive posteromedial approach and suture anchors. The patients all had displaced fractures that exceeded 1 cm and fracture fragments less than 2 cm in diameter. Plaster splints were used for 4 to 6 weeks. At a mean of 18 months postoperatively, all cases showed satisfactory reduction and bony healing and all but one patient had returned to their former occupation.

Chen and coworkers[36] treated 36 patients with displaced PCL tibial avulsion fractures (>3 mm of upward displacement of the bony fragment) and posterior knee instability of grade II or higher. Arthroscopic reduction and suture fixation of the bone fragments was accomplished through two tibial tunnels. The knees were immobilized in a brace the first postoperative week, followed by 0 to 60 degrees of motion during weeks 2 to 4 and 120 degrees by week 8. All fractures demonstrated union within 3 months. At a mean of 3 years postoperatively, all but three patients were participating in strenuous or moderate activities, 92% rated their knee function as normal or nearly normal, and three patients (8%) were rated as abnormal because of limitations in knee flexion.

The concept of immediate postoperative knee motion is addressed in detail in Chapter 18. The therapist initiates early and protected knee motion within the first postoperative week, applying an anteriorly directed load to protect the relatively weak suture fixation. The use of a posterior calf pad and careful positioning in the brace is required for the first 4 postoperative weeks until suitable healing has occurred. Knees with suture or pin fixation have relatively low tensile strength repairs and require expert postoperative rehabilitation.

The surgeon should select either an arthroscopic or open technique for tibial avulsion fractures based on experience. In general, it is relatively straightforward to use an arthroscopic approach for cannulated screw fixation for large and medium avulsion fractures. For PCL tibial avulsions with small bony fragments that require a combination of sutures and bone fixation, an open posterior tibial approach is favored by the senior author because it provides good exposure and allows for secure fixation.

A peel-off type of PCL rupture from the femoral attachment has been described as a hyperextension knee injury, such as that reported by Mayer and Micheli[142] in a child while jumping on a trampoline or in patients suffering from trauma from motor vehicle accidents.[37,176] This type of PCL rupture directly at the femoral attachment may occur at the fibrocartilaginous junction, with minor associated damage to the bulk of the PCL fibers. The PCL attachment is easily repaired with sutures passed through small drill holes, avoiding the proximal physeal growth plate. Arthroscopic approaches to PCL femoral soft tissues avulsions have been described by several authors,[62,176,186,232] although clinical data remain scarce. Ross and associates[186] described an arthroscopic approach for repair of acute femoral peel-off tears. Three No. 2 nonabsorbable sutures were passed through the PCL substance, through a femoral tunnel at the PCL footprint, and tied over the medial cortex. Park and Kim[176] reported an arthroscopic technique that used two transfemoral tunnels for the anterior strand and two posterior tunnels for suture repair of the posterior strand. These authors noted that femoral avulsion injuries were exceedingly rare.

The senior author's preferred technique for femoral peel-off or proximal PCL repairs is to use an arthroscopic-assisted approach in which two to three guide pin tunnels (small-diameter for sutures) are placed at the anterior and posterior aspects of the PCL footprint, distal to the physis, to fan out the PCL fiber attachment. A VMO-sparing approach is used and respective suture passers are brought into the knee joint. Through a limited medial arthrotomy and under direct visualization using a headlight, multiple nonabsorbable baseball looped sutures are placed at appropriate sites in the PCL fibers to approximate the broad elliptical femoral PCL attachment. The miniarthrotomy has limited morbidity and allows the surgeon to carefully place multiple sutures into the broad PCL fibers. Secure fixation is achieved along with anatomic placement of disrupted PCL fibers.

In PCL injuries that extend away from the femoral attachment and involve the proximal third of the PCL fibers, an augmentation is favored (assuming the growth plate is closed). The postoperative protocol for a direct suture repair should take into account the low repair tensile strength, requiring maximum protection. The knee is

maintained in full extension and the therapist assists in gentle range of knee motion for the first 4 weeks postoperatively. Only toe-touch weight bearing is permitted during this time period. Then, the patient may progress to 50% weight bearing with the brace locked at full extension. At 6 weeks postoperative, weight bearing is progressed in the brace. Knee motion is advanced to 0 to 90 degrees. The brace is removed at 8 weeks.

Posterior Cruciate Ligament Augmentation Approaches and Techniques

In select knees, an acute tear of the PCL may occur at the proximal third femoral attachment (and not through the midsubstance). A considerable bulk of the PCL attachment still exists and may be repaired to the femoral attachment, as discussed for the "peel-off" type of tear. In these cases, it is worthwhile to add a graft augmentation to the attachment site, which may be performed in an arthroscopic-assisted manner (assuming the growth plate is closed). An 8-mm femoral tunnel is placed at the desired site where the PCL fibers require a graft augmentation, usually in the more proximal aspect of the femoral attachment.

Sutures are used to repair the more distal fibers to the femoral attachment as already described. The placement of an 8-mm tibial tunnel must be well chosen and not interfere with the PCL attachment site. The tunnel is placed just medial to the tibial PCL attachment, carefully avoiding the medial and lateral meniscal attachments. A lateral tibial tunnel is not used because PCL fibers attach, in part, to the posterolateral meniscus tibial attachment. We prefer a three- or four-strand semitendinosus-gracilis (STG) autogenous graft, although an allograft may also be considered.[6,44,93,115,226] Suture fixation to a femoral or tibial post, or absorbable interference tibial and femoral screws in adults, is required.

In skeletally immature knees, Kocher and associates[107] reported the use of a small-diameter graft placed through the distal femoral and proximal epiphysis, avoiding the physeal plate. An augmentation graft has the advantage of maintaining tibiofemoral reduction and preventing posterior tibial subluxation in the early postoperative healing period.

In very select knees with a prior PCL rupture and abnormal posterior tibial subluxation, the remaining PCL fibers may appear healed and intact, although with a residual elongation. Rarely, the senior author has performed a distal advancement of the tibial PCL attachment; this is only considered when the MRI shows a normal signal to the PCL fibers and arthroscopic examination shows also a normal-appearing PCL. The operative approach is similar to a tibial inlay procedure, except the native PCL tibial bone attachment is advanced distally the required amount to restore posterior stability. A proximal advancement (recession) at the femoral insertion is avoided owing to the marked influence of the PCL femoral attachment on PCL fiber function previously described.

CRITICAL POINTS Posterior Cruciate Ligament Augmentation Approaches and Techniques

- Indications: acute PCL tear at proximal third femoral attachment. Considerable bulk of PCL attachment still exists, may be repaired.
- 8-mm femoral tunnel placed, usually in proximal aspect of femoral attachment. 8-mm tibial tunnel placed just medial to tibial PCL attachment (closed physis).
- Prefer 3- or 4-strand STG, allograft may be considered.
- Rare cases of chronic PCL with normal-appearing PCL on MRI, residual PCL elongation: distal advancement similar to tibial inlay.

OUR CLINICAL STUDIES

In this section, the analysis of 130 knees with PCL deficiency that were placed into clinical investigations is reported. All of the studies involved a prospective consecutive patient enrollment, the minimum follow-up of each study was 2 years, and the results were evaluated by clinical research staff and not the surgeon. All patients were entered into the studies and then tracked with sequential follow-up appointments. The results were determined with posterior stress radiography and/or knee arthrometer testing, and two validated knee rating instruments (CKRS[13] and IKDC rating system[78]). More specific clinical outcome details are provided in the References section; this section provides a brief summary of the results and conclusions.

Posterior Cruciate Ligament Two-Strand Quadriceps Tendon-Patellar Bone Autograft Tibial Inlay

We[153] followed 20 consecutive patients that underwent a two-strand PCL QT-PB autograft reconstruction with a tibial inlay technique. All patients were included in the investigation except for one who lived outside the United States and who could not return for follow-up. Therefore the study group consisted of 19 patients who were followed a mean of 2.9 years (range, 2-7 years) postoperatively. The PCL

CRITICAL POINTS Our Clinical Studies: Posterior Cruciate Ligament Two-Strand Quadriceps Tendon-Patellar Bone Autograft Tibial Inlay Technique

- $n = 19$ consecutive knees followed mean 2.9 years (range, 2-7 years) postoperatively.
- PCL reconstructions mean 3.6 years (range, 0.3-18 years) after original knee injury.
- Prior PCL procedures done elsewhere had failed in 9 knees.
- Associated procedures: 5 posterolateral procedures, 2 ACL reconstructions, 2 MCL reconstructions, 1 meniscus transplant.
- Outcome assessment: stress radiography, KT-2000 testing, Cincinnati Knee Rating System, IKDC rating system.
- Stress radiographs: mean preoperative, 11.6 ± 2.9 mm; follow-up, 5.0 ± 2.6 mm ($P < .0001$).
- KT-2000 (70 degrees): mean preoperative, 10.4 ± 2.9 mm; follow-up, 2.3 ± 2.2 mm ($P = .004$).
- Preoperatively, all knees graded C or D on IKDC rating. At follow-up, 2 knees (10%) graded A; 12 knees (63%), B; 3 knees (16%), C; 2 knees (10%), D.
- Pain with ADL: preoperative, 58%; follow-up, 5%.
- 58% returned to mostly low-impact sports.
- Abnormal articular cartilage surfaces in 42%.
- Difference between patients with normal cartilage and those with abnormal cartilage in mean scores for patient rating of the overall knee condition, squatting, running.
- No infections, permanent limitations of knee motion, donor site problems, patellar fractures.
- 74% compounding problems articular cartilage damage, prior meniscectomy, additional ligament procedures, or osteotomy. Recommend early operative treatment be considered for PCL ruptures.
- Objective assessment of posterior stability demonstrated superior results compared with the single-bundle PCL allografts.

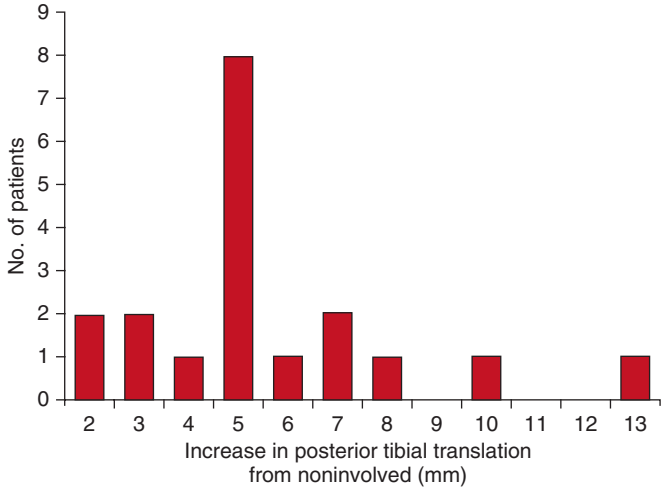

FIG 16-46 Distribution of residual posterior tibial translation at 90 degrees of knee flexion on stress radiography a mean of 2.9 years after posterior cruciate ligament quadriceps tendon-patellar bone two-strand autograft reconstruction with a tibial inlay technique. (From Noyes FR, Barber-Westin SD. Posterior cruciate ligament replacement with a two-strand quadriceps tendon-patellar bone autograft and a tibial inlay technique. *J Bone Joint Surg Am.* 2005;87:1241-1262.)

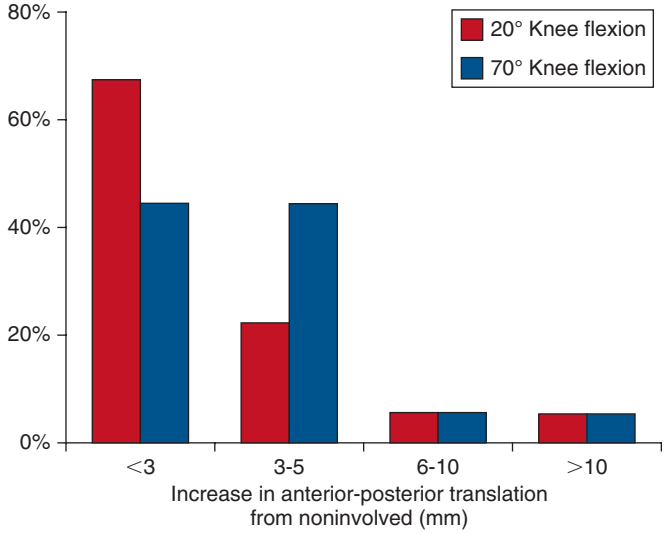

FIG 16-47 Distribution of residual total anterior-posterior translation on KT-2000 testing a mean of 2.9 years after posterior cruciate ligament quadriceps tendon-patellar bone two-strand autograft reconstruction with a tibial inlay technique. (From Noyes FR, Barber-Westin SD. Posterior cruciate ligament replacement with a two-strand quadriceps tendon-patellar bone autograft and a tibial inlay technique. *J Bone Joint Surg Am.* 2005;87:1241-1262.)

reconstructions were done a mean of 3.6 years (range, 0.3-18 years) after the original knee injury. In nine knees, prior PCL procedures had been done elsewhere and failed. The tibial inlay method was advantageous in these revision knees because prior tibial tunnels were avoided and bone grafting was not required. Associated procedures included posterolateral procedures in five knees, ACL reconstruction in two knees, MCL STG reconstruction in two knees, and meniscus transplantation[162] in one knee.

For all 19 knees, the mean increase in posterior tibial translation (compared with the contralateral knee) on stress radiography improved from 11.6 ± 2.9 mm preoperatively to 5.0 ± 2.6 mm at follow-up (mean ± standard deviation; $P < .0001$; Fig. 16-46). The mean increase in AP displacement on arthrometer testing improved from 10.8 ± 3.0 mm preoperatively to 2.0 ± 2.2 mm at follow-up ($P = .005$) at 20 degrees of flexion; and from 10.4 ± 2.9 mm preoperatively to 2.3 ± 2.2 mm at follow-up ($P = .004$) at 70 degrees of flexion (Fig. 16-47). All of the associated knee ligament procedures received an IKDC rating of A or B at follow-up.

Before surgery, 11 patients (58%) had pain with daily activities, but only one (5%) had such pain at follow-up. Eighteen patients (95%) rated the condition of the knee as improved. Significant improvements were noted for symptoms and limitations with daily and sports activities (Table 16-14). Eleven patients (58%) were participating in low-impact sports at follow-up without problems, and two were participating in more strenuous sports without problems. Two patients were participating with symptoms against advice. Three patients did not return to sports because of the knee condition, and one patient did not return to sports because of reasons not related to the knee condition.

Abnormal articular cartilage surfaces were found during the operation in eight knees; in the patellofemoral compartment in two knees, the medial tibiofemoral compartment in seven knees, and the lateral tibiofemoral compartment in one knee. A difference was noted between patients with normal cartilage and those with abnormal cartilage surfaces in the mean scores in the patient rating of the overall knee condition (7.3 ± 1.5 and 5.4 ± 2.2 points, respectively; $P = .05$), squatting (29 ± 11 and 10 ± 14 points, respectively; $P = .005$), and running (82 ± 21 and 57 ± 25 points, respectively; $P < .05$).

Eleven patients had an isolated PCL replacement, and eight had an additional knee ligament reconstruction. There was no difference in the mean millimeters of posterior tibial translation measured on stress radiography among these subgroups. There also appeared to be no difference in the mean pain or patient perception scores at follow-up among the subgroups.

There were no infections, permanent limitations of knee motion, donor site problems, or patellar fractures. One patient required an arthroscopic lysis of adhesions to resolve a limitation of knee motion.

All patients except one rated their knee condition as improved. Still, the residual symptoms prevented the majority from returning to strenuous sports. Fourteen knees (74%) had compounding problems of articular cartilage damage, prior meniscectomy, additional ligament procedures, or osteotomy. The results affirmed the recommendation that early operative treatment be considered for PCL ruptures, because by the time surgical reconstruction is necessary for symptoms with daily activities, knee symptoms may not be improved by reconstruction owing to the arthritic joint damage.

The objective assessment of posterior stability at 70 degrees of knee flexion in this study demonstrated superior results compared with the authors' single-strand PCL allograft study.[154] Stress radiography revealed that 68% of the knees had no more than a 5-mm increase in posterior tibial displacement, compared with 37% of the knees in the allograft population (who had chronic PCL ruptures). Still, in acute injury situations or in dislocated knees that require multiple ligament reconstructive procedures, allografts may be more suitable as previously discussed.

Posterior Cruciate Ligament Two-Strand Quadriceps Tendon-Patellar Bone Autograft Tibial Tunnel

We[159] followed 29 patients who underwent a two-strand PCL QT-PB autograft reconstruction with an all-inside tibial tunnel technique. All

patients were prospectively followed a mean of 3.6 years (range, 2-7 years) postoperatively. Eighteen patients had the PCL reconstruction for chronic ruptures, and 11 for acute injuries. Six patients had prior PCL reconstructions that had failed. Fifteen knees required an associated ligament reconstruction, including ACL reconstruction in nine knees, MCL repair or reconstruction in six, posterolateral procedures in five, and meniscus allograft, in one.

The mean increase in posterior tibial translation measured with stress radiography improved from 10.5 ± 2.9 mm preoperatively to 6.5 ± 4.3 mm at follow-up ($P = .06$). Preoperatively, all knees received an IKDC rating of C or D according to the stress radiographic data. At follow up, three knees (10%) were rated A; seven knees (24%), as B; 17 knees (59%), as C; and two knees (7%), as D.

Preoperatively, the KT-2000 total AP displacement values were 9.6 ± 3.9 mm at 20 degrees of flexion and 9.8 ± 3.1 at 70 degrees of flexion. At follow-up, the total AP displacement at 20 degrees of flexion was 2.2 ± 2.0 mm ($P < .0001$) and at 70 degrees of flexion, 3.3 ± 2.9 ($P = .0001$). All of the associated ligament reconstructions were rated as A or B, except one ACL reconstructions that was rated C.

Before surgery, 87% of the patients with chronic PCL ruptures had pain with daily activities, but only 11% had such pain at follow-up. Statistically significant improvements were noted for pain, swelling, giving-way, walking, stairs, running, jumping, and twisting/turning ($P < .01$). Ninety-four percent rated the knee condition as improved. For all 29 patients, 15 (52%) returned to low-impact sports and seven (24%) were participating in strenuous sports without problems. One patient was participating with symptoms against advice, and six patients did not return because of their knee condition. There were no infections or patellar fractures. Two patients reported residual pain at the patellar donor site.

TABLE 16-14 Symptoms and Functional Limitations Before and After PCL QT-PB Two-Strand Reconstruction With a Tibial Inlay Technique in 19 Knees

Factor	Point Scale	Preoperative*	Follow-up*	*P* Value
Pain	0-10	3.4 ± 1.8	6.6 ± 2.6	<.0001
Swelling	0-10	4.3 ± 2.3	7.4 ± 2.4	<.001
Full giving-way	0-10	5.6 ± 3.1	8.3 ± 2.6	<.001
Patient perception	1-10	3.2 ± 1.2	6.5 ± 2.1	.0001
Walking	0-40	29 ± 8	37 ± 9	<.01
Stair-climbing	0-40	29 ± 7	34 ± 10	<.05

Causes of Failure of Posterior Cruciate Ligament Reconstructions

A study was conducted to analyze the potential factors that contributed to the failure of PCL operations.[157] Between June 1989 and July 2003, 41 knees in 40 patients were referred to our center for treatment after 52 failed PCL operative procedures. The patients were evaluated a mean of 3.4 years (range, 1 month to 23.7 years) after the failed PCL procedures. There were 24 males and 16 females whose mean age at the initial PCL procedure was 30 years (range, 11-51 years). The initial PCL procedures were done for an acute knee injury in 15 knees and for chronic deficiency in 26 knees.

A total of 155 operative procedures had been done in the 41 knees. PCL graft reconstructions had been done in 31 cases; primary repairs, in 14; synthetic replacements, in four; and thermoplasties, in three. A single PCL procedure had been done in 32 knees; two procedures, in seven knees; three procedures, in one knee; and four procedures, in one knee. Only four knees (10%) had an isolated PCL reconstruction with no associated or further surgery performed.

Reconstruction of other knee ligaments had been done in 27 knees (66%). These involved 21 FCL or posterolateral complex procedures in 14 knees, 19 ACL reconstructions in 16 knees, and nine MCL procedures in nine knees.

CRITICAL POINTS Our Clinical Studies: Posterior Cruciate Ligament Two-Strand Quadriceps Tendon-Patellar Bone Autograft Tibial Tunnel Technique

- $n = 29$ followed mean 3.6 years (range, 2-7 years) postoperatively.
- PCL chronic 18, acute 11.
- Associated procedures: 9 ACL reconstructions, 6 MCL repairs, reconstructions, 5 posterolateral procedures, 1 meniscus transplant.
- Stress radiographs: mean preoperative, 10.5 ± 2.9 mm; follow-up, 6.5 ± 4.3 mm ($P = .06$).
- Preoperatively, all knees rated C or D on IKDC scale. At follow-up, 3 knees (10%) graded A; 7 knees (24%) graded B; 17 knees (59%) graded C; 2 knees (7%) graded D.
- KT-2000 (70 degrees): mean preoperative, 9.8 ± 3.1 mm; follow-up, 3.3 ± 2.9 mm ($P = .0001$).
- Pain ADL: preoperative, 87%; follow-up, 11%.
- 94% rated knee improved.
- 52% returned to low-impact sports, 24% returned to strenuous sports.

CRITICAL POINTS Our Clincal Studies: Analysis of the Causes of Failure of Posterior Cruciate Ligament Reconstruction

- $n = 40$ patients with 52 failed PCL operations.
- Patients evaluated mean 3.4 years (range, 1 month to 23.7 years) after failed PCL procedures.
- Total 155 prior PCL operative procedures: 31 graft reconstructions, 14 primary repairs, 4 synthetic replacements, and 3 thermoplasties.
- Other ligament procedures: 21 posterolateral (16 failed), 19 ACL (9 failed), 9 MCL.
- Most common probable causes of failure: associated posterolateral deficiency (40%), improper graft tunnel placement (33%), associated varus malalignment (31%), primary suture repair (25%).
- 71% pain with ADL.
- 75% no sports possible.

Medical records, operative notes, radiographs, and MRI scans were reviewed and a comprehensive knee examination performed. A single factor that caused the operations to fail was identified in 23 (44%) of the 52 operations and multiple factors were identified in 29 (56%, Table 16-15). The most common probable causes of failure were associated posterolateral deficiency (40%), improper graft tunnel placement (33%), associated varus malalignment (31%), and primary suture repair (25%).

Sixteen of 21 (76%) prior posterolateral procedures had failed, as had nine of 19 (47%) prior ACL reconstructions. Twenty-nine knees (71%) presented with pain with activities of daily living. Thirty-four knees (83%) had compounding problems of joint arthritis, prior meniscectomy, associated ligament deficiencies, or varus malalignment.

In the patients' rating of their own knee condition, 20 (49%) rated the knee as poor; 12 (29%), as fair; and nine (22%), as good. Thirty-one (75%) patients had given up sports activities completely and 10 were participating with significant limitations and symptoms. Significant functional limitations were found with walking in 19 (46%) patients and during squatting in 37 (90%) patients.

TABLE 16-15 Factors Contributing to Failure of 52 Posterior Cruciate Ligament Operations Referred to Our Center for Treatment

	Single Factor (23/52 Procedures)	Multiple Factors (29/52 Procedures)	Total
Deficiency of other knee ligaments:			
Fibular collateral, posterolateral	1	20	21
Anterior cruciate	0	12	12
Medial collateral	0	3	3
Misplaced tunnels:

From Noyes FR, Barber-Westin SD. Posterior cruciate ligament revision reconstruction. Part 1: causes of surgical failure in 52 consecutive operations. *Am J Sports Med.* 2005;33:646-654.

In 22 knees (54%), a PCL revision reconstruction was performed. In 19 knees (46%), revision was not performed. Eleven of these 19 knees had developed advanced knee joint arthritis with significant loss of joint space on radiographs (with only a few millimeters remaining in tibiofemoral compartments) that contraindicated PCL revision. Eight patients declined further operative treatment.

Failure to restore associated ligament instabilities and incorrect tunnel placement were major factors contributing to surgical failure of PCL operative procedures. The results suggest the need for greater emphasis on the initial reconstruction in graft tunnel placement, correction of associated ligament instabilities, and correction of varus osseous malalignment. Failure of concurrent posterolateral complex reconstructions was frequently encountered, suggesting the need for higher-strength augmentation procedures or anatomic graft replacement as discussed in Chapter 17. The results of this study were verified in 2012 by Lee and coworkers,[116] who found in a cohort of 28 failed PCL-reconstructed knees that the most common causes of failure were posterolateral deficiency and improper graft tunnel placement. Kim and associates[100] reported that patients with generalized joint laxity (Beighton and Horan criteria) had an increased risk of failure of single-strand PCL reconstruction compared with those without such laxity (nine of 24 patients [37.5%] and six of 29 patients [20.7%], respectively).

Posterior Cruciate Ligament Revision Two-Strand Quadriceps Tendon-Patellar Bone Autograft Reconstruction

From June 1995 until January 2002, a PCL revision reconstruction with a two-strand QT-PB autograft was performed in 15 knees referred after prior failed procedures.[158] There were 10 males and five females whose mean age at the time of PCL revision was 29 years (range, 17-49 years). All patients were followed a mean of 3.7 years (range, 2-7 years) postoperatively.

A total of 21 prior failed PCL operations had been done in these 15 knees, including 12 graft reconstructions, five primary repairs, two synthetic graft replacements, and two thermoplasties. A single PCL

CRITICAL POINTS Our Clinical Studies: Revision Posterior Cruciate Ligament Two-Strand Quadriceps Tendon-Patellar Bone Autograft Reconstruction

- $n = 15$ followed mean 3.7 years (range, 2-7 years) postoperatively.
- Mean 3.8 years (range, 0.3-15.6 years) between failed PCL procedures and revision.
- Staged HTO required in 3 knees, autogenous bone grafting of prior graft tunnels in 1 knee before PCL revision.
- Tibial inlay 9 knees, tibial tunnel 6 knees.
- Concomitant procedures: 4 ACL reconstruction, 4 posterolateral, 1 MCL reconstruction.
- Stress radiographs: mean preoperative, 11.7 ± 3.0 mm; follow-up, 5.1 ± 2.4 mm ($P < .001$).
- KT-2000 (70 degrees): mean preoperative 8.9 ± 2.5 mm; follow-up, 3.3 ± 3.9 mm ($P < .01$).
- Before revision, all knees rated C or D according to IKDC system. At follow-up, 1 knee rated A; 9 knees, B; 4 knees, C; 1 knee, D.
- 87% rated knee condition improved.
- 53% returned to low-impact sports.
- 80% improved pain, 87% improved patient perception scores.
- Results inferior to primary PCL reconstructions, majority salvage knees.

procedure had been done in 11 knees and two or more PCL procedures had been done in four knees. A mean of 3.8 years (range, 0.3-15.6 years) had elapsed between the failed PCL procedures and the revision. The possible causes of failure of PCL reconstructions were previously presented in a larger series of knees described above; these 15 knees were a subgroup of that study.

Reconstruction of other knee ligaments had been done in nine knees: ACL procedures, in seven knees; FCL or posterolateral complex procedures, in three knees; and MCL procedures, in three knees. Before the PCL revision reconstruction, a staged HTO was required in three knees, and an autogenous bone grafting of prior graft tunnels was done in one knee.

The tibial inlay technique was used in nine knees, and the tibial tunnel technique was done in six knees. Six knees had one or more concomitant ligament reconstructive procedures with the PCL revision. In four knees, a concomitant ACL allograft reconstruction was done. One knee had an associated MCL autograft reconstruction for chronic instability. Four knees had a posterolateral reconstruction: three had a proximal advancement of the posterolateral complex[156] and one had an autograft reconstruction of the FCL, popliteus, and popliteofibular ligament.[160]

Stress radiograph posterior tibial translation values improved from 11.7 ± 3.0 mm preoperatively to 5.1 ± 2.4 mm at follow-up ($P < .001$). The KT-2000 total AP displacement values at 20 degrees improved from 9.1 ± 3.3 mm preoperatively to 2.7 ± 3.1 mm at follow-up (mean ± standard deviation, $P < .001$). At 70 degrees, the displacement values improved from 8.9 ± 2.5 mm preoperatively to 3.3 ± 3.9 mm at follow-up ($P < .01$). Before the revision, all knees were rated as C or D according to stress radiographic data. At follow-up, one knee was rated A; nine knees as B, four knees as C, and one knee as D. Two of the 15 revisions failed. Associated knee ligament reconstructive procedures restored anterior, medial, and posterolateral stability.

Significant improvements occurred in pain, function, and patient's perception scores (Table 16-16). Eighty-seven percent felt the overall knee condition was better postoperatively. However, the subjective and functional results were inferior to those reported after primary acute PCL reconstruction. Only 53% returned to light sports without problems.

The QT-PB two-strand revision provided reasonable results in this group of complex knees; however, this is a small series of PCL revision cases and definitive conclusions cannot be reached. Thirteen of 15 knees (87%) had compounding problems of articular cartilage damage, prior meniscectomy, need for associated ligament procedures, or varus malalignment with medial tibiofemoral compartment damage. Improvements were noted in 80% of the patients for pain and in 87% for the patient perception of the knee condition. However, the results were inferior to those obtainable from primary PCL reconstructions because the majority of patients were in a salvage knee situation. The goals in a revision population are to reduce symptoms with daily activities and expect that approximately 50% will be able to resume light recreational activities.

TABLE 16-16 Symptoms and Functional Limitations Before and After Revision PCL QT-PB Two-Strand Reconstruction in 15 Knees

Factor	Point Scale	Preoperative*	Follow-up*	*P* Value
Pain	0-10	2.7 ± 1.8	5.3 ± 2.4	.0001
Swelling	0-10	3.2 ± 2.5	6.4 ± 2.8	.002
Full giving-way	0-10	4.7 ± 3.3	7.3 ± 2.7	.01
Patient perception	1-10	2.8 ± 1.4	5.2 ± 1.9	.05
Walking	0-40	25 ± 12	35 ± 7	.0002
Stair climbing	0-40	23 ± 13	32 ± 11	.004

CRITICAL POINTS Our Clincal Studies: Posterior Cruciate Ligament Single-Strand Allograft Reconstruction

- *n* = 25 patients followed mean 3.7 years (range, 2-6.1 years) postoperatively.
- PCL acute 10, chronic 15.
- 11 associated posterolateral proximal advancement.
- KT-2000 (70 degrees) at follow-up: >5.5 mm detected 40% acute, 63% chronic cases.
- Acute cases significantly higher scores for all symptom and function scores.
- Majority of patients with chronic PCL rupture advised to avoid strenuous athletics after surgery owing to preexisting articular cartilage damage.
- No infections, evidence of rejection of the allografts, or cases of disease transmission.

Posterior Cruciate Ligament Single-Strand Allograft Reconstruction

Historically, the outcome of arthroscopic-assisted, single-strand PCL allograft reconstructions was determined in 25 patients.[154] All patients were followed a mean of 3.7 years postoperatively (range, 2-6.1 years). In 10 patients, an allograft reconstruction (B-PT-B or AT) was done alone and in 15 patients, the allograft was augmented with a ligament augmentation device (LAD). Ten patients received the operation for acute PCL ruptures, and 15 for chronic ruptures. Additional operative procedures were done in 12 knees; one required a repair of an MCL rupture, and 11 had a proximal advancement of the posterolateral complex.[155]

KT-1000 (MEDmetric) testing at follow-up revealed no difference between patients who had an allograft alone and those who had an allograft-LAD composite in total AP displacement at 20 and 70 degrees of knee flexion. The mean AP displacement value at 20 degrees of flexion for patients who had acute PCL ruptures was not significantly different from that of patients who had chronic ruptures (0.6 ± 1 mm and 1.4 ± 2.3 mm, respectively). Posterior stability was restored at this knee flexion angle in all knees (Fig. 16-48). At 70 degrees of knee flexion, an increase in AP displacement of more than 5.5 mm was detected in 40% of acute and 63% of chronic knees; the mean values were not significantly different among these subgroups (5.8 ± 2 mm and 6.5 ± 4 mm, respectively).

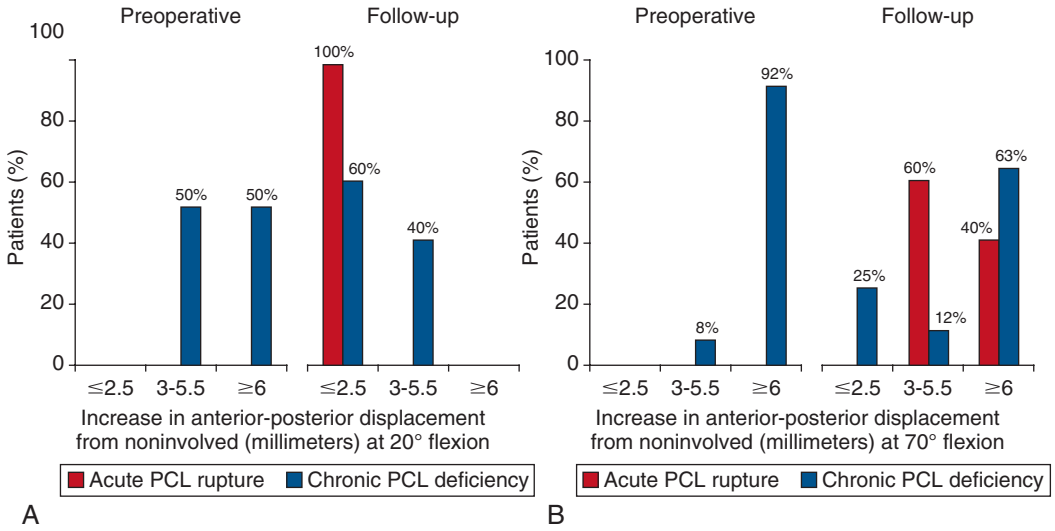

FIG 16-48 Follow-up results of KT-1000 arthrometer testing at 20 degrees (**A**) and 70 degrees (**B**) of knee flexion following PCL single-strand allograft reconstruction. (From Noyes FR, Barber-Westin S.D. Posterior cruciate ligament allograft reconstruction with and without a ligament augmentation device. *Arthroscopy*. 1994;10:371-382.)

Patients who had the operation for chronic PCL ruptures had significant improvements at follow-up in the mean scores for pain, swelling, and giving-way ($P < .001$) and for walking, stair climbing, and squatting/kneeling ($P < .05$). However, patients who had acute PCL ruptures had significantly higher scores in all of the symptom and function analyses (Table 16-17). All but one of the patients with acute PCL ruptures returned to sports activities without problems, whereas only two of the 15 patients with chronic PCL ruptures returned to athletics. The majority of patients with chronic PCL ruptures were advised to avoid strenuous athletics after surgery owing to the preexisting articular cartilage damage.

There was no benefit of the LAD in regard to posterior knee stability or the functional outcome. The single-strand allograft reconstruction restored posterior stability at 20 degrees of knee flexion, but not uniformly at 70 degrees of flexion. From a historical standpoint, the increased posterior subluxation at high flexion angles led us to a biomechanical and clinical analysis of two-strand PCL reconstructions with the goal of achieving improved stability.

TABLE 16-17 Symptom and Function Scores After Single-Bundle PCL Allograft Reconstruction for Acute and Chronic PCL Ruptures in 25 Knees

Factor	Point Scale	Chronic PCL Ruptures ($n = 15$)	Acute PCL Ruptures ($n = 10$)	*t* Test *P* Value
Pain	0-10	6 ± 2	9 ± 1	.001
Swelling	0-10	7 ± 2	9 ± 1	.01

RESULTS FROM OTHER CLINICAL STUDIES

Isolated Posterior Cruciate Ligament Single-Strand Reconstruction

Inconsistent results have been reported following single-strand isolated PCL reconstructions in restoration of normal posterior tibial displacement and knee function (Tables 16-18 and 16-19). Generally, improved knee symptoms and activity levels have been reported in the majority of studies, even though normal stability was not always restored.[122,150,223,224] It is not possible at present to scientifically analyze the effects of various graft materials or surgical techniques on the outcome of isolated single-strand PCL reconstructions. Kim and associates[106] conducted a systematic review of isolated PCL single-bundle transtibial reconstruction studies, of which 10 met the inclusion criteria. Autografts were used in 78% of the knees and allografts were selected in 22%. Stress radiographs were done in only one investigation. The IKDC objective knee evaluation form, completed in six studies, reported 75% of the knees were rated as normal or nearly normal at follow-up. The authors concluded that the procedure improved posterior drawer testing by an average of 1 grade, but did not reliably restore normal knee stability.

At the time of writing, only two studies had directly compared the outcomes of a single-strand transtibial tunnel method with a single-strand tibial inlay method.[129,196] Both investigations found no significant differences in knee rating scores and stability. Unfortunately, neither of these studies was randomized and both involved small cohorts. Historically, many studies used the KT-2000 to quantify the results of the PCL reconstructions. Although the knee arthrometer is a valid tool for the measurement of total AP translation at 20 degrees of knee flexion, it underestimates the true amount of posterior tibial

translation in PCL-deficient and reconstructed knees at 70 degrees of knee flexion. Stress radiography is the preferred device for measuring posterior tibial translation.

Few authors have described results of isolated two-strand PCL reconstructions.[33,58,146] Min and associates[146] performed a transtibial two-strand reconstruction with a tibialis anterior allograft in 21 patients who were followed a mean of 4.1 years postoperatively. The graft was passed through two femoral tunnels into one tibial tunnel, which the authors referred to as a single-sling method. At follow-up, a mean KT-2000 90 degrees of flexion value of 3.4 ± 0.8 mm (range, 1.6-6.3 mm) was reported. Three knees had grade II posterior instability. Overall IKDC grades were normal in 38%, nearly normal in 38%, abnormal in 19%, and severely abnormal in 5%. Chen and Gao[33] performed a two-strand PCL reconstruction in 19 patients in whom a quadruple semitendinosus graft was used to replace the ALB of the PCL and a quadruple gracilis tendon graft was used to reconstruct the PMB. A suture suspension technique was used for fixation. Mean posterior stress radiographs improved from 10.6 ± 2.0 mm preoperatively to 2.0 ± 1.2 mm postoperatively ($P < .001$). The IKDC subjective score increased from 65.6 ± 5.1 preoperatively to 92.1 ± 3.7 ($P < .001$). One knee had a grade II posterior drawer test.

Posterior Cruciate Ligament Single-Strand Versus Two-Strand Reconstruction

Comparisons have been made between one- and two-strand PCL procedures, with little to no difference in stability and knee function reported in recent studies (Tables 16-20 and 16-21).[49,101,104,122,202] The few studies available at the time of writing typically had low evidence levels and were not randomized.[49,82,101,104,202,227] One prospective randomized study was conducted by Li and colleagues[122] in which 50 patients were randomized to receive either a single-strand or two-strand tibialis anterior allograft. At a mean of 2.4 years postoperatively, the two-strand group had a significantly lower mean amount of posterior translation on KT-1000 testing compared with the single-strand group (2.2 ± 1.3 and 4.1 ± 1.3 mm, respectively; $P < .05$). The difference in the mean posterior translation of 1.9 mm has questionable clinical

application. The authors did not provide ranges of this test, or the number of knees with a grade II or III posterior drawer. There was a significantly greater percentage of patients in the two-strand group with overall IKDC knee examination scores of normal/nearly normal compared with the one-strand group (92 and 82%, respectively; $P <$ .05). In addition, the mean IKDC subjective knee score was higher in the two-strand group compared with the single-strand group (72 ± 7 and 65 ± 8, respectively; $P <$ .05).

Posterior Cruciate Ligament Reconstruction With Associated Ligament Instabilities

Because isolated, complete PCL ruptures are rare, the majority of clinical studies have described cohorts in which all or the majority of patients had associated ligament instabilities (Tables 16-22 and 16-23). STG autografts and a variety of allografts were the most frequently used grafts to replace cruciate and posterolateral structures in these studies. The majority of investigations published to date had short-term follow-up of typically 2 to 4 years and the heterogeneous cohorts make comparisons among investigations not possible. Most authors reported some improvement in posterior tibial translation, although return of normal values varied among studies.

Posterior Cruciate Ligament Augmentation, Preservation of Remnant

Preserving the PCL remnant, in combination with usually a single-strand PCL graft, has been performed by several investigations in an effort to achieve superior results compared with graft reconstructions

(Tables 16-24 and 16-25). A systematic review was recently conducted by Del Buono and coworkers[44] to determine whether significant differences existed between PCL augmentation and PCL reconstruction studies regarding functional and stability results. The review included 24 studies that involved 623 PCL reconstructions and 158 PCL augmentation (remnant preservation) procedures. Overall, equivalent outcomes were found between the two operative techniques for IKDC scores, Lysholm scores, and KT-1000 and stress radiographic measurements. For instance, IKDC overall evaluation scores of normal or nearly normal were reported in a mean of 89.8% of patients who underwent PCL augmentation and in 80.1% of those who had PCL reconstruction. Posterior stress radiograph side-to-side differences improved by a mean of 8.6 ± 1.6 mm after PCL augmentation (from 11.1 ± 1.4 mm preoperatively to 2.5 ± 0.4 mm postoperatively) and by a mean of 8.0 ± 5.8 mm after PCL reconstruction (from 11.5 ± 2.2 mm preoperatively to 3.5 ± 1.3 mm postoperatively). The concern was expressed that no long-term data were available and subsequent rates of arthritis remain unknown.

Posterior Cruciate Ligament Revision Reconstruction

Other than our study just described, only one investigation of PCL revision reconstruction had been published at the time of writing. Lee and associates[116] followed 22 patients who underwent a modified two-strand tibial inlay procedure with an AT allograft a mean of 3.3 years postoperatively. Concomitant posterolateral reconstruction was performed in 17 knees; MCL reconstruction, in one knee; and HTO, in one knee. Posterior tibial translation on stress radiographs improved from a mean of 9.9 ± 2.8 mm before surgery to 2.8 ± 1.8 mm postoperatively. Two patients had more than 5 mm of increased displacement. The subjective IKDC score was classified as normal or nearly normal in 73%; abnormal, in 18%, and severely abnormal, in 9%.

Conclusions

To date, there remain too few long-term and high evidence-based data to determine the indications for a two-strand versus a one-strand technique, the most advantageous graft to select for different circumstances, and the failure rate for autografts and allografts.[83,106,108,141,174,175,229] There is an important need for well-designed Phase I multicenter trials, because individual centers seldom have a sufficient number of PCL cases for statistical analysis and definitive recommendations. Studies that have compared results of various techniques have typically been underpowered to provide definitive conclusions.[82,104,202,227,229]

ILLUSTRATIVE CASES

Case 1. A 16-year-old female athlete injured her left knee playing soccer. A PCL thermoplasty had been performed, which failed, and she was referred to our center 9 months later for consideration of reconstruction. The patient complained of functional limitations with all athletics and had not been able to return to soccer. Physical examination revealed 10 mm of increased posterior tibial translation (90 degrees), 7 mm of increased lateral joint opening (30 degrees), and 30 degrees of increased external tibial rotation (30 degrees). Posterior stress radiographs showed 11 mm of increased posterior tibial translation. The patient was a potential collegiate soccer scholarship candidate.

The patient underwent a two-strand quadriceps tendon-patellar bone PCL reconstruction with a tibial inlay technique (Fig. 16-49). The posterolateral deficiency was treated with a proximal advancement of the posterolateral complex. The *arrows* in Figure 16-49, *A* show the location of the two tunnels in the medial femoral condyle.

The patient was able to return to soccer without problems. Two years postoperatively, she had 4 mm of increased posterior tibial translation on stress radiographs at 90 degrees of flexion, no increase on KT-2000 testing at 20 degrees of flexion, and no increase in lateral joint opening or external tibial rotation. She rated the overall condition of her knee as very good.

Our comment: As discussed, the all-inside PCL reconstruction that places the bone plug within an arthroscopically-placed tibial tunnel has replaced the open tibial inlay procedure, with equivalent clinical results.

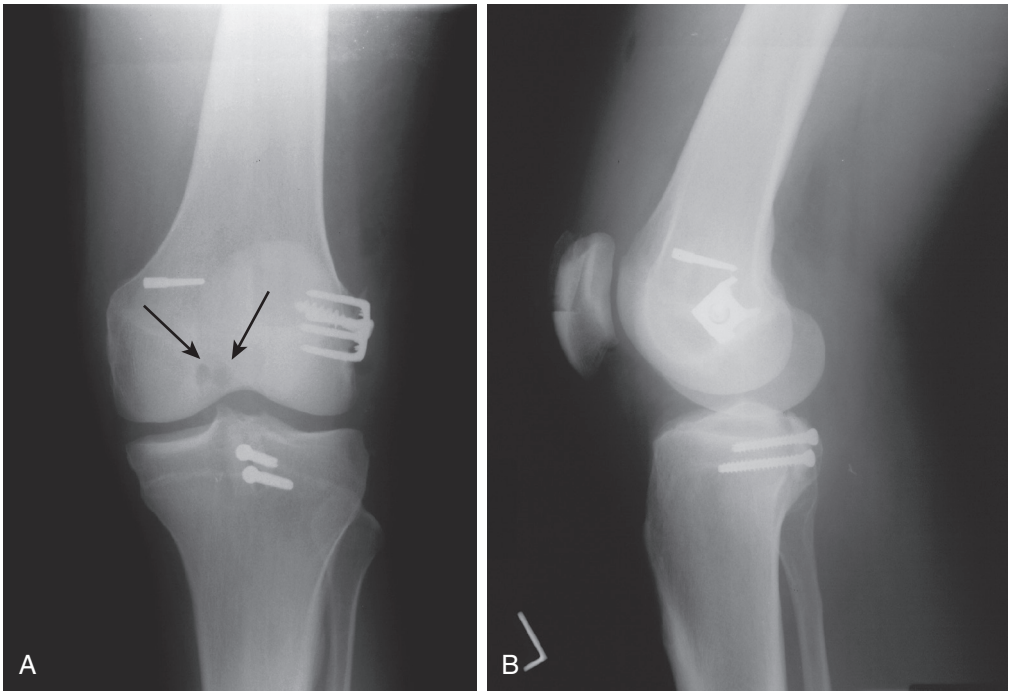

FIG 16-49 Case 1. (From Noyes FR, Barber-Westin SD. Posterior cruciate ligament replacement with a two-strand quadriceps tendon-patellar bone autograft and a tibial inlay technique. *J Bone Joint Surg Am.* 2005;87:1241-1262.)

Case 2. A 45-year-old man sustained a complete PCL rupture during a recreational basketball game and underwent a PCL Achilles tendon-bone allograft reconstruction. He presented to our center 1 year later with complaints of moderate pain with daily activities and severe difficulty with walking, stair-climbing, and squatting. He was disabled from his occupation. Radiographs demonstrated proximal and anterior placement of the tibial tunnel and enlargement of both tunnels with an obvious posterior tibial subluxation (Fig. 16-50). Physical examination showed 10 mm of increased posterior tibial translation (90 degrees), 6 mm of increased lateral joint opening (30 degrees), and moderate patellofemoral crepitus. The patient had a tibial nerve palsy, which was improving. Stress radiographs showed 12 mm of increased posterior tibial translation.

The treatment recommendation was a staged autogenous femoral bone graft procedure followed by a PCL revision posterolateral reconstruction, based on further evaluation at the time of surgery. The patient declined further operative treatment.

Our comment: Inadequate placement of the primary PCL graft represents one of the most common causes of failure, particularly with an anterior tibial placement that produces a vertical PCL graft. In revision PCL reconstructions, approximately 60% of knees have an undiagnosed posterolateral ligament deficiency that requires a concurrent operative procedure.

Case 3. A 36-year-old woman sustained a work-related injury and underwent a single-strand posterior cruciate ligament (PCL) bone-patella tendon-bone allograft reconstruction. The patient's surgical history also included a medial collateral ligament reconstruction with a semitendinosus graft and a proximal patellar realignment. She presented 1 year later at our center with complaints of severe pain and functional limitations with all daily activities. Sagittal, coronal, and axial magnetic resonance imaging scans showed enlarged femoral and tibial tunnels (Fig. 16-51). Physical examination revealed 12 mm of increased posterior tibial translation (90 degrees), 5 mm of increased medial joint opening (30 degrees), and moderate patellofemoral and tibiofemoral crepitus.

The treatment recommendation was a staged autogenous femoral and tibial graft procedure followed by a PCL revision reconstruction. The patient declined and underwent a total knee replacement 3 years later for unresolved pain.

Our comment: This case demonstrates an unfortunate reaction to the allograft with severe tunnel widening, not seen in our experience with autograft tissue.

Case 4. A 28-year-old man sustained complete PCL and posterolateral ligamentous ruptures in a work-related injury and underwent a single-strand PCL allograft and fibular collateral ligament allograft reconstruction. He presented 14 months later with complaints of severe pain and limitations with daily activities. He had not been able to return to work owing to his knee symptoms. Radiographs demonstrated underlying varus osseous malalignment and severe deficiency of the posterolateral structures (Fig. 16-52). Physical examination revealed 10 mm of increased posterior tibial translation (90 degrees), 15 mm of increased lateral joint opening (30 degrees), a grade III pivot shift, and 25 degrees of increased external tibial rotation. There was a varus osseous malalignment (weight-bearing line, 34% on standing hip-knee-ankle radiograph with lateral compartment closure). The patient's body mass index was 32, indicating an obese condition. He also had severe patellofemoral arthritis and compression pain.

Because of the patient's age, the treatment recommendations were a weight loss program (with a targeted amount to be indicated), followed by an opening wedge high tibial osteotomy. Upon recovery from the osteotomy, a combined two-strand PCL revision reconstruction and an anatomic posterolateral reconstruction was performed as described in the text.

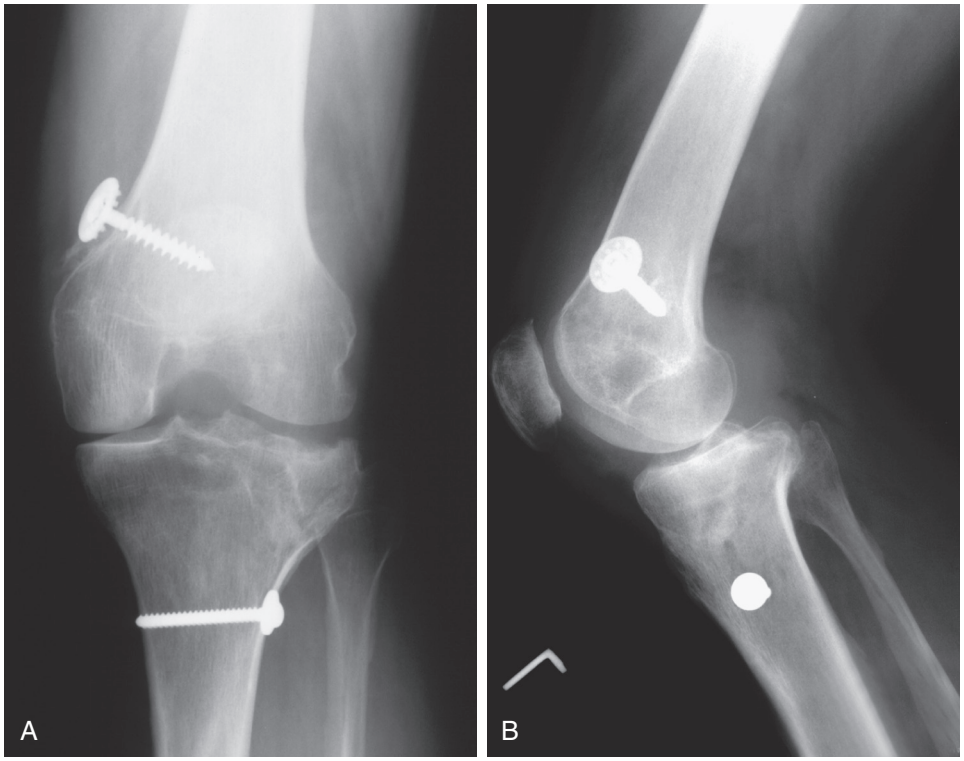

FIG 16-50 Case 2. (From Noyes FR, Barber-Westin SD. Posterior cruciate ligament revision reconstruction, part I. Causes of surgical failure in 52 consecutive operations. *Am J Sports Med.* 2005;33:646-654.)

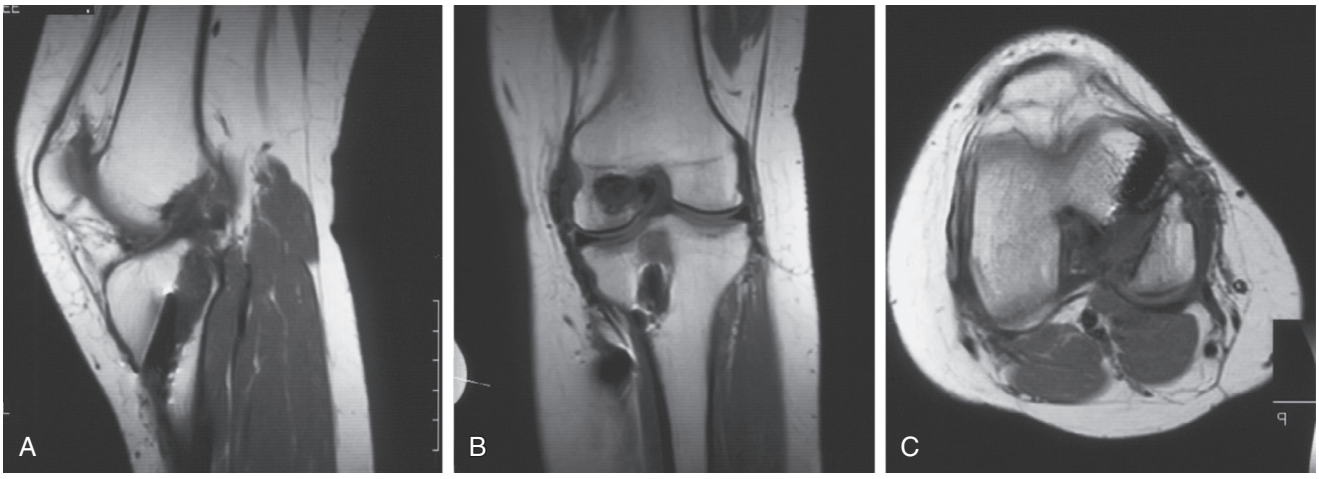

FIG 16-51 Case 3. (From Noyes FR, Barber-Westin SD. Posterior cruciate ligament revision reconstruction. Part 1: causes of surgical failure in 52 consecutive operations. *Am J Sports Med.* 2005;33:646-654.)

Our comment: This case shows the difficulty in achieving a successful posterolateral reconstruction in a varus-angulated knee, particularly in patients with a large body habitus that induces excessive tensile loading of the posterolateral structures. Another option in this patient, although controversial, would have been not to perform an acute operative procedure, allow healing of the posterolateral structures, and accept that a chronic reconstructive procedure would be necessary under more ideal conditions and after corrective tibial osteotomy.

Case 5. A 40-year-old man presented 2 months after an injury sustained to his right knee during a fall in which he suffered a direct blow to the anterior aspect of the tibia. The injury was initially treated conservatively elsewhere, without physical therapy or bracing. The patient presented with complaints of swelling and instability with daily activities and rated the overall condition of his knee as poor. Physical examination revealed a moderate effusion, a limitation of knee flexion of 110 degrees, moderate quadriceps weakness, and 11 mm of increased posterior tibial translation on stress radiographs (Fig. 16-53, *A*).

The patient was treated with rehabilitation to restore knee motion and muscle strength and then underwent an arthroscopic-assisted two-strand quadriceps tendon-patellar bone posterior cruciate ligament reconstruction. He demonstrated noteworthy cartilage damage on the

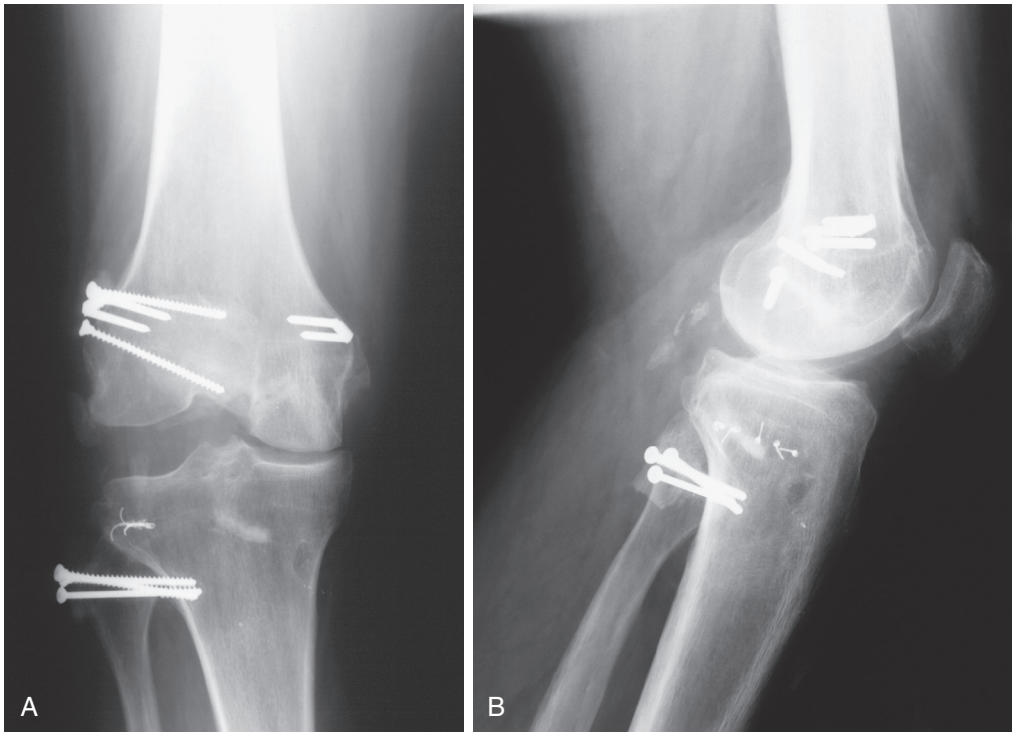

FIG 16-52 Case 4. (From Noyes FR, Barber-Westin SD. Posterior cruciate ligament revision reconstruction. Part 1: causes of surgical failure in 52 consecutive operations. *Am J Sports Med*. 2005;33:646-654.)

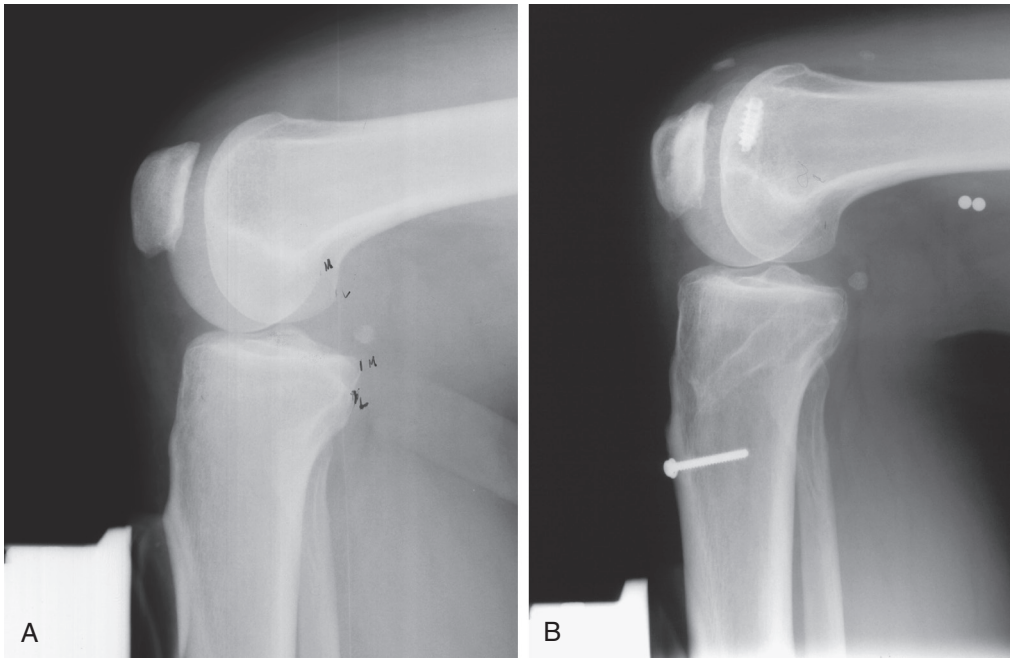

FIG 16-53 Case 5.

undersurface of the patella, femoral sulcus, and medial femoral condyle.

At the most recent follow-up evaluation, 6 years postoperatively, the patient had no effusion, a normal range of knee motion, 4 mm of increased posterior tibial displacement on stress radiographs at 90 degrees of flexion (see Fig. 16-53, *B*), and no increase in posterior tibial displacement on KT-2000 testing at 20 degrees of flexion. He had no symptoms with low-impact athletic activities, hiking, or with his occupation as a machinist. He rated the overall condition of his knee as normal.

Case 6. A 23-year-old man was referred 2 years after a left knee dislocation that was sustained during a motor vehicle accident. He had undergone a PCL B-PT-B allograft reconstruction and an FCL fascia lata autograft reconstruction, both of which had failed. The ACL had been ruptured but not surgically addressed.

Physical examination demonstrated 10 mm of increased posterior tibial translation (90 degrees), a grade III pivot shift test, 9 mm of increased AP displacement on KT-2000 testing, 20 mm of increased lateral joint opening (30 degrees), and 20 degrees of increased external tibial rotation (30 degrees). The patient had a significant peroneal nerve palsy at the time of the injury, which persisted. AP (Fig. 16-54, *A*) and lateral (see Fig. 16-54, *B*) radiographs revealed anterior tibial tunnel placement of the PCL graft. The patient had severe giving-way symptoms with daily activities.

The patient was treated with a PCL two-strand quadriceps tendon-patellar bone autograft reconstruction (tibial inlay approach, graft harvested from contralateral knee), an anatomic FCL semitendinosus autograft reconstruction, an advancement of the PLC, and an ACL B-PT-B allograft.

At follow-up, 4 years postoperative, the patient had no increase in lateral joint opening or external tibial rotation. Stress radiographs at 90 degrees of knee flexion showed restoration of posterior stability (see Fig. 16-54, *C*). He had a grade I pivot shift test and 5 mm of increase in lateral joint opening on stress radiographs. The patient was participating in low-impact activities without symptoms and rated the overall condition of his knee as good.

Case 7. A 42-year-old women presented 3 weeks after a fall complaining of left knee pain, swelling, and an inability to bear weight. The patient had experienced an unusual hyperextension-twisting injury while walking at work. On physical examination, the patient's left knee demonstrated a mild amount of swelling. Although the patient was quite guarded to examination, she appeared to have significant instability in the anterior, posterior, medial, and lateral directions. The neurovascular examination was normal and there was no evidence of localized or focal numbness in the peroneal nerve distribution. Magnetic resonance imaging showed evidence of a complete tear of the ACL, posterior cruciate ligament (PCL), fibular collateral ligament (FCL), and medial collateral ligament (MCL).

The patient underwent an initial course of rehabilitation, protective knee motion, and muscle reeducation. The decision was made 2 weeks later to perform an acute repair and reconstruction of the lateral and posterolateral disrupted structures. She had an arthroscopic-assisted ACL reconstruction with a bone-patella tendon-bone (B-PT-B) allograft, a PCL reconstruction with a single-strand quadriceps tendon-patellar bone allograft, an FCL reconstruction with a B-PT-B allograft, and a repair of the posterolateral capsule and popliteus tendon. Noteworthy articular cartilage damage (grade 2 B) was noted on the undersurface of the patella and trochlea.

At the most recent evaluation, 2 years postoperative, the patient had no complaints with daily activities. Physical examination demonstrated a negative pivot shift, no increase in Lachman, and no increase in medial or lateral joint opening. The neurosensory examination was normal and there was no effusion. Stress radiographs revealed 4 mm of lateral tibiofemoral joint opening, compared with 12 mm on the contralateral knee (Fig. 16-55, *A* and *B*). There was no increase in posterior translation noted on stress radiographs compared with the opposite knee (see Fig. 16-55 *C* and *D*).

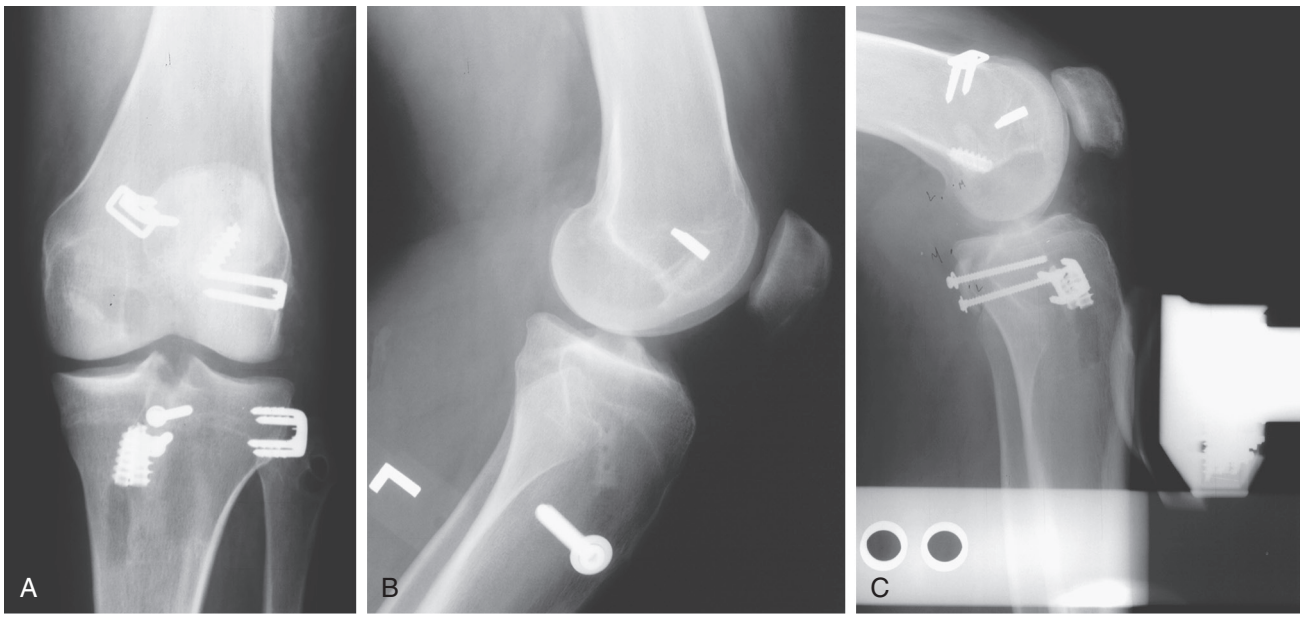

FIG 16-54 Case 6. (From Noyes FR, Barber-Westin SD, Albright JC. An analysis of the causes of failure in 57 consecutive posterolateral operative procedures. *Am J Sports Med.* 2006;34:1419-1430.)

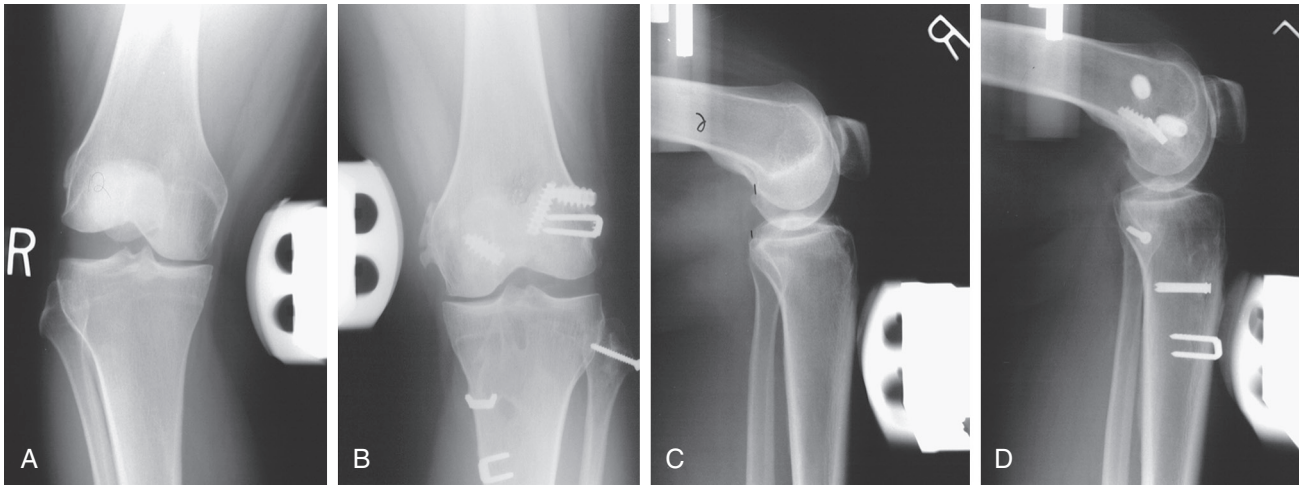

FIG 16-55 Case 7.

Our comment: This patient responded to an initial course of protected rehabilitation that allowed early surgical intervention. Otherwise, a delayed chronic reconstruction would have been performed. The postoperative therapy was done at our center with immediate knee motion to decrease the risk of arthrofibrosis. Only allografts were used not to because of operative time and to decrease postoperative pain and limitation of knee motion. The B-PT-B reconstruction of the FCL provided a strong lateral graft that allowed postoperative knee motion from 0 to 90 degrees. However, a bivalved cylinder cast was still required for 6 weeks to prevent abnormal lateral joint opening and graft disruption.

CRITICAL POINTS Indications

- 6- to 10-mm increased lateral tibiofemoral joint opening 20 degrees of flexion.
- ≥15 degrees increased external tibial rotation 30 degrees, 90 degrees of flexion.
- ± Varus recurvatum, standing and supine.
- ± Hyperextension gait abnormality.
- Double or triple varus knee, after osteotomy.
- Acute injuries, bony avulsions amendable to internal fixation.

INDICATIONS

The primary soft tissue–stabilizing structures of the posterolateral (PL) aspect of the knee joint are the fibular collateral ligament (FCL) and popliteus muscle-tendon-ligament unit (PMTL), including the popliteofibular ligament (PFL) and posterolateral capsule (PLC) shown in Figure 17-1. These structures function together to resist lateral joint opening (LJO), posterior subluxation of the lateral tibial plateau with tibial rotation, knee hyperextension, and varus recurvatum.[13,14,38,39,55,64]

The mechanism of injury may be contact or noncontact and usually involves a combined varus and hyperextension joint displacement. The proper management of injuries involving the PL structures requires knowledge of the complex anatomy and potential variations that may exist, the function of the major soft tissue stabilizers, appropriate diagnostic techniques, and surgical options for reconstruction. Isolated PL injuries are rare; however, on occasion an avulsion fracture at the femoral attachment occurs requiring internal fixation.[29] PL injuries are frequently accompanied by anterior cruciate ligament (ACL) or posterior cruciate ligament (PCL) ligament ruptures.[1,3,9,28]

Although the incidence of PL injury is unknown (owing to misdiagnosis or failure to detect the injury), the consequences of untreated PL ruptures are readily apparent. Chronic deficiency of the PL structures may be a factor in the failure of cruciate reconstructions[43,44,49] and

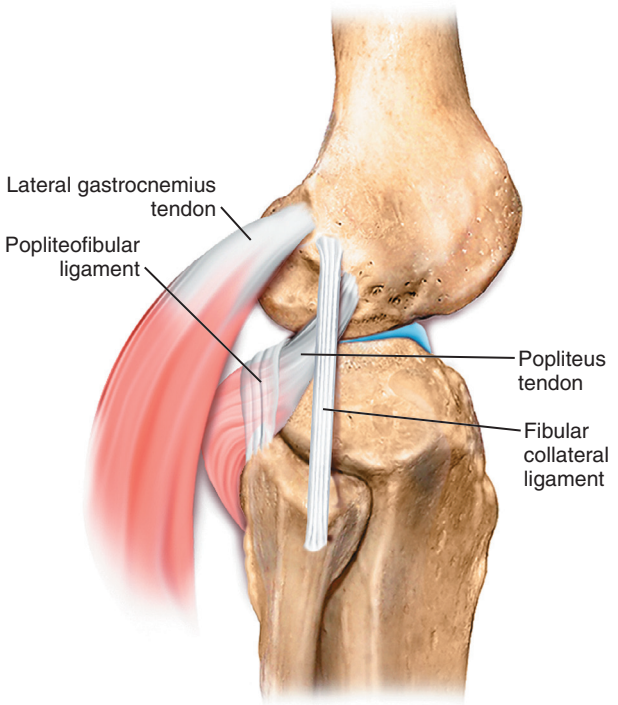

FIG 17-1 The anatomic relationships of the posterolateral structures.

may also play a role in the development of gait abnormalities and giving-way.[50,52,60] The detection and proper treatment of these problems is critical, because failure to properly treat all of the abnormalities may result in a poor outcome. The patient will complain of a varus type of instability with LJO during stance phase and show either a neutral or valgus alignment. The abnormal LJO during stance phase is always greater than that detected on the varus stress test. The patient may demonstrate the abnormal LJO by producing a varus loading at the knee joint while standing.

Knees that fulfill the double or triple varus diagnosis criteria (varus osseous malalignment with increased LJO, external tibial rotation, varus recurvatum, and knee hyperextension [see Chapter 26])[47] require high tibial osteotomy (HTO) first, followed approximately 6 months later, with an appropriate PL reconstruction. In many instances, an ACL or PCL deficiency also exists, which is corrected at the time of the PL reconstruction.

There are different surgical options available for acute knee injuries, dislocated knees with multiple ligament ruptures, chronic knees, and revision knees. The decision-making process for determining the appropriate PL procedure is discussed in detail under "Operative Treatment of Acute Posterolateral Ruptures" and "Operative Treatment of Chronic Posterolateral Ruptures" later in this chapter.

CONTRAINDICATIONS

Contraindications to PL reconstruction are findings of less than 12 mm of absolute increased lateral tibiofemoral joint opening and less than 15 degrees of increased external tibial rotation. These findings are frequently noted in knees with associated varus osseous malalignment (double varus knees) that are candidates for HTO (see Chapter 26).[40]

Patients with varus malalignment who do not undergo HTO and have associated chronic insufficiency of the PL structures are not candidates for a PL procedure. Untreated varus osseous malalignment is a frequent cause of failure of PL reconstructions.[46] In many cases, a knee hyperextension gait abnormality also exists, which must be corrected before surgery with a specific gait retraining program described in Chapter 29.[50] Failure to correct a hyperextension gait abnormality places PL reconstructions at risk for failure owing to the excessively high tensile forces placed on the PL soft tissues with weight bearing after surgery. Gait retraining usually decreases abnormally high knee extension and adduction moments to normal values.[50]

Patients with a history of prior joint infection or who are obese (body mass index > 30) are not candidates for PL reconstruction. Patients with muscle atrophy of the lower extremity undergo preoperative rehabilitation before PL reconstruction.

Knees that demonstrate a loss of lateral tibiofemoral compartment joint space, with less than 2 mm remaining on 45-degree posteroanterior (PA) weight-bearing radiographs, are usually not candidates for PL reconstruction.

CRITICAL POINTS Contraindications

- <5-mm increased lateral tibiofemoral joint opening 20 degrees of flexion.
- <10 degrees increased external tibial rotation 30 degrees, 90 degrees flexion.
- Double varus knee, in which valgus osteotomy and subsequent adaption (decreased laxity) of posterolateral structures eliminate abnormal lateral joint opening and external tibial rotation.
- Triple varus knee without correction of varus malalignment.
- Prior joint infection.
- Patient noncompliant with rehabilitation, bracing, weight-bearing restrictions.
- Hyperextension gait abnormality with no preoperative gait retraining.
- Advanced joint arthritis, <2 mm remaining joint space.

CLINICAL EVALUATION

The PL structures are injured when excessive varus, external tibial rotation, and hyperextension forces are applied to the lower extremity. A blow to the anteromedial tibia during sports participation appears to be one of the most common injury mechanisms. These injuries frequently involve rupture of other knee ligament structures, complicating the diagnosis. An isolated complete PL rupture is rare because, usually, the injury is accompanied by an ACL or PCL rupture. In some cases, the PL structures are only partially disrupted and do not require surgical restoration. It is important to correctly determine the increases in LJO, external tibial rotation, and knee hyperextension of the injured knee (compared with the contralateral knee) preoperatively and intraoperatively. The decision of whether surgical restoration of the PL structures is indicated is based on the abnormal knee motion limits, joint subluxations, and the tissues disrupted.

One frequent patient presentation is a failed ACL or PCL reconstruction owing to untreated PL insufficiency. Another patient presentation is a chronic varus osseous malalignment and underlying ACL insufficiency in which, over time, interstitial stretching and slackening of the PL structures occurred.[40,47] In these cases, HTO unloads the PL soft tissues to the extent where physiologic remodeling and shortening may subsequently occur in some knees and a PL reconstruction is not required.[47]

A comprehensive physical examination is required, including assessment of knee flexion and extension, patellofemoral indices, tibiofemoral crepitus, tibiofemoral joint line pain, and gait abnormalities. Pain in the medial tibiofemoral compartment occurs owing to

CRITICAL POINTS Clinical Evaluation

History
- Common injury mechanism blow to anteromedial tibia causing excessive knee hyperextension, external tibial rotation, lateral tibiofemoral joint opening.
- Most posterolateral injuries occur with anterior cruciate ligament or posterior cruciate ligament ruptures.

Physical Examination
- Knee flexion, extension
- Joint effusion
- Patellofemoral (medial and lateral subluxation, Q-angle, crepitus, compression pain)
- Tibiofemoral crepitus, joint line pain, compression pain
- Recurvatum (standing, supine)
- Gait (severe hyperextension stance phase)
- Muscle strength

Tibiofemoral Rotation Dial Test
- Diagnosis of posterolateral injury is based on final position of the lateral tibial plateau.
- Subluxation of the medial and lateral tibial plateaus separately at 30 degrees, 90 degrees of knee flexion.
- Produce maximal external tibial rotation, determine change in position of medial and lateral tibial plateaus separately.
- Qualitatively determine if anterior or posterior subluxation occurred in each tibial plateau.

Diagnostic Clinical Tests
- External rotation recurvatum
- Lateral and medial tibiofemoral joint opening 5 degrees, 20 degrees of flexion
- Pivot shift, Lachman
- Reverse pivot shift
- Posterior drawer, 90 degrees of flexion
- KT-2000 20 degrees of flexion, 134 N

Radiographs
- Lateral, 30 degrees of flexion
- Posteroanterior, weight-bearing, 45 degrees of flexion
- Patellofemoral axial
- Lateral stress, neutral tibial rotation select knees
- Posterior cruciate ligament ruptures: posterior stress lateral, 90 degrees of flexion, neutral tibial rotation
- Varus malalignment: full standing radiographs, mechanical axis and weight-bearing line

Cincinnati Knee Rating System
- Sports Activity and Function Form
- Occupational Rating Form
- Symptom Rating Form

increased compressive forces related to varus osseous malalignment. Pain in the PL soft tissues may occur from increased soft tissue tensile forces caused by a varus thrusting gait pattern. The abnormal knee hyperextension involves increased extension in the sagittal plane and is often accompanied by a varus alignment in the coronal plane, which has been described as a varus recurvatum alignment. Together with a varus osseous malalignment, this is referred to as a *triple varus knee* (see Chapter 26). Patients with chronic PL insufficiency have varying amounts of altered gait mechanics and knee hyperextension. Some individuals may present with a markedly abnormal gait that is severely disabling and limits ambulation. Other patients may have a less noticeable alteration because the abnormal knee hyperextension occurs only after prolonged walking and muscle fatigue. The abnormal gait pattern is characterized by excessive knee hyperextension during the stance phase, which does respond to gait retraining that initiates normal stance phase flexion (see Chapter 29). Subjective complaints of giving-way during routine daily activities, along with severe quadriceps atrophy, often accompany this gait abnormality.

The surgeon must determine all of the abnormal translations and rotations in the knee joint. The ligament injuries that result in knee hyperextension and varus recurvatum frequently involve not only the PL structures, but also other ligament and capsular structures. The biomechanic and kinematic studies that form the basis for the interpretation and diagnosis of the manual stress tests are described in Chapter 15.

The increases in LJO and external tibial rotation shown in Table 17-1 are only approximations of what would be expected with clinical injury to the PL structures. Importantly, an increase of only a few millimeters (2-5 mm) in LJO occurs with complete rupture of the FCL, whereas an increase of 5 to 9 mm occurs with complete rupture of all the PL structures (FCL, PMTL, and PFL). These values are based on biomechanic studies discussed in Chapter 15. LaPrade and colleagues[24] conducted a cadaveric study in which lateral stress radiography was applied at 12 N-m (on an experimental apparatus) and the increase in LJO over the intact state was compared with that measured during a clinician-applied load after an isolated FCL rupture and a combined FCL, PMTL, and PFL rupture. Compared with the intact state, LJO induced by the clinician-applied load increased by 2.7 mm (isolated FCL rupture) and 4.0 mm (combined PL rupture). However, the mean values showed a wide standard deviation and variation among specimens, making extrapolation to the clinical setting difficult. In addition, the lateral joint space measurement showed wide confidence intervals (CI). For an isolated FCL rupture, the mean lateral gap distance was 10.99 mm (CI, 7.8-14.3 mm) and for the combined PL rupture, the mean distance was 12.2 mm (CI, 9.3-15.2 mm). This amount of overlap indicates that it would not be possible to accurately separate a FCL rupture alone from a combined PL injury. The measurements are important and useful in providing the clinician with a baseline in interpreting lateral stress radiographs. The gap test is based on the joint separation between articular cartilage seen at arthroscopy, and not the tibiofemoral separation on a stress radiograph. Even so, the measurements are somewhat equivalent as to the increase in the amount of millimeters with PL injuries. For example, Figure 17-2 shows an approximate normal lateral gap of 4 mm at the closest point of the lateral compartment at arthroscopy. An increase of only 6 mm results in 10 mm of absolute opening at the closest point or 12 mm at the periphery, which is viewed as a positive gap test and indicative of injury to the PL structures. Fortunately in most knees, these are the lesser values and it is more common that the lateral gap exceeds these measurements, indicating that concurrent PL reconstruction is necessary.

An increase in external tibial rotation may occur with anterior subluxation of the medial tibial plateau, posterior subluxation of the lateral tibial plateau, or a combination of both subluxations. The dial test, which the senior author (F.R.N.) published,[54] allows a diagnosis of tibial rotational subluxations of the medial and lateral tibiofemoral compartments at 30 and 90 degrees of knee flexion (see Table 17-1). Other variations of this test have been described.[7,51,65]

Text continued on p. 534

TABLE 17-1 Comprehensive Knee Examination

Examination	Technique	Illustration	Grading	Significance
Dial test 30 degrees	Supine position, palpate anterior tibial prominence, medial and lateral joint, maximum external rotation, posterior position, lateral tibia (PL) subluxation, anterior position medial tibia (anteromedial subluxation).		Compare external rotation between knees.	External tibial rotation with PL subluxation. Increase 3-5 degrees FCL tear. Increase 6-10 degrees FCL tear, partial PMTL. Increase ≥15 degrees FCL, PMTL, PLC.
Dial test 90 degrees	Maximum external tibial rotation. Determine PL tibial subluxation.		Compare external rotation between knees.	Increase at 30 and 90 degrees means PCL and PLC injury. With PCL tear, degrees of external rotation difficult to estimate owing to posterior tibial position.
PL external rotation test	Knee at 90 degrees, posterior and external rotation loading on tibia, palpate posterior subluxation lateral tibiofemoral joint.		Qualitative PL tibial subluxation 90 degrees (less accurate at 30 degrees of flexion).	Similar to dial test but foot held stationary. Dial test allows tibia to externally rotate fully, providing better estimate of increased tibial rotation. PL subluxation 90 degrees, combined PCL, PLC injury.
Posterior drawer test	Knee at 90 degrees position, posterior load proximal tibia, no tibial rotation. Palpate medial tibiofemoral step-off.		Partial PCL: increase 0-9 mm translation; complete PCL tear: increase >10 mm translation.	Stress radiography more accurate. Increases >10 mm indicate secondary restraints torn or physiologic slack (combined injury).

TABLE 17-1 **Comprehensive Knee Examination—cont'd**

Examination	Technique	Illustration	Grading	Significance
Quadriceps active test	Knee position at 70-90 degrees. Foot stabilized by examiner, patient activates quadriceps by pushing foot against table or attempting to extend knee.		Qualitative. Observe, palpate tibiofemoral position.	Confirms posterior tibial subluxation, PCL injury at resting position. Quadriceps contraction produces anterior translation knee position ≥70 degrees.
Lachman (anterior drawer, 30 degrees of flexion)	Anterior load proximal tibia.		Observe anterior translation tibia; compare with opposite knee.	Estimate increase translation in millimeters. Soft endpoint, ACL not resisting anterior translation, indicates ACL tear. Increase 3- to 5-mm ACL tear. >5 mm ACL plus secondary restraints.
Pivot shift	Knee position 10-30 degrees of flexion. Anterior load tibia, gentle internal tibial rotation (subluxation) followed by posterior load, gentle external rotation (reduction).		Qualitative. Grade: I slipping. II thud, clunk with reduction. III gross anterior subluxation lateral tibiofemoral joint, anterior impingement tibia limits reduction event.	Grade I physiologic laxity, no or partial ACL tear. II ACL tear. Grade III ACL tear plus secondary restraints lax.
Reverse pivot shift test	Similar loading as pivot shift.		PL subluxation with external rotation confused for reduction in pivot shift. No abnormal anterior tibial subluxation.	Observe obvious PL tibial subluxation with posterior and external rotation loading. Dial test more accurate.
Varus stress testing	Thigh supported on examination table. Knee position 0 degree, 30 degrees. Varus load with no external-internal tibial rotation. Palpate lateral joint line opening.		Subtle 30 degrees increase LJO. 2-4 mm complete FCL tear, further increase LJO with PLC injury.	Stress radiography more accurate. 30 degrees of flexion. Increase 2- to 4-mm FCL tear. Increase 5- to 9-mm complete PLC tear (also perform valgus stress test).

Continued

TABLE 17-1 **Comprehensive Knee Examination—cont'd**

Examination	Technique	Illustration	Grading	Significance
External rotation recurvatum test	Grasp and hold both feet above table, allow gravity knee hyperextension.		Qualitative. Tibia externally rotates, varus position caused by PL joint opening, knee.	Hyperextension, indicates PLC injury, >10 degrees frequently associated ligament injury (ACL, PCL).
Standing recurvatum test	Patient stands, feet together pushes knees backward into hyperextension, compare knees.		Qualitative, observe varus hyperextension position (can be measured with goniometer). Increased loading over supine recurvatum test brings out deformity.	10 degrees hyperextension with varus alignment PLC disruption, lateral, PL joint abnormal opening, often combined PLC, ACL tear, confirm with other tests.
Standing frontal alignment	Standing 0-5 degrees of flexion. Avoid hyperextension.		Confirm varus alignment. Hip-knee-ankle radiographs 0-5 degrees of flexion.	Classify primary, double, triple varus based on all tests (see Chapter 26).

TABLE 17-1 Comprehensive Knee Examination—cont'd

Examination	Technique	Illustration	Grading	Significance
Knee hyperextension gait or varus thrust	Observe gait walking to and from examiner.		Qualitative. Knee goes into hyperextension on stance phase. Knee has varus thrust without hyperextension.	Two hyperextension patterns (see Chapter 29). Forward trunk position, loss of quadriceps control, ankle dorsiflexion push-off, requires gait retraining. Varus thrust increases medial compartment loads and tensile forces lateral ligaments, osteotomy may be required.
Range of motion	Perform passive flexion-extension.	 	Normal 3-0-135 degrees. Hyperextension to neutral to flexion	10 degrees hyperextension posterior capsule possible ACL or PCL injury. ≥15 degrees multiple ligament injury.
Effusion, soft tissue swelling, pain	Palpate joint for effusion, tenderness, meniscus, ligament attachments.		Qualitative. Complex examination necessary + meniscus tests.	Partial to complete tears PLC. FCL local tenderness, pain varus, dial tests.
Patellofemoral examination	Comprehensive examination. All tests. Alignment, PF crepitus, medial/ lateral translation, patella height.		See Chapter 35.	Increased external tibial rotation 30 degrees, PLC tear, produces abnormal lateral shifting tibial tubercle, increases Q-angle.

TABLE 17-1 Comprehensive Knee Examination—cont'd

Examination	Technique	Illustration	Grading	Significance
Neurovascular examination	Complete examination. Both lower extremities, PT, DP pulses, lower extremity muscle function.			Peroneal nerve injuries associated with severe PLC disruption (10%-30%). Arterial studies indicated multiple ligament injuries, dislocations.

ACL, Anterior cruciate ligament; *DP*, dorsalis pedis; *FCL*, fibular collateral ligament; *LJO*, lateral joint opening; *PCL*, posterior cruciate ligament; *PF*, patellofemoral; *PL*, posterolateral; *PLC*, posterolateral capsule; *PMTL*, popliteus muscle-tendon-ligament; *PT*, posterior tibial.

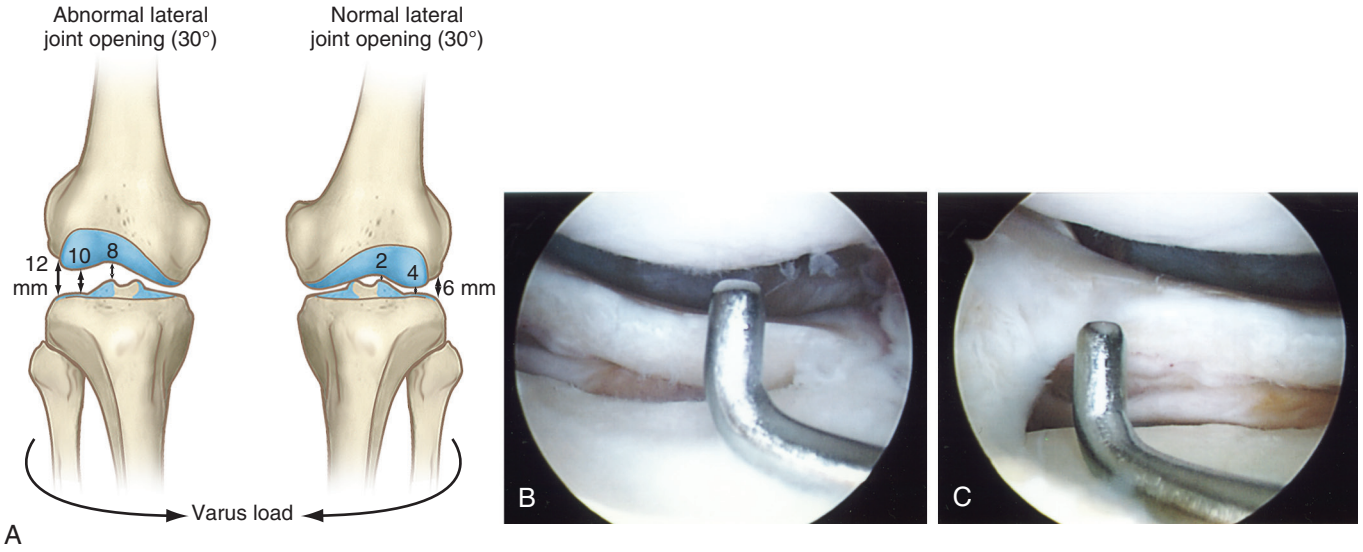

FIG 17-2 The gap test. **A,** The amount of lateral tibiofemoral joint opening is measured with the knee at 25 degrees of flexion. Knees with insufficiency of the posterolateral structures will demonstrate 12 mm of joint opening at the periphery of the lateral tibiofemoral compartment, 10 mm at the midportion of the compartment, and 8 mm at the innermost medial edge. **B,** Normal gap test. **C,** Abnormal gap test.

The position of the medial and lateral tibial plateau is assessed at the starting position (neutral tibial rotation) with the knee flexed to 30 and 90 degrees and at the final position with the tibia in maximal external rotation. The examiner palpates the position of the medial and lateral tibial plateau, which is compared with the normal knee to assess whether a subluxation (anterior or posterior) of the medial or lateral tibial plateau is present. An increase in internal tibial rotation occurs with both lateral ligament, medial ligament, and PCL disruption (see Chapter 15). The axis of tibial rotation is observed in the involved knee and compared with the normal knee to detect a shift in the medial or lateral tibiofemoral compartment during tibial rotation. It is not recommended that the dial test be performed in the prone position because the tibiofemoral joint cannot be accurately palpated to distinguish an anteromedial from a PL tibial subluxation.

It is not possible to clinically determine the actual millimeters of translation of the medial and lateral tibial plateaus in reference to the femoral condyle. A qualitative determination is made of the anterior or posterior subluxation of the medial or lateral tibiofemoral joint.

With PL injuries, there is an abnormal lateral deviation of the tibial tubercle in the dial test compared with the opposite knee.

The use of the dial test in knees with PCL ruptures requires maintenance of a normal anatomic tibiofemoral position. This is accomplished by applying an anterior translation, loading the ACL in both limbs, during the external tibial rotation. It is still necessary to use the supine position so that the examiner can palpate the tibiofemoral position.[61] The dial test is less accurate with a PCL rupture because it is difficult to compare limbs, and other tests to be described (LJO, gap test at arthroscopy, varus recurvatum) for the integrity of the PL structures need to be carefully assessed.

When a posterior subluxation of the lateral tibial plateau is positively identified by the tibiofemoral rotation test, additional tests must be conducted to determine the integrity of other ligament structures. The amount of LJO at 5 and 20 degrees of knee flexion should be determined to further assess the integrity of the FCL and other secondary ligament restraints. The posterior tibial subluxation of the central tibial and medial tibiofemoral joint determines the amount of increased translation because of a PCL injury, which adds to the maximum posterior subluxation to the lateral compartment with external tibial rotation.

The presence of a varus recurvatum in both the supine and standing positions must be carefully assessed. Often, the varus recurvatum reaches its maximum position when the patient is standing and asked to maximally hyperextend both knees.

The appropriate tests to determine the integrity of the ACL and PCL are performed, including KT-2000 (MEDmetric) arthrometer testing at 20 degrees of flexion (134 N) to quantify total anteroposterior (AP) displacement. The pivot shift test is recorded on a scale of 0 to III (grade 0, no pivot shift; grade I, slip or glide; grade II, jerk or clunk; grade III, gross subluxation with impingement of the PL aspect of the tibial plateau against the femoral condyle). A misdiagnosis of a positive pivot shift test may occur with PL injuries as the lateral tibial plateau is brought to a reduced position (starting from a posterior subluxated position) with knee extension and then posteriorly subluxates with knee flexion (reverse pivot shift test). The medial posterior tibiofemoral step-off on the posterior drawer test is done at 90 degrees of flexion.

Radiographs taken during the initial examination include AP, lateral at 30 degrees of knee flexion, weight-bearing PA at 45 degrees of knee flexion, and patellofemoral axial views. Lateral stress radiographs may be required of both knees (20 degrees of flexion, neutral tibial rotation, and 67-N varus force). A comparison is made of the millimeters of lateral tibiofemoral compartment opening between knees.

A lateral radiograph is used to determine the approximate length required for FCL anatomic grafts. The distance from the anatomic femoral insertion site to the anatomic fibular insertion site is measured and adjusted for magnification. A measurement of the patellar tendon length is also made when a bone-patellar tendon-bone (B-PT-B) FCL autograft is planned; however, in most knees, a B-PT-B allograft is used, as will be discussed.

Posterior stress radiographs are obtained in patients with PCL ruptures, especially those in which the distinction of a partial versus complete PCL deficiency is difficult to determine on clinical examination.[15] A lateral PCL stress radiograph is taken of each knee at 90 degrees of flexion. The limb is placed in neutral rotation with the tibia unconstrained and the quadriceps relaxed, and 89-N force applied to the proximal tibia. Measurement is made of the millimeters of posterior tibial translation in both knees. Knees with 10 mm or more of increased posterior tibial translation are considered candidates for PCL reconstruction.

Full standing radiographs of both lower extremities, from the femoral heads to the ankle joints, are done in knees with varus lower extremity alignment. The mechanical axis and weight-bearing line are measured to determine whether HTO is indicated.[11]

Patients complete questionnaires and are interviewed for the assessment of symptoms, functional limitations, sports and occupational activity levels, and patient perception of the overall knee condition according to the Cincinnati Knee Rating System (CKRS; see Chapter 41).[2]

CLASSIFICATION AND TREATMENT OF PARTIAL TO COMPLETE PL INJURIES

The classification and treatment of first-, second-, and third-degree acute PL injuries are detailed in Table 17-2. It is important to diagnose partial tears of the PL structures, with a mild to moderate increase in LJO and external tibial rotation, to allow protection and maintain lateral tibiofemoral joint closure in the initial 3 weeks to allow "stick-down" and healing of lateral soft tissues. This is a program similar to that recommended for medial ligament ruptures (see Chapter 19).

PREOPERATIVE PLANNING: TIMING OF SURGERY

Acute Injuries

There is a distinct advantage for repairing completely disrupted PL structures and meniscal attachments in acute injuries (Fig. 17-3). At the time of surgery, extensive disruption of these structures is observed. Careful dissection is required to identify anatomic tissue planes and maintain an intact vascular and neural supply. The so-called golden period to perform an acute surgical repair is within 7 to 14 days of the injury. After this time, scar tissue will obliterate tissue planes and make the dissection and repair difficult.

A lower extremity venous ultrasound is obtained before surgery in acute multiligament knee injuries that have swelling and soft tissue damage to detect occult venous thrombosis that requires urgent treatment and contraindicates surgery. An initial delay in surgery for 5 to 7 days allows for observation of the neurovascular status, soft tissue swelling, skin integrity, and some clearing of hemorrhage in soft tissues in the injured extremity.

During this time, the lower extremity is supported in a soft-hinged full-leg brace in extension with a well-padded compression dressing. In knees with extensive damage to the PL structures and PCL, a bivalved cylinder cast with a posterior plaster shell and posterior foam calf pad may be required to provide added stability and prevent posterior tibial subluxation. Reduction of the tibiofemoral joint is verified by a lateral radiograph. Lower limb elevation, ice, and compression are important. The physical therapist initiates early protected knee motion, patellar mobilization, active quadriceps function, and electrical muscle stimulation. Dislocated knees scheduled for surgery require vascular consultation, ankle/brachial studies (ankle/brachial index ≥90%), and possible arteriography to exclude arterial injuries, even when intact peripheral pulses are present.

Contraindications to acute surgical repair are excessive soft tissue swelling, hemorrhage, and edema that are frequently present in dislocated knees with multiple ligament ruptures. The operative procedure adds to the injury by increasing edema and soft tissue swelling, risk of infection, vascular problems (including compartment syndromes), and skin flap necrosis. In these cases, it is preferable to treat the acute injury and perform ligament reconstructive procedures later after tissue swelling is resolved and muscle function and knee motion have been restored.

In addition, there is a significant incidence of knee arthrofibrosis after acute surgical treatment of knee dislocations, which is lessened

TABLE 17-2 Diagnosis and Classification of Acute Posterolateral Injuries

	First Degree	Second Degree	Third Degree*		
Anatomic lesion	Minor tearing fibers	Partial tears, one third to two third fibers	FCL tear[†]	FCL tear, partial tear PMTL, PL capsule	FCL tear, PMTL tear, PL capsule tear
Signs	Minor tenderness and swelling	Tenderness and swelling lateral tissues		Tenderness and swelling lateral tissues	
Increase in lateral joint opening[‡]					
30 degrees	None	None	2-3 mm	2-5 mm	5-9 mm
0 degree	None	None	None	None	3-5 mm
Increase in external tibial rotation (dial test, 30 degrees)[‡]	None	None	3-5 degrees	6-10 degrees	15 degrees
Treatment	Progress per symptoms, no crutches	Progress per symptoms, soft support brace	Bivalved cylinder cast 3 wk ROM 0-90 degrees 2 wk Support brace 3-6 week Wean crutches 3-6 wk		Operative repair, reconstruction; usually associated ACL, PCL

*Avulsion FCL, popliteus tendon: surgical indication to reattach.
[†]Even though FCL shows complete tear, adjacent lateral tissues maintain ligament continuity for healing. Bivalved cylinder cast with protected motion, maintain lateral tibiofemoral joint closure.
[‡]See Chapter 15. Increases related to degrees of knee flexion, minor opening may be less under clinical conditions with lower joint loading.
ACL, Anterior cruciate ligament; *FCL*, fibular collateral ligament; *PCL*, posterior cruciate ligament; *PL*, posterolateral; *PMTL*, popliteus muscle-tendon-ligament; *ROM*, range of motion.

CRITICAL POINTS Preoperative Planning

Acute Injuries
- Golden period acute surgical repair: 7-14 days after injury.
- Lower extremity venous ultrasound, vascular consult for multiple ligament ruptures.
- Delay surgery 5-7 days, observe neurovascular status, soft tissue swelling, skin integrity.
- Soft hinged full-leg brace, well-padded compression dressing.
- PCL rupture: bivalved cast with posterior plaster shell, posterior calf pad.
- Verify tibiofemoral reduction with lateral radiograph in multiligament injuries.
- MRI for location of major ligament disruptions.
- Protected knee motion, patellar mobilization, isometrics.
- Contraindications to acute surgery in dislocated knees: excessive soft tissue swelling, hemorrhage, edema. Delay reconstruction until swelling resolved, muscle function and knee motion restored.

Chronic Injuries
- Muscle atrophy requires preoperative rehabilitation.
- Hyperextension gait abnormality requires gait-retraining program before PL reconstruction.
- Varus osseous malalignment requires osteotomy before PL reconstruction.
- Absent lateral meniscus, early tibiofemoral arthritis, consider lateral meniscus transplant.

Cruciate Graft Reconstruction
- Ensure B-PT-B, Achilles tendon allografts available.
- Determine appropriate grafts for ACL or PCL reconstruction.

ACL, Anterior cruciate ligament; *B-PT-B*, bone-patellar tendon-bone; *MRI*, magnetic resonance imaging; *PCL*, posterior cruciate ligament; *PL*, posterolateral.

with a staged approach. In our experience, the majority of multiligament disruptions in dislocated knees are not candidates for acute surgical procedures. A delay in surgical reconstruction results in a decreased incidence of knee arthrofibrosis and markedly improves surgical outcomes. Other obvious contraindications include open wounds and skin abrasions.

Magnetic resonance imaging (MRI) provides important information regarding ligament ruptures, articular cartilage damage, and meniscus tears. Frequently, the sites of rupture to the FCL, popliteus muscle and tendon, PFL, and meniscal attachments may be identified before surgery. One note of caution is the edema and swelling in the PL tissues leads to a conclusion of greater tissue damage and disruption than what is actually encountered at surgery.

Chronic Injuries

Patients with chronic knee injuries often present with severe lower limb muscle atrophy requiring months of preoperative rehabilitation. Patients with a hyperextension gait abnormality must complete a gait retraining program[50] described in detail in Chapter 29. This program is done in addition to lower extremity muscle strengthening exercises. In our experience, patients will convert to a more normal gait pattern after 4 to 6 weeks of training.

Varus osseous malalignment must be corrected before chronic PL reconstruction, as described previously. Failure to address varus malalignment will greatly increase the risk of failure of any PL procedure (Fig. 17-4). In anatomic PL reconstructions, the ligament surgery is staged after healing of the HTO. The indications for the various PL procedures are described in detail under the "Operative Treatment of Acute Posterolateral Ruptures" and "Operative Treatment of Chronic Posterolateral Ruptures" sections.

Patients who have undergone prior lateral meniscectomy and who demonstrate early tibiofemoral arthritis are considered for a staged lateral meniscus transplantation after the PL reconstruction.[48]

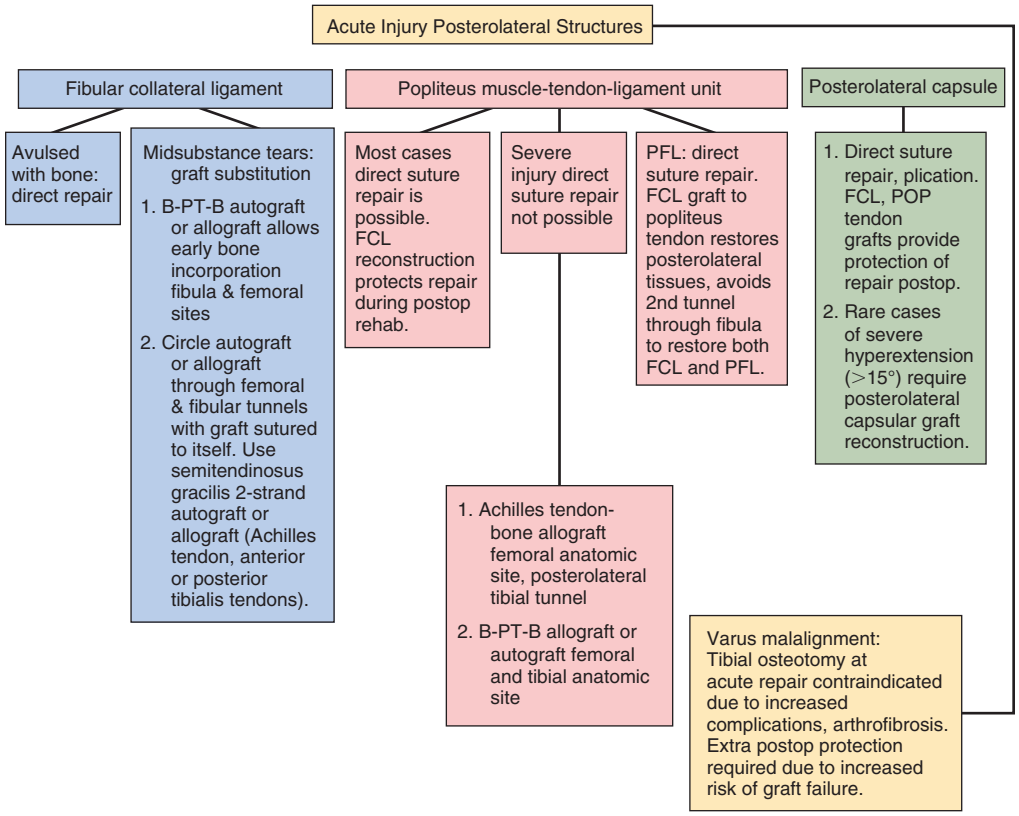

FIG 17-3 Algorithm for treatment of acute injuries to the posterolateral structures. *B-PT-B*, Bone-patellar tendon-bone; *FCL*, fibular collateral ligament; *PFL*, popliteofibular ligament; *POP*, popliteus.

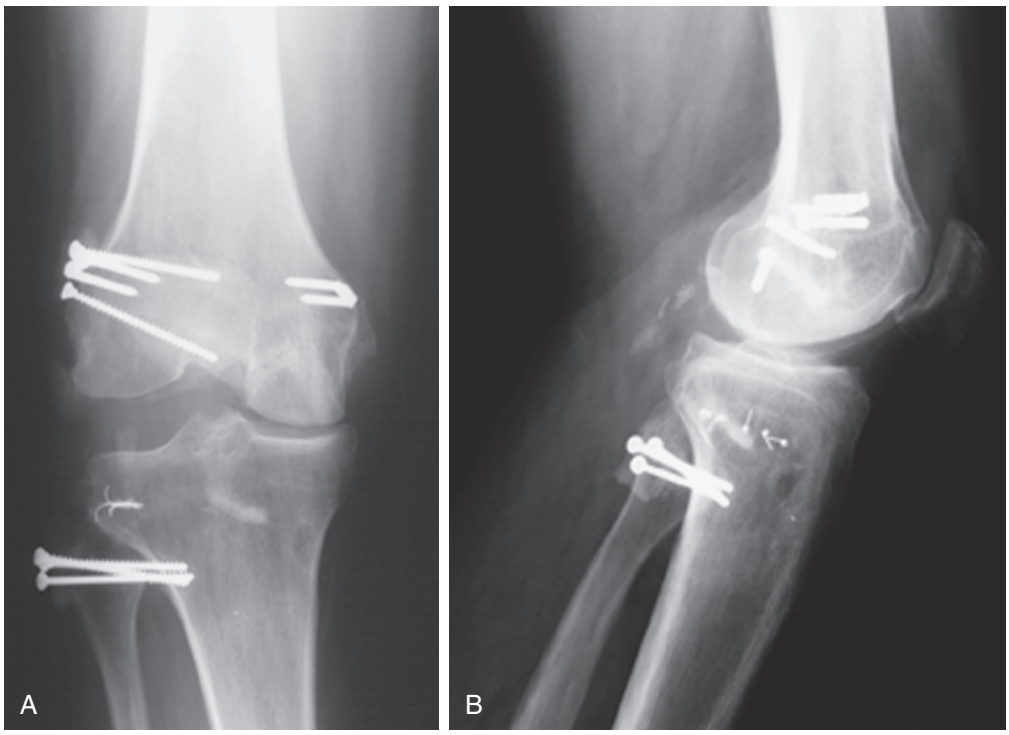

FIG 17-4 Standing anteroposterior; **(A)** and lateral **(B)** radiographs of a 28-year-old man referred to our center 14 months after failure of an acute repair of the posterolateral structures and posterior cruciate ligament allograft reconstruction. The patient had underlying varus osseous malalignment, which likely was a factor in the failure of the ligament reconstructions. This malalignment requires correction before revision surgery. (From Noyes FR, Barber-Westin SD. Posterior cruciate ligament revision reconstruction. Part 1: causes of surgical failure in 52 consecutive operations. *Am J Sports Med.* 2005;33:646-54.)

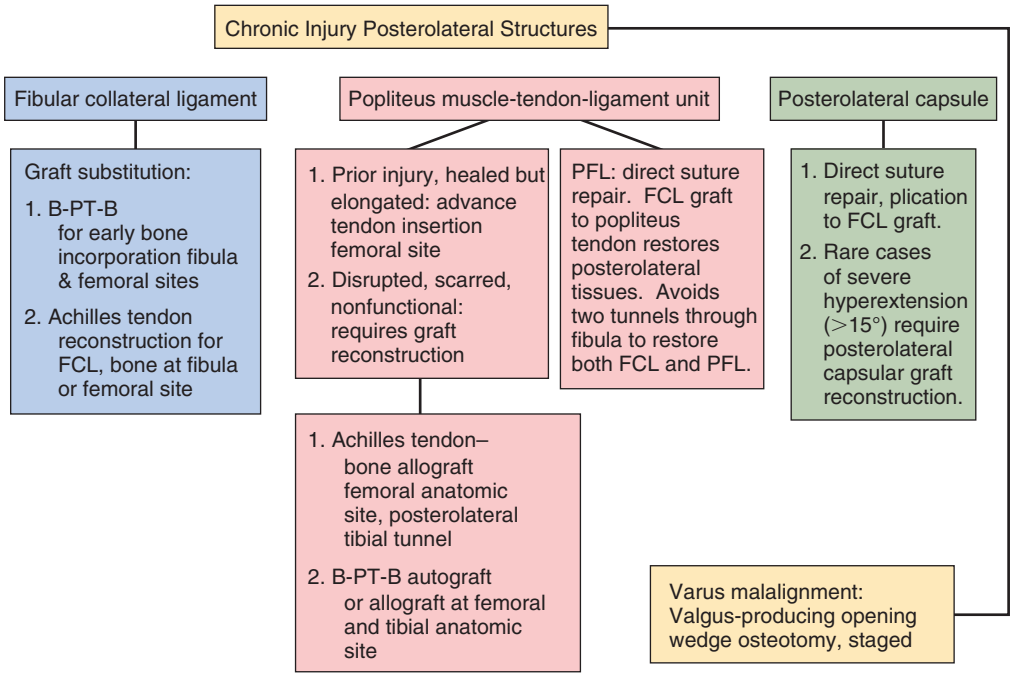

FIG 17-5 Algorithm for treatment of chronic injuries to the posterolateral structures. *B-PT-B*, bone-patellar tendon-bone; *FCL*, fibular collateral ligament; *PFL*, popliteofibular ligament.

Cruciate Graft Reconstruction

The majority of patients who undergo PL reconstruction require a concomitant ACL or PCL reconstruction (Fig. 17-5). The appropriate grafts for the cruciate procedures should be determined; autogenous tissues with bony fixation are preferred. However, the surgeon should ensure that B-PT-B and Achilles tendon-bone (AT-B) allografts are available the day of surgery. These will be required if autogenous tissue is unavailable or not suitable for the PL or cruciate procedures.

INTRAOPERATIVE EVALUATION

All knee ligament tests are performed after the induction of anesthesia in both the injured and contralateral limbs. The amount of increased anterior tibial translation, posterior tibial translation, LJO, and external tibial rotation is documented. A thorough arthroscopic examination is conducted, documenting articular cartilage surface abnormalities (see Chapter 44) and the condition of the menisci.[53]

The gap test is done during the arthroscopic examination.[47] The knee is flexed to 30 degrees and a varus load is applied. A calibrated nerve hook is used to measure the amount of lateral tibiofemoral compartment opening (see Fig. 17-2). Knees with 12 mm or more of joint opening at the periphery of the lateral tibiofemoral compartment require a PL reconstructive procedure.

In knees that undergo ACL reconstruction, the millimeters of joint opening at the intercondylar area at the site of the ACL graft is the critical distance in the gap test. Increases in LJO will occur postoperatively, allowing increases in ACL graft length. This space is normally 3 to 5 mm under varus loading.

Following the surgical exposure, the FCL and its fibular head and femoral attachment sites, the PMTL, PL capsule, and PFL are inspected. The distal popliteal tibia and fibula attachments of the popliteus tendon are identified and inspected to determine the appropriate surgical treatment. All of the lateral and PL structures, including meniscus attachments, are inspected in a stepwise manner, to be described. The peroneal nerve is identified and protected at all times.

CRITICAL POINTS Intraoperative Evaluation

- Repeat all knee ligament tests under anesthesia, both limbs.
- Rate all articular cartilage surfaces for abnormalities, size of lesion
  - Normal
  - Grade 1, softening
  - Grade 2A, fissuring & fragmentation <50% depth of the articular surface
  - Grade 2B, fissuring & fragmentation >50% depth of the articular surface
  - Grade 3, subchondral bone exposed
- Gap test at arthroscopy
  - Knee 30 degrees of flexion
  - Varus load
  - Measure millimeters lateral tibiofemoral opening with calibrated nerve hook
- Surgical exposure inspection
  - Peroneal nerve
  - FCL, fibular and femoral attachments
  - PMTL, PLC, PFL
  - Popliteus muscle, tendon attachments
  - Meniscus attachments

FCL, Fibular collateral ligament; *PFL*, popliteofibular ligament; *PLC*, posterolateral complex; *PMTL*, popliteus muscle-tendon-ligament.

OPERATIVE TREATMENT OF ACUTE PL RUPTURES

Operative Setup and Patient Positioning

The patient is instructed to use a chlorhexidine soap scrub of the operative limb ("toes to groin") three days before and the morning of

surgery. Lower extremity hair is removed by clippers, not a shaver. Antibiotic infusion is begun one hour before surgery. A nonsteroidal antiinflammatory drug (NSAID) is given to the patient with a sip of water upon arriving on the morning of surgery (which is continued until the fifth postoperative day unless there are specific contraindications to the medicine). The use of an NSAID and a postoperative firm double-cotton, double-Ace compression dressing for 72 hours (cotton, Ace, cotton, Ace-layered dressing) has proven very effective in diminishing soft tissue swelling and is used in all knee surgery cases. In complex multiligament surgery, the antibiotic is repeated at 4 hours and continued for 24 hours. A urinary indwelling catheter is not used unless there are specific indications. The patient's urinary output and total fluids are carefully monitored during the procedure and in the recovery room. The knee skin area is initialed by the surgeon before entering the operating room, with a nurse observing the procedure. The identification process is repeated with all operative personnel with a "time out" before surgery to verify the knee undergoing surgery, procedure, allergies, antibiotic infusion, and special precautions that apply. All personnel provide verbal agreement.

The patient is placed supine on the operative table and appropriately padded. The knee portion of the table is flexed 20 degrees, and the table is tilted into a mild Trendelenburg position. A posterior thigh pad is placed behind the proximal thigh to suspend the knee joint at 20 to 30 degrees of knee flexion. There is no pressure exerted on the posterior popliteal space, allowing the posterior neurovascular tissues and popliteal tissues to drop posteriorly away from the operative approach. A common mistake is to place a posterior bolster in the popliteal space that pushes the neurovascular structures into the operative dissection.

In cases of acute dislocation, the entire lower limb is draped free to allow vascular checks of the anterior and posterior tibial pulses at the foot during the operative procedure.

An initial arthroscopic examination is performed under low-pressure conditions with a free or controlled open outflow to prevent fluid extravasation. The arthroscopic examination confirms damage to intraarticular structures and allows photographic documentation of the injury. If a leg holder is used, it is removed for the open surgery.

The tourniquet is placed at the proximal portion of the thigh with appropriate padding. The tourniquet is inflated (275 to 300 mm Hg) during the initial exploration of the ligamentous injury and identification of the common peroneal nerve (CPN). The tourniquet may often be deflated for the remainder of the procedure. The surgeon may elect to be seated, directly facing the lateral aspect of the knee, with a headlight for careful dissection of the lateral soft tissues including the CPN.

CRITICAL POINTS Operative Treatment of Acute Posterolateral Ruptures: Operative Setup and Patient Positioning

- "Time out" before surgery: verify signed knee at surgery, procedure, allergies, antibiotic infusion, and special precautions.
- Complete examination of knee joint under anesthesia, compare with opposite knee.
- Acute dislocation or questionable vascular status: drape entire lower limb free to check anterior and posterior tibial foot pulses during procedure.
- Arthroscopic examination under low pressures with free or controlled open outflow to prevent fluid extravasation. Confirm damage to intraarticular structures, photograph injury.
- Place tourniquet at proximal thigh with appropriate padding. Inflate (275-300 mm Hg) during initial exploration, identify common peroneal nerve. Deflate for surgical repair, reconstruction.

Identification of Ligament and Soft Tissue Rupture Pattern

A 10- to 12-cm skin incision is made in a straight line centered over the joint line and 1 cm posterior to the iliotibial band (ITB) attachment at the tibia (Fig. 17-6, *A*). After careful mobilization of the skin flaps, the ITB, biceps tendon, and lateral structures are encountered.

Before dissection of the lateral aspect of the knee, the location of the CPN must be identified. If the CPN cannot be easily palpated and its course determined, then it is necessary at this point to expose and identify the nerve along the entire lateral aspect of the knee. The CPN does not have to be removed from its anatomic bed but requires protection throughout the subsequent surgery.

In the majority of knees, the ITB will be intact or demonstrate only partial tearing. In select cases, the ITB will be completely disrupted at the joint line or avulsed off its tibial attachment at Gerdy's tubercle. If the ITB is intact, an incision is made along its posterior border and the ITB is elevated proximally to allow visualization of all of the underlying structures (see Fig. 17-6, *B*).

The lateral capsular tissues and meniscal attachments are the next structures visualized. A vertical incision is made into the anterior third of the capsule and extended to the lateral meniscus just anterior to the anterolateral ligament attachment. The popliteus tendon and meniscus attachments at the femoral popliteal recess are identified. Frequently, it is necessary to repair the anterior inferior meniscal fasciculi (Fig. 17-7) and tibial meniscal attachments. Careful varus stress is placed on the knee joint to allow inspection of the lateral meniscus attachments and tibiofemoral articular cartilage. In some knees, an additional anterior ITB incision is required for visualization of underlying anatomy (see Fig. 17-6, *C*).

The fibular head and attachments of the biceps femoris short and long head are the next structures visualized, which have been described in detail in Chapter 2. The two tendinous components (direct and anterior arms) and one of the fascial components (lateral aponeurotic expansion) make up the key portion of the long head anatomy. The other fascial components are the reflected arm and the anterior aponeurotic expansion.

CRITICAL POINTS Operative Treatment of Acute Posterolateral Ruptures: Identification of Ligament and Soft Tissue Rupture Pattern

- Skin incision straight line 10-12 cm in length, centered over joint line, 1 cm posterior to the ITB attachment at tibia.
- Intact ITB: incision along its posterior border to allow anterior displacement, visualize all underlying structures.
- Small bursa located superficial and anterolateral to distal portion of FCL: open to allow better exposure of distal FCL attachment.
- Proximal third of posterior capsule attaches to proximal portion of gastrocnemius muscle and fabellum.
- Interval between posterior capsule and gastrocnemius tendon entered just above fibula.
  - Exposes PL structures, popliteus muscle tibial attachments, popliteus muscle tendon junction, PFL, popliteus tendon attachment at the femur, fabellofibular ligament.

FCL, Fibular collateral ligament; *ITB*, iliotibial band; *PFL*, popliteofibular ligament; *PL*, posterolateral.

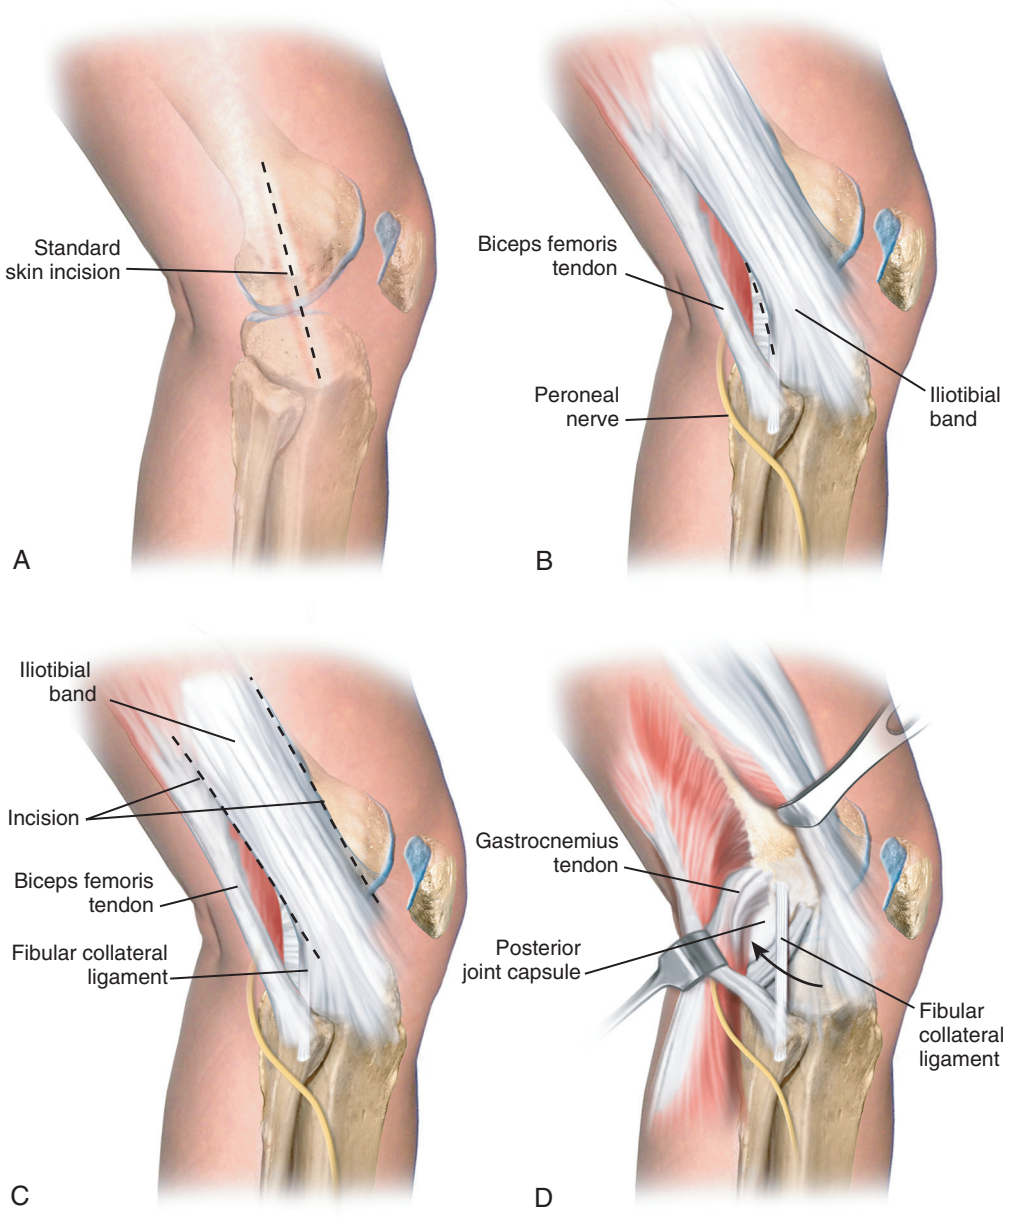

FIG 17-6 Posterolateral (PL) surgical technique. **A**, Site for the skin incision. **B,** Incision site in the interval between the posterior edge of the iliotibial band (ITB) and the anterior edge of the biceps tendon. **C,** In chronic cases with severe scarring, it may be necessary to add an anterior incision and displace the ITB posteriorly during the reconstructive procedure to allow better exposure. **D,** With the ITB retracted anteriorly, the interval between the lateral head of the gastrocnemius and the PL aspect of the capsule is opened bluntly, just proximal to the fibular head, without entering the joint capsule proximally.

The most proximal component is the reflected arm. It originates just proximal to the fibular head and ascends anteriorly to insert on the posterior edge of the ITB. The direct arm inserts onto the PL edge of the fibula just distal to the tip of the styloid. A portion of the anterior arm inserts onto the lateral aspect of the fibular head, and the rest continues distally just lateral to the FCL. Portions of the anterior arm ascend anteriorly, forming the lateral aponeurotic expansion that attach to the posterior and lateral aspect of the FCL. Here, a small bursa separates the anterior arm from the distal fourth of the FCL. The anterior arm forms the lateral wall of this bursa (see Fig. 2-15). This is an important surgical landmark, because a small horizontal incision can be made here, 1 cm proximal to the fibular head, to enter this bursa and locate the insertion of the FCL into the fibular head. The anterior arm then continues distally over the FCL, forming the anterior aponeurosis, which covers the anterior compartment of the leg. The primary areas of injury are tendon avulsions off of the fibula, which often have a major osseous component that can be repaired. In addition, the fascial extensions anteriorly and laterally are repaired.

The short head of the biceps courses just deep (or medial) and anterior to the long head tendon, sending a majority of its proximal muscular fibers to the long head tendon itself.[63] It has six distal attachments described in detail in Chapter 2. The most important attachments are those of the direct arm, the anterior arm, and the capsular arm.

The capsular arm originates just before the short head reaching the fibula and continues deep to the FCL to insert onto the PL knee capsule and fabella. Here the fibers of the capsular arm continue distally as the fabellofibular ligament. Just distal to the capsular arm, a capsulo-osseous layer forms a fascial confluence with the ITB (the biceps-capsulo-osseous iliotibial tract confluent). The direct arm of the short head inserts onto the fibular head just posterior and proximal to the direct arm of the long head tendon. The anterior arm then continues medial or deep to the FCL, partially blends with the anterior tibiofibular ligament, and inserts onto the tibia 1 cm posterior to Gerdy's tubercle. This site is also the attachment of the mid-third lateral knee capsule. The lateral aponeurotic expansion of the short head inserts onto the medial aspect of the FCL. The FCL may be torn at its femoral attachment or within its substance or avulsed along with the biceps attachment at the fibula.

Proceeding posteriorly, the next structure encountered is the lateral gastrocnemius muscle tendinous attachment to the femur. The proximal third of the posterior capsule attaches to the proximal portion of the gastrocnemius muscle and fabellum (osseous or cartilaginous analogue).

The interval between the posterior capsule and the gastrocnemius tendon is entered just above the fibula, similar to the exposure for a lateral meniscus repair. This exposes the popliteus muscle tibial attachments, popliteus muscle-tendon junction, PFL, popliteus tendon attachment at the femur, and fabellofibular ligament (see Fig. 17-6, *D*).

In dissection studies, LaPrade and coworkers[23] described a fabellum (osseous or cartilaginous) present in all specimens. This structure forms an attachment for the oblique popliteal ligament and fabellofibular ligament, which along with the posterior capsule, are important restraints for limiting knee hyperextension. Although individual capsular components and structures are difficult to discern with extensive capsular ruptures, it is important to repair disrupted posterior capsular tissues after completion of the initial dissection.

Common Peroneal Nerve Identification

It is important at the initial stages of the dissection to palpate and determine the location of the CPN. To expose the CPN, it is safest to begin in the proximal aspect of the operative exposure. A large retractor is used to elevate the muscular portion of the biceps femoris, placing the fascial tissues beneath the biceps muscle under gentle tension. This gentle upward displacement of the biceps muscle and vastus lateralis muscle is key to visualize and dissect the CPN, because the normal curviform undulations are removed and the CPN assumes a straighter appearance (Fig. 17-8). The investing crural fascia is incised over the CPN to the fibula.

The CPN and its branches are not removed from their normal anatomic position to avoid damaging the delicate blood supply, particularly in the region where the CPN approaches and then passes around the fibular neck. Kadiyala and associates[18] reported measurements in cadaveric specimens of the blood supply to the CPN in the popliteal fossa and fibular neck region. These investigators hypothesized that the susceptibility of the CPN to injury or lack of a response to operative treatment when injured may be related to deficiencies in intraneural and extraneural vascular supply and anastomoses.

The most common source of blood supply to the proximal portion of the CPN is a direct branch of the popliteal artery. This branch divides into proximal and distal anastomotic vessels that run in the connective tissue sheath of the nerve and anastomoses with the anterior recurrent tibial artery. The vessels, located in the epineurium, give rise to many small vessels of fine caliber, which extend 20 to 30 mm within the substance of CPN. It is important not to disturb this blood supply. Kadiyala and associates[18] noted that the blood supply of the CPN was somewhat sparse with poor vascularization. A connection of

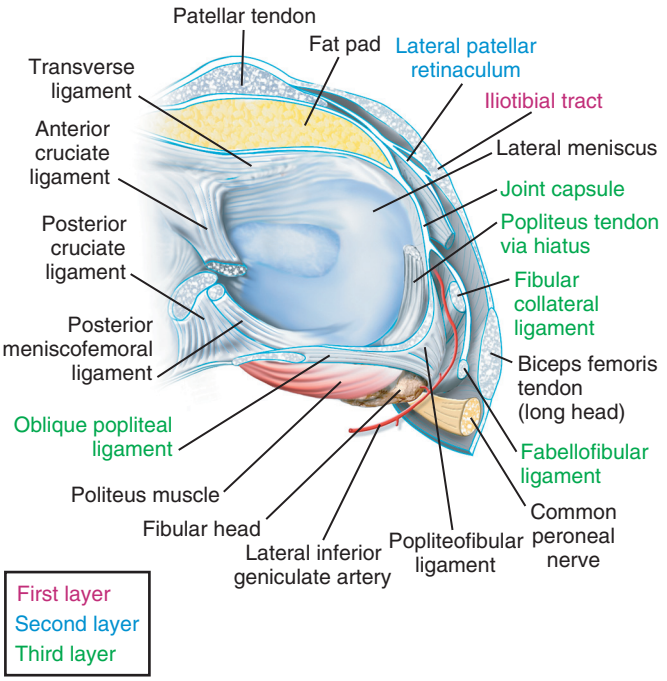

FIG 17-7 Illustration of the popliteus tendon and its surrounding popliteomeniscal fascicles and lateral meniscus attachments that are frequently disrupted, requiring repair.

CRITICAL POINTS Operative Treatment of Acute Posterolateral Ruptures: Common Peroneal Nerve Identification

- Initial dissection: proximal aspect operative exposure, palpate, determine location common peroneal nerve (CPN).
- Gently displace, elevate biceps muscle to visualize, dissect fascial covering over CPN.
- CPN and its branches are not removed from normal anatomic position to avoid damaging delicate blood supply.
- Most common source of blood supply to proximal portion of CPN from direct branch popliteal artery. Branch divides into proximal and distal anastomotic vessels.
- The vessels, located in the epineurium, give rise to many small vessels of fine caliber within CPN. Do not disturb this blood supply.
- Gerdy's safe zone: area where CPN and anterior recurrent branch define an arc with an average radius of 45 mm.
- Region advantageous for surgical exploration, damage to peroneal nerve and its branches avoided.
- In cases of partial to complete peroneal nerve injury, avoid added trauma to neural tissues.
- CPN passage into the lateral and anterolateral compartment at the entrance of the peroneal longus muscle at the fibular neck potential area for nerve compression. Requires identification, division of variant fascial tissue bands. Further CPN dissection avoided.

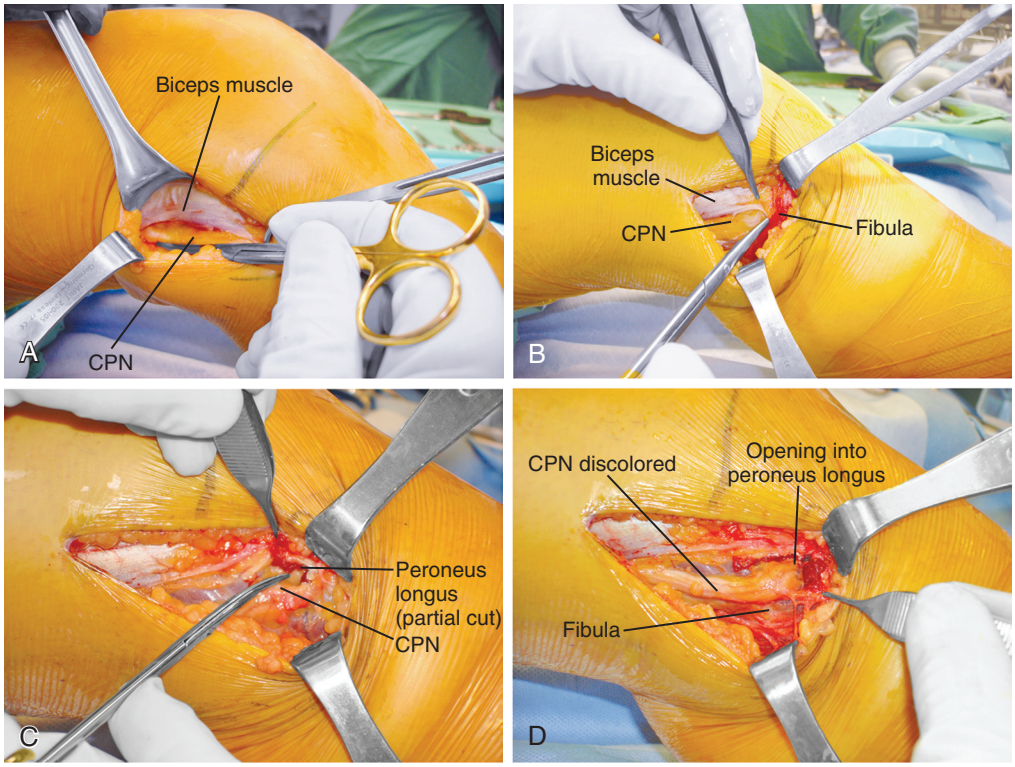

FIG 17-8 Exposure of the common peroneal nerve (CPN). **A,** Proximal exposure of the CPN inferior to the long head of the biceps tendon. **B,** The superficial fascia over the peroneus longus is incised. **C,** The peroneus longus muscle at the fibular neck is partially incised adjacent to the CPN. **D,** Complete exposure of the CPN entering into the anterolateral compartment. In this knee, the CPN is shown to be distinctly abnormal and edematous at this site. The CPN is not displaced from its normal anatomic site to protect the vascular supply.

the vasa nervorum was not found from the geniculate arteries, but occasional contributions from muscular branches were recognized (Fig. 17-9).

Bottomley and colleagues[4] reviewed the anatomic position of the CPN in 54 patients who had extensive traumatic disruption of the PL structures. The CPN was noted to be displaced from its normal position in 16 of 18 patients who had biceps avulsions or associated fibular head fractures. These authors advised that the surgeon should expect an abnormal nerve position on surgical exploration in knees with bone or soft tissue avulsion from the fibular head and the potential for iatrogenic damage.

Rubel and coworkers[58] conducted an anatomic investigation of the CPN in 31 cadaveric limbs by dissecting the CPN to its intramuscular branches. The authors described Gerdy's safe zone as the area where the CPN and anterior recurrent branch defined an arc with an average radius of 45 mm. The distance between the fibular head and Gerdy's tubercle was used to determine the radius of the safe zone. Therefore this region in the proximal aspect of the tibia is advantageous for surgical exploration, because damage to the peroneal nerve and its branches is avoided (Fig. 17-10). The CPN divides into three branches as it enters the anterolateral musculature, with the anterior recurrent branch more proximal to the superficial and deep peroneal branches.

Dellon and associates[10] reported on the anatomic variations of the CPN at the fibular head in 29 cadavers (bilaterally) and 65 patients treated with a CPN decompression for symptoms. Three possible anatomic variants were described that require attention and decompression in chronic neuropathies for a successful outcome. First, the superficial fascia of the superficial head of the peroneus longus muscle is divided by a proximal and distal transection of the fascia (found in 30% of cadavers and 78% of patients, see Fig. 17-8, *B*). Second, when the peroneus longus muscle at the fibular neck is partially incised adjacent and superior to the CPN and the peroneus muscle is lifted anteriorly, a fibrous band may be found that requires release (soft tissue restriction found in 43% of cadavers and 20% of patients, see Fig. 17-8, *C*). Third, there may be a fibrous connection between the peroneus longus and soleus muscle requiring division (found in 9% of cadavers and 6% of patients). These authors advise that after CPN decompression, the surgeon's index finger should be able to gently pass along the CPN and into the anterolateral compartment (see Fig. 17-8, *D*).

In cases of partial to complete peroneal nerve injury, added trauma to neural tissues should be avoided. The goal is to identify the nerve pathway to avoid further damage during the ligament reconstructive procedure. The CPN passage into the lateral and anterolateral compartment at the entrance of the peroneal longus muscle at the fibular neck is a potential area for nerve compression. This area requires identification and division of variant fascial tissue bands, as previously described. Further CPN dissection is avoided.

Surgical Repair and Reconstruction of Acute Injuries

The key to restore function to the disrupted PL structures, muscle attachments, and lateral meniscus attachments is a meticulous dissection, identification of damaged tissues, and repair of all injured structures. There is an unacceptably high risk of failure of primary repairs of disrupted PL structures, particularly the FCL, owing to high lateral tensile forces exerted on these tissues postoperatively.[59] Therefore it is necessary to reconstruct one or more disrupted PL structures with an autograft or allograft. This adds tissue integrity and sufficient repair

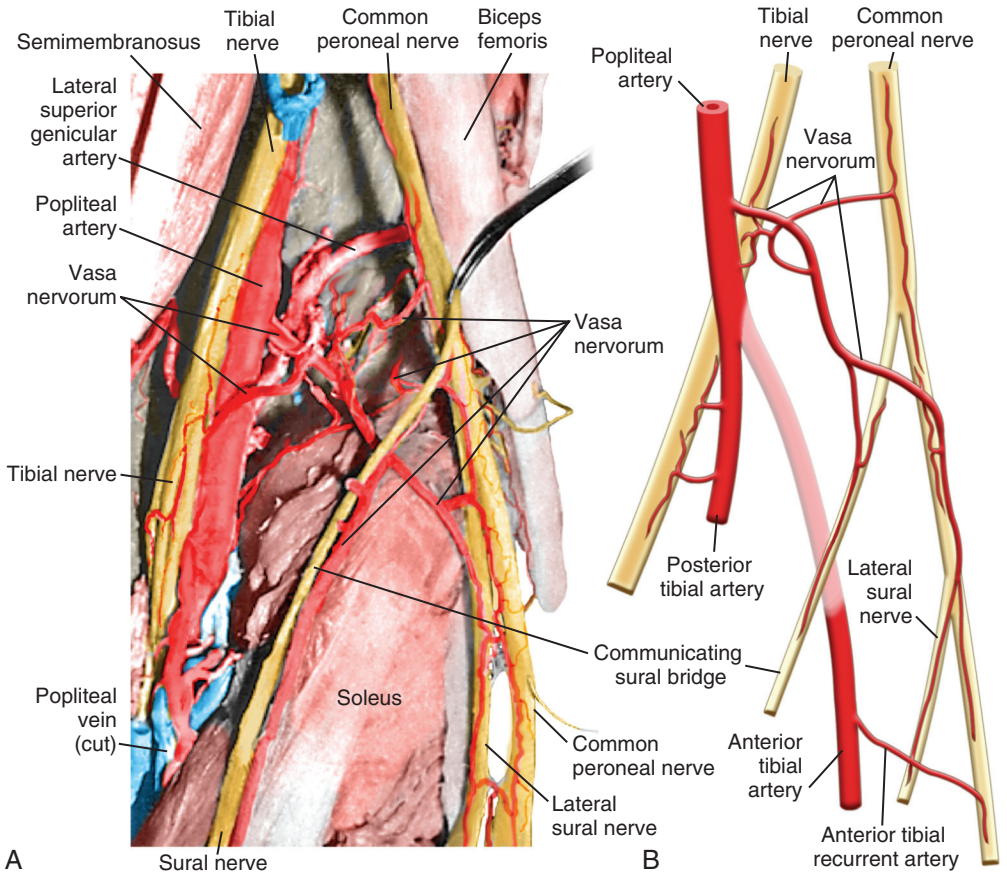

FIG 17-9 **A,** Gross dissection of the popliteal fossa of the right leg. The vessel branching from the popliteal artery gives rise to vasa nervorum to the tibial nerve and common peroneal nerve (CPN) and a branch that bifurcates into a vessel accompanying the sural nerve and the epineurial vessel running with the CPN. **B,** The major vascular arrangements supplying the CPN in the popliteal fossa. Anatomic location of the peroneal nerve at the level of the proximal aspect of the tibia: Gerdy's safe zone. *J Bone Joint Surg Am.* 2004;86:1625-1658.)

strength to resist LJO and external tibial rotation in the initial healing period of 4 to 6 postoperative weeks.

In most acute PL injuries, the FCL is reconstructed and the other PL soft tissues and PMTL are treated by primary repair. The FCL graft reconstruction resists lateral tibiofemoral compartment opening and posterolateral subluxation, protecting the overall repair process during the initial healing stage. In more severe injuries, a graft reconstruction of both the FCL and PMTL may be necessary. The reconstruction procedures are discussed in detail in the "Operative Treatment of Chronic Ruptures" section later in this chapter.

Surgical Approach and Order of Repair

The surgical approach the senior author prefers involves a graft reconstruction of the FCL to stabilize the lateral side of the knee joint using a B-PT-B allograft or an AT-B allograft. A femoral-fibular reconstruction[41] is a second option described later in this chapter. The FCL reconstruction provides for secure fixation, prevents abnormal joint displacements in the immediate postoperative period, and allows for early protected knee motion. These procedures are not difficult because the attachment sites on the femur and fibula are easily identifiable. Importantly, the graft provides the cornerstone about which the remainder of the soft tissue repair of the PL structures is performed. A B-PT-B allograft requires an appropriate tendon graft length of 60 mm, which may not always be available. Alternative graft options are an AT-B or anterior tibialis allograft. The bone portion of the AT-B may be placed at either the FCL fibular attachment (preferred for bone fixation and healing) or femoral attachment. If a soft tissue tendon graft is selected, the graft is passed through a fibular tunnel (anterior-to-posterior), the tendon is sutured back on itself, and a soft tissue interference screw is used at the femoral fixation site and, frequently, at the fibular site.

After all of the anatomic structures and rupture sites are identified and carefully exposed, the order of the operative repair starts with deeper structures and proceeds to superficial structures. Examples of an acute operative repair are shown in Figures 17-11 and 17-12.

1. Meniscofemoral and tibial capsular repairs
   - Meniscus attachment repair.
   - FCL reconstruction with femoral and fibular tunnel placement and graft fixation.
   - Posterior capsule repair with sutures tied with the knee in full extension.
2. PMTL repair options
   - Musculotendinous repair with direct suture (backup by FCL reconstruction).
   - PFL primary repair (tissues often of poor quality; FCL graft provides suitable tissue for additional sutures).
   - Popliteus tendon femoral attachment: avulsion (while rare) may be reattached.
   - Repair of disrupted biceps attachments: ITB repair of distal insertion, posterior femoral attachments, patellar retinaculum.

CRITICAL POINTS Operative Treatment of Acute Posterolateral Ruptures: Surgical Repair and Reconstruction of Acutely Disrupted Ligament and Soft Tissues

- Unacceptably high risk for failure of primary repairs of FCL owing to high lateral tensile forces postoperatively.
- FCL graft reconstruction, other PL soft tissues and PMTL repaired.
- Severe injuries: PMTL graft reconstruction may be necessary.
- Surgical approach, order of repair
  - Prefer B-PT-B autograft or AT-B allograft replacement of FCL.
  - Graft provides secure bone fixation, prevents abnormal joint displacements, and allows early protected knee motion.
  - Graft provides the cornerstone for repair of other PL structures.
  - Operative repair starts with deep structures and proceeds to superficial structures.

OPERATIVE TREATMENT OF CHRONIC POSTEROLATERAL RUPTURES

Overview of Operative Options

The surgical options in knees with chronic injuries to the PL structures are based on the quality and integrity of these tissues determined at the initial surgical dissection. The surgical approach is similar to that described for acute dissection of the PL structures. The CPN is always identified before any lateral dissection, as previously described. The posterior border of the ITB is incised and elevated to allow complete exposure. In chronic instabilities, the ITB may be lax and nonfunctional. In such knees, the attachment at Gerdy's tubercle is osteotomized, and at the conclusion of the operative procedure, the proximal ITB attachments (lateral intermuscular septum, femoral posterior attachments) are sutured and the ITB osseous attachment is advanced distally by staple fixation to the tibia. The importance of identification of meniscus attachments, PMTL attachment, PL capsular structures, the biceps short and long head attachments, and the peroneal nerve has been previously discussed.

Markolf and colleagues[35-37] reported a series of cadaveric studies on the effect of a nonanatomic PL ligament reconstruction, which has the potential to overconstrain internal tibial rotation and adduction throughout knee flexion. The authors concluded there was no consensus on the graft tensioning routine for PL reconstructions.

The approach advocated in this chapter is an anatomic FCL reconstruction. The FCL may be deficient from prior disruption or replaced with scar tissue in which a well-defined structure cannot be identified. An FCL reconstruction provides a cornerstone for the PL reconstruction.

An anatomic PMTL reconstruction will be described later in this chapter. In the majority of chronic unstable knees, the distal attachments of the PMTL are disrupted or replaced with scar tissue and it is necessary to perform a graft substitution of the PMTL. In rare cases in

CRITICAL POINTS Operative Treatment of Chronic Posterolateral Ruptures: Overview of Operative Options

- Anatomic reconstruction for PL structures
- Unstable, disrupted, or scar tissue replacement of FCL and PMTL requires anatomic graft substitution. If distal PMTL attachments are intact, possible advancement and recession of popliteus tendon at femoral attachment site performed and PFL attachment tissues repaired.
- Nonanatomic femoral-fibular graft reconstruction performed when operative time is limited (dislocated multiligament injuries).
- Proximal advancement PL structures: select knees with chronic stretching and interstitial injury without traumatic ligament disruption.

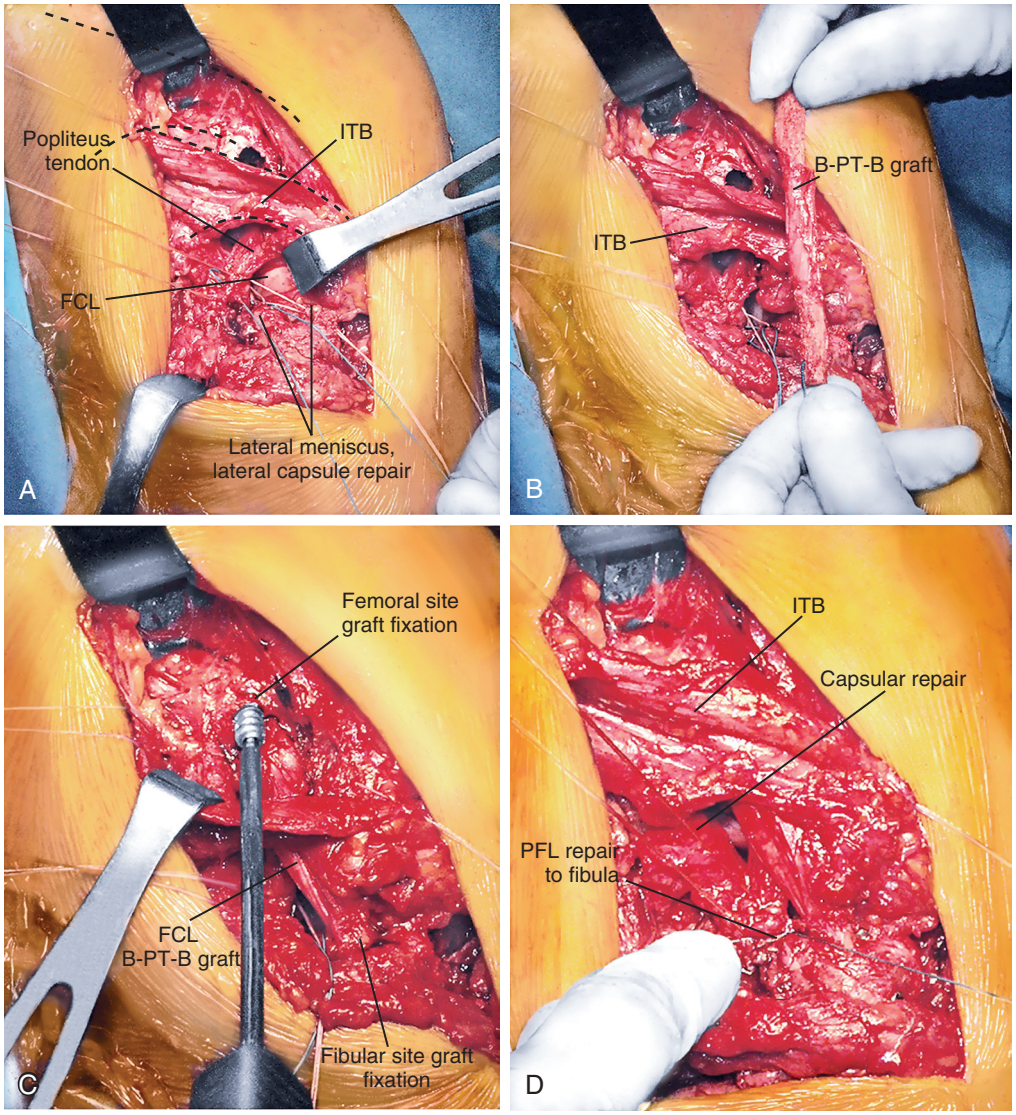

FIG 17-11 Acute repair of rupture to the posterolateral (PL) structures. **A,** Lateral approach; anterior and posterior incisions have been made into the iliotibial band (ITB). Sutures are placed to repair the lateral meniscus tibial attachments. **B,** Fibular collateral ligament (FCL) reconstruction with a bone-patellar tendon-bone (B-PT-B) allograft and suture of the popliteofibular ligament (PFL) to the fibula. The popliteus tendon attachment at the femur was intact. **C,** Fixation of the FCL graft at the femoral and tibial anatomic attachments. **D,** Repair of PL capsule, biceps attachments, and posterior ITB.

which the distal attachments of the PMTL are intact, an advancement and recession of the popliteus tendon at the femoral attachment site may be performed.

A nonanatomic femoral-fibular graft reconstruction is described as an option that is occasionally performed for acute or chronic ruptures of the PL structures. This procedure is indicated when the FCL is elongated or deficient and the PMTL does not require graft substitution. The operative procedure is advantageous when operative time is limited (as in dislocated multiligament knees) or when a relatively rapid stabilizing procedure is required. However, anatomic reconstruction and repair of both the FCL and PMTL are necessary in grossly unstable chronic knee instabilities.

A third operative approach is described using a proximal advancement of the PL structures when chronic insufficiency of the PL structures exists from a minor injury (without traumatic ligament disruption). In knees with varus osseous malalignment and a varus thrust on ambulation, there is frequently an insufficiency of the PL structures because of chronic interstitial tearing. In these situations, a definitive FCL of normal width and integrity (although lax) may be identified at surgery and the PMTL attachments are intact though elongated. A graft reconstruction of the FCL and PMTL is not indicated in these knees. Instead, the PL structures may be advanced proximally in a more simplified operative procedure that avoids the added complexity and morbidity from major graft reconstructive procedures. The PL structures must be carefully inspected at surgery, because this procedure will fail if there is scar tissue replacement, lack of a normal appearance of the structures (although lax), or if the distal attachments of the PL structures are disrupted.

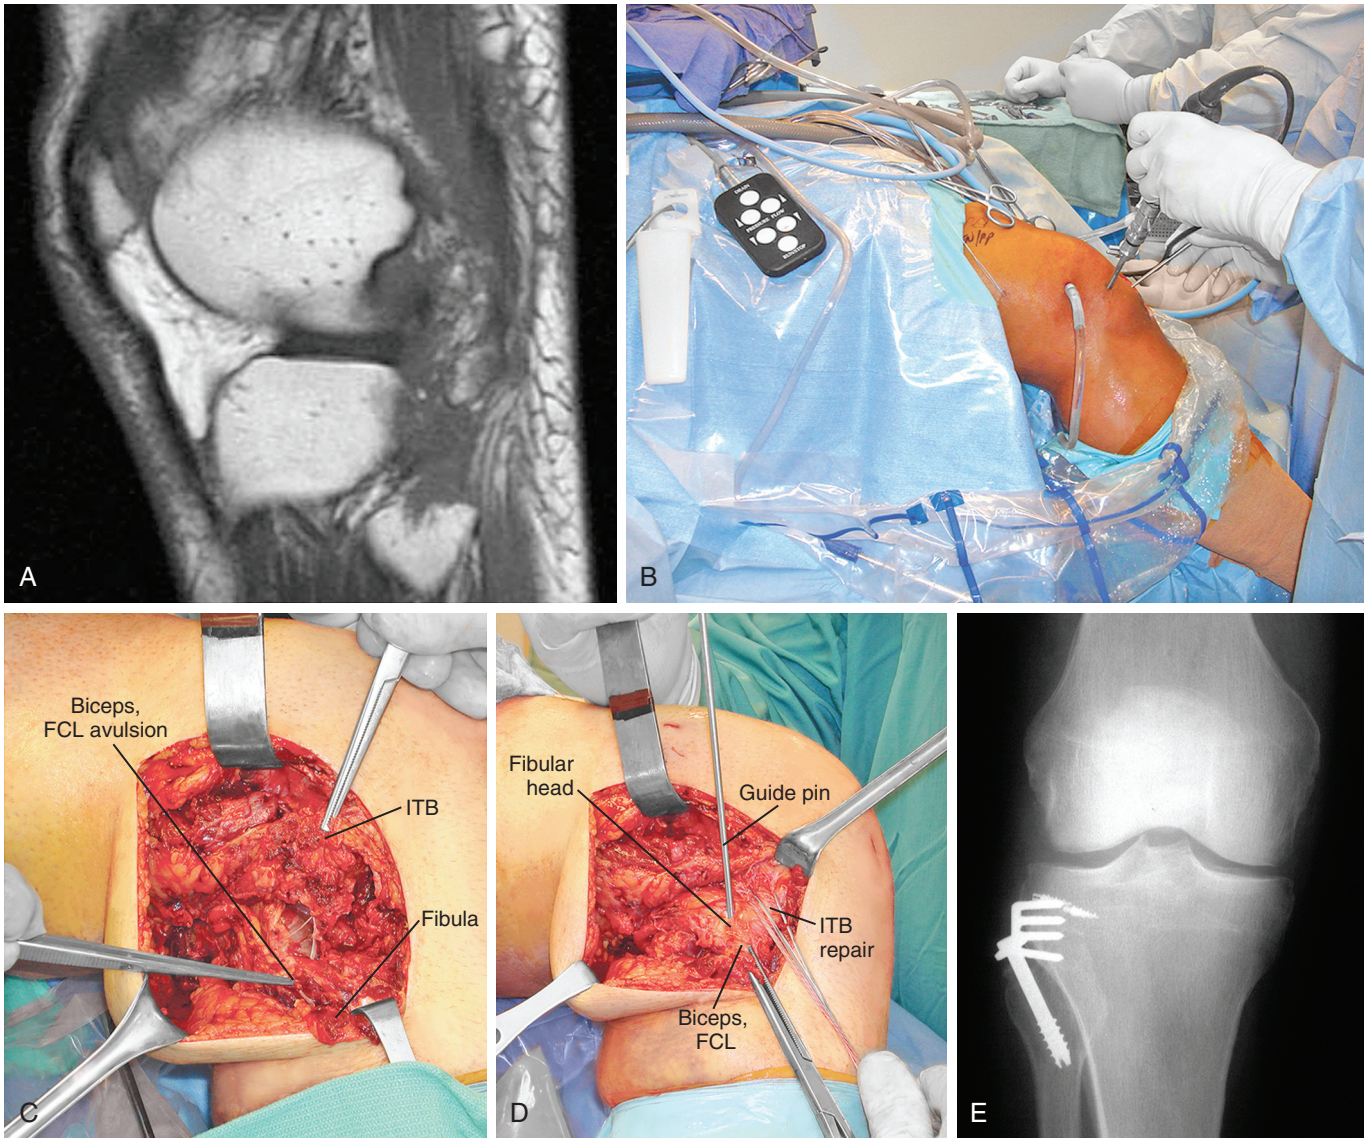

FIG 17-12 Acute disruption of posterolateral structures with avulsion of biceps and fibular collateral ligament (FCL) from fibula. **A,** Magnetic resonance imaging shows avulsion of biceps and FCL from fibular head. **B,** Initial arthroscopic procedure 10 days after injury, performed under low pressure and volume conditions. **C,** Surgical exploration shows avulsion of iliotibial band (ITB) from tibial insertion and biceps, FCL attachment to fibula. The common peroneal nerve was identified to be in a normal anatomic position. **D,** Repair of capsular attachments and ITB (sutures). Guide pin placed in the proximal fibula for screw and washer fixation of biceps and FCL. **E,** Anteroposterior postoperative radiograph shows fixation of biceps and FCL to the proximal fibula, four-prong staple for ITB attachment to tibia, soft tissue anchor for deep capsular attachments.

Anatomic Reconstruction of the Fibular Collateral Ligament and Popliteus Muscle-Tendon-Ligament Unit

Patient Positioning and Surgical Approach

An operative time-out and identification of the operative limb are performed as already described. The patient is positioned on the operative table, with a high thigh tourniquet placed as previously described in the "Acute Injuries" section. A leg holder is only used if a meniscus repair is anticipated to provide for limb control and opening of the medial tibiofemoral compartment. Otherwise, the lower limb is draped free with a bolster placed under the proximal thigh to allow the popliteal neurovascular structures to drop posteriorly away from the dissection plane. The initial arthroscopic evaluation is performed, including meniscus repairs and drilling of tunnels for concurrent cruciate reconstructions for placement of cruciate grafts as described in Chapters 7 and 17. There are two options with cruciate reconstructions. The cruciate grafts may be placed with the distal fixation performed after the lateral dissection. If this approach is selected, the order of final graft tensioning and fixation is (1) PCL, (2) ACL, (3) FCL, and (4) PMTL. The rationale is to restore the tibiofemoral joint in the sagittal plane and then perform the final PL graft fixation and repair of disrupted tissues. The second option is to complete the cruciate reconstruction and then repair and reconstruct the PL structures. If

CRITICAL POINTS Anatomic Reconstruction of the Fibular Collateral Ligament and Popliteus Muscle-Tendon-Ligament: Patient Positioning and Surgical Approach

- Initial arthroscopic evaluation performed.
- Tourniquet inflated during initial operative approach, deflated remainder of procedure.
- Skin incision: straight line 10-12 cm in length, centered over joint line, 1 cm posterior to ITB attachment at the tibia.
- Skin flaps created by undermining the skin in proximal, distal, anterior, posterior directions.
- Skin dissection beneath superficial fascia, not in fatty subcutaneous plane.
- Identify, protect CPN and possible nerve branches as first priority.
- ITB incised along posterior margin at the junction of the band and biceps muscle.
- ITB posterior attachments excised to short head of biceps femoris muscle.
- ITB lifted anteriorly to expose lateral aspect of lateral femoral condyle and attachments of popliteus, FCL, lateral gastrocnemius muscle tendon attachment.
- Interval anterior to lateral gastrocnemius tendon at joint line, directly at top of fibula entered, avoid inferior geniculate artery. Visualize space behind posterior capsule, lateral meniscus attachment, popliteus muscle attachment, posterior gastrocnemius tendon.
- Second anterior ITB incision may be required for exposure.
- VLO lifted gently in anterior direction, S retractor placed beneath muscle fibers.
- Vertical incision 2 cm in length into capsule just anterior to anterolateral capsule ligament and popliteus tendon attachment. Joint entered, lateral meniscus attachments inspected. Similar incision into PL capsule, starting at its femoral attachment, inspect posterior meniscus attachments.

CPN, Common peroneal nerve; *FCL*, fibular collateral ligament; *ITB*, iliotibial band; *PL*, posterolateral; *VLO*, vastus lateralis obliquus.

this sequence is followed, the surgeon must carefully control the limb during the dissection and repair steps to make sure there is no inadvertent opening of the lateral tibiofemoral joint, which would disrupt the cruciate graft fixation. In general, the first option is safest.

The surgeon is seated with a headlight to allow a meticulous dissection of the CPN first, followed by the PL structures. The tourniquet is inflated during the initial dissection and then deflated during the remainder of the surgical procedure. A skin incision 10 to 12 cm in length is made in a straight line, centered over the joint line and 1 cm posterior to the ITB attachment at the tibia, using the same approach as already described (see Fig. 17-6).

Skin flaps are created by undermining the skin in proximal, distal, anterior, and posterior directions. A cosmetic approach is used in which the skin incision is transposed to different portions of the operative field, thereby reducing the skin incision length. The skin dissection is accomplished beneath the superficial fascia and not in the fatty subcutaneous plane to avoid damage to the blood and neural supply to the skin flaps. The surgeon avoids skin necrosis by not placing tension on the skin edges and flaps.

Peroneal Nerve Dissection and Visualization

The CPN is identified, beginning proximally as already described. A retractor is used to elevate the proximal biceps muscle and vastus lateralis to place tension on the lateral fascial tissues and gently elongate the CPN. The fascia is incised directly anterior to the CPN, and care is taken to avoid opening the surrounding neural sheath. At the fibular head, the peroneal longus muscle is partially incised for a few millimeters overlying the CPN at the fibular neck. The area is inspected for fibrous or fascia tissues that may potentially compromise the CPN entrance into the lateral and anterolateral muscular compartments, as described in the previous section. The yellow fatty tissue about the CPN is protected.

The nerve is not displaced from its anatomic bed to protect its blood supply. In cases in which scar tissue is encountered that surrounds the nerve, further dissection of the CPN is avoided because injury may easily occur as the scar tissue prevents a safe dissection plane. The CPN is identified proximally and distally to the scar tissue, so its location can be protected during the ligament reconstruction.

Only in rare cases in which there is near-complete to complete loss of CPN function and a compressive neuropathy exists, is it justified to dissect the CPN from the encased scar tissue, because the risk of nerve damage is high. In either situation, the surgeon must always know where the CPN and its branches are located during the operative procedure.

The ITB is incised at the posterior edge and anterior to the biceps tendon. The ITB attachments are excised to the short head of the biceps femoris muscle, and the ITB is gently lifted anteriorly to expose the entire lateral aspect of lateral femoral condyle and attachments of the popliteus, FCL, and lateral gastrocnemius muscle tendon attachment.

The tissues overlying the FCL and PL structures may have fascia tissues that require dissection to identify the structures. These fascia tissues should be grasped and gently stripped with dissection scissors, protecting the biceps tendon attachment and underlying posterior capsule and FCL. The bursa located anterolateral to the distal fourth of the FCL is used as a landmark. In chronic knee injuries considerable scar tissue may be encountered at this point that prevents clear identification of all the PL structures.

The interval anterior to the lateral gastrocnemius tendon at the joint line, and directly at the top of the fibula, is entered, avoiding the inferior genicular artery. The space behind the posterior capsule, lateral meniscus attachment, popliteus muscle attachment, and posterior gastrocnemius tendon is visualized, as already described in the "Acute Injuries" section.

A second anterior ITB incision may be required when there is extensive scar involving all of the PL structures. The ITB is incised along its anterior margin at the junction of the band and fascia, 10 cm from its tibial attachment. The vastus lateralis obliquus (VLO) is carefully elevated from the lateral intermuscular septum, avoiding any penetrating vessels. The VLO is lifted gently in an anterior direction and an S retractor is placed beneath the muscle fibers. The surgeon should avoid entering the suprapatellar synovial pouch by placing the retractor adjacent to the periosteum. Occasionally, blunt dissection with a Cobb elevator is required to gently displace the suprapatellar synovial pouch to allow placement of the S retractor.

A vertical incision approximately 2 cm in length is made into the capsule just anterior to the anterolateral ligament and popliteus tendon attachment. The joint is entered and the lateral meniscus attachments are inspected. If necessary, a vertical incision into the PL capsule may be required to allow for further inspection and repair of the posterior meniscus attachments. This posterior incision cannot be extended distally, because the popliteus tendon will be observed crossing into the popliteus meniscus recess.

It may be beneficial to place a curved Kelly in the anterolateral capsular incision, with the instrument passed beneath the popliteus tendon and FCL, to place tension into these tissues to facilitate further identification and inspection. The femoral anatomic attachments of all

the PL structures are shown in Figure 2-1, *C* and *D*, and the surgeon should be thoroughly familiar with this anatomy because the goal of the surgical procedure is to restore normal anatomic attachment sites. Note the femoral FCL attachment is just posterior and superior to the lateral epicondyle, and that the insertion of the lateral gastrocnemius tendon is on the lateral aspect of the femoral condyle.

LaPrade and coworkers[27] reported a mean distance of 18.5 mm from the FCL insertion to the popliteus tendon insertion, indicating that two separate grafts are required to anatomically reconstruct the FCL and popliteal tendon femoral attachments. Although some authors recommend a single graft placed at the femoral attachment and split into two strands to reconstruct both the FCL and PMTL, this procedure does not reproduce the anatomic femoral attachment sites. For these reasons, a separate graft and femoral attachment for the FCL and PMTL are recommended.

The PMTL, PFL attachments, and lateral meniscus attachments are identified by careful probing to determine the integrity of these structures and the appropriate procedure required. Disruption of the popliteomeniscal attachments is usually present, requiring suture repair. Chronic cases of rupture to the PL structures usually demonstrate severe deficiency of the FCL and PMTL, which are encased in scar tissue and require a two-graft anatomic reconstruction. The dissection is limited to the respective structures to be reconstructed to avoid soft tissue injury and devascularization.

Fibular Collateral Ligament Bone-Patellar Tendon-Bone Reconstruction

The goal of a FCL reconstruction is to use a strong graft, attached by bone to anatomic insertion sites on the femur and fibula. This construct provides the cornerstone for the remainder of the PL repair and reconstruction. With an FCL graft resisting LJO and external tibial rotation, immediate protected knee motion may be initiated postoperatively to counteract the expected limitation of joint motion and scar tissue that occurs after major ligament reconstructive procedures.

Graft choices for fibular collateral ligament reconstruction. The normal anatomic attachment sites of the FCL to the lateral femur and anterolateral aspect of the fibular head are carefully identified.[27] A suture is placed between the two attachment sites and the length measured to determine the required graft size. The bone portion of each end of the graft is 22 to 25 mm in length. The fibular graft attachment is performed using a proximal fibular tunnel. The femoral graft attachment is performed by placing a femoral tunnel at the anatomic attachment site. A second option is a femoral inlay of the proximal bone portion of the graft, which is only required if there is a 5- to 8-mm discrepancy of graft length that will not allow full coverage of the bone in a femoral tunnel.

The patellar tendon graft must normally be 55 to 60 mm to be suitable for an anatomic FCL reconstruction; the senior author keeps these lengths of allografts available. The average cross-sectional area of the FCL (reported by LaPrade and associates[22]) is 11.9 ± 2.9 mm^2. The FCL graft is 8 to 10 mm × 4 mm, resulting in a 32- to 40-mm^2 graft. If the patient's own tissue is of sufficient length, an autograft harvested from the ipsilateral or contralateral patellar tendon is an added consideration. In select cases in which a prior FCL allograft reconstruction has failed, an autograft approach is favored. The hypothesis is that an autograft will heal at the fibular and femoral tunnels, with minimal remodeling and weakening of the graft in the postoperative phase. The complications of a meticulously performed B-PT-B graft harvest from the contralateral knee are less than 1% in terms of infection, scar formation, and graft site pain.[43]

CRITICAL POINTS Fibular Collateral Ligament Bone-Patellar Tendon-Bone Reconstruction

- Anatomic FCL attachment sites to lateral femur, anterolateral aspect of fibular head identified.
- Femoral graft attached via tunnel at FCL anatomic site. Inlay procedure useful if 5- to 8-mm discrepancy of graft length that does not allow full coverage of bone portion of graft.
- Patellar tendon graft length not counting bone: 55-60 mm.
- B-PT-B allograft favored over soft tissue FCL graft owing to prompt osseous incorporation and healing at femoral and fibular attachment sites.
- Placement of fibular and femoral tunnels
  - Anterior bare area of fibula exposed 20 mm, avoid lateral dissection that may injure CPN.
  - Fibular tunnel drilled using guide pin to depth of 25 mm.
  - Avoid drilling too deep.
  - Femoral tunnel placed eccentric to normal FCL attachment, allows collagen portion of graft to occupy normal FCL anatomic location.
- B-PT-B graft placement
  - Bone portion of graft gently taped into fibular tunnel, bone entirely seated into tunnel and level with proximal fibular head.
  - Ideal graft fixation: one or two small fragment cortical screws.
  - Proximal bone portion of graft placed in femoral tunnel.
  - Graft conditioned by cycling knee 20-30 times.
  - Graft fixed with interference screw, 30 degrees of flexion, neutral tibial rotation, 22 N.

B-PT-B, Bone-patellar tendon-bone; *CPN*, common peroneal nerve; *FCL*, fibular collateral ligament.

If an allograft is chosen, as is the usual case in multiligament reconstructions, a B-PT-B allograft is favored over a soft tissue graft owing to more prompt osseous incorporation and healing at femoral and fibular attachment sites. It is recognized that soft tissue allografts in bone tunnels require added maturation time and may incompletely remodel even under the best of circumstances.[34,57]

Placement of fibular and femoral tunnels. The attachment sites at the fibula and femur are identified. The anterior *bare area* of the fibula is exposed for 20 mm, avoiding lateral dissection that may injure the CPN. The fibular tunnel is drilled first, using a guide pin to a depth of 25 mm. The drills are gradually increased in diameter to create a final 9-mm tunnel (Fig. 17-13). Care should be taken to avoid drilling too deep, because the drill would break out the cortex distally at the fibular neck, close to the location of the CPN. The normal cortical integrity of the fibular head is not disrupted to maintain circumferential cortical fixation strength at the fibular attachment site.

The femoral tunnel is placed 5 mm eccentric to the normal FCL attachment to allow the collagenous portion of the graft to occupy the normal FCL anatomic location. Before drilling the femoral socket, a suture is attached to the fibular graft site and positioned at the desired femoral location to check graft isometry. If the femoral position is too anterior, the graft will be under high tension with knee flexion. The opposite will occur if the graft is too posterior, because it will be under tight tension with knee extension. The goal is to have tension in the graft ideally in the 0 to 70 degrees knee motion limits, which replaces the normal FCL function. A Beath guide pin is passed for the femoral tunnel, which is angulated in an anterior and proximal direction in line with the FCL fibers at 30 degrees of knee flexion.

If an ACL reconstruction is performed, it is necessary to diverge the FCL tunnel in an anterior direction away from the ACL tunnel to

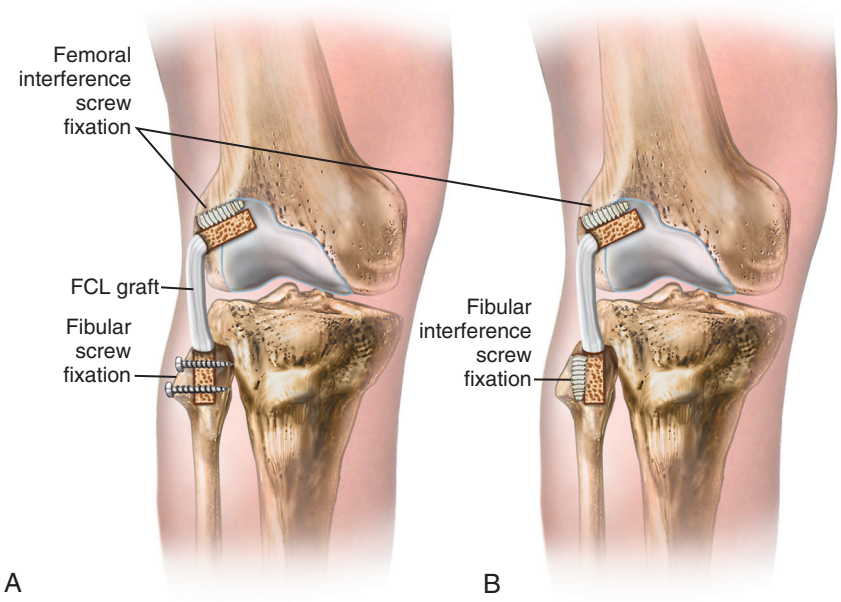

FIG 17-13 Anatomic substitution of the fibular collateral ligament (FCL) with a bone-patellar tendon-bone autograft or allograft shows two methods for fibular graft fixation. **A,** Two small fragment screws are used to fix the bone into a slot created in the proximal fibula (our choice). Interference screw fixation is used at the femoral anatomic site of the FCL. **B,** A fibular tunnel is made, the graft seated, and an interference screw is used for fixation.

maintain integrity of the two tunnels. The edges of the femoral tunnel are smoothed with a rasp to avoid graft abrasion.

The use of a FlipCutter (Arthrex) for the ACL femoral tunnel is ideal because it maintains the integrity of the lateral femoral cortex, particularly if two femoral sockets are required for an FCL and PTML graft reconstruction. Selecting grafts with a bone portion at the femoral site is advantageous because it avoids soft tissue graft tunnels that in the senior author's experience always remain and potentially weaken the lateral femoral condyle. The bone portion of the allograft will incorporate within the femoral condyle.

Bone-patellar tendon-bone graft placement. The bone portion of the graft is gently taped into the fibular tunnel so that the bone is entirely seated into the tunnel and level with the proximal fibular head to preserve graft length. The bone-tendon junction is marked with ink to define the correct depth in the fibular tunnel. The fibular graft fixation is done with one or two small-fragment cortical screws placed at the anterolateral bare area to engage the center bone portion of the graft and both fibular cortices (Fig. 17-14). The angle of the screw is posterior and medial (and never lateral) to protect the CPN. The cortical screws may be 2.7 or 3.5 mm, based on the size of the graft and fibular head. A washer is used anteriorly. Alternative graft fixation methods, rarely required, include an interference screw or sutures tied over the fibular cortex.

The proximal bone of the graft is advanced into the femoral tunnel. The graft is conditioned by cycling the knee 20 to 30 times. The graft is fixed at the femoral site with an interference screw at 30 degrees of knee flexion, in neutral tibial rotation, under an approximate 5-lb tensile load (22-N) on the sutures, which have been advanced by the Beath needle to the medial aspect of the knee joint. The graft is purposely not overtensioned to avoid overconstraining the lateral tibiofemoral joint.

Graft Replacement of Popliteus Muscle-Tendon-Ligament Unit: Acute or Chronic Cases

The graft replacement of the PMTL is shown in Figure 17-15. An AT-B allograft is favored, with the bone portion of the graft placed at the anatomic femoral insertion site and the collagenous portion of the graft passed in the tibial tunnel.

An incision is made just beneath Gerdy's tubercle, extending from the bare area of the anterior fibula to the tibial tubercle and then 3 cm distally along the anterolateral tibia. Careful subperiosteal dissection exposes the anterolateral aspect of the tibia in Gerdy's safe zone, as already described.

The posterolateral dissection is anterior to the lateral gastrocnemius muscle at the same interval as described for a lateral meniscus repair. A retractor is placed anterior to the lateral gastrocnemius muscle directly behind the posterior tibia to expose the popliteus muscle. One mistake is to place the posterior tibial tunnel too proximally because the tibia has a normal posterior convexity. A second mistake is to place the posterior tibial tunnel too far medially. A lateral placement of the tibial tunnel is required to increase the moment arm of the graft to resist external tibial rotation. Distal dissection over the popliteus muscle and distal placement of retractors are avoided as the anterior tibial artery courses laterally to enter the anterolateral compartment.

The final tibial 8- to 9-mm tunnel is at the most lateral aspect of the tibial margin and 15 mm distal to the joint line, passing through the popliteus muscle attachment and just medial to the tibiofibular joint (see Fig. 17-15). A guide pin is placed anterior-to-posterior, with a retractor placed posteriorly and the correct position confirmed with the tunnel drilled protecting the posterior structures. The total length of the graft is measured from the femoral to tibial tunnels, plus the length for the tibial fixation distal to the anterior tibial tunnel.

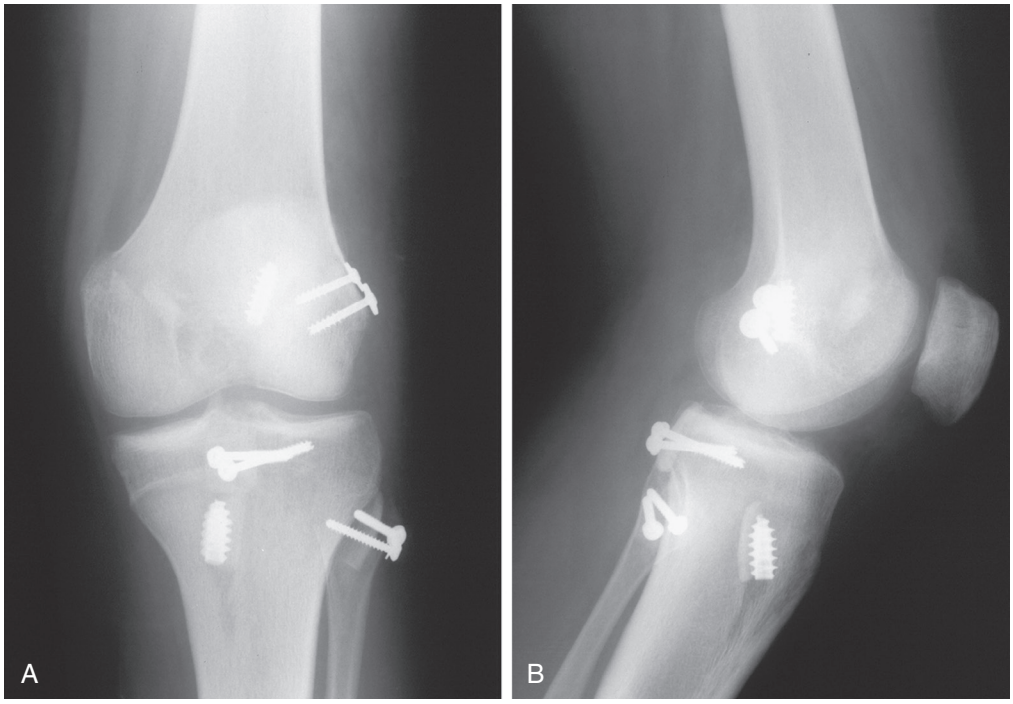

FIG 17-14 Postoperative anteroposterior (**A**) and lateral (**B**) radiographs of a 22-year-old man who underwent a posterior cruciate ligament quadriceps tendon-patellar bone autograft tibial inlay two-strand reconstruction, an anterior cruciate ligament bone-patellar tendon-bone (B-PT-B) allograft reconstruction, and a posterolateral reconstruction. The fibular collateral ligament (FCL) B-PT-B allograft fixation is shown. The method of fixation at the femur was a bone inlay at the anatomic FCL fixation site and at the fibula with two small fragment screws. An advancement of the popliteus tendon at the femur and repair of the popliteofibular ligament were also performed. (From Noyes FR, Barber-Westin SD. Posterolateral knee reconstruction with an anatomical bone-patellar tendon-bone reconstruction of the fibular collateral ligament. *Am J Sports Med.* 2007;35:259-273.)

CRITICAL POINTS Graft Replacement of Popliteus Muscle-Tendon-Ligament Unit

- AT-B allograft preferred, bone portion placed at anatomic femoral insertion site. Collagenous portion of graft passed into tibial tunnel.
- Careful subperiosteal dissection exposes anterolateral aspect of tibia in Gerdy's safe zone.
- Retractor placed anterior to lateral gastrocnemius muscle to expose popliteus muscle.
- Graft brought out though 8-mm tunnel placed at most lateral aspect of tibial margin, 15 mm distal to the joint line, passes through popliteus muscle attachment to tibia.
- Graft passed and fixed femoral tunnel, conditioned by repetitive knee flexion-extension. Fixation interference screw in tibial tunnel, 30 degrees of flexion, neutral tibial rotation, 22-N tension. Additional suture fixation screw post on tibia.
- Final graft assessment determined under adequate tension, resists abnormal external tibial rotation and knee hyperextension.
- Direct suture of PMTL graft to FCL graft at the level of fibular head.

AT-B, Achilles tendon-bone; *FCL*, fibular collateral ligament; *PMTL*, popliteus muscle-tendon-ligament unit.

The graft is passed through the femoral tunnel and then through the tibial tunnel and fixed at the femoral site by an interference screw. The graft is conditioned by repetitive knee flexion and extension, and fixation is performed with a soft tissue interference screw in the tibial tunnel with the leg at 30 degrees of knee flexion, neutral tibial rotation, and approximately 5 lb (22 N) of tension placed on the graft. A backup suture fixation screw post is used on the anterolateral aspect of the tibia.

A final graft assessment is done to determine that it is under adequate tension and resists abnormal external tibial rotation and knee hyperextension. With graft reconstructions of both the FCL and PMTL, it is not necessary to add additional drill holes to the fibula to perform a graft reconstruction of the PMTL. Rather, a direct suture of the PMTL graft to the FCL graft at the level of the fibular head is performed (see Fig. 17-15, *F* and *G*). A plication procedure is performed of the PLC at 10 degrees of flexion, avoiding overtension, which would limit normal extension (see Fig. 17-15, *H* and *I*).

Posterolateral Capsule Reconstruction for Severe Varus Recurvatum

In patients who demonstrate 15 degrees or more of knee varus recurvatum and hyperextension, severe deficiency exists of the entire posterior capsule and oblique popliteal ligament in addition to possible cruciate, FCL, and PMTL damage (Fig. 17-16). In these severe knee injuries, a PMTL reconstruction and posterior capsule plication will

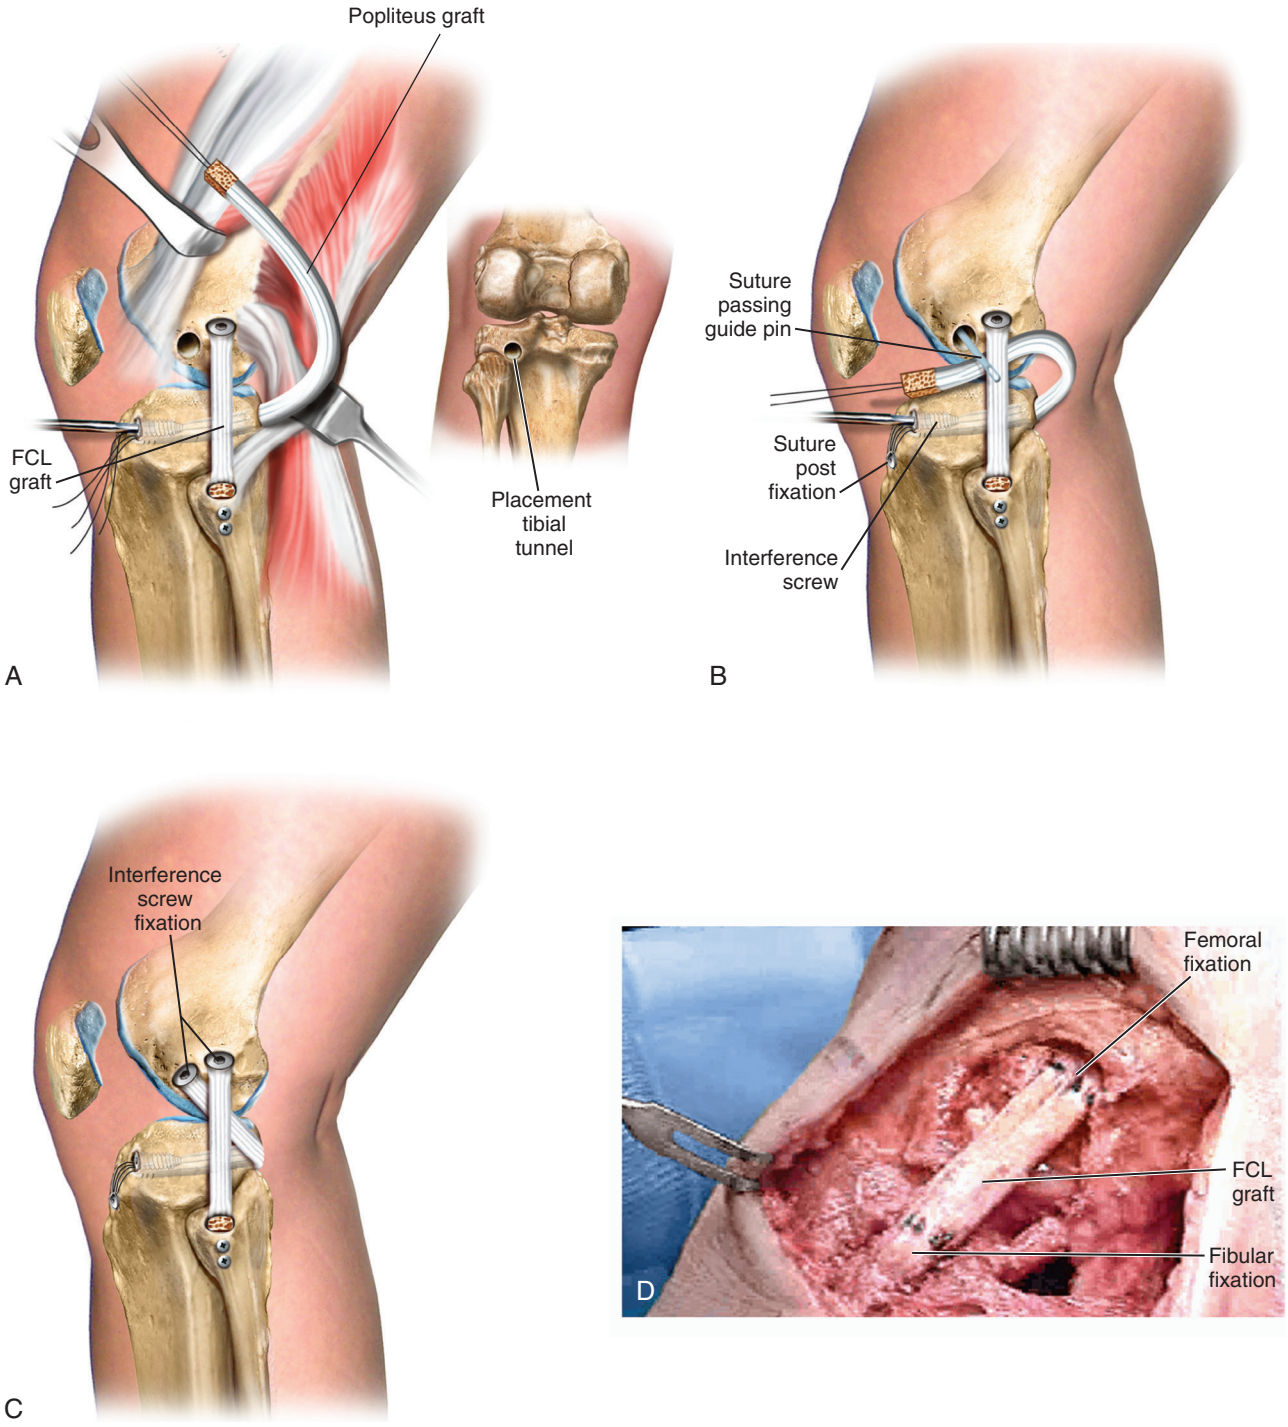

FIG 17-15 Anatomic popliteus muscle-tendon-ligament reconstruction and fibular collateral ligament (FCL) reconstruction with bone-patellar tendon-bone (B-PT-B) autograft or allograft. **A,** Location of posterolateral tibial tunnel and graft passage. A soft tissue interference screw and suture post are used for tibial fixation of the popliteus graft. **B,** Passage of popliteus graft beneath the FCL B-PT-B graft. **C** to **E,** Final fixation of the popliteus and FCL graft reconstructions.

not resist the severe varus recurvatum deformity. A PLC reconstruction is required in addition to a reconstruction of the PMTL and FCL (Fig. 17-17). The operative approach and placement of the tibial tunnel for the capsular reconstruction using an AT-B allograft (8-9 mm in diameter) is the same as described for the PMTL reconstruction. The tibial tunnel is enlarged as required for both graft passage. The bone portion of the graft is located adjacent to the lateral gastrocnemius tendon origin using either a femoral tunnel or a bone inlay technique. The inlay technique is required when a concurrent ACL reconstruction is performed to avoid a second femoral tunnel. The fixation at the femoral attachment requires a portion of the lateral gastrocnemius tendon insertion (which is very broad) to be partially incised to expose

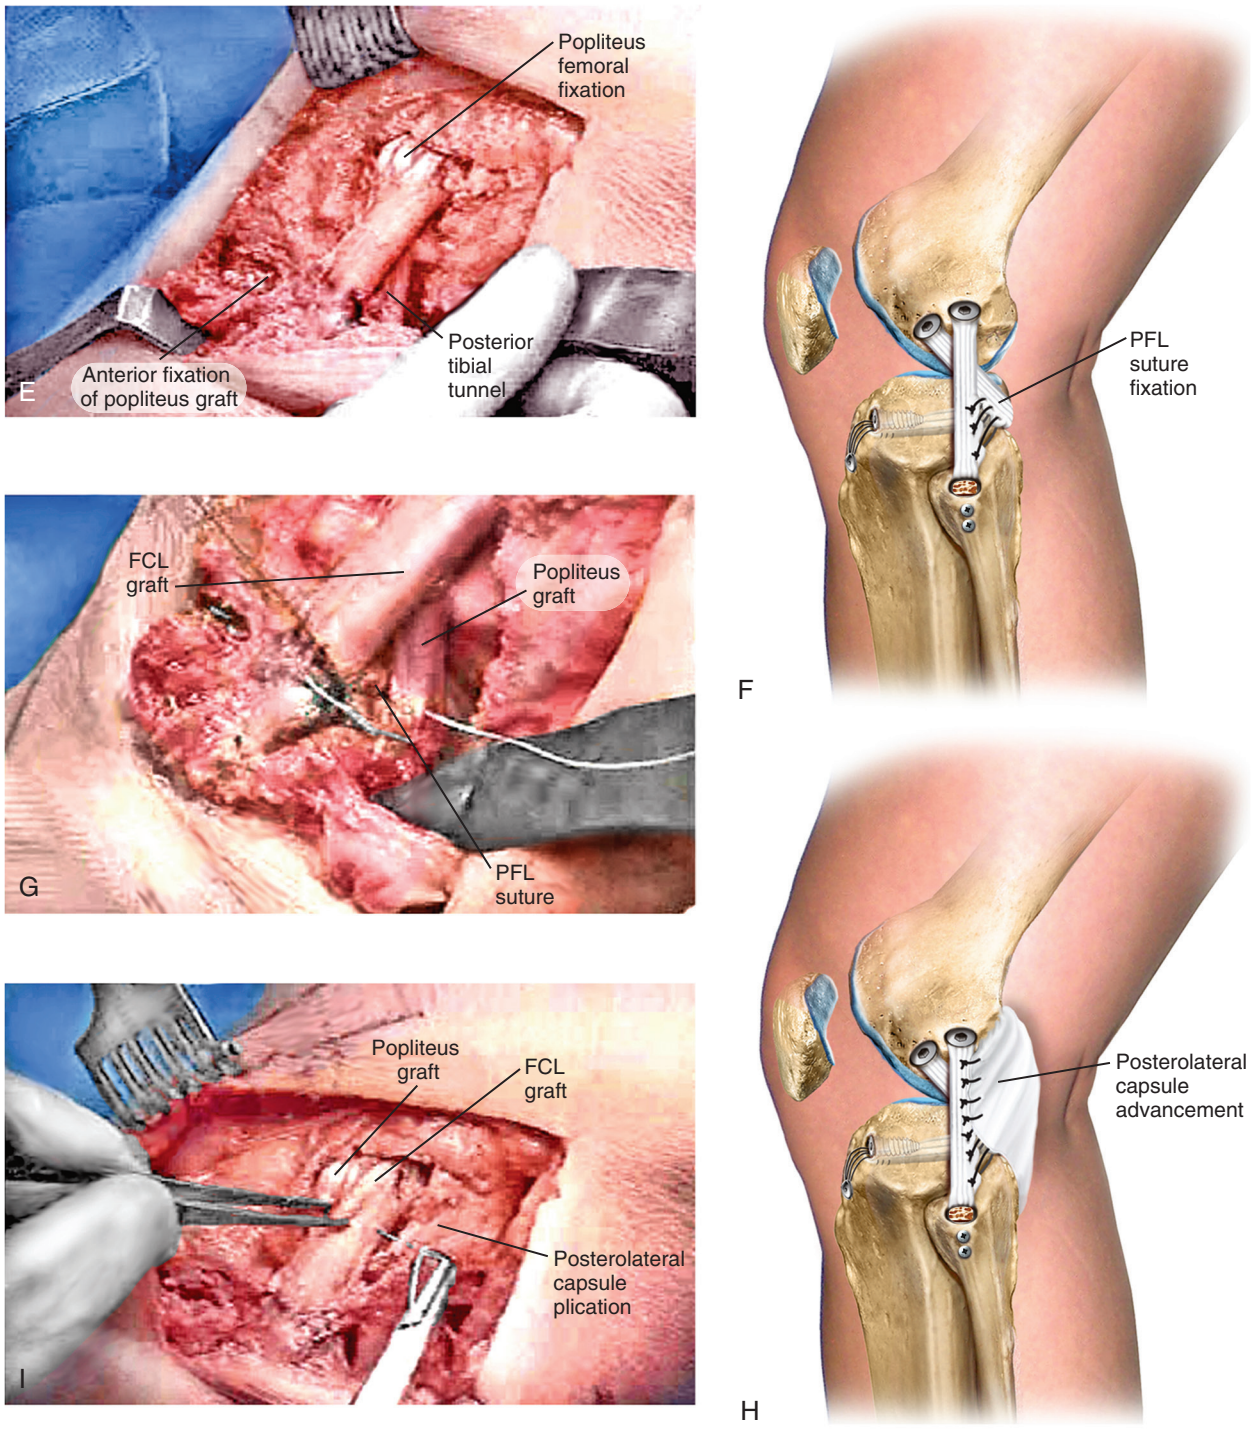

FIG 17-15, cont'd **F** and **G,** Suture of popliteus graft to posterior margin of the FCL graft at the fibular attachment site to restore the popliteofibular ligament (PFL). **H** and **I,** Suture plication of the posterolateral capsule to posterior margin of the FCL graft.

the site for the AT-B graft fixation. The fixation of the bone inlay is accomplished with two small-fragment cancellous screws and washers (Fig. 17-18). This provides a stable bone-to-bone attachment. If a femoral tunnel is used, a 7-mm interference screw is selected. The graft lies along the PLC, which is plicated and the graft is passed through the tibial tunnel.

The tendon portion of the graft is fixated at the tibia after graft conditioning similar to that previously described for the PMTL reconstruction. The knee is placed at 10 degrees of flexion with 5 lb (22 N) of graft tension. The knee joint will passively go to 0 degrees. Ultimately, the graft will stretch a few millimeters; the goal is to allow 0 to −2 degrees of hyperextension, which effectively blocks knee hyperextension and varus recurvatum. Frequently, the ACL is ruptured and the two ligaments grafts (ACL and PLC) work in concert to block varus recurvatum. The same is true when a concomitant PCL reconstruction is performed.

FIG 17-16 **A,** A 20-year-old gymnast with chronic deficiency of the posterolateral structures and complaints of recurrent hyperextension injuries with athletic activities. The anterior cruciate ligament and posterior cruciate ligament were intact, although a prior partial disruption could not be excluded. **B,** Dial test at 30 and 90 degrees demonstrates increased tibial rotation of the right knee.

CRITICAL POINTS Posterolateral Capsule Reconstruction

- Indicated 15 degrees of knee hyperextension, severe deficiency entire posterior capsule, cruciate, FCL, and PMTL damage.
- PMTL reconstruction alone will not block severe varus recurvatum deformity.
- Operative approach, place tibial tunnel using AT-B allograft, same as PMTL reconstruction.
- Bone portion of graft placed adjacent to lateral gastrocnemius tendon origin by tunnel or inlay.
- Inlay technique required with ACL reconstruction to avoid second femoral tunnel.
- Tendon portion of graft lies along posterolateral capsule, which is plicated, graft fixed at tibia with interference screw, suture post after graft conditioning.
- Goal: obtain 0 to –2 degrees of hyperextension, block knee hyperextension, varus recurvatum.
- Highly unstable knees with severe disruption of all PL structures may require PMTL and PL capsular grafts. Both grafts brought out through tibial tunnel drilled to appropriate diameter. Soft tissue interference screw used at tibial tunnel after graft suture post fixation.

AT-B, Achilles tendon-bone; *FCL*, fibular collateral ligament; *PL*, posterolateral; *PMTL*, popliteus muscle-tendon-ligament unit.

Femoral-Fibular Reconstruction

The nonanatomic femoral-fibular graft reconstruction is indicated primarily in acute knee repairs to provide the stable graft cornerstone about which other soft tissues are repaired. This technique is contraindicated when a combined PMTL graft reconstruction is required. In these knees, an anatomic FCL and PMTL reconstruction is performed.

The femoral-fibular reconstruction provides a large graft reconstruction of the FCL and a posterior graft arm to augment the PL structures. The PLC reconstruction is performed by a plication procedure. The popliteus tendon is plicated to the fibular FCL reconstruction to restore the PFL. The procedure is termed a *nonanatomic reconstruction* because the femoral-fibular graft is placed adjacent but not directly at the FCL femoral and fibular anatomic attachment sites.

The FCL femoral-fibular reconstruction does have some advantages. The graft placement (by drilling a tunnel anterior and posterior to the FCL femoral and fibular attachment sites) is relatively simple and allows a large doubled graft to be placed at the lateral side of the knee joint. Direct suture of the graft to itself provides lateral stability in acute operative repairs to initiate immediate protected knee motion postoperatively. The double-strand FCL graft provides a cornerstone for plication or repair of the other disrupted PL structures.

A femoral-fibular reconstruction has disadvantages. In cadaver studies, a femoral-fibular graft was found not to unload a concurrent PCL graft reconstruction in the same manner as a combined FCL and PMTL graft reconstruction.[36] In addition, although a single femoral-fibular graft stabilizes the knee at time zero, this graft may stretch out in the long term when there is loss of the PMTL, which does not participate in load sharing. Therefore all of the load is transferred to the single graft. The goal of PL repairs and reconstruction is to restore the function of all of the soft tissue structures and not just the femoral-fibular component. A modification of a femoral-fibular technique is to cross the graft, placing the anterior femoral portion to the posterior fibula to restore PFL function. However, whether this option is superior to two parallel femoral-fibular graft arms is not known.

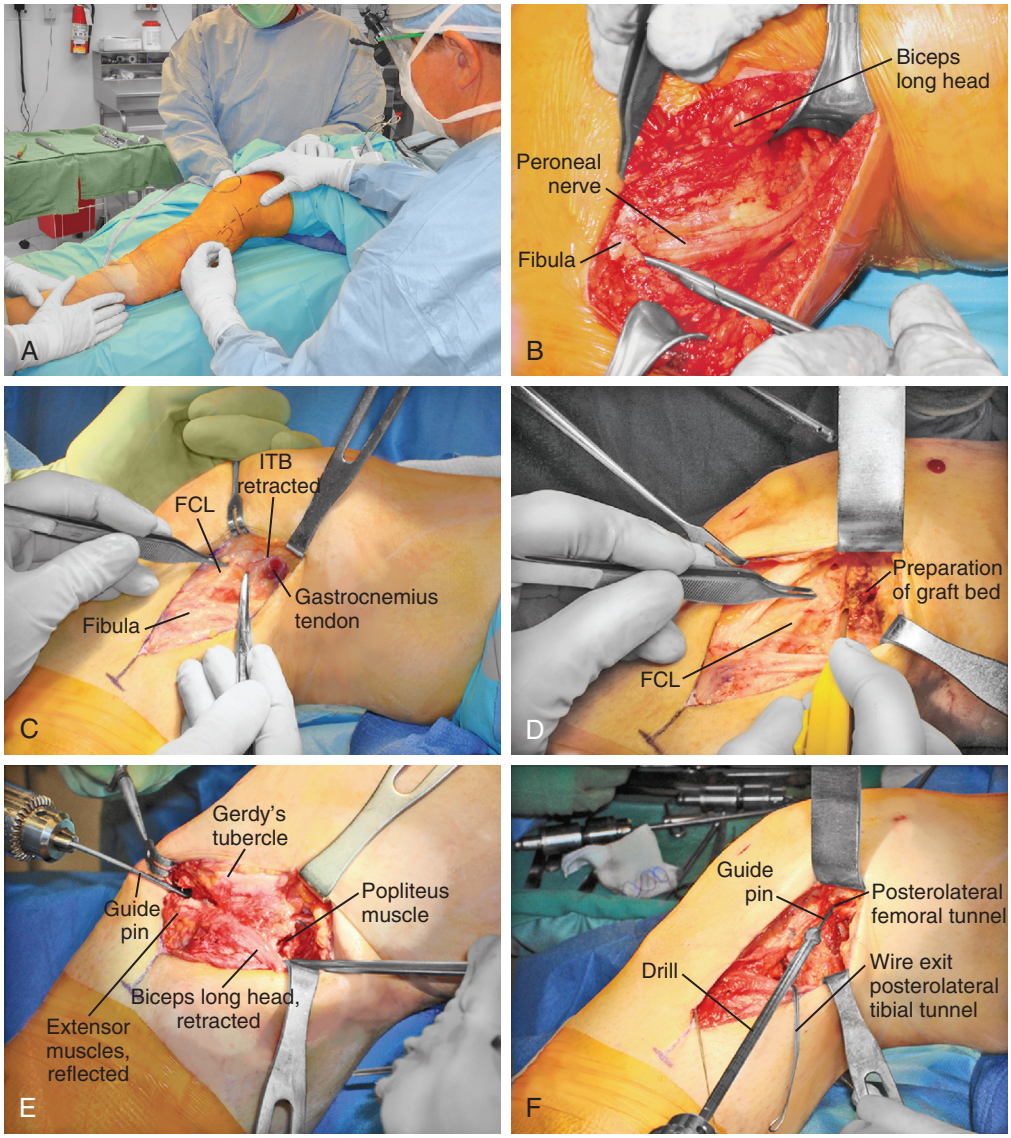

FIG 17-17 Posterolateral capsular reconstruction for severe knee varus recurvatum and hyperextension using an Achilles tendon-bone (AT-B) allograft. **A,** Patient positioning. **B,** Identification of the peroneal nerve at fibular neck. **C,** Identification of fibular collateral ligament (FCL) and popliteus muscle-tendon-ligament, functionally intact. **D,** Exposure of femoral graft site at lateral gastrocnemius tendon attachment. **E,** Placement of the tibial drill hole lateral and distal to the joint line. **F,** Placement of the femoral drill hole.

A straight lateral incision, approximately 12 cm in length, is used centered over the lateral joint line. The surgical approach already described is followed. The incision is extended distally to allow exposure of the fibular head and peroneal nerve and proximally to allow exposure of the attachment of the FCL to the femur. The skin flaps are mobilized beneath the subcutaneous tissue and fascia to protect the vascular and neural supply to the skin. The attachment of the ITB is identified.

An inferior incision is made along the posterior aspect of the ITB and the attachments overlying the biceps muscle. This allows the ITB to be reflected anteriorly so that the anatomy of the PL aspect of the knee is easily visualized.

The CPN is carefully protected throughout the surgical procedure for the drill hole made through the proximal fibula for placement of the FCL graft. It is usually not necessary to dissect the peroneal nerve when its course can be identified; however, if there is any question, it is prudent to dissect the sheath over the nerve around the fibular neck for complete identification.

The fibular head is exposed anteriorly and posteriorly by subperiosteal dissection. Only 12 to 15 mm of the proximal fibula is exposed. A 6-mm drill hole is carefully made anteriorly and posteriorly in the center of the fibular head; a drill guide is used to ensure that soft tissues are protected. A straight curette is used to dilate the 6-mm cortical hole from anterior to posterior, compressing the cancellous bone. Care is taken not to disturb the tibiofibular joint capsule, thereby preserving joint stability.

At the femoral attachment of the FCL, one of two approaches may be selected. In the first approach, the femoral tunnel is made just posterior and superior to the FCL attachment for a single tunnel, with the graft passed into the tunnel by use of a Beath needle. A second approach

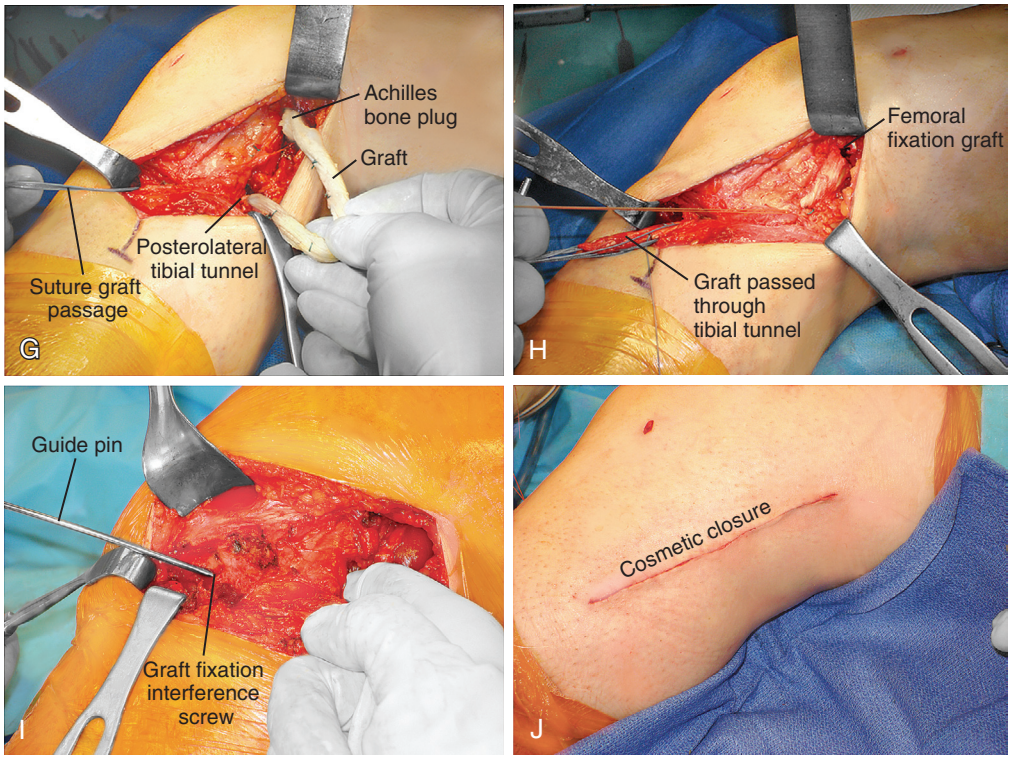

FIG 17-17, cont'd **G,** Placement of the AT-B allograft with bone plug at femoral site. **H,** Fixation at the femoral site and graft conditioning with tension of distal graft. **I,** Graft fixation at the tibia with interference screw and suture post. **J,** Cosmetic closure. *ITB,* Iliotibial band.

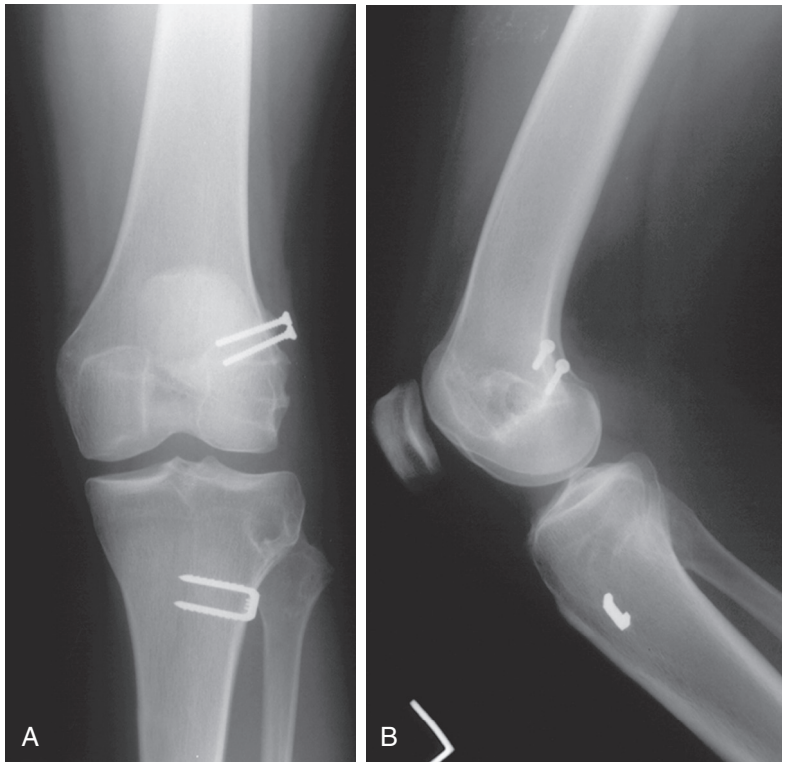

FIG 17-18 Anteroposterior **(A)** and lateral **(B)** radiographs show fixation of posterolateral capsular reconstruction with two 4.0-mm cancellous screws at the femoral site and an absorbable interference tibial screw and suture post. At the femoral site, either a bone inlay or tunnel may be selected.

CRITICAL POINTS Femoral-Fibular Reconstruction

- Indicated when FCL is deficient, contraindicated when PMTL graft reconstruction required.
- Provides large graft reconstruction of FCL and posterior graft arm to augment PL structures. PL capsule plicated.
- FCL graft provides cornerstone for plication or repair of the other PL structures. In global knee ligament reconstructions, procedure provides lateral stability with less operative time and complexity compared with anatomic reconstruction.
- Straight lateral incision, approximately 15 cm in length, centered over lateral joint line.
- Inferior incision along posterior aspect of ITB and attachments overlying the biceps muscle.
- CPN identified, protected.
- Proximal fibular head exposed anteriorly and posteriorly 12-15 mm by subperiosteal dissection.
- 6-mm drill hole anteriorly and posteriorly center of fibular head.
- 6-mm drill hole anterior-to-posterior beneath FCL femoral insertion.
- Curved curette used to make bone tunnel underneath FCL femoral insertion without removing excess bone.
- Autograft or allograft, 6-8 mm in diameter, prepared with sufficient length (19-20 cm) for proximal and distal posterior arms to overlap posteriorly.
- Graft inserted through bony tunnels in femur and fibula with disrupted FCL between graft arms.
- Interrupted sutures through anterior-posterior arms of graft.
- Popliteus tendon, PFL sutured to graft to restore PFL.
- PL capsule plication or advancement performed under sufficient tension to allow 0 degree of extension without hyperextension.
- Knee taken through 0-90 degrees, normal internal-external rotation determined at 30 degrees of flexion to avoid overconstraining joint.

CPN, Common peroneal nerve; *FCL*, fibular collateral ligament; *ITB*, iliotibial band; *PFL*, popliteofibular ligament; *PL*, posterolateral.

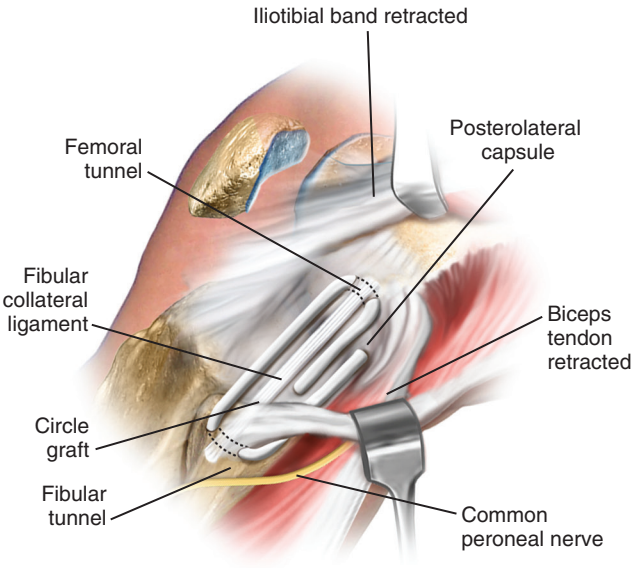
is to place a tunnel using a 6-mm drill hole anterior-to-posterior to the FCL insertion. The drill hole is deepened, leaving approximately 10 mm of cortex between the anterior and posterior tunnels. This step requires care to preserve the lateral femoral cortex at the FCL attachment site. A curved curette is used to make a bony tunnel underneath the ligament insertion without removing excess bone, which would weaken the insertion site.

A tendon allograft or semitendinosus-gracilis (STG) autograft (6 to 8 mm in diameter) is prepared. The graft is measured to allow sufficient length (19 to 20 cm) for the anterior and posterior arms of the circle graft to overlap posteriorly, which provides additional collagenous tissue to the PL aspect of the joint (Fig. 17-19, *A* and *B*). Two interlocking closed loop sutures (FiberLoop, Arthrex) are placed into both ends of the graft. The graft is initially stretched for 15 minutes under an 89-N load with a ligament-tensioning device.

An incision is made vertically just behind the FCL into the PLC. The tissues of the PLC, PMTL, and FCL are carefully inspected. The popliteus tendon is inspected from its insertion site to the muscle belly. If the PLC has excessive redundancy, then a simple capsular plication can be performed. The graft is inserted through bone tunnels in the femur and fibula, with the graft strands next to the slack FCL. The graft is placed under slight tension with the knee at 30 degrees of flexion, neutral tibial rotation, and with the lateral side of the joint closed (after repair of meniscal attachments when necessary). It is important not to internally rotate the tibia during graft tensioning, which would result in an abnormal restraint of external rotation. Multiple interrupted sutures are used through the posterior overlapped arms of the graft (see Fig. 17-19, *C* and *D*). The disrupted FCL fibers are interposed between the anterior and posterior arms of the circled graft, and horizontal sutures are placed between both structures (see Fig. 17-19, *E* and *F*). Sutures are placed between the popliteus tendon at the musculotendinous junction to restore the attachment to the fibula (PFL). If the PMT is lax, the tendon may be shortened by direct repair or the tendon is advanced and recessed at its anatomic femoral attachment into a tunnel and fixated with an absorbable interference screw.

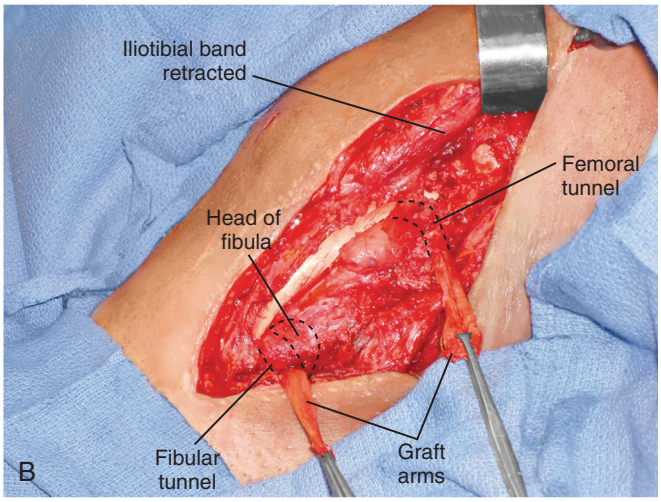
The knee is taken through a range of 0 to 90 degrees of flexion, and normal internal-external rotation is ascertained at 30 degrees of knee flexion to avoid overconstraining the joint. The PLC plication or advancement is then performed under sufficient tension to allow 0 degree of extension without hyperextension.

There are many different types of femoral-fibular reconstructions with modification of the two graft arms crossing as discussed or with a graft strand passing posteriorly from the femoral to posterior tibial attachment to reconstruct the PMTL. Clinical data are insufficient to recommend one procedure over another.

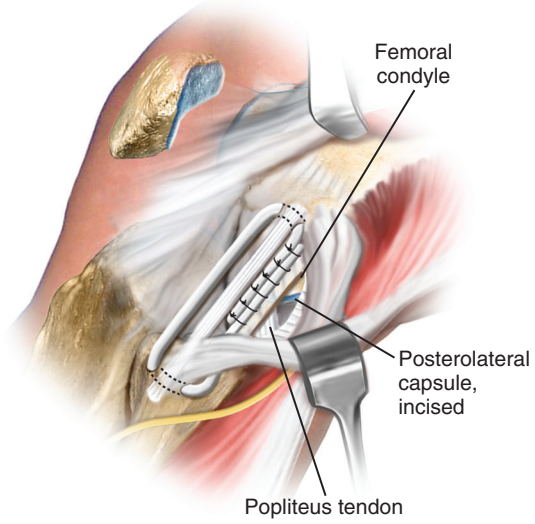


Proximal Advancement of the Posterolateral Structures

A straight lateral incision, approximately 12 cm in length, is used centered over the lateral joint line and dissection proceeds as already described. The incision extends distally to allow exposure of the fibular head and proximally to allow exposure of the attachment of the FCL to the femur. The skin flaps are mobilized beneath the subcutaneous tissue and fascia, protecting the vascular and neural supply. The attachment of the ITB is identified. An incision is made along the posterior border of the ITB and continued proximally, as already discussed for the initial approach. The attachment of the ITB to the lateral intramuscular septum is preserved.



The PL structures are carefully identified. A definitive FCL of normal width and integrity (although lax) is identified, and the PL structures are verified to have adequate thickness (and not replaced by scar tissue). It is important to verify that the popliteus attachments to the fibula (PFL) and tibia are intact. If a definitive normal-appearing FCL is not observed, or if there is scar tissue replacement of the PL structures, then an anatomic reconstruction is required. The PL structures appear normal except for a mild to moderate increase in elongation.



The CPN is palpated and protected throughout the procedure and is not dissected from its anatomic position. The joint capsule of the knee is incised vertically 10 mm anterior to the popliteal tendon's femoral attachment site, preserving the anterolateral capsular ligament. This permits the popliteal tendon attachment to be visualized on the lateral femoral condyle. A Kelly clamp is passed through this opening in the capsule and under the popliteus tendon, FCL, and anterior third of the lateral gastrocnemius muscle tendon attachment. An anterior-to-posterior incision is made in the periosteum just proximal to the FCL attachment. This incision is continued with a vertical, posterior arm into the anterior third of the LGT and anterior arm just anterior to the popliteus tendon attachment.

A straight osteotome initially cuts the rectangular edges, followed by a curved osteotomy that is used to remove an 8-mm-thick × 15-mm-wide wedge of bone at the attachment site of the PL structures, extending distally to the joint, avoiding the articular cartilage (Fig. 17-20, *A* and *B*). Two Alice clamps are placed on the osteotomized bone attachment of the PL structures. Any remaining soft tissue attachments are incised. The PLC attachment is incised along its posterior attachment approximately 10 to 15 mm to tension the capsule with final fixation (see Fig. 17-20, *C* and *D*).

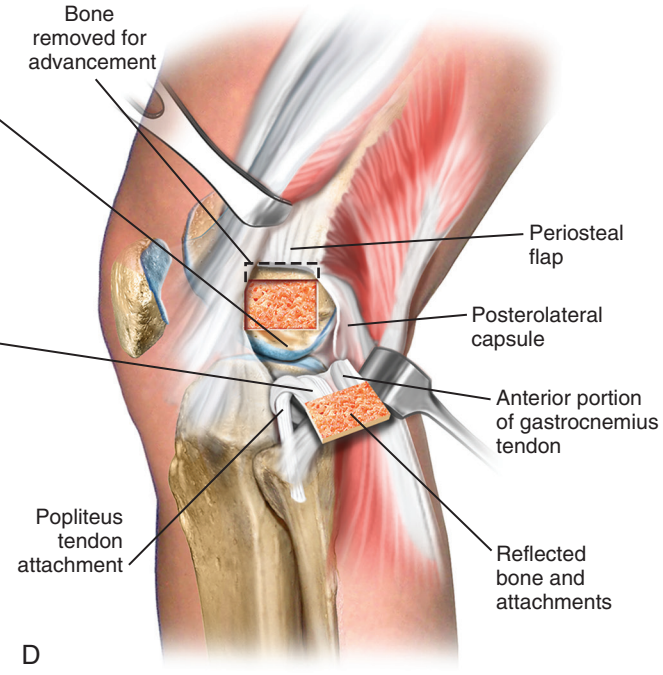

FIG 17-20 Proximal advancement of intact but lax posterolateral (PL) structures **A** and **B,** The PL structures are identified and have a normal, although lax, appearance. The line for the osteotomy of the femoral attachment of the fibular collateral ligament (FCL), popliteus muscle tendon, and anterior portion of the gastrocnemius tendon is shown. **C** and **D,** The osteotomy is 8 mm deep to provide sufficient bone to maintain the attachments of the FCL, popliteus tendon, anterior gastrocnemius tendon, and PL capsule. The PL capsule is incised 10 to 15 mm in length.

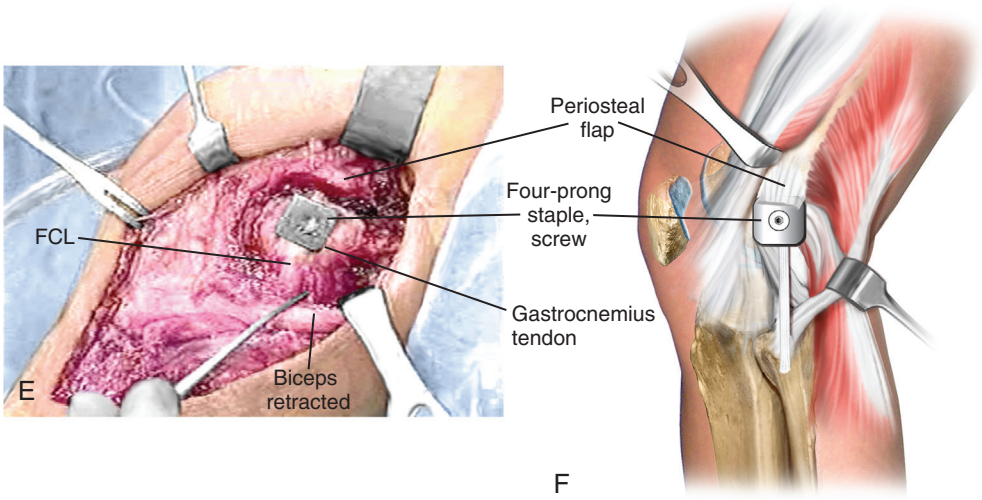

FIG 17-20, cont'd E and **F,** The bone attachment of the PL structures is advanced proximally in line with the FCL, with the knee in neutral tibial rotation and 30 degrees of flexion. Reattachment of the bone is achieved with a four-pronged staple and screw. *ITB*, Iliotibial band.

CRITICAL POINTS **Proximal Advancement of Posterolateral Structures**

- Straight lateral incision, 12 cm in length, centered over lateral joint line.
- Incision made along posterior border of ITB. Attachment of ITB to lateral intramuscular septum preserved. Posterior ITB incision may be required.
- Identify definitive FCL of normal area and integrity (although lax). Verify PL structures have adequate thickness, not replaced by scar tissue.
- CPN palpated, protected.
- Kelly clamp passed through opening in capsule and under popliteus tendon, FCL, and anterior third of lateral gastrocnemius muscle tendon attachment.
- Incision in periosteum just superior and proximal to FCL femoral attachment.
- New attachment site for PL structures prepared by elevating periosteum proximal to FCL.
- Curved osteotome elevates 8-mm thick × 15-mm wide wedge of bone at attachment site of PL structures, extending distally to the joint avoiding the articular cartilage.
- PL capsular attachments incised posteriorly, avoiding popliteus tendon.
- Proximal attachment site dissected subperiosteally, contoured with an osteotome. Sufficient amount of bone removed to allow the osteotomized bone attachment inlay to be placed and the staple to not be prominent.
- Bone attachment site of PL structures advanced in proximal direction of FCL with knee in 30 degrees of flexion, neutral tibial rotation.
- Inferior margin of staple placed at FCL anatomic attachment site to restore normal FCL length.
- PL function determined after fixation: 2- to 3-mm lateral joint opening, no abnormal external tibial rotation or hyperextension.

CPN, Common peroneal nerve; *FCL*, fibular collateral ligament; *ITB*, iliotibial band; *PL*, posterolateral.

The proximal attachment site is dissected subperiosteally, contoured with an osteotome, and a sufficient amount of bone is removed to allow the osteotomized bone attachment to be placed as an inlay, which decreases the prominence of the four-prong staple and screw fixation. It is necessary to inspect that the popliteus tendon is well attached to the anterior portion of the osteotomized bone so that it will be taut when tension is applied. The bone attachment of the PL structures is advanced in the proximal direction of the FCL with the knee in 30 degrees of flexion and neutral tibial rotation. The 90 degrees of flexion position is not recommended because this produces an anterior and distal attachment of the PL structures, which induces large forces with knee flexion-extension and risks stretching out the PL structures.

The goal is to advance the FCL in a proximal direction to remove excessive slackness and to use staple fixation at the normal anatomic site. The bone attachment site may be slightly rotated to adjust the tension in the posterior capsular tissues with extension. Fixation is with a large four-prong staple (see Fig. 17-20, *E* and *F*), and the distal margin of the staple is directly at the anatomic attachment of the FCL to restore normal FCL length. A cancellous bone screw is used for additional fixation.

The function of the FCL is determined after fixation to ensure that there is only 2 to 3 mm of LJO on varus stress testing and no abnormal external tibial rotation or hyperextension. The PL tissues are tensioned to allow the knee to come to 5 degrees of flexion and to resist further extension after this point, gradually reaching 0 to −2 degrees hyperextension during the postoperative rehabilitation period. The ITB tension is determined. A distal advancement of the ITB at the tibial attachment may be (rarely) required to restore normal tension in this structure. The ITB is closed with absorbable sutures. To prevent lateral tethering on the patella, any incisions into the ITB and lateral patellar retinaculum are loosely closed (Fig. 17-21).

An example of the proximal advancement with an all-inside PCL reconstruction is shown in Figure 17-22. The PL complex was functionally intact but lax and did not require graft reconstruction as previously described.

OUR CLINICAL STUDIES

The results of a series of prospective clinical studies of consecutive patients are reported using the CKRS and the International Knee Documentation Committee (IKDC) system.[2] The results were evaluated by a senior clinical research associate and not the surgeon.

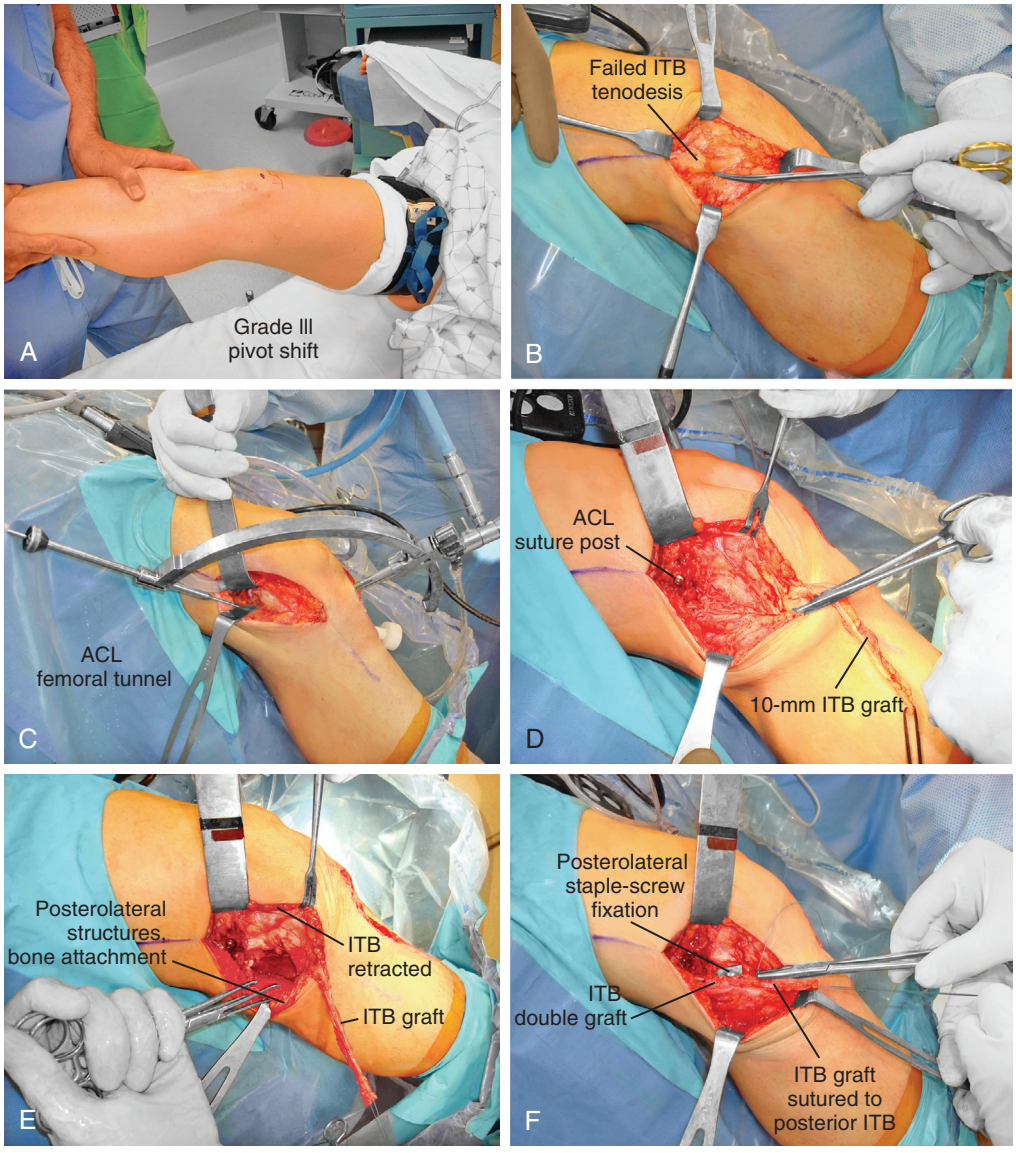

FIG 17-21 A 38-year-old female physician with symptomatic chronic anterior cruciate ligament (ACL) rupture referred to our center after failure of iliotibial band (ITB) tenodesis. An acute superficial medial collateral ligament repair at the index procedure was successful. **A,** Grade III pivot shift. A harvest of a semitendinosus-gracilis graft was performed (not shown) through the prior medial incision. **B,** Identification of failed ITB tenodesis with deficient anterolateral structures. **C,** Outside-in femoral tunnel at ACL anatomic site on lateral wall of femur. **D,** Harvest of ITB for extraarticular (EA) reconstruction because of severe anterior instability. **E,** Osteotomy and advancement of posterolateral (PL) structures that were intact but lax, allowing abnormal increased lateral joint opening and external tibial rotation at 30 degrees of flexion. **F,** Internal fixation of proximal advancement and EA reconstruction. The ITB graft was looped under one of the staple prongs and sutured to itself and the remaining ITB to provide a secondary restraint. The remaining ITB was closed. This procedure was successful in restoring PL and anterior stability.

Anatomic Posterolateral Reconstruction

A consecutive group of knees that had an anatomic PL reconstruction including an FCL B-PT-B reconstruction were prospectively followed 2 to 13.7 years postoperatively.[45] All major PL structures were surgically restored as required. The procedure represented a primary reconstruction in seven patients and a revision in six patients. ACL ruptures were found in seven patients and bicruciate ruptures in five patients, all of which were reconstructed.

At follow-up, 13 of the 14 (93%) PL reconstructions restored normal or nearly normal LJO and external tibial rotation (Fig. 17-23). The ACL reconstructions were normal or nearly normal in 11 knees and abnormal in one knee. All patients achieved at least 0 to 135 degrees of knee motion; one required a gentle manipulation, and one had an arthroscopic lysis of adhesions to achieve this range of knee motion.

Significant improvements were found at follow-up for pain ($P = .0001$), swelling ($P = .02$), patient rating of the overall knee condition ($P < .001$), walking ($P < .05$), and stair climbing ($P < .05$). Before the operation, 9 of the 12 patients had moderate or severe pain with daily activities, but at follow-up, only 1 patient had such pain. Eleven of the

FIG 17-22 A proximal advancement and all-inside posterior cruciate ligament quadriceps tendon-patellar bone reconstruction with TightRope (Arthrex) fixation on the femur.

12 patients had given up sports activities completely before the operation, and 1 was participating in low-impact activities without problems. At follow-up, 11 patients were participating in mostly low-impact athletics (swimming, bicycling) without symptoms and 1 patient was participating in sports that involved pivoting and cutting with pain and limitations against advice.

The results of the anatomic PL reconstructions were similar for primary and revision cases. The only failure occurred in a revision knee. A total of 17 PL procedures had been performed in the six revision knees before the anatomic reconstruction. The failed PL procedures included nonanatomic graft augmentation procedures, primary repairs in knees with chronic PL ruptures, or biceps tendon procedures. None of these knees had surgical restoration of all of the PL structures in one setting. In addition, none of the revision knees had a successful ACL procedure; therefore all required ACL reconstruction or revision during the anatomic PL graft reconstruction.

Femoral-Fibular Allograft Reconstruction

Two investigations were performed on the femoral-fibular allograft reconstruction for chronic instability.[41] The first study followed 20 consecutive patients from 2 to 7.8 years postoperatively. Lateral stress radiographs and a comprehensive knee examination showed that 16 knees (76%) had a functional FCL and PL reconstruction and 5 failed. All knees but 1 had at least 0 to 135 degrees of knee motion at follow-up and no patient required an additional operation for a limitation of motion.

Significant improvements were found for symptoms and functional limitations ($P < .01$). Before the operation, 9 patients had moderate pain with activities of daily living, 7 had pain with any sports activities,

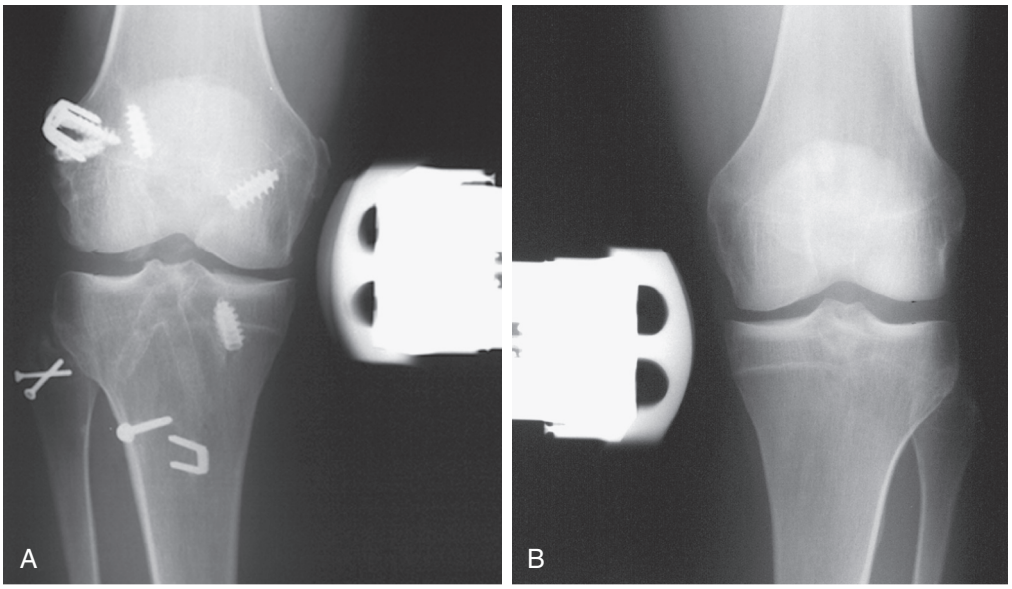

FIG 17-23 Lateral stress radiographs of a 22-year-old man 2 years after a combined fibular collateral ligament bone-patellar tendon-bone (B-PT-B) autogenous reconstruction, an anterior cruciate ligament B-PT-B allograft reconstruction, and a posterior cruciate ligament two-strand quadriceps tendon-patellar bone reconstruction. There is no measurable difference in the millimeters of lateral tibiofemoral joint opening between the reconstructed **(A)** and opposite **(B)** knee. (From Noyes FR, Barber-Westin SD. Posterolateral knee reconstruction with an anatomical bone-patellar tendon-bone reconstruction of the fibular collateral ligament. *Am J Sports Med.* 2007;35:259-273.)

and 4 had no pain with light sports but had pain with moderate sports (running, twisting, turning activities). At follow-up, 2 patients had pain with daily activities, 2 had pain with any sports activity, and 16 could participate in mostly light sports without pain.

A longer-term follow-up of the femoral-fibular reconstruction was conducted in a group of 27 patients. In 10 patients, the reconstruction failed before the minimum 2 years follow-up period. These cases were included in the overall failure rate, but not in the subjective and functional analyses. Five of these patients had undergone prior unsuccessful PL procedures before the femoral-fibular reconstruction. In six of these patients, a revision of the FCL and PL structures was performed and in two patients with chronic pain, a total knee replacement was done. In one patient, the allograft was removed, and in one patient, no further operative procedure had been done at the time of writing.

The remaining 17 patients were evaluated a mean of 15 years (range, 4-19 years) postoperatively. Statistically significant improvements were found in the scores for pain, swelling, giving-way, walking, stair climbing, running, and twisting ($P < .05$). Before the operation, 50% of the patients had moderate to severe pain with daily activities, but at follow-up, only 13% had these complaints. Before the operation, all patients had either given up all athletic activities or had severe limitations with even light recreational activities. At follow-up, 63% were participating in low-impact activities such as swimming and bicycling without problems, 6% were participating with symptoms, and 31% were not participating in athletic activities. In these 17 patients, the FCL reconstructions were rated as normal or nearly normal (IKDC ratings, LJO and external tibial rotation) in all knees. Twelve patients had required a concomitant ACL reconstruction, which were rated as normal or nearly normal in eight and abnormal in four.

CRITICAL POINTS

Our Clinical Studies: Anatomic PL Reconstruction

- $n = 14$ followed 2 to 3.7 years postoperative.
- ACL reconstructed in 7 knees, ACL and PCL reconstructed in 5 knees.
- Evaluation: comprehensive knee examination, lateral stress x-ray, KT-2000, 20 degrees, 134 N, IKDC, Cincinnati Knee Rating System.
- Results
  - 93% normal/nearly normal lateral tibiofemoral joint opening and external tibial rotation.
  - All knees at least 0-135 degrees.
  - Significant improvements pain, swelling, patient rating, walking, stair climbing.
  - 11 patients returned low-impact sports without problems.

Our Clinical Studies: Femoral-Fibular Allograft Reconstruction

- $n = 27$ followed mean 12.7 years (range, 2-1 years).
- Evaluation: comprehensive knee examination, lateral stress x-ray, KT-2000, 20 degrees, 134 N, IKDC, Cincinnati Knee Rating System.
- Results
  - 64% normal/nearly normal lateral tibiofemoral joint opening and external tibial rotation.
  - All knees at least 0-135 degrees.
  - Significant improvements pain, swelling, giving-way, walking, stair climbing.
  - 63% returned to low-impact sports without problems.

ACL, Anterior cruciate ligament; *IKDC*, International Knee Documentation Committee; *PCL*, posterior cruciate ligament.

Because of the increased failure rate, which was attributed to patients with poor PL tissues and prior failed PL procedures, we now recommend anatomic PL reconstruction. A femoral-fibular procedure is used only in chronic knees in which the PMTL is functional and the goal is to augment a deficient FCL. This operation is also useful in acute PL disruptions to restore FCL function, along with a primary repair of the remaining PL tissues.

Proximal Advancement of Posterolateral Structures

A proximal advancement of the PL structures was done in conjunction with a cruciate ligament reconstruction in 23 consecutive patients.[42] One patient was lost to follow-up. A second patient had an early failure and required a revision PL reconstruction; this result was included in the study's overall failure rate. Therefore 21 patients made up the study group and were evaluated 2 to 6.1 years postoperatively. The ACL was also reconstructed in nine knees, the PCL was reconstructed in 11 knees, and both cruciates were reconstructed in one knee.

At follow-up, 20 knees (91%) had normal or nearly normal LJO and external tibial rotation, and two (9%) failed. At least 0 to 135 degrees of knee motion was found in 16 patients. Two patients had mild limitations (between 1 and 5 degrees) in both extension and flexion, one patient had a mild limitation of extension only, and two patients had mild limitations in flexion only. No further operations were performed for losses of knee motion.

Before the operation, eight patients had pain with daily activities, eight had pain with any sports activity, and five could participate in light sports but had pain with moderate sports (running, twisting and turning activities). At follow-up, two patients had pain with daily activities, nine patients had pain with any sports activity, and 10 were able to participate in low-impact sports without pain. Overall, 71% of patients showed improvement in the pain score or had no symptoms with light sports.

Before the operation, all patients had either given up sports activities or were participating with symptoms and functional limitations. At follow-up, 62% had returned to mostly low-impact activities without symptoms. The other patients did not return owing to their knee condition. At the time of the operation, 52% of the patients had abnormal articular cartilage lesions (Grade 2-A, 2-B, or 3-A >15 mm, CKRS). This study shows the advantage of this operation in properly selected patients who have interstitial stretching of the PL structures without prior traumatic disruption, allowing advancement to restore normal tension.

CRITICAL POINTS Our Clinical Studies: Proximal Advancement Posterolateral Structures

- $n = 21$ followed 2-6.1 years.
- ACL reconstructed in 8 knees, PCL reconstructed in 10 knees, ACL and PCL reconstructed in 4 knees.
- Evaluation: comprehensive knee examination, lateral stress x-ray, KT-2000, 20 degrees, 134 N, IKDC, Cincinnati Knee Rating System.
- Results
  - 91% normal/nearly normal lateral tibiofemoral joint opening, external tibial rotation.
  - ACL normal/nearly normal in 92%.
  - 62% patients returned to low-impact sports without problems.

†3 knees had more than one factor identified.
‡7 of 17 knees had more than one factor identified.
§ACL and/or PCL rupture: either not treated or not adequately restored; procedure failed.
ACL, Anterior cruciate ligament; *PCL*, posterior cruciate ligament; *PL*, posterolateral.

Causes of Failure of Posterolateral Operative Procedures

The potential causes of failure of 57 operative procedures (30 index and 27 revisions) to the PL structures of the knee were studied in a consecutive series of 30 knees of patients who were referred to our center.[46] The index PL procedures were done for an acute knee injury in 13 knees (mean, 3 weeks; range, 1 to 11 weeks after the injury) and for chronic deficiency in 17 knees a mean of 56 months (range, 4 to 312 months) after the original injury.

The review of medical records in all cases was done by an independent surgeon not involved in the care of the patients. At the initial evaluation, a comprehensive knee examination and lateral stress radiographs were performed. KT-2000 testing was done in knees with ACL ruptures, and posterior stress radiographs were done in knees with PCL ruptures.

Overall, for all 57 failed PL operations, nonanatomic graft procedures had been done in 23 knees (77%, Table 17-3). The definition of an anatomic reconstruction was a graft placed in anatomic ligament attachment sites with secure internal fixation. Therefore suture repairs, extraarticular ITB augmentations, and biceps tendon rerouting methods (Fig. 17-24) were not considered anatomic procedures.

Untreated varus malalignment was identified in 21 failed PL procedures (37%) or in 10 of 30 knees (Tables 17-4 and 17-5). Patients who presented with PL deficiency and varus osseous malalignment were diagnosed with triple varus knees. Associated ACL, PCL, or bicruciate deficiency was identified in 27 knees (93%). ACL deficiency was identified in 41 of the 57 (72%) failed PL procedures and associated PCL deficiency was noted in 15 (26%) of the failed PL procedures.

PL deficiency subjects ACL and PCL grafts to excessive tensile loading owing to the abnormal lateral tibiofemoral joint opening that occurs with activity. Several in vitro studies report significantly increased forces on ACL and PCL grafts in knees with sectioned PL structures (see Chapter 15), providing further evidence of the deleterious effects of FCL and PMTL insufficiency after ACL or PCL reconstruction.

Limitations of this study were similar to those of other investigations in which the potential causes of ligament reconstruction failure were defined. It is difficult to determine in a retrospective manner the exact causes of failure. Several theoretical factors exist that cannot always be detected or measured. These include failure of grafts to fully remodel or heal, poor tissue quality caused by extensive disruption to the popliteus and FCL, limited healing potential of soft tissues caused by repeated operations and diminished blood supply, osteopenic bone preventing appropriate fixation, and gait hyperextension abnormalities that may have occurred postoperatively without the knowledge of the investigators.

In addition, since the study period extended over two decades, the evolution of the diagnosis and management of PL injuries and

FIG 17-24 A patient with a failed biceps femoris tenodesis for posterolateral instability was unable to actively rotate the left tibia externally. This procedure is not recommended.

CRITICAL POINTS Our Clinical Studies: Causes of Failure of Posterolateral Operative Procedures

- $n = 57$ failed PL procedures in 30 knees.
- Evaluation: review of medical records by an independent surgeon, comprehensive knee examination, lateral stress x-ray, KT-2000, 20 degrees, 134 N, PCL stress x-ray, IKDC, Cincinnati Knee Rating System.
- Causes of PL failure
  - 93% associated cruciate deficiency (either untreated or failed reconstruction).
  - 77% nonanatomic PL procedures (suture repair, iliotibial band augmentations, biceps tendon rerouting).
  - 37% untreated varus osseous malalignment (triple varus knee).
- Conclusions
  - Emphasis during index operation on anatomic PL reconstruction, concurrent reconstruction all torn cruciate ligaments.
  - If varus osseous malalignment exists, correct with osteotomy before PL reconstruction.

IKDC, International Knee Documentation Committee; *PCL*, posterior cruciate ligament; PL, posterolateral.

associated abnormalities has altered the treatment of these problems. Some of the procedures in this series represent operations that are no longer routinely performed. Even so, the results of this study suggest greater emphasis during the index operation for anatomic graft reconstruction of one or more of the PL structures as necessary, restoration of all ruptured cruciate ligaments, and correction of varus malalignment. We have long advocated anatomic PL reconstruction over suture repair in patients who sustain acute high-energy injuries and extensive disruption of the PL structures. Usually at least one component of the PL structures requires graft reconstruction, which is the FCL in nearly all cases.

OTHER OPERATIVE TECHNIQUES AND RESULTS

Several authors have reported clinical outcome data from PL reconstructive procedures (Table 17-6). LaPrade and coworkers[26] described an anatomic PL reconstruction shown in Figure 17-25, *A* and *B*. Biomechanic testing of this technique demonstrated restoration of normal knee motion limits to external tibial rotation and LJO. The operation restores the anatomic attachment sites for the FCL and popliteus tendon and allows load sharing between these two structures, which appears to have a distinct advantage over a single femoral-fibular graft reconstruction. The clinical outcomes of this operation were reported in 54 patients, 18 of whom had an isolated

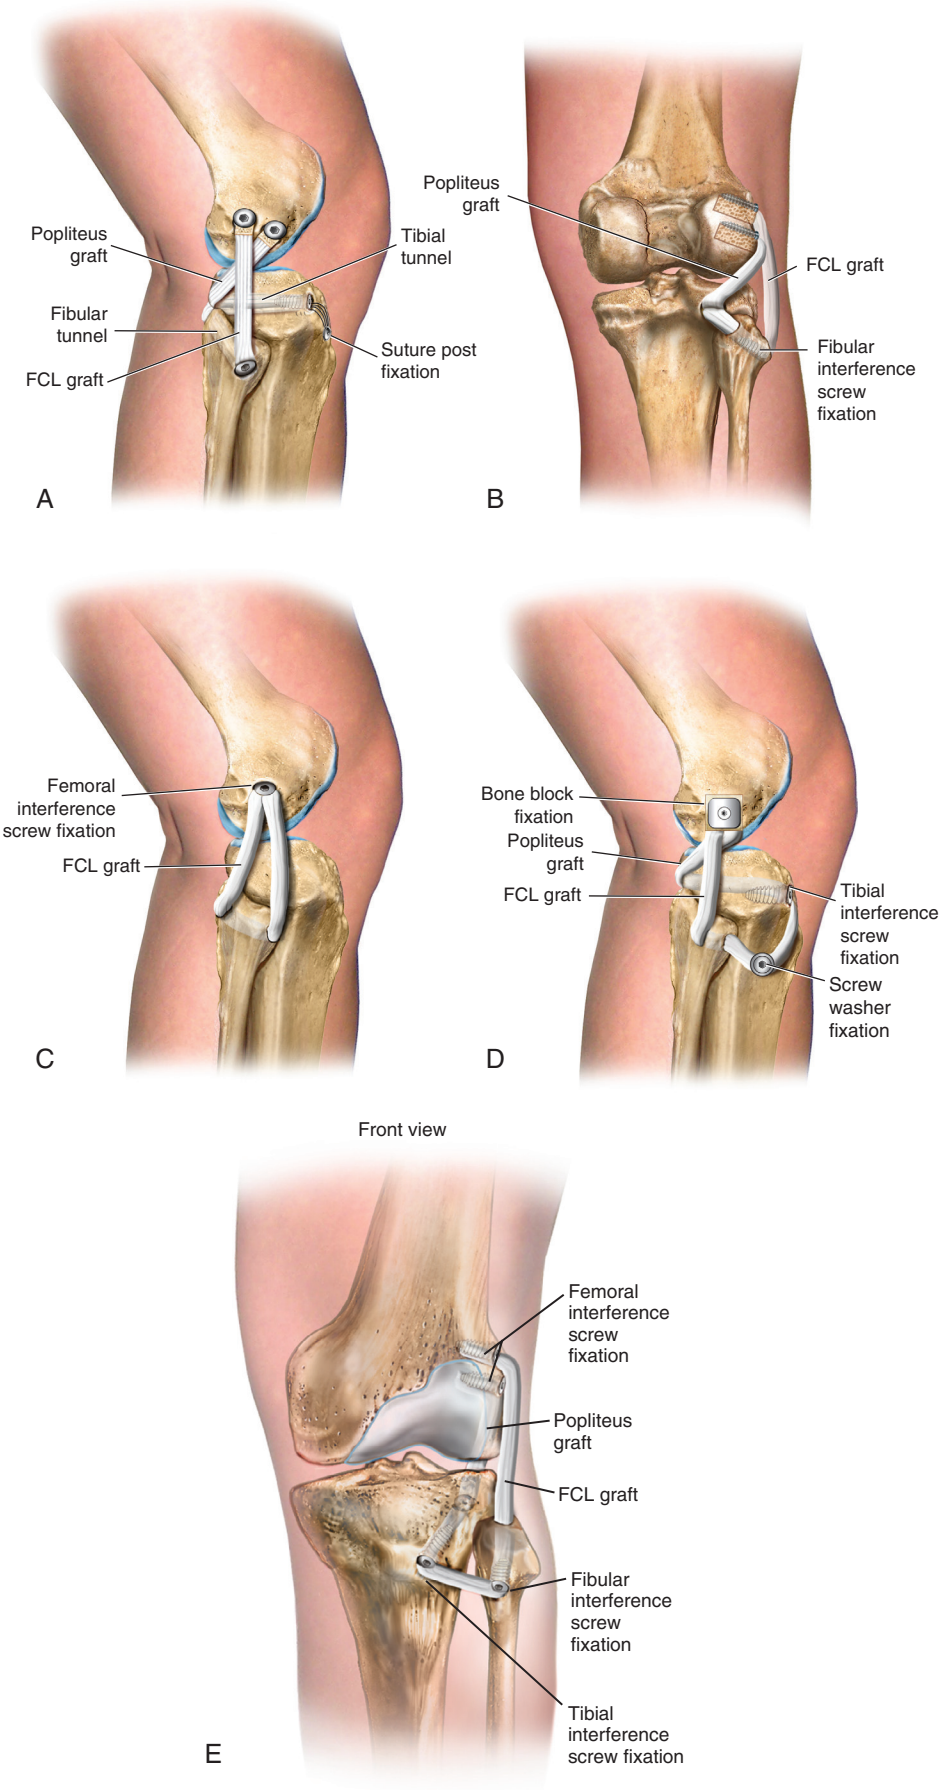

FIG 17-25 Alternative techniques for posterolateral (PL) reconstructions. **A** and **B,** The anatomic PL reconstruction described by LaPrade and coworkers[26] that uses Achilles tendon-bone (AT-B) allografts. **A,** The bone portion of the graft is placed at the femoral insertion of the fibular collateral ligament (FCL) and popliteus tendon. **B,** The popliteus graft is passed through a tunnel at the PL tibia. The FCL graft is passed through a fibular tunnel. **C,** PL technique described by Larson and Belfie[30] that uses a semitendinosus autograft. **D,** A technique demonstrating a single AT-B allograft in which a bone inlay is placed at the FCL femoral insertion. This technique avoids creating two femoral tunnels that may potentially weaken the lateral femoral condyle and is considered advantageous in knees that have prior tunnels from anterior cruciate ligament surgery. **E,** Technique using a single graft to replace the FCL and popliteus tendon described by Kim and associates.[21] The proximal ends of the graft are fixed by using bioabsorbable screws.

posterolateral reconstruction and the remainder of whom required concomitant cruciate ligament reconstruction.[25] At a mean of 4.3 years postoperatively, IKDC ratings for varus opening and external tibial rotation (30 degrees) were A or B in 50 patients and C in 4. The IKDC subjective mean score was 62.6 points (range, 20-100) and the overall modified Cincinnati score was 65.7 points (range, 20-100). Three patients required a revision posterolateral reconstruction for recurrent instability.

Tardy and colleagues[62] reviewed 20 patients who underwent combined PL-cruciate ligament reconstructions a mean of 3.2 years postoperatively. The PL procedure used a hamstrings autograft to reconstruct the FCL, popliteus tendon, and PFL. Static measurements were made of internal and external tibial rotation using the rotameter knee laxity measurement device,[33] which measured the dial test at 30 degrees under a 5 N-m torque. Side-to-side differences were measured between the reconstructed and contralateral knees of the patients. These differences were then compared with side-to-side differences in 20 healthy controls. There was no significant mean difference in external rotation between the knees of the patients (−1.0 ± 4.1 degrees) or between the patients and controls (2.5 degrees). However, there was a significant difference between patients and controls in internal tibial rotation of 17.15 degrees ($P < .05$). The authors reported that 65% of the patients had an *altered* rotational profile of either increased external or internal tibial rotation compared with the 95% CIs of the control group.

Buzzi and colleagues[5] described an FCL reconstruction using a semitendinosus tendon autograft. In a group of 13 patients studied at a mean of 5 years postoperatively, all had normal or nearly normal restoration of LJO and external tibial rotation postoperatively. Cooper and Stewart[8] presented two operative options for PL ruptures. One consisted of a combined FCL and PFL reconstruction (with a semitendinosus tendon autograft) with capsular imbrication. The second option consisted of reconstruction of the PFL only in knees with an intact FCL. In a group of 19 patients with combined PCL and PL ruptures, no patient had greater than 10 degrees of external rotation or more than 1+ increase in LJO postoperatively.

Stannard and colleagues[59] followed 57 patients who received either a primary repair of acutely ruptured PL structures or a graft reconstruction of chronically deficient FCL, PFL, and popliteus tendon structures. At an average of 2.7 years postoperatively, 37% of the primary repair procedures had failed, compared with 9% of the graft reconstructions. The authors concluded that primary repair of the FCL is indicated only for bony avulsions that are amendable to internal fixation. Otherwise, graft reconstruction of the FCL is recommended, especially if an immediate knee motion program is to be used postoperatively.

The PL technique described by Larson and Belfie[30] that uses a semitendinosus autograft is shown in Figure 17-25, *C*. The operative procedure is designed to restore FCL function, as in acute operative cases. However, it does not restore the PMTL unit, which may be required in chronic PL reconstructions. The outcomes of this operation were reported by Lee and associates[31] in 70 patients with chronic PCL and PL deficiency. These investigators used this operation in patients with grade 2 PL injuries, reserving an anatomic reconstruction for patients with grade 3 PL injuries. At a mean of 3.3 years postoperatively, external tibial rotation was overconstrained in 20%, constrained in 71%, and lax in 9%. LJO was rated as grade 0 in 97% and grade 1 in 3%. Definitions of overconstrained, constrained, and lax were not provided. Zorzi and colleagues[69] performed this operation, along with a single-bundle PCL reconstruction, in 19 patients. At a mean of 3.2 years postoperatively, 17 patients had a negative dial test and varus stress test and 14 patients had a grade 0 posterior step-off. There was a mean reduction of 10 degrees of knee flexion. This investigation did not use stress radiographs.

A technique demonstrated in Figure 17-25, *D* avoids creating two femoral tunnels that may potentially weaken the lateral femoral condyle. This procedure is considered advantageous in knees that have prior tunnels as in ACL revision surgery and the surgeon wishes to avoid an additional tunnel and, instead, use a single bone inlay technique for femoral graft fixation. An alternative technique using a single graft to replace the FCL and popliteus tendon described by Kim and associates[21] is illustrated in Figure 17-25, *E*. This technique was compared with a biceps rerouting tenodesis in a cohort of 46 patients.[19] At 2 years postoperatively, the FCL reconstruction produced significantly less mean side-to-side difference compared with the tenodesis procedure in external rotation at 30 degrees and 90 degrees of flexion (differences of 4 ± 1 degrees and 7 ± 1 degrees, respectively; $P = .02$). The IKDC overall knee examination rating was A or B in 76% of the knees that underwent the FCL reconstruction compared with 40% of the knees that had the tenodesis procedure.

ILLUSTRATIVE CASES

Case 1: Revision of ACL and PL Failed Procedures in a Salvaged Knee. A 28-year-old man was referred with a history of four failed ACL reconstructions that included an extraarticular Iliotibial band procedure, a B-PT-B autograft, and two B-PT-B allografts. The most recent surgical procedure done elsewhere had consisted of an ACL B-PT-B allograft and a semitendinosus tendon graft reconstruction of the PMTL. The FCL was not surgically addressed. The patient complained of pain and giving-way with daily activities and had been unable to work since his original injury. The examination demonstrated a grade III pivot shift, 12 mm of increased lateral joint opening, and 10 degrees of increased external tibial rotation.

Diagnostic arthroscopy performed before the revision ACL and PL procedure demonstrated an abnormal lateral tibiofemoral gap test (Fig. 17-26, *A*), a deficient PMTL (see Fig. 17-26, *B*), and fissuring and fragmentation of the articular cartilage (Grade 2-B damage, see Chapter 44) in the patellofemoral, medial tibiofemoral, and lateral tibiofemoral compartments.

The patient underwent an ACL quadriceps tendon-patellar bone autograft reconstruction using a notch approach owing to the close proximity of prior femoral tunnels that had not healed completely (but did not require bone grafting). In addition, an anatomic FCL B-PT-B allograft reconstruction, repair of the popliteofibular ligament advancement of the popliteus tendon, and advancement of the posterolateral corner were performed (see Fig. 17-26, *C* and *D*).

Our comment: This case demonstrates the protracted course and failure of three ACL reconstructions owing to unrecognized PL deficiency. Secondly, when the PL deficiency was recognized, a popliteal tendon reconstruction was done without addressing the FCL deficiency, which most likely led to failure of all of the procedures. The importance of surgical reconstruction of both the FCL and PMTL is emphasized.

Case 2: Treatment of Combined Failure of ACL and Posterolateral Deficiencies in a Varus-Angulated Knee. A 35-year-old man presented 5 months after failure of a PL biceps tendon transfer procedure and ACL B-PT-B autograft reconstruction. AP (Fig. 17-27, *A*) and lateral (see Fig. 17-27, *B*) radiographs demonstrated abnormal expansion of both the femoral and tibial tunnels and a vertical ACL graft.

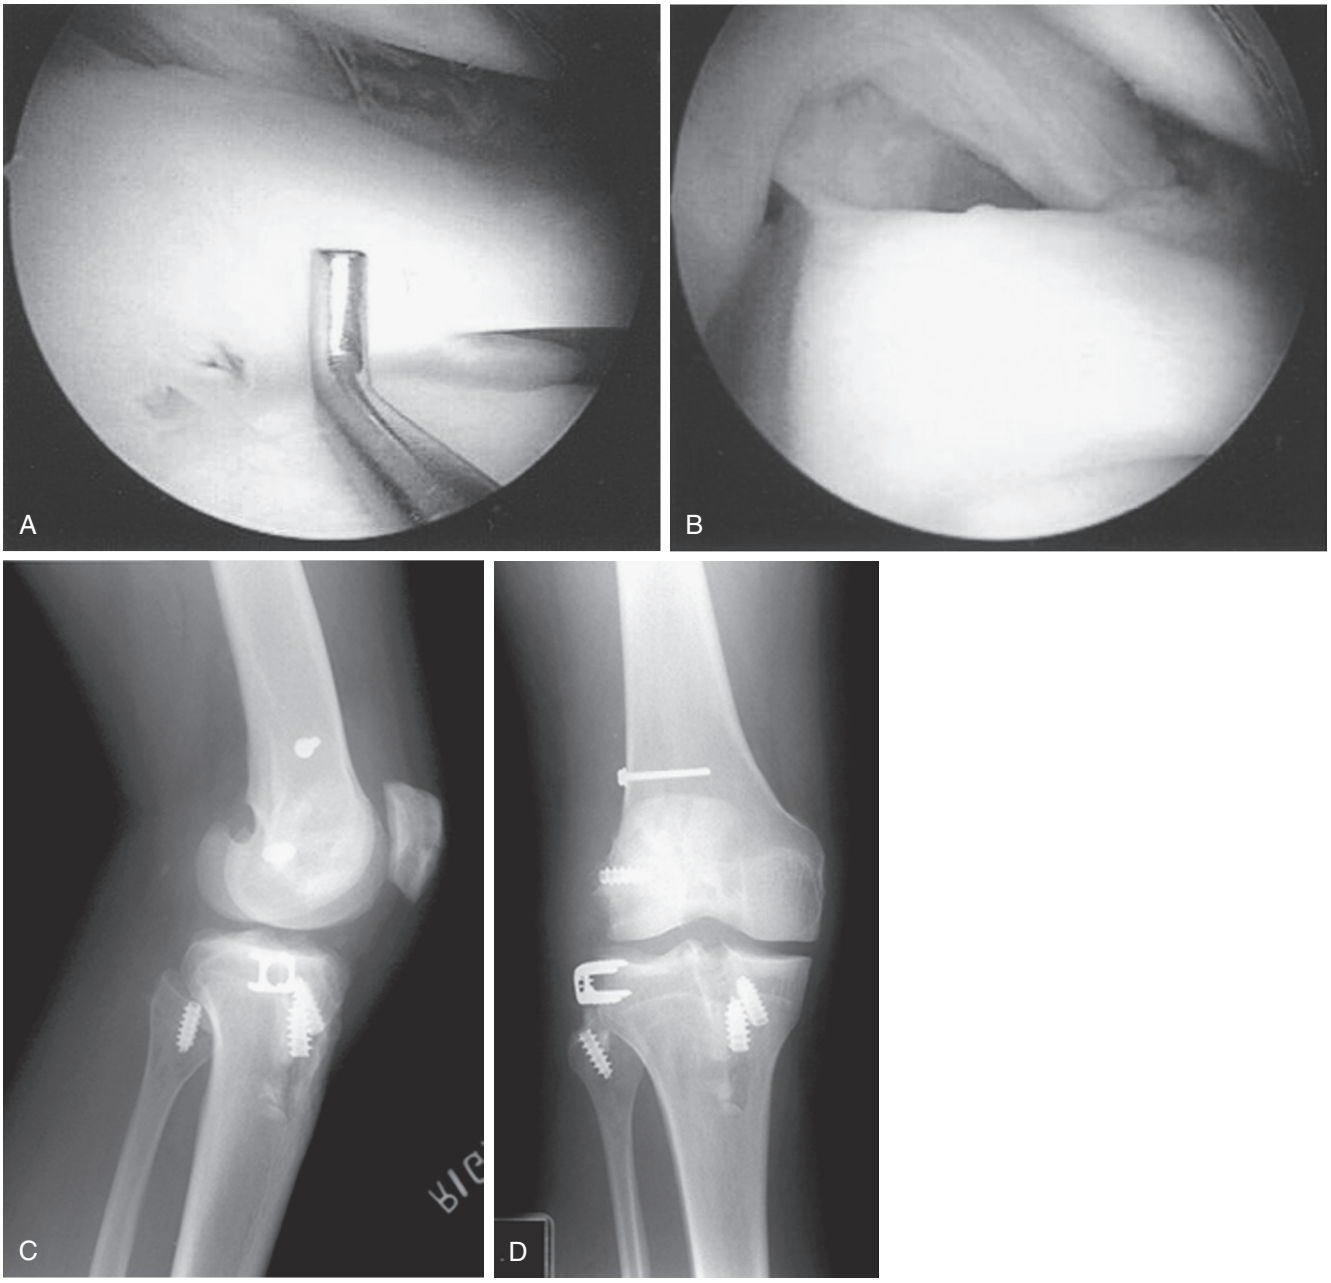

FIG 17-26 Case 1.

Physical examination revealed a grade III pivot shift, 7 mm of increased AP displacement on KT-2000 testing, and 10 mm of increased LJO. Full standing radiographs showed a weight-bearing line of 42%. The patient had not been able to return to work since his original injury and had moderate pain with daily activities.

The patient was treated with a staged approach of a corrective closing-wedge high tibial osteotomy, followed 4 months later with an anatomic PL reconstruction consisting of a fibular collateral ligament B-PT-B allograft, a popliteus muscle-tendon-ligament B-PT-B allograft, and a PL capsule plication. In addition, an ACL quadriceps tendon-patellar bone autograft revision reconstruction was performed that bypassed the previously placed vertical graft (see Fig. 17-27, *C*). At the latest follow-up evaluation, 4.4 years postoperative, there was no increase in LJO or external tibial rotation and the pivot shift test was negative. The patient had returned to work and light recreational sports without problems.

Our comment: This case demonstrates the increased failure rate when a PL reconstruction is performed in a varus-angulated knee. The first ACL reconstruction had a vertical ACL graft that was placed on the femoral notch roof outside the normal ACL femoral attachment.

Case 3: Treatment of Prior Multiple Failed Posterolateral Procedures in a Dislocated Knee. A 21-year-old man was referred 2 years after a knee dislocation sustained during football. He had undergone three failed PL operative procedures, including a biceps tendon reconstruction, a FCL allograft reconstruction, and a popliteal tendon allograft reconstruction. The deficient ACL had not been surgically treated. The medial collateral ligament was repaired during the first operative procedure.

Physical examination revealed a grade III pivot shift, 8 mm of increased AP displacement on KT-2000 testing, 12 mm of increased LJO, and 20 degrees of increased external tibial rotation. Stress radiographs demonstrated a severe increase in lateral joint opening (Fig. 17-28, *A*).

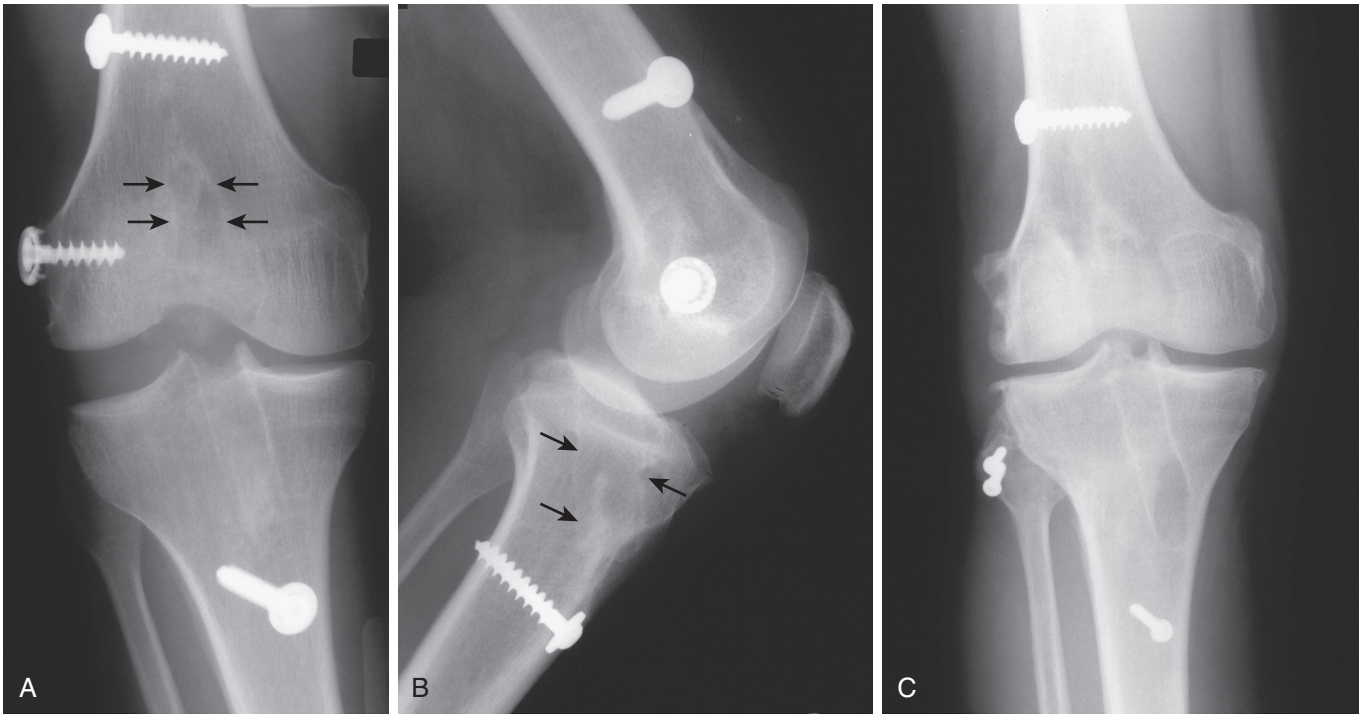

FIG 17-27 Case 2. (From Noyes FR, Barber-Westin SD, Albright JC. An analysis of the causes of failure in 57 consecutive posterolateral operative procedures. *Am J Sports Med.* 2006;34:1419-1430.)

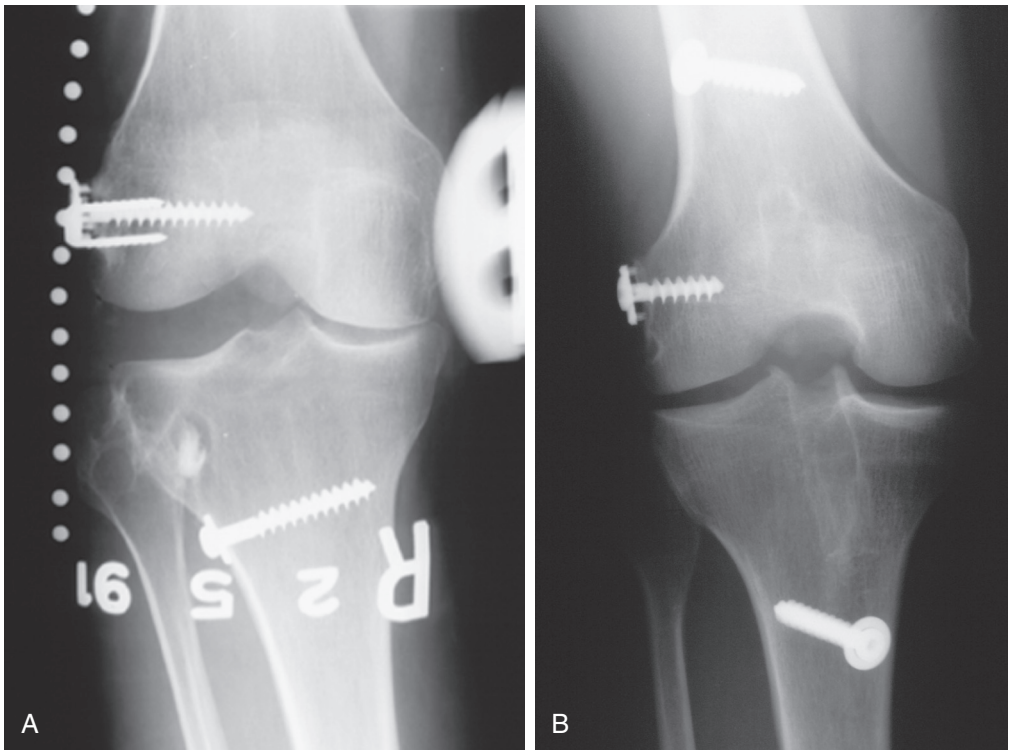

FIG 17-28 Case 3. (From Noyes FR, Barber-Westin SD, Albright JC. An analysis of the causes of failure in 57 consecutive posterolateral operative procedures. *Am J Sports Med.* 2006;34:1419-1430.)

The patient also had 5 mm of increased medial joint opening and 5 mm of increased posterior tibial translation. He complained of pain and giving-way with daily activities and rated the overall condition of his knee as poor.

The patient underwent an anatomic FCL B-PT-B autograft reconstruction (harvested from the contralateral knee) and a proximal advancement of the popliteus tendon. An ACL quadriceps tendon-patellar bone autograft was placed at the anatomic tibial and femoral attachment sites (see Fig. 17-28, *B*). Fissuring and fragmentation (grade 2-A damage) were noted in all three compartments.

At the most recent follow-up examination, 13.7 years postoperatively, the patient had no increase in LJO or external tibial rotation and

3 mm of increased AP displacement on KT-2000 testing. He was participating in low-impact activities without symptoms.

Our comment: In revision PL cases, it is necessary to address all PL structures as described. In this knee, after failure of three prior PL procedures, a contralateral B-PT-B autograft provided stability.

Case 4. A 50-year-old male physician presented 5 months after a right knee dislocation sustained during an attempted side tackle while playing soccer. The injury had been treated conservatively and the patient was experiencing increasing symptoms with daily and work activities. Physical examination revealed a lower limb varus malalignment with a mechanical axis of 5 degrees varus, a grade III pivot shift, 12 mm of increased LJO, and 10 mm of increased posterior tibial translation. The patient desired surgical reconstruction to return to his active lifestyle, which included skiing and mountain climbing.

An opening-wedge high tibial osteotomy was performed, followed 5 months later with a multiligament reconstruction that included an ACL B-PT-B allograft, a two-strand posterior cruciate ligament quadriceps tendon-patellar bone autograft, a fibular collateral ligament B-PT-B allograft, and a popliteus muscle-tendon-ligament reconstruction. The lateral meniscus was repaired. The patient had noteworthy articular cartilage damage (grade 2-B) on the patella undersurface and in the medial tibiofemoral compartment.

At follow-up, 4 years postoperatively, the patient had a full range of knee motion, no effusion, a grade 0 pivot shift, an increase of 5 mm of anteroposterior displacement on KT-2000 testing (at 20 degrees of knee flexion), 2 mm of increase in posterior tibial translation on posterior stress radiographs (Fig. 17-29, *A* and *B*), and no increase in LJO

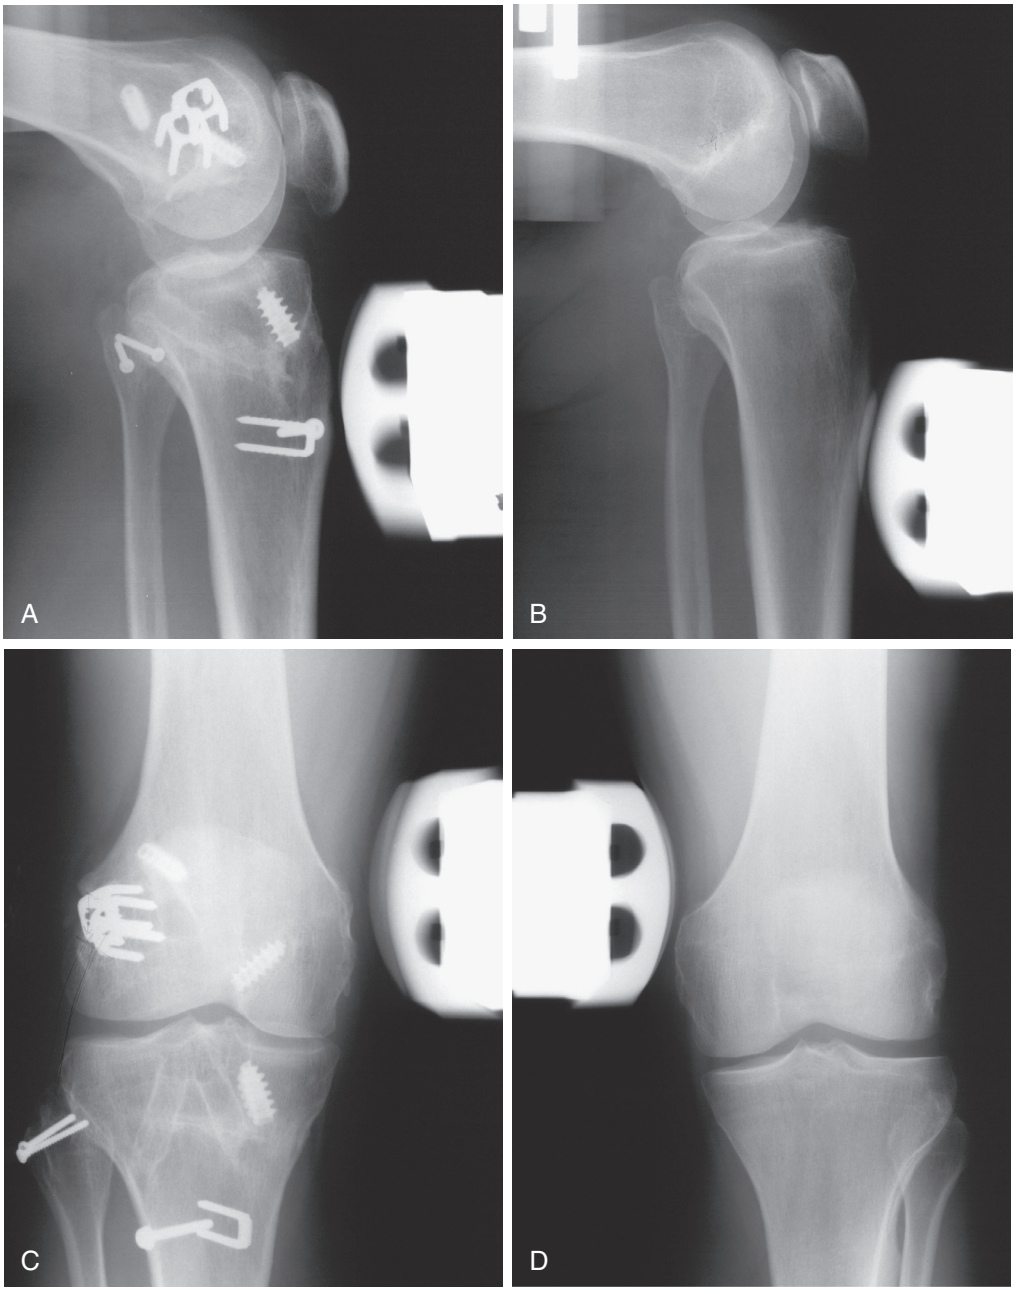

FIG 17-29 Case 4.

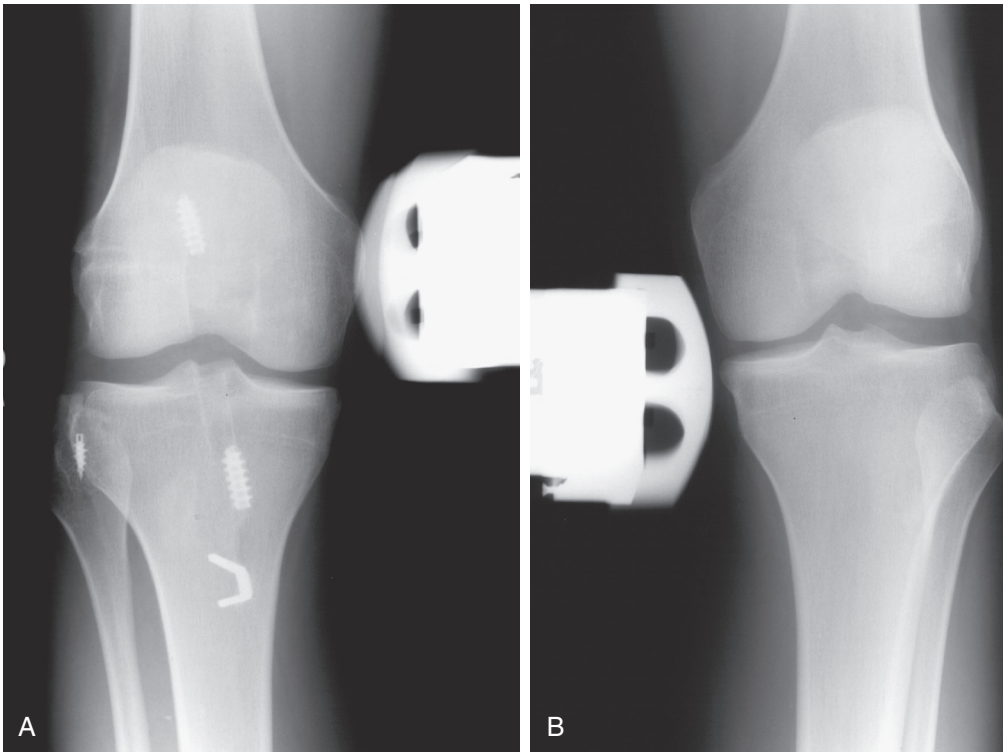

FIG 17-30 Case 5.

on lateral stress radiographs (Fig. 17-29, *C* and *D*). He had successfully returned to skiing and mountain climbing without symptoms, had run a marathon, and rated the overall condition of his knee as very good.

Case 5. A 15-year-old male presented 2 weeks after a contact injury to his right knee sustained while playing football. Physical examination revealed a moderate effusion, knee motion from 0 to 110 degrees, moderate lateral joint line tenderness, a grade II pivot shift, 12 mm of increased LJO, and 5 mm of increased posterior tibial displacement. Magnetic resonance imaging demonstrated a complete rupture of the FCL, popliteal tendon, and ACL and a partial disruption of the PCL.

After an initial week of rehabilitation and protected knee motion, the patient underwent an ACL B-PT-B autograft (harvested from the contralateral knee), an FCL B-PT-B autograft, a direct repair of the popliteus muscle-tendon-ligament and posterolateral capsule, and a lateral meniscus repair.

At follow-up, 4 years postoperatively, the patient had a normal range of knee motion, an increase of 3 mm in anteroposterior displacement on KT-2000 testing, no increase in lateral joint opening stress radiographs (Fig. 17-30, *A* and *B*), and a grade 0 pivot shift. He had returned to basketball, baseball, and football without symptoms or limitations and rated the overall condition of his knee as normal.

Case 6. A 35-year-old man presented 2 years after bilateral knee injuries sustained during a motor vehicle accident. The right knee was initially treated with an ACL B-PT-B autograft reconstruction, an MCL repair, and a medial meniscus repair. The left knee was initially treated with a primary repair of the ACL and FCL. A second surgery involved a left ACL semitendinosus-gracilis autograft and an FCL B-PT-B autograft reconstruction. A third surgery involved a left high tibial osteotomy and biceps tendon transfer. The patient presented with left knee symptoms of moderate pain, swelling, and lateral giving-way with daily activities and was unable to work.

Physical examination of the left knee demonstrated no effusion, a normal range of motion, a grade II pivot shift, 25 mm of increased LJO, and 10 degrees of increased external tibial rotation. The patient's left lower limb was in valgus, with a weight-bearing line of 74%; however, he drifted into varus in the unloaded position secondary to the lateral ligament instability. The biceps femoris muscle was nonfunctional.

The patient was treated first with a biceps femoris muscle reconstruction and neurolysis of the peroneal nerve. At this operation, arthroscopy showed grade 2-A articular cartilage lesions on the undersurface of the patella, trochlea, and medial femoral condyle. Five months later, he underwent an ACL B-PT-B allograft, an anatomic FCL B-PT-B autograft, proximal advancement of the posterolateral capsule, and distal advancement of the iliotibial band.

At follow-up, 12 years postoperatively, the patient had a normal range of knee motion, no effusion, 4 mm of increased anteroposterior displacement on KT-2000 testing, 2 mm of increase in LJO on stress radiographs on the involved left knee (Fig. 17-31, *A*) compared with the right knee (Fig. 17-31, *B*), and a grade 0 pivot shift. Weight-bearing posteroanterior radiographs showed preservation of tibiofemoral joint space in both compartments compared with the contralateral limb (Fig. 17-31, *C*). He had no symptoms with low-impact athletic activities or with his occupation and rated the overall condition of his knee as good.

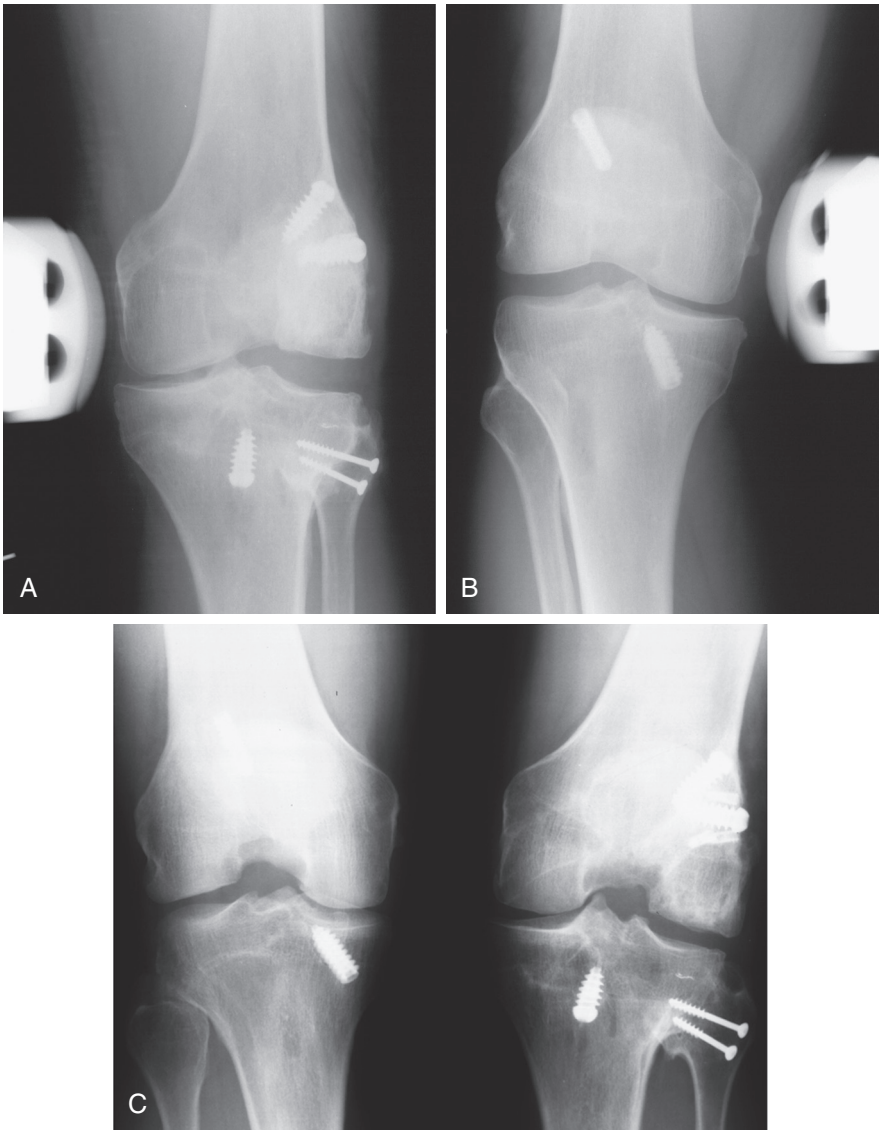

FIG 17-31 Case 6.

Case 7. A 15-year-old male presented 3 weeks after a knee dislocation sustained during football. The patient was placed into an immobilizer but had not undergone any further medical treatment for his injury. Physical examination revealed moderate swelling, only 20 degrees of knee motion, a loss of sensation over the lateral aspect of the leg as well as the dorsum of the foot, and a complete foot drop with 0 to 5 dorsiflexion and 0 to 5 extension of the great toe. His vascular status was intact. Magnetic resonance imaging revealed torn ACL, PCL, FCL, and PL structures. He underwent 2 months of supervised physical therapy. A staged global reconstruction was then performed involving first an ACL B-PT-B allograft and arthroscopic PCL two-strand B-PT-B allograft reconstruction. One week later, an FCL B-PT-B allograft reconstruction and a popliteofibular ligament and popliteus tendon reconstruction were done (Fig. 17-32, *A* and *B*).

Three years postoperative, the patient had a negative pivot shift, no increase in anterior tibial translation, no increase in external tibial rotation, and no increase in medial or LJO. He had a neurovascular intact lower extremity and a full range of knee motion. Lateral (Fig. 17-32, *C*) and posterior (Fig. 17-30, *D*) stress radiographs showed no increase in LJO or posterior tibial translation. The patient had returned to recreational basketball and running without symptoms. He rated the overall condition of his knee as normal.

Our comment: This patient had an arthroscopic ACL and PCL reconstruction, at which time the decision was made, owing to operative time, to later stage by 1 week the anatomic PL reconstruction. During that week, it is required that no abnormal LJO occurs that would place the ACL and PCL grafts at risk for stretching or failure.

CLINICAL CONCEPTS

A paucity of information exists in the literature regarding rehabilitation for injuries to the posterior cruciate ligament (PCL) and posterolateral structures. The posterolateral structures comprise the fibular collateral ligament and popliteus muscle-tendon-ligament unit, including the popliteofibular ligament and posterolateral capsule. A recent systematic review[36] failed to find high-level evidence studies of rehabilitation protocols for either conservative or operative treatment of these injuries. The rehabilitation protocols described in this chapter consist of a careful incorporation of exercise concepts supported by biomechanic and clinical data[3-7,9,11-13,15-17,30,31,33,35,43,44] and over 3 decades of patient experience.[19-26,28] The goal is to progress a patient at a rate that takes into account the condition of the articular surfaces and menisci, return of muscle function and lower limb control, postoperative graft healing and remodeling, and athletic and occupational goals. Modifications to the postoperative exercise program may be required if noteworthy articular cartilage deterioration is found during surgery.

The protocol for PCL reconstruction was developed for high-strength quadriceps tendon-patellar bone (QT-PB) autografts or Achilles tendon-bone allografts with interference screw fixation of the bone and soft tissue portions (and additional suture fixation of the tendon portion over a suture post; see Chapter 16). The protocol for posterolateral reconstruction may be used after the various operative options described in detail in Chapter 17, including anatomic reconstructions, femoral-fibular reconstructions, and proximal advancement techniques of the posterolateral structures.

The supervised rehabilitation programs are always supplemented with home exercises performed daily. The therapist must routinely examine the patient in the clinic to implement and progress the appropriate protocol. Therapeutic procedures and modalities are used as required for successful rehabilitation. For the majority of patients, a range of 11 to 21 postoperative physical therapy visits is expected to produce a desirable result. A few more visits may be required between the sixth and twelfth postoperative months for certain patients who desire to return to strenuous activities for advanced training.

For all patients, joint swelling, pain, gait pattern, knee motion, patellar mobility, muscle strength, and flexibility are continually monitored postoperatively.

Patients are warned to avoid any exercises or activities that place high posterior shear forces on the tibia such as walking down inclines or squatting for the first 6 postoperative months. In addition, patients are cautioned that an early return to strenuous activities postoperatively carries a risk of a repeat injury or the potential of compounding the original injury. These risks cannot always be scientifically predicted, and patients are cautioned to avoid strenuous activities for 9 to

CRITICAL POINTS Clinical Concepts

- Protocol for posterior cruciate ligament reconstruction for procedures with high-strength two-strand graft (quadriceps tendon-bone, bone-patellar tendon-bone).
- Progress patient on athletic and occupational goals, condition of the articular surfaces and menisci, return muscle function, postoperative healing, remodeling.
- Supervised rehabilitation program supplemented with home exercises performed daily.
- Monitor joint swelling, pain, gait pattern, knee motion, patellar mobility, muscle strength, and flexibility continually after surgery.
- Avoid any exercises or activities that place high posterior shear forces on the tibia, such as walking down inclines, squatting, or hamstring flexion curl machines for the first 6 postoperative months.
- Avoid strenuous activities for 9 to 12 months and activities that produce pain, swelling, or a feeling of instability.
- Posterolateral reconstruction: too early resumption of weight bearing is deleterious to healing graft.

12 postoperative months and to avoid activities that produce pain, swelling, or a feeling of instability. These patients are monitored after surgery with posterior drawer testing and stress radiography if an increase in posterior tibial displacement is detected.

Patients with posterolateral reconstruction are warned specifically at the fourth to eighth postoperative weeks when weight bearing and weaning of crutches occur to avoid hyperextension, varus, or internal tibial rotation positions that could place high tensile forces on the posterolateral structures.[29,32] It is important that the patient demonstrates good lower extremity control with suitable muscle strength to maintain tibiofemoral compression and avoid a lift-off of the lateral tibiofemoral joint that would disrupt the posterolateral reconstruction.

PCL CLINICAL BIOMECHANICS

Many studies have demonstrated that posterior tibial subluxation occurs in PCL-deficient knees during activities of daily living in high knee flexion positions, but not usually at low flexion positions where smaller posterior shear forces are present. In activities such as sudden stopping, deceleration, or walking down a ramp, a posterior subluxation of the tibia is expected to occur.

Using knee models created from magnetic resonance imaging (MRI) and dual fluoroscopy, several recent investigations found significant differences in knee kinematics at higher knee flexion angles during a single-leg lunge between PCL-deficient and contralateral normal knees.[8,14,40-42] For instance, Gill and colleagues[8] reported PCL-deficient knees had significantly increased posterior tibial translation between 60 degrees and 120 degrees of flexion compared with normal knees (mean difference, 3.5 ± 1.1 mm, $P < .05$). Significant decreases in patellar rotation and tilt were also observed between PCL-deficient knees and normal knees between 75 degrees and 120 degrees of knee flexion.

Using lateral radiographs, Castle and colleagues[5] measured posterior tibial subluxation during a static double-legged squat in patients with PCL-deficient knees. The results revealed a statistically significant mean increase of 5.9 mm in posterior tibial translation ($P < .05$) of the injured knee compared with the contralateral knee at high knee flexion angles. At low flexion angles, the magnitude of increase in mean posterior tibial translation was only 2.1 mm. Tibiofemoral shear forces were small compared with tibiofemoral joint compression forces.

CRITICAL POINTS PCL Clinical Biomechanics

- Isokinetic flexion exercise exerts moderate posterior shear forces; use cautiously after PCL reconstruction.
- Posterior shear forces significantly increased during standing by anterior flexion of the trunk.
- Static squat: significant increase in posterior tibial translation occurs at high knee flexion angles.
- Large posterior shear forces exist during jogging, ascending and descending stairs.
- Open kinetic chain flexion exercise produces posterior shear forces beyond 30 degrees of knee flexion.
- Closed kinetic chain leg press produces significantly less posterior shear forces than OKC flexion. Cocontraction of quadriceps and hamstrings occurs during CKC, greatest at 30 degrees and 60 degrees of knee flexion.
- Posterior shear forces during CKC squat exercise are relatively low from 0 to 45 degrees of knee flexion. Cocontraction of quadriceps and hamstrings occurs from 0 to 30 degrees of flexion.
- OKC knee extension produces posterior shear forces from 60 to 100 degrees of knee flexion, but these forces are lower than those measured during CKC leg press and squat exercises.
- Leg press induces minimal hamstring muscle activity.
- In situ forces in the PCL significantly increase with knee flexion in response to an isolated hamstrings load, reaching a maximum at 90 degrees of flexion. A simulated cocontraction of the quadriceps and hamstrings reduces the in situ forces in the PCL.
- Isokinetic extension exercise at knee flexion angles less than 70 degrees safe early postoperatively.
- Isokinetic flexion and deep squats should be avoided early after PCL reconstruction.
- Hamstrings load significantly increases PCL force from 15 to 120 degrees of knee flexion.
- The application of tibial torque in either an anterior or posterior direction when the knee is flexed greater than 60 degrees increases PCL force. Isolated hamstrings activity (with tibial torque) further increases PCL force.

Two- and 3-dimensional biomechanic models have been used to predict forces generated during exercises and on standing at different knee flexion angles. Kaufman and coworkers[13] used a 3-dimensional biomechanic model to predict dynamic patellofemoral and tibiofemoral forces generated during isokinetic exercises at 60 degrees/sec and 180 degrees/sec. During isokinetic extension, posterior shear forces were detected at knee flexion angles of 40 degrees and greater. The maximum posterior shear force occurred at 70 to 80 degrees of knee flexion and measured 0.5 ± 0.1 body weight at 60 degrees/sec and 0.6 ± 0.1 body weight at 180 degrees/sec. A posterior shear force occurred throughout the entire flexion exercise at all knee flexion angles, reaching a peak at 75 degrees of knee flexion of 1.7 ± 0.8 body weight (60 degrees/sec) to 1.4 ± 0.5 body weight (180 degrees/sec). The authors concluded that isokinetic exercise exerted moderate posterior shear forces and should be used cautiously after PCL rupture and reconstruction.

Ohkoshi and associates[35] used a 2-dimensional model to calculate shear force exerted on the tibia during standing at various knee flexion angles in 21 healthy subjects. Posterior shear forces were found in the upright position of the trunk and at knee flexion angles of 15 to 90 degrees (Fig. 18-1). At 30 degrees and 60 degrees, the posterior drawer force was significantly increased by anterior flexion of the trunk.

Berchuck and coworkers[3] calculated large posterior shear forces during gait analysis for the activities of jogging, ascending stairs, and

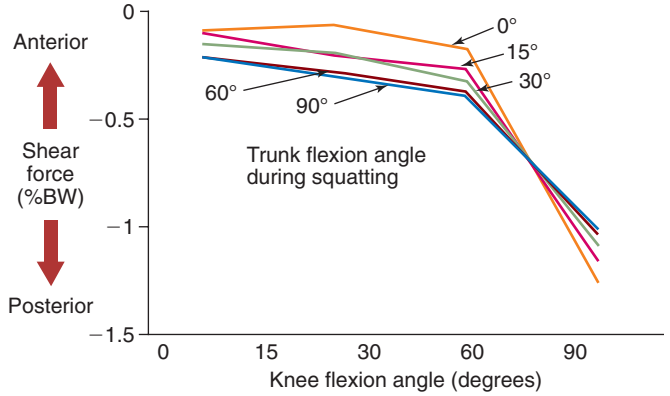

FIG 18-1 Calculated shear force (kilograms) per body weight (BW) (kilograms) while standing on both legs at various flexion angles of the knee and trunk. (From Ohkoshi Y, Yasuda K, Kaneda K, et al. Biomechanical analysis of rehabilitation in the standing position. *Am J Sports Med.* 1991;19:605-611.)

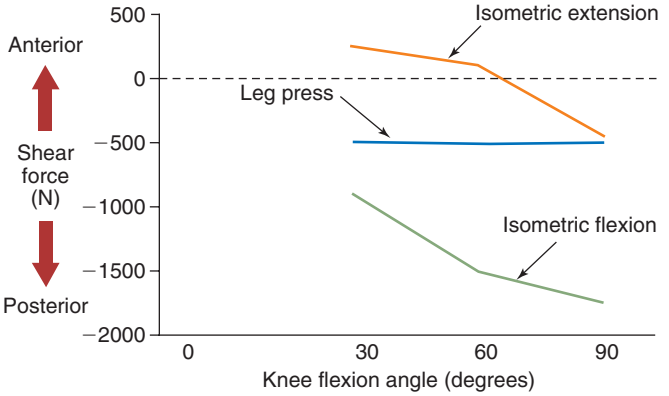

FIG 18-3 Average tibiofemoral shear forces observed during the closed kinetic chain leg press, the open kinetic chain extension, and the open kinetic chain flexion exercise. (From Lutz GE, Palmitier RA, An KN, Chao EY. Comparison of tibiofemoral joint forces during open-kinetic-chain and closed-kinetic-chain exercises. *J Bone Joint Surg Am* 1993;75:732-739.)

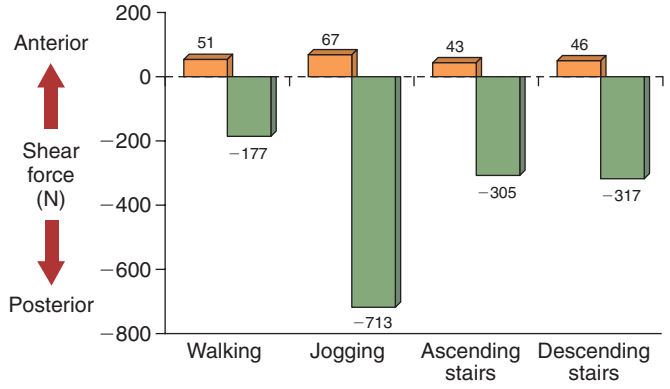

FIG 18-2 Calculated tibiofemoral shear forces during activities.

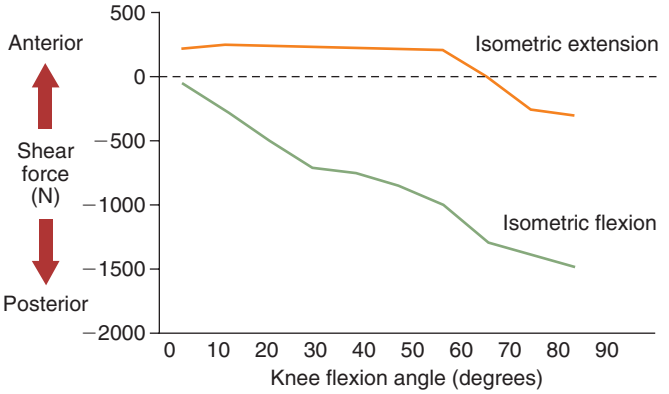

FIG 18-4 Calculated tibiofemoral shear forces during isometric knee extension and flexion.

descending stairs (Fig. 18-2) in five normal subjects. Lutz and associates[15] evaluated tibiofemoral joint shear and compressive shear forces using a 2-dimensional biomechanic model and electromyographic (EMG) of hamstrings and quadriceps muscle activity during a closed kinetic chain (CKC) leg press exercise, an isometric open kinetic chain (OKC) extension exercise, and an OKC flexion exercise. Measurements of maximum muscle contractions were obtained at 30, 60, and 90 degrees of knee flexion. The OKC isometric flexion exercise produced posterior shear forces at all knee flexion angles (Fig. 18-3), ranging from –939 ± 174 N at 30 degrees of knee flexion to a maximum of –1780 ± 699 N at 90 degrees of knee flexion. The CKC exercises produced significantly lower posterior shear forces at 60 degrees and 90 degrees of flexion (–538 N, $P < .05$). These findings were similar to those reported by Smidt[38] during isometric knee extension and flexion exercises (Fig. 18-4). Maximum hamstrings EMG activity was detected during the OKC exercise at 90 degrees of flexion (82% ± 15% of maximum contraction). The antagonistic muscle activity was minimal during this exercise at all knee flexion angles. In contrast, cocontraction of the quadriceps and hamstrings was observed during the CKC exercise, which was greatest at 30 degrees and 60 degrees of flexion. The authors concluded that CKC exercise produced significantly lower tibiofemoral shear forces compared with OKC exercise ($P < .05$).

Wilk and colleagues[43] evaluated tibiofemoral shear forces and EMG activity of the quadriceps, hamstrings, and gastrocnemius muscles during OKC extension and CKC leg press and squat exercises. Both CKC exercises produced posterior shear forces. However, during the squat, these forces were relatively low (245 to 565 N) from 0 to 45 degrees of knee flexion. A rapid increase in posterior shear forces was detected from 45 to 72 degrees of flexion. In addition, cocontraction of the quadriceps and hamstrings occurred from 0 to 30 degrees of flexion.

Wilk and colleagues[43] also found that the knee extension exercise produced posterior shear forces from 60 to 100 degrees of knee flexion; however, these forces were lower than those measured during both CKC exercises. The leg press induced minimal hamstring muscle activity.

Hoher and coworkers[11] reported that the in situ forces in the PCL significantly increased with knee flexion in response to an isolated hamstrings load, reaching a maximum at 90 degrees of flexion. These findings were in agreement with other authors[6,44] who also reported increased strain in the PCL with knee flexion. The addition of a 200-N quadriceps load (simulating cocontraction of the quadriceps and hamstrings) reduced the in situ forces in the PCL.

Toutoungi and associates[39] combined noninvasive experimental measurements with geometric modeling of the lower extremity to calculate ligament forces during isometric, isokinetic, and squat exercises. The data indicated that isokinetic extension at knee flexion angles less than 70 degrees should be safe in the early postoperative period

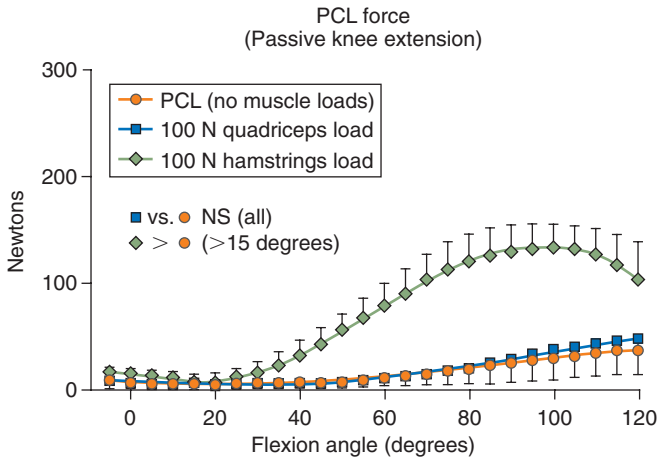

FIG 18-5 Posterior cruciate ligament (PCL) forces from 0 to 120 degrees of knee flexion with no tibial force. Application of a 100-N hamstring load significantly increased mean PCL force at flexion angles greater than 15 degrees. (From Markolf KL, O'Neill G, Jackson SR, McAllister DR. Effects of applied quadriceps and hamstrings muscle loads on forces in the anterior and posterior cruciate ligaments. *Am J Sports Med.* 2004;32:1144-1149.)

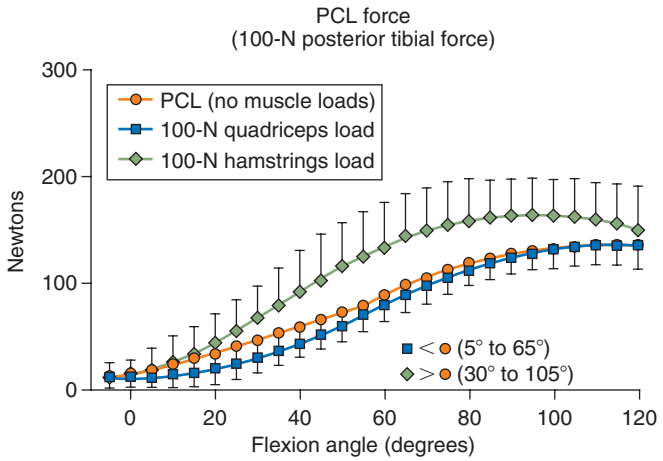

FIG 18-6 Posterior cruciate ligament (PCL) forces from 0 to 120 degrees of knee flexion under a constant 100-N posterior tibial force. Application of a 100-N hamstrings load significantly increased mean PCL force at flexion angles between 30 and 105 degrees. (From Markolf KL, O'Neill G, Jackson SR, McAllister DR. Effects of applied quadriceps and hamstrings muscle loads on forces in the anterior and posterior cruciate ligaments. *Am J Sports Med.* 2004;32:1144-1149.)

following PCL reconstruction. However, isokinetic flexion and deep squats should be avoided. During isokinetic flexion, only the PCL is loaded and peak forces may reach over four times the patient's body weight at 90 degrees of knee flexion. During squatting, PCL forces may reach 3.5 times body weight at high knee flexion angles. Shallow squats with knee flexion angles kept below 50 degrees may be considered.

Markolf and colleagues[16] studied the effects of muscle loads on cruciate force levels when the knee was subjected to external forces and moments. Load cells were installed into cadaveric knees to record forces in the ACL and PCL under five loading conditions. These force measurements were repeated with a 100-N load applied to the quadriceps tendon and with a combined 50-N load applied to both the biceps and semimembranosus-semitendinosus tendons.

With no applied tibial force, application of hamstrings load significantly increased mean PCL force from 15 to 120 degrees of knee flexion (Fig. 18-5). With the application of a 100-N posterior tibial force, the addition of hamstrings load significantly increased mean PCL force between 30 degrees and 105 degrees of flexion (Fig. 18-6). When a 5 N-m external tibial torque was applied, the addition of hamstrings load significantly increased mean PCL force beyond 75 degrees of knee flexion ($P < .05$). Under a 5 N-m internal tibial torque, application of hamstrings load also significantly increased mean PCL force between 60 degrees and 100 degrees of flexion ($P < .05$). The authors concluded that, in general, the hamstrings were more effective in producing changes in cruciate force levels. Application of tibial torque in either an anterior or posterior direction when the knee was flexed greater than 60 degrees increased PCL force, and isolated hamstrings activity (with tibial torque) further increased PCL force.

PROTOCOL FOR PARTIAL OR ACUTE ISOLATED PCL RUPTURES

This program does not apply to PCL avulsions in which surgery may be indicated, and partial PCL tears with 5 mm or less of increased posterior tibial translation. The goal with complete PCL disruptions (8-10 mm of increased posterior tibial translation at 90 degrees of flexion) is to allow PCL healing and reduce abnormal posterior tibial translation. Importantly, this includes maintaining normal tibiofemoral contact at full knee extension or with knee flexion. An anterior drawer produced by the therapist during motion in the early phases of rehabilitation will allow for protection of healing PCL fibers. This protective program for acute PCL ruptures has been used by us for over 20 years. The rules to treat partial or acute isolated PCL tears are as follows:

FIG 18-7 Knee extension brace with posterior calf pad to maintain tibiofemoral reduction.

1. Patient is within 14 days of the injury.
2. Protect for 6 weeks in full knee extension with a brace and posterior calf pad (Fig. 18-7) or bivalved cylinder cast to maintain tibiofemoral reduction.[1] Use quadriceps isometrics, electrical muscle stimulation (EMS), leg raises, and 25% weight bearing.
3. Obtain a lateral radiograph to verify no posterior tibial subluxation exists, which can occur in up to 50% of knees.
4. At 2 weeks, the therapist initiates 0 to 90 degrees of motion, maintaining anterior tibial translation load during knee motion

exercises. The patient must sleep in the brace and is not allowed unsupervised knee motion. Only passive flexion with the therapist is permitted.

5. At 4 weeks, the patient is allowed to perform active quadriceps extension without the brace, use 50% weight bearing with crutch support, and continue brace protection.
6. At 5 to 6 weeks, the patient is weaned from the brace and crutch support and the rehabilitation protocol (described later) is begun. It should be noted that some centers use a Jack PCL Brace (Albrecht, Germany) to provide added protection against posterior tibial subluxation, which may be considered if insomnia issues are resolved.
7. At 6 months, a posterior stress radiograph determines the amount of posterior tibial translation compared with the opposite knee.

PCL RECONSTRUCTION REHABILITATION PROTOCOL

Immediate Postoperative Management

Patients are instructed in the rehabilitation program preoperatively. They present to physical therapy the first day after surgery on bilateral axillary crutches in a postoperative dressing with a long-leg brace locked in full extension with a posterior calf pad (Table 18-1). The postoperative bandage and dressing are changed to allow the application of thigh-high compression stockings and a compression bandage. Early control of postoperative effusion is essential for pain management and early quadriceps reeducation. In addition to compression, cryotherapy is important in this time period.

Patients are instructed to keep the lower limb elevated as frequently as possible during the first week. The initial response to surgery and progression during the first 2 weeks sets the tone for the initial phases of the rehabilitation program. Common postoperative complications include excessive pain or swelling, quadriceps shutdown, and range of motion (ROM) limitations. Early recognition and treatment of these problems are critical for a successful outcome.

Patients who undergo a QT-PB autograft harvest have increased pain with knee flexion and during quadriceps contractions. They require added attention for the first 4 weeks postoperatively to ensure the rehabilitation goals are achieved.

Modalities

Therapeutic modalities after PCL reconstruction are used as required by the evaluation. If the patient demonstrates a fair or poor rating of the quadriceps or vastus medialis obliquus (VMO) musculature, then EMS is initiated. Electrodes are placed over the VMO and on the central to lateral aspect of the upper third of the quadriceps muscle belly. The patient actively contracts the quadriceps muscle simultaneously with the machine's stimulation. Treatment sessions last for 20 minutes. A portable neuromuscular electric stimulator such as the Empi Continuum or Phoenix (garment device, DJO Global) may be helpful in individuals whose muscle rating is poor. These devices are used 4 to 6 times per day for 15 minutes per session until the muscle grade is rated as good.

Biofeedback therapy is also quite useful in facilitating quadriceps muscle contractions. The surface electrode is placed over the selected muscle component to provide information to the patient and clinician regarding the quality of active or voluntary quadriceps contraction. This modality can enhance relaxation of the hamstring musculature if the patient has difficulty achieving full knee extension because of knee pain or muscle spasm. The electrode is placed over the belly of the hamstring muscle while the patient performs ROM exercises.

Cryotherapy is begun in the recovery room after surgery. Several different modalities are available for use in both the clinic and home settings. Clinically, devices such as the Game Ready cryotherapy machine are used to provide compression simultaneously with the cold program. For most patients, cryotherapy is accomplished with an ice bag or commercial cold pack. Patients may also receive a commercial cooling unit that is used four to eight times daily at home. Other commercially available cold therapy units include motorized cooler units that maintain a constant temperature and circulation of ice water through a pad that provides excellent pain control. Gravity-flow units also provide effective pain management; however, the maintenance of a constant temperature is more difficult with these devices. The temperature can be controlled by using gravity to backflow and drain the water, refilling the cuff with fresh ice water as required. Standard treatment times are 20 minutes in length, performed from four times a day to every waking hour depending on the extent of pain and swelling. In some cases, the treatment time can be extended based on the thickness of the buffer used between the skin and the device. Cryotherapy is typically used after exercise or when required for pain and swelling control and is maintained throughout the entire postoperative rehabilitation protocol.

Brace Support

For patients who undergo PCL reconstruction without a concurrent posterolateral procedure, a long-leg hinged postoperative brace with a posterior calf pad is worn for the first 6 weeks postoperatively. The brace is worn 24 hours a day, including during sleep, to avoid sudden knee flexion motions that may occur. Initially, the brace is worn in full extension for the first 3 to 4 weeks and is then opened to 0 to 90 degrees. For individuals evaluated with physiologic joint laxity or poor muscle control of the lower limb, the brace is used for up to 12 weeks postoperatively.

During this phase, the patient may also be measured for a functional PCL brace, which is indicated for higher-level occupational or sports activities. For patients who return to lower levels of activity or who develop patellofemoral symptoms, a patellofemoral knee sleeve may be indicated for prolonged standing and walking activities.

A standard soft-hinged brace is not considered adequate for protection of complex reconstructions that involve both the PCL and posterolateral structures. These braces do not prevent excessive lateral forces (joint opening) that place the posterolateral reconstruction at risk in the initial 4 weeks postoperatively. In these knees, a bivalved cast is used to limit lateral joint opening during ambulation and activities of daily living. The bivalved cast is removed four times a day under controlled conditions, and active knee extension and passive knee flexion are performed in a seated position. The cast is then carefully reapplied to protect the knee joint during walking activities. After the first 4 postoperative weeks, sufficient healing of the posterolateral ligamentous reconstructive procedure should occur, and the patient is placed in a long-leg hinged brace.

Range of Knee Motion

Passive knee motion from 0 to 90 degrees is allowed immediately postoperatively. The return of full knee flexion to 135 degrees places high shear forces on the PCL reconstruction and it is unknown when this amount of flexion is safe to obtain. Accordingly, the program is designed to initially regain 120 degrees by 8 weeks, with final flexion gradually achieved at 10 to 12 weeks. Knee flexion greater than 135 degrees is not encouraged unless athletic or occupational indications exist. The total number of daily knee motion cycles is limited to 60 (20 cycles, three times/day) for the first 4 weeks to limit undue abrasion of the PCL graft at the tibial and femoral tunnels.[19,37]

PHASE 1: WEEKS 1-2 (VISITS 2-4)

General Observation

Toe-touch to 25% weight bearing
Brace

Evaluation (Goal)

Pain (controlled)
Hemarthrosis (mild)
Patellar mobility (good)
ROM minimum (0-90 degrees)
Quadriceps contraction and patella migration (good)
Soft tissue contracture (none)

Goals

ROM 0-90 degrees
Adequate quadriceps contraction
Control inflammation, effusion
Prevent soft tissue contracture
Protect ligament reconstruction at insertion sites

Continued

TABLE 18-1 Rehabilitation Protocol After Posterior Cruciate Ligament Reconstruction—cont'd

PHASE 1: WEEKS 1-2 (VISITS 2-4)

	Frequency	Duration
ROM	3-4 ×/day, 10 min	
0-90 degrees (active extension/passive flexion with 10-lb anterior drawer)		20 cycles
Patellar mobilization		10 reps, 30 sec
Ankle pumps (plantar flexion with resistance band)		
Hamstring, gastrocnemius-soleus stretches		5 reps, 30 sec
Strengthening	3 ×/day, 15 min	
Straight-leg raises (flexion, 0- to 5-lb ankle weight)		3 sets × 10 reps

FIG 18-8 Extension overpressure using hanging weights.

Regaining knee extension as soon as possible is important to avoid excessive scarring in the intercondylar notch or a posterior capsular contracture. Patients who do not achieve this extension goal by the seventh postoperative day are placed into an overpressure program. The foot and ankle are propped on a towel or other device that elevates the hamstrings and gastrocnemius, allowing the knee to drop into full extension. This exercise is performed for 10 minutes and repeated approximately six times per day. A 10-lb weight may added to the distal thigh and knee to stretch the posterior capsule (Fig. 18-8). Care should be taken to keep the hanging weight away from the proximal tibia to avoid posterior shear stresses. Zero degrees of knee extension should be obtained by the third to sixth postoperative week. If this is not accomplished, or if the clinician notes a firm end feel, a serial casting program may be required (see Chapter 38). Hyperextension is avoided to protect the healing PCL graft.

Passive knee flexion exercises are performed in the seated position, using an anterior manual force to provide proximal tibial support to prevent posterior drop-back. A 10-lb anterior drawer is maintained on the proximal tibia during passive knee flexion (Fig. 18-9) because PCL forces significantly increase after 70 degrees of flexion. Knee flexion exercises are primarily passive for the first 6 weeks and are then active. Care must be taken to avoid activating the hamstrings. Other overpressure techniques to assist in gaining flexion include chair-rolling (Fig. 18-10), wall-sliding using the opposite extremity (Fig. 18-11), commercial devices (Fig. 18-12), and passive quadriceps stretching exercises.

Weight Bearing

Patients are allowed to bear 25% of their body weight during the first 1 to 2 postoperative weeks. Weight bearing is then slowly progressed and crutches are usually discontinued at postoperative week 6. Once the brace is unlocked, weight bearing is progressed using a normal gait technique, limiting a locked-knee position and encouraging normal flexion throughout the gait cycle. This allows for normal patterning of heel-to-toe ambulation, quadriceps contraction during midstance, and hip and knee flexion during the gait cycle. The prolonged locked-knee position is avoided owing to the potential of the development of a quadriceps-avoidance gait pattern.

Once patients are fully weight bearing, they are warned to avoid squatting, walking down hills or ramps, or any sudden deceleration movements that may place high forces on the PCL graft. These precautions are maintained for at least the first 6 postoperative months.

FIG 18-9 Flexion knee motion exercises using anterior tibial pressure to prevent posterior tibial drop-back.

Patellar Mobilization

Patellar mobilization is important in the promotion of a full range of knee motion. The loss of patellar mobility is often associated with knee motion complications and, in extreme cases, the development of patella infera.[34] Patellar glides are performed in all four planes (superior, inferior, medial, and lateral) with sustained pressure applied to the appropriate patellar border for at least 10 seconds (Fig. 18-13). This exercise is performed for 5 minutes before ROM exercises are completed. Caution is warranted if an extensor lag is detected, because this may be associated with poor superior migration of the patella, indicating the need for additional emphasis on this exercise. Patellar mobilization is performed for approximately 8 weeks postoperatively.

Flexibility

Hamstring and gastrocnemius-soleus flexibility exercises are begun the first postoperative day. A sustained static stretch is held for 30 seconds and repeated five times. The modified hurdler stretch is the most common hamstring exercise, and the towel pull is the most common gastrocnemius-soleus stretch. These exercises assist in controlling pain that occurs because of the reflex response created in the hamstrings when the knee is kept in the flexed position. As well, the towel-pulling exercise can help lessen discomfort in the calf, Achilles tendon, and ankle. These stretches represent critical components of the ROM program, because the ability to relax these muscle groups is imperative to achieving full passive knee extension. The patient must be instructed not to perform harsh, aggressive stretching, which could result in activation of the hamstring muscles. The PCL reconstruction is protected at all times with a posterior soft calf pad, maintaining knee extension.

Iliotibial band stretches are begun at the ninth postoperative week. These exercises assist in achieving full knee flexion and controlling

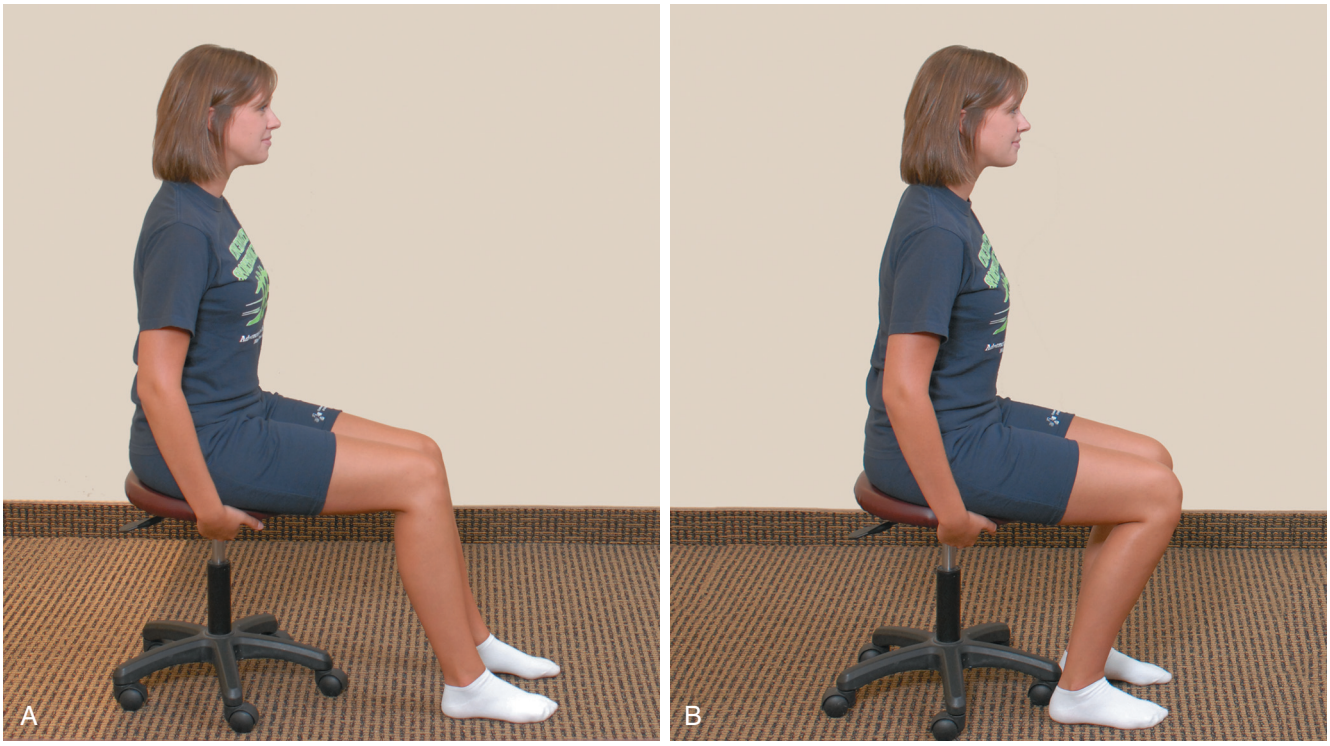

FIG 18-10 Flexion overpressure using a rolling stool.

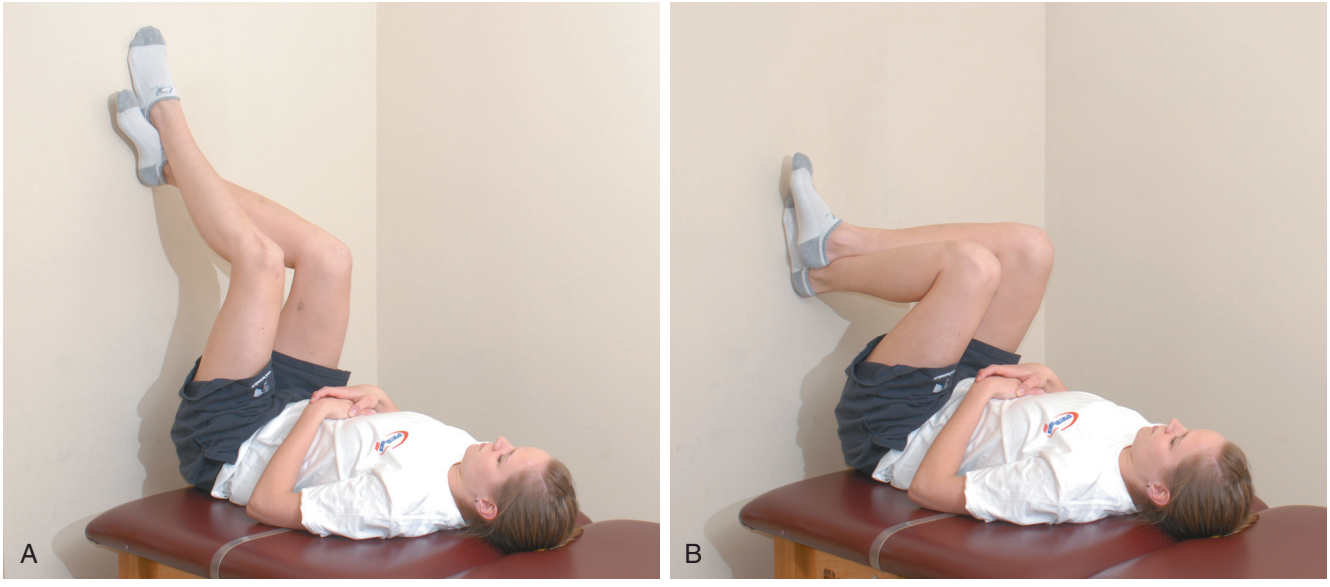

FIG 18-11 Flexion overpressure using a wall-slide technique.

lateral hip and thigh tightness. When designing a flexibility program, the therapist should determine the particular sport or activity the individual wishes to return to, as well as the position or physical requirements of that activity. The flexibility program should be continued after the patient is discharged from formal care.

Strengthening

The strengthening program is begun on the first postoperative visit. Early emphasis on the quadriceps muscle group is critical for a safe return to functional activities and to prevent posterior subluxation of the tibia from occurring during activities in which the knee is flexed greater than 50 degrees. In this phase of rehabilitation, initiation of a good voluntary quadriceps contraction sets the tone for the progression of the strengthening program.

Isometric quadriceps contractions are done every hour following the repetition rules of 10 second holds, 10 repetitions, 10 times per day. Evaluation of the contraction by both the therapist and patient is critical. The patient can monitor contractions by visual or manual means, comparing the quality of the contractions to those achieved by the contralateral limb. He or she can also assess the superior migration of

FIG 18-12 A commercial knee flexion overpressure device.

FIG 18-13 Patellar mobilization.

the patella during the contraction, which should be approximately 1 cm, and the inferior migration of the patella during the initial relaxation of the contraction.

Other exercises performed immediately postoperatively include supine straight-leg raises and active-assisted knee extension (70 to 0 degrees postoperative week 1 and 2, then 90 to 0 degrees). The patient must achieve a sufficient isometric quadriceps contraction with the leg raises to benefit the quadriceps. Initially, 1- to 2-lb ankle weights are used; eventually, an ankle weight up to 10 lb is used as long as this does not represent more than 10% of the patient's body weight.

Active-assisted extension exercises facilitate the quadriceps muscle if poor tone is observed during isometric contractions. At postoperative weeks 3 to 4, adduction and abduction straight-leg raises are incorporated. The exception are knees that undergo concomitant posterolateral procedures, for which abduction leg raises are delayed until postoperative weeks 7 to 8. Extension (prone) leg raises are initiated at postoperative week 9. These exercises are continued through at least postoperative week 12.

Once partial weight bearing is initiated, CKC exercises are begun. The first CKC exercise is cup walking, an activity designed to facilitate adequate quadriceps control during midstance of gait to prevent knee hyperextension from occurring (Fig. 18-14). When the patient progresses from 50% to 75% weight bearing, toe raises for gastrocnemius-soleus strengthening, wall-sitting isometrics for quadriceps control, and minisquats for quadriceps strengthening are begun. The goal of wall-sitting is to improve quadriceps contraction by performing the exercise to muscle exhaustion. This exercise may be modified to decrease patellar pain or place additional stress on the quadriceps muscle. Patellar pain may be decreased by either altering the knee flexion angle of the sit or by subtly changing the toe-out/toe-in angle by no more than 10 degrees.

Additional stress to the quadriceps during the wall-sit can be accomplished by several methods. First, the patient can voluntarily set the quadriceps muscle once he or she reaches his or her maximum knee flexion angle, which is typically between 30 and 45 degrees. This contraction and knee flexion position is held until muscle fatigue occurs, and the exercise is repeated two to three times, for eight repetitions per day. In a second modification, the patient performs a hip adduction contraction by squeezing a ball between the distal thighs. This modification promotes a stronger VMO contraction. In a third variation, the patient holds dumbbell weights in his or her hands to increase body weight, which promotes an even stronger quadriceps contraction. Finally, the patient can shift his or her body weight over the involved side to stimulate a single-leg contraction. These exercises are highly beneficial and result in the patient experiencing a true muscle burn as each repetition is held to maximum quadriceps muscle fatigue, which is typically not achieved at this point with other exercises. The sets should be performed ideally two times each and repeated four times a day.

The last CKC exercise is the minisquat. Initially, the patient's body weight is used as resistance. Gradually, TheraBand or surgical tubing is used as a resistance mechanism (Fig. 18-15). The depth of the squat is controlled to protect the patellofemoral joint. Quick, smooth, rhythmic squats are performed to a high-set/high-repetition cadence to promote muscle fatigue. Hip position is important to monitor to emphasize the quadriceps. Increased trunk flexion facilitates increased hamstring contractions[35] and therefore must be carefully monitored to avoid forceful hamstring contractions for a minimum of 3 to 6 months.

OKC exercises are included in the rehabilitation program owing to the advantage of muscle group isolation provided by weight machines. Initially, if the lightest amount of weight on the machine is too heavy to be lifted by the involved limb alone, the patient is instructed to lift the weight with both legs and lower it with the involved side. Eccentric contractions can also be used in the advanced stages of strength training if tendinitis or overuse syndromes develop. Weight training is used in the latter stages of rehabilitation and continues after the patient has returned to activity.

The timing of the initiation of extension, hip, leg press, and hamstring curl OKC exercises is shown in Table 18-1. Knee flexion hamstring curls and hip abduction-adduction exercises are delayed until the fourth postoperative month to avoid excessive posterior shear forces. Leg press (range, 50-0 degrees) is allowed at the eighth postoperative week. Caution is warranted owing to the potential problems knee extension OKC exercises may create for the healing graft and the patellofemoral joint. Many patients have an unsatisfactory outcome

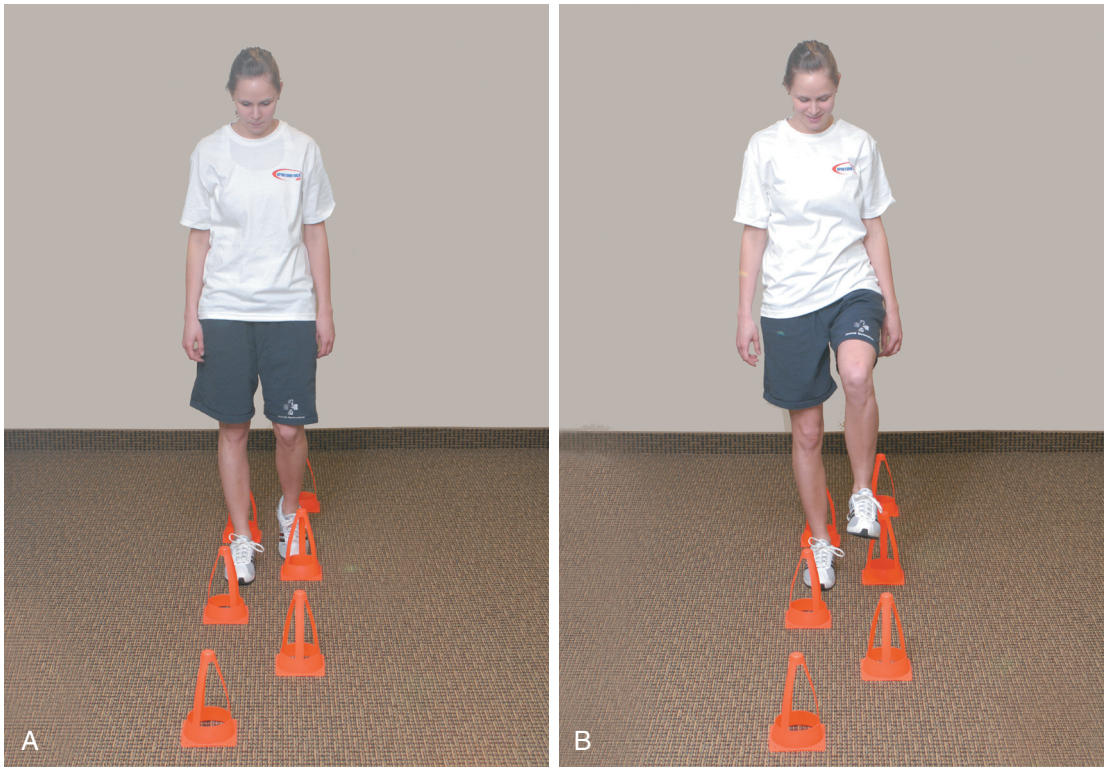

FIG 18-14 Cup walking used early postoperatively to develop symmetry between the surgical and contralateral limbs, hip and knee flexion, quadriceps control during midstance, hip and pelvic control during midstance, and adequate gastrocnemius-soleus control during push-off.

FIG 18-15 Minisquats made more difficult with a TheraBand.

based on persistent anterior or patellofemoral knee pain that can occur from improper training in the terminal phase of extension (0-30 degrees). Therefore this exercise may be initially delayed to protect the PCL graft (avoiding lower flexion angles) versus protecting the patella (not going into terminal extension). Recommendations for knee extension exercises include emphasis on patellofemoral protection (monitoring for changes in pain, swelling, and crepitus) and a gradual progression of weight to avoid overuse syndromes.

A full lower extremity strengthening program is critical for long-term success of the rehabilitation program. Gastrocnemius-soleus strength is a key component for both early ambulation and running. In addition, upper extremity and core strength programs are important for safe return to work or sports. These exercises are included as part of general conditioning and general strength-training concepts are emphasized. Sport and position specificity are taken into account when devising the program to maximize its benefits.

Balance, Proprioceptive, and Perturbation Training

Balance and proprioceptive training are initiated at approximately 4 to 6 weeks postoperatively when the patient is partially weight bearing. The first exercise involves weight shifting from side to side and front to back. This activity assists the patient's confidence in the leg's ability to withstand the pressures of weight bearing and initiates the stimulus to knee joint position sense. A second exercise is cup walking, which is designed to both promote strength and develop symmetry between the surgical and uninvolved limbs. Cup walking helps develop hip and knee flexion, quadriceps control during midstance, hip and pelvic control during midstance, adequate gastrocnemius-soleus control during push-off, and controls hip hiking.

FIG 18-16 Single-leg stance on an unstable platform.

FIG 18-17 Perturbation technique. The therapist stands behind the patient and intermittently touches the patient's back to disturb balance.

When full weight bearing is achieved, another helpful activity for balance control is the single-leg balance exercise. The stance position is key to making this exercise beneficial. The patient is instructed to point the foot straight ahead, flex the knee approximately 20 to 30 degrees, extend the arms outward to horizontal, and position the torso upright with the shoulders above the hips and the hips above the ankles. The object of this activity is to stand in position until balance is disturbed. A minitrampoline or unstable surface can be used to make this exercise more challenging. The unstable position created with the soft surface requires greater dynamic limb control than that used to stand on a flat surface (Fig. 18-16).

In the early phases of full, unassisted weight bearing, half foam rolls are used as part of the gait-retraining program. Walking on half rolls helps the patient develop balance and dynamic muscular control required to maintain an upright position and to be able to walk from one end of the roll to the other. Additional gait and balance activities may include band walking for forward, backward, lateral, and monster walking (diagonal forward walking). These activities challenge single-leg balance and proximal leg control. Developing a center of balance, limb symmetry, quadriceps control in midstance, and postural positioning are benefits obtained from this type of training.

Perturbation-training techniques are initiated at approximately the seventh to eighth postoperative weeks. The therapist stands behind the patient and disrupts her or his body posture and position periodically to enhance dynamic knee stability. The techniques involve either direct contact with the patient (Fig. 18-17) or disruption of the platform the patient is standing on (Fig. 18-18).

Another effective proprioceptive exercise is a balance board with the patient assuming first a double-leg stance and eventually a single-leg stance as strength and balance improve. To provide a greater functional challenge, patients may assume the single-leg stance position

FIG 18-18 Perturbation technique. The therapists stands behind the patient and intermittently taps the unstable platform to disturb balance.

and throw/catch a weighted ball against an inverted minitrampoline until fatigue occurs.

The use of more sophisticated devices adds another dimension to the proprioception program, because certain units objectively attempt to document balance and dynamic control. There are many balance systems available, with a wide cost variance. Two of the more common units include the Biodex Balance System and the Neurocom Balance System. Although these systems may provide objective information, more research is required to justify the cost and reliability of each unit.

Conditioning

The primary consideration for the conditioning program throughout the rehabilitation protocol is to stress the cardiovascular system without compromising the joint. Depending on accessibility, a cardiovascular program may be initiated at approximately the third to fourth postoperative week with an upper extremity ergometer. The surgical limb should be elevated to minimize lower extremity swelling. This exercise is performed to tolerance.

Stationary bicycling is begun at postoperative weeks 5 to 6. During bicycling, the seat height is adjusted to its highest level based on patient body size and a low resistance level is used during the workout. Toe clips should be avoided to decrease hamstring involvement. Gradually, between the ninth and twelfth postoperative weeks, cross-country skiing, elliptical cross-trainer, and stair-climbing machines are incorporated. Protection against high stresses to the patellofemoral joint is strongly advocated in patients with symptoms or articular cartilage deterioration. If a stair-climbing machine is tolerated, a short step and lower resistance levels should be encouraged. Monitoring the heart rate will ensure that work levels are sufficient to improve cardiovascular fitness.

The goals of early conditioning exercises include facilitation of full ROM, gait retraining, and cardiovascular reconditioning. To improve cardiovascular endurance, the program should be performed at least three times per week for 20 to 30 minutes, and the exercise performed to at least 60% to 85% of maximal heart rate. It is generally regarded that performing in the higher levels of percentage of maximal heart rate achieves greater cardiovascular efficiency and endurance.

A complete cardiovascular exercise program is an important component of the latter phases of rehabilitation. In addition to the previously described exercises, an aquatic program that includes lap work using freestyle or flutter kicking, water walking, water aerobics, and deep-water running is initiated. Determining which cardiovascular exercises are appropriate is based on each individual patient. Factors to assess include concomitant operative procedures, secondary injuries, access to specific equipment, individual preferences, and prior experience.

Running and Agility Program

Current studies do not allow a prediction of return of strength of PCL grafts; hence, conservative estimates regarding return to strenuous activities are warranted. To initiate the running program, the patient must demonstrate no more than a 30% deficit in average torque for the quadriceps and hamstrings on isometric testing, have no more than 3 mm of increase in anteroposterior displacement on arthrometer testing, and be at least 6 months postoperative. The running program in an elite athlete under ideal conditions described after a quadriceps tendon-patellar bone autograft has been found in our clinic to be safe and not result in graft stretching or an increase in posterior tibial translation. However, most recreational athletes do not start the program until 9 to 12 months after surgery. The rules for when to introduce more strenuous running and cutting activities for allografts have not been scientifically established. In general, a prudent rule is to provide additional time for graft healing and remodeling and wait until 12 months, although it is recognized that allograft healing is delayed even further. The running program is designed based on the sport the patient desires to return to, as well as the particular position or physical requirements of the activity. For instance, an individual returning to short-duration, high-intensity activities participates in a sprinting program rather than a long-distance endurance program.

The beginning level running program is first performed with a straight-ahead walk/run combination. Running distances are 20, 40, 60, and 100 yards (18, 37, 55 and 91 m) in both forward and backward directions. Initially, running speed is approximately one-fourth to one-half of the patient's normal speed and gradually progresses to three-fourths to full speed. An interval training-rest approach is applied where the rest phase is two to three times the length of the training phase. The running program is performed three times per week, on opposite days of the strength program. Because the running program may not reach aerobic levels initially, a cross-training program is used to facilitate cardiovascular fitness. The cross-training program is performed on the same day as the strength workout.

After the patient is able to run straight ahead at full speed, the program progresses to include lateral running and crossover maneuvers. Short distances, such as 20 yards (18 m), are used to work on speed and agility. Side-to-side running over cups may be used to facilitate proprioception. At this time, sport-specific equipment is introduced to enhance skill development (e.g., a soccer ball for a soccer player to work on dribbling and passing activities). These variations are useful to motivate the patient and minimize training boredom.

The third level of the running program incorporates figure-eight running drills. These drills begin with long and wide movement patterns to encourage subtle cutting. The training distance initially is 20 yards (18 m); as speed and confidence improve, the distance is decreased to approximately 10 yards (9 m). Progression through this phase is similar to that used in the lateral side-to-side program just described. Speed and agility are emphasized and, equipment is also introduced to develop sports-specific skills.

The fourth phase in the running program introduces cutting patterns. These patterns include directional changes at 45-degree and 90-degree angles that allow the patient to progress from subtle to sharp cuts.

Plyometric Training

Plyometric training is begun upon successful completion of the running program to minimize bilateral alterations in neuromuscular function and proprioception. This training begins after the ninth postoperative month for patients who desire to return to strenuous athletics. Again, this training should be delayed on an empiric basis for 12 months when PCL allografts are used. The patient should demonstrate no more than a 20% deficit for the quadriceps and hamstrings on isokinetic testing. Important parameters when performing plyometric exercises are surface, footwear, and warm-up. The jump drills should be done on a firm, yet forgiving surface such as a wooden gym floor. Very hard surfaces like concrete should be avoided. A cross-training or running shoe should be worn to provide adequate shock absorption, as well as adequate stability to the foot. Checking wear patterns and outer sole wear will help avoid overuse injuries.

During the jumps, the patient is instructed to keep the body weight on the balls of the feet, to jump and land with the knees flexed and shoulder-width apart to avoid knee hyperextension and an overall valgus lower limb position (Fig. 18-19), as described in detail in Chapter 14. The patient should understand that the exercises are reaction and agility drills and while speed is emphasized, correct body posture must be maintained throughout the drills.

FIG 18-19 An improper, overall valgus lower limb position on landing a plyometric jumping exercise.

The first exercise is level-surface-box jumping using both legs. A four-square grid is created with tape on the floor of four equally sized boxes. The patient is instructed to first jump from box 1 to box 3 (front-to-back) and then from box 1 to box 2 (side-to-side). The second level incorporates both of these directions into one sequence and also includes jumping in both right and left directions (e.g., box 1 to box 3 to box 4 to box 2 to box 1). Level three progresses to diagonal hops, and level four includes pivot jumps in 90 degrees and 180 degrees directions. Once the patient can perform level four double-leg jumps, the same exercises are done on a single leg. The next phase incorporates vertical box hops.

It is important to stress that plyometric exercise is intense and adequate rest must be included in the program. Individual sessions can be performed in a manner similar to interval training. Initially, the rest period lasts two to three times the length of the exercise period and is gradually decreased to one to two times the length of the exercise period. Plyometric training is performed two to three times weekly.

Improvement is measured by counting the number of hops in a defined time period. The initial exercise time period is 15 seconds. The patient is asked to complete as many hops among the squares as possible in 15 seconds. Three sets are performed for each direction and the number of hops recorded. The program is progressed as the number of hops increases, along with patient confidence.

For athletes who wish to resume high-risk sports that involve jumping, cutting, twisting, and pivoting, we recommend that a course of Sportsmetrics training be completed to reduce the risk of a reinjury before returning to these activities.[27] Although initially developed to prevent anterior cruciate ligament (ACL) injuries in female athletes, we empirically believe this program is applicable to end-stage postoperative rehabilitation after both ACL and PCL/posterolateral ligament reconstructions. This belief is caused by the fact that this program teaches athletes to control the upper body, trunk, and lower body position; lower the center of gravity by increasing hip and knee flexion during activities; and develop muscular strength and techniques to land with decreased ground reaction forces. In addition, athletes are instructed to preposition the body and lower extremity before initial ground contact to obtain the position of greatest knee joint stability and stiffness. The program consists of a dynamic warm-up, plyometric jump training, strengthening exercises, aerobic conditioning, agility, and risk-awareness training. The training is conducted three times a week on alternating days for 6 weeks, and is described in detail in Chapter 14.

Return to Sports Activities

Discharge criteria after PCL reconstruction are based on patient goals for athletics and occupations, the rating of symptoms, stress radiography (90 degrees of flexion), KT-2000 (MEDmetric) testing, muscle strength testing, and single-leg hop function testing (Table 18-2). First, patients complete the Cincinnati Sports Activity Scale and Occupational Rating Scale[2] to provide sports and occupational levels that are desired after surgery. Upon completion of the protocol, pain, swelling, and giving-way are rated on the Cincinnati Symptom Rating Scale.[2] The patient must not experience these symptoms at the level of activity that he or she wishes to participate in before discharge.

Stress radiography is performed as described previously[10] and the difference between knees must be within 5 mm before recommendation of return to strenuous activities.

Muscle strength testing is performed with a Biodex isokinetic dynamometer (Biodex) to ensure adequate strength exists before the initiation of the plyometric, running, and cutting programs. At least two single-leg hop function tests are completed and limb symmetry calculated as previously described[18] before the final discharge.

As previously discussed, athletes who wish to resume high-risk sports that involve jumping, cutting, and pivoting are encouraged to complete a course of Sportsmetrics training to reduce the risk of a reinjury before returning to these activities

A trial of function is encouraged where the patient is monitored for overuse symptoms or giving-way episodes. Upon successful return to activity, the patient is encouraged to continue with a maintenance program. During the in-season, a conditioning program of two workouts per week is recommended. In the off-season or preseason, this program should be performed three times per week to maximize gains in flexibility, strength, and cardiovascular endurance.

POSTEROLATERAL RECONSTRUCTION REHABILITATION PROTOCOL

Patients who have chronic ruptures to the posterolateral structures may develop over time an alteration in gait in which excessive knee hyperextension occurs during the stance phase, described in detail in Chapter 29. A preoperative gait-retraining program is implemented for these patients, as failure to correct this problem leads to an increased risk of failure of any posterolateral reconstructive procedure.

There are a variety of surgical options for ruptures of the posterolateral structures, which are detailed in Chapter 17. The rehabilitation protocol incorporates immediate protected knee motion but stresses maximal protection against undue joint loads to prevent stretching and failure of posterolateral grafts or advancement procedures (Table 18-3). Patients are warned to avoid hyperextension and activities that would incur varus loading on the joint. Delays in return of full knee flexion, full weight bearing, initiation of certain strengthening and conditioning exercises, running, and return to full sports activities are incorporated.

PHASE 1: WEEKS 1-2 (VISITS 2-4)

General Observation
Non–weight bearing, maximum protection
Bivalved cylinder cast
Must avoid hyperextension, varus loads, lateral joint opening

Evaluation (Goal)
Pain (controlled)
Hemarthrosis (mild)
Patellar mobility (good)
ROM minimum (0-90 degrees)
Quadriceps contraction and patellar migration (good)
Soft tissue contracture (none)

Goals
ROM 0-90 degrees
Protect ligament reconstruction
Adequate quadriceps contraction
Control inflammation, effusion

	Frequency	Duration
ROM	3-4 ×/day, 10 min	
Passive, 0-90 degrees with 10-lb valgus force		
Patellar mobilization		
Ankle pumps (plantar flexion with resistance band)		
Hamstring, gastrocnemius-soleus stretches		5 reps × 30 sec
Strengthening	3 ×/day, 15 min	
Straight-leg raises (flexion)		3 sets × 10 reps
Active quadriceps isometrics		1 set × 10 reps
Knee extension (active assisted, 90-30 degrees, per quad control)		3 sets × 10 reps
Modalities	As required	
EMS		20 min
Cryotherapy		20 min

TABLE 18-3 Rehabilitation Protocol After Posterolateral Knee Reconstruction—cont'd

PHASE 2: WEEKS 3-4 (VISITS 2-4)

General Observation	Non–weight bearing, maximum protection Bivalved cylinder cast Must avoid hyperextension, varus loads, lateral joint opening	
Evaluation (Goal)	Pain (controlled) Effusion (mild) Patellar mobility (good) ROM minimum (0-90 degrees) Quadriceps contraction and patellar migration (good) Soft tissue contracture (none)	
Goals	ROM 0-90 degrees Protect ligament reconstruction Control inflammation, effusion Muscle control	
	Frequency	**Duration**
ROM	3-4 ×/day, 10 min	
Passive, 0-90 degrees with 10-lb valgus force		
Patellar mobilization		
Ankle pumps (plantar flexion with resistance band)		
Hamstring, gastrocnemius-soleus stretches		5 reps × 30 sec
Strengthening	2-3 ×/day, 20 min	
Straight-leg raises (flexion)		3 sets × 10 reps
Isometric training: multiangle (0, 60 degrees)		1 set × 10 reps
Knee extension (active assisted, 90-30 degrees, per quad control)		3 sets × 10 reps
Aerobic Conditioning	2 ×/day, 10 min	
UBC		
Modalities	As required	
EMS		20 min
Cryotherapy		20 min

PHASE 3: WEEKS 5-6 (VISITS 1-2)

General Observation	Partial (25%-50%) weight bearing when: • Pain is controlled without narcotics • Hemarthrosis is controlled • ROM 0-100 degrees • Muscle control throughout ROM Custom medial unloader brace or hinged soft tissue brace Avoid hyperextension, varus loads
Evaluation (Goal)	Pain (mild/no CRPS) Effusion (minimal) Patellar mobility (good) ROM (0-110 degrees) Muscle control (3/5) Inflammatory response (none)
Goals	ROM 0-110 degrees Control inflammation, effusion Protect ligament reconstruction Muscle control Early recognition of complications (motion abnormalities, CRPS, patellofemoral changes) 50% weight bearing

PHASE 3: WEEKS 5-6 (VISITS 1-2)

	Frequency	Duration
ROM	3 ×/day, 10 min	
Passive, 0-110 degrees		
Patellar mobilization		
Hamstring, gastrocnemius-soleus stretches		5 reps × 30 sec
Strengthening	2 ×/day, 20 min	
Straight-leg raises (flexion, ankle weight <10% body weight)		3 sets × 10 reps
Isometric training: multiangle (90, 60, 30 degrees)		2 sets × 10 reps
Knee extension (active, 90-30 degrees)		3 sets × 10 reps
Closed-chain:		
Minisquats		3 sets × 20 reps
Heel raises/toe raises		3 sets × 20 reps
Aerobic Conditioning (Patellofemoral Precautions)	2 ×/day, 10 min	
UBC		
Stationary bicycling		
Gait Retraining (High Risk for Stretching Reconstruction With Resumption of Weight Bearing)		
Muscle control, quadriceps and hamstrings		
Walking with toe-out gait; avoid toe-in varus position		
Observe gait for any varus thrust or hyperextension		
Smooth stance phase flexion pattern		
Modalities	As required	
EMS		20 min
Cryotherapy		20 min

PHASE 4: WEEKS 7-8 (VISITS 1-2)

General Observation	Full weight bearing with cane when: • Pain is controlled • Hemarthrosis is controlled • ROM 0-120 degrees • Voluntary quadriceps contraction is achieved Custom medial unloader brace or hinged soft tissue brace
Evaluation (Goal)	Pain (mild/no CRPS) Effusion (minimal) Patellar mobility (good) ROM (0-120 degrees) Muscle control (4/5) Inflammatory response (none)
Goals	Full weight bearing Muscle control Protect ligament reconstruction Control inflammation, effusion ROM 0-120 degrees

Posterolateral reconstructions are monitored with manual examination of lateral joint opening and external tibial rotation. Any patient who experiences difficulty progressing through the protocol or who develops a complication is expected to require additional supervision in the formal clinic setting.

The immediate postoperative management is similar to that described for PCL reconstructions. A bivalved cast is used for the first 4 postoperative weeks to provide maximum protection to the knee joint and posterolateral structures. The cast is used in this time period because many soft-hinged postoperative braces do not provide sufficient protection against excessive lateral joint opening that could occur with ambulation and produce a failure of the posterolateral reconstruction. The cast is removed four times per day for passive knee motion exercises, which are performed in a seated position with a 10-lb valgus load applied to decrease lateral joint forces. If associated with a PCL reconstruction, a combined medial-anterior load should be applied to control both varus and posterior loads. At 4 weeks postoperative, a lower extremity, hinged, double-upright brace is applied locked at 10 degrees of flexion. The brace is removed four times daily for ROM exercises. At 6 weeks postoperative, the brace is unlocked as knee flexion to 110 degrees is encouraged and partial weight bearing allowed.

It is important to recognize that, on occasion, there will be excessive soft tissue swelling or skin problems in which the bivalved cylinder cast is contraindicated. There are commercially available soft tissue hinged braces with a design where the hinge support and medial-lateral arms are more rigid, providing (when properly applied) a resistance to prevent abnormal lateral joint opening with ambulation. A more flexible hinged soft tissue brace is not advised. The surgeon provides information on the expected strength of the posterolateral reconstruction. For example, a double-graft anatomic reconstruction provides considerable strength to allow a soft-hinged brace. A single femorofibular graft reconstruction has less strength, and more postoperative protection is required for the first 4 weeks.

At 7 to 8 weeks, a custom medial unloading brace is applied as weight bearing progresses to full and flexion is advanced to 120 degrees. The brace is also used as patients return to activity to provide protection against knee hyperextension and excessive varus loads.

Patients are allowed 0 to 90 degrees immediately postoperatively. Flexion is slowly advanced to 110 degrees by postoperative week 5, 120 degrees by week 8, and 130 degrees by week 12. Patients are cautioned to avoid varus tensioning when performing knee flexion exercises. They are taught (and the assistance of a partner is encouraged) to place a hand on the lateral aspect of the knee and create a 10-lb valgus load to protect the posterolateral structures.

Patients are not allowed to bear weight for the first 2 postoperative weeks. Then, partial weight bearing (25% of the patient's body weight) is begun at postoperative weeks 3 to 4. There is a slow advancement to full weight bearing by weeks 8 to 10 with the brace unlocked and cane or crutch support, which is used for approximately another 3 to 4 weeks. The patient must have good control of the lower extremity and adequate muscle strength to maintain joint compression and avoid an abnormal lift-off of the lateral tibiofemoral compartment. Patients are warned to avoid knee hyperextension and activities that would incur varus loading, internal tibial rotation, or lateral joint opening.

TABLE 18-4 Discharge Rehabilitation Criteria After Posterolateral Reconstruction

Desired Sports	Occupation Rating*	Symptom Rating* Pain, Swelling, Giving Way	Lateral Joint Opening (20 Degrees, I-N, mm)	Biodex Isometric Test (% Deficit I-N)	Single-leg Hop Function Testing Limb Symmetry (%)
Jumping, pivoting, cutting*†‡	Heavy/very heavy	None, level 10	None	≤15	≥85
Running, turning, twisting	Moderate	None, level 8	<3	≤20	≥85
Swimming, bicycling	Light	None, level 6	3-5	≤30	≥75
None, daily activities only	Very light	None, level 4	3-5	<30	≥75

*See Chapter 41.
†Level 10, normal knee, no symptoms with strenuous work/sports with jumping, hard pivoting; level 8, no symptoms with moderate work/sports with running, turning, twisting; level 6, no symptoms with light work/sports such as swimming, bicycling; level 4, no symptoms with daily activities.
‡Also consider completing a course of Sportsmetrics before return to these athletic activities.
I-N, Involved minus noninvolved limb.

Patellar mobilization, flexibility exercises, modality usage, and the strengthening and conditioning programs are all similar to those described in the PCL reconstruction protocol.

In select athletes, a running program is begun at approximately the ninth postoperative month, and plyometric- and sports-specific-training programs are initiated at the twelfth postoperative month. However, the majority of patients who require multiple ligament reconstructive procedures do not desire to return to high-impact sports; therefore this advanced conditioning and training is usually not required. Patients who have articular cartilage damage are advised to return to low-impact activities only to protect the knee joint.

Discharge criteria after lateral and posterolateral graft reconstructions is based on patient goals for athletics and occupations and the rating of symptoms, lateral joint opening, muscle strength testing, and function testing (Table 18-4). Lateral joint opening is assessed either by stress radiography or manual testing at 20 degrees of flexion. The remainder of the assessment is performed as previously described for PCL reconstructions.

Video 3-1 Comprehensive Knee Exam: Clinical Rationale and Diagnosis

INDICATIONS

Medial ligament injuries are among the most frequently treated problems of the knee joint, with the majority not requiring operative intervention. Whereas isolated superficial medial collateral ligament (SMCL) ruptures are common,[60] concomitant damage to the anterior cruciate ligament (ACL) also occurs in many cases, especially in young and active patients.[10,14,22,49,58,71]

Overall, there are four types of SMCL injury patterns: (1) SMCL tears that also almost always involves the meniscofemoral and meniscotibial attachments (deep medial collateral ligament [DMCL]); (2) associated posteromedial capsular (PMC) tears (posterior oblique ligament [POL]); (3) associated ACL or posterior cruciate ligament (PCL) tears with patterns 1 or 2; and (4) multiple ligament injuries or knee dislocations.

The mechanism of injury to the medial ligaments involves a valgus stress with usually a combined external tibial rotation component from either a noncontact (pivoting or cutting) or a contact injury (direct blow to the lateral side of the thigh or knee). The decision process regarding the appropriate treatment of medial ligament injuries involves determining the severity of the injury to the entire knee, including the other knee ligaments, and the specific injury pattern of the medial structures and menisci.

The medial structures identified for purposes of surgical treatment consist of the SMCL, DMCL (including meniscus attachments), and the PMC, which includes the structures referred to as the POL and semimembranosus attachments.[32,68] The key to the diagnosis and treatment of medial ligament injuries relies on a comprehensive understanding of the intricate anatomy on the medial side of the knee. This is presented in detail in Chapter 1. In Figure 19-1, the osseous attachments of the medial structures are shown. Figure 19-2 shows the medial and posteromedial ligament structures, which are discussed in detail. Figure 19-3 shows the relationship of the semimembranosus muscle attachments to the posteromedial structures and POL. These include the bifurcation of the semimembranosus tendon into a direct and anterior arm just distal to the joint line and a minor attachment of the direct arm to the medial coronary ligament along the posterior horn of the medial meniscus. The semimembranosus tendon sheath makes up a distal tibial expansion that includes a medial and lateral division. A major attachment of the semimembranosus forms the oblique popliteal ligament, which is a broad fascial band that courses laterally attaching to the fabella, posterolateral capsule, and plantaris (see Chapter 1, Fig. 1-6).

It is important to understand and classify the soft tissue injury of all the medial structures. The majority of acute medial ligament injuries that involve damage to the SMCL alone, or SMCL and PMC, are treated conservatively. The nonoperative treatment algorithm is shown in Figure 19-4 and discussed later in more detail. Gross major disruption of all of the medial structures alone or in addition to the ACL or

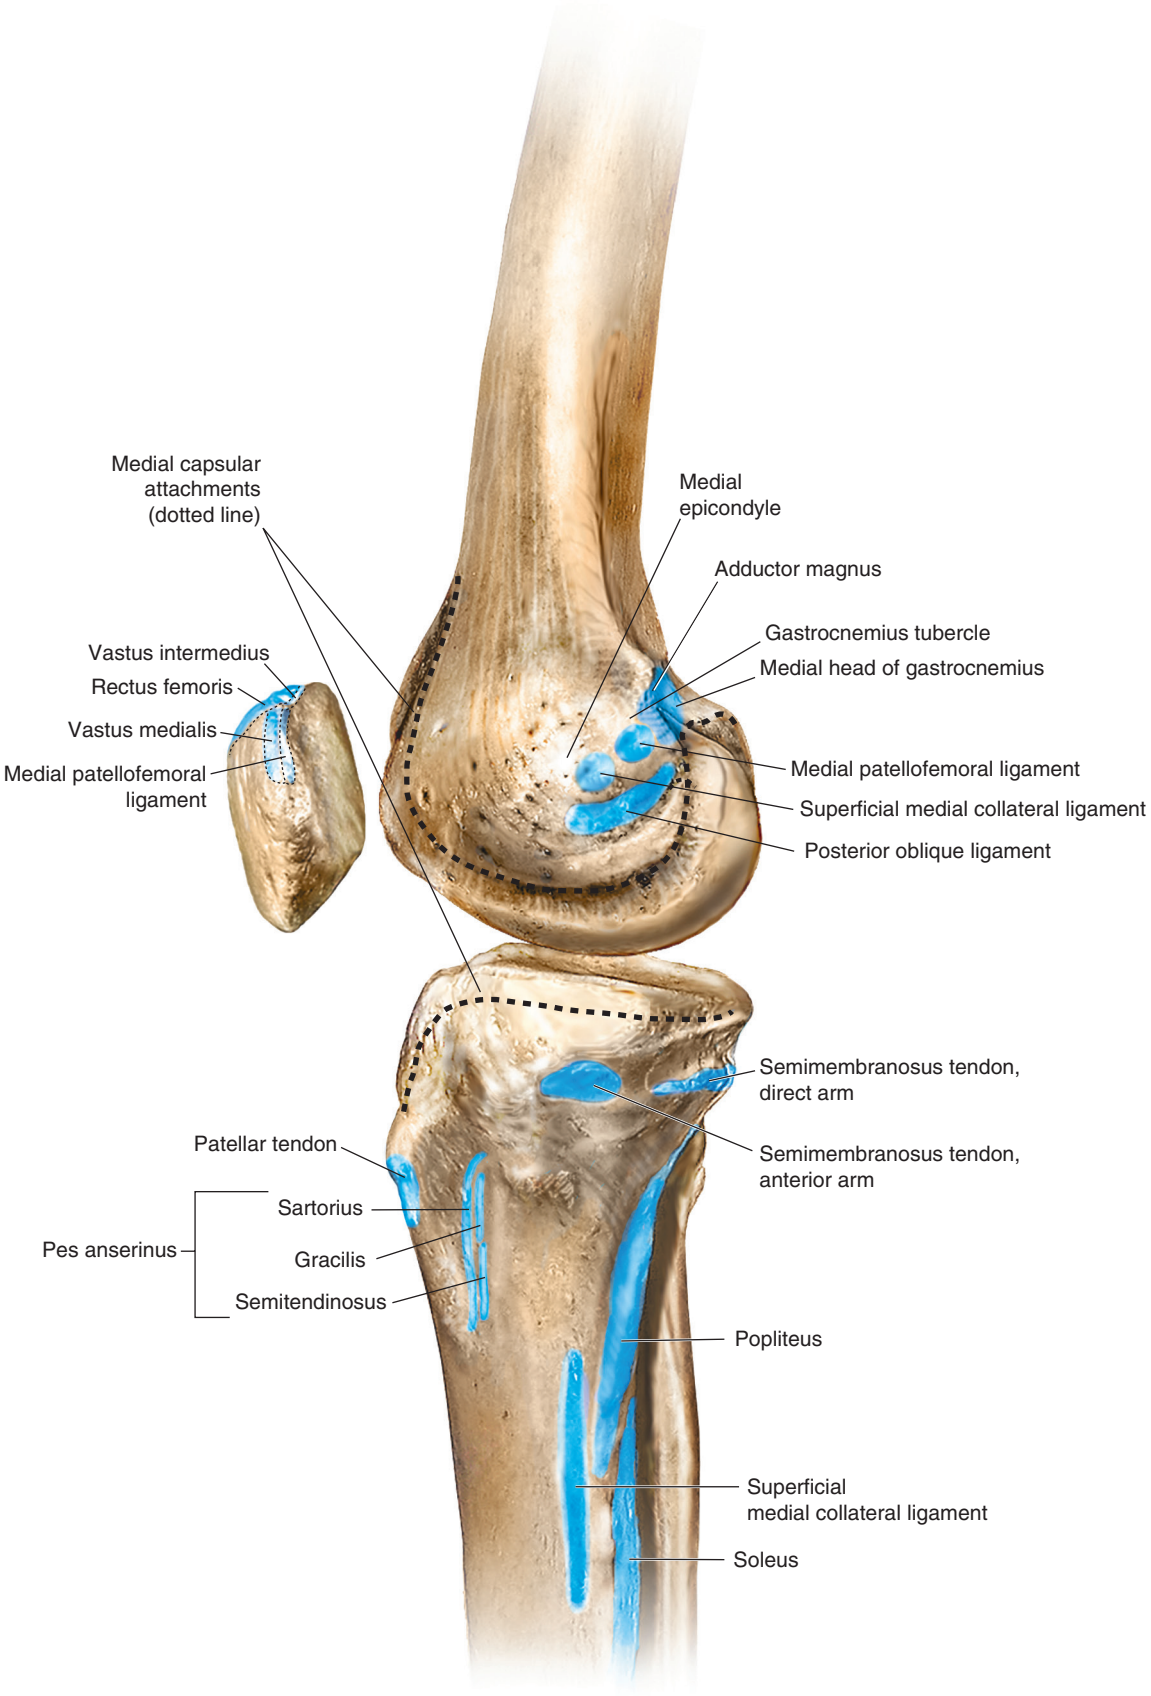

FIG 19-1 The medial capsule, ligament, and muscle bone attachments are shown. A key to surgical repair and reconstruction of medial injuries is to restore normal anatomy and attachment locations.

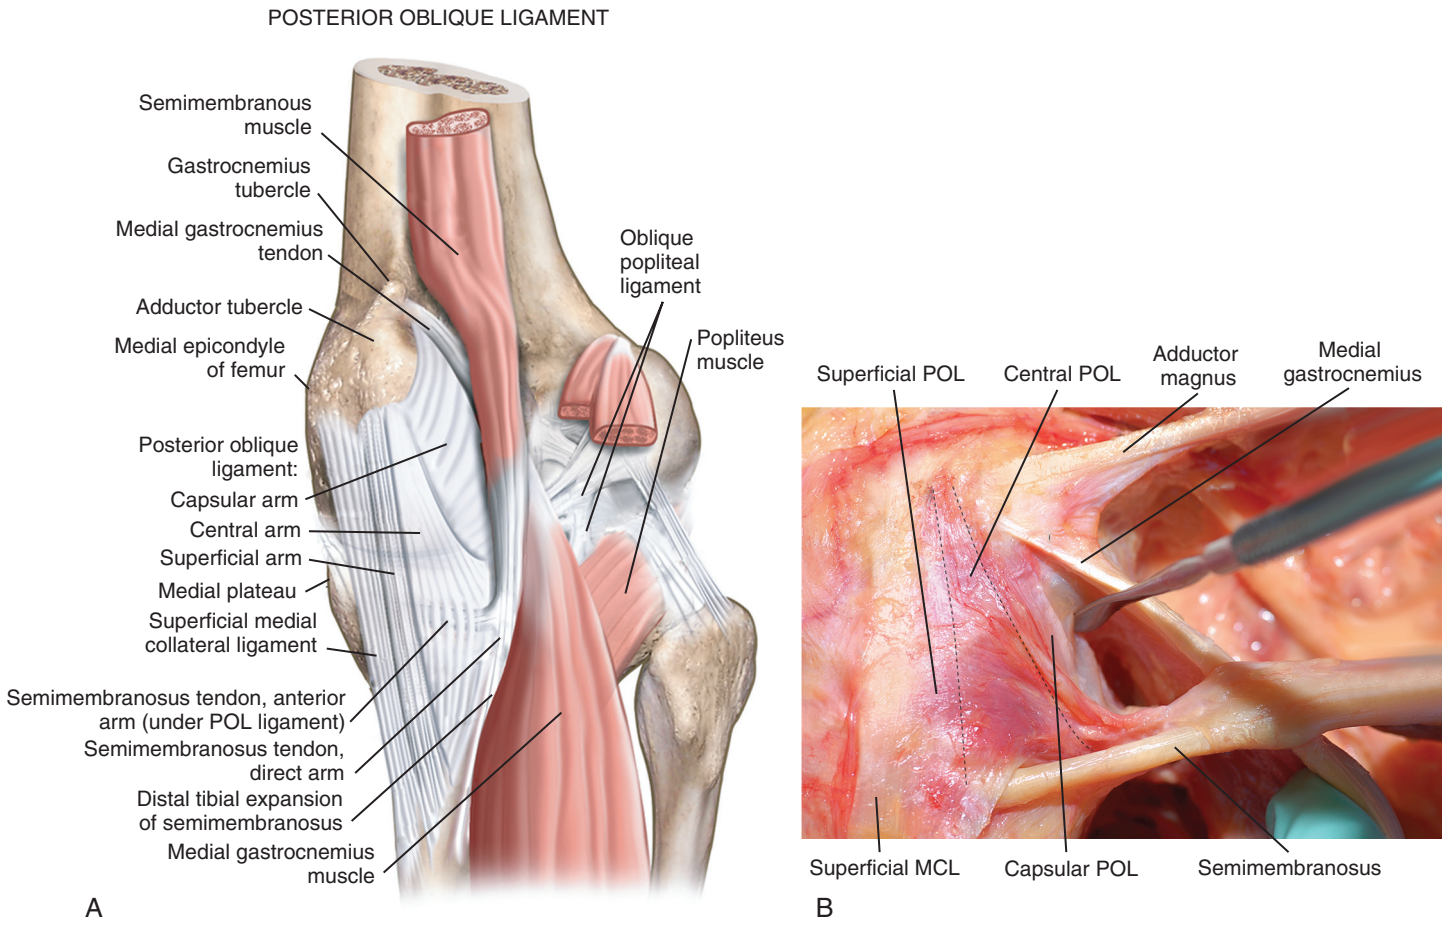

FIG 19-2 **A** and **B,** The anatomy of the medial and posteromedial aspect of the knee. The posteromedial capsule is shown divided into three functional regions, commonly designated as the *posterior oblique ligament* (POL). *MCL,* Medial collateral ligament.

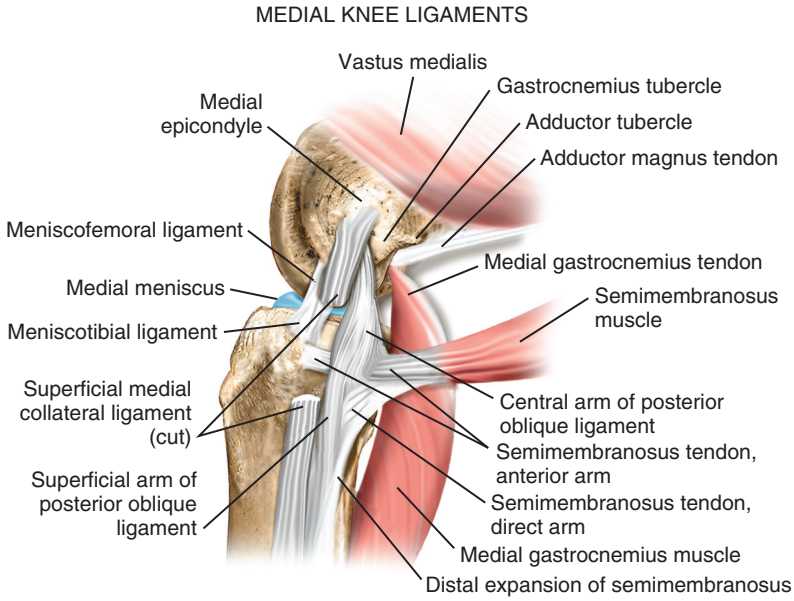

FIG 19-3 Semimembranosus muscle attachments to the posteromedial structures.

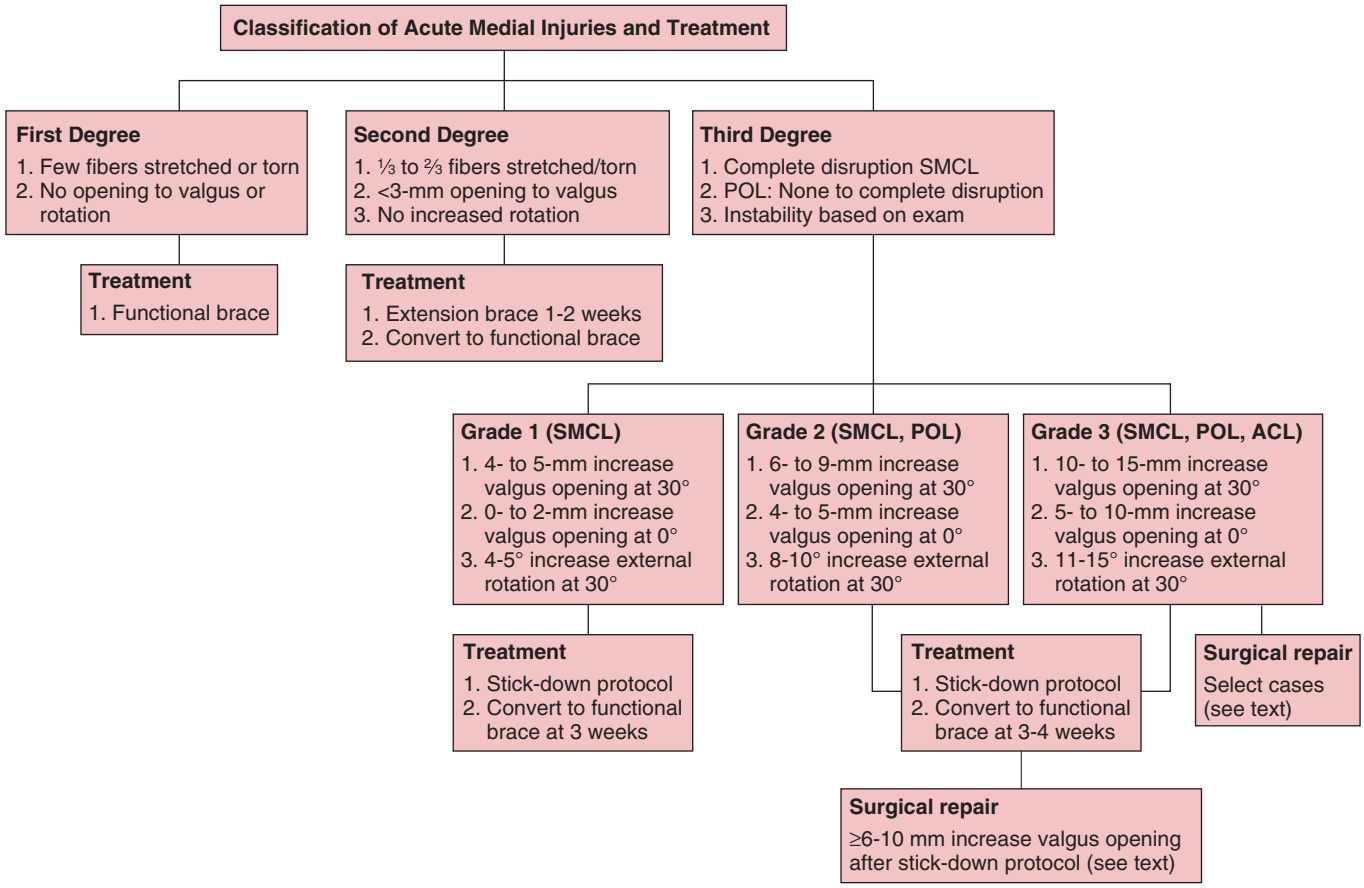

FIG 19-4 Treatment algorithm for patients with acute medial ligament ruptures. *ACL*, Anterior cruciate ligament; *POL*, posterior oblique ligament; *SMCL*, superficial medial collateral ligament.

PCL tears involve a group of select knees. The treatment of these gross ligament disruptions is discussed in a later section of this chapter.

In cases of chronic injury to the medial ligaments, it is important to obtain a complete history and objective and functional rating. We use the Cincinnati Knee Rating System (CKRS) for this analysis (see Chapter 41) to determine patient complaints of giving-way and the levels of activity at which this symptom occurs as an indication for surgical stabilization procedures. In this chapter, *instability* refers to an increase in abnormal motion limits as detected on the physical examination and is not used to indicate giving-way events.

CONTRAINDICATIONS

Patients who have medial ligament tears classified as first, second-, or third degree that demonstrate either no increase or a mild to moderate increase in medial joint opening at 0 and 30 degrees of flexion do not require acute medial ligament repair or reconstruction.

A valgus malalignment and valgus thrust on walking contraindicates a medial ligament reconstruction in chronic cases without first performing an osteotomy to correct the lower limb malalignment. Alternatively, a genu varus provides a theoretical benefit of decreased tensile loads on the medial ligament structures.

In chronic cases of disruption of the medial ligaments, particularly associated with ACL or PCL tears, joint arthritis and associated pain and swelling may exist that contraindicate a soft tissue reconstruction. The patient goals and anticipated symptoms from the preexisting arthrosis are carefully considered.

Sedentary, nonathletic patients who do not experience pain, swelling, or giving-way with daily activities do not require surgery. These patients are advised to maintain their ideal body weight and obtain yearly consultations to monitor the knee joint.

In chronic cases, patients with marked lower extremity muscle atrophy are not candidates for surgery until adequate muscle strength is regained. The high potential for postoperative complications exceeds the potential benefits in these patients, especially in regard to developmental patella infera, quadriceps shutdown, and arthrofibrosis. A formal program of physical therapy should be pursued, which may be required for many months to improve overall lower limb muscle strength and function, particularly in multiligament injuries.

Associated medical problems may exist that either require treatment or contraindicate surgery, including complex regional pain syndrome, diabetics, vascular insufficiency, skin lesions, infectious conditions, obesity, or other medical diseases.

CLINICAL BIOMECHANICS

Classification of Ligament Injury and Instability

A considerable amount of discrepancy exists in the literature regarding the use of terminology to describe and classify the medial ligament injuries from an anatomic standpoint and the abnormal motion limits that exist (see Chapter 3). We agree with Hughston and coworkers[29] that the clinician must clearly separate and classify medial ligament tears as either first degree (tear involving a few fibers), second degree (partial tear, no instability, 3 mm or less of medial joint opening), or

TABLE 19-1 Published Classification Systems for Ruptures to the Medial Structures of the Knee

Reference	System
Hughston et al[30,31] (1976, 1983)	Injury severity: • First degree: Involves a few fibers resulting in localized tenderness but no instability • Second degree: Disruption of more fibers with more generalized tenderness but no instability • Third degree: Complete disruption of the ligament with resultant instability Degree of instability (total separation medial joint, not increase): • 1+: ≤5-mm separation medial joint surfaces • 2+: 5- to 10-mm separation medial joint surfaces • 3+: >10-mm absolute medial separation
Fetto & Marshall[14] (1978)	Grade I: Full anatomic integrity, full stability to valgus stress both 0 and 30 degrees of flexion, hard endpoint, no opening on stress x-rays Grade II: Partial anatomic discontinuity, unstable to valgus stress 30 degrees but stable at 0 degrees. Firm endpoint if chronic, soft if acute, some medial opening stress x-rays Grade III: Complete anatomic disruption, unstable to valgus stress at both 0 and 30 degrees of flexion, no endpoint, marked medial opening stress x-rays
Garrick[16] (2004)	Primary (grade I): Stretching of fibers with localized tenderness, no instability Second degree (grade II): More disruption of fibers, mild to moderate instability Third degree (grade III): Complete disruption of the ligament, gross instability
Bergfeld[6] (1979)	First degree: No valgus instability at 20 degrees Second degree: Definite valgus laxity at 20 degrees, 5-15 degrees greater laxity than the opposite knee, but firm endpoint Third degree: Opening >15 degrees with no or a "mushy" end point
Shelbourne & Patel[66] (1995)	Grade I: No laxity, solid end point Grade II: Some medial laxity, firm end point Grade III: Complete disruption of the MCL with substantial medial opening and no detectable end point
Petersen & Laprell[57] (1999)	First degree: Painful valgus stress test with no instability Second degree: Positive valgus stress test with an endpoint Third degree: Positive valgus stress test without an endpoint
Fanelli & Harris[13] (2007)	A: Axial plane rotation, instability, usually represents posteromedial capsular laxity B: Combined axial plane rotation and valgus laxity with a firm end point, usually caused by posteromedial and medial capsular laxity combined with superficial MCL laxity C: Combined axial plane rotation and valgus laxity with no end point, often caused by posteromedial and medial capsular laxity, disruption, or avulsion, combined with superficial MCL laxity, disruption, or avulsion

MCL, Medial collateral ligament.

third-degree (complete rupture, see Table 19-1 and Fig. 19-4). This is one of the earliest systems devised and is based on a classification proposed by the American Medical Association.[1] The problem has arisen, as amply demonstrated in Table 19-1, that this classification system has been modified extensively by different authors and it is often not possible to categorize the injury severity of the knees under treatment. A grade 1 instability (0 to 5-mm increased joint opening) may represent a second-degree injury (0 to 3-mm increased joint opening) or a third-degree injury (5-mm increased joint opening), requiring protection to allow healing as discussed. This also applies to a grade 2 instability where a 6- to 9-mm increased joint opening is treated conservatively with immobilization, whereas other studies include these as operative cases. Thus it is necessary in the review of the literature to perform a subset analysis, which has been done in this chapter, to try to obtain the category or type of injury under treatment and our treatment recommendations.

For purposes of this chapter, the injury classification in acute cases of medial ligament injuries is based on the clinical examination shown in Figure 19-4. Note that the medial ligament injuries are based on the first-, second-, and third-degree original classification system. The approximate increases in medial joint opening and external tibial rotation are shown for the different categories of injury. Some classification schemes use a system in which each grade represents a further 5-mm increase in joint opening (grades 1, 2, and 3) over the contralateral normal knee, whereas Hughston and colleagues use a grade to classify the degree of injury and then represent the absolute amount of joint opening in the injured knee (1+, 2+, and 3+ in 5-mm increments; see Table 19-1). This chapter uses the increase in millimeters of medial joint opening between the injured and contralateral normal knee because this is the system used in published biomechanical and kinematic studies to be discussed.

A review of the in vitro cadaveric biomechanical function of the medial ligaments and ACL in resisting medial joint opening, external tibial rotation, and internal tibial rotation is provided in Figure 19-5, summarized in Table 19-2,[20] and discussed in more detail in Chapter 3. A finding of increased medial joint space at 30 degrees of flexion (third-degree sprain, parallel fibers of the SMCL), but not at 0 degrees of flexion indicates the PMC (including the POL) is still functional. Any further increase in medial joint opening at 0 degrees indicates concurrent damage to the PMC. With complete disruption of the SMCL and PMC, the ACL and PCL become a restraint to further medial joint opening. The increase in abduction for a combined MCL/POL injury and MCL/ACL injury at 15 to 45 degrees of flexion is nearly the same (see Fig. 19-5, *B*). The major difference between these injuries is in increased abduction at full extension in the MCL/POL-ruptured knee. In summary, knees with rupture to both the medial collateral

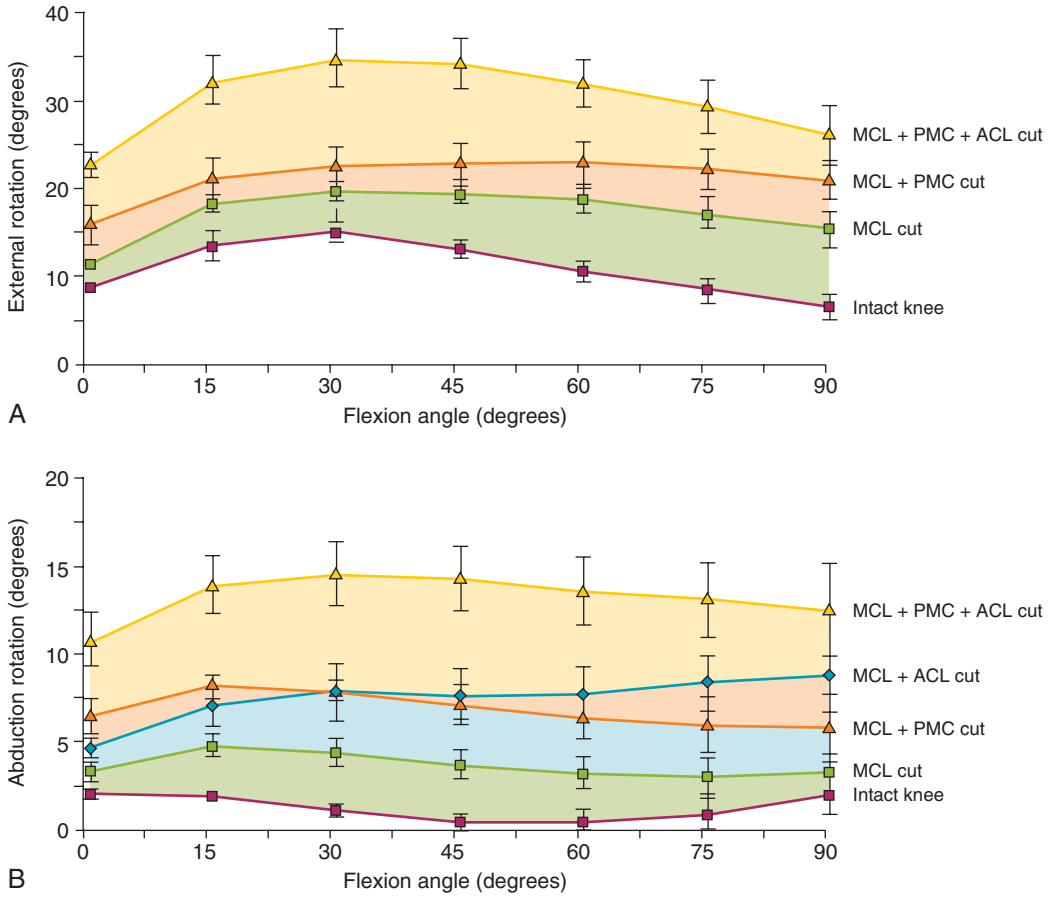

FIG 19-5 A, The external rotation limits in the intact knee first increased with flexion to 30 degrees and then decreased with further flexion (11 donors). Cutting just the superficial MCL increased the external rotation limits (16 donors). Further cutting of the PMC produced a further increased in the external limit at all flexion angles, but the increase was again greater in flexion than extension. Cutting the superficial MCL, the PMC, and the ACL allowed for a large increase in the external limit, particularly from 15 to 45 degrees of flexion. **B,** The abduction rotation limits (valgus opening) of the intact knee (11 donors). Cutting only the MCL produced a small increase (~2 to 4 degrees) in the abduction limit from 15 to 75 degrees of flexion. Cutting the ACL (MCL + ACL cut) increased the abduction limit (6 donors). Cutting the PMC in addition to the MCL with the ACL intact allowed for a further small but consistent increase (2 to 3 degrees) over the superficial MCL alone (6 donors). When compared with the intact knee, this injury combination increased the abduction limit approximately 6 to 7 degrees at both 15 and 30 degrees of flexion. Subsequently cutting the ACL caused a large increase in the abduction limits at all flexion angles (9 donors). Note that the MCL + ACL cut produced a similar increase in abduction at 15, 30, and 45 degrees of flexion as the MCL + PMC cut, but not at full extension. *ACL,* Anterior cruciate ligament; *MCL,* medial collateral ligament; *PMC,* posteromedial corner. (From Haimes JL, Wroble RR, Grood ES, Noyes FR. Role of the medial structures in the intact and anterior cruciate ligament-deficient knee. Limits of motion in the human knee. *Am J Sports Med.* 1994;22: 402-409.)

ligament (MCL) and POL will demonstrate approximate increases in external tibial rotation (average of 9 degrees at 30 degrees of flexion), internal tibial rotation (average of 9 degrees at 30 degrees of flexion), and abduction testing at 0 and 30 degrees of flexion (averages of 5 degrees and 7 degrees, respectively).

The increase in medial joint opening and external tibial rotation shown in Figure 19-5 provides an indication of an associated ACL tear when these motion limits are distinctly abnormal. In these knees, there is a large increase in anterior tibial translation and the pivot shift test is in the grade III category.

The results show the importance of performing the dial tibial rotation test (see Chapter 17) to determine the anterior subluxation of the medial tibial plateau with medial ligament injuries.[18] With a combined MCL/POL injury, there will be a noticeable increase in internal and external tibial rotation (see Fig. 19-5 and Fig. 19-6).

The medial structures resisting external rotation in the dial test show the SMCL is the primary restraint; however, the increase in external rotation is small (4.6-8.7 degrees at 30 and 90 degrees of flexion) and may not be clinically detectable. The increase in external tibial rotation approximately doubles when the SMCL and PMC are injured (9-15 degrees at 30 and 90 degrees of flexion), resulting in a qualitative detectable positive dial test. An even greater increase occurs with ACL rupture. It should be noted that Griffith and associates[18] reported even larger increases in the dial test with SMCL sectioning, suggesting that some knees may have a positive dial test with this injury.

TABLE 19-2 Increases in Motion Limits Relative to the Intact Knee That Occurred When the Indicated Structures Were Sectioned

ACL, Anterior cruciate ligament; *MCL*, superficial medial collateral ligament; *POL*, posterior oblique ligament; *PMC* posteromedial capsule.

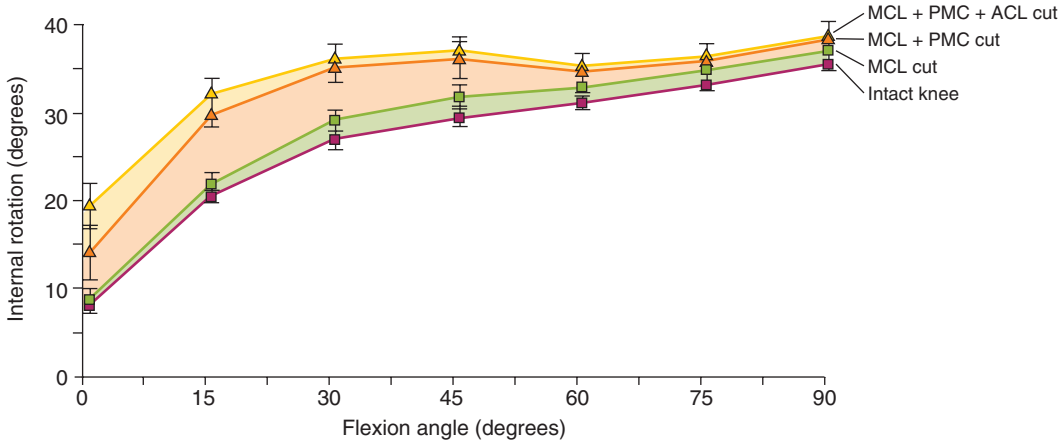

FIG 19-6 The internal rotation limits of the intact knee increased progressively as the knee was passively flexed (11 donors). Cutting the superficial MCL produced only a small increase in the internal rotation limits (6 donors). Cutting the MCL and PMC caused large increases in the internal rotation limits from 0 to 45 degrees of flexion (6 donors). Cutting the MCL, the PMC, and the ACL caused similarly large increases in the internal limits from 0 to 45 degrees of flexion relative to the intact knee (6 donors). However, these increases were not significantly different from those seen with the MCL and PMC cut. *ACL,* Anterior cruciate ligament; *MCL*, medial collateral ligament; *PMC*, posteromedial corner. (From Haimes JL, Wroble RR, Grood ES, Noyes FR. Role of the medial structures in the intact and anterior cruciate ligament-deficient knee. Limits of motion in the human knee. *Am J Sports Med.* 1994;22:402-409.)

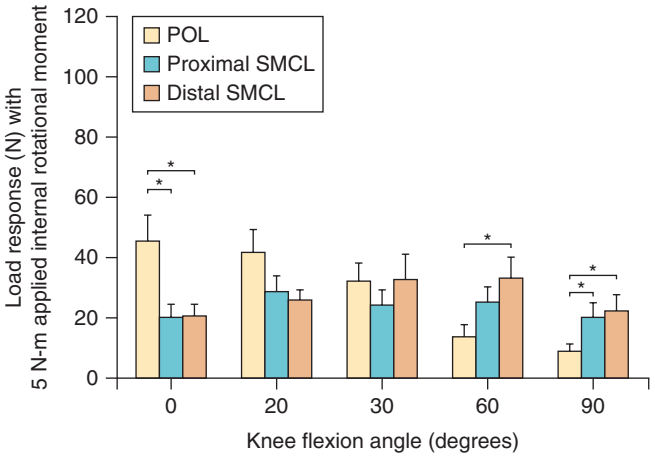

FIG 19-7 Forces measured on the posterior oblique ligament (POL) and the proximal and distal superficial medial collateral ligament (SMCL) divisions during application of a 5 N-m internal rotation torque. *$P < .05$. Error bars indicate the standard error of the mean. (From Griffith CJ, Wijdicks CA, LaPrade RF, et al. Force measurements on the posterior oblique ligament and superficial medial collateral ligament proximal and distal divisions to applied loads. *Am J Sports Med.* 2009;37:140-148.)

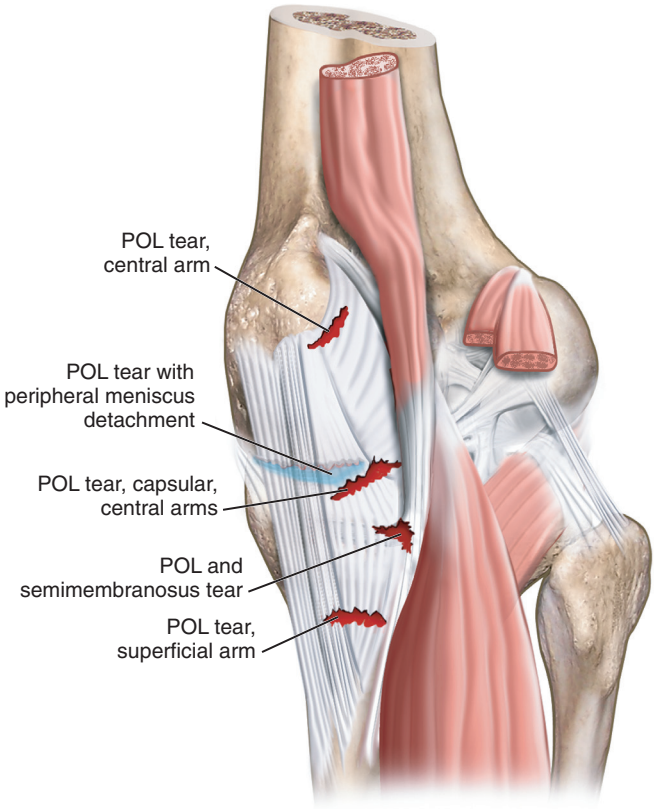

FIG 19-8 Three major acute injury patterns (injury to the posterior oblique ligament [POL] are common to all): (1) injury to the POL with semimembranosus disruption, (2) injury to the POL with complete peripheral meniscocapsular detachment, and (3) POL injury with semimembranosus injury and peripheral meniscocapsular detachment. Disruption at any level is capable of disabling the dynamic function of the semimembranosus.[68]

The medial structures resisting internal tibial rotation involve two primary restraints: the PMC/POL and SMCL, with the SMCL having a higher resistance in force measurements at 90 degrees and the PMC/POL having a higher resistance at 0 degrees of flexion (Fig. 19-7).[19] In the dial test for internal rotation, there are discrepancies in ligament sectioning studies regarding the magnitude of internal tibial rotation that occurs. In addition, there are no studies on the amount of anterior or posterior tibiofemoral compartment translation that occurs with medial ligament injuries. In general, sectioning the SMCL or PMC/POL individually produces only small increases in internal rotation whereas sectioning both structures results in an approximate 10 degrees increase in internal rotation at 30 degrees of flexion, with a lesser increase at 90 degrees of flexion. One study showed a similar amount of increased internal tibial rotation at both 30 and 90 degrees of flexion.[18]

Sims and Jacobson[68] reviewed 93 knees that underwent operative treatment for acute MCL injuries. These authors reported that 93% had associated injury to the POL following the description of Hughston and Eilers.[32] The authors emphasized the importance of identification and repair of the POL and tears of the semimembranosus capsular attachment (present in 70% of knees) and associated peripheral detachment of the medial meniscus (present in 30% of knees, Fig. 19-8). The authors postulated that a dynamic function of the semimembranosus attachments exists for knee stability, but this is unproven experimentally. Although some authors describe rupture and surgical repair of the POL alone (anteromedial rotatory instability), the biomechanic data show that the POL is not a primary restraint for medial joint opening or external tibial rotation.

CLINICAL EVALUATION

History and Physical Examination

A detailed history is taken that includes any previous knee injury and the mechanism of the current injury. The CKRS is used to evaluate the subjective, objective, and functional categories. In acute knee injuries, there may be a swollen knee, with a tense joint effusion and skin ecchymosis that is difficult to examine. Still, it is possible to rule out a multiligament injury with gross instability and complete a neurovascular examination, which includes assessment of signs of a deep venous thrombosis (DVT). The limb is immobilized and the acute injury appropriately treated (ice, compression, elevation, gentle range of motion [ROM], and early muscle activation) and the examination repeated after other diagnostic tests (radiographs, magnetic resonance imaging [MRI]) in 3 to 5 days.

The comprehensive examination of the knee joint required to detect all abnormalities includes (among other items) assessment of (1) range of knee flexion and extension, (2) knee joint effusion and swelling, (3) the knee motion limits and subluxations compared with the contralateral knee,[54] (4) alignment of the patellofemoral joint, (5) patellofemoral and tibiofemoral crepitus, (6) tenderness along the medial joint line and along the entire course of the SMCL from proximal to distal, (7) overall lower limb alignment, (8) neurovascular status, and (9) gait.

The palpation of the medial joint is particularly important to determine if the SMCL tear is more proximal at the femoral attachment, diffuse, or more distal at the tibial attachment. These findings are correlated with MRI. In a young athlete with open physes, palpation at the femoral physis is usually painful and careful radiographic stress views are always obtained to rule out a physeal fracture. A MRI is always helpful to confirm the diagnosis.

FIG 19-9 Demonstration of manual knee stability tests. **A** and **B**, Posterior drawer test at 90 degrees of knee flexion. **C**, Lachman test. **D**, Pivot shift test. **E**, Valgus test, palpating for medial joint opening at 30 and 0 degrees of flexion. **F**, Varus manual test, palpating for lateral joint opening, at 30 and 0 degrees of flexion. **G** to **I**, External rotation-internal rotation dial test. **G**, Starting position (performed at 30 and 90 degrees of flexion. **H**, Maximum at 30 degrees of flexion. **I**, Maximum at 90 degrees of flexion. **J** and **K**, Hyperextension and varus recurvatum tests supine and standing positions.

Diagnostic Clinical Tests

The clinical tests for the assessment of ligament injuries are shown in Figure 19-9. SMCL disruption is determined by manual valgus stress testing at 0 and 30 degrees of knee flexion. The surgeon estimates the amount of joint opening (in millimeters) between the initial closed contact position and open position of each tibiofemoral compartment (avoiding internal or external tibial rotation). The result is recorded according to the approximate increase in the tibiofemoral compartment of the injured knee compared with that of the opposite normal knee. This estimated increase in medial joint opening is easily confirmed at a later time by the gap test if arthroscopy is indicated, as in cases of associated ACL injury.

The integrity of the ACL is determined by Lachman and pivot shift testing. The result of the pivot shift test is recorded on a qualitative scale of 0 to III, with a grade of 0 indicating no pivot shift; grade I, a slip or glide; grade II, a jerk or clunk with the subluxation-reduction; and grade III, gross subluxation with impingement of the posterior aspect of the lateral side of the tibial plateau against the femoral condyle. A KT-2000 (MEDmetric) arthrometer test may be done at 20 degrees of flexion (134-N force) to quantify total anteroposterior (AP) displacement. The medial posterior tibiofemoral step-off on the posterior drawer test is done at 90 degrees of flexion.

The tibiofemoral rotation dial test is done at 30 and 90 degrees of knee flexion with the patient in the supine position to determine whether increases in external tibial rotation occur with anterior subluxation of the medial tibial plateau (and not posterior subluxation of the lateral tibial plateau, indicating a posterolateral ligament injury).[54] An increase in internal rotation may occur with MCL/POL disruptions (maximum 15 to 45 degrees of flexion). Associated lateral and posterolateral disruptions are determined by varus stress testing at 0 and 30 degrees of knee flexion.

A careful observation of the patient's standing alignment and gait is performed to determine whether there is a lower limb valgus alignment and valgus thrust during ambulation.

Radiographs and Imaging Studies

Radiographs taken during the initial examination include standard AP, lateral at 30 degrees of flexion, weight-bearing posteroanterior (PA) at 45 degrees of flexion, and patellofemoral axial views. Medial stress

radiographs may be required of both knees (20 degrees of flexion, neutral tibial rotation, 67-N valgus force). The difference in millimeters of medial tibiofemoral compartment opening between knees is documented. Stress views are usually too painful in acute knee injuries and are obtained more frequently in knees with chronic injuries.

Posterior stress radiographs are obtained in patients with PCL ruptures, especially those in whom the distinction of a partial versus complete PCL tear is difficult to determine on clinical examination (see Chapter 16).[25] Lateral stress radiographs may be required in knees with lateral ligament injury (see Chapter 17). Full standing radiographs of both lower extremities, from the femoral heads to the ankle joints, are done in knees with varus or valgus lower extremity malalignment (see Chapter 26). The mechanical axis and weight-bearing line are measured.[12] Of concern is to exclude a knee with lower extremity valgus alignment and increased medial soft tissue tensile forces with a valgus thrust, indicating the need for a corrective osteotomy in chronic medial injuries.

MRI is required to reveal the location of ligament anatomic disruptions, bone contusions, other ligament ruptures, and meniscus tears (Fig. 19-10). A high rate of concurrent lateral meniscus tears has been reported with MCL ruptures, making MRI an important adjunct for an accurate diagnosis.[52,65] Ligament avulsion or osteochondral injuries requiring treatment within the initial 7- to 10-day period after injury may exist.

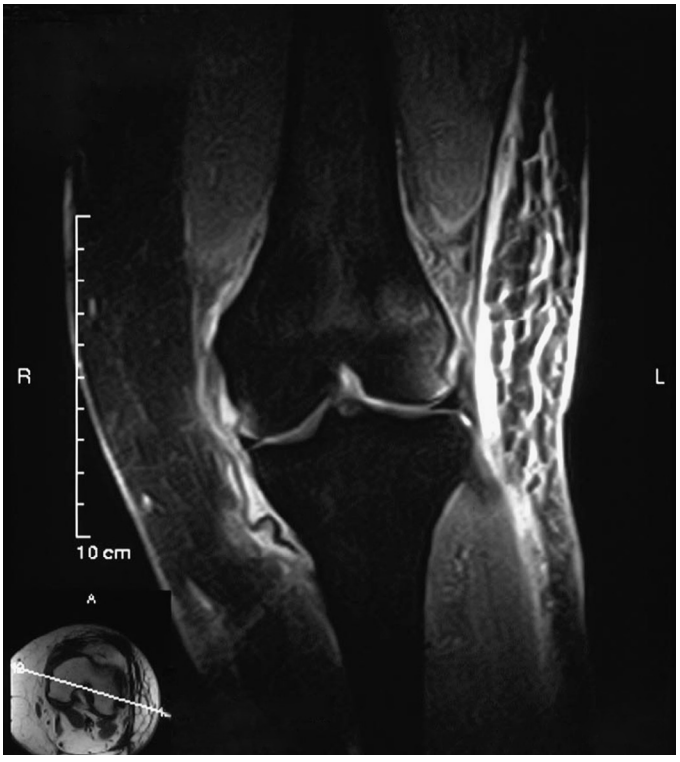

FIG 19-10 Magnetic resonance imaging (MRI) demonstrates extensive damage to the medial ligamentous structures. The superficial medial collateral ligament (SMCL) is disrupted from its proximal attachment and there is disruption of meniscus attachments and the posterior oblique ligament (POL). MRI provides important information on the injury severity. The finding of a coiled lax SMCL, particularly close to an attachment site, is a relative indication for surgery because immobilization would not be expected to allow for approximation of the SMCL/POL injury. An open operative repair was performed in this athlete, along with an anterior cruciate ligament reconstruction.

CONSERVATIVE VERSUS OPERATIVE TREATMENT: RULES AND PLANNING

Acute Medial and Posteromedial Ligament Ruptures

The treatment rationale for patients with acute medial ligament ruptures is shown in Figure 19-4. The algorithm is divided into three major sections based on the extent of injury to the SMCL and PMC/POL. The first- and second-degree injuries are treated initially with a functional brace, weight bearing as tolerated, and rehabilitation as detailed in Chapter 20. Some second-degree injuries may have considerable medial pain and swelling; in these cases, an extension brace is used for the initial 1 to 2 weeks after the injury.

The rule for conservative treatment of all third-degree medial ligament injuries involves the necessity for short-term immobilization to allow the medial ligament structures to heal with the least elongation or laxity by limiting medial joint opening and external tibial rotation. In addition, meniscotibial attachment tears requiring protection for healing may exist. The lower limb is placed in a cylinder cast to allow *stick-down* of the disrupted medial soft tissues. Fiberglass immobilization is required because a soft hinged or functional brace, even if maintained at 0 degrees of extension, does not provide sufficient protection to maintain medial joint line closure to allow close approximation of the disrupted medial ligament and meniscus attachment soft tissues. Patients are allowed toe-touch weight bearing and perform quadriceps isometrics every hour, palpating the muscle tension and increase in thigh volume with their hand. Electrical muscle stimulation is also used. These modalities are important because thigh atrophy can occur even with short-term immobilization.

At 7 to 10 days, the cylinder cast is split into an anterior and posterior shell (Fig. 19-11) and the therapist assists the patient with ROM from 0 to 90 degrees in a figure-four position (Fig. 19-12) with the hip joint externally rotated to protect the healing medial tissues, described in detail in Chapter 38. This protected ROM program is taught to the patient and performed three to four times a day. The split-cylinder cast protection in extension is maintained for three to four weeks, followed by a soft hinged brace. The rehabilitation and crutch-weaning program is detailed in Chapter 20. It must be stressed that the senior author (F.R.N.) has commonly encountered knees referred for treatment in which a complete SMCL injury (and partial-to-complete POL injury) was treated with a soft functional brace where the golden period of the first few weeks after the injury was lost. A residual symptomatic increased medial joint opening and

FIG 19-11 A cylinder cast split into an anterior and posterior shell to allow the patient to perform range of motion exercises.

FIG 19-12 Flexion overpressure exercise in a figure-four position.

external tibial rotation required a chronic medial and posteromedial reconstruction.

It is possible to treat almost all medial ligament injuries (with or without concomitant ACL ruptures) using this conservative stick-down program. Operative treatment is recommended for select cases, as discussed next. A displaced meniscus tear on MRI would indicate the necessity to perform a meniscus repair. When there is an associated ACL tear, the stick-down protocol is followed to treat the medial injury. Then an ACL reconstruction may be performed at an elective time. In high-performance athletes with gross disruption of the SMCL and POL (with or without ACL tear), the senior author prefers to perform an anatomic repair to restore anatomic continuity and function. In addition, in these gross medial disruptions, the repair of the medial meniscus attachments is always required. In select knees with acute SMCL, POL, and ACL injuries, the medial meniscus may be partially dislodged from the joint, and the distal SMCL so extensively displaced or coiled with a reduced chance of protected immobilization, would result in functional medial ligament structures (see Fig. 19-10). An example is the illustrative case described later in this chapter. In our experience, these knees do better with operative repair. For ACL reconstruction, a four-strand semitendinosus-gracilis (STG) autograft may be selected if there is an indication to decrease the morbidity of a bone-patellar tendon-bone (B-PT-B) autograft. We prefer an autograft over allografts for reasons discussed in detail in Chapter 7.

In select acute PCL tears with gross disruption of the SMCL and POL that do not have excessive soft tissue swelling and edema, the senior author prefers an all-inside arthroscopic PCL reconstruction and open medial repair. These knees have a gross amount of medial joint opening and posterior subluxation and surgical stabilization is preferred in younger active patients. Sedentary patients are treated with the stick-down cast program, with a posterior calf pad added to prevent posterior subluxation (confirmed with a lateral radiograph). An SMCL femoral or tibial avulsion may exist in which operative reattachment is indicated through a limited medial approach.

In knees considered for operative intervention, the knee is rehabilitated for 7 days, motion to 90 degrees is obtained, and early quadriceps muscle function is restored. The joint and extremity soft tissue swelling must not be excessive. A routine venous ultrasound is conducted before surgery. In acute medial injuries, it is usually not necessary to perform an augmentation of the repair (described later for chronic reconstructions), because the suture fixation methods restoring ligament continuity and healing after surgery is prompt. However, in select knees, this augmentation option may be required. All knees are treated with an immediate ROM figure-four program as detailed in Chapter 20. Proximal medial ligament disruptions with extensive edema and soft tissue swelling are at risk for ectopic calcification and limitation of joint motion in the first 2 to 3 weeks after surgery. Indomethacin (Indocin) treatment is not routinely administered; however, observation is warranted because indomethacin is effective only if given within the early postoperative course.

Acute Medial Ligament Ruptures With Knee Dislocation

A traumatic knee dislocation with involvement of the medial ligament structures along with the ACL and PCL represents a difficult treatment entity. Too often, these knees have a high incidence of arthrofibrosis after surgery.[71] In our opinion, it is prudent to treat these knees with the stick-down conservative program and manage the associated ACL or PCL injuries at a later time. A posterior calf pad is added to the cylinder cast to maintain a gentle posterior loading and prevent posterior tibial subluxation. Again, a lateral radiograph is obtained to verify tibiofemoral reduction. It is possible for the physical therapist to begin a careful ROM program with the bivalved cylinder cast at the second week as detailed in Chapter 38. In select athletes, under ideal circumstances, operative intervention may be considered; these knee injuries are evaluated and treated on a case-by-case basis. Issues related to evaluation of the vascular system are discussed in Chapter 22. The surgery is delayed for 7 days and the initial rehabilitation program begun, as previously discussed. Consultation is always obtained with exclusion of a vascular injury by repeated evaluation and appropriate diagnostic tests including ankle-brachial indices. A venous ultrasound is obtained. At surgery, the foot and ankle are positioned to allow vascular checks including Doppler, and tourniquet use is avoided or limited to only the initial open exploration to define the injury pattern and is then deflated for the repair procedure.

Chronic Medial and Posteromedial Ruptures

Patients with chronic knee injuries who present with severe muscle atrophy require preoperative rehabilitation and patient education before consideration of surgical reconstruction. Frequently, patients who undergo MCL reconstruction (Fig. 19-13) require a concomitant ACL or PCL reconstruction. The appropriate grafts for the cruciate procedures should be determined, as detailed in separate chapters, and autogenous tissues are preferred. However, the surgeon should ensure that B-PT-B and Achilles tendon-bone allografts are available in multiligament reconstructions if needed and advise the patient of this possible choice.

INTRAOPERATIVE EVALUATION

All knee ligament subluxation tests are performed after the induction of anesthesia in both the injured and contralateral limbs. The amount of increased anterior tibial translation, posterior tibial translation, lateral joint opening, medial joint opening, and external-internal tibial rotation is documented. With ACL and/or SMCL/POL disruptions, the lower portion of the bed is flexed (retroflexion to flex the hip joint and eliminate femoral nerve tension) and flexion of the knee portion is performed as required for the arthroscopic and open approaches (Fig. 19-14, *A*). A leg holder is used for the initial arthroscopic and meniscus procedures and is then removed. An alternative approach used in multiligament and PCL disruptions is to position the lower extremity with the foot in an Alvarado holder or thigh post and foot rest to allow the desired amount of knee flexion during surgery (Fig. 19-14, *B*). The arthroscopic pressure is maintained at a low setting with adequate outflow at all times to prevent fluid extravasation and popliteal and calf swelling, which is documented throughout the case. A thorough

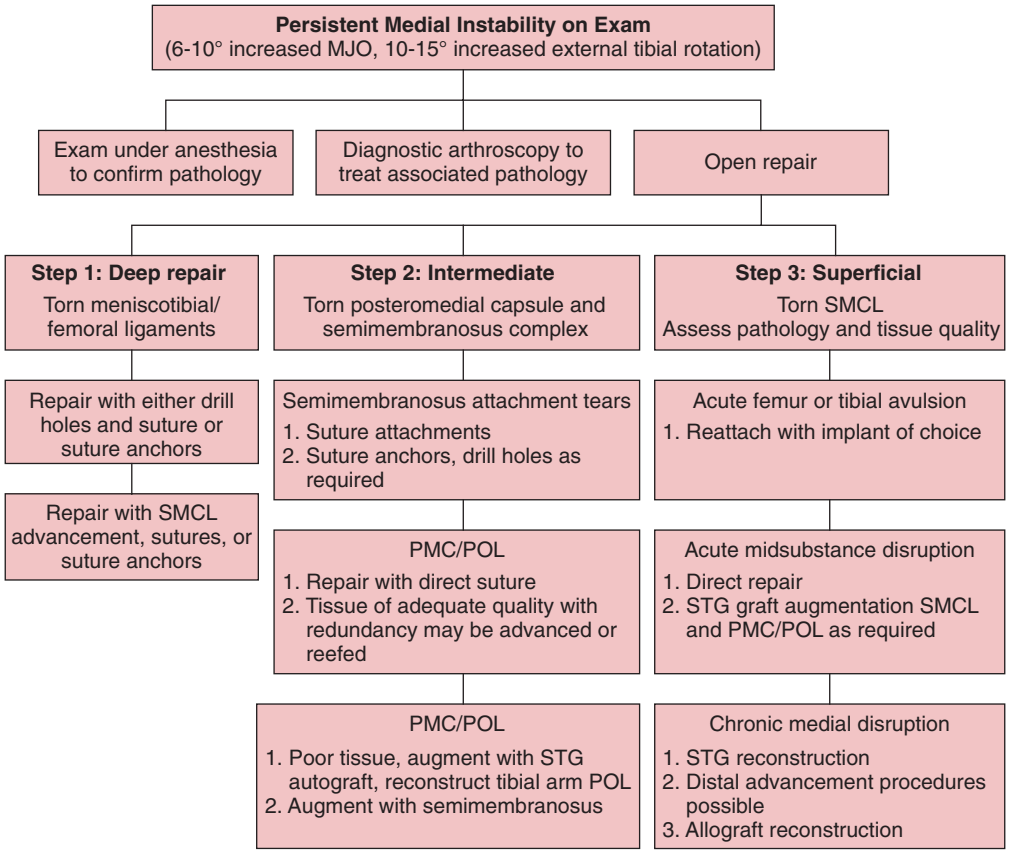

FIG 19-13 Surgical algorithm. *PMC*, Posteromedial capsule; *POL*, posterior oblique ligament; *SMCL*, superficial medial collateral ligament; *STG*, semitendinosus-gracilis.

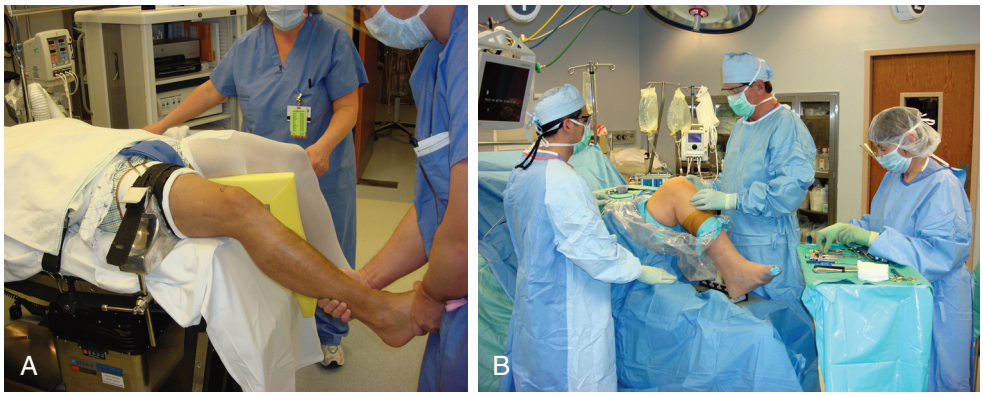

FIG 19-14 **A,** Initial operating room setup and patient positioning. Use of thigh holder to achieve tibiofemoral joint opening, particularly for meniscus repairs. The thigh holder is removed after the arthroscopic procedure. The foot of the bed is placed at 90 degrees of flexion, the bed is placed at 15 degrees for hip flexion, and a soft support is placed under the proximal thigh for the operative approach. **B,** In multiligament injuries with gross instability, a lower extremity leg holder may be used if required to control knee position during the arthroscopic anterior/posterior cruciate ligament reconstruction and associated medial dissection. The medial ligament repair/reconstruction is performed with the knee at 15 to 30 degrees of flexion and a soft tissue pad beneath the thigh.

arthroscopic examination is conducted, documenting articular cartilage surface abnormalities and the condition of the menisci. It is rare to have the complication of fluid extravasation if these precautions are taken; however, if extravasation occurs, an open approach is used throughout the remainder of the procedure.

Medial and lateral tibiofemoral gap tests are done during the arthroscopic examination. The knee is flexed to 30 degrees and a varus and valgus load of approximately 89 N applied. A calibrated nerve hook is used to measure the amount of lateral and medial tibiofemoral compartment opening. Knees with 12 mm or more of absolute joint opening at the periphery of the medial or lateral tibiofemoral compartment indicate gross disruption of all the ligament structures. An absolute opening of 10 mm (~7 mm increase over the contralateral limb) also indicates significant injury to the SMCL and PMC and, along with

increased external tibial rotation, usually represents a problem for athletic patients in twisting and cutting activities.

Appropriate arthroscopic procedures are performed as indicated, including meniscus repairs or partial excision, debridement, and articular cartilage procedures.

SELECTION OF GRAFTS FOR MEDIAL LIGAMENT RECONSTRUCTION

Robinson and associates[62] conducted a cadaveric study in eight unpaired knees (mean age, 77 years; range, 72 to 89 years). The ultimate failure loads of the medial structures were 534 N for the SMCL, 194 N for the DMCL, and 425 N for the PMC (including the central POL arm). Wijdicks and colleagues[72] reported on the failure properties of the medial ligament structures in 20 unpaired cadaveric knees (mean age, 54 years; range, 27 to 68 years). The mean failure loads were 557 N for the SMCL, 88 N for the femoral-to-proximal tibial portion of the MCL, 101 N for the DMCL, and 256 N for the POL. These data provide approximate failure load conditions that are useful for graft substitute decisions.

Noyes and colleagues[53] reported the first biomechanic study of properties of tendons and fascia lata used as ligaments grafts in 18 unpaired knees in younger donors (mean age, 26 ± 6 years) under high strain rate conditions. The mean failure loads of the semitendinosus tendon and the gracilis tendon were 1216 ± 50 N and 838 ± 30 N, respectively. These data imply that a semitendinosus tendon graft would have more than adequate load properties at time zero compared with the patient's native SMCL. It is possible that all of these studies may underestimate the ultimate failure load of the native SMCL because of asymmetric laboratory loading conditions in uniaxial tendons that do not simulate in vivo loading conditions. From a practical standpoint, we use a STG autograft, to be described.

In regard to graft fixation strength for SMCL and POL reconstructions, many different methods have been described.[2,43,69,76] There is a concern for the adequacy of tunnel fixation of a soft tissue graft at the distal SMCL attachment owing to the lack of cancellous tissue. A tibial tunnel Endo Button technique may be selected. Another option keeps the distal STG insertion intact by placing sutures to locate the tendons within the center portion of the distal SMCL fibers. This avoids a nonisometric anterior graft placement and is the senior author's preferred technique. The estimated fixation strength of soft tissue interference screws in the distal tibial SMCL in humans is unknown. In a porcine model, Wijdicks and associates[72] estimated the fixation strength of interference screws in the distal tibial SMCL to be 445 ± 72 N.

There is a lack of consensus in the published literature regarding the selection of grafts to reconstruct the SMCL and POL. Some investigators reconstruct the SMCL alone. The senior author advocates that POL function must always be restored either by plication using the vest-over-pants technique described by Hughston and Eilers[28] or with a graft reconstruction when POL tissues are deficient. Studies that reconstructed only the SMCL have reported acceptable results, to be described later (see Results From Other Clinical Studies). Even so, at surgery, the opportunity exists to repair or reconstruct all of the medial ligament structures and not take the chance that insufficient, unrestored POL function could compromise the overall result. It is relatively straightforward to restore POL function either by plication (in mild to moderate injuries) or graft substitution in cases of gross medial instability. What remains controversial is whether a separate femoral graft tunnel is required for POL reconstruction,[9] or if the femoral graft used for the SMCL can be fixated at a single femoral SMCL attachment and then directed to the POL tibial attachment where it is fixated with either suture, a tunnel and interference screw, or a screw and spiked washer. In multiligamentous reconstructions where operative time needs to be carefully monitored, a single femoral fixation of an STG graft by screw and spiked washer and fixation of the remaining STG graft at the POL tibial attachment site by screw and spiked washer (adjacent to the anterior medial arm of the ST tendon) avoids the complexity of two femoral and tibial tunnels.[41]

OPERATIVE TREATMENT

Acute Medial and Posteromedial Ligament Repairs

The key to the operative procedure is a thorough understanding of the medial anatomy (see Figs. 19-1 to 19-3), because the integrity and injury to the SMCL, POL, semimembranosus attachments, and meniscus attachments (DMCL) need to be identified. The goal is to restore normal anatomy and function of all of these structures. The surgical dissection uses a layered approach[70] following the description provided in Chapter 1 (Fig. 19-15).

Before surgery, the operative extremity is signed by the patient and surgeon with nursing personnel present. A time-out is performed with

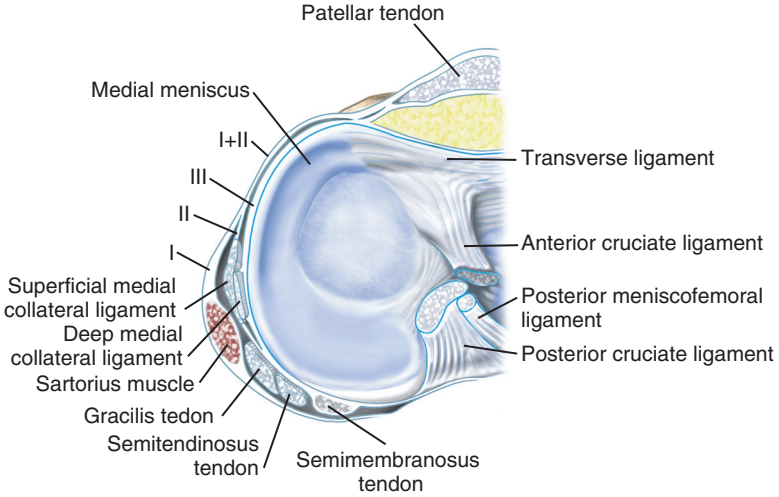

FIG 19-15 Medial layers of the knee. The gracilis and semitendinosus lie between layers I and II.

TABLE 19-3 Operative Steps for Acute Medial Ligamentous Ruptures

1. Use a limited medial approach, dissection of skin flaps beneath fascia and not in subcutaneous tissue to preserve blood supply to overlying skin.
2. Approach carefully avoids superficial nerve structures, protects infrapatellar nerve branches to limit a postoperative neuroma or loss of cutaneous sensation.
3. Incision anterior sartorial fascia extending to anterior border of SMCL, identify pes bursae, posterior retraction of pes tendons, proceed proximal to VMO.
4. Limited medial dissection at the site of injury, but not beyond, with preservation of vascular and nerve supply.
5. Identification of SMCL tear site preoperatively on MRI and confirmation at surgery including medial patellofemoral ligament, which may require repair.
6. Identification of PMC tear site on MRI and operatively at anatomic attachments. There may be an interstitial tear or disruption at femoral or tibial attachments.
7. Identification of semimembranosus attachments and tears at POL and meniscus attachments.
8. Identification of deep MCL and meniscal attachments requiring repair.
9. Appropriate repair of all disrupted structures using nonabsorbable and absorbable sutures to decrease overall suture load. Initial repair proceeds deep to superficial with meniscus attachments meticulously first repaired, usually by sutures or suture anchors.
10. SMCL repairs performed next to provide stable medial column. Repair frequently requires baseball-type sutures fixed to a suture post at attachment site, which provides high-tensile strength for immediate postoperative motion. Avulsion at femur or tibia fixed by screw and soft tissue washer. Suture anchors may be used to supplement repair.
11. Assess need for STG reconstruction of SMCL and POL when extensive medial disruption exists with poor tissue quality for primary repair; will allow increased tissue strength and immediate range of knee motion.
12. Avoid shortening SMCL at the tibial attachment site by fixation too proximal, goal is to restore normal anatomic attachment locations.
13. Avoid placement of tibial staples or other large metallic fixation devices, which frequently are painful and require subsequent repeat surgery.
14. POL repair performed next, frequently requires suture anchor fixation at respective tear site. Anterior portion of POL sutured to posterior SMCL after femoral or tibial attachment repaired. Avoid constraint to full knee extension, which is tested after POL repair.
15. Perform final full knee extension and flexion at operative table to make sure that suture fixation of all soft tissue structures has not constrained normal joint motion.
16. Medial patellofemoral ligament and retinaculum closed with knee at 20 degrees, avoiding overtensioning with a normal lateral patellar glide of approximately one quadrant (25% patellar width) to avoid "capture" of the patellofemoral joint and limited knee flexion.
17. Close sartorial fascia over SMCL, medial repair.
18. Meticulous hemostasis and closure of dead spaces beneath skin flaps to avoid hematoma.
19. Routine closure, double compression bandage with cotton, ice bladder, and soft hinged postoperative brace.

MCL, Medial collateral ligament; *MRI*, magnetic resonance imaging; *PMC*, posteromedial capsule; *POL*, posterior oblique ligament; *SMCL*, superficial medial collateral ligament; *STG*, semitendinosus-gracilis; *VMO*, vastus medialis obliquus.

the patient's name, procedure, allergies, and preoperative antibiotics, special precautions given and agreed upon by the surgeon, anesthetist, and nursing personnel.

The operative steps are outlined in Table 19-3 and Figure 19-13. It is important to perform a careful limited dissection to avoid further disruption of the neurovascular supply of tissues (Fig. 19-16). Based on preoperative MRI and limited medial dissection, it is possible to identify the tear site of the soft tissue structures for the operative repair. A tourniquet is used for the initial exploration and then deflated during the repair portion of the procedure. A limited cosmetic incision along the anteromedial aspect of the tibia provides good exposure for both ACL and medial repairs and is favored over a two-incision approach (Fig. 19-17).

During the initial dissection, an incision is made into the sartorius fascia just anterior to the SMCL and the fascia and pes tendons are reflected posteriorly to allow identification of the medial structures. The tear site of the SMCL is usually easily identified. However, it may be more difficult to recognize the tear site for the PMC capsular arms referred to as the POL divisions (see Fig. 19-2). There may be interstitial tearing of capsular tissues without a definite tear, or the POL may be torn off its femoral or tibial attachment, requiring reattachment. The first goal is to restore normal anatomy. The SMCL, POL, and meniscus sutures are placed to restore anatomic attachment sites (see Table 19-3). After the DMCL and SMCL are repaired, the POL is repaired at 10 to 15 degrees of flexion and the knee is taken to full extension to ensure the sutures are not overtensioned to constrain knee extension and produce a flexion contracture.

The second goal is to perform a meticulous anatomic repair of sufficient strength to allow immediate knee motion following the protocol provided in Chapter 20. Numerous ligament fixation devices are available, and a low-profile screw and soft tissue washer or four-prong staple and screw are favored, along with suture anchors. Standard baseball locking sutures of two to three throws are sufficient to tension soft tissues using a combination of nonabsorbable and absorbable sutures. When the medial ligament disruption is extensive, it is necessary to perform an augmentation graft for the SMCL and PMC (POL division B; see Fig. 19-2) following the techniques outlined in a chronic medial reconstruction with either an STG autograft or allograft approach, as discussed next.

Chronic Medial and Posteromedial Ligament Repairs

The operative steps are the same as outlined for acute medial repairs in terms of the initial surgical approach and dissection. The specific additional steps that apply are provided in Table 19-4.

Based on the extent of injury and integrity of the medial ligament structures, the surgeon has three options that require judgment at surgery. These are (1) advancement of the SMCL and plication of the POL using existing tissues, (2) advancement and plication of existing tissues and graft reconstruction of the SMCL and POL, and (3) onlay SMCL/POL graft reconstruction without use of existing tissues for severe cases of medial ligament disruption.

In Figure 19-17, the cosmetic medial skin incision is shown for a patient who had a combined ACL and MCL reconstruction. The standard ACL skin incision is extended proximally to provide adequate exposure for the medial ligament procedure. Advancement procedures are used only when there has been a robust healing response in the medial ligament structures, with good integrity noted of these tissues that are moderately lax, but otherwise intact. The meniscus

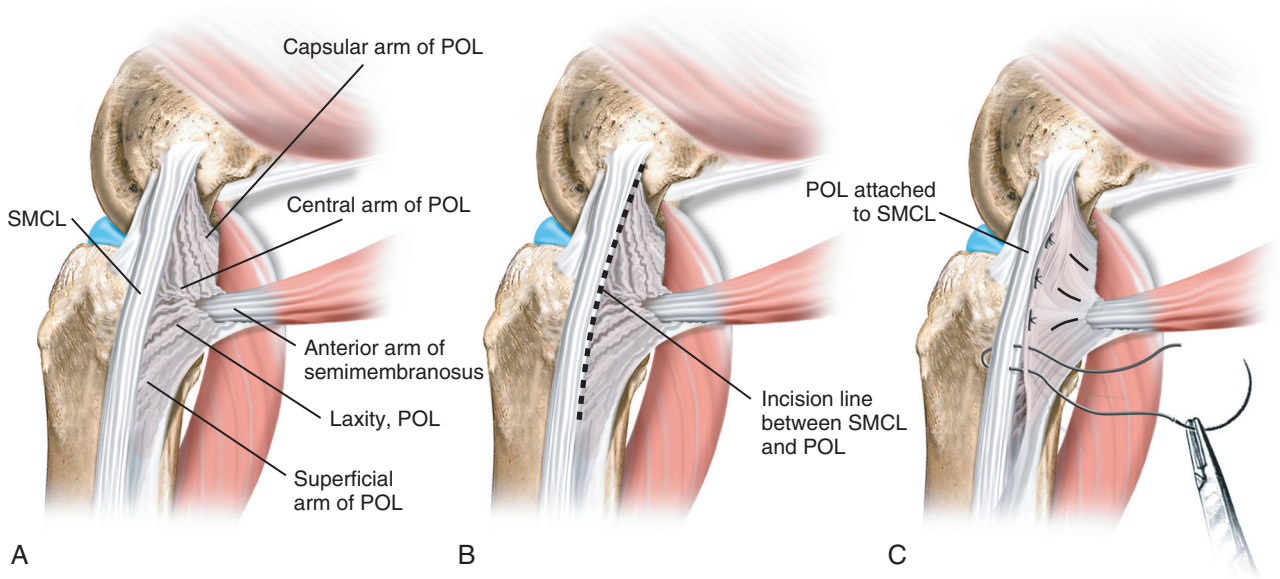

FIG 19-16 Surgical plication procedure for the posterior oblique ligament (POL). **A,** Identification of laxity and redundant POL that involves all three components. In the majority of knees, there will exist concurrent laxity of the superficial medial collateral ligament (SMCL), which also requires surgical reconstruction as described (not shown). **B,** Incision into POL just behind the SMCL, avoiding medial meniscus tibial attachments. Confirm the POL is not avulsed from femoral or tibial attachments because reattachment may be required. **C,** Suture plication vest-over-pants technique to restore tension in the POL, performed at 20 degrees of flexion to avoid overtensioning that would limit full knee extension.

FIG 19-17 **A** and **B,** Cosmetic skin incision of the knee joint in an expert skier, 6 months after bone-patellar tendon-bone anterior cruciate ligament (ACL) autograft and superficial medial collateral ligament, posterior oblique ligament, and displaced medial meniscus repair followed by an immediate motion program. In this knee with a gross medial disruption and a medial meniscus that was displaced into the joint, the decision was made to proceed with a combined arthroscopic and open repair of all structures. An ACL autograft (semitendinosus-gracilis) reconstruction is preferred over an allograft.

TABLE 19-4 Operative Steps for Chronic Medial Ligamentous Ruptures

1. Follow initial exposure steps provided in Table 19-3.
2. Identify integrity and healing of remaining SMCL and POL to select knees in which these structures may be incorporated into reconstruction or in which complete graft replacement of the SMCL and POL is indicated.
3. Place incision along anterior POL border, just posterior to SMCL fibers. Confirm femoral, tibial attachments intact or require reattachment.
4. Identify semimembranosus, attachments, need for reattachment or repair.
5. Place incision along anterior border of SMCL, identify meniscus tibial and femoral attachments that require repair.
6. In some knees when distal SMCL advancement is possible, place fixation at distal attachment site not to shorten SMCL length. It will be first necessary to reattach meniscotibial attachments with suture anchors. Arthroscopy before procedure indicates need for meniscus peripheral repair based on proximal-distal meniscus displacement.
7. PMC plication procedures performed when capsular attachments to femur and tibia are intact and goal is to remove redundancy. Plication to posterior portion of SMCL accomplishes goal of restoring normal PMC tension as knee approaches extension.
8. STG autograft reconstruction of the SMCL and POL is the senior author's preferred choice in chronic cases with poor medial ligament structures that have undergone injury and scar replacement. Harvest STG with closed-end tendon stripper leaving tibial attachments intact. Relocate distal STG to middle of SMCL. Locate isometric point at femur with guide pin and suture, followed by screw and spiked washer fixation. Proceed with remaining STG for POL reconstruction. Suture STG graft to remaining SMCL and POL tissues.
9. Severe loss of all medial tissues requiring complete SMCL replacement treated with long B-PT-B allograft for secure bone fixation at tibial and femoral attachments. Alternative option is Achilles tendon-bone allograft reconstruction with bone placed at femoral attachment and collagenous portion of graft at tibial attachment. Another option is anatomic double-graft SMCL and POL reconstruction.
10. Careful adjustment of medial patellofemoral ligament and medial retinaculum at 30 degrees of knee flexion to restore normal tension and allow normal lateral patellar glide.
11. Closure as detailed in Table 19-3.

B-PT-B, Bone-patellar tendon-bone; *PMC*, Posteromedial capsule; *POL*, posterior oblique ligament; *SMCL*, superficial medial collateral ligament; *STG*, semitendinosus-gracilis.

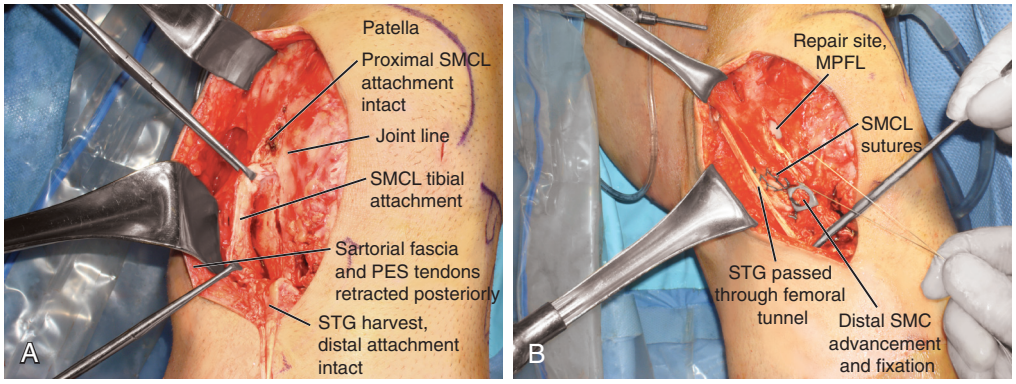

FIG 19-18 Demonstration of distal advancement of the superficial medial collateral ligament (SMCL) with semitendinosus-gracilis (STG) reconstruction for chronic MCL insufficiency. **A,** The SMCL is dissected at its distal attachment and proximally to the joint. Arthroscopic examination showed the medial meniscus attachments would be restored by reattachment of the meniscus tibial attachments, which was performed (not shown). **B,** Distal SMCL advancement supplemented with nonabsorbable baseball sutures through distal SMCL to provide secure fixation. A plication of the posteromedial corner (PMC) to the posterior edge of the SMCL has been performed. The STG tendons are passed through a small-diameter tunnel just anterior to the SMCL attachment and brought out posterior to the attachment and in line with the posterior oblique ligament (POL). The STG tendons are sutured anteriorly to the SMCL and posteriorly to the POL. In some cases, a screw and washer are used for added fixation at the tibial POL attachment (see Illustrative Case). The use of the remaining SMCL provides for additional joint stabilization and the STG reconstruction allows for immediate protected knee motion. *MPFL*, Medial patellofemoral ligament.

attachments medially require appropriate suture fixation to restore the meniscotibial attachment, with distal SMCL advancement. In chronic medial injuries that are extensive, a SMCL reconstruction with STG tendons is required. The STG tendons are tensioned based on isometric length-tension behavior with knee flexion-extension at surgery. In addition, after femoral fixation, the distal portion of the STG graft is used for POL reconstruction.

Following the operative principles outlined in Table 19-4, an example of a distal SMCL advancement supplemented with an STG reconstruction for chronic MCL deficiency is shown in Figure 19-18. In Figure 19-19, a more complex medial reconstructive procedure is shown that involved extensive repair of the meniscus attachments and STG tendon reconstruction of both the SMCL and PMC (POL, see Illustrative Case). The operative procedure provides sufficient strength to allow immediate knee motion postoperatively to lessen the risk of a joint contracture.

The correct attachment points for the STG SMCL graft are at the native femoral and tibial attachments (Figure 19-20). The SMCL

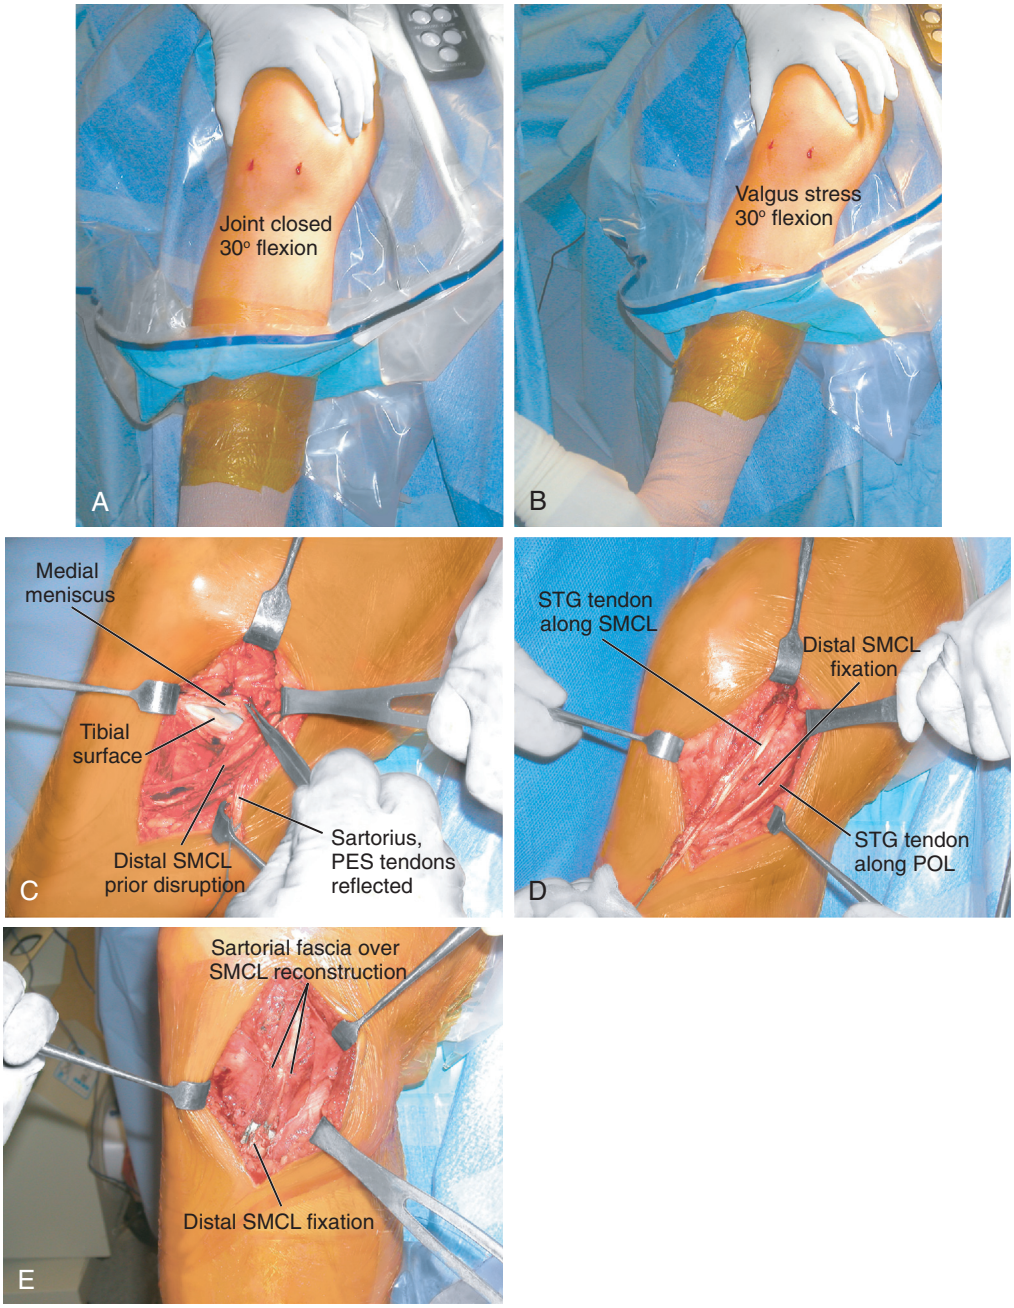

FIG 19-19 A 22-year-old female elite soccer planer referred for treatment for giving-way episodes on cutting movements after a prior partial anterior cruciate ligament and complete disruption of the superficial medial collateral ligament (SMCL) treated conservatively. There was a negative pivot shift and Lachman test; however, there were 12 mm of medial joint opening at 30 degrees, 5 mm of medial joint opening at 0 degrees, and 10 degrees of increased external tibial rotation on the dial test. **A** and **B,** Demonstration of the valgus test at surgery with medial joint opening confirmed on arthroscopic examination. **C,** On surgical exploration, the medial meniscus attachment to the tibia required repair. The proximal SMCL was intact; however, the distal SMCL attachment was the site of the prior disruption. **D,** Semitendinosus-gracilis (STG) tendons left attached distally and advanced to reconstruct the posterior portion of the posterior oblique ligament (POL) were placed through a femoral tunnel from posterior to anterior and brought along the anatomic course of the SMCL. **E,** Final closure; sartorius attachments closed over SMCL that had been advanced distally with STG tendon reconstruction.

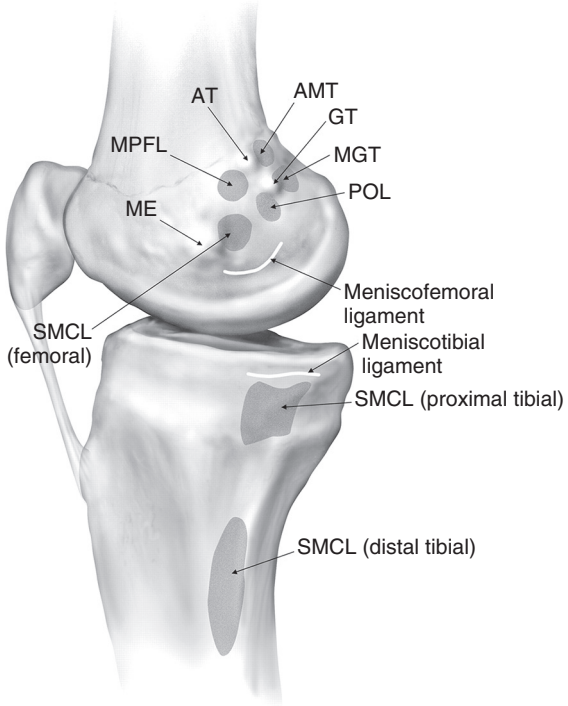

FIG 19-20 The femoral osseous landmarks and attachment sites of the main medial knee structures. *AMT*, Adductor magnus tendon; *AT*, Adductor tubercle; *GT*, gastrocnemius tubercle; *ME*, medial epicondyle; *MGT*, medial gastrocnemius tendon; *MPFL*, medial patellofemoral ligament; *POL*, posterior oblique ligament; *SMCL*, superficial medial collateral ligament. (From LaPrade RF, Engebretsen AH, Ly TV, et al. The anatomy of the medial part of the knee. *J Bone Joint Surg Am.* 2007;89:2000-2010.)

femoral attachment is, on average, 3.2 mm proximal and 4.8 mm posterior to the medial epicondyle. The SMCL has two tibial attachment sites (see Fig. 19-20). Care is taken not to allow the STG graft to be anterior at the SMCL tibial attachment because this portion of the graft is under increased tension with knee flexion. The STG graft is sutured to the middle portion of the SMCL. In some knees, additional screw/washer STG fixation at the distal SMCL attachment may be required. The SMCL femoral graft attachment site is verified by placing a K-wire at the femoral site, attaching suture to the distal tibial site, and taking the knee through a full ROM. A change of 2 to 3 mm in length is acceptable. The POL is reattached to its native femoral or tibial site when proximal or distal disruption has occurred. For capsular redundancy, a plication procedure is performed to the posterior edge of the SMCL graft, which provides the stable medial column for the capsular reconstruction.

In Figure 19-21, the use of a B-PT-B allograft is shown for severe cases of chronic medial ligament disruption. The Achilles tendon is an alternative allograft, with the bone portion placed at the native SMCL femoral attachment and the full-thickness tendon fixed by a screw and soft tissue washer with additional baseball sutures at the native tibial attachment. All of these procedures involve extensive postoperative rehabilitation, which is described in Chapter 20.

COMPLICATIONS

The most frequent complication of medial and posteromedial ligament surgery relates to the approximately 10% of operated knees that will have initial limitations in regaining normal flexion and extension.

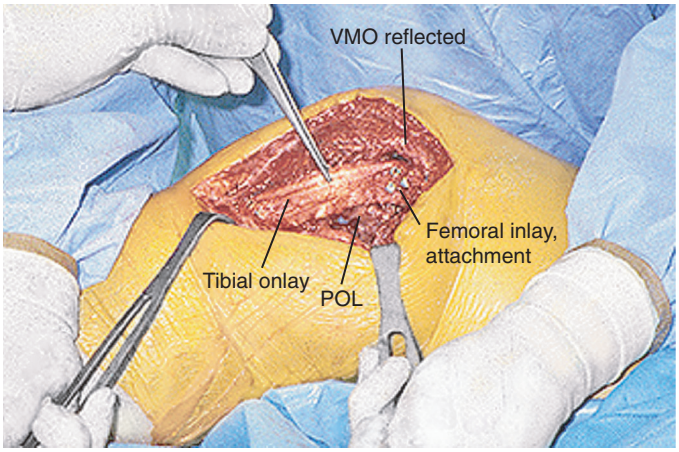

FIG 19-21 Demonstration of the use of a long 25-mm wide bone-patellar tendon-bone (B-PT-B) allograft for a severe medial ligament disruption in which no remaining superficial medial collateral ligament (SMCL) was present. This patient had a prior total knee replacement and presented with complete loss of the SMCL. The bone portions of the graft are placed as an inlay on the femur and as an onlay on the tibia and fixated with cancellous and small fragment screws, respectively. A posterior oblique ligament (POL) plication was performed (see Table 19-4 for operative steps). The procedure was successful and prevented a revision total knee arthroplasty. Because of the large limb and body size, the B-PT-B graft was chosen to provide more secure fixation compared with a semitendinosus-gracilis graft. *VMO*, Vastus medialis oblique.

It is necessary at surgery not to overtighten the POL plication or repair. The repair is performed at 10 to 15 degrees of flexion, and the knee is taken to full extension at the end of the procedure. The SMCL augmentation or replacement is fixated at native femoral and tibial attachments and not overtensioned so as not to constrain the knee joint. The treatment of knee motion limitations, principles of patellofemoral mobilization, and muscle rehabilitation exercises are covered in detail in Chapter 20.

We use a 5-day course of maximum-dose nonsteroidal antiinflammatory medication, which begins the night before surgery. A firm double compression wrap and cotton dressing, ice delivery system, and elevation are used for the first week after surgery. Patients are carefully examined preoperatively and postoperatively for deep venous thrombosis, with ultrasound used on all acutely injured knees before surgery and postoperatively if warranted. After surgery, patients use calf compression venous return devices, and ankle pumps are performed hourly. Aspirin prophylaxis (325 mg 2 ×/day for 7 days) is prescribed. It is important to establish that there is no family history of DVT or blood clot formation, because there is a 2% to 5% incidence of inherited coagulation defects.

The complication of infection is rare with the use of preoperative intravenous antibiotics at appropriate doses, careful handling of tissues, and other precautions as detailed in Chapter 7. A femoral nerve block may be used for pain control.

OUR CLINICAL STUDY

A prospective study was conducted to determine the outcome of 46 knees with acute ACL-MCL ruptures in which all patients received an ACL reconstruction and either conservative or operative management of the medial ligament injury, based on the extent of the injury.[52] The inclusionary criteria were a complete rupture of the ACL, rupture to a

From Noyes FR. Barber-Westin SD. The treatment of acute combined ruptures of the anterior cruciate and medial ligaments of the knee. *Am J Sports Med.* 1995;23:380-391.

portion or all of the medial ligamentous structures, no rupture to the other knee ligaments, and reconstruction performed within 10 weeks of the original knee injury.

Group I consisted of 34 patients who sustained a complete rupture to the SMCL and PMC that had acute repair and ACL reconstruction. The medial meniscus was repaired in 12 knees and the lateral meniscus was repaired in seven knees. The patients were followed a mean of 5.7 years (range, 2-8.9 years) postoperatively.

Group II consisted of 12 patients who sustained a complete rupture to the SMCL/PMC who were treated without surgery for the medial ligament injury, followed by a staged ACL reconstruction. The medial meniscus was repaired in three knees and the lateral meniscus was repaired in six knees. The patients were followed a mean of 4.1 years (range, 2.2-5.6 years) postoperatively.

At follow-up, no patient had more than 2 to 3 mm of increase in medial joint opening (Table 19-5). Healing was demonstrated in both the surgically repaired complete medial ligament disruptions and in the conservatively treated knees with SMCL disruption. The ACL reconstructions were rated (based on knee arthrometer and pivot shift testing) as normal in 61% in group I and in 82% in group II; nearly normal in 21% in group I and in 18% in group II; and failed in 18% of group I.

Before the injury, all patients except one were participating in sports activities (Table 19-6). At follow-up, all except three patients in group I had returned to athletics, although over half had returned to a lower level of participation. Seven patients in group I had significant difficulty squatting or kneeling. More patients in group I had swelling and pain with sports activities than those in group II (Fig. 19-22).

The rehabilitation program and early treatment of knee motion limitations successfully restored at least 0 to 135 degrees of knee motion in 96% of the patients. The treatment program of knee motion limitations, described in Chapter 38, was instituted in 24% of the knees (26% of group I and 17% of group II). Patients with ruptures at or proximal to the medial joint line had a higher incidence of motion complications (7 of 15 patients, 47%) than those with ruptures located distal to the joint line (2 of 18 patients, 11%). Similar findings were reported by Robins and associates.[61]

The overall rating scores for group I, based on the CKRS, were excellent/good in 19 patients, fair in seven, and poor in seven. For group II, the overall ratings were excellent/good in 10 patients and fair in one. Seven of the patients with a fair or poor rating had failure of the ACL allograft reconstruction; we advocate autogenous B-PT-B grafts for this procedure. At the time of the study, we used irradiated allografts and, as discussed in Chapter 7, the irradiation process appeared to increase the rate of failure compared with other studies in which fresh-frozen allografts were selected. The results of this study and other investigations[5,48,50,57,67] promoted a worthwhile reevaluation of the recommendation for operative management of both ACL and medial ligament ruptures.

RESULTS FROM OTHER CLINICAL STUDIES

Historically, studies have presented various treatment options for MCL injuries. One problem in the analysis of the literature is that the severity of the medial ligamentous injuries varies and, in many instances, is difficult to interpret owing to the ambiguous terminology used to describe the degree or grade of the injury and the lack of data on the estimated (or measured) millimeters of medial joint opening (at both 30 degrees and 0 degrees of knee flexion) before and after treatment.

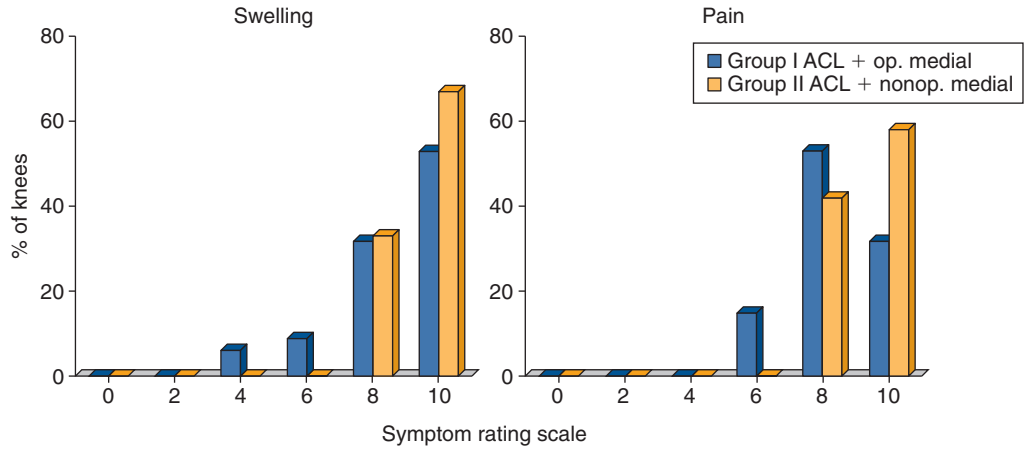

FIG 19-22 The postoperative distributions of swelling and pain scores are shown. 0, Severe symptoms with activities of daily living; 2, moderate symptoms with activities of daily living; 4, no symptoms with activities of daily living but symptoms with sports; 6, no symptoms with swimming or cycling but symptoms with other sports activities; 8, no symptoms with running, twisting, or turning, but symptoms with jumping, hard pivoting, or cutting; 10, no symptoms with jumping, hard pivoting, or cutting. *ACL*, Anterior cruciate ligament; *nonop.*, nonoperated; *op.*, operated. (From Noyes FR, Barber-Westin SD. The treatment of acute combined ruptures of the anterior cruciate and medial ligaments of the knee. *Am J Sports Med.* 1995;23:380-391.)

Therefore the exact structures that are ruptured (and those that remain intact) in many studies are unknown. In light of this issue, investigators have begun using stress radiography to measure medial joint space opening at 20 to 30 degrees of knee flexion before and after treatment, which is a reliable method to quantify medial tibiofemoral compartment opening.[11,22,38,41,44,74,75] Using valgus stress radiographs, LaPrade and associates[40] reported that a mean increase in medial joint space opening of 3.2 mm occurred at 20 degrees of flexion (10-N valgus load) in cadaver lower extremities with a simulated grade III SMCL injury (versus the intact state). Intraobserver repeatability and interobserver reproducibility intraclass correlation coefficients were 0.99 and 0.98, respectively.

Truly isolated MCL injuries are rare and the few studies published in the 1980s and 1990s showed that reasonable results could be obtained with a program of protective bracing and rehabilitation (Table 19-7).[34,35,45,56,59] During this time period, acute MCL ruptures that occurred with other knee ligament injuries (usually the ACL) were treated by some surgeons with primary suture repair.[3,4,15,26,29,61,64] Other studies reported successful nonoperative management of SMCL ruptures provided the ACL was either intact or reconstructed.[5,24,27,33,34,36,48,57,67] Halinen and coworkers[22] published to date the only study of acute grade III medial ligament ruptures (defined as >10-mm increase in medial joint opening at 25 degrees of flexion and a subtle increase at 5 degrees of flexion) that were randomized to either a primary repair or conservative management group. All 47 patients in the study also had complete ACL ruptures that were reconstructed with a B-PT-B autograft. At follow-up, a mean of 2.2 years postoperatively, stress radiographs revealed a mean increase in medial joint opening of 0.9 mm (range, −0.8 to 3.6 mm) in the SMCL-operatively treated group, and 1.7 mm (range, −0.5 to 6.4 mm) in the SMCL-conservatively treated group. The SMCL-conservatively treated group had a faster restoration of knee flexion and quadriceps muscle power.[21] Halinen and coworkers[22] concluded that SMCL ruptures do not require operative treatment.

The majority of studies published since 2004 recommend initial conservative management of nearly all acute MCL injuries owing to the self-healing capability of this ligament.[17,23,46,48,63,73] Exceptions to this strategy have been discussed in detail earlier in this chapter.

Surgery for MCL ruptures is usually reserved for failure of nonoperative treatment according to symptoms[51] and the severity of medial instability (Table 19-8). A variety of reconstructive procedures have been described for severe and symptomatic medial instability. Although the effectiveness of some operative techniques has yet to be determined clinically,[2,7,43,69] many investigations have reported satisfactory restoration of function of the MCL, with few complications (see Table 19-8).[29,55]

Achilles tendon allografts[11,41,44,47] and semitendinosus[37,38,42] or STG[74] autografts have been used to reconstruct chronic MCL insufficiency. Operative techniques either reconstruct the SMCL alone or also reconstruct or repair the POL. It appears more appropriate to refer to the anatomic structure reconstructed, rather than to reference a technique as either a single- or double-bundle procedure. The major differences among studies are the grafts used and the number of femoral graft site locations (one versus two), addressing the need for further clinical studies. Plication techniques for the POL still have a role along with a SMCL graft reconstruction, as previously discussed. All injured or deficient medial ligament structures should be restored.

Liu and associates[44] found Achilles tendon allografts effectively resolved chronic, symptomatic valgus instability in 16 patients that were followed from 2 to 5.5 years postoperatively. Stress radiographs revealed a mean of 1.1 mm (range, −1.1 to 3.2 mm) of increased medial joint opening compared with the opposite knee. Dong and coworkers[11] performed a double MCL allograft reconstruction in 56 patients, 68% of whom also had anteromedial rotatory instability. The mean amount of medial joint opening on stress radiographs was reduced from 10.1 ± 0.05 mm before surgery to 2.9 ± 1.2 mm ($P < .05$) at follow-up that ranged from 6 to 27 months. There was no difference in results between isolated MCL and combined MCL-ACL injuries. LaPrade and colleagues[41] used two allografts to replace both the SMCL and the POL in 28 patients; both grafts were placed in the anatomic attachment sites of these structures. A mean of 1.5 years postoperatively, stress radiographs showed a mean of 1.3 mm (range, −1 to 2 mm) of increased medial joint opening, which was improved from the mean of 6.2 mm (range, 3.5-14 mm) measured before surgery. We LaPrade et al[41] concluded the procedure was effective in patients with chronic, symptomatic grade III instability.

TABLE 19-7 Results of Treatment of Isolated Medial Collateral Ligament Ruptures

Study	N	Follow-up	MCL Grade, Medial Joint Opening	Treatment of MCL	Follow-up Medial Joint Opening	Follow-up Symptoms, Function, Activity Level	Reinjuries	Recommendations
Lundberg & Messner[45] (1996)	38	10 yr	Grade I: 16 Grade II: 22	Early function rehabilitation, weight bearing as soon as tolerated	No increase: 31 Grade I: 7	Slight reduction knee function and sports activity levels, unknown if knee-related.	4 MCL reinjury, 2 ACL injuries; 5 ACL injuries on other knee	Isolated partial MCL ruptures successfully managed without surgery. Unusually high incidence of subsequent ACL rupture (~20%).
Petermann[56] (1993)	102	86 followed mean 3.6 yr	30 degrees 1+ (≤5 mm): 39 2+ (6-10 mm): 41 3+ (>10 mm): 6	Cast brace 4 wk, ROM 10-90 degrees, weight bearing as tolerated, return to activity 8 weeks	No increase in all except 2 knees with 1+ instability	97% returned to previous activity level	None	Isolated MCL injuries can be successfully managed nonoperatively.
Reider[59] (1994)	36	34 completed questionnaires, 30 examined 2.5-8 yr	Grade III (tenderness over MCL, abnormally increased valgus laxity, soft endpoint in flexion)	Lateral hinged brace, weight bearing as tolerated, ROM, supervised therapy program	No increase: 8 <5 mm: 17 6-9 mm: 5	23 patients had at least 1 residual symptom. 18 patients had mild pain. 11 patients had feeling of looseness. All returned to preinjury sports, 7 at a lower level.	7 new knee injuries, 6 during football	Early functional rehabilitation isolated grade III MCL injuries effective, but residual symptoms common. Unknown correlation with reinjuries; longer follow-up required.
Indelicato et al[34] (1990)	28 football players	21 followed 18-72 mo	Grade III (>10-mm medial opening 30 degrees, soft endpoint)	Immobilized 2 wk, 4 wk brace 30-90 degrees, weight bearing as tolerated, rehabilitation	No increase: 8 1+ (<5 mm): 13	18 returned contact drills mean 9.2 weeks	None	Conservative management for grade III MCL tears is successful as long as there is no damage to ACL or menisci.
Jones[35] (1986)	22 football players	followed mean 6 mo	Grade III	Immobilized 1 wk in brace, then ROM allowed with weight bearing as tolerated, supervised rehabilitation as required	All 0-1+	All returned to football 24-38 days after injury	None; 1 ACL rupture missed at initial diagnosis	Conservative management for isolated grade III MCL injuries gives satisfactory short-term results.

Both Lind and colleagues[42] and Kim and coworkers[37] used an ST autograft, whose tibial attachment was left intact, to reconstruct both the MCL and POL. Lind and colleagues[42] followed 50 patients from 2.1 to 5.6 years postoperatively and reported that all but one had normal or nearly normal restoration of medial stability. Kim and coworkers[37] included 26 patients in their series who were followed from 2.1 to 7.7 years after surgery. Medial joint space opening on stress radiographs improved from a mean of 7.8 mm (range, 5-12 mm) preoperatively to 1.1 mm (range, 0-5 mm) postoperatively. Yoshiya and associates[74] used an STG autograft to restore the anterior longitudinal portion of the SMCL in 24 patients with chronic, gross medial instability who were followed from 2 to 4 years postoperatively. Stress radiographs showed a mean of 0.2 mm (range, −1 to 2 mm) of increased medial joint opening at follow-up, which was significantly improved from a mean of 4.1 mm (range, 3-6 mm) measured before surgery ($P < .05$).

In summary, these studies show that different types of medial surgical procedures have very similar success rates. However, the studies are level IV, with no investigation to date having a sufficient number of patients to perform a level I study.

ILLUSTRATIVE CASE

Acute Combined ACL, PCL, SMCL, POL Ligament Disruption With Staged Medial Ligament Reconstruction

A 52-year-old real estate executive fell from a ladder and sustained a knee dislocation with gross disruption of the medial ligaments, ACL, and PCL. The neurovascular examination that included a computed tomography angiogram was intact. He was referred 10 days after the injury and physical examination showed moderate swelling of the extremity, a positive Lachman, 8 mm of increased posterior tibial translation at 90 degrees of flexion, and 15 mm of valgus opening at 0 degrees and 30 degrees of flexion. After a negative venous Doppler was obtained, reconstruction and repair of all of the medial ligament structures was performed (Fig. 19-23 to 19-25). Rehabilitation was begun the first postoperative day with ROM (0 to 90 degrees 3 times/day for 3 weeks) and was progressed as described in Chapter 20. In view of the

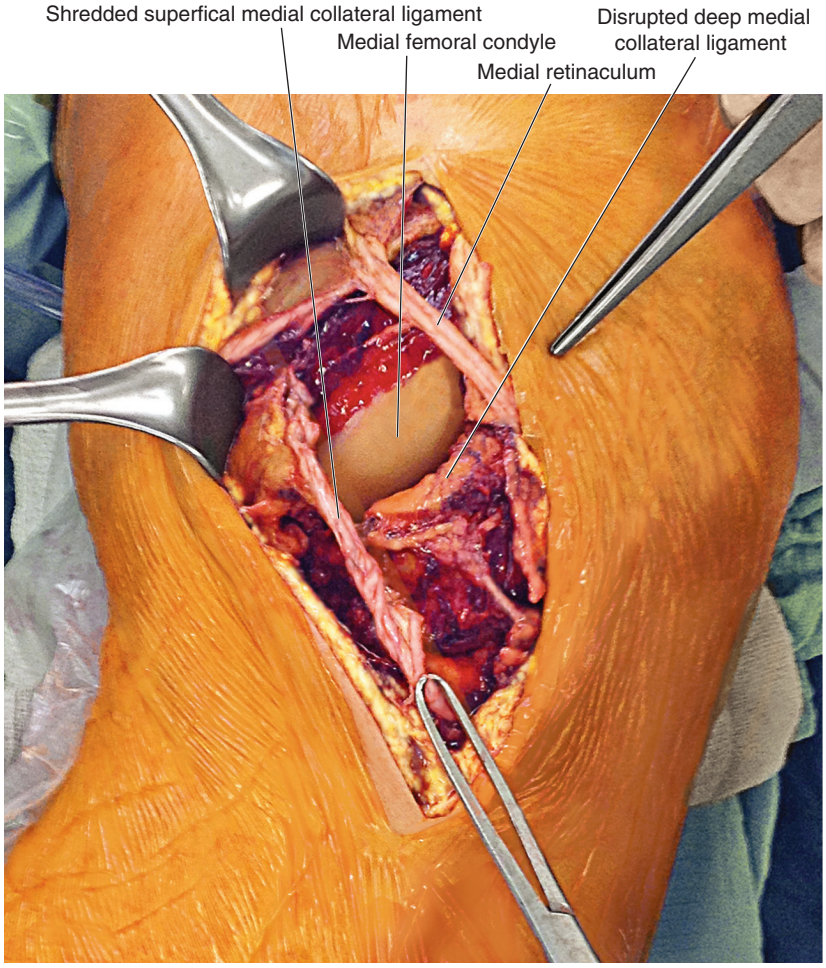

FIG 19-23 Exploration at surgery shows a shredded superficial medial collateral ligament and deep medial collateral ligament. The posterior oblique ligament is disrupted from its tibial attachment. Note the prominent infrapatellar nerve, which was saved.

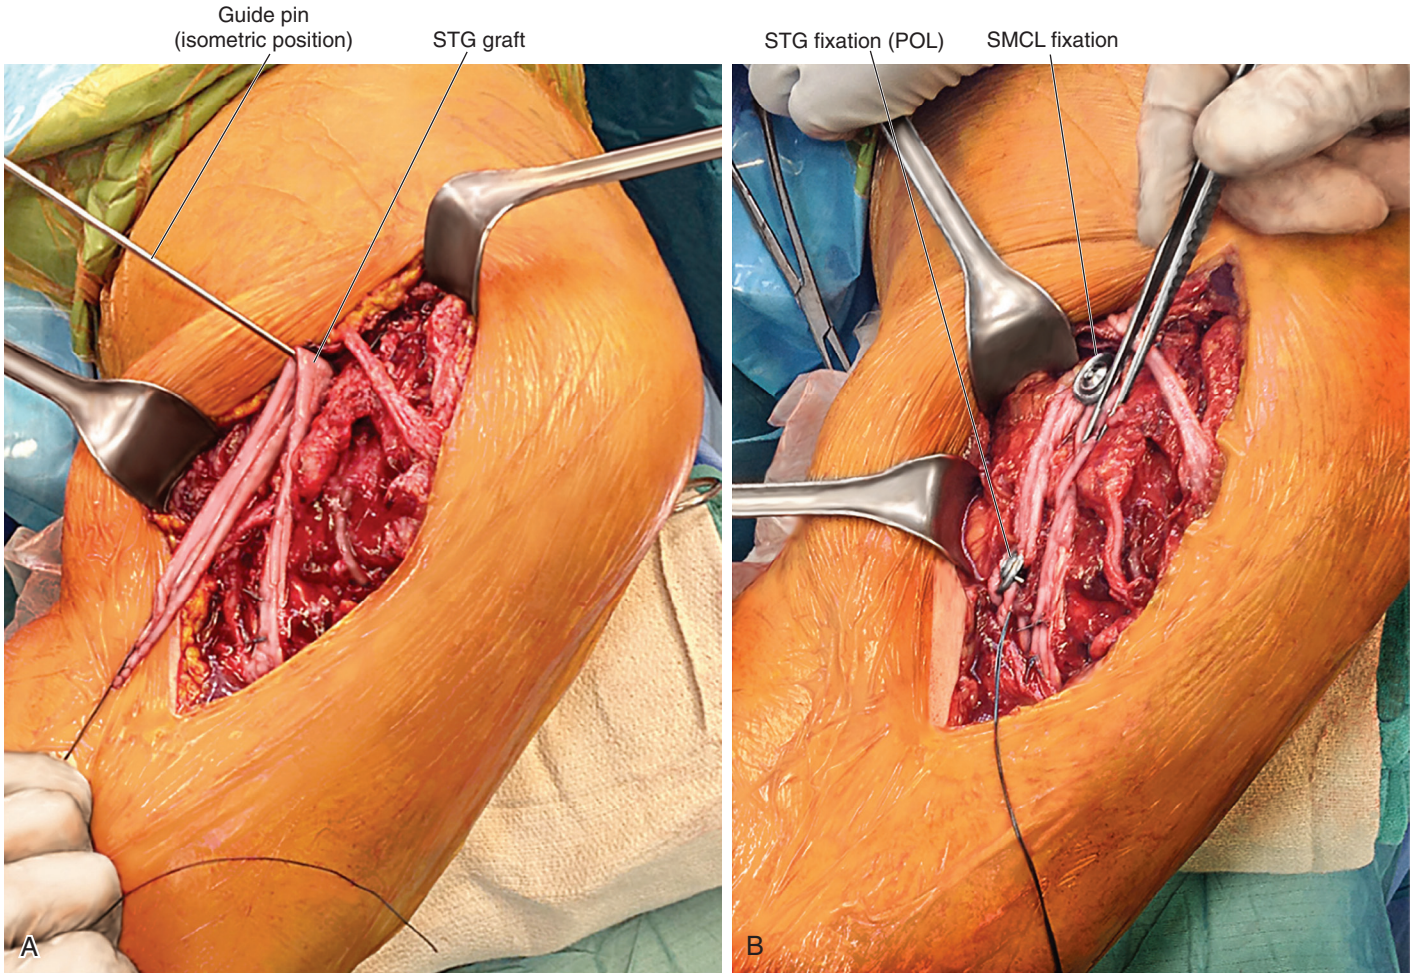

FIG 19-24 A, Repair is performed of the remaining fibers of the posterior oblique ligament (POL), deep medial collateral ligament, and superficial medial collateral ligament (SMCL) to the tibia. Then, a large-diameter semitendinosus-gracilis (STG) graft is passed over a pin just proximal and slightly posterior to the medial epicondyle to determine the correct isometric femoral point that is then fixated with a screw and spiked washer at 30 degrees of flexion, neutral tibial rotation. The STG is fixated at the middle of the distal SMCL fibers. **B,** The remaining STG is brought to the POL tibial attachment for screw and spiked washer fixation at 10 degrees of flexion, neutral tibial rotation.

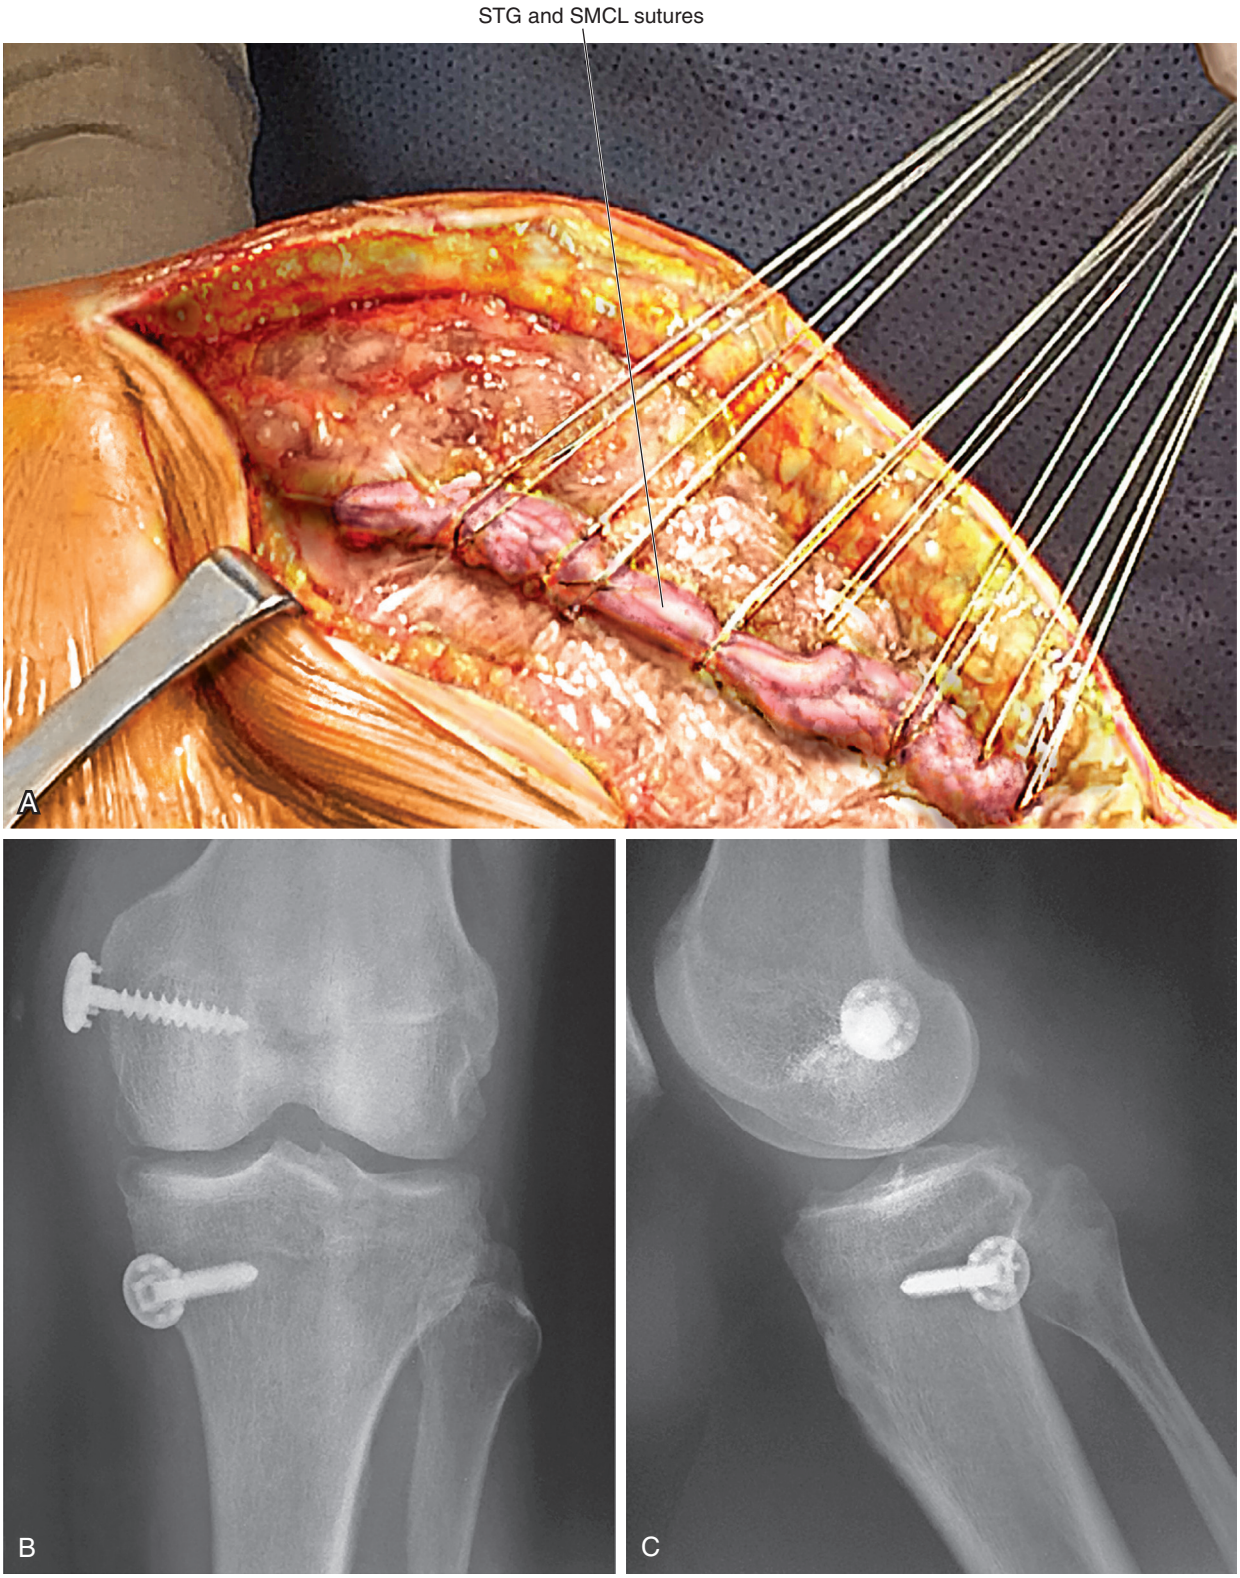

FIG 19-25 A, After the semitendinosus-gracilis (STG) graft and the superficial medial collateral ligament (SMCL) and posterior oblique ligament reconstruction, the remaining SMCL is sutured to the STG graft along the distal and proximal tibial attachments. The sartorial fascia is reflected under the retractors and later brought over the STG reconstruction. Anteroposterior **(B)** and lateral **(C)** radiographs show femoral STG fixation and POL-STG tibial fixation.

medial soft tissue swelling and edema, the decision was made to reconstruct all of the medial ligamentous structures, followed by a period of healing and rehabilitation, and staged elective ACL and PCL reconstruction. An exception would be if there was gross posterior subluxation in which a PCL reconstruction would be required concurrently with the medial reconstruction. The patient regained full range of movement and restoration of normal medial ligament stability.

CLINICAL CONCEPTS

Medial ligament injuries are among the most frequently treated problems of the knee joint. Whereas isolated superficial medial collateral ligament (SMCL) ruptures are common, concomitant damage to the anterior cruciate ligament (ACL) occurs in many cases, especially in younger active patients.[1,2,6] The majority of isolated acute injuries that involve damage to the SMCL alone, or to the SMCL and posteromedial capsule (PMC), do not require surgery.[8] Patients who have medial ligament tears classified as first-degree (tear involving a few fibers), second-degree (partial tear, no instability, ≤3 mm of increased medial joint opening), or third-degree (complete rupture) who demonstrate either a mild to moderate increase in medial joint opening at 30 degrees of flexion and no increase at 0 degrees do not require acute medial ligament reconstruction. These knees are treated with the conservative rehabilitation program; if concomitant injury exists to other ligaments, the decision of whether to reconstruct those structures is based on the extent of the injury, patient goals, and other issues addressed for the ACL in Chapter 7, the posterior cruciate ligament (PCL) in Chapter 16, and the posterolateral ligament structures in Chapter 17.

An acute third-degree injury consisting of gross major disruption of all of the medial structures (SMCL, deep medial collateral ligament, meniscus attachments, PMC, posterior oblique ligament [POL], and semimembranosus attachments), either alone or in combination with cruciate ligament tears, often requires surgical intervention. In these knees, large increases in medial joint opening are present at 30 degrees of flexion, and at least 5 mm of increased medial joint opening exists at 0 degrees. In addition, repair of medial meniscus attachments is indicated to retain meniscus function. Chronic deficiency of the medial ligament structures that causes partial giving-way during athletic activities may require reconstruction. In these knees, partial or complete ACL deficiency is frequently noted. The indications for medial ligament surgery and the appropriate candidates are discussed in detail in Chapter 19.

CONSERVATIVE TREATMENT OF MEDIAL LIGAMENT INJURIES

The goals of rehabilitation of medial ligament injuries are as follows:

- Provide appropriate protection initially after the injury to allow the disrupted medial ligament structures to "stick-down" and heal with the least amount of residual ligament elongation or abnormal medial joint opening.
- Control joint pain, swelling, and hemarthrosis.
- Regain a normal range of knee motion.
- Restore a normal gait pattern and neuromuscular stability for ambulation.
- Recover normal lower limb muscle strength.
- Regain normal proprioception, balance, coordination, and neuromuscular control for desired activities.
- Achieve optimal functional outcome based on orthopedic and patient goals.

The treatment rationale for patients with acute medial ligament ruptures is shown in Figure 20-1. The algorithm is divided into three

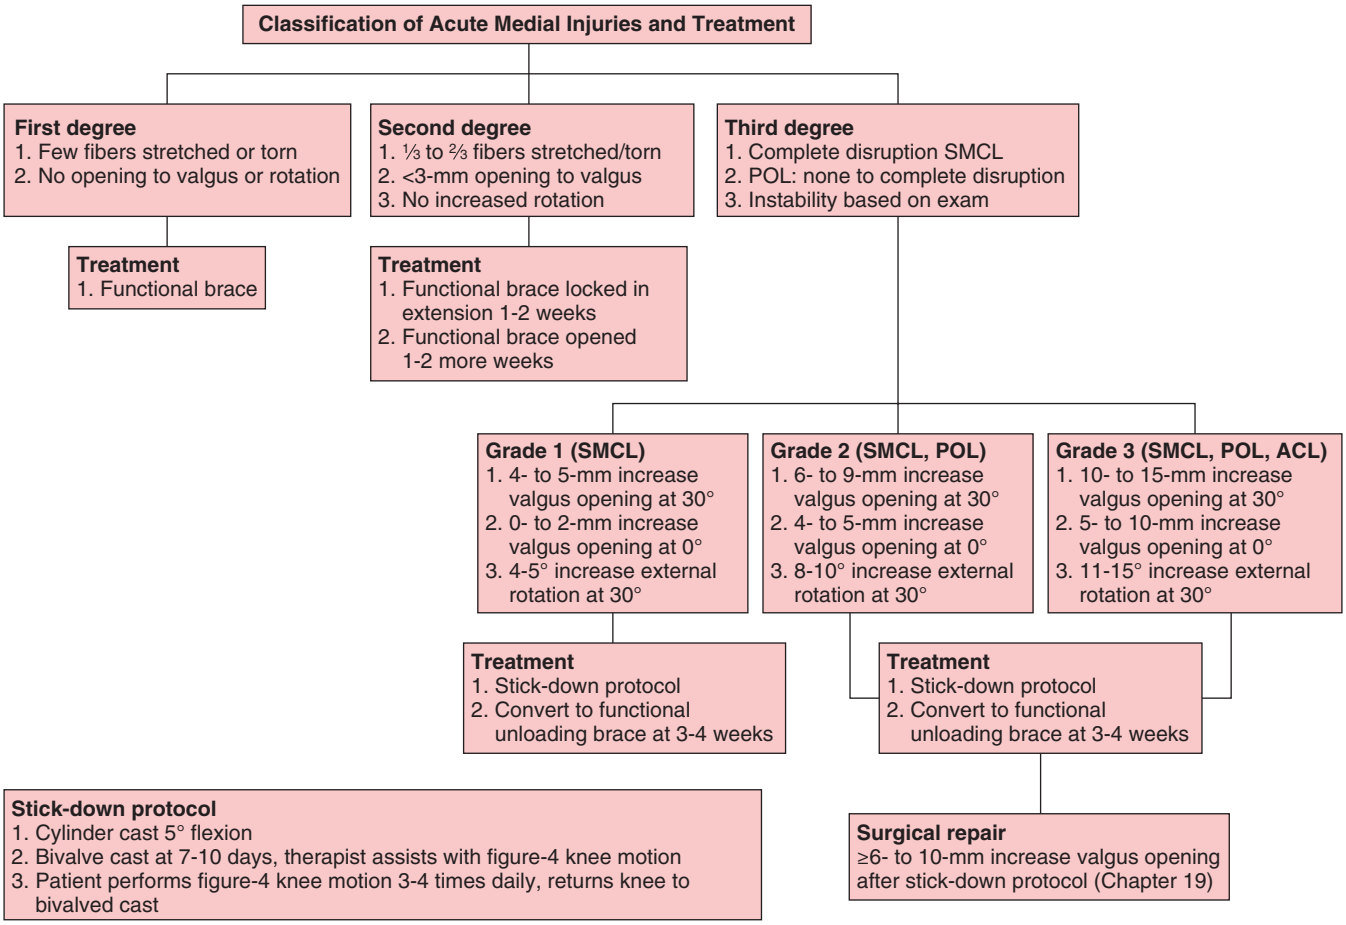

FIG 20-1 Treatment rationale for patients with acute medial ligament ruptures. *ACL,* Anterior cruciate ligament; *POL,* posterior oblique ligament; *SMCL,* superficial medial collateral ligament.

TABLE 20-1 Conservative Management of First-Degree Medial Ligament Injuries

Weight bearing as tolerated with assistive device if required.
Functional brace for protection for 3-4 weeks postinjury.
Active ROM exercises to achieve full ROM as tolerated.
Strengthening exercises: open and closed kinetic chain as tolerated.
Progress to agility, proprioceptive, neuromuscular, sports-specific activities as tolerated.
Return to full activities when strength is equal to the opposite side and all symptoms have resolved.

ROM, Range of motion.

major sections based on the extent of injury to the SMCL and PMC/POL. The first- and second-degree injuries are treated initially with a long-leg hinged brace, weight bearing as tolerated, and the rehabilitation program summarized in Tables 20-1 and 20-2. Some second-degree injuries may have considerable medial pain and swelling and, in these cases, the brace is used locked in extension with assistive ambulatory devices for the initial 1 to 2 weeks after the injury. The brace is then opened and used for another 2 to 4 weeks.

Third-Degree Injuries: Weeks 1 to 3

The treatment of third-degree medial ligament injuries involves short-term immobilization to allow the medial ligament structures time to heal, with the least elongation or laxity, by limiting medial joint opening and external tibial rotation. The lower limb is placed in a cylinder cast positioned in slight varus and internal rotation for 1 week to allow the disrupted medial soft tissues to "stick-down." Fiberglass cast immobilization is required because a long-leg hinged brace, even if locked at 0 degrees, does not provide sufficient protection to maintain medial joint line closure to allow close approximation of the disrupted medial ligament and meniscus attachment soft tissues. The patient is instructed to maintain the leg in an elevated position with the limb supported to control lower extremity swelling. The patient is also instructed to stay off of the lower limb as much as possible. In addition, ankle-pumping exercises are performed to maintain lower extremity circulation, and quadriceps isometrics are done hourly. Electrical muscle stimulation (EMS) is used to augment the voluntary quadriceps contraction. Windows may be cut into the cast to observe the electrodes to ensure they do not irritate the skin or to determine whether or not they need to be replaced. EMS is used approximately six times per day for 15-minute sessions. A cocontraction should occur between the stimulator and the patient's voluntary contraction. Hamstring and gastrocnemius flexibility exercises are also encouraged to promote posterior muscle relaxation.

At 7 to 10 days, the cylinder cast is split into an anterior and posterior shell (Fig. 20-2) to allow the patient to begin passive range of motion (ROM) exercises, which are initially assisted by the therapist. The cast is used for an additional 2 weeks to allow for early stick-down of the medial ligament structures. The patient is allowed to bear 25%

FIG 20-2 Cylinder cast bivalved (split) into an anterior and posterior shell.

TABLE 20-2 Conservative Management of Second-Degree Medial Ligament Injuries

Weight bearing as tolerated with assistive device if required.
Functional brace locked in extension for 1-2 weeks postinjury if excessive medial compartment pain and swelling.
Functional brace opened for next 4-6 weeks.
Active ROM exercises to achieve full ROM as tolerated.
Electrical muscle stimulation and straight-leg raises begun immediately.
Strengthening exercises: open and closed kinetic chain as tolerated.
Progress to agility, proprioceptive, neuromuscular, sports-specific activities upon resumption of full weight bearing as tolerated.
Return to full activities when strength equal to the opposite side and all symptoms have resolved.

ROM, Range of motion.

of her or his body weight as long as the cast is in place. ROM exercises are initiated in a figure-four position from 0 to 90 degrees to avoid valgus and external rotation loads on the healing ligaments (Fig. 20-3). A 4-inch tubular stocking is double-wrapped around the foot and ankle to allow the patient under her or his own power to flex the knee. This protected ROM program is performed three to four times a day for 10 to 15 minutes per session. Quadriceps strengthening exercises including isometrics and flexion straight-leg raises are emphasized. TheraBand resistance for plantar flexion is used to maintain gastrocnemius tone. Ice, compression, and elevation are used for pain and swelling control.

Third-Degree Injuries: Weeks 4 to 6

At the end of the first 3 to 4 weeks, the bivalved cast is discontinued and the patient is placed into a functional unloading brace depending on the extent of the knee effusion and residual tenderness to medial soft tissue pressure. Weight bearing is progressed approximately 25%

FIG 20-3 Patient performs range-of-motion exercises from 0 to 90 degrees in a figure-four position with the hip joint externally rotated to protect the healing medial tissues.

each week to discontinue crutches by the sixth week. Gait retraining is encouraged to allow for return of the normal reciprocal gait pattern (sufficient push-off during toe-off, midstance quadriceps contraction, hip and knee flexion during swing, and an upright posture).

Cryotherapy and EMS are continued to maintain control of pain and swelling as well as quadriceps reeducation. Exercises include quadriceps isometrics and straight-leg raises in the flexion and prone positions through the fourth week. Abduction and adduction leg raises may then be initiated as long as there is sufficient quadriceps control to limit varus/valgus loading. Any resistance in a side-to-side fashion is kept above the knee through at least the sixth week. Closed-chain exercises such as standing calf raises and wall-sitting isometrics are encouraged. ROM is progressed with figure-four protection continued through the fourth to sixth week.

Emphasis during this time period focuses on ligament protection during gait and exercise. The progression of exercise allows knee motion to be restored within normal limits. Muscle strengthening includes both closed-chain and table exercises (straight-leg raises). Emphasis is placed on hip and core control, plus progression of quadriceps strengthening (Table 20-3).

Third-Degree Injuries: Weeks 7 to 9

The brace is continued for ambulation. Gait and ROM should be normal or nearly normal, with restoration to normal as soon as possible. Pain and swelling should be within normal limits. Emphasis during this phase of treatment is on returning lower extremity strength to normal and to begin cross-training for cardiovascular endurance. Balance and proprioception exercises are also important components of this phase (see Chapter 11).

Straight-leg raises in multiple planes with ankle weights are used for hip control. Ten pounds of resistance represents the target goal for these exercises. Progression of the closed-chain program includes performing calf raises off the edge of a step or with weight added for resistance. Isometric wall-sits are done with a gradual increase in hold time and then with handheld weights added. TheraBand resistance is used with minisquats and terminal knee extension. Gait retraining is done with a heavy elastic band positioned about the thighs. In addition, the patient is progressed to a machine-oriented program for leg press (80 to 10 degrees), knee extension (90-30 degrees), seated hamstring curls (0-90 degrees), hip abduction/adduction, and calf presses.

PHASE 1: WEEKS 1-2 (VISITS 2-4)

General Observation

Non–weight bearing, maximum protection
Brace locked at 0 degrees (motion exercises 3-4 times/day) or cast
Avoid valgus loads, abnormal external tibial rotation

Evaluation (Goals)

Pain (controlled)
Hemarthrosis (mild)
Patellar mobility (good)
ROM minimum (0-90 degrees)
Quadriceps contraction and patellar migration (good)
Soft tissue contracture (none)

Continued

TABLE 20-3 Cincinnati Sports Medicine and Orthopaedic Center Rehabilitation Protocol for Medial Ligament Repair or Reconstruction—cont'd

PHASE 1: WEEKS 1-2 (VISITS 2-4)		
Goals	ROM 0-90 degrees Adequate quadriceps contraction Control of inflammation, effusion	
	Frequency	**Duration**
ROM	3-4 ×/day, 10 min	
Passive, 0-90 degrees, figure-four protection		
Patellar mobilization		
Ankle pumps (plantar flexion with resistance band)		
Hamstring, gastrocnemius-soleus stretches		5 reps × 30 sec
Strengthening	3 ×/day, 15 min	
Straight-leg raises (flexion)		3 sets × 10 reps
Active quadriceps isometrics		1 set × 10 reps
Knee extension (active assisted, 90-30 degrees, per quad control)		3 sets × 10 reps
Modalities	As required	
EMS		20 min
Cryotherapy		20 min
PHASE 2: WEEKS 3-4 (VISITS 2-4)		
General Observation	Partial weight bearing: toe touch to 25% body weight Brace unlocked (motion exercises 3-4 times/day) or cast Avoid valgus loads, abnormal external tibial rotation	
Evaluation (Goals)	Pain (controlled) Effusion (mild) Patellar mobility (good) ROM minimum (0-90 degrees) Quadriceps contraction and patellar migration (good) Soft tissue contracture (none)	
Goals	ROM 0-110 degrees Control of inflammation, effusion Muscle control

*Does not include combined anterior cruciate ligament/medial collateral ligament injuries; these require a longer period of protection and training. See text for criteria required to begin these activities.
BAPS, Biomechanical Ankle Platform System (Patterson Medical); *BBS*, Biodex Balance System; *CRPS*, complex regional pain syndrome; *EMS*, electrical muscle stimulation; *ITB*, iliotibial band; *ROM*, range of motion; *UBC*, upper body cycle.

Endurance training includes a stationary bicycle, elliptical cross-trainer, and/or aquatics for 20 to 30 minutes at least three times per week. Activities such as cutting or twisting that place valgus and external rotation torques on the lower extremity are still limited. Proprioception and balance training includes unidirectional exercises balancing on a rocker board and multidirectional activities such as a wobble board or balance board. Balance activities at home progress from tandem balance positioning to single-leg stance. In select patients, isokinetic testing is performed to measure quadriceps and hamstrings muscle strength. The goals for initiating a running program are at least 70% on bilateral comparison for quadriceps and hamstrings at 180 degrees/sec and 300 degrees/sec, torque/body weight ratios (based on age and gender), and a hamstring-quadriceps ratio of 60%.

Third-Degree Injuries: Weeks 10 to 12

The focus of this final phase is on return to activity. By this time, gait, ROM, activities of daily living, and symptoms should be within normal limits. The exercise progression advocates return of isokinetic muscle strength parameters within 70% and 90% for straight-ahead running and more strenuous turning/cutting drills, respectively. The cross-training program is advanced to a full running program that then allows for sports-specific training. Distance and direction-specific running and agility drills are incorporated. Heavy strength training occurs on opposite days of the running program. Injury prevention and neuromuscular retraining programs include jump training activities with emphasis on technique, position, alignment, and repetition as discussed in detail in Chapter 14. Isokinetic testing is performed, with the goal of achieving a 90% bilateral comparison for quadriceps and hamstrings at 180 degrees/sec and 300 degrees/sec, torque/body weight ratios (corrected for age and gender), and a hamstring/quadriceps ratio greater than 60%. Patients continue brace use for activity only. Follow-up treatment is based on either the need for symptom control and/or functional progression for unrestricted return to activity.

Concomitant Cruciate Ligament Injuries

Patients who have a concomitant ACL rupture and third-degree medial ligament rupture undergo the initial stick-down program and treatment described. According to the severity of the medial ligament injury, sufficient time is required to stick down the medial structures, allow for figure-four ROM, protect with partial weight bearing, and initiate early quadriceps exercises. Initial knee motion goals are 0 to 90 degrees. Normally, 3 to 6 weeks of conservative management is required before the patient undergoes ACL reconstruction. The progression of exercises and weight bearing is consistent with that described above.

Patients who have concomitant PCL and medial ligament ruptures also undergo the initial stick-down program with a posterior calf pad to prevent posterior tibial subluxation. The cast is bivalved at 2 to 4 weeks, allowing protected passive ROM exercises to be performed initially by the therapist and then by the patient. Figure-four ROM exercises with an anterior drawer support allow for protection of both ligaments. Two weeks later, the bivalved cast is replaced with a long-leg hinged brace with a posterior pad, which is used for another 4 weeks. Weight bearing, ROM, and quadriceps exercises are all progressed as tolerated. The initial knee motion goal is 0 to 90 degrees, which is then gradually progressed to a full 6 weeks after the cast is discontinued. Full weight bearing is permitted at this time, with emphasis on quadriceps control. Hamstring contractions are not allowed for the initial 6 weeks, and are then permitted in the active mode only for an additional 6 weeks. The patient's gait, knee motion, quadriceps control, and symptoms should be back to normal limits to consider surgical intervention. Knee injuries with combined third-degree medial ligament ruptures and PCL ruptures often require operative repair; the postoperative course is described in Chapter 18.

POSTOPERATIVE REHABILITATION OF MEDIAL LIGAMENT REPAIRS/RECONSTRUCTIONS

The surgical treatment of acute third-degree medial ligament ruptures involves anatomic repair to restore continuity and function, including repair of the medial meniscus attachments. Knees with chronic deficiency of the medial ligament ruptures often require a graft reconstruction using a semitendinosus-gracilis autograft or allograft, discussed in Chapter 19. The operative procedure is designed to provide sufficient tensile strength to the reconstructed medial tissues to allow immediate knee motion and restore early limb function. The goal is to provide 4 weeks of maximum protection, using either a long-leg hinged postoperative brace or bivalved cast in cases where the surgical repair was tenuous, extensive disruption occurred, the patient is obese, or compliance with brace wear is questionable. After this period, the rehabilitation program progresses, as soft tissue healing provides sufficient strength for ambulatory activities.

The postoperative protocol (see Table 20-3) is divided into seven phases according to the time period postoperatively (e.g., phase 1 comprises postoperative weeks 1-2). Each phase has four main categories that describe the factors evaluated by the therapist and exercises performed by the patient:

- General observation of the patient's condition.
- Evaluation and measurement of specific variables, with goals identified for each variable
- Treatment and exercise program according to frequency and duration.
- Rehabilitation goals that must be achieved to enter the next phase.

Specific criteria are evaluated throughout the rehabilitation program to determine whether the patient is ready to progress from one phase to the next. The protocol incorporates a home self-management program, along with an estimated number of formal physical therapy visits. For most patients, 11 to 21 postoperative visits are expected to produce a desirable result.

The following signs are continually monitored postoperatively: joint swelling, pain, gait pattern, knee motion, patellar mobility, muscle strength, flexibility, and medial tibiofemoral compartment opening. Any individual who experiences difficulty progressing through the protocol or who develops a complication is expected to require additional supervision in the formal clinic setting.

The first postoperative week represents a critical time period in regard to control of knee joint pain and swelling, return of adequate quadriceps muscle contraction, initiation of immediate knee motion exercises from 0 to 90 degrees, and maintenance of adequate limb elevation. A bulky compression dressing is used for 48 hours and then converted to compression stockings with an additional compression bandage if necessary. Patients are encouraged to stay in bed and elevate the limb above their heart for the first 5 to 7 days, rising only to perform exercises and attend to personal bathing issues. Prophylaxis against deep venous thrombosis includes one aspirin (325 mg) a day for 10 days or, for larger patients, one aspirin twice a day, ambulation (with crutch support) six to eight times a day for short periods of time, ankle pumping every hour the patient is awake, and close observation of the lower limb by the therapist and surgeon. Knee joint hemarthrosis require aspiration. Nonsteroidal antiinflammatories are used for 5 days postoperatively. Appropriate pain medication is prescribed to provide relief and allow the immediate exercise protocol described below to be performed.

Modalities

In the immediate postoperative period, knee effusion must be controlled to avoid the quadriceps inhibition phenomenon. Electrogalvanic stimulation or high-voltage EMS may be used along with ice, compression, and elevation to control swelling. Treatment duration is approximately 20 minutes, the intensity is set to patient's tolerance, and the treatment frequency is three to six times per day.

Once joint effusion is controlled, functional EMS is used for quadriceps muscle reeducation based on the evaluation of quadriceps muscle tone. One electrode is placed over the vastus medialis oblique (VMO) and a second electrode is placed on the central to lateral aspect of the upper third of the quadriceps muscle belly. The treatment duration is 20 minutes. The patient actively contracts the quadriceps muscle simultaneously with the machine's stimulation.

Biofeedback therapy is important to facilitate an adequate quadriceps muscle contraction early postoperatively. The surface electrode is placed over the selected muscle component to provide feedback to the patient and clinician regarding the quality of active or voluntary quadriceps contraction. Biofeedback is also useful in enhancing hamstring relaxation if the patient has difficulty achieving full knee extension owing to knee pain or muscle spasm. The electrode is placed over the belly of the hamstring muscle while the patient performs ROM exercises.

Cryotherapy is begun in the recovery room after surgery. The standard method of cold therapy is an ice bag or commercial cold pack, which is kept in the freezer until required. Empirically, patients prefer motorized cooler units. These units maintain a constant temperature and circulation of ice water through a pad, which provides excellent pain control. Cryotherapy is used from three times a day to every waking hour for 20 minutes at a time depending on the extent of pain and swelling. Cold therapy is typically done after exercise or when required for pain and swelling control and is maintained throughout the entire postoperative rehabilitation protocol.

Postoperative Bracing

Immediately after surgery, patients in whom excellent stability was obtained and are of normal body weight are placed into a long-leg hinged postoperative brace that is locked at 0 degree extension for 2 weeks until the initial postoperative pain has receded and return of lower limb muscle control occurs. At this time, the brace is unlocked and the patient taught to resume a normal gait, with flexion during the stance phase, under 25% body weight. In cases where the surgical repair was tenuous, questionable tissue quality exists even with a graft reconstruction, or in cases of obesity, a bivalved cast is used as described earlier for third-degree injuries. The cast is used for 3 to 4 weeks and then converted to a functional unloading brace. The brace (lateral compartment-medial soft tissues) is prescribed for at least the first year postoperatively in select knees in which extensive surgery was performed and additional protection is indicated.

Weight Bearing

Patients are kept non–weight bearing for the first 2 weeks. Then, toe touch to 25% of the patient's body weight is permitted from weeks 3 to 4. Partial weight bearing is allowed as long as pain and swelling are controlled and a voluntary quadriceps contraction is demonstrated. The patient is taught to walk with a toe-in gait and avoid a toe-out valgus position. The therapist should observe the gait cycle for any tendency for a valgus thrust or external tibial rotation, which requires immediate correction to avoid placing excessive loads on the medial ligament repair or graft reconstruction. Weight bearing is slowly progressed to full by the seventh to eighth week.

Range of Knee Motion

The goal in the first postoperative week is to obtain 0 to 90 degrees. A continuous passive motion machine is not required. Patients perform

FIG 20-4 Early postoperatively, the therapist performs range-of-motion exercises by applying a mild amount of varus and internal tibial rotation stress during flexion to unload the medial compartment.

passive and active ROM exercises in a seated position for 10 minutes a session, approximately four to six times per day. Initially, the therapist performs this exercise by applying a mild amount of varus and internal tibial rotation stress during flexion to unload the medial compartment (Fig. 20-4). Full passive knee extension must be obtained immediately to avoid excessive scarring in the intercondylar notch and posterior capsular tissues. It is important to note that patients undergoing SMCL repair or reconstruction are at an increased risk for developing a knee motion problem postoperatively.[3] Supervision and close monitoring of the patient's progress by the therapist is essential to avoid a potential arthrofibrotic response. If the patient has difficulty regaining at least 0 degrees by the seventh postoperative day, an overpressure program is begun as described in detail in Chapter 11 and Chapter 38. Overpressure exercises and modalities include hanging weight, extension board, and a drop-out cast (Fig. 20-5).

Passive knee flexion exercises are performed initially in the figure-four position for the first 4 to 6 weeks to protect the healing medial ligament tissues (see Fig. 20-3). Knee flexion is then gradually increased to 130 degrees by the seventh to eighth postoperative week. Other methods to assist in achieving flexion include chair rolling, wall-slides, commercial devices (Fig. 20-6), and passive quadriceps stretching exercises.

Patellar Mobilization

Maintaining normal patellar mobility is critical to regain normal ROM. The loss of patellar mobility is often associated with arthrofibrosis and, in extreme cases, the development of patella infera.[4,5,7] Patellar glides are performed beginning the first postoperative day in all four planes (superior, inferior, medial, and lateral) with sustained pressure applied to the appropriate patellar border for at least 10 seconds (Fig. 20-7). This exercise is performed for 5 minutes before ROM exercises. Caution is warranted if an extensor lag is detected because this may be associated with poor superior migration of the patella, indicating the need for additional emphasis on this exercise. Patellar mobilization is performed for approximately 12 weeks postoperatively.

Flexibility

Hamstring and gastrocnemius-soleus flexibility exercises are begun the first day postoperatively. A sustained static stretch is held for 30 seconds and repeated five times. These exercises help control pain caused by the reflex response created in the hamstrings when the knee is kept in the flexed position. In addition, the gastrocnemius-soleus towel pulling exercise can help lessen discomfort in the calf, Achilles tendon, and ankle. Quadriceps and iliotibial band flexibility exercises are initiated at week 9. The flexibility program is maintained throughout the course of the rehabilitation program.

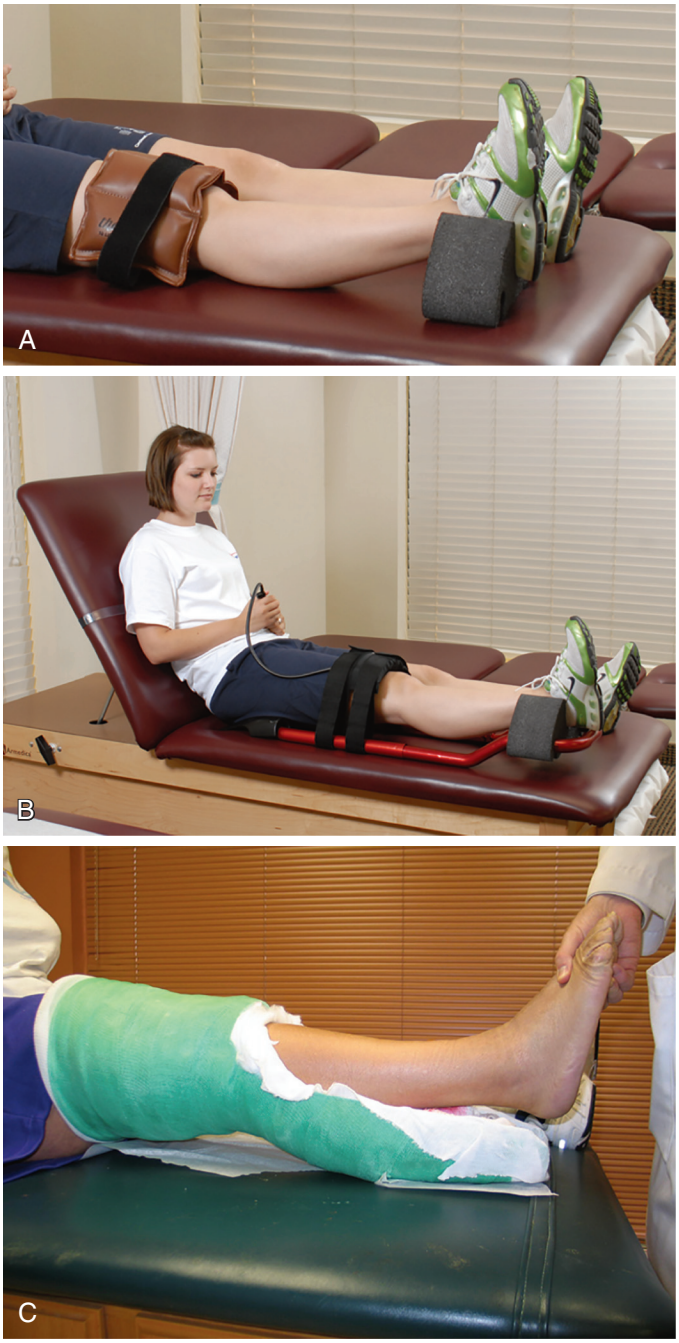

FIG 20-5 Extension overpressure exercises. **A,** Hanging weight. **B,** Extension board (ERMI Knee Extensionater). **C,** Drop-out cast.

Strengthening

The strengthening program is begun on the first postoperative day. Early emphasis on the generation of a good voluntary quadriceps contraction is critical for a successful and safe return to functional activity. Isometric quadriceps contractions, along with a hamstring cocontraction to prevent knee hyperextension, are completed hourly

FIG 20-6 Flexion overpressure exercises. **A,** Rolling stool. **B,** Wall-slides. **C,** Commercial device (ERMI Knee Flexionater).

FIG 20-7 Patellar mobilization.

following the rules of 10 second holds, 10 repetitions, 10 times per day. Adequate evaluation of the quadriceps contraction by both the therapist and patient is critical. If necessary, biofeedback can also be used to reinforce a good voluntary quadriceps contraction.

Straight-leg raises are initiated the first postoperative day in the hip flexion plane. At weeks 7 to 8, the other three planes (adduction, abduction, and extension) are added to this exercise. As leg raises become easy to perform, ankle weights are added to progress muscle strengthening. Initially, 1- to 2-lb weights are used and eventually, up to 10 lb may be added as long as this is not more than 10% of the patient's body weight.

Active-assisted ROM can also be used to facilitate the quadriceps muscle if poor tone is observed during isometric contractions. These exercises are primarily used during the first 8 postoperative weeks where emphasis is placed on controlling pain and swelling, regaining full ROM, achieving early quadriceps control and proximal stabilization, and resuming a normal gait pattern.

Closed kinetic chain exercises are begun when partial weight bearing of at least 50% is tolerated. Patients are instructed to avoid valgus loading during these exercises. These activities initially consist of minisquats from 0 to 45 degrees, toe raises, and wall-sits. During the wall-sitting exercise, the patient may use an elastic band around the distal thigh to produce a varus-directed force to avoid loading the MCL repair/reconstruction, or hold dumbbell weights in his or her hands to increase body weight (Fig. 20-8). The patient can also shift his or her body weight over the involved side to stimulate a single-leg contraction. The wall-sitting position should be held to a maximum burning of the quadriceps and repeated. This is an excellent exercise to mimic a stationary leg press, achieve quadriceps muscle fiber recruitment, and induce muscle fatigue to build strength.

Lateral step-ups are begun when the patient has achieved full weight bearing. The height of the step is gradually increased based on patient tolerance from 2 to 8 inches.

Hamstring curls are begun with Velcro ankle weights between weeks 9 and 12 and eventually advanced to weight machines. The patient exercises the involved limb alone, as well as both limbs together. Weight training is used throughout the program and continues in the return to activity and maintenance phases of rehabilitation.

FIG 20-8 Strengthening exercises. **A,** Wall-sitting while holding hand weights. **B,** Toe raises. **C,** Lateral step-ups.

Open kinetic chain extension exercises are incorporated within the first few weeks to further develop quadriceps muscle strength. Caution is warranted owing to the potential problems these exercises may create for the patellofemoral joint. Resisted knee extension is begun with Velcro ankle weights from 90 to 30 degrees at postoperative weeks 3 to 4. The terminal phase of extension is avoided owing to the forces placed on the patellofemoral joint. The patellofemoral joint must be monitored for pain, swelling, and crepitus to avoid a conversion in which painful patellofemoral crepitus develops with articular cartilage damage. The surgeon should advise the therapist if patellofemoral joint damage was observed at surgery. The therapist should palpate the patellofemoral joint during active knee extension every therapy session to detect pain or an onset of joint crepitus. A patellofemoral conversion to a symptomatic state will occur in select knees, especially those with

preexisting patellofemoral joint damage. In these knees, modification of the entire rehabilitation program is required.

A full lower extremity strengthening program is critical for early and long-term success of the rehabilitation program. Other muscle groups included in this routine are the hip abductors, hip adductors, hip flexors, and hip extensors. These muscle groups may be exercised on either a multihip or cable system machine or a hip abductor-adductor machine. Gastrocnemius-soleus strength is a key component for both early ambulation and the running program. In addition, upper extremity and core strengthening are important for a safe and effective return to work or sports.

Balance, Proprioceptive, and Perturbation Training

Balance and proprioceptive training are initiated when the patient achieves 50% weight bearing. Initially, the patient stands and shifts weight from side to side and front to back. This activity promotes confidence in the leg's ability to withstand the pressures of weight bearing and initiates the stimulus to knee joint position sense. Cup walking is then done to promote symmetry between the surgical and uninvolved limbs by facilitating early midstance quadriceps activation and focusing on sufficient active knee flexion during swing phase (Fig. 20-9).

Double- and single-leg balance exercises in the stance position are beneficial and initiated during phases 5 to 6, depending on patient tolerance. During the single-leg exercise, the foot is pointed straight ahead, the knee flexed 20 to 30 degrees, the arms extended outward to horizontal, and the torso positioned upright with the shoulders above the hips and the hips above the ankles. The patient remains in this position until balance is disturbed. A minitrampoline or unstable platform makes this exercise more challenging. The patient may assume the single-leg stance position and throw/catch a weighted ball against an inverted minitrampoline until fatigue occurs.

Perturbation training techniques are initiated during balance exercises. The therapist stands behind the patient and disrupts her or his body posture and position periodically to enhance dynamic knee stability. The techniques involve either direct contact with the patient or disruption of the platform on which the patient is standing.

Walking on half foam rolls is also used in the gait retraining and balance program. This activity helps the patient develop the balance and dynamic muscular control required to maintain an upright position and be able to walk from one end of the roll to the other. Developing a center of balance, limb symmetry, quadriceps control in midstance, and postural positioning are benefits obtained from this type of training.

Conditioning

Depending on accessibility, a cardiovascular program is begun as soon as the patient can sufficiently tolerate the upright position with an upper extremity ergometer. The surgical limb should be elevated to minimize lower extremity swelling. This exercise is performed as tolerated. Stationary bicycling is begun in the fifth to sixth postoperative week if tolerated.

Water walking, swimming, and the use of an elliptical machine are allowed during the ninth to twelfth postoperative weeks. Then, cross-country ski and stair-climbing machines are permitted. Protection against high stresses to the patellofemoral joint is strongly advocated. During bicycling, the seat height is adjusted to its highest level based on patient body size and a low-resistance level is used initially. Stair-climbing machines are adjusted to produce a short step and low resistance.

To improve cardiovascular endurance, the program should be performed at least three times per week for 20 to 30 minutes, and the exercise performed to at least 60% to 85% of maximal heart rate. It is generally regarded that performing in the higher levels of percentage

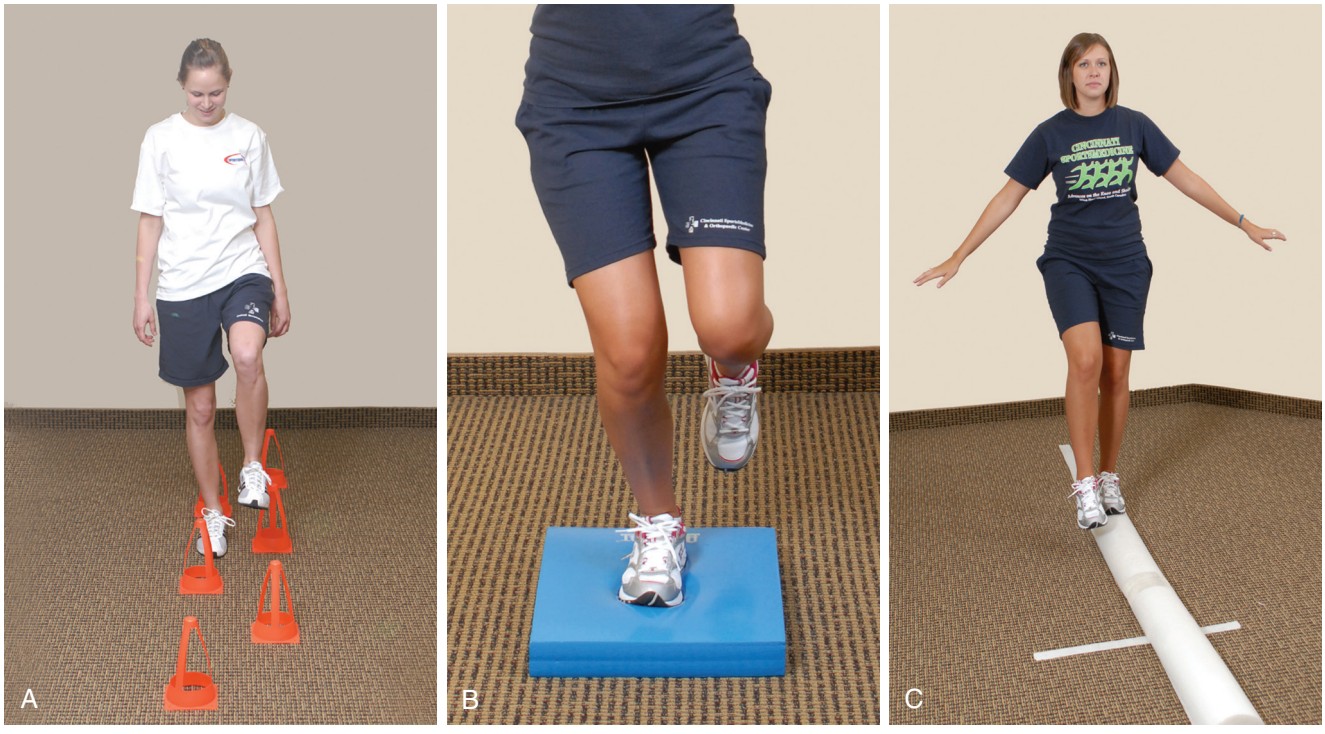

FIG 20-9 Balance and proprioceptive training. **A,** Cup (or cone) walking. **B,** Single-leg balancing on an unstable platform. **C,** Walking on half foam rolls.

of maximal heart rate achieves greater cardiovascular efficiency and endurance.

Running and Agility Program

To initiate the running program, the patient must demonstrate no more than a 30% deficit in average torque for the quadriceps and hamstrings on isokinetic testing and have no more than 3 mm of increase in medial joint opening (30 degrees of flexion). The majority of patients are at least 5 months postoperative.

The running program is based on the patient's athletic goals, particularly the position or physical requirements of the activity, and is described in detail in Chapter 11. The program is performed three times per week, on opposite days of the strength program. Since the running program may not reach aerobic levels initially, a cross-training program is used to facilitate cardiovascular fitness. The cross-training program is performed on the same day as the strength workout. Sports-specific agility drills are an important part of the return to activity program. Patients must be taught proper body alignment and positioning during cutting and pivoting to avoid abnormal and potential dangerous forces, discussed in detail in Chapter 14.

Plyometric Training

Progressive plyometric training is initiated upon successful completion of the running program in patients who desire to return to high-risk sports activities. Important parameters to consider when performing plyometric exercises include surface, footwear, and warm-up. The jump training should be done on a firm, yet forgiving surface such as a wooden gym floor. Very hard surfaces like concrete should be avoided. A cross-training or running shoe should be worn to provide adequate shock absorption, as well as adequate stability to the foot. Checking wear patterns and outer sole wear will help avoid overuse injuries. Beginning plyometric training is done in individual sessions performed in a manner similar to interval training. Initially, a rest period is incorporated that lasts 2 to 3 times the length of the exercise period; this is gradually decreased to 1 to 2 times the length of the exercise period. Plyometrics are also performed 2 to 3 times each week in addition to strength and cardiovascular endurance exercises.

The program begins with level-surface box hopping. A four-square grid of four equally sized boxes is created on the floor with tape. The patient first hops from box 1 to box 3 (front-to-back), and then from box 1 to box 2 (side-to-side). This drill is initially performed using both legs, with the body weight kept on the ball of the foot. The patient hops as fast as possible with the knees bent and lands in flexion to avoid knee hyperextension. It is important for the patient to focus on limb symmetry during this exercise.

The initial exercise time period lasts 15 seconds, with the patient completing as many hops between the squares as possible. Three sets are performed for both directions, and the number of hops is recorded. Progression of the program occurs as the number of hops, as well as patient confidence, improves. This exercise has four levels. The first level includes front-to-back and side-to-side hopping, as previously described. The second level incorporates both of the directions in level one into one sequence and also includes hopping in both right and left directions (box 1 to box 2 to box 4 to box 2 to box 1). Level three progresses to diagonal hops, and level four includes pivot hops in a 180-degree direction. Once the patient can perform level-four double-leg jumps, similar exercises are initiated using single-leg hops.

During the various jumps, the patient is instructed to keep his or her body weight on the balls of the feet. He or she should jump and land with the knees flexed and shoulder-width apart to avoid knee hyperextension and an overall valgus lower limb position. The patient should understand that the exercises are reaction and agility drills and, although speed is emphasized, correct body posture must be maintained throughout the drills.

For patients who undergo a combined ACL-SMCL reconstruction, advanced plyometric training is recommended before release to strenuous high-risk sports activities such as soccer and basketball. Our Sportsmetrics program is described in detail in Chapter 14. The program is applicable for both female and male athletes.

Return to Sports

Once the patient has completed the running and plyometric programs, sport-specific drills and cutting patterns of 45 degrees and 90 degrees angles may be implemented based on their athletic goals. Return to sports activities is based on successful completion of the running and functional training program.

For patients who undergo a combined ACL-SMCL reconstruction, a longer period of protection and training is required. Although in general these patients may be released to full sports around 7 months postoperatively, the following specific criteria are recommended before release is granted:

- Isokinetic test 180 degrees/s and 300 degrees/s quadriceps, hamstrings: 10% or less deficit
- No pain, swelling, patellofemoral crepitus
- Lachman, KT-2000 (MEDmetric) arthrometer test: less than 3-mm increase over opposite side
- Negative pivot shift test
- Single-leg hop tests: less than 15% deficit
- Successful completion advanced plyometric training
- Greater than 60% normalized knee separation distance on video drop-jump test
- No valgus motion or medial-lateral movement of knee on single-leg squat test

A trial of function is encouraged where the patient is monitored for knee swelling, pain, overuse symptoms, and giving-way episodes. Some athletes will experience transient knee swelling upon return to strenuous activities and should be educated on how to recognize this problem and the importance of reducing activities until the swelling subsides. If swelling persists, the athlete is advised to reduce athletics for 2 to 6 weeks, consider use of nonsteroidal antiinflammatories, and use ice and elevation. Upon successful return to activity, the patient is encouraged to continue with a maintenance program. During the in-season, a conditioning program of two workouts a week is recommended. In the off-season or preseason, this program should be performed three times a week to maximize gains in flexibility, strength, and cardiovascular endurance.

During the entire functional progression, the therapist and surgeon should individualize the program based on the initial injury (particularly to the menisci and articular cartilage), magnitude of the operative procedure, and healing response of the patient. Athletes with loss of a meniscus or articular cartilage damage are advised to refrain from high-impact activities and are followed yearly to detect progression of the joint injury. These patients frequently have episodes of joint swelling and pain during the functional progression and are instructed to "play smart" and not be a knee abuser.

INTRODUCTION

The concept of a dislocated knee has changed markedly over the past few decades. In 1971, Meyers and Harvey[16] predicted that most orthopedists would not see more than one knee dislocation in their entire career. However, evidence indicates that knee dislocations are being seen with increasing frequency for a variety of reasons. Increasing trauma, the growing epidemic of obesity, changes in automotive design, and recognition of spontaneously reduced knee dislocations have all added to the increased incidence.[2,7] The increasing number of knee dislocations has created the need for a classification system that will help guide the management of these complex injuries. Classification systems should be simple and reproducible, provide information to the clinician that will be helpful in making treatment decisions, aid in the communication of similar injuries, and assist in developing prognoses for the injuries. This chapter reviews the shortcomings of older classification systems of knee dislocations and presents an anatomic classification that is simple, accurate, reproducible, and useful.[25-27,35]

DEFINITION OF KNEE DISLOCATION

Classically, a knee dislocation was defined as greater than 100% displacement of the tibiofemoral articulation. This displacement had to be present on either physical examination or on radiographic imaging. Since the 1990s, several authors have recognized the existence of *reduced* knee dislocations. These are knees that present to the treating physician as reduced but have multiple injured ligaments (usually including both cruciate ligaments) and gross instability on stress testing. Some of these injuries represent a spontaneous reduction of a knee dislocation and others are dislocated knees that are reduced in the field before transport to a medical facility. The incidence of this type of reduced knee dislocation may be as high as 50% of all knee injuries classified as a dislocation.[5,35,39] A study from our institution showed that the incidence of vascular injury in reduced dislocations was equal to that of knees that presented as dislocated (Fig. 21-1).[39] Recent studies have shown the risk of arterial injury ranges from 3% to 43% in knees diagnosed as dislocated.[3,15,19,33,40] Clinicians must be alert to the presence of reduced dislocations so as not to miss a limb-threatening arterial injury. A multiligament-injured knee with gross instability must be treated the same as a knee that presents as dislocated.

Although most knee dislocations involve tears of both cruciate ligaments (posterior cruciate ligament [PCL] and anterior cruciate ligament [ACL]), case reports of cruciate intact knee dislocations do exist. A PCL-intact knee dislocation was first described in 1975.[16] Some authors[4,30] have reported on patients with a radiographically documented knee dislocation that, upon reduction, demonstrated an intact, functional cruciate ligament on physical examination or at the time of operative exploration. Although some of these patients were noted to have sustained partial PCL tears, the presence of a functional PCL provides increased stability and changes the management of these PCL-intact dislocations. In most PCL-intact knee dislocations, the tibia is perched anterior on the distal femur (Fig. 21-2). In addition to an ACL tear, there is often complete rupture of either the medial collateral ligament (MCL) or posterolateral structures.

Similarly, ACL-intact knee dislocations have also been reported. These are also extremely rare injuries. The tibia is perched posterior on the femur, and there is a complete tear of the PCL associated with a complete collateral ligament injury. Again, the presence of a functional ACL provides increased stability in the knee and changes the management of these injuries. A classification system for knee dislocations must take into account the presence of both reduced and cruciate-intact knee dislocations.

CRITICAL POINTS Assessment of Knee Dislocations

- Clinicians must be alert to the presence of "reduced" dislocations so as not to miss a limb-threatening arterial injury.
- Although rare, cruciate-intact knee dislocations do occur, adding to the stability of the knee and changing the management of these injuries.
- A classification system for knee dislocations must take into account the presence of both reduced and cruciate-intact knee dislocations.

POSITION CLASSIFICATION SYSTEM

In 1963, Kennedy[14] was the first to classify knee dislocations. He proposed a classification system based on the tibial position with respect to the femur. For example, an anterior knee dislocation implies that

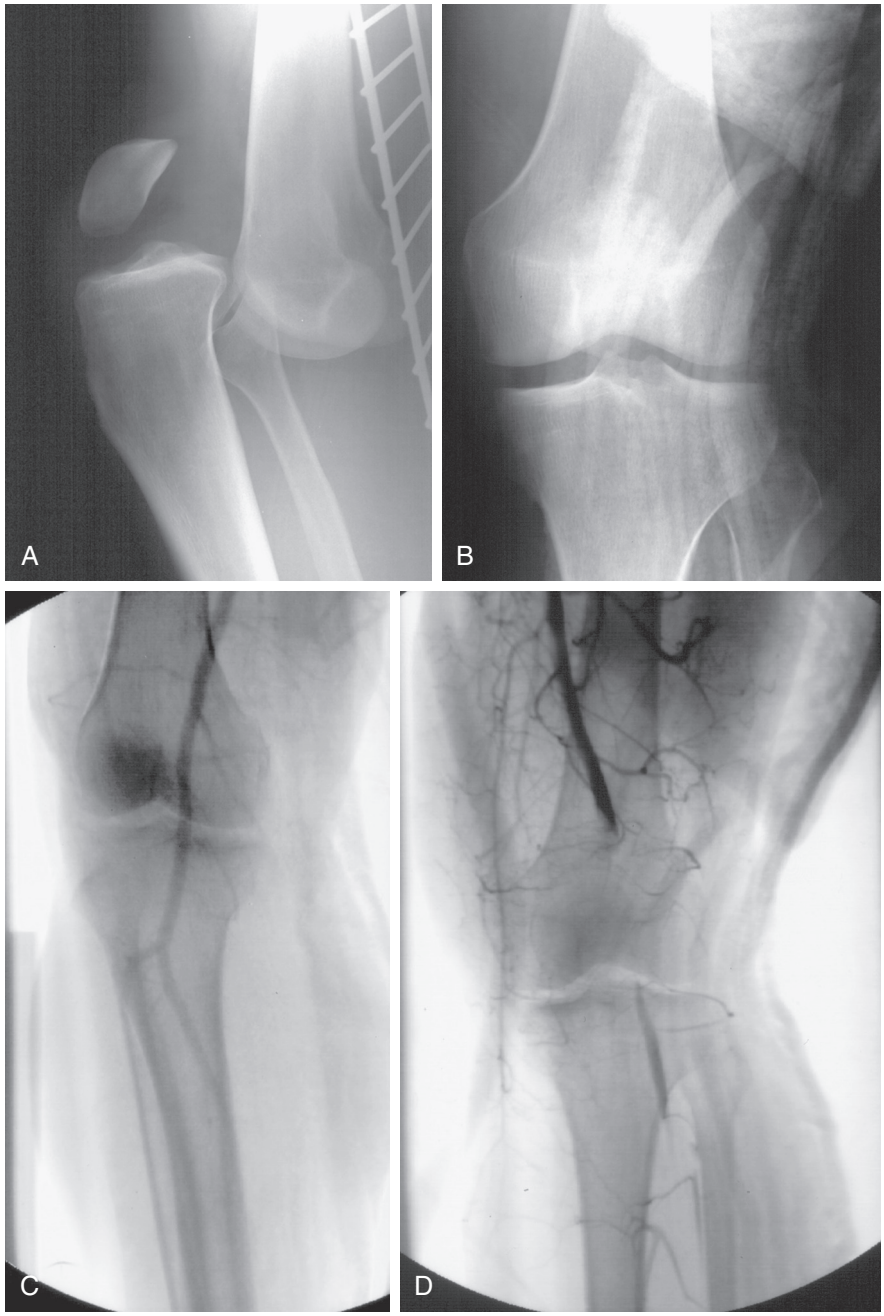

FIG 21-1 Bilateral knee injuries, both classified as dislocation, presenting in the same patient. **A,** A lateral radiograph of the right knee demonstrates an anterior dislocation. On examination, the patient was noted to have sustained an anterior cruciate ligament/posterior cruciate ligament/medial collateral ligament (ACL/PCL/MCL) injury (knee dislocation [KD] III-M). **B,** An anteroposterior view of the left knee on initial presentation shows the knee is reduced. On physical examination, the injury pattern involved the ACL/PCL/fibular collateral ligament (FCL) (KD III-L-C). **C,** An arteriogram of the right knee reveals good flow through the popliteal artery. **D,** An arteriogram of the reduced left knee demonstrates complete occlusion of the left popliteal artery and hence required revascularization. (From Wascher DC. High-energy knee dislocations. In: Drez D Jr, DeLee JC, eds. *Operative Techniques in Sports Medicine*, vol 11. Philadelphia: Saunders; 2003: 235-245.)

the tibia is positioned anterior to the femoral condyles. Kennedy identified five types of knee dislocation: anterior, posterior, lateral, medial, and rotatory. Rotatory dislocations were further subdivided into four groups: anteromedial, anterolateral, posteromedial, and posterolateral.[8,10,20,21] This classification system has been widely used in the literature.[6,8,13,16,20-22,29,31,32,34]

The position classification system can help the physician plan a reduction maneuver for the dislocated knee. However, most knee dislocations can be easily reduced with longitudinal traction. The position classification system can also be useful to alert the clinician to the possibility of coexisting injuries. For example, studies have shown a higher incidence of popliteal artery injury in anterior dislocations.[14]

FIG 21-2 This patient presented with a posterior cruciate ligament–intact knee dislocation. Note how the tibia is perched anterior on the distal femur. This type of injury would be classified as KD I according to the anatomic classification system, to be discussed later.

CRITICAL POINTS Position Classification System

The position classification system is based on the tibial position with respect to the femur.

Uses

- For a posterolateral knee dislocation, the position classification alerts the clinician to the injured structures and the means of treating the injury.
- The position classification system can help the physician to plan a reduction maneuver for the dislocated knee, although most knee dislocations can be easily reduced with longitudinal traction.
- The position classification system can alert the clinician to the possibility and type of co-existing injuries (neurovascular), although vascular injury can occur with any position of knee dislocation.

Limitations

- Up to half of knee dislocations are unable to be classified.
- Reduced knees cannot be described within the structure of the position classification system.
- The position classification system does not give any information about what structures (ligamentous, neurovascular) have been injured and what treatment is required, with the exception of the posterolateral dislocation.

Knowledge of the position of dislocation along with an understanding of the biomechanics of the knee may also provide the clinician with useful information regarding the type of arterial injury. Anterior dislocation often causes arterial stretch injuries and resultant intimal tears, with possible delayed progression to thrombosis and limb-threatening distal ischemia. Posterior dislocations predispose to popliteal artery disruptions largely because of the popliteal artery's fixed tethers proximally at the adductor hiatus and distally at the fascial arch of the soleus.[7] However, any type of vascular injury can occur with any position of knee dislocation and one must have a high index of suspicion for associated acute and delayed vascular injuries in any dislocated knee, regardless of position. Although knowing that anterior dislocation carries an increased risk of vascular injury and that arterial stretch injuries may have a delayed clinical presentation is helpful to the clinician, information is not provided regarding which structures (ligamentous, neurovascular) have been injured and what treatment is required.

Another example of the use of the position classification is the rare but important posterolateral dislocation (Fig. 21-3). The mechanism of injury is an abduction force to a flexed knee coupled with internal rotation of the tibia. This force causes the medial femoral condyle to "buttonhole" through the medial capsule and the MCL invaginates into the knee joint. The trapped condyle and MCL prevent closed reduction. The clinical hallmark of the posterolateral dislocation is a transverse furrow seen on the medial aspect of the knee.[10,21] Peroneal nerve palsy, theoretically resulting from a traction injury to the nerve over the lateral femoral condyle, is frequently associated with this type of dislocation. Skin necrosis secondary to pressure from the medially displaced femur has also been reported. For a posterolateral knee dislocation, the position classification system alerts the clinician to the injured structures (ACL, PCL, or MCL) and the means of treating the injury (open reduction).

The major limitation of the position classification system is that up to half of knee dislocations are unable to be classified. Knees that present with a spontaneous reduction or that have been reduced in the field cannot be described. The clinician does not have information regarding damaged ligaments nor of the possibility of coexisting vascular or nerve injury. Even more dangerous is the fact that because this injury is not included in the position classification system, the inexperienced physician may not recognize the reduced knee dislocation as a significant ligamentous injury and will not undertake the rigorous vascular examination required to detect a popliteal artery injury.

ENERGY OF INJURY CLASSIFICATION SYSTEM

Knee dislocations have also been classified by the degree of energy imparted to the knee joint. Most commonly, knee dislocations result from high-energy mechanisms such as motor vehicle wrecks, industrial accidents, and falls from a height (Fig. 21-4). The injury mechanisms in high-energy knee dislocations often cause significant associated head, chest, abdominal, and extremity injuries as well as soft tissue injury about the affected knee. Many of these injuries can be life threatening and their management takes precedent over the knee ligaments. Regardless of the energy of injury, the clinician must remain vigilant about the possibility of a popliteal artery injury in any knee dislocation. The orthopedic surgeon must be alerted to the possibility of other life-threatening trauma in a patient with a knee dislocation. Conversely, trauma surgeons must include a gross assessment of knee stability in all patients involved in high-energy injury mechanisms. The risk of vascular and nerve injury is increased in high-energy knee dislocations.[14,18,29,38]

Knee dislocations can also occur from low-energy trauma such as that seen in sports activities or in minor falls from low heights. Sports where knee dislocations are occasionally encountered include football, rugby, horseback riding, and alpine sports such as skiing or snowboarding. Patients who sustain low-energy knee dislocations rarely

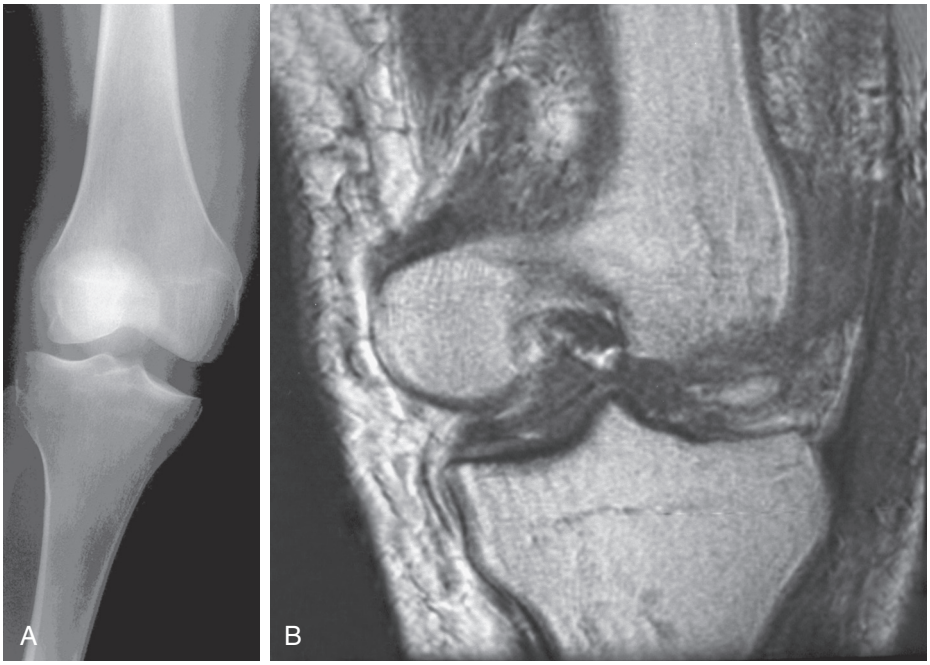

FIG 21-3 Anteroposterior radiograph (**A**) and magnetic resonance image (**B**) of a posterolateral dislocation. The injury pattern involved the anterior cruciate ligament/posterior cruciate ligament/medial collateral ligament and included damage to the peroneal nerve (KD III-M-N).

FIG 21-4 This patient sustained a severe dashboard injury in a high-speed car accident. He presented with a severe open knee dislocation, with rupture of the anterior cruciate ligament/posterior cruciate ligament/fibular collateral ligament and posterolateral capsule (KD III-L). (From Wascher DC. High-velocity knee dislocation with vascular injury: treatment principles. In Miller MD, Johnson DL., eds. *Clinics in Sports Medicine: The Dislocated Knee*, vol. 19. Philadelphia: Saunders; 2000:467.)

CRITICAL POINTS Energy of Injury Classification System

The energy of injury classification system is based on the degree of energy imparted to the knee joint.

Uses

- The energy of injury classification system often dictates management of the dislocated knee (early versus delayed treatment).
- High-energy knee dislocations (e.g., motor vehicle accident) alert the physician to the increased risk of vascular and nerve injury, although vascular injury can occur regardless of the energy of injury.
- Ultra-low-velocity knee dislocations may act more like high-energy injuries, with a high incidence of vascular injury and poorer clinical outcomes. A high clinical suspicion is required to avoid missed injuries and to optimize management.

Limitations

- The energy of injury classification system categories are somewhat arbitrary.
- The energy of injury classification system does not alert the orthopedic surgeon as to which knee structures (ligamentous, neurovascular) have been injured and what treatment is required.

have associated traumatic injuries. Although the risk of vascular injury is lower in low-energy mechanisms, the physician must still be vigilant in assessing the popliteal artery in all patients with a knee dislocation.

In the past, knee dislocations have been described as low- or high-velocity injuries.[29] Recently, Azar and colleagues[3] proposed a third group of patients presenting to emergency departments with increasing frequency. These are morbidly obese individuals who present with a dislocated knee from a fall from standing height or from stepping awkwardly. They termed this group *ultra-low-velocity (ULV) knee dislocation*.[3,40] These patients tend to have a body mass index (BMI) greater than 48 kg/m^2 and are more commonly female. Because $E_k = 1/2mv^2$, the large mass in these patients can still produce enough energy to dislocate the knee despite the very low velocity involved. Reports regarding this cohort of patients are largely responsible for the increased incidence of vascular injury among knee dislocations because they are much more likely to have associated vascular and neurologic injury than even high-velocity knee dislocations. Recent literature has

reported popliteal artery injury and neurologic injury rates as high as 43% in this population.[3] Initial examination and imaging (magnetic resonance imaging [MRI]) is often limited because of body habitus, and postoperative rehabilitation and bracing are often challenging given body habitus and limited mobility. This group presents specific challenges at presentation and throughout treatment that require clinical diligence to minimize complications and to maximize treatment outcomes.

It is our opinion that the term *energy*, rather than the term *velocity*, more accurately describes the injury mechanism. Notwithstanding the mechanism, the energy of injury often dictates management of the dislocated knee. The associated injuries in high-energy dislocations frequently preclude early operative management of the knee ligaments. Initial management of the knee dislocation in a patient with multiple injuries commonly includes the use of external fixation spanning the knee joint to stabilize the knee in a reduced position and to facilitate patient transport and positioning. The use of an external fixator to maintain reduction and allow some soft tissue healing must be balanced against the risk of arthrofibrosis with prolonged use. Delayed treatment of high-energy dislocations often requires collateral ligament reconstruction in addition to reconstruction of both cruciate ligaments. Conversely, low-energy dislocations can frequently undergo early operative intervention. The collateral ligaments can often be primarily repaired or reconstructed, yielding superior results compared to that obtained with delayed reconstruction. ULV knee dislocations present additional treatment challenges. These patients tend to do poorly with nonoperative treatment, but their size and medical comorbidities (diabetes mellitus, compromised circulation, and cardiopulmonary disease) make surgical treatment difficult and risky. Patients who sustain ULV knee dislocations have been shown to have higher rates of surgical complications, including reoperation rates, wound infection, deep venous thrombosis, vascular claudication, and above-knee amputation. In addition, this cohort has demonstrated poorer outcome scores compared with low-velocity dislocations.[3]

One of the problems with the energy of injury classification system is that the categories are somewhat arbitrary. If a patient sustains a knee dislocation when hit by a slow-speed car in a parking lot, is this a high- or low-energy dislocation? What about a patient who falls off a roof or a high tower? At what weight does a ULV dislocation become high-energy? Although it is useful for the clinician to think in terms of the energy imparted to the knee, ultimately it is the pattern of ligamentous injury, the presence or absence of neurovascular injuries, and the overall clinical assessment that will dictate treatment of the knee dislocation. A morbidly obese patient with a major psychiatric illness who dislocates a knee slipping on a wet bathroom floor (low-energy dislocation) may be treated definitively with external fixation. Conversely, an athletic patient with an isolated knee dislocation from a motorcycle wreck (high-energy dislocation) might be best treated by early ligament repair or reconstruction. Finally, the energy of injury classification system does not assist the orthopedic surgeon in planning which knee structures need to be repaired or reconstructed.

ANATOMIC CLASSIFICATION SYSTEM

A classification system for knee dislocations has been described and is based on which ligamentous structures are torn.[35] The ligament anatomy of the knee is complex, with many injury patterns possible when a knee dislocation occurs.[26,27,39] Conceptually, the knee can be separated into four simply identifiable structures: the ACL, the PCL, the medial ligamentous structures, and the posterolateral corner. The medial structures include the superficial and deep MCL as well as the oblique popliteal ligament, semimembranosus, and posteromedial capsule. The posterolateral corner is primarily composed of the fibular (lateral) collateral ligament, the popliteofibular ligament, the popliteus tendon, and the lateral joint capsule. This simplistic representation of knee anatomy can be useful to the clinician in planning treatment of a dislocated knee.

To classify a knee dislocation by the injured anatomy, it is important to obtain a complete assessment of the injured knee. The clinician must perform a thorough physical examination of the knee on initial presentation to the emergency room or office. At a minimum, this should include a Lachman test, a posterior drawer test, varus and valgus stress testing at 0 degrees and 30 degrees, and a spin or dial test at 30 degrees and 90 degrees in the prone and supine positions.

A thorough neurovascular examination must also be performed and repeated at regular intervals. Vascular evaluation using angiography has previously been recommended for all knee dislocations. In addition to complete arterial transections or occlusions, angiography has the ability to identify intimal flap tears. Because of the morbidity and cost of angiography, Stannard and colleagues[33] have proposed the use of selective angiography. They have suggested a protocol that uses angiography only when triggered by abnormal ankle brachial indices (ABIs) or change/asymmetry in serial examination performed at regular intervals for 48 hours by both nursing staff and the on-call physician.[33] This vascular screening protocol has a very high sensitivity for identifying clinically significant arterial injury.[9] In addition, many patients with high-energy knee dislocations have associated injuries that are evaluated by computed tomography (CT) scanning. In these patients, it is relatively easy to simultaneously perform a CT angiogram to evaluate the popliteal artery. It has been shown that multislice CT angiography is an alternative to the traditional gold standard of catheter-based angiography that is both sensitive and specific for arterial evaluation in the injured lower extremity.[12]

CRITICAL POINTS Anatomic Classification System

The anatomic classification system for knee dislocations is based on the anatomic structures injured.

- The anatomic classification system requires a thorough ligamentous and serial neurovascular assessment of the knee, consisting of three parts: an initial examination in the trauma room or office, a preoperative magnetic resonance imaging study, and an examination under anesthesia at the time of surgery.
- The anatomic classification system describes five major ligamentous injury patterns and associated neurovascular injury (if applicable).

Advantages

- All knee dislocations can be adequately described by the anatomic classification system, even those presenting as reduced.
- No judgment is required for placing a dislocated knee within a specific group.
- The anatomic classification system has the ability to help guide the clinician in treatment by simple and accurate identification of the injured structures and planning of surgical intervention.
- The anatomic classification system rapidly communicates the extent of the injuries among clinicians and allows for comparisons of like injuries in the wide spectrum of knee dislocations.
- The anatomic classification system helps the clinician predict outcomes in the treatment of dislocated knees.

A complete neurologic examination may be difficult in a patient with head trauma, but in most cases, a gross assessment of tibial and peroneal nerve function can be obtained. As soon as the patient's overall condition allows, we recommend obtaining an MRI of the knee to better assess the degree and location of ligament injuries. Authors[23] have commented on the use of MRI in the evaluation of ligament injury in knee dislocations. Certain injuries (e.g., the presence of a PCL peel-off injury or a popliteus tendon avulsion) can only be accurately detected preoperatively by MRI. Knowing preoperatively which ligaments are torn and detecting the presence of avulsions can help the surgeon plan the number and types of allograft required and the fixation devices necessary to restore functional stability to the knee.[25,28,36] The final and most critical assessment of knee ligament function occurs with an examination under anesthesia (EUA) at the time of knee reconstruction. The EUA provides a final assessment of the degree of translation, the presence of an endpoint on ligament stress testing, and the overall functionality of the specific ligamentous structure. Although MRI can identify which ligaments are injured, the EUA gives an accurate assessment of the functional status of the injured knee ligaments.[1,11,27,30,37] In the dislocated knee, partial ligament tears can sometimes be treated nonoperatively. To summarize, the assessment of the dislocated knee consists of four parts: an initial examination in the trauma room or office, vascular imaging or serial neurovascular exams, a preoperative MRI, and an EUA at the time of surgery.

The anatomic classification of knee dislocation (KD) is a simple system based on which ligaments are torn. Five major injury patterns may occur (Table 21-1). Injuries are classified by roman numerals; in general, higher-number injuries have sustained greater trauma than lower-number injuries. A *KD I* injury is a cruciate-intact knee dislocation and includes both PCL-intact and ACL-intact injuries (see Fig. 21-2). A *KD II* injury is a bicruciate injury with functionally intact collateral ligaments (Fig. 21-5). *KD III*, the most common injury pattern, involves tears of both cruciate ligaments and one of the collateral ligaments. These injuries are further subdivided into medial (KD III-M; Fig. 21-6) or lateral (KD III-L; Fig. 21-7) injuries. A *KD IV* injury involves complete disruption of all four major knee ligaments (Fig. 21-8). Finally, the *KD V* injury group involves a knee dislocation with the presence of a major periarticular fracture and is described by other authors as a fracture-dislocation of the knee (Fig. 21-9).[17,28] Fracture-dislocations of the knee involve a ligamentous injury to the knee in association with a major fracture of the tibial plateau or femoral condyles that further destabilize the knee joint. Although avulsion injuries are frequently seen in purely ligamentous knee dislocations (arcuate avulsion fractures, tibial spine avulsions, or Segond fractures), they should be classified as a ligamentous injury in one of the first four categories, despite the small fracture present.[6,32]

TABLE 21-1 Anatomic Classification of Knee Dislocations

Class*	Injury
KD I	PCL- or ACL-intact KD, variable collateral involvement
KD II	Both cruciate ligaments torn, collaterals intact
KD III	Both cruciate ligaments torn, one collateral torn, subset M or L
KD IV	All four ligaments torn
KD V	Periarticular fracture-dislocation

*Subtypes are C for arterial injury and N for nerve injury.
ACL, Anterior cruciate ligament; *KD*, knee dislocation; *L*, lateral; *M*, medial; *PCL*, posterior cruciate ligament.

The final component of the anatomic classification is the use of additional labels to identify associated neurovascular injuries. A subtype C indicates a significant arterial injury and alerts the clinician to the need for revascularization of the limb. A subtype N indicates a peripheral nerve injury, either the tibial nerve or, more commonly, the peroneal nerve. This N subtype is used for any neurologic deficit (neurapraxia, neurotmesis, or axonotmesis). For example, a dislocated knee with complete tears of the ACL, PCL, and posterolateral corner with an associated popliteal artery injury and a peroneal nerve palsy would be classified as a *KD III-L-CN*.

The anatomic classification has significant advantages over older classifications. Unlike the position classification, all knee dislocations can adequately be described by the anatomic classification system. Even knee dislocations presenting as reduced can be classified after a physical examination and MRI have identified the torn ligaments and associated injuries. In contrast to the energy of injury classification system, no judgment is required for placing a dislocated knee within a specific group. If a ligament is injured and functionally incompetent, it is "torn" for the purposes of the anatomic classification system. Most important, however, is the ability of the anatomic classification system to help guide the clinician in treatment. The surgeon can readily identify the injured structures and can then proceed to plan how best to "fix what is torn." The anatomic classification rapidly communicates among clinicians the extent of the injuries and allows for comparisons of similar injuries in the wide spectrum of knee dislocations. At our institution, residents and attending physicians quickly describe the ACL/PCL/MCL knee injury as a KD III-M. The injury diagnosis and ligamentous involvement are easily communicated. Here are a few additional examples of the usefulness of the anatomic classification: The C subtype quickly alerts the physician to the need for urgent vascular surgery to restore flow to the ischemic limb. A KD II injury has functionally intact collateral ligaments and can be treated just as successfully with either an early or a delayed reconstruction of the cruciate ligaments. Studies of the degree of injury show that KD III-M

injuries more frequently have complete deep MCL tears and posterior oblique ligament tears compared with KD IV injuries, which may aid in the decision of medial-side reconstruction versus nonoperative management.[41] A KD IV injury identifies a knee with severe instability that may require external fixation to maintain joint reduction before ligament reconstruction.

Finally, the anatomic classification system will help the clinician predict outcomes in the treatment of dislocated knees. On average, knees with higher roman numeral classification will have inferior outcome scores. For example, KD III-M knees have better Lysholm scores than KD IV knees.[41] Likewise, it has been shown that KD III-L injuries fare worse than KD III-M injuries.[5,35] Knee dislocations with neurovascular injuries (subtypes C or N) are also more likely to have unsatisfactory outcome measurements. KD V injuries are associated with a high complication rate related to the increased incidence of arterial injury, inadequate fracture reduction, or difficulty in achieving a satisfactory ligament reconstruction.

CONCLUSION

Successful treatment of the dislocated knee requires a thorough understanding of the knee injury. Older classification systems are not able to categorize all knee dislocations, do not guide treatment, and are not predictive of outcome. The anatomic classification we have used for the past 20 years readily allows the physician to classify all knee dislocations on the basis of the injured structures identified by physical examination and imaging studies. This simple system helps the surgeon plan treatment of the dislocated knee and has been predictive of outcomes in published reports. Hopefully, more widespread use and reporting of this classification system in future series of knee dislocations will yield additional insight into the optimal treatment of these uncommon yet challenging injuries.

INTRODUCTION

Knee dislocations are uncommon but serious injuries. These injuries not only pose a potential threat to the limb involved, but often result in long-term pain and functional disability. What was thought to be an injury pattern caused by high-energy collision in motor vehicles or in collision sports, has also emerged as a common diagnosis in the ever-increasing obese population. Although diagnosis and initial management principles have progressed over the past several decades, ultimate treatment strategies remain controversial. Having a high index of suspicion and taking the right steps in initial evaluation and management are paramount to maximize potential outcomes and avoid disastrous consequences associated with these complex injuries.

EVALUATION

Knee dislocations are typically the result of high-energy, violent trauma. Therefore the initial evaluation should always begin in the same fashion as that for a polytrauma patient. Where appropriate, a primary survey consisting of assessment of the patient's airway, breathing, and circulation (ABCs) is performed first. The secondary survey seeks life-threatening injuries and conditions. Polytrauma patients require a thorough neurologic and vascular examination, followed by an assessment of the chest, abdomen, and pelvis in addition to a detailed musculoskeletal examination of the extremities and spine. Whenever possible, the medical history should be reviewed while the patient is assessed for common polytrauma conditions, such as hypovolemia and concussion. Once the basics of trauma care have been attended to, the injured extremity should be carefully examined.

The vascular and neurologic examinations are of utmost importance and are detailed in the following sections. Starting with visual inspection, all open injury sites should be identified and cleansed. Palpation of bony prominences, areas of soft tissue swelling, and key insertion sites provides important information. If possible, the extensor mechanism should be tested to ensure the status of the quadriceps and patellar tendon. If the patient is unconscious or cannot cooperate, these structures should undergo magnetic resonance imaging (MRI) followed by a physical examination, when possible. Lastly, a complete ligament examination is conducted to assess the anterior cruciate ligament (ACL), posterior cruciate ligament (PCL), fibular collateral ligament (FCL), medial collateral ligament (MCL), and posterolateral and posteromedial structures using translation and rotation testing. Stress view imaging may be helpful, but may not be appropriate in the acute setting.

CRITICAL POINTS Evaluation

- Polytrauma patients require a thorough neurologic/vascular examination followed by an assessment of the chest, abdomen, and pelvis along with a detailed musculoskeletal examination of the extremities and spine.

CLASSIFICATION

A patient with two or more torn major ligaments may have sustained a knee dislocation.[78] This definition accounts not only for those knees that are dislocated at the time of evaluation but also for those that have spontaneously reduced. Clinically, the degree of ligament disruption can be misleading. Because ligaments may not appear completely disrupted, especially on MRI, the severity of these injuries can be easily underestimated.

The following variables are the basis for classification and complete description of a dislocated knee: (1) direction of dislocation, (2) open or closed, (3) high- or low-energy trauma, and (4) time from dislocation.[25] Schenck[72] has also recommended that the extent of ligamentous injury be included in the classification of knee dislocations (see Chapter 21).

The direction of dislocation may be unidimensional (anterior, posterior, medial, or lateral) or a rotatory combination. If the knee has spontaneously reduced, classification is based on direction of instability.[67] Anterior dislocations caused by hyperextension of the knee are the most common, occurring in 40% according to Green and Allen's review[26] of 245 knee dislocations. Posterior dislocations, often caused by a high-energy dashboard mechanism, accounted for 33% of the cases. Medial and lateral dislocations were present in 18% and 4% of the cases, respectively.

CRITICAL POINTS Classification

- A patient with two or more torn major ligaments may have sustained a knee dislocation.
- Because ligaments can stretch and may not appear completely disrupted, especially on magnetic resonance imaging, the severity of these injuries can be easily underestimated.

In 1963, Kennedy's biomechanic study[38] in cadavers elucidated the mechanisms for both anterior and posterior dislocations. This investigation demonstrated that by progressively hyperextending the knee, the posterior capsule ruptured followed by the posterior cruciate ligament (PCL) and the anterior cruciate ligament (ACL). Without adequate ligamentous restraint, the knee dislocated in an anterior direction. A high posteriorly directed force on the proximal tibia in knee flexion caused a posterior dislocation.

Posterolateral dislocations are the most common type of rotatory dislocations. The flexed and weight-bearing knee undergoes a sudden rotatory moment that abducts and internally rotates the lower leg on the femur.[65] This causes the medial femoral condyle to "buttonhole" through the anteromedial capsule, which may be irreducible. Inspection of the knee will reveal a transverse groove in the skin along the medial joint line secondary to invagination of the medial capsule. This "dimple sign" becomes more prominent with attempted reduction and is pathognomonic of the irreducible posterolateral dislocation.[25,59,66,69,71]

Open dislocations of the knee are emergencies that require antibiotics and urgent irrigation and debridement in the operating room. Open injuries, present in 19% to 35% of knee dislocations, are most commonly seen with anterior and posterior mechanisms.[54,79]

VASCULAR INJURIES

Knee dislocations associated with arterial trauma are limb-threatening injuries. The incidence of popliteal artery disruption during a knee dislocation is 32% to 45%.[26,35] Delay in diagnosis longer than 6 to 8 hours is associated with an increasing amputation rate.[26,35] Because of the high rate of injury and the devastating consequences associated with a delay in diagnosis, it is imperative to recognize vascular injuries early.

It is not clear yet how many vascular injuries require surgery, but several recent studies have sought to answer this question. In a nationwide population-based study in Finland between 1998 and 2011, the occurrence of popliteal injury requiring surgical interventions was 1.6%.[80] Using the Finnish Hospital Discharge Register and International Classification of Diseases, Tenth Revision (ICD-10) diagnoses, this study extracted all adult patients who were admitted to Finnish hospitals with an acute knee dislocation and characterized them further based on the presence and type of operation performed. A total of 837 patients over this 14-year period were hospitalized with a primary or secondary diagnosis of acute knee dislocation and 84% required some form of surgical intervention. Of the 1.6% (13) of patients who had a vascular injury requiring surgical repair, all involved the popliteal artery. The surgeries performed included bypass surgery from the femoral artery to the distal popliteal artery (nine cases), direct repair of the popliteal artery (one case), and a nonspecified bypass operation (three cases).[80]

Another recent study, with differing results was a systematic review by Medina et al.[51] After an initial Medline search for "knee dislocation" and "multiligament knee," 15 studies met the final inclusion criteria, totaling 862 patients. The frequency of vascular injury was 20% (171 of 862), and 84% (134 of 160) underwent surgical intervention. Seventy-six percent of the studies reported injury to only the popliteal artery; other vessels included the medial genicular artery, anterior tibial artery, posterior tibial artery, superficial femoral artery, and common femoral artery. Of the 134 vascular injuries requiring surgical repair, 22 underwent amputation, yielding an amputation frequency of 12% for those with popliteal artery injury. The majority (73%, 16 of 22) of amputations were performed because of infection or ischemia subsequent to failed vascular repair, while the remainder of amputations were performed at presentation because of prolonged ischemia or complete neurovascular disruption. The Schenck and Kennedy[38,74] knee dislocation classifications with the highest vascular injury prevalence involved the ACL, PCL, and lateral collateral ligament (KD III-L, 32%) and posterior dislocation (25%).[51]

CRITICAL POINTS Vascular Injuries

- Arterial trauma associated with knee dislocations are limb-threatening injuries. The incidence of popliteal artery disruption during a knee dislocation is 32% to 45%. Delay in diagnosis longer than 6 to 8 hours is associated with an increasing amputation rate.
- The diagnosis of a vascular injury should be made on the assimilation of a variety of clinical and diagnostic tests: physical examination, ankle/brachial index (ABI), and arteriography.
- The presence of pulses with a warm foot is not a guarantee that an arterial injury is not present.
- An ABI of less than 0.90 is abnormal and should prompt arteriography. A selective angiography algorithm has become the gold standard in vascular injury assessment and management in the setting of acute knee dislocations.
- Hard signs for emergent surgical exploration with or without angiography include absent distal pulses, active hemorrhage, and/or expanding pulsatile hematoma.
- Clinicians should be aware that not all arterial trauma is detectable with arteriography. Stretch injuries of the intimal wall and small intimal flap tears may not be visualized on the arteriogram but may subsequently clot and result in arterial occlusion.

Despite the continued discrepancy in the true frequency of vascular injuries requiring surgical intervention, an abnormal vascular examination should prompt imaging and/or an immediate vascular surgery consultation.

The popliteal artery is at risk of injury during a knee dislocation owing to its anatomic location (Fig. 22-1). The popliteal artery is tethered proximally by the adductor hiatus and distally by the soleus arch. The artery bifurcates into the anterior and posterior branches at the soleus arch. Collateral circulation in the form of the genicular arteries originates within the popliteal fossa. The geniculate arterial system is usually not sufficient to perfuse the limb should there be obstruction or transection of the popliteal artery.[25,61] Anterior dislocations of the knee can place significant traction on the popliteal artery, leading to extensive intimal injury and/or vasospasm (Fig. 22-2).[26] Posterior dislocations can result in complete transection of the artery (Fig. 22-3).[62]

The diagnosis of a vascular injury should be made on the assimilation of a variety of clinical and diagnostic tests including physical examination, ankle/brachial index (ABI), and arteriography. The dorsalis pedis arterial pulse is palpated on dorsum of the foot, and the posterior tibial arterial pulse is palpable posterior to the medial malleolus. The presence of these pulses with a warm foot is not a guarantee that an arterial injury is not present. There are multiple reports of vascular occlusion or intimal tears with normal distal pulses; the incidence is 5% to 15%.[1,35,49,87] In 2004, Barnes and coworkers[6] performed a meta-analysis that included 284 multiligamentous knee injuries in

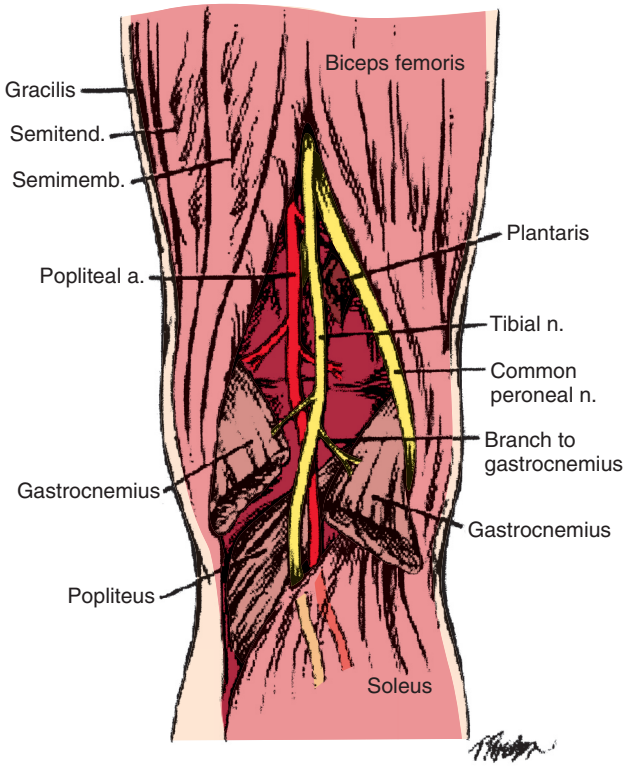

FIG 22-1 Schematic diagram of the sciatic, tibial, and common peroneal nerves and their relationship to the other structures in the popliteal fossa. *a,* Artery; *n.*, nerve; *semimemb.*, semimembranosus; *semitend.*, semitendinosus. seven studies. Seven of 52 patients requiring vascular surgery had normal pulses on presentation. Thirteen of 140 patients with normal pulses who underwent arteriography had nonocclusive intimal defects that were safely observed. Abnormal pulses had a sensitivity rate of 0.79 (95% confidence interval [CI], 0.64-0.89), specificity rate of 0.91 (95% CI, 0.78-0.96), positive predictive value of 0.75 (95% CI, 0.61-0.83), and a negative predictive value of 0.93 (95% CI, 0.85-0.96). The low sensitivity and specificity may be associated with hypotension in the acutely traumatized patient, as well as intimal lesions that may initially present with normal pulses.

The ankle brachial index (ABI) is the second diagnostic tool that should be used and requires little technology. It is easy to perform, readily available, and capable of detecting serious vascular injuries and conditions. ABIs are determined by measuring the systolic blood pressure for all four extremities using a Doppler probe and a standardized blood pressure cuff. For the lower extremity, the systolic pressure is measured at the posterior tibial and dorsalis pedis arteries. The ABI is then calculated by dividing the highest measured pressure in the ankle or foot by the higher of the brachial arterial pressures. An ABI of less than 0.90 is considered abnormal and should prompt arteriography. In 2004, Mills and associates[55] demonstrated that 11 of 11 patients with ABIs less than 0.90 required a reverse saphenous vein graft for popliteal artery injury (3 popliteal artery transections, 6 popliteal artery occlusions, 1 common femoral and peroneal artery thrombosis, and 1 high-grade superficial femoral artery occlusion with intimal flap altering popliteal artery flow). None of the 27 patients with ABIs greater than 0.90 had evidence of vascular injury by serial examination or duplex ultrasonography. The sensitivity and specificity was 100%, making this an outstanding diagnostic test for serious vascular injuries and/or conditions.[55] In 1998, Cole and colleagues[11] evaluated 70 consecutive patients with blunt trauma and found no arterial injury with ABI greater than 0.90, whereas an ABI lower than 0.90 had a positive predictive value of 88%. Lynch and Johansen[46] studied blunt and penetrating trauma in 100 consecutive patients and found an ABI less than 0.90 predicted vascular surgery with a sensitivity of 87%, specificity of 97%, and positive predictive value of 91%.

Arteriography, developed in the 1960s, has improved outcomes and reduced the number of negative explorations. Many authors have

advocated routine use of arteriography to evaluate the limb after a suspected knee dislocation.[1,13,26,37,38,44,48,49,94] The routine use of arteriograms for suspected knee dislocations is justified by the relative low morbidity of the test, the high incidence of popliteal injury, and the devastating consequences of a delay in diagnosis.[67] However, clinicians should be aware that not all arterial trauma is detectable with arteriography. Stretch injuries of the intimal wall and small intimal flap tears may not be visualized on the arteriogram but may subsequently clot and result in arterial occlusion. Those patients whose conditions worsen usually do so within the first 3 months, but more commonly, within a week after injury. McDonough and Wojtys[50] reported on three patients with normal initial arteriograms. Two patients who had a loss of pulse after tourniquet release during ligament reconstruction were found to have chronic intimal flaps with thrombi at immediate revascularization. One patient developed a pseudoaneurysm, which was recognized by a second arteriogram undertaken after significant postoperative swelling.[50] These "silent injuries" should be a consideration in the evaluation of a patient for acute surgical repair and/or the use of a tourniquet.

Arteriograms can be performed in the operating room if there are obviously diminished pulses or if the delay in obtaining a formal arteriogram in the angiography suite would compromise limb survival. Six to 8 hours of warm ischemic time will significantly compromise a lower extremity.[26] Formal angiography is performed with a femoral artery puncture followed by insertion of a pigtail catheter. Next, a bolus of contrast is injected and an angiographic unit is used to capture images. The length of the segment to be imaged determines the number of acquisitions needed. Intraoperative arteriogram can be performed by injecting 45 mL of contrast through an 18-gauge catheter with a single film exposure[52] or a vascular fluoroscopic unit.

Unfortunately, arteriography is not without risks, costs, and false-negative results. The complication rate has been reported to be 1.7% and includes thrombosis, arteriovenous fistulae, bleeding, renal failure, reaction to contrast material, and pseudoaneurysm formation.[3,39,55,87,93] The reported false-positive results have ranged from 2.4% to 7%, which could lead to unnecessary surgical intervention.[3,84,87,93] The cost of the arteriograms ranged from $750 to $1500 per study in 1990; a more recent figure was $5240 in 2003.[3,84,87]

The recent systematic review and meta-analysis performed by Medina et al.[51] revealed that the most frequently (61%) used diagnostic modality for vascular injury is selective angiography. Although protocols vary with respect to the time of observation required, frequency of physical examination, and whether adjunctive tests are used, they can rule out a clinically significant vascular injury.[37,47,56,57,84,87] Many protocols for selective angiography dictate that in acute knee dislocations with symmetric distal pulses and normal ABIs, patients should be admitted for at least 24 hours' duration for observation and serial physical examination. The algorithm used at the University of Washington and Harborview Medical Center is the most frequently cited in current literature (Fig. 22-4).[56,57,84]

In addition to formal angiography, new techniques such as computed tomographic angiography (CTA) and magnetic resonance angiography (MRA) are being developed. These techniques make use of readily available imaging techniques, often with a bolus of contrast to define the lower extremity arterial system. Potter and coworkers[64] demonstrated 100% correlation between conventional angiography and MRA in a small cohort of patients (six patients: four normal, one intimal tear, one decreased flow).

Duplex ultrasonography is a noninvasive and less expensive alternative to arteriography with comparable accuracy in detecting traumatic vascular injury; however, no study specific to knee dislocations has been performed.[7,22] Although not specific to vascular trauma, in general, this modality has limitations in assessing lower extremity vasculature in the morbidly obese.[70]

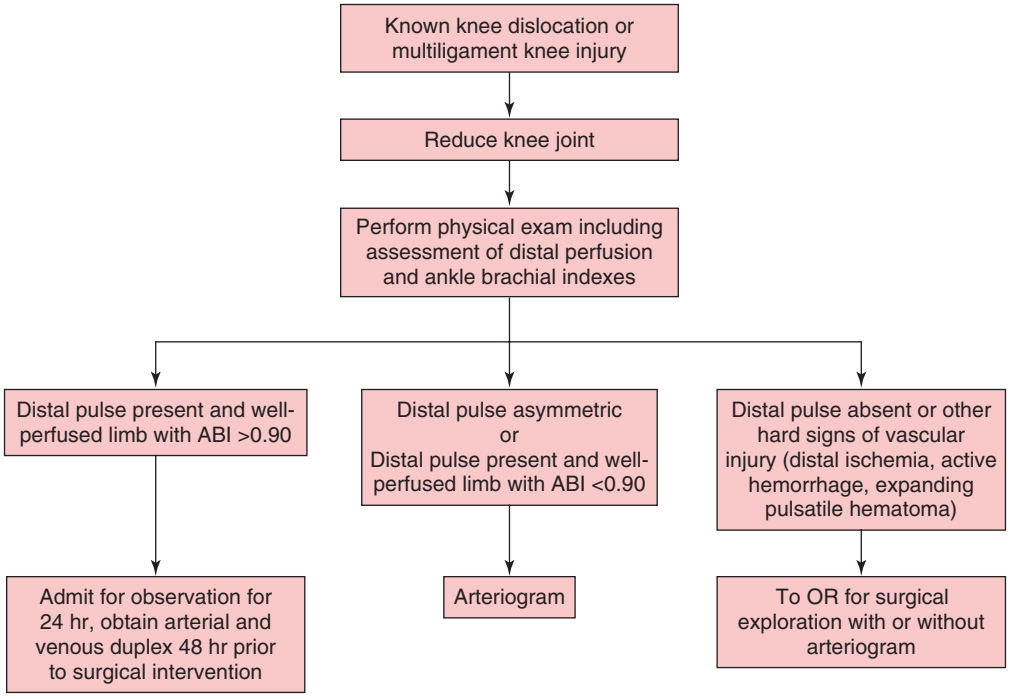

FIG 22-4 University of Washington and Harborview Medical Center algorithm for diagnosis of vascular injury following multiligament knee injuries. *ABI,* Ankle/brachial index; *OR,* operating room. (From Nicandri GT, Dunbar RP, Wahl CJ. Are evidence-based protocols which identify vascular injury associated with knee dislocation underutilized? *Knee Surg Sports Traumatol Arthrosc* 2010;18;1005-1012.)

NEUROLOGIC INJURIES

Neurologic damage occurs in 16% to 40% of knee dislocations.[2,82] This may range from a stretch injury (neurapraxia) to a complete transection (neurotmesis). The peroneal nerve is most commonly injured as it is stretched over the fibular neck during a posterolateral dislocation (Fig. 22-5).[23,68,86,88,94] A common presentation for peroneal nerve injuries is a patient with a drop foot and sensory deficit over the dorsum of the foot. Tibial nerve injury associated with a popliteal artery injury has also been reported.[94] Although difficult, a complete neurologic examination of both lower extremities should be performed both before and after any attempt at reducing a knee dislocation. Repeated examinations are recommended during the course of treatment because there is a potential for nerve compromise caused by soft tissue swelling and compartment syndrome, pressure, immobilization, and/or positioning.

In the posterior mid-thigh, the sciatic nerve divides into the common peroneal nerve and the tibial nerve (Fig. 22-6).[41] The common peroneal nerve courses obliquely through the popliteal fossa, then traverses along the fibular neck in an exposed subcutaneous fibroosseous tunnel.[75,86] This subcutaneous position adjacent to the fibula makes the nerve susceptible to direct contact during sports and to indirect injury during a forced varus stress as it is stretched over the fibular neck.[28] The tibial nerve lies lateral to the popliteal vessels within the popliteal fossa. As it courses distally, it crosses posterior to the vessels and then lies medially. It passes between the two heads of the gastrocnemius muscle and anterior to the arch of the soleus muscle to lie in the deep posterior compartment of the lower leg. Within the popliteal fossa, the tibial nerve gives off several branches. The medial sural cutaneous nerve joins the peroneal communicating branch of the common peroneal nerve to form the sural nerve. The posterior articular branch pierces the posterior capsule to innervate the contents of the knee. Finally, there is a motor branch to the popliteus muscle.[41]

A complete neurologic examination including motor and sensory evaluation of the peroneal and tibial nerve should be well documented before and after any intervention including reductions, surgical procedures, splinting, or casting. The peroneal nerve is divided into superficial and deep branches. The superficial peroneal nerve (lumbar nerve root 5 [L5] and sacral nerve roots 1 and 2 [S1, S2]) controls the peroneal muscles of the foot, which provide foot eversion. The superficial peroneal nerve provides sensation to lateral aspect of the leg and dorsum of the foot. The deep peroneal nerve (L4, L5, and S1) controls the tibialis anterior, extensor hallucis longus, and extensor digitorum longus muscles. This function can be tested manually by having the patient perform resisted ankle dorsiflexion and great and lesser toe

CRITICAL POINTS Neurologic Injuries

- Neurologic damage occurs in 16% to 40% of knee dislocations.
- The peroneal nerve is most commonly injured as it is stretched over the fibular head during a posterolateral dislocation.
- A complete neurologic examination, including motor and sensory evaluation of the peroneal and tibial nerve, should be well documented before and after any intervention including reductions, surgical procedures, splinting, or casting.
- A progressive deterioration in the neurologic examination may indicate compartment syndrome or ischemia.
- Most commonly, nerve injury from a knee dislocation is a stretch injury or lesion in continuity.
- These injuries are observed for 4 to 6 months to allow for spontaneous recovery and/or delineation of the zone of injury.

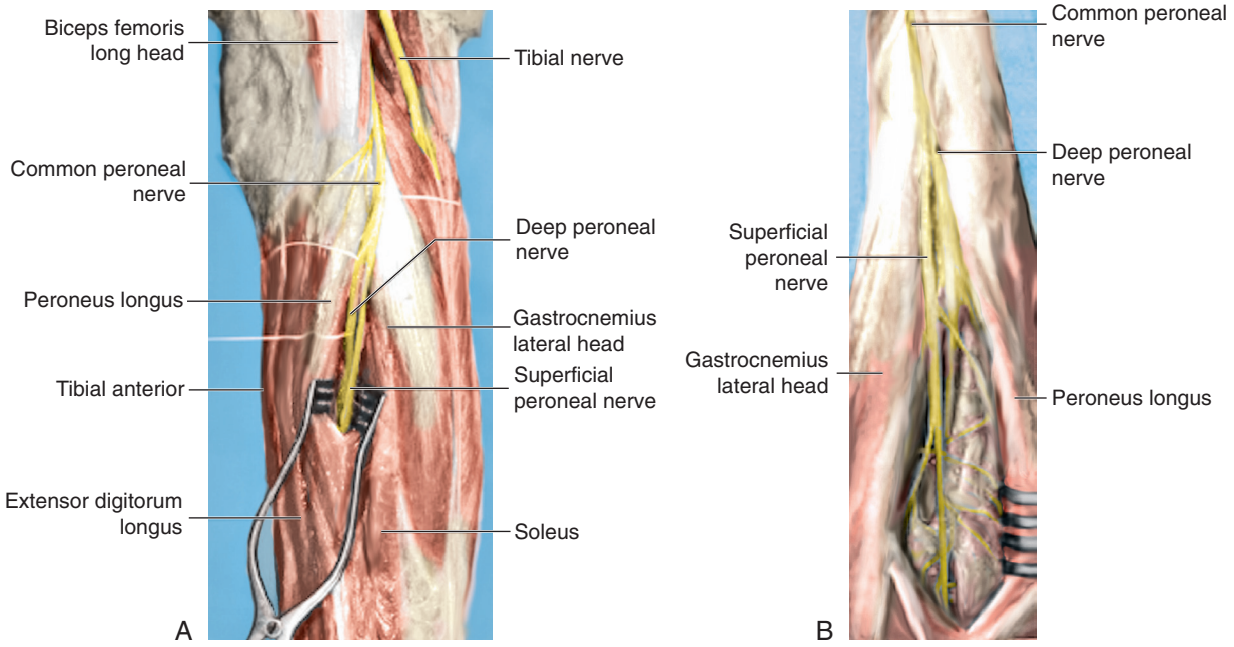

FIG 22-5 **A,** Posterolateral view of a left lower extremity cadaveric microdissection depicts the common peroneal nerve in the distal popliteal fossa and its branches, the superficial and deep peroneal nerves. **B,** Lateral view of a right lower extremity cadaveric microdissection shows the deep peroneal nerve muscular branches supplying the tibialis anterior, extensor digitorum longus, extensor hallucis longus, and peroneus tertius muscles. (From Kim DH, Murovic JA, Tiel RL, Kline DG. Management and outcomes in 318 operative common peroneal nerve lesions at the Louisiana State University Health Sciences Center. *Neurosurgery* 2004;54:1421-1428.)

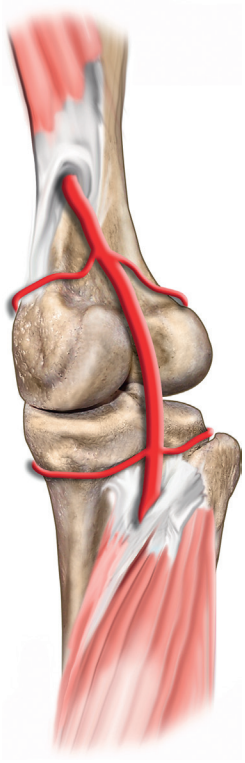

FIG 22-6 Schematic diagram of the popliteal artery.

extension, respectively. Sensory function of the deep peroneal nerve is located primarily within the first web space on the dorsum of the foot. The tibial nerve (L5, S1, and S2) innervates the muscles of the superficial and deep posterior compartments of the leg. The gastrocnemius and soleus muscles are tested by resisted plantar flexion of the foot. The flexor hallucis longus and flexor digitorum longus are tested by having the patient curl his or her great and lesser toes, respectively, and then performing resisted plantar flexion. The tibialis posterior is tested by resisted plantar flexion and inversion of the foot. Sensory distribution for the tibial nerve is located on the plantar aspect of the foot.[31]

Manual muscle testing is graded on a 5-point scale with 0 indicating no muscle activation; 1, muscle activation without joint movement; 2, motion observed when gravity eliminated; 3, motion against gravity; 4, resisted submaximal contraction; and 5, maximal resisted motion. As with the vascular examination, the patient should have frequent neurologic examinations that are well documented. A progressive deterioration in the neurologic examination may indicate compartment syndrome or ischemia.[67] Compartment pressure testing is indicated in this scenario.

Further neurologic studies may be indicated when a nerve deficit is noted on physical examination. These include electromyography, nerve conduction studies (NCS), ultrasonography, and MRI. MRI is more commonly used to identify ligament, meniscal, or articular cartilage injuries. Ultrasonography may be helpful but is definitely operator dependent. Electromyography and NCS cannot differentiate extraneural and intraneural causes of nerve impairment, nor can they distinguish between a damaged but continuous nerve and a completely dissected nerve. These studies are usually used in the subacute or chronic setting.

Ultrasonography of the peroneal nerve is performed with the patient in the prone position and the knee flexed 20 degrees with the ankle positioned in a cushion to allow access to the popliteal region. A 12.5-MHz and 15.7-MHz broadband linear array transducer and a silicone standoff pad are used. Gruber and associates in 2005[28] demonstrated that sonography by experienced technicians reliably demonstrated the state of the nerve and the surrounding soft tissues. Specifically, the level of the lesion and any scar tissue or hematoma that was surrounding the nerve were identified. It correlated precisely with intraoperative findings. It is important to identify a treatment program for peroneal nerve injury associated with dislocation.[21]

Nerve injuries from sharp laceration should be repaired acutely; those from blunt laceration should be delayed 3 to 4 weeks to delineate proximal and distal stump damage. Most commonly, nerve injury from a knee dislocation is a stretch injury or lesion in continuity. These injuries are observed for 4 to 6 months to allow for spontaneous recovery and/or delineation of the zone of injury.[40] Within this time interval, splinting and dedicated therapy with nerve stimulation and reeducation should be instituted. An ankle-foot orthosis (AFO) should be used to maintain the ankle in a neutral position and prevent contracture of the Achilles tendon. Initiating stretching exercises to correct the equinovarus foot positions may help prevent the development of contractures. Baseline electrodiagnostic studies should be performed at 6 weeks and again at 3 months if there has been no clinical evidence of tibialis anterior muscle function.[86]

With ongoing absence of clinical signs of recovery, nerve exploration may be indicated.[25,86] At the time of surgery, nerve action potentials across the lesion are assessed. If conduction is demonstrated, neurolysis can be performed with 80% to 88% recovery of grade 3 muscle strength (peroneal and anterior tibial muscle contract against gravity and some resistance).[39,40] End-to-end suturing or nerve grafting is recommended when there is no conduction across the deficit. Resection and suturing of short-segment deficits with partial fibulectomies may result in an 84% chance of grade 3 recovery.[40] Kim and colleagues[40] also found grade 3 functional return in 42% of grafts overall; 75% of those that were less than 6 cm in length had good outcome. The outcome depends strongly on the degree of neural damage and the surgical technique used.[28] Recently data were published from an academic Level I trauma center that has developed a registry for analyzing outcomes after multiligament knee reconstruction.[51] Patient follow-up averaged 6.2 years and patients were excluded if they had less than 2 years follow-up. Objective outcomes revealed that 69% of patients with peroneal nerve injury recovered antigravity or better tibial anterior strength. Three patients with complete nerve palsy (38%) and 15 patients with partial nerve palsy (83%) regained antigravity ankle dorsiflexion strength ($P = .06$). In comparison, one patient with complete nerve palsy (13%) and 13 patients with partial nerve palsy (72%) regained antigravity strength of the extensor hallucis longus ($P = .01$). Subjectively, no significant differences in Lysholm and International Knee Documentation Committee scores were detected between those who did or did not regain antigravity dorsiflexion or between those who had complete versus partial peroneal nerve palsy originally. These latter findings likely demonstrate a limitation in these knee outcome–measuring tools in measuring functional outcome in this patient population. Another recent 5-year retrospective review focused on factors influencing peroneal nerve injury and recovery. Gender (odds ratio, 5.47), body mass index (odds ratio, 1.14), and fibular head fracture (odds ratio, 4.77) were associated with peroneal nerve injury. The rate of full peroneal nerve recovery in this study was 31%; younger patient age was the only favorable factor for peroneal nerve recovery. The average age of patients who had spontaneous recovery of peroneal nerve function was 22.7 years.[42] When sufficient return of function does not occur, an anterior transfer of the posterior tibial tendon or other technique can maintain neutral ankle dorsiflexion and eliminate the need for the AFO.[18,30,34,63,81,89,90,92]

CRITICAL POINTS Ligamentous Injuries

- The most accurate examination for identification of anterior cruciate ligament integrity is the Lachman test.
- With the knee at 90 degrees, a posterior drawer or posterior force on the tibia is used to assess the posterior cruciate ligament.
- The medial and lateral collateral ligaments are evaluated by applying a valgus or varus stress, respectively, at both extension and 30 degrees of flexion.
- A posteromedial or posterolateral complex injury can be identified with additional joint space opening at 0 degrees of flexion.

CRITICAL POINTS Reduction and Immobilization

- Knees that are dislocated at the time of presentation should be reduced immediately.
- Reduction is accomplished by applying traction to the tibia while manipulating the proximal tibia in the appropriate direction.
- Reevaluation of joint congruence and neurovascular status must follow reduction.
- Adequate reduction and maintenance of tibiofemoral alignment must be documented in both the anteroposterior and the lateral planes.

LIGAMENTOUS INJURIES

Dislocation of the knee results in damage to the soft tissue stabilizers of the knee. Physical examination of the ligamentous stabilizers should be performed only after the life- and limb-threatening injuries have been addressed. It should also be delayed in the case of femoral or tibial fractures. Examination in this setting may further displace the fracture, and it may make the ligamentous examination less reliable. Pain may also hinder accurate examination.

A systematic approach to the evaluation of knee stability should be undertaken. The most accurate examination for identification of ACL integrity is the Lachman test.[16] This is performed by applying an anteriorly directed force on the tibia with the knee in 20 to 30 degrees of flexion. With the knee at 90 degrees, a posterior drawer or posterior force on the tibia is used to assess the PCL. Translation and endpoint are evaluated. Evaluation of posterior sag, or the position of the medial femoral condyle with respect to the tibial plateau, is also useful to identify PCL injuries.

The MCL and FCL are evaluated by applying a valgus or varus stress, respectively, at both 0 degree and 30 degrees of flexion. Increased medial or lateral joint space opening at 30 degrees typically indicates a collateral ligament injury. A posteromedial or posterolateral complex injury can be identified with additional joint space opening at 0 degree of flexion. The posterolateral corner can be assessed further with the dial test. Increased external rotation of the tibia, a greater than 10- to 15-degree side-to-side thigh-foot angle at 30 degrees of knee flexion, indicates a posterolateral corner injury. If there is additional external rotation of the dial test at 90 degrees of flexion, a PCL and lateral corner injury are present. Twaddle and coworkers[88] in 2003 presented 63 dislocatable knees in 60 patients. These authors reported bicruciate ligament injuries in 71% of patients. The ACL was injured in 84%, the PCL in 87%, the MCL in 44%, and the FCL in 62%.

REDUCTION AND IMMOBILIZATION

Often, spontaneous reduction has taken place before presentation. If the knee is dislocated at the time of presentation, reduction on the field by knowledgeable medical personnel is preferred. The neurovascular status of the limb must be assessed before reduction. The use of intravenous adjuvant medications is usually sufficient anesthesia. Reduction is accomplished by applying traction to the tibia while manipulating the proximal tibia in the appropriate direction.

The presence of a dimple sign, indication of a posterolateral dislocation, may be a contraindication to closed reduction. Imaging should be pursued if possible. Reevaluation of joint congruence and neurovascular status must follow reduction.[25] The limb should then be immediately immobilized in a long-leg splint or knee immobilizer. Once the patient is out of the emergency department, a hinged knee brace locked in extension is the preferred form of immobilization during the time period antecedent to surgical intervention. Adequate reduction and maintenance of tibiofemoral alignment must be documented in both the anteroposterior (AP) and the lateral planes. If reduction cannot be maintained in a splint, the knee may be transfixed temporarily with cross pins (through the notch) or an external fixator until sufficient capsular healing occurs. Other potential indications for use of an external fixator are the presence of fractures, vascular injury, and skin coverage issues.

FIG 22-7 Anteroposterior radiograph of an acute knee dislocation.

IMAGING

Radiographs of the knee should be obtained for all suspected knee dislocations (Fig. 22-7). Routine radiographs may be useful not only in assessing joint congruity and finding potential fractures, but also in determining a diagnosis. In a case series by Edwards et al.[17] in 2013, four obese females with a low-energy fall and no noticed deformity to the leg in the field or in the emergency department were found to have knee dislocations only with radiography (Fig. 22-8). Radiographs may be delayed until a clinically apparent knee dislocation has been adequately reduced. The basic knee series consists of an AP and a lateral

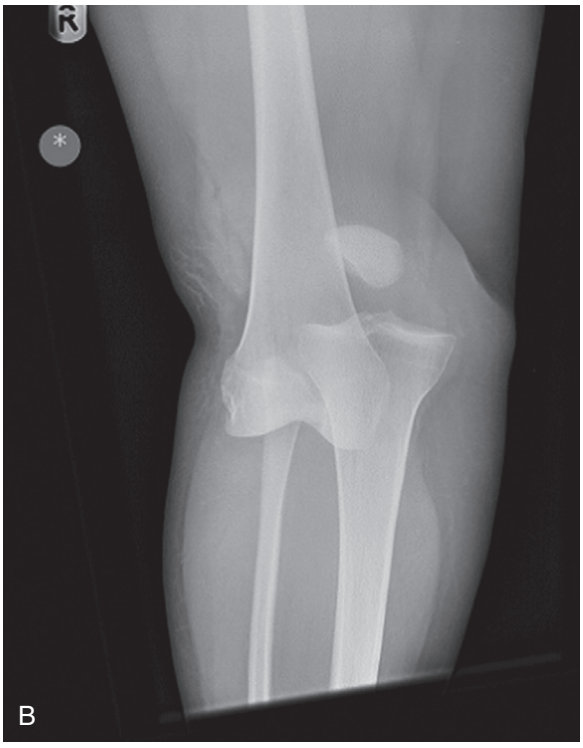

FIG 22-8 Lateral (**A**) and anteroposterior (**B**) radiographs of a 33-year-old woman, body mass index 35, who fell in her garden. (From Edwards GA, Sarasin SM, Davies AP. Dislocation of the knee: an epidemic in waiting? *J Emerg Med.* 2013;44[1]:68-71, 2013.)

CRITICAL POINTS Imaging

- Radiographs of the knee should be obtained for all suspected knee dislocations.
- Magnetic resonance imaging will further define soft tissue and cartilage injuries and aid in planning of definitive care.

plain radiograph. In cases in which fracture is noted or suspected, oblique views or stress views of the knee may be indicated. These views can determine the direction of dislocation as well as assess the adequacy of reduction and note any residual subluxation. In addition, the identification of fractures may direct treatment. Often, femoral and/or tibial fractures will require stabilization before the dislocation can be addressed.

A tibial eminence fracture and lateral capsular avulsion fractures from the tibia, also known as *Segond fractures*, indicate an ACL injury (Fig. 22-9).[8,15,76] The tibial eminence fractures may be complete, incorporating the entire ACL footprint, or incomplete, primarily affecting the anteromedial bundle.[27] The Segond fracture, best detected on the AP projection, is indicative of detachment of the middle third of the lateral capsular ligament and is associated with an ACL rotational instability (Fig. 22-10). The fracture originates from the lateral cortex of the proximal tibia, superior, and posterior to Gerdy's tubercle, approximately 2 to 10 mm distal to the articular surface.[24] Tears of the ACL are present in 75%[11] to 100%[24] of patients with Segond fractures.

PCL and posterolateral ligament injuries can also be identified on plain radiographs (Fig. 22-11). PCL injuries may present as posterior avulsion fractures of the proximal tibia. These fractures will usually involve the entire PCL and may be comminuted or split sagitally.[27] A cortical avulsion of the middle medial tibial plateau, a *reverse* Segond fracture, caused by a valgus and external rotation force, corresponds to an avulsion of the deep MCL. This is usually associated with a PCL injury and medial meniscal tear. This may be the only radiologic suggestion of a knee dislocation/multiligamentous injury.[18]

On the lateral side, the *arcuate sign* describes an avulsion fracture of the fibular head consisting of the FCL, popliteal fibular ligament, and fabellofibular ligaments. Huang and associates[33] found that, in addition to the injury to the posterolateral stabilizers, 13 of 13 patients with the arcuate sign had PCL disruptions (six tibial avulsions and seven midsubstance) and MCL injuries (five acutely abnormal and eight with chronic fibrous thickening). Also identified were medial and lateral meniscal tears (five medial and six lateral).

After a knee dislocation has been reduced, the patient stabilized, and plain radiographs confirm reduction, MRI can be obtained subacutely (Fig. 22-12). MRI will further define soft tissue and cartilage injuries and aid in planning definitive care. Whereas the physical examination is best for determining degrees of abnormal translation and rotation, MRI can help determine the location of the injury (e.g., midsubstance tear). This information can be useful in deciding the need for repair—augmentation versus reconstruction.

A precise description of the following pathology should be made by the interpreting radiologist[36,64,91]: location of any fractures, especially the presence of ligament avulsion fractures, including fragment dimensions; bone contusions and osteochondral injuries, the location of which may clarify direction of dislocation; ligament tears and nonosseous avulsions, including location of the tear (proximal, midsubstance or distal) and severity (partial versus complete); tendon injuries (quadriceps, patellar, biceps femoris, popliteus, and iliotibial band); meniscal tears, including location of displaced meniscal fragments; soft tissue damage, such as muscle tears and capsular injury; vascular assessment, including evaluation for perivascular hematoma or signs of vessel thrombosis, dissection, or the development of a pseudoaneurysm; and visual description of the tibial and common peroneal nerves, including alteration in signal, morphology, and location. Regardless of the level of detail provided by the interpreting radiologist in describing the injuries seen on MRI of the dislocated knee, the orthopedic surgeon should personally review all imaging modalities before taking a patient to the operating room for surgical intervention. Intraobserver and interobserver reliability in describing the lesions seen on MRI in the dislocated knee are low.[5]

EMERGENT SURGERY

Although the rationale for determining the type of treatment (surgical or nonsurgical) most appropriate for a patient with a dislocated knee

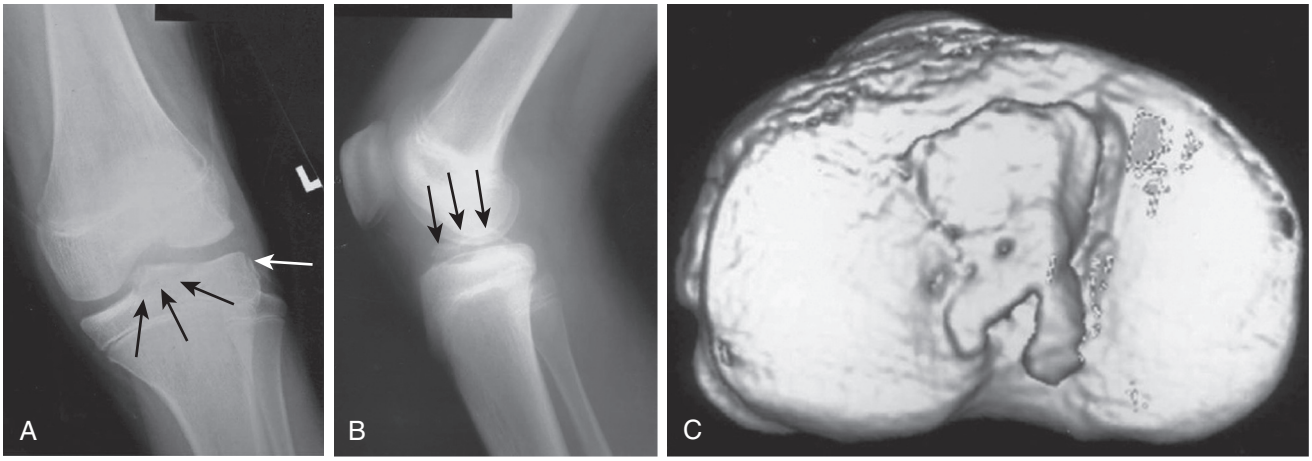

FIG 22-9 A 13-year-old boy with a twisting knee injury sustained while playing basketball. Frontal (**A**) and lateral (**B**) radiographs of the knee show a large avulsion fracture of the anterior cruciate ligament ([ACL]; *black arrows*). There is a Segond fracture of the proximal tibia (*white arrow*). C**,** A 3-dimensional computed tomographic image shows this fracture fragment to be a large, noncomminuted fragment extending beyond the insertion area of the ACL toward, but not involving, the posterior cruciate ligament insertion area. (From Griffith JF, Antonio GE, Tong CWC, Ming CK. Cruciate ligament avulsion fractures. *Arthroscopy.* 2004;20:803-812.)

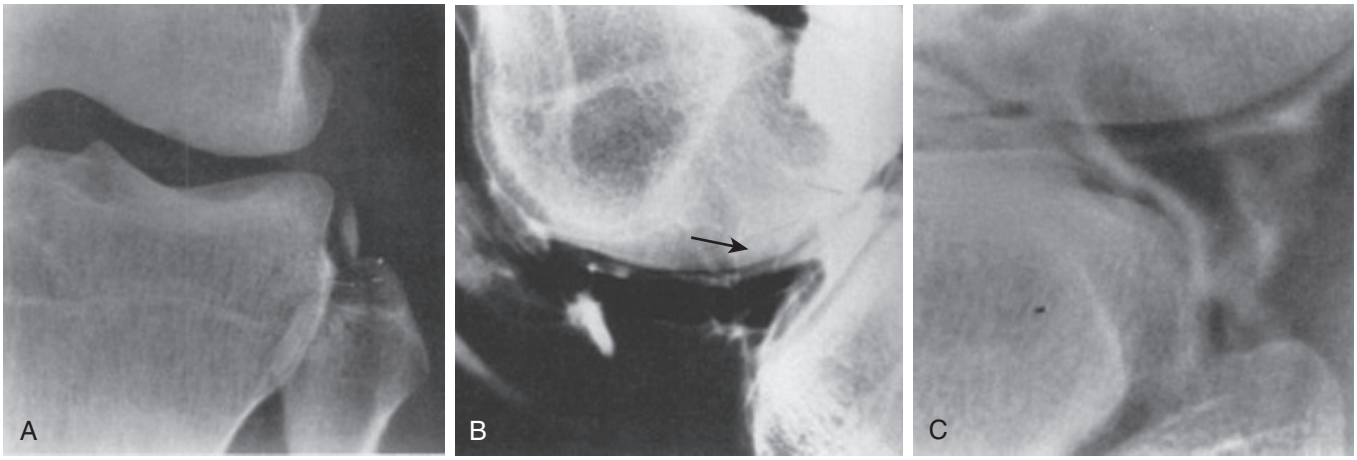

FIG 22-10 Segond fracture with characteristic arthrographic findings. Four days before presentation, this 26-year-old man fell while playing tennis. **A,** Anteroposterior view shows a 9-mm avulsion fracture arising from the lateral tibial cortex. Site of origin is 3 mm below the plateau. **B,** Overpenetrated cross-table lateral view during double-contrast arthrogram shows absence of normal anterior cruciate ligament (*arrow*). **C,** Arthrogram of the posterior horn of the lateral meniscus shows compression of the normal tendon sheath. (From Goldman AB, Pavlov H, Rubenstein D. The Segond fracture of the proximal tibia: a small avulsion that reflects major ligamentous damage. *Am J Roentgenol.* 1998;151:1163-1167.)

is beyond the scope of this chapter, the timing of surgical procedures is dependent on the postinjury physical examination and associated injuries.

Emergent surgery is indicated for vascular injury, compartment syndrome, open injury, or irreducible dislocations.[67] Vascular reconstruction, often performed with reverse saphenous vein grafts, should be performed within 6 hours to minimize ischemia to the muscles and increase the chances for limb survival. The orthopedic surgeon may need to stabilize the limb with an external fixator to allow access to the limb during reconstruction and for postoperative wound management. Fasciotomies are often required after revascularization to prevent compartment syndrome.

Acute compartment syndrome is a condition in which the pressure within a fascial compartment rises to a level that decreases tissue perfusion, leading to cellular anoxia, muscle ischemia, and death. Diagnosis is primarily clinical with supplementation by compartment pressure measurements. Clinical signs of compartment syndrome include pain out of proportion, pain aggravated by passive stretch, paresthesia, and late signs that include pulselessness, paralysis, and pallor. Compartment pressure measurements of 20 mm Hg below diastolic pressure or 30 mm Hg below the mean arterial blood pressure suggest muscle ischemia. Urgent restoration of perfusion and normalization of compartment pressures is accomplished by complete fasciotomy of all compartments.[60]

When open knee dislocations are encountered, wound management principles should be used. Irrigation and debridement of the open wound should be performed urgently. The patient should be started on appropriate antibiotics and tetanus immunization. Acute

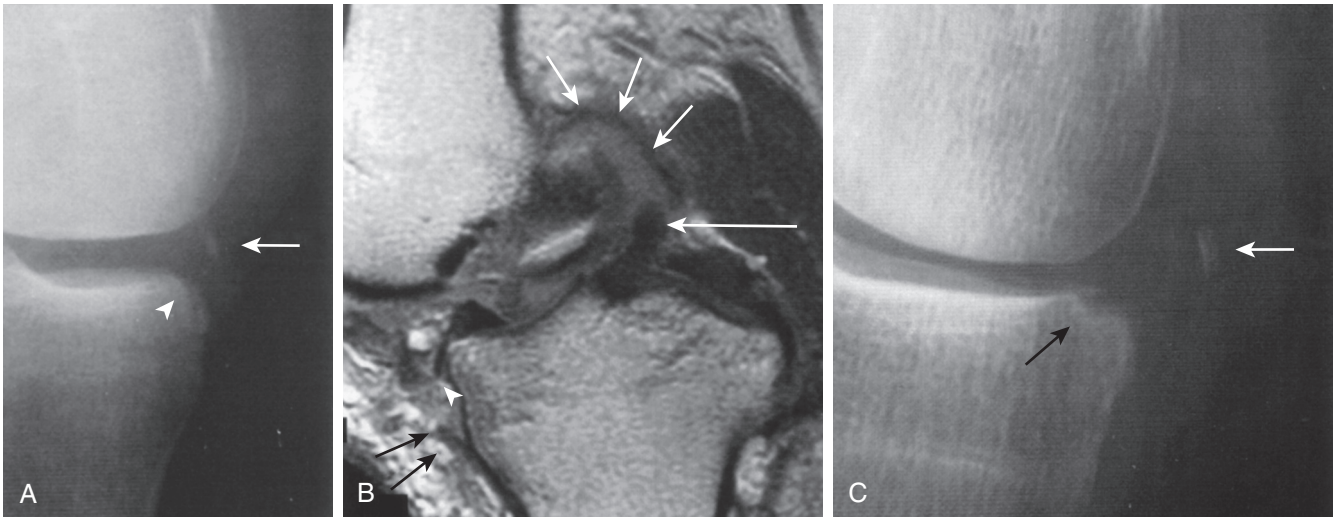

FIG 22-11 A 52-year-old woman involved in a high-energy motor vehicle collision. **A,** Anteroposterior (AP) intraoperative fluoroscopic spot film of the knee shows a small avulsion fragment (*arrow*) adjacent to the medial joint line and evidence of cortical disruption (*arrowhead*) of the medial tibia. **B,** Proton density–weighted fast spin-echo sagittal magnetic resonance image shows disruption of the posterior cruciate ligament (PCL). Note the coronal position of the tibia that results from ligamentous instability. The distal end of the PCL (*long white arrow*) is intact, but the entire proximal portion (*short white arrows*) is disrupted. Disruption (*black arrows*) of the superficial medial collateral ligament (*arrowhead*) is shown. The deep medial collateral ligament (*arrowhead*) is also torn. **C,** AP radiograph of the knee 6 months after trauma shows avulsion fragment (*white arrow*), now well corticated. The *black arrow* indicates the medial tibial bony defect. (From Escobedo EM, Mills WJ, Hunter JC. The "reverse Segond" fracture: association with a tear of the posterior cruciate ligament and medial meniscus. *Am J Roentgenol.* 2002;178:979-983.)

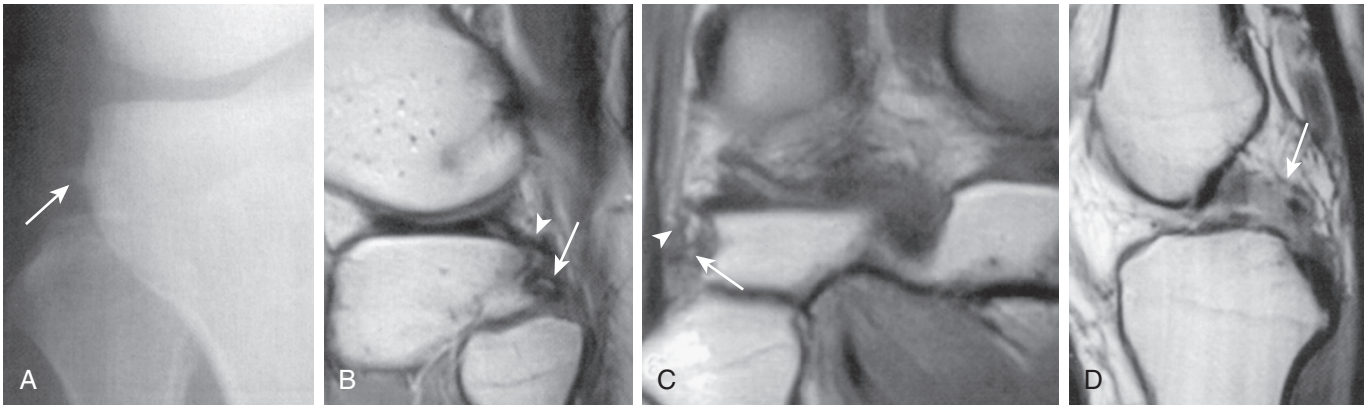

FIG 22-12 A 21-year-old man with chronic posterolateral instability of the right knee after a motor vehicle collision. **A,** Anteroposterior radiograph reveals avulsed bone fragment of the fibular styloid process (*arrow*). **B,** Sagittal spin-echo proton density–weighted magnetic resonance image (MRI) (TR/TE, 1800/20) reveals avulsed osseous fragment (*arrow*) adjacent to the popliteal tendon (*arrowhead*). **C,** Coronal spin-echo proton density–weighted MRI (1800/20) reveals disruption of the lateral collateral ligament (*arrowhead*) and avulsed osseous fragment (*arrow*) in the corresponding course of the popliteofibular ligament. **D,** Sagittal spin-echo proton density–weighted MRI (1800/20) obtained medial to image **B** reveals a tear of the posterior cruciate ligament (*arrow*). *TE*, Echo time; *TR*, repetition time. (From Huang G-S, Yu JS, Munshi M, et al. Avulsion fracture of the head of the fibula [the "arcuate sign"]: MR imaging findings predictive of injuries to the posterolateral ligaments and posterior cruciate ligament. *Am J Roentgenol.* 2003;180:381-387.)

CRITICAL POINTS Emergent Surgery

- Emergent surgery is indicated for vascular injury, compartment syndrome, open injury, or irreducible dislocations.
- Acute compartment syndrome is a condition in which the pressure within a fascial compartment rises to a level that decreases tissue perfusion, leading to cellular anoxia, muscle ischemia, and death.
- Urgent restoration of perfusion and normalization of compartment pressures is accomplished by complete fasciotomy of all compartments.

ligament reconstruction is contraindicated in the face of an open wound. Soft tissue issues may delay reconstruction for several months.[67]

Irreducible dislocations, most commonly posterolateral dislocations with a dimple sign, require surgical reduction to avoid neurovascular compromise. Although possible, ligament reconstruction should be delayed until adequate imaging of the knee and appropriate resources for reconstruction have been assembled.

DEFINITIVE MANAGEMENT

Except for knee dislocations occurring in the severely obese (body mass index ≥40),[4,95] there is firm evidence in the literature supporting definitive surgical intervention to manage these complicated injuries.[14,32,45,58,96] Controversies still exist with regard to timing, repair versus reconstruction of medial and lateral structures, graft types, surgical techniques, and postoperative rehabilitation. Most, if not all, surgeons would agree that soft tissue dissection, ligament, and capsular repairs are easier in the acute setting, less than 2 weeks after the injury. Unfortunately, this is when the knee is usually swollen and range of motion is poor with decreased or absent muscle control of the limb. All of these factors can increase the risk of a permanently stiff knee. Even in the environment of a high-volume knee trauma center,[9,83] loss of motion with a multiple ligament reconstruction is difficult to prevent. Therefore these decisions must take into account this risk of stiffness along with other patient factors, such as complicating injuries, medical comorbidities, participation in rehabilitation efforts, ability to maintain knee reduction, soft tissue coverage and skin condition, and patient expectations. External fixators are best removed within 10 to 14 days to allow protected knee motion, even when vascular surgery is required. This is a decision between the vascular surgeon and orthopedist regarding when knee motion would not risk disrupting the vascular repair.

With respect to surgical timing, many advocate for early intervention (within 2-3 weeks).[6,29,32] In a recent systematic review of early versus delayed surgery, significantly better outcomes were achieved with early intervention (within 3 weeks).[45] Arthroscopically assisted surgery should usually be delayed a minimum of 10 days after the injury to allow the joint capsule to heal and therefore minimize the risk of fluid extravasation and subsequent compartment syndrome.[73] Single versus staged operative intervention remains without consensus and depends on the severity of dislocation and potentially associated fracture patterns.[12,20,53] Reconstruction of cruciate injury is well accepted predominantly because of the large body of literature indicating superior results in single-ligament injury. With regard to the posterolateral corner, repair has shown a significantly higher failure rate in comparison with reconstruction, as well as a reduced rate of return to sporting activities.[45] Stannard and coworkers[83] compared acute repair (within 3 weeks) of the posterolateral corner with reconstruction. These investigators found significantly inferior results of repair (37% failure) compared with reconstruction (9% failure) in 56 patients with 57 posterolateral corner injuries at 2 years. Reconstruction is therefore recommended and a multitude of techniques are described.[29,32,43,53] Multiple grafts are often required and graft type is generally determined by autologous structures still present and surgeon preference. No single combination of graft types has demonstrated superiority, but a combination of autologous and allografts is used.[19,53,77,85]

CRITICAL POINTS Definitive Management

- For patients with high physical demands, optimizing the condition of the knee (muscle function, range of motion, and swelling) and relying on reconstruction rather than acute repair may yield a superior functional result.

Ultimately, knee dislocation is a serious injury and is often only one of many medical problems in the patient with multiple injuries. The initial and definitive management of the dislocated knee presents one of the most challenging and complex injuries the orthopedic surgeon is intimately involved in treating.

INTRODUCTION

The crucial roles of the menisci in the human knee are well understood and include load bearing, load transmission, shock absorption, knee joint stability, and lubrication and nutrition of articular cartilage.[120] Meniscectomy frequently leads to irreparable joint damage, including articular cartilage degeneration, flattening of articular surfaces, and subchondral bone sclerosis. Poor long-term clinical results have been reported by many investigators following partial and total meniscectomy.[8,49,75,118,125,139,170,181,183,184,189,199] For instance, Scheller and coworkers[189] followed 75 patients who underwent partial lateral meniscectomy 5 to 15 years postoperatively and noted that 78% had Fairbank's signs of radiographic deterioration. Rockborn and Messner[181] reported a 50% rate of radiographic osteoarthritis in 30 patients a mean of 13 years after meniscectomy. Roos and associates[184] found that 48% of 107 patients had advanced radiographic osteoarthritis compared with a control group 21 years after meniscectomy. These authors reported that the relative risk of developing advanced degenerative radiographic changes was 14.0. It is important to note that some problems exist in meniscectomy natural history studies, such as including both partial and total meniscectomy in the same cohort; not assessing the effects of patient body weight, activity level, and overall lower limb alignment on the functional result; failure to include weight-bearing posteroanterior (PA) radiographs in the assessment; and lack of a carefully defined control group for comparison.

At least half of patients who sustain injuries to the anterior cruciate ligament (ACL) also sustain meniscus tears,[61,112,117] which is markedly concerning because well over 1 million ACL injuries occur yearly worldwide.[152] We conducted a systematic review to determine the treatment of meniscus tears during ACL reconstruction based on studies published from 2001 to 2011.[153] There were 11,711 meniscus tears in

159 investigations, of which 65% were treated by meniscectomy, 26% were treated by repair, and 9% were left in situ. These results were distressing because the majority of patients in the studies were young athletes in whom resection of meniscal tissue may accelerate the development of osteoarthritis, regardless of the outcome of the ACL reconstruction. This study included investigations from 16 different countries, approximately one third of which were from the United States.

In comparing the incidence of meniscectomy and meniscus repair just within the United States between the years 2005 and 2011, Abrams and colleagues[1] reported that the incidence of meniscus repairs increased 11% in isolated cases and 48% when a concomitant ACL reconstruction was performed. Approximately half of these repairs were done in patients younger than 25 years, and 20% were done in individuals ages 25 to 34 years. These authors attributed the increase in the attempt to preserve meniscal tissue to improved surgeon education, arthroscopic techniques, meniscus-specific rehabilitation protocols, and an overall comfort level with the procedure.

Several studies have reported superior results of meniscus repair compared directly with meniscectomy.[90,166,199,228] In addition, our recent systematic review that encompassed 1326 meniscus repairs for tears in the central third region found an overall clinical healing rate of 83%.[20] The repairs in this review were performed with either newer flexible suture-based all-inside suture devices or the traditional inside-out technique. It is well known that complications and deteriorating results have occurred with rigid all-inside meniscus fixation devices such as meniscal arrows, screws, and darts.[107,110,116,134,194,210] More recently, flexible all-inside devices have become commercially available that contain anchors attached to suture that are passed into the periphery of the meniscus.[15,22,122] These devices include:

- Ultra Fast-Fix (Smith & Nephew, Andover, MA)
- RapidLoc (DePuy-Mitek, Raynham, MA)
- OmniSpan (DePuy-Mitek)
- Meniscal Cinch (Arthrex, Naples, FL)
- Sequent (ConMed Linvatec, Largo, FL)
- MaxFire (Biomet, Warsaw, IN)
- NovoStitch (Ceterix Orthopaedics, Menlo Park, CA)

The lack of long-term, prospective, randomized level I clinical studies precludes definitive recommendations for these devices[15,116]; however, the short-term clinical outcomes achieved in mostly single longitudinal meniscus repairs found in our systematic review were encouraging.[20] This chapter focuses on surgical techniques using newer all-inside suture devices and inside-out repair procedures for a variety of meniscus tears and published clinical outcomes. The postoperative rehabilitation program is described in detail in Chapter 25.

INDICATIONS

Candidates

Candidates for meniscal repair are active patients younger than 60 years, including skeletally immature children and adolescents.[105] Trauma during sports activities involving sudden twisting and turning is one of the most common etiologies of meniscus tears. Many meniscus tears that occur during ACL injuries extend into the middle third avascular region and are amendable to a meticulous inside-out suture repair. Magnetic resonance imaging (MRI) provides important information regarding the type of meniscus tear and potential for repair to preserve function.[48,66,77,93,149,209] In knees in which repair is deemed possible, it is important to restrict strenuous activities and athletics until surgery to avoid further damage to the joint and meniscus.

Degenerative meniscus tears are much less frequently repaired because the meniscus tissue is poor in quality[135] and often fragmented into multiple pieces. Occasionally, MRI will indicate that a repair may be possible, such as in cases of large horizontal tears. Frequently, the symptoms of tibiofemoral pain will diminish over 6 to 12 weeks in degenerative tears in older patients, allowing a conservative approach. In other knees, symptoms of locking episodes and joint swelling are more persistent or severe and require arthroscopic intervention.

CRITICAL POINTS Indications

- Meniscus tear with tibiofemoral joint line pain
- Active patient younger than 60 years
- Concurrent knee ligament reconstruction or osteotomy
- Meniscus tear reducible, good tissue integrity, normal position in the joint once repaired
- Meniscus tear classified by location, type of tear, integrity, damage to meniscus tissue, remaining meniscus bed
- Peripheral single longitudinal tears: R/R, one plane: repairable in all cases, high success rates
- Middle third region: R/W (vascular supply present) or W/W (no blood supply)
- Outer third and middle third regions longitudinal, radial, horizontal tears: R/W, one plane: often repairable
- Outer third and middle third regions complex double or triple longitudinal, flap tears: R/W, multiple planes: repair versus excision

Meniscus repair is frequently performed with concurrent operative procedures such as knee ligament reconstruction.[20,117] Patients with lower extremity varus or valgus malalignment and associated meniscus tears are especially considered for meniscus repair. The malalignment produces high medial or lateral tibiofemoral compartment loads, and a functional meniscus is required to prevent articular cartilage deterioration. Unfortunately, many meniscus tears in varus- or valgus-aligned limbs are degenerative in nature and not repairable.

Candidates for meniscus repair must be compliant and willing to follow the postoperative program of rehabilitation, including crutch support for 4 weeks. Those in whom complex tears are repaired must agree to avoid strenuous activities and deep knee flexion for 4 to 6 months; otherwise, the repair site may be disrupted and fail.

Meniscus Tear Classification

Meniscus tears are classified according to location, type of tear, and integrity and damage to meniscal tissue and the meniscus attachment sites.[7,190] This classification, along with meticulous arthroscopic inspection of the tear site, allows the surgeon to determine whether a tear is repairable. The meniscus body is divided into anterior, mid body, and posterior thirds. In addition, Anderson and associates[7] recommended a classification system of zone 1 (rim width <3 mm), zone 2 (rim width 3-4 mm), and zone 3 (rim width >5 mm). Tears located at the peripheral attachment sites (meniscofemoral and meniscotibial), or zone 1, are referred to as *outer third* or *red-red* (R/R) tears. Single longitudinal tears are usually located in this region (Fig. 23-1). These tears are classified as R/R because both portions have an internal blood supply and are repaired in all cases with high success rates expected.

Tears located in the middle third region (zone 2) are classified as red-white (R/W), and tears located in the inner third (zone 3) are termed white-white (W/W). R/W tears occur at the junction between the outer and middle third regions, approximately 4 mm from the meniscal attachment, with a vascular supply present predominately in the outer third of the tear. White-white tears are located in the region in which no blood supply exists to either portion of the tear. When a repair is performed for these tears, the sutures may provide access to the vascular supply. In addition, rasping of the meniscus-synovial

border provides a vascular supply to the repair site from synovial migration of cells on the surface of the meniscus.[216] It should also be noted that the vascular supply to the meniscus, particularly in younger patients, still requires study and may extend greater than 5 mm in depth into the central zone.

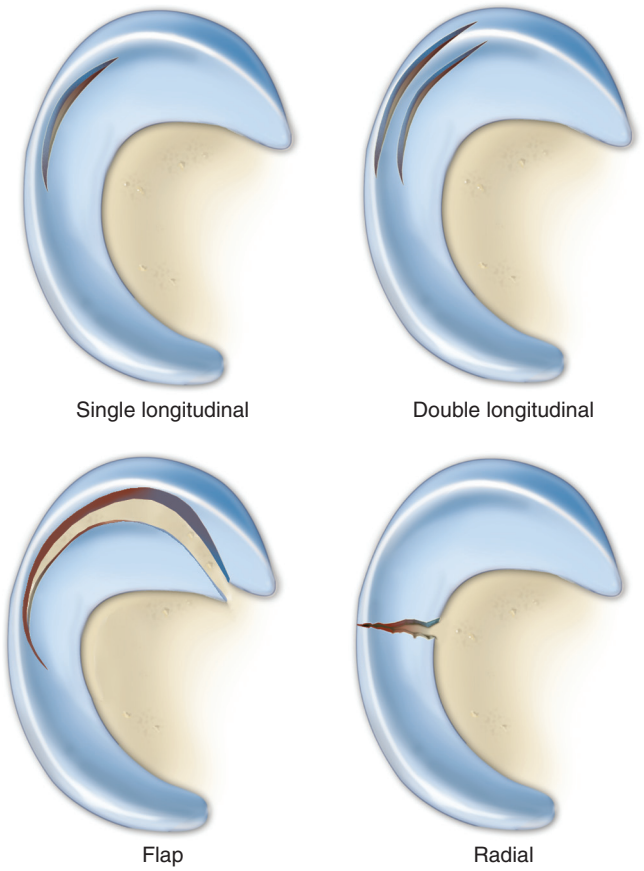

FIG 23-1 The common complex and avascular meniscus tear patterns. Note the single plane configuration of the single longitudinal and radial tears and the multiplane (complex) configuration of the double longitudinal and flap tears.

Repairs of complex tears and tears that extend into the middle third region are evaluated on an individual basis. Tear patterns in this region include single longitudinal, double longitudinal, triple longitudinal, horizontal, radial, and flap. The rationale for repair of these tears is that removal results in essentially a total meniscectomy because a substantial amount of meniscal tissue is resected (Fig. 23-2). This is especially concerning in younger patients in their second to fourth decades of life and all athletically active individuals. These tears are often repairable with reasonable success rates, as described later in this chapter.

Single meniscal tears occur in a single plane, regardless of location. These include longitudinal, radial, and horizontal tears. These tears are most commonly found in the posterior horn and are usually repairable. Complex tears occur in more than one plane or direction. These include tears in the vertical plane (double or triple longitudinal), in the vertical and horizontal planes, or in the vertical and radial planes (flap tears). Each component of the tear is identified and may or may not be repairable.

The decision for repair is based on the qualitative evaluation of the meniscus tissue's integrity and absence of traumatic or degenerative changes. The meniscus tissue should appear nearly normal, with no secondary tears or fragmentation that would affect its projected function. The meniscus rim should be trimmed of tear fragments. A horizontal tear into the meniscus rim is a negative variable because it is difficult with sutures to fully restore the tear site owing to inner gaps between the horizontal tear arms. This is one indication in which a fibrin clot may provide a benefit. A large flap tear may be reduced and approximated, and if the tissue has adequate integrity, repair is considered in active patients. A meniscus that has been displaced in the notch may shorten and contract within 3 to 4 weeks, preventing reduction, and accordingly, early arthroscopy and repair are indicated. More specific recommendations of repair indications and techniques are provided for specific tears later in this chapter. The role of incorporating a fibrin clot or platelet-rich plasma to aid the healing process remains poorly understood. Clinical studies are lacking at present; the surgeon's judgment is therefore required on a case-by-case basis.

CONTRAINDICATIONS

Meniscus tears located in the W/W region are not repairable and require debridement. Chronic degenerative tears usually have tear

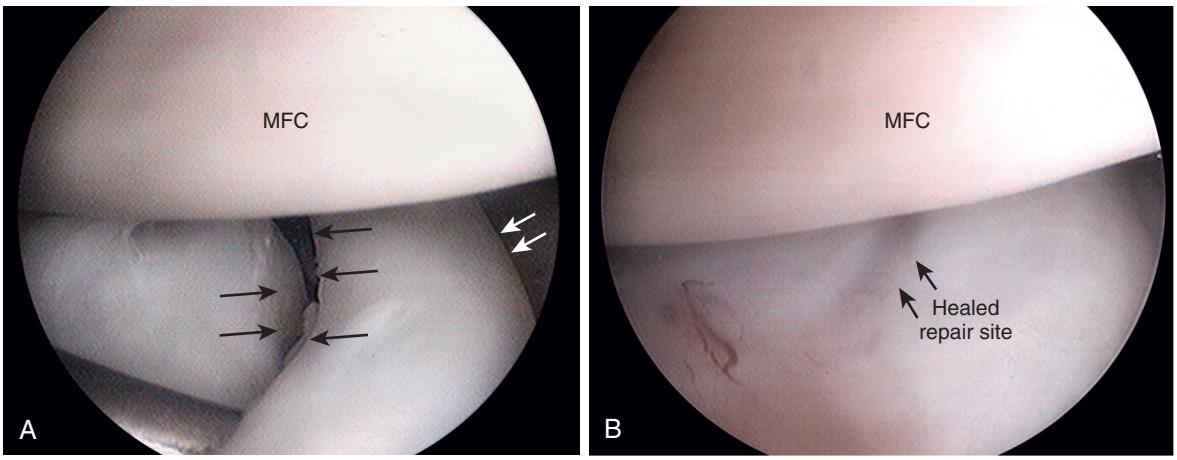

FIG 23-2 **A,** A double-longitudinal medial meniscus tear with a peripheral tear and another tear at the red-white junction. Removal of the red-white tear and repair of the peripheral tear would result in substantial loss of meniscus function; accordingly, a repair of both tears was performed. **B,** Complete healing of the tears on subsequent arthroscopy 1 year later. *MFC,* Medial femoral condyle.

CRITICAL POINTS Contraindications

- Meniscus tears located in inner third (W/W) region
- Chronic degenerative tears in which the tissue is of poor quality, not amendable to suture repair
- Longitudinal tears <10 mm in length
- Incomplete radial tears that do not extend into the outer third region
- Patient >60 years
- Patient unwilling to follow postoperative rehabilitation program

components in multiple planes and are classified as complex. The surgeon must carefully assess the tear pattern and determine the amount and integrity of meniscal tissue that is present. Many of these tears are not repairable (Fig. 23-3). Chronic degenerative tears in which poor tissue quality is encountered require debridement.[135] The tissue may be thickened or abnormally firm and altered in shape or length. Horizontal tears frequently involve displacement of the meniscus from the joint such that a repair of the horizontal flaps would not result in restoration of meniscus function.

Small longitudinal tears less than 10 mm in length are not repaired. In addition, incomplete radial tears that do not extend into the outer third region are either left alone or treated by minimal debridement of the unstable edges. Radial tears should not be debrided into functional meniscal tissue, which would disrupt circumferential hoop fibers and alter meniscus function. The goal in the repair of radial tears is to restore function in the outer and middle zones because the chance of a repair that extends into the inner zone retaining function is highly questionable.

Patient education is required before surgery because complex tears that extend into the avascular region may have a 20% to 40% failure rate and require a repeat arthroscopic meniscus debridement procedure. Patient education is important regarding the goals of the procedure and the failure rate. Patients involved in construction work or other demanding occupations may choose not to have a complex or avascular type of repair. A more difficult problem is the request to remove a repairable R/R tear owing to occupational or athletic pursuits. The senior author (F.R.N.) does not perform this procedure. The senior author categories meniscus tears into three different types. A R/R tear is repaired and, in select small medial tears (15-25 mm in length), an all-inside approach may be considered. However, if there is any associated meniscus tear site damage indicating the need for multiple sutures, an inside-out repair is performed. A R/W tear of either meniscus is repaired with an inside-out technique with accessory posteromedial or posterolateral approaches and multiple vertical sutures because this procedure offers a firmer internal fixation and chance of healing over two to four all-inside sutures. This procedure is performed in all active patients, except older patients (>50 years) who are sedentary. A complex tear that extends into both the R/W and W/W regions may have a success rate of approximately 50%, and the repair of these more difficult tears is usually performed in young patients in an attempt to preserve some meniscal function. In others, a partial meniscectomy is performed.

CLINICAL BIOMECHANICS

Meniscus Function

The menisci provide several vital mechanical functions in the knee joint. They act as a spacer between the femoral condyle and tibial plateau and, when there are no compressive weight-bearing loads across the joint, limit contact between the articular surfaces. The amount of joint narrowing due strictly to the physical absence of the menisci is in the range of 1 to 2 mm.

CRITICAL POINTS Clinical Biomechanics

Functions of the Menisci

- Spacer, prevents contact between articular surfaces
- Load-bearing:
  - 50% compressive load of knee joint transmitted through menisci at 0 degrees of extension
  - 85% compressive load of knee joint transmitted through menisci at 90 degrees of flexion
- Increase contact area, reduce contact stress
  - Partial meniscectomy (15%-34%) increases contact pressures by >350%
- Contributes to joint stability
- Shock absorption during walking
- May assist in overall lubrication of articular surfaces

Suture Repair Biomechanics

- Studies comparing biomechanic properties of vertical and horizontal sutures, and sutures to meniscus repair devices
  - Vertical sutures superior initial fixation strength and stiffness during load-to-failure testing compared with horizontal sutures and repair devices
  - Vertical sutures lower displacements under cyclical loading conditions compared with horizontal sutures and repair devices
- Future studies required to determine fixation strength and performance under cyclic loading of all-inside suture-based devices

Under static-loading conditions, the menisci assume a significant load-bearing function in the tibiofemoral articulation.[2,33,67,124,168] At least 50% of the compressive load of the knee joint is transmitted through the menisci in 0 degrees of extension, and approximately 85% of the load is transmitted at 90 degrees of flexion.[2,163] The presence of the menisci increases the contact area to 2.5 times the size compared with a meniscectomized joint.[24] The larger contact area provided by the menisci reduces the average contact stress (force/unit area) acting between the joint surfaces. Removal of as little as 15% to 34% of a meniscus increases contact pressures by more than 300%.[168,191] After total meniscectomy, the tibiofemoral contact area decreases by approximately 50%, and the contact forces increase twofold to threefold.[2,24,67,106,126,141,163,192,207,219]

Lee and colleagues[111] evaluated the effects of serial meniscectomies in the posterior segment of the medial meniscus. Compared with the intact state, the medial contact area decreased from 20% (after removal of 50% of the posterior segment of the medial meniscus) to 54% (total meniscectomy). Medial contact stress increased from 24% (50% meniscectomy) to 134% (total meniscectomy). Medial peak contact stress increased from 43% (50% meniscectomy) to 136% (total meniscectomy). The peripheral portion of the medial meniscus provides a greater contribution to increasing contact area and decreasing contact stresses compared with the central portion. Muriuki and associates[145] created 15- to 20-mm single longitudinal tears in the R/W portion of the posterior horn of the medial meniscus in cadaver knees and reported significant increases in maximum contact pressure and reductions in contact area that were similar to those associated with total meniscectomy.

The menisci remain in constant congruity to the tibial and femoral articular surfaces throughout knee flexion and extension[208,229] and contribute to stability of the knee joint.[144] Medial meniscectomy

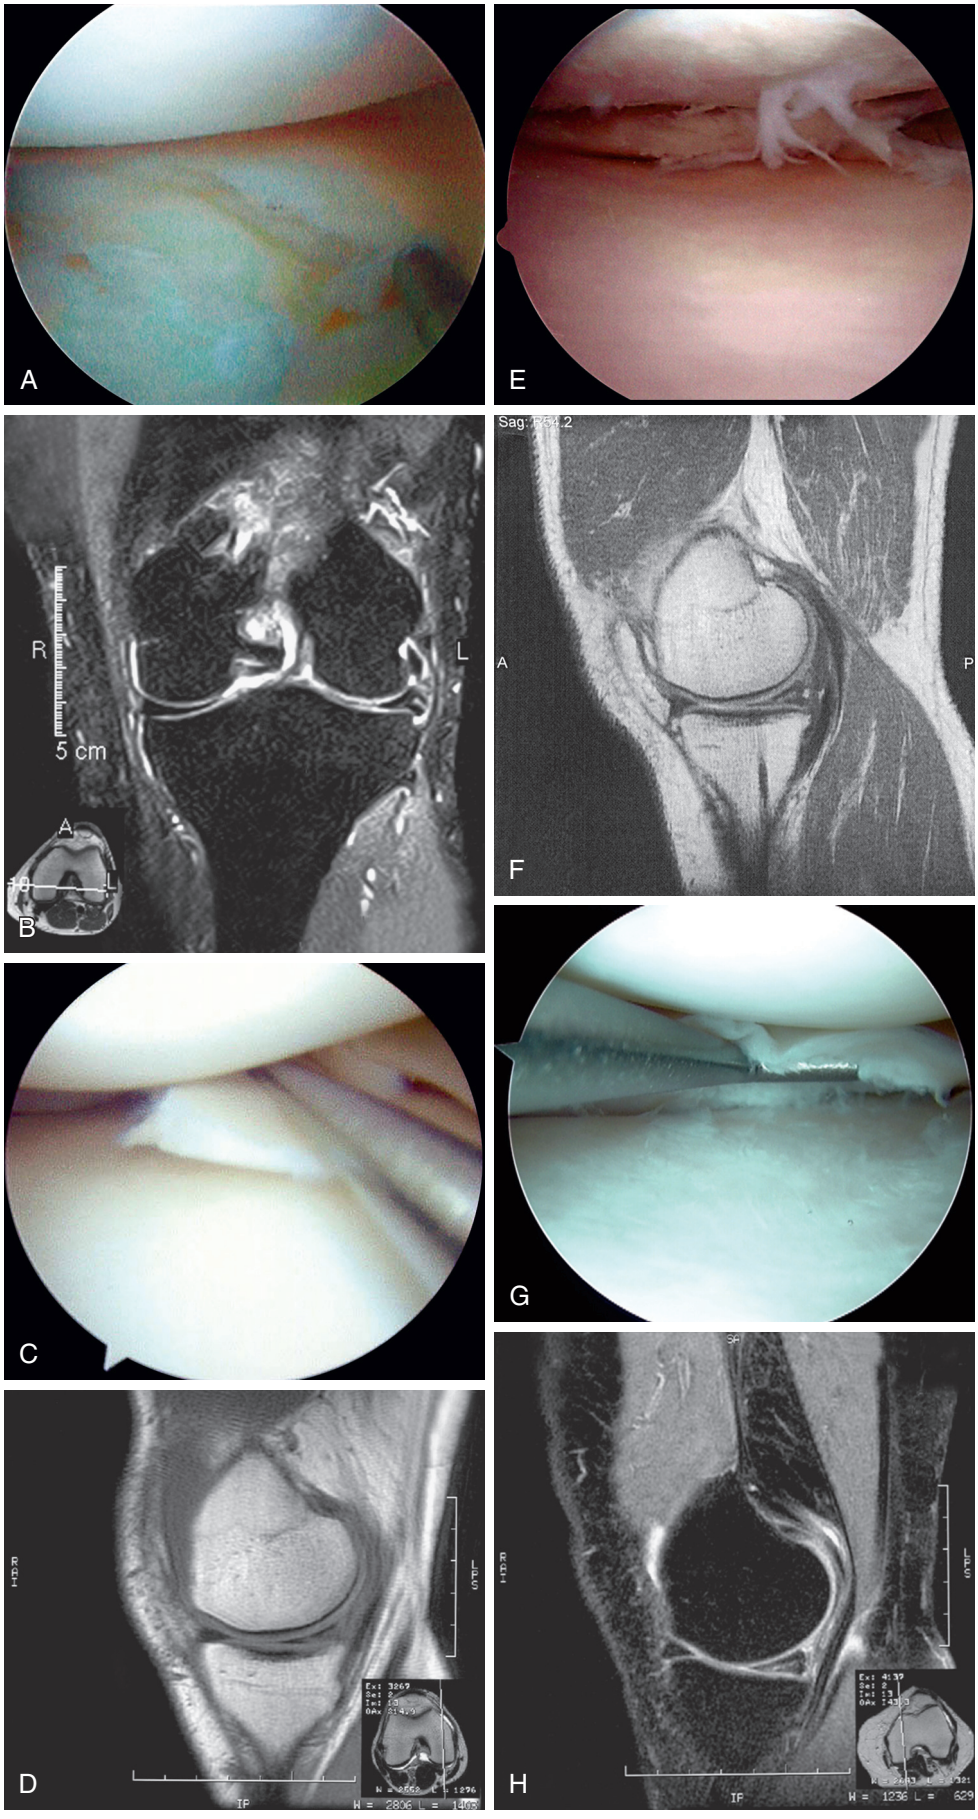

FIG 23-3 Examples of irreparable meniscus tears. **A** and **B,** A 40-year-old man with a complex middle third longitudinal tear of the lateral meniscus. **C** and **D,** A 39-year-old man with a complex flap tear to the posterior horn of the medial meniscus. **E** and **F,** A 43-year-old man with a degenerative tear extending to the under surface of the medial meniscus. **G** and **H,** A 55-year-old woman with a degenerative longitudinal tear to the medial meniscus. Magnetic resonance imaging does not provide sufficient detail of the tear and integrity of the meniscus tissue to determine if a repair of the complex tear is possible.

performed after sectioning of the ACL results in increased anterior tibial translation at 20 to 30 degrees of knee flexion during a Lachman test compared with that measured in knees with an intact ACL.[6,57,113,146,196] Thus the loss of the medial meniscus after an ACL rupture is problematic, especially in varus-angulated knees. Spang and associates[196] reported significant increases in ACL strain measured with a variable reluctance transducer in cadaver knees following medial meniscectomy at 60 and 90 degrees of knee flexion ($P < .05$). Increases in meniscal strain have also been reported following ACL transection in the laboratory.[86,165] In knees with posterior cruciate ligament (PCL) ruptures, the increase in posterior tibial translation allows a change in tibiofemoral contact in which the menisci posterior horns have a reduced weight-bearing function. This is sometimes referred to as a *PCL meniscectomy*. The effect is greater for the medial compartment in which the middle and anterior thirds of the medial meniscus have less weight-bearing function than the lateral meniscus.

The lateral meniscus provides concavity to the lateral tibiofemoral joint owing to the normal posterior convexity of the lateral tibial condyle, allowing the stabilizing effect of joint weight-bearing forces to reduce lateral compartment anterior and posterior translations.[121] Lateral meniscectomy performed after sectioning of the ACL results in increased anterior tibial translation at 30 degrees of knee flexion during a pivot shift test compared with that measured in knees with an intact ACL.[146] Recent studies indicate that the lateral meniscus may be a more important restraint than the medial meniscus to anterior tibial translation during the combined loads applied during the pivot shift test.[146] Partial lateral meniscectomy has been estimated to increase contact pressures by 50% during the stance phase of gait.[141] Total lateral meniscectomy results in a 45% to 50% decrease in total contact area and a 235% to 335% increase in peak local contact pressure.[163]

Loss of the medial meniscus results in a smaller, more medial displacement of the center of pressure. Load is subsequently transmitted through the articular cartilage and subchondral bone to the underlying cancellous bone through this more central route, thus stress-shielding the proximal aspects of the medial tibial cortex. The deleterious effects of meniscectomy on tibiofemoral compartment articular cartilage have been demonstrated in multiple experimental studies.[24,101,168,203,227] For these reasons, it is paramount to preserve meniscal function, if possible, in knees with varus osseous malalignment.

In addition, the menisci provide specific load-bearing functions to the knee joint during walking[141,201,224] and are theorized to assist in overall lubrication of the articular surfaces.[144,220] Even partial meniscectomy affects knee joint kinetics by reducing range of knee motion and increasing knee adduction moments during stance.[119,201]

Meniscus Suture Repair Biomechanics

Historically, biomechanical investigations have compared properties of suture techniques with those of rigid all-inside meniscus fixation devices.* Problems with devices such as meniscal arrows, screws, and darts have been well-documented experimentally and clinically.[107,116,131,134,137,194,210] In addition, several studies concluded vertical sutures were superior to both horizontal sutures and meniscus arrows in mean load-to-failure and maximum tensile strength values.†

More recently, suture repair techniques, suture materials, and all-inside devices have been tested experimentally to determine initial fixation strength and performance under cyclic loading with varying results (Table 23-1). The majority of studies published to date have been performed in porcine knee models rather than human models. Ultra-high-molecular-weight polyethylene-based (UHMWPE) sutures used in all-inside techniques are now available with newer all-inside repair devices, such as NovoStitch (Ceterix), Hi-Fi (Conmed Linvatec), and FiberWire (Arthrex).[15,62,177] Further studies are required to determine the biomechanical properties of these sutures and devices as used for meniscus repair. The lack of both experimental and clinical data precludes definitive recommendations for any one of the currently available all-inside devices over the others. In addition, the reported load-to-failure rates for most of these devices that use one or two sutures is low, justifying consideration for inside-out repairs with multiple sutures to be described. In addition, the low load-to-failure rates and creep properties identify the need for slower postoperative rehabilitation in regard to resumption of full weight bearing, especially for complex meniscus repairs and root repairs. At present, there is little scientific justification regarding when it is safe to resume full weight bearing or return to sports after these types of repairs, although it is appreciated that peripheral longitudinal tears at the R/R junction demonstrate adequate healing within the first 4 to 6 weeks after surgery. The postoperative rehabilitation recommendations are provided in Chapter 25, with empirical rules build in to protect the meniscus repair.

Meniscus Repair Healing

There are few published experimental studies on the strength of a healing meniscus suture repair (without cell-based therapy or growth factors) subjected to tensile loads or assessed for residual defects and complications.[89,137,138,148,180,182] In 1995, Miller and associates[138] reported acceptable healing rates of single longitudinal meniscus tears repaired in the periphery in a goat model. More recently, Miller and colleagues[137] found unacceptably high rates of chondral damage 6 months after implantation of Meniscal Fastners (Mitek, Westwood, MA), BioStingers (Linvatec), and Clearfix Screws (Mitek) in this same animal model. The authors cautioned against the use of these rigid all-inside devices in humans. In 2009, Hospodar and coworkers[89] reported superior healing of meniscus repairs done with an inside-out suture technique compared with the all-inside FasT-Fix device in goats. The FasT-Fix group had longer residual full-thickness defects ($P = .01$) and longer residual partial-thickness defects ($P < .001$) 6 months postoperatively.

CLINICAL EVALUATION

A thorough history includes assessment of the injury mechanism, initial and residual symptoms, and functional limitations. Common injury mechanisms are a sudden twist, change in direction (cut), or deep knee flexion. Meniscus tears are frequently encountered in knees with ACL ruptures. A comprehensive knee examination is performed that includes assessment of knee motion, patellofemoral indexes, tibiofemoral pain and crepitus, muscle strength, ligament subluxation tests, and gait abnormalities.

The presence of tibiofemoral joint line pain on joint palpation is a primary indicator of a meniscus tear. Other clinical signs include pain on forced flexion, obvious meniscal displacement during joint compression and flexion and extension, lack of full extension, and a positive McMurray test result.[127,140] All ligament stability tests are performed and compared with the opposite knee joint. MRI may be obtained with a proton density weighted, high-resolution, fast spin-echo sequence[172,173] to determine the status of the articular cartilage and menisci. This evaluation is useful in knees with suspected degenerative tears[221] and

TABLE 23-1 Results of Cyclic Loading Studies of Meniscus Repair Suture Techniques and All-Inside Devices

Study	Type of Sutures or Devices	Models	Cycles	Results
Beamer et al[22] (2015)	Radial tears: one all-inside Ceterix NovoStitch suture or one 2-0 Force Fiber inside-out suture	Porcine	100, 200, 500	Load to failure (N): 95 inside-out, 111 all-inside ($P = .03$). Stiffness (N/mm): 11.19 inside-out, 14.53 all-inside ($P = .02$). Displacement (mm): 2.36 inside-out, 1.52 all-inside ($P < .001$). Vertical all-inside technique superior to horizontal inside-out technique.
Ramappa et al[177] (2014)	Bucket-handle tears: two running mattress sutures Sequent, two vertical mattress sutures Ultra FasT-Fix, 2 vertical sutures No. 0 Hi-Fi inside-out	Porcine	100, 300, 500	Load to failure (N): 138 ± 23 Sequent, 140 ± 30 Ultra FasT-Fix, 188 ± 42 Hi-Fi suture ($P < .001$). No differences in stiffness among three groups. Sequent lowest displacement after cycling ($P < .001$) but questionable clinical relevance.
Feucht et al[64] (2014)	Posterior medial root tears*: transtibial pull-out repair with two vertical sutures TP, or suture anchor repair with two SA	Porcine	100, 500, 1000	Load to failure (N): 180 ± 45 TP, 241 ± 45 SA, 862 ± 135 native posterior medial meniscus root. SA lower displacement all conditions ($P < .001$), higher stiffness ($P < .05$). Both techniques higher displacement, lower maximum load to failure, and stiffness compared with intact menisci ($P < .05$). SA technique beneficial; slow rehabilitation recommended.
Feucht et al[62] (2013)	Posterior medial root tears: TSS 5 mm apart, one HMS, MAA, two modified LS	Porcine	100, 500, 1000	Load to failure (N): 235 ± 39 TSS, 250 ± 57 TLS, 280 ± 65 HMS, 335 ± 59 MMA. MMA highest max load to failure ($P < .01$), less displacement after cycling ($P < .05$), higher stiffness ($P < .05$).
Feucht et al[63] (2013)	Posterior medial root tears: one suture No. 2 PDS, Ethibond, FiberWire, FiberTape	Porcine	100, 500, 1000	Load to failure (N): 133 ± 35 PDS, 146 ± 21 Ethibond, 169 ± 43 FiberWire, 196 ± 62 FiberTape. None of the suture materials had superior properties over the others.
Rosslenbroich et al[186] (2013)	Posterior lateral root tears: transtibial approach one suture or two sutures, 3 mm apart tied over button	Porcine	1000	Load to failure (N): 150 ± 24 SS, 301 ± 41 two sutures. Two-suture technique lower displacement, higher stiffness, higher ultimate failure load ($P < .05$).
Matsubara et al[123] (2012)	Radial tears: DHS, CS	Cadavers	500	Load to failure (N): 68 ± 13 DHS, 79 ± 19 CS. CS higher ultimate failure loads, greater stiffness, lower displacement ($P < .05$).
Herbort et al[83] (2010)	Radial tears: DHS, SS wider distance from meniscal rim	Porcine	1000	DHS higher maximum load (108 ± 12 N), highest stiffness, lower displacement ($P < .05$) compared with SS configurations.
Chang et al[44] (2009)	Single longitudinal tears: single vertical repair No. 2 FiberWire, No. 2 Ethibone, FasT-Fix, RapidLoc, Meniscal-Dart, BioStinger	Porcine	300	Load to failure (N): 16 Dart, 34 BioStinger, 41 RapidLoc, 68 FasT-Fix, 114 No. 2 Ethibone, 175 No. 2 FiberWire. Failure strength and stiffness highest in No. 2 FiberWire ($P < 0.05$). Failure load higher and displacement lower in suture groups compared with devices ($P < .01$).

Continued

TABLE 23-1 Results of Cyclic Loading Studies of Meniscus Repair Suture Techniques and All-Inside Devices—cont'd

Study	Type of Sutures or Devices	Models	Cycles	Results
Mehta & Terry[131] (2009)	Single longitudinal tear 25 mm: one HMS Meniscal Cinch, Ultra FasT-Fix, MaxFire	Cadavers	100, 500	Load to failure (N): 64 MaxFire, 86 Ultra FasT-Fix, 85 meniscal Cinch. Ultra FasT-Fix and Meniscal Cinch had more desirable biomechanical profiles (lower failure rate, greater stiffness, $P < .05$). MaxFire larger gap formation and lower load to failure ($P < .05$).
Nyland et al[156] (2008)	Single longitudinal tear 20 mm: two vertically or horizontally placed FasT-Fix, two horizontally placed RapidLoc devices	Cadavers, implants placed 5 mm apart	500	Vertical FasT-Fix less displacement, greater stiffness ($P < .001$).
Kocabey et al[103] (2006)	Single longitudinal tear 20 mm: two vertical, horizontal, oblique sutures	Bovine, sutures placed 5 mm apart	100	Load to failure (N): 89 ± 8 horizontal suture, 146 ± 32 vertical suture, 172 ± 26 oblique suture. Oblique and vertical sutures greater stiffness ($P < .05$), load to failure ($P = .001$) than horizontal. No difference in displacement.
Kocabey et al[102] (2006)	Single longitudinal tear 20 mm: two vertically or horizontally placed FasT-Fix, two horizontally placed RapidLoc devices	Cadavers	500	Load to failure (N): 87 ± 13 RapidLoc, 90 ± 14 horizontal FasT-Fix, 125 ± 39 Vertical FasT-Fix. Vertical FasT-Fix less displacement ($P < .01$), greater load to failure ($P < .05$), greater stiffness ($P < .001$).
Chang et al[43] (2005)	Single longitudinal tear 20 mm: two Vertical mattress sutures, two Meniscal Viper Repair sutures, two vertical FasT-Fix sutures	Porcine	500	Load to failure (N): 111 ± 30 Meniscal Viper, 133 ± 10 vertical mattress sutures, 146 ± 9 Vertical FasT-Fix. Vertical mattress suture less displacement, higher stiffness during cyclic testing ($P < .001$), suggesting potential for better healing.

BioStinger, No. 0 Hi-Fi suture, and Sequent manufactured by Linvatec; Ethibond and PDS manufactured by Ethicon; Ethibone, Meniscal Cinch, FiberTape, FiberWire, Meniscal Dart, and Meniscal Viper Repair System manufactured by Arthrex; Fast-Fix manufactured by Smith & Nephew; MaxFire manufactured by Biomet; No. 2 RapidLoc manufactured by Mitek; and Ultra FasT-Fix manufactured by Smith & Nephew.
*Root tear: avulsion of the tibial insertion of the meniscus or a radial tear close to the meniscal insertion.
CS, cross suture; *DHS*, double horizontal suture; *HMS*, horizontal mattress suture; *LS*, loop stich; *MAA*, Modified Mason-Allen suture; *P*, tied over plate; *SA*, vertical sutures; *SS*, single suture; *TSS*, two separate sutures.

CRITICAL POINTS Clinical Evaluation

Physical Examination
- Tibiofemoral joint line pain, compression pain
- McMurray test
- Knee flexion and extension
- Joint effusion
- Patellofemoral (medial and lateral subluxation, Q-angle, crepitus, compression pain)
- Muscle strength

Magnetic Resonance Imaging
- Proton-density-weighted, high-resolution, fast-spin-echo sequence

Ligament Subluxation Tests
- Pivot shift, Lachman
- KT-2000 (MEDmetric) 20 degrees of knee flexion, 134 N force
- Posterior drawer, 90 degrees of knee flexion
- External tibial rotation 30 degrees, 90 degrees of knee flexion
- Tibiofemoral rotation dial 30 degrees, 90 degrees of knee flexion
- External rotation recurvatum
- Lateral tibiofemoral joint opening 5 degrees, 20 degrees of knee flexion
- Reverse pivot shift
- Medial tibiofemoral joint opening 5 degrees, 20 degrees of knee flexion

Radiographs
- Anteroposterior
- Lateral, 30 degrees of knee flexion
- Posteroanterior, weight bearing, 45 degrees of knee flexion
- Patellofemoral axial

Assessment of Symptoms and Functional Limitations With Activity: Cincinnati Knee Rating System
- Sports Activity and Function Form
- Occupational Rating Form
- Symptom Rating Form

chronic ACL ruptures and to determine whether a meniscus cyst is present. A recent investigation that examined the ability of MRI to predict reparability of longitudinal full-thickness meniscus lesions reported high sensitivity and specificity rates (overall, 94% and 81%, respectively).[149]

LaPrade and Konowalchuk[109] described a figure-four test that attempts to replicate symptoms in patients with tears of the lateral meniscus popliteomeniscal attachments. The patient is placed supine, the knee flexed to approximately 90 degrees, the foot placed over the contralateral knee, and the hip externally rotated. A varus loading at the knee joint increases tensile loading in the damaged posterolateral soft tissue meniscal attachments. The primary symptom from popliteomeniscal tears is lateral compartment pain with activities, especially turning and twisting with sports. MRI findings are frequently negative. These authors described an open approach to repair the popliteomeniscal attachments. However, peripheral tears are amendable to an inside-out repair technique, as described.

The clinical examination may reveal tenderness on palpation at the posterolateral aspect of the joint at the anatomic site of the popliteomeniscal attachments. The McMurray test is performed in maximum flexion, progressing from maximum external rotation to internal rotation and then back to external rotation. This test may produce a lateral palpable snapping sensation, representing an anterior subluxation of the posterior horn of the lateral meniscus with maximum internal rotation. The snapping is produced with external rotation as the meniscus returns to a normal position. Of interest, patients with physiologic joint laxity and increases in tibial rotation limits can commonly produce this lateral snapping sign in both knees under examination, which is not painful. Patients with tears of the popliteomeniscal attachments may have a positive snapping sign in only the symptomatic knee, which produces posterolateral joint pain.

Radiographs taken during the initial examination include lateral at 30 degrees of knee flexion, weight-bearing PA at 45 degrees of knee flexion, and patellofemoral axial. Axial lower limb alignment is measured using full standing hip-knee-ankle weight-bearing radiographs[56] in knees that demonstrate varus or valgus alignment. Knees that have deficiency of the posterolateral structures may require lateral stress radiographs. Posterior stress radiographs may be obtained in patients with PCL ruptures.

Patients complete questionnaires and are interviewed to rate symptoms, functional limitations, sports and occupational activity levels, and patient perception of the overall knee condition according to the Cincinnati Knee Rating System (CKRS).[21]

PREOPERATIVE PLANNING

Concomitant injuries should be evaluated and may include cruciate or collateral ligament rupture, extensor mechanism injury or malalignment, chondral fracture, osseous malalignment, or an overuse syndrome. The patient is informed that the rehabilitation program may require modification according to the procedures performed. Knees with ACL or PCL deficiency require concomitant ligament reconstruction with the meniscus repair to achieve knee stability and protect the repair site. Knees with varus osseous malalignment that require osteotomy may also have chronic medial meniscus tears that are occasionally repaired.

CRITICAL POINTS Preoperative Planning

- Knees with cruciate deficiency: plan reconstruction with meniscus repair
- Other concomitant injuries may include collateral ligament ruptures, extensor mechanism injuries, chondral fractures
- Associated chronic conditions may include extensor mechanism malalignment, overuse syndrome, varus osseous malalignment. Consider meniscus repair whenever possible in these knees.

INTRAOPERATIVE EVALUATION

All knee ligament subluxation tests should be performed after the induction of anesthesia in both the injured and the contralateral limbs. The amount of increased anterior tibial translation, posterior tibial translation, lateral and medial joint opening, and internal-external tibial rotation should be documented.

A thorough arthroscopic examination is conducted, documenting articular cartilage surface abnormalities.[155] A probe inserted from the medial infrapatellar portal is used to tension the meniscus to determine the integrity of the peripheral rim and the anterior and posterior attachments. The probe is placed underneath the meniscus to visualize the entire undersurface (see Fig. 23-2). Flap tears that otherwise may not be evident may be discovered during this examination.

A 30- or 70-degree arthroscope is used in the anteromedial portal to examine the posteromedial meniscal region. The anteromedial portal is purposely placed immediately adjacent to the medial border of the patellar tendon. The arthroscope sheath with a blunt obturator is passed along the lateral aspect of the medial femoral condyle distal to the PCL attachment into the posteromedial compartment. The meniscal-synovial junction, the peripheral edge of the meniscus, the opening of a synovial cyst, and the posterior articular surface of the medial femoral condyle are inspected. A nerve hook is passed from the anteromedial portal and brought over the top of the meniscus into the posteromedial compartment. The peripheral attachment of the posterior horn of the medial meniscus frequently cannot be completely visualized unless this view is obtained.[34]

The posterolateral compartment of the knee may be inspected by passing the arthroscope adjacent to the medial aspect of the lateral

CRITICAL POINTS Intraoperative Evaluation

- Repeat all knee ligament subluxation tests under anesthesia, both injured and contralateral limbs.
- Rate all articular cartilage surfaces for abnormalities:
  - Normal
  - Grade 1, softening
  - Grade 2A, fissuring and fragmentation less than 50% depth of the articular surface
  - Grade 2B, fissuring and fragmentation more than 50% depth of the articular surface
  - Grade 3, subchondral bone exposed
- 30- or 70-degree arthroscope used in the anteromedial portal to examine the posteromedial meniscal region
- Inspect meniscal-synovial junction, peripheral edge of the meniscus, opening of a synovial cyst, and posterior articular surface of the medial femoral condyle.
- Perform displacement tests of the posterior horn at 60 to 70 degrees of flexion to detect subtle interstitial tearing of the meniscotibial posterior horn attachments.

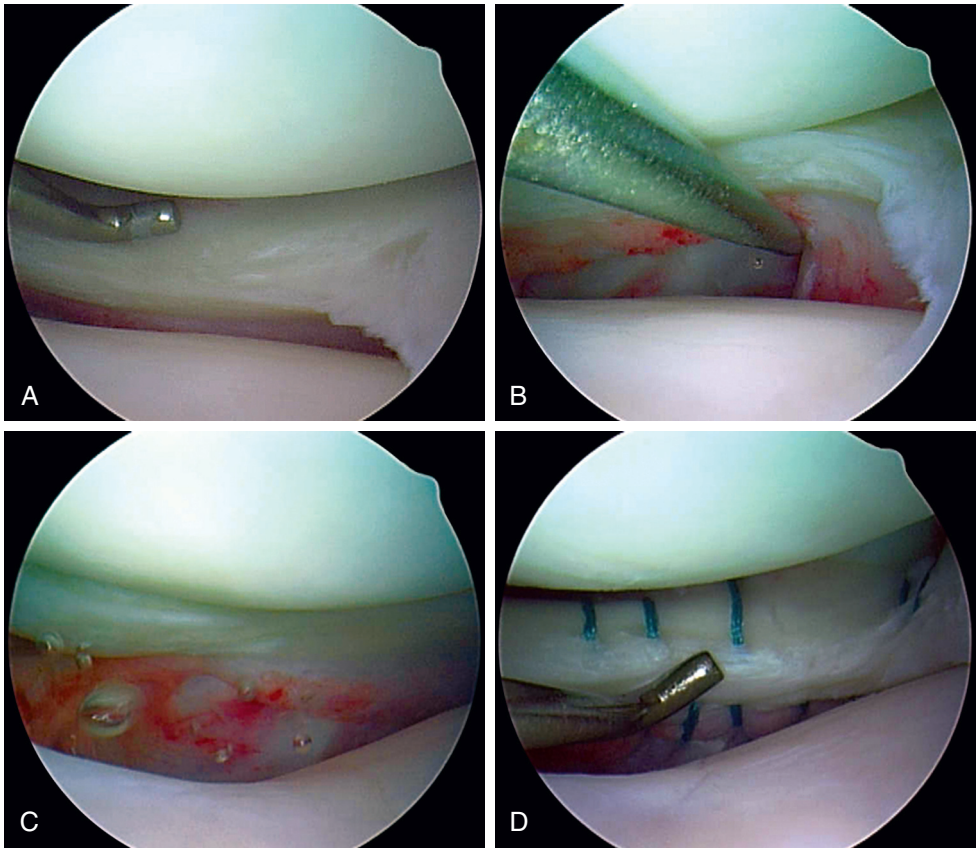

FIG 23-4 An athlete who had a prior negative arthroscopic examination and magnetic resonance imaging and continued posterolateral joint pain shows a demonstrable posterior horn popliteomeniscal attachment tear that required suture repair. **A,** A normal-appearing lateral meniscus. **B,** Enlarged popliteal hiatus showing laxity of the meniscotibial attachments. **C,** Meniscotibial attachments, and thin, disrupted tissues with cephalad displacement of the meniscus body. **D,** Multiple vertical divergent superior and inferior inside-out sutures.

femoral condyle at the notch, just distal to the ACL femoral attachment.

The meniscus tear pattern is classified as previously described. When a longitudinal tear in the middle third region is found, a thorough examination of the peripheral margin of the meniscus is required to determine whether a double longitudinal tear exists in the remaining meniscus rim.

The arthroscopic examination in patients with lateral and posterolateral joint pain may not reveal obvious tears of the posterosuperior meniscus attachments. There may be observable tears in the inferior meniscus tissues about the popliteal hiatus and meniscotibial attachments (Fig. 23-4). There is frequently enlargement of the popliteal hiatus and subtle interstitial tearing of the meniscotibial posterior horn attachments that allow the posterior horn to be abnormally elevated and displaced anteriorly into the lateral compartment. These displacement tests of the posterior horn are performed at 60 to 70 degrees of flexion using a figure-four position because the increased joint gap allows a nerve hook to easily displace the posterior horn and demonstrate the abnormal slackness of the attachments. We have frequently encountered athletes who have had a prior negative arthroscopic examination and MRI results who have demonstrable posterior horn popliteomeniscal attachment tears that require suture repair.

OPERATIVE TECHNIQUE

Patient Preparation

The patient is instructed to use a Hibiclens antimicrobial soap scrub of the operative limb ("toes to groin") the evening before and morning of surgery. Lower extremity hair is removed by clippers, not shaved. Antibiotic infusion is begun 1 hour prior to surgery. A nonsteroidal antiinflammatory drug (NSAID) is given to the patient with a sip of water upon arising the morning of surgery (and continued until the fifth postoperative day unless there are specific contraindications to the medicine). The use of an NSAID and a postoperative firm double-cotton, double-Ace compression dressing for 72 hours (cotton, Ace, cotton, Ace layered dressing) has proven very effective in diminishing soft tissue swelling and is used in all knee surgery cases. The patient's urinary output and total fluids are carefully monitored during the procedure and in the recovery room. The knee skin area is initialed by both the patient and surgeon before entering the operating room, with a nurse observing the procedure. The identification process is repeated with all operative personnel with a "time-out" before surgery to verify the knee undergoing surgery, procedure, allergies, antibiotic infusion, and special precautions that apply. All personnel provide verbal agreement.

The patient is placed in the supine position on the operating table so that the affected leg is elevated (Fig. 23-5). The foot of the

CRITICAL POINTS Operative Technique

Patient Preparation
- Tourniquet and leg holder used, but tourniquet inflated only for initial exposure
- Meniscus tear analyzed according to location, type, size
- Meniscus repair site and synovial junction prepared
- Rasp stimulates bleeding at meniscus-synovial border
- Meniscus tear reduced anatomically
- Inside-out meniscus repair technique requires accessory posteromedial or posterolateral incision

Exposure for Medial Meniscus Repair
- Knee flexed 60 degrees, 3-cm vertical skin incision made just posterior to superficial medial collateral ligament
- Infrapatellar bundles of saphenous nerve identified to avoid injury
- Interval medial gastrocnemius tendon and posterior capsule bluntly dissected
- Henning retractor or spoon inserted to allow safe suture placement and needle retrieval

Exposure for Lateral Meniscus Repair
- Knee flexed to 60 degrees, 3-cm skin incision centered just behind fibular collateral ligament
- Interval between biceps tendon insertion and iliotibial band identified, incised
- Remain posterior to fibular collateral ligament and other posterolateral structures
- Henning retractor pushes neurovascular bundle medially, protects common peroneal nerve
- Position anterior to the gastrocnemius muscle and tendon and directly posterior to the posterior capsule and posterior meniscus bed

Patient Positioning and Equipment
- Assistant sits in chair on medial or lateral side of the knee with headlight to see sutures.
- Scrub nurse stands opposite surgeon to pass sutures through single cannula, one at a time.
- Assistant holds lower leg with knee at 20 to 30 degrees of flexion, applies force to open tibiofemoral compartment.

Medial Meniscus Suture Repair Techniques
- Knee flexed 30 degrees, abduction load applied
- 30-degree arthroscope positioned through medial portal to visualize meniscus
- Cannula positioned through lateral portal
- Assistant passes 10-inch flexible needle through cannula
- First assistant catches double-armed needles, suture tied with five knots
- Vertical divergent sutures alternated; first, on superior surface to reduce meniscus and second, on inferior surface to close the tear
- For medial meniscus tears that extend around the posterior horn, place needle cannula in lateral portal to angle sutures away from neurovascular structures

Lateral Meniscus Suture Repair Techniques
- First assistant sits on lateral side of the knee, adduction stress applied.
- Sutures inserted through superior and inferior meniscal surfaces in an interrupted vertical fashion.
- Multiple 2-0 braided polyester nonabsorbable sutures used on 10-inch straight cutting needle.

Single and Double Longitudinal Tears
- Double-stacked suture technique, two layers of sutures placed at 3- to 4-mm intervals along length of tear.
- First pass of double-armed suture placed in meniscal synovial junction (periphery) of intact portion of meniscus
- Second pass of double-armed suture placed through torn portion of meniscus in vertical plane to bridge tear
- Sutures brought out through accessory incision, tied directly over posterior meniscal attachment and capsule
- Tension in each suture is confirmed arthroscopically after knot is tied.
- Double longitudinal meniscus tears require an additional set of sutures.

Radial Tears
- Horizontal sutures placed at 2- to 4-mm intervals along tear site
- Inner sutures placed first and securely tied followed by sutures in the periphery
- Three to four sutures on superior surface, one or two sutures on inferior surface

Lateral Radial Tear Associated With Cyst
- Excise cyst through limited open lateral exposure.
- Repair peripheral meniscus rim, open technique.
- Repair radial tear, any associated horizontal tears using arthroscopic techniques.

Horizontal Tears
- Rasp through superior and inferior synovial attachments and within tear.
- Use vertical divergent sutures to close tear site.

Meniscus Attachment Root Tears
- Repair with NovoStitch (Ceterix) or Scorpion (Arthrex) instruments to pass two mattress or looped sutures.
- Leg holder required.
- 4- to 5-mm tibial tunnel placed directly at attachment site.
- Sutures tied over tibial post.

Flap Tears
- Tension sutures inserted through flap and into intact meniscal rim to anchor, reduce flap into anatomic bed
- Remaining tear repaired in same fashion as longitudinal tear

Repair of Lateral Popliteomeniscal Fascicles and Attachments
- At arthroscopy, nerve hook is placed at superior and inferior popliteal hiatus to displace lateral meniscus anteriorly and superiorly.
- Knee joint placed in 30 to 60 degrees of flexion, figure-four varus load applied to allow distraction of lateral tibiofemoral joint and maximum meniscus displacement.
- Meticulous inside-out repair technique with multiple sutures.

Techniques to Stimulate Healing of Meniscus Repairs
- Incorporation of fibrin clot at repair site theoretically beneficial, provides scaffold to support reparative cells, provides chemotactic and mitogenic stimuli.
- Fibrin clot inserted between meniscus tear edges prevents meticulous suturing superiorly and inferiorly.
- Synovial abrasion stimulates vessels and mesenchymal cells to form a proliferate vascular pannus that migrates into repair site.
- Specific chemotactic and mitogenic agents may someday play an important role in stimulating the repair process.

FIG 23-5 Operating room setup for meniscus repair. A figure-four position for a lateral meniscal repair is shown with the assistant seated with a headlight to grasp the inside-out sutures.

surgical bed is adjusted to allow 90 degrees of knee flexion. A tourniquet and leg holder are used, but the tourniquet is inflated only for the initial exposure. The leg holder is placed at the middle of the thigh, which allows an assistant to open the tibiofemoral compartment under maximum tension for visualization and meniscus surgery. The extremity is draped free to allow easy positioning during surgery. Standard medial and lateral patellar arthroscopic portals, placed directly adjacent to the patellar tendon, are used for the diagnostic arthroscopy. A common mistake is to place the arthroscopic portals too far medially or laterally over the femoral condyles, where instrument passage damages the femoral articular cartilage. The safe area for instrument passage is with the portal just medial and lateral to the patellar tendon with passage into the femoral notch region.

Diagnostic arthroscopy is performed and the meniscus tear analyzed according to its location, type, and size. The meniscus tissue and synovial junction are rasped to stimulate bleeding at the meniscus-synovial border.[216] Loose, unstable meniscus fragments are removed. In bucket-handle tears, the meniscus rim is prepared before the displaced meniscus is reduced because there are often fragments or partial horizontal clefts in the rim preventing close apposition of the meniscus body to the meniscus rim. Once the synovial fringe and meniscal edges are roughened, the meniscus tear is reduced anatomically. The goal is to restore the meniscus to its original size and shape to promote healing and restore its normal hoop stresses and biomechanical properties.

The inside-out meniscus repair technique requires an accessory posteromedial or posterolateral incision. This exposure allows protection of the neurovascular structures during suture retrieval and knot tying. In our opinion, an outside-in repair does not allow for the meticulous placement of vertical divergent sutures required for complex and avascular repairs, although it may be adequate for anterior horn tears.

Exposure for Medial Meniscus Repair

With the surgeon seated using a headlight and the sterile prepped foot in the surgeon's lap, the knee is flexed to 60 degrees, and a 3-cm vertical skin incision is made just posterior to the superficial medial collateral ligament (SMCL; Fig. 23-6). The tourniquet is inflated for the surgical exposure. The incision is centered just below the joint line (one third above, two thirds below) to allow retrieval of sutures. Avoid placing the incision too posterior in order to protect the saphenous vein and nerve. The subcutaneous dissection proceeds from the superior aspect of the wound down to the fascia. Care must be taken in the inferior aspect of the wound to avoid damage to the saphenous vein and nerve. Two retractors are used to provide visualization of the next layer of structures, the crural fascia and sartorius.

The anterior sartorial fascia is incised, avoiding the sartorius muscle. The pes muscle group is retracted posteriorly. The infrapatellar branches of the saphenous nerve may be present at this location and are protected to avoid injury. The retractors are repositioned to expose the posterior capsule and the semimembranosus sheath and tendon attachments. The key step is to incise the sheath overlying the semimembranous tendon. This opens a window to visualize the medial gastrocnemius tendon. Often, a small synovial Baker cyst is encountered in this interval, which is easily excised. The interval between the medial gastrocnemius tendon and the posterior capsule is bluntly dissected. This plane is developed superior to the semimembranosus tendon. This may be difficult because the semimembranosus tendon may be partially adhered to the posterior capsule. In some knees, the oblique popliteal ligament attachment to the semimembranosus tendon is partially incised to allow the tendon to be posteriorly displaced for exposure and suture retrieval.

Blunt dissection with an index finger allows development of a plane between the medial gastrocnemius tendon and the posterior capsule. A Henning retractor or spoon is inserted, allowing safe suture placement and needle retrieval (Fig. 23-7). The anesthesiologist is asked to provide muscle relaxation so that the gastrocnemius and semimembranosus muscles can be retracted. If the exposure is inadequate at this point, an alternative approach is to further dissect the semimembranosus tendon, which is elevated proximally to gain exposure just distal to the tendon. This is a less ideal approach because it is necessary to avoid placing sutures through the semimembranosus tendon just above its tibial attachment site.

Exposure for Lateral Meniscus Repair

The tourniquet is inflated, and the surgeon is seated and wearing a headlight, with the sterile prepped foot in the surgeon's lap. The knee is flexed to 60 degrees, and a 3-cm skin incision is made just behind the fibular collateral ligament (FCL; Fig. 23-8). The incision is centered just below the joint line (one third above, two thirds below) to allow retrieval of sutures. The interval between the biceps tendon insertion and the iliotibial band is identified and incised, staying superior to the biceps short head muscle fibers. The fascia overlying the posterolateral structures and FCL is gently dissected and peeled from superior to the fibular head. This is performed by applying tension with forceps to the incised fascia and using a thin-blade scissor to peel and strip the fascial tissues to the head of the fibula, protecting the FCL. The retractors are positioned between the biceps tendon and iliotibial band. The deep layer consists of the posterior capsule and the lateral gastrocnemius tendon. The gastrocnemius tendon has a normal proximal attachment to the posterior capsule, making it necessary to gently dissect the tendon with scissors off the posterior capsule at the joint line. The peroneal nerve inferior to the biceps tendon is palpated and protected but is not dissected.

The surgeon must be careful to remain posterior to the FCL and other posterolateral structures. The key step is to initially enter the space anterior to the lateral gastrocnemius tendon just above the fibular head. This avoids penetrating and opening the posterior capsule. The space between the posterolateral capsule and the lateral

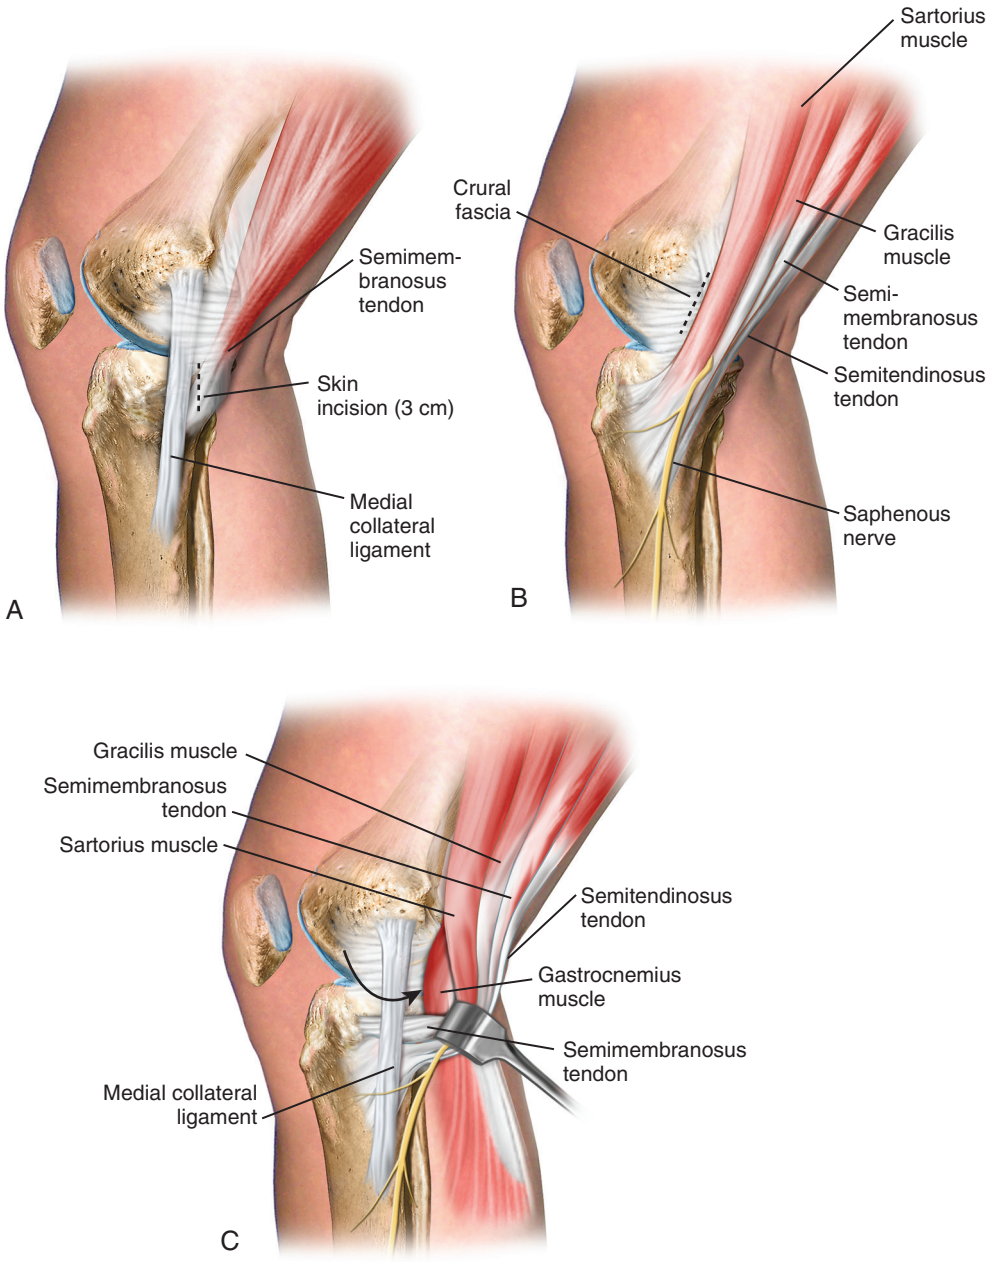

FIG 23-6 The accessory posteromedial approach is shown for a medial meniscus repair. **A,** Site of the posteromedial skin incision. **B,** The incision is shown through the anterior portion of the sartorius fascia. **C,** The interval is opened between the posteromedial capsule and the gastrocnemius tendon, just proximal to the semimembranosus tendon (*arrow*). The fascia over the semimembranosus tendon is excised to its tibial attachment to facilitate retrieval of the posterior meniscus sutures.

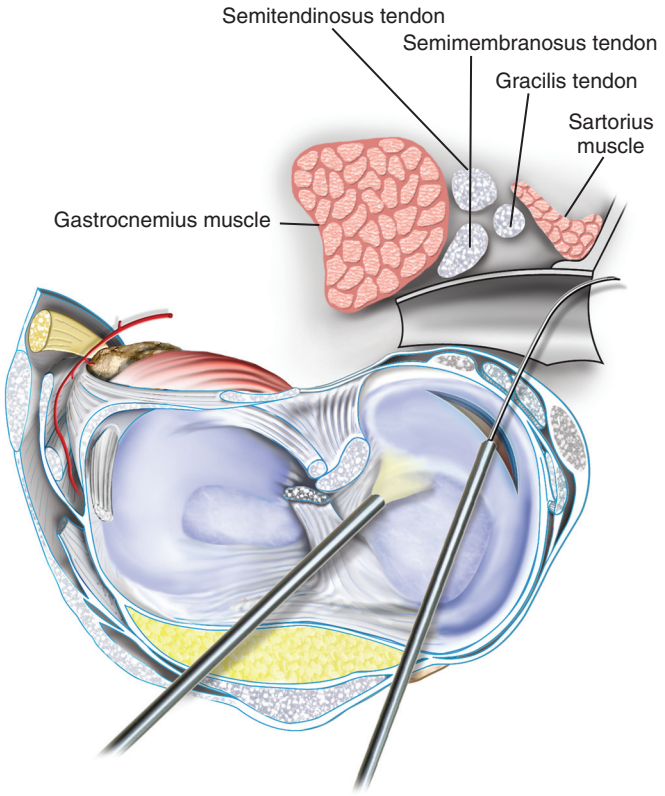

FIG 23-7 Cross-section shows popliteal retractor between the capsule and the medial gastrocnemius. The suture cannula is placed through the lateral or medial portal with care taken to angle the needle away from the neurovascular structures.

gastrocnemius tendon is further developed bluntly with the index finger. A Henning retractor is used to push the neurovascular bundle medially (Fig. 23-9). The inferior lateral geniculate artery may be visualized in the inferior aspect of the exposure and may be damaged and require electrocoagulation (which is avoided if possible to maintain the vascular supply to the lateral meniscus). The retractor must always be positioned anterior to the gastrocnemius muscle and tendon and directly posterior to the posterior capsule and posterior meniscus bed. The retractor blocks the suture needles from passing too posterior and potentially injuring the common peroneal nerve. During the meniscus suture steps, the surgeon should frequently check the position of the retractor to always ensure that it is anterior to the gastrocnemius muscle. If the retractor is mistakenly placed posterior to the gastrocnemius muscle, the peroneal nerve may be injured.

Patient Positioning and Equipment for Inside-Out Suture Repair

An assistant sits in a chair on the medial or lateral side of the knee with a headlight to visualize the posterior meniscus and capsule penetration of the inside-out-directed suture needles. The assistant has a needle holder to catch the suture needles and suture scissors. An inverted clamp is attached to the drapes to act as an instrument holder for this equipment. A scrub nurse stands opposite the surgeon to pass sutures through the single cannula, one at a time, after the surgeon has positioned the cannula. An assistant holds the lower leg with the knee at 20 to 30 degrees of flexion and applies the force required to open the tibiofemoral compartment. The articular cartilage is carefully protected at all times to avoid damage.

Instruments required in addition to routine arthroscopic equipment are a ball-tipped rasp for synovial rasping, a Henning or similar popliteal retractor for protection of the posterior neurovascular structures, a single-barrel straight and curved cannula for suture passage, and 10-inch double-armed meniscal sutures. Nonabsorbable sutures are used for interbody tears.

Suture Repair Techniques

For medial meniscus repairs, the knee is flexed 30 degrees, and an abduction load is applied. A 30-degree arthroscope is positioned through the medial portal to visualize the meniscus. The cannula is positioned through the lateral portal and pointed to the exact location of suture placement. This allows the suture needle to angle away from the midline neurovascular structures. Occasionally, the tibial spines block access for the suture cannula, and the surgeon must place the suture cannula in the medial portal. The suture cannula with a large radius curve is selected to angle the needle away from the neurovascular structures posteriorly. The second assistant passes a 10-inch flexible needle through the cannula. The first assistant, seated on the medial side of the knee, catches the needle with the needle holder as it exits through the exposed meniscus bed. The next suture is passed in the same manner. The first assistant catches the double-armed needles and pulls the suture through. Both needles are cut, and the suture is tied with five knots. The surgeon closely observes the reduction of the meniscus body and closure of the tear site with passage and tying of the vertical divergent sutures. The next sutures are placed in a similar fashion. Vertical divergent sutures are alternated; the sutures are placed first on the superior surface to reduce the meniscus, and second, on the inferior surface to close the inferior tear.

The neurovascular structures are protected throughout the procedure with the appropriate posteromedial exposure and a Henning retractor. For tears of the medial meniscus that extend entirely to the posterior horn, the surgeon must always place the needle cannula in the lateral portal to angle the sutures away from the neurovascular structures.

For lateral meniscus repairs, the first assistant is seated on the lateral side of the knee, and an adduction stress is applied to the flexed knee. Otherwise, the positioning and technique are the same as described for the medial meniscus repair.

Multiple 2-0 braided nonabsorbable sutures are used on a 10-inch straight cutting needle to repair all meniscus tears. The sutures are inserted through the superior and inferior meniscal surfaces in an interrupted vertical fashion to close the meniscus tear both superiorly and inferiorly. The vertical placement is used owing to its higher failure strength compared with horizontally placed sutures.[179] In addition, the vertical suture orientation mimics the function of the radial collagen fibers within the meniscus, which can improve its load-carrying capacity.[37]

In addition, a single-barrel straight or curved arthroscopic cannula is used that allows for accurate placement of the sutures along the edge in tissue that will hold the stitches. A double-barrel cannula is not advocated because the distance between the barrels is insufficient, and needle control is compromised. The location of sutures depends on the tear pattern to be described.

Single and Double Longitudinal Tears

Only select double longitudinal tears are repaired; those with a peripheral meniscal-capsular disruption and those in which the second tear is at or close to the red-white junction. A tear entirely within the central meniscus third is only of 6 to 7 mm in width and is not repaired. A longitudinal tear of the anterior horn of the medial or lateral meniscus

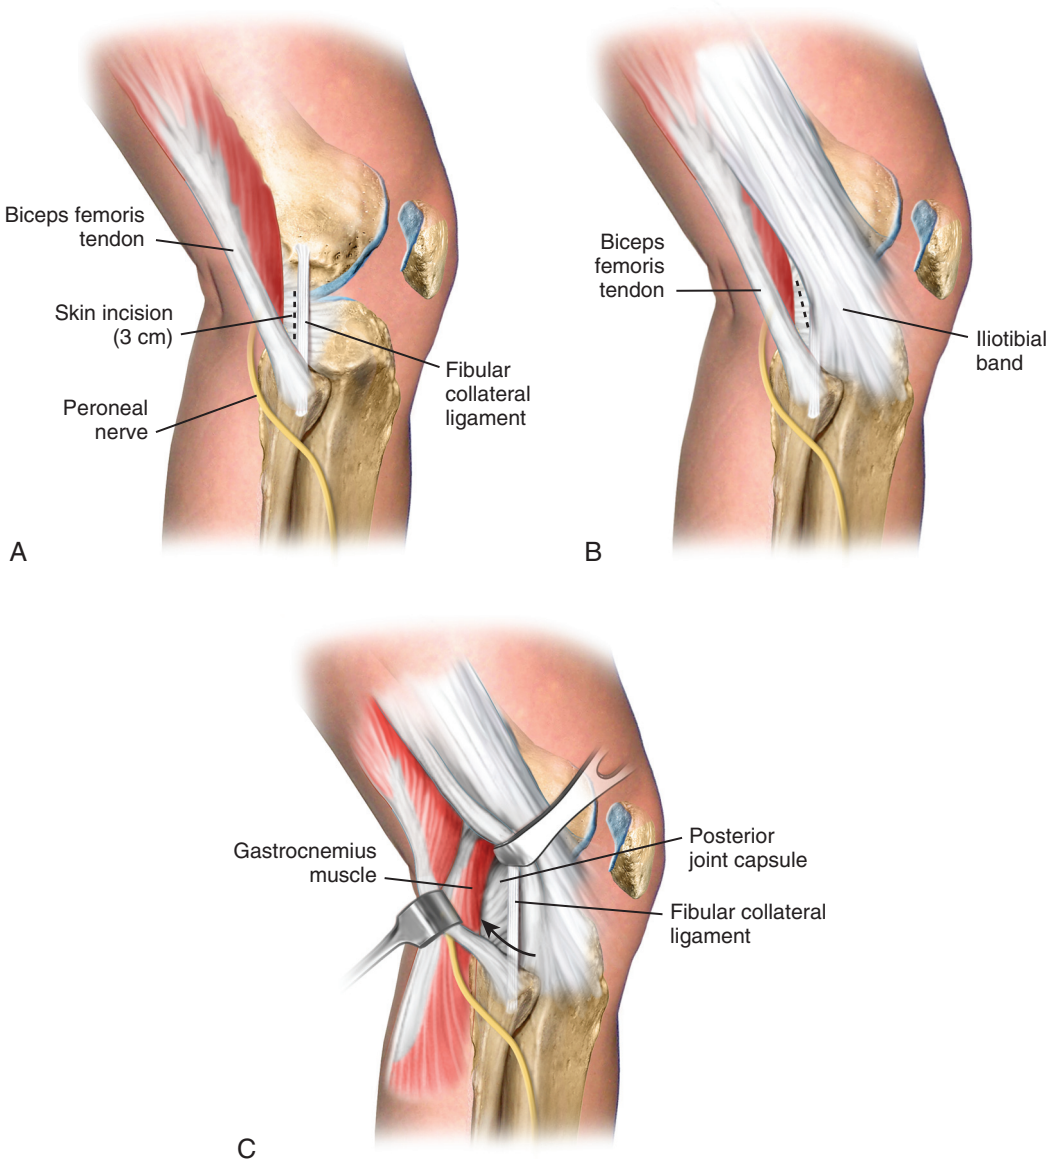

FIG 23-8 A, Site of the posterolateral incision for a lateral meniscus repair. **B,** Incision site in the interval between the posterior edge of the iliotibial band and the anterior edge of the biceps tendon. **C,** The interval between the lateral gastrocnemius and posterolateral capsule is opened bluntly, just proximal to the fibular head, avoiding entering the joint capsule.

that is at the periphery or extends into the red-white junction that fulfills the repair criteria is occasionally encountered. The senior author performs a mini-open direct 2- to 3-cm incision for an open repair. An outside-in placement of sutures for a simple tear is a second option.

A double-stacked suture technique is used for single and double longitudinal meniscus tears. This technique consists of two layers of sutures (Figs. 23-10 and 23-11) placed at 3- to 4-mm intervals along the length of the tear. The first layer of sutures is placed superiorly to anchor the meniscus to its bed and prevent superior migration of the meniscus during the repair. The cannula is used to hold and reduce the torn meniscus on the tibia.

The first pass of the double-armed suture is placed in the meniscal-synovial junction (periphery) of the intact portion of the meniscus. The second pass of the double-armed suture is placed through the torn portion of the meniscus in a vertical plane so that it bridges the tear (Fig. 23-12). The inferior sutures are placed next in a vertical plane, crossing the tear in the same manner as the superior sutures. The sutures are brought out through the accessory incision and tied directly over the posterior meniscal attachment and capsule. The sutures are tied as they are passed to determine the apposition of the tear surfaces. The tension in each suture is confirmed arthroscopically after the knot is tied. This double-stacked technique provides stable fixation of the meniscal tear on both sides and entirely closes the meniscus gap at the repair site (Fig. 23-13).

Double-longitudinal meniscus tears require an additional set of sutures. The peripheral tear is repaired in the same manner as a single longitudinal tear with superior and inferior sutures. The longitudinal tear located in the middle body is repaired with two or three additional superior and inferior sutures. Care is taken to avoid excessive suture

placement between tears in order to maintain meniscus integrity and function.

Radial Tears

Horizontal sutures are placed at 2- to 4-mm intervals along the tear to repair radial meniscus tears. The inner sutures are placed first and securely tied, followed by sutures located in the periphery (Fig. 23-14). Three to four sutures are used on the superior surface, and one or two sutures are used on the inferior surface. The initial sutures are placed first through the body using the needle to displace the meniscus toward the tear site, followed by needle passage through the meniscus bed. This allows the tear site gap to be closed. Only radial tears that extend to the outer third of the meniscus body are repaired because those that are confined to the inner and middle zones have a poor blood supply and will not heal. A radial tear that extends to the meniscus rim compromises the hoop stress and is equivalent to a total loss of meniscus function. Occasionally, the edges of the radial tear are degenerative with poor suture-holding capability and repair is not possible. Traumatic radial tears have a better chance of healing. The goal is to retain partial meniscus function, if possible, because it is rare to have successful healing of a tear in the inner third of the meniscus. As shown in Table 23-1, horizontal sutures carry low load-to-failure values, and therefore a period of non–weight bearing for 4 weeks is required to prevent disruption of the repair site. The patient is advised that this type of repair has a guarded prognosis in terms of providing function. The repair may heal, but the meniscus tear edges separate in the healing process with the interval replaced with poorly organized fibrous tissue with an elongated meniscus structure that displaces from the joint.

There is a common clinical presentation of a radial tear of the posterior horn of the medial meniscus in older patients. This type of tear represents a degenerative tear without trauma, and there is usually associated osteoarthrosis to the medial compartment. The radial tears are usually widely separated and are not repairable because of the poor quality of the tissues.[6,29,161]

Lateral Radial Tears Associated With a Cyst

Because partial meniscectomy and cyst excision may remove a substantial portion of the meniscus body and disrupt its peripheral rim, a cyst should be excised through a limited open lateral exposure (Fig. 23-15). This is followed by repair of the peripheral rim of the meniscus using an open technique. The radial tear and any associated horizontal tears may then be repaired using the arthroscopic techniques described previously. It is not recommended to evacuate the cyst through the intra-articular radial tear site because this damages meniscus tissues and prevents repair. A lateral meniscus cyst is commonly associated with combined radial and horizontal tears that are not repairable; however, this is difficult to determine preoperatively. The mistake is to excise the meniscus in a patient age 50 years or younger in whom a repair is possible to preserve some meniscus function in which progression to lateral compartment arthritis occurs in a short time, particularly in a valgus-aligned lower extremity.

Horizontal Tears

The majority of horizontal tears are degenerative with poor tissue quality and are not reparable. These irreparable tears have thickened tissues, fatty deposition, and partial flap tears. Occasionally, a large

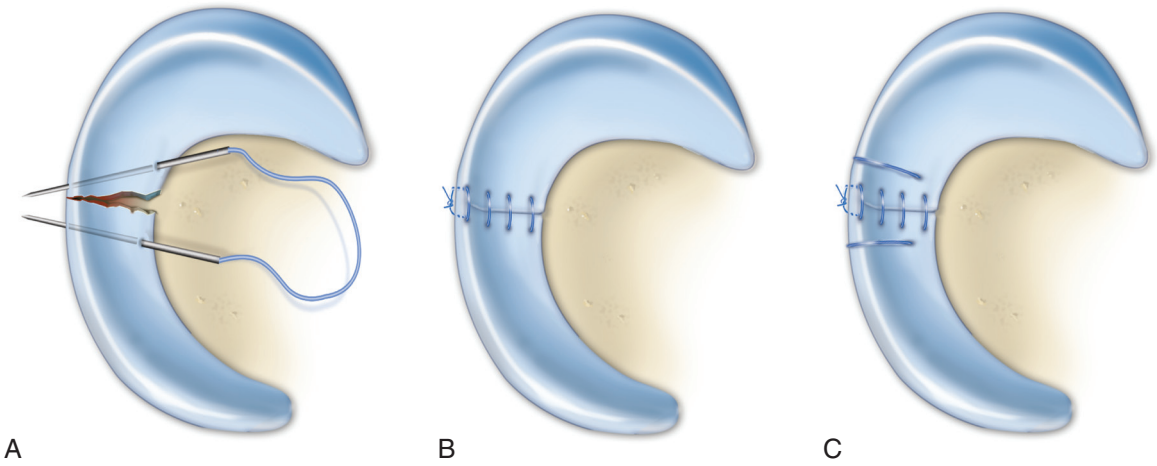

FIG 23-14 Repair technique for radial meniscal tears. The inner sutures (**A**) are placed first, followed by the peripheral sutures (**B**). The first suture needle is placed midway through the meniscus body and then used to apply a circumferential tension to reduce the tear gap, then advanced through the posterior meniscus bed. The second suture needle is placed in a similar manner. This reduces the radial gap, allowing subsequent sutures to be placed. Usually, 3 to 4 sutures are placed superiorly and two sutures, inferiorly. **C,** Occasionally, superior vertical divergent sutures are placed along the tear site to help stabilize the repair.

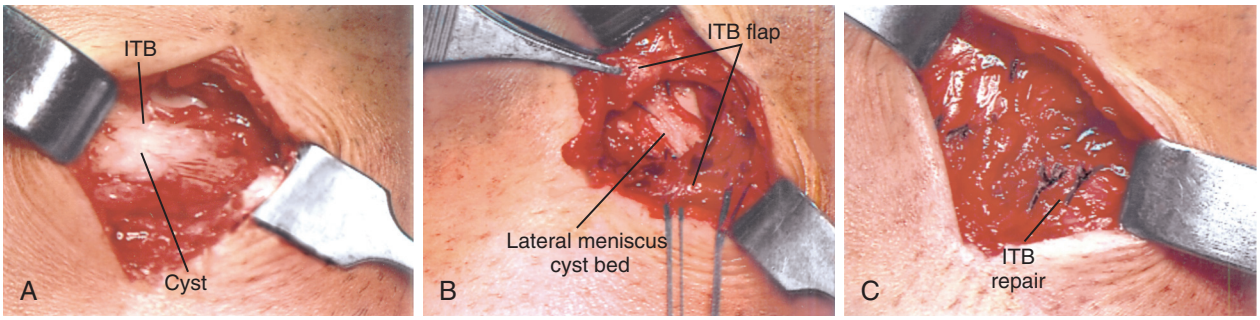

FIG 23-15 Demonstration of repair of lateral meniscus horizontal tear with a meniscal cyst. **A,** A 3-cm lateral joint incision placed directly over the cyst shows iliotibial band and obvious protruding cyst. **B,** Iliotibial band is split in a line of fibers over the cyst and retracted, the cyst is removed, and repair is performed of the remaining meniscus to attachments. **C,** Closure iliotibial band over the meniscus. Vertical sutures placed through the peripheral meniscus and iliotibial band help stabilize the repair. The arthroscopic inside-out repair of the meniscus body tear is then performed.

horizontal flap tear is encountered in patients younger than 50 years in which the tear extends throughout the body, creating superior and inferior segments, but the meniscal tissue is of good quality, has not displaced outside the tibiofemoral compartment, and can be repaired. The meniscus is rasped through the superior and inferior synovial attachments and within the horizontal tear. Minor meniscus fragments are removed. Vertical divergent sutures are used to close the tear site. A fibrin clot may be added to the repair site and placed within the horizontal tear. However, whether this technique increases the repair success rate has not been scientifically proven.

Meniscus Attachment Root Tears

Recently, there has been increased attention on the importance of identifying meniscus tears at their attachment site and repairing these root tears to restore medial or lateral meniscus function.[98,108,186,197,222] Without a suture repair, there is a complete loss of meniscus function because it displaces under weight-bearing loads. It is important to note that tears located 8 to 10 mm from the meniscus root attachment are frequently degenerative in nature and may not be amenable to repair. This section focuses on the successful repair of a meniscus directly at its attachment site. In a cadaveric study, LaPrade and associates[108] showed the importance of an anatomic repair to restore function of medial or lateral meniscus root tears. Johannsen and coworkers[98] described the quantitative arthroscopically pertinent anatomy of the posterior meniscal root attachments (Fig. 23-16).

During surgery, a thigh holder is required to allow sufficient joint opening for passing a suture device, particularly for medial meniscus root tears. A 4- to 5-mm tibial tunnel using an ACL tibial guide is placed directly at the attachment site. Different suture lasso instruments may be selected, and increased tensile strength may be gained by using multiple single sutures, a Mason-Allen suture, mattress sutures, or looped sutures. There is still considerable disagreement among studies regarding which suture fixation type is best used for root tears.

As shown in Table 23-1, all the suture configurations have relatively low maximum failure loads. Anz and associates[9] performed a biomechanical comparison of four different suture configurations for posterior meniscus root tears. All repairs used No. 2 braided polyester and

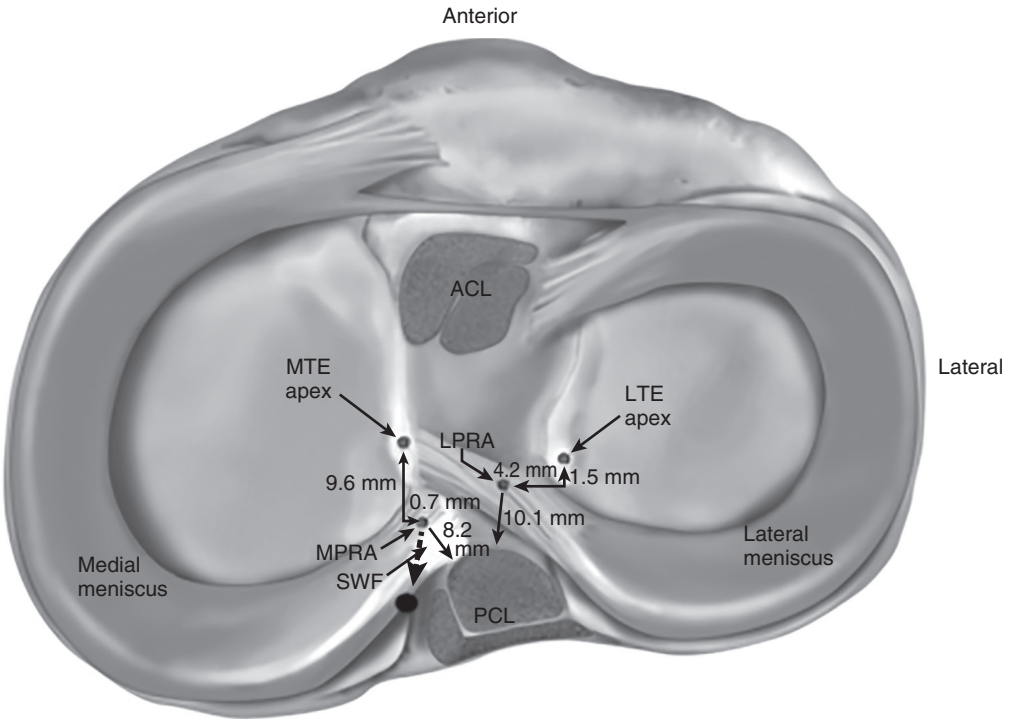

FIG 23-16 The medial and lateral meniscal posterior root attachments and relevant arthroscopically pertinent anatomy (right knee, superior view). *ACL,* Anterior cruciate ligament; *LPRA,* lateral meniscus posterior root attachment; *LTE,* lateral tibial eminence; *MPRA,* medial meniscus posterior root attachment; *MTE,* medial tibial eminence; *PCL,* posterior cruciate ligament; *SWF,* shiny white fibers of posterior horn of medial meniscus. (From Johannsen AM, Civitarese DM, Padalecki JR, et al. Qualitative and quantitative anatomic analysis of the posterior root attachments of the medial and lateral menisci. *Am J Sports Med.* 2012;40: 2342-2347.)

ultrahigh molecular weight polyethylene sutures. The configuration of two double-locking loop sutures had the highest failure load (368 ± 76 N), followed by a single double-locking loop suture (186 ± 43 N), one inverted mattress suture (126 ± 44 N), and two simple sutures (137 ± 49 N). These results provide the surgeon with objective data on the highest strength repair configuration possible. Native meniscal root strength was assessed in 43 cadaver specimens by Kopf and colleagues,[104] who reported a mean failure load of 678 ± 200 N for the posteromedial root and 648 ± 140 N for the posterolateral root.

A cadaveric investigation by Feucht and associates[63] showed the tendency of some suture repairs to elongate under cyclic loading. These findings indicates that, with any suture repair, the surgeon should proceed with conditioning (as is done with an ACL graft), loading the sutures (10 lb, empirical) with knee flexion-extension to diminish the potential for creep elongation of the construct.

Starke and coworkers[197] performed a cadaveric study on the tensile forces that occurred after a repair of a medial meniscus root tear. The highest mean tension of 60 ± 20 N occurred with internal tibial rotation and a 500-N compressive load at 90 degrees of knee flexion. The authors cautioned that, on weight bearing, there may be considerable tensile forces that occur within the medial meniscus root repair. This study is frequently quoted as providing a safe level for the suture fixation strength at the time of surgery. However, it should be noted that the loading conditions were only 500 N, which is less than one body weight as applied to a patient population and considerably less than the three to five times body weight loads incurred under certain activities of daily living.

The senior author prefers the use of the Novostitch (Ceterix) to place two looped or mattress type sutures (shown later in Illustrative Case 9). The sutures are tied over a tibial post. Weight bearing is restricted as described in Chapter 25.

Flap Tears

Two sets of sutures are required to repair flap tears (Fig. 23-17). Tension sutures are inserted first through the flap and then into the intact meniscal rim to anchor and reduce the flap into its anatomic bed. This restores the longitudinally running fibers of the meniscus and is performed in a manner similar to that for a radial tear repair. With the meniscus reduced, the remaining tear is repaired in the same fashion as a longitudinal tear, with superior and inferior vertical divergent sutures. The radial portion of the flap tear may only partially heal; however, the more peripheral longitudinal tear may heal, retaining partial meniscus function. Flap tears that represent 75% of the meniscus with the tear at the periphery or R/W junction are amendable for repair. Smaller flap tears 10 to 12 mm in length that occupy the R/W and W/W zone are not repaired.

Repair of the Lateral Meniscus Popliteomeniscal Fascicles and Attachments

During arthroscopy, a nerve hook is placed at the superior and then inferior popliteal hiatus to displace the lateral meniscus anteriorly and superiorly. The knee joint is placed in 60 to 90 degrees of flexion with a figure-four varus load applied to allow lateral tibiofemoral joint opening and maximum meniscus displacement (which is otherwise obstructed by the lateral femoral condyle). The posterior horn may be subluxated anteriorly 8 mm or more (usually not enough for locking into the joint) and superior "lift-off" of 10 to 12 mm is usually present, indicating laxity of the meniscotibial attachments. There is usually a

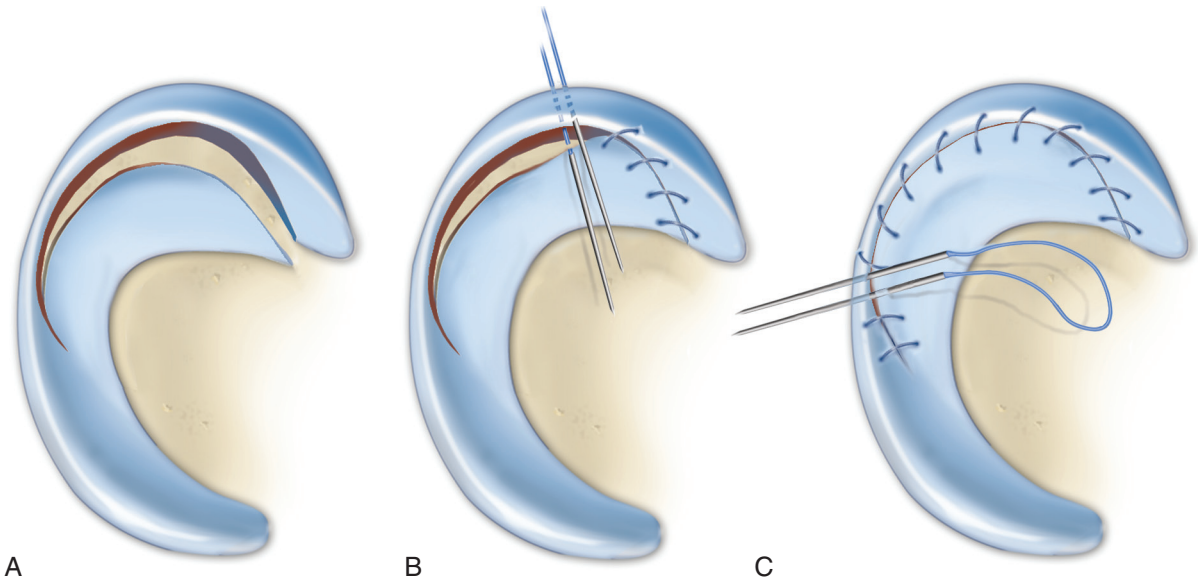

FIG 23-17 Repair technique for flap tears. **A,** The tear is identified and reduced. **B,** Horizontal tension sutures are placed to anchor the radial component of the tear. **C,** The longitudinal component is sutured using the double-stacked suture technique.

tear of the meniscotibial attachments in which the normal posterior-inferior popliteal hiatus is enlarged with attenuation or tearing of the meniscus attachments. The normal width of the popliteal hiatus is 10 to 15 mm. A larger width, particularly extending medially, allows for anterior subluxation of the posterior horn of the lateral meniscus to occur, even though the posterior-superior attachments are intact.[167,202]

The repair of the popliteomeniscal fascicles requires a meticulous inside-out technique with multiple sutures to obtain stability of the lateral meniscus and alleviate clinical symptoms. All-inside meniscus fixators or use of only a few sutures is not suitable to provide a stable construct and repair. The arthroscope is placed in the lateral portal and the suture cannula in the medial portal. The superior and inferior sites are rasped to encourage healing. The inside-out meniscus repair technique requires placement of multiple vertical divergent sutures, placed superiorly at the anteroinferior and posterosuperior fascicle attachments (either side of the popliteus tendon) to reduce the lateral meniscus posterior horn to a normal tibial position and restore the meniscus attachments.

The more difficult repair involves inferior vertical divergent sutures at the inferior popliteal hiatus and meniscotibial meniscus attachments. The tissues may be thin, and four to six sutures must be placed through the inferior capsule at the level of the tibial attachment and then in a vertical manner through the inferior outer third of the meniscus posterior horn. It is important that the previously placed superior vertical sutures retain the meniscus reduction so that placement of the inferior sutures does not displace the meniscus in an abnormal cephalad direction.

Techniques to Stimulate Healing of Meniscus Repairs

The initial vascular response of the meniscus to injury and tearing is characterized by the formation of a fibrin clot that is rich in inflammatory cells. This clot acts as a scaffold through which cells from the synovial membrane adjacent to the meniscus migrate.[10,11] The meniscal fibrochondrocytes may add to the intrinsic healing process.

Several experimental studies have investigated techniques to stimulate meniscus healing, including trephination or vascular ingrowth,[11,69,233,235] abrasion of the meniscal-synovial region,[41,81,147,159,180] grafting of the synovial pedicle,[70] incorporation of a fibrin clot,[147,180] and use of growth factors and cell-based therapy.[26,78,84,85,96,99,169,200,213,214] Although trephination, or creation of vascular access channels, has been demonstrated experimentally to promote healing,[11,180,234,236] the creation of these channels disrupts the normal peripheral structure and architecture of the meniscus.[115]

The incorporation of a fibrin clot[12,82,176,217] at the repair site of radial and avascular meniscus repairs is theoretically beneficial because it provides a scaffold to support the reparative cells and provide chemotactic and mitogenic stimuli.[225] The absence of a well-defined fibrin clot in the initial healing period along with a limited vascular supply may be the most important factors limiting meniscus healing in tears located in the middle third region. The problem is that a fibrin clot inserted between the tear edges of the meniscus prevents meticulous suturing of the tear both superiorly and inferiorly. A fibrin clot may be beneficial in horizontal tears in which the clot may be placed between the superior and inferior tear sites. The clot is prepared with a glass stirring rod. The clot is passed into the knee joint through a cannula, guided by a loop of suture placed around the clot from previously passed meniscus suture needles.

Ritchie and coworkers[180] found that abrasion of the parameniscal synovium was more effective than the incorporation of a fibrin clot in central meniscus repairs. Synovial abrasion stimulates vessels and mesenchymal cells to form a proliferate vascular pannus that migrates into the repair site.[53,80,190]

Several studies have demonstrated that an ACL reconstruction performed concomitantly with meniscal repair increases the success rate because the reconstruction protects the meniscus repair site owing to the restored knee stability and provides the beneficial healing effects of the postoperative hemarthrosis, including the release of growth factors.[40,51,54,97,142,206] In the majority of meniscus repairs done without concomitant ACL reconstruction, the meniscal-synovial junction is abraded (rasped), and a micropick is used in the intercondylar notch region to produce bleeding, which promotes adherence of platelets and fibrin at the repair site.[158] The meticulous suture placement described in this chapter stabilizes the tear and prevents gap formation at the repair site, allowing the subsequent repair process to progress.

The remodeling events and extent of reformation of a normal collagen architecture following meniscus repair remain unknown. Whether repaired meniscal tears in the middle third region have normal load-sharing capabilities and mechanical and material properties to prevent joint arthrosis remains unanswered. In the future, specific chemotactic and mitogenic agents may play an important role in stimulating the repair process of tears that extend into the avascular portions of the meniscus. Investigations of cytokines, growth factors, platelet rich plasma, and cell-based therapies have all been experimental to date, with no published clinical trials to document the potential effectiveness.[79,94,115,128-130,204,213-215,225]

OUR CLINICAL STUDIES

Arthroscopic Evaluation of 79 Meniscus Repairs in the R/R and R/W Zones

We conducted an investigation in 66 patients who underwent meniscus repair and ACL reconstruction, then follow-up arthroscopy 6 to 25 months postoperatively.[38] There were 79 meniscus repairs: 51 for tears located in the R/R zone and 28 for complex tears that extended into the R/W zone. The postoperative rehabilitation program included immediate knee motion and strengthening exercises the first postoperative day. Early partial weight bearing was initiated between the first and third postoperative weeks and was progressed to full by the eighth to tenth week. Follow-up arthroscopy was done for symptoms related to either tibial hardware or tibiofemoral joint pain.

The arthroscopic videotapes and operative records were reviewed by a surgeon who had not been involved in the care of the patients. The rate of meniscus healing was classified as completely healed (no visible surface defect), partially healed (at least 50% healed with meniscus stability and continuity restored), or failed (no visible healing). The three healing categories were analyzed separately, and then the categories of healed and partially healed were combined into one category (retained meniscus) and compared with the failure rates.

Repairs of R/R tears were classified as completely healed in 94%, partially healed in 4%, and failed in 2% (Table 23-2). Repairs of R/W tears were classified as completely healed in 54%, partially healed in 32%, and failed in 14%. The other factors analyzed in this study had no significant effect on the healing rates.

The program of immediate knee motion and early weight bearing was not deleterious to the healing meniscus repairs. This was one of the first investigations to demonstrate that repair of meniscus tears located in either the R/R or R/W zones have a satisfactory rate of healing when clinical grounds warrant the procedure. The increase in healing of meniscus tears when concurrent ACL surgery is performed is well appreciated. In knees that undergo meniscus repairs without ACL surgery, the femoral notch region is trephinated to induce joint bleeding and potentially aid in the deposition of blood products at the healing site for the initial fibrin clot formation.

CRITICAL POINTS Our Clinical Studies: Arthroscopic Evaluation of 79 Meniscus Repairs in the R/R and R/W Zones

- $n = 79$ meniscus repairs: 51 tears in R/R, 28 in R/W zones
- All had anterior cruciate ligament reconstruction with meniscus repair.
- Follow-up arthroscopy 6 to 25 months after repair
- Healing rates:
  - R/R: 94% healed, 4% partially healed, 2% failed
  - R/W: 54% healed, 32% partially healed, 14% failed
- No effect on meniscus repair healing rates: length of meniscus tear, tibiofemoral compartment of repair, patient age, length of time from injury to repair, length of follow-up, arthroscopic versus open procedure
- Use of immediate knee motion and early weight bearing not deleterious to healing meniscus repair

Outcome of 198 Meniscus Repairs in the R/W Zone

The clinical outcome of 198 meniscus tears in 177 patients that extended into the R/W, or who had a rim width of 4 mm or greater, was determined in a prospective study.[187] A total of 180 repairs (91%) were evaluated with a clinical examination a mean of 3.5 years (range, 2-9.7 years) postoperatively, and 91 repairs (46%) were evaluated with a follow-up arthroscopic examination a mean of 1.5 years (range, 2 months to 6.7 years) after the initial repair.

Seventy-six of the meniscus repairs were performed for acute or subacute tears and 122 for chronic tears. ACL ruptures also occurred in 128 patients. Of these, 126 (71%) underwent ACL reconstruction either with the meniscus repair (96 patients) or a mean of 22 weeks following the repair (30 patients). The ACL reconstructions were done with allografts in 72 knees and with bone-patellar tendon-bone (B-PT-B) autografts in 54 knees. After surgery, patients began immediate knee motion from 0 to 90 degrees. Flexion was advanced to 125 degrees by the third postoperative week. Crutches were used for the first 4 weeks for longitudinal tears and for the first 6 weeks for horizontal, radial, or

TABLE 23-2 Effect of Six Factors on Healing Rate of Meniscal Repairs

Factor	Complete Healing (*n*)	Partial Healing (*n*)	Failed (*n*)
Rim Width

CRITICAL POINTS Our Clinical Studies: Outcome of 198 Meniscus Repairs in the R/W Zone

- $n = 198$ meniscus repairs in 177 patients
- 71% had anterior cruciate ligament reconstruction either with or after the meniscus repair.
- 91% evaluated clinically 2 to 9.7 years postoperatively
- 46% evaluated follow-up arthroscopy 2 months to 6.7 years postoperatively
- Advanced rehabilitation program allowed 0 to 90 degrees of knee motion immediately postoperatively
- Deep knee flexion, full sports delayed for 6 months to protect repair site
- Overall reoperation rate for tibiofemoral symptoms: 20%
- 80% asymptomatic for tibiofemoral symptoms, not interpreted as rate of healing
- Significant differences in healing rates in menisci evaluated with follow-up arthroscopy:
  - Higher rate retention lateral meniscus compared with medial meniscus
  - Higher rate healing repairs assessed ≤12 months compared with repairs assessed >12 months with follow-up arthroscopy
  - Higher rate healing in knees without tibiofemoral joint symptoms compared with those with joint line pain
- Results support repair of meniscus tears that extend into the middle avascular region, especially in patients between 20 and 40 years of age.

complex multiplanar tears. Squatting or deep knee flexion greater than 125 degrees was not permitted for 4 to 6 months postoperatively. Return to full sports was restricted for 6 months.

At follow-up arthroscopy, the meniscus repairs were classified as healed if full-thickness apposition of the original tear occurred with no more than 10% of the original tear remaining. Repairs were considered partially healed if at least 50% of the original tear was healed and was stable when probed and the meniscus body was in its normal position in the tibiofemoral joint. Repairs were considered failed if more than 50% of the original tear was present or if unstable fragments required additional sutures. On clinical examination, a McMurray test was used with joint line palpation and compression to detect tibiofemoral joint symptoms.

The overall reoperation rate for tibiofemoral symptoms was 20% (39 meniscus tears). All patients who had tibiofemoral pain underwent follow-up arthroscopy. The reoperation rates according to the type of tear are shown in Table 23-3. The limited number of meniscal tears in the individual classification categories precludes specific conclusions on the outcome for each tear pattern. Of the 39 menisci examined, 2 were classified as healed, 13 as partially healed, and 24 as failed.

A total of 91 meniscus repairs were evaluated by follow-up arthroscopy: the 39 described earlier and 52 others that underwent surgery for reasons other than tibiofemoral joint symptoms. Of these 91, 23 (25%) were classified as healed, 35 (38%) as partially healed, and 33 (36%) as failed.

The effects of six factors on healing rates of meniscal repairs were evaluated (Table 23-4). Statistically significant differences were found in the rates of healing for three factors: tibiofemoral compartment of the meniscus repair (higher healing rate in lateral meniscus repairs than in medial meniscus repairs), time from repair to follow-up arthroscopy (higher healing rate in patients evaluated at ≤12 months compared with those evaluated >12 months postoperatively), and the presence of tibiofemoral symptoms (higher healing rate in asymptomatic patients compared to symptomatic patients).

The significantly higher rate of retention of lateral meniscus repairs found in this study agrees with those of other reports.[142,185,190] The reasons for the higher failure rate of medial meniscus repairs are unknown at present. The results of this investigation support the repair

TABLE 23-3 Reoperation Rates for Meniscal Repairs Attributed to Tibiofemoral Joint Symptoms

Type of Meniscus Tear	Total Meniscus Tears in Study	Number Requiring Repeat Arthroscopy

ACL, Anterior cruciate ligament.

of meniscus tears that extend into the middle third region, especially in patients in their 20s and 30s and in highly competitive athletes. The study's reoperation rate should not be interpreted as the rate of meniscal healing. The long-term function and chondroprotective effects of the repaired menisci need to be determined, and this group of patients is under prospective long-term evaluation.

Outcome of 30 Meniscus Repairs in the R/W Zone in Patients 40 Years of Age and Older

The clinical outcome of 30 meniscus tears that extended into the R/W zone in patients 40 years of age and older was prospectively determined.[150] ACL reconstruction was performed concurrently with the meniscus repair in 72%. Ten meniscus repairs were done for acute knee injuries (≤10 weeks from injury), and 20 were done for chronic injuries. Twenty-eight repairs were evaluated with a clinical evaluation a mean of 2.8 years (range, 2-5.9 years) postoperatively, and six repairs were evaluated with arthroscopy a mean of 2 years (range, 1.3-3 years) after the repair.

At follow-up, 26 meniscus repairs (87%) were asymptomatic for tibiofemoral joint symptoms and had not required further surgery. There was no significant effect of the tibiofemoral compartment of the meniscus repair, chronicity of injury, concomitant ACL reconstruction, or condition of the articular cartilage on the presence of tibiofemoral pain or meniscus resection (Table 23-5).

A subjective evaluation using the CKRS was completed at follow-up on 25 knees; 3 knees whose meniscal repairs failed and required removal at follow-up arthroscopy and 1 other knee that had follow-up arthroscopy but not a clinical evaluation 2 years postoperatively were not included. Of these 25 knees, 17 had chronic meniscal tears and eight had acute tears before the index repair procedure. Nineteen had a concomitant ACL reconstruction.

The 17 knees with chronic symptoms had statistically significant improvements in the mean scores for pain, swelling, and giving-way ($P < .01$); squatting ($P < .05$); and running, jumping, and cutting ($P < .0001$). Before the meniscal repair, 12 had given up sports, and five were participating with symptoms and functional limitations. At follow-up, 12 had returned to sports without problems, 1 was participating with symptoms, and 4 had not returned to sports owing to the knee condition. In the patient rating of the overall knee condition, 11 rated their knees as normal or very good, 3 as good, 2 as fair, and 1 as poor.

Seven of the eight patients with an acute injury were involved in athletics prior to their injuries. The one patient who was not involved in athletics returned to normal activities of daily living without symptoms. Six patients returned to athletics without problems. Only one patient reported difficulty with squatting, and one patient had problems with running, jumping, and cutting. All eight patients rated their overall knee condition as normal or very good. There were no infections, knee motion problems, saphenous neuritis, or other major complications.

With many patients remaining active in middle age, the ability to retain the meniscus after an injury is an important goal. This study demonstrated that repair of complex tears in older adults is feasible and that the majority are asymptomatic for tibiofemoral joint symptoms an average of 3 years postoperatively. In athletically active patients, the indications of meniscus repair are based on current and future activity levels and the authors recommend preservation of meniscal tissue wherever possible regardless of age. It should be noted that the majority of meniscus tears in patients older than 40 years are degenerative and not repairable. This group of select patients had tears that were classified as amendable to repair by the criteria already provided.

Outcome of 71 Meniscus Repairs in the R/W Zone in Patients 20 Years of Age or Younger

A prospective study was conducted on 71 consecutive meniscus repairs done in 58 patients younger than 20 years to determine the clinical outcome.[151] A total of 67 meniscal repairs were examined clinically a mean of 4.2 years (range, 2-16.3 years) postoperatively, and 36 were evaluated during follow-up arthroscopy a mean of 1.4 years (range, 3 months to 5 years) postoperatively.

CRITICAL POINTS Our Clinical Studies: Outcome of Meniscus Repairs in the R/W Zone in Patients ≥40 Years

- $n = 30$ meniscus repairs in 29 patients
- 72% had ACL reconstruction with the meniscus repair.
- 93% evaluated clinically 2 to 5.9 years postoperatively
- 20% evaluated follow-up arthroscopy 1.3 to 3 years postoperatively
- 87% asymptomatic for both tibiofemoral symptoms and had not required further surgery
- No significant effect on presence of tibiofemoral pain or meniscus resection of tibiofemoral compartment of meniscus repair, chronicity of injury, concomitant ACL reconstruction, condition of articular cartilage
- Knees with chronic injuries had significant improvements in symptoms, functional limitations with sports and daily activities.
- Patient rating overall knee condition: 76% normal/very good, 12% good, 12% fair/poor
- 76% returned to sports or regular activities with no problems, 4% returned to sports but had symptoms, and 20% did not return to sports.
- Indications for meniscus repair should be based on patient's current and future desired activity level, not on age.

TABLE 23-5 Effect of Four Factors on Presence of Tibiofemoral Symptoms or Arthroscopic Second-Look Failure of Meniscal Repair

Factor	Asymptomatic	Tibiofemoral Symptoms or Arthroscopic Failure	*P* Value
Tibiofemoral Compartment of Meniscal Repair			
Medial ($n = 19$)	17 (89%)	2 (11%)	0.55
Lateral ($n = 11$)	9 (82%)	2 (8%)	
Time From Injury to Meniscal Repair			
≤10 weeks ($n = 10$)	9 (90%)	1 (10%)	0.7
>10 weeks ($n = 20$)	17 (85%)	3 (15%)	
Concomitant ACL Reconstruction			
Yes ($n = 22$)	20 (91%)	2 (9%)	0.26
No, ACL intact ($n = 8$)	6 (75%)	2 (25%)	
Articular Cartilage			
Normal ($n = 16$)	13 (81%)	3 (19%)	0.35
Abnormal ($n = 14$)*	13 (93%)	1 (7%)	

ACL, Anterior cruciate ligament.
*Abnormal defined as fissuring and fragmentation of more than half of the involved surface, or subchondral bone exposed.

CRITICAL POINTS Our Clinical Studies: Outcome of 71 Meniscus Repairs in R/W Zone in Patients <20 Years

- $n = 71$ meniscus repairs in 58 patients
- 61% had anterior cruciate ligament reconstruction either with or after the meniscus repair.
- 94% evaluated clinically 2 to 16.3 years postoperatively
- 51% evaluated follow-up arthroscopy 3 months to 5 years postoperatively
- 75% had no tibiofemoral symptoms or failed meniscus repair according to arthroscopic classification.
- Reoperation rates attributed to tibiofemoral joint symptoms: 8% single longitudinal tears, 33% double longitudinal tears, 14% complex multiplanar tears
- No effect on tibiofemoral joint symptoms or arthroscopic classification of failure: tibiofemoral compartment of meniscal repair (medial vs. lateral), chronicity of injury, concomitant ACL reconstruction
- Presence of tibiofemoral pain: sensitivity rate of 57%, specificity rate of 93% in identifying repairs classified as failed at follow-up arthroscopy
- Knees with concomitant meniscus repair and ACL reconstruction:
  - No problems with daily activities
  - 73% return to sports without problems
  - 87% rated overall knee condition as normal or very good
  - No complications, arthrofibrosis
- Presence of tibiofemoral pain not always indicative of a failed meniscus repair; consider MRI before arthroscopy to determine source of pain.
- Results allow recommendation repair meniscus tears that extend into middle third region when conditions indicate that a stable repair can be obtained.
- This recommendation is particularly appropriate in young active individuals in whom removal of a meniscus tear that extends into the middle avascular region would result in major loss of meniscus function and risk for future joint arthrosis.

TABLE 23-6 Diagnostic Test Rates of Tibiofemoral Joint Pain on Clinical Examination in Identifying Failed Meniscal Repairs

Diagnostic Test	Result (%)
Prevalence	58
Sensitivity	57
Specificity	93
False-positive	7
False-negative	43
Positive predictive value	92
Negative predictive value	61

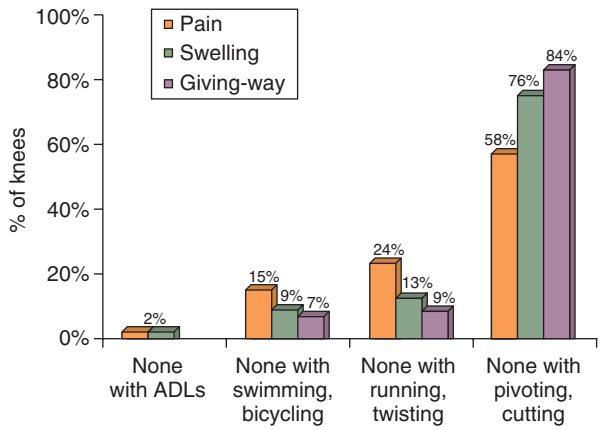

FIG 23-18 Analysis of symptoms at follow-up (mean, 47 mo after the operation) for 45 knees that had anterior cruciate ligament reconstruction and meniscus repair procedures. *ADL*, Activities of daily living. (From Noyes FR, Barber-Westin SD. Arthroscopic repair of meniscal tears extending into the avascular zone in patients younger than twenty years of age. *Am J Sports Med.* 2002;30:589-600.)

There were 36 males and 25 females whose mean age at the time of the meniscus repair was 16 years (range, 9-19 years). Skeletal maturity, according to closed or nearly closed physes on radiographs of the distal femur and proximal tibia, had been reached in 54 knees (88%). Forty meniscal repairs were done for an acute knee injury (1-12 weeks after the injury), and 31 meniscal repairs were done for a chronic knee injury. Forty-three meniscal repairs (61%) were performed concurrently with an ACL reconstruction. Fourteen meniscal repairs (20%) were done in 11 knees a mean of 34 weeks (median, 4 weeks; range, 4-176 weeks) prior to an ACL reconstruction. Skeletal maturity had been completed in all knees that had ACL reconstructions.

At follow-up, 53 of 71 meniscal repairs (75%) had no tibiofemoral symptoms and had not been classified as failed on follow-up arthroscopy.

Fourteen meniscal repairs (20%) developed tibiofemoral joint symptoms; all but one of these had follow-up arthroscopy a mean of 19 months (range, 3-49 months) postoperatively. One repair had healed, and four had partially healed. Eight repairs had failed: two required removal at the prior repair site, three required near-total meniscectomy, and two had a repeat repair. In one knee that required a near-total lateral meniscectomy, a meniscus allograft was implanted.

Twenty-three other meniscal repairs had follow-up arthroscopy for reasons other than tibiofemoral symptoms a mean of 17 months postoperatively (range, 7-60 months). Twelve of these meniscal repairs had healed. Seven repairs had partially healed; partial meniscectomy was required in five, and meniscal tears were deemed stable and left intact in 2. Four of these 23 meniscal repairs (in three knees) failed. A lateral and medial meniscus allograft were implanted 40 months and 42 months, respectively, after the index repair procedure in one knee. A repeat meniscus repair was done in one knee, and a partial meniscectomy at the prior repair site was required in another knee.

There was no statistically significant effect of the tibiofemoral compartment of the meniscal repair, chronicity of injury, or concomitant ACL reconstruction on the presence of tibiofemoral joint symptoms or arthroscopic classification of failure. The presence of tibiofemoral pain on the physical examination was found to have a sensitivity rate of 57% and a specificity rate of 93% (Table 23-6) in identifying meniscus repairs classified as failed or that required partial resection at follow-up arthroscopy. The positive predictive value was 92% and the negative predictive value was 61%.

Of the 45 knees that had a concomitant meniscal repair and ACL reconstruction, 26 (58%) had no pain, 34 (76%) had no swelling, and 38 (84%) had no giving-way with sports activities involving jumping cutting, and pivoting at follow-up (Fig. 23-18). None of these knees

TABLE 23-7 Sports Activities of Patients Before the Meniscal Repair and at Follow-up*

CRITICAL POINTS Our Clinical Studies: Long-Term Outcome of 29 Meniscus Repairs in the R/W Zone in Patients ≤20 Years of Age

- $n = 29$ meniscus repairs followed 10.1 to 21.9 years postoperatively
- Success rate determined from MRI, 45 degrees weight-bearing posteroanterior radiographs, two knee rating systems
- Overall success rate: 62% (18 of 29)
- Failures: six partial meniscectomy, two loss joint space on radiographs, three MRI criteria
- No association return to strenuous sports, concurrent ACL reconstruction, chronicity of injury and failure of repair
- No significant difference between 4 years and 17 years evaluations for pain, swelling, patient rating
- Chondroprotective effect demonstrated in patients with healed meniscus repairs

had functional limitations with walking, stair climbing, or squatting. Forty (89%) had no or only slight problems with running, jumping, and twisting.

Before the meniscus repair, 34 patients were participating in various types of athletic activities, and 11 had given up sports owing to knee problems (Table 23-7). At follow-up, 33 (73%) had returned to athletics without symptoms or limitations, and three (7%) were participating in sports with symptoms against advice. Two (4%) had not returned to sports owing to the knee condition, and 7 (16%) had given up sports activities owing to factors unrelated to the knee condition. At follow-up, 39 (87%) rated the overall knee condition as normal or very good, 2 (4%) as good, 3 (7%) as fair, and 1 (2%) as poor.

There were no instances of infection, accessory posteromedial or posterolateral incision pain, saphenous neuritis, or arthrofibrosis.

The results of this study allow recommendation of repair of simple or complex meniscal tears that extend into the R/W zone when the conditions are met that a stable repair of a potentially functional meniscus can be obtained. This recommendation is particularly appropriate in young active individuals in whom removal of a meniscus tear that extends into the middle third region would result in major loss of meniscus function and risk for future joint arthrosis.

Long-Term Outcome of 29 Meniscus Repairs in the R/W Zone in Patients 20 Years of Age or Younger

From the group of 71 meniscus repairs just described, a homogenous cohort of 29 repairs for single longitudinal R/W tears was selected for a long-term analysis of outcome and chondroprotective effects of the operation.[154] The patients were followed a mean of 16.8 years (range, 10.1-21.9 years) postoperatively. The success rate was determined with a critical rating system that required normal or nearly parameters from two validated knee rating systems, MRI, 45-degree weight-bearing PA radiographs, a comprehensive knee examination, and a KT-2000 knee arthrometer test. A 3T MRI scanner with cartilage-sensitive pulse sequences was used, and T2 mapping was performed by an independent radiologist. The CKRS and the International Knee Documentations Committee Rating System (IKDC) were completed.

The overall success rate was 62% (18 of 29 repairs). The failures included six (21%) that required partial meniscectomy, 2 (that were asymptomatic) that had a loss of joint space on radiographs, and 3 (that were asymptomatic and had normal radiographs) that failed according to MRI criteria.

There was no significant association between return to strenuous sports, concurrent ACL reconstruction, or chronicity of the injury and failure of the meniscus repair. There was a higher rate of failure in medial meniscal repairs compared with lateral repairs ($P = .05$). There were no instances of infection, incision pain, saphenous neuritis, or arthrofibrosis.

There was no significant difference between the initial (4-year) and long-term (17-year) follow-up evaluations for the mean scores of pain, swelling, jumping, the patient rating of the overall knee condition, or the overall rating score. All but four patients were participating in mostly low-impact sports activities at follow-up without problems; the four not participating had given up athletics for reasons other than their knee condition. The results of the KT-2000 test were rated as normal or nearly normal in all 18 patients who underwent concurrent ACL reconstruction.

This study was the first long-term investigation that used weight-bearing PA radiographs and MRI in addition to the clinical examination to determine the healing rates of R/W single longitudinal repairs. A chondroprotective effect was demonstrated in patients with healed meniscus repairs, which is especially important considering the patient age at the time of surgery (9.4-20 years) and concurrent ACL injuries. Healing adjuncts in the future are most likely required to increase the success rate.

RESULTS OF MENISCUS REPAIRS FROM OTHER CLINICAL STUDIES

A summary of the clinical outcome of R/W meniscal repairs from a variety of investigations is shown in Table 23-8. Recent studies assessing clinical healing rates for tears located in other regions of the meniscus, or those that combined regions together in the investigation's analysis, are shown in Table 23-9.

Complications such as chondral damage, cyst formation, chronic effusions, joint irritation, synovitis, and device breakage and migration into the extra-articular soft tissues and deteriorating results have been reported following the use of rigid, all-inside fixation devices.[5,39,91,92,100,107,110,133,134,160,194,210] Investigations of newer flexible

all-inside suture systems (Fig. 23-19) reported acceptable short-term clinical healing rates, as shown in Tables 23-8 and 23-9. However, longer term follow-up is required of these devices to ensure that the rate of failure does not increase with time. In addition, most surgeons use only two to three sutures with the all-inside systems. Concern exists regarding the fixation strength of these devices compared with the multiple vertical divergent suturing procedure described in this chapter.

The question of whether meniscal repair is effective in preventing joint deterioration remains unanswered according to published clinical data. The problem of commonly associated ACL tears or other injuries found in these knees precludes scientifically justifiable answers. However, based on the well-documented irreparable joint damage and poor results of long-term clinical studies after partial and total meniscectomy, preservation of meniscal tissue is paramount for long-term joint function. It is our opinion that the gold standard for meniscus repair procedures remains a meticulous inside-out repair with multiple vertical divergent sutures and an accessory posteromedial or posterolateral approach to tie the sutures directly posterior to the meniscus attachment. This procedure requires added time and assistants. The newer all-inside devices are more time efficient, but longer term clinical studies are required. We consider meniscus repair as important, if not more important, as an ACL reconstruction in regard to long-term knee function. The procedures and surgical approaches are not difficult, and the anatomical approach is straightforward. There should be an exceedingly low risk of intraoperative complications such as nerve damage and arthrofibrosis if the operative procedure and rehabilitation program discussed in this and other chapters are followed.

We disagree with the approach of leaving a meniscus tear greater than 10 mm in length untreated at the time of ACL surgery. To use a

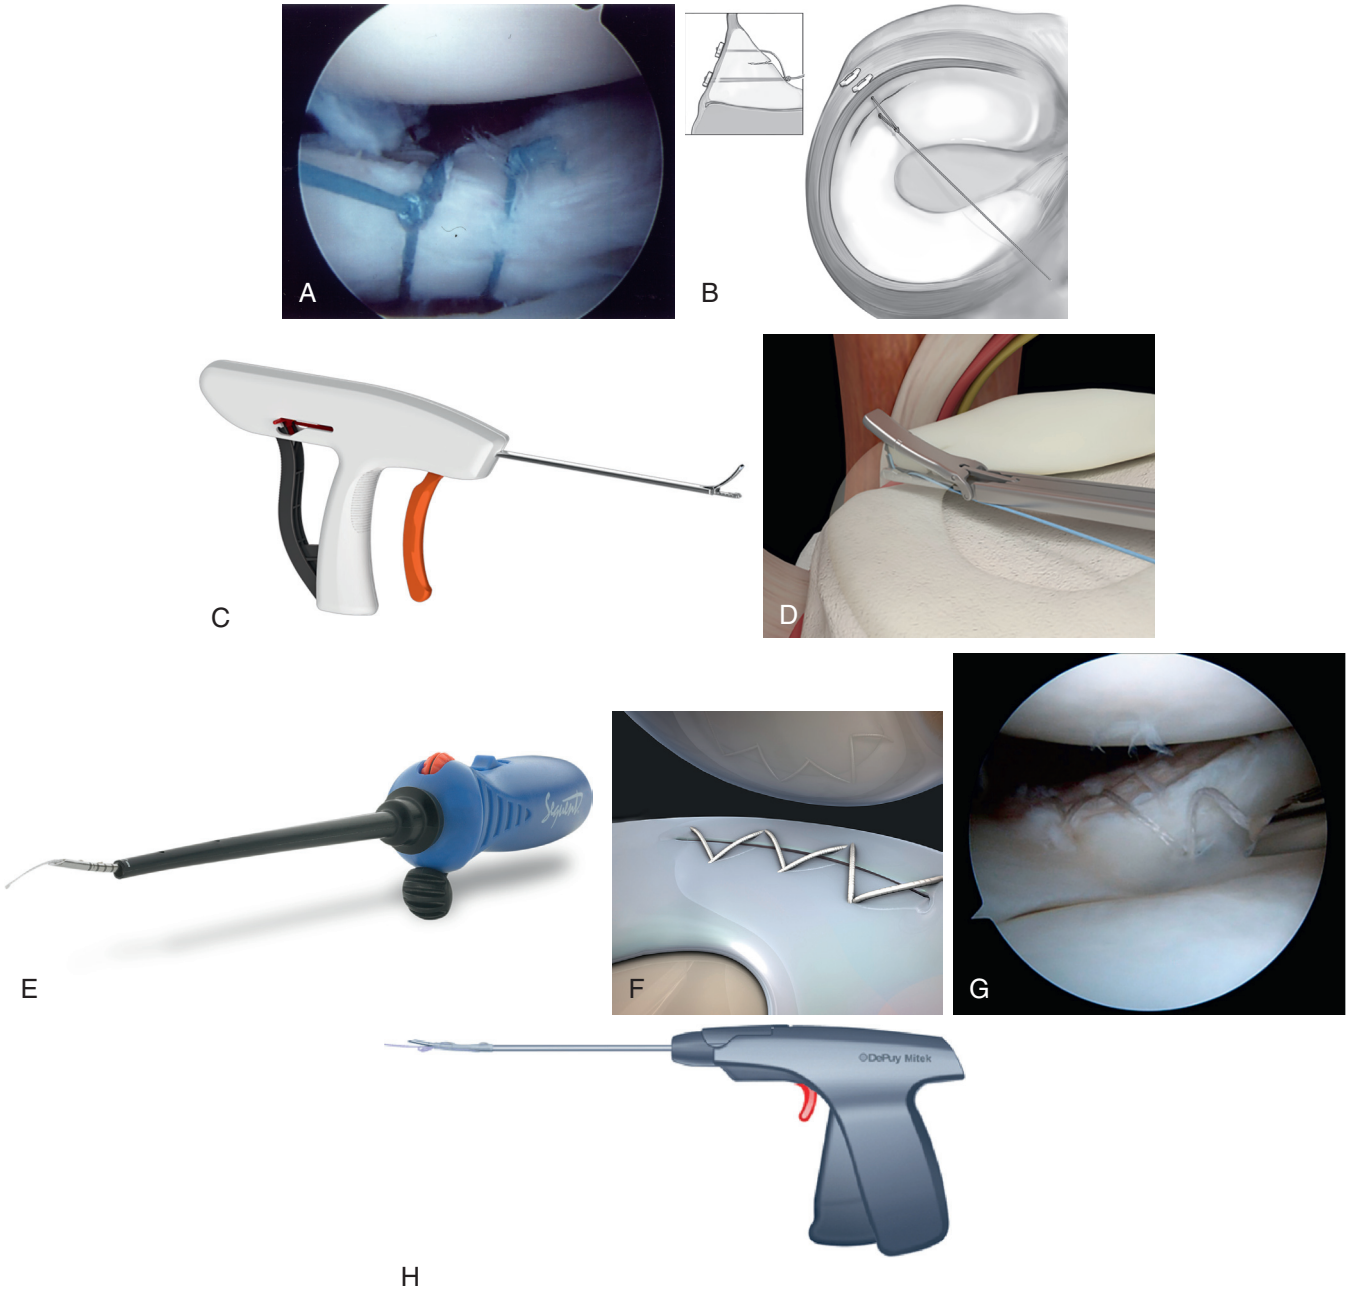

FIG 23-19 Examples of meniscus repairs using newer generation all-inside suture-based devices that allow tensioning. See text for published results of these procedures. Careful selection of the type of meniscus tear for these techniques is required because usually only two to four sutures are used and the fixation strength is inferior to that of multiple vertical divergent sutures. With proper selection of tears and avoidance of complex tears, there appears to be a role for these procedures in simple longitudinal tears in the red-red and red-white zones. **A** and **B,** Ultra Fast-Fix. **C** and **D,** NovoStitch. **E** to **G,** Sequent; **H,** Omnispan. conservative approach and hope for healing may risk further tearing and subsequent loss of meniscus function. Unfortunately, once a meniscectomy has been performed in a younger patient, few options exist and even meniscus transplants do not provide a dependable long-term successful solution. In patients requiring meniscus transplants, we have frequently observed that the original treatment of the meniscus tear was ineffective; either a large tear was left untreated, a repair was done with too few sutures or with fixators that provided only limited stability, or a tear that extended into the middle third region was removed that may have been repaired.

In the future, tissue engineering may provide increased success rates of meniscus repair, especially for tears that extend into the avascular region.[42,50,87,88,120,143,188,212] Cell-based therapy using meniscal fibrochondrocytes, articular chondrocytes, or mesenchymal stem cells seeded onto scaffolds offers promise, as does the introduction of growth factors into repair sites.[58,76,95,162,213-215,232]

ILLUSTRATIVE CASES

Case 1. A 30-year-old female U.S. military instructor presented with complaints of pain to the lateral aspect of her right knee of 3 years' duration. The symptoms began after the patient had completed a 7-mile marathon and gradually progressed to pain with daily activities. MRI was negative for a lateral meniscus abnormality. Physical examination revealed tenderness to the lateral tibiofemoral joint, but all other tests and radiographs were normal. All meniscus tests were negative, including standing single-leg rotation, McMurray flexion-rotation, and varus axial loading.

Arthroscopy was performed that initially demonstrated a normal lateral meniscus (Fig. 23-20, *A*). However, further evaluation revealed a large tear of the meniscotibial attachments (Fig. 23-20, *B*) with an abnormal lift-off and anterior subluxation of the posterior horn from the tibia (Fig. 23-20, *C*). Maximal varus loading and lateral joint opening were required to separate the tibiofemoral joint, which produced the subluxation of the posterior horn. Multiple vertical divergent sutures were placed superiorly and inferiorly with an outside-in technique, avoiding the popliteal tendon (Fig. 23-20, *D* and *E*). The initial sutures were placed superiorly to reduce the meniscus onto the tibia. The patient recovered and returned to athletic activities 6 months postoperatively without pain. The cosmetic appearance of the 2-cm posterolateral approach is shown (Fig. 23-20, *F*).

Case 2. A 16-year-old male athlete presented with a chronic medial meniscus tear that had been treated conservatively. Physical examination demonstrated medial tibiofemoral joint pain, but all other tests and radiographs were normal. At arthroscopy, an unusual complex horizontal meniscal tear was found that extended throughout the entire meniscal body from the periphery to the inner meniscal margin (Fig. 23-21, *A*). Removal of either the superior or inferior tear

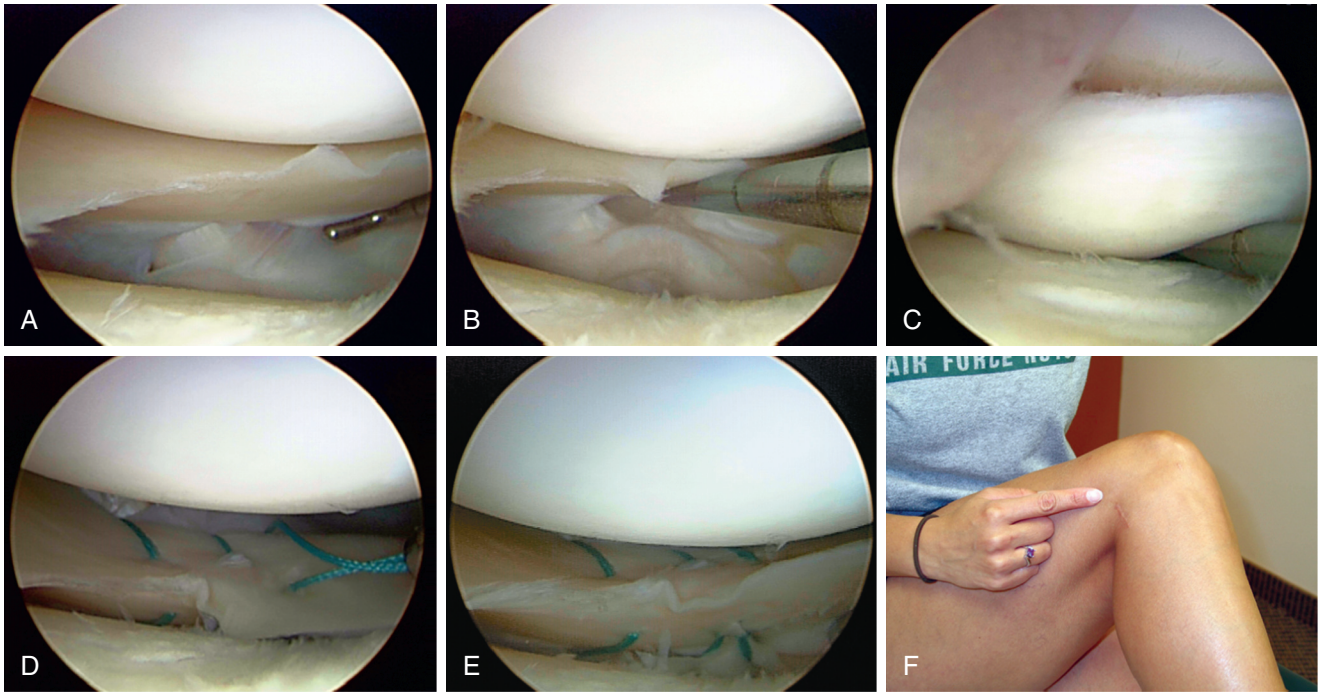

FIG 23-20 Case 1.

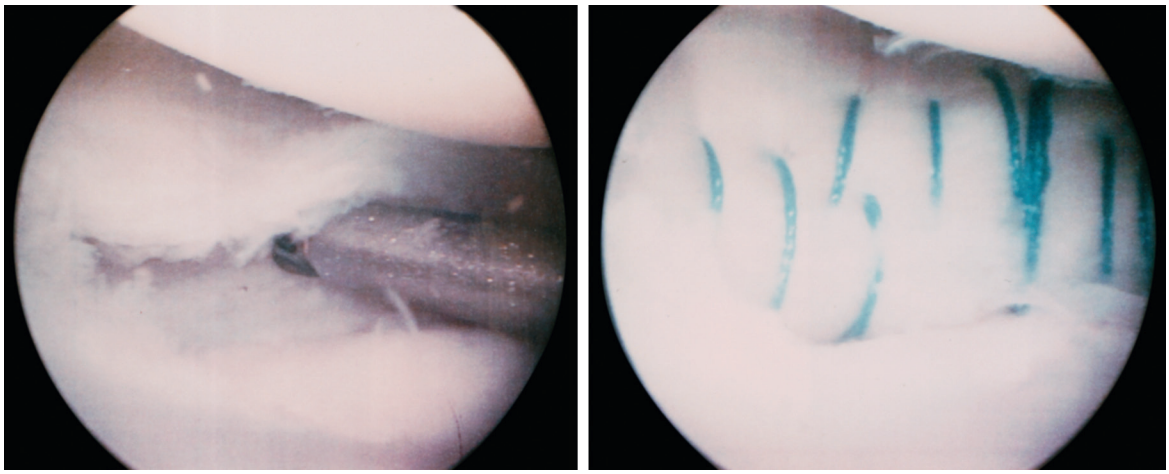

FIG 23-21 Case 2.

component would have substantially compromised the remaining meniscal tissue and function. The body of the meniscus, between the superior and inferior tear edges, was rasped. Multiple vertical divergent sutures were placed to close the gap between the superior and inferior tear edges (Fig. 23-21, *B*).

At the most recent follow-up evaluation, 4 years postoperative, the patient had no symptoms and had returned to recreational athletics without problems.

Case 3. An 18-year-old Division I collegiate hockey player presented 10 months after sustaining a right knee injury in which the lateral aspect of his leg was struck with a helmet. He complained of pain with squatting, twisting, and turning activities. Examination demonstrated lateral joint line tenderness in deep flexion but no other abnormalities. MRI was negative for a lateral meniscus tear. The patient continued to have pain over the ensuing 5 months and elected to undergo arthroscopy for a potential hypermobile meniscus abnormality. The lateral meniscus hiatus was noted to be increased in size (Fig. 23-22, *A*), and although the meniscus was firmly attached to the capsule, there was increased translation in the central portion of the lateral tibiofemoral compartment. In addition, the anterior rim at the meniscocapsular junction demonstrated fraying (Fig. 23-22, *B*). An inside-out lateral meniscus repair was performed with eight sutures under arthroscopic control, which successfully resolved the meniscus hypermobility (Fig. 23-22, *C*).

The patient did well and returned to collegiate hockey without problems. Three years later, he sustained a twisting injury to the same knee and sustained a complete ACL tear and a radial lateral meniscus tear. An ACL autogenous B-PT-B reconstruction was performed. The lateral compartment demonstrated the healed prior meniscus repair in the posterior horn (Fig. 23-22, *D*). A new radial tear, found at the junction of the anterior and middle thirds, extending to the capsular margin was repaired with six horizontal mattress sutures (Fig. 23-22, *E*). The patient recovered without complications.

Case 4. A 33-year-old man presented 1 week after a left knee injury sustained while playing basketball. Physical examination revealed 7 mm of increased anterior tibial translation and severe medial joint line tenderness. The patient had a mild effusion and 90 degrees of knee flexion. He was referred to physical therapy for 4 weeks of rehabilitation to regain normal knee motion and muscle function. A B-PT-B ACL autograft, repair of a complex multiplanar lateral meniscus central third tear, and repair of a 15-mm single longitudinal medial meniscus central third tear were performed (Fig. 23-23, *A*). The patient had a chronic PCL rupture on the right knee of 12 years' duration, which had been treated conservatively.

At the latest follow-up evaluation, 15 years postoperatively, the patient had no complaints with his right knee. He had participated in basketball without symptoms and rated the overall condition of his knee as normal. Physical examination demonstrated a grade 1 pivot shift, a full range of knee motion, and no crepitus, swelling, or joint line pain. All meniscus tests were negative. Standing PA radiographs demonstrated only 1 mm of decrease in the lateral tibiofemoral compartment joint space compared with the opposite knee and no decrease in the medial tibiofemoral compartment joint space (Fig. 23-23, *B*).

Case 5. A 31-year-old man presented 2 months after a twisting injury to the right knee sustained during a soccer game that had been treated elsewhere with diagnostic arthroscopy. Physical examination revealed 10 mm of increased anterior tibial translation, moderate medial tibiofemoral joint line pain, and a mild effusion. The patient underwent a B-PT-B autogenous ACL reconstruction and a repair of a 20-mm peripheral medial meniscus tear (Fig. 23-24, *A*). Noteworthy fissuring and fragmentation were noted on the medial femoral condyle (Fig. 23-24, *B*). The patient recovered and was released to full sports activities 9 months later.

At the most recent follow-up evaluation, 16 years postoperative, the patient stated he had participated in competitive soccer without symptoms or functional limitations until a reinjury that had occurred 3

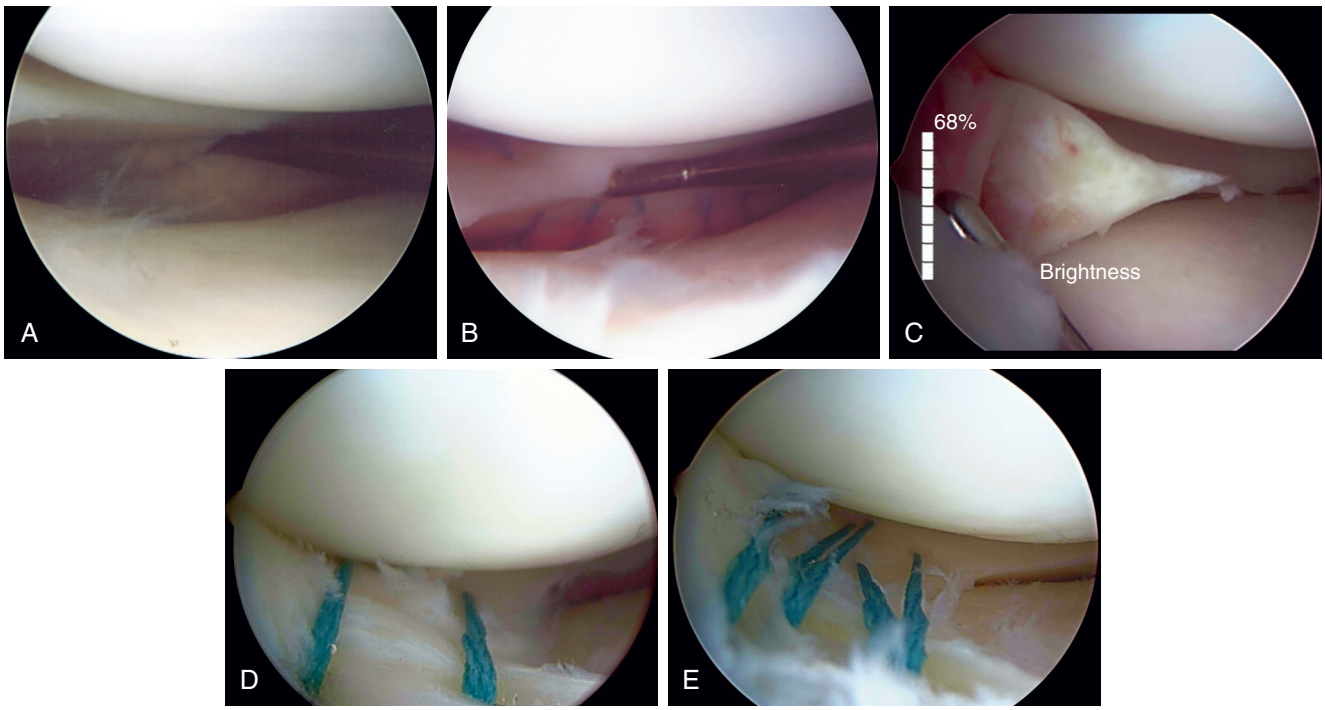

FIG 23-22 Case 3.

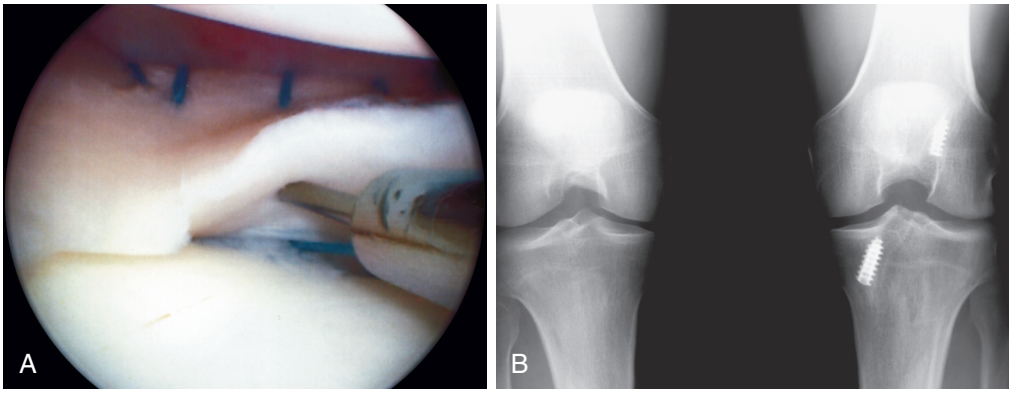

FIG 23-23 Case 4.

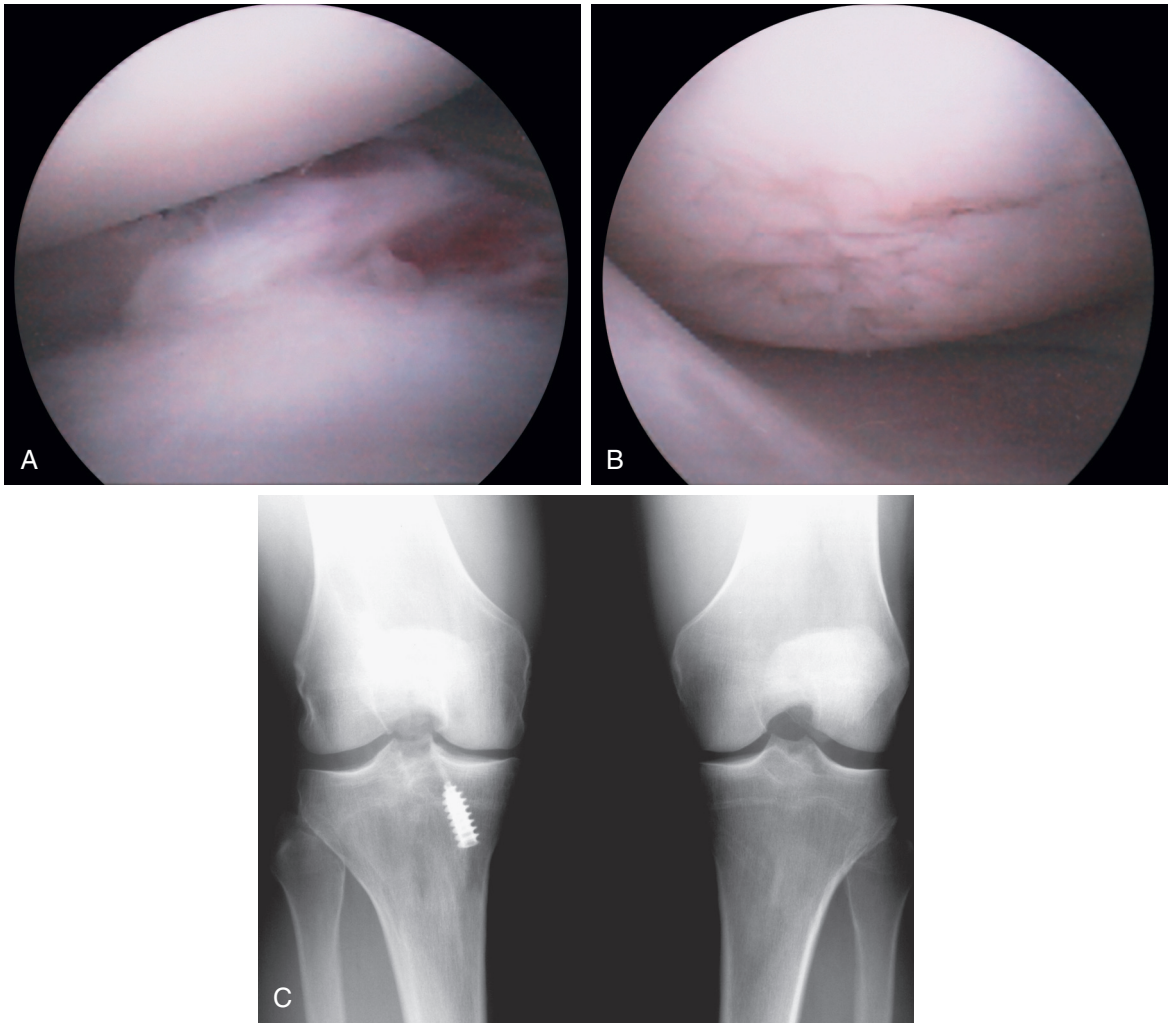

FIG 23-24 Case 5.

months prior to his examination. He underwent a partial medial meniscectomy elsewhere. Physical examination revealed 2 mm of increased anteroposterior tibial displacement on KT-2000 testing, no crepitus, a normal range of motion, and no joint line pain. The patient rated the overall condition of his knee as very good. Radiographs demonstrated preservation of the medial tibiofemoral compartment (Fig. 23-24, *C*). However, the patient was warned that continued high-impact activities might accelerate medial compartment joint arthrosis with the loss of the medial meniscus and preexisting damage noted on the medial femoral condyle.

Case 6. An 18-year-old man sustained a right knee injury playing basketball and presented 2 weeks later with a mild effusion, 12 mm of increased anterior tibial translation, medial joint line pain, and a nearly normal range of knee motion. He underwent a B-PT-B autogenous ACL reconstruction and bilateral meniscus repairs for double longitudinal posterior horn tears (Fig. 23-25, *A*). There was noteworthy fissuring and fragmentation of the medial femoral condyle (Fig. 23-25, *B*). He recovered well and returned to basketball for several years. The patient sustained a left knee injury 5 years later and underwent an ACL reconstruction and total medial meniscectomy elsewhere.

At the most recent follow-up evaluation, 14 years postoperative, the patient rated his right knee as nearly normal without symptoms. Physical examination of the right knee demonstrated negative Lachman and pivot shift, no meniscus pathology, a full range of knee motion, and no joint effusion. The left knee was symptomatic for medial tibiofemoral compartment symptoms and had drifted into varus malalignment. Radiographs demonstrated preservation of the medial and lateral tibiofemoral compartment joint spaces in the right knee (Fig. 23-25, *C*) but loss of medial joint space in the left knee (Fig. 23-25, *D*). An opening wedge high tibial osteotomy was subsequently performed on the left knee.

Case 7. A 24-year-old man presented 3 days after a right knee injury sustained playing volleyball. Physical examination demonstrated a moderate effusion, range of motion from 10 to 70 degrees, poor quadriceps contraction, moderate medial joint line pain, and 5 mm of increased anterior tibial translation. He underwent 4 weeks of physical therapy to regain knee motion and quadriceps strength. A B-PT-B autogenous ACL reconstruction and a repair of a 30-mm double longitudinal medial meniscus tear were done. Noteworthy fissuring and fragmentation were noted on the medial and lateral femoral condyles.

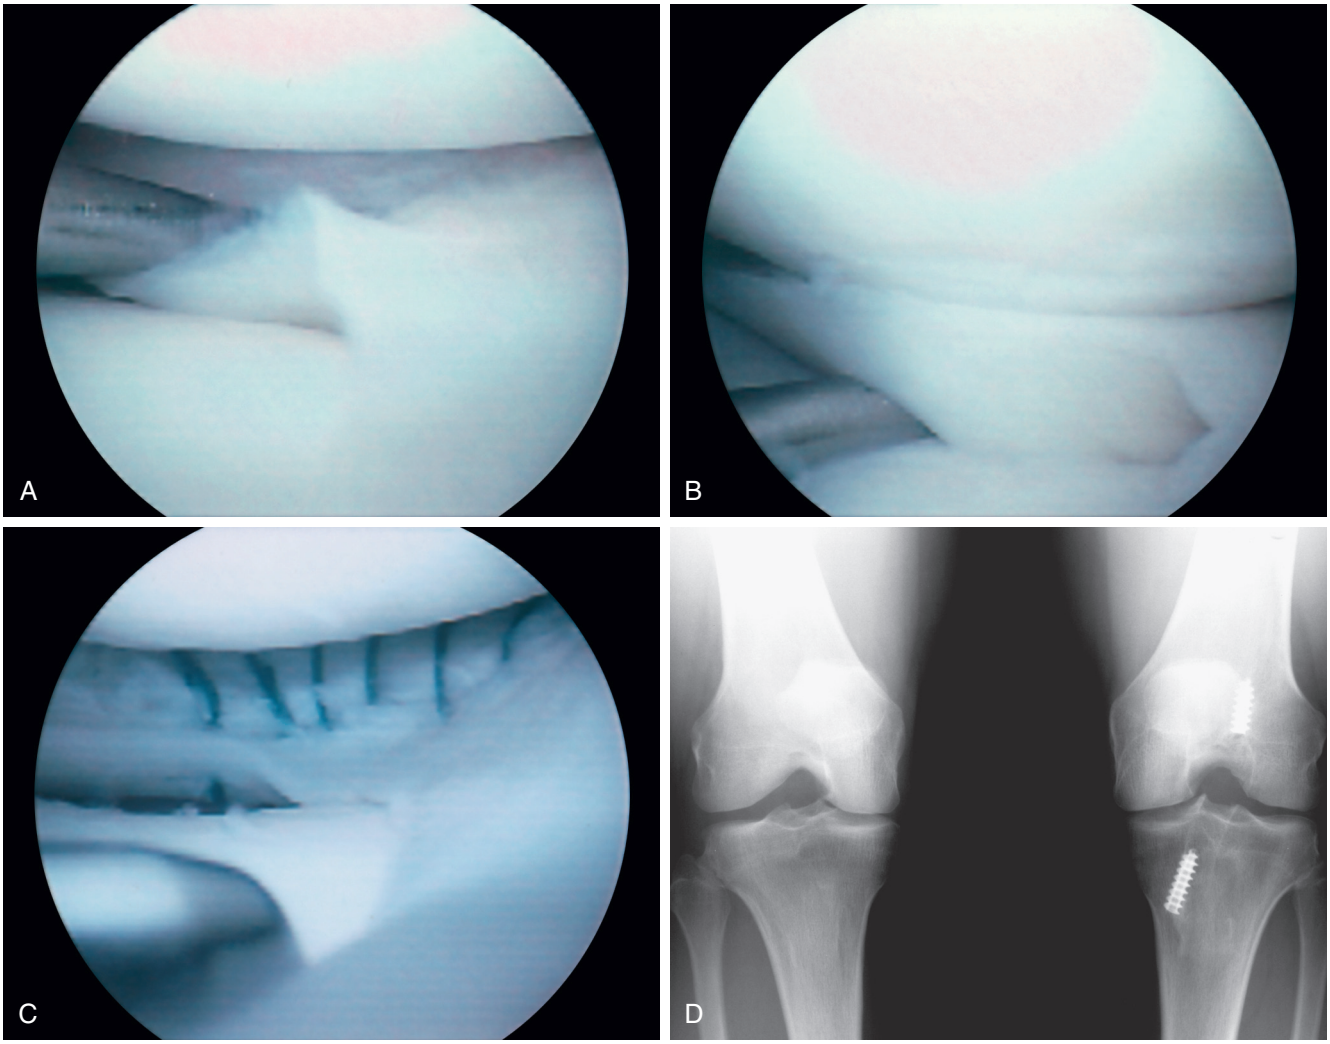

FIG 23-25 Case 6.

At the most recent follow-up evaluation, 14 years postoperatively, the patient reported no symptoms, locking, or catching and rated the overall condition of his knee as normal. Physical examination demonstrated a negative pivot shift test, 3 mm of increased AP displacement on KT-2000 testing, no tibiofemoral joint line pain or crepitus, and a normal range of knee motion. The patient had a sedentary occupation and weighed 265 pounds. Radiographs detected narrowing to the medial tibiofemoral compartment and 2 degrees of varus alignment (Fig. 23-26). MRI revealed deterioration of the medial meniscus, with only a small remnant remaining. The patient was counseled regarding the potential for a future high tibial osteotomy based on medial tibiofemoral compartment symptoms.

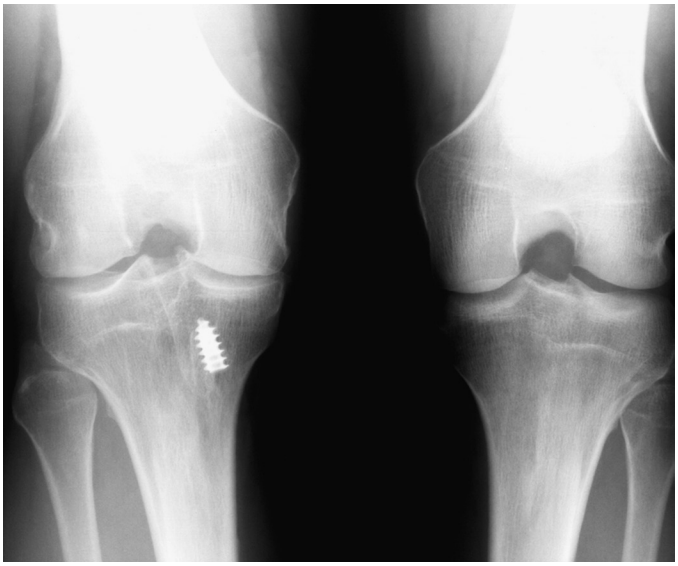

FIG 23-26 Case 7.

Case 8. A 32-year-old man sustained a left knee twisting injury and underwent arthroscopy and removal of the anteromedial bundle of the ACL elsewhere. The patient was treated conservatively for 7 years but gradually developed symptoms and presented for treatment. MRI demonstrated a complex bucket-handle medial meniscus tear. Arthroscopy revealed a complex 20-mm longitudinal tear with an additional vertical tear component. Noteworthy fissuring and fragmentation were found on the medial femoral condyle and in the patellofemoral compartment. Repair of the meniscus tear with multiple divergent sutures was performed.

The patient did well for 1 year until he developed medial joint line pain and catching symptoms. Repeat arthroscopy demonstrated a complex medial meniscus tear extending from the posterior horn to the midbody with horizontal and vertical longitudinal components. A revision meniscus repair was successfully performed with only a small portion of the posterior horn removed. Six years later, the patient reported no problems with light recreational sports and daily activities and rated the overall condition of the knee as good. Physical examination demonstrated a normal range of knee motion, no effusion, no tibiofemoral pain or crepitus, and no meniscus symptoms. Radiographs showed preservation of the medial tibiofemoral joint space (Fig. 23-27).

Case 9. A 22-year old collegiate football player sustained an ACL tear and a lateral meniscus root tear. Arthroscopic visualization of the lateral meniscus root tear is shown in Figure 23-28, A. A 4-mm drill is

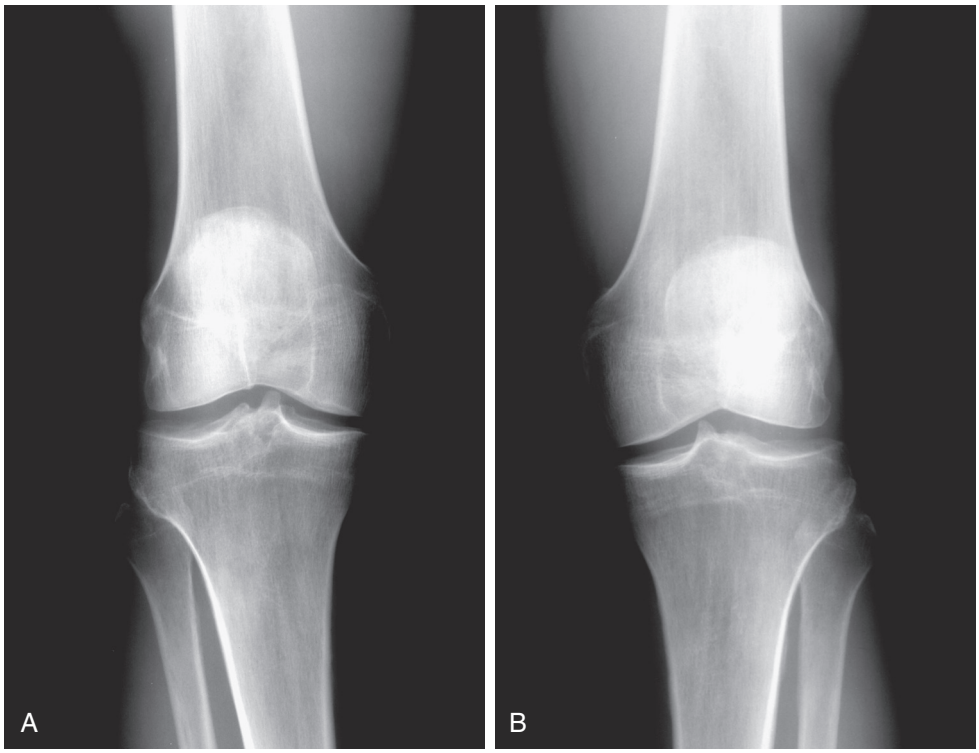

FIG 23-27 Case 8.

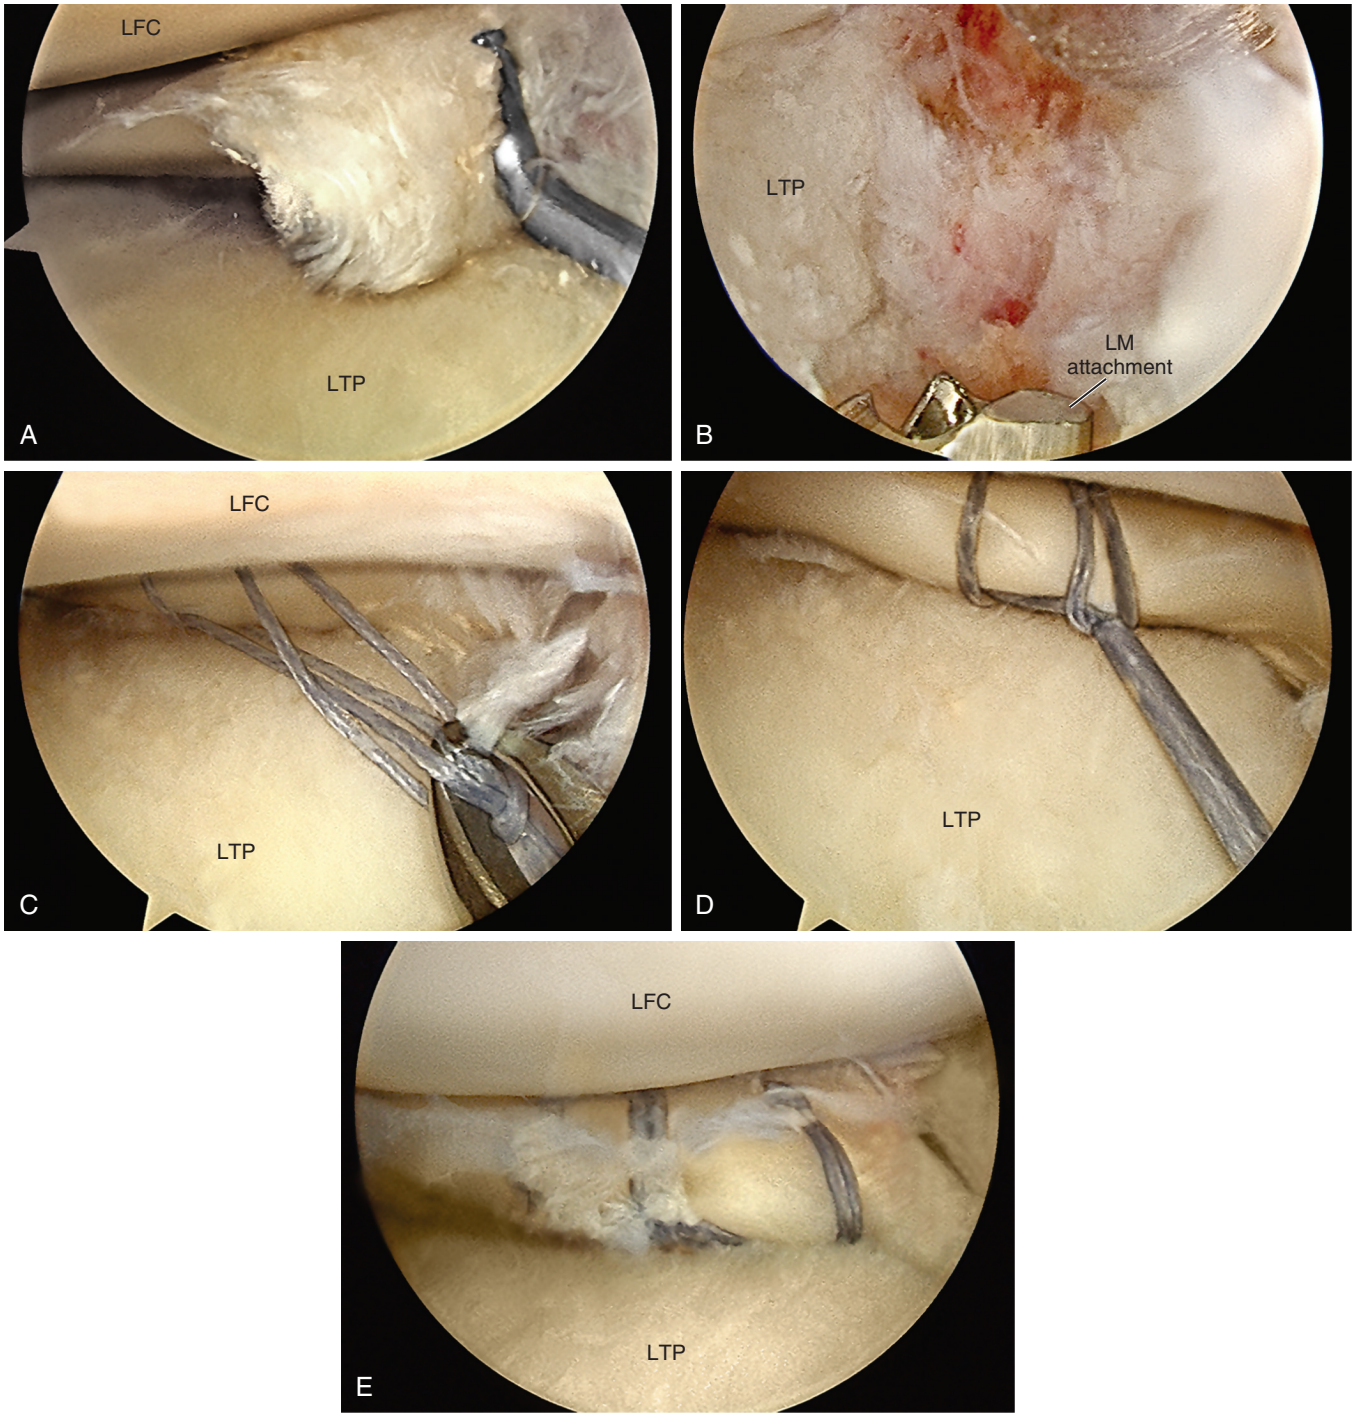

FIG 23-28 Case 9.

placed over a guide pin in the center of the meniscus tibial attachment (Fig. 23-28, *B*). The meniscus root base is curetted to establish a bleeding base for the repair. A central drill hole is created for passage of the sutures that will be tied over a button. A double locking loop stitch (NovoStitch, Ceterix) is placed through the meniscus at the tear site (Fig. 23-28, *C*). Three loop stitches were used in this case to achieve a high strength fixation owing to the large body size of the patient (Fig. 23-28, *D*). Final configuration of lateral meniscus repair with the meniscus pulled flush to the repair site is shown in Figure 23-28, *E*.

INDICATIONS

The meniscus performs important functions that are vital for the integrity of the articular cartilage of the human knee, including load bearing, shock absorption, stability, and joint nutrition. Although many meniscus tears can be successfully repaired, including complex tears that extend into the central third region,[67,80] not all are salvageable, especially if considerable tissue damage has occurred. The goals of transplantation of human menisci are to restore partial load-bearing meniscus function, decrease patient symptoms, and provide some chondroprotective effects.[23,34,42,65,88,101] However, the procedure remains in an evolving state, as investigations of tissue-processing, secondary sterilization, and long-term function continue to evaluate its effectiveness.[48] Clinical studies have shown that meniscus transplantation decreases tibiofemoral joint pain in the short term.[23,32,34] Many investigations report, however, that most transplants gradually deteriorate, tear, extrude from their normal position, or shrink in size, thereby losing the ability to provide function.[19,30,44,74] Accordingly, the goal is to provide short-term benefits until a more suitable meniscus transplant is clinically available. At best, the transplant provides only partial function, and therefore strenuous sports and high-impact activities are not advised postoperatively even though many younger patients have the desire to return to unrestricted athletics. Education of the patient and family is required so that all understand and accept these current limitations of the procedure.

The optimal candidate is a patient younger than 50 years who has had a total meniscectomy, has pain that limits daily activities, and demonstrates early articular cartilage deterioration in the involved tibiofemoral compartment. There should be no radiographic evidence of advanced tibiofemoral joint arthritis. At least 2 mm of tibiofemoral joint space should be visible on 45-degree weight-bearing posteroanterior (PA) radiographs.[78] Arthroscopic examination performed before meniscus transplantation confirms the patient is a suitable candidate. In the most advanced cases, there should be no or only minimal bone exposed on tibiofemoral surfaces. Few treatment options are available for these individuals, especially those less than 30 years of age. In these cases, the goals in the short term are to decrease pain, increase knee function, allow pain-free activities of daily living (ADLs), and delay the

CRITICAL POINTS Indications

- Prior meniscectomy
- Age ≤50 years
- Pain in the meniscectomized tibiofemoral compartment
- No radiographic evidence of advanced joint deterioration; ≥2 mm of tibiofemoral joint space on 45-degree weight-bearing PA radiographs
- No or only minimal bone exposed on tibiofemoral surfaces
- Normal axial alignment
- BMI within normal range

CRITICAL POINTS Contraindications

- Advanced knee joint arthrosis with flattening of the femoral condyle, concavity of the tibial plateau, osteophytes that prevent anatomic seating of the meniscus transplant
- Uncorrected varus or valgus axial malalignment
- Uncorrected knee joint instability, ACL deficiency
- Knee arthrofibrosis
- Significant muscular atrophy
- Prior joint infection with subsequent arthrosis
- Symptomatic noteworthy patellofemoral articular cartilage deterioration
- Obesity (BMI >30)
- Prophylactic procedure (asymptomatic patient with no articular cartilage damage)
- Untreated full-thickness femoral condylar defect with bone exposure

onset of tibiofemoral arthritis. Normal axial alignment and a stable joint are required. The body mass index (BMI) must be within normal range.

The association of an anterior cruciate ligament (ACL) tear and underlying posterolateral ligament insufficiency (either physiologic or traumatic) results in major abnormal anterior translation of the lateral tibial plateau and, in a case-by-case basis, may warrant meniscus transplantation in addition to ligament reconstruction.

CONTRAINDICATIONS

Patients who have had a meniscectomy are evaluated with 45-degree PA weight-bearing radiographs and magnetic resonance imaging (MRI)[73,74] to determine the status of the joint, articular cartilage, and subchondral bone edema. Contraindications include advanced knee joint arthritis with flattening of the femoral condyle, concavity of the tibial plateau, and osteophytes that prevent anatomic seating of the meniscus transplant. Clinical studies have shown poor results and high failure rates in knees with this amount of joint damage.[26,39,61,74,89]

Untreated lower limb malalignment is associated with failed meniscus transplantation[13,18,93,94]; therefore the patient must be willing to first undergo a staged corrective osteotomy. Axial correction is recommended in knees in which the weight-bearing line is less than 45% (varus) or greater than 55% (valgus), representing a 2- to 3-degree change from normal alignment. Uncorrected knee joint instability, especially ACL deficiency, is also associated with poor outcomes after meniscus transplantation.[94] Patients must undergo concurrent or staged ACL reconstruction to restore normal stability to protect the meniscus transplant.

Preexisting knee arthrofibrosis, significant lower limb muscular atrophy, and a history of prior joint infection with subsequent arthritis are all contraindications for this operation. Symptomatic noteworthy patellofemoral articular cartilage deterioration (subchondral bone exposure) and obesity (BMI >30) are also contraindications.

Prophylactic meniscus transplantation following total meniscectomy is not recommended in asymptomatic patients who do not have articular cartilage deterioration because long-term predictable success rates for transplants are not available. In addition, the operative procedure does carry a slight risk for complications that could make the patient's condition worse.

This clinical problem is often encountered involving patients younger than 30 years of age who have undergone meniscectomy years ago, do not have articular cartilage damage, and are asymptomatic. Clinical studies show that eventual deterioration of the meniscectomized tibiofemoral compartment will most likely occur. These patients are advised that there is no optimal or predictable operative procedure to replace meniscus function and that they should decrease or refrain from participating in high-impact, strenuous activities. There are sensitive and accurate MRI cartilage techniques to determine the status of the articular cartilage in the meniscectomized compartment.[72,73] When early but definite articular cartilage damage is detected, it can be logically assumed that joint deterioration will continue over time and the opportunity exists to perform a meniscus transplantation. This still represents a difficult choice for the patient in terms of undergoing surgery before the onset of major joint symptoms. In addition, the transplant may not function, and further arthroscopic surgery may be required to remove the tissue. Most patients who develop early cartilage damage in the meniscectomized compartment complain of pain with strenuous athletic activities but not with recreational or daily activities. These patients are not truly asymptomatic and desire to lessen the risk of further joint deterioration to the level at which it will affect lower intensity activities. Patient education and a conservative approach to transplant recommendation are important until a more dependable transplant is available.

The presence of a full-thickness femoral condylar defect with bone exposure is a relative contraindication to isolated meniscus transplantation. Concurrent articular cartilage restorative procedures (e.g., osteochondral grafts or autologous chondrocyte implantation) can be successfully performed with meniscus transplantation[3,25,27,32,66,81,82,90] and expand the indications to include knees with these lesions.

CLINICAL BIOMECHANICS

Chondroprotective Effects

The overall goal of meniscus transplantation is to protect the articular cartilage from subsequent deterioration.[88] To date, few experimental investigations have been conducted on large animal models to determine the ability of a transplant to provide chondroprotective effects. Szomor and associates[92] conducted a study in which medial meniscectomy, medial meniscus autografts, and medial meniscus allografts were performed in 24 sheep. The grafts were placed into the anatomic anterior and posterior horn attachment sites and secured to the tibial plateau with three suture anchors. At 16 postoperative weeks, both the allograft and autograft knees demonstrated a 34% to 40% reduction in the score for macroscopic damage to the articular cartilage and an approximate 50% reduction in the area of damage to the articular cartilage compared with the meniscectomized knees. However, neither of the grafts provided complete protection, which the investigators hypothesized could have been caused by nonisometric positioning and tensioning and graft fixation. Histologic analysis revealed that the allografts had fibrinoid degeneration, areas of hypocellularity, and cloning of meniscus cells.

CRITICAL POINTS Clinical Biomechanics

Chondroprotective Effects

- Few large animal model studies have been conducted to date.
- Medial meniscus transplants showed 50% reduction in area of damage to the articular cartilage compared with meniscectomized knees.
- Lateral meniscus transplants increased total contact area by 42% to 65% compared with meniscectomized knees.

Knee Joint Contact Mechanics After Meniscus Transplantation

- Medial meniscus transplants reduced normalized maximum and mean contact pressures by 75% compared with meniscectomized cadaver knees.
- However, the transplants did not restore normal contact mechanics and demonstrated greater variability in normalized maximum and mean pressure than autografts.
- Lateral meniscus transplants sized >10% of native menisci restored contact mechanics close to normal.
- Lateral meniscal transplants increased total contact area by 42% to 65% compared with meniscectomized cadaver knees.

Effect Fixation and Location of Meniscus Transplants

- The method of fixation of meniscus transplants is critical for subsequent load-bearing function and chondroprotective effects.
- Transplant with bone for fixation is required. Soft tissue meniscus transplants, without bone fixation, are not recommended.
- Experimental studies show that implants with either a bony bridge or bone plug fixation of both horns produce contact area, peak contact pressure, and average central pressure results similar to those of an intact meniscus.
- Posterior horn tunnel of medial meniscus allograft should be placed as close to its anatomic position as possible, with a tolerance tighter than 5 mm medial and 5 mm posterior to this location.

Kelly and colleagues[42] developed a meniscus allograft surgical technique that attempted to restore the anatomic anterior tibial and posterior femoral meniscal attachments in a sheep model. Fixation of the allografts was accomplished through bone tunnels. Lateral meniscus allografts were implanted into 17 animals, and lateral meniscectomies were performed in 24 animals. Gross inspection, histologic analysis, biomechanic testing, MRI, and T2 mapping of the central weight-bearing portion of the lateral tibial plateau performed 2 and 4 months postoperatively demonstrated protective effects of the allografts. Significantly decreased cartilage wear and increased cartilage stiffness were found in the allografted joints compared with the meniscectomized knees. However, at 4 months after surgery, the allografted knees had significantly worse values for these outcome measures than the intact knees. The authors noted the successful use of MRI with T2 mapping to detect early articular cartilage degeneration.

Knee Joint Contact Mechanics After Meniscus Transplantation

Alhalki and coworkers[5] measured the maximum pressure, mean pressure, and contact area of the medial tibial articular surface after medial meniscectomy and implantation of ipsilateral medial meniscus autografts and cryopreserved allografts in 10 cadaveric knees (mean age, 70 years). The autografts and allografts were implanted using bone plug fixation through anterior and posterior horn transtibial tunnels. The allografts significantly reduced normalized maximum and mean contact pressures by 75% compared with meniscectomized knees. In addition, the maximum pressure was restricted to a small region of the contact area. The authors hypothesized that a reduction of this magnitude could mitigate the rate of cartilage wear compared with that in a meniscectomized knee. However, the allografts did not restore normal contact mechanics and demonstrated greater variability in normalized maximum and mean contact pressures than the autografts. The authors concluded that the variability in contact mechanics could have been caused by poor matching of the 3-dimensional geometry of the allograft to the recipient knee. Dimensions for the allograft were matched from standard anteroposterior (AP) and lateral radiographs in the transverse plane. Studies by Paletta and associates[70] and Haut and colleagues[33] revealed that measurements made in the transverse plane only weakly predict the cross-sectional shape of the meniscus.

The effect of the size of lateral meniscus allografts (in comparison with native menisci) on tibial plateau contact mechanics was investigated by Dienst and coworkers.[20] Allografts that were 17.5% larger than native menisci had significantly greater contact forces across the articular cartilage. Allografts sized 10% smaller than native menisci resulted in increased forces across the meniscal tissue, which the authors hypothesized could cause early transplant failure. The authors concluded that the surgeon should select lateral meniscus transplants (LMT) that are slightly larger than native menisci (rather than smaller) to reduce the risk of early failure.

Paletta and associates[70] investigated the effects of lateral meniscectomy, cryopreserved lateral meniscus transplantation with bone plug fixation, and lateral meniscus transplantation without fixation of the anterior and posterior horn attachments. The study involved 10 cadaver knees less than 48 years of age. The lateral meniscal transplants increased total contact area from 42% to 65% compared with meniscectomized knees at all flexion angles (0, 30, and 60 degrees), However, there remained a residual 17% to 23% decrease in contact area compared with intact knees. Release of the horn attachments resulted in a contact area that was identical to meniscectomized specimens. McDermott and associates[58] assessed the effects of lateral meniscal transplantation with and without bone block fixation in eight cadaver knees. These investigators reported no difference between the two methods in peak contact pressures compared with intact knees. The cadaver specimens used in the study were ages 81 to 98 years, and all had moderate to severe degenerative changes. In addition, no formal size matching was performed with the allografts and recipient knees.

Effect of Fixation and Location of Meniscus Transplants

The method of fixation of meniscus transplants to the surrounding tissues is believed to be paramount in subsequent load-bearing function and chondroprotective effects. The goal is to reproduce the normal attachment sites, allowing lateral and medial transplants to remain in their anatomic locations and move normally throughout knee motion.[16,76,99] The use of a transplant with bone for fixation incorporated with either a central bone bridge or a two-tunnel technique (as described later in this chapter) is, in our opinion, required to obtain these goals. Soft tissue meniscus transplants, without bone fixation, are not recommended. Although soft tissue transplants are far easier to prepare and implant surgically, scientific data are inadequate to support that the soft tissue ends of the meniscus implant will heal and provide the circumferential tension in the meniscus that is required for function (Fig. 24-1).[28,57]

The importance of securing the anterior and posterior horns of an LMT was documented by Chen and colleagues,[15] who investigated a variety of surgical methods for meniscus implantation. Using an

autograft cadaver model, the study revealed that a transplant that had either a bony bridge or bone plug fixation of both horns produced contact area, peak contact pressure, and average central pressure results similar to those of an intact meniscus. Procedures in which either only one horn was secured or neither horn was secured demonstrated a loss of mechanical function and subsequent expected benefit from the transplant.

Alhalki and coworkers[4] compared three fixation methods of medial meniscus autografts in cadaver knees to determine which method restored tibial contact mechanics closest to normal. The experimental design tested bone plug fixation alone, bone plug fixation combined with peripheral suturing of the transplant to the native rim, and suturing of the horns through bone tunnels combined with peripheral suturing of the transplant to the native rim. The study revealed that bone plug fixation produced contact mechanics closest to normal; however, the maximum pressure was significantly greater than that in the intact knee. There was no benefit in adding peripheral sutures to the bone plug fixation model. Importantly, fixation with sutures only did not restore normal contact mechanics and was not recommended by the investigators.

Verma and associates[103] measured medial compartment peak pressure, mean pressure, and contact area in eight cadaver knees to determine whether a difference existed between medial meniscus transplants (MMTs) implanted with a bone plug technique and those with a bone trough technique. The data indicated no difference between the two techniques for all three variables, which were restored to values similar to those measured in the intact knees. The authors cited clinical advantages with the trough technique for both medial and lateral meniscus transplantation.

The effect of variations in placement of the posterior horn attachment of an MMT were investigated by Sekaran and colleagues.[83] Using a cadaver autograft model, the posterior horn tunnel was placed either in its anatomic position or 5 mm posterior to the anatomic location. The study showed that placing the posterior horn tunnel 5 mm medial to its anatomic position caused an increase in normalized maximum pressure, a posterior shift in the location of the center of the contact area, and an increase in the normalized mean pressure. Placing the posterior horn tunnel 5 mm posterior was not as detrimental; however, this location resulted in a significant shift in the centroid of contact area. The authors concluded that surgeons should place the posterior horn tunnel as close to its anatomic position as possible, with a tolerance limit of less than 5 mm medial and 5 mm posterior to this location.

FIG 24-1 Visual inspection of meniscus transplant before implantation.

CLINICAL EVALUATION

A thorough history including assessment of prior operative records and current symptoms and functional limitations is taken. A comprehensive knee examination is performed. This includes assessment of knee flexion and extension, patellofemoral indices, tibiofemoral pain and crepitus, muscle strength, and gait abnormalities. Also, the appropriate clinical tests for the ACL, posterior cruciate ligament (PCL), medial, and posterolateral structures are performed.

MRI is obtained using proton-density-weighted, high-resolution, fast-spin-echo sequences[73,74] to determine the status of the articular cartilage and the previously meniscectomized tibiofemoral compartment. Radiographs include AP, lateral at 30 degrees of knee flexion, weight-bearing PA at 45 degrees of knee flexion, and patellofemoral axial views. Axial lower limb alignment is measured using double-limb standing hip-knee-ankle weight-bearing radiographs[22] in knees that demonstrate varus or valgus alignment.

CRITICAL POINTS Clinical Evaluation

Physical Examination
- Tibiofemoral joint line pain, compression pain, crepitus
- McMurray test
- Knee flexion and extension
- Joint effusion
- Patellofemoral (medial and lateral subluxation, Q-angle, crepitus, compression pain)
- Muscle strength
- Alignment
- Gait

Ligament Subluxation Tests
- Pivot shift, Lachman
- KT-2000 (MEDmetric) 20 degrees of knee flexion, 134-N force
- Posterior drawer, 90 degrees of knee flexion
- Tibiofemoral rotation dial 30 degrees, 90 degrees of knee flexion
- External rotation recurvatum
- Lateral tibiofemoral joint opening 5 degrees, 20 degrees of knee flexion
- Reverse pivot shift
- Medial tibiofemoral joint opening 5 degrees, 20 degrees of knee flexion

MRI
- Proton-density-weighted, high-resolution, fast-spin-echo sequences

Radiographs
- Anteroposterior
- Lateral, 30 degrees of knee flexion
- Posteroanterior, weight-bearing, 45 degrees of knee flexion
- Patellofemoral axial
- Double-limb standing hip-knee-ankle weight-bearing for varus or valgus malaligned knees

Assessment of Symptoms and Functional Limitations With Activity: Cincinnati Knee Rating System
- Sports Activity and Function Form
- Occupational Rating Form
- Symptom Rating Form

Patients complete questionnaires and are interviewed for the assessment of symptoms, functional limitations, sports and occupational activity levels, and patient perception of the overall knee condition according to the Cincinnati Knee Rating System (CKRS).[7]

Knees with associated varus osseous malalignment require a staged corrective osteotomy before the meniscus transplant procedure. Knees with ligament deficiency require a staged ligament reconstruction. Some studies have advocated concurrent ACL reconstruction and meniscus transplantation.[29,84,107] The normal ACL tibia attachment site and the ACL tibial graft tunnel may compromise meniscus transplant tibial fixation. This may occur when the slot technique to be described is selected in patients whose central tibial intercondylar region is not wide enough to accommodate both the meniscus transplant slot and ACL tibial graft tunnel. Because it is not possible in these knees to use the central slot technique, a two-tunnel procedure is selected for the MMT.

PREOPERATIVE PLANNING

Tissue Bank and Sterilization Issues

In the United States, meniscus transplants are obtained from tissue banks accredited by the American Association of Tissue Banking (AATB) and inspected by the U.S. Food and Drug Administration (FDA). Tissues in which serologic testing meets or exceeds the standards of these organizations are selected. Importantly, donor selection criteria may vary among tissue banks, and the surgeon should understand the specific criteria used by the bank chosen to supply the transplant. We recommend that the donor age be less than 30 years to offset any potential age-dependent alterations in biomechanic or biochemical properties of the transplant.[11]

A variety of sterilization techniques have been described for meniscus transplants, including none (fresh-frozen), irradiated, cryopreserved, and proprietary chemical techniques. Some authors[13] advocate combined secondary sterilization using low-dose irradiation (1-2 mrad) and chemical agents. To date, no scientific data exist to select one type of graft processing method over another.

Surgeons should be aware that so-called *sterilization processes* may not prevent contamination and do not guarantee a sterile graft. Prophylactic antibiotics are administered intravenously before surgery, and patients are carefully monitored postoperatively for any signs of infection. The implications of different processing techniques on graft sterility and donor selection issues, allograft harvesting techniques, and disease testing are beyond the scope of this chapter and have been discussed in detail by others.[8,35,98]

CRITICAL POINTS Preoperative Planning

- Obtain transplants from tissue banks accredited by AATB and inspected by the U.S. FDA.
- Transplant processing includes fresh-frozen, irradiated, cryopreserved, and proprietary chemical techniques. No scientific data are available to select one type of graft processing method over another.
- No standard exists for transplant sizing. AP, lateral radiographs are usually obtained to measure width and length measurements for transplant. The surgeon must select, according to his or her own comfort level, the technique preferred from those currently available to determine the transplant size required.
- Request a photograph of the transplant with metric ruler placed adjacent to inspect size and shape of graft.
- Grafts may vary up to 10% in length and width; the surgeon may need to adjust the transplant to fit the patient's tibial plateau.
- Advise the patient that the transplant will be inspected in the operating room before the induction of anesthesia.

Meniscus Sizing Issues

Although there is no standard protocol at present, AP and lateral radiographs are typically used to obtain approximate width and length measurements for the meniscus transplant (based on tibial plateau measurements), as described by Pollard and associates.[71] A number of studies have been recently performed to determine the most reliable sizing method and this issue clearly remains unresolved.[9,21,33,86,91,109,110] Other methods that have been investigated include MRI; 3-dimensional computed tomography (CT); photographs of the transplant; and calculations to predict transplant size based on patient height, weight, and gender.

Berhouet and associates[9] compared direct anatomic measurements of menisci in cadaver knees with measurements obtained from radiographs and photographs of the specimens. No significant difference was found between the anatomic and radiographic method discussed by Pollard and colleagues[71]; the mean overall measurement error for the radiographic method was 7.9% (4.3% on AP views and 11.45% on lateral views). The photographic method was deemed unreliable because it produced significantly different measurements than the direct anatomic measurements and had a mean overall measurement error of 20.1%. Many tissue banks will provide a photograph of the transplant specimen, which is advantageous because it allows the surgeon to inspect the size and shape of the meniscus. Berhouet and colleagues[9] reported that the problem with the photographic method arose from distortions incurred from the position of the camera and ruler, which produced magnification errors. The ruler was placed in line with the bottom of the specimen, the tibial plateau, which was below the plane of the menisci. The recommendation was made that, during transplant harvest, the ruler should be placed in the plane of the menisci to reduce the measurement error.

Yoon and colleagues[109] presented a slightly different radiographic protocol to identify bony landmarks of the lateral tibial plateau to more precisely measure lateral meniscus length. The radiographic beam was angled 10 degrees caudally at neutral rotation. This lateral view enabled the lateral plateau cortical margins to be differentiated from the medial plateau margins. The authors determined a best-fit equation for predicting meniscal size from Pollard's method of bone size: anatomic length = 0.52 × plateau length ± 5.2. Compared with the Pollard method, this investigation's method reduced the deviation from the anatomic dimensions from 4.1 to 1.4 mm, respectively, and increased the accuracy (within 10% of actual length) from 40% to 98%, respectively.

Stone and associates[91] suggested that recipient height, weight, and gender be considered as important matching criteria when selecting meniscus transplants. These investigators measured meniscus and tibial plateau dimensions in 111 patients using MRI and correlated the dimensions with the patients' height, weight, BMI, and gender. Height correlated well with total tibial plateau width ($R = 0.7194$), and females generally had smaller meniscus dimensions than males. In addition, patients with a BMI greater than 25 had larger meniscus dimensions than patients with a lower BMI at any given height. This concept was further advanced by Van Thiel and colleagues[97] who provided a validated regression model that used height, weight, and gender to predict meniscus transplant size based on data from 930 donors and the dimensions of their menisci. Compared with published radiographic and MRI data, the model produced

measurement results that were "slightly more accurate." However, their findings were later refuted by Yoon and coworkers,[110] who found that height, weight, gender, and BMI failed to estimate the size of the lateral meniscus based on a sample of 91 fresh menisci obtained during total knee arthroplasty.

Prodromos and coworkers[75] conducted an investigation to determine the accuracy of MRI performed on the contralateral knee to determine transplant size. Using tissue bank records, the investigators compared the dimensions of right and left knees of 500 donors and determined that 97% were within 3 mm of each other in the AP and medial-lateral directions. Then the menisci of 10 cadaveric knees were directly measured and compared with tibial plateau dimensions obtained from radiographs (Pollard method). The MRI scans had an average error rate of 4.7% compared with 14.4% for the radiographic method. Radiographs oversized 18 meniscal measurements and undersized 23 measurements. The authors concluded that MRI of the contralateral meniscus should be used to determine transplant size.

Donahue and colleagues[21] developed an algorithm for meniscus transplant sizing based on MRI measurements. The authors recommended that tissue banks follow the algorithm, which involves a series of six steps. These include making four transverse and six cross-sectional measurements for each transplant in the bank's inventory using a 3-dimensional coordinate digitizing system, obtaining MRI of the recipient's uninjured knee, and measuring nine parameters for the medial or lateral meniscus, as well as performing a series of calculations to determine the best match.

McConkey and associates[55] recommended 3-dimensional CT scanning to improve the accuracy and reliability of sizing the tibial plateau. In their investigation, CT estimates of plateau size were closer to anatomic measurements in cadaveric knees than AP and lateral radiographs in all dimensions ($P < .0001$). CT scans fell within 5 mm of the anatomic measurements 100% of the time and within 2 mm of the anatomic measurements 76% of the time. In comparison, radiographic measurements fell within 5 mm of the anatomic measurements 76% of the time and within 2 mm of the anatomic measurements 34% of the time.

These studies show that there is no consensus in the literature regarding meniscus sizing criteria. Studies generally show that radiographic techniques tend to overestimate meniscus size, and MRI tends to underestimate size.[14,55,86] The surgeon must select, according to his or her own comfort level, the technique preferred from those currently available to determine the transplant size required. In addition, the surgeon should be aware of the method the tissue bank uses to measure transplant dimensions and understand that the specimen obtained may vary up to 10% in length and width. In these cases, the surgeon may need to adjust the transplant to fit the patient's tibial plateau. The use of the two-tunnel technique allows for this adjustment to be made because the tunnels are placed at the anatomic attachment sites on the respective medial or lateral tibial plateau. The bone end is pulled into the tunnel (3-5 mm) to maintain tension on the implant and prevent extrusion. Judgment is also required during surgery when the meniscus bone bridge technique is performed because it requires good size matching to prevent medial or lateral meniscus extrusion. We prefer to take the added time to use a bone bridge or bone plug technique (bone-meniscus-bone implant), which requires a good geometric and anatomic fit. Alternative techniques are available in which the meniscus is sutured in place without bone plugs, a procedure that is not recommended.

The problem still exists that even though an approximate size can be determined preoperatively, in many knees, the tibiofemoral joint has undergone degenerative changes that produce subtle alterations in joint geometry, leading to permanent alterations in the normal surface stress distribution of the joint surface.[12] A meniscus transplant does not have the ability to restore the native or normal state of the menisectomized compartment. Future studies are required to determine the effect of subtle size and shape mismatch of the transplant on retaining articular cartilage functional properties. A chondroprotective effect of meniscus transplants has yet to be proven. This involves sophisticated questions regarding the chondrocyte function, cartilage collagen, and glycosaminoglycan homeostasis and resultant biomechanic properties.

Certain medial menisci may have a hypoplastic anterior horn that is narrow and inserts distal to the medial tibial surface (type III),[10] which is not acceptable for implantation. The middle third of a medial or lateral meniscus may be 8 to 10 mm in width and suitable only for small patients. The lateral meniscus may have reduced anterior-to-posterior length, less than that calculated on the sagittal radiograph, and not be suitable for implantation.

The patient is advised that the transplant will be inspected in the operating room before the induction of anesthesia. It is rare that the operative procedure cannot be performed as planned; however, there is always the chance that the transplant will not meet the desired criteria.

INTRAOPERATIVE EVALUATION

MMTs are not prepared until the surgeon determines whether the central bone bridge technique (which is preferred) or the two-tunnel technique (separate anterior and posterior bone attachments and tunnels) will be performed, as is described later.

LMTs are prepared before the operative procedure to determine the depth and width required for the tibial slot in the central bone bridge technique. The central bone portion of the LMT incorporates the anterior and posterior meniscal attachments and usually measures 8 mm in width in smaller patients and 9 mm in larger patients. The posterior 6 to 8 mm of tibia bone bridge that protrudes beyond the posterior horn attachment is removed to produce a buttress against the prepared bone slots in the host knee. Commercially available (Stryker Endoscopy and Cryolife) sizing blocks and channel cutters are helpful for appropriate sizing, as is described later.

All knee ligament subluxation tests should be performed after the induction of anesthesia in both the injured and contralateral limbs. The amount of increased anterior tibial translation, posterior tibial translation, lateral and medial joint opening, and external tibial rotation should be documented. A thorough arthroscopic examination should be conducted, documenting articular cartilage surface abnormalities[68] and the condition of the menisci.

CRITICAL POINTS Intraoperative Evaluation

- Inspect the transplant before administration of anesthesia.
- MMT: choose either central bone bridge or two-tunnel technique.
- Lateral meniscus transplant: Prepare implant to determine depth and width required for tibial slot.
- Repeat all knee ligament subluxation tests with the patient under anesthesia on both injured and contralateral limbs.
- Rate all articular cartilage surfaces and inspect menisci for abnormalities.

OPERATIVE TECHNIQUE: LATERAL MENISCUS TRANSPLANT

The patient is placed in a supine position on the operating room table with a tourniquet applied with a leg holder, and the table is adjusted to allow 90 degrees of knee flexion. The opposite lower extremity is placed in a thigh-high elastic stocking and is padded to maintain mild hip flexion to decrease tension on the femoral nerve. After examination under anesthesia, diagnostic arthroscopy confirms the preoperative diagnosis and articular cartilage changes. A meniscus bed of 3 mm is retained when possible, except at the popliteal tendon region where the native meniscus rim is removed. The meniscus bed and adjacent synovium are rasped to aid in revascularization of the transplant.

The tourniquet is inflated for only the two initial operative approaches. A limited 3-cm lateral arthrotomy is made just adjacent to the patellar tendon. Although arthroscopic techniques are available to prepare the tibial slot, the limited arthrotomy provides superior visualization and avoids incising into the patellar tendon, which must be displaced medially to properly place the tibial slot. A common mistake involves placing the anterior aspect of the tibial slot lateral to the normal attachment of the anterior horn of the lateral meniscus.

A second 3-cm posterolateral incision is made just behind the fibular collateral ligament (FCL; Fig. 24-2), similar to that described in Chapter 23 for inside-out lateral meniscus repairs.[59,79] The interval between the short head of the biceps muscle and the iliotibial band is identified and incised. The biceps capsular attachments are gently dissected with Metzenbaum scissors off the posterior capsule and FCL to just above the fibular head. Care is taken at this point because dissection that extends too far anterior or proximal to the joint line would enter the joint capsule. If this occurs, a capsular repair is required to maintain joint integrity during the inside-out meniscal repair procedure.

The inferior lateral geniculate artery, in close proximity, is identified and preserved. The space between the posterolateral capsule and the lateral head of the gastrocnemius is further developed bluntly. An appropriately sized popliteal retractor is placed directly behind the lateral meniscus bed and anterior to the lateral gastrocnemius muscle. Care is taken during the subsequent inside-out suture passage that the retractor remains anterior to the lateral gastrocnemius muscle to protect the peroneal nerve, which lies posterior to the muscle.

The width of the transplant is determined. A template made out of aluminum foil of the transplant's width and length is cut and inserted into the lateral compartment to determine the proper placement of the bone slot. This sizing step is important to ensure there is no lateral overhang (extrusion) of the meniscal body produced by placing the bone slot too far laterally. If there is a mismatch that results in lateral extrusion, the procedure may be converted from the bone bridge technique to one using two separate bone plugs and bone tunnels. The posterior bone plug is located directly at the lateral meniscus attachment. The anterior bone plug is placed more medially by a few millimeters to prevent lateral extrusion. The use of the bone bridge technique does require adequate size matching, and judgment is required at surgery in using the central bridge or separate bone plug technique. This same concept applies to MMTs. A rectangular bone slot is prepared at the anterior and posterior meniscus tibial attachment sites to match the dimensions of the prepared transplant.

The sequence of steps to prepare the lateral tibial slot is shown in Figure 24-3. The tibial bone slot is 1 to 2 mm wider than the transplant to facilitate implantation. The anterior and posterior horns of the transplant are placed into their normal attachment locations, adjacent to the ACL. It is important to note that a prior ACL reconstruction in which the tibial tunnel was placed in a lateral position may produce a technical problem in creating the tibial slot.

A starter chisel and finishing chisels provide an alternative technique to create and fashion the tibial slot to its final depth and width (Fig. 24-4, *A*). A tibial slot sizing guide is used to check the length and depth (see Fig. 24-4, *B*). A sizing block (see Fig. 24-4, *C*) confirms that the transplant bone bridge is of the correct width and depth.

A dovetail technique may also be considered, which has the advantage of providing added stability to the fixation at the tibial bone portion of the transplant (Fig. 24-5). This procedure entails cutting a trapezoidal bone block that includes a narrower 7-mm bone bridge and requires additional time to prepare the transplant.

The transplant is inserted into the slot, and the bone portion of the graft is seated against the posterior bone buttress to achieve correct anterior-to-posterior placement of the attachment sites. A vertical suture in the posterior meniscus body is passed posteriorly to provide tension and facilitate transplant placement. The suture is tied later in the procedure. The knee is flexed, extended, and rotated to confirm that correct placement of the transplant has been obtained. Sutures are placed into the anterior third of the meniscus, attaching it to the prepared meniscus rim under direct visualization.

Two fixation methods are available for the central bone attachment. Two 2-0 non-absorbable sutures may be placed retrograde into the tibial slot, passed over the central bone bridge before transplant

CRITICAL POINTS Operative Technique: Lateral Meniscus Transplant

- Diagnostic arthroscopy confirms preoperative diagnosis, articular cartilage changes.
- Limited 3-cm lateral arthrotomy just adjacent to patellar tendon
- Patellar tendon displaced medially to properly place tibial slot
- Second 3-cm posterolateral incision made just behind fibular collateral ligament
- Interval between short head of biceps muscle and iliotibial band is identified and incised.
- Biceps capsular attachments are gently dissected off the posterior capsule.
- Inferior lateral geniculate artery is identified and preserved.
- Space between posterolateral capsule and lateral head of the gastrocnemius is further developed bluntly.
- Width of transplant is determined, and template is inserted into lateral compartment to determine proper placement of bone slot.
- Sizing step ensures there is no lateral overhang of the meniscal body.
- Tibial bone slot 1-2 mm wider than transplant to facilitate implantation. Anterior and posterior horns of implant placed into normal attachment locations.
- Transplant sizing block confirms transplant bone bridge is correct width and depth.
- Dovetail technique or rectangular bone technique is chosen.
- Implant is inserted into slot; bone portion of graft is seated against posterior bone buttress to achieve correct anterior-to-posterior placement of the attachment sites.
- Transplant is sutured to native meniscus rim.
- Two fixation methods for the central bone attachment: two 2-0 nonabsorbable sutures are placed retrograde into the tibial slot, passed over the central bone bridge, and tied to tibial post (preferred).
- Place a 7 × 25 mm interference screw adjacent medially to the bone bridge.
- Arthrotomy is closed, and inside-out meniscal repair is completed with multiple vertical divergent sutures.

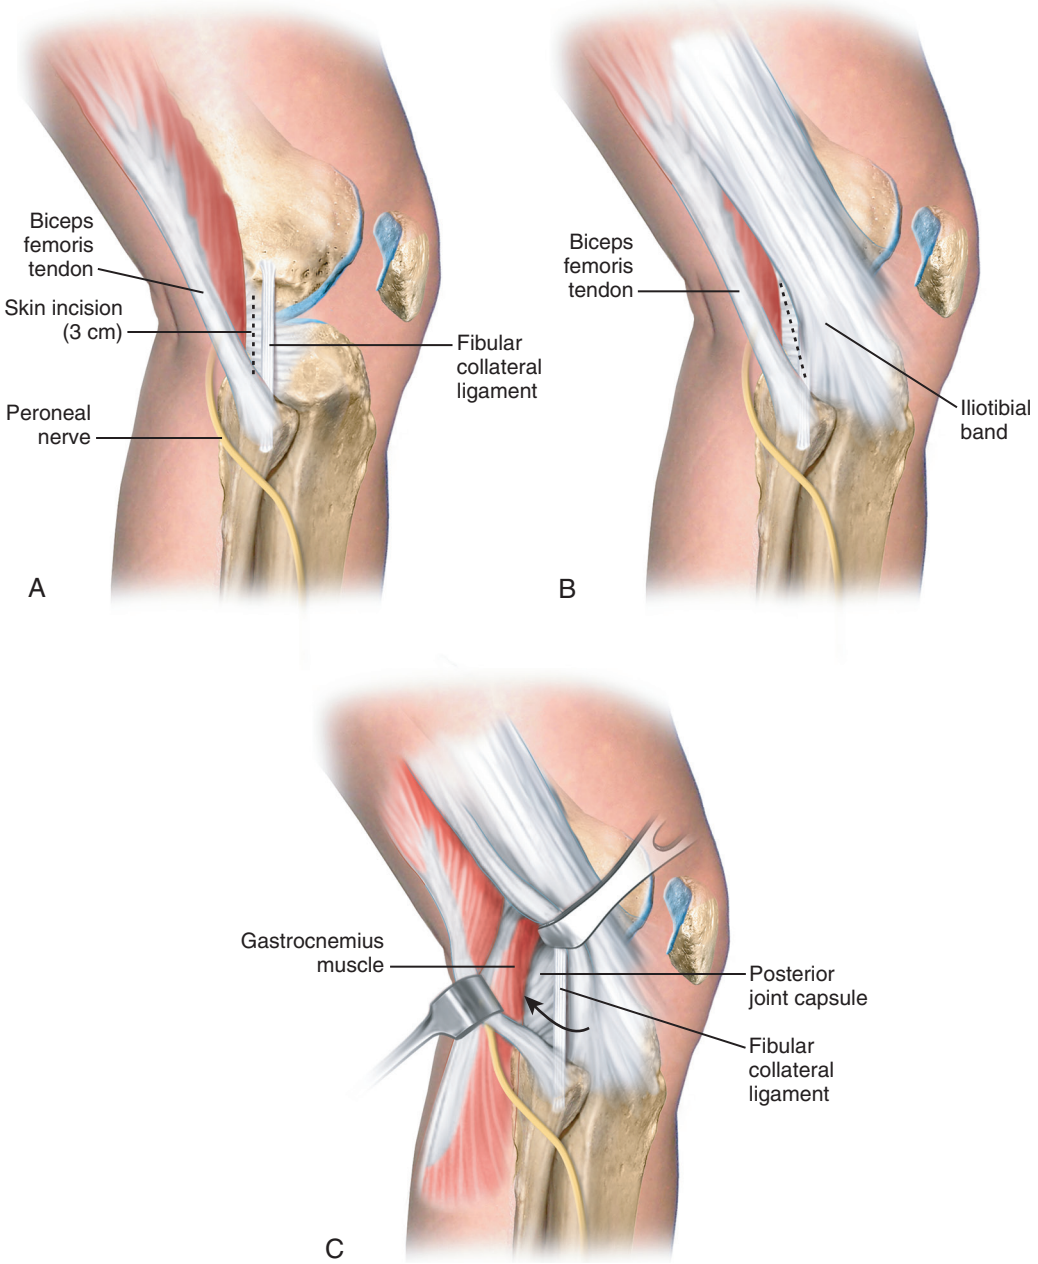

FIG 24-2 **A,** Site of the posterolateral incision for a lateral meniscus transplant. **B,** Incision site in the interval between the posterior edge of the iliotibial band and the anterior edge of the biceps tendon. **C,** The interval between the lateral gastrocnemius and posterolateral capsule is opened bluntly, just proximal to the fibular head to avoid entering the joint capsule proximally.

passage, and tied to a tibial post. The sutures securely hold the transplant in the tibial slot and, along with the peripheral sutures, provide fixation. This is the preferred technique because it is simple and effective. Another option is to place a 7 × 25 mm interference screw composed of an absorbable composite material medially adjacent to the bone bridge.[24] A tap is inserted over the guidewire to create a path for the interference screw with the bone bridge held in place manually. This technique is not used if there is tibial bone osteopenia or if a prior ACL graft tunnel exists because inadequate fixation will occur.

The arthrotomy is closed, and the inside-out meniscal repair completed with multiple vertical divergent sutures that are placed first superiorly to reduce the meniscus (Fig. 24-6) and then inferiorly in the outer third of the transplant. Sutures are not placed in the middle and inner thirds to avoid weakening the transplant owing to its limited healing capability in these regions (Fig. 24-7). Although all-inside suture techniques have been used in some studies, we do not recommend this procedure because multiple superior and inferior vertical divergent sutures provide excellent fixation that allows immediate range of motion and 25% weight bearing.

OPERATIVE TECHNIQUE: MEDIAL MENISCUS TRANSPLANT

The patient is placed in a supine position on the operating room table with a tourniquet applied using a leg holder, and the table is adjusted

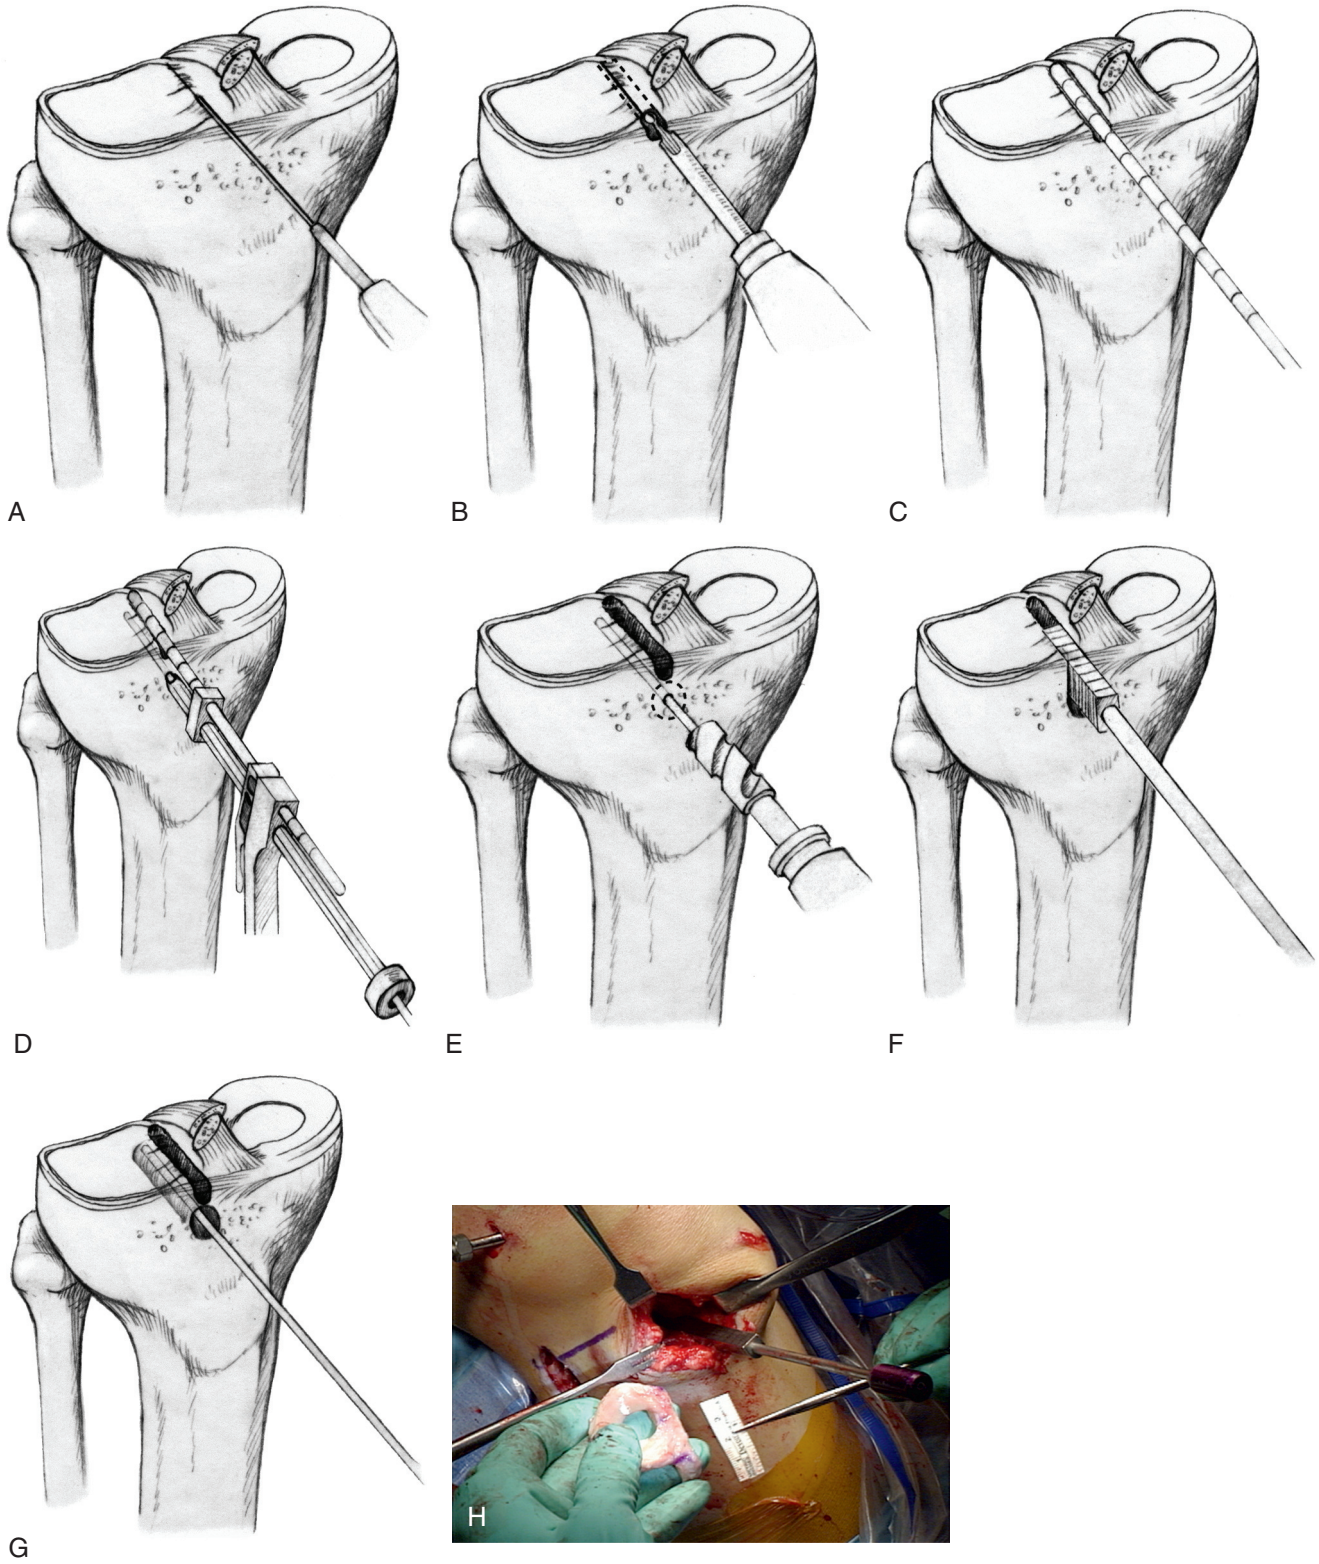

FIG 24-3 **A,** Tibial slot technique for lateral meniscus transplantation. An arthroscopic-assisted technique or minilateral arthrotomy may be used in this procedure. We prefer the miniarthrotomy because it offers superior visualization and avoids incising the patellar tendon. Establish a line connecting the center of the anterior and posterior horn attachments using an electrocautery device. In the mini-open arthrotomy, a template of the meniscus coronal width is used to verify the medial-to-lateral width of the transplant to move the slot appropriately to prevent tibial overhang of the transplant. **B,** A burr removes the tibial spine and creates a 4-mm straight anterior-to-posterior reference slot along the plane of the tibial slope. **C,** This calibrated guide pin sits flush with the articular cartilage. **D,** The drill guide uses a guide pin that has been marked with a laser to set the depth of a second guide pain, allowing a drill to ream 5 mm less to retain the posterior portion of the tibial slot. **E** to **G,** The 8-mm drill bit with a collar at the defined depth is used, followed by use of a box cutter to create a rectangular slot of the desired depth and width. **H,** The lateral meniscus transplant with the central bone bridge technique is ready to be placed into the tibial slot. (**A** to **H,** From Noyes FR, Barber-Westin SD, Rankin M. Meniscal transplantation in symptomatic patients less than fifty years old. Surgical technique. *J Bone Joint Surg Am.* 2005;87(suppl 1[pt 2]):149-165.)

to allow 90 degrees of knee flexion. The opposite lower extremity is placed in a thigh-high elastic stocking and is padded to maintain mild hip flexion to decrease tension on the femoral nerve. After knee examination and diagnostic arthroscopy, the meniscus bed is prepared by removing remaining meniscal tissue. It is important to preserve, whenever possible, a 3-mm rim to help contain the meniscus and prevent extrusion. Although there are techniques for suturing the meniscus implant without bone plugs, we prefer to take the added time to secure a bone-meniscus-bone implant. Biomechanic studies[4,5,15,70] support this concept and have shown that sutured meniscus implants, without additional bony fixation, do not restore normal joint contact pressures, although one study did not agree.[58] Any loss of meniscus tissue to its bony attachment may result in loss of function. Sekaran and colleagues[83] showed that even a 5-mm malposition in the medial meniscus posterior bone plug adversely affects joint contact pressure. The meniscus bed and synovium are rasped to aid in revascularization of the transplant.

The tourniquet is inflated only for the anteromedial and posteromedial surgical approaches. For the anterior arthrotomy, a 4-cm skin anteromedial incision is made adjacent to the patellar tendon. A second 3-cm vertical posteromedial incision is made, similar to that described for inside-out meniscus repairs (Fig. 24-8).[59] The fascia is incised anterior to the sartorius muscle, and the pes anserine muscle group is retracted posteriorly. Great care is taken to identify and avoid injury to the infrapatellar branches of the saphenous nerve. The interval between the semimembranosus tendon and the capsule is dissected.

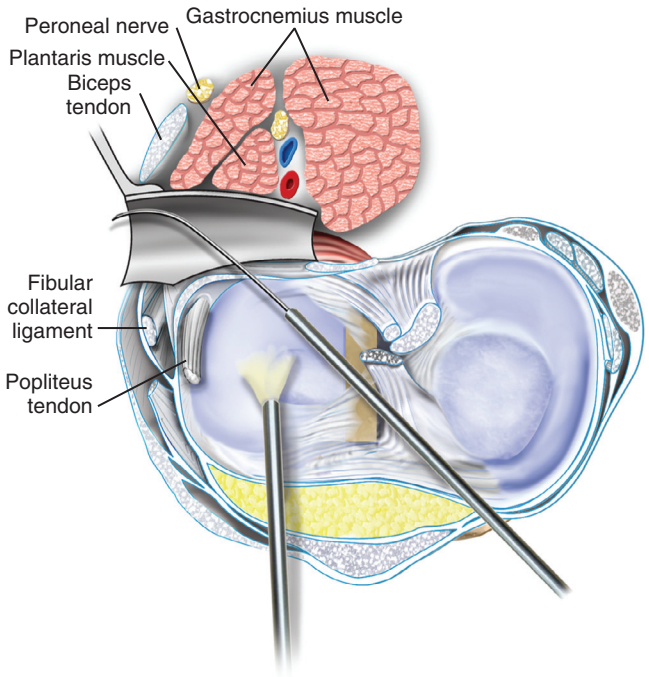

FIG 24-6 Cross-section showing popliteal retractor between the lateral gastrocnemius and the posterior capsule. A single cannula is introduced from the adjacent portal to facilitate placement of the vertical sutures into the periphery of the meniscus transplant.

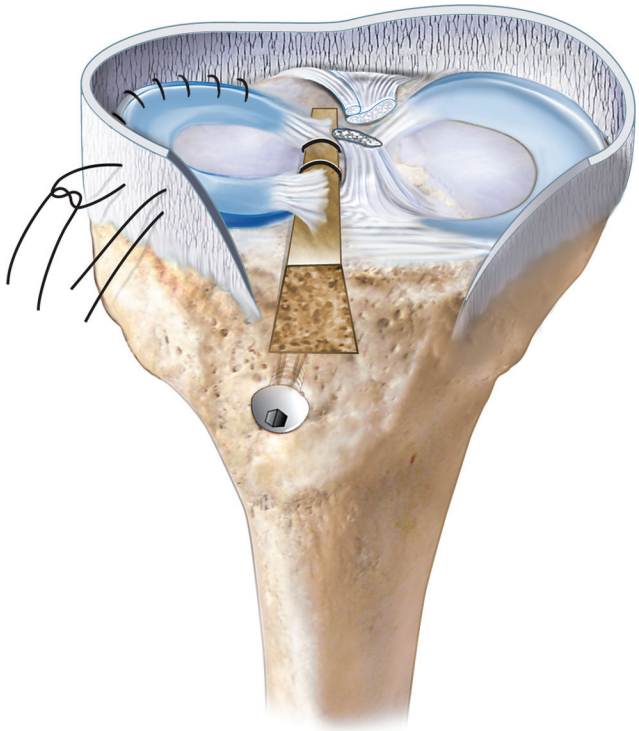

FIG 24-7 Lateral meniscus graft in place and sutured.

The tendon sheath of the semimembranosus is incised to facilitate exposure. The layer between the medial gastrocnemius tendon and the posterior capsule is separated with blunt dissection. A meniscus retractor is placed in the interval anterior to the gastrocnemius tendon and directly posterior to the meniscus bed and posterior capsule. The two

CRITICAL POINTS Operative Technique: Medial Mensicus Transplant

- Diagnostic arthroscopy confirms preoperative diagnosis and articular cartilage changes.
- Tourniquet is inflated only for anteromedial, posteromedial surgical approaches.
- 4-cm skin anteromedial incision adjacent to tibial tubercle and patellar tendon.
- 3-cm vertical posteromedial incision.
- Identify and avoid injury to the infrapatellar branches of the saphenous nerve.
- Tendon sheath of the semimembranosus is incised to facilitate exposure.
- Meniscus retractor is placed in the interval anterior to gastrocnemius tendon, directly posterior to meniscus bed, posterior capsule.
- Aluminum foil template of the MMT is made, measured according to anterior-posterior, medial-lateral dimensions.
- Template is inserted through anterior arthrotomy to measure medial tibial plateau.
- Position of central bone slot is marked.
- Surgeon determines whether meniscus implant will be properly positioned; if so, central bone bridge technique is used.
- If implant requires adjustment for improper fit in medial compartment, two-tunnel technique is selected.

approaches are performed with the tourniquet inflated to 275 mm and usually require less than 15 minutes; otherwise, the tourniquet is not used.

The goal of the operative procedure is to transplant the medial meniscus and bone attachments into the normal anterior and posterior attachments and to suture the transplant to maintain the desired position in the knee joint. An aluminum foil template of the MMT is measured according to its anterior-to-posterior and medial-to-lateral dimensions and is inserted through the anterior arthrotomy to measure the medial tibial plateau. This allows the position of the central bone slot to be marked and to determine whether the meniscus transplant will be properly positioned adjacent to the ACL tibial attachment without medial tibial overhang.

The anterior and posterior meniscus attachment locations are verified to be at the anatomically correct sites. The central bone bridge technique removes 4 to 6 mm of the medial intercondylar tubercle. If the transplant is suitable and no medial tibial overhang is present, the central bone bridge technique may be used. If the transplant needs to be adjusted to fit to the medial tibial plateau to avoid medial extrusion, then the two-tunnel technique is selected. This sizing step is critical to obtain proper placement of the MMT into the host tibia.

In many knees, the central slot technique will not be possible owing to a sizing problem that results in excessive medial displacement of the meniscus body or that would compromise the ACL tibial attachment. Once the appropriate technique has been determined, the meniscus transplant is prepared.

Medial Meniscus Central Bone Bridge Technique

The technique is similar to that already described for LMT. The meniscus transplant is prepared using either a rectangular or dovetail technique. A reference slot is first made on the tibial plateau in the anterior-to-posterior direction. A guide pin is positioned in the slot, inferiorly on the tibia, and a cannulated drill bit is placed over the pin to drill a tunnel. An alternative technique is to use osteotomes and chisels to prepare the tibial slot. The ACL attachment is directly lateral

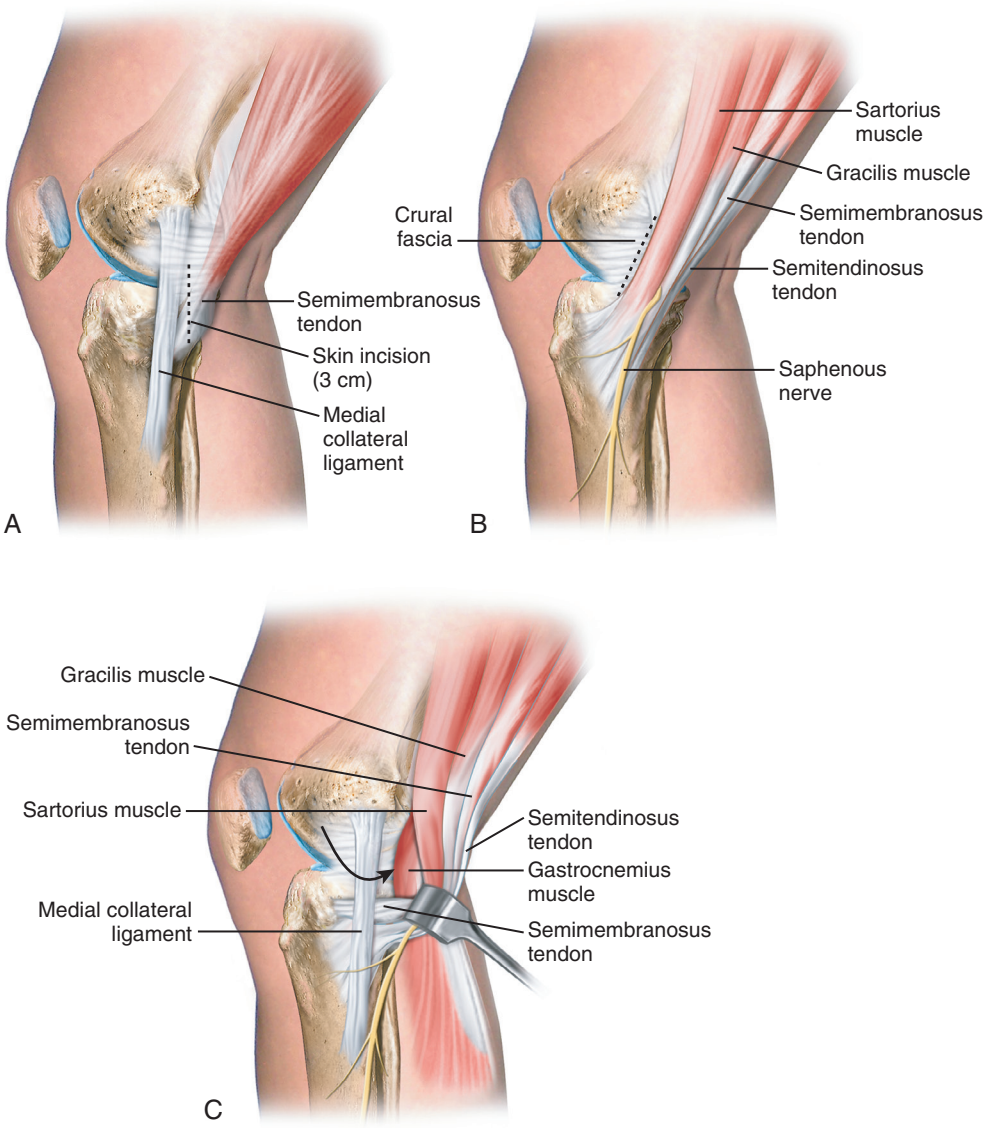

FIG 24-8 The accessory posteromedial approach is shown for a medial meniscus transplant. **A,** Site of the posteromedial skin incision. **B,** The incision is shown through the anterior portion of the sartorius fascia. **C,** The interval is opened between the posteromedial capsule and the gastrocnemius tendon, just proximal to the semimembranosus tendon (*arrow*). The fascia over the tendon is excised to its tibial attachment to facilitate retrieval of the meniscus sutures.

to the tibial slot, and no more than 2 mm of its attachment may be compromised. The final tibial slot is 8 to 9 mm in width and 10 mm in depth. A rasp is used to smooth the slot to allow insertion of the transplant central bone bridge.

In the dovetail technique, the central bone bridge of the transplant is sized to a width of 7 mm (1 mm less than the dimension at the tibial site) and a depth of 10 mm.[24] The dovetail technique requires less central bone resection and therefore is more protective of the ACL attachment.

A vertical suture is placed through the posterior meniscus horn and advanced through the capsule to exit through the posteromedial incision. The meniscus is passed through the arthrotomy into the knee with tension placed on the posterior suture to facilitate proper positioning in the knee joint. Care is taken to align the meniscus bone bridge with the recipient tibial slot. The adjustment of the central bone bridge position is performed in the anterior-to-posterior direction to fit in the anatomically correct position relative to the femoral condyle. The knee is taken through flexion, extension, and tibial rotation to align the transplant. Occasionally, there will be an osteophyte on the anterior portion of the medial tibial plateau, which must be resected to avoid meniscal transplant compression.

The fixation of the central bone bridge is accomplished with two sutures that are passed through a tunnel in the central tibial slot or with an interference absorbable screw, as already described. The anterior horn of the meniscus is sutured with vertical sutures (2-0 Ethibond) under direct visualization (Fig. 24-9). The anterior arthrotomy is closed, and the inside-out vertical divergent sutures are placed, as described, to suture the meniscus to the meniscus bed, removing any

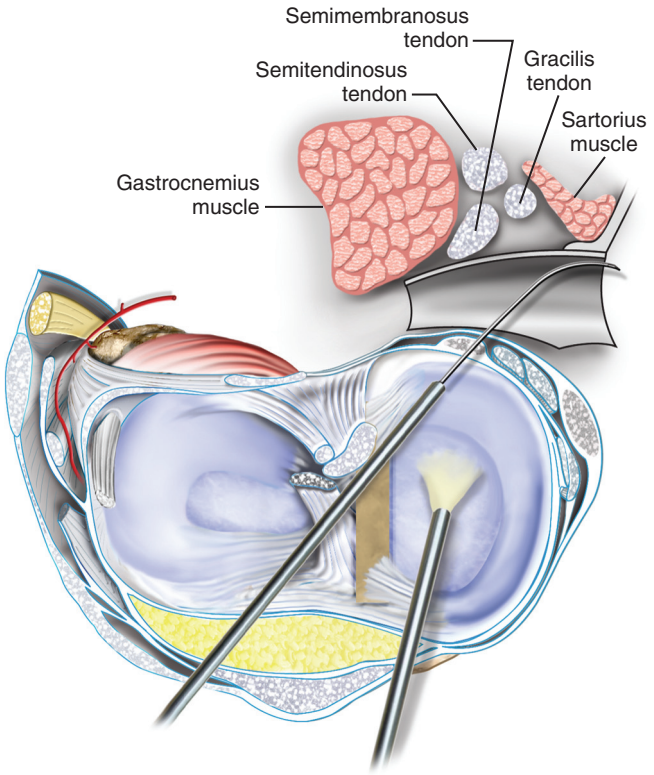

FIG 24-9 Cross-section showing the arthroscope, needle cannula, and popliteal retractor in place. The meniscus is passed through the arthrotomy into the knee with tension placed on the sutures to facilitate proper positioning in the knee joint. Using a single-barrel cannula, the suture is advanced through the capsule at the corresponding attachment site of the meniscus and exits through an accessory incision.

FIG 24-10 Weight-bearing posteroanterior radiograph of a 36-year-old woman 6 years after medial meniscus central bone bridge implantation shows incorporation of the bone bridge into the host, with preservation of the medial joint space. (From Noyes FR, Barber-Westin SD, Rankin M. Meniscal transplantation in symptomatic patients less than fifty years old. Surgical technique. *J Bone Joint Surg Am.* 2005;87(suppl 1[pt 2]):149-165.)

CRITICAL POINTS Operative Technique: Medial Meniscus Central Bone Bridge Technique

- Transplant is prepared using rectangular or dovetail technique.
- Reference slot is tibial plateau, anterior-to-posterior direction.
- ACL attachment is directly lateral to tibial slot; no more than 2 mm of its attachment may be compromised.
- Final tibial slot should be 8-9 mm wide, 10 mm deep.
- Dovetail technique: central bone bridge sized to a width of 7 mm (1 mm less than the dimension at the tibial site) and a depth of 10 mm.
- Meniscus passed through arthrotomy into knee with tension on posterior suture.
- Align meniscus bone bridge with recipient tibial slot.
- Fixation: Two sutures are passed through a tunnel in the tibial slot or an absorbable bone interference screw.
- Anterior horn is sutured with vertical sutures under direct visualization.
- Anterior arthrotomy is closed, and inside-out vertical divergent sutures are placed to suture transplant to meniscus bed.

transplant undulations and restoring circumferential meniscal tension. A final arthroscopic inspection confirms proper transplant fixation and placement. The central bone bridge of the transplant provides for fixation of the anterior and posterior portions of the transplant and subsequent healing to the host tibia (Fig. 24-10).

Medial Meniscus Two-Tunnel Technique

If it is determined that the central bone bridge technique is not acceptable, the surgeon must prepare separate anterior and posterior bone attachments for the meniscus transplant that will be secured to the normal anatomic attachment sites (Fig. 24-11). The transplant is prepared with a posterior bone plug 8 mm in diameter and 12 mm in length. Although techniques have been described that use only soft tissue fixation of the posterior horn and removal of the posterior bone attachment of the meniscus graft to allow easier graft passage, it is our opinion that this provides less secure fixation, does not adequately restore hoop tension, and leads to a higher failure rate. The anterior bone attachment is 12 mm in width, length, and depth. Two 2-0 nonabsorbable sutures are passed retrograde through each bone attachment, with two additional locking sutures placed in the meniscus adjacent to the bone attachment for secure fixation.

The anteromedial and posteromedial approaches are performed as already described. A guide pin is placed adjacent to the tibia tubercle and directed to the anatomic posterior meniscus attachment. A tibial tunnel is drilled over the guidewire to a diameter of 9 mm. The bone tunnel edges are chamfered and slightly enlarged with a curette to allow easier passage of the graft into the tibial tunnel. A limited medial femoral condyle notchplasty is usually required. At least 8 mm of opening adjacent to the PCL and medial femoral condyle is required to pass the posterior bone attachment of the graft. Rarely, a subperiosteal release of the long fibers of the tibial attachment of the distal medial collateral ligament (MCL) (with later suture anchor repair) is required to sufficiently open the medial tibiofemoral joint. This

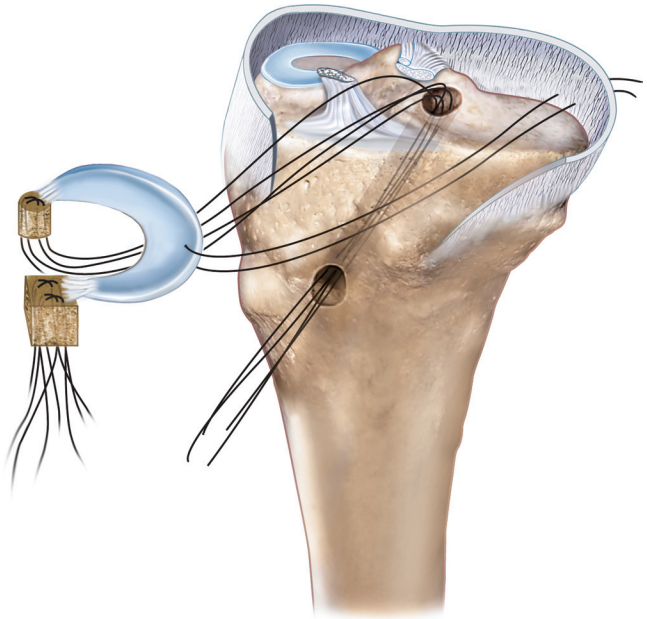

FIG 24-11 Two-tunnel technique for medial meniscus transplantation. The illustration shows insertion of transplant, including the posteromedial suture placed to facilitate meniscus reduction. The anterior and posterior bone attachments of the medial meniscus transplant are fixed into separate tibial tunnels.

technique is preferred over "pie crust" techniques to weaken the MCL because MCL repair restores normal tension.

The graft is passed through the anteromedial arthrotomy. The surgeon is seated with a headlight in place, and the knee is flexed to 90 degrees. A guidewire is passed retrograde through the tibial tunnel, and the sutures attached to the posterior bone are retrieved. A second suture is placed into the posterior horn and is passed inside out through the posteromedial approach to guide the meniscus.

The knee is flexed to 20 degrees under a maximum valgus load to pass the posterior bone plug with the meniscus body suture held by an assistant. A nerve hook or blunt instrument is used to gently assist the passage of the graft. With direct visualization, it is possible to confirm appropriate meniscus graft passage and positioning into the medial tibiofemoral compartment. Care is taken not to advance the posterior meniscus body into the tibial tunnel but only to seat the bone portion of the graft to not shorten the overall circumferential length of the meniscus graft.

The posterior meniscus bone attachment sutures are tied over the tibial post to provide tension to the posterior bone attachment. One or two sutures are passed to secure the posterior horn. The knee is flexed and extended to assess meniscus fit and displacement. The optimal location for the anterior meniscal bone attachment is identified to restore proper meniscus position and prevent medial transplant overhang. In the majority of cases, this should be at the anterior anatomic attachment. The knee is placed in full extension, and correct positioning of the transplant is verified.

A 12-mm rectangular bone attachment is fashioned in the tibia to correspond to the anterior bone attachment of the meniscus graft. A 4-mm bone tunnel is placed at the base of this bone slot and exits at the anterior tibia just proximal to the posterior bone tunnel. The sutures are passed through the bone tunnel, and the anterior horn is seated. Full knee flexion and extension are again performed to determine proper graft placement and fit. Tension is applied to the anterior bone sutures, which are not tied at this point but are used to maintain tension in the graft during the inside-out suture repair. This meticulous seating of the meniscus transplant under circumferential tension with bone attachment of both the anterior and posterior horns is believed to be crucial for meniscus weight-bearing position and function.

The anterior arthrotomy is closed and the arthroscope placed in the anteromedial portal. The suture cannula is then inserted into the anterolateral portal for the meniscal repair. The meniscal repair is performed in an inside-out fashion, starting with the posterior horn, with use of multiple vertical divergent sutures of 2-0 nonabsorbable material both superiorly and inferiorly, constantly tensioning the meniscus from posterior-to-anterior to establish circumferential tension. The assistant is seated with a headlight and retrieves the suture needles through the posteromedial approach. Each suture is placed and tied, bringing the meniscus directly to the meniscus bed with observation that correct meniscus placement, fixation, and tension exist. The fixation technique requires a meticulous approach and time to avoid medial meniscus extrusion that has been frequently reported in MRI studies as previously discussed.

Alternative techniques such as all-inside meniscus suture devices are not recommended because these devices lessen the ability to precisely secure and restore tension to the meniscus transplant. The anterior arthrotomy is opened, and final tensioning and fixation of the anterior horn bone attachment is performed. Additional sutures are

CRITICAL POINTS Operative Technique: Medial Meniscus Two-Tunnel Technique

- Transplant is prepared with posterior bone plug 8 mm in diameter, 12 mm in length, anterior bone attachment 12 mm in width, length, depth.
- Approaches are performed, guide pin is placed adjacent to tibia tubercle and directed to anatomic posterior meniscus attachment.
- Tibial tunnel is drilled over guidewire to diameter of 9 mm.
- ≥8 mm opening adjacent to posterior cruciate ligament and medial femoral condyle is required to pass graft posterior bone attachment.
- Graft is passed through anteromedial arthrotomy.
- Knee is flexed 20 degrees under maximum valgus load to pass posterior bone plug. Do not advance the posterior meniscus body into the tibial tunnel; this will shorten the overall circumferential length of the graft.
- Posterior meniscus bone attachment sutures are tied over tibial post to provide tension to posterior bone attachment.
- Knee is flexed and extended to assess meniscus fit and displacement.
- Knee is placed in full extension, and position of transplant is verified to be correct.
- 12-mm rectangular bone attachment is fashioned in tibia to correspond to anterior bone attachment of graft.
- 4-mm bone tunnel is placed at base of anterior tibia proximal to posterior bone tunnel.
- Tension is applied to anterior bone meniscus sutures during inside-out suture repair.
- Anterior arthrotomy is closed, and suture cannula is inserted into lateral portal for meniscal repair.
- Meniscal repair is performed inside out, starting with posterior horn, using multiple vertical divergent sutures. Each suture is placed and tied to bring meniscus directly to meniscus bed.
- Observe correct meniscus placement, fixation, and tension.
- Anterior arthrotomy opened, final tensioning, and fixation of anterior horn bone attachment.
- All-inside suture devices are not recommended.

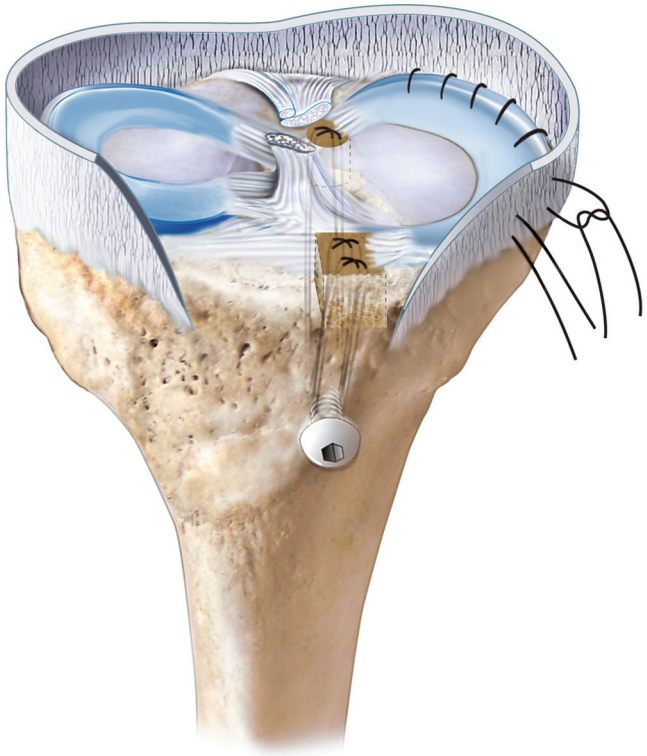

FIG 24-12 Final anterior and posterior tunnel fixation appearance of medial meniscus transplant and vertical divergent sutures.

required to secure the most anterior third of the meniscus to the capsular attachments, which is performed under direct vision (Fig. 24-12). An alternative method of fixation is to use a 3.5-mm cancellous screw with a washer for fixation of the anterior horn meniscus-bone attachment. After final inspection of the graft with knee flexion, extension, and tibial rotation, the operative wounds are closed in a routine fashion.

OUR CLINICAL STUDIES

Clinical Outcomes: Initial Studies

The clinical outcome of 40 consecutive cryopreserved and 96 fresh-frozen irradiated MMTs and LMTs were previously described in detail.[61,64,65,76] A 100% follow-up was obtained in these prospective studies.

Forty cryopreserved meniscus transplants were implanted into 38 patients from November 1995 to March 2000.[65] Four of the meniscus transplants failed and were removed before the minimum 2-year follow-up study period; these cases were included in the overall failure rate. Thirty-five patients were followed (36 meniscus transplants; 18 lateral, 16 medial, one bilateral) a mean of 3.3 years (range, 2-5.7 years) postoperatively. There were 18 males and 17 females whose mean age at surgery was 30 years (range, 14-49 years).

A mean of 11.6 years (range, 1-31 years) had elapsed between the knee injury and the meniscus transplant. A total of 128 prior operative procedures had been done, including 61 partial or total meniscectomies, 13 ACL reconstructions, 4 PCL reconstructions, 1 FCL reconstruction, 5 high tibial osteotomies (HTOs), and 3 osteochondral autograft transfer procedures.

At the time of the LMT, a concurrent osteochondral autograft transfer of the lateral femoral condyle was done in 13 knees for full-thickness articular cartilage defects. Knee ligament reconstructions were done before the meniscus transplant in four knees and at the same time as the transplant in another four knees. In six knees, ACL reconstructions were done using either bone-patellar tendon-bone (B-PT-B) or semitendinosus-gracilis autografts. A PCL two-strand quadriceps tendon autograft reconstruction[60] was done in one knee, and both the PCL and ACL were reconstructed in another knee.

Abnormal articular cartilage surfaces (lesion >15 mm in diameter with fissuring and fragmentation extending greater than half of the depth of the cartilage or subchondral bone exposed) were detected in the meniscectomized tibiofemoral compartment in 31 knees (88%) at the time of meniscus transplantation. Subchondral bone exposure was found in 18 knees, and extensive fissuring and fragmentation were noted in 13 others.

The subjective and functional results were assessed with the CKRS. A classification system of meniscus transplant characteristics was developed on the basis of MRI, clinical examination, follow-up arthroscopy (when performed), and tibiofemoral symptoms (Table 24-1). The International Knee Documentations Committee (IKDC) classification system was used to determine knee ligament graft function.

Before surgery, 27 patients (77%) had moderate to severe pain with daily activities, but at follow-up, only two (6%) had pain with daily activities (Fig. 24-13, $P < .0001$). All patients had pain in the meniscectomized tibiofemoral compartment preoperatively, but at follow-up, only 10 (29%) had some component of tibiofemoral pain.

CRITICAL POINTS Our Clinical Studies: Clinical Outcomes Initial Studies

- $n = 40$ cryopreserved meniscus transplants in 38 patients followed a mean 3.3 yr (range, 2-5.7 yr).
- Average 11.4 yr from knee injury to transplant
- Concurrent osteochondral autograft transfer done in 13 knees.
- Staged or concurrent cruciate reconstructions done in 8 knees: 6 ACL, 1 PCL, 1 ACL + PCL.
- 88% knees had abnormal articular cartilage surfaces.
- 73% meniscus transplants assessed with MRI 12-67 mo postoperative.
- Meniscus transplant characteristics determined with classification system: MRI, clinical examination, follow-up arthroscopy (when performed).
- Pain with daily activities: 77% before surgery, 6% at follow-up.
- Pain in meniscectomized tibiofemoral compartment: 100% before surgery, 29% at follow-up.
  - Pain at follow-up rated as light by majority.
- 94% patients believed knee condition improved by operation.
- Sports without problems: 3% before surgery, 77% at follow-up (mostly low-impact activities).
- Reoperation rate for meniscus transplant symptoms: 25%.
- Meniscus transplant characteristics: 42.5% normal, 30% altered, 27.5% failed.
- Correlation between arthrosis rating on MRI and the transplant characteristics ($P = .01$).
  - 16 transplants in knees with mild arthrosis: 10 normal characteristics, 6 altered characteristics.
  - 12 transplants in knees with moderate arthrosis: 3 normal characteristics, 4 altered characteristics, 5 failed.
- $n = 96$ irradiated meniscus transplants, 82 patients, historical study. Correlation MRI arthrosis rating and transplant failure rate.
  - No/mild arthrosis: 6%
  - Moderate arthrosis: 45%
  - Advanced arthrosis: 80%

TABLE 24-1 Meniscus Allograft Classification

MAGNETIC RESONANCE IMAGING EVALUATION (*N* = 29)				CLINICAL EXAMINATION: TIBIOFEMORAL (*N* = 39)		FOLLOW-UP ARTHROSCOPY (*N* =13)
Allograft Classification	**Peripheral Attachment**	**Position in Joint***	**Signal Intensity**	**Meniscus Signs**	**Pain, Clinical Symptoms**	**Meniscus Tears**
Normal	Healed	Normal (0%-25% of meniscus width)	None	None	None	None
Altered		Displacement (26%-50% of meniscus width)		Grades 1, 2	Mild pain, improved over preoperative	Partial meniscectomy (<1/3; removed)
Failed	Not healed	Major displacement (>50% of meniscus width)	Grade 3 (tearing, signal intensity extended to articular surface)	Obvious signs of meniscus tear	Definite pain, not improved over preoperative	Partial or total meniscectomy (>1/3; removed)

One abnormal result was considered failed.
*Coronal and sagittal planes, percentage of displacement of posterior or medial plateau margin perpendicular to the joint line.

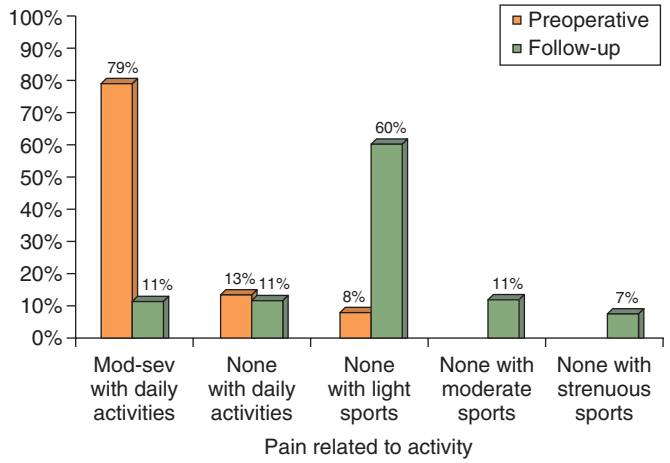

FIG 24-13 The pain scale shows the highest level of activity possible without the patient experiencing knee pain. The difference between preoperative and follow-up was statistically significant ($P < .0001$). *Mod-sev,* moderate to severe. (From Noyes FR, Barber-Westin SD, Rankin M. Meniscus transplantation in symptomatic patients under fifty years of age. *J Bone Joint Surg Am.* 2004;68:1392-1404.)

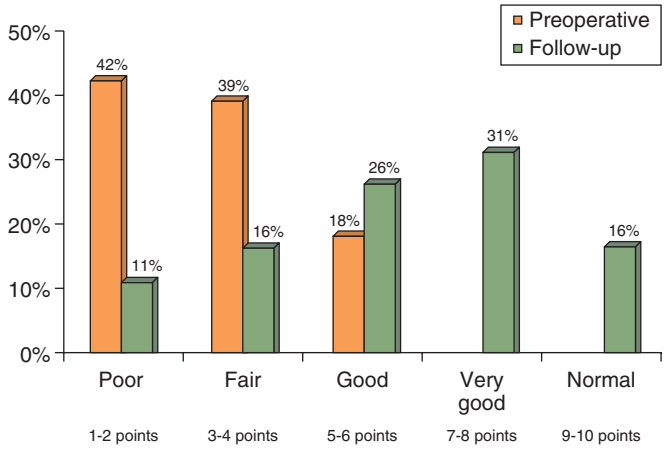

FIG 24-14 Distribution of patient perception of the overall knee condition. The difference between preoperative and follow-up was statistically significant ($P < .0001$). (From Noyes FR, Barber-Westin SD, Rankin M. Meniscus transplantation in symptomatic patients under fifty years of age. *J Bone Joint Surg Am.* 2004;68:1392-404.)

Thirty-three of 35 (94%) patients stated their knee condition had improved on self-assessment ratings (Fig. 24-14). The mean preoperative patient perception score (scale, 1-10) of 3.1 points (range, 1-6 points) improved to a mean of 6.2 points (range, 1-9 points) at follow-up (Table 24-2, $P < .0001$). Preoperatively, only 1 patient was able to participate in sports without problems. At follow-up, 27 patients (77%) were participating in light, low-impact sports without problems, and 1 patient was participating with symptoms against advice (Table 24-3).

Before the operation, 15 patients had symptoms and limitations during work activities (Table 24-4), but at follow-up, only 2 patients continued to have problems related to the knee condition at work.

One patient had signs of a meniscus transplant tear at follow-up. One patient had tibiofemoral joint line pain and increased palpable crepitation compared with the preoperative examination. All patients had a normal range of knee motion.

All knees that had an ACL reconstruction had normal or nearly normal anterior stability restored except one in which the reconstruction failed. The PCL reconstructions restored nearly normal function in both knees at 20 and 90 degrees of flexion, except for one knee in which partial function was restored at 90 degrees of flexion.

Five patients had follow-up arthroscopy for symptoms related to the transplant. In three patients, tears in the periphery of the meniscus transplant at the capsular junction were successfully repaired. In two patients, small tears in the transplant were resected. None of these patients had further complaints. One other patient had a total knee replacement 35 months after the meniscus transplant for unresolved knee pain. With the six patients described above, and the four meniscus transplants that required early postoperative removal, the reoperation rate for meniscal transplant symptoms was 25% (10 of 40 meniscus transplants).

Seventeen of the meniscus transplants (42.5%) had normal characteristics, 12 (30%) had altered characteristics, and 11 (27.5%) failed.

TABLE 24-2 Pain and Function Scores Before and After Meniscal Transplantation

Of the 20 LMTs, nine had normal characteristics, seven had altered characteristics, and four failed. Of the 20 MMTs, eight had normal characteristics, five had altered characteristics, and seven failed. There was a correlation between the arthritis rating on MRI and the transplant characteristics ($P = .01$). Of the 16 transplants in knees with mild arthritis, 10 had normal characteristics and six had altered characteristics. Of the 12 transplants in knees with moderate arthritis, three had normal characteristics, four had altered characteristics, and five failed.

The results of 96 consecutive irradiated meniscus transplants implanted into 82 patients were previously described.[64] Twenty-eight menisci in 27 patients required early arthroscopic resection owing to lack of meniscal healing a mean of 10 months (range, 2-20 months) postoperatively. These 28 menisci were included in the overall failure rate. In addition, 1 patient died of causes unrelated to the knee condition before the 2-year follow-up. This left 67 menisci (57 medial, 10 lateral) in 62 patients (63 knees) who all returned for follow-up a mean of 3.6 postoperative years (range, 1-9.2 years).

The patients were divided into three groups for analysis of the meniscus transplant. Group 1 had normal to mild articular cartilage arthritis on MRI, group 2 had moderate arthritis, and group 3 had severe arthritis. The meniscus transplant failure rates were 6% (1 of 18 knees) in knees with normal or only mild arthritis on MRI, 45% (14 of 31 knees) in knees with moderate arthritis, and 80% (12 of 15 knees) in knees with advanced arthritis (Fig. 24-15). The relationship between the meniscus transplant failure rate and increasing severity of joint arthritis was significant ($P < .001$).

Histologic evaluations were conducted by independent examiners on the 28 meniscus allografts with early postoperative failure. Nine specimens (five medial, four lateral) that included the peripheral meniscal–capsular junction and an intact meniscal body were critically analyzed (Fig. 24-16). These allografts had been removed a mean of 11 months (range, 2-21 months) postoperatively, and the tibiofemoral and inner-outer orientations were easily identifiable. There was no evidence of a cellular reaction suggestive of a rejection phenomenon in any of the tissues examined. The specimens consistently demonstrated minimal, if any, cellular repopulation of the femoral and tibial surfaces or central core of the meniscus (Fig. 24-17, *A* and *B*). The predominant cell type was a fibrocyte (Fig. 24-17, *C*). Remodeling with abnormal collagen orientation was found in 6 specimens. The remodeling phenomenon resulted in a loss of the normal surface radial collagen architecture and a loss of the normal circumferential fibers within the meniscal substance (see Fig. 24-17, *D*).

The role of low-dose irradiation (2.0-2.5 mrad) in terms of increasing the failure rate of meniscus allografts is not scientifically known. From a historic standpoint, this study provided needed information on patient selection criteria for meniscus transplants. Patients with advanced arthritis, alterations in joint geometry (major tibial

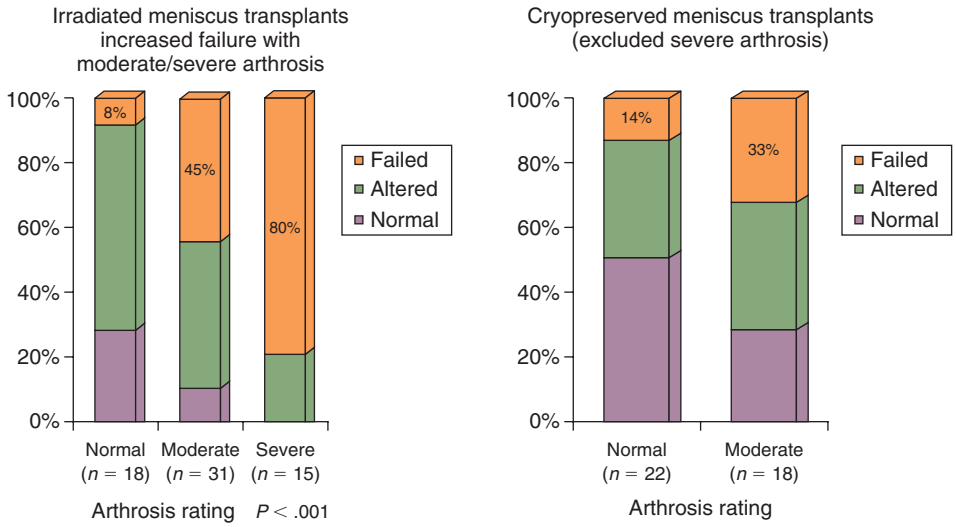

FIG 24-15 Distribution of meniscus transplants rated on magnetic resonance imaging as normal, altered, and failed for our clinical investigations.

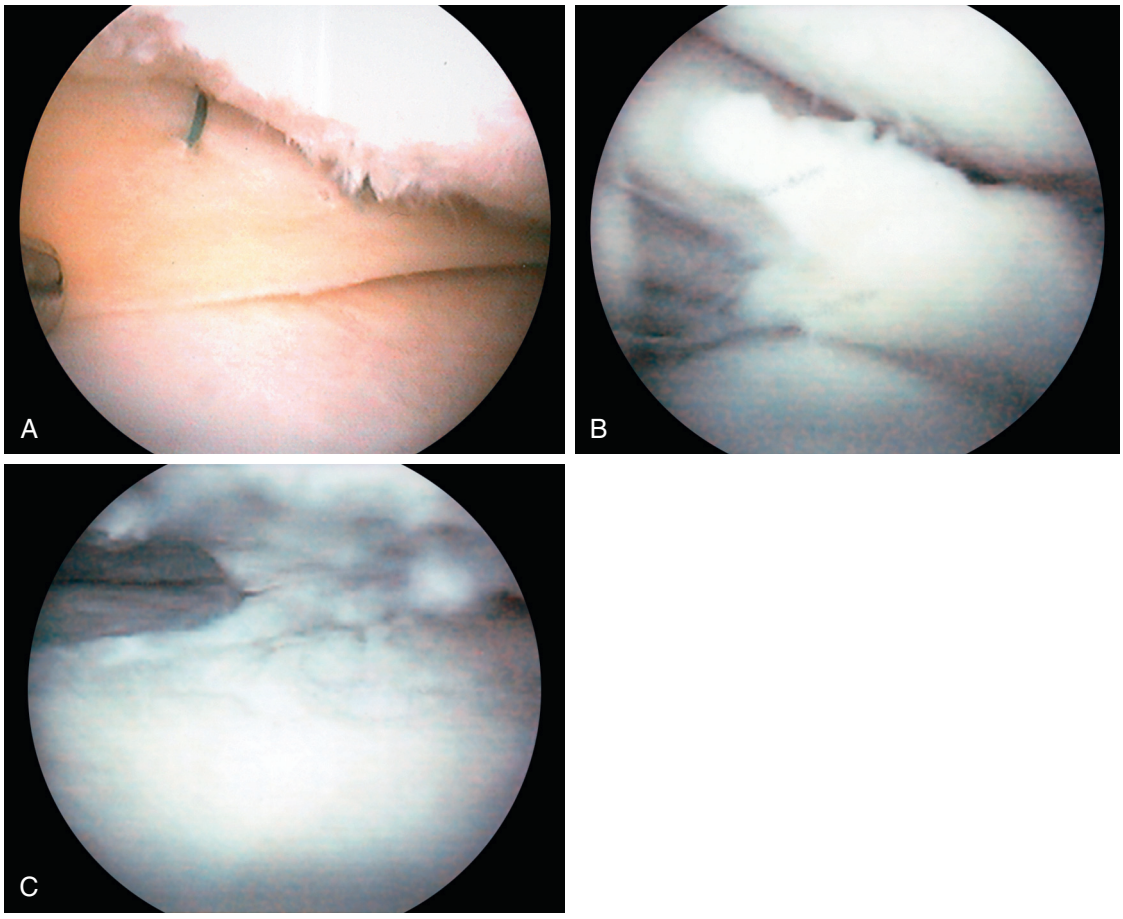

FIG 24-16 **A,** Irradiated medial meniscus-bone transplant upon initial implantation. **B** and **C,** At follow-up arthroscopy 7 months later, the medial meniscus transplant had torn and failed and was removed. This case was included in the histologic assessment of failed meniscus transplants.

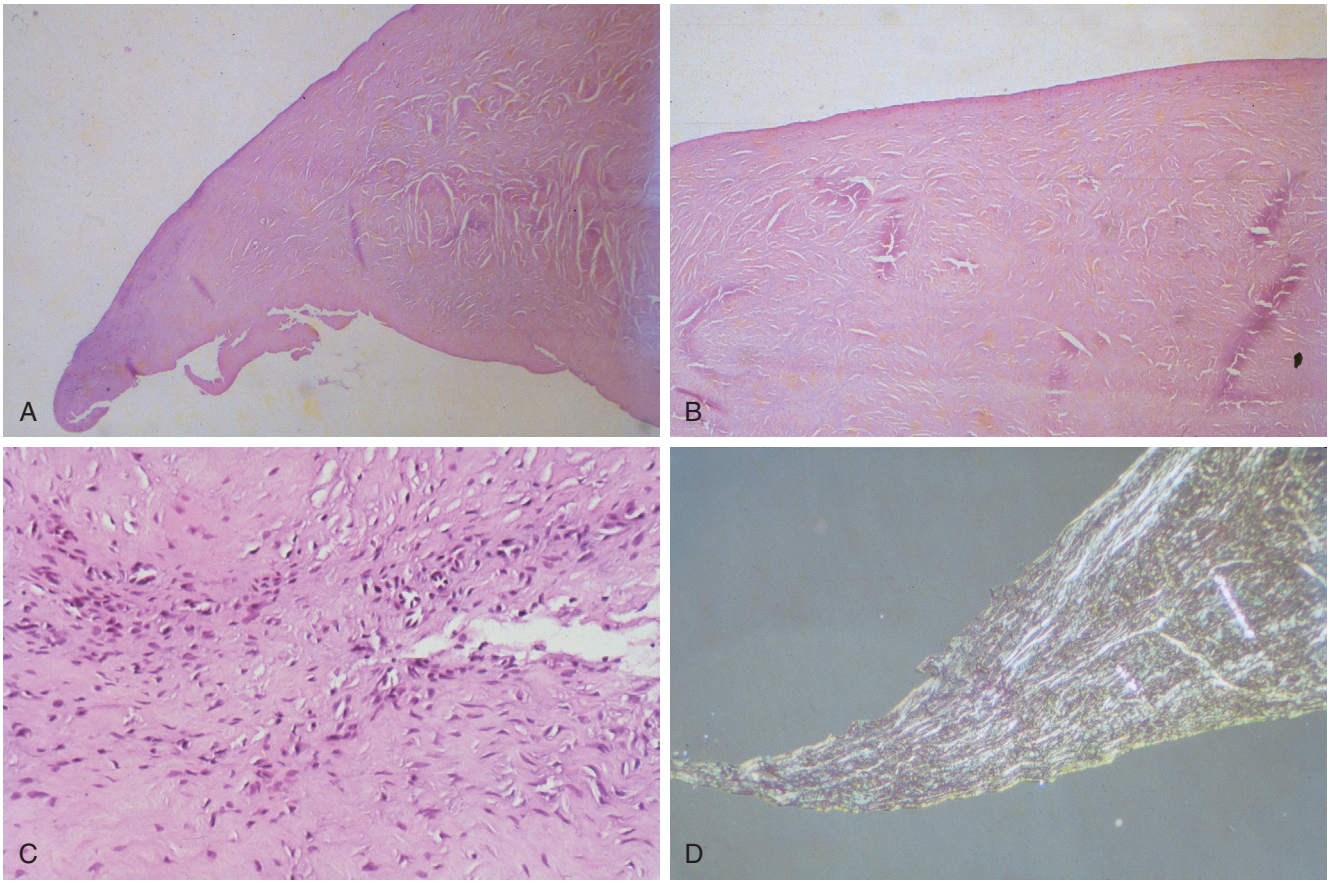

FIG 24-17 Coronal section of a meniscus allograft 17 months after implantation. Photomicrographs show incomplete repopulation of the femoral surface (**A,** ×40) and the remaining tissue acellular (**B,** ×40), with some cells resembling fibrochondrocytes (**C,** ×200). **D,** Polarized light micrograph shows fibers aligned parallel to the surface, with poorly organized collagen fibers at the remodeling site. There is a loss of normal radial and circumferential collagen orientation in the body of the allograft, which has not undergone remodeling (×4).

concavity, femoral condyle flattening) with exposed bone surfaces over the majority of the tibiofemoral compartment are not candidates for meniscus transplantation.

Magnetic Resonance Imaging Analysis: Meniscus Transplant Characteristics

A total of 29 cryopreserved meniscus transplants (73%) were analyzed with MRI using the research protocol previously described in detail[65,76] an average of 2.9 years (range, 1-5.5 years) postoperatively. The films were reviewed and measured by independent orthopedic surgeons blinded to patient information. The height, width, and displacement of the transplants were determined during full or partial weight-bearing conditions.

The mean displacement of the 29 meniscus transplants was 2.2 ± 1.5 mm (range, 0-5 mm) in the coronal plane (Table 24-5). Seventeen transplants (59%) had no displacement, 11 had minor displacement, and 1 could not be evaluated. In the sagittal plane, the mean displacement of the posterior horn of the transplants was 1.1 ± 2.0 mm (range, 0-9 mm). Twenty-five transplants (86%) had no displacement of the posterior horn, 3 had minor displacement, and 1 had major displacement (9 mm). The mean displacement of the anterior horn of the transplants was 1.2 ± 1.7 mm (range, 0-6 mm). Twenty-five transplants had no displacement of the anterior horn, three had minor displacement, and one had major displacement (6 mm). Intrameniscal signal intensity was normal in 1, grade 1 in 13, grade 2 in 11, grade 3 in 3, and could not be evaluated in one case.

TABLE 24-5 Results of Magnetic Resonance Imaging Studies of 29 Meniscus Allografts

Structure	Imaging Plane	Height (mm)	Width (mm)	Displacement (mm)
Posterior horn	Sagittal	7.7 ± 1.9	10.4 ± 2.6	1.1 ± 2.0
Anterior horn	Sagittal	7.1 ± 1.4	10.1 ± 1.8	1.2 ± 1.7
Allograft midbody	Coronal	7.8 ± 1.9	11.7 ± 3.7	2.2 ± 1.5

Data are mean ± standard deviation.

A subset of eight meniscus transplants in 7 knees were studied 1.2 to 2.8 years postoperatively[76] in an open configuration Signa SP MRI System (General Electric Medical Systems). This system is a 0.5-T superconducting magnet in which the windings are located in separate but communicating cryostats. The vertical orientation of the scanner allows the patient to stand between the cryostats with the knee at the isocenter (Fig. 24-18). Single-slice sagittal and coronal images were obtained on both knees at 0, 30, 60, and 90 degrees of knee flexion.

CRITICAL POINTS Our Clinicl Studies: MRI Analysis Meniscus Transplant Characteristics

- *n* = 29 transplants analyzed MRI mean of 2.9 yr (range, 1-5.5 yr) under full or partial weight-bearing conditions
- Films reviewed and measured by independent orthopedic surgeons blinded to patient information
- Mean meniscus extrusion
  - Meniscus body: 2.2 ± 1.5 mm (range, 0-5 mm).
  - Posterior horn: 1.1 ± 2.0 mm (range, 0-9 mm).
  - Anterior horn: 1.2 ± 1.7 mm (range, 0-6 mm).
  - 1 transplant major extrusion (9 mm)
- Signal intensity
  - Normal: 1
  - Grade 1: 13
  - Grade 2: 11
  - Grade 3: 3
  - Could not be evaluated: 1
- *n* = 8 transplants full-standing, sagittal and coronal images of both knees at 0, 30, 60, and 90 degrees of flexion
  - Mean height, width of anterior and posterior horns of the transplants similar to native menisci
  - Extrusion similar to native menisci
  - Anterior horn native menisci moved mean 5 mm more anterior to posterior

FIG 24-18 An open configuration 0.5-T superconducting magnet. The vertical orientation of the scanner allows the patients to stand and images to be taken under full weight-bearing conditions. (From Rankin M, Noyes FR, Barber-Westin SD, et al. Human meniscus allografts in-vivo size and motion characteristics: Magnetic resonance imaging assessment under weightbearing conditions. *Am J Sports Med.* 2006;34:98-107.)

In this subgroup, the mean height and width of the anterior and posterior horns of the transplants were similar to those of native menisci (Table 24-6). The millimeters of coronal displacement of motion of the midbody was also similar between the transplants and native menisci. The anterior horn of the native medial menisci moved an average of 5 mm more (total anterior-to-posterior translation, $P < .05$) than the transplants. The posterior horn of the native medial menisci and both horns of the native lateral menisci also tended to move more than the corresponding horns of the transplanted menisci (Fig. 24-19), although this could not be confirmed statistically, given the number of menisci studied.

We are currently studying the outcome of fresh-frozen meniscus transplants and will compare the results with those historically obtained to evaluate the effect of chemical and irradiation processing as just described. The rigorous evaluation matches that conducted previously and includes preoperative and serial postoperative MRI, yearly clinical evaluations and standing PA radiographs, and completion of IKDC and CKRS forms.

Clinical Outcomes: Long-Term Study

We evaluated the long-term outcomes and determined survivorship rates for the cohort of 40 knees that underwent cryopreserved meniscus transplantation.[62] All patients in whom the meniscus transplant had initially survived from the first study and had not undergone a subsequent procedure related to the transplant were contacted to return for a follow-up evaluation. The long-term evaluations began when the patients were at a minimum of 10 years after surgery. Eleven of 40 meniscus transplants failed in the initial study. Subsequently, 11 other transplants failed and required reoperations. This left 18 transplants in 18 patients who completed a long-term evaluation a mean of 14.1 years after surgery (range, 10.3-17.3 years).

Kaplan-Meier survivorship analysis was performed to estimate time-defined probabilities for survival of all 40 meniscus transplants at 5, 7, 10, 13, and 15 years postoperatively. Two survivorship analyses were performed. The first used transplant removal or replacement,

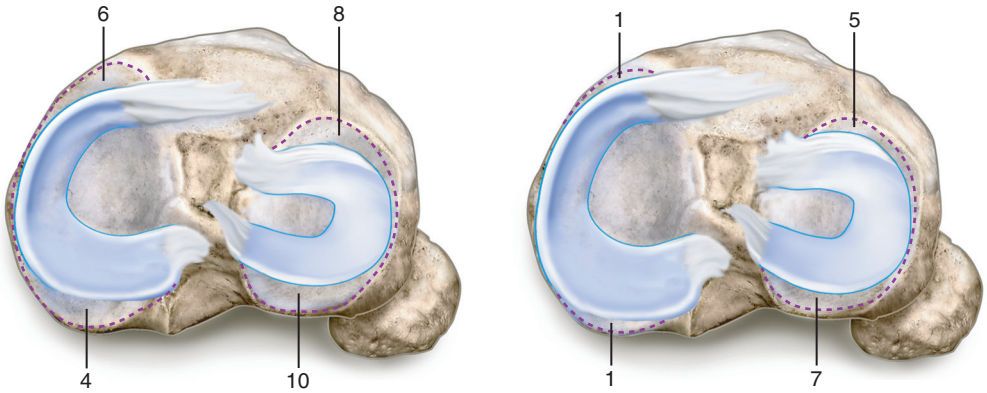

FIG 24-19 Illustrations in the axial plane of the native and transplanted menisci approximating the pattern of meniscal displacement from full extension to 90 degrees of flexion (*dashed lines*; not to scale). (From Rankin M, Noyes FR, Barber-Westin SD, et al. Human meniscus allografts' in-vivo size and motion characteristics: Magnetic resonance imaging assessment under weightbearing conditions. *Am J Sports Med* 2006;34:98-107.)

CRITICAL POINTS Our Clinical Studies: Clinical Outcomes Long-Term Study

- Survival rates determined for 40 cryopreserved meniscus transplants.
- Of initial cohort, 18 knees that had not failed completed long-term evaluation a mean of 14.1 yr (range, 10.3-17.3 yr) postoperatively.
- Endpoints: transplant removal or replacement, revision (total or unicompartmental knee replacement or osteotomy), or pain with daily activities in the involved tibiofemoral compartment.
  - 88% at 5 years, 80% at 7 years, 65% at 10 years, 43% at 15 years
- Worst-case scenario: additional endpoints grade 3 signal intensity or major extrusion (>50% of meniscal width) on MRI, signs of meniscal tear on clinical examination, or complete loss of joint space in the involved tibiofemoral compartment on 45-degree weight-bearing posteroanterior radiographs.
  - 73% at 5 years, 68% at 7 years, 48% at 10 years, 20% at 10 years.

revision (total or unicompartmental knee replacement or osteotomy), or pain with daily activities in the involved tibiofemoral compartment as end points. A worse-case scenario was used in the second analysis where, in patients who did not demonstrate symptoms directly related to the meniscus transplant, additional end points were grade 3 signal intensity or major extrusion (>50% of meniscal width) on MRI signs of meniscal tear on clinical examination, or complete loss of joint space in the involved tibiofemoral compartment on 45-degree weight-bearing PA radiographs. No patients were lost to follow-up, and no transplants were censored.

Statistically significant improvements were detected for pain, swelling, patient perception of knee condition, walking, and stair climbing. Although 72% of the 18 patients had moderate or severe pain with daily activities before the operation, only 11% were continuing to experience such pain at follow-up. Seventy-two percent could participate in sports without pain, although the majority was participating in low-impact athletics only. All regained at least 0 to 135 degrees of knee motion, and none had a knee effusion.

The survivorship analysis revealed an estimated probability of transplant survival of 88% at 5 years (95% confidence intervals [CI], 72%-95%), 80% at 7 years (95% CI, 64%-90%), 65% at 10 years (CI, 48%-79%), and 43% at 15 years (CI, 27%-59%). The worse-case scenario revealed estimated probability of transplant survival of 73% at 5 years (95% CI, 56%-85%), 68% at 7 years (95% CI, 51%-81%), 48% at 10 years (CI, 32%-64%), and 20% at 15 years (CI, 10%-36%). The mean postoperative time at which failures were noted was 7.8 years for medial and lateral transplants.

The 10-year survival probability of 48% is similar to that described by Hommen and associates[36] (45%), who also used multiple endpoints for failure (Lysholm score <65 points, no improvement in the pain score, and grade III signal on MRI). A survival analysis of 63 consecutive cryopreserved meniscal transplants was conducted by van Arkel and de Boer[94] and used persistent pain, a poor Lysholm score, a poor Knee Assessment Scoring System result, or a detached transplant as end points. The cumulative 10-year survival rates of lateral, medial and combined transplants in the same knee were 76%, 50%, and 67%, respectively.

Meniscus Transplant Extrusion

We conducted a systematic review of the medical literature to determine the incidence and clinical significance of postoperative meniscus transplant extrusion.[63] A systematic electronic search was performed using PubMed and Cochrane databases. Inclusionary criteria were English language, clinical trials published from 1984 to 2014, meniscus extrusion measured on MRI, and all evidence levels. The search initially identified 192 original research articles, of which 23 met the inclusionary criteria.* A total of 803 patients underwent 814 meniscus transplants. The MRIs were obtained from 2 days to 10 years postoperatively. The majority of studies used the radiographic method described by Pollard et al[71] to obtain transplant size measurements. Eighteen studies used fresh-frozen meniscus transplants implanted with bone (n = 612) or with suture fixation (n = 116), four studies used cryopreserved transplants, and one used irradiated transplants (Table 24-7).

Twenty-one investigations obtained the MRIs in the supine, non-weight-bearing position. Two studies conducted the scans under partially loaded (50% weight bearing)[65] or fully loaded (100% weight bearing)[76] conditions. Three measurements were used to assess extrusion, and variability was found in each, including absolute millimeters

CRITICAL POINTS Our Clinicl Studies: Systematic Review of Meniscus Transplant Extrusion

- Systematic search performed using PubMed and Cochrane databases.
- $n = 23$ articles met criteria: English language, clinical trials published from 1984 to 2014, meniscus extrusion measured on MRI, all evidence levels.
- 814 transplants in 803 patients.
- MRI obtained from 2 days to 10 years postoperatively.
- 18 studies used fresh-frozen meniscus transplants implanted with bone ($n = 612$) or suture fixation ($n = 116$).
- 4 studies used cryopreserved transplants, 1 used irradiated transplants.
- Absolute millimeters of extrusion ranged from 0-8.8 mm.
- Relative percentage of extrusion ranged from 0%-100%.
- Percent of transplants that were extruded ranged from 0%-100%.
- No correlation between transplant extrusion and clinical rating scales, joint space narrowing on posteroanterior radiographs, and arthrosis grade progression on MRI and follow-up arthroscopy.
- Nonanatomic placement of lateral meniscus transplants and suture fixation of medial and lateral transplants were associated with greater extrusion.
- Short- to mid-term results were encouraging in regard to knee function with activities of daily living and low failure rates, regardless of the presence or amount of extrusion.

of extrusion (0-8.8 mm), relative percentage of extrusion ([Width of extruded meniscus]/[Width of entire meniscus] × 100; 0%-100%), and the percent of transplants that were extruded (0%-100%). All authors used different indicators to determine the percent of transplants that were extruded, including subjective terms such as *partial* or *some degree*, or an objective measurement such as greater than 3 mm.

There appeared to be no correlation between transplant extrusion and clinical rating scales, joint space narrowing on PA radiographs, and arthrosis grade progression on MRI and follow-up arthroscopy. Nonanatomic placement of lateral meniscus transplants and suture fixation of medial and lateral transplants were associated with greater extrusion.

Recently, Jeon and associates[39] compared meniscus transplant extrusion between 44 patients who had a tibial plateau osteophyte excised concomitantly with the transplant with 44 patients who had an osteophyte that was not excised. One year postoperatively, the nonexcised group had significantly greater absolute transplant extrusion (5.5 ± 1.6 mm vs. 3.5 ± 1.5 mm; $P < .001$) and relative percentage of extrusion (54.7 ± 20.7% vs. 34.1 ± 15.9%; $P < .001$). The total incidence of transplant extrusion (>3.0 mm) was 93% in the nonexcised group and 64% in the excised group ($P < .001$). There were no significant differences in the Lysholm or Hospital for Special Surgery (HSS) scores between the groups at 2 postoperative years. Lee and coworkers[47] reported that ICRS grade 3 or more on the tibia was a significant risk factor for LMT extrusion (bone bridge fixation) in a series of 71 knees (odds ratio 6.9; $P = .001$). Nonsignificant risk factors included patient age, gender, BMI, mechanical axis, and chronicity of injury.

Inconsistencies among studies preclude definitive conclusions regarding the incidence and clinical significance of meniscus transplant extrusion. Even so, the short- to midterm results were encouraging in regard to knee function with ADLs and low failure rates, regardless of the presence or amount of extrusion. Future studies should report absolute transplant extrusion, relative percent of extrusion, the percent coverage (percent of transplant located within the tibiofemoral compartment), and the percent of transplants that were extruded. More sophisticated 3-dimensional MRI modeling should be used if feasible to obtain these values. MRIs should be obtained at the same postoperative time period in all patients.

RESULTS FROM OTHER CLINICAL STUDIES

Since 1984,[52] a multitude of clinical investigations have reported outcomes of meniscus transplant surgery (Tables 24-8 to 24-10). Differences in tissue processing, secondary sterilization, preservation, operative technique, concomitant procedures, and rating systems make comparisons among studies difficult and others have performed lengthy reviews of these investigations.[23,32,34,48,53,54,69,87,88]

The majority of meniscus transplant studies published to date assessed outcome of fresh-frozen grafts (see Table 24-8). Using a minimum of 2 years of follow-up as inclusionary criteria, 15 studies have investigated results of transplants implanted using bone fixation techniques, three studies have assessed transplants implanted using soft tissue suture fixation, and two studies included both bone and suture fixation in their cohorts. Typically, significant improvements have been reported in terms of pain reduction and function with daily activities and the patient perception of knee condition.[25,27,44,46,82,90,102] High levels of patient satisfaction have been noted by several authors.[25,27,46,82,102] Only two studies that assessed the outcome of bone fixation had long-term follow-up (8.5 and 20 years), and nearly all patients underwent combined procedures.[82,104]

In terms of fresh transplants implanted with suture (no bone) fixation, one investigation has reported survival rates at the time of writing. Verdonk and associates[101] followed 100 patients a mean of 7.2 postoperative years. Endpoints for failure were moderate or severe occasional or persistent pain or poor knee function, based on the HSS pain and functional scores. Failure rates for medial meniscus and lateral meniscus transplants were 28% and 16%, respectively, and these occurred at a mean of 4.8 years postoperatively. The average cumulative survival time (11.6 years) was identical for medial and lateral transplants. MMTs done concurrently with HTO had a higher cumulative survival rate of 83.3% at 10 years.

Stone and colleagues[90] followed 119 fresh-frozen transplants a mean of 5.8 years. All the transplants were accompanied by an articular cartilage restorative procedure. The endpoints for failure were removal of the transplant or progression to unicompartmental or total knee replacement. Overall, 20% of the transplants failed an average of 4.6 years postoperatively. These investigators reported a survival time of 9.9 years for medial and 10.2 years for lateral transplants. Survival was not associated with gender, severity of articular cartilage damage, or the involved tibiofemoral compartment. This study used both fresh-frozen and cryopreserved transplants, and it is unknown if a difference existed in the failure rate between tissue processing techniques.

Cryopreserved meniscus transplants implanted with bone fixation techniques were investigated in five studies that followed patients from 2.8 to 5.4 years postoperatively (see Table 24-9).[17,77,81,85,89] These studies reported failure rates ranging from 0% to 30%. Three other investigations of cryopreserved transplants implanted with suture fixation reported failure rates of 20% to 50% from 5 to 13.8 years postoperatively.[36,90,96] For instance, Hommen and associates[36] followed 20 patients for 9 to 13 years postoperatively and reported a 10-year survival rate of 45% based on poor Lysholm scores (<65 points), no improvement in the pain score, and grade 3 signal on MRI. A survival analysis of 63 consecutive cryopreserved meniscal transplants followed a mean of 5 years was conducted by van Arkel and de Boer[94] followed a mean of 5 years. Criteria for failure were persistent pain, a poor Lysholm score, a poor Knee Assessment Scoring System result, or a detached transplant. The cumulative 10-year survival rates of lateral, medial, and combined transplants in the same knee were 76%, 50%, and 67%,

TABLE 24-8 Clinical Outcome Studies of Fresh-Frozen Meniscus Transplants With Minimum 2-Year Follow-up

Study	Menisci (*n*)	Mean Follow-up (yr)	Fixation	Concurrent Procedures (*n*)	Evaluation Methods (*n*)	Results, Conclusions
Getgood et al[27] (2015)	48	6.8	Bone	Osteochondral allograft (all)	Questionnaires, subsequent surgery	23% failed; 5-year survival, 78%, 10-year survival, 69%; mean time to failure, 3.2 years
von Lewinski et al[104] (2007)	5	20	Bone	ACL reconstruction (all), MCL advancement	Clinical examination, MRI, x-rays	Severe shrinkage of all transplants on MRI; all patients in varus (no HTO performed); 3 patients moderate/severe radiographic degenerative changes
Saltzman et al[82] (2012)	22	8.5	Bone	Articular cartilage restorative (11), ACL reconstruction (3)	Clinical examination (6)	12% failed; significant improvements in subjective knee function IKDC, KOOS, SF-12; 91% would have surgery again
Lee et al[50] (2010)	43	5.1	Bone	None	Clinical examination, MRI, x-rays	No progression of joint space narrowing; significant improvement in Lysholm scores
McCormick et al[56] (2014)	172	4.9	Bone	Articular cartilage procedure (4), cartilage procedure + HTO (14), ACL reconstruction (23), HTO (8)	Subsequent surgery	32% required follow-up operative procedures, 69% for debridement; 4.7% failed. At 5 years, patients requiring subsequent surgery had an 88% survival rate; those who did not had a 98% survival rate. Patients requiring subsequent surgery had an odds ratio of 8.4 for future TKA or transplant revision.
Farr et al[25] (2007)	29	4.5	Bone	ACI (all), HTO (6), ACL reconstruction (8)	Clinical examination	12% failed; significant improvements in Cincinnati and Lysholm scores, patient satisfaction score
Kim et al[43] (2011)	29	4.4	Bone	None	Clinical examination, MRI, x-rays, arthroscopy (7)	No progression of joint space narrowing; significant improvement in Lysholm, HSS scores; 31% rated fair/poor according to MRI or follow-up arthroscopy
Kim et al[44] (2012)	110	4.1	Bone	ACL reconstruction (23)	Clinical examination, MRI (108), arthroscopy (20)	Significant improvements in Lysholm, Knee Society pain scores; 92% showed varying degrees of degeneration on MRI; 18% rated fair/poor according to MRI, follow-up arthroscopy, Lysholm score
Yoon et al[111] (2014)	91	3.3	Bone	Articular cartilage procedure (37), ACL recon (32), ACL recon ± ACI (5)	Clinical examination, MRI (35), arthroscopy (27)	No difference in outcome of MMT vs. LMT; significant improvements in IKDC, Lysholm, Tegner scores; 4% failed
Yoldas et al[107] (2003)	34	2.9	Bone	ACL reconstruction (20)	Clinical examination, x-ray	No failures; good function with daily activities but lower with sports; no baseline data collected
Koh et al[45] (2012)	99	2.7	Bone	ACL reconstruction (15), OAT (9)	Clinical examination, MRI	Significant improvement in Lysholm score

TABLE 24-9 Clinical Outcome Studies of Cryopreserved Meniscus Transplants With Minimum 2-Year Follow-up

Study	Menisci (*n*)	Mean Follow-up (yr)	Fixation	Concurrent Procedures (*n*)	Evaluation Methods (*n*)	Results, Conclusions
Rath et al[77] (2001)	22	5.4	Bone	ACL reconstruction (11)	Clinical examination, x-ray, histologic (4)	36% failed; tissue showed reduced cellularity, reduced cytokine expression compared with normal menisci
Stollsteimer et al[89] (2000)	23	3.3	Bone	None	Clinical examination, x-ray, MRI (12)	35% additional surgery related to transplant (1 total removal, 5 partial removals, 1 refixation bone plug, 1 repair). Correlation between clinical results and Outerbridge scores. Mean meniscus size, 63% (31%-100%) compared with normal menisci.
Rue et al[81] (2008)	31	3.1	Bone	ACI (16), osteochondral allograft (15), HTO (1)	Clinical examination	7% failed; significant improvements in functional scores; 76% satisfied, 90% would have surgery again
Cole et al[17] (2006)	44	2.8	Bone	Articular cartilage procedure (9), ligament reconstruction (6), osteotomy (1)	Clinical examination	16% failed; significant improvement in subjective scores; 77% satisfied; trend to greater improvement with LMT over MMT
Sekiya et al[84] (2003)	28	2.8	Bone	ACL reconstruction (all)	Clinical examination, x-ray	0% failed; 86% normal/nearly normal IKDC subjective scores
van der Wal et al[96] (2009)	57	13.8	Suture	ACL reconstruction (2)	Clinical examination	29% failed at mean 7.9 years: 35% medial, 25% lateral. 15-year survival rate of 52.5% (endpoint: complete resection of transplant). Mean 16 years between meniscectomy and transplant; 33% patients had grade 4 damage. Indications improved with experience.
Stone et al[90] (2010)	119	5.8	Suture	Articular cartilage procedure (all), osteotomy (15), ACL reconstruction (17)	Clinical examination	20% failed at a mean 4.6 years; survival time 9.9 years (endpoints: transplant removal, TKA, UKA). Survival not affected by gender, severity of cartilage damage, or involved compartment. Fresh frozen (94), cryopreserved (24), irradiated (1).
van Arkel & de Boer[94] (2002)	63	5	Suture	None	Clinical examination, arthroscopy (16)	Cumulative success rates: 88% LMT, 63% MMT. Survival rates: 76% LMT, 50% MMT (endpoints: persistent pain, mechanical damage). Not all ACL-deficient knees reconstructed; correlated with high failure MMT.
Hommen et al[36] (2007)	20	9-13	Bone or suture	None	Clinical examination, x-ray (15), MRI (7), arthroscopy (14)	10-year survival rate 45% (endpoints: Lysholm <65, no improvement in pain score, transplant removal, MRI grade III). Failures noted in 58% (7/12) of MMT and 50% (4/8) of LMT. Retrospective study; variety of surgical techniques and fixation methods used.
Vundelinckz et al[105] (2010)	39	8.9	Bone or suture	Osteotomy (3), microfracture (2)	Clinical examination, x-ray	10% failed. Significant improvements in KOOS, Lysholm, SF-36 scores. Increase radiographic arthritis grade: 24% slight, 18% moderate.
Jiang et al[40] (2014)	18	4.2	Bone or suture	ACL reconstruction (6)	Clinical examination, MRI, x-ray	Patients who received transplants immediately after meniscectomy had higher IKDC subjective scores, better isokinetic muscle strength. MRI: 2 patients grade 3 signal; meniscus body extrusion in all.
Sekiya et al[85] (2006)	25	3.3	Bone (17) or suture (8)	None	Clinical examination (17), x-ray	83% had no symptoms with daily activities. IKDC symptoms in 8 were normal/nearly normal, 12 were abnormal, 5 were severely abnormal. Significantly worse loss knee motion in suture fixation group; all but 1 patient satisfied; no deterioration in joint space.

ACI, Autologous chondrocyte implantation; *ACL*, anterior cruciate ligament; *HTO*, high tibial osteotomy; *IKDC*, International Knee Documentations Committee; *LMT*, lateral meniscus transplant; *MMT*, medial meniscus transplant; *MRI*, magnetic resonance imaging; *OAT*, osteochondral autograft transfer; *SF-36*, Short Form 36; *TKA*, total knee arthroplasty; *UKA*, unicompartmental knee arthroplasty.

TABLE 24-10 Clinical Outcome Studies of Irradiated Meniscus Transplants with a Minimum 2-Year Follow-up

Study	Menisci (*n*)	Mean Follow-up (yr)	Fixation	Concurrent Procedures (*n*)	Evaluation Methods (*n*)	Results, Conclusions
Graf et al[29] (2004)	9	8.5-10.3	Bone	ACL reconstruction	Clinical examination, x-ray, arthroscopy (6)	1 failed; 8 satisfied with outcome; transplants also cryopreserved
Cameron & Saha[13] (1997)	67	2.5	Bone	HTO (35)	Clinical examination, arthroscopy (10)	10% failed. HTO group: 85% good to excellent clinical results. Isolated transplant group: 90% good to excellent results.
Zhang et al[112] (2012)	18	2	Bone	ACL reconstruction (7)	Clinical examination, MRI, arthroscopy	11% failed; 61% transplants partially extruded; 67% satisfied

respectively. Failure of lateral transplants occurred an average of 4.4 years after implantation, and failure of medial transplants occurred a mean of 2.1 years postoperatively.

In our opinion, the use of survival criteria based only on the need for subsequent surgery results in a significant overestimation of the long-term function of meniscus allograft transplantation (MAT). This opinion is based on MRI studies of MAT that demonstrate signal intensity alterations[28,74,89,95,106] and high rates of meniscus extrusion.[19,28,30,31,43-45,50,95,102,111,112] For instance, Potter et al[74] investigated 29 meniscal transplants with MRI and clinical examination 3 to 41 months postoperatively. Increased signal intensity was detected on the posterior horn in 15 knees, and peripheral displacement at the body was noted in 11; all of these knees had moderate or severe chondral degeneration. Histologic analysis demonstrated peripheral cellular repopulation but a central core that was acellular or hypocellular with evidence of disorganized collagen fibers. Knees with mild chondral degeneration had no abnormalities noted in the meniscus transplants and demonstrated superior clinical results compared with those with severe chondral degeneration.

Although most authors exclude patients with significant tibiofemoral compartment arthritis from meniscus transplantation, others have combined this procedure with articular cartilage restorative procedures to expand the indications.[25,32,90] As described previously, Stone and associates[90] followed 119 patients a mean of 5.8 years and reported a 9.9-year survival rate. Farr and colleagues[25] reported encouraging results in 29 patients followed a mean of 4.5 years after meniscus transplantation and autologous chondrocyte implantation. Significant improvements were found in several validated rating scales and 91% indicated they would undergo the operation again. Harris and coworkers[32] conducted a systematic review of combined transplant-cartilage procedures that involved six studies comprising 110 patients. During a mean of three postoperative years, failures had occurred in 12% of patients owing mainly to problems with the transplant. Although the short-term knee functional results were improved, a high rate of subsequent surgery (nearly 50%) was found.

CONCLUSION

The biology of meniscus healing and remodeling after implantation determines the final outcome regarding potential load-bearing function and chondroprotective effects. The meniscus transplant heals to the peripheral transplant-host rim junction within a short period of time, usually by 6 weeks, providing initial stability of the transplant in the knee joint. Animal[6] and human[64] studies indicated that an incomplete and disordered remodeling process occurs. This includes minimal cellular repopulation of the central and inner portions of the transplant, disorganization of collagen tissue (which lacks the normal collagen orientation required for load-sharing), and a predominant fibrocyte cellular structure. An increase in water content and a decrease in proteoglycan concentration in meniscus transplants have been documented.[37]

MRI done immediately after meniscus transplantation demonstrates uniform low signal intensity throughout the transplant tissue. Increased signal intensity at the capsular attachments of the transplant to the host meniscus rim is most likely caused by progressive healing. The low signal intensity within the body of the meniscus remains until remodeling of the transplant occurs. It is possible to see retention of

CRITICAL POINTS Conclusions

- Biology of meniscus healing and remodeling after implantation determines final outcome.
- Transplant heals to peripheral transplant-host rim junction within a short period of time providing initial stability of the transplant in the knee joint.
- An incomplete and disordered remodeling process occurs, expected to affect nearly all transplants, which results in altered mechanical properties and potential for tearing, fragmentation, and degeneration under joint-loading conditions.
- Uniform low signal intensity seen up to 4 years after implantation, advantageous in preserving function.
- First goal is to implant meniscus in manner that prevents graft extrusion.
- Results of meniscus transplantation are more favorable when operation is done before onset of moderate or severe tibiofemoral joint arthrosis.
- Procedure acceptable for younger patients, especially those who have symptoms with daily activities, because there are few if any other available treatment options.
- Whether meniscus transplantation provides a chondroprotective effect remains unknown.
- Patients advised that the procedure only has short-term benefits and, in the long term, further surgery will likely be required.

the native meniscus low intensity signal for up to 4 years after implantation, indicating a delayed remodeling response, which is advantageous in preserving the function and integrity of the MAT.

When remodeling occurs, MRI demonstrates an increased signal intensity that represents an ingrowth of mesenchymal and poorly differentiated cells into the transplant, removal of portions of the dense well-formed collagen framework, and replacement with randomized and disorganized collagenous tissues. During this stage, alterations in mechanical properties and decreased load-sharing capabilities of the transplant occur. With further remodeling, there commonly appears a grade 3 signal intensity indicating early degeneration and tears in the transplant. We hypothesize that all meniscus transplants will undergo this deleterious remodeling process, resulting in altered mechanical properties and potential for tearing, fragmentation, and degeneration under joint loading conditions. At this point, the meniscus represents a fibrous tissue interposition transplant.

The first goal of this operation is to implant the MAT in a manner that prevents extrusion. Our previous studies[65,76] showed the operative techniques described in this chapter successfully met this goal. It is recommended that surgeons obtain MRI after surgery to assess meniscus extrusion, which is believed to be deleterious to future expected function. The occurrence of MAT extrusion in the long term is expected in all transplants because of subsequent deterioration as just described.

On the basis of our investigations, the results of meniscus transplantation are believed to be more favorable when the operation is done before the onset of moderate tibiofemoral joint arthritis. A correlation exists between the outcome of meniscus transplants and knee joint arthritis because success rates are higher in knees that have only mild arthritis.

Abnormal limb alignment and ligament instability require simultaneous or staged corrections to warrant meniscus transplantation.

This procedure is acceptable for younger patients, especially those who have symptoms with daily activities, because there are few if any other available treatment options. The short-term results show the majority of patients have improved knee function and relief or decreases in pain in the affected compartment. However, whether or not meniscus transplantation provides a chondroprotective effect remains unknown. The long-term outcome of meniscus transplants is one of eventual deterioration, degeneration, and loss of function. Patients are advised that the procedure only has short-term benefits and, in the long term, that further surgery will likely be required. In our long-term studies, some patients require a second MAT and have achieved beneficial short-term results from the revision procedure.

There are several important research areas that may improve the success rates of meniscus transplantation. These include issues related to transplant remodeling; collagen fiber restoration of microarchitecture to resist tensile, compressive, and shear forces; transplant collagen matrix changes with altered material and structural properties; cellular repopulation and function in maintaining transplant homeostasis; role of fresh transplants with viable cells; and the role of meniscus scaffolds, tissue engineering, and possible meniscus prosthetic devices.

ILLUSTRATIVE CASES

Case 1. A 21-year-old man presented 2 years after an injury sustained to his left knee playing basketball that had been treated with three partial lateral meniscectomies. The patient had lateral tibiofemoral pain and swelling with all athletic activities and had not been able to return to sports. Physical examination revealed moderate lateral tibiofemoral crepitus but no associated ligament deficiency or osseous malalignment. Arthroscopy performed before the meniscus transplantation demonstrated no remaining functional lateral meniscal tissue, diffuse grade 2A damage to the lateral femoral condyle, and a 15- × 20-mm grade 2B lesion on the tibial plateau (Fig. 24-20, *A*). The patient was treated with a cryopreserved LMT (see Fig. 24-20, *B*) and an osteochondral autograft transfer of the lateral femoral condyle.

At the most recent follow-up evaluation, 4 years postoperative, the patient had no lateral tibiofemoral compartment pain and had returned to low-impact activities without symptoms. He rated the overall condition of his knee as very good. MRI demonstrated grade 1 signal intensity and no displacement of the transplant (see Fig. 24-20, *C* and *D*). Using our strict rating system of meniscus transplant characteristics, the implant was classified as normal.

Case 2. A 33-year-old male construction worker presented 19 years after an injury sustained to his left knee playing soccer. His operative history included two lateral meniscectomies and an FCL reconstruction. The patient had lateral tibiofemoral pain and swelling with daily activities, especially during work. Physical examination revealed mild lateral tibiofemoral crepitus and 3 mm of increased lateral joint opening. No other abnormalities were noted.

Arthroscopy performed before meniscus transplantation demonstrated no remaining functional lateral meniscal tissue (Fig. 24-21, *A*), a grade 3A lesion on the lateral femoral condyle, and grade 2B damage to the tibial plateau. The patient was treated with a cryopreserved LMT (see Fig. 24-21, *B*) and an osteochondral autograft transfer of the lateral femoral condyle.

At the most recent follow-up evaluation, 3 years postoperative, the patient had no lateral tibiofemoral compartment pain and had returned to low-impact activities without symptoms. He had changed his occupation to office work. He rated the overall condition of his knee as very good. MRI demonstrated grade 2 signal intensity, and minor displacement of the transplant (see Fig. 24-21, *C*) that was classified as altered. Standing PA radiographs showed no loss of tibiofemoral compartment joint space (see Fig. 24-21, *D*).

Case 3. A 49-year-old woman presented 15 years after an injury to her right knee which had occurred during a fall. She had undergone an ACL allograft reconstruction, two medial meniscectomies, and a microfracture of the medial tibial plateau. She complained of pain, swelling, and partial giving-way with daily activities. Physical examination demonstrated a grade 3 pivot shift, moderate patellofemoral crepitus, and medial tibiofemoral compartment pain. Arthroscopy performed before meniscus transplantation demonstrated no remaining functional medial meniscal tissue, full-thickness defects of the medial femoral condyle and tibial plateau, and noteworthy fissuring and fragmentation of the patellar undersurface. The patient was treated with a cryopreserved MMT (Fig. 24-22, *A*), an osteochondral autograft transfer of the medial femoral condyle, and a proximal patellar realignment. Seven months later, a revision ACL B-PT-B autograft reconstruction was performed as a staged procedure. The MMT had healed and had a relatively normal arthroscopic appearance (see Fig. 22-22, *B*). However, an MRI scan performed 3 years later showed major displacement of the meniscus transplant and a grade 3 signal intensity (see Fig. 24-22, *C*). The meniscus transplant was classified as failed.

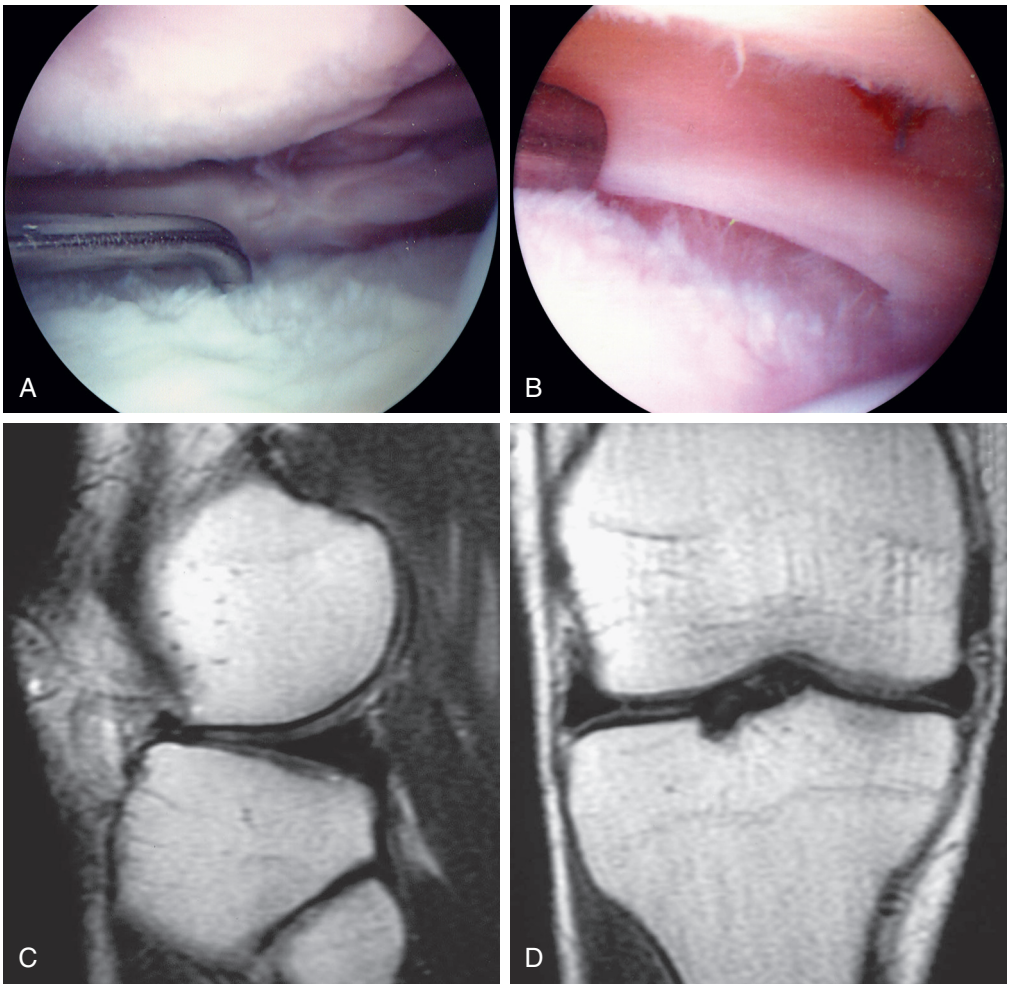

FIG 24-20 Case 1.

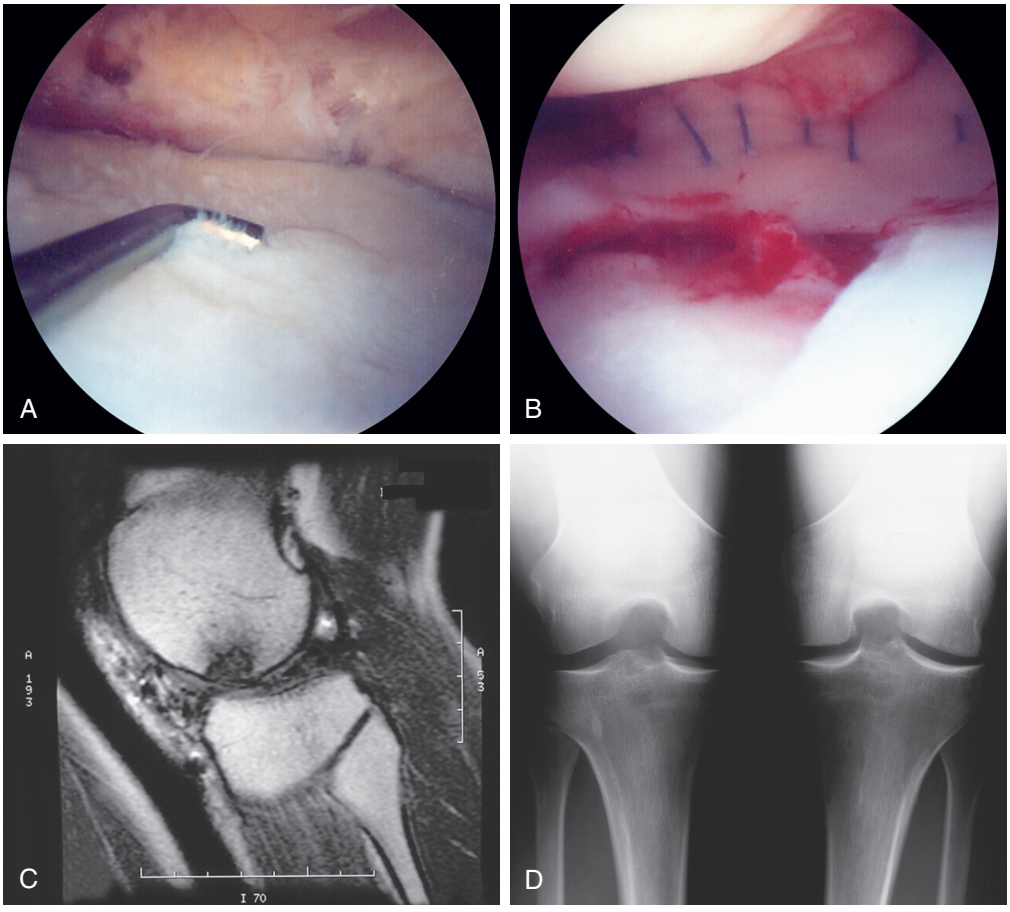

FIG 24-21 Case 2.

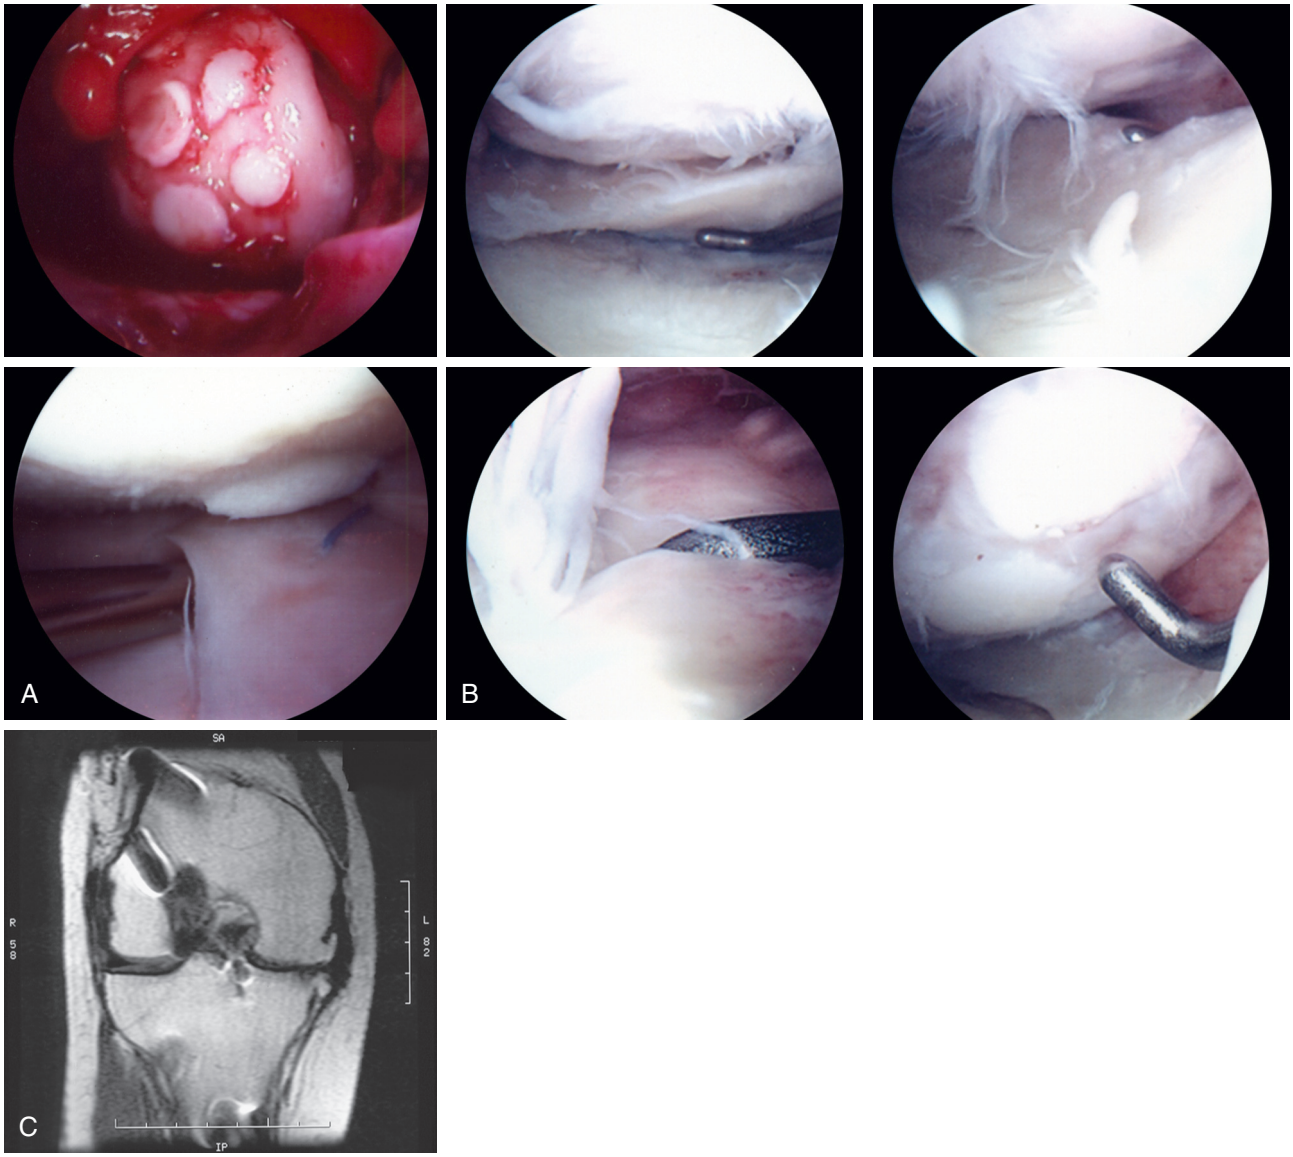

FIG 24-22 Case 3.

At the most recent follow-up evaluation, 5 years postoperative, the patient had no symptoms with low-impact activities and did not complain of medial tibiofemoral compartment pain. She had a grade 1 pivot shift, 3 mm of increased anterior tibial displacement, moderate but asymptomatic patellofemoral crepitus, and a normal range of knee motion. She rated the overall condition of her knee as good despite the lateral tibiofemoral arthritis.

Case 4. A 32-year-old woman presented with left knee medial tibiofemoral pain, locking, and instability with daily activities of 6 months' duration. She had undergone a medial meniscectomy 17 years previously and an ACL allograft reconstruction 7 years before her initial evaluation. Physical examination demonstrated 15 mm of increased AP displacement compared with the contralateral knee on KT-2000 (MEDmetric) testing, no other ligament deficiencies, a marked varus recurvatum deformity, and a hyperextension gait abnormality. Full standing radiographs showed a weight-bearing line of 19%, a mechanical axis of 5 degrees varus, and moderate narrowing of the medial tibiofemoral compartment (Fig. 24-23, *A*). An MRI demonstrated advanced articular cartilage deterioration in the medial tibiofemoral compartment. Owing to the patient's age, she was not considered a candidate for a unicompartmental knee replacement. The treatment recommendation was to first correct the lower limb varus malalignment and then perform meniscus transplantation and ACL revision. The patient underwent a gait retraining program (see Chapter 29) to correct the hyperextension abnormality before proceeding to an HTO.

A closing-wedge osteotomy was performed, with a small 12- to 15-mm area of grade 3A articular cartilage deterioration noted in the medial tibiofemoral compartment at the time of surgery (see Fig. 24-23, *B*). Four months later, an MMT and osteochondral autograft transfer of the medial femoral condyle were performed. An ACL B-PT-B autogenous revision reconstruction was done 3 months later, along with removal of hardware from the osteotomy.

At the most recent follow-up evaluation, 5.5 years posttransplantation, the patient had no symptoms or limitations with daily

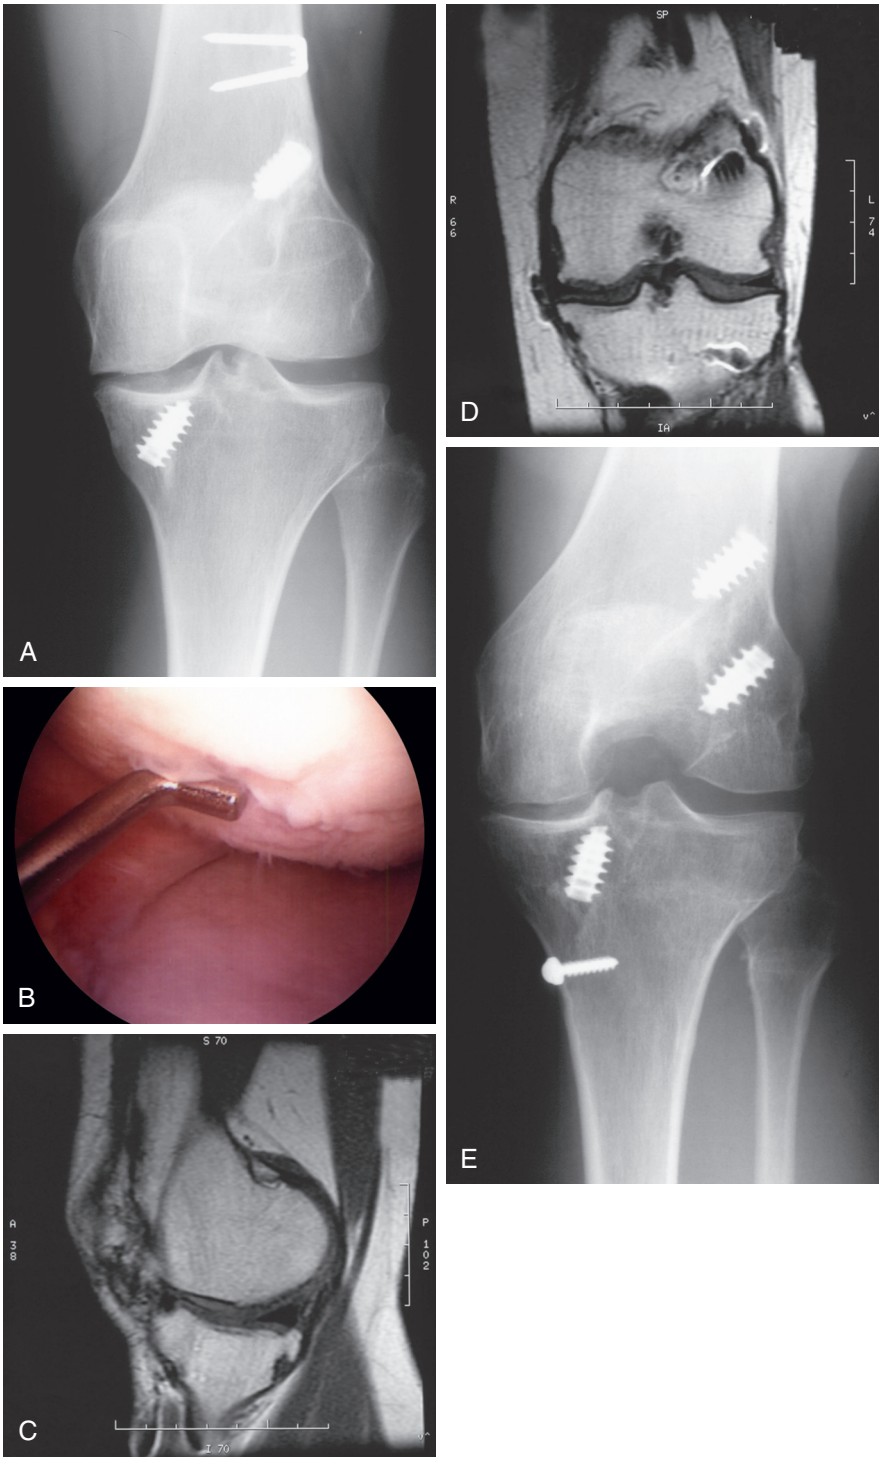

FIG 24-23 Case 4.

activities. She rated the overall condition of her knee as good and had no problems with her occupation in engineering. MRI showed an intact meniscus transplant (see Fig. 24-23 *C* and *D*), still in position in the tibiofemoral joint. There was increased signal intensity noted and some extrusion of the implant. Standing PA radiographs showed no progression of loss of the medial tibiofemoral joint space (see Fig. 24-23, *E*). She had no increase in anterior tibial translation, a negative pivot shift test, and a normal range of knee motion.

Case 5. A 16-year-old female presented 3 years after a right lateral meniscectomy for a symptomatic discoid meniscus. She complained of pain and swelling with all sports activities of 6 months' duration. Her walking tolerance was 1 hour and she was unable to kneel or squat. Physical examination revealed a normal range of knee motion, no ligament deficiencies, moderate pain and crepitation in the lateral tibiofemoral compartment, and an overall valgus alignment. Arthroscopic examination conducted elsewhere 5 months earlier revealed noteworthy articular cartilage deterioration on the lateral tibial plateau. Owing to the patient's young age and rapid deterioration of the lateral compartment (Fig. 24-24, *A*), she was treated with an LMT (see Fig. 24-24, *B*). In addition, an osteochondral autograft transfer of the lateral femoral condyle was performed for a full-thickness defect that measured approximately 7 × 7 mm (see Fig. 24-24, *B* and *C*).

Ten years postoperatively, the patient reported no symptoms with her occupation as an emergency department nurse. She had mild tenderness to palpation of the lateral tibiofemoral compartment, but the remainder of the physical examination was normal. Full standing radiographs demonstrated a valgus alignment (see Fig. 24-24, *D*), and the patient was advised that a femoral osteotomy may be required in the future. Standing PA radiographs showed maintenance of the lateral tibiofemoral joint space (see Fig. 24-24, *E*). However, an MRI showed a meniscus transplant that was decreased in size and displaced, with grade 2 signal intensity (see Fig. 24-24, *F*). The patient was advised to return for yearly examinations to continue to assess the need for a future femoral osteotomy.

Case 6. A 45-year-old man presented 2 years after a left medial meniscectomy. He had medial joint line pain, catching, and partial giving-way with daily activities that had not been resolved by the procedure. Physical examination showed a normal range of knee motion, no ligament instabilities, and mild medial tibiofemoral crepitus. The patient had significant medial joint line tenderness to palpation. Radiographs showed only minor medial joint space narrowing (Fig. 24-25, *A*) and

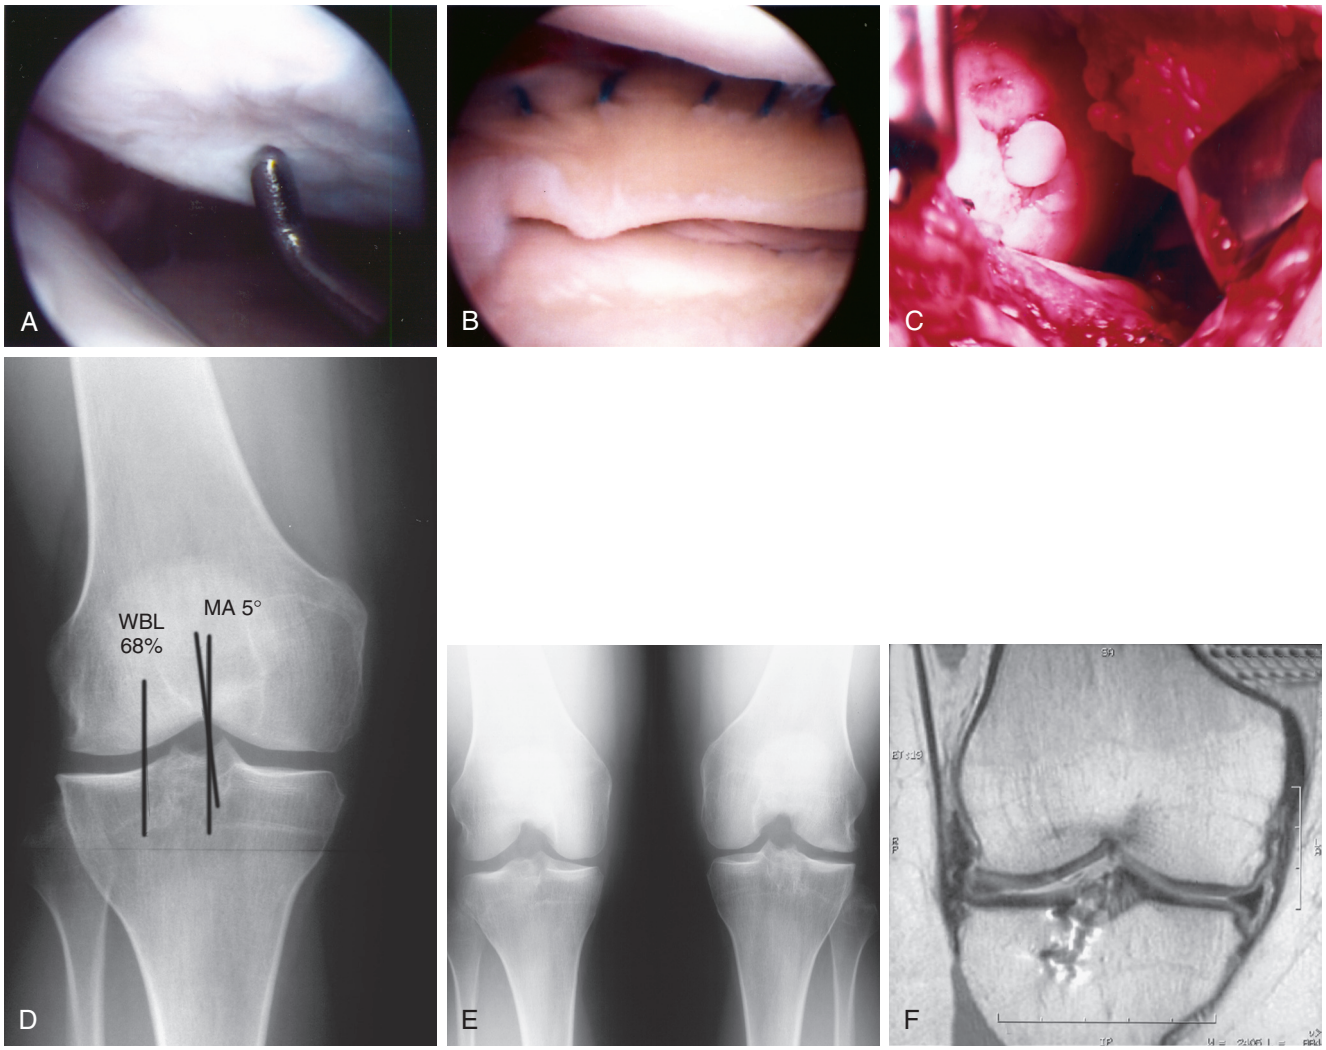

FIG 24-24 Case 5.

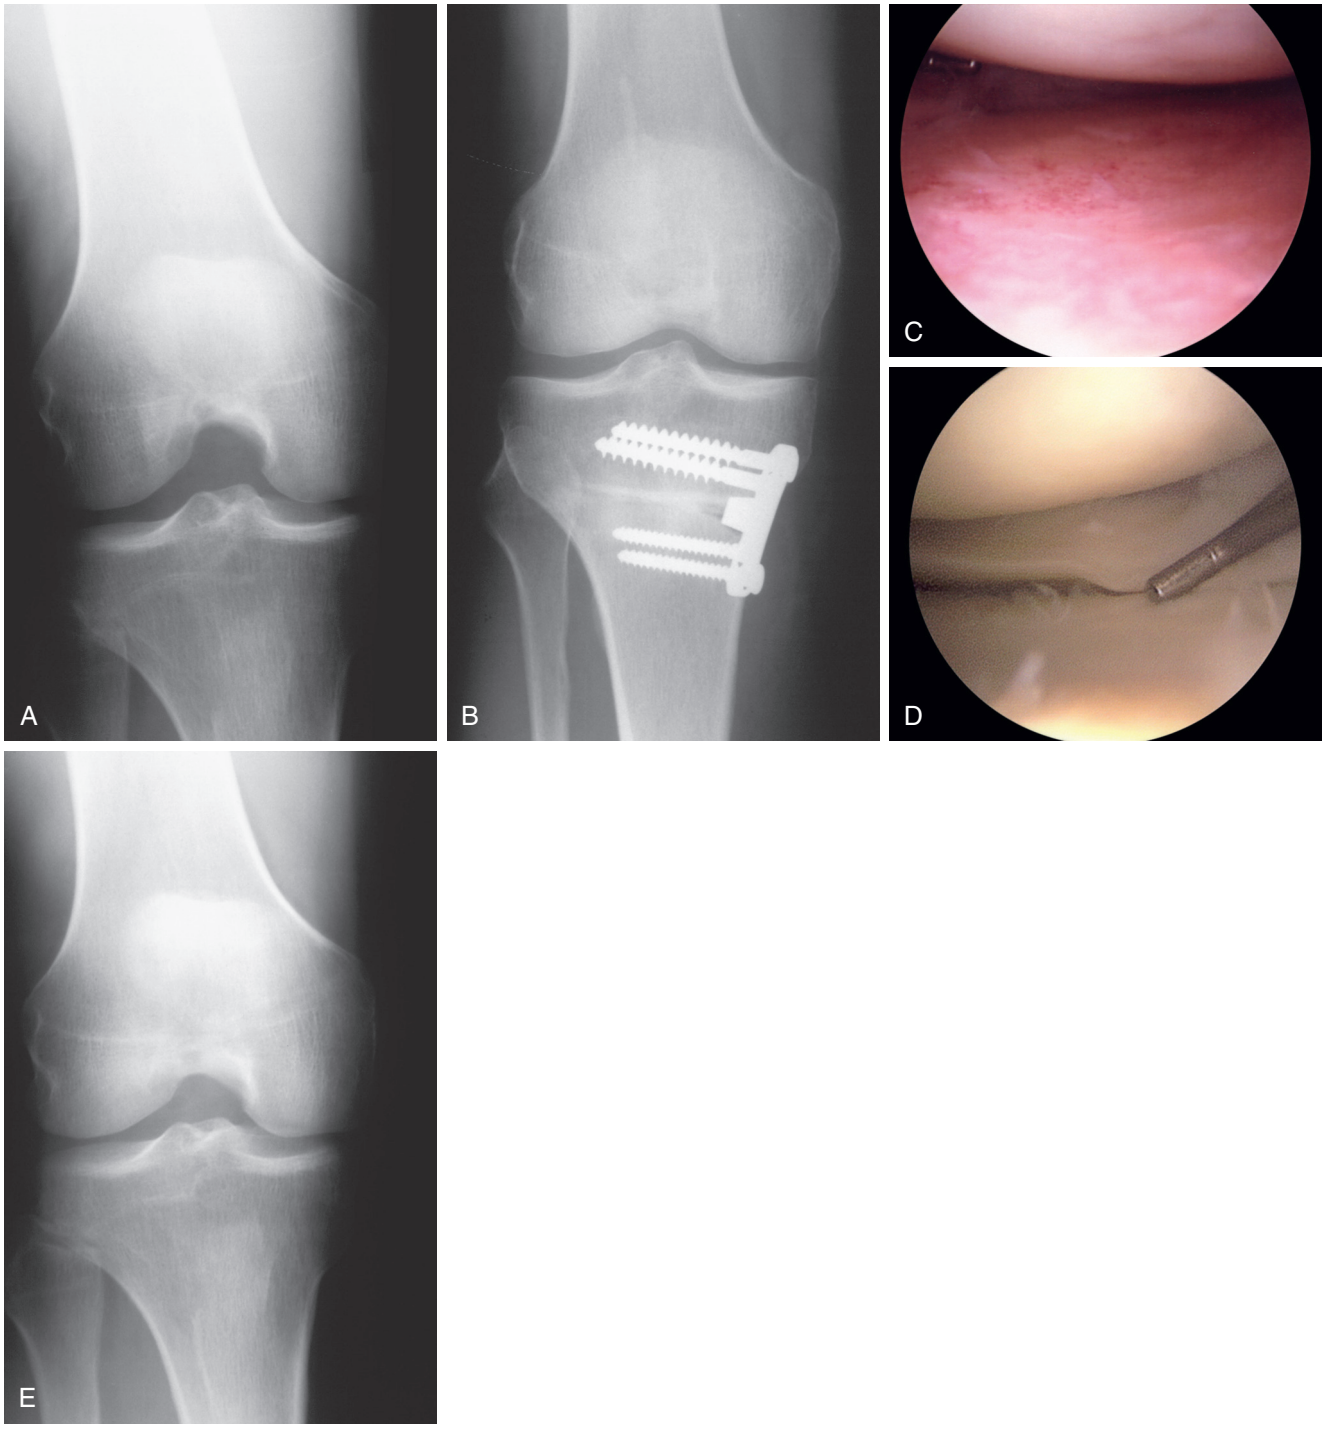

FIG 24-25 Case 6.

a varus malalignment, with the weight-bearing line at the 30% point. The patient ambulated with a varus thrust.

An opening wedge osteotomy was first performed to correct the varus osseous malalignment (see Fig. 24-25, *B*). At the time of surgery, the articular cartilage in the medial tibiofemoral compartment had minor fissuring and no subchondral bone exposed (see Fig. 24-25, *C*). Eight months later, an MMT was performed using a central bone bridge technique. The patient sustained a twisting injury 3 months postoperatively and presented with pain in the medial compartment. Arthroscopy was performed to assess the status of the transplant, which was determined to be normal (see Fig. 24-25, *D*).

Four months later, the patient presented with aching pain in the medial tibiofemoral compartment and pain after walking more than 10 minutes. Radiographs revealed a healed HTO and preserved medial joint space (see Fig. 24-25, *E*). The patient also had burning pain and tenderness to light touch along the anterior tibia. Marked atrophy was noted in the lower extremity. Three months later, the patient had not experienced relief from his symptoms, which were determined to be related to the arthritis and not to a complex regional pain syndrome. The patient subsequently underwent total joint replacement 17 months following the meniscus transplant.

Case 7. A 43-year-old male construction worker presented 4 months after a left medial meniscectomy. The patient complained of medial pain with daily activities and had not been able to return to work. An unloader brace had been prescribed, which provided minimal relief. Physical examination demonstrated normal knee motion, mild pain and crepitation to the medial compartment, no ligament instabilities, a normal lower extremity overall alignment, and moderate patellofemoral pain on compression. At the time of the patient's meniscectomy, noteworthy deterioration had been detected on the medial femoral condyle. Radiographs demonstrated only minimal narrowing of the medial compartment (Fig. 24-26, *A*). The patient was treated conservatively for 5 months with nonsteroidal antiinflammatory medications and physical therapy, but his symptoms continued.

Arthroscopy revealed a 20 × 20 mm area of subchondral bone exposure on the medial femoral condyle (see Fig. 24-26, *B*) and extensive fissuring and fragmentation on the undersurface of the patella. An osteochondral autograft transfer was performed on the medial femoral condyle (see Fig. 24-26, *C*). Eight months later, an MMT was performed, at which time excellent healing of the autograft bone plug in the medial femoral condyle was noted (see Fig. 24-26, *D*).

At follow-up, 5 years postoperatively, the patient had minimal pain and had returned to his construction occupation. No problems were incurred with walking on uneven ground or stair climbing. He had a normal range of motion, no tenderness to palpation to the medial joint line, and no effusion. Radiographs demonstrated preservation of the tibiofemoral compartment (see Fig. 24-26, *E*). An MRI revealed an intact transplant, with no displacement or extrusion and no increase in signal intensity (see Fig. 24-26, *F* and *G*).

Case 8. A 38-year-old man presented 3 months after a falling injury in which he landed directly onto his left knee. His history included a lateral meniscectomy at age 16 years, but he had not experienced knee-related symptoms until his recent injury. The patient had moderate pain and giving-way with activities. Physical examination demonstrated 10 mm of increased posterior tibial translation, 13 mm of increased lateral joint opening, 10 degrees of increased external tibial rotation, tenderness over the medial and lateral joint lines, and moderate crepitus in the lateral tibiofemoral compartment. Standing PA radiographs showed narrowing of the lateral compartment and stress radiographs revealed 6.5 of increased posterior tibial translation compared with the contralateral knee.

A PCL two-strand quadriceps tendon autograft reconstruction, a posterolateral reconstruction, and a lateral meniscus allograft were performed. At the latest follow-up evaluation, 5 years postoperatively, the patient had no symptoms and rated the overall condition of his knee as good. The KT-2000 (MEDmetric) showed 5 mm of increased AP displacement at 20 degrees of knee flexion and 9 mm of increase at 70 degrees of flexion. Physical examination showed no increase in lateral joint opening or external tibial rotation, a normal range of knee motion, no effusion, and no lateral joint line pain.

Case 9. A 19-year-old competitive soccer player sustained a left knee injury during a game that was treated 3 months later with an ACL B-PT-B autogenous reconstruction, a medial meniscus repair for a single longitudinal tear, and a lateral meniscus repair for a complex, double longitudinal tear that was 20 mm in length. She did well and returned to competitive soccer for 3 years until she had a gradual onset of left knee pain. MRI showed a complex tear to the lateral meniscus that was treated with an arthroscopic subtotal meniscectomy. At that time, noteworthy fissuring and fragmentation were found on the lateral tibial plateau, and a 10-mm area of subchondral bone exposure was noted on the lateral femoral condyle. Three months later, an LMT and an osteochondral autograft transfer to the lateral femoral condyle were performed. The patient did well and played soccer (against medical advice) for 7 years. She returned for a routine follow-up evaluation, at which time MRI demonstrated major extrusion of the transplant that was deemed nonfunctional. Because the patient was not experiencing symptoms, she elected conservative treatment and continued playing soccer for another 6 years. Thirteen years after the initial LMT, the patient developed symptoms, and arthroscopy demonstrated a complex tear of the LMT (Fig. 24-27, *A*) that was revised (Fig. 24-27, *B*). Extensive fissuring and fragmentation were noted on the medial and lateral femoral condyles, as well as the entire trochlea. At the latest follow-up evaluation, 2 years postrevision transplant, the patient was asymptomatic and rated her overall knee condition as very good. However, standing PA radiographs showed a moderate loss of joint space in the lateral tibiofemoral compartment (Fig. 24-27, *C*), and the patient was advised of the probability of a future TKA.

Case 10. An 18-year old women sustained a twisting injury playing basketball, underwent a lateral meniscectomy, and presented to our center 5 years later complaining of knee pain with all activities, occasional swelling, and a popping sensation in the anterior aspect of the right knee. Her symptoms were so severe she was unable to walk up and down stairs. A lateral meniscus transplant was performed, at which time a 10 × 10 mm area of erosion of the weight-bearing surface of the lateral condyle directly over the absent lateral meniscus was noted. The medial tibiofemoral and patellofemoral joints were pristine. The patient did well until, 5 years later, she experienced a popping sensation in the lateral aspect of her right knee. After nine additional episodes of locking, arthroscopy was performed. A tear of the lateral meniscus transplant was found and repaired in a satisfactory manner.

Twelve years later, the patient was seen for long-term follow-up (17.3 years posttransplant). She was asymptomatic with her activities that included walking 4 to 5 times a week and golfing. She rated the overall knee condition as very good. Follow-up MRI demonstrated normal joint space, with no meniscus extrusion into the joint (Figs. 24-28, *A* to *C*).

Video 24-6 Patient 4: 31-Year-Old, 3-Week Postoperative Medial Meniscus Bone Bridge Allograft Transplant

CLINICAL CONCEPTS

The postoperative program for meniscus repair and transplantation is shown in Table 25-1. Because high compressive and shear forces can disrupt healing meniscus repair sites (especially radial repairs) and transplants, the initial goal is to prevent excessive weight bearing. Variations are built into the protocol according to the type, location, and size of the meniscus repair and whether concomitant procedures (such as ligament reconstructions) are performed. The surgeon has the responsibility to inform the physical therapy team of details regarding the type of tear and repair that was performed. Meniscus repairs with all-inside fixators have inferior holding strength and commonly, only a few sutures are used. These repairs require more protection during the first 6 postoperative weeks to allow for healing. Inside-out meniscus repair techniques, on the other hand, involve multiple vertical divergent sutures (see Chapter 23) and have superior holding strength.

Clinicians should be aware that meniscus repairs located in the periphery (outer third red-red [R/R] region) heal rapidly, whereas complex repairs that extend into the central third red-white (R/W) region tend to heal more slowly and require greater caution. In addition, modifications to the postoperative exercise program may be required if noteworthy articular cartilage deterioration is found during the arthroscopic procedure. This rehabilitation program has been used at our institution in hundreds of meniscus transplant and repair recipients, and the results of clinical investigations[3-5,7,8] demonstrate its safety and effectiveness in restoring normal knee motion, muscle, and gait characteristics.

Patients receive instructions before surgery regarding the postoperative protocol. Thus, they have a thorough understanding of what is expected after surgery. Patients are warned that an early return to strenuous activities such as impact loading, jogging, deep knee flexion, or pivoting carries a definite risk of a repeat meniscus tear or tear to the transplant. This is particularly true in the first 4 to 6 postoperative months.

Before surgery, the surgeon screens for any deep vein thrombosis (DVT) risk factors, including a prior patient or family history suggestive of an inherited coagulation defect. In women, all estrogen products and oral contraceptives are stopped 1 month before surgery.

The supervised rehabilitation program is supplemented with daily home exercises. The therapist routinely examines the patient in the clinic to implement and progress the appropriate protocol. Therapeutic procedures and modalities are used as required for successful rehabilitation. On average, patients require 11 to 16 physical therapy visits over a period of 9 to 12 months to produce a desirable result.

Lateral and anteroposterior plain radiographs are obtained 1 week after surgery to verify the position of the osseous component of meniscus transplants and at 6 to 8 weeks to verify healing and retention of the bony portion of the transplant within the slot or tunnels. Any onset of tibiofemoral joint line clicking or pain may indicate failure of the meniscus repair or transplant, and the surgeon should be notified immediately for consideration of refixation.

TABLE 25-1 Rehabilitation Protocol Summary for Meniscus Repairs and Transplants

	WEEKS					MONTHS			
	1-2	3-4	5-6	7-8	9-12	4	5	6	7-12
Long-leg postoperative brace	C, A, T	C, A, T	C, T						
Range of motion minimum goals:									
0-90 degrees	X								
0-120 degrees		X							
0-135 degrees			X						
Weight-bearing:									
Toe touch to 50% body weight	P								
75%-100% body weight		P							
Toe touch to 25% body weight	C, T, A								
50%-75% body weight		C, T, A	C, A						
100% body weight			T	C, A					
Patella mobilization	X	X	X						
Stretching: Hamstring, gastrocnemius-soleus, iliotibial band, quadriceps	X	X	X	X	X	X	X	X	X
Strengthening:									
Quadriceps isometrics, straight-leg raises, active knee extension	X	X	X	X	X	X	X	X	X
Closed-chain: gait retraining, toe raises, wall-sits, minisquats		P	C	X	X	X	X	X	
Knee flexion hamstring curls (90 degrees)			P	C	X	X	X	X	X
Knee extension quadriceps (90-30 degrees)			X	X	X	X	X	X	X

A, All-inside meniscus repairs; *BAPS*, biomechanical ankle platform system (Patterson Medical); *BBS*, Biodex Balance System; *C*, complex red-white inside-out meniscus repairs; *P*, peripheral red-red meniscus repairs; *T*, transplants; *X*, all meniscus repairs and transplants.

CRITICAL POINTS Clinical Concepts

Initial rehabilitation goal: prevent excessive compressive and shear forces through limited weight bearing

General Postoperative Healing Expectations

- Rapid healing of peripheral meniscus repairs
- Delayed healing of complex meniscus repairs in middle third region
- Further delayed healing of meniscus transplants (1-2 yr)

Preoperative patient counseling and education during entire rehabilitation program are paramount.

Premature return to high-impact loading activities (jogging, deep knee flexion, pivoting) risks repeat meniscus tear or tear to transplant.

Obtain lateral and anteroposterior x-rays 1 and 6-8 weeks after meniscus transplantation to verify position of osseous component.

IMMEDIATE POSTOPERATIVE MANAGEMENT

Important early postoperative signs for the therapist to monitor include effusion, pain, gait, knee flexion and extension, patellar mobility, strength and control of the lower extremity, lower extremity flexibility, and tibiofemoral symptoms indicative of a meniscal tear (Table 25-2). The protocol to prevent DVT that includes aspirin (325 mg, 2 ×/day), compression dressings, thromboembolic hose, early ambulation, and active ankle pumps (performed hourly) is carefully followed.

Patients present to physical therapy on the first day after surgery on bilateral axillary crutches in a postoperative dressing with a long-leg brace locked in full extension. The postoperative bandage and dressing are changed to allow the application of thigh-high compression stockings and a compression bandage. Early control of postoperative effusion is essential for pain management and early quadriceps reeducation. In addition to compression, cryotherapy is critical during this time period. Patients receive a commercial cooling unit, which is used 6 to 8 times daily at home. In the clinic, the use of various cryotherapy

TABLE 25-2 Postoperative Signs and Symptoms Requiring Prompt Treatment

Postoperative Sign or Symptom	Treatment Recommendations
Continued pain in the medial or lateral tibiofemoral compartment of the meniscus repair or transplant	Physician examination, assess need for refixation or repeat repair
Tibiofemoral compartment clicking or a subjective sensation by the patient of "something being loose" within the tibiofemoral joint	Physician examination, assess need for refixation or repeat repair
Failure to meet knee extension and flexion goals	Overpressure program, early gentle manipulation under anesthesia if 0-135 degrees not met by 6 postoperative weeks
Decreased patellar mobility (indicative of early arthrofibrosis)	Aggressive knee flexion, extension overpressure program, or gentle manipulation under anesthesia to regain full ROM and normal patellar mobility
Decrease in voluntary quadriceps contraction and muscle tone, advancing muscle atrophy	Aggressive quadriceps muscle strengthening program, EMS
Persistent joint effusion, joint inflammation	Aspiration, rule out infection, close physician observation

From Heckmann T, Barber-Westin SD, Noyes FR. Meniscal repair and transplantation: Indications, techniques, rehabilitation, and clinical outcome. *J Orthop Sports Phys Ther.* 2006;36:795-814.
EMS, Electrical muscle stimulation; *ROM*, range of knee motion.

CRITICAL POINTS Immediate Postoperative Management

Early Postoperative Therapist Monitors:

- Knee effusion, pain, gait, flexion and extension, patellar mobility, lower extremity strength and flexibility, tibiofemoral joint symptoms
- Postoperative compression dressing, long-leg brace, compression stockings, cryotherapy, lower limb elevation, pain management

Common Complications:

- Excessive pain or swelling
- Quadriceps shutdown
- Limitation knee flexion, extension
- Saphenous nerve irritation

Early detection and treatment of complications are critical.

machines provides compression simultaneously with the cold program (Fig. 25-1).

Patients are instructed to maintain lower limb elevation as frequently as possible during the first week. A portable neuromuscular electric stimulator may be helpful for quadriceps reeducation and pain management (Fig. 25-2). These devices are used 4 to 6 times per day, 15 minutes per session, until the patient displays an excellent voluntary quadriceps contraction.

The patient's initial response to surgery and progression during the first 2 weeks sets the tone for the initial phases of the rehabilitation program. Common postoperative complications include excessive pain or swelling, quadriceps shutdown or loss of voluntary isometric contraction, range of motion (ROM) limitations, and saphenous nerve irritations for medial repairs. Monitor patient complaints of posteromedial or infrapatellar burning, posteromedial tenderness along the distal pes anserine tendons, tenderness of the Hunter canal along the medial thigh, hypersensitivity to light pressure, and hypersensitivity to temperature change. These abnormal symptoms or signs occur in early cases of complex regional pain syndrome (see Chapter 40) and require immediate medical treatment.

FIG 25-1 A clinical cryotherapy machine that provides compression with the cold program (Game Ready) is used in the initial postoperative period.

FIG 25-2 A portable neuromuscular electric stimulator (EMPI) is effective for quadriceps reeducation and pain management in the early postoperative phase.

BRACE AND CRUTCH SUPPORT

All patients receive a long-leg postoperative brace immediately after surgery to prevent hyperflexion and rotation of the knee that may damage the repair or transplant. The brace is opened from 0 to 90 degrees, but it is locked at 0 degrees of extension at night for the first 2 weeks. Thereafter, the brace is not routinely locked except in patients who cannot maintain 0 degrees of extension. In these cases, the brace

TABLE 25-3 Range of Motion, Flexibility, and Modality Use After Meniscus Repair and Transplantation

Postoperative Time	Frequency	Extension-Flexion Limits	Patellar Mobilization	Flexibility (5 reps × 20 sec)	EMS (20 min)	Cryotherapy (20 min)
1-2 wk	3-4 ×/day, 10-min sessions	0-90 degrees	Medial-lateral Superior-inferior	Hamstring, gastrocnemius-soleus	Yes	Yes
3-4 wk	3-4 ×/day, 10-min sessions	0-120 degrees	Medial-lateral Superior-inferior	Hamstring, gastrocnemius-soleus	Yes	Yes
5-6 wk	3 ×/day, 10-min sessions	0-135 degrees	Medial-lateral Superior-inferior	Hamstring, gastrocnemius-soleus	Yes	Yes
7-8 wk	2 ×/day, 10-min sessions	0-135 degrees	If required	Hamstring, gastrocnemius-soleus, quadriceps, iliotibial band	Yes	
9-52 wk	2 ×/day, 10-min sessions	Should be full	Hamstring, gastrocnemius-soleus, quadriceps, iliotibial band	Yes

EMS, Electrical muscle stimulation.

CRITICAL POINTS Brace and Crutch Support

Brace Used for 4 Weeks

- Locked 0 degrees at night for first two postoperative weeks.
- Opened 0-90 degrees during the day.

is locked at 0 degrees of extension as required during the day and night. The brace is used for 4 weeks.

Crutches with partial weight bearing are recommended for the first 4 weeks in all cases. Weight bearing is gradually progressed as shown in Table 25-1, and patients are encouraged to use a normal gait that avoids a locked knee and assumes normal flexion throughout the gait cycle. Patients who had a repair of a radial meniscus tear are kept non–weight bearing for 4 weeks to protect the repair site.

RANGE OF KNEE MOTION AND FLEXIBILITY

Passive knee flexion and passive and active/active-assisted knee extension exercises are begun on the first postoperative day. Active knee flexion is limited to avoid hamstring strain to the posteromedial joint. ROM exercises are performed in seated position initially from 0 to 90 degrees. Flexion is gradually advanced to 120 degrees by the third to fourth week and 135 degrees by the fifth to sixth week (Table 25-3). Patients who had extensive repairs may be required to limit ROM to 0 to 90 degrees for the first 2 weeks. Knee motion exercises are performed 3 to 4 times daily until normal motion is achieved. Hyperextension is avoided in individuals who had anterior horn meniscus repairs.

If 0 to 90 degrees of knee motion is not easily achieved by the end of the first postoperative week, the patient may be at risk of a knee motion complication. Individuals who develop such a limitation are placed into a specific treatment program previously described in detail.[2,6] Overpressure exercises are usually successful in achieving the last few degrees of extension if initiated within the first few weeks after surgery. The patient props the foot and ankle on a towel to elevate the hamstrings and gastrocnemius, which allows the knee to drop into full extension. A 10- to 15-lb weight may be added to the distal thigh and

CRITICAL POINTS Range of Knee Motion and Flexibility

Begin passive flexion, passive and active-assisted extension exercises on first postoperative day, 0-90 degrees.

Advance Flexion

- Goal: 135 degrees by 5-6 weeks

Begin ROM Overpressure Program 1 wk After Surgery if 0-90 Degrees Not Achieved

- Extension: hanging weights, 10-min sessions
- Flexion: chair rolls, wall-slides, ERMI Knee Flexionator device

Patellar mobilization and flexibility exercises are paramount to achieving full ROM.

knee to stretch the posterior capsule (Fig. 25-3). This program is done for 10 minutes at a time, 6 to 8 times per day.

Flexion exercises are performed in seated position using the opposite lower extremity to provide overpressure (Fig. 25-4). Chair rolling, wall-sliding, passive quadriceps stretching, and ROM devices such as the ERMI Knee Flexionator are also helpful in regaining full knee flexion. No squatting exercises should be performed for at least 5 months because these exercises place large tensile forces on posterior meniscus repairs and transplants.

ROM exercises are accompanied by patellar mobilization (in the superior, inferior, medial, and lateral directions), which is paramount to achieve full knee motion (Fig. 25-5). Flexibility exercises, beginning with hamstring and gastrocnemius-soleus, are begun on the first postoperative day and are done 3 times per day. Quadriceps and iliotibial band flexibility exercises are incorporated at 7 to 8 weeks after surgery. Sustained static stretching is performed, with the stretch held for 30 seconds and repeated 5 times.

The knee motion program is effective because no patient in our clinical studies who had an isolated meniscus repair or transplant required further surgery for a knee motion complication. Only 2 of 193 patients who had meniscal repair and 4 of 38 patients who had a transplant required a gentle manipulation for a limitation of flexion.

In these six patients a major concomitant procedure, such as a cruciate ligament reconstruction, had been performed.

Close supervision and additional exercises to successfully restore normal knee motion may be required in patients who undergo combined procedures. No difference exists between medial and lateral meniscus repairs or transplants regarding knee motion complications.

BALANCE, PROPRIOCEPTION, AND NEUROMUSCULAR TRAINING

Restoration of normal neuromuscular function after meniscus repair and transplantation is paramount for a successful outcome. Knee joint proprioception and balance are crucial elements of neuromuscular function. Therefore balance and proprioception exercises are initiated as soon as patients achieve partial weight bearing, typically the first week after surgery. Crutches are used for support during these exercises until full weight bearing is allowed. Initially, patients perform weight shifting from side to side and front to back. Then gait retraining, including cup walking, is encouraged. This helps develop symmetry between the surgical and contralateral limbs, hip and knee flexion, quadriceps control during midstance, hip and pelvic control during midstance, and adequate gastrocnemius-soleus control during push-off (Fig. 25-6).

Tandem balance is begun during the partial weight-bearing phase to assist with position sense and balance. This is progressed to a single-leg balance exercise, which is done by pointing the foot straight ahead, flexing the knee to between 20 and 30 degrees, extending the arms outward horizontally, and positioning the torso upright with the shoulders above the hips and the hips above the ankles. The patient stands in position until balance is disturbed. A minitrampoline is used to make this exercise more challenging after it is mastered on a hard surface.

Many devices are available to assist with balance and gait retraining, including Styrofoam half rolls and whole rolls, and the Biomechanical Ankle Platform System (BAPS). Patients walk (unassisted) on Styrofoam half rolls to develop a center of balance, quadriceps control in midstance, and postural positioning. The BAPS board is used in double-leg and single-leg stance to promote proprioception. More sophisticated devices are also available (Fig. 25-7), including the Biodex

FIG 25-3 Extension overpressure hanging-weight exercise.

FIG 25-4 Flexion exercise using the opposite knee to apply pressure.

FIG 25-5 Patellar mobilization exercises (in the superior, inferior, medial, and lateral directions), which are paramount in regaining full range of motion, are initiated on the first postoperative day.

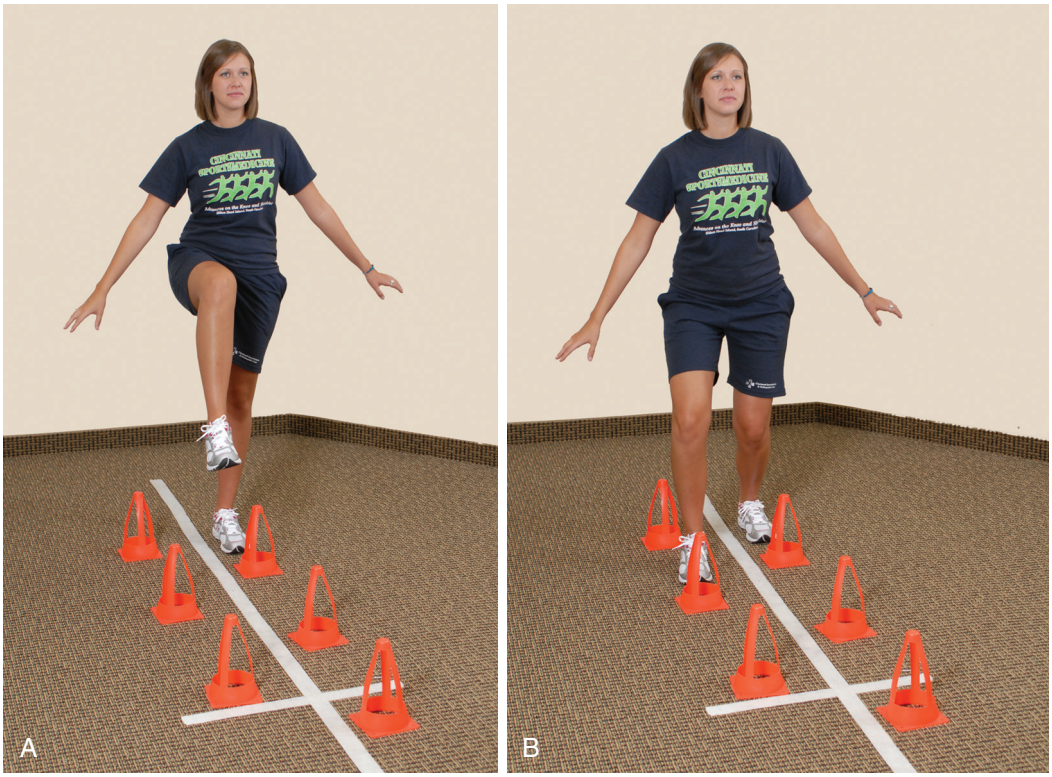

FIG 25-6 Cup walking is used early in postoperative recovery to develop symmetry between the surgical and the contralateral limbs, hip and knee flexion, quadriceps control during midstance, hip and pelvic control during midstance, and adequate gastrocnemius-soleus control during push-off. This exercise also facilitates quadriceps control to prevent knee hyperextension from occurring during gait.

CRITICAL POINTS **Balance, Proprioception, Neuromuscular Training**

Begin Balance, Proprioception Training 1 wk Postoperative

- Side-to-side weight shifting
- Cup walking
- Tandem balance
- Single-leg balance
- Styrofoam half and full rolls
- BAPS board, double-leg and single-leg stance
- Balance systems
- Computerized stability systems

Balance System and Neurocom Balance System. These devices provide visual feedback to assist with a variety of balance activities.

In patients who desire to return to sports activities, more advanced exercises to promote neuromuscular function are necessary. These include front step-downs, lateral step-downs, single-leg balance drills, progressive perturbation training with the therapist, and lunge exercises in various directions using a resistance cord onto an unstable surface. It is crucial that the patient be taught correct posture and form while performing these exercises. This includes avoiding varus or valgus lower limb alignment, maintaining knee flexion to prevent knee hyperextension, avoiding hip adduction and internal rotation, maintaining balance and control throughout the exercise, and landing softly to decrease ground reaction forces. The progression of exercises to running, pivoting/cutting, plyometrics, and return to full activities

FIG 25-7 A sophisticated balance device (Biodex) provides visual feedback to assist with a variety of balance activities.

is based on specific criteria described later. Plyometric exercises are especially important in younger athletic patients who have an associated anterior cruciate ligament (ACL) reconstruction.

STRENGTHENING

The strengthening program is begun on the first postoperative day with quadriceps isometrics, straight-leg raises (Fig. 25-8), and active-assisted knee extension from 90 to 30 degrees (Table 25-4). Initially, straight-leg raises are performed in the flexion plane only. The patient must achieve a sufficient quadriceps contraction to eliminate an extensor lag before adding straight-leg raises in the other three planes (abduction, adduction, and extension). These exercises are performed as 3 to 5 sets of 10 repetitions, and this set/repetition rule allows for systematic progression of ankle weights as tolerated.

At weeks 3 to 4, weight-bearing exercises are begun. Toe raises for gastrocnemius-soleus strengthening, wall-sits, and minisquats for quadriceps strengthening are initiated when patients are 50% weight bearing. Wall-sits (Fig. 25-9) and minisquats (Fig. 25-10) are begun at 5 to 6 postoperative weeks after meniscal transplantation. These activities should be limited from 0 to 60 degrees of flexion to protect the posterior horn of the meniscus.

Wall-sitting isometrics can be made more challenging by modifying the exercise technique. First, the patient can voluntarily set the quadriceps muscle once he or she reaches the maximum knee flexion angle, which is typically between 30 and 45 degrees. This contraction and knee flexion position are held until muscle fatigue occurs. In a second modification, designed to promote a stronger vastus medialis obliquus contraction, the patient performs a hip adduction contraction by squeezing a ball between the distal thighs. In a third variation, the patient holds dumbbell weights in the hands to increase body weight, which promotes an even a stronger quadriceps contraction. The patient can shift their body weight over the involved side to simulate a single-leg contraction, or perform the wall-sit on just one leg.

Minisquats are initially done using the patient's body weight as resistance. Gradually, TheraBand or surgical tubing is used as a resistance mechanism. The depth of the squat is controlled to protect the meniscus repair or transplant and the patellofemoral joint. Quick, smooth, rhythmic squats are performed at a high-set/high-repetition cadence to promote muscle fatigue. Hip position is important to monitor to emphasize work on the quadriceps.

Open kinetic chain non–weight-bearing exercises are begun 5 to 6 weeks after surgery (see Table 25-4). Knee extension progressive resistive exercises (PREs) are initiated from 90 to 30 degrees to protect the patellofemoral joint.[1] By keeping the quadriceps exercises in this protected ROM, minimal forces will be placed along peripheral and midsubstance repair sites. Progression from ankle weights to machines occurs as the patient progresses the amount of weight in the exercise program. Quadriceps control is critical for program progression.

CRITICAL POINTS Strengthening

First Postoperative Day

- Quadriceps isometrics
- Straight-leg raises
- Active-assisted knee extension, 90-30 degrees

Postoperative Weeks 3 to 4

- Toe raises
- Wall-sits (0-60 degrees)
- Minisquats (0-60 degrees)

Delay wall-sits, minisquats until 7 to 8 weeks after meniscus transplantation.

Postoperative Weeks 5 to 6

- Open kinetic chain knee extension 90-30 degrees
- Hamstring curls 0-90 degrees (delayed until 7-8 weeks after complex meniscus repair, 9-12 weeks after transplant)
- Leg press machine 70-10 degrees (delayed 9-12 weeks after transplant)
- Multiangle hip machine

FIG 25-8 Straight-leg raises shown in hip extension (**A**), flexion (**B**), adduction (**C**), and abduction (**D**) planes.

TABLE 25-4 Muscle Strengthening Exercises after Meniscus Repair and Transplantation*

Postoperative Time, Frequency	Quadriceps Isometrics (Active)	Straight-Leg Raises	Knee Extension (90-30 Degrees)	Toe Raises	Wall-Sits (to Fatigue)	Minisquats	Lateral Step-ups (5- to 10-cm Block)	Hamstring Curls (0-90 Degrees)	Multihip (Flex, Ext, Abd, Add)	Leg Press (70-10 Degrees)
1-2 w 3 ×/day, 15 min	1 set × 10 reps (every hour)	Flex; 3 sets × 10 reps	Active-assisted 90-0 degrees all but anterior horn repairs, 90-30 degrees, 3 sets × 10 reps							
3-4 wk 2-3 ×/day, 20 min	Multi-angle 0, 60 degrees; 1 set ×10 reps each	Flex, ext, add; 3 sets × 10 reps	Active-assisted 90-0 degrees all but anterior horn repairs, 90-30 degrees, 3 sets × 10 reps	**Meniscus repairs only** 3 sets × 20 reps	**Meniscus repairs only** 3 sets × 3 reps	**Meniscus repairs only** 3 sets × 20 reps				
5-6 wk 2 ×/day, 20 min	Multiangle 30, 60, 90 degrees; 2 sets × 10 reps	Add ankle weight ≤10% of body weight; 3 sets × 10 reps	Active, 90-30 degrees, 3 sets × 10 reps	**Transplants start** **Meniscus repairs** Add heel raises, 3 sets × 10 reps	**Transplants start** 3 sets × 3 reps	**Transplants start** 3 sets × 20 reps		**Peripheral repairs only** Active, 3 sets × 10 reps	3 sets × 10 reps	**Peripheral repairs only** 3 sets × 10 reps
7-8 wk 2 ×/day, 20 min		Add abd; 3 sets × 10 reps Add rubber tubing, 3 sets × 30 reps	Active, 90-30 degrees with resistance, 3 sets × 10 reps	**Transplants** Add heel raises, 3 sets × 10 reps	3 sets × 3 reps	3 sets × 20 reps	3 sets × 10 reps	**All meniscus repairs** Active, 3 sets × 10 reps	3 sets × 10 reps	**Peripheral repairs only** 3 sets × 10 reps
9-12 wk 2 ×/day, 20 min		3 sets × 10 reps Rubber tubing, 3 sets × 30 reps	Active, 90-30 degrees with resistance, 3 sets × 10 reps		3 sets × 3 reps	Add rubber tubing, 0-40 degrees, 3 sets × 20 reps	3 sets × 10 reps	**Transplants start** Active, 3 sets × 10 reps	3 sets × 10 reps	**Transplants start** 3 sets × 10 reps
13-26 wk 2 ×/day, 20 min		Rubber tubing, high speed, 3 sets × 30 reps	Active, 90-30 degrees with resistance, 3 sets × 10 reps			3 sets × 20 reps		Add resistance, 3 sets × 10 reps	3 sets × 10 reps	3 sets × 10 reps
27-52 wk 1 ×/day, 20-30 min		Rubber tubing, high speed, 3 sets × 30 reps	Active, 90-30 degrees with resistance, 3 sets × 10 reps			3 sets × 20 reps		With resistance, 3 sets × 10 reps	3 sets × 10 reps	3 sets × 10 reps

*Exercises done by recipients of either meniscus repair or transplantation unless otherwise indicated.
Abd, Abduction; *Add*, adduction; *Ext*, extension; *Flex*, flexion.

FIG 25-9 Wall-sit exercises are begun 3 to 4 weeks after meniscus repair and 5 to 6 weeks after meniscal transplantation. These exercises are limited from 0 to 60 degrees of flexion to protect the posterior horn of the meniscus.

FIG 25-10 Minisquats, begun 3 to 4 weeks after meniscus repair and 5 to 6 weeks after meniscal transplantation, are an effective quadriceps strengthening exercise.

Hamstring curls from 0 to 90 degrees are initiated in patients who had peripheral meniscus repairs at the same time as the knee extension PREs. Care should be taken to avoid hyperextension, which places tension on the posterior capsule. This exercise is delayed until at least 7 to 8 weeks after a complex meniscus repair and until 9 to 12 weeks after meniscus transplantation. Isolated resisted hamstring curls are limited in complex repairs and transplants owing to the medial hamstring insertion along the posteromedial joint capsule. This limitation is designed to lessen potential traction forces being imposed onto the repair site. Initially, hamstring curls are done with Velcro ankle weights; then the exercise is progressed to weight machines.

A leg press machine is initiated in the range of 70 to 10 degrees at 5 to 6 weeks after all meniscus repairs and at 9 to 12 weeks after transplantation. The limitation in flexion is incorporated owing to the increased load placed on the posterior horn of the meniscus after 60 to 70 degrees of flexion.

Side-lying straight-leg raises are initiated early in the rehabilitation program. Later, when patients have access to equipment, the seated abduction-adduction machine and cable column or multihip machine for hip flexion, extension, abduction, and adduction are also included in the exercise program. These activities are implemented at 5 to 6 weeks after surgery.

CONDITIONING

A cardiovascular program may begin as early as 2 to 4 postoperative weeks if the patient has access to an upper body ergometer (Table 25-5). Stationary bicycling is begun 7 to 8 weeks after surgery. The seat height is adjusted to its highest level based on patient body size and a low-resistance level is used. A recumbent bicycle may be substituted in patients that have damage to the patellofemoral joint articular cartilage or anterior knee pain.

Water walking may be implemented during this timeframe. Walking in waist-high water decreases the impact load to the knee by 50%. To protect the healing meniscus, swimming with straight-leg kicking and dry land walking programs are initiated between the ninth and twelfth weeks. At this time, patients who had a meniscus repair may also begin using stair-climbing, elliptical cross-trainers, or cross-country ski machines. Protection against high stresses to the patellofemoral joint is required in patients with symptoms or articular cartilage damage. If a stair-climbing machine is tolerable, a short step is maintained with low resistance levels. The cardiovascular program should be done at

CRITICAL POINTS Conditioning

Postoperative Weeks 2-4
- Upper body ergometer

Postoperative Weeks 7-8
- Stationary bicycling (patellofemoral joint precautions)
- Water walking

Postoperative Weeks 9-12
- Swimming with straight-leg kicking
- Walking
- Stair-climbing machine
- Elliptical cross-trainer
- Cross-country ski machine

Cardio program should be done 3 times/wk, in 20- to 30-min sessions.
Exercise level should be at least 60%-85% of maximal heart rate.

TABLE 25-5 Aerobic Conditioning Exercises After Meniscus Repair and Transplantation*

Postoperative Time, Frequency	UBE	Stationary Bicycle	Water Walking	Swimming	Walking	Stair-Climbing Machine (Low Resistance and Stroke)	Ski Machine (Short Stride and Level and Low Resistance)	Running (Straight)	Cutting	Functional Training

*Exercises done by recipients of either meniscus repair or transplantation unless otherwise indicated.

†Begin running program when ≤30% deficit elicited on isokinetic testing; begin cutting program when ≤20% deficit elicited on isokinetic testing.

UBE, Upper body ergometer.

least three times a week for 20 to 30 minutes and the exercise performed to at least 60% to 85% of maximal heart rate.

RUNNING PROGRAM

A running program is begun at approximately 16 to 20 weeks postoperative in patients who had peripheral meniscus repairs and who have no more than a 30% deficit in average peak torque for the quadriceps and hamstrings on isometric testing performed on a Biodex dynamometer. This program is delayed until approximately 30 postoperative weeks in patients who had complex meniscus repairs and until at least 1 year in patients who had a meniscus transplant.

Isometric muscle testing is initially performed at an angle of 60 degrees of knee flexion, which places the knee in a protected position for both the meniscus and patella. Progression to isokinetic testing at high speeds is important, but the initial goal is to test the integrity of the quadriceps and hamstring musculatures. Other testing parameters worth evaluating include peak torque/body weight ratios, agonist/antagonist ratios, and time to peak torque values.

Patients begin with a walk/run combination program, using running distances of 18, 37, 55, and 91 meters. Initially, patients run at 25% to 50% of their normal speed. Once patients can run straight ahead at full speed, lateral and crossover maneuvers are added. Short distances (such as 18 m) are used to work on speed and agility. Side-to-side running over cups may be used to facilitate agility and proprioception. Figure-eight and carioca running drills are also useful.

CRITICAL POINTS Running and Plyometrics

Running, Begin

- 16-20 postoperative wk in peripheral meniscus repairs
- 30 postoperative wk in complex meniscus repairs
- Minimum 1 yr postoperative in meniscus transplants

Patient must demonstrate ≤30% deficit quadriceps and hamstrings peak torque on isometric testing.

Use Walk/Run Program Initially

- 18, 37, 55, 91 m
- 25%-50% normal running speed, straight
- Progress to 100% speed

Add lateral, crossover, side-to-side, figure-eights, carioca drills for agility.

Plyometric Training

- Patient should be able to run straight ahead at full speed with no symptoms
- Begin at 6-9 postoperative mo after meniscus repair
- Majority of meniscus transplant patients are not candidates for this program

Considerations

- Surface: firm but forgiving such as wooden gym floor; avoid hard surfaces such as concrete
- Footwear: cross-training or running shoe; check wear patterns, outer sole wear
- Warm-up: include light cardiovascular workout

Training Progression

- Begin with level surface box hopping on 4-square grid
- Double-leg jump initially, land in flexion
- Complete four levels
- Single-leg hops
- Vertical box hopping

PLYOMETRIC TRAINING

Progressive plyometric training is initiated upon successful completion of the running program. This training program is typically begun after 6 months of surgery in patients who have had a large peripheral or complex repair. In patients who had a radial meniscus repair, this program may be delayed until 9 months postoperative, owing to the disruption that occurred in the hoop stresses of the meniscus. The majority of patients who undergo meniscal transplantation have noteworthy articular cartilage deterioration and are not candidates for strenuous plyometric training.

Plyometric training starts in individual sessions performed in a manner similar to interval training. Initially, a rest period is incorporated that lasts 2 to 3 times the length of the exercise period; this is gradually decreased to 1 to 2 times the length of the exercise period. Plyometrics are performed 2 to 3 times each week in addition to strength and cardiovascular endurance exercises. Plyometrics should be done on a surface that is firm, yet forgiving, such as a wooden gym floor. Very hard surfaces such as concrete should be avoided. In addition, a cross-training or running shoe should be worn to provide adequate shock absorption as well as adequate stability to the foot. Checking wear patterns and outer sole wear will help avoid overuse injuries.

The program beings with level-surface box-hopping. A four-square grid of four equally sized boxes is created on the floor with tape. The patient first jumps with two legs from box 1 to box 3 (front to back) and then from box 1 to box 2 (side to side). This drill is initially performed using both legs, with the body weight kept on the balls of the feet. The patient jumps as fast as possible with the knees bent and lands in flexion to avoid knee hyperextension. It is important for the patient to focus on limb symmetry during this exercise.

The initial exercise time period lasts 15 seconds, with the patient completing as many jumps between the squares as possible. Three sets are performed for both directions, and the number of jumps is recorded. Progression of the program occurs as the number of jumps, as well as patient confidence, improves. This exercise has four levels. The first level includes front-to-back and side-to-side jumping, as previously described. The second level incorporates both of the directions in level one into one sequence and also includes jumping in both right and left directions (i.e., box 1 to box 2 to box 4 to box 2 to box 1). Level three progresses to diagonal jumps, and level four includes pivot jumps in a 180-degree direction. When the patient can perform level-four double-leg jumps, similar exercises are initiated using single-leg hops.

For patients who undergo a combined meniscus repair and ACL reconstruction, advanced plyometric training is recommended before release to strenuous high-risk sports activities such as soccer and basketball. This program is described in detail in Chapter 14. The program is applicable for both female and male athletes.

RETURN TO SPORTS ACTIVITIES

Sport-specific drills and cutting patterns of 45- and 90-degree angles may be implemented, based on the patient's athletic goals. Repeat isokinetic testing is typically performed monthly, progressing from isometric testing for the first 6 months to isokinetic testing at speeds of 180 and 300 degrees per second. This testing not only provides the patient with feedback on performance but also serves to assist the clinician with program progression. Goals for testing should be at least 70% to begin running and 90% for full activity for the bilateral torque

CRITICAL POINTS Return to Sports Activities

- Sports-specific drills completed based on patient goals
- Successful completion of running and functional training
- ≤10% deficit quadriceps and hamstrings peak torque on isokinetic testing
- No symptoms
- ≤15% deficit single-leg hop tests
- >60% normalized knee separation distance on drop-jump test
- Trial of function recommended; monitor for overuse symptoms
- Majority of meniscus transplant patients not candidates owing to joint damage; encourage low-impact activities, weight control

comparisons and approximately 60% for agonist/antagonist ratios. Torque/body weight ratios are based on age, sex, and body weight parameters.

Return to sports activities is based on successful completion of the running and functional training program. A trial of function is encouraged, during which time the patient is monitored for overuse symptoms. For patients who undergo a combined meniscus repair and ACL reconstruction, the following is recommended for release to unrestricted athletics:

- Isokinetic test 180 degrees/sec and 300 degrees/sec quadriceps, hamstrings: 10% deficit or less
- No pain, swelling, patellofemoral crepitus
- Lachman, KT-2000 (MEDmetric) arthrometer test: less than 3 mm increase over opposite side
- Single-leg hop tests: less than 15% deficit[9]
- Successful completion of advanced plyometric training
- More than 60% normalized knee separation distance on video drop-jump test[10]
- No valgus motion or medial-lateral movement of knee on single-leg squat test[11]

The majority of patients who undergo meniscal transplantation have noteworthy articular cartilage deterioration and are not candidates for strenuous plyometric training or sports activities. Return to low-impact activities is therefore recommended for these individuals.

INDICATIONS

High tibial osteotomy (HTO) has gained wide acceptance as a treatment option for patients with medial tibiofemoral osteoarthritis and varus deformity of the lower extremity. Most candidates are in their third to fifth decade and wish to remain active and avoid unicompartmental or total knee replacement. The recommendations for this procedure are derived from a careful evaluation of subjective symptoms, findings on physical examination, and radiographic evidence of malalignment and arthritis.

The predominant indication for HTO is lower limb osseous malalignment (Fig. 26-1) in younger patients who have medial tibiofemoral joint pain and wish to maintain an active lifestyle. The goal is to correct the mechanical abnormality of excessive loading of the medial tibiofemoral compartment by redistributing weight-bearing loads onto the lateral compartment. Varus malalignment is present when the weight-bearing line (WBL) crosses less than 50% of the mediolateral transverse width of the tibial plateau.

Unfortunately, a prior medial meniscectomy is a major risk factor for progression of arthritis in these knees. Because any underlying arthritis is expected to progress,[190] it is advisable to perform HTO while the joint damage is in the early stages before the development of severe articular cartilage deterioration and loss of tibiofemoral joint space.[62,67,214]

One advantage of performing HTO in young patients who have early medial tibiofemoral arthritis after medial meniscectomy is the opportunity to also perform a meniscus transplant and a cartilage restoration procedure if indicated.

The appropriate level of physical activity that can be recommended after HTO remains questionable. Patient education is important so that activity limitations to be followed postoperatively are well understood. The goal of the osteotomy is to allow an active, pain-free lifestyle that includes low-impact recreational pursuits but not high-loading athletics that involve twisting, jumping, and pivoting.

The majority of patients who undergo HTO are age 50 years or younger with varus malalignment and mild to moderate medial tibiofemoral joint arthritis. Many patients have had a prior medial meniscectomy. Patients older than 60 years are usually candidates for partial or total joint replacement. The difficult decision is the treatment recommendation for patients between 50 and 60 years old. With the increasing longevity of unicompartmental knee replacements, patients who have advanced medial compartment damage with major areas of bone exposure will likely experience symptoms after HTO and are better candidates for partial replacement. Individuals who undergo a unicompartmental replacement may participate in recreational activities similar to those who undergo HTO. Osteotomy is performed in patients 50 years old and younger who are athletically active, have remaining medial tibiofemoral cartilage (although thinned), and wish to maintain reasonable athletic pursuits such as tennis and skiing. These patients have early medial compartment symptoms; however, the joint damage is not advanced to a bone-on-bone state that would warrant unicompartmental replacement. Careful patient selection is the key issue, and the surgeon should not overstate or guarantee results of an HTO because the arthritis will eventually progress. In short, the goal of an HTO is to buy time in younger-aged patients (hopefully 10-15 years) before joint replacement. If there is any question that the arthritis of the medial tibiofemoral compartment is advanced to the point where the HTO will not last 10 years, it is preferable in patients age 50 years or older to perform a partial replacement. This is particularly true for sedentary patients in whom the goals of ambulating activities are achieved with partial joint replacement, avoiding the more prolonged postoperative recovery from an HTO.

There exists a group of varus-angulated knees with associated symptomatic ligament deficiencies requiring reconstruction. These ligament deficiencies most commonly involve the anterior cruciate ligament (ACL) and posterolateral structures (fibular collateral ligament [FCL], popliteus muscle-tendon-ligament unit [PMTL] and posterolateral capsule). In these double and triple varus knees, a normal

FIG 26-1 Bilateral varus malalignment in a 40-year-old man who presented with bilateral medial joint pain after 1 to 2 hours of ambulation.

CRITICAL POINTS Indications

- Varus osseous malalignment: weight-bearing line <50% of tibial width
- Mild to moderate symptomatic arthrosis medial tibiofemoral compartment
- Articular cartilage retained in medial tibiofemoral compartment
- To achieve normal limb alignment before:
  - Medial meniscus transplant
  - Articular cartilage restorative procedures
  - Cruciate ligament or posterolateral reconstruction in double and triple varus knees
- Patients ≤50 years old, athletically active, wishing to maintain reasonable athletic pursuits

axial alignment must be achieved before proceeding with ligament reconstructive procedures. Lower limb varus malalignment is not overcorrected to valgus when there is no damage to the articular cartilage in the medial tibiofemoral compartment. The goal in these patients is to correct the varus to a neutral alignment and then proceed in a staged manner with a cruciate and posterolateral reconstruction as required. Correction of the varus alignment decreases the risks of failure of the ligament reconstructive procedures.[153,155,158,160]

CONTRAINDICATIONS

One commonly debated issue regarding contraindications to osteotomy is the extent of damage to the medial tibiofemoral compartment. In general, HTO is avoided in knees in which there is more than a 15 × 15 mm area of exposed bone on both the tibial and femoral surfaces. There are knees in younger patients in which the area of exposed bone may be greater and partial replacement is not an option. However, as a general rule, remaining articular cartilage should be present over the majority of the medial joint surfaces.

Major concavity of the medial tibial plateau with loss of bone stock is a contraindication to HTO.[115] On standing 45-degree posteroanterior (PA) radiographs,[184] knees that demonstrate no remaining articular cartilage space to the medial compartment are not candidates. An arthroscopic procedure just before HTO helps to assess the amount of remaining articular cartilage and remove symptomatic meniscus fragments and other tissues.

Additional contraindications are a limitation of knee flexion (>10 degrees), lateral tibial subluxation (>10 mm), prior lateral meniscectomy, or lateral tibiofemoral joint damage.[115]

An absolute contraindication for a medial opening wedge osteotomy is the use of nicotine products in any form. The complication of a nonunion is not worth the risk, and a minimum of 8 to 12 weeks of abstinence before surgery is required. The patient is warned that there may still be an increased risk in regard to osteotomy healing.

A relative contraindication is a body weight over 200 lb (91 kg; Fig. 26-2). Although there may be some patients in whom HTO is indicated that weigh up to 225 lb (102 kg), this operation is avoided in patients

CRITICAL POINTS Contraindications

- Medial tibiofemoral compartment bone exposure over an area >15 × 15 mm on femur and tibia
- Major concavity medial tibial plateau, loss of bone stock
- No joint space in medial compartment on standing 45-degree PA radiographs
- Patients 50-60 years old with advanced medial compartment damage (candidates for unicompartmental knee replacement)
- Patient >60 years old (candidates for partial or total joint replacement)
- >10 degrees of limitation of knee flexion
- >10 mm of lateral tibial subluxation
- Prior total lateral meniscectomy, lateral tibiofemoral cartilage damage
- Use of products containing nicotine
- Obesity (body mass index >30)
- Increased slope to affected medal tibial plateau; teeter-totter knee
- Marked symptomatic and advanced patellofemoral arthrosis
- Prior joint infection, diabetes, rheumatoid arthritis, autoimmune diseases, malnutrition state

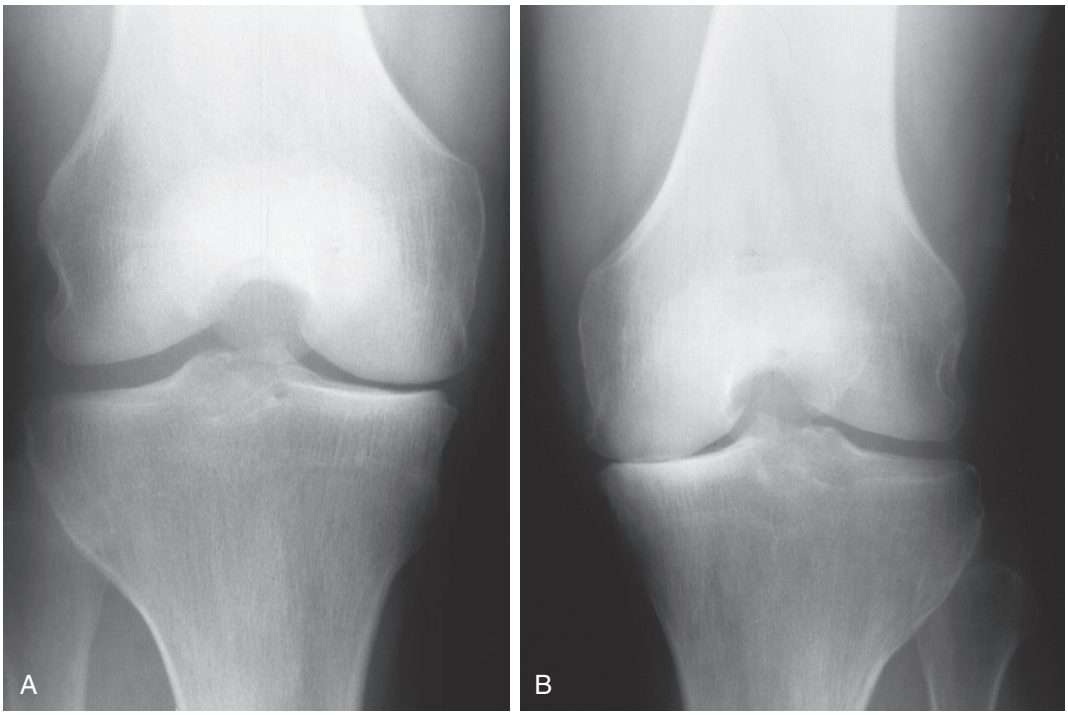

FIG 26-2 Anteroposterior (AP) radiographs of the right (**A**) and left (**B**) knee in a 45-year-old retired professional football player. The patient's weight was 260 lb. His chief complaint was bilateral medial joint pain with walking. The patient was advised to lose a significant amount of weight to decrease body size. In our opinion, high tibial osteotomy (HTO) is contraindicated in the left knee because of the advanced medial compartment arthritis. However, HTO may be an option in the right knee after achieving a normal body mass index. Many athletes of large stature with varus malalignment undergo medial meniscectomy, continue athletic participation, and rather promptly lose the remaining cartilage in the medial tibiofemoral joint. Patient counseling and close follow-up are necessary.

with a higher body weight because the beneficial effect of unloading the medial compartment will not be achieved.[6,67,97,138]

A relative contraindication is increased medial slope to the affected medial tibial plateau in the coronal plane because of advanced medial plateau concavity.[46,115] This finding indicates that it will not be possible to significantly unload the medial compartment with HTO, and the joint will remain with all of the weight bearing confined to the medial compartment. This problem can be tested before surgery with varus-valgus stability tests at 30 degrees of knee flexion. In knees with advanced medial arthritis, there is no neutral point in which there is simultaneous contact of the medial and lateral compartments. The tibia behaves like a teeter-tooter, with contact alternating between the medial and the lateral compartment and obvious separation of the noncontacted compartment.

The issue of concurrent patellofemoral arthritis has been addressed by prior studies.[47,137,186] In general, the symptomatic state should be addressed and the patient warned preoperatively that patellofemoral symptoms may continue or progress. Marked patellofemoral symptoms contraindicate a HTO.[115,186] The finding of asymptomatic articular cartilage changes to the patellofemoral joint is not a contraindication to HTO because clinicians have noted that the end result in terms of longevity of the HTO depends on the symptomatic medial tibiofemoral compartment.[47,114,152]

Medical contraindications to HTO include diabetes, rheumatoid arthritis, autoimmune diseases, and malnutrition states.

LOWER LIMB ALIGNMENT: PRIMARY, DOUBLE, AND TRIPLE VARUS KNEES

An added complexity in the varus-angulated knee with medial compartment arthritis is the presence of ACL deficiency. An associated deficiency of the posterolateral structures may add to the varus angulation and clinical symptoms. Patients who have these combined abnormalities often experience pain, swelling, giving way, and functional limitations that may result in a disabling condition. In these complex knees, multiple abnormalities exist to the lower limb and knee joint that must be correctly diagnosed to outline a rational treatment program. These include the anatomic tibiofemoral osseous coronal and sagittal alignment, abnormal knee motion limits, abnormal knee positions (subluxations of the medial and lateral tibiofemoral compartments), and the corresponding specific deficiencies of the ligament structures (single and combined).

The terms *primary varus*, *double varus*, and *triple varus* knee were devised to classify varus-aligned knees with associated ligament deficiencies (Table 26-1).[152] This classification system is based on the underlying tibiofemoral osseous alignment and the additional effect of separation of the lateral tibiofemoral compartment (because of deficiency of the posterolateral structures) on the overall varus lower limb alignment, as calculated from the WBL.

In patients with a varus-angulated knee, a bilateral physiologic varus tibiofemoral alignment is usually present. In others, a normal

TABLE 26-1 Causes of Varus Angulation in the Anterior Cruciate Ligament–Deficient Knee

Tibiofemoral Alignment or Geometry	Knee Motion Limits	Knee Joint Position	Ligament Deficiency	Comments
Primary varus Physiologic tibiofemoral varus alignment; narrowing or loss of medial joint cartilage	NA ↑ Varus or adduction rotation	NA ↓ Separation of medial tibiofemoral compartment	NA Pseudolaxity or slackness of medial ligament structures	Medial displacement of weight-bearing tibiofemoral line. Effect on varus alignment is more pronounced when preexisting physiologic varus alignment is present.
Double varus Added deficiency of FCL, posterolateral soft tissue structures	↑↑ Varus or adduction rotation Often coupled with lateral tibial translation and secondary support, intercondylar eminence against lateral femoral condyle	Separation of lateral tibiofemoral joint on standing Varus thrust on walking caused by lateral condylar lift-off Increased tension in FCL, posterolateral soft tissues	FCL, lateral capsule, iliotibial band (femorotibial portion) Amount of joint opening depends on slackness of lateral soft tissue restraints Absence of ACL secondary restraint to varus angulation	Weight-bearing tibiofemoral line shifts far enough medially to produce separation of the lateral tibiofemoral joint during walking, sports activities. Under states of maximal muscle contraction (quadriceps, biceps femoris), sufficient compressive forces may exist to prevent lateral condylar lift-off.
Triple varus Added deficiency of all PL structures (FCL, PMTL, PL capsule)	↑↑↑ Varus or adduction rotation Varus recurvatum in extension: Increased external tibial rotation Increased hyperextension Increased external tibial rotation in flexion	↑ Separation of lateral compartment plus varus recurvatum may occur on standing, walking Varus recurvatum thrust if quadriceps and ankle plantar flexors do not prevent knee hyperextension Posterior subluxation of lateral plateau with external tibial rotation	As above, plus PMTL, PL capsule Knee hyperextension increases with associated damage to ACL, PCL (partial to complete)	Gait training is required to teach patient not to walk with varus recurvatum thrust, maintaining 5 degrees of knee flexion on initial weight bearing. Knee hyperextension with physiologic slackness to ACL and PCL may be present without actual injury to cruciates allowing varus recurvatum.

ACL, Anterior cruciate ligament; *FCL*, fibular collateral ligament; *PCL*, posterior cruciate ligament; *PL*, posterolateral; *PMTL*, popliteal muscle-tendon-ligament.

CRITICAL POINTS Lower Limb Alignment: Primary, Double, and Triple Varus Knees

Primary varus: amount of varus angulation caused by physiologic tibiofemoral angulation and osteocartilaginous (narrowing) of the medial tibiofemoral compartment

Double varus: amount of varus angulation caused by:

1. Tibiofemoral osteocartilaginous and geometric alignment
2. Separation of the lateral tibiofemoral compartment from moderate deficiency of the posterolateral structures (>5 mm increased lateral joint opening, 10 degrees increased external tibial rotation)

Triple varus: amount of varus angulation caused by:

1. Tibiofemoral osteocartilaginous and geometric alignment
2. Separation of the lateral tibiofemoral compartment
3. Varus recurvatum in extension, severe deficiency posterolateral ligamentous structures

Restraints resisting lateral tibiofemoral compartment separation under dynamic weight-bearing conditions: quadriceps, biceps femoris, gastrocnemius, iliotibial band

tibiofemoral alignment may convert to a varus malalignment after medial meniscectomy. With loss of the medial meniscus and resultant articular cartilage deterioration, narrowing of the medial tibiofemoral compartment occurs along with an increase in varus lower limb alignment. For example, a patient with a physiologic varus alignment of 3 degrees (mechanical axis) with an additional loss of 3 mm of the medial articular cartilage would develop an overall 6 degrees varus tibiofemoral alignment.

The term *primary varus* refers to the physiologic tibiofemoral osseous angulation and any further increase in angulation owing to altered geometry (narrowing) of the medial osteocartilaginous tibiofemoral joint (Fig. 26-3). The tibiofemoral WBL shifts into the medial tibiofemoral compartment as the narrowing progresses and the lateral compartment is unloaded. Three degrees of varus angulation approximately doubles medial compartment pressures.[61,81]

As the WBL shifts into the medial compartment, there are increased tensile forces in the posterolateral soft tissues, including the iliotibial tract and ligament structures. There is corresponding separation of the lateral tibiofemoral compartment during standing, walking, and running activities (lateral condylar lift off).[122,189] This is called a *double varus knee* because the lower limb varus malalignment results from two factors: the tibiofemoral osseous and geometric alignment and separation of the lateral tibiofemoral compartment from deficiency of the posterolateral structures.

A combination of active and passive restraints resists separation of the lateral tibiofemoral compartment under dynamic loading conditions.[78,141] The quadriceps, biceps femoris, and gastrocnemius muscles and iliotibial band act in a dynamic manner to resist adduction moments at the knee joint during gait, and with weight-bearing loads, resist lateral tibiofemoral separation. If these muscle forces do not provide a functional restraint to excessive lateral tensile forces, separation of the lateral tibiofemoral joint occurs.

The FCL normally allows a few millimeters of separation of the tibiofemoral compartment, and pathologic stretching (interstitial injury) may occur to this ligament in chronic varus-angulated knees. Under these circumstances, a transfer of all of the weight-bearing loads to the medial compartment occurs, which can be especially deleterious if damaged articular cartilage or prior meniscectomy is present.

The patient symptoms commonly increase with pain in both the medial compartment and lateral aspect of the knee joint owing to

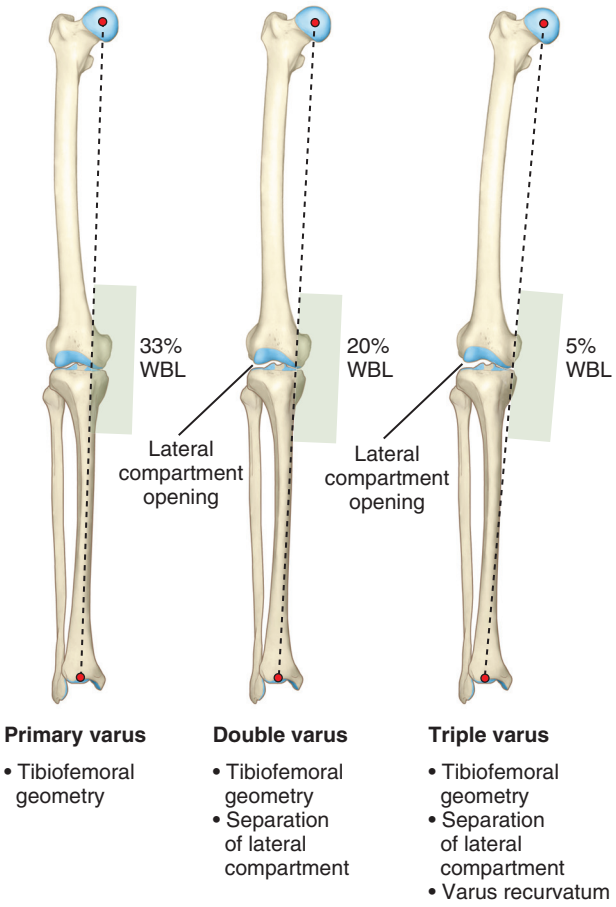

FIG 26-3 Schematic illustration of primary, double, and triple varus knee angulation. *WBL*, Weight-bearing line.

excessive medial compressive and lateral soft tissue tensile forces, respectively.

In a triple varus knee, injury to the FCL and posterolateral structures produces a varus recurvatum position of the limb.[95] A *triple varus knee* results from three causes: tibiofemoral varus osseous malalignment, increased lateral tibiofemoral compartment separation caused by marked insufficiency of the FCL and PMTL, and varus recurvatum in extension. The varus recurvatum occurs because of abnormal external tibial rotation and knee hyperextension, reflecting deficiency of the posterolateral structures and possibly the ACL. Owing to the increase in lateral compartment opening, the WBL shifts further medially as shown in Figure 26-3.

HTO is indicated in patients with varus malalignment who demonstrate a varus thrust on walking. An ACL reconstruction in these knees would not address the instability and would be expected to fail if the varus osseous malalignment was not first corrected owing to the abnormal lateral tibiofemoral joint opening. A varus recurvatum or back-knee instability indicates a triple varus knee in which the posterolateral structures require reconstruction along with the ACL, after first correcting the osseous malalignment.

Eckhoff and coworkers[61] reported important 3-dimensional measurements in 90 individuals (180 limbs) and showed that there is considerable variation in coronal alignment between subjects and between right-left lower limbs (Fig. 26-4). One qualification to the data is that the hip-knee-ankle computed tomography (CT) measurements were obtained under non–weight-bearing conditions.

Given the variation in lower limb alignment in individuals, a frequent question is what is the effect of correcting one limb to neutral or a mild valgus overcorrection on overall gait and the (unoperated) opposite limb, particularly when a marked varus alignment is present bilaterally. In our experience, the opposite extremity does not require HTO, except in a small percentage of patients who have marked bilateral varus alignment and medial tibiofemoral pain.

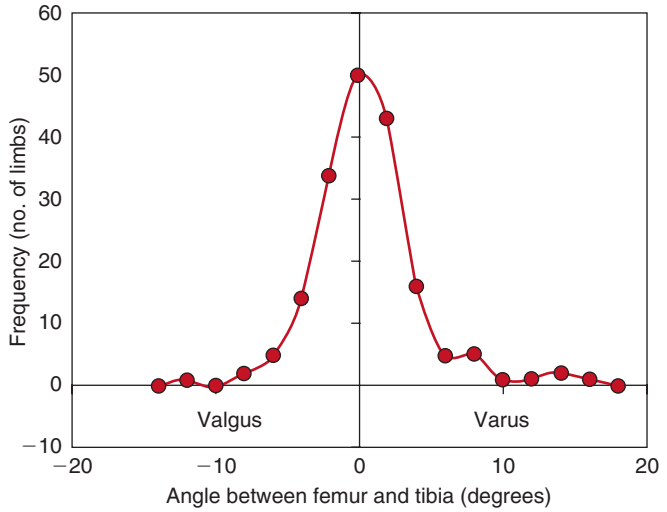

FIG 26-4 Histogram of the data illustrating the relative deviation of limb alignment from a straight line in the normal population of 180 limbs. Of the 90 individuals, 37 had bilateral valgus, 22 had bilateral varus, and 31 had varus alignment of one limb and valgus of the other limb or varus or valgus alignment of one limb and neutral alignment of the other limb. (From Eckhoff DG, Bach JM, Spitzer VM, et al. Three-dimensional mechanics, kinematics, and morphology of the knee viewed in virtual reality. *J Bone Joint Surg Am.* 2005;87:71-80.)

GAIT ANALYSIS

Although a high adduction moment may be anticipated as a result of varus malalignment, the moments and loads on the knee joint cannot be reliably predicted from the static measurement of lower limb alignment on radiographs.[98,168] Many factors in patients with ACL-deficiency, varus malalignment, and posterolateral deficiency can be assessed by gait analysis. Abnormal limb alignment, either varus or valgus in the coronal plane or hyperextension in the sagittal plane, produces substantial alterations in the moments and forces about the knee joint (Fig. 26-5).[28,55,72,118,168,181,198] The analysis of external moments about the knee during gait allows the clinician to understand the effect of the altered gait dynamics on the knee joint. Abnormally high knee adduction moments increase the risk for progression of medial tibiofemoral arthritis owing to excessive loading.[16,139,180,182] The success of HTO has been related to lowering these moments to below normal values.[28,180,217] In addition, gait analysis allows calculation of abnormally high tensile forces in the lateral soft tissue restraints that increase the risk of elongating these tissues from lateral condylar lift-off with activity. Abnormal tensile loads on posterolateral soft tissues preclude successful FCL and PMTL reconstruction. Markholf and associates[123] reported that lateral tibiofemoral compartment condylar lift-off had a marked effect on producing joint instability.

Many studies have documented that the external moments about the knee joint and the corresponding tibiofemoral compartment loads are markedly influenced by individual gait characteristics and adaptations that occur after injury.[11,14,15,17,18,26,42,107,180,217] ACL deficiency may produce marked abnormalities in moments about the knee joint in the sagittal plane, which is further affected by lower limb varus

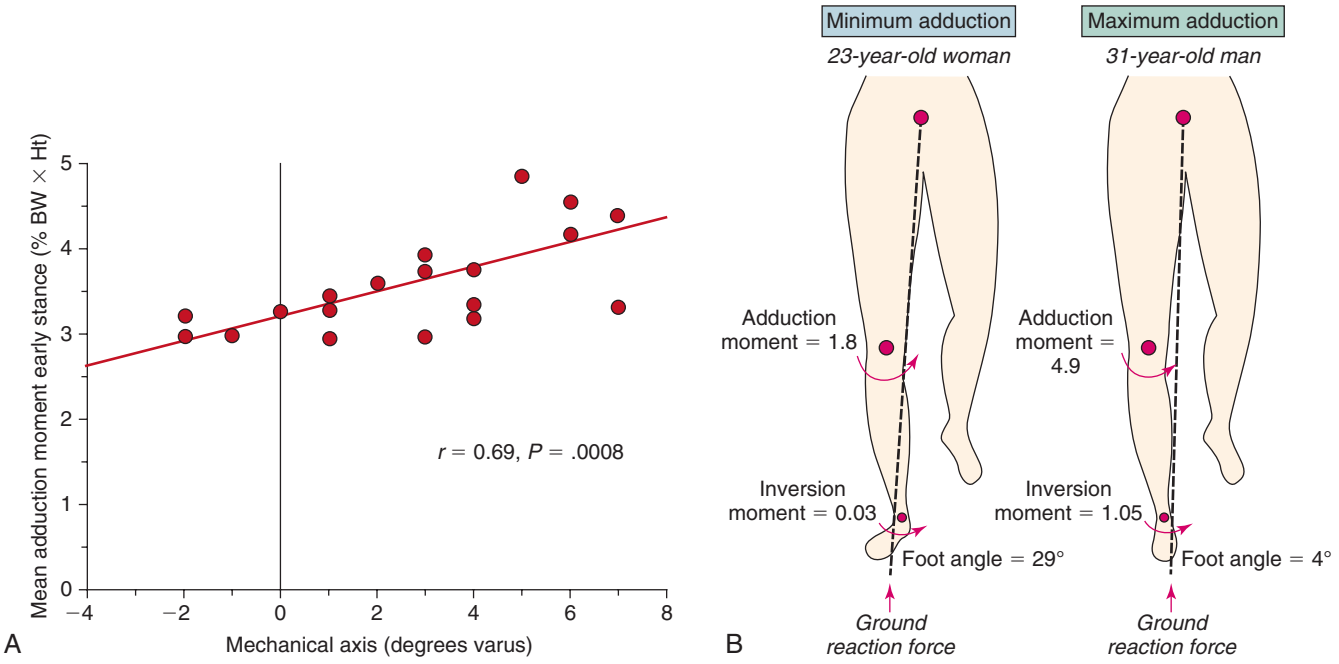

FIG 26-5 The knee adduction moment that produces medial tibiofemoral compartment loading and lateral joint tensile loads is dependent on both the mechanical axis (**A**) and patient gait characteristics such as the rotation of the lower limb and the foot angle at stance phase (**B**). *BW,* Body weight; *Ht,* height. (From Andrews M, Noyes FR, Hewett TE, Andriacchi TP. Lower limb alignment and foot angle are related to stance phase knee adduction in normal subjects: a critical analysis of the reliability of gait analysis data. *J Orthop Res.* 1996;14:289-295.)

CRITICAL POINTS Gait Analysis

Moments and loads on knee joint cannot be reliably predicted from static measurement of lower limb alignment on radiographs. Abnormally high knee adduction moments increase the risk for progression of medial tibiofemoral arthrosis. Success of HTO is related to lowering abnormal moments to normal or below-normal values.

Our study conclusions:

- Majority ACL-deficient varus-angulated knees have abnormally high adduction moments on walking.
- One third of patients have normal or low adduction moments, normal to low medial tibiofemoral compartment loads. Gait characteristics/adaptations lowered medial tibiofemoral loads despite varus angulation.
- Significant correlation between high adduction moments and high medial tibiofemoral compartment loads, high lateral soft tissue forces.
- In knees with high lateral ligament tensile forces, separation of the lateral tibiofemoral joint may occur with "condylar lift-off" during weight bearing.
- Large tensile loads on posterolateral tissues cause stretching, deficiency (double and triple varus knees), and failure of posterolateral reconstructive procedures.

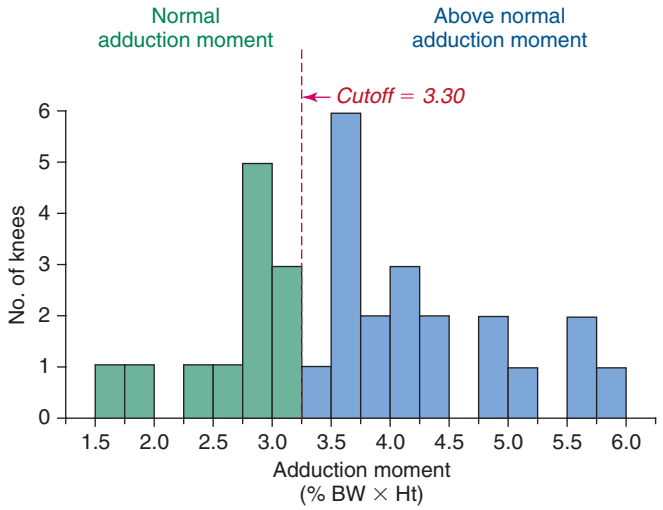

FIG 26-6 The distribution of the adduction moments during walking in the anterior cruciate ligament–deficient knees. The cutoff value (3.30, % body weight [BW] × height [Ht]) represents the control mean minus 1 standard deviation. (From Noyes FR, Schipplein OD, Andriacchi TP, et al. The anterior cruciate ligament-deficient knee with varus alignment. An analysis of gait adaptations and dynamic joint loadings. *Am J Sports Med.* 1992;20:707-716.)

malalignment. Patients with ACL deficiency may show a decrease in the magnitude of the external flexion moment (quadriceps-reduced gait) or an increase in the external extension moment (hamstrings-protective muscle force).[12,13] These effects are discussed in Chapter 6. The alignment of the foot markedly influences the knee adduction moment. Patients with toe-in, or less than normal external axial rotation of the foot during stance phase, tend to have a higher knee adduction moment as the WBL passes farther medial to the knee joint.[10,98]

Gait analyses were conducted in a study at our institution[168] involving 32 patients with ACL deficiency and varus angulation. A force plate and optoelectronic system were used to measure forces and moments of the lower limb and knee joint. Knee joint loads and ligament tensile forces were calculated using a previously described mathematical model.[189] Sixty-two percent of the patients had an abnormally high magnitude of the moment, tending to adduct the affected knee (Fig. 26-6). The calculated medial tibiofemoral loads were excessively high in 66% of the patients ($P < .01$). Forty-seven percent of the patients had predicted abnormally high lateral ligament tensile forces ($P < .05$). The adduction moment showed a statistically significant ($P < .05$) correlation to predicted high medial tibiofemoral compartment loads and high lateral ligament tensile forces ($P < .01$). A shift had occurred in the center of maximal joint pressure to the medial tibiofemoral compartment, with a corresponding increase in the lateral ligament tensile forces to achieve frontal plane stability (Figs. 26-7 and 26-8). If muscle forces are not sufficient to maintain lateral tibiofemoral compressive loads, tensile forces develop in the lateral ligament tissues. The data indicate that in knees with high lateral ligament tensile forces, separation of the lateral tibiofemoral joint occurs with condylar lift-off during weight bearing.

The magnitude of the flexion moment (which is related to quadriceps muscle force) was significantly lower in 47% of the patients ($P < .05$), and the extension moment (related to hamstring muscle force) was significantly higher in 50% ($P < .05$). These findings indicated that a gait adaptation occurred that diminished quadriceps muscle activity and enhanced hamstring muscle activity hypothesized to provide anteroposterior (AP) stability in these ACL-deficient knees.[26]

Equally important in the results was the finding that approximately one third of the patients had normal or low adduction moments and corresponding normal to low medial tibiofemoral compartment loads. These patients had gait characteristics or adaptations that lowered medial tibiofemoral loads despite the varus lower limb alignment. Gait analysis allowed identification of patients with a potentially better overall prognosis; the adduction moment and medial tibiofemoral loads were not excessively high, and an HTO would result in a substantial lowering of the loads placed on the medial tibiofemoral joint.

We[158] studied patients with varus-angulated knees with insufficient posterolateral structures in whom prior posterolateral reconstructive procedures failed and an HTO was required before further soft tissue reconstructive procedures could be done. One explanation for these clinical findings is that these knees had a varus or hyperextension thrust during the stance phase of gait, which placed undue tensile forces on the deficient posterolateral structures (Fig. 26-9). Untreated varus malalignment has also been identified as a predisposing cause of failure of ACL reconstructions[153,160] and posterior cruciate ligament (PCL) reconstructions[155] as well.

CLINICAL EVALUATION

Subjective and Functional Outcome

Patients complete questionnaires and are interviewed for the assessment of symptoms, functional limitations, sports and occupational activity levels, and patient perception of the overall knee condition according to the Cincinnati Knee Rating System (CKRS; see Chapter 41).[22]

Symptoms of pain, swelling, and giving way are well recognized consequences of ACL deficiency.[167] However, in a knee with combined varus malalignment and ACL deficiency, several different knee subluxations may produce symptoms of instability. These include anterior subluxation of the tibia, separation of the lateral tibiofemoral compartment on walking (varus thrust), posterior subluxation of the lateral tibial plateau (with knee flexion and external tibial rotation), and excessive hyperextension or varus recurvatum with a back-knee or feeling of the knee joint going into hyperextension. By history and asking the patient to demonstrate the knee instability, the surgeon must carefully determine the subluxations present.

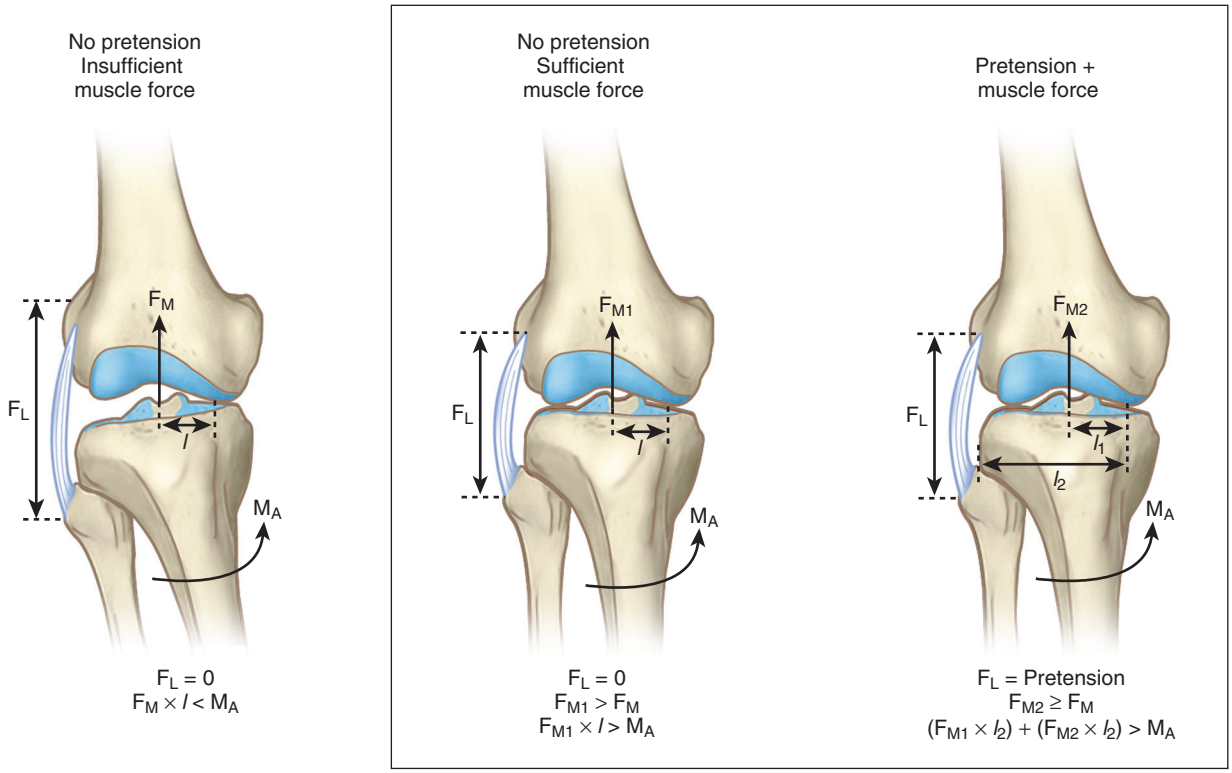

FIG 26-7 A critical interaction between the dynamic muscle forces and the forces in the passive soft tissues is needed to stabilize the knee joint during walking. The knee joint remains closed laterally if either pretension in the lateral soft tissues or increased muscle force resulting from antagonistic muscle groups is present. Distances l and l_1 = 20 mm; l_2 = 60 mm. F_l, Soft tissue force; F_M, F_{M1}, F_{M2}, muscle forces; M_A, adducting moment.

CRITICAL POINTS Clinical Evaluation

Assessment of Symptoms and Functional Limitations With Activity: Cincinnati Knee Rating System

Physical Examination

- Knee flexion and extension
- Joint effusion
- Patellofemoral: extensor mechanism malalignment
- Tibiofemoral crepitus, joint line pain, compression pain, inflammation
- Gait abnormalities
- Abnormal knee motion limits and subluxations

Diagnostic Clinical Tests

- Posterior drawer, 90 degrees of knee flexion
- KT-2000, 20 degrees of knee flexion, 189-N force
- Pivot shift, Lachman
- Lateral and medial tibiofemoral joint opening at 0 and 25 degrees of knee flexion
- Varus recurvatum: supine

Tibiofemoral Rotation (Dial Test)

- 30 and 90 degrees of knee flexion
- An increase in external tibial rotation represents either a posterior subluxation of the lateral tibial plateau (injury to the posterolateral structures) or anterior subluxation of the medial tibial plateau (injury to the medial collateral ligament and posteromedial structures)
- Supine position preferred; difficult to palpate the medial and lateral tibiofemoral position in the prone position

Radiographic Assessment

- Double-stance, hip-knee-ankle to measure mechanical axis, WBL, lateral compartment separation
- Lateral, 30 degrees of knee flexion (patellar height measurement)
- PA, weight bearing, 45 degrees of knee flexion
- Patellofemoral axial
- Lateral stress, neutral tibial rotation, tibia unconstrained, 67-N varus force

Physical Examination

A complaint of medial joint line pain may or may not correlate with the degree of medial compartment articular cartilage damage.[89,101] In the early stages, the patient usually complains of medial pain occurring with sports activities but not with daily activities. When pain occurs with daily activities, there is a high likelihood that extensive damage exists to the joint articular cartilage. Loss of the medial meniscus is the major risk factor for the progression of arthritis in the medial compartment.[64]

The physical examination of the knee joint to detect all of the abnormalities in a varus-angulated knee is comprehensive (Table 26-2) and includes assessment of (1) the patellofemoral joint, especially possible extensor mechanism malalignment caused by increased external tibial rotation and posterolateral tibial subluxation; (2) medial tibiofemoral crepitus on varus loading, indicative of articular cartilage

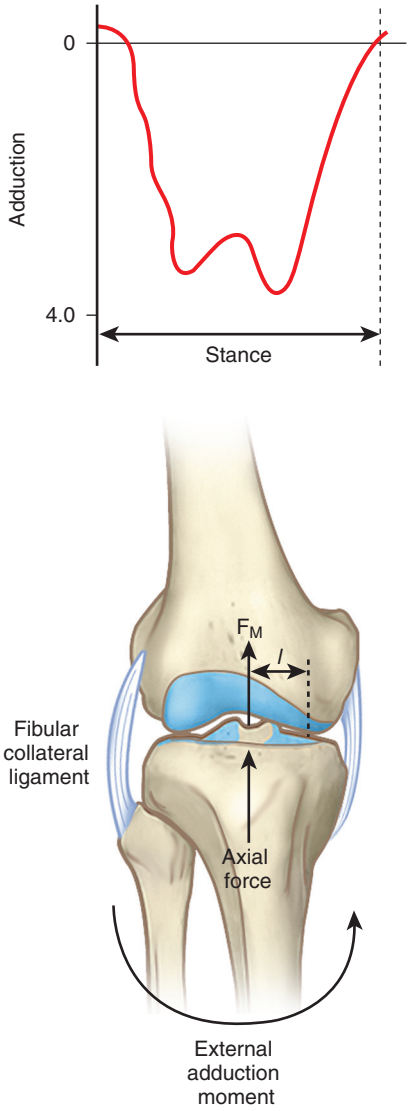

FIG 26-8 The external adducting moment is resisted by the minimum sagittal plane muscle force (F_m) and axial load acting over *l*. Pretension in the lateral soft tissues would maintain equilibrium if the muscle force were insufficient.

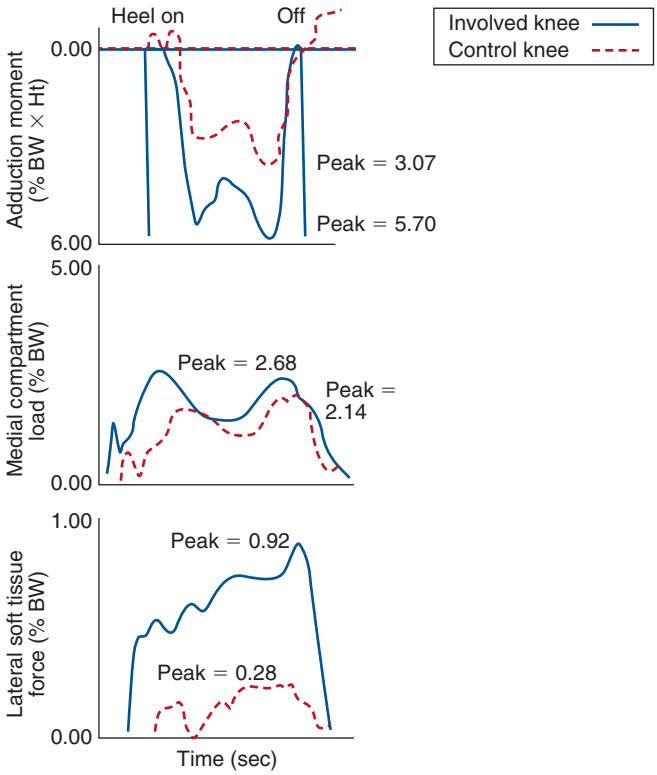

FIG 26-9 The increased adduction moment, medial compartment load, and lateral soft tissue force in an involved knee compared with a control knee. *BW*, Body weight; *Ht*, height. (From Noyes FR, Schipplein OD, Andriacchi TP, et al. The anterior cruciate ligament-deficient knee with varus alignment. An analysis of gait adaptations and dynamic joint loadings. *Am J Sports Med.* 1992;20:707-716.)

damage even if not visible on radiographs; (3) pain and inflammation of the lateral soft tissues caused by tensile overloading; (4) gait abnormalities (excessive hyperextension or varus thrust) during walking and jogging[163]; and (5) abnormal knee motion limits and subluxations compared with the contralateral knee.[165]

Diagnostic Clinical Tests

The medial posterior tibiofemoral step-off on the posterior drawer test is done at 90 degrees of flexion (Fig. 26-10). This test is performed first to identify that the tibia is not posteriorly subluxated, indicating a partial or complete PCL tear. A KT-2000 (MEDmetric) arthrometer test may be done at 20 degrees of flexion (134-N force) to quantify total AP displacement. The Lachman test is performed at 20 degrees of knee flexion. The pivot shift test is done and the result recorded on a scale of 0 to III, with a grade of 0 indicating no pivot shift; grade I, a slip or glide; grade II, a jerk with gross subluxation or clunk; and grade III, gross subluxation with impingement of the posterior aspect of the lateral side of the tibial plateau against the femoral condyle.

FCL insufficiency is determined by the varus stress test at 0 and 30 degrees of knee flexion (see Fig. 26-10). The surgeon estimates the amount of joint opening (in millimeters) between the initial closed contact position of each tibiofemoral compartment, performed in a constrained manner avoiding internal or external tibial rotation, to the maximal opened position. The result is recorded according to the increase in the tibiofemoral compartment of the affected knee compared with that of the opposite normal knee. This comparison is crucial, and it is important to avoid measuring only the degrees of varus or valgus rotation in the involved knee.

An increase in medial joint opening may occur compared with the opposite knee that represents a pseudolaxity because the increase is actually caused by medial tibiofemoral joint narrowing. When the test is conducted under a varus stress, the medial joint opening returns the limb to a more normal alignment, and there is no true medial ligamentous damage. The true amount of medial and lateral tibiofemoral compartment opening is later confirmed during the arthroscopic examination with gap tests. The primary and secondary restraints that resist lateral joint opening have been described previously.[78] The abnormal medial joint opening depends on the knee flexion angle at which the test is conducted and the integrity of the secondary restraints.

Tibiofemoral Rotation Test (Dial Test)

The tibiofemoral rotation test was first described by the senior author (F.R.N.)[162] and is used to estimate the amount of posterior tibial

TABLE 26-2 Diagnosis of Abnormalities

Abnormality	Diagnostic Test
Tibiofemoral alignment	Full-length standing radiograph: double support (closure of lateral tibiofemoral joint required)
Narrowing of medial tibiofemoral joint	Change in millimeters from opposite side on 45-degree PA weight-bearing x-ray or stress radiograph
FCL insufficiency	Increase in lateral joint opening at 30 degrees of flexion
FCL, PMTL, PL capsule insufficiency	Further increase in lateral joint opening at 30 degrees of flexion; increase in external tibial rotation at 30 degrees of flexion; varus recurvatum in extension
Lateral tibiofemoral joint separation	Standing radiograph shows increased joint width compared with opposite side; amount of increase on stress radiograph compared with opposite side
Varus recurvatum	Defined by degrees of hyperextension and varus angulation; elicited on supine varus recurvatum test. Standing tests with patient assuming maximal knee hyperextension position provides greatest subluxation. Estimate degrees of increase in varus and hyperextension.

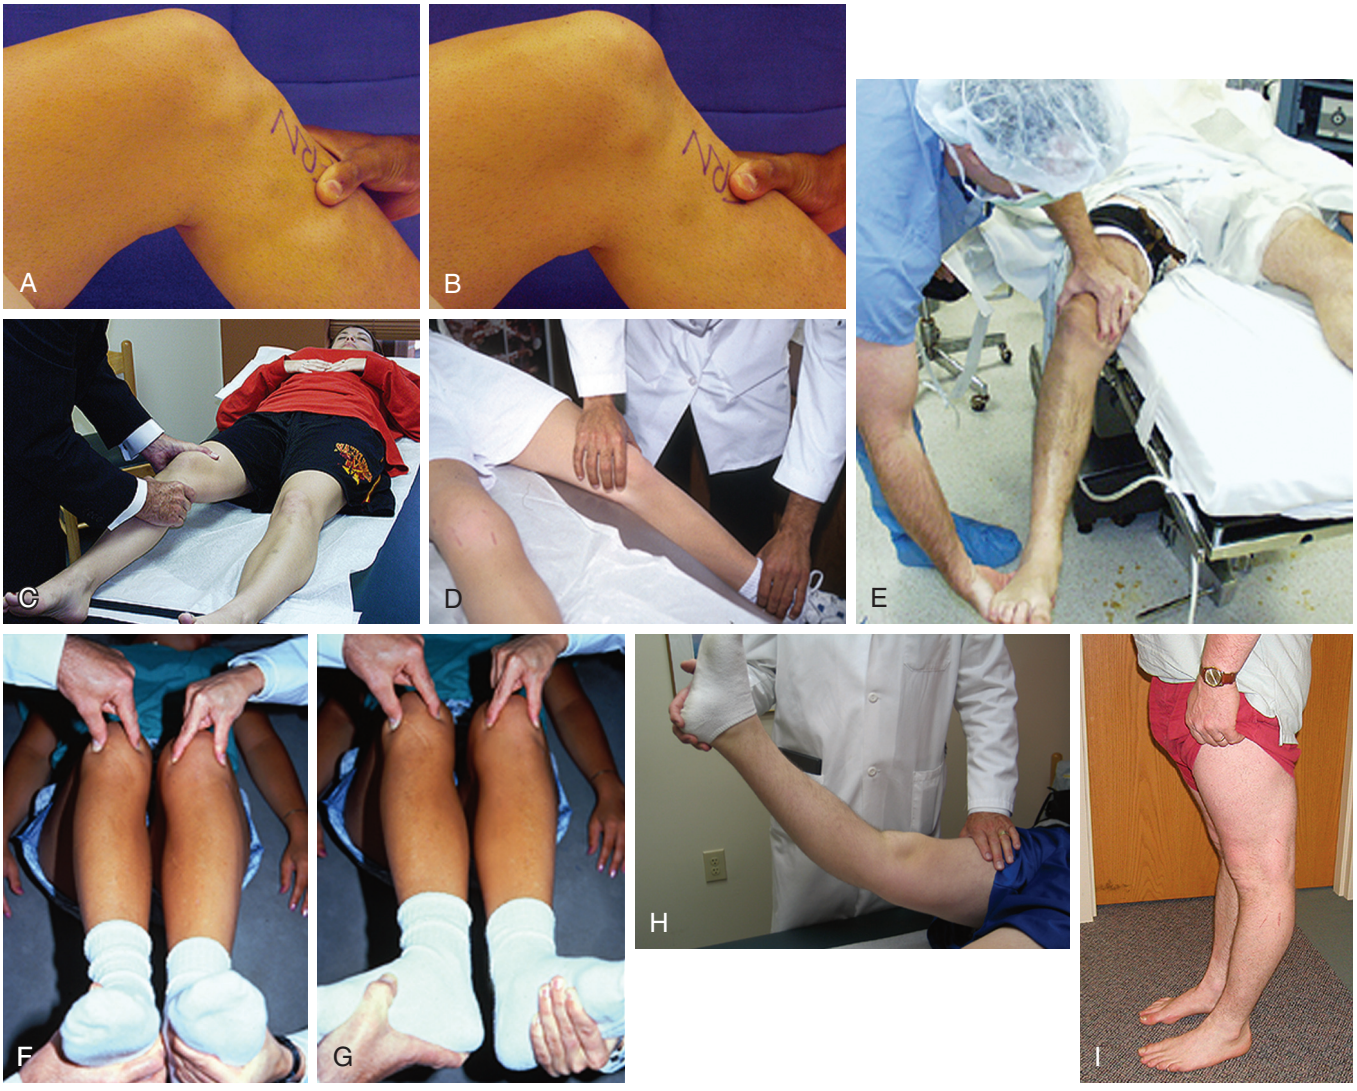

FIG 26-10 Manual knee tests. **A** and **B,** Posterior drawer test at 90 degrees of knee flexion. **C,** Lachman test. **D,** Valgus manual test for medial joint opening. **E,** Varus manual test for lateral joint opening. Dial test at 90 degrees of knee flexion in neutral tibial rotation (**F**) maximum external tibial rotation (**G**). Varus recurvatum in the supine (**H**) and standing (**I**) positions.

subluxation (see Fig. 26-10). The test is conducted in the following manner: (1) the tibia is positioned at 30 degrees of knee flexion, in neutral rotation; (2) the position of the anterior aspect of the medial and lateral tibial plateaus are determined in reference to the femoral condyles by palpation; (3) the tibia is externally rotated to its maximum position; (4) the positions of the medial and lateral tibial plateaus are palpated to determine an abnormal posterior subluxation of the lateral compartment or anterior subluxation of the medial compartment; (5) the examiner observes the location of the tibial tubercle to determine any increase in external tibial rotation compared with the opposite normal knee; and (6) the test is repeated at 90 degrees of knee flexion and may also be conducted by starting at the neutral tibial rotation position, progressing to internal tibial rotation.

If an increase in external tibial rotation is present, it represents either a posterior subluxation of the lateral tibial plateau (indicating injury to the FCL and PMTL) or anterior subluxation of the medial tibial plateau (indicating injury to the superficial medial collateral ligament [SMCL] and posteromedial structures). In some knees, both anteromedial and posterolateral subluxations are present.

The tibiofemoral rotation test involves close observation of the location of the internal and external tibial rotation axis and comparison of the location of this axis with that in the normal knee. With posterior subluxation of the lateral tibial plateau during external tibial rotation, the examiner may detect a shift in the axis of tibial rotation to the medial tibiofemoral compartment. Alternatively, with an anterior subluxation of the medial tibial plateau, the center of tibial rotation shifts to the lateral tibiofemoral compartment as the maximal external tibial rotation position is reached.

The advantages of the tibiofemoral rotation test over the traditional posterolateral drawer test[96] are (1) the knee may be positioned at varying flexion positions (30 and 90 degrees); (2) the tibia is less constrained because the foot is not held fixed to the examining table; and (3) the axis of tibial rotation can be observed as the tibia is rotated externally and internally. More information is gained when the tibiofemoral rotation tests are performed in a supine position. In the prone position, it is difficult to palpate the medial and lateral tibiofemoral position required to diagnose the abnormal compartment subluxations. The only indication for the prone dial test is a PCL-deficient knee in which the tibia can be gently displaced to a reduced anterior position during the rotation tests. In the supine position, the tibia can also be displaced anteriorly to prevent posterior subluxation, which makes the interpretation of the dial test more difficult.

A varus recurvatum test in both the supine and standing positions and the reversed pivot shift test are included in the assessment of posterolateral tibial subluxation. However, these represent qualitative tests that are difficult to measure in objective terms. Still, they provide useful information regarding the magnitude of the overall subluxation of the knee joint when two or more abnormal motion limits are present.

Radiographic Assessment

Radiographic assessment of lower limb alignment is based on full-length radiographs of the extremity with the patient in the standing position.[60,198] Separation of the lateral tibiofemoral compartment may occur, preventing a correct assessment of true tibiofemoral osseous alignment. Double-stance, full-length AP radiographs showing both lower extremities from the femoral heads to the ankle joints are obtained. The knee is flexed 3 to 5 degrees to avoid a hyperextension position, and the foot angle is set to approximately 10 to 12 degrees. If separation of the lateral tibiofemoral joint is observed on radiographs, it is necessary to subtract the lateral compartment opening so that the true tibiofemoral osseous alignment is determined and a valgus overcorrection at surgery is avoided as is discussed under Preoperative Planning.

FIG 26-11 Lateral stress radiographs used to quantify the increase in lateral tibiofemoral joint opening between knees. Approximately 67 N of varus force is applied, and a comparison is made of the millimeters of lateral tibiofemoral compartment opening between knees.

During varus-valgus testing at 30 degrees of flexion, the clinician should assess for a possible teeter-totter effect, in which simultaneous contact of the medial and lateral tibiofemoral compartments is not possible owing to advanced tibial obliquity and bone loss of the medial tibiofemoral joint.

Additional radiographs taken during the initial examination include a lateral at 30 degrees of knee flexion, weight-bearing PA at 45 degrees of knee flexion, and patellofemoral axial views. Telos medial or lateral stress radiographs may be required in select knees (Fig. 26-11).

The height of both patellas is measured on lateral radiographs (Fig. 26-12) to determine whether or not an abnormal patella infera or alta position exists that may be a factor in selecting an opening or closing wedge osteotomy, which would further decrease or elevate the patella position.[170,171]

The clinical algorithm for the preoperative clinical and radiographic assessment to determine candidates for either a medial opening wedge or lateral closing wedge osteotomy is shown in Figure 26-13.

PREOPERATIVE PLANNING

Calculations to Determine Angular Correction

The preoperative calculations for HTO involve measurements to determine the amount of angular correction desired to redistribute tibiofemoral forces while not altering tibial slope and tibiofemoral joint obliquity in the frontal plane.[60,166] The radiographic measurement and correction may require alteration at surgery with fluoroscopic analysis, as described. The normal tibiofemoral coronal alignment is shown in

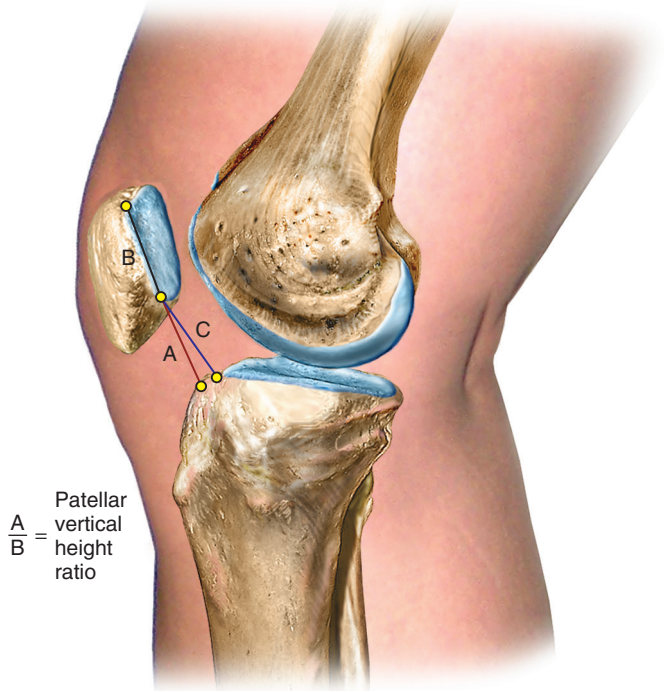

FIG 26-12 Method used to determine patellar vertical height ratio on lateral radiograph. The numerator, *line segment A*, is the distance between the most ventral (anterosuperior) rim of the tibial plateau and the lowest end of the patellar articular surface. The denominator, *line segment B*, is the maximum length of the patellar articular surface. An alternative numerator, *line segment C*, locates the tibial reference point on the middle of the tibial plateau. The patellar vertical-height ratio equals A/B or C/B.

Figure 26-14. In varus angulated knees, there is a slight increase in obliquity caused by medial tibiofemoral joint arthrosis principally involving the medial condyle.

An undercorrection or overcorrection in the coronal plane may result if the surgeon fails to recognize the effect of lateral tibiofemoral separation on increasing varus angulation from slack or deficient lateral soft tissues. Inaccurate calculations may also arise from failure to use the WBL from double-stance, full-length, standing radiographs of both lower extremities. A single-stance radiograph of the affected limb will show the maximum varus angulation caused by lateral condylar lift off; however, this should not be used for osteotomy calculations. A double-stance radiograph helps close the lateral tibiofemoral compartment so the osseous alignment is calculated, which is required for surgical correction.

Sabharwal and Zhao[187] compared lower limb coronal alignment on full-length, standing radiographs to supine intraoperative hip-knee-ankle fluoroscopy measurements in 102 limbs. There was a statistically significant mean difference between the two techniques (mean, 13.4 mm deviation in the WBL, measured from the center of the joint). This difference in the two techniques is of concern in the preoperative planning and the final intraoperative osteotomy correction in the coronal plane. There was no description of the effect of abnormal lateral joint opening on the standing radiographs that may account for errors in preoperative measurements. Furthermore, during surgery there was no description of the fluoroscopy technique. The surgeon must verify medial and lateral tibiofemoral joint contact to account for possible opening of the medial or lateral tibiofemoral joint during the WBL measurement.

CRITICAL POINTS Preoperative Planning

- Determine angular correction to achieve redistribution of tibiofemoral forces without altering tibial slope.
- Take into account abnormal lateral tibiofemoral separation from deficient posterolateral structures.
- Measure WBL on bilateral standing hip-knee-ankle radiographs. WBL is dependent on femoral and tibial lengths and angular deformity.
- Measure tibial slope on lateral radiographs.
- Increasing tibial slope increases anterior tibial translation and potentially tensile loads on the ACL.
- Decreasing tibial slope increases posterior tibial translation and potentially tensile loads on PCL.
- Do not alter normal tibial slope unless it is abnormal (>2 standard deviations above normal).
- Do not alter a normal tibial slope in ACL- or PCL-deficient knees.
- Maintain normal tibial slope: anterior gap at medial opening wedge should be half the posteromedial gap. Every millimeter of anterior gap change = 2 degrees change in tibial slope.

Timing of HTO in Knees with Ligament Deficiencies

Primary Varus Knees

- Cruciate reconstruction with HTO or later (no abnormal lateral joint opening present)

Double Varus Knees

- HTO first
- Posterolateral structures may shorten with valgus alignment
- Perform cruciate, posterolateral reconstructions later if required

Triple Varus Knees

- HTO first; cruciate and posterolateral reconstruction later

Opening Wedge Advantages

- Avoids lateral dissection, fibular osteotomy
- Large correction >12 degrees, avoids tibial shortening
- Distal advancement or reconstruction of the MCL in chronic MCL ruptures
- In subsequent posterolateral reconstructions, avoids proximal fibular osteotomy, allows FCL grafts to be fixated securely to proximal fibula

Closing Wedge Advantages

- Faster healing
- Earlier resumption of weight bearing
- Superior strength initial osteotomy fixation
- Decreased risk early loss of correction, nonunion
- More difficult to achieve correction at surgery
- Large closing wedge may elevate patellar height and decrease lower limb length; reverse applies with opening wedge

Opening Wedge HTO: Maintenance of Tibial Slope

- Opening wedge angle is dependent on the angle of coronal valgus correction and the angle of obliquity of the anteromedial tibial cortex.
- Every millimeter of alteration in anterior gap height results in a change of 2 degrees in tibial slope.

The fluoroscopy technique during HTO involves the surgeon placing an axial load against the foot to overcome medial or lateral joint opening, which is verified by the fluoroscopic image. The lower extremity should be held in 10 degrees of knee flexion and approximately 10 to 12 degrees of external rotation (hip to ankle axial

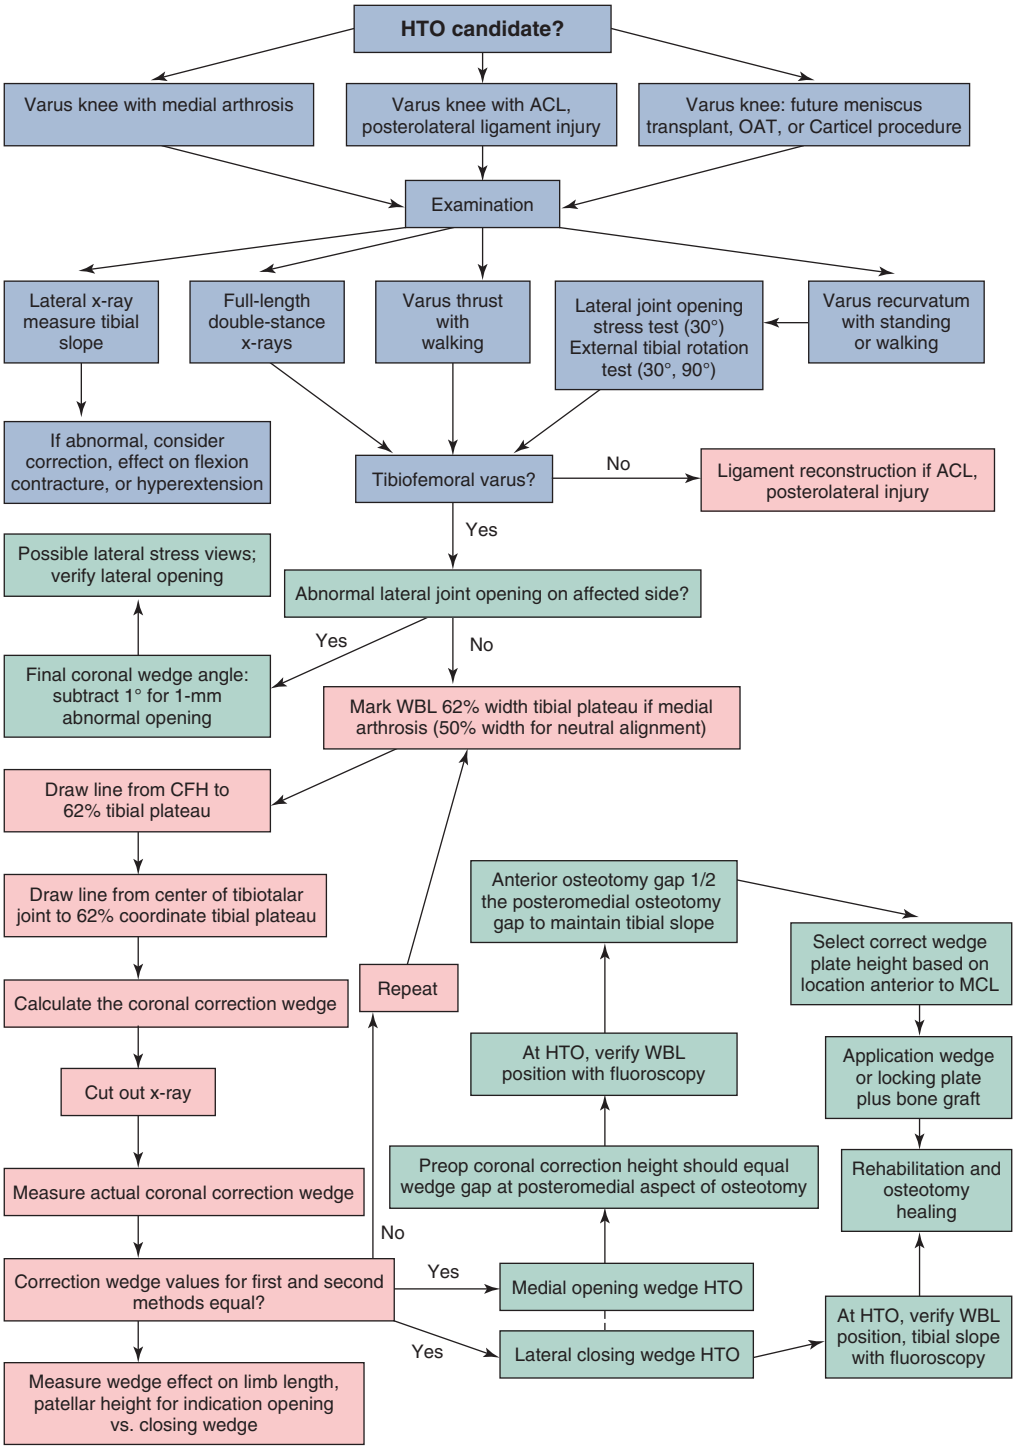

FIG 26-13 The clinical algorithm for the preoperative clinical and radiographic assessment to determine candidates for medial opening wedge or lateral closing wedge osteotomy. *ACL*, Anterior cruciate ligament; *CFH*, center femoral head; *HTO*, high tibial osteotomy; *MCL*, medial collateral ligament; *OAT*, osteochondral autograft transfer; *WBL*, weight-bearing line.

alignment simulating foot progression angle). The limb alignment rod at the knee joint can be observed to move medial to lateral with internal to external limb rotation, which is another source of error in measuring the WBL intersection at the tibia. This is because the alignment rod is placed anterior to the true center of axial rotation at the ankle joint, and therefore lower limb rotation induces this error. One advantage of the computerized navigation technique is that the WBL is centered through the hip-knee-ankle joints, and an alignment rod or cord used at surgery is placed anterior to these respective joints.

An example of the potential effect of the failure to account for increased lateral joint opening is shown in Figure 26-15. The case represents a 38-year-old man whose full-length, standing radiograph shows a varus angular deformity (mechanical axis) of 7 degrees and a 4-mm increase in lateral joint opening. The width of the tibial plateau

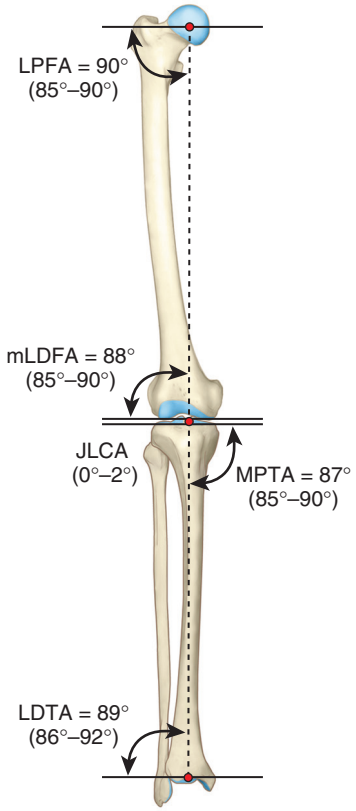

FIG 26-14 The normal tibiofemoral coronal alignment.

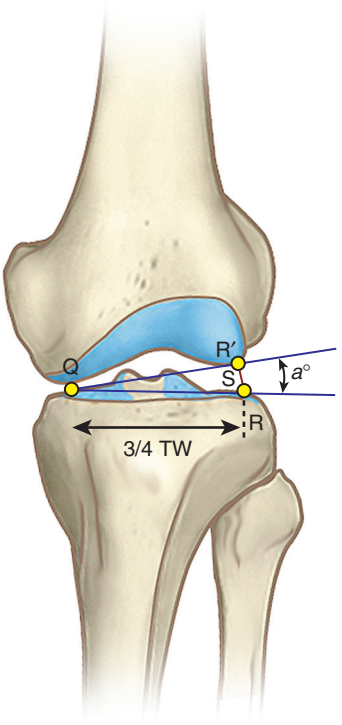

FIG 26-16 The effect of abnormal lateral joint opening on varus angular deformity. With a varus moment applied through a fulcrum, or center of rotation (Q), lateral joint space opening (S) occurs in the presence of slack lateral soft tissues resulting in an additional α degrees of varus angular deformity. *TW,* Total width tibial plateau.

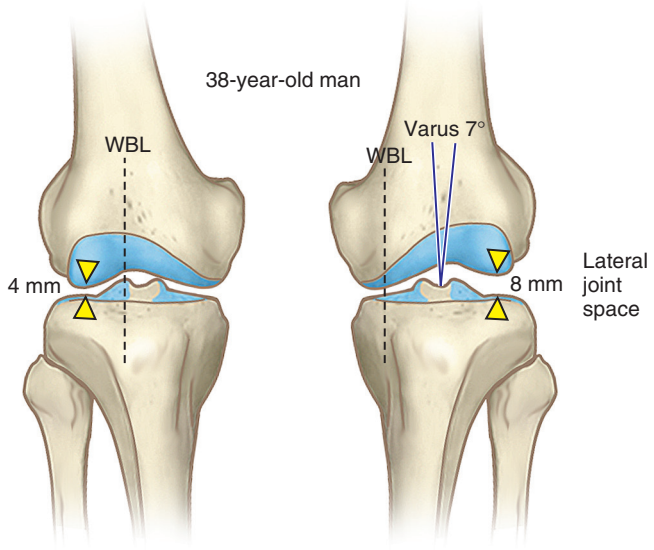

FIG 26-15 Sketch of standing anteroposterior radiograph. The lateral joint space is 8 mm on the left side and 4 mm on the right side. The calculated angular deformity resulting from the 4-mm joint opening is 3.7 degrees of the total 7 degrees of deformity. *WBL,* Weight-bearing line.

is 81 mm. The equation to determine the angular deformity resulting from the lateral tibiofemoral separation distance is:

$$\alpha = 76.4S/TW$$

Therefore, in this patient, the calculated amount of varus angular deformity caused by the lateral joint opening increase of 4 mm is 76.4 (4 mm)/81 mm = 3.7 degrees, or approximately 1 degree/mm increased lateral joint separation. Failure to account for the lateral joint opening would result in approximately 4 degrees of valgus overcorrection after HTO, assuming closure of the lateral tibiofemoral joint (Fig. 26-16). A WBL crossing the knee lateral to the 75% coordinate has the potential for a lift off of the medial femoral condyle and a cosmetic abnormal valgus alignment. Unicondylar weight bearing resulting from distraction of the medial compartment is undesirable and could result in subsequent arthritis of the lateral compartment, MCL laxity, and a progressive valgus deformity (Fig. 26-17). The WBL–tibial intersection depends on the coronal mechanical axis angle and the femoral and tibial lengths of the patient; the senior author's published study[60] showed the WBL axis to be more accurate than the anatomic axis for osteotomy correction.

Two methods are used to determine the correction wedge on preoperative radiographs.[60] First, the centers of the femoral head and tibiotalar joint (center of the talus) are marked on the full-length radiograph (Fig. 26-18). The desired correction in the WBL coordinate of the tibial plateau is identified and marked. This is usually placed at 62% of the tibial width (just at the down slope of the lateral tibial spine), which allows the WBL to pass through the lateral tibiofemoral compartment, providing a 2 to 3 degrees of angular valgus overcorrection. The 62% WBL coordinate is used if there is medial tibiofemoral articular cartilage damage, and the intention is to transfer major loads to the lateral compartment. A 50% to 54% WBL coordinate is chosen if there is no medial tibiofemoral joint damage and the surgeon wishes to correct to a neutral axial alignment (e.g., before posterolateral reconstruction). One line is drawn from the center of the femoral head to the selected percent WBL intersection at the tibia, and a second line is drawn from the center of the tibiotalar joint to the same tibial

FIG 26-17 A 32-year-old woman with abnormal lateral joint opening underwent high tibial osteotomy elsewhere. The preoperative planning failed to account for the abnormal lateral joint opening, which resulted in a severe valgus overcorrection and need for revision osteotomy.

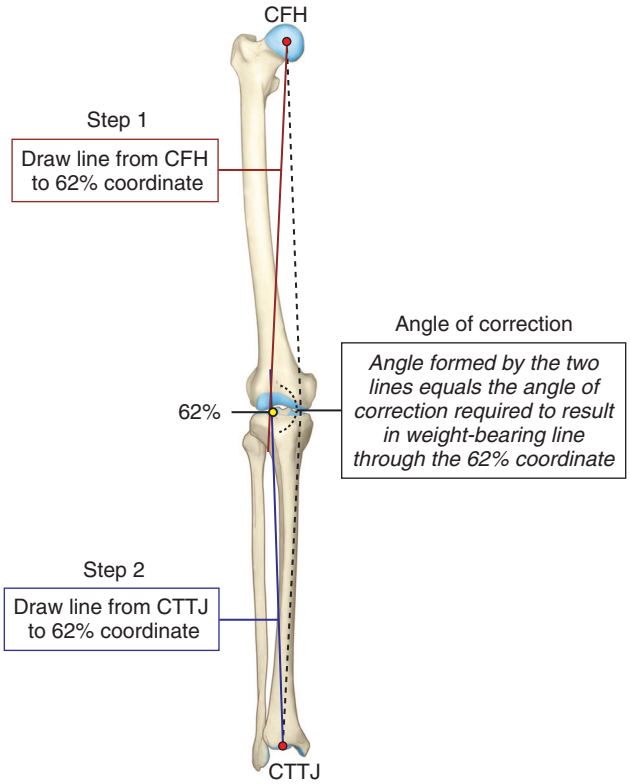

FIG 26-18 The method used to calculate the correction angle of a high tibial osteotomy using a full-length anteroposterior radiograph of the lower extremity. The lines from the centers of the femoral head (CFH) and tibiotalar joint (CTTJ) converge in this example at the 62% coordinate.

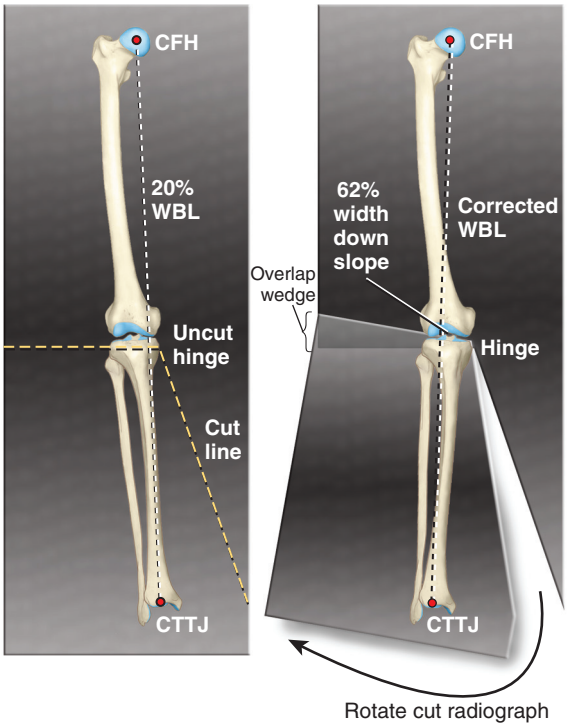

FIG 26-19 An alternative method used to calculate the correction angle of a high tibial osteotomy using a full-length anteroposterior radiograph of the lower extremity. The radiograph is cut to allow the center of the femoral head (CFH), the 62% coordinate, and the center of the tibiotalar joint (CTTJ) to become collinear. The angle of the resulting wedge of radiograph overlap equals the desired angle of correction. The example is provided for a closing wedge osteotomy. The same technique is used for an opening wedge osteotomy in which the medial tibial opening wedge is made to obtain the desired correction. *WBL,* Weight-bearing line.

coordinate position. The angle formed by the two lines intersecting at the tibia represents the angular correction required to realign the WBL through this coordinate. An alternative method was published[60] in which the previously discussed femoral and tibial axis lines intersect at the hinge point of the tibial osteotomy. This technique ends up with a similar measurement for the angular correction. However, the surgeon does not have the measured WBL tibial intersection required for intraoperative fluoroscopy verification.

The second method of determining the correction wedge involves cutting the full-standing radiograph horizontally through the line of the superior osteotomy cut (Fig. 26-19). A vertical cut of the lower tibial segment (opening or closing wedge) is made to converge with the first cut. The distal portion of the radiograph is aligned until the center of the femoral head, the selected WBL coordinate point on the tibial plateau, and the center of the tibiotalar joint are all collinear. With the radiograph taped in this position, the angle of the wedge formed by the overlap of the two radiographic segments is measured and compared with the value obtained using the first method. The mechanical axis is measured to determine the angular correction. If there is a discrepancy between the two correction wedge angles, the procedures should be repeated.

Calculations to Determine Tibial Slope and Clinical Indications to Change Tibial Slope

Lateral radiographs are examined and measurements made of the tibial slope. Abnormal posterior sloping of the tibia in the sagittal plane may

occur after tibial osteotomy, tibial fractures, growth abnormalities, or rarely, as a congenital abnormality.

Several methods have been reported to measure the medial and lateral tibial slope based on lateral tibial radiographs (Table 26-3).[44,50,83,86,120,172,178] Each method results in different slope values for the same tibia (Fig. 26-20), and all studies show high standard deviations and ranges, indicating that tibial slope may show variation among individual patients. Brazier and colleagues[36] measured 83 lateral knee radiographs and concluded that the methods of slope measurement of proximal tibial anatomic axis (PTAA) and posterior tibial cortex were more reliable than other methods. Genin and coworkers[70] and Julliard and associates[108] recommended using the tibial mechanical axis to represent the true tibial slope. The PTAA is our preferred method for HTO, and the anterior tibial cortex measurement is used when cutting the proximal tibia during total knee arthroplasty (TKA).

Most authors have measured the medial tibial slope; only a few have measured and provided data on the lateral tibial slope.[129,203,229] The lateral tibial slope is less angled than the medial tibial slope. Few investigators have distinguished between the tibial plateau osseous slope and the change that would occur in slope if the articular cartilage and meniscus were added to the calculations. The osseous tibial slope is most commonly noted in the literature and is measured from sagittal radiographs. The true tibial slope, which includes the articular cartilage and meniscus, was noted to be 6 degrees less than the osseous tibial slope according to Jenny and colleagues.[104]

Increasing the tibial slope increases anterior tibial translation and, potentially, tensile loads on the ACL or an ACL reconstruction (Fig. 26-21).[51] Conversely, decreasing the tibial slope theoretically would increase tensile loads on the PCL and shift the tibia to a more anterior position. Shelburne and colleagues[191] studied how changes in posterior tibial slope affected tibial shear force, anterior tibial translation, and knee ligament loading during standing, squatting, and stance-phase walking activities. These authors used a validated computer modeling of the lower extremity and altered the posterior tibial slope in 1-degree increments up to a maximum of 10 degrees of change in slope. The results showed that anterior tibial translation increased as posterior tibial slope increased, and ACL force increased (for standing and walking) as tibial slope increased. It is important to note that the increased ACL force values were in the modest range because ACL force increased by 16 N for each degree of increase in posterior tibial slope. The model predicted a 6-N decrease in PCL force and a 15-N decrease in posterolateral ligament force for each degree increase in posterior tibial slope. Similar results were reported by Marouane and associates[124] who used two finite element models of the knee joint to

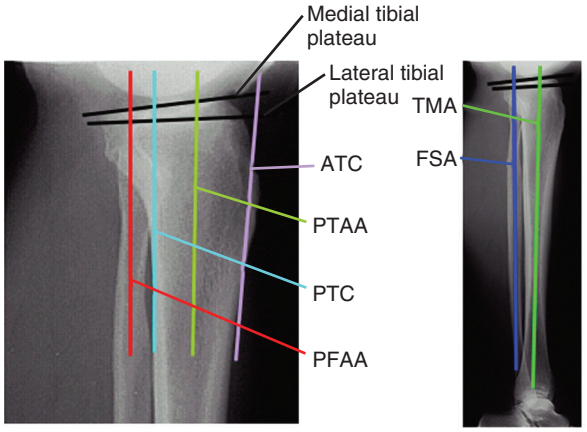

FIG 26-20 Some reported radiographic techniques to measure the tibial slope. The values obtained depend on the anatomic site selected on the tibia. Selected literature references for reported values are shown in Table 26-3. *ATC*, Anterior tibial cortex; *FSA*, fibular shaft axis; *PFAA*, proximal fibular anatomic axis; *PTAA*, proximal tibial anatomic axis; *PTC*, posterior tibial cortex; *TMA*, tibial mechanical axis. FIG 26-21 The effect of an increase in the tibial slope is shown. The degree of tibial slope is based on proximal tibial anatomic axis.

model the effect of changes in posterior tibial slope on ligament loads and tibial translation and to predict contact pressures of the lateral and medial plateau (under 100-N axial load). The data showed that, at mid stance in the gait model, a change in posterior tibial slope from –5 to +5 degrees resulted in a change in ACL force from –79 to +136 N from the 0 neutral reference point. This corresponded to a change in AP position from –1.2 to +1.2 mm from the 0 neutral position. In comparison, the study by Shelburne and colleagues[191] showed an alteration in posterior tibial slope of –5 to +5 degrees in walking resulted in a change from –75 to +80 N in ACL force, as well as a change from –2.3 to +2.4 mm in anterior tibial translation relative to reference values. Accordingly, these studies show that there is the potential for higher ACL forces on a healing ACL graft substitute with an abnormal tibial slope; however, the increase in forces is in the modest range and well below predicted ACL graft rupture. It would thus be prudent to measure the tibial slope in patients undergoing ACL surgery and determine those outliers (±2 standard deviations) in whom a more conservative rehabilitation program should be used to protect the healing graft in the early to mid postoperative period. This suggestion may even have increased relevance with low-strength ACL grafts that have decreased healing potential, as shown with allografts. Marouane and associates[124] reported in their second finite element model that a 1400-N axial load at 45 degrees of knee flexion at posterior tibial slopes of –5 degrees, neutral 0 degree, and 5 degrees produced calculated ACL forces of 102 N, 181 N, and 317 N, respectively.

Giffin and coworkers[75] reported in cadaveric knees that an increase of 5 degrees in the tibial slope produced an anterior shift in the resting position of the tibia (maximum, 3.6 mm ± 1.4 mm at full extension). However, under a 200-N axial load, there was only a 2-mm anterior shift in the tibiofemoral contact position (30 and 90 degrees) and no increase in ACL forces. The authors concluded that small changes in tibial slope under simulated weight-bearing conditions would have little effect on tibiofemoral position; however, the 200-N axial load does not simulate larger weight-bearing loads with activity.

In a second study conducted by Giffin and associates,[74] a 5-mm anterior opening wedge osteotomy in PCL-sectioned cadaveric knees was performed, and an anterior shift in the tibia resting position of approximately 4 mm was measured. The beneficial effect of an increase in tibial slope in a PCL-deficient knee should be viewed in terms of functional loading conditions, and it is questionable whether the resting no-load position data are applicable to in vivo loading conditions. In this study, under a combined 134-N tibial translation load and 200-N axial compressive load, there was no statistical difference in the amount of posterior tibial subluxation between the PCL-deficient and PCL-deficient osteotomy knees. The data show that the tibia reached a similar abnormal posterior tibial position (mean, 90 degrees AP translation: intact knee, 10 mm; PCL deficient, 20.6 mm; PCL deficient osteotomy, 20.3 mm). The authors concluded that "increasing the tibial slope would improve stability in the PCL-deficient knee"; however, this would be true only for conditions of no posterior tibial loading not expected in functional activities. The data in this study may be viewed from an opposite standpoint to indicate that PCL graft reconstruction is warranted in symptomatic knees because the opening wedge osteotomy is not effective in preventing posterior tibial subluxation under posterior tibial loading conditions.

In cadaveric knees, Agneskirchner and colleagues[4] studied the effect of an opening wedge osteotomy combined with a flexion osteotomy (to change the tibial slope) on tibiofemoral contact pressures and the resultant tibiofemoral position. The study reported that the flexion osteotomy shifted the tibiofemoral contact to a more anterior position (15 degrees of flexion osteotomy, ~5 mm, 30 degrees of knee flexion) that neutralized the effect of sectioning the PCL and reduced pressures of the posterior half of the tibial plateau. The authors suggested in varus-angulated, PCL-deficient knees with associated posterolateral knee ligament injury and knee hyperextension that an associated change in tibial slope would have a beneficial effect. Only quadriceps-induced leg extension loading was used without weight-bearing loads or posterior translational loads that are required to determine the resultant tibiofemoral position under more physiologic loading conditions. The quadriceps loading (to resist the applied external flexion moment) changed with the quadriceps extension force, nearly doubling with the flexion osteotomy (without osteotomy, ~550 N, with 15 degrees of flexion; with osteotomy, ~1100 N quadriceps applied load). In fact, the increased quadriceps loading increased joint contact pressures.

In contrast to the study just discussed, Rodner and coworkers[183] reported in cadaveric knees that an increase in tibial slope in the ACL-deficient knee at the time of an HTO has the potential to redistribute

tibiofemoral contact pressures to a more posterior position on the tibial plateau. From a theoretical standpoint, a redistribution of pressures posterior on the tibial plateau would be detrimental to the long-term success of an HTO in ACL-deficient knees with meniscectomy and posterior tibial plateau articular damage. The cadaver knee studies involved uniaxial loading knee joint loads instead of the quadriceps loading in the study by Agneskirchner and colleagues,[4] thereby demonstrating the marked effect that in vitro experimental loading conditions have on joint contact pressures and study conclusions.

Brandon and associates[35] measured the tibial slope in 100 ACL-deficient patients and 100 controls and reported that female and male patients had similar tibial slope measurements. ACL-deficient female and male patients had increases in tibial slope (mean values increased 3.6 degrees and 2.4 degrees, respectively), and the high-grade pivot shift patient group had an increase in tibial slope (mean value increased ~2 degrees). The measurements show high standard deviations (~35% of the mean values), and it is probable that the few degrees difference among patient groups are not clinically significant or would result in increased ACL load and anterior tibial displacement.

Dejour and colleagues[53] evaluated chronic ACL-deficient knees with monopodal lateral weight-bearing films (knee flexed 20 to 30 degrees with the quadriceps contracted) and compared the anterior tibial translation with the tibial slope. The tibial slope was defined as the angle between the medial tibial plateau and the long axis of the tibia, which had an average value of 6 degrees. The anterior tibial translation was defined as the distance between a parallel line at the posterior medial tibial plateau and a posterior point on the medial femoral condyle. The authors reported a statistically significant relationship between the standing anterior tibial translation and the tibial slope in both normal and chronic ACL-deficient knees. The regression line showed a 6 mm increase in anterior tibial translation for every 10-degree increase in tibial slope. However, it should be noted that a wide variation was present in the data between knees. For example, in chronic ACL-deficient knees with a tibial slope of 10 degrees, anterior tibial translation varied from approximately –2 to 12 degrees.

Griffin and Shannon[73] summarized the clinical role of HTO with knee ligament instability, showing the benefit of an anterior opening wedge HTO for severe recurvatum and correcting an abnormal increased tibial slope in select patients who had failed multiple ligament reconstructions.

Marti and coworkers[125] recommended that knees with ACL insufficiency and associated medial arthritis with a tibial slope of 10 degrees or more undergo correction at the time of a varus-producing osteotomy. However, no clinical data were provided to demonstrate whether a change in slope decreased instability symptoms. Other authors[54] have discussed increases in ACL tensile loads when tibial slope exceeded 10 degrees and postulated the need for correction, again without clinical data.

Griffin and Shannon[73] noted that the anterior tibial subluxation with ACL insufficiency results in a "copula" owing to increased damage of the medial plateau; however, the effect of a medial meniscectomy on producing the same effect should be considered.

We agree with recommendations to correct tibial slope when a distinct abnormality is present (Figs. 26-22 and 26-23). The published literature does not provide objective data regarding the degrees of abnormal increase or decrease in tibial slope when corrective osteotomy is indicated where there is an associated ACL or PCL insufficiency.

It is probable that a change in AP shear forces, cruciate tensile loads, and tibiofemoral contact under dynamic conditions would not have clinical significance after a 5-degree change in the tibial slope when the preoperative tibial slope is in the normal range. Therefore changing

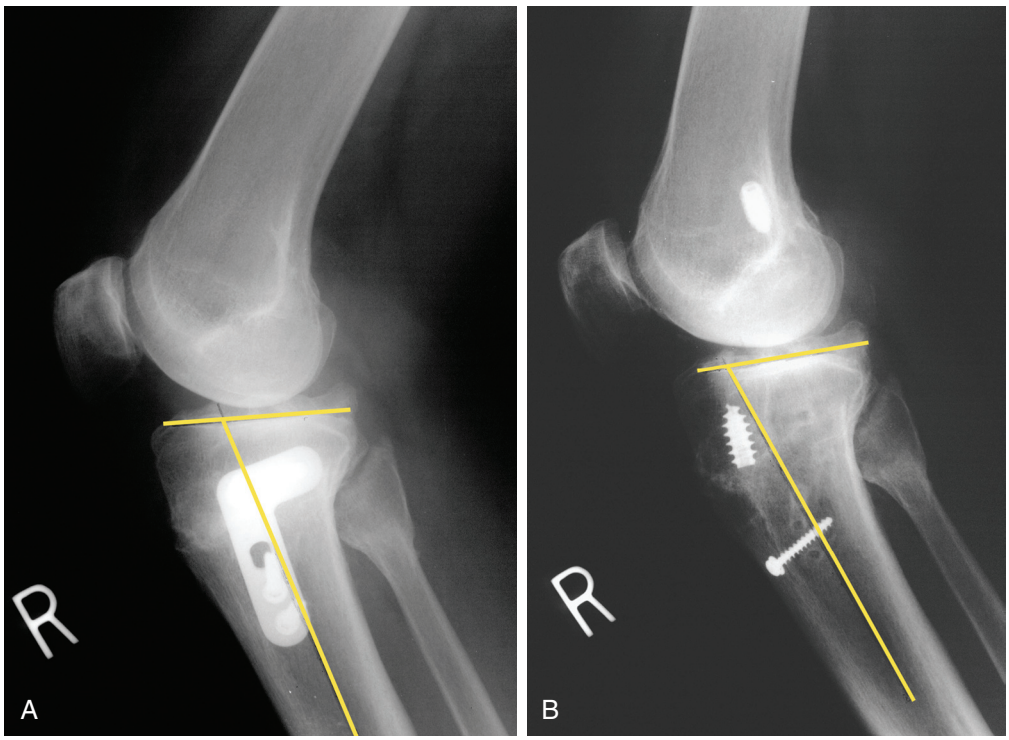

FIG 26-22 Radiographs of a 52-year-old physician referred for treatment after a closing wedge osteotomy (**A**) and subsequent anterior cruciate ligament (ACL) bone-patellar tendon-bone autograft (**B**) that failed. It would have been desirable to correct the abnormal tibial slope, which may have been a factor in the ACL graft failure.

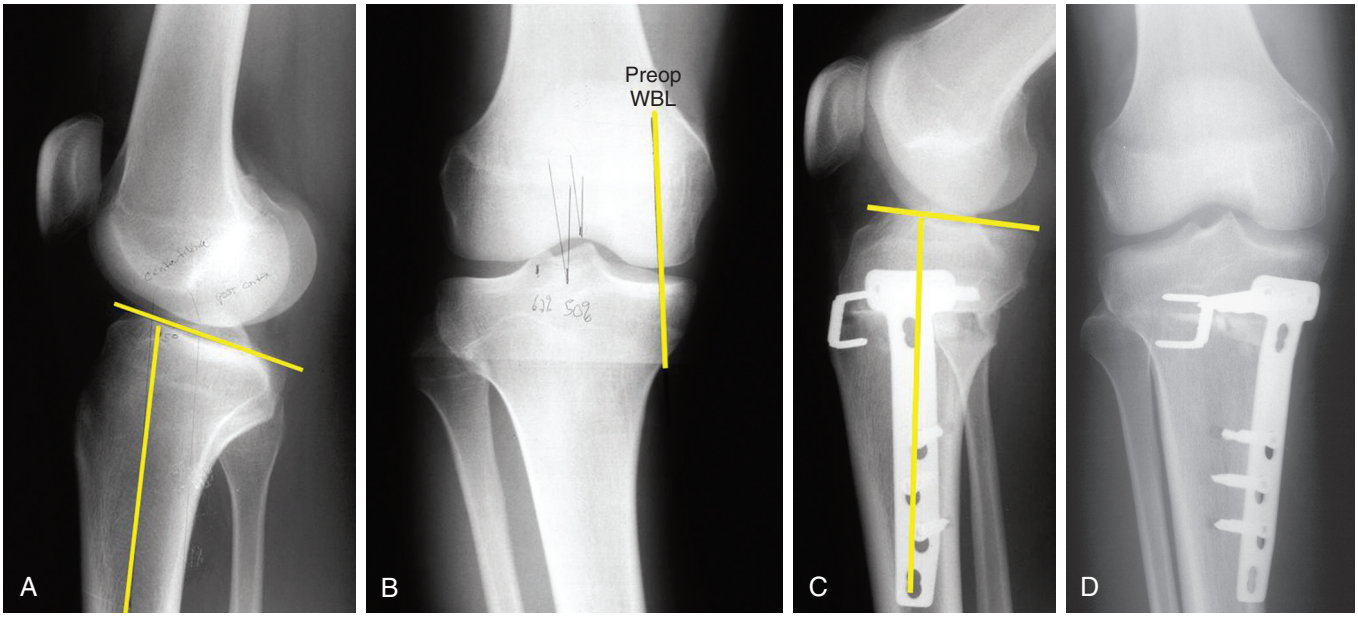

FIG 26-23 **A** and **B,** Preoperative radiographs of a 24-year-old man with bilateral severe varus angulation with medial joint line pain. **C** and **D,** Postoperative radiographs after a biplanar opening wedge osteotomy that was done to correct the abnormal tibial slope. *WBL,* Weight-bearing line.

the tibial slope to alter the tibiofemoral contact position by a few millimeters to produce an anterior or posterior shift in tibia position (to an area of less cartilage damage) has theoretical benefits but has not been proven in clinical studies to be adopted as a treatment recommendation.

There are patients who have a distinctly abnormal tibial slope from a prior osteotomy, tibial fracture, or growth abnormality or an underlying genetic variability in which correction of the tibial slope is required before cruciate ligament surgery or other conditions discussed. Occasionally, ACL revision patients have an abnormally increased slope that should be corrected before ACL revision surgery. Empirically, a tibial slope 2 standard deviations above normal or more (based on the method) may be considered for correction. In these knees, at the time of HTO, it is possible to decrease the tibial slope to normal or below normal in ACL-deficient knees, or to increase the slope in PCL-deficient knees to alter loads on the respective cruciate ligament and possibly change the abnormal resting tibiofemoral weight-bearing position.

A normal tibial slope should not be altered in ACL-deficient knees or PCL-deficient knees undergoing a varus-producing opening wedge osteotomy. The rule is described elsewhere in this chapter (Opening Wedge Osteotomy: Preservation of Tibial Slope) that the anterior gap at the medial opening wedge should be one half of the posteromedial gap to maintain a normal tibial slope.[164] For every 1 mm of anterior gap change, an approximate 2-degree change in tibial slope would be produced. This is based on the angle of the anteromedial tibial cortex, the tibial width, and the AP distance where the gap measurement is made (see Table 26-5). It is common in opening wedge osteotomies to incorrectly produce a symmetrical anterior and posterior gap at the osteotomy site, which results in a considerable increase in the tibial slope, potentially leading to a decrease in knee extension and increase in ACL tensile loads. For example, a change in the tibial slope by 10 degrees would result if an anterior gap measurement error of only 5 mm occurred. The final tibial slope is verified at surgery by lateral fluoroscopic views.

If the surgeon elects to decrease the tibial slope, a staple may be placed at the tibial tubercle after the osteotomy is carefully closed anteriorly to the desired amount. In the senior author's experience, biplanar corrections require the use of a secure locking plate design to maintain the correction because it is necessary to extend the osteotomy through the lateral tibial cortex to close the anterior osteotomy gap (Fig. 26-24). Caution is required when closing the anterior osteotomy gap to apply only gentle hyperextension pressure on the tibia. If any resistance is obtained, it is necessary to be sure the posterolateral tibial cortex has been osteotomized to prevent a lateral tibial plateau fracture from occurring just anterior to the remaining posterolateral cortex.

Song and associates[194] reported that the normal tibial slope would be maintained if the gap or millimeters of opening along the anteromedial cortex of the anterior plate was two thirds the gap at the location of the posterior plate. The reader should note that the authors are referring to the location of two plates placed along the anteromedial tibial cortex and not the most posterior and anterior gap of the tibial opening wedge discussed in a Noyes and colleagues study (anterior gap 50% of posterior gap).[164] The data of Noyes and colleagues' study allow the gap to be computed along the entire anteromedial cortex. The Song et al[194] study does not specify where the two plates are placed, whereas data of the Noyes and colleagues' study[164] show the actual gap distance where one or two plates would be placed.

Hohmann and coworkers[91] retrospectively reviewed the radiographs of 67 patients who had a closing wedge HTO and reported a mean decrease of 4.9 degrees in the tibial slope. They suggested that this occurred because of the triangular geometry of the tibia, with a larger width of bone removed from the anterolateral portion of the lateral tibia.

Timing of Procedures

The timing of HTO and ligament reconstructive procedures is based on several factors (Table 26-4 and Fig. 26-25). In primary varus knees that do not demonstrate abnormal lateral joint opening and external

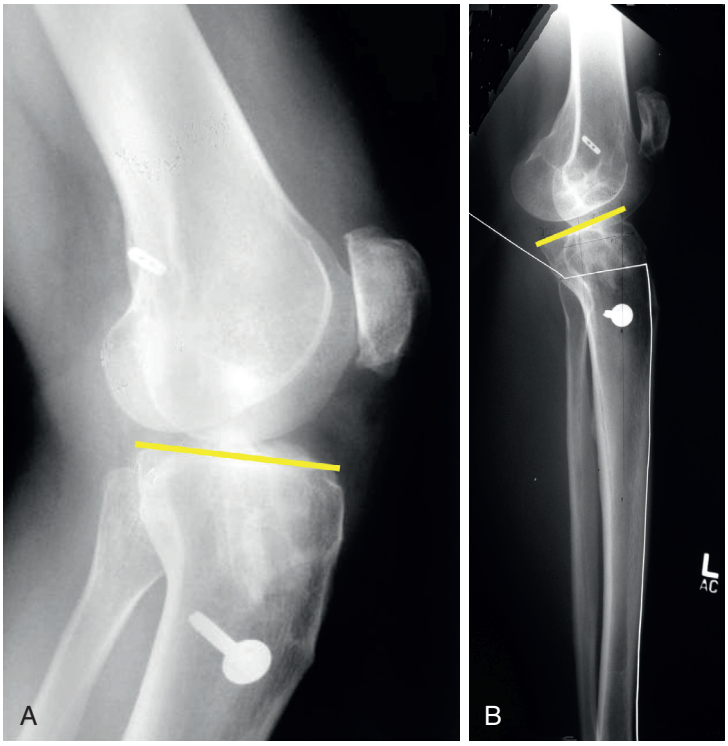

FIG 26-24 A 42-year-old athletic woman sustained an anterior cruciate ligament (ACL) rupture and subsequently underwent an ACL reconstruction that failed for unknown reasons. Two ACL revision reconstructions also failed. She became disabled and had severe giving way with walking and all daily activities. **A,** Lateral radiograph in which the abnormal posterior tibial slope was not recognized. **B,** The posterior tibial slope measured on this long-leg radiograph was 22 degrees. The opposite leg had a similar congenital abnormal tibial slope. The patient required a biplanar osteotomy and ACL revision reconstruction.

TABLE 26-4 Indications and Timing of Knee Ligament Reconstructive Procedures

Ligament Deficiency	Surgical Procedure	Timing Related to HTO	Indications/Comments
ACL	**Autograft***: 1. Central third B-PT-B 2. Semitendinosus-gracilis four-strand 3. QT-PB **Allograft:** 1. B-PT-B 2. Achilles tendon 3. Others†	With HTO only in primary varus knees that do not have abnormal lateral joint opening. Stage HTO double, triple varus knees.	Any patient who had instability before HTO and who should not risk a further trial of function and possible reinjury Consider when secondary ligamentous restraints are lost (pivot shift III + impingement, >10 mm increased anterior displacement involved knee) and with associated medial or FCL, PL deficiency. When meniscus repair is performed; athletically active patient desiring best knee possible for return to sports
FCL, PMTL (PL structures partial injury, increase 5-mm lateral joint opening, 5-10 degrees external rotation)	Usually not required after HTO. Confirm negative gap test for abnormal lateral joint opening if ACL reconstruction required (primary vs. double varus knee).	Avoid FCL reconstruction	Expect adaptive shortening of FCL, lateral tissues in majority after valgus producing osteotomy. Prefer opening wedge HTO. If closing wedge HTO, avoid disrupting tibiofibular joint, with proximal migration and laxity of PL structures.
FCL, PMTL, PL capsule complete deficiency	1. Proximal advancement PL structures (interstitial stretching). 2. FCL, PMTL anatomic reconstruction with autograft or allograft.	Staged procedure: HTO first, followed by combined ACL, FCL/PMTL anatomic reconstruction	Usually have increased lateral joint opening of 8 mm at the intercondylar notch (≥12 mm at periphery), increased external tibial rotation of 15 degrees, varus recurvatum, requiring PL reconstruction. PL and ACL reconstructions always performed together.

*Ipsilateral or contralateral autogenous grafts preferred over allografts.
†We prefer allografts with bone compared with anterior tibialis.
ACL, Anterior cruciate ligament; *B-PT-B*, bone-patellar tendon-bone; *FCL*, fibular collateral ligament; *HTO*, high tibial osteotomy; *PL*, posterolateral; *PMTL*, popliteal muscle-tendon-ligament; *QT-PB*, quadriceps tendon-patellar bone.

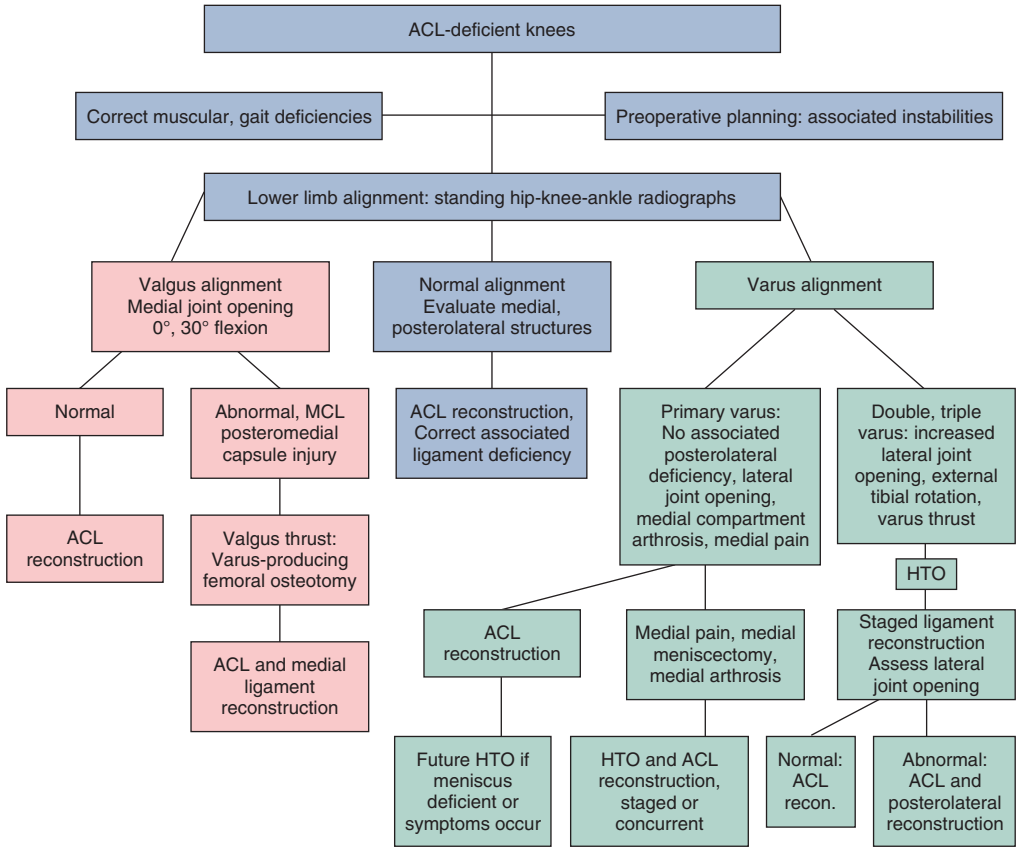

FIG 26-25 Timing of a high tibial osteotomy (HTO) and knee ligament reconstructive procedures. *ACL,* Anterior cruciate ligament; *MCL,* medial collateral ligament. (From Noyes FR, Barber-Westin SD. Revision anterior cruciate ligament surgery with use of bone-patellar tendon-bone autogenous grafts. *J Bone Joint Surg Am.* 2001;83:1131-1143.)

tibial rotation, the HTO and cruciate reconstruction may be performed at the same setting.[152] In double and triple varus knees, the ligament reconstructive procedures are performed after the HTO to reduce the risk of complications.[159] Prolonged rehabilitation and an increased risk of knee arthrofibrosis and motion problems have been described after HTO and ligament reconstructive procedures are performed simultaneously.[34,117,208]

We prefer to perform the HTO first and, after adequate healing of the osteotomy, the required ligament reconstructive procedures are performed. In ACL-deficient double varus knees, an increase in the lateral tibiofemoral joint gap test contraindicates ACL reconstruction. HTO is effective in decreasing abnormal loads in the lateral and posterolateral tissues, allowing physiologic remodeling and shortening to occur, particularly when the deficiency of the posterolateral structures is only moderate (5 to 8 mm of increased lateral joint opening, 10 degrees of increased external tibial rotation).[152,159] In a study conducted by us,[152] described later in this chapter, 22 of 41 double varus knees (54%) had abnormally increased lateral joint opening on varus stress testing before osteotomy. Of these, only five (12%) had this abnormal joint opening at follow up. An FCL and posterolateral reconstruction was avoided in many patients. A subgroup of 11 patients (27%) did not require ACL reconstruction because instability symptoms did not exist after the HTO.[152]

In triple varus knees, the ACL and posterolateral structures are reconstructed after the HTO to allow all ligament structures to function together to resist anterior subluxation, abnormal lateral tibiofemoral joint opening, and varus recurvatum. These represent major surgical procedures that are always staged and not combined with the HTO.

Cruciate Graft Options

A four-strand semitendinosus-gracilis (STG) autograft may be harvested from the involved side with little morbidity. Most patients undergoing HTO will not be involved in strenuous athletics, and a STG autograft provides suitable stability for light recreational activities. In revision knees, a STG graft may be used if there are no enlarged femoral or tibial tunnels.

A bone-patellar tendon-bone (B-PT-B) autograft is preferred if there is gross anterior subluxation (grade III pivot shift). In knees undergoing revision ACL reconstruction in which the ipsilateral patellar tendon was previously harvested, the contralateral B-PT-B graft or the ipsilateral quadriceps tendon-patellar bone (QT-PB) graft are preferred substitutes.[153,157] However, care must be taken when harvesting these autografts from the same knee at the time of the osteotomy. The opposite knee may be used for graft harvest.

The use of allografts for ACL reconstruction is controversial owing to the higher graft stretch-out and failure rates compared with bone-patellar tendon-bone autografts as discussed in detail in Chapters 7 and 8.[149-151,160] If an allograft is required, the B-PT-B has an advantage of more secure bone fixation.

Graft preferences for PCL reconstruction are a two-strand QT-PB autograft or allografts, further described in Chapter 16.[154,156] The options for surgical restoration of deficient posterolateral structures are described in Chapter 17.

Opening Versus Closing Wedge Osteotomy

The two most common operative techniques for correcting a varus deformity are the opening and the closing wedge tibial osteotomies. An opening wedge avoids the lateral dissection and fibular osteotomy. Knees that require a large angular correction of greater than 12 degrees are candidates for the opening wedge procedure because it avoids excessive tibial shortening.

Opening wedge osteotomy is advantageous in knees that have chronic medial ligamentous deficiency (MCL, posteromedial capsule), in which a distal advancement or reconstruction of the MCL is required. Knees with rupture of the posterolateral structures requiring posterolateral reconstruction are candidates for opening wedge osteotomy to avoid a proximal fibular osteotomy because an FCL graft will be anchored to the proximal fibula. Opening wedge osteotomy is advantageous in cases of patella alta or decreased lower limb length which would be made worse by a closing wedge osteotomy. A significant patella infera is a relative contraindication for an opening wedge osteotomy. A significant patella alta is a relative contraindication for a closing wedge osteotomy.

The major disadvantage of an opening wedge osteotomy is that an appropriate structural corticancellous autograft or allograft is required to restore the anteromedial and posteromedial cortex, add fixation strength, and promote osseous union (with major corrections). Autogenous bone grafting of the open defect aids in promoting prompt union with reduced risk of varus collapse caused by a delayed union.

Several opening wedge plate designs are available. We prefer a tibial plate with locking screws to achieve secure osseous fixation.[200] The reader is referred to the appropriate literature by the respective manufacturer, because each locking plate design is different and the recommended technique must be followed. There are rules that must be followed to avoid changing the tibial slope with the use of any fixation plate. A greater chance of increasing the posterior tibial slope exists if an opening wedge buttress plate is placed in an anterior position.[39] With attention to this problem during surgery, the normal tibial slope in the sagittal plane can be preserved with any of the available plate designs.[164]

A disadvantage of an opening wedge osteotomy is that transection of the superficial distal attachment of the MCL is required. In an opening wedge osteotomy of 5 mm, the MCL fibers may be incompletely transected at several different levels (pie-crust approach) to lengthen the ligament. However, osteotomies entailing a correction greater than 5 mm require distal MCL sectioning, careful reflection from the osteotomy site, and reattachment.

The closing wedge osteotomy has the advantage of faster healing and early resumption of weight bearing because contact of two large cancellous surfaces of the proximal tibia is achieved. The initial interval fixation of the osteotomy is more secure than an opening wedge procedure, and there is less chance for a change in osteotomy position and loss of correction. It is more difficult (compared with the opening wedge technique) to achieve or change the desired amount of bone resection to obtain accurate angular alignment correction at surgery.

The closing wedge osteotomy involves more soft tissue dissection. Osteotomy of the fibula is preferred at the proximal fibular neck region. The lateral dissection must be meticulous to avoid the peroneal nerve. It is more tedious to resect more bone and alter the lower limb valgus correction if it is necessary to achieve additional angular correction. The triangular bone wedge is removed and saved in case it is necessary to reinsert bone during the procedure if an overcorrection occurs.

Brouwer and associates[40] conducted a prospective clinical trial in 92 patients randomized to either an opening wedge (Puddu plate) or a closing wedge osteotomy. At 1 year postoperatively, a valgus alignment (defined as 0 to 6 degrees valgus) was noted in 79% of the closing wedge osteotomies compared with 56% of the opening wedge osteotomies. The authors concluded that the Puddu plate had insufficient strength to maintain the operative correction. The investigation had several flaws because it involved four surgeons, and hip-knee-ankle radiographs were not obtained in the initial postoperative period. The number of opening wedge osteotomies that received autogenous bone grafting was not provided. The results emphasize the importance of determining that the appropriate valgus correction is achieved during surgery and maintained in the early postoperative period until union has occurred. The failure to achieve the desired valgus alignment would be expected to decrease long-term success rates. Full-standing weight-bearing hip-knee-ankle radiographs may be obtained by 3 to 4 weeks postoperative after either opening or closing wedge osteotomy to verify that correction has been achieved. In a small percentage of cases in which the correction is found not to be ideal on early postoperative radiographs, a revision angular correction may then be performed.

The use of an external fixator has been advocated with tibial osteotomy, with the advantage of allowing adjustments in lower limb alignment that is helpful in difficult or biplanar corrections.[201,219] Disadvantages of an external fixator are the risk of pin tract infection[2,19,71,201,219] and the 12-week period that the fixator is typically used. The use of an external fixator is ideal when both coronal lower limb alignment and tibial rotation need to be corrected.

Opening Wedge Osteotomy: Preservation of Tibial Slope

On cross-section, the proximal anteromedial tibial cortex has an oblique or triangular shape, whereas the lateral tibial cortex is more perpendicular at the posterior margin of the tibia. Because of this relationship, a medial opening wedge osteotomy that has an anterior tibial tubercle width equal to the width at the posteromedial margin would increase tibial slope, decrease knee extension, and possibly increase ACL tensile loads. A lateral closing wedge osteotomy with an equal anterior-to-posterior width or gap along the lateral tibial cortex tends to decrease the tibial slope by a few degrees, as is described next.

A study was conducted using 3-dimensional analysis of the proximal tibia to determine how the angle of the opening wedge along the anteromedial tibial cortex influences the tibial slope (sagittal plane) and valgus correction (coronal plane) when performing a medial opening wedge osteotomy.[164]

The data in this study on the obliquity of the anteromedial cortex of the proximal tibia relative to the posterior tibial cortex (Fig. 26-26) are presented from 35 magnetic resonance imaging (MRI) films in healthy young individuals (mean age, 32.7 years). Serial CT images of a cadaveric tibia were made in 1.25-mm slices and digitized using a computer-aided design package to create a solid model of the proximal tibia.

A medial opening wedge osteotomy was created along the AP axis to include a hinge axis on the lateral margin of the tibia. The open wedge osteotomy was just proximal to the tibial tubercle, ending 20 mm below the cortical margin of the lateral tibial plateau. The distal portion of the tibia was rotated on the virtual model about the hinge axis through the lateral point of the osteotomy maintaining the anatomic tibial slope (sagittal plane). Measurements of the width of the wedge angle and gap angle (Fig. 26-27) along the anteromedial tibial cortex were made from the resulting computerized model. Standard algebraic calculations were made using the law of triangles to determine the effect of different degrees of opening wedge osteotomy on coronal (valgus) and sagittal (tibial slope) alignment.

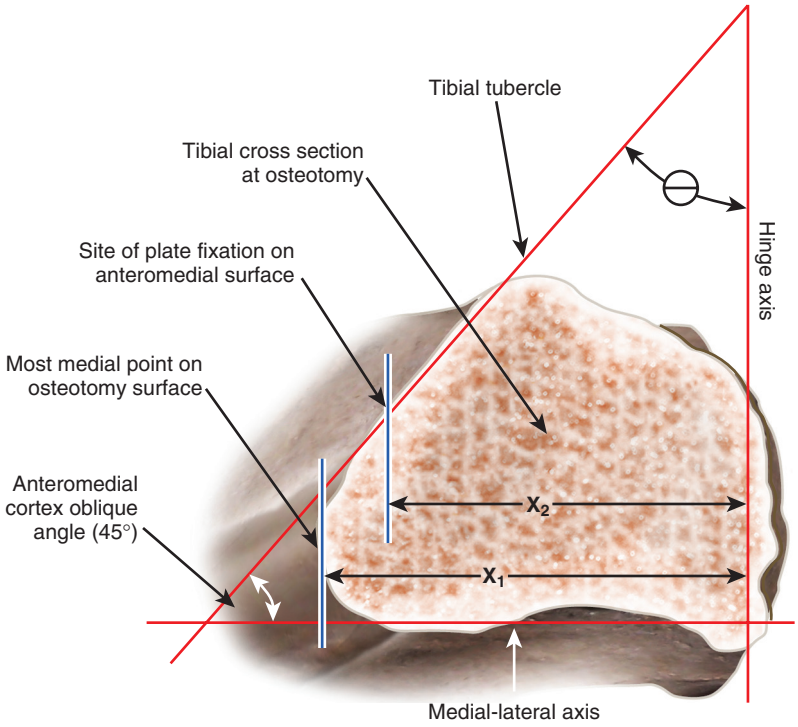

FIG 26-26 An axial cut of the proximal tibia at the diaphyseal-metaphyseal junction. The angle formed by the intersection of the mediolateral axis along the posterior tibia and the axis along the anteromedial tibial cortex is called the *anteromedial cortex oblique angle* (⊖). This angle measures approximately 45 degrees to the coronal plane.

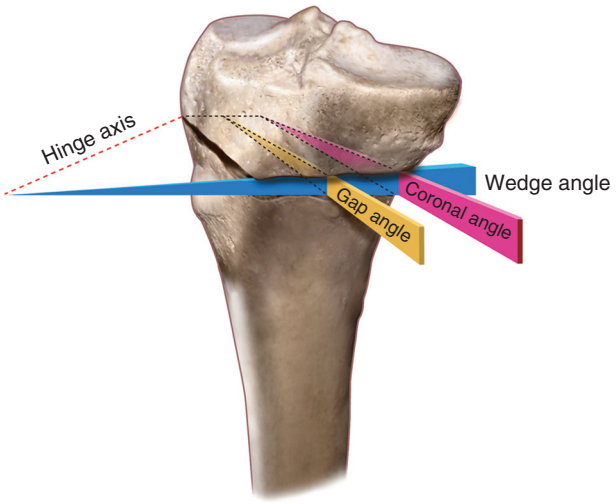

FIG 26-27 The distal portion of the tibia was rotated about an anteroposterior axis, which ran through the hinge point of the osteotomy to maintain the posterior tibial slope. A solid model of a high tibial osteotomy plate was placed at a series of positions around the medial aspect of the tibia, just anterior to the medial collateral ligament. The anteromedial cortex wedge angle is that angle formed along the oblique anteromedial tibial cortex during a prescribed opening wedge osteotomy (coronal plane). The gap angle is formed by planes that are perpendicular to the wedge angle along the anteromedial tibial surface.

The MRI measurement of the anteromedial tibial cortex oblique angle at the site of the opening wedge osteotomy was 45 ± 6 degrees (range, 34-56 degrees). The opening wedge angle, along the anteromedial tibial cortex to maintain the tibial slope, was found to be dependent on the angle of coronal valgus correction (HTO coronal angle) and the angle of obliquity of the anteromedial tibial cortex. In Figure 26-28, the results are shown for the calculation of the opening wedge angle (along the anteromedial tibial cortex) for five different osteotomy corrections in the coronal valgus plane (2.5-12.5 degrees).

The gap angle is perpendicular to the anteromedial oblique surface of the tibia with a vertex on the hinge axis posterior to the tibia. This is shown in Figure 26-29, in which the gap angle in degrees is shown for five different osteotomy corrections as a function of the obliquity of the anteromedial tibial cortex.

As an example, a 10-degree coronal valgus correction (assuming a normal 45-degree obliquity of the anteromedial tibial cortex) would result in a 7-degree gap angle at the osteotomy site. An error in the anteromedial tibial cortex opening wedge angle would result in an error in the tibial slope. An example of this is shown in Figure 26-30, which represents the desired wedge angle for a 10-degree coronal correction. An equal anterior and posterior opening or gap at the osteotomy site would result in an increased tibial slope and loss of normal knee extension.

These variables are shown in Table 26-5. For example, an error of 5 mm in the Y_2 gap (Fig. 26-31) at the tibial tubercle, assuming the length of the anteromedial cortex (L) is 45 mm, would result in an unexpected change in the tibial slope of 10 degrees. As a general rule in this example, every millimeter of alteration in the gap height induces a change of 2 degrees in the tibial slope.

The opening wedge angle can be set at surgery by measuring and altering the vertical gap (width) at two points along the osteotomy site,

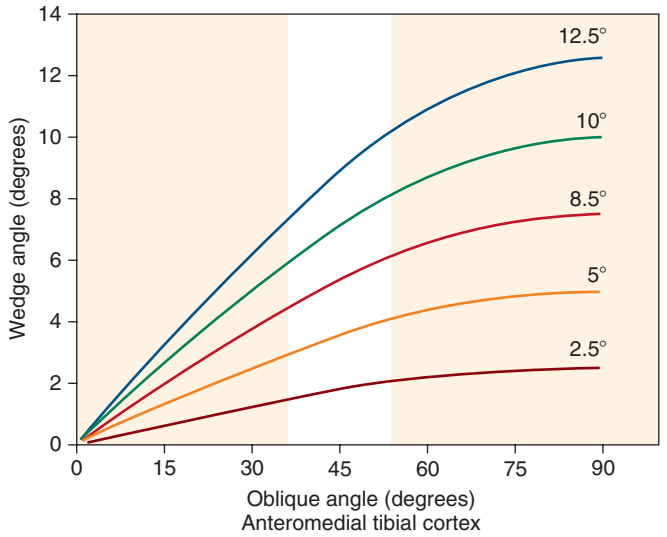

FIG 26-28 The anteromedial cortex opening wedge angle depends on the oblique angle of the tibial cortex with respect to the hinge axis. Each line represents the desired calculated degrees of correction for the opening wedge osteotomy in the true coronal (90-degree) plane. (From Noyes FR, Goebel SX, West J. Opening wedge tibial osteotomy: the 3-triangle method to correct axial alignment and tibial slope. *Am J Sports Med.* 2005;33:378-387.)

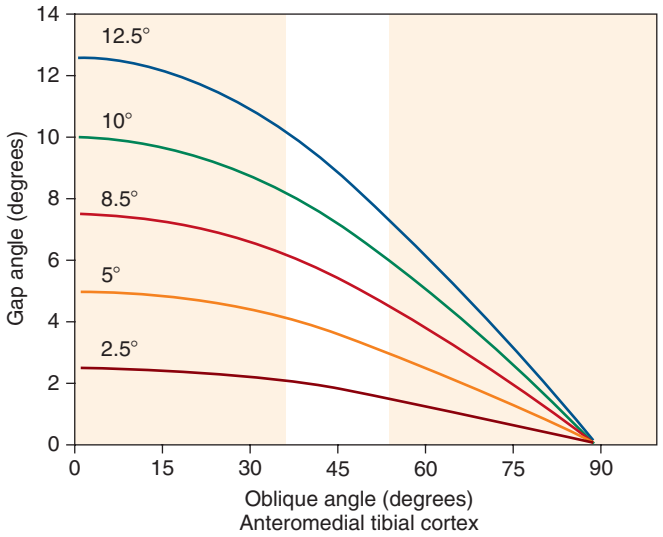

FIG 26-29 The magnitude of the gap angle changes with the obliquity of the anteromedial tibial cortex angle. Each line represents the calculated degrees of correction for the opening wedge osteotomy in the coronal plane. (From Noyes FR, Goebel SX, West J. Opening wedge tibial osteotomy: the 3-triangle method to correct axial alignment and tibial slope. *Am J Sports Med.* 2005;33:378-387.)

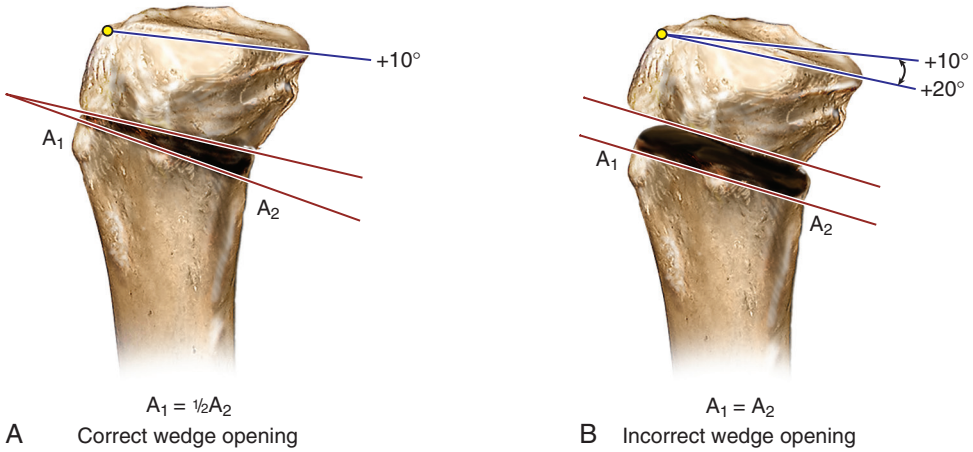

FIG 26-30 **A,** Appropriate choice of the wedge angle to maintain the sagittal tibial slope. **B,** Inappropriate wedge angle results in increased tibial slope.

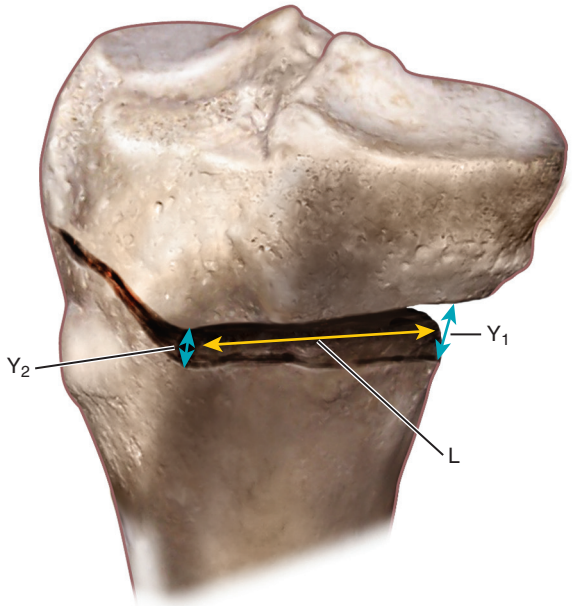
Y_1 and Y_2 (Fig. 26-32). This has importance in determining that the correct wedge angle is obtained before internal fixation at the osteotomy site. The site at which the vertical gap measurement is taken depends on the coronal distance from the hinge axis, the obliquity of the anteromedial tibial cortex, and the distance along the osteotomy site on the anteromedial surface (Tables 26-6 and 26-7).

In Table 26-6, the millimeters of opening at the osteotomy site are based on the width of the tibia and the angle of correction. In Table 26-7, an average 45-degree oblique angle of the anteromedial cortex and a tibial width of 60 mm are assumed. This allows the surgeon to calculate at the time of surgery the desired gap height at two points along the osteotomy to maintain the tibial slope.

For example, the measurement of the posterior tibial width is made at the osteotomy site (X_1). The opening height at the most posteromedial point (Y_1) and the distance between the two measurement points (Y_1-Y_2) are used in Table 26-7 to determine the second opening height at a defined distance (L) along the osteotomy site to maintain tibial slope.

If the tibial plate is placed just anterior to the superficial MCL on the anteromedial tibial cortex, approximately 20 mm anterior to the most posteromedial point of the osteotomy, the osteotomy gap at this site can be determined in Table 26-7, with a 10-mm posteromedial opening (Y_1), the correct width at the tibial plate would be 7.6 mm (tibial width, 60 mm).

For a 12-mm posteromedial opening, the correct width of the gap at the tibial plate would be 9.2 mm. A wider gap at the tibial plate would result in excessive valgus alignment and altered tibial slope. The change in the oblique angle of the anteromedial cortex, within the standard deviations reported, would have only a small and negligible effect on the width measurements of the opening wedge (see



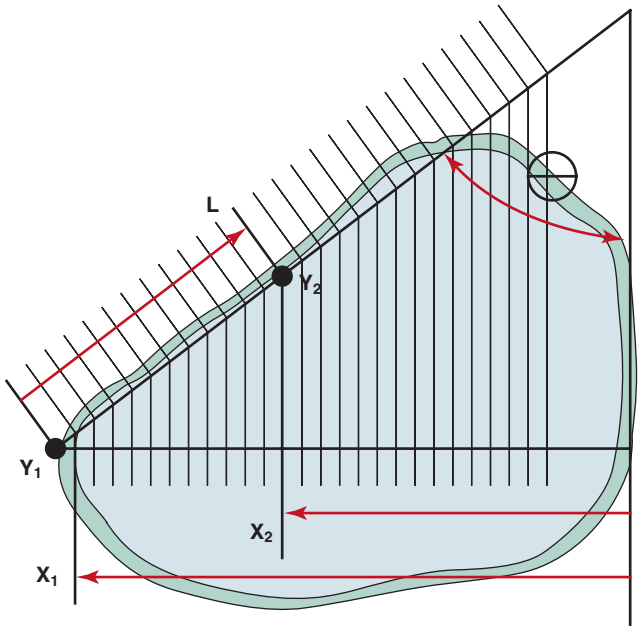


FIG 26-31 The opening wedge angle along the anteromedial tibial cortex can be calculated using the three linear measurements along the osteotomy opening wedge. *Y*$_1$, Gap anterior to Y_2; *Y*$_2$, posterior gap; *L*, length between Y_1 and Y_2.

$$L = \frac{X_1 \, 2 \, X_2}{\text{Sin}\,(\theta)} \qquad Y_2 = \frac{(X_2)\ 2(Y_1)}{X_1}$$

FIG 26-32 Vertical gap measurements of the opening wedge osteotomy are a function of distance from the hinge axis of the lateral tibial cortex for the opening wedge (X_1, X_2), oblique angle of the anteromedial tibial cortex (Θ), and distance along the osteotomy site L. (From Noyes FR, Goebel SX, West J. Opening wedge tibial osteotomy: the 3-triangle method to correct axial alignment and tibial slope. *Am J Sports Med.* 2005;33:378-387.)

TABLE 26-5 Errors in the Tibial Slope Caused by Errors in Vertical Gap Height (Y_2)

Error at Y_2 (mm)	LENGTH OF ANTEROMEDIAL CORTEX (mm)

Values are in degrees.

Table 26-7). To maintain the proper anterior and posterior gaps at the osteotomy site, appropriate distraction instruments at surgery are required to maintain the desired coronal and sagittal angular correction.

Final Recommendations to Obtain Correct Coronal and Slope Alignment

1. Determine the coronal valgus angular correction in degrees based on preoperative full-standing radiographs for the desired placement of the WBL at the tibial plateau and measure the tibial slope based on a lateral radiograph.
2. Determine the millimeters of opening at the posteromedial osteotomy site at surgery (Y_1 gap) using the width of the tibia (X_1 distance) for the coronal valgus correction based on the law of triangles (first triangle; see Table 26-6).
3. Determine the proper gap width of the osteotomy opening wedge along the anteromedial cortex to maintain tibial slope and the proper width beneath the tibial plate based on its location along the anteromedial cortex (see Table 26-7). The opening wedge gap will always be 3 to 4 mm less where the plate is located. If the tibial slope is to be increased or decreased, the effect on the degrees of tibial slope is shown in Table 26-5.
4. Confirm final coronal and sagittal angular correction based on intraoperative fluoroscopy and early postoperative full standing and lateral radiographs.

INTRAOPERATIVE EVALUATION

An operative "time-out" and identification of the operative limb by the surgeon and patient are performed as described in detail in Chapter 7. All knee ligament subluxation tests should be performed after the induction of anesthesia in both the injured and contralateral limbs. The amount of increased anterior tibial translation, posterior tibial translation, lateral joint opening, and external tibial rotation should be documented as previously described.

A thorough arthroscopic examination should be conducted, documenting articular cartilage surface abnormalities[169] and the condition of the menisci. The gap test is done during the arthroscopic examination.[159] The knee is flexed to 30 degrees, and a varus load of approximately 89 N is applied. A calibrated nerve hook is used to measure the amount of lateral tibiofemoral compartment opening (Fig. 26-33). Knees that have 12 mm or more of joint opening at the periphery of

By measuring the width of the tibia, the opening wedge height at the most medial point (Y_1), and the distance between vertical measurement points (L), the vertical height at the second measurement point (Y_2) at which the plate implant can be found on the table. Calculations are based on a 45-degree angle of the anteromedial tibial cortex at the osteotomy site.

the lateral tibiofemoral compartment will usually require a staged posterolateral reconstructive procedure.

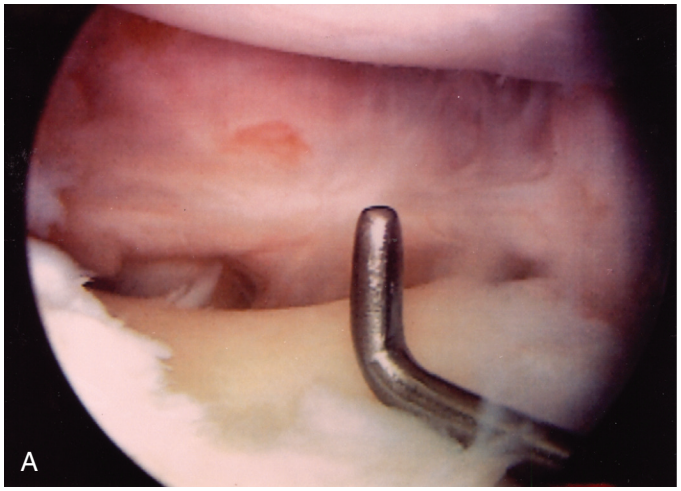
A medial gap test is performed with a valgus load to measure the opening of the medial tibiofemoral compartment. There may be an increased medial opening because of medial joint damage and loss of cartilage and flattening of the femoral and tibial condyles. In rare cases, there is increased opening caused by a chronic MCL rupture. In most knees with varus malalignment, adaptive shortening of the medial ligamentous tissues occurs, and MCL advancement and posteromedial plication procedures are not indicated.

CRITICAL POINTS Intraoperative Evaluation

Repeat all knee ligament subluxation tests under anesthesia on both injured and contralateral limbs.

Rate All Articular Cartilage Surfaces for Abnormalities and Millimeters of Involvement

- Normal
- Grade 1, softening
- Grade 2A, fissuring and fragmentation < half the depth of the articular surface
- Grade 2B, fissuring and fragmentation > half the depth of the articular surface
- Grade 3, subchondral bone exposed



Gap Test during Arthroscopy

- Knee 30 degrees of flexion
- Varus load, valgus load
- Measure millimeters lateral and medial tibiofemoral compartment opening with calibrated nerve hook

OPERATIVE TECHNIQUE: OPENING WEDGE TIBIAL OSTEOTOMY

Step 1: Initial Operating Room Preparations

Preoperative calculations are made as previously described. The entire lower extremity is prepped and draped free with the tourniquet placed high on the proximal thigh to assist visual observation of lower limb alignment. If an autogenous iliac crest autograft is to be performed, the ipsilateral anterior iliac crest is prepped and draped for the limited iliac crest bone harvest of the outer cortex. The patient is positioned to allow fluoroscopic views of the hip-knee-ankle WBL to verify the angular correction at surgery, and lateral views are obtained for tibial slope analysis.

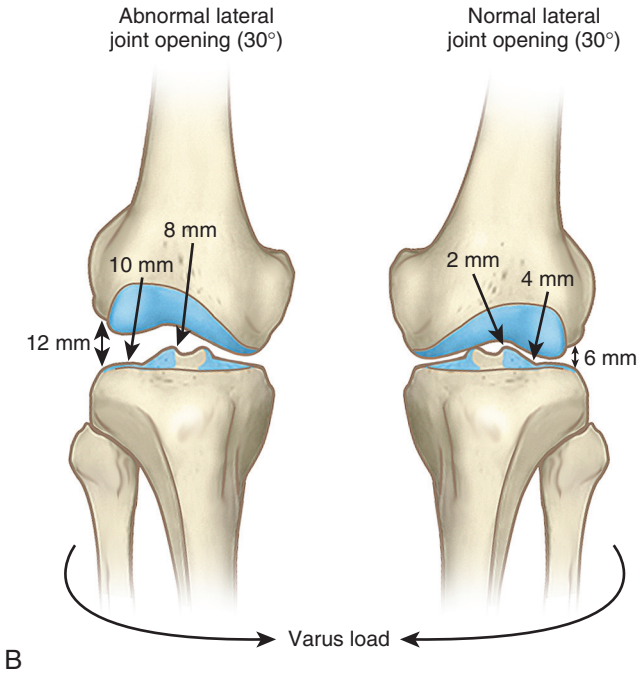


FIG 26-33 **A** and **B,** Arthroscopic gap test for determining the amount of lateral joint opening.

Step 2: Knee Arthroscopy

Arthroscopy is performed at the time of the HTO to evaluate articular surfaces of the medial and lateral tibiofemoral compartments and patellofemoral joint to confirm that the patient is an appropriate candidate for the osteotomy. ACL-deficient knees may have associated meniscus tears that require repair[185] or partial removal. Appropriate debridement of tissues, inflamed synovium, and notch osteophytes limiting knee extension is performed. In particular, there is a secondary weight-bearing area established in varus-angulated knees in which the lateral tibial spine produces a bone erosion over the inner margin of the lateral femoral condyle. The femoral condylar bone erosion may be debrided to remove the painful weight-bearing site.

Step 3: Anterior Iliac Crest Bone Graft Harvest (Opening Wedge ≥15 mm)

Large osteotomies that require 15 mm or more of correction are empirically treated with an iliac crest bone graft. Mid range corrections of 10 to 12 mm are treated with freeze-dried allograft bone wedges plus a locking plate and screws.

A 4-cm incision is made over the anterior iliac crest with care to avoid the ilioinguinal nerve. The incision is deepened to the periosteum (Fig. 26-34), which is sharply incised and reflected medially only to the inner cortex. Laterally, meticulous subperiosteal dissection is

CRITICAL POINTS Operative Technique for Opening Wedge Osteotomy

- Arthroscopy before HTO to assess all knee compartments, confirm HTO indicated, and treat meniscus tears and notch osteophytes blocking knee extension.
- Anterior iliac crest meticulous dissection; remove outer cortex; do not disturb inner cortex or muscle attachments.
- Harvest graft 40 mm in length, 10 mm in width, 30 mm in depth to produce three triangular bone grafts.
- HTO incision: 5-cm vertical medial tibia midway between tibial tubercle and posteromedial tibial cortex, starting 1 cm inferior to joint line.
- Partially detach gracilis and semitendinosus tendons at their tibial insertion; retract posteriorly exposing SMCL and posterior border of the tibia.
- Sharp periosteal incision just anterior to SMCL; meticulous subperiosteal dissection beneath the SMCL fibers. Protect inferior medial geniculate artery beneath the SMCL.
- Posterior tibial subperiosteal dissection to protect neurovascular structures. Wide dissection not necessary. Surgeon's headlight always used.
- Small osteotomies ≤5 mm: "pie-crust" procedure using multiple transverse incisions may effectively lengthen SMCL.
- Osteotomies >5 mm: transect distal SMCL attachment, carefully elevated to the tibial border, protected and reattached after osteotomy.
- Keith needle placed in anteromedial joint above tibia; distance marked for desired point of osteotomy. Second Keith needle placed posteromedial tibial joint space, distance marked. Two marks connected.
- Anterior and posterior guide pins placed at 15 degrees obliquity to tibial shaft; verify position with fluoroscopy.
- Ensure guide pins are at least 20 mm distal to the lateral joint line to prevent lateral tibial plateau fracture.
- Begin osteotomy with oscillating saw for medial and anterior cortices. Follow by nonflexible thin ¾-inch osteotome placed anterior, directly above the guide pin, verified by fluoroscopy.
- Use ½-inch osteotomy for posterior cortex, with osteotome edge visualized and palpated posterior to the tibia as the osteotomy is advanced.
- Carry osteotomy to within 10 mm of the posterolateral cortex; confirm by fluoroscopy.
- Place thin spreader bars across osteotomy. Initial distraction requires several minutes to prevent fracture of the lateral cortex; if major resistance, place holes in lateral cortex with guide pin.
- Anterior gap of osteotomy should be half that of the posterior gap to maintain tibial slope. Maintain osteotomy gap; use anterior tibial staple, if necessary and posterior wedge; confirm alignment by fluoroscopy.
- Apply and fixate locking plate with fluoroscopy verification; confirm final coronal and sagittal (slope) alignment.
- Suture SMCL fibers distally and secure to either plate screws or suture anchors to maintain tension. Reapproximate pes anserine tendons and sartorius fascia.
- Knees with chronic SMCL deficiency require distal advancement if the ligament appears normal without scar replacement.
- Semitendinosus augmentation of SMCL is required in knees with scar replacement.
- When the SMCL is advanced distally or reconstructed, repair medial meniscus attachments.

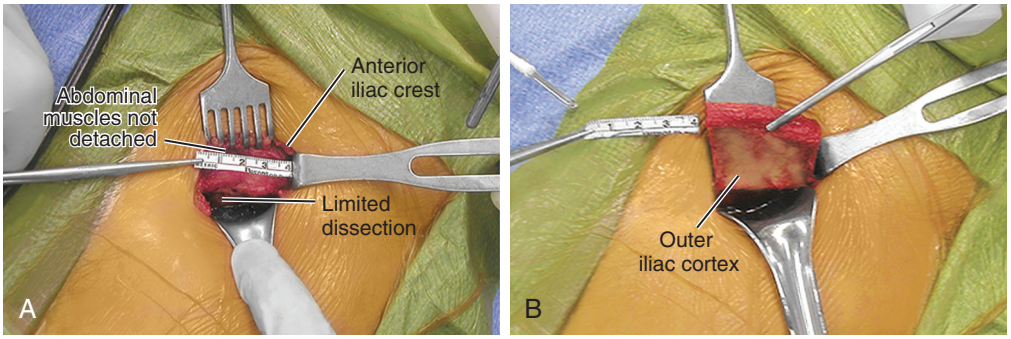

FIG 26-34 **A,** A 4-cm incision over the anterior iliac crest is made to harvest the iliac crest bone graft. The graft is composed of the anterior crest and outer iliac cortex; the inner table is not removed. **B,** The usual iliac crest bone graft dimensions are 40 mm in length, 10 to 12 mm in width, and 30 mm in depth. (From Noyes FR, Mayfield W, Barber-Westin SD et al. Opening wedge high tibial osteotomy. An operative technique and rehabilitation program to decrease complications and promote early union and function. *Am J Sports Med.* 2006;34:1262-1273.)

carried along the outer table of the pelvis, avoiding the lateral muscles. The graft size is defined on the outer cortex using electrocautery. In most patients, the graft will be 40 mm in length, 10 mm in width, and 30 mm in depth. However, in smaller patients, the graft may be smaller in width and approximately 8 mm in depth. Patients undergoing large osteotomies may require a longer graft of approximately 45 to 50 mm.

The inner iliac cortex is not dissected; the muscle attachments are not disturbed, which reduces postoperative pain; and a spacer of the iliac crest defect is not required. Additional cancellous bone is removed from the inner graft site. A drain is not required at the iliac crest harvest site. The wound is closed in layers with deep sutures to close the dead space. The graft is later fashioned into three carefully sized triangles: one triangle is placed posterior to the tibial plate to close the gap at the posterior tibial cortex, one triangle is placed in the midportion of the osteotomy deep to the plate, and one smaller-width triangle is placed in the gap in the anterior tibial cortex. In large osteotomy corrections (>10 mm gap), autogenous bone is always used, and any remaining defect filled with corticocancellous freeze-dried tibial or iliac crest allografts.

Step 4: Initial Anteromedial Tibial Approach

The operative technique is shown in Figure 26-35. A 5-cm vertical skin incision is made medially midway between the tibial tubercle and posteromedial tibial cortex, starting 1 cm inferior to the joint line. A vertical incision is preferred over an oblique or transverse incision because vertical incisions are subsequently used in knees progressing to partial or complete TKA. The sartorius fascia is incised in line with its fibers, proximal to the gracilis tendon, exposing the distal SMCL attachment.

The gracilis and semitendinosus tendons are partially detached at their tibial insertion in an L-shaped manner and retracted posteriorly to further expose the SMCL and posterior border of the tibia. The SMCL is transected at its most distal tibial attachment. Anteriorly, the retropatellar bursa is entered by incising the medial patellar retinaculum, allowing the patellar tendon to be lifted to expose the anterior tibia.

A sharp periosteal incision is just anterior to the SMCL to allow the SMCL to be dissected subperiosteally in a proximal direction and to allow meticulous posterior tibial subperiosteal dissection by a Cobb elevator. Care is taken to identify the inferior medial geniculate artery, which lies just beneath the SMCL. Only sufficient posterior tibial subperiosteal dissection is used to protect the neurovascular structures; wide dissection is not necessary. A malleable retractor is placed in the subperiosteal posterior tibial space.

Step 5: Proximal Osteotomy and Placement of Tibial Guide Pins

The patellar tendon and retropatellar bursa are exposed medially. The superior attachment of the tendon is recessed 5 mm using a scalpel to provide adequate exposure for the osteotomy. Retractors are placed anteriorly and posteriorly to complete the exposure. A Keith needle is placed in the anteromedial joint just above the tibia, and the distance is marked on the desired point of the osteotomy at the tibial tubercle patellar tendon attachment. A second Keith needle is placed at the posteromedial tibial joint space, and the same millimeters are marked. The two marks are connected to provide the osteotomy line perpendicular to the tibial slope.

A 2-mm guide pin is placed at the posteromedial cortex at the marked line and advanced across the tibia at an oblique angle (Fig. 26-36). The anterior and posterior guide pins are placed at 15 degrees of obliquity to the tibial shaft and verified by intraoperative fluoroscopy. An alternative technique is to place the site of the osteotomy directly at the posterior guide pin, maintaining the oblique angle of the pin across the osteotomy site without using the osteotomy guide system.

To prevent a fracture extending into the joint at the lateral tibial plateau, it is important for the guide pins to be at least 20 mm distal to the lateral joint line. An error that may occur is to have too much obliquity to the guide pin.

A this point, it is imperative to ensure that the medial osteotomy line (from anterior to posterior) is in line with the tibial slope based on the radiographs and prior anteromedial cortex joint line measurements by the Keith needles. A measurement of the perpendicular cut from the joint line confirms the distance of each guide pin from the articular surface of the tibia. The length of the posterior pin (medial to lateral cortex) is measured and used following the law of triangles[164] to determine tibial width and the millimeters of osteotomy opening to obtain the desired angular correction (Table 26-6).

The osteotomy is initially performed using an oscillating saw for the medial and anterior cortices, followed by a nonflexible thin ¾-inch and ½-inch osteotome, placed in the same orientation and anterior to

FIG 26-35 **A,** Initial draping of varus-aligned lower extremity. **B,** Incision location, anterior third of medial tibia. **C,** Initial exposure beneath patella tendon under retraction. **D,** Initial subperiosteal dissection of superficial medial collateral ligament. The distal attachment has been incised. **E,** Posterior subperiosteal exposure to protect neurovascular structures. **F,** Placement of navigation femoral and tibial markers; used only in special cases. **G,** A Keith needle placed at the anterior, and later the posterior, aspect of the joint line is used to outline the planned osteotomy.

Continued

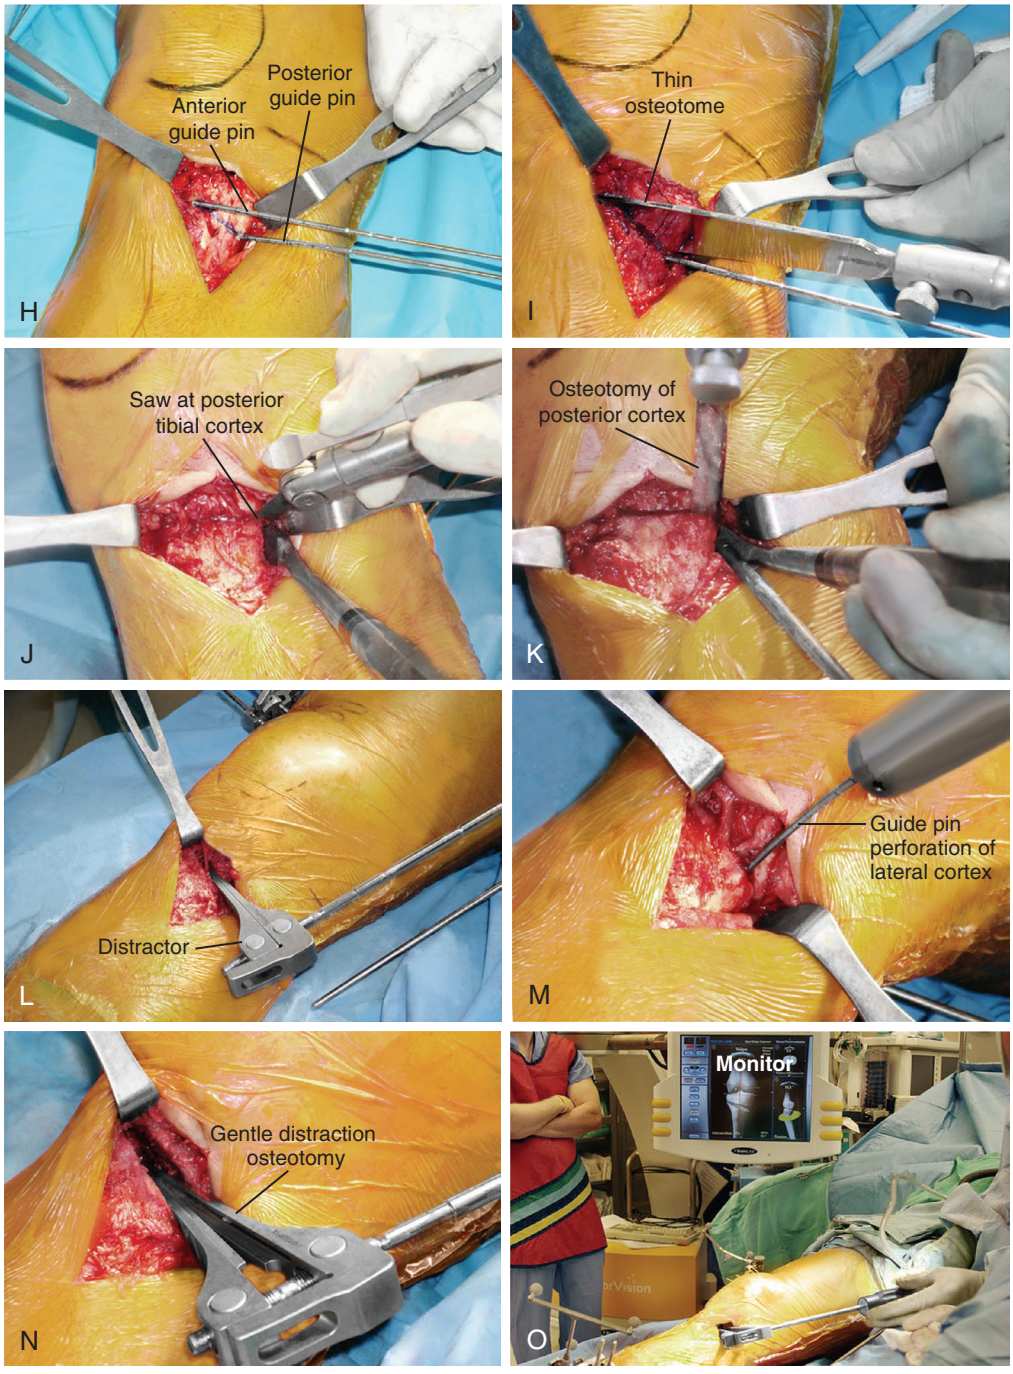

FIG 26-35, cont'd **H,** Two guide pins are placed under fluoroscopic control. **I,** A thin osteotomy blade is placed under fluoroscopic control. Different width blades are used to complete the osteotomy within 5 mm of the lateral cortex. **J,** Initial posterior cortex osteotomy using thin power saw under direct visualization. **K,** Completion of the posterior cortex osteotomy to within 5 mm of posterolateral cortex. **L,** Initial gentle opening of osteotomy. **M,** Guide pin perforation of dense posterolateral tibial cortex to weaken bone owing to failure of the osteotomy gap to increase under gentle dislocation. **N,** Further opening of osteotomy site. **O,** Use of computerized navigation to monitor valgus alignment, or use fluoroscopy with rigid rod from center of hip to ankle for corrected weight-bearing line. Compression at foot closes both tibiofemoral compartments.

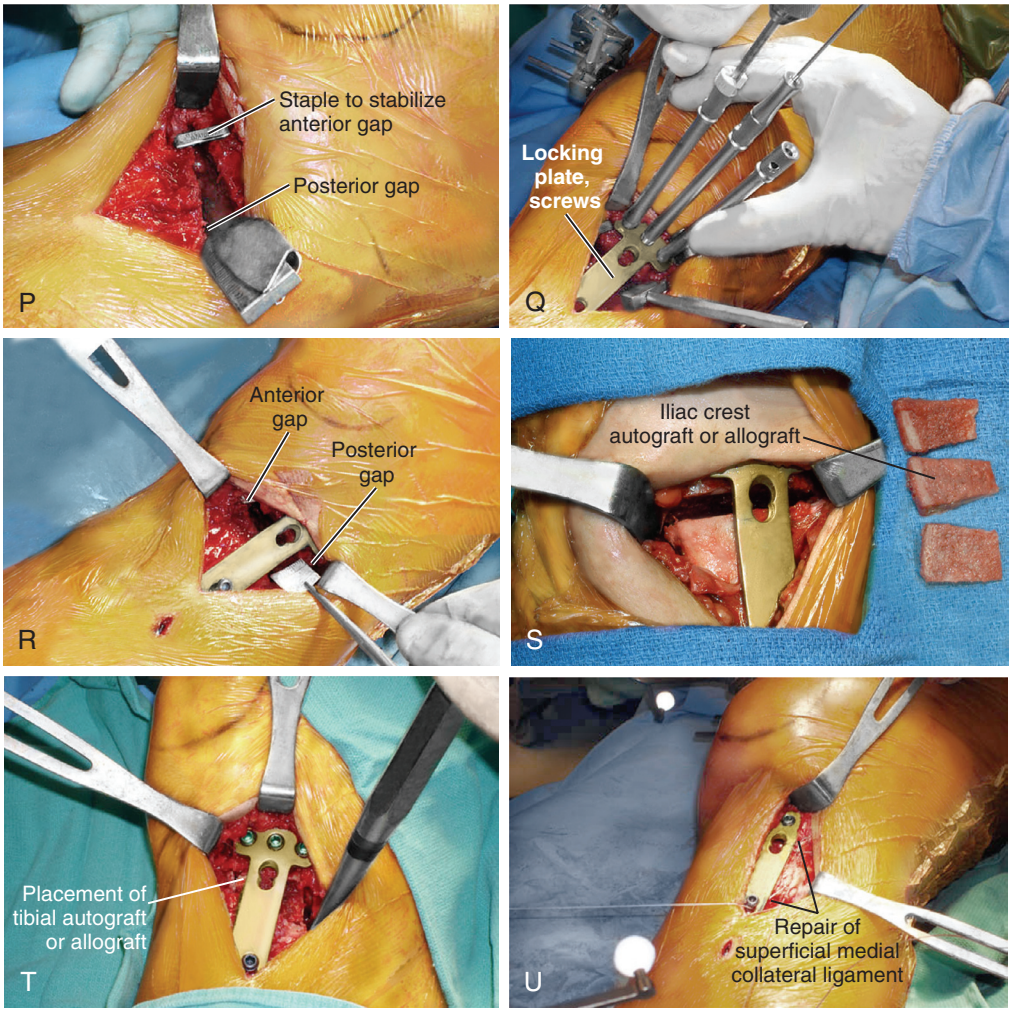

FIG 26-35, cont'd **P,** Staple is placed anterior to the tibial gap to control tibial slope. **Q,** Initial fixation of osteotomy, maintaining the measured osteotomy correction. **R,** Confirmation of the anterior and posterior osteotomy gap measurement. **S,** Bicortical iliac crest autograft or freeze-dried allograft bone is selected. **T,** Placement of the anterior, central, and posterior bone grafts. **U,** Fixation of the anterior border of the superficial medial collateral ligament to the tibial plate.

the guide pin and verified by fluoroscopy (Fig. 26-36). The lateral cortex is osteotomized to Gerdy's tubercle, leaving the posterolateral tibial cortex hinge. A ½-inch osteotome is used for the posterior cortex, with the osteotome exposed 2 to 3 mm and viewed posterior to the tibia as the osteotomy is advanced. The osteotomy is carried to within 10 mm of the posterolateral cortex. It is imperative that the lateral cortex not be fractured because this would produce loss of the lateral cortex buttress and potential collapse and loss of the angular correction. If a fracture of the lateral cortex does occur, with gross instability to the osteotomy site, the lateral tibial cortex may be secured with a two-hole small plate through a limited lateral incision to achieve stability.

Step 6: Opening Wedge Technique and Measurement of Gaps to Confirm Tibial Slope

Commercially available calibrated opening wedges are gently inserted into the osteotomy site to achieve the desired angular correction with the opening medial gap hinging on the intact posterolateral cortex. This step requires several minutes to prevent fracture of the lateral tibial pillar. The spreader bars are inserted entirely across the osteotomy site to prevent a fracture extending into the lateral tibial plateau. If there is a rigid nonyielding response to the spreader bars, the lateral cortex is weakened with three to four guide pin perforations.

The anterior gap of the osteotomy site should be one half of the posterior gap, following rules previously described to maintain the tibial slope.[164] The width of the tibial plate along the anteromedial cortex and just anterior to the SMCL is measured and is always less than the millimeters at the posterior medial gap owing to the angular inclination of the anteromedial tibial cortex.

In select cases as previously described, the tibial slope may be purposefully increased in PCL-deficient knees, decreased in ACL-deficient knees, or altered with abnormal knee hyperextension or flexion contracture. The method to complete the desired change in tibial slope and corresponding width of the anterior and posterior osteotomy sites has been presented in an earlier section of this chapter. A locking plate design is always used in single and biplanar corrections.

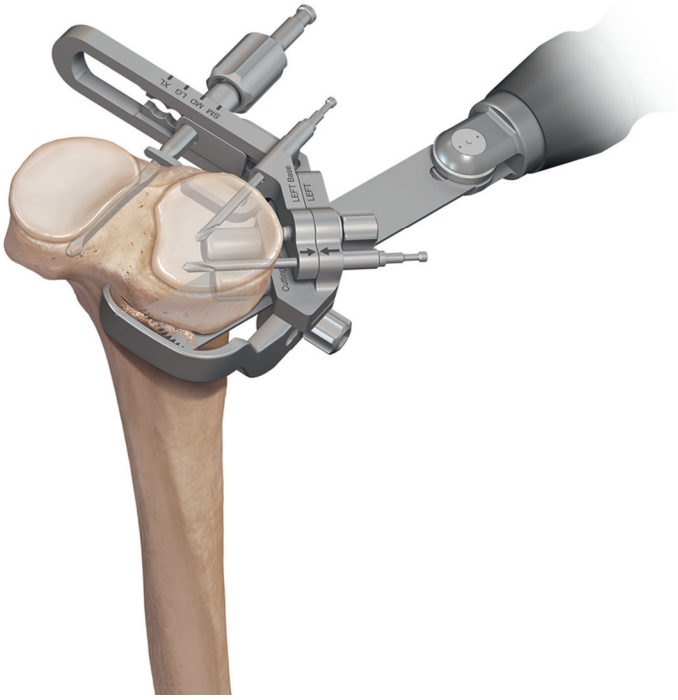

FIG 26-36 A commercial osteotomy wedge system (Arthrex iBalance Opening Wedge Osteotomy System, Arthrex, Inc.) provides protection of neurovascular structures and allows precise guidance of the osteotomy blade. (Courtesy Arthrex.)

Step 7: Intraoperative Verification of Desired Limb Alignment Correction

In addition to preoperative measurements of axial alignment (obtained from double-stance hip-knee-ankle radiographs) and calculations to correct for increased lateral joint opening as previously described, the surgeon must verify intraoperatively that the desired limb alignment has been achieved. After the selected wedge correction (which is maintained using one of the commercial wedge-shaped instruments), a small pad is positioned behind the knee to avoid hyperextension, and the knee is placed in 5 degrees of flexion. With the lower limb lying on the table, the surgeon gently determines that there is closure of both the medial and lateral tibiofemoral compartments viewed by fluoroscopy. An axial load is placed across the bottom of the foot to compress the knee joint to maintain the correct axial alignment. The lower limb is positioned in 10 to 12 degrees of external rotation to simulate the normal lower limb position during gait. A rigid rod is placed at the center of the hip to the center of the ankle, verified by fluoroscopy, and the WBL at the tibia is determined. Adjustment in the millimeters of gap at the osteotomy site is made to obtain the preoperatively selected WBL. The procedure is repeated after internal plate fixation to verify the final alignment correction. The fluoroscopic technique for lower limb positioning to obtain accurate WBL measurements and verify the operative correction does take time and may require repeated steps. The lateral fluoroscopic view determines the final position of the tibial slope. The role of computer navigation is discussed later in this chapter (see "Role of Computerized Navigation for High Tibial Osteotomy").

Obtaining an alignment correction in which the WBL is transferred to the lateral tibiofemoral compartment within the desired 50% to 62% range is the key to achieving short- and long-term decreases in pain in the medial tibiofemoral compartment. The surgeon cannot simply rely on the preoperative calculations because the intraoperative hip-knee-ankle fluoroscopic measurements may indicate that the desired correction of the tibial WBL has not been achieved. This problem was demonstrated in a report by Marti and coworkers,[125] who described the accuracy of obtaining the desired alignment correction using preoperative and postoperative double-stance radiographs following opening wedge osteotomy in 32 knees. In their series, only 50% of the limbs demonstrated the desired correction on postoperative radiographs (±5 degrees of calculated correction). An undercorrection was found in 31% and an overcorrection in 19%. These authors did not report on the use of intraoperative fluoroscopy to verify the lower limb correction. Many authors have described problems in obtaining the desired angular correction at surgery, with a substantial percentage of limbs remaining in varus or overcorrected into excessive valgus. Either fluoroscopy or computerized navigation techniques require defining accurate anatomic landmarks and precision to obtain accurate measurements.

Step 8: Placement of Bone Graft and Internal Fixation

An appropriate plate is selected and secured. The senior author uses only a locking plate design. If the surgeon elects to use allograft bone, the added fixation strength of a locking plate and screws is strongly recommended to prevent varus collapse at the osteotomy site. Various commercial locking plates and screw systems are available that provide added stability at the operative site.

The senior author recommends structural corticocancellous wedge bone grafts (autograft or allograft) and avoids the use of synthetic grafts or cancellous grafts. The clinical studies using these grafts have shown an unacceptable nonunion rate, as is discussed later in this chapter. The senior author prefers autograft iliac crest grafts or freeze-dried tibia corticocancellous allografts.

The three corticocancellous bone graft triangular segments are fashioned based on direct measurements of the anterior and posterior widths at the osteotomy site. The three grafts are impacted tightly into the posterior, middle, and anterior portions of the osteotomy site to obliterate the space and provide added stability, particularly in the sagittal plane. Fluoroscopy is used to confirm the final alignment and tibial slope.

The SMCL fibers are sutured distally and secured to either the plate screws or to suture anchors to maintain tension. The pes anserine tendons and sartorius fascia are reapproximated. The tourniquet is deflated and hemostasis obtained. A drain is not required. The wound is closed in layers in the usual manner. The lower limb is wrapped with cotton, and additional padding is placed posteriorly and over the peroneal nerve. A commercial ice delivery system with the bladder incorporated a few cotton layers from the wound is always used. A postoperative hinged brace and bilateral sequential compression devices are applied.

The neurovascular status is immediately checked in the operating room and over the initial postoperative period. The importance of limb elevation for the first postoperative week and use of a venous compressive system is emphasized. Close observation for lower limb soft tissue swelling is mandatory. There is a high suspicion for a venous thrombosis, and therefore aspirin is prescribed. There is also a low threshold for venous ultrasound of both lower extremities, which is obtained in the majority of patients in the first 3 to 7 postoperative days. The postoperative protocol is covered extensively in Chapter 28.

Management of the Superficial Medial Collateral Ligament

There are three surgical approaches for management of the SMCL. In a small opening wedge osteotomy of 5 to 7 mm, a "pie-crusting" procedure using multiple transverse incisions at different places may effectively lengthen the SMCL. In larger opening wedge osteotomies, it is

necessary to transect the distal attachment and perform a distal elevation of the attachment in a subperiosteal plane. This allows for the SMCL to be reattached distally after the opening wedge osteotomy with the SMCL bridging the osteotomy site. Transecting the SMCL at the most distal attachment site preserves its length, allows excellent exposure and bone grafting, and allows the tibial fixation plate to be placed in a correct midline position. The tibial slope is not altered, and function of the SMCL is retained.

A third approach is used when distal advancement of the SMCL is required as a reconstructive procedure owing to SMCL insufficiency and abnormal medial joint opening. At the conclusion of the osteotomy and plate fixation, the SMCL is dissected to the medial joint, including the deep medial fibers. A posterior incision is made at the junction of the SMCL and posteromedial capsule (posterior oblique ligament). The anterior incision extends only to the joint and preserves the attachment of the medial patellofemoral ligament. The medial meniscus position is carefully examined when a distal advancement of the SMCL is performed. It may be necessary to incise the medial meniscus capsular attachment (deep meniscotibial ligament) and then resuture the attachment to preserve the correct anatomic location of the meniscus when the SMCL is advanced distally.

The SMCL should appear relatively normal without scar replacement because advancement of only scar tissue would not provide medial stability. In select cases, a STG augmentation of the SMCL may be necessary, as described in Chapter 19. The need to surgically reconstruct the SMCL is infrequent; however, the surgical techniques presented allow for restoration of function when required.

OPERATIVE TECHNIQUE: CLOSING WEDGE TIBIAL OSTEOTOMY

Step 1: Initial Operating Room Preparation and Arthroscopy

The entire lower extremity is prepped and draped free with the tourniquet placed high on the proximal thigh to assist visual observation of lower limb alignment. The patient is positioned to allow fluoroscopic views of the hip-knee-ankle WBL to verify the angular correction at surgery, and arthroscopy is performed as already described.

Step 2: Initial Anterolateral Tibial Approach

A sterile tourniquet is inflated, and an oblique incision is made 1 cm distal to the head of the fibula in a line directed to the center the tibial tubercle (Fig. 26-37). The subcutaneous tissues are incised down to the fascia of the anterolateral tibial musculature. A fascial incision is made from the lateral aspect of the tibial tubercle sloping up proximally to the distal aspect of Gerdy's tubercle and is extended posteriorly and laterally to the anterior bare area of the fibula. The anterior bare area of the fibula is an important and safe anatomic landmark. The FCL and peroneal nerve are safely avoided when one identifies this area, which is used to initiate the limited subperiosteal exposure of the fibular neck for the fibular osteotomy.

Subperiosteal dissection on the tibia is initiated just distal to Gerdy's tubercle, using a scalpel followed by a Cobb elevator. The dissection is continued just lateral to the patellar tendon and should be done cleanly, with a relatively bloodless field and without damage to muscle tissue. The retinaculum adjacent to the patellar tendon is incised and the retropatellar space entered. The patellar tendon is retracted anteriorly.

The dissection is continued posteriorly on the tibia. It is important to remain in a subperiosteal plane because of the proximity of neurovascular structures. The safe zone is just distal to Gerdy's tubercle to avoid the peroneal nerve. Posteriorly, the dissection is completed across the width of the tibia in one location and is then carefully extended proximally and distally in this safe posterior tibial subperiosteal plane.

CRITICAL POINTS Operative Technique for Closing Wedge Osteotomy

- Arthroscopy first to assess all compartments, confirm HTO indicated, treat meniscus tears and notch osteophytes blocking knee extension.
- Oblique incision from fibular head to tibial tubercle.
- Subperiosteal dissection on tibia begun just distal to Gerdy's tubercle. Clean dissection; relatively bloodless field without damage to muscle tissue.
- Identify anteromedial bare area of fibula when initiating limited subperiosteal exposure of the fibular neck. Be aware of anatomic variability of the superficial peroneal nerve.
- Complete subperiosteal dissection posteriorly across width of tibia; extend proximally and distally in posterior tibial subperiosteal plane as required.
- Proximal fibular osteotomy through fibular neck region recommended.
- Fibular bone section removed is 2-3 mm less than the computed tibial wedge to allow compaction at the osteotomy site. Avoid bone step-off adjacent to peroneal nerve.
- Pass a smooth guide pin transversely at the posterolateral tibia to the medial cortex, 25-30 mm distal to joint line. Use fluoroscopy to ensure proper placement. Measure tibial width; compute desired bone width to obtain WBL correction. Place second guide pin anterior to first guide pin.
- Leave at least 25 mm of proximal tibia to avoid tibial plateau fracture.
- Make initial osteotomy cuts with a micro-oscillating saw to only cut outer cortex. Complete osteotomy with thin osteotomes.
- Place a malleable retractor in the subperiosteal plane posteriorly to protect the neurovascular structures with knee flexed 10 degrees.
- Surgeon seated with a headlamp. Osteotomy plane is maintained in a coronal triangular plane. The midpoint of the tibia width is half of the lateral wedge.
- Posteromedial cortex preserved to provide stability and prevent medial or lateral tibial translation or varus recurrence.
- Close osteotomy gap with gentle valgus force applied over a few minutes to gradually deform remaining medial cortex.
- Sagittal plane of osteotomy should be perpendicular to the long axis of the tibia. Equal width of cortex removed both anteriorly and posteriorly to preserve normal posterior tibial slope.
- Under fluoroscopy, position alignment guide rod over center of femoral head and center of tibiotalar joint to determine corrected WBL intersection at tibial plateau. Axially load the lower limb at the foot to maintain closure of medial and lateral tibiofemoral compartments at 5 degrees of flexion to avoid hyperextension.
- Further bone may be resected if necessary to adjust WBL.
- Internal fixation: locking plate and screws.
- Tourniquet released; hemostasis obtained.
- Reattach fascia of the anterior compartment musculature to anterolateral aspect of the tibial border with absorbable sutures.
- Generous cotton Ace compression bandage, multiple layers. Commercial ice delivery system and bilateral venous foot pumps applied.

Close observation of limb swelling, maintain frequent limb elevation, deep venous thrombosis protocol, ultrasound within first postoperative week in majority of patients.

Step 3: Fibular Osteotomy

There are three options for the fibula when performing an HTO: proximal slide, proximal fibular osteotomy, and distal fibular

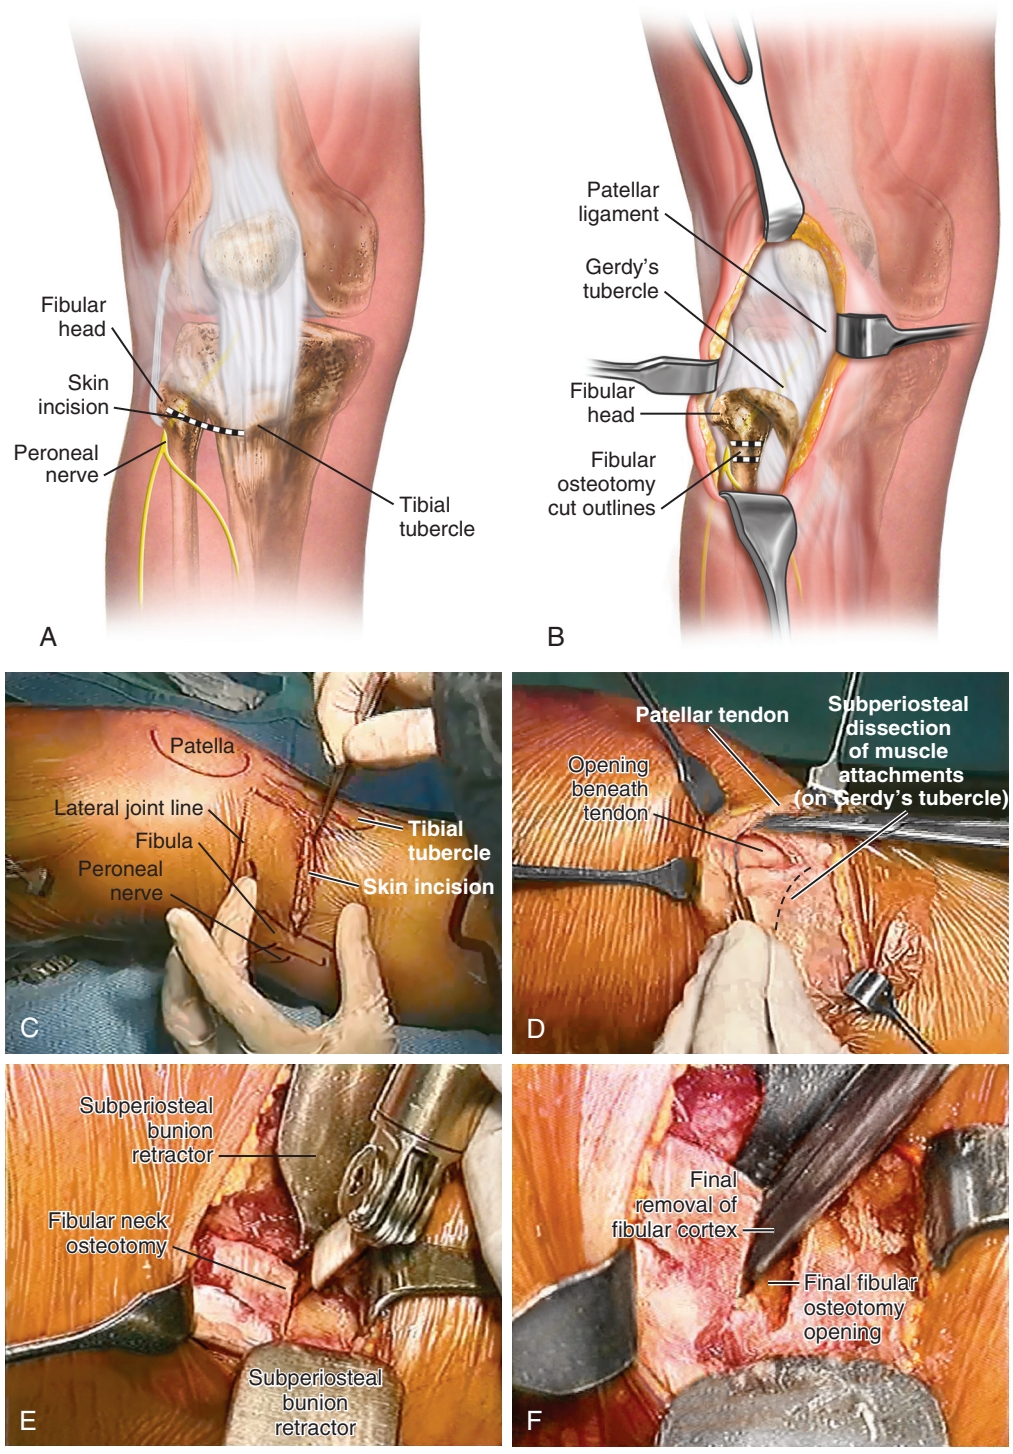

FIG 26-37 Closing wedge osteotomy technique. **A,** Skin incision. **B,** Exposure for the lateral tibial and fibular osteotomy. **C,** Landmarks for the skin incision. **D,** Subperiosteal dissection of the muscles to expose the lateral tibia and proximal fibula. **E,** Osteotomy of the fibula at head-neck junction. **F,** Removal of the fibular bone.

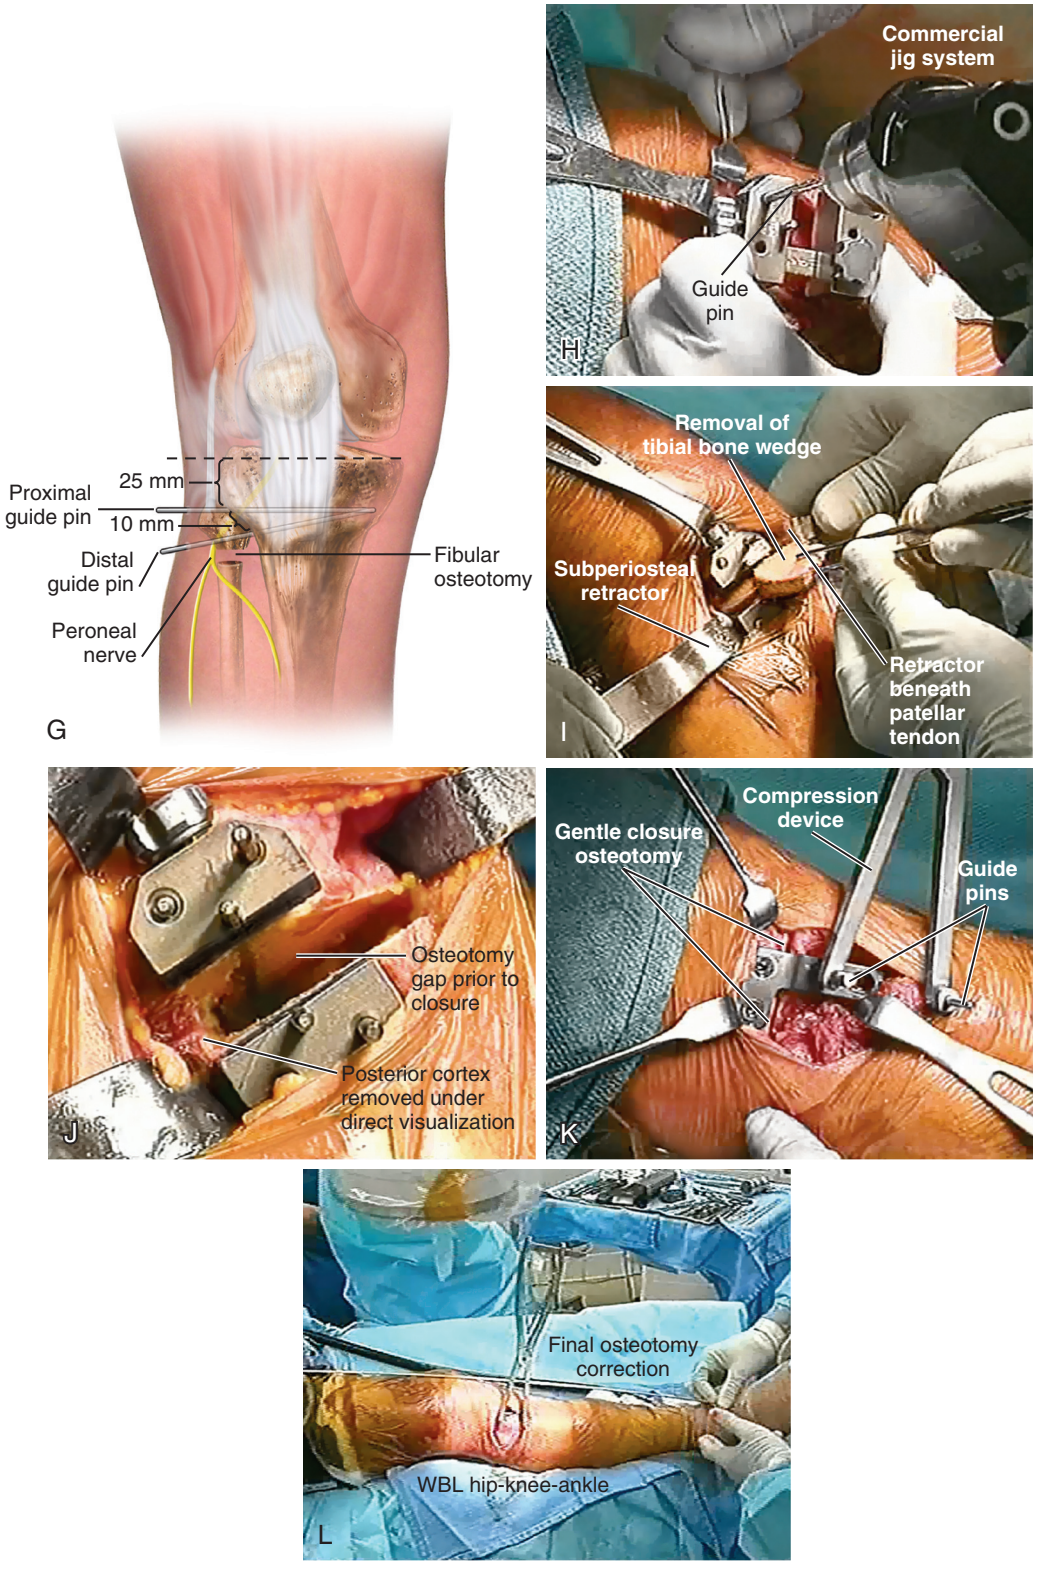

FIG 26-37, cont'd **G,** Placement of two guide pins at predetermined measured angles and depth for correction. **H,** Alternative use of a commercial guide system for guide pin placement. **I,** Removal of the bone wedge. **J,** Lateral gap is equal except for the anterior triangular portion where the gap narrows to prevent alteration of the tibial slope. **K,** Gentle closure of the osteotomy to protect the medial cortex. **L,** Determination of the weight-bearing line correction by fluoroscopy and computerized navigation, which is recommended.

osteotomy. A proximal slide (disruption of tibiofibular joint) is strongly contraindicated because this shortens the FCL and posterolateral structures and may lead to a severe posterolateral instability in an already unstable knee.

The preferred procedure is a proximal fibular osteotomy through the fibular neck region (see Fig. 26-37). Meticulous surgical technique with protection and palpation of the peroneal nerve is essential. To protect the peroneal nerve, the lateral and posterior periosteal sleeve about the fibular neck is carefully preserved and not retracted under tension. If there is any question as to the position of the nerve or chance of nerve damage, exposure of the entire nerve is indicated with direct visualization and protection.

The fibular bone section removed is 2 to 3 mm less than the computed tibial wedge to allow compaction at the fibular osteotomy site. Excellent bony apposition is achieved when the osteotomy is closed, and it is not necessary to add internal fixation. Careful inspection of the fibular osteotomy is done to remove any rough osteotomy edges which would be adjacent to the peroneal nerve.

An alternative choice for a fibular osteotomy is at the junction of the middle and distal thirds of the fibula through a 3-cm posterolateral incision. The peroneal muscles are retracted anteriorly and two bunion retractors can be used for exposure after subperiosteal exposure. A lateral section of the fibula is removed. The medial cortex of the proximal fibula is osteotomized at one site and allowed to slide to maintain bone contact and promote union. A bone graft from the tibial site is added. With this technique, it is not necessary to add internal fixation.

The surgeon should be well aware of the anatomic variability of the superficial peroneal nerve (SPN) in the middle third of the leg. Barrett and colleagues[23] reported on this factor in 35 nonpaired and 40 paired cadaver lower extremities. The SPN was identified in the lateral compartment adjacent to the fascial septum in 72%, in the anterior compartment in 23%, or with a branch in both the anterior and lateral compartments in 5% of the specimens. Ducic and coworkers,[59] in a study of 111 cadaver and clinical specimens, described a similar variability of the location of the SPN in the middle third of the leg. The SPN traveled to the lateral compartment in 70% of the specimens or split with branches in both the lateral and anterior compartments in 16%. In 6% of the specimens, the SPN was found within the intermuscular septum, and in 8%, it traveled only within the anterior compartment.

Step 4: Proximal Osteotomy: Removal of Tibial Wedge

The proximal tibial closing wedge osteotomy technique may be performed using commercially available calibrated osteotomy guide systems, or the bone cuts may be determined using a free-hand method. A smooth guide pin is placed transversely at the proximal tibia to the medial cortex, 25 mm distal to the joint line with fluoroscopy used to ensure proper placement. It is critical to leave at least 25 mm of proximal tibia to avoid a tibial plateau fracture. The transverse length of the guide pin determines the proximal tibia width.

Following the preoperative measurements and based on tibial width (see Table 26-6), the entry point of the second guide pin distally is marked with proper positioning of the guide pins confirmed with fluoroscopy. These guide pins determine the osteotomy triangular bone wedge that is removed to achieve the desired correction. It is important to determine whether or not the lateral cortex is entirely perpendicular at the osteotomy site. In some knees, there will be a slight triangular anterior slope where it is necessary to downsize the osteotomy gap anteriorly not to decrease the tibial slope. The width of the tibia anteriorly is measured and the anterior gap determined (see Table 26-6).

The initial osteotomy cuts are made using a micro-oscillating saw. Initially, only the outer cortex is cut and then the osteotomy is completed with thin osteotomies. An oscillating saw in the cancellous bone may wander and potentially change the correction angle.

A malleable retractor is placed in the subperiosteal plane posteriorly to protect the neurovascular structures at all times with the knee flexed 10 degrees. The lateral half of the wedge is removed as a single piece. Portions of this bone wedge may rarely need to be replaced if an inadvertent overcorrection is obtained at surgery. The remaining triangular wedge of bone is removed under direct visualization.

The surgeon is seated, and a headlamp is always used to view the depth of the osteotomy. The osteotomy plane is maintained in a triangular plane, noting that at the midpoint of the tibia, the tibial width is one half that at the lateral cortex.

The 7 to 10 mm of the wedge adjacent to the posteromedial cortex is left intact to provide stability and prevent medial or lateral tibial translation or varus angulation postoperatively. The posterior tibial cortex of the wedge is removed under direct visualization. The patellar tendon is carefully protected.

Two to three perforations of the posteromedial cortex with a guidewire are often required before the osteotomy gap can be closed with a gentle valgus force that is applied over a few minutes to gradually deform the remaining medial cortex. An option is to use a commercially available compression device to close the osteotomy. Apposition of the bony surfaces of the tibia and fibula should be visualized and inspected.

It is important that the HTO does not increase or decrease the normal posterior tibial slope. The sagittal plane of the osteotomy should be perpendicular to the long axis of the tibia with the width of posterolateral cortex removed based on the coronal angular corrections required (see Table 26-6). In select cases, a biplanar osteotomy for correction of an abnormal tibial slope may be required, as already described. An opening or closing gap in the sagittal plane is performed to the necessary degrees of slope correction.

Step 5: Fluoroscopic Verification of the Weight-Bearing Line for Corrected Alignment

Using fluoroscopy, an alignment guide rod (rigid 3- to 4-mm rod, 1 m in length) is positioned over the center of the femoral head and the center of the tibiotalar joint to determine the corrected WBL intersection at the tibial plateau. A large single staple may be placed across the lateral tibial osteotomy site for provisional fixation. During fluoroscopy, the lower limb is axially loaded at the foot to maintain closure of both the medial and lateral tibiofemoral compartments at 5 to 10 degrees of flexion to avoid hyperextension. It is important to view by fluoroscopy that there is no abnormal opening of the medial or lateral compartment. The knee is taken through a gentle varus-valgus loading to palpate the respective compartments and confirm closure of both because significant errors in the final axial alignment occur if great care is not taken at this junction. A second source of error in the WBL tibial intersection occurs if the lower limb is positioned incorrectly with excessive hip internal or external rotation. The lower limb and foot are positioned with a normal 10 to 12 degrees of external rotation, representing the normal gait foot progression alignment. The alignment guide rod represents a new WBL, which should agree with preoperative calculations. If necessary, further bone may be removed or added to the osteotomy to adjust the WBL. The tibial slope is also verified with fluoroscopy.

Internal fixation of the osteotomy is achieved using a locking plate and screws (Fig. 26-38). Rarely, a 6.5-mm cancellous screw is placed in a lag fashion across the osteotomy site into the medial aspect of the proximal tibial bone for additional fixation. Newer locking plates and

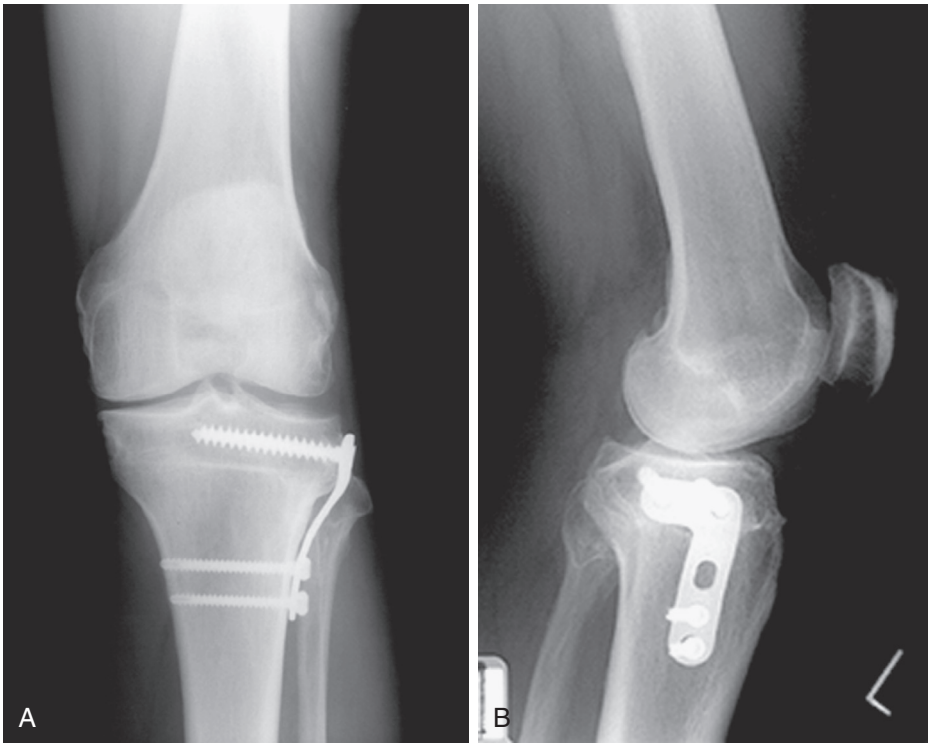

FIG 26-38 Anteroposterior (**A**) and lateral radiographs (**B**) show the postoperative appearance after proximal tibial osteotomy, fibular osteotomy, and internal fixation. (From Noyes FR, Barber-Westin SD, Hewett TE. High tibial osteotomy and ligament reconstruction for varus angulated anterior cruciate ligament-deficient knees. *Am J Sports Med.* 2000;28:282-296.)

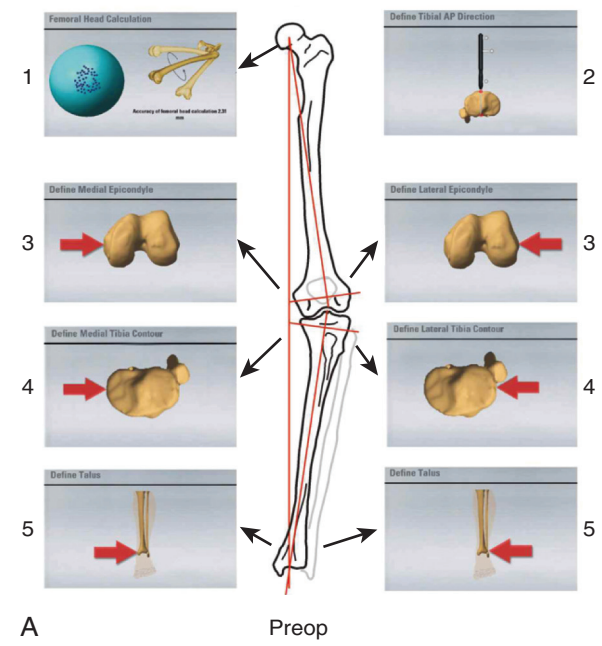
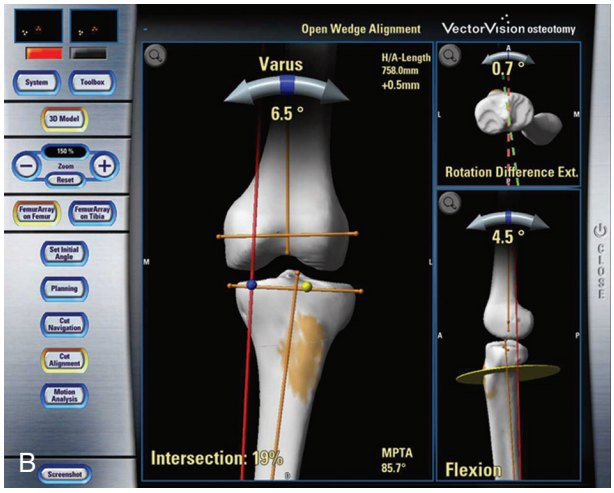
screws provide the advantage of more secure fixation. The final WBL is determined after fixation.

The tourniquet is released and hemostasis obtained. The fascia of the anterior compartment musculature is reattached to the anterolateral aspect of the tibial border with absorbable sutures. It is important to reattach the muscles with adequate suture fixation because muscle tension postoperatively may disrupt the muscle attachment site. A drain is not used.

The lower limb is wrapped with cotton, and additional padding is placed posteriorly and over the peroneal nerve, followed by an Ace bandage, postoperative hinged brace, and bilateral ankle-foot compression boots. A commercial ice delivery system with the bladder incorporated over the initial cotton wrapping, a few layers from the wound, is always used. The neurovascular status is checked immediately in the operating room and carefully monitored in the initial postoperative period. A calf or foot compression system is used for the first 24 hours to promote venous blood flow. Aspirin is prescribed and, rarely in high-risk patients, low-molecular-weight heparin (LMWH) or warfarin sodium (Coumadin). Early rehabilitation emphasizes early quadriceps isometrics, range of knee motion, ankle pumping, and ambulation (see Chapter 28). The surgeon should have a high suspicion for venous thrombosis and a low threshold for ordering ultrasound evaluation in the postoperative period, which is obtained in the majority of patients in the first few days after surgery.



With the meticulous dissection technique described, a postoperative compartment syndrome should be an exceedingly rare occurrence, if at all. The operative limb is always elevated for the first postoperative week, except for periods of ambulation with crutches. The maximum swelling of limb tissues after HTO is usually present 48 to 96 hours postoperatively. The postoperative rehabilitation program is discussed in Chapter 28.



ROLE OF COMPUTERIZED NAVIGATION FOR HIGH TIBIAL OSTEOTOMY

For surgeons who are trained on computerized navigation for total knee joint replacement, the addition of the same techniques for HTO in select cases offers an advantage in determining the final WBL and overall limb alignment. The registration process is easier with fewer points required than total knee replacement (Fig. 26-39, *A*). The software allows for the preoperative and postoperative varus-valgus position and WBL to be determined (Fig. 26-39, *B*). We recommend that the lower limb be held with the knee in 5 degrees of flexion for the measurement of the WBL and degrees of valgus overcorrection. This compares with the full-standing hip-knee-ankle radiographs in 5 degrees of flexion to avoid a hyperextension position in which different WBL measurements would be erroneously obtained. The operating room setup combining the computerized navigation system with fluoroscopy is shown in Figure 26-39, *C*.

Keppler and associates[109] reported on the use of a computer-aided surgical navigation system of opening wedge tibial osteotomy in a plastic bone model and cadaveric lower limbs. These authors found high consistency among operators in registering anatomic landmarks and concluded that improved accuracy and reliability of correcting the mechanical axis would be the benefits of this approach. A number of studies have shown that full-standing radiographic measurements may have errors induced in the coronal plane (affecting WBL measurements) owing to the rotation of the lower limb during the radiographic procedure.[105,140,224] Song and associates[194] reported that a navigation-assisted opening wedge HTO procedure improved the surgeon's ability to obtain a more accurate postoperative alignment correction.

Clinical studies are still required to determine in a large patient series the increased accuracy obtained with computerized navigation

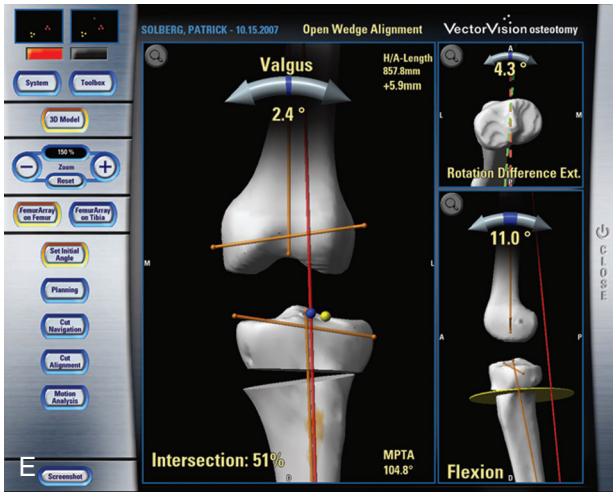


FIG 26-39 **A,** The registration points for the computerized navigation procedure (BrainLAB). **B,** Preoperative measurement shows the angular malalignment of 6.5 degrees varus and a 19% weight-bearing line (WBL) intersection. **C,** Operating room setup. The fluoroscopy and computer navigation instruments are on the operative side. The surgeon is able to perform the medial opening wedge procedure from the medial aspect, usually in a seated position. The photographs shows the ability of the surgeon to determine the lower limb alignment from the foot of the table. **D,** Demonstration of the navigation instrumentation that may be used to determine the osteotomy plane (see text). **E,** Final operative correction obtained, with a 2.4 degrees valgus alignment and a 51% WBL intersection.

CRITICAL POINTS Role of Computerized Navigation for High Tibial Osteotomy

- Offers advantage in determining final overall limb alignment in select cases
- Hold lower limb with the knee in 5 degrees of flexion to measure WBL, degrees of valgus overcorrection.
- Full standing radiographic measurements may have errors induced in the coronal plane (affecting WBL measurements) caused by the rotation of the lower limb during the radiographic procedure.
- Fluoroscopy still required on pin placement and to determine depth of osteotomy during surgery.
- Fluoroscopy confirms final WBL coronal correction and tibial slope.

techniques. However, in our experience, the following points are important. It is still necessary to determine the tibial slope (using the Keith needle technique previously described in the "Operative Techniques" sections) for each knee, although an arbitrary tibial slope may be selected for the navigation technique (Fig. 26-39, *D*). The navigation of the actual osteotomy cut can be performed as easily as with the placement of guide pins and fluoroscopy. In essence, fluoroscopy is still required on pin placement and to determine the depth of the osteotomes during surgery to maintain integrity of the opposite cortex. Increased accuracy of determining the final WBL, compared with hip-knee-ankle fluoroscopy, is expected because the variable of internal-external limb rotation and its effect on the WBL is nearly eliminated (Fig. 26-39, *E*). An error may occur in determining the WBL intersection at the tibia with the standard hip-knee-flexion fluoroscopy method because the measurement line or rigid rod is placed on the limb and does not correspond to the central measurement line in the hip-knee-ankle joints based on navigation.

OPENING WEDGE DISTAL FEMORAL OSTEOTOMY

A femoral closing or opening wedge osteotomy is an accepted treatment for the correction of an abnormal valgus lower limb alignment. Details of the operative indications and procedures are also covered in Chapter 27 and are therefore only summarized here.

The indications and contraindications for surgical treatment are similar to those for an HTO except that the osteotomy is designed to decrease weight-bearing forces on the lateral tibiofemoral compartment. The most common presentation is a younger patient who has undergone lateral meniscectomy and shows progressive valgus alignment and narrowing of the lateral tibiofemoral compartment and has lateral joint symptoms. The procedure is often performed before a lateral meniscus transplantation or other articular cartilage restorative procedures to the lateral compartment (see Illustrative Cases 10, 11, and 12). Similar to a corrective procedure for varus malalignment already discussed, the goal of the procedure is to buy time. It is important not to correct the lower limb to an excessive varus alignment, as is discussed next. If there has been a prior medial meniscectomy or if medial tibiofemoral joint damage is present, a relative contraindication to the varus-producing femoral osteotomy may exist, or the correction should only obtain a neutral alignment. The goal is to correct an abnormal abduction moment at the knee joint but not to produce an abnormal adduction moment that would overload the medial compartment (see Fig. 26-5).

Contraindications to a varus-producing osteotomy are similar to those previously discussed for HTO and include the absence of remaining lateral tibiofemoral articular cartilage and lateral joint tibial concavity, indicating advanced lateral joint arthritis.

CRITICAL POINTS Opening Wedge Femoral Osteotomy

- Indications, contraindications for surgical treatment are similar to those for an HTO except the osteotomy is designed to decrease weight-bearing forces on the lateral tibiofemoral compartment.
- Goal is to correct abnormal abduction moment at the knee joint but not to produce an abnormal adduction moment that would overload the medial compartment.
- Contraindications: absence of remaining lateral tibiofemoral articular cartilage and lateral joint tibial concavity, advanced lateral joint arthritis
- It is important to determine there is no abnormal opening of the medial joint space, which must be accounted for in the preoperative correction measurements.
- Target zone is a WBL at the 45%-47% intersection, equal to a 1- to 2-degree varus lower limb alignment, respectively.
- Cosmetic skin incision of limited length, with upper locking screws placed through small 3- to 4-mm skin incisions.
- Guide pins placed in the line of the osteotomy 15 mm proximal to the femoral trochlea region, slight oblique fashion to end at the proximal metaphyseal junction.
- Gradual distraction, leaves 8 mm of the medial femoral cortex intact
- Maintain equal anterior and posterior osteotomy gap to not change knee flexion or extension in the sagittal plane.
- Use autogenous iliac crest bone graft, locking plate and screws.

The clinical evaluation includes an analysis of the patient's gait and observation for a valgus thrust. There are usually lateral joint line tenderness to examination and mild lateral joint crepitus with a valgus loading of the joint during flexion and extension. This maneuver is frequently painful and reproduces the patient's symptoms. It is important to examine specifically for associated patellofemoral arthritis and articular cartilage damage to the lateral patella facet and trochlea. The valgus lower limb alignment increases the lateral deviation of the patella, producing increased lateral patellofemoral joint loading. Accordingly, symptoms related to the patellofemoral joint may be permanent and should be considered in determining whether the patient is a suitable candidate for the femoral osteotomy.

The radiographic assessment for lower limb alignment has already been presented, including obtaining weight-bearing 45-degree PA views, axial patellofemoral views, lateral view for tibial slope, and a full-standing radiograph for measurement of the hip-knee-ankle mechanical alignment and WBL. Determine that there is no abnormal opening of the medial joint space that must be accounted for in the preoperative correction measurements. In Figure 26-14, the normal tibiofemoral coronal alignment is shown. In valgus-angulated knees, there is frequently a coronal obliquity to the joint line because of the lateral joint damage primarily effecting the lateral femoral condyle. Owing to this obliquity, an opening wedge tibial osteotomy is contraindicated because this would increase the joint obliquity. A lateral opening or medial closing wedge femoral osteotomy would theoretically correct the joint obliquity. Even though there are reports in the literature on opening wedge tibial osteotomy, we have observed clinical cases in which the increased joint obliquity leads to abnormal loading of the lateral tibial tubercle and lateral femoral condyle with subsequent loss of articular cartilage and arthritis. References of publications of closing wedge femoral osteotomy are provided for the

reader[20,65,87,133]; this section deals primarily with the surgical technique for an opening wedge femoral osteotomy.

The preoperative planning for the opening wedge osteotomy follows the same rules as previously presented, and the measurement techniques are the same except that a final WBL intersection at the tibia is just medial to the 50% tibial width. The target zone is a weight-bearing line at the 45% to 47% intersection, which is equivalent to a 1- to 2-degree varus lower limb alignment, respectively. A WBL more medial to this point would induce a varus overcorrection. The degrees of correction and the corresponding osteotomy opening gap in millimeters (rule of triangles, Table 26-7) are usually in the 5- to 8-mm range because of the narrow width of the femur at the osteotomy site. This means that a few millimeters of error would have a major effect in producing an undercorrection or overcorrection. For this reason, the careful and accurate fluoroscopic measurements at surgery of the desired correction and new WBL tibial intersection are important.

The operative steps the senior author follows in performing the opening wedge femoral osteotomy are detailed in Figure 26-40. Important steps in the operative procedure include a cosmetically placed skin incision of limited length, with upper locking screws placed through small 3- to 4-mm skin incisions. The surgeon sits adjacent to the lateral aspect of the lower limb with a headlight on to visualize beneath the raised skin flaps. The guide pins are placed in the line of the osteotomy 15 mm proximal to the femoral trochlea region and in a slightly oblique fashion to end at the proximal metaphyseal junction. The osteotomy involves a gradual distraction process that leaves 8 mm of the medial femoral cortex intact. If the medial femoral cortex is thick and dense, it may be necessary to weaken the cortex with two to three small drill holes. It is important to maintain an equal anterior and posterior osteotomy gap to not change the tibiofemoral slope. An autogenous limited iliac crest bone harvest (discussed under "Operative Technique: Opening Wedge Tibial Osteotomy") is performed, and the width of the outer iliac crest that is harvested matches the opening osteotomy gap. Clinical data are insufficient to recommend allografts or synthetic grafts over autografts for femoral osteotomy, and I prefer an autograft (supplemented with a freeze-dried allograft) for prompt healing and faster resumption of full weight-bearing activities. A limited iliac crest autograft approach in combination with a locking plate and screw design provides for secure femoral fixation, avoiding the serious risks of delayed or nonunion and loss of the lower limb angular correction, which should be a rarity.

An alternative approach involves the Arthrex distal femoral osteotomy system, shown in Figure 26-41.

The rehabilitation program is the same as for an HTO. Full standing radiographs are obtained postoperatively to measure the operative correction obtained and the progression of osteotomy healing. It is usual to begin partial weight bearing at 4 weeks and full weight bearing at 7 to 8 weeks after surgery.

A prospective study is in progress at our institution. Twenty DFOs have been performed, with complete healing noted in all cases. Ten patients have been followed for 10 years or more, two patients for 7 to 8 years, and eight patients for 2 years. There have been no failures as of the time of writing.

OUR CLINICAL STUDIES

Closing Wedge High Tibial Osteotomy in Anterior Cruciate Ligament–Deficient Varus-Angulated Knees

A study was conducted which reported the results of 41 patients (100% follow up) who were followed an average of 4.8 years after closing wedge osteotomy (range, 2-7.2 years).[152] These patients also had ACL-deficient knees, of which 30 were treated with a reconstruction.

CRITICAL POINTS Our Clinical Studies: Closing Wedge Osteotomy in ACL-Deficient Varus-Angulated Knees

- 41 patients, 100% follow-up 2-7 years postoperatively.
- Statistically significant improvements in pain, swelling, function.
- 59% returned to low-impact sports activities.
- 88% satisfied.
- 22 knees had increased lateral tibiofemoral joint opening preoperatively (double varus knees), which resolved in 17 (77%) without a posterolateral reconstructive procedure.
- 27% did not require subsequent ACL reconstruction.
- Determined each patient's desired level of activity and instability symptoms. ACL reconstruction not required in all.
- Goal of HTO was return to daily activities, not athletics, in most patients.
- Goal of HTO in patients with recent onset of pain and no advanced joint damage may be return to athletics or strenuous work activities. ACL reconstruction frequently required in these patients.

Significant improvements were found for all symptoms; the most noteworthy finding was the decrease in pain (Fig. 26-42). Preoperatively, 41% of the patients had moderate to severe pain with activities of daily living, whereas only 10% had this level of pain at follow up. The decrease in pain could have occurred as a result of patient counseling on activity modification and owing to the fact that none of the patients returned to strenuous sports involving jumping, pivoting, and cutting.

Before surgery, 22 patients were participating in some form of sports activities with pain or functional limitations. At follow up, 24 patients (59%) had returned to sports with no symptoms; however, the majority were biking or swimming only.

A separate analysis was conducted on a subgroup of 15 patients who had subchondral bone exposed in the medial tibiofemoral compartment. These patients were followed a mean of 5.5 years (range, 3-7.4 years) postoperatively. A statistically significant improvement was noted in the mean overall rating score at follow up ($P < .01$). Nine patients returned to light sports activities, whereas the other six did not participate, thus following medical advice.

The radiographic evaluation performed in the early postoperative period showed that 37 of 41 (90%) patients were surgically corrected with a WBL between 50% and 80%. Three patients drifted back into varus, and one had settled into valgus. At the final follow-up examination, 25 patients (61%) still demonstrated optimal correction (mean WBL, 60%; range, 46%-79%). However, 11 patients (27%) were in varus (mean WBL, 37%; range, 25%-44%), and 5 (12%) had an increased valgus position (mean WBL, 90%; range, 81%-108%). These findings indicated that progression of the medial arthritis in the varus-angulated knee continues and long-term correction was not achieved in one out of four patients. Even in the knees that returned to a varus angulation, there was short-term relief of pain symptoms; however, the long-term function in these patients is expected to decline.

A statistically significant improvement was found between the preoperative and follow-up overall rating scores (scale, 0-100 points, $P < .01$). The mean increase between evaluations was 14 points (range, –8 to 38 points).

An interesting finding was that whereas 22 knees (54%) had abnormally increased lateral joint opening on varus stress testing preoperatively, only 5 (12%) had this abnormal joint opening at follow up. The valgus-producing osteotomy appeared to have unloaded the FCL and

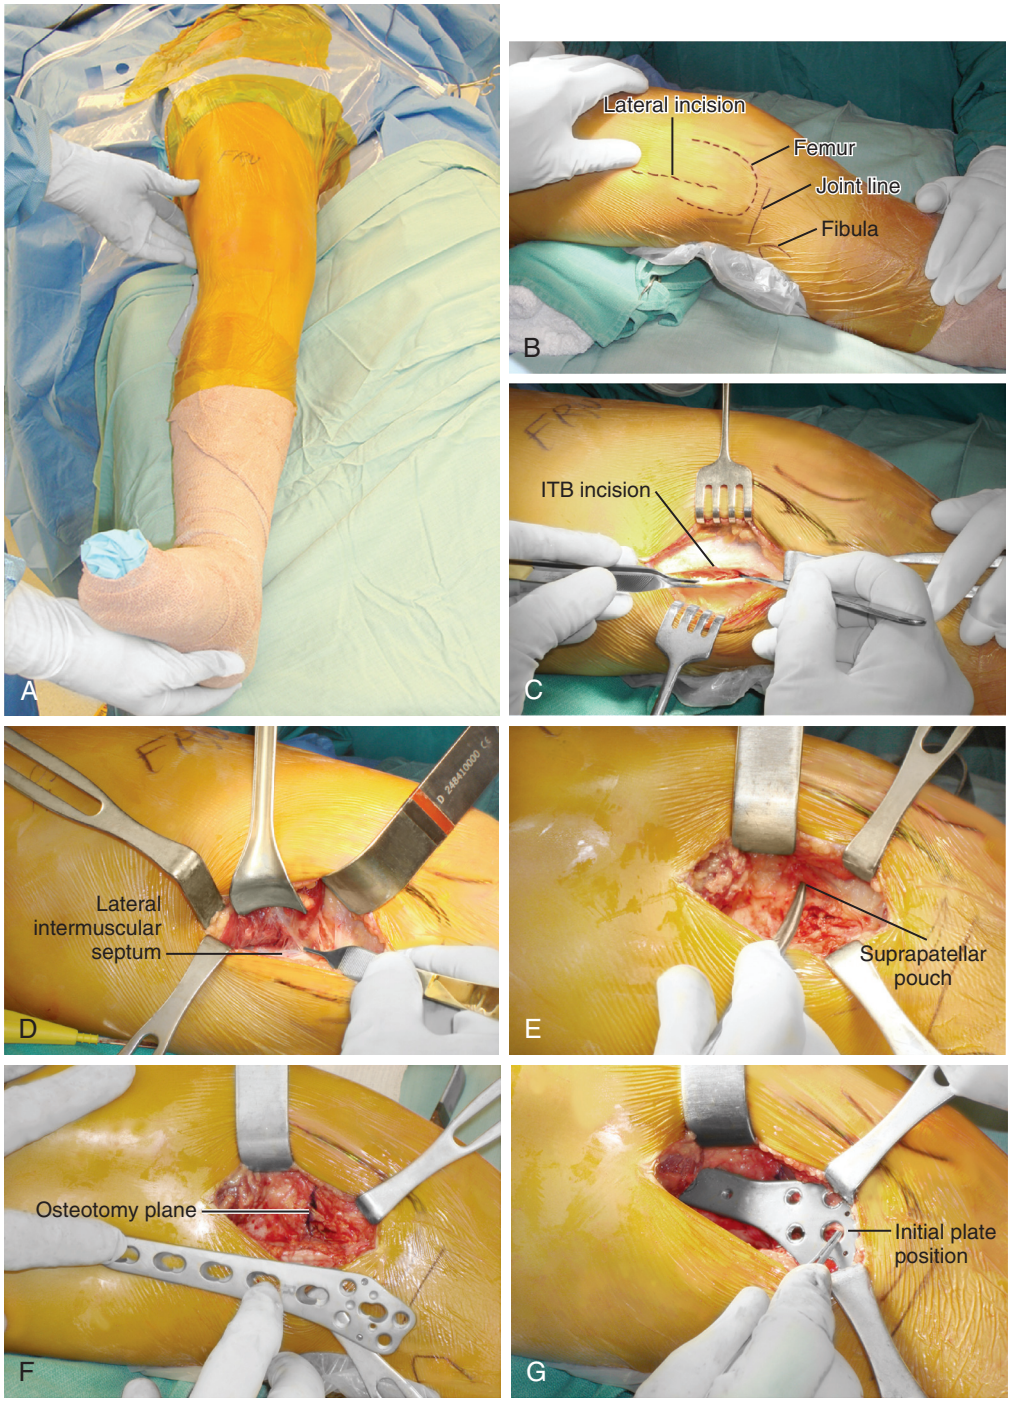

FIG 26-40 An opening wedge femoral osteotomy for correction of lower limb valgus malalignment. **A,** Surgical setup with high thigh tourniquet and the complete lower extremity draped, including the ipsilateral iliac crest (not shown) for bone graft procedure. **B,** Initial limited incision at the distal lateral thigh just above the joint line. The surgeon is seated with a headlamp for adequate visualization. A small posterior thigh roll is placed to prevent the popliteal neurovascular structures from being displaced anteriorly toward the operative site. **C,** Incision into the posterior third of the iliotibial band (ITB) that extends in a proximal subcutaneous plane. **D,** A careful dissection of the vastus lateralis insertion at the lateral intermuscular septum is shown with identification of perforating small arteries and veins for control of hemostasis and prevention of hematoma. **E,** An S retractor is placed underneath the vastus lateralis and the proximal joint suprapatellar pouch is identified, which is not opened. **F,** The approximate location of the femoral osteotomy site is identified by fluoroscopy and the locking plate is selected. **G,** Proximal to distal positioning of the locking plate in reference to the distal femoral condyle and osteotomy site.

Continued

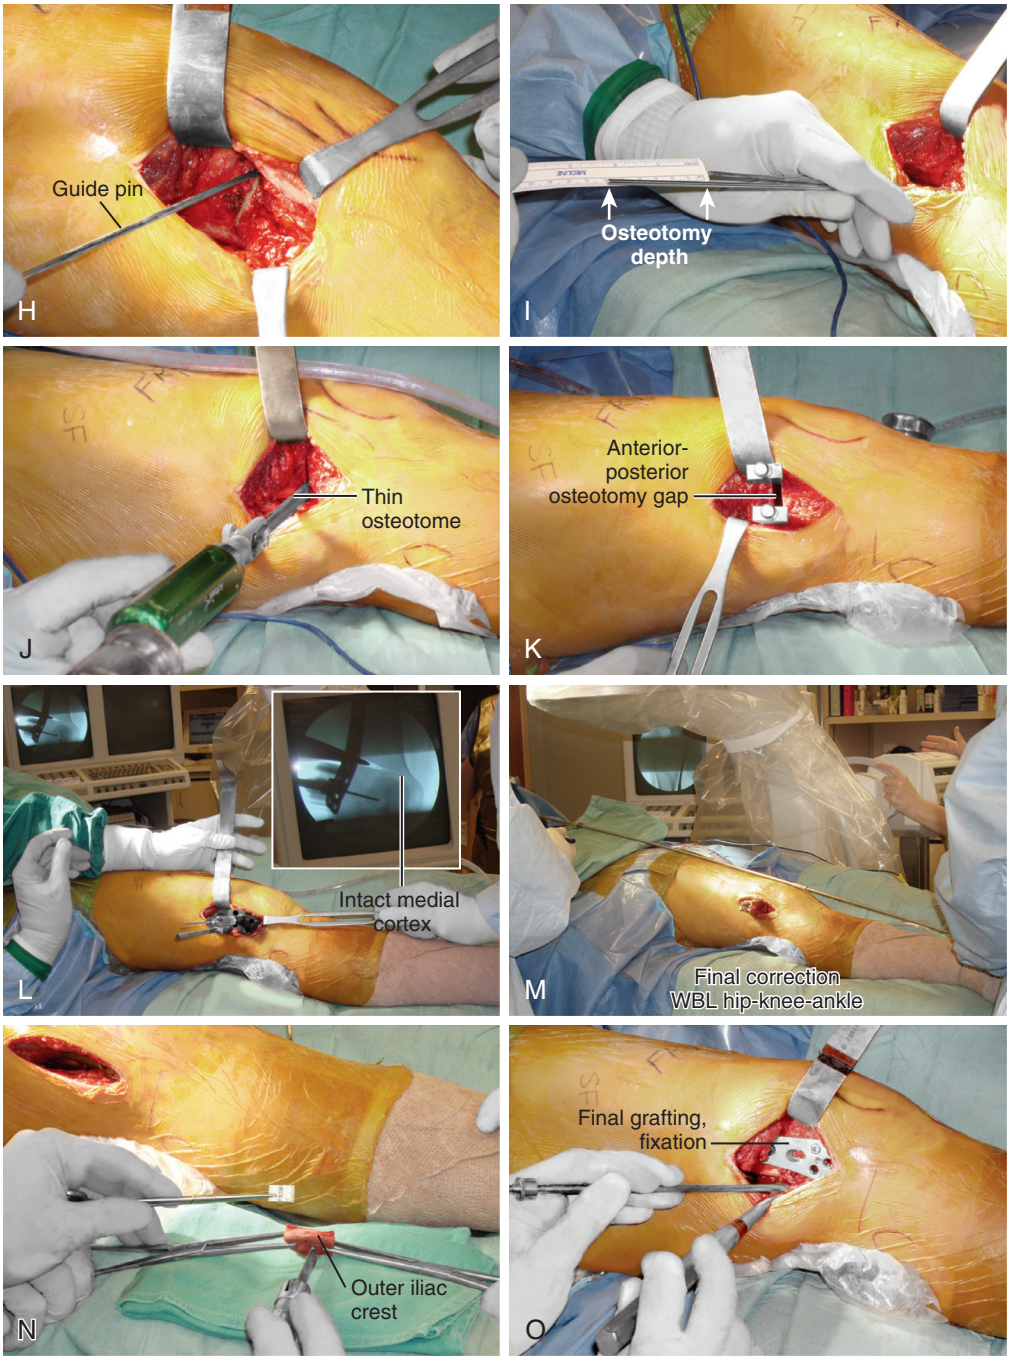

FIG 26-40, cont'd **H,** The anterior guide pin is placed in slight oblique line, 15 mm proximal to the femoral trochlea, which can be palpated and verified by fluoroscopy. The guide pin is placed to intersect the proximal medial metaphyseal flare, which is left intact and provides for medial stabilization. Note that that there has been no subperiosteal dissection even though the anterior and posterior cortex is visualized for later osteotomy. **I,** The posterior guide pin is placed perpendicular to the femoral shaft, and the depth of the planned osteotomy site is measured off a free guide pin. **J,** The initial osteotomy of the lateral cortex is started with a power saw and thin blade followed by a hand-held thin osteotomy blade, which provides better control as the osteotomy progresses. A malleable retractor may be placed posterior to the posterior cortex to protect the neurovascular structures. **K,** The osteotomy site has been gently distracted by thin spreader bars (not shown) and two wedges placed to maintain the opening gap. The medial metaphyseal cortex has been preserved as confirmed by fluoroscopy. **L,** The locking plate is fixed under fluoroscopy control. The monitor shows the osteotomy opening wedge and preservation of the medial metaphyseal cortex. The locking plate is bent to conform to the osteotomy and is fixed with only a few screws to verify the correction. **M,** A rigid rod is placed to establish the new weight-bearing line (WBL) tibial intersection and verify the lower limb alignment. The surgeon provides axial compression at the foot to maintain closure of both the medial and lateral tibiofemoral joints. An inadvertent joint opening of a few millimeters would result in an inaccurate alignment measurement. **N,** The iliac crest autograft is sectioned into anterior, middle, and posterior triangles and subsequently gently wedged into the osteotomy opening gap. Final plate fixation is performed. **O,** The final appearance of the osteotomy with bone graft in place.

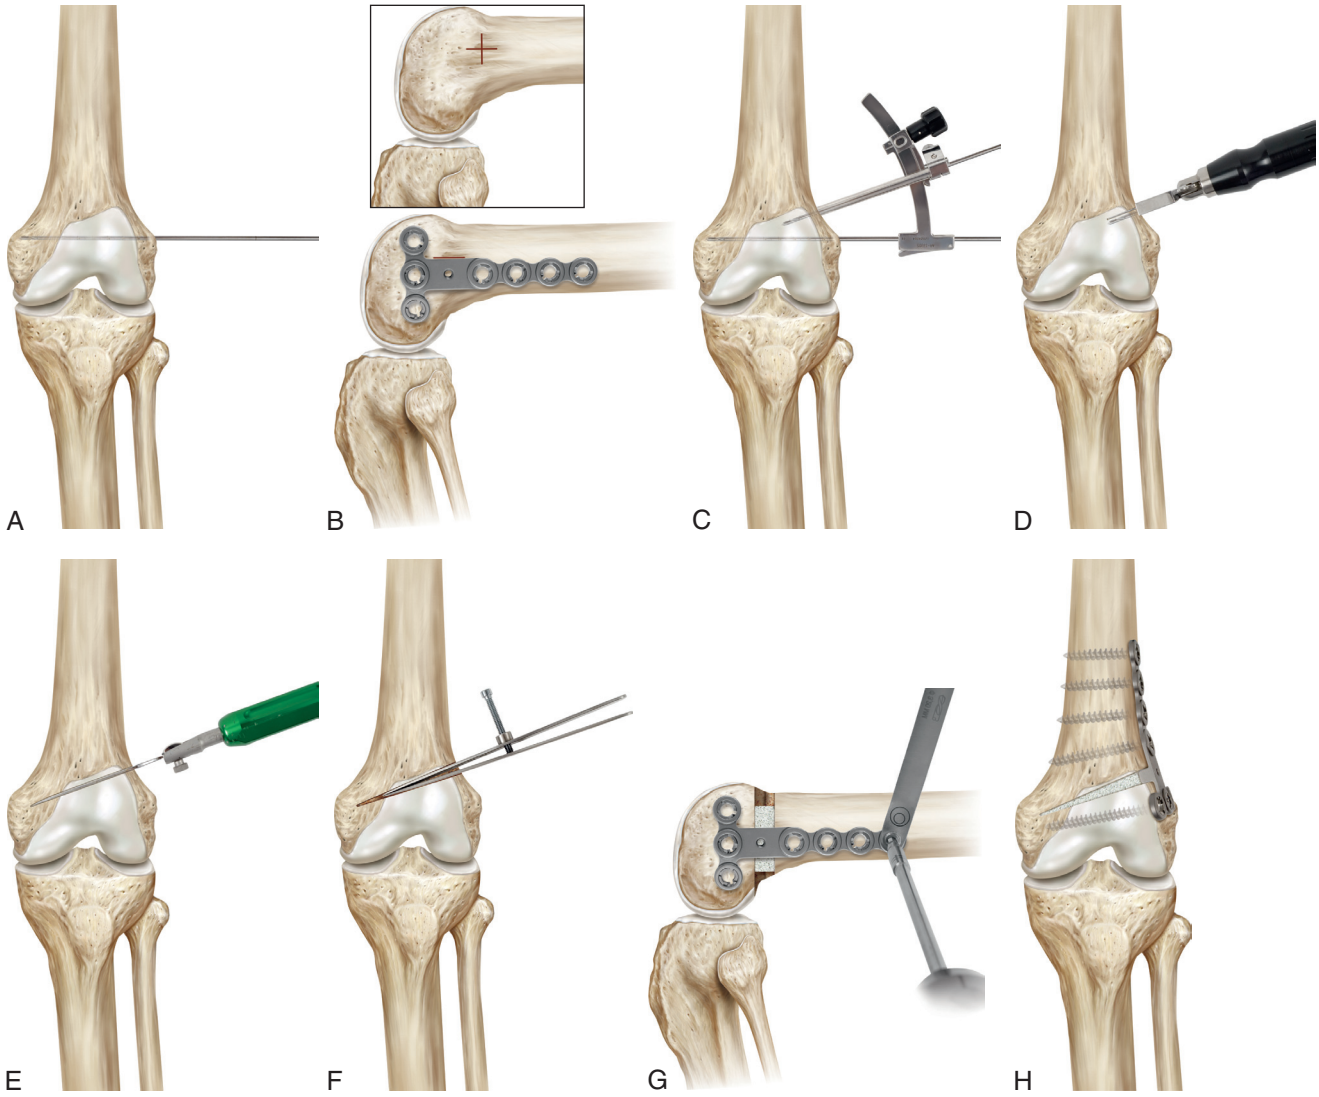

FIG 26-41 The Arthrex femoral opening wedge osteotomy system. **A,** The 3-mm Osteotomy Guide Pin is inserted under fluoroscopic control, transversely from the lateral epicondyle to the cortex of the medial epicondyle (parallel to the joint line). **B,** The Femoral Osteotomy plate is held up in the desired position, and a line is made parallel to the long axis of the femur. A second line (*inset*), perpendicular to the first, is then made at the desired osteotomy level. This will serve as a guide for the cut and assures the plate is centered on the femur. **C,** The osteotomy guide assembly is inserted onto the guide pin, ensuring the black laser line of the guide pin meets the back end of the guide housing. Two 2.4-mm osteotomy guide pins are drilled obliquely under fluoroscopic control from the lateral diaphyseal–metaphyseal junction, aiming at the origin of the medial collateral ligament on the medial epicondyle, making sure to avoid the femoral trochlea. **D,** Retractors are used to clear any soft tissue and an oscillating saw is used to cut the cortex superior to the guide. The pins will protect against accidental saw/osteotome migration into the joint. The cortical bone is cut laterally, anteriorly, and medially. **E,** An osteotome blade and handle are used to complete the cut, preserving approximately 1 cm of the medial cortex. **F,** The osteotomy wedge or an osteotomy jack is inserted to open the osteotomy to the desired height. This can be measured directly from the osteotomy wedge, the wedge trial, of the depth gauge for the osteotome jack. The osteotomy should be opened slowly to preserve the medial cortex. The correct weight-bearing line is confirmed by fluoroscopy as described in this chapter. **G,** Screws are inserted, starting distally with the 6.5-mm cancellous screws and then proximally using the 4.5-mm cortical screws. **H,** Once the osteotomy is complete, alignment is confirmed with x-rays and fluoroscopic guidance. Additional bone graft can be packed into the osteotomy site around the plate.

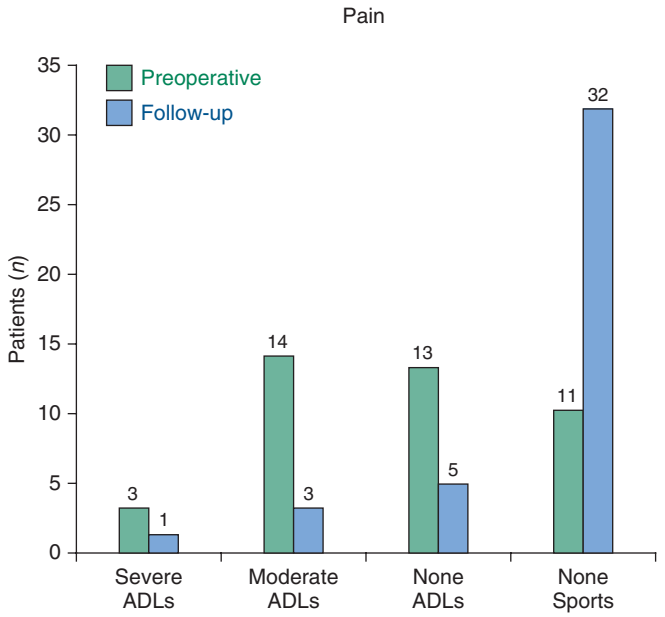

FIG 26-42 The distribution of patient responses to the pain scale are shown preoperatively and at follow up. The improvement was statistically significant ($P < .05$). *ADL,* Activities of daily living. (From Noyes FR, Barber-Westin SD, Hewett TE. High tibial osteotomy and ligament reconstruction for varus angulated anterior cruciate ligament-deficient knees. *Am J Sports Med.* 2000;28:282-296.)

posterolateral ligament tissues, allowing physiologic remodeling and shortening to occur. Therefore no associated posterolateral reconstruction was required during the subsequent ACL reconstruction. This clinical finding appears to support the recommendation to first perform the HTO in double varus knees and then assess knee stability and symptoms to determine the requirement for future ligament reconstruction.

There was no evidence of infection, peroneal nerve palsy, or tibial nonunion. One patient had a gentle manipulation under anesthesia, and full motion was successfully regained.

Three patients required a repeat osteotomy owing to complications. One patient settled into a valgus position 16 months postoperatively. One patient required a repeat internal fixation procedure 4 weeks postoperatively caused by a loss of fixation at the osteotomy site. A falling injury 3 weeks postoperative caused a 4-mm collapse at the osteotomy site in another patient who underwent an opening wedge osteotomy. In all three patients, follow-up examinations performed 2 to 3 years after the reoperation procedures demonstrated WBL and mechanical axes within the optimal range.

One patient had a nonunion at the distal fibula osteotomy site; the tibial osteotomy site healed in a satisfactory manner. The fibula nonunion site was resected 12 months postoperatively, and symptoms resolved.

Patients who had the ACL reconstruction typically had giving-way symptoms with daily or light sports activities. Because many patients modify their sports activities after surgery, it is not always necessary to perform an ACL reconstruction. Eleven knees in this study that were ACL deficient did not require ACL reconstruction. Patients should be individually profiled regarding the level of activity they wish to resume, and an ACL reconstruction done if symptoms warrant the procedure.

Two distinct groups of young, active patients exist in whom the goals of HTO may differ. One group has significant medial tibiofemoral arthritis and pain and swelling with daily activities. The goal of HTO for these patients is to diminish these symptoms, not to return to athletics. These patients are counseled regarding the extent of the disease process and the goal of the HTO, which is to buy time until total joint replacement is required.

The second group of patients does not have advanced joint arthritis; their pain symptoms are of relatively recent onset and occur with sports or manual labor activities. These individuals desire HTO to continue some form of athletics, or they may have strenuous occupations. These patients also usually require an ACL reconstruction because they have higher activity demands and frequently have experienced a giving-way injury. However, data are not available that accurately predict whether or not athletic activities are advisable after successful HTO. Large in vivo joint loading occurs with athletics, and patients who resume these activities do so at their own risk of further joint damage.

The Treatment of Double and Triple Varus Knees: Closing Wedge High Tibial Osteotomy, Anterior Cruciate Ligament Reconstruction, and Posterolateral Reconstruction

A second prospective investigation followed 41 knees (23 double, 18 triple varus) a mean of 4.5 years (range, 2-12 years) after HTO.[159] Before referral, 19 ACL reconstructions had been done in 15 patients that subsequently failed. Many of these ACL failures were attributed to an associated posterolateral deficiency that was not corrected at the time of the initial ACL reconstruction. Thirty patients (73%) had a partial or total medial meniscectomy before the HTO.

In 17 patients (12 double, 5 triple varus), gait analysis testing was conducted preoperatively and a mean of 2 years after HTO. The GaitLink system (Computerized Functional Testing Corporation) included a two-camera, a video-based optoelectronic digitizer for measuring motion, and a multicomponent force plate (Bertec) for measuring ground reaction force which was camouflaged under a 10 meter walkway. A control population of 28 age- and sex-matched normal subjects was used for comparisons. All moments were normalized to the product of body weight multiplied by height (BW × Ht) and were expressed as a percentage of that product.

Thirty knees had abnormal articular cartilage lesions. Twenty-six (63%) had abnormal lesions in the medial compartment.

In 21 (91%) of the double varus knees, the ACL was reconstructed a mean of 9 months after the HTO, and in two knees, the HTO and ACL reconstruction were done simultaneously.

In 13 (72%) of the triple varus knees, the ACL was reconstructed a mean of 8 months after the HTO. One patient had the HTO and ACL reconstruction done simultaneously. Four patients had the ACL reconstruction done before the HTO in an attempt to avoid HTO.

All triple varus knees had a posterolateral reconstruction; 12 (67%) had a proximal advancement of the posterolateral complex with the ACL reconstruction and 6 had an FCL femoral-fibular graft procedure. The knees that had the proximal advancement procedure had a definitive, although lax, FCL of normal width and integrity and intact popliteal muscle-tendon and fibular attachments, previously described as an indication for this procedure. The knees that had the FCL reconstruction had extensive damage to posterolateral tissues.

At follow up, statistically significant improvements were found for pain, swelling, and giving way (Fig. 26-43, $P < .001$). Before the HTO, 18 patients (44%) had severe to moderate pain with activities of daily living, whereas at follow up, only 7 (17%) had such pain. Overall, 29 patients (71%) improved their pain scores, and 28 (68%) improved their swelling score. Giving way was eliminated in 85%.

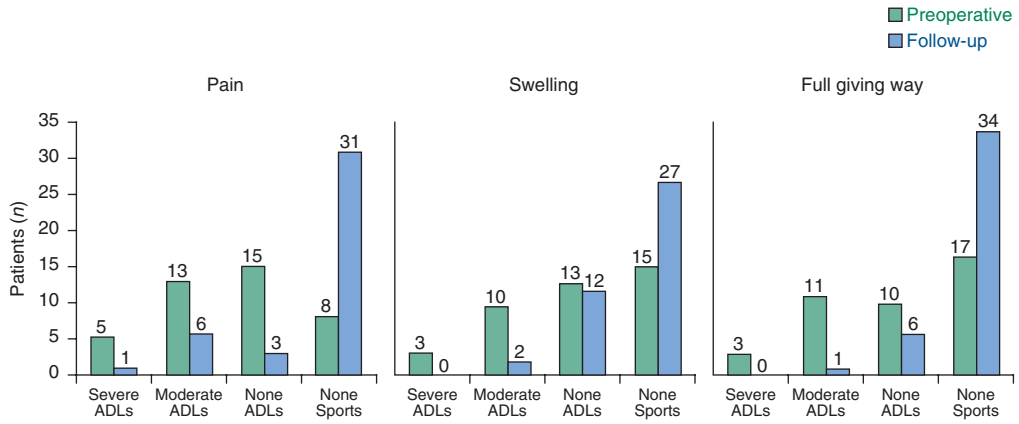

FIG 26-43 Statistically significant improvements were found for pain, swelling, and giving way from preoperative to follow up ($P < .01$). *ADL*, Activities of daily living. (From Noyes FR, Barber-Westin SD, Hewett TE. High tibial osteotomy and ligament reconstruction for varus angulated anterior cruciate ligament-deficient knees. *Am J Sports Med.* 2000;28:282-296.)

CRITICAL POINTS Our Clinical Studies: Treatment of Double and Triple Varus Knees: Closing Wedge Osteotomy, ACL Reconstruction, and Posterolateral Reconstruction

- 41 patients, 100% follow-up mean 4.5 years postoperatively.
- 73% had medial meniscectomy before HTO; 63% had abnormal articular cartilage lesions.
- Gait analysis conducted in 17 patients before and an average of 2 years after the HTO.
- Double varus knees: HTO + ACL reconstruction.
- Triple varus knees: HTO + ACL reconstruction + posterolateral reconstruction.
- Pain with daily activities: 44% before HTO; 17% after HTO.
- 66% returned to low-impact athletics.
- One patient rated the overall knee condition as normal; 14 as very good; 14 as good; 10 as fair; and 2 as poor.
- Triple varus knees: all but one rated functional or partially functional at follow-up for lateral joint opening and external tibial rotation.
- Double varus knees: all rated functional at follow-up for lateral joint opening and external tibial rotation.

Preoperative Gait Analysis

- Mean adduction moment 35% higher in patients compared with control population.
- Predicted medial compartment loads above normal in 71%.

Postoperative Gait Analysis

- Adduction moment decreased to lower than values of control group.
- Medial compartment loads decreased to values equivalent to control group.
- No complications related to knee motion, infection, peroneal nerve palsy.
- 80% knees in acceptable lower limb alignment at follow-up.

Twenty-seven patients (66%) were able to return to mostly low-impact athletics without symptoms. One patient rated the overall knee condition as normal, 14 as very good, 14 as good, 10 as fair, and 2 as poor.

Statistically significant improvements were found in the mean overall rating score from preoperative to follow up (63 ± 11 points and 82 ± 14 points, respectively, $P = .0001$). The average increase was 20 ± 10 points (range, 2-39 points).

At follow up, 19 knees (42%) had functional ACL reconstructions, 11 knees (24%) had partial function, and 15 knees (33%) failed. Ten of the 15 knees that failed represented ACL revision cases. A statistically significant difference was found in the failure rate for ACL revision cases compared with primary reconstruction cases (67% and 33%, respectively; $P = .03$).

Preoperatively, all of the triple varus knees had varus recurvatum, increases in lateral joint opening (mean, 8 mm; range, 3-15 mm), and increases in external tibial rotation (mean, 9 degrees; range, 3-15 degrees). At follow-up, 13 knees were rated as functional rating, 4 as partially functional, and 11 as failed.

Preoperatively, all patients with double varus knees had abnormal increases in lateral joint opening (mean, 4 mm; range, 2-10 mm). At follow up, no patient had more than 2 mm of increase in lateral joint opening, and none had an increase in external tibial rotation. All were rated as functional in lateral joint opening and external tibial rotation.

There was no significant difference in the mean preoperative adduction moment between the double varus and triple varus knees (4.1% ± 0.3% and 4.2% ± 0.3%, respectively). The preoperative mean adduction moment of the study group was 35% higher ($P < .001$) than the control group value; 10 of the 17 patients (59%) had values that were greater than one standard deviation above control values (Fig. 26-44). The study group also had a 22% higher calculated medial compartment load and a 40% higher lateral ligament tensile force compared with the control group (Table 26-8; $P < .01$). Above-normal medial compartment loads were predicted preoperatively in 71% of the involved knees, and above-normal lateral soft tissue forces during walking were predicted in 43% of the involved knees.

Postoperatively, the adduction moment and lateral ligament tensile force decreased to values that were significantly lower than controls. The medial compartment load decreased to values equal to those of controls (Fig. 26-45).

There was no evidence of infection, peroneal nerve palsy, patella infera, or knee motion limitations at follow up. No patient required additional treatment intervention for losses of knee flexion or extension.

Preoperatively, the mean WBL was 22% (range, 3%-49%), and the mean mechanical axis was –6.2 degrees (range, –12 to –1 degrees). At

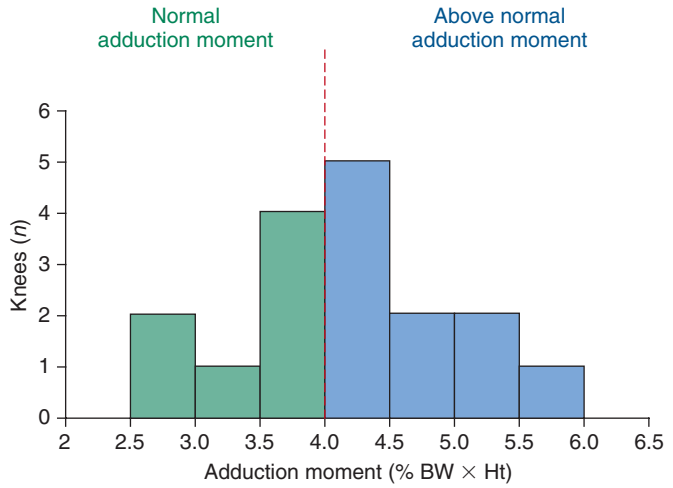

FIG 26-44 The distribution of the preoperative adduction moments of the 17 patients tested. The mean adduction moment for the study group was 35% higher than that for the control group ($P < .001$). *BW,* Body weight; *Ht,* height. (From Noyes FR, Barber-Westin SD, Hewett TE. High tibial osteotomy and ligament reconstruction for varus angulated anterior cruciate ligament-deficient knees. *Am J Sports Med.* 2000;28:282-296.)

surgery, all knees were corrected to a WBL of 62%. In two knees, a valgus overcorrection occurred, and these were subsequently revised.

At follow up, 33 knees (80%) were in an acceptable position (mean WBL, 61%; range, 50%-75%), 7 knees were in varus, and 1 knee was in valgus (WBL, 81%).

Two knees required revision of the HTO. In both, the optimal correction in the 62% WBL range was obtained at surgery; however, excessive valgus (WBL, 86%) occurred with full weight bearing. A revision opening wedge osteotomy was done 2 months postoperative in one knee and 6 months postoperative in the other. At follow up, one knee had maintained the optimal WBL position, but the other had reassumed a varus position (WBL, 40%).

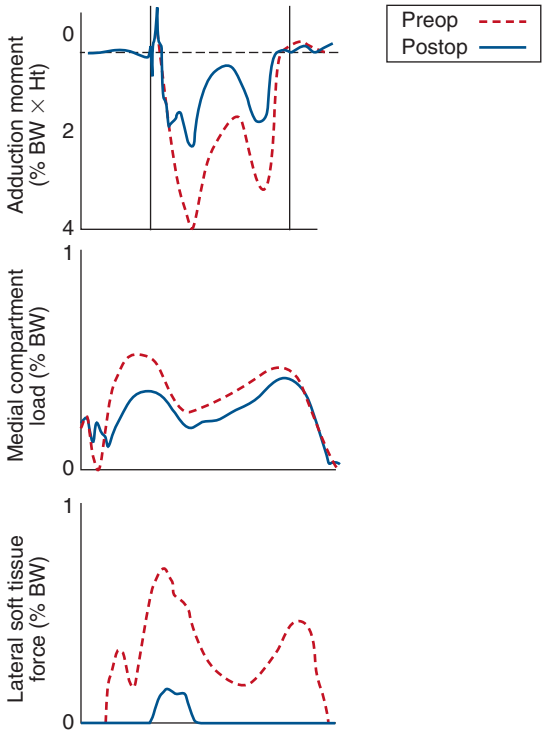

FIG 26-45 The preoperative and postoperative adduction moment, medial compartment load, and lateral ligament tensile forces for the 17 patients tested. Postoperatively, the adduction moment and lateral ligament tensile force decreased to significantly lower than control values. The medial compartment load decreased to values equal to those of controls. *BW,* Body weight; *Ht,* height. (From Noyes FR, Barber-Westin SD, Hewett TE. High tibial osteotomy and ligament reconstruction for varus angulated anterior cruciate ligament-deficient knees. *Am J Sports Med.* 2000;28:282-296.)

One knee had a loss of internal fixation of the osteotomy at the fourth postoperative week that was corrected. The HTO healed without difficulty. Two patients required resection of a distal fibular painful nonunion osteotomy site 12 and 26 months postoperatively.

Opening Wedge High Tibial Osteotomy: An Operative Technique and Rehabilitation Program to Decrease Complications and Promote Early Union and Function

A prospective study was conducted of 59 consecutive patients who had a medial opening wedge proximal tibial osteotomy.[166] All but four patients were followed for at least 6 months postoperative, the minimum follow-up time period required for this study. The 55 patients were followed a mean of 20 months postoperatively (range, 6-60 months).

The hypothesis was that a technique for opening wedge osteotomy that incorporated an autogenous iliac crest bone graft would prevent delayed or nonunion and allow early rehabilitation, weight bearing, and return in function. A second hypothesis was that a methodology for calculating the desired correction of valgus alignment would prevent undesired alterations in tibial slope.

Independent physicians examined radiographs preoperatively and postoperatively for tibial slope and patellar height and postoperatively for bony union. Postoperative radiographs were taken at 4 and 8 weeks after surgery and then as required until bone consolidation was evident. *Delayed union* was defined as lack of bridging callous and

CRITICAL POINTS Our Clinical Studies: Opening Wedge Osteotomy: an Operative Technique and Rehabilitation Program to Decrease Complications and Promote Early Union and Function

- 55 patients reviewed mean 20 months (range, 6-60 months) postoperatively.
- Independent physicians examined preoperative and postoperative radiographs for tibial slope, patellar height, and bone consolidation.
- Concurrent ACL reconstruction in four knees.
- Staged ACL and posterolateral reconstruction in three knees; staged ACL, PCL, and posterolateral reconstruction in one knee; staged PCL reconstruction in two knees; staged medial meniscus allograft in three knees.
- Delayed union in three patients (5%); healed 6 to 10 months postoperatively.
- Early postoperative loss of fixation in one patient (noncompliant with weight-bearing rules); HTO revised.
- No patellar infera, change in tibial slope, infection, arthrofibrosis, deep venous thrombosis, vascular injury, fracture, or problems at iliac crest harvest site.
- Full weight bearing achieved at mean of 8 weeks (range, 4-11 weeks) postoperatively.

presence of radiolucent areas within the opening wedge defect past a period of 3 months postoperatively.

In six knees, a concurrent operative procedure was performed and included ACL primary reconstruction in two knees, ACL revision reconstruction in one knee, ACL and MCL reconstructions in one knee, and an osteochondral autograft transfer procedure on the medial femoral condyle in two knees.

In nine knees, staged procedures were performed an average of 8 months (range, 3-19 months) after the osteotomy. These included knee ligament reconstructions of both the ACL and posterolateral structures in three knees; combined ACL, posterolateral, and PCL reconstruction in one knee; PCL reconstruction in two knees; and medial meniscus transplants in three knees. All nine knees achieved bony union at the osteotomy site and were full weight bearing before undergoing the staged procedures. No complications related to the HTO occurred in these nine knees.

Healing and union at the osteotomy site was radiographically evident an average of 3 months postoperatively in 52 patients (95%). A delay in union (with no loss of fixation or correction) occurred in three patients (5%). The size of the opening wedge osteotomy in these three patients ranged from 11.0 to 16 mm. In two of these patients, a bone stimulator was applied, and union was achieved by 6 to 8 months postoperatively. The other patient achieved union without intervention by 10 months.

An early postoperative loss of fixation occurred in one patient who admitted to full weight bearing immediately after surgery. The osteotomy was successfully revised 10 days postoperatively and proceeded uneventfully to union. There were no instances of shortening of the patellar tendon related to a patella infera syndrome.

There was no significant difference between the mean preoperative (9 degrees ± 4 degrees; range, 2-16 degrees) and postoperative (10 degrees ± 3 degrees; range, 3-21 degrees) tibial slope measurements. One patient with a PCL-deficient knee had an intentional increase in posterior slope.

There were no deep infections, loss of knee motion requiring intervention, deep vein thrombosis, nerve or arterial injury, fracture, or complications related to bone grafting.

Full weight bearing was achieved a mean of 8 weeks (range, 4-11 weeks) postoperatively.

The dissection was limited to include only 10 mm of the superior iliac crest. The iliac crest harvest procedure can be painful with trunk flexion activities for up to 4 weeks postoperatively, and patients are advised accordingly. The standard cortical iliac crest graft harvested was 40 mm in length, 12 mm in width, and 30 mm in depth, although larger osteotomies required a longer graft of approximately 45 mm. The width of the osteotomies varied from 5 to 15 mm, with 35% of the procedures being 10 mm or more.

The argument may be made that autogenous bone grafting is only required for large osteotomies, such as those over 10 mm, but in fact, no well-designed clinical studies have been published to date that provide evidence for such recommendations. When an opening wedge osteotomy proceeds to a delayed union or nonunion, there is usually a loss of correction and a prolonged course of restricted weight bearing, potential muscle disuse, and need for further surgical intervention. In these knees, failure to arrive at the desired goal of the osteotomy ensues, and therefore specific steps are taken to avoid this sequela in all patients regardless of the size of correction required.

The iliac crest graft harvest adds operative time and most likely increases the risk of complications at a second operative site. In this study, no patient complained of pain at the iliac crest harvest site with activities at follow up. Two patients had a small hematoma at the iliac crest harvest site, which resolved uneventfully. Despite this, patients should be advised of the expected postoperative pain and increased risk of complications.

Many commercial allograft wedges are available for opening wedge osteotomies. Allograft bone may have a marked delay in incorporation and healing at the osteotomy site. There may be a higher risk of delayed union, prolonged need for crutch protection, delay in allowing weight bearing, and disuse effects with both allografts and other substitute materials. A high rate of complications was reported in a series in which tricalcium phosphate was used to fill the wedge defect in 20 knees.[177] Nonunions occurred in 35%, loss of correction in 15%, infections in 10%, and material failure in 30%. No problems with union have been reported in several studies of opening wedge osteotomy when an iliac crest bone autograft was used.[48,126,173,176,218,226]

The following operative principles are promoted to prevent fracture: ensure that a proximal lateral tibial plateau width of at least 20 mm exists, avoid too much obliquity at the osteotomy site, and perforate to within 10 mm of the lateral cortex with the osteotome. Forceful completion of the osteotomy should be avoided. Several surgeon-controlled factors can help minimize the risk of inadequate or loss of correction (Table 26-9). Meticulous preoperative planning is imperative. Intraoperatively, the mechanical axis must be accurately verified. Because the size of the osteotomy is not set before fixation, opening wedge osteotomy affords the surgeon ample opportunity to adjust the angular correction and aids in producing the desired alignment. The alignment after surgery should be verified by the fourth postoperative week under partial weight-bearing conditions.

A prospective HTO investigation recently begun at our institution involves studying the effect of the Synthes locking plate and freeze-dried corticocancellous tibial allograft wedges. The hypothesis is that there will be no difference in the rate of nonunions and delayed unions and loss of angular correction compared with our prior clinical study owing to the added protection from the locking plate design. To date, 13 patients have been enrolled, and the preliminary results show no complications. It appears that locking plate techniques allow for allografts to be safely used, thereby avoiding the need for autogenous iliac crest procedures, except perhaps in cases of large (≥15 mm) opening wedge osteotomies.

TABLE 26-9 Technical Pearls to Avoid Complications for Opening Wedge High Tibial Osteotomy

1. Perform meticulous subperiosteal dissection to protect SMCL, posterior neurovascular structures.
2. Verify osteotomy starting point medial cortex; use anterior and posterior Keith needles to verify tibial slope.
3. Placement of guide pin and osteotomy too proximal can lead to lateral tibial plateau fracture.
4. Maintain approximately 15-degree pin angulation at medial tibial site; avoid large obliquity to osteotomy.
5. Measurement pitfalls: anterior tibial gap should be one half of posteromedial gap to avoid tibial slope increase. Verify coronal alignment with fluoroscopy, 5 degrees of knee flexion, medial and lateral tibiofemoral compartments closed and in contact.
6. Secure fixation SMCL repair to avoid valgus instability. No release of deep MCL.
7. Implement immediate knee motion, patellar mobilization, and quadriceps function to avoid patella infera.
8. Maintain lateral cortex hinge by leaving 10 mm laterally, gentle distraction opening wedge.
9. Autograft iliac crest bone graft if >15 mm opening.
10. Allograft bone grafts: expect delay in union; requires locking plate and screws
11. Postoperatively maintain close follow-up, prevent swelling, elevate limb, use thromboembolic hose, perform hourly ankle pumps, check for DVT, obtain routine ultrasound.

DVT, Deep venous thrombosis; *MCL*, medial collateral ligament; *SMCL*, superficial medial collateral ligament.

CRITICAL POINTS Results From Other Clinical Studies

Survival Rates Endpoints
- Conversion TKA
- Conversion unicompartmental knee replacement
- Low HSS score
- Patient dissatisfaction
- Failure to relieve knee pain

Survival Rates
Closing Wedge Osteotomy
- 5 years postoperative: mean 90% (range, 73%-99%)
- 10 years postoperative: mean 77% (range, 41%-98%)
- 15 years postoperative: mean 69% (range, 39%-93%)

Opening Wedge Osteotomy
- 5-8 years postoperative: 70%-97%
- 10 years postoperative: 85% (only 1 study)
- 15 years postoperative: 68% (only 1 study)

Opening vs. Closing Wedge
- No difference in survival rates
- No differences in pain scores, Lysholm score, HSS score, complications
- Lower patellar height, greater posterior tibial slope in some opening wedge studies

HTO and Associated Cartilage Restorative Procedures
- Microfracture, osteochondral allografts, osteochondral autograft, autologous chondrocyte implantation have been done with HTO
- Satisfactory mid-term survival rates reported in three studies

Long-Term Knee Symptoms and Function
- HTO alleviates knee pain and improves function in most studies, but longevity of improvements correlates with length of follow-up.
- Many patients able to return low-impact sports activities in short- to mid-term periods after HTO.
- Satisfactory relief of symptoms and improvement in knee function reported in most studies that combined HTO with ACL reconstruction.

HTO vs. Unicompartmental Knee Replacement
- Only a few studies available that compared HTO with modern unicompartment knee replacement procedures. No short-term differences found between operations.
- One long-term study reported equivalent 10-year revision rates in patients aged 30-64 years.

RESULTS FROM OTHER CLINICAL STUDIES

High Tibial Osteotomy Survival Rates

Survival rates that have been reported after HTO are shown in Table 26-10. Although conversion to TKA was uniformly used as an endpoint for survival, some investigators also incorporated additional endpoints such as a UKA, a low overall Hospital for Special Surgery (HSS) knee rating score, patient dissatisfaction, or failure to relieve pain. There is little agreement among studies regarding factors that may negatively affect survival rates after HTO. Preoperative factors reported include age greater than 50 years, obesity, Ahlback radiographic grade 2 or more, female gender, knee flexion less than 100 degrees, and varus malalignment greater than 9 degrees. After surgery, poor quadriceps strength and inadequate correction (that varied in studies from greater than 6 degrees valgus, less than 8 degrees valgus, more than 15 degrees valgus, and more than 16 degrees valgus) were associated with lower survival rates in a few studies.

In regard to closing wedge osteotomy, an analysis of 16 investigations that calculated survival rates (see Table 26-10) revealed an average 5-year rate of 90% (range, 73%-99%) and an average 10-year rate of 77% (range, 51%-98%). At the time of writing, 11 studies provided 15-year survival rates that averaged 69% (range, 39%-93%), and 5 studies calculated 20-year rates that were quite variable, ranging from 30% to 85%.

Fewer data are available regarding survival rates after opening wedge osteotomy. Six studies reported mid term (5-8 years) rates that ranged from 70% to 98.7%. Hernigou and Ma's series of 203 knees calculated 10- and 15-year survival rates of 85% and 68%, respectively.[88]

In 2013, Harris and associates[84] published a systematic review of 69 studies in which 57 assessed the outcome of isolated HTO, 9 assessed HTO with articular cartilage restorative procedures (microfracture, autologous chondrocyte implantation [ACI], osteochondral autograft transfer, or osteochondral allograft transplantation), and 3 assessed HTO with medial meniscus transplantation. The authors calculated survival rates for each study and found no significant differences between opening and closing wedge osteotomy at 5 and 10 years postoperatively. There was a slightly higher survival rate noted for HTO when done in conjunction with articular cartilage procedures at 5 years compared with isolated HTO procedures (98% and 92%, respectively; $P < .001$) and HTO combined with meniscus transplantation (91%; $P < .001$); however, differences in the length of follow up preclude comparison of longer term survival rates. The authors did

not conduct a separate analysis that compared the survival rates according to the various types of cartilage restorative procedures.

High Tibial Osteotomy Opening Versus Closing Wedge Osteotomy

There does not appear to be a significant difference in survival rates between opening and closing wedge osteotomy procedures. The systematic review conducted by Harris and associates[84] previously described compared rates of 1850 opening wedge with 2665 closing wedge osteotomies and found nearly identical results up to 10 years postoperatively. However, there are longer follow-up time periods in closing wedge osteotomy studies, and data are currently lacking on 15- and 20-year survival rates of opening wedge procedures for comparison.

A meta-analysis by Smith and colleagues[193] compared radiologic and clinical outcomes and rates of complications of 324 opening wedge osteotomies to those of 318 closing wedge osteotomies from nine investigations. The follow-up time periods in the studies were short, ranging from 1 to 27 months postoperatively. There was no significant difference between procedures in visual analogue pain scores, Lysholm score, HSS score, or incidence of complications (including infection, deep venous thrombosis (DVT), nonunion, peroneal nerve palsy, revision surgery, or TKA). There were a significantly lower patellar height ($P < .001$) and a significantly greater posterior tibial slope ($P < .0001$) in the opening wedge group. There was no difference in the angle of correction.

Other investigators have reported significant differences between opening and closing wedge procedures in changes in regard to patellar height, posterior tibial slope, or both.[8,58,63,111,196] Unfortunately, the studies did not always provide detailed descriptions of the operative procedures and calculation of angular correction required at surgery. However, Hinterwimmer and colleagues[90] found no significant changes in tibial slope or patellar height following opening wedge osteotomy when techniques described in this chapter were used to prevent these changes. Song and associates[196] found no differences between opening and closing wedge procedures 3 to 4 years postoperatively in the average amount of patellar tilt, lateral patellar displacement, extent of anterior knee pain, and HSS scores.

High Tibial Osteotomy and Associated Cartilage Restorative Procedures

At the time of writing, 12 studies have been conducted in which HTO was combined with an articular cartilage restorative procedure. The restorative procedures included microfracture in four investigations,[130,175,202,223] osteochondral allografts in three,[79,132,134] osteochondral autograft transfer in two,[9,138] ACI in two,[24,29] and either microfracture or ACI in one.[148] Satisfactory mid term survival rates were reported 4.5 years after ACI by Bode and associates[29] (90%), 7 years after microfracture by Sterett and colleagues[202] (91%), and 7.5 years after osteochondral autograft transfer by Minzlaff and coworkers (90%).[138] The other investigations were either short term in duration or did not provide results of patients who underwent combined osteotomy-cartilage repair procedures compared with the rest of the study cohort.

Few authors have presented results of combined HTO-meniscus transplantation procedures,[41,77,215] and others only briefly mentioned that the procedure was done in small numbers of patients.[1,82,205,228,230]

Effect of High Tibial Osteotomy on Long-Term Knee Symptoms and Function

The ability of HTO to alleviate knee pain and improve function has been demonstrated in many studies; however, the longevity of improvement tends to correlate with the length of follow up achieved postoperatively in most investigations (Table 26-11). For instance, Benzadour and colleagues[25] followed 192 patients (224 knees) for 15 years postoperatively; 118 had an opening wedge and 106 had a closing wedge osteotomy. There were no significant differences in Knee Society rating scores between the two groups at 5, 10, and 15 years, with both showing a gradual deterioration in scores over time. Revision osteotomy or TKA was required in 60 knees (27%). The authors concluded that either procedure was effective for at least 10 years.

Functional limitations with daily activities such as walking and stair climbing are typically reported in the majority of patients before HTO. In addition, few patients are able to participate in even light sports

TABLE 26-11 Long-Term Clinical Outcome of High Tibial Osteotomy

activities without experiencing noteworthy symptoms. After surgery, the ability to walk an unlimited distance or more than 1 km is an important measure of daily function. Koshino and coworkers[114] reported that 94% of 75 patients could walk more than 1 km without pain at 15 to 28 years postoperative after a closing wedge HTO. However, the American Society Knee Function significantly decreased from 93 ± 13 points at 5 to 9 years postoperative to 80 ± 19 points at 15 to 28 years postoperative ($P < .0001$). Pfahler and associates[179] reported that 57% of 62 patients followed 6 to 14 years postoperatively could walk more than 1 hour.

Several studies have reported that, in the short- to mid term period after HTO, many patients return to mostly low-impact, recreational sports activities.[21,31,32,142,188,221] For instance, Salzmann and coworkers surveyed 65 patients who were 1.1 to 7 years after opening wedge osteotomy and reported that 91% were participating in activities such as bicycling, swimming, and fitness. There was no significant change in the frequency or duration of activities compared with preoperative levels, and no patients were involved in competitive sports. Bonnin and associates[32] surveyed 139 patients who were 2.5 to 6.1 years postoperative and reported that 71% participated in light, low-impact activities. However, 62% of the patients thought their activities were limited by their knee, and "several" patients had a high or very high level of discomfort during sports activities. Long-term data (>10 years) are lacking on the ability of patients to continue to participate in athletics and the effect of such participation on the knee condition.

Satisfactory relief of symptoms and improvement in knee function has been reported in most studies involving patients who had an HTO and ACL reconstruction either concomitantly or staged (Table 26-12). In a manner similar to that noted with isolated osteotomies, combined ACL-HTO procedures typically allow a return to recreational or low-impact activities.

High Tibial Osteotomy Versus Unicompartmental Knee Replacement

The outcomes of modern osteotomy and UKA techniques have been compared in only a few investigations.[33,56,210,216,227] Although several others have conducted comparisons of these operations prospectively, retrospectively, or in meta-analyzed data, these investigators combined different types of osteotomy techniques and older UKA prostheses, which had a higher rate of failure compared with more recently available designs.[38,69,100,197,207] In a randomized, prospective study, Borjesson and colleagues[33] found no differences in clinical outcome measures 5 years postoperatively for pain during walking, the patient's subjective opinion of improvement in the knee condition, and levels of physical activity between 18 patients who had HTO and 22 who had UKA. A short-term study by Dettoni and associates[56] reported similar Knee Society scores and survivorship rates between 54 HTO and 56 UKA patients who were 2 to 4 years postoperative. Yim and coworkers[227] also found no differences between 58 HTO and 50 UKA recipients in clinical outcome measures of Tegner and Lysholm scores and range of knee motion, 3 years postoperatively. Using data from the Swedish Knee Arthroplasty Register, W-Dahl and colleagues[216] reported equivalent 10 year revision rates for HTO and UKA (17%) in patients aged 30 to 64 years.

Opening Wedge Distal Femoral Osteotomy

Four clinical investigations have been published to date regarding the outcome of opening wedge DFO.[49,57,103,232] Three of the four investigations noted generally good outcomes but emphasized the need for clear indications of the procedure because patients with bicompartmental or tricompartmental arthrosis tended to have poorer results than those with isolated lateral arthrosis. Three of the four studies filled the osteotomy gap with some type of material (cement, autogenous bone, allograft bone). Fixation was accomplished with a Puddu plate in two studies, a Tomofix plate in one study, and a blade plate bent to 95 degrees in one study. Survival rates were provided by two studies at 7[57] and 8[232] years postoperatively.

Dewilde and associates[57] followed 19 consecutive patients a mean of 5.7 years (range, 2.6-10.6 years) postoperatively. There were six men and 13 women whose average age at surgery was 47 years (range, 30-51 years). The preoperative mechanical axis ranged from 3 to 10 degrees valgus (mean, 5.3 ± 2.5 degrees). The osteotomy gap was injected with bioresorbable calcium phosphate cement and secured with a Puddu plate. Patients began range of motion exercises 3 to 5 days postoperatively, were allowed partial weight bearing at 4 weeks, and progressed to full weight bearing after 8 weeks. At follow up, a statistically significant improvement was found in the mean Knee Society Knee Score (preoperative, 43 ± 8; follow up, 78 ± 23 points; $P < .0001$). The mean postoperative mechanical axis improved to −1.3 ± 4.0 degrees. Two patients were converted to TKA at 13 and 30 months postoperatively, and one patient required a revision because of a fall that occurred 2 months postoperatively. The 7-year survival rate was 82% (95% confidence interval [CI], 57%-93%).

Zarrouk and colleagues[232] followed 22 knees (in 20 patients) a mean of 4.5 years (range, 3-11 years) postoperatively. There were 7 men and 13 women whose average age at surgery was 53 years (range, 27-66 years). The preoperative mechanical axis ranged from 188 to 198 degrees (mean, 194.5 degrees). No bone grafting was used, and the osteotomy site was secured with a blade plate bent to 95 degrees. Patients were kept non–weight bearing for 3 months and were then progressed based on radiographic documentation of healing. The mean time to union was 14 weeks. Delayed union occurred in one patient. There were significant improvements in the mean International Knee Society score (preoperative, 49; postoperative, 74 points; $P < .001$), the function score (preoperative, 50 points; postoperative, 72 points; $P < .001$), and the pain score (mean improvement 26 points; $P < .001$). The postoperative mechanical axis ranged from 177 to 186 degrees. Twelve knees had a correction between 0 to 6 degrees valgus, eight knees had a slight overcorrection (<3 degrees varus), and two knees were overcorrected (>6 degrees varus). The 8-year survival rate was 91% (95% CI, 69%-100%).

Das and coworkers[49] performed an opening wedge DFO on 12 patients who were reviewed clinically a mean of 2.8 years (range, 1-4.1 years) and by telephone interview a mean of 6.1 years (range, 4.2-7.4 years) postoperatively. There were five men and seven women whose mean age at surgery was 55 years (range, 46-71 years). The osteotomy gap was filled with allograft bone and secured with a Puddu plate. Patients were kept partial weight bearing for 8 weeks until radiographic signs of healing were noted. The mean correction was 11 degrees valgus (preoperative, 10-21 degrees valgus and postoperative, 1-8 degrees). Full standing radiographs were not available, and therefore these values represented only "an indication of the real alignment." Two patients converted to TKA, and two others required plate removal. One delayed union (7 months) occurred. The Lysholm score improved only slightly, from 64 points preoperatively to 77 points at follow up. HSS score improved from 58 to 72 points.

Jacobi and associates[103] performed an opening wedge DFO on 14 patients who were followed a mean of 3.7 years (range, 2.3-5.2 years) postoperatively. There were eight men and six women whose mean age at surgery was 46 years (range, 28-63 years). In seven patients, an autogenous iliac crest bone graft was used, and in all patients, the

ACL, Anterior cruciate ligament; *ADLs,* activities of daily living; *CW*, closing wedge; *F/U*, follow up; *HSS*, Hospital for Special Surgery; *HTO*, high tibial osteotomy; *IKDC*, International Knee Documentations Committee; *LAD*, ligament augmentation device; *NA*, not available; *OW*, opening wedge; *PT*, patellar tendon; *STG*, semitendinosus-gracilis.

osteotomy site was secured with a Tomofix plate. The mean correction was 5.8 degrees (range, 3-9 degrees). Full weight bearing was allowed at 3 months in seven patients and was delayed in the others. At 6 months, two patients had insufficient healing, and one of them required spongious bone augmentation and an additional medial plate. The other knee healed within 9 months. Plate removal was required in 12 patients. The mean overall Knee Injury and Osteoarthritis Outcome Score improved from 31 ± 17 points before surgery to 69 ± 22 points at follow-up ($P = .002$). Bone grafting did not affect the slow healing time (3-12 months) and all patients were nonsmokers. These authors no longer perform this procedure, favoring medial closing wedge osteotomy instead.

PREVENTION AND MANAGEMENT OF COMPLICATIONS

Bony Instability, "Teeter Effect"

Kettlekamp and colleagues[110] described the teeter effect in 1975 as a contraindication to proximal tibial osteotomy. Excessive bone loss and concavity on the medial tibial plateau prohibits simultaneous weight bearing on both plateaus after HTO and results in an unstable knee in the coronal plane. A teeter effect occurs because tibiofemoral contact shifts, or teeters, from one plateau to the other depending on the relationship of the center of gravity to the center of the knee.

CRITICAL POINTS Prevention and Management of Complications

Bony Instability, Teeter Effect
- Preoperative radiographs determine bone loss, slope
- Intraoperatively, use fluoroscopy with both compartments loaded to confirm simultaneous medial and lateral tibiofemoral contact.

Inadequate or Loss of Axial Correction
- Caused by inadequate internal fixation, progressive loss articular cartilage medial compartment, stretching or deficiency of posterolateral soft tissues
- Preoperative: correct calculation mechanical axis and weight-bearing line.
- Intraoperative: confirm adequate correction with fluoroscopy, computerized navigation.

Delayed Union or Nonunion
Closing Wedge
- Perform osteotomy proximal to tibial tubercle to increase amount of cancellous bone surface contact.

Opening Wedge
- Use autogenous iliac crest bone graft for large corrections, corticocancellous allograft wedges for smaller corrections; locking plate and screw fixation in all.
- Toe-touch weight bearing at 4 weeks.

Tibial Plateau Fracture
- Ensure proximal lateral tibial plateau width is ≥20 mm.
- Avoid forceful closure of osteotomy.

Arterial Injury
- Recognize anterior tibial artery, popliteal artery at risk during surgical dissection caused by anatomic position.
- Flex the knee; gently retract popliteal structures.

Peroneal Nerve Injury, Palsy
- Caused by cast or bandage applied too tightly after surgery; double padding over peroneal nerve.
- Use internal fixation to avoid cast.
- Avoid injury to nerve during surgery.
- Avoid dome osteotomy below the tibial tubercle.

Arthrofibrosis, Patella Infera
Detection
- Bilateral, lateral radiographs preoperatively and postoperatively to measure patellar vertical height
- Inability of patient to perform strong quadriceps contraction
- Decreased patellar mobility and tension in patellar tendon
- Distal malposition of involved patella compared with opposite side

Minimize Risk
- Immediate rehabilitation: straight-leg raises, isometrics, electrical muscle stimulation, patellar mobilization
- Early recognition and treatment of limitation of knee motion

Iliac Crest Harvest Site Pain
- Limit dissection to only 10 mm of superior iliac crest.
- Meticulous subperiosteal exposure of outer iliac crest.
- Do not violate muscle plane or inner iliac cortex.
- Keep muscle attachments intact.

Deep Vein Thrombosis
- Before surgery, screen for any risk factors for DVT, including a prior history or family history suggestive of an inherited coagulation defect.
- Women should stop estrogen, oral contraceptives 1 month before surgery.
- Use aspirin twice daily after surgery.
- Use foot-ankle compression devices and thromboembolic hose.
- Early ambulation.
- Perform active ankle pumps hourly.

Osteotomy is contraindicated when bone loss makes simultaneous contact of both plateaus impossible. Preoperative radiographic evaluation of the bone loss on the tibial plateaus should be performed, specifically evaluating the slope of the plateaus to determine whether loading of both compartments will occur after HTO.

It has been suggested, but not experimentally confirmed, that if the combined cartilaginous and bony loss on the medial side is greater than 1 cm, it would be impossible to achieve loading of both the compartments after HTO. During surgery, the WBL should be evaluated under fluoroscopy with both compartments loaded to confirm that simultaneous medial and lateral tibiofemoral contact is present.

Inadequate or Loss of Axial Correction

Inadequate or overcorrection of lower limb alignment has been reported by many authors after HTO. Hernigou and associates[89] reported persistent varus occurring in 10 of 93 knees immediately after closing wedge osteotomy. In that investigation, 71 of 76 knees showed some degree of recurrent varus deformity 10 to 13 years postoperatively. Magyar and colleagues[121] described a loss of correction after closing wedge osteotomy, with 9 of 16 knees proceeding into increased valgus by 1 year postoperatively despite normal alignment achieved immediately postoperatively.

Marti and coworkers[125] followed 32 knees that had an opening wedge osteotomy with bone grafting. At follow up, 24 to 62 months postoperative, 31% demonstrated a recurrence of the varus deformity and 19% were in excessive valgus. Stuart and associates[206] evaluated standing tibiofemoral angles, which decreased from a mean of 9.3 degrees of varus to 7.8 degrees of valgus at final follow up. Using the Kaplan-Meier survival analysis method, the authors predicted that varus alignment was likely to occur in 18% of knees, lateral compartment arthritis was likely to progress in 60%, and medial and lateral compartment arthritis was likely to progress in 83% by 9 years after surgery.

In a biomechanic study, Stoffel and coworkers[204] showed that an intact lateral tibial hinge cortex largely determined the stability after opening wedge HTO. When the lateral cortex was disrupted, a locking plate and screw designed showed superior stability in both compression and torsion compared with the Puddu plate.

Loss of the axial alignment obtained at the time of surgery may be attributed to several factors. These include the use of inadequate internal fixation with collapse of the distal fragments settling into the cancellous bone of the plateau. Late drifting into a varus position may be caused by a progressive loss of the medial osteochondral cartilage complex or by stretching of the posterolateral structures. Coventry[45] reported no loss of surgical correction obtained immediately

postoperatively. He attributed the success of the procedure to stability of the closing wedge, the hinge effect of the medial periosteum and cortex, internal fixation, and avoidance of a shift of the fragments.

Careful preoperative planning is required to avoid inadequate correction, which begins with the calculation of the mechanical or anatomic axis using full-length standing radiographs. Stress radiographs may be used to evaluate medial osseocartilaginous complex loss and lateral joint opening.[60] Calculations to determine the amount of bone to be resected should be performed before the osteotomy as discussed.

During surgery, confirmation of adequate correction that was determined by preoperative measurements is done using fluoroscopy. The knee will be placed in an overall excessive valgus position if the amount of lateral opening is not evaluated and if too much bone is resected. Even though an ideal position may be verified during surgery, a change in alignment may be detected when postoperative standing radiographs are obtained. The alignment should be verified by the fourth postoperative week under partial weight-bearing conditions.

Delayed Union or Nonunion

Delayed union or nonunion has been reported following HTO. Warden and colleagues[218] reported incidence rates of delayed union (6.6%) and nonunion (1.8%) in 188 opening wedge osteotomies in which an iliac crest bone autograft was used in the majority of knees. There was a trend toward an increased incidence of delayed union or nonunion when a coral wedge was used either alone or in conjunction with the autogenous graft (15%, 5 of 33 knees) compared with when an iliac crest graft was used alone (6%, 8 of 128 knees). No problems with union were reported by Marti and associates,[126] Pace and Hofmann,[173] or Patond and Lokhande[176] after opening wedge osteotomy and iliac crest bone autograft procedures. Lobenhoffer and Agneskirchner[119] found that 6% of 101 knees that had an opening wedge HTO with a variety of bone graft substitutes and fixation with an Arthrex plate progressed to a nonunion.

The incidence of healing problems can be reduced by following several technical suggestions. First, the osteotomy should be performed proximal to the tibial tubercle because this will increase the amount of cancellous bone surface contact, which will enhance healing and inherent stability. The two surfaces should be cut in a manner that maximizes the amount of surface area that will be in contact in closing wedge osteotomies. In opening wedge osteotomies, a stable construct created by the use of an iliac crest autogenous bone graft (in the anterior, mid, and posterior portions of the osteotomy) and appropriate plate fixation with protection of the lateral tibial buttress (cortex) will sustain postoperative compressive and torsional loads. The argument may be made that autogenous bone grafting is only required for large osteotomies and that allograft or corticocancellous wedges with locking plate technology provides no increase in delayed healing or loss of osteotomy correction. No well-designed clinical studies with a sufficient number of patients have been published to date that provide evidence for such recommendations. Dallari and colleagues[48] showed that the addition of platelet gel or platelet gel combined with bone marrow stromal cells substantially increased the rate of bone healing in a small group of opening wedge osteotomies.

Many investigators have demonstrated that external fixators may accomplish adequate union and correction, such as the series reported by Sterett and Steadman[201] in which only 1 of 33 patients had a loss of correction early postoperatively. However, pin tract infections were reported in 45% of the patients. Several other investigations have reported high rates of pin tract infections, such as 67% (10 of 15 knees) from Adili and associates,[2] 62% (23 of 37 knees) from Bachhal and coworkers,[19] and 54% (12 of 22 knees) from Gerdhem and colleagues.[71]

Plate designs that incorporate locking screws provide added stability and are necessary in cases of any violation of the lateral tibial cortex to maintain stability under axial compressive or torsional loads. An alternative fixation method for a lateral tibial cortex fracture at osteotomy is to add a lateral two-hole plate through a separate incision; however, angulated locking screws from a medial plate may also be used.

The rehabilitation program allows toe touch weight bearing during the first 4 weeks and then allows progression over the next 4 weeks to full weight bearing based on radiographic signs of osteotomy healing. A delayed union can be treated, if the overall alignment is acceptable, by electric stimulation.

Tibial Plateau Fracture

The reported prevalence of fracture after closing wedge osteotomy ranges from 1% to 20%.[89,131] This complication appears uncommon after opening wedge osteotomy, although Amendola and associates[7] reported 7 of 37 patients (19%) in their initial series of opening wedge osteotomies had intraarticular fractures that extended into the lateral compartment. The fractures were believed to be caused by a combination of the osteotomy site closer to the lateral tibial plateau joint line than the lateral cortex and use of thick osteotomes. After adjusting the obliquity of the osteotomy and switching to thin, flexible osteotomes, the authors did not experience any further cases of fracture.

There are important operative techniques to prevent tibial plateau fracture as described. The proximal osteotomy should remain parallel to the joint surface. It is important to keep the proximal tibial portion 20 to 25 mm thick to avoid fracture. The cortex on the lateral side of the wedge may be penetrated by drill holes, and forceful closure of the wedge should be avoided. If a tibial plateau fracture does occur, anatomic reduction and internal fixation of the plateau fragments should be performed.

Arterial Injury

Vascular complications are exceedingly rare. Recognition of the anatomic relationship of the vessels to the surgical dissection is imperative. The anterior tibial artery is at risk because it pierces the proximal interosseous membrane. Injury to this artery may result in an anterior compartment syndrome, which must be recognized and dealt with promptly. The popliteal artery is at risk during posterior dissection and osteotomy of the posterior tibial cortex. By flexing the knee and gently retracting the popliteal structures, the risk of injury to these structures will be significantly reduced.

Peroneal Nerve Injury or Palsy

Jackson and Waugh[102] reported 27 of 226 cases (12%) of partial or complete injury to the peroneal nerve during osteotomy. Because there was a higher incidence of injury during curved osteotomies located below the tibial tuberosity, the authors concluded that osteotomy in this location was too dangerous. A 7% incidence of peroneal nerve injury was reported by Sundaram and coworkers,[209] and a 6% incidence was described by Harris and Kostuik.[85] Slawski and associates[192] reported a 4.3% incidence of peroneal neurapraxias in 225 pediatric tibial osteotomies.

Flierl and colleagues[68] compared the incidence of neurologic complications after opening wedge osteotomy between a technique using a conventional oscillating saw with a technique that created multiple drill holes and osteoclasis. After the conventional method, acute

transient peroneal nerve palsy developed in 15.7% of 89 patients, with persistent deficits found in 12.4%, 6 months postoperatively. In the osteoclasis group, 14% had acute transient events, and 4.7% reported permanent weakness. Other than the report by Flierl and colleagues,[68] nerve injury after opening wedge HTO appears to be extremely rare.

Peroneal nerve palsy may result from several causes; the most common is a cast or bandage applied too tightly after surgery. The use of internal fixation alleviates the need for casting. The nerve may also be directly injured during surgery.

Osteotomy of the fibula is performed at different sites by different authors depending on the operative technique. A risk of injuring the peroneal nerve exists if the osteotomy is performed in the proximal third of the fibula.[112] In addition, osteotomy in the middle portion of the fibula may injure the peroneal nerve innervation to the extensor hallicis longus. The rate of injury has been reported to be extremely high (25%) after dome osteotomy below the tibial tubercle.[102]

Arthrofibrosis and Patella Infera

Many early HTO studies cited unacceptably high rates of arthrofibrosis and patella infera after postoperative immobilization. Windsor and associates[222] reported that 80% of 45 knees had patella infera after closing wedge HTO and postulated that postoperative plaster immobilization allowed the decreased quadriceps muscle forces and shortening of the patellar tendon. Westrich and coworkers[220] demonstrated the beneficial effects of early motion after closing wedge osteotomy; 16 of 34 knees (47%) treated with cast immobilization developed patella infera compared with 3 of 35 (8%) that received immediate postoperative motion.

A decrease in the patellar height ratio as measured by the Blackburn-Peel ratio is expected after opening wedge osteotomy.[39] Wright and associates[225] reported that all 28 patients in their series of medial opening wedge osteotomies had a decrease in patellar height but no significant change in patellar ligament length (as measured by the Insall-Salvati ratio[99]). The authors explained that because the osteotomy increased the distance between the tibial tubercle and tibial articular surface, the patella migrated distally.

Similar findings in decreased patellar height following opening wedge osteotomy have been reported others.[39,88,144,146,212] Patella infera correlated with the magnitude of angular correction after HTO in two series.[212,225] For example, Wright and associates[225] evaluated patellar height and ligament length in 28 patients and found a relationship between the amount of infera and the degree of angular correction.

Postoperatively, lateral radiographs are taken to detect any decrease in the patellar vertical height ratio; these are repeated for any patient who shows early signs of developmental patella infera (inability to perform a strong quadriceps contraction after surgery, decreased patellar mobility, decreased palpable tension in the patellar tendon with failure of the patella to displace proximally on quadriceps contraction, or distal malposition of the involved patella compared with the opposite side). Rigid internal fixation should also help to reduce the occurrence of arthrofibrosis and a resultant patella infera.

In our opening wedge osteotomy study, the patellar height was not significantly affected by the magnitude of angular correction owing mostly to the desire not to change the tibial slope and ensuring that the anterior gap at the osteotomy site was less than half of the posterior gap. In addition, no patient had a limitation in knee motion that required treatment intervention such as manipulation or arthroscopic release of adhesions.

An immediate knee motion program and exercise protocol of straight-leg raises, multiangle isometrics, and electrical muscle stimulation are advocated to decrease the incidence of quadriceps weakness and knee motion limitation following HTO. In addition, a phased treatment program is begun for limitations of motion early in the postoperative course when restriction of either extension or flexion is noted.[161] This program is discussed in Chapter 28.

Iliac Crest Harvest Site Pain

Most, if not all, of the complications described in the literature related to iliac crest bone graft harvest may be avoided by the surgical technique described in this chapter. For example, the dissection is limited to include only a bicortical 12-mm width of the superior iliac crest. A meticulous subperiosteal exposure of the outer iliac crest is performed without violating the inner muscle attachments. The inner iliac cortex is never dissected, and the muscle attachments are kept intact. This minimally invasive harvest technique avoids the frequency of complications reported by larger exposures such as those used for spine fusions.

The standard cortical iliac crest graft harvested is 40 mm in length, 12 mm in width, and 30 mm in depth, although larger osteotomies require a longer graft of approximately 45 mm. The iliac crest harvest procedure may be painful with trunk flexion activities for up to 4 weeks postoperatively, and patients are advised accordingly. Even though there were no complications in our series, added time is required for the operative procedure and a complication is always possible, which must be weighed against the benefits of the rapid healing provided by autogenous bone at the osteotomy site.

Deep Vein Thrombosis

We reviewed HTO clinical studies and review articles that were published between January 2000 and March 2014 to determine the incidence of DVT and pulmonary embolism (PE) and prophylaxis protocols used to prevent these complications. A total of 118 studies were included in which 8340 knees in 7883 patients underwent HTO. Overall, 119 DVT (1.4%) and 8 PE (0.096%) events (with one fatality) were reported.[5,24,25,30,37,55,62,80,127,128,147,175,211,213] There appeared to be no difference in the incidence rate of thromboembolic complications between opening and closing wedge osteotomies or between investigations that used or did not use a thrombophylaxis protocol.

A thromboembolic prophylaxis program was described in only 26 studies (22%). There was no consistency among these studies regarding the choice of chemoprophylaxis agents, mechanical devices, or exercises. No study mentioned discontinuation of oral contraceptives before surgery. The use of low-molecular-weight heparin, without other mechanical devices or exercises, was the most frequently reported measure to prevent DVT. A few authors also recommended compression boots, antiembolism stockings, and/or ankle pump exercises.[5,76,116,136,159,166,195]

In conclusion, the occurrence of DVT after HTO is low, and the occurrence of a PE after HTO is exceedingly rare. The majority of publications did not provide recommendations for prophylaxis. In studies that provided recommendations, there is no consensus, and protocols vary widely. Even so, the incidence of DVT occurring in 4% to 7% in some studies[24,55,62,80] warrants the use of a reasonable prophylaxis protocol. Surgeons are urged to carefully screen all patients well before surgery to assess personal and family history of thrombotic events and to obtain appropriate blood and genetic testing when warranted. Women should be questioned regarding use of oral contraceptives and a decision reached on discontinuation of the medication 6 weeks before surgery. We have empirically used, in standard-risk patients, a program that includes intermittent pneumatic compression devices in both extremities for the first 24 hours, immediate knee range of motion exercises, early ambulation and partial weight bearing, antiembolism stockings, ankle pumps

performed for 5 minutes every hour the patient is awake, and aspirin (325 mg/twice a day for 10 days).[166] Whether or not this program is efficacious requires further study; however, in our opinion, based on the information available, the program appears to be safe, reasonable, and effective. We obtain a Doppler ultrasound if the patient demonstrates any suspicion of a DVT including abnormal calf tenderness, a positive Homans sign, or increased lower extremity edema. The use of ultrasound to screen for DVT of the lower extremities is used with even the slightest suspicion of calf tenderness and tibial edema or a positive Homans sign.

ILLUSTRATIVE CASES

Case 1: Treatment of Varus Angulation and Severe Articular Cartilage Damage to the Medial Femoral Condyle in a Patient Younger Than 20 Years old

A 19-year-old man presented with a complaint of pain to the medial aspect of his left knee with activities of daily living. He had a 4-year history of osteochondritis dissecans that had been treated elsewhere with internal fixation of the fragment that failed to heal. A subsequent arthroscopic debridement of the medial femoral condylar fragment was performed. Full-length, standing radiographs revealed a mechanical axis of 5 degrees varus and a WBL of 29% of the tibial width (Fig. 26-46, *A*). All ligamentous structures were intact. Medial tibiofemoral compartment narrowing of 50% was evident on posteroanterior 45-degree weight-bearing radiographs.

HTO was indicated to unload the damaged medial tibiofemoral compartment. The arthroscopic examination showed a 20 × 20 mm area of subchondral bone exposure on the medial femoral condyle (see

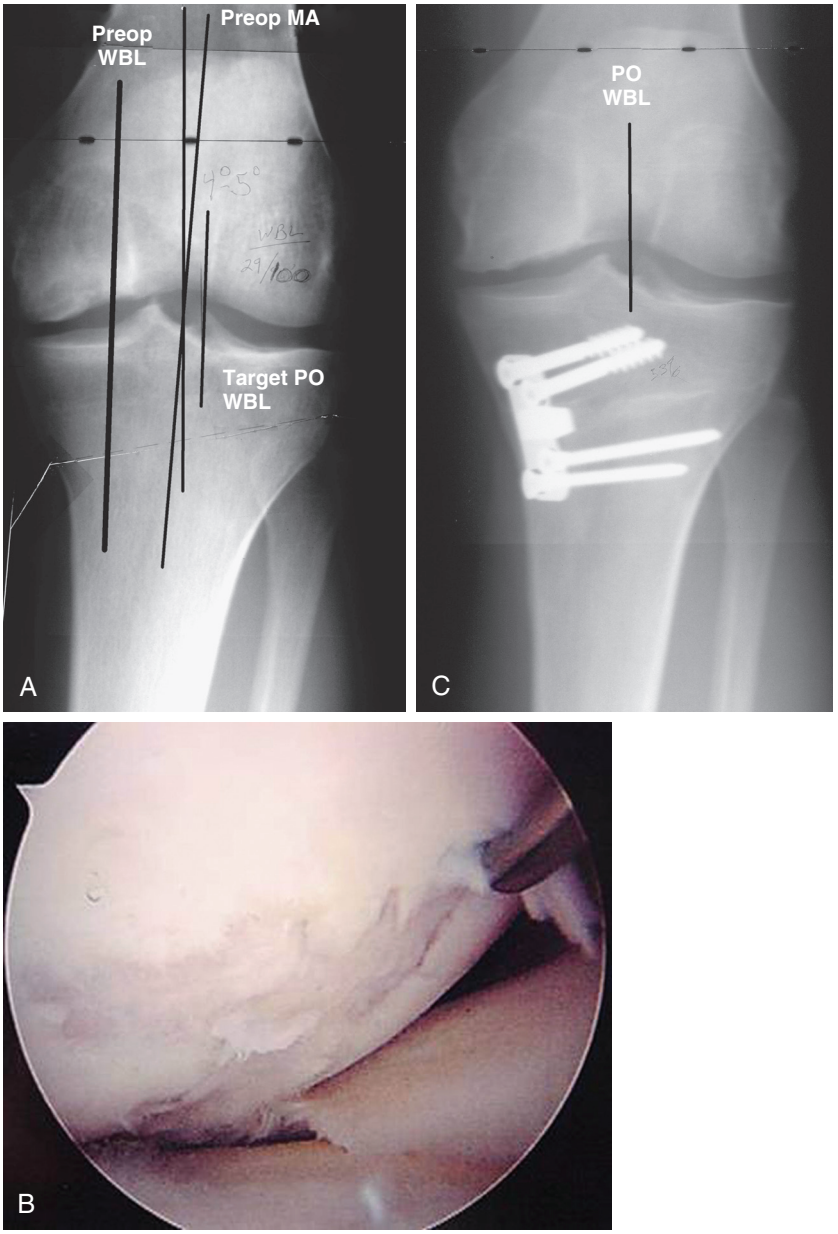

FIG 26-46 Case 1. *MA*, Mechanical axis; *PO,* postoperative; *WBL*, weight-bearing line.

Fig. 26-46, *B*). A biopsy was obtained for a staged autologous chondrocyte implantation, which was done 5 months later. The full standing radiograph showed correction to 62% WBL line (see Fig. 26-46, *C*). At the most recent follow-up evaluation, 7 years postoperative, the patient reported marked improvement in all symptoms with the ability to perform light recreational sports without problems. He rated his overall knee condition as nearly normal. The overall alignment was neutral.

Comments: There is the expectation that a repeat cartilage restorative procedure will be required in this patient. The importance of measuring the correction obtained at surgery with full-length, standing radiographs and close follow up of the patient to determine maintenance of the valgus overcorrection is stressed. Future magnetic resonance imaging including articular cartilage sequences will be obtained. The Puddu plate is historical; locking plate techniques are now used as described.

Case 2: Treatment Options in a Varus-Angulated, Anterior Cruciate Ligament-Deficient, Medial Meniscectomized Knee

A 33-year-old woman presented with moderate to severe medial joint pain and giving way with daily activities. She had a prior medial meniscectomy 15 years ago and a failed ACL allograft reconstruction 8 years ago. The examination showed a positive pivot shift and 15 mm of increased anteroposterior tibial displacement on KT-2000 testing. There was no increase in external tibial rotation, lateral joint opening, or posterior tibial translation. Full-length, standing radiographs revealed a weight-bearing line of 20% of the tibial width (Fig. 26-47, *A*) and early narrowing of the medial tibiofemoral compartment.

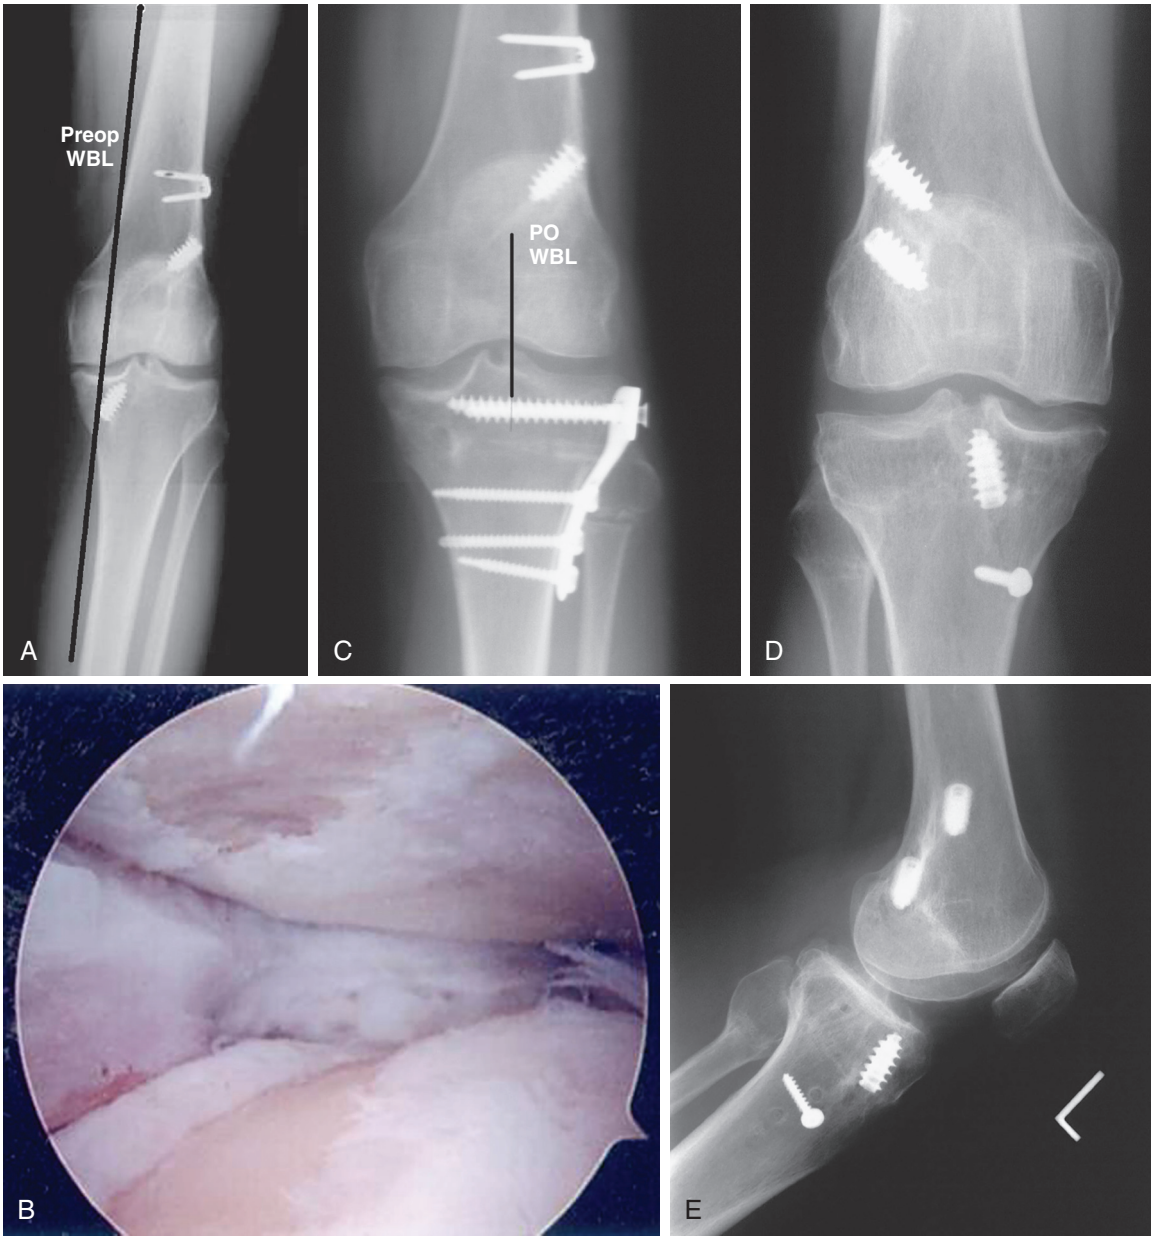

FIG 26-47 Case 2. *WBL*, Weight-bearing line.

Arthroscopy demonstrated subchondral bone exposure on the medial femoral condyle and tibial plateau and an absent medial meniscus (see Fig. 26-47, *B*). The lateral tibiofemoral compartment and lateral meniscus were normal. The lateral gap test showed 10 mm of opening under varus loading at 30 degrees of knee flexion.

A closing wedge osteotomy was performed followed 5 months later with a medial meniscus transplant and osteochondral autograft transfer for the medial femoral condylar defect.

Seven months after the high tibial osteotomy, a revision ACL bone-patellar tendon-bone autograft reconstruction was performed owing to continued instability symptoms. The lateral tibiofemoral compartment gap test was only slightly increased and therefore no posterolateral reconstruction was required.

The most recent follow-up examination, 16.4 years after the osteotomy, showed a valgus alignment of 2 degrees (see Fig. 26-47, *C*), but loss of the medial tibiofemoral compartment joint space. The patient had negative pivot shift and Lachman tests and was able to perform light recreational activities without problems.

Comments: In this case, either an opening or closing wedge osteotomy was indicated. The standing radiograph suggested increased lateral tibiofemoral joint opening (double varus knee), which was confirmed at arthroscopy, contraindicating a concurrent ACL reconstruction. The subsequent ACL revision used a B-PT-B autograft to provide a potentially higher chance of success compared with an allograft (in our opinion). The vertical femoral tunnel was bypassed with an outside-in reorientation of the femoral tunnel (see Fig. 26-47, *D* and *E*). A bone graft of prior tunnels was not required. A tibial graft suture and post is always performed in revision knees for added graft fixation strength.

Case 3: Treatment of a Varus-Angulated, Posterior Cruciate Ligament–Deficient Knee in a High School–Aged Athlete

A 17-year-old male high school athlete sustained a contact injury during football. A complete PCL rupture was verified by physical examination and arthroscopy performed elsewhere. He was referred to our center 3 months later for treatment. He complained of giving-way sensations and mild aching to the medial aspect of his knee with running and cutting activities. The preoperative radiographic evaluation demonstrated a WBL of 21% tibial width (Fig. 26-48, *A*) and 10 mm of increased posterior tibial translation (see Fig. 26-48, *B*). All other ligamentous structures were normal on examination. The patient's goal was to play collegiate football and have the "best knee possible."

The patient was treated with an opening wedge osteotomy followed 3 months later with a two-strand quadriceps tendon–patellar bone autogenous PCL reconstruction with a tibial inlay approach. All articular cartilage surfaces were normal and both menisci were intact.

At 13.6 years postoperative, the patient had a negative posterior drawer test result on physical examination (negative medial tibiofemoral step-off). Anteroposterior radiographs demonstrated 2 degrees of valgus (see Fig. 26-48, *C*), approximately 2 mm of decrease in medial tibiofemoral joint space, and posterior stress radiographs showed 3 mm of increased posterior tibial translation (see Fig. 26-48, *D*). He had no symptoms with strenuous athletics or his occupation as a surgical technician and rated the overall condition of his knee as normal.

Comments: The most controversial aspect of this case was defining the necessity for a corrective osteotomy before the PCL reconstruction. Most varus-aligned knees with an intact medial meniscus and ACL or PCL rupture do not require a staged osteotomy. Concurrent medial meniscus loss with early articular cartilage damage would be the usual indication for corrective osteotomy. However, in this knee, the varus angulation (20% WBL) was judged to be so advanced that operative correction was deemed necessary. In addition, early medial tibiofemoral compartment aching symptoms with activity were present. A second option would be to perform the PCL reconstruction and then follow the patient to define the subsequent need for a high tibial osteotomy.

Case 4: Treatment of Bilateral Varus Malalignment in a Middle-Aged Patient

A 40-year-old woman presented with bilateral varus malalignment and complaints of medial compartment pain with daily activities of many years' duration that had increased in severity over the previous 2 years. She expressed a lifelong difficulty with the visual appearance of her lower extremities. Initial evaluation showed an obvious varus malalignment (Fig. 26-49, *A*). Full-length, standing radiographs showed a WBL of 20% (right) and 13% (left) of the lower extremities. All ligaments were intact and no other abnormality was found.

Opening wedge osteotomies with autogenous iliac crest bone grafting were performed 3 months apart (see Fig. 26-49, *B*). The correction was made to a neutral alignment, avoiding an overcorrection. The medial tibiofemoral compartment showed early articular cartilage fibrillation, but no major damage. The postoperative correction is shown in Figure 26-49, *C*.

The most recent evaluation, conducted 9 years postoperative, showed resolution of medial compartment symptoms in both knees. The patient rated both of her knees as normal and stated she was able to wear shorts without feeling embarrassed for the first time.

Comments: Clinical data on the natural history of severe varus malalignment (WBL < 30%) over a patient's lifetime are insufficient. Clinicians have noted the frequent occurrence of medial joint pain in patients in their 40s and 50s, and degenerative medial meniscus tears are common. High tibial osteotomy is not a cosmetically indicated procedure and this patient did have an early onset of medial joint arthritis symptoms, which responded to the corrective procedure. Locking plate techniques are recommended as described.

Case 5: Treatment of Varus-Angulated, Anterior Cruciate Ligament–Deficient Knee: Simultaneous Osteotomy and Anterior Cruciate Ligament Reconstruction

A 43-year-old athletically active man presented 9 months after a knee injury sustained while playing basketball. The patient had been diagnosed with an ACL rupture and varus osseous malalignment. He wished to resume sports activities, including basketball and coaching soccer. The patient was referred for surgical management. The initial examination revealed a positive pivot shift, 10 mm of increased AP tibial translation on KT-2000 testing, and a WBL of 18% on full standing radiographs (Fig. 26-50, *A*). All other ligament tests were normal.

The patient elected a simultaneous opening wedge osteotomy and ACL reconstruction, which was done with a four-strand STG autograft using a two-incision technique. The menisci were intact, and fissuring and fragmentation (classified as 2-B damage) were noted in the medial tibiofemoral compartment and on the undersurface of the patella.

Intraoperative fluoroscopy during the osteotomy verified an adequate correction of the varus malalignment. The guide pin was placed to allow maximum width to the lateral plateau to avoid fracture (see Fig. 26-50, *B*). The technique of using thin spreader blades was performed to gradually spread the osteotomy site, which was maintained by a calibrated wedge (see Fig. 26-50, *C*). Placement of the osteotomy plate just before iliac crest bone grafting is shown in Figure 26-50, *D*. The high tibial osteotomy healed rapidly with the incorporation of the autogenous bone graft.

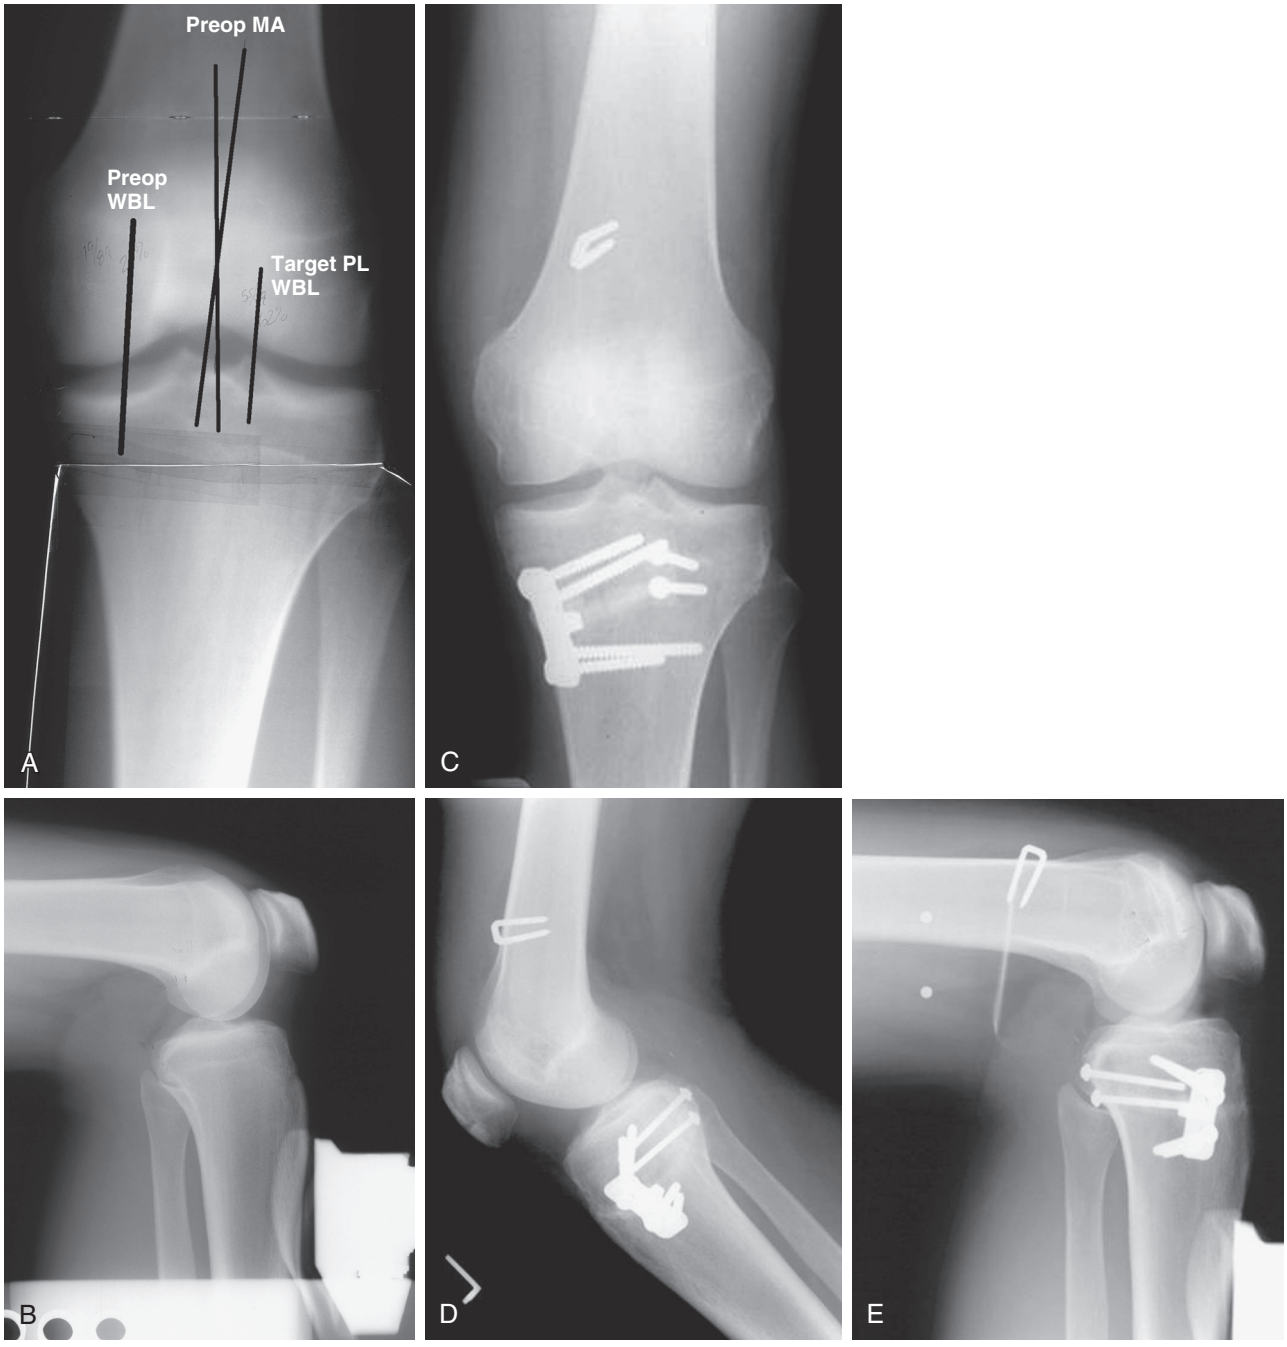

FIG 26-48 Case 3. *MA*, Mechanical axis; *PL*, posterolateral; *WBL*, weight-bearing line.

At the most recent follow up, 7.2 years postoperatively, the patient had no symptoms with recreational sports activities. Full-length, standing radiographs demonstrated a WBL of 52% (see Fig. 26-50, *E*), and KT-2000 examination revealed 4 mm of increased AP tibial translation (25 degrees of flexion, 134 N). He rated the overall condition of his knee as normal.

Comments: The operative fluoroscopy photographs show proper placement of the guide pin and distraction of the opening wedge, which was done gradually to preserve the lateral tibial cortex. Loss of the lateral tibial cortical buttress produces an unstable osteotomy that requires additional fixation such as a locking plate. The four-strand STG graft was anatomically placed at insertion sites using an outside-in technique to achieve a coronal graft with maximum femoral and tibial tunnel lengths. The STG graft fixation was achieved using both a suture post and absorbable interference screws.

Case 6: Treatment of Excessive Valgus Lower Limb Malalignment After Closing Wedge Osteotomy

A 26-year-old woman presented 9 months after a left lateral closing high tibial osteotomy performed for medial joint line pain and early medial tibiofemoral damage. The patient was unable to participate in any athletic activities, had developed hip pain over the past 3 to 4 months, and complained of increasing diffuse knee pain located primarily in the lateral aspect of the knee during standing and walking.

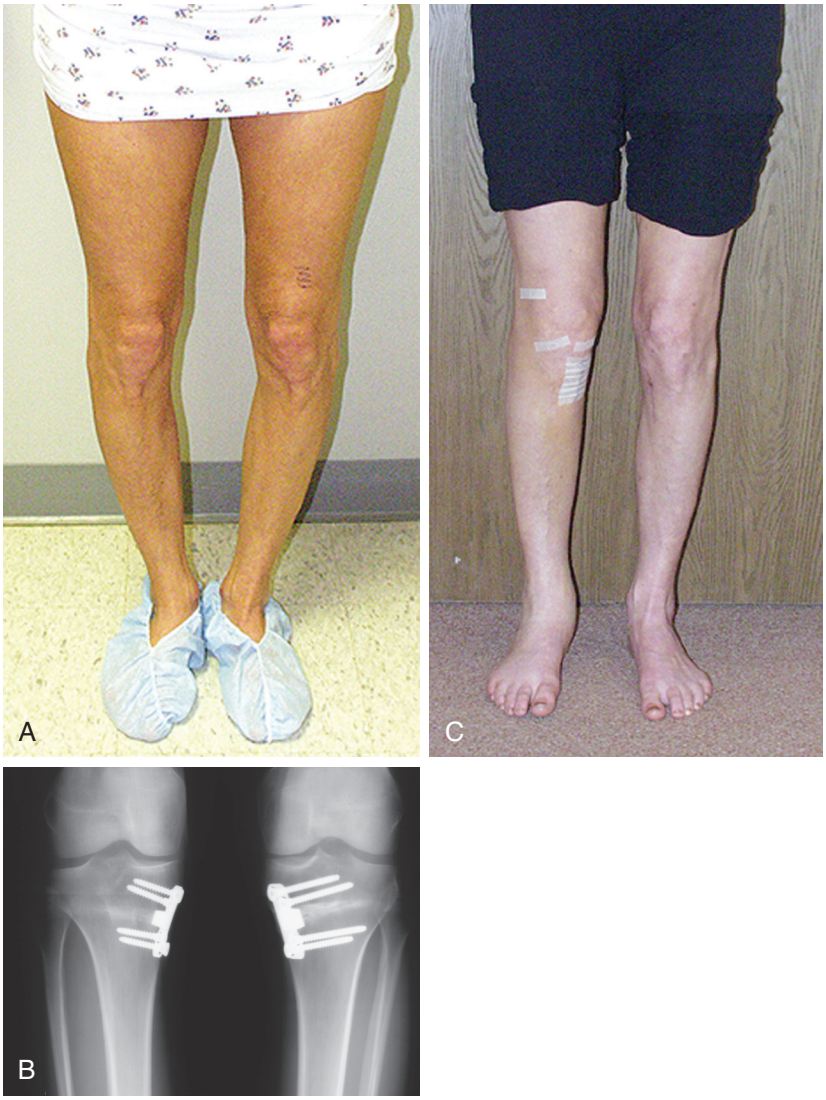

FIG 26-49 Case 4.

She was aware of the abnormal lower limb alignment and highly concerned with the cosmetic appearance (Fig. 26-51, *A*).

On physical examination, the patient ambulated with a marked valgus angulation and valgus thrust. The lower extremity neurovascular exam was normal, and the range of knee motion was 0 to 155 degrees. There was pain on palpation over the lateral joint line. There was no increase in anterior or posterior tibial translation. The patient had 15 degrees of increased external tibial rotation at 30 degrees of flexion but only 5 degrees of increased external tibial rotation at 90 degrees of flexion. Varus stress radiographs showed 10 mm of increased lateral joint opening. Full-length, standing radiographs revealed a healed lateral closing wedge HTO. The coronal joint line was sloped laterally, and the WBL was 80% (see Fig. 26-51, *B*).

Two major problems were identified in this patient. First, a valgus overcorrection was noted, which occurs when the WBL is more than 70% of the tibial width. A WBL of 62% normally represents an approximate 2 to 3 degrees of overcorrection. The overcorrection of the HTO in this patient was 6 degrees mechanical axis (80% WBL), which resulted in a cosmetically unacceptable appearance. This amount of overcorrection frequently results in arthritis of the lateral tibiofemoral compartment. To avoid this error, the degrees of correction of the WBL must be measured on full-length, standing double-stance radiographs, as described in this chapter. Single-stance radiographs allow abnormal lateral joint opening to occur, which must then be subtracted in the calculation for the true degrees of tibial correction required. In addition, the lower limb alignment must be verified at surgery and early postoperatively.

If an abnormal valgus alignment is detected, it can be easily corrected within the first 4 weeks postoperatively by readjusting the osteotomy gap. In this patient, osseous healing had already occurred, and the revision procedure was therefore more difficult.

The second problem was that a fibular osteotomy (either at the fibular neck or distal third region) had not been performed. The proximal tibiofibular joint was disrupted, which allowed the fibula to slide proximally. The abnormal fibular position produced laxity of the FCL and other posterolateral structures that attached to the proximal fibula. The operative plan was to restore the normal tibiofibular relationship to retension the posterolateral structures. The patient was warned that if the tibiofibular joint was destroyed, a tibiofibular fusion would be required, placing the fibula into a normal tibial relationship to restore

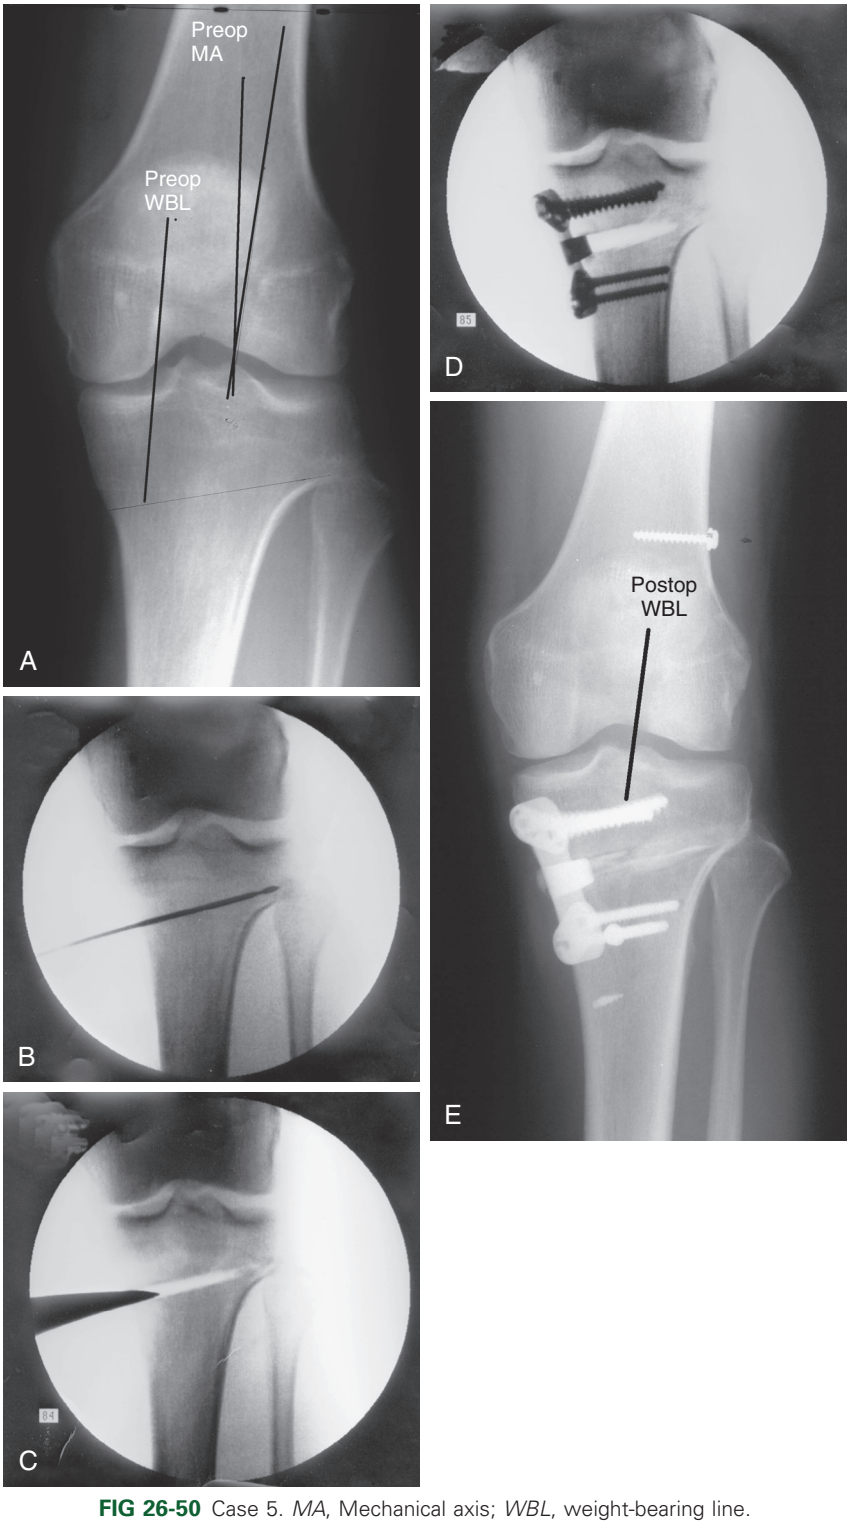

FIG 26-50 Case 5. *MA*, Mechanical axis; *WBL*, weight-bearing line.

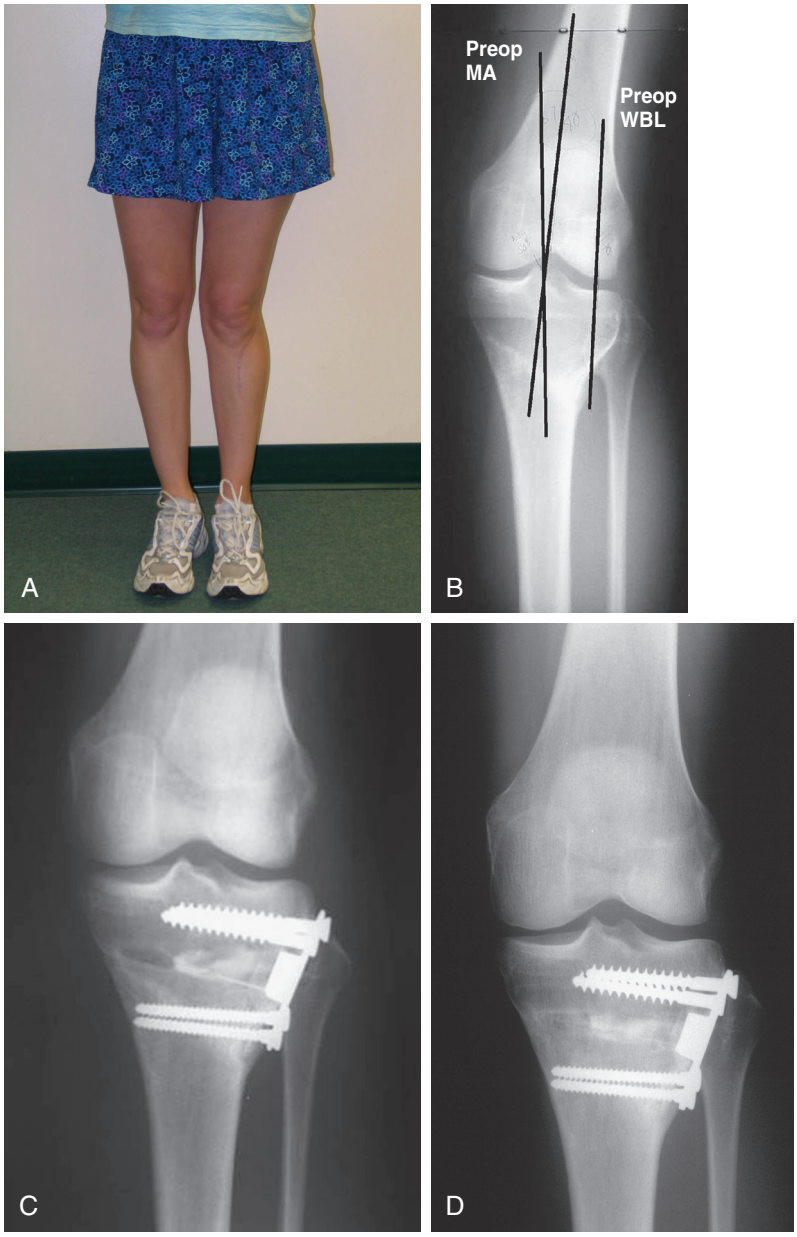

FIG 26-51 Case 6. *MA*, Mechanical axis; *WBL*, weight-bearing line.

the proper length-tension relationship of the native or reconstructed posterolateral structures.

The patient was treated with a revision opening wedge osteotomy. During surgery, the proximal tibiofibular joint and attached ligaments were carefully dissected after the common peroneal nerve was identified and protected. An opening wedge osteotomy was performed, preserving the medial tibial buttress. Careful distraction of the osteotomy with spacer plates that spanned the length of the osteotomy was performed to prevent fracture of the tibial plateau, which was osteopenic from the prior surgery. The fibula was gradually relocated to a normal position relative to the tibia. In other revision cases, the senior author has used two proximal tibiofibular 4.0 cancellous screws to provide temporary stabilization of the joint; however, this was not required. An autogenous iliac crest bone graft was used and healing successfully occurred.

Immediately postoperative, radiographs demonstrated correction of the abnormal valgus alignment and a normal tibiofibular position (see Fig. 26-51, *C*). The position was maintained at the most recent evaluation, 16 months postoperative (see Fig. 26-51, *D*).There was no increase in lateral joint opening or external tibial rotation with functional posterolateral ligament structures. The correction has been maintained over the years. Locking plate techniques are recommended as described.

Case 7: Treatment of Failed Internal Fixation After Opening Wedge Osteotomy

A 41-year-old man presented complaining of pain to the medial aspect of his right knee joint. He had previously undergone a partial medial meniscectomy, chondroplasty, and microfracture of the medial femoral condyle. The patient was employed as an automobile mechanic and had discomfort with squatting and kneeling.

On physical examination, the patient had an obvious varus malalignment and walked with a mild varus thrust. He had mild lateral joint line pain, moderate patellofemoral crepitus, and moderate

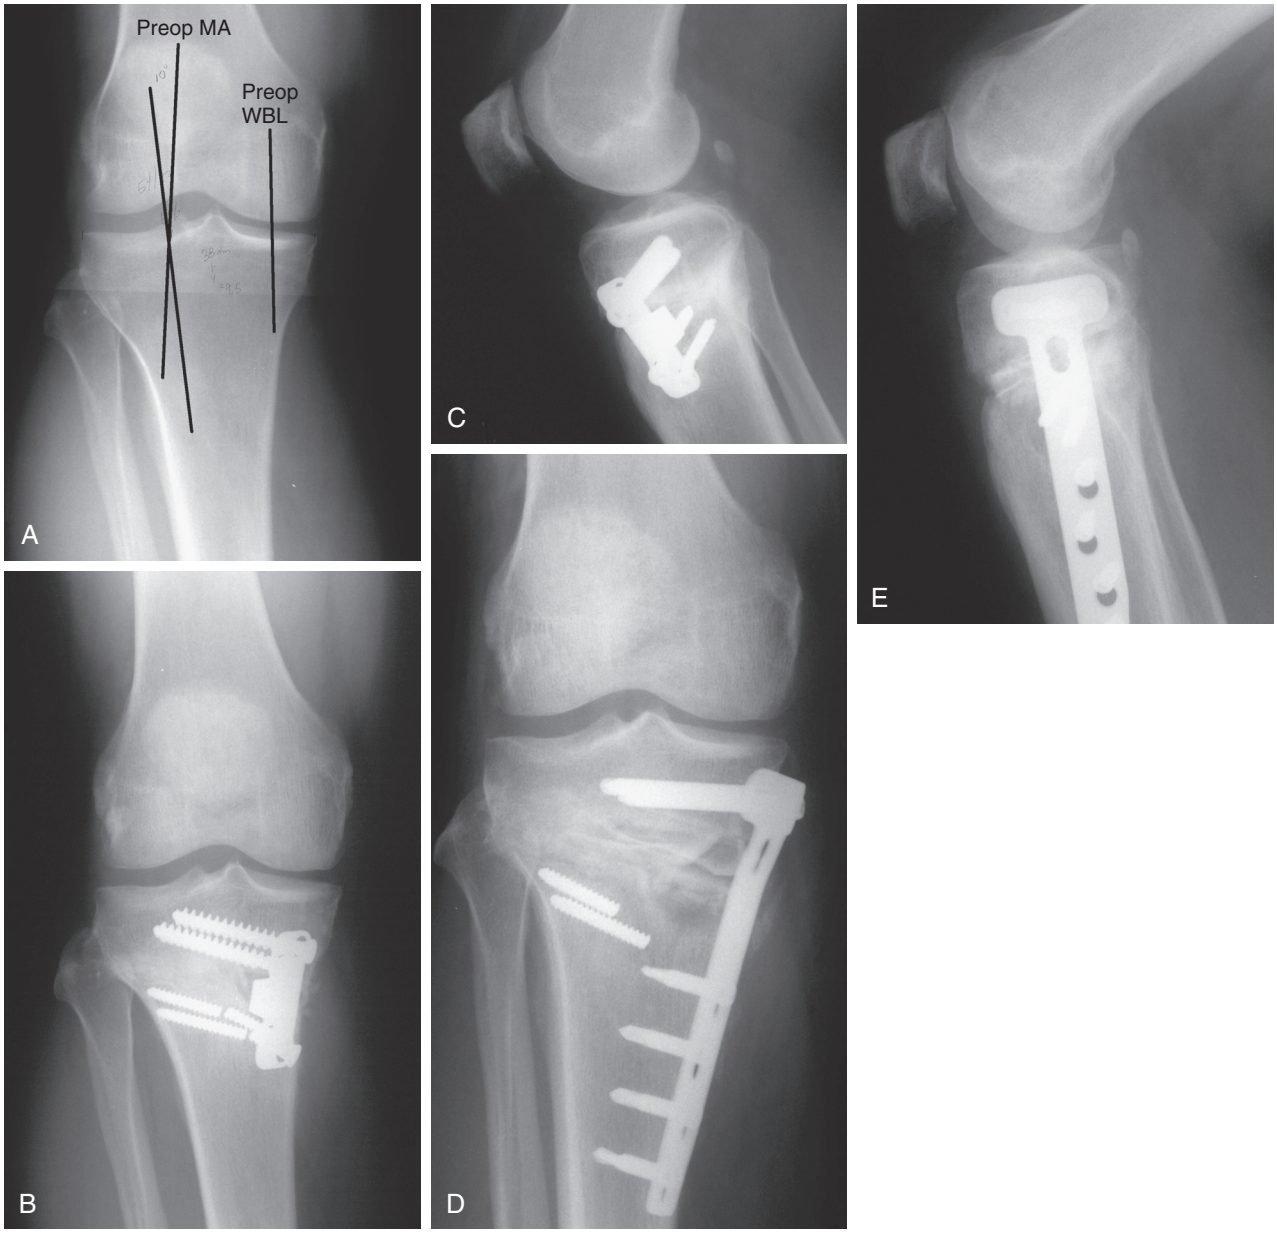

FIG 26-52 Case 7. *MA*, Mechanical axis; *WBL*, weight-bearing line.

patellar pain on compression. The ligament examination was normal. Radiographs demonstrated a WBL of 20% (Fig. 26-52, *A*) and preserved medial tibiofemoral joint space. Magnetic resonance imaging revealed a posterior horn medial meniscus tear and articular cartilage damage to the trochlea.

The patient underwent an opening wedge osteotomy with autogenous iliac crest bone graft and internal fixation with a Puddu plate. A 62% WBL was confirmed intraoperatively.

The initial postoperative course was normal with initial radiographs showing correction of the malalignment. However, at 5 months postoperative, the patient complained of a new onset of pain in the region of the anteromedial tibial osteotomy. Radiographs demonstrated nonunion of the osteotomy site and two broken distal screws with loss of the valgus alignment correction (see Fig. 26-52, *B* and *C*). The patient underwent a revision osteotomy with a locking plate (see Fig. 26-52, *D* and *E*), which successfully corrected the malalignment. The tibial slope was maintained, and the mechanical axis postoperatively was 2 degrees valgus. The osteotomy healed without problems.

Comments: This case demonstrates the potential inherent weakness of the Puddu plate. If there is any delay in healing after opening wedge osteotomy, even with autogenous bone grafting, early failure can be expected and revision indicated. A locking plate, which became available during the treatment of this patient, provides a more stable construct and is now our preference.

Case 8: Treatment of a Varus-Angulated Knee Following Failed Multiple Ligament Procedures

A 27-year-old man presented after a knee dislocation from an industrial accident, which had been treated with an ACL

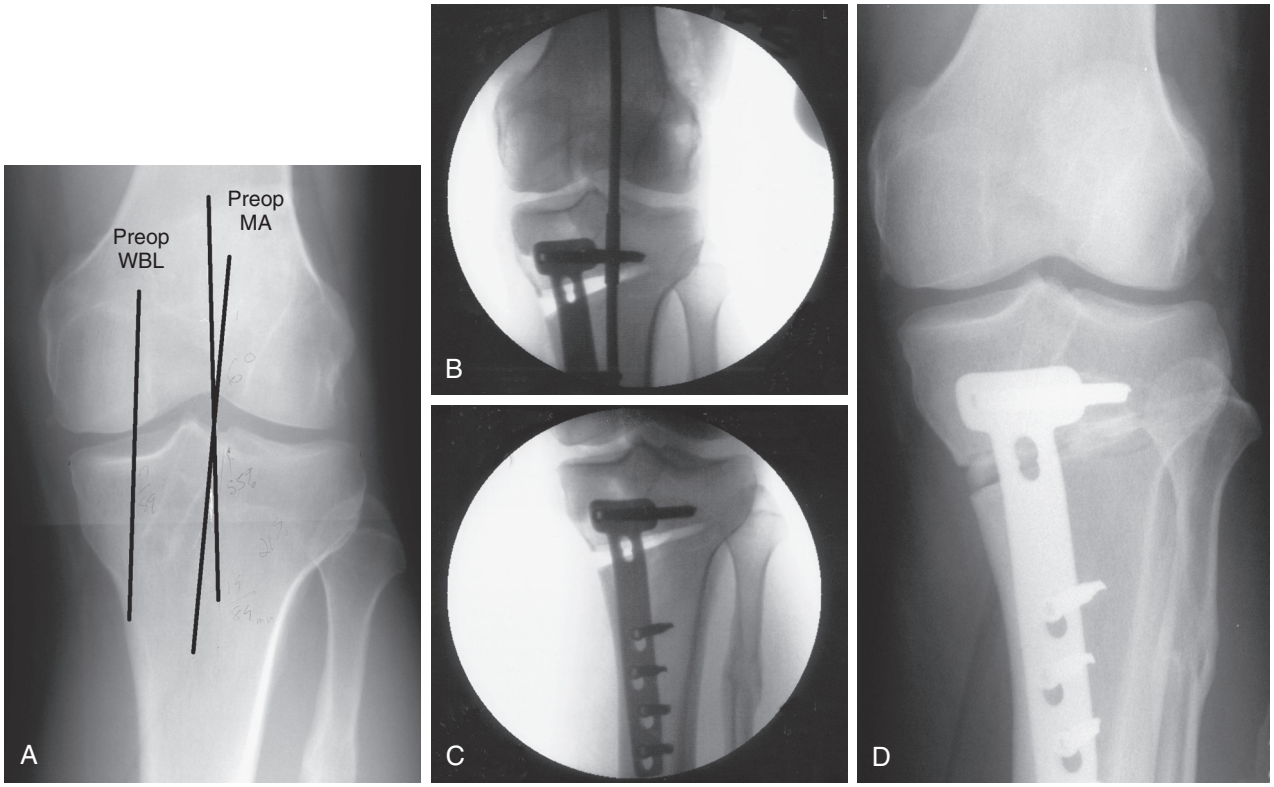

FIG 26-53 Case 8. *MA*, Mechanical axis; *WBL*, weight-bearing line.

semitendinosus-gracilis reconstruction and medial collateral ligament primary repair. The patient complained of medial tibiofemoral compartment pain and instability with daily activities.

On physical examination, the patient demonstrated varus malalignment and a varus thrust on ambulation. There were a mild effusion and a normal range of motion. A positive pivot shift was elicited indicating failure of the ACL reconstruction. In addition, an increase of 8 mm in lateral tibiofemoral opening was noted. Radiographs revealed a WBL of 20% and mild medial tibiofemoral joint space narrowing (Fig. 26-53, *A*). Posterior stress radiographs demonstrated 7 mm of increased posterior tibial translation compared with the contralateral limb, indicating partial posterior cruciate ligament deficiency.

The patient was treated with an opening wedge osteotomy with an autogenous iliac crest bone graft and a locking plate for secure fixation; fluoroscopy confirmed correction of the WBL at 62% (see Fig. 26-53, *B* to *D*). Six months later, a revision ACL reconstruction was performed using the contralateral patellar tendon autograft. The lateral tibiofemoral gap at surgery was 5 mm, and therefore no posterolateral reconstruction was required.

At the latest follow-up evaluation, 6.5 years postoperative, the patient had a valgus alignment of 2 degrees (see Fig. 26-53, *E*) and was satisfied with the overall condition of his knee.

Comments: With large angular corrections, we prefer to stage osteotomy and ACL revision reconstructive procedures. Staging the procedures ensures that the osteotomy correction will be maintained postoperatively and reduces the risk of complications, especially arthrofibrosis. In addition, adaptive shortening of the fibular collateral ligament and posterolateral structures occurred, avoiding a posterolateral reconstructive procedure.

Case 9: Treatment of Severe Bilateral Varus Malalignment

A 44-year-old male teacher presented with complaints of bilateral medial compartment pain of 16 months' duration. He had pain at rest, with walking tolerance of only 1 minute. He had undergone multiple cortisone injections of both knees and had also tried an unloading brace on the left knee, which made the pain worse. Physical examination revealed a full range of motion in both knees, severe bilateral medial joint line pain, no patellofemoral symptoms, intact ligaments, and a bilateral varus thrust on ambulation. Radiographs demonstrated severe medial tibiofemoral compartment narrowing in both the right (Fig. 26-54, *A*) and left (see Fig. 26-54, *B*) knees. Marked varus malalignment was present bilaterally.

Although another surgeon recommended an HTO, the patient was advised that the loss of joint space was too severe for an HTO to be effective. The patient underwent bilateral unicompartmental knee replacement, first in the left knee (see Fig. 26-54, *C*) and then 3 months later in the right knee (see Fig. 26-54, *D*). The patient recovered uneventfully from both procedures.

Case 10: Treatment of a Valgus-Angulated Knee After Lateral Meniscus Transplantation

An elite female gymnast initially presented to our center at age 16 years with complaints of aching pain in the posterior and lateral aspect of her left knee. She denied any specific episode of trauma. Arthroscopy and partial lateral meniscectomy were performed. The patient continued with high-level training for Olympic gymnastics competition, and subsequently, her symptoms of pain and swelling became worse, requiring repeat arthroscopy. Grade III changes were noted on the weight-bearing surface of the lateral femoral condyle (Fig. 26-55, *A*).

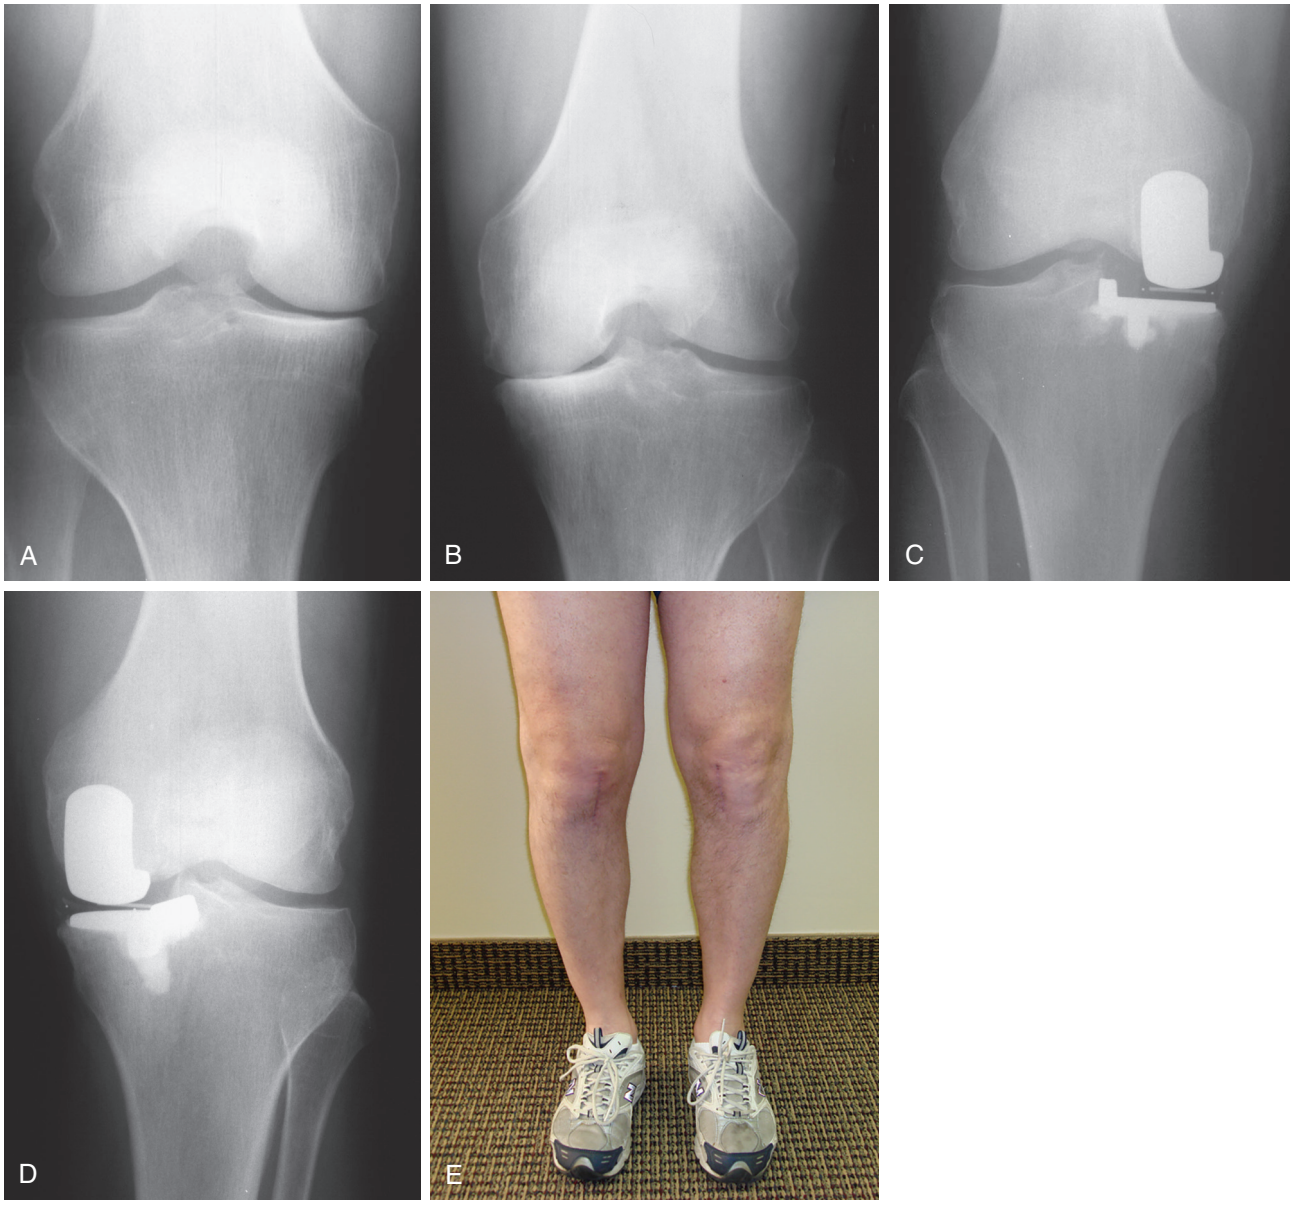

FIG 26-54 Case 9.

Two years later, physical examination demonstrated a mild increase in the valgus alignment (58%). Standing radiographs, at 30 degrees of knee flexion, demonstrated narrowing of approximately 50% joint width. The patient had tenderness to the lateral tibiofemoral compartment and mild swelling in the joint. She elected to have a lateral meniscus transplant and osteochondral autograft transfer procedure.

The patient did well for 7 years after the lateral meniscus transplant and osteochondral plug procedure. She returned with chief complaints of pain, catching, and swelling in the knee. Over the course of treatment, it had been noted that the patient had a progression of symptoms in the lateral compartment, as well as an increase in valgus malalignment. Physical examination revealed obvious valgus alignment present of the left lower extremity, full range of motion, no joint effusion, no ligamentous instability, and no crepitus to the lateral compartment. Standing 45 degrees posteroanterior radiographs demonstrated 50% narrowing of the lateral compartment. Full-length, standing radiographs demonstrated a 5 degrees valgus mechanical axis and a 65% WBL (see Fig. 26-55, *B*).

The patient underwent an opening wedge femoral osteotomy with an autogenous iliac crest graft (see Fig. 26-55, *C*) which obtained a correction to a 45% WBL. Postoperative radiographs show the correction of the valgus alignment and healing of the osteotomy site (see Fig. 26-55, *D*).

Case 11: Treatment of Valgus Malalignment in a Young Patient with Pain with Activities of Daily Living

A 20-year-old woman presented with a chief complaint of lateral knee pain with activities of daily living and anterior knee pain when ascending stairs. She had a total lateral meniscectomy 5 years previously. Prior arthroscopy demonstrated moderate articular cartilage damage to the lateral tibiofemoral joint. She had given up running and squatting activities as a result of the pain in her knee.

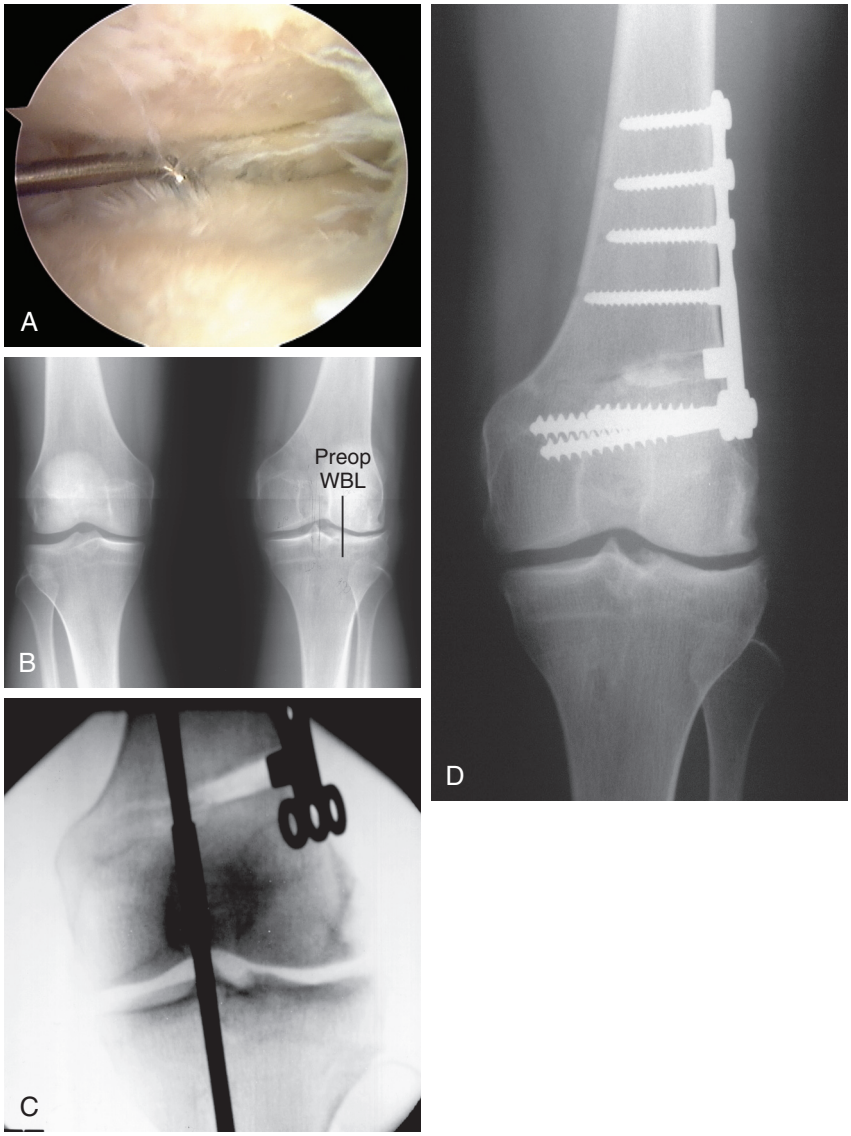

FIG 26-55 Case 10. *WBL,* Weight-bearing line.

Physical examination demonstrated a mild effusion, a standing valgus position of the lower extremity, and a valgus thrust on walking. The patient had normal ligamentous stability. Standing 45 degrees posteroanterior radiographs demonstrated 50% joint narrowing. Full-length, standing views showed a WBL of 71% and a mechanical axis of 4 degrees valgus (Fig. 26-56, *A*).

The patient underwent an opening wedge femoral osteotomy for correction of the valgus malalignment. A locking plate with screws was used with an iliac crest autogenous bone graft (Fig. 26-56, *B*). Postoperative radiographs show a correction to 45% WBL (see Fig. 26-56, *C* and *D*).

Case 12: Staged Femoral Osteotomy, Meniscus Transplantation, and Autologous Chondrocyte Implantation

A 23-year-old woman presented 8 years after an ACL reconstruction, lateral meniscus transplant (LMT), and autologous chondrocyte implantation (ACI) that had been done on the lateral femoral condyle. The ACL graft was intact and functional. However, two subsequent arthroscopic debridement procedures had been done in which the LMT had been removed. Posteroanterior radiographs showed 50% joint narrowing of the lateral tibiofemoral compartment and a marked valgus malalignment, with a WBL of 70% (Fig. 26-57, *A*). The patient had lateral tibiofemoral compartment knee pain with walking, knee stiffness, difficulty with stair-climbing and squatting, and was unable to participate in any recreational sports activities.

The patients underwent an opening wedge distal femoral osteotomy and autogenous bone graft from the iliac crest that was secured with a Tomofix locking plate and screws. At arthroscopy, grade 3-A (bone exposed, 20 × 20 mm) articular cartilage degeneration was found on the prior site of the ACI on the weight-bearing portion of the lateral femoral condyle (Fig. 26-57, *B*). The medial meniscus and articular cartilage in the medial compartment were intact. Eight months later, a revision LMT and ACI to the lateral femoral condyle were performed (Fig. 26-57, *C* and *D*). The osteotomy healed without complications, with the new WBL established at 45% of the tibial width. She is ambulatory and has no pain in the lateral tibiofemoral compartment and has been advised not to participate in any strenuous sports owing to the arthritis that has occurred. The goal of the procedure was to buy 10 years, at which time a unicompartmental knee replacement would be performed.

INTRODUCTION

The use of osteotomies has decreased, particularly in North America, caused by the advent of more reliable and predictable arthroplasty solutions for younger and middle-aged patients with knee arthrosis. However, interest in osteotomy has recently undergone resurgence with the advent of cartilage repair procedures, increased understanding of multiligament knee instability in the context of malalignment, and loss of meniscal tissue and function.

Fewer reports have been published regarding osteotomy for valgus knee arthrosis when compared with varus knee arthrosis. Opening-wedge osteotomy on the medial tibial side has been well established as the procedure of choice for varus deformity malalignment.[10] The majority of studies on femoral osteotomy have focused on medial closing-wedge procedures, and survivorship rates have varied from 64% to 87%.[2,9,21,24] Small case series have reported lateral opening-wedge distal femoral osteotomy survivorship rates of 82% at 7 years and 91% at 8 years.[14,25] Overall, these studies had statistically significant improvements in the functional outcomes.[6,14,23,25]

Osteotomy is a biologic treatment alternative for unicompartmental disease for patients in whom total knee replacement (TKR) is undesirable owing to age, life expectancy, or activity level, which would be considered inappropriate for prosthetic replacement. In this patient population, distal femoral osteotomy (DFO) can be an appropriate joint-preserving solution that relies on the redistribution of forces in the knee joint away from a mechanically overloaded, and thus symptomatic, lateral tibiofemoral compartment. In general, opening-wedge techniques allow a smaller approach and a reliable deformity correction and have gained popularity lately to adequately address cases of dysplastic lateral femoral condyles in valgus knees as well as medial tibial plateau defects in varus gonarthrosis.

INDICATIONS

Despite less predictable pain relief and relatively inferior long-term results compared with TKR, joint-preserving osteotomy is an appealing, yet reluctant, choice for high-demand patients with increased life expectancies and reservations about prosthetic replacement. The main indication for DFO is the correction of frontal plane deformities, especially in valgus knees with lateral compartment arthrosis, posttraumatic arthrosis, and in valgus knees eligible for lateral cartilage repairs and meniscal transplantation.[9,22] A second indication is to correct malalignment associated with medial ligamentous insufficiency, such as in valgus knees with *valgus thrust* or to unload any ligament reconstruction.[19] A less common and reliable indication is the correction of maltracking patella caused by excessive valgus deformity.[12] This chapter focuses on the main indication of DFO.

The DFO procedure has gained significance as part of a joint-preserving treatment for less advanced cartilage or meniscal disease of the lateral compartment. At our institution, osteotomy has also been used increasingly to unload and optimize the biologic environment of a compartment undergoing osteochondral or meniscal transplantation. Therefore different groups of patients with valgus limb malalignment may benefit from the procedure.

Primary osteotomy to correct malalignment will alleviate symptoms by reducing stresses on the articular cartilage and the underlying subchondral bone. Secondary osteotomy, adjunct to resurfacing procedures addressing osteoarticular lesions resulting from a pathologic biomechanic environment, protects the resultant repair tissue by correcting the underlying condition that contributed to the original lesion.

According to the International Society of Arthroscopy, Knee Surgery and Orthopaedic Sports Medicine (ISAKOS) guidelines on the management of osteoarthritis of the knee before TKR[20], the ideal patient for DFO has isolated lateral compartment symptoms, ages 40 to 60 years, body mass index (BMI) less than 30, nonsmoker, high-demand activity but no running or jumping, alignment of less than 15 degrees valgus deformity in the distal femur, range of motion (ROM) with less than 10 degrees of extension loss, more than 90 degrees of flexion, normal medial and patellofemoral compartments, normal ligament balance, and no notch osteophytes. Although some have

CRITICAL POINTS Indications for Distal Femoral Osteotomy

- Valgus limb malalignment in a knee with symptomatic lateral compartment arthrosis in young and active patients
- Joint preservation in less advanced cartilage or meniscal disease of the lateral compartment
- Ancillary procedure to osteochondral repair or meniscal transplantation procedures

CRITICAL POINTS Contraindications

- Symptomatic medial or patellofemoral compartment arthrosis
- Gross ligamentous instability
- Inflammatory arthrosis including advanced crystal-induced arthropathy
- Metabolic bone disorders
- Severe angular deformity
- Limited knee ROM (>15 degree flexion contracture or <90 degrees of flexion)
- Poor motivation or rehabilitation potential

considered men to be better candidates for osteotomy than women, we have not found a correlation between gender and outcome.

Because of the generally good clinical results and survivorship of TKR, the threshold for considering osteotomy over arthroplasty is typically patients ages 65 and younger. Older, physically active patients may be candidates for DFO if they are expected to return to an activity level that would be inappropriate for TKR. Young, active patients (<50 years) are better candidates for joint-preserving osteotomy owing to the absence of implant-related activity restrictions despite the relatively inferior long-term results compared with TKA. In these individuals, the osteotomy should be considered a temporizing procedure amenable to possible future conversion to TKR. The 50- to 65-year-old group presents a unique challenge in determining whether or not osteotomy is the most appropriate treatment choice. Finally, young patients (<40 years) with even small amounts of valgus limb malalignment should be carefully evaluated for osteotomy when there is symptomatic loss of lateral compartment chondral or meniscal tissue. In this setting, it may be reasonable to consider (though not proven) that the osteotomy may delay the progression to more advanced arthrosis. When cartilage or meniscal restoration is performed in the lateral compartment, the adjunctive use of DFO may help protect the reconstruction as well.

CONTRAINDICATIONS

Absolute contraindications to DFO include the presence of symptomatic medial compartment arthrosis, inflammatory arthrosis including advanced crystal-induced arthropathy, and metabolic bone disorders that would significantly interfere with osseous healing of the osteotomy. Conversely, neuromuscular disorders are not a contraindication because the osteotomy may be a more reasonable and durable operation than TKR in this setting.

Relative contraindications include severe angular deformity (consideration in these cases should be given to a double osteotomy of the distal femur and proximal tibia), limited knee ROM (>15 degree flexion contracture or <90 degrees of flexion), poor motivation, or poor rehabilitation potential. Although excessive BMI has not been proven to be a contraindication, it may be assumed that the well-described orthopedic surgical risk factors associated with obesity also apply to osteotomy, and some surgeons consider a BMI greater than 30 a relative contraindication. Rehabilitation issues of concern include the inability to follow postoperative weight-bearing restrictions and the use of drugs or substances such as nicotine that may interfere with bone healing. The extent of lateral joint arthrosis (as defined by the amount of cartilage loss on the femoral and tibial surfaces) has not, to our knowledge, been shown to have a demonstrable effect on outcome, barring frank end-stage arthrosis. Therefore we do not use the amount of radiographic or clinical joint space loss as a criterion or contraindication. The presence of patellofemoral arthrosis as a relative contraindication is controversial. Some studies have shown that arthrosis of the patellofemoral joint has no bearing on the outcome, but others have even shown improvement in patellofemoral symptoms with DFO.[14]

CLINICAL BIOMECHANICS

The *weight-bearing line* (WBL) of the lower extremity is defined as the line drawn from the center of the femoral head through the center of the ankle mortise. Depending on where this line crosses the knee joint, overall limb alignment is considered varus (medial to the center of the knee), valgus (lateral to the center of the knee), or neutral relative to the center of the knee. Based on morphologic studies of normal subjects with neutral overall alignment, Hsu and coworkers[13] determined that 75% of weight-bearing forces are transmitted through the medial compartment of the knee in a one-legged simulated weight-bearing stance. Other studies have determined that 60% of the load is passed through the medial compartment during weight bearing.[1,16] Alterations in the overall alignment will change these forces and create an unfavorable mechanical environment, potentially leading to injury and degeneration of the overstressed compartment that may be stopped or slowed by timely correction of the malalignment.[18]

With a valgus deformity, the mechanical axis passes through (or lateral to) the lateral compartment of the knee, thus overburdening that compartment and leading to pain and development of arthritis. Additional pathologic features of the valgus knee include progressive posterolateral soft tissue contractures including the iliotibial band, popliteus, lateral collateral ligament, posterolateral capsule, lateral head of the gastrocnemius, lateral intermuscular septum, and long head of the biceps. In addition, these contractures may lead to attenuation of the medial collateral ligament and medial capsular laxity.

Osseous deformities should be understood in the context of "normal" anatomy and "physiologic" valgus. Kapandji[14a] illustrated that the average distal femoral angle is 7 to 9 degrees of valgus, and the average proximal tibial angle is 0 to 3 degrees of varus, producing the overall tibiofemoral angle of 5 to 7 degrees of valgus, which, after accounting for hip offset, leads to a mechanical limb axis through the center of the knee. Osseous deformities in the valgus knee are usually limited to the lateral femoral condyle, which is typically hypoplastic, thus leading to excessive distal femoral valgus. Conversely, the lateral tibial plateau is usually well preserved, except in the case of fracture.

The important distinction is that for the majority of valgus knees, the deformity lies in the distal femur and not in the tibia. In some cases, this excessive distal femoral valgus may be minimal, but in other more severe cases, the distal femoral angle can be around 15 to 20 degrees of valgus. Although the exact prevalence of valgus deformity of the knee is unknown, it is generally considered less common than varus deformity about the knee. Cooke and associates[3] examined full-length

CRITICAL POINTS Common Characteristics of the Valgus Knee

- Mechanical axis passes through (or lateral to) the lateral compartment of the knee
- Posterolateral soft-tissue contractures
- Medial collateral ligament and medial capsular laxity
- Osseous deformities of the distal lateral femoral condyle, usually hypoplastic lateral femoral condyle

radiographs of 167 white patients with osteoarthritis. Valgus alignment was seen in 24% and varus in 76%. In addition, valgus deformity has been noted to be more common in females, patients with inflammatory arthritis, and posttraumatic arthritis, as well as those with metabolic abnormalities such as rickets or renal osteodystrophy.

The rationale of the DFO is to correct the excessive tibiofemoral valgus by shifting the mechanical axis line from the lateral compartment to a more median or even medial position. Historically, this correction has been performed both above and below the level of the joint line. Initial reports of correction of painful valgus deformity described a proximal tibial varus-producing osteotomy. However, Coventry[4] recommended that deformity of greater than 12 degrees of tibiofemoral valgus should be corrected above the joint line to avoid excessive joint line obliquity, which leads to increased shear stresses across the joint, ligamentous and capsular attenuation, and subsequent joint subluxation. A general rule is that the osteotomy should be performed at the site of the primary deformity, which in most patients with valgus deformity lies in the distal femur.

CLINICAL EVALUATION

History and Physical Examination

Patients who are candidates for DFO are rare, but when they present, the deformity is quite evident. Symptoms are localized to the lateral compartment, and patients complain of difficulty ascending and descending stairs, often with a feeling of giving-way. On physical examination, ROM should be at least 90 degrees and any flexion contracture less than 15 degrees. The knee should be stable, and the medial and patellofemoral compartments should have minimal or no articular cartilage damage. Ambulation demonstrates genu valgum with an occasional abduction-type lurch and a stiff-knee gait, attempting to avoid the worn cartilage in the posterior aspect of the knee, which makes contact in flexion.

Radiographic Evaluation

All patients who are candidates for DFO obtain full-length, standing anteroposterior (AP) radiographs of bilateral lower extremities. In addition, standing AP views of both knees, standing posteroanterior (PA) views in 45 degrees of flexion (Rosenberg), lateral flexion views of the knee, and patellofemoral (Merchant) views are obtained. The long-alignment films help determine the overall mechanical axis of the limb and whether the lateral compartment is experiencing overload caused by overall genu valgum. The standing AP and Rosenberg views of the knee allow determination of the amount of joint space narrowing in the anterior and posterior portions of the lateral compartment, respectively. The lateral and patellofemoral views are helpful for determining the condition of the patellofemoral joint. If there is any concern, stress radiographs may be obtained to test for ligamentous stability and joint subluxation.

CRITICAL POINTS Radiographic Evaluation

- Full-length, standing anteroposterior (AP) radiographs of bilateral lower extremities
- Standing AP views of bilateral knees
- Standing posteroanterior view in 45 degrees of flexion (Rosenberg).
- Lateral flexion view of the knee.
- Patellofemoral (Merchant) view.
- Reestablish the mechanical axis to fall through the center or just medial to center of the knee.
- Correct distal femoral angle to a mechanical axis between 0 and 2 degrees varus (WBL, 45%-50%), depending on the patient's circumstance and proximal tibial anatomy.
- Millimeter value of the linear correction at the osteotomy site is roughly equivalent to the degree correction of axial alignment.
- Stage osteotomy to be the last of the concomitant procedures performed.

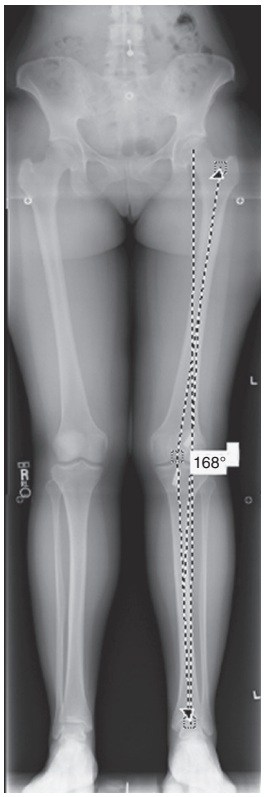

FIG 27-1 Preoperative weight-bearing long-leg anteroposterior radiograph shows valgus alignment of the left lower extremity in a 45-year-old woman with left lateral knee pain.

PREOPERATIVE PLANNING

Radiographic studies are essential in the preoperative planning of the intended corrections. These are determined by calculating the tibiofemoral angle and the proximal tibial and distal femoral angles (Fig. 27-1). The goal is to shift the mechanical axis so that it falls through the center or just medial to the center of the knee. Overcorrection of the deformity, as for example in high tibial osteotomy (HTO), will place extreme loads through the medial compartment. We recommend instead aiming for a mechanical axis of 0 to 2 degrees of varus

(representing an approximate WBL of 45% to 50%) that the literature suggests as acceptable. When performing an osteotomy as an ancillary procedure to cartilage repair in young patients, the goal of correction is to restore the WBL through the center of the knee because overcorrection may be detrimental to long-term joint health. When used to treat cases of arthritis, in which undercorrection can lead to a poor outcome, the minimum correction should result in neutral alignment with the maximum correction resulting in the WBL falling through the medial tibial spine. These corrections result in various degrees of tibiofemoral valgus alignment depending on other parameters such as hip offset. This is most easily determined preoperatively using tracing paper cutouts of the proposed osteotomy on standing long-alignment films.

The millimeter value of the linear correction at the osteotomy site is roughly equivalent to the degree of correction of axial alignment (e.g., a 10-mm opening will usually result in 10 degrees of correction). In general, the distal femoral angle is corrected to a mechanical axis between 0 and 2 degrees varus (WBL, 45%-50%), depending on the patient's circumstance and proximal tibial anatomy.

The use of arthroscopy preceding the osteotomy to indicate or predict outcome has not been well defined. Currently, no substantial scientific evidence exists that findings at arthroscopy predict the outcome of DFO, and therefore these data should not be used in isolation but rather used with careful correlation to clinical and radiographic evaluation. When considering realigning osteotomy as an adjunct procedure to an osteochondral graft of the ipsilateral lateral femoral condyle, staging the procedure is advised so as not to jeopardize the microvascularity of the recipient bone bed.

OPERATIVE TECHNIQUE

The patient is placed supine on a radiolucent operating table that will allow fluoroscopic imaging of the entire lower extremity from the hip to the ankle. Our anesthesia preference for surgery is a regional anesthetic that will provide 1 to 2 days of postoperative pain control. If the osteotomy is to be combined with an allografting procedure (e.g., lateral tibial plateau allograft), the osteotomy is generally the last procedure performed.

CRITICAL POINTS **Surgical Technique**

- Establish starting point under fluoroscopy, approximately 3 cm above the lateral femoral epicondyle.
- Angle guide pin medial and distal to exit the cortex at the level of the medial epicondyle.
- Palpate superior trochlea to ensure guide pin position proximally and avoid violating the patellofemoral joint.
- Second guide pin should completely overlap the first guide pin on anteroposterior view.
- Confirm symmetry and perpendicularity of the osteotomy on multiple fluoroscopic views before making bone cuts.
- Start osteotomy with an oscillating 1-inch saw using both pins as a guide.
- Complete osteotomy with wide osteotomes, preserving the medial cortex as a hinge.
- Insert the distraction device and distract osteotomy slowly.
- Assess weight-bearing line on fluoroscopy by stretching a radiopaque cord from the center of the femoral head to the center of the ankle.
- Secure the osteotomy plate with three unicortical cancellous screws distally and three bicortical cortical screws proximally.
- Bone graft can use autograft or allograft bone products or a combination thereof.

The operated limb, including the ipsilateral hip, is prepared free, and a small bump is placed under the hip to align the extremity in the coronal plane. For reasons previously described, a lateral opening wedge osteotomy fixed with an osteotomy plate and filled with either allograft or iliac crest bone graft is preferred. We generally use autologous bone graft in addition to allograft when the required correction is 10 mm or more. A sterile tourniquet is placed but is used only if necessary. An 8- to 10-cm incision is made over the lateral aspect of the distal femur. The iliotibial band is incised in line with the incision, and the vastus lateralis is dissected posteriorly off the lateral intermuscular septum to expose the femoral shaft and the metaphyseal flare (Fig. 27-2). The joint can be entered, if necessary.

Using fluoroscopy, the starting point for the osteotomy is located, which is approximately 3 cm above the lateral femoral epicondyle. The guide pin is angled medially and distally so that it exits the cortex at the level of the medial epicondyle (Fig. 27-3). The goal is to create the osteotomy in the metaphyseal bone, which has excellent healing potential without violating the patellofemoral joint. The superior most aspect of the trochlea should be palpated to ensure the guide pin is not too distal. If this is the case, the superior aspect of the joint will be

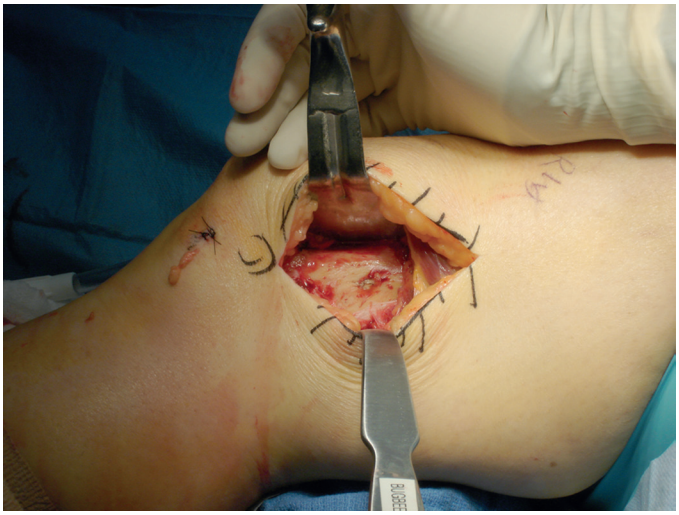

FIG 27-2 Intraoperative view of the left knee of the same patient shows exposure of the femoral shaft and the metaphyseal flare.

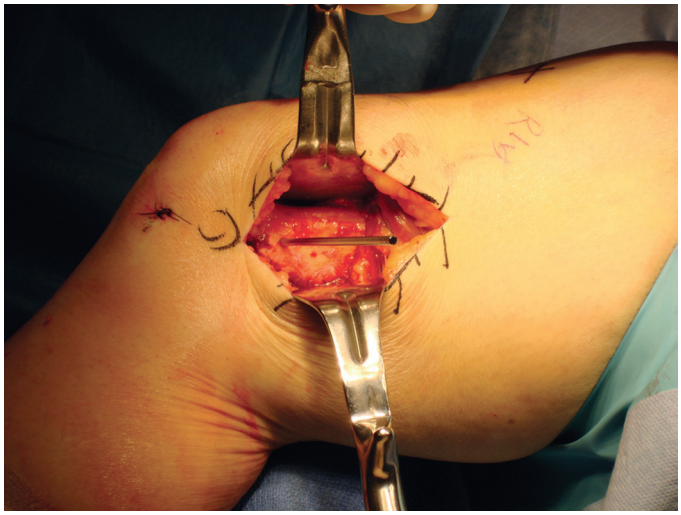

FIG 27-3 Intraoperative view of guide pin placement.

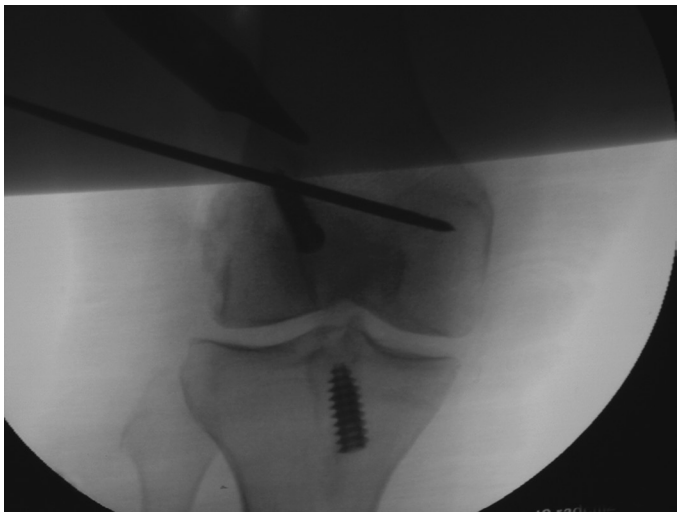

FIG 27-4 Fluoroscopic confirmation of guide pin placement, with retained interference screws from prior anterior cruciate ligament reconstruction.

FIG 27-5 The osteotomy is begun with the oscillating saw.

violated during the osteotomy. In these instances, the guide pin should be removed and placed more proximally.

Consider the angle of the osteotomy not only on the AP view but also in the lateral plane. To preserve the sagittal plane alignment of the femur, the osteotomy should be performed perpendicular to the axis of the femur in the lateral plane. Any deviation will create either excessive flexion or extension of the femur, depending on the angle of the osteotomy. This may be desirable, for example, if the patient has a fixed flexion contracture at the knee and the goal is to create a mild hyperextension of the distal femur to counter the contracture. In general, however, our preference is to create a symmetrical osteotomy perpendicular to the axis of the femur in the lateral plane.

Once the first guide pin is accurately placed, a second guide pin should be placed either directly anterior or directly posterior to that pin in the same plane, so that both pins completely overlap on an AP view of the distal femur. This ensures that an osteotomy created parallel to the plane of both guide pins will be perpendicular to the long axis of the femur in the lateral plane. After the guide pins have been placed in the appropriate position on the AP view (Fig. 27-4), the osteotomy may then be performed using both pins as a guide. An oscillating saw with a 1-inch saw blade is used to start the osteotomy, either just above or just below the guide pins, to create the proper plane (Fig. 27-5). Once this has been done, wide osteotomes are used to complete the osteotomy (Fig. 27-6). The goal is not to create a complete fracture but instead to keep the medial cortex intact to act as a hinge. Occasionally, the medial cortex is perforated to allow for opening of the osteotomy, which may be done with a small Kirschner wire.

Once the majority of the cortex has been freed, the distraction device is placed in the osteotomy site (Fig. 27-7) and slowly distracted (Fig. 27-8). The goal is for the mechanical axis to pass through the medial tibial spine. The amount of distraction required to attain this goal correlates with the amount of correction attained. For small osteotomies, this is usually 5 to 8 mm, and for large osteotomies, 10 to 15 mm. Once the desired amount of correction is obtained, fluoroscopy is used to evaluate the WBL. An electrocautery cord is stretched from the center of the femoral head to the center of the ankle, and the overall mechanical axis is assessed (Fig. 27-9). Undercorrection is associated with a higher rate of failure, whereas overcorrection places extreme loads on the medial side. If the mechanical axis is overcorrected or undercorrected, it can be adjusted at this time using the

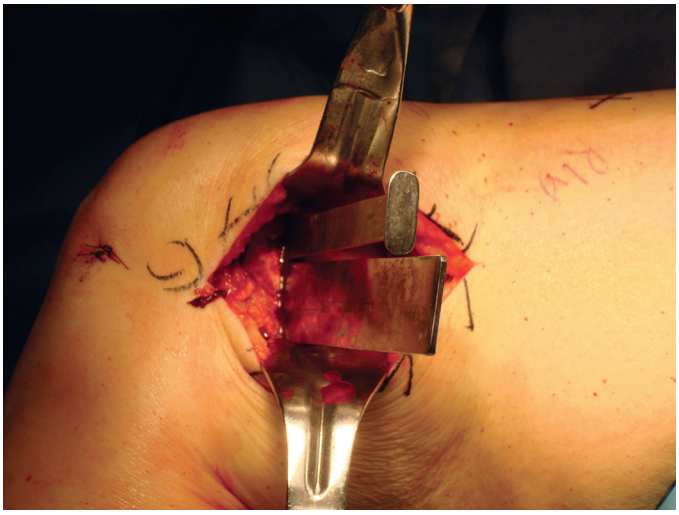

FIG 27-6 Osteotomes are used to complete the osteotomy.

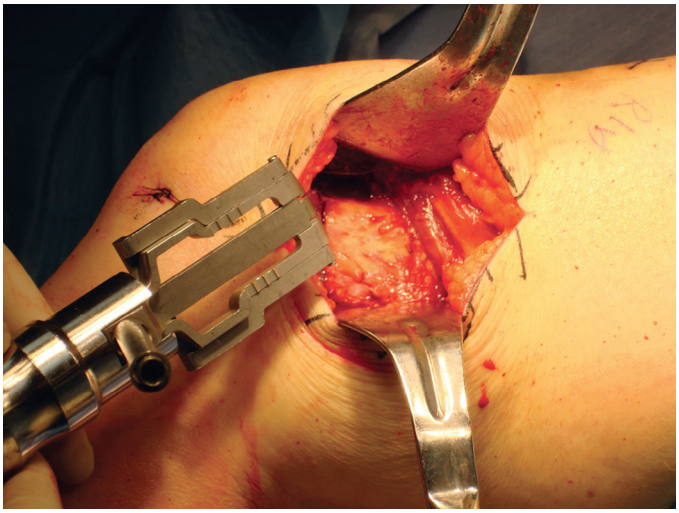

FIG 27-7 The distraction device is introduced into the osteotomy.

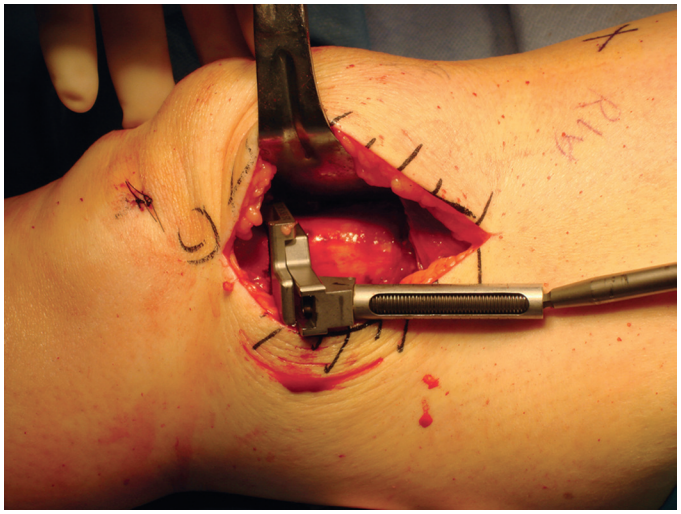

FIG 27-8 The osteotomy is distracted.

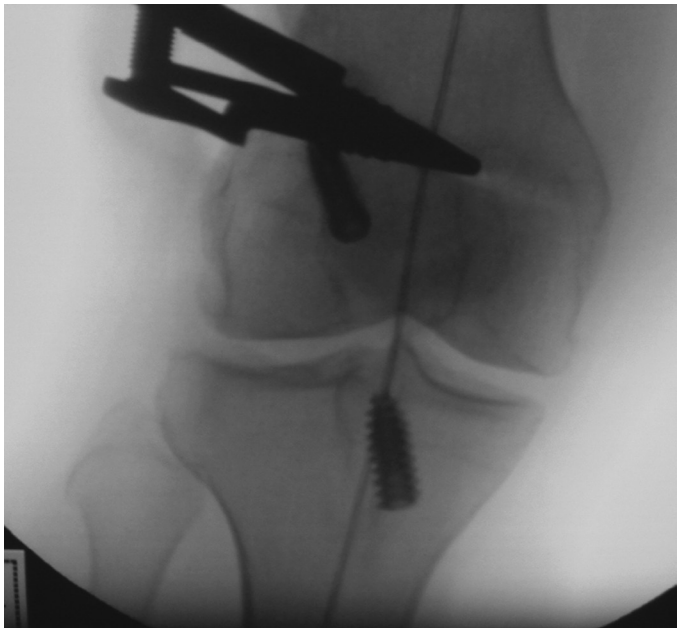

FIG 27-9 Fluoroscopic confirmation of distraction, with radiopaque cord indicating the approximate weight-bearing line.

CRITICAL POINTS Postoperative Regimen

- Knee immobilizer overnight for pain control.
- ROM brace for osteochondral allograft patients, unlocked on postoperative day 1.
- Start ROM exercises immediately and isometric strengthening when tolerated.
- Keep patients touch-down weight bearing for 8 to 12 weeks or until radiographic evidence of healing.
- Low-resistance exercise bike at 4 weeks.
- Resistance training after radiographic evidence of osseous healing.

distraction device. Once the correction is believed to be appropriate, a plate is used to secure the osteotomy. Most recently, our preference is to use the Biomet DynaFix VS plate (Biomet Trauma), originally designed for tibial osteotomy, owing to its strength of fixation and low profile (Figs. 27-10, 27-11, and 27-12). Large locking plates should be

FIG 27-10 The osteotomy is secured with an osteotomy plate.

FIG 27-11 Intraoperative anteroposterior fluoroscopic view shows plate and screw fixation of the osteotomy.

available in case of loss of medial hinge. Depending on the patient and magnitude of correction, either autologous iliac crest bone graft and/or allograft bone is used (Fig. 27-13). For younger, female patients and those concerned with cosmesis, allograft is preferred, but both methods of bone grafting have been equally successful.

Postoperatively, the patient is placed in a knee immobilizer overnight for pain control. If osteochondral allografting has also been performed, an ROM brace is placed and unlocked on postoperative day 1. We generally refrain from prophylactic anticoagulation in most

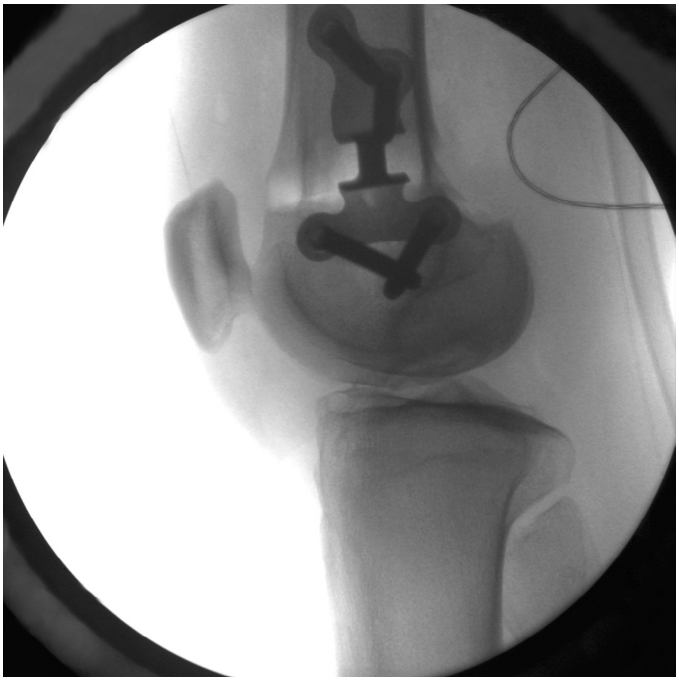

FIG 27-12 Intraoperative lateral fluoroscopic view shows plate and screw fixation of the osteotomy.

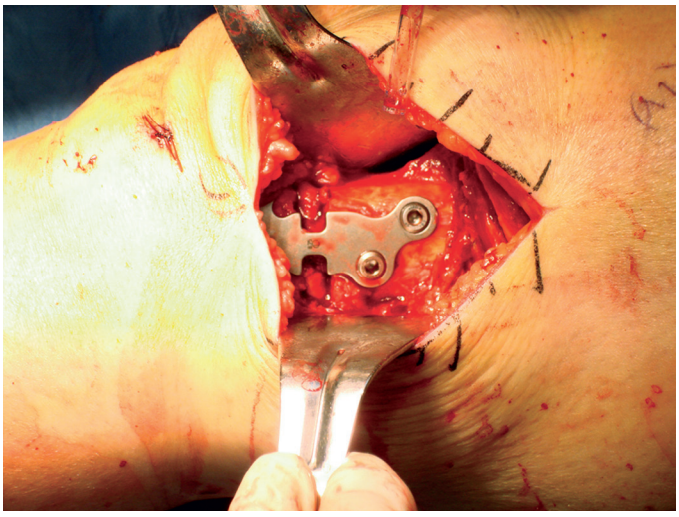

FIG 27-13 Intraoperative view of fixed osteotomy plate after placement of the autologous bone graft and bone matrix.

patients, but if risk factors are identified (e.g., age >50 years, oral contraceptive use, planned travel, or positive prior history of blood clots), we prefer to use low-molecular-weight-heparin or Coumadin and try to avoid nonsteroidal antiinflammatory medications owing to interference with bone healing. Patients begin ROM exercises immediately and isometric strengthening when pain and swelling subside. Patients are kept touch-down weight bearing for 8 to 12 weeks or until radiographic evidence of healing is confirmed. At 4 weeks, patients are started on a low-resistance exercise bike; resistance training is initiated when the osteotomy is healed (Fig. 27-14). Regular activities are usually resumed at approximately 6 months postoperatively, with continued improvement for up to 1 year.

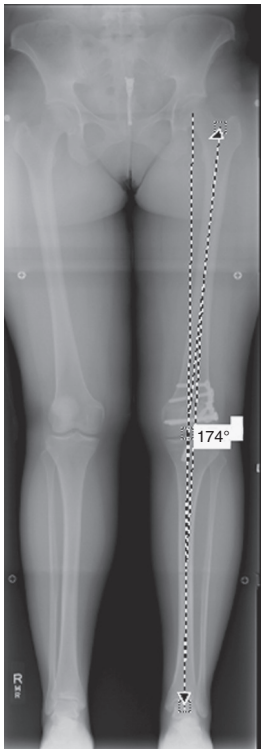

FIG 27-14 Postoperative weight-bearing long-leg anteroposterior radiograph shows physiologic valgus and normal alignment of the left lower extremity.

OUR CLINICAL OUTCOMES

Between 2000 and 2010, we performed 40 distal femoral osteotomies. Two knees (two patients) underwent a medial closing-wedge osteotomy and were excluded from the present study. Thirty-eight knees (97%) in 36 patients were lateral opening-wedge varus-producing osteotomies; of those, 31 knees (82%) in 30 patients had follow-up at a minimum of 2 years (mean, 5 ± 2 years; range, 2-12 years). The indications for osteotomy included symptomatic lateral compartment arthritis with clinical valgus deformity or a cartilage or meniscal defect in the lateral compartment with clinical valgus alignment. The study population was stratified into two groups based on reason for osteotomy: patients with isolated symptomatic lateral compartment arthritis (arthritis group; 19 knees, 61%) and patients who underwent joint preservation procedures, including osteochondral allograft transplantation or meniscal allograft transplantation (joint preservation group; 12 knees, 39%). Twenty-one of 31 knees had postoperative radiographic data available for review. Of these, 7 of 15 knees in the arthritis group and 3 of 6 knees in the joint preservation group were within the correction goal of ±3 degrees from neutral mechanical alignment. In the arthritis group, the mean International Knee Documentations Committee (IKDC) total score improved from 47 ± 15 preoperatively to 67 ± 10 postoperatively. In the joint preservation group, the mean IKDC total score improved from 36 ± 12 preoperatively to 62 ± 18 postoperatively. One nonunion occurred in the arthritis group. No postoperative complications were experienced. Ten knees in the arthritis group and six knees in the joint preservation group had additional surgery after the osteotomy, consisting primarily of hardware removal, arthroscopy for cartilage-related conditions, or conversion to arthroplasty. Survivorship at 5 years, with conversion to arthroplasty as the endpoint, was 74% in the arthritis group and 92% in the joint preservation group.

Lateral opening-wedge distal femoral osteotomy was less accurate in correction of valgus deformity than expected, but the procedure was associated with improved knee pain and function scores. These clinical and radiographic results are comparable with published series evaluating medial closing-wedge distal femoral osteotomy.

CLINICAL OUTCOMES FROM OTHER AUTHORS

Compared with HTO, very few reports have been published in the orthopedic literature on the results of distal femoral varus-producing osteotomy for painful lateral compartment gonarthrosis. The first study for lateral compartment gonarthrosis was published by Coventry in 1987,[4] who described the results of 31 knees that underwent a varus-producing proximal tibial osteotomy. In this report, 77% of cases were considered successful. Failures occurred in patients with a large valgus deformity or in whom the results of the surgery produced a tilt of the articular surface greater than 10%. For these patients, Coventry recommended a distal femoral varus-producing osteotomy.

The first report of varus-producing DFO was by Healy and colleagues in 1988.[11] The series included 23 patients (average age, 56 years) with painful valgus deformity of the knee with lateral joint space narrowing. Diagnoses included osteoarthritis in 15, posttraumatic osteoarthritis in three, rheumatoid arthritis in three, and renal osteodystrophy in two. The technique used in this series included a medial closing-wedge osteotomy in all patients, fixed with a blade plate. Results an average of 4 years postoperatively were good or excellent in 83% (19 of 23). In the osteoarthritis subgroup, 93% had good or excellent outcomes. The authors of this study concluded that 86% of the patients were satisfied with their outcome; however, they did not recommend the procedure in patients with rheumatoid arthritis or decreased ROM.

McDermott and coworkers[15] reported their experience with distal femoral varus-producing osteotomy in 24 patients with painful valgus deformity of the knee. The average age at the time of operation was 53 years. The goal of the procedure was to obtain a final mechanical tibiofemoral angle of 0%. A medial closing-wedge osteotomy technique was used, fixed with a blade plate in all patients. At follow-up 4 years postoperatively, 22 patients (92%) had a successful result and were satisfied. The greatest improvement was in the category of pain. There was one fixation failure, and one patient developed medial compartment gonarthrosis and converted to TKR.

Edgerton and associates[7] followed 24 knees for 5 to 11 years (average, 8.3 years) after DFO for painful valgus deformity of the knee. At follow-up, 71% of patients had good or excellent results, with no differences in those followed for longer periods. Complications occurred in 63% of the cases, including nonunion (25%) and loss of correction (21%). Both of these complications were associated exclusively with staple fixation, which the authors subsequently abandoned. Thirteen percent of the cases converted to TKR. The authors concluded that with current indications and techniques, a DFO is effective in up to 80% at long-term evaluation if the fixation is rigid, the correction is adequate, and the procedure is done relatively early in the course of the disease.

Finkelstein and colleagues[9] reported on 21 knees that underwent DFO for painful valgus deformity and were followed long term (mean, 133 months; range, 97-240 months) or until failure. A medial-based closing-wedge osteotomy fixed with a blade plate was performed. The study reported that 13 osteotomies survived, seven failed, and one patient died. The probability of survival at 10 years was 64%. The authors concluded that this is an effective procedure for relieving pain in patients with symptomatic valgus deformity of the knee.

Wang and Hsu[24] reported on 30 knees in 30 patients that were managed with distal femoral varus osteotomy (DFVO) for the treatment of noninflammatory lateral compartment arthritis of the knee associated with a valgus deformity. Twelve knees had isolated lateral compartment arthritis, 10 had mild to moderate degenerative changes in the other two compartments, and eight knees had severe patellofemoral arthritis in addition to lateral compartment disease. The osteotomy site was fixed with a 90-degree blade plate. At an average follow-up of 99 months, 25 patients (83%) had a satisfactory result, and two had a fair result according to the Hospital for Special Surgery (HSS) rating system. The remaining three patients converted to a TKR. With conversion to TKR as the endpoint, the cumulative 10-year survival rate for all patients was 87% (95% confidence interval [CI], 69%-100%). Improvement in patellar tracking, which persisted at the time of the latest follow-up, was observed in seven of eight knees with associated severe patellofemoral arthritis. The authors concluded that DFVO with blade plate fixation is a reliable procedure for the treatment of lateral compartment osteoarthritis of the valgus knee and that the result of the osteotomy does not appear to be affected by the presence of severe patellofemoral arthritis.

Backstein and coworkers[2] reported on 40 DFOs followed a mean of 123 months. At the most recent follow-up, 24 knees (60%) had good or excellent results, 3 (7.5%) had fair results, and 3 (7.5%) had poor results. Four in the fair or poor categories were awaiting TKR, and eight (20%) had been converted to TKR. The mean Knee Society objective score improved from 18 points (range, 0-74) to 87.2 points (range, 50-100). The mean Knee Society function score improved from 54 points (range, 0-100) to 85.6 points (range, 40-100). The 10-year survival rate of the DFO was 82% (95% CI, 75%-89%), and the 15-year survival rate was 45% (95% CI, 33%-57%).

Recently, Saithna and coworkers[21] reported on 21 DFOs; the mean follow-up population was 4.5 years (range, 1.6-9.2 years) with a cumulative survivorship of 79% at 5 years. Four patients underwent conversion to arthroplasty at a mean time of 3.3 years. In the remaining 17 osteotomies, all patients reported that outcome measures improved from baseline. The author found a high reoperation for non–arthroplasty-related surgery. The majority was caused by symptoms related to prominence of metalwork (10). Other reasons included nonunion (1), loss of correction (2), infection (1), and persistent symptoms (2).

Dewilde and colleagues[6] reported on the outcome of 19 patients who underwent opening-wedge DFOs with the Puddu plate and calcium phosphate. Knee Society knee scores improved from 43 to 78. Four patients who had an opening-wedge osteotomy underwent hardware removal, one patient underwent fracture fixation, and two patients were converted to TKA. Survivorship at 7 years with revision surgery or conversion to TKA as endpoints was 82%.

Das and associates[5] reported on 12 patients whose average age was 52 years who underwent opening-wedge DFO with the Puddu plate. At 74 months follow-up, Lysholm scores improved from 64 to 77 and the HSS knee score improved from 42 to 64. One patient had a delayed union that prolonged rehabilitation, and 7 patients required hardware removal. Survivorship at 74 months with the endpoint of TKA was 83%.

Stahelin and coworkers[22] reported the results of 21 medial closing-wedge osteotomies in 19 patients whose mean age was 57 years at 2- to 12-years follow-up. The authors reported that 18 of 19 patients were satisfied. At latest follow-up, HSS knee scores improved from 65 to 84.

Medial closing-wedge distal femoral osteotomy studies have reported similar outcomes. Finkelstein and colleagues[9] reported outcomes of 21 knees in 20 patients with a mean 11-year follow-up. The authors reported a survivorship of 64% at 10 years, which included

seven failures (3 early and 4 late). Sternheim and associates[8] recently reported on the outcome of 45 knees treated with medial closing-wedge DFO for lateral compartment arthritis. Survivorship at 10, 15, and 20 years were 90%, 79%, and 21.5%, respectively. The authors concluded that osteotomy was indicated in younger (mean, 46 years) high-activity patients, but after 20 years most patients were converted to TKA. Wang and coworkers[24] reported results of 30 knees that had varus osteotomy with a medial blade plate. At an average 99-month follow-up, 83% were reported as satisfactory, and 3 had converted to TKA.

COMPLICATIONS

The complications reported for DFO are similar to those reported for HTO. It should be noted that this is mostly empirical because reports on the results of opening-wedge DFO in the literature are limited. Usual concerns include loss of fixation, nonunion, loss of correction, and conversion to arthroplasty. Joint stiffness after osteotomy has not been an issue with rigid fixation and early mobilization, although some patients do have preexisting flexion contractures that may persist for many months. As with HTO, particular attention to avoiding flexion or extension of the osteotomy site is critical to avoid an asymmetrical opening wedge.

One concern after DFO is the potential difficulty in performing a subsequent knee replacement, if necessary. Nelson and associates[17] retrospectively evaluated the results of TKR performed after varus osteotomy of the distal part of the femur. The study group included nine patients (11 knees) with an average age of 44 years. The mean interval from osteotomy to TKR was 14 years, and the average time to follow-up after TKR was 5 years. The Knee Society score increased from 35 points before TKR to 84 points after TKR. Of note, a constrained prosthesis was required in 5 of the 11 knees. Two knees reported excellent results, five had a good result, and four had a fair result. The authors concluded that whereas TKR is effective for pain relief and improvement of function after DFO, it is technically more challenging and the results are inferior when compared with the results of primary arthroplasty performed without prior osteotomy of the knee.

In contrast to the previous report, Finklestein and colleagues[9] reported on seven knees that converted to TKR after DFVO. The authors believed that at the time of conversion, there was little or no scarring, and there was no difficulty with exposure. Similarly, there was no difficulty gaining correct femoral alignment. The authors believed that in some patients in whom there is difficulty with soft-tissue balancing and patellar tracking because of severe valgus deformity, a varus osteotomy of the distal part of the femur could make a future TKR technically easier. It should be noted that these studies involved conversion of closing-wedge osteotomies rather than of opening-wedge osteotomies. These scarce and somewhat conflicting data reflect the limited experience with conversion of lateral opening-wedge osteotomies to TKR.

SUMMARY

The treatment of symptomatic lateral compartment gonarthrosis with a varus-producing DFO has proved to be a successful procedure at our institution. The indications for this procedure have been expanded to include unloading of an allograft performed for lateral compartment disease and genu valgum. Failure of fixation or healing of the osteotomy has not been a relevant problem, with sound union usually achieved at 6 to 8 weeks. The pain relief from osteotomy can be dramatic but usually is inferior to relief from knee arthroplasty. However, we believe this is an excellent biologic solution that preserves the native joint and is an excellent surgical option for younger patients who are too active to be considered for prosthetic joint replacement. The opening-wedge technique is technically less demanding than previously described techniques and may be more easily converted to TKR should this be necessary in the future.

CLINICAL CONCEPTS

The protocol described in this chapter was designed for opening-wedge high tibial osteotomy (HTO) and distal femoral osteotomy (DFO). The operative techniques, detailed in Chapter 26, prevent delayed union or nonunion and collapse at the osteotomy site and allow a rehabilitation program of immediate knee motion and early weight bearing, preventing the complications of arthrofibrosis and patella infera[1-5] As discussed in Chapter 26, allograft instead of iliac crest autograft is frequently used in opening-wedge HTO cases. In these knees, a more cautious approach is required for resuming weight bearing because healing is delayed approximately twofold. An iliac crest autograft is still favored in opening-wedge DFO to promote prompt healing because of the larger torques placed across the femoral osteotomy site. Full weight bearing is not allowed until the surgeon advises based on radiographic evidence of healing. In addition, the physical therapist should be informed whether or not a locking plate and screw fixation were used because they provide more rigid fixation. If a smaller non-locking plate and screws were used, protection from weight bearing is required until osteotomy healing is advanced. In rare cases when the opening-wedge has been compromised at the lateral tibial cortex or medial femoral cortex, no weight bearing is allowed until near complete healing of the osteotomy is verified.

Patients receive instructions before surgery regarding the postoperative protocol so they have a thorough understanding of what is expected after the procedure. The supervised rehabilitation program is supplemented with home exercises that are performed daily. The therapist routinely postoperatively examines the patient in the clinic to progress him or her through the protocol in a safe and effective manner. Therapeutic procedures and modalities are used as required to achieve a successful outcome.

The overall goals of the osteotomy and rehabilitation are to control joint pain, swelling, and hemarthrosis; regain normal knee flexion and extension; protect the osteotomy to prevent displacement; resume a normal gait pattern and neuromuscular stability for ambulation; regain lower extremity muscle strength, proprioception, balance, and coordination for desired activities; and achieve the optimal functional outcome based on orthopedic and patient goals.

Immediately after surgery, the lower limb is wrapped with cotton with additional padding placed posteriorly, followed by a double compression and cotton bandage, a postoperative hinged brace, and bilateral ankle-foot compression boots. A commercial ice delivery system is used with the bladder incorporated over the initial cotton wrapping, a few layers from the wound. The neurovascular status is checked immediately in the operating room and carefully monitored in the initial postoperative period. A calf or foot compression system is used for the first 24 hours to promote venous blood flow. Aspirin is prescribed and, rarely in high-risk patients, low-molecular-weight heparin (LMWH) or warfarin sodium. During the first postoperative week, patients are ambulatory for short periods of time but are instructed to elevate the limb, remain home, and not resume usual activities. This program helps address the soft-tissue edema and limb swelling that may occur after surgery.

Prophylaxis for deep venous thrombosis (DVT) includes intermittent compression calf or foot boots on both extremities, immediate knee motion exercises, antiembolism stockings, ankle pumps performed hourly, and aspirin (325 mg 2 ×/day for 10 days). Doppler ultrasound is obtained if a patient demonstrates abnormal calf tenderness, a positive Homans sign, or increased edema.

Important postoperative signs to monitor include (Table 28-1):

- Loss of correction, reoccurrence of varus or valgus malalignment
- Swelling of the knee joint or soft tissues
- Abnormal pain response, increased pain with weight bearing
- Abnormal gait pattern
- Insufficient flexion or extension, limited patellar mobility
- Weakness (strength/control) of the lower extremity

TABLE 28-1 Postoperative Signs and Symptoms Requiring Prompt Treatment

Signs and Symptoms	Treatment Recommendations
Failure to meet knee extension and flexion goals	Overpressure program, early gentle manipulation under anesthesia if 0-135 degrees not met by 6 weeks postoperatively
Decreased patellar mobility (indicative of early arthrofibrosis)	Aggressive knee flexion, extension overpressure program or gentle manipulation under anesthesia to regain full ROM and normal patellar mobility
Decrease in voluntary quadriceps contraction and muscle tone, advancing muscle atrophy	Aggressive quadriceps muscle-strengthening program, EMS
Persistent joint effusion, joint inflammation	Aspiration, rule out infection, close physician observation
Loss of angular correction	Immediate referral to physician for revision
DVT: abnormal calf tenderness, a positive Homans sign, or increased edema	Immediate ultrasound evaluation

DVT, Deep venous thrombosis; *EMS*, electrical muscle stimulation; *ROM*, range of motion.

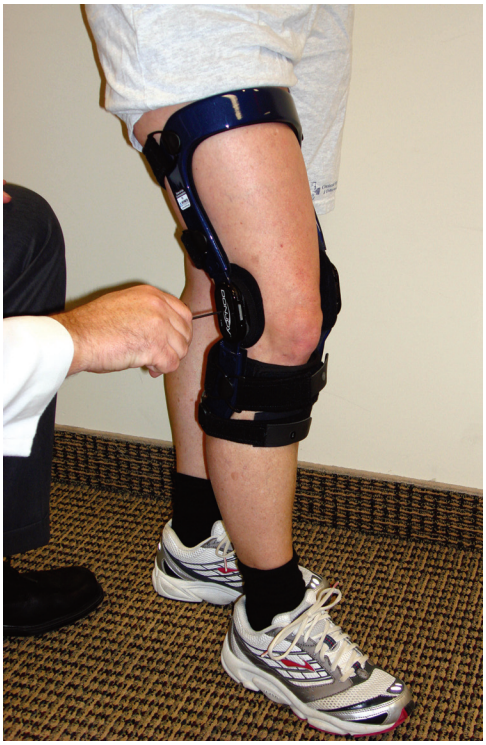

FIG 28-1 An unloading brace may be used and adjusted based on patient pain response.

- Insufficient lower extremity flexibility
- Peroneal nerve palsy
- DVT (calf pain, Homans, tibial edema)
- Delayed union or nonunion

POSTOPERATIVE REHABILITATION PROTOCOL

Modalities

The postoperative rehabilitation protocol following tibial and femoral osteotomy is summarized in Table 28-2. In the immediate postoperative period, knee pain and effusion must be controlled to avoid quadriceps muscle inhibition or shutdown. Electrogalvanic stimulation (EGS) or high-voltage electrical muscle stimulation (EMS) may be used in addition to ice, compression, and elevation to control swelling. The treatment duration is approximately 30 minutes, and the intensity is set to patient tolerance.

Once the joint effusion is controlled, functional EMS is begun for muscle reeducation and facilitation of an adequate quadriceps contraction. One electrode is placed over the vastus medialis obliquus and the second electrode is placed on the central to lateral aspect of the upper third of the quadriceps muscle belly. The patient is instructed to actively contract the quadriceps muscle simultaneously with the machine's stimulation. The treatment duration is 20 minutes. A portable EMS machine for use at home may be required in individuals whose muscle rating is poor. EMS is continued until the muscle grade is rated as good.

Biofeedback therapy is an important adjunct to facilitate an adequate quadriceps muscle contraction early postoperatively. The surface electrode is placed over the selected muscle component to provide feedback to the patient and clinician regarding the quality of active or voluntary quadriceps contraction. Biofeedback is also useful in enhancing hamstring relaxation if the patient experiences difficulty achieving full knee extension secondary to knee pain or muscle spasm. The electrode is placed over the belly of the hamstring muscle while the patient performs range of motion (ROM) exercises.

Cryotherapy is begun immediately after surgery. The standard method is an ice bag or commercial cold pack. However, patients prefer motorized cooler units because they maintain a constant temperature and circulation of ice water, which provides excellent pain control. Gravity flow units are also effective; however, temperature maintenance is more difficult with these devices than with the motorized cooler units. Cryotherapy is used from three times a day to every waking hour for 20 minutes at a time depending on the extent of pain and swelling. In some cases, the treatment time is extended owing to the thickness of the buffer that exists between the skin and the device. Cryotherapy is typically done after exercise or when required for pain and swelling control and is maintained throughout the entire postoperative rehabilitation protocol.

Postoperative Bracing and Weight Bearing

A long-leg postoperative brace is worn for the first 7 to 8 postoperative weeks. Patients then discontinue use of the brace, but if they continue to experience pain, Visco (Bauerfeind) heel pads are used to unload the affected compartment. A lateral wedge is used for patients who underwent HTO, whereas a medial wedge is used for those who had a DFO. If pain remains, an unloading brace, used initially in a neutral position and then adjusted based on patient response, is recommended (Fig. 28-1).

Initially, patients are only allowed toe-touch weight bearing. They are encouraged during this time period to lightly touch the ground with the toes of the operated limb while standing, with the visual image of stepping on a sponge, as frequently as possible during the day. At 4

weeks postoperative, double-stance, full-length anteroposterior radiographs are taken to determine osteotomy alignment and healing. Patients are then allowed to bear 25% of their body weight if the radiographs demonstrate adequate healing and maintenance of the osteotomy position and fixation implant (Fig. 28-2). A normal gait pattern that encourages normal knee flexion throughout the gait cycle is advocated. This technique allows for normal patterning of heel-to-toe ambulation, quadriceps contraction during midstance, and hip and knee flexion during the gait cycle. Average healing of the fracture site occurs at approximately 8 to 10 weeks postoperatively. In patients in whom allograft bone is used to fill the osteotomy gap, an additional delay in full weight bearing may be required for up to 12 postoperative weeks to allow for bony consolidation.

Range of Knee Motion

The postoperative goals for knee flexion and extension are shown in Table 28-3. Patients are encouraged to regain 0 to 90 degrees within the first 2 weeks. Patients perform passive and active ROM exercises in a seated position for 10 minutes per session, approximately three to four times per day.

Patients who have difficulty regaining at least 0 degrees by the second week are placed into an overpressure program using a propped

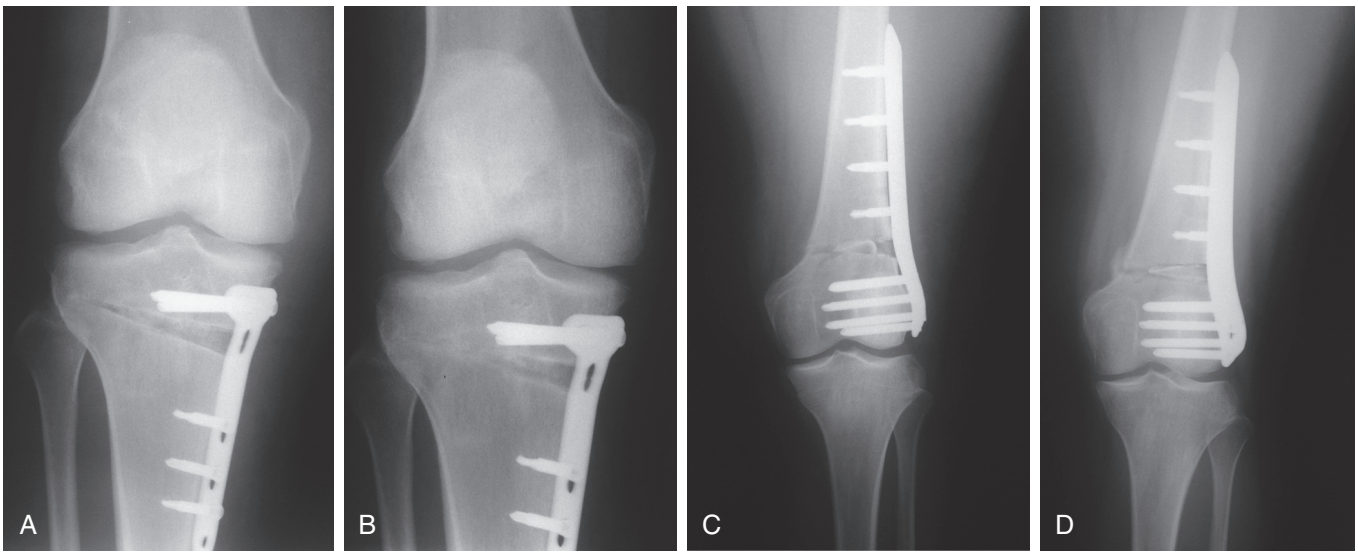

FIG 28-2 **A** and **B,** Postoperative radiographs of an 18-year-old male athlete with varus malalignment. The patient underwent an opening-wedge high tibial osteotomy with a Tomofix locking plate and screw configuration (DePuy Synthes). This fixation construct provides great stability to the osteotomy site, allowing for freeze-dried allograft bone to fill the opening wedge defect. **A,** Radiograph at 6 weeks shows good healing and consolidation over half of the osteotomy site. Although there is no osseous healing adjacent to the plate, there is sufficient healing for full weight bearing. **B,** Radiograph at 12 weeks shows complete healing of the osteotomy defect. This demonstrates the role of radiographs to assess healing before full weight bearing. **C** and **D,** Postoperative radiographs of an 18-year-old woman with valgus malalignment who underwent an opening-wedge distal femoral osteotomy. **C,** The iliac crest autograft, freeze-dried allograft, and Tomofix locking plate and screws 1 week postoperative. **D,** Maintenance of the correction with early healing at the osteotomy site 7 weeks postoperatively. The internal fixation allows for resumption of normal weight bearing.

foot/ankle position (Fig. 28-3). This position is maintained for 10 minutes and repeated four to six times per day. A 10-lb weight may be added to the distal thigh and knee to provide overpressure to stretch the posterior capsule. If this method is not successful in achieving full extension or if the clinician notes a firm end feel, then an extension board or additional weight of 15 to 20 pounds may be used up to six times a day.

Knee flexion is gradually increased to 110 degrees by the third to fourth postoperative week, 130 degrees by the fifth to sixth week, and 135 degrees by the seventh to eighth week. Methods to assist in achieving flexion greater than 90 degrees include chair rolling, wall slides, knee flexion devices, and passive quadriceps stretching exercises (Fig. 28-4).

FIG 28-3 Overpressure extension exercise.

FIG 28-4 Flexion overpressure exercise options include rolling stool (**A**), wall slides (**B**), and use of commercial device (ERMI Knee Flexionater) (**C**).

Patellar Mobilization

The resumption of normal patellar mobility is critical to regain a normal range of knee motion. The loss of patellar mobility is often associated with arthrofibrosis and, in extreme cases, the development of patella infera. Patellar glides are performed in all four planes (superior, inferior, medial, and lateral) beginning the first postoperative day with sustained pressure applied to the appropriate patellar border for at least 10 seconds (Fig. 28-5). This exercise is done for 5 minutes before ROM exercises. Caution is warranted if an extensor lag is detected because this may be associated with poor superior migration of the patella, indicating the need for additional emphasis of this exercise. Patellar mobilization is performed for approximately 8 weeks postoperatively.

FIG 28-5 Patellar mobilization.

Flexibility

Hamstring and gastrocnemius-soleus flexibility exercises are begun the first day after surgery. A sustained static stretch is held for 30 seconds and repeated five times. Common methods for stretching these muscle groups include the modified hurdler stretch and the towel pull. These

exercises help control pain because of the reflex response created in the hamstrings when the knee is maintained in the flexed position. As well, the towel-pulling exercise can help lessen discomfort in the calf, Achilles tendon, and ankle. Quadriceps and iliotibial band flexibility exercises are begun at the ninth postoperative week.

Strengthening

The strengthening program is begun on the first postoperative day (Table 28-4). Isometric quadriceps contractions are done hourly using the repetition rules of 10-second holds, 10 repetitions, 10 times per day. The patient is taught to monitor the contractions by visual or manual means, comparing the quality with those achieved by the contralateral limb. The superior migration of the patella is observed and should be approximately 1 cm during contractions, with inferior migration also seen during the initial relaxation of the contraction. The knee is held in a slightly flexed position during isometric contractions. Biofeedback may be used to reinforce an adequate voluntary quadriceps contraction.

Open kinetic chain extension exercises are incorporated within the first few weeks to further develop quadriceps muscle strength. Caution is warranted owing to the potential problems these exercises may create for the patellofemoral joint. Resisted knee extension is begun with Velcro ankle weights from 90 to 30 degrees. The terminal phase of extension is avoided owing to the high forces placed on the patellofemoral joint. The patellofemoral joint must be monitored for changes in pain, swelling, and crepitus to avoid a patellar conversion in which painful patellofemoral crepitus develops with articular cartilage damage. A word of caution in DFO cases is to warn the patient against turning and twisting motions that may disrupt the osteotomy site before healing has occurred. Partial weight bearing is for forward walking only, and other activities are avoided in the early postoperative period (6-8 weeks).

Straight-leg raises are begun the first postoperative day in the hip flexion plane (supine position) only. These exercises are advanced to include the hip extension plane during the third week. Patients who underwent HTO begin straight leg raises in the abduction/adduction planes between 4 and 6 weeks postoperatively based on x-ray evidence of healing. These exercises are begun between 6 and 8 weeks postoperatively in patients who underwent DFO based on x-ray evidence of healing. As these exercises become easy to perform, ankle weights are added to progress muscle strengthening. Initially, 1 to 2 pounds of weight are used, and eventually, up to 10 pounds is added as long as this is not more than 10% of the patient's body weight. Initially, weight is applied above the patella to control forces to the healing fracture. The use of rubber tubing to provide increased resistance may also be of benefit starting at the seventh to eighth postoperative week.

Another common exercise effective in helping with quadriceps reeducation is the straight-leg plus raise (Fig. 28-6). The quadriceps is contracted, and the leg is lifted approximately 6 inches off the table or chair, held in the lifted position for 15 seconds, and then lowered and relaxed for 45 seconds. This 1-minute cycle is maintained and progressed in ratios (1:3, 1:2, and eventually 1:1) and then progressed from 5 to 10 repetitions, with additional ankle weight added to increase the difficulty of the exercise.

Toe raises are begun during the third to fourth week as tolerated. Closed kinetic chain exercises may be initiated during the fifth to sixth week. Minisquats from 0 to 45 degrees are begun when tolerated by the patient. Initially, the patient's body weight is used as resistance, and gradually, TheraBand or surgical tubing is added for resistance (Fig. 28-7). Quick, smooth, rhythmic squats are performed to a high-set/high-repetition cadence to promote muscle fatigue. Wall sitting

FIG 28-6 The straight-leg raise plus exercise.

exercises are also begun during this time period. The goal of wall sitting is to improve quadriceps contraction by performing the exercise to muscle exhaustion. If anterior knee pain is experienced, either the knee flexion angle of the sit or the toe-out/toe-in angle is altered. The exercise may also be modified by the patient squeezing a ball between the distal thighs, holding dumbbell weights, or shifting the body weight over the involved side to simulate a single-leg contraction. This exercise is promoted as an excellent one to perform at home four to six times per day to achieve quadriceps fatigue in a knee flexion angle that does not induce anterior knee pain. Leg press exercises in the range of 70 to 10 degrees are begun during this time period as well.

It is important that the physician provides the therapist with the results of radiographs that show healing and obliteration of the fracture line and incorporation of the bone graft. A delayed union or nonunion indicates that 25% to 50% weight bearing continues into the 5- to 6-week period, thereby necessitating a delay in full weight-bearing strengthening exercises.

Lateral step-ups are initiated when the patient has achieved full weight bearing, at approximately 7 to 8 weeks. The height of the step is gradually increased from 4 to 8 inches based on patient tolerance. Strengthening is also initiated during this time for hip abductors, adductors, flexors, and extensors by using either a multihip or cable system machine or a seated hip abductor/adductor machine. Hamstring curls on a weight machine are begun at 9 to 12 weeks postoperative.

Balance, Proprioceptive, and Perturbation Training

Cup walking is an exercise that promotes symmetry between the surgical and uninvolved limbs. This exercise helps develop hip and knee flexion and quadriceps control during midstance of gait to prevent knee hyperextension (see Chapter 29). In addition, cup walking controls hip and pelvic motion during midstance, gastrocnemius-soleus activity during push off, and excessive hip hiking (Fig. 28-8). This exercise may be initiated during the partial weight-bearing phase.

Balance and proprioceptive training are initiated when the patient has resumed full weight bearing. Initially, the patient stands and shifts the body weight from side to side and front to back. This activity encourages confidence in the leg's ability to withstand the pressures of weight bearing and initiates the stimulus to knee joint position sense.

Double-leg and single-leg balance exercises in the stance position are also beneficial. During the single-leg exercise, the foot is pointed straight ahead, the knee flexed 20 to 30 degrees, the arms extended

TABLE 28-4 Muscle Strengthening Exercises Following Osteotomy

Time Postoperative	Frequency	Quadriceps Isometrics (Active)	Straight-Leg Raises	Knee Extension (Active Assisted) 90-30 Degrees	Toe Raises	Wall-Sits (to Fatigue)	Minisquats	Lateral Step-ups (5- to 10-cm Block)	Hamstring Curls (0-90 Degrees)	Multihip (Flex, Ext, Abd, Add)	Leg Press (70-10 Degrees)
1-2 wk	3 ×/day, 15 min	1 set × 10 reps (every hour)	Flex, 3 sets × 10 reps	3 sets × 10 reps							
3-4 wk	2-3 ×/day, 20 min	Multiangle 0, 60 degrees, 1 set × 10 reps each	Flex, ext, 3 sets × 10 reps	3 sets × 10 reps	3 sets × 10 reps						
5-6 wk	2 ×/day, 20 min	Multiangle 30, 60, 90 degrees, 2 sets × 10 reps	Add ankle weight ≤10% of body weight, 3 sets × 10 reps	Active, 3 sets × 10 reps	3 sets × 10 reps	3 sets to fatigue	3 sets to fatigue				3 sets × 10 reps
7-8 wk	2 ×/day, 20 min		Add abd, add 3 sets × 10 reps; add rubber tubing, 3 sets × 30 reps*	Active, 3 sets × 10 reps	3 sets × 10 reps	3 sets to fatigue	3 sets to fatigue; add rubber tubing, 0-30 degrees	3 sets × 10 reps		3 sets × 10 reps	3 sets × 10 reps
9-12 wk	1-2 ×/day, 20 min		3 sets × 10 reps; add rubber tubing, 3 sets × 30 reps	With resistance, 3 sets × 10 reps	3 sets × 10 reps	3 sets to fatigue	Add rubber tubing, 0-40 degrees, 3 sets × 20 reps	3 sets × 10 reps	Active, 3 sets × 10 reps	3 sets × 10 reps	3 sets × 10 reps
13-26 wk	1-2 ×/day, 20 min		Rubber tubing, high speed, 3 sets × 30 reps	With resistance, 3 sets × 10 reps			3 sets × 20 reps		Active, 3 sets × 10 reps	3 sets × 10 reps	3 sets × 10 reps

*Opening-wedge distal femoral osteotomy with locking plate and screw fixation; physician must confirm healing on radiographs across osteotomy with obliteration of the fracture line to progress to these exercises.

FIG 28-8 Cup (or cone) walking.

outward to horizontal, and the torso positioned upright with the shoulders above the hips and the hips above the ankles. The patient is encouraged to remain in this position until balance is disturbed. A minitrampoline or unstable platform may be used to make this exercise more difficult. Patients may assume the single-leg stance position and throw or catch a weighted ball against an inverted minitrampoline until fatigue occurs.

Perturbation training techniques are also performed during balance exercises. The therapist stands behind the patient and disrupts her or his body posture and position periodically to enhance dynamic knee stability (Fig. 28-9). The techniques involve either direct contact with the patient or disruption of the platform the patient is standing on, and the patient is instructed to then correct the unbalanced position.

Half foam rolls are also used in this time period as part of the gait-retraining and balance program (Fig. 28-10, *A*). This technique helps the patient develop balance and the dynamic muscular control required to maintain an upright position and be able to walk from one end of the roll to the other. Use of a balance board or other unstable platform in double-leg and single-leg stance is another effective measure (Fig. 28-10, *B*). Developing a center of balance, limb symmetry, quadriceps control in midstance, and postural positioning are benefits obtained from this type of training.

Conditioning and Return to Activities

Depending on accessibility, a cardiovascular program with an upper body cycle may be initiated as soon as tolerated by the patient (Table 28-5). The surgical limb should be elevated to minimize lower extremity swelling. Stationary bicycling is begun during the fifth to sixth postoperative week. Based on incision healing, water walking is also begun during this time period.

FIG 28-9 Perturbation-training techniques.

FIG 28-10 Balance training techniques include walking on a half foam roll (**A**) and single-leg stance on an unstable surface (**B**).

TABLE 28-5 Aerobic Conditioning Exercises After Osteotomy

Time Postoperative	Frequency	Upper Body Cycle	Bicycle (Stationary)	Water Walking	Swimming	Walking	Stair-Climbing Machine (Low Resistance, Low Stroke)	Ski Machine (Short Stride, Level, Low Resistance)
3-4 wk	1-2 ×/day	10 min						
5-6 wk	2 ×/day	10 min	10 min	10 min				
7-8 wk	1-2 ×/day	15 min	15 min	15 min				
9-12 wk	1 ×/day (select one activity per session)		15-20 min	15-20 min	15-20 min	15-20 min	15-20 min	15-20 min
13-26 wk	3 ×/week (select one activity per session)		20 min	20 min	20 min	20 min	20 min	20 min

Cross-country ski, elliptical, and stair climbing machines are permitted 9 to 12 weeks postoperatively. Protection against high stresses to the patellofemoral joint is required. The seat height of the bicycle is adjusted to its highest level based on patient body size, and a low resistance level is recommended. Stair-climbing machines are adjusted to produce a short step with low resistance. An aquatic program that includes lap work using freestyle or flutter kicking, water walking, and water aerobics is encouraged if the patient has access to a pool. To improve cardiovascular endurance, the program should be done at least three times per week for 20 to 30 minutes, with the exercise performed to at least 60% to 85% of maximal heart rate.

The majority of patients who undergo HTO or DFO are advised to return to only light, low-impact activities to maintain an active and healthy lifestyle and weight control. Patients who express the desire to return to higher-impact sports activities are advised of the risk of further cartilage deterioration if damage was noted during the operation. The usual goal of osteotomy is to buy time before the necessity for a partial or total joint replacement; therefore participation in high-loading activities is discouraged.

INTRODUCTION AND DIAGNOSIS

Patients with chronic insufficiency of the lateral and posterolateral structures of the knee may develop a gait abnormality that is characterized by excessive knee hyperextension during the stance phase (initial contact or heel strike, loading response, midstance, and toe off) of the gait cycle (Fig. 29-1). The primary lateral and posterolateral structures of the knee joint are the fibular collateral ligament (FCL) and popliteus muscle-tendon-ligament unit (PMTL), including the popliteofibular ligament (PFL) and posterolateral capsule (PLC). These structures function together to resist lateral tibiofemoral compartment opening, posterior subluxation of the lateral tibial plateau with tibial rotation, knee hyperextension, and varus recurvatum (see Chapter 15).[8,9,12,13,19,27] Posterolateral injuries are frequently accompanied by a rupture to the anterior cruciate ligament (ACL) and, in some cases, a rupture to the posterior cruciate ligament (PCL).[5,7,11] In addition, many knees with insufficiency to the posterolateral structures also have varus osseous malalignment. The comprehensive physical examination and radiographic evaluation required to determine all of the abnormalities that exist in these complex knee joint injuries are detailed in Chapters 16 and 26.

The gait abnormality described in this chapter is easily identifiable in the clinic if the examiner devotes a small amount of time to observation during the initial patient presentation. An abnormal knee hyperextension gait pattern involves increased extension (>0 degrees) in the sagittal plane and, frequently, associated varus malalignment in the coronal plane (varus recurvatum). The varus recurvatum position of the knee will be markedly worse if there is associated osseous tibiofemoral varus malalignment. The *triple varus knee*, described in detail in Chapter 26, refers to varus alignment caused by three factors: tibiofemoral varus osseous malalignment, increased lateral tibiofemoral compartment separation because of marked insufficiency of the FCL and PMTL, and varus recurvatum in extension. An abnormal increase in hyperextension usually indicates damage to not only the posterolateral structures but the ACL as well.

Some knees with uninjured but physiologically slack posterolateral structures demonstrate a passive varus recurvatum and excessive knee hyperextension. After a knee injury or muscle atrophy of any cause, the patient may demonstrate a hyperextension gait pattern caused by muscle weakness. Other patients with symptomatic patellofemoral arthritis develop a hyperextension gait pattern to avoid knee flexion that loads the patellofemoral joint and causes anterior knee pain. These patients are the most difficult to manage because the knee arthritis symptoms require treatment to relieve the painful state in addition to correcting quadriceps weakness and the knee hyperextension gait pattern.

In our experience, patients with knee hyperextension gait problems present with varying amounts of altered gait mechanics, symptoms, and functional limitations. Some may demonstrate a markedly abnormal gait that is severely disabling and limits ambulation, requiring crutch or cane support. Others may have a less noticeable alteration, with the abnormal knee hyperextension occurring only after excessive walking (or other weight-bearing activities) and muscle fatigue. The degree of the gait abnormality during the stance phase depends on the magnitude of associated ligamentous deficiencies, quadriceps muscle atrophy, and symptomatic patellofemoral arthritis.

Subjective complaints of knee instability of either partial or full giving-way during routine daily activities often accompany the knee hyperextension gait abnormality. Pain is frequently located in the medial tibiofemoral compartment, which is caused by increased compressive forces owing to the varus malalignment. Pain in the posterolateral tissues also occurs from increased soft tissue tensile forces. In addition to the pain and instability caused by this gait pattern, there is an increased risk of failure of posterolateral reconstructions if the gait abnormality is not corrected before surgery. This is because of the excessively high tensile forces from high knee extension and adduction

moments that are expected be resumed during weight-bearing activities after surgery.[16] In addition, patients with associated ACL or PCL deficiency may have an increased risk of failure of cruciate ligament reconstructions if the hyperextension pattern is not corrected before surgery.[14,15] Therefore, gait retraining and avoidance of the gait hyperextension pattern are paramount for both resolution of patient symptoms and reduction of the risk of failure of soft tissue ligament reconstructive procedures.

Many investigators have described a quadriceps-avoidance abnormal gait pattern in patients with ACL ruptures.[1,2,6,18,20,28] An investigation at our center[18] documented diminished quadriceps activity and enhanced hamstring muscle activity in half of 32 ACL-deficient varus-angulated knees. Although the increased hamstring muscle force could be assumed to be beneficial because it provides a protective mechanism in decreasing anterior tibial translation, the increased muscle force creates high axial compressive forces and therefore increases medial and lateral joint compartment (calculated) loads. These loads could be deleterious to the joint over the long term, especially in knees with associated varus osseous malalignment. The abnormal gait characteristics of the ACL-deficient knee are discussed in detail in Chapter 6.

FIG 29-1 A lower limb varus deformity and hyperextension gait abnormality is evident in this 32-year-old man with chronic deficiency of the posterolateral structures and varus malalignment.

A hyperextension gait abnormality pattern is also found in patients who have had a stroke or traumatic brain injury, cerebral palsy, or poliomyelitis.[10] In these instances, the disorder may occur owing to many factors, including quadriceps weakness, ankle plantar flexion spasticity, heel cord contracture, and gastrocnemius-soleus weakness. The concern is that the abnormal knee hyperextension may cause stretching of the posterior ligamentous and capsular structures from the increased external extensor torque that is placed across the knee during stance. It is not the purpose of this chapter to discuss the treatment of this problem in patients with neurologic pathology. Rather, this chapter focuses on the treatment of this gait disorder in patients with chronic insufficiency of the posterolateral structures, with or without cruciate ligament ruptures or varus malalignment.

ABNORMAL KNEE HYPEREXTENSION PATTERNS

The normal pattern of knee motion that occurs during the gait cycle is shown in Figure 29-2. A detailed description of normal human gait mechanics is beyond the scope of this chapter and has been presented by many authors.[3,4,21,24,25] The loss of the normal knee flexion and extension patterns throughout the stance phase noted in patients with hyperextension gait abnormalities has important functional implications. During the loading response, normal amounts of knee flexion are required for the knee joint to absorb shock. A limb that is instead hyperextended transfers body weight directly from the femur to the tibia, resulting in abnormally high compressive forces. The usual muscle energy absorption and cushioning effect a flexed knee provides are lost.[22,23] The thrusting hyperextension motion at the knee is associated with an abnormally high adduction moment, which tends to increase medial tibiofemoral compartment compressive forces and lateral distraction forces. The increased compressive forces manifest as pain in the medial tibiofemoral compartment and posterolateral soft tissues.

We have reported two distinct knee hyperextension gait patterns. In *pattern I*, the abnormal hyperextension occurs during two periods

CRITICAL POINTS Introduction and Diagnosis

- Patients with chronic insufficiency of the lateral and posterolateral structures may develop a gait abnormality characterized by excessive knee hyperextension during the stance phase of the gait cycle.
- Gait abnormality is easily identifiable in the clinic: increased extension (>0 degrees) in the sagittal plane, associated varus recurvatum.
- Patients with knee hyperextension gait problems present with varying amounts of altered gait mechanics, symptoms, and functional limitations.
- Degree of the gait abnormality during the stance phase depends on the magnitude of associated ligamentous deficiencies, quadriceps muscle atrophy, and symptomatic patellofemoral arthrosis.
- Complaints of either partial or full giving-way during routine daily activities are frequent.
- Pain is in medial compartment, posterolateral tissues.
- Increased risk of failure of cruciate and posterolateral reconstructions exists if the gait abnormality is not corrected before surgery.

CRITICAL POINTS Abnormal Knee Hyperextension Patterns

- Loss of normal knee flexion and extension patterns throughout the stance phase is noted in patients with hyperextension gait abnormalities.
- Pattern I: Abnormal hyperextension occurs during heel strike and terminal extension, with knee flexion noted during the loading response. Exceedingly high knee extension moments exist, along with an abnormal reversal of hip extension and ankle dorsiflexion.
- Pattern II: Prolonged knee hyperextension pattern from heel strike throughout midstance. Knee flexion moment is markedly below normal.
- Abnormal tibiofemoral alignment (varus-valgus osseous malalignment or anterior-posterior tibial slope) affects knee-thrusting motions in the sagittal or coronal plane.
- Varus thrust gait abnormality is caused by a varus tibiofemoral osseous malalignment. Thrusting motion occurs with the knee near full extension immediately after heel strike.

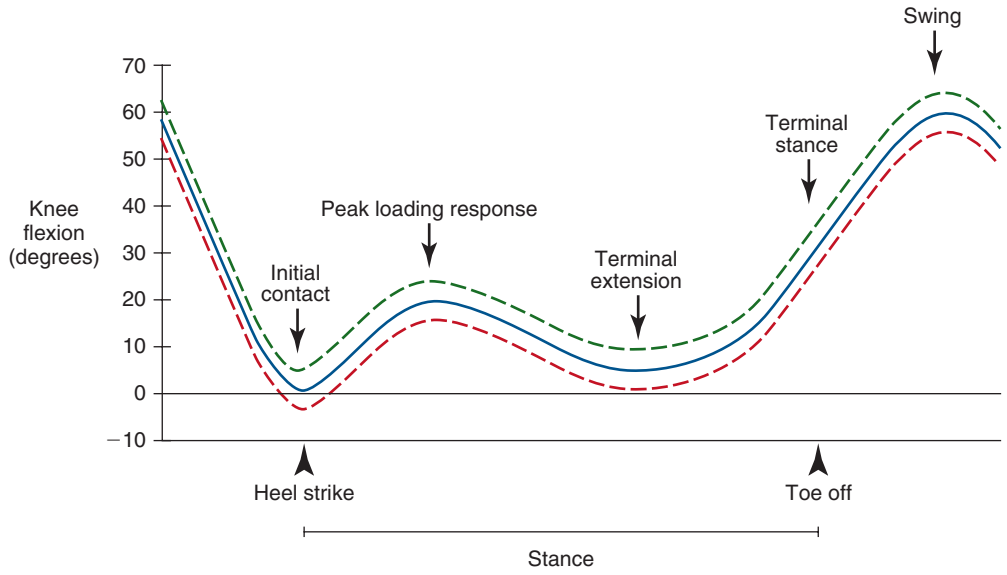

FIG 29-2 Knee motion (in degrees) during a normal gait cycle is shown. Phases of stance gait are indicated. (From Noyes FR, Dunworth LA, Andriacchi TP, et al. Knee hyperextension gait abnormalities in unstable knees. Recognition and preoperative gait retraining. *Am J Sports Med.* 1996;24:35-45.)

TABLE 29-1 Abnormal Knee Motion Patterns and Subluxations During Stance Phase

Stance Phase Event	Abnormal Knee Position	Motion Limit Increased	Phase of Stance	Possible Additional Subluxations	Comments
Hyperextension motion (thrust)	Hyperextension (pattern I)	Extension	Initial contact, terminal extension phases	Varus-external tibial rotation (recurvatum)	Sudden knee hyperextension-flexion-hyperextension even during stance. Markedly abnormal gait; retraining difficult.
Hyperextension motion (thrust)	Hyperextension (pattern II)	Extension	Entire stance phase	Varus-external tibial rotation (recurvatum)	No back-and-forth motion during stance. Gait retraining less difficult.
Varus thrust	Tibial adduction (lateral joint opening)	Adduction	Initial contact and loading response phase	Tibiofemoral compartment rotational subluxation*	Usually occurs at loading response. Gait retraining not possible. External tibial rotation may decrease thrusting; internal rotation increases thrusting. Increased external tibial rotation (lateral-posterolateral injury, medial-posteromedial injury, or both). Increased internal tibial rotation is rare, usually ACL plus lateral ligament injury.
Valgus thrust	Tibial abduction (medial joint opening)	Abduction	Initial contact and loading response phase	Tibiofemoral compartment rotational subluxation*	Increased external tibial rotation (medial-posteromedial ligament injury), with anterior subluxation of medial plateau. Increased external tibial rotation with lateral-posterolateral injury with posterior subluxation of the medial plateau.

From Noyes FR, Dunworth LA, Andriacchi TP, et al. Knee hyperextension gait abnormalities in unstable knees. Recognition and preoperative gait retraining. *Am J Sports Med.* 1996;24:35-45.
*Rotational subluxations may also occur in the absence of a varus or valgus thrust.

of the stance phase, heel strike and terminal extension (Fig. 29-3), with knee flexion noted during the loading response. Exceedingly high knee extension moments are present, along with an abnormal reversal of hip extension and ankle dorsiflexion. *Pattern II* is characterized by a prolonged knee hyperextension pattern from heel strike throughout midstance (Fig. 29-4). In these patients, the knee flexion moment is markedly below normal, with its effects incurred primarily at the knee with only a slight delay in ankle dorsiflexion.

Our clinical observations[17] on the various types of abnormal knee motions and thrusts in the sagittal, coronal, and transverse rotational planes that occur during the stance phase of gait are summarized in Table 29-1. Any abnormality in tibiofemoral alignment (varus-valgus osseous malalignment or anterior-posterior tibial slope) may affect knee-thrusting motions in the sagittal or coronal plane. The most common of these is a varus-thrusting gait abnormality caused by a varus tibiofemoral osseous malalignment. The thrusting motion

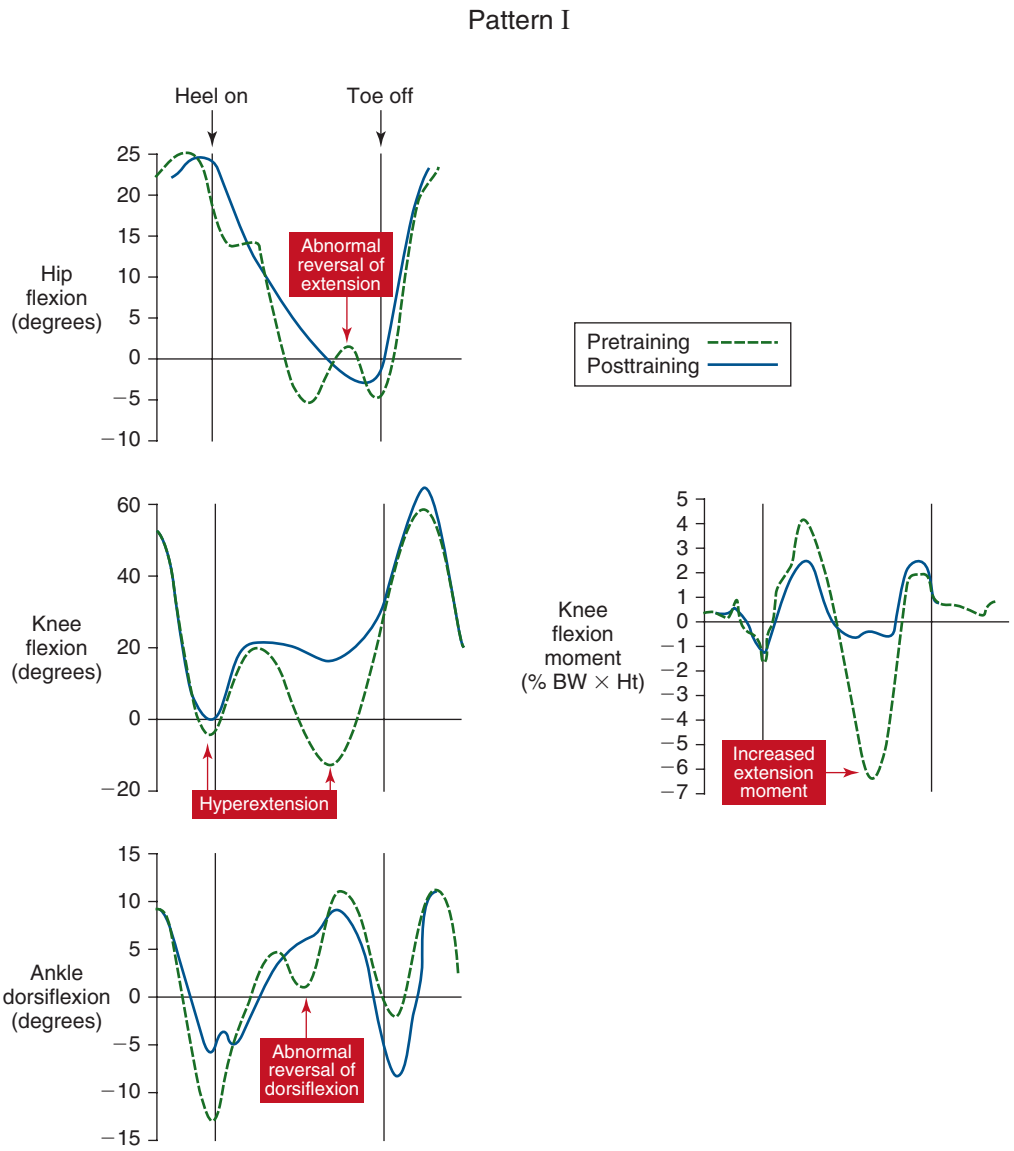

FIG 29-3 Generalized motion at the hip, knee, and ankle (in degrees), and flexion and extension moment (percentage of body weight × height) for patients showing pattern I, knee hyperextension at heel strike and midstance only. *BW*, Body weight; *Ht*, body height. (From Noyes FR, Dunworth LA, Andriacchi TP, et al. Knee hyperextension gait abnormalities in unstable knees. Recognition and preoperative gait retraining. *Am J Sports Med.* 1996;24:35-45.)

occurs with the knee near full extension immediately after heel strike, during the loading response. There may be an associated external or internal rotational subluxation with the varus thrust, depending on the presence of associated deficiency to the posterolateral structures. A less common abnormality, a valgus-thrusting gait, is usually associated with valgus lower limb malalignment. This disorder is typically accompanied by external rotation of the tibia. Knees with these osseous malalignment and associated knee ligament deficiency require surgical correction of the malalignment by osteotomy before ligament reconstructive procedures.

GAIT RETRAINING PROGRAM FOR ABNORMAL KNEE HYPEREXTENSION

A gait retraining program has been successfully used at our center[17] for knee hyperextension abnormalities since the middle of the 1980s. The program requires two to four initial clinical sessions (held preferable every week) with an experienced physical therapist to instruct the patient on the abnormal gait mechanics that occur and the adaptations required to restore a normal gait pattern (Table 29-2). The patient is instructed to practice at home for at least 2 to 4 hours daily. In addition, the patient undergoes muscle strengthening and neuromuscular coordination training as part of the comprehensive rehabilitation process. To have a successful outcome, the patient must be compliant with the time commitment and constant motivation required of this program. A family member is also taught the same instructions so he or she can observe and assist with the patient's retraining at home. It is also helpful to video the patient's abnormal and corrected gait to aid the education process. The patient may ultimately require 8 to 12 therapy sessions over 6 to 12 weeks to return to a normal asymptomatic gait pattern.

The initial focus of the retraining process is placed on the hyperextension of the knee for the patient to understand that this is the

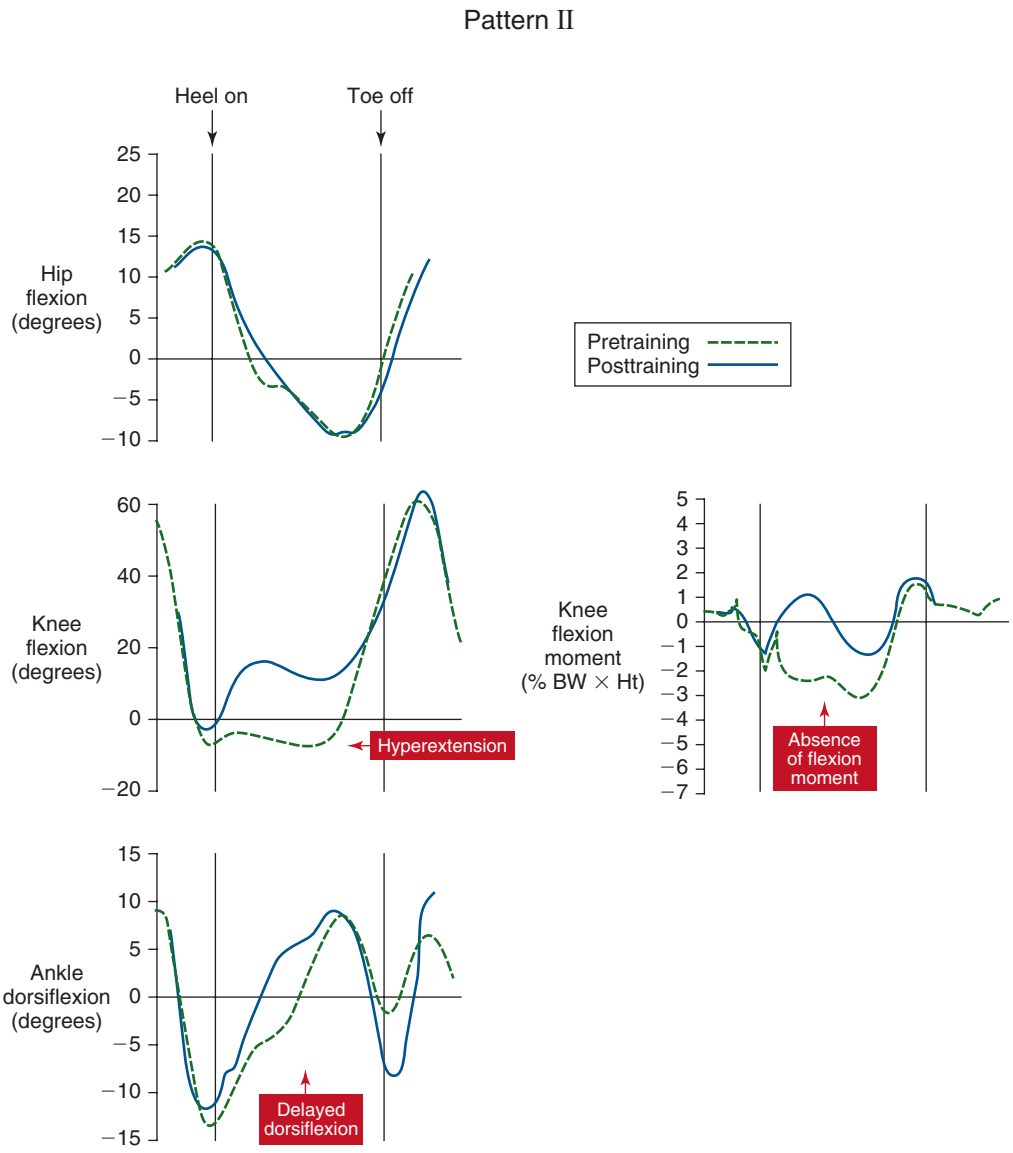

FIG 29-4 Generalized motion at the hip, knee, and ankle (in degrees), and flexion and extension moment (percentage of body weight × height) for patients showing pattern II, hyperextension of the knee throughout stance phase. *BW*, Body weight; *Ht*, body height. (From Noyes FR, Dunworth LA, Andriacchi TP, et al. Knee hyperextension gait abnormalities in unstable knees. Recognition and preoperative gait retraining. *Am J Sports Med.* 1996;24:35-45.)

primary abnormality that requires modification (Fig. 29-5). The patient is instructed to maintain 5 degrees of flexion with each step. This requires walking in a very slow and deliberate manner. A visual aid to provide to the patient is the mental image of a woman walking in high heels, which produces 5 to 8 degrees of knee flexion. In addition, a 1- to 2-inch elevated heel may be used to help maintain flexion throughout stance phase. The clinician should be aware that problems may occur during gait retraining when the patient practices the flexed knee stance. Although the flexed knee gait is advantageous in contributing to quadriceps strengthening, it may aggravate preexisting patellofemoral pain, which must be treated promptly.

The second step of the training process involves educating the patient on the abnormal ankle and foot motions that occur concurrently with knee hyperextension. The patient practices elevating the heel and pushing off with the forefoot and toes in the midstance phase to avoid knee hyperextension. The patient must limit excessive ankle plantar flexion and assume early ankle dorsiflexion to maintain forward progression of the tibia and flexion of the knee joint. It is helpful to have the patient notice and feel the pressure against the forefoot during the end of stance phase. With the first and second steps, the patient is taught to say "knee-foot" with each stance cycle as a reminder of the normal gait pattern.

When the patient is not practicing the knee-foot adaptation, he or she will revert to the abnormal knee hyperextension pattern. However, within 4 to 6 weeks, it is surprising to note that the gait pattern often returns to normal, and the patient is no longer required to perform a conscious reminder of the gait adaptation. In short, the gait pattern becomes routine.

The third step analyzes the hip and body trunk position (see Table 29-2). The fourth and final step of the retraining program determines whether an abnormal lower limb alignment (varus or valgus thrust) or an external or internal rotational knee subluxation occurs during

CRITICAL POINTS Gait Retraining Program for Abnormal Knee Hyperextension

- Program requires two to four sessions with an experienced physical therapist to instruct the patient on the abnormal gait mechanics that occur and the adaptations required to restore a normal gait pattern.
- Patient practices at home for at least 2 to 4 hours daily.
- Muscle strengthening and neuromuscular coordination training are also performed.
- Initial focus is on the knee hyperextension. Patient is instructed to maintain 5 degrees of flexion with every step, walking in a very slow and deliberate manner.
- Patient is educated on the abnormal ankle and foot motions that occur concurrently with knee hyperextension. Practices elevating the heel and pushing off with the forefoot and toes in the midstance phase to avoid knee hyperextension.
- Hip and body trunk position are analyzed.
- Clinician determines whether an abnormal lower limb alignment (varus or valgus thrust) or an external or internal rotational knee subluxation occurs during stance. Functional knee brace and additional gait retraining may be required.
- Heel wedge may be used to place the knee in slight flexion.
- Unloading brace or a lateral or medial heel wedge is used for significant varus or valgus malalignment.
- Exercises done to target specific muscles used during gait: toe raises for gastrocnemius-soleus complex, straight-leg plus raise and wall-sits for quadriceps.
- Balance and proprioception: weight shifting, tandem balance, single-leg balance (stable and unstable), rocker board (front to back and side to side), cup walking, resisted gait activity with a heavy elastic band.
- Two to three months may be required to complete the training to the point at which a normal gait pattern becomes routine on a subconscious level.

stance. This is important because a primary cause of a patient's abnormal knee hyperextension may be instability of the knee with flexion, so that coronal plane or rotational transverse plane subluxations occur. In these patients, a functional knee brace and additional gait retraining may be required.

In some cases, a heel wedge may be used to place the knee in slight flexion to minimize the midstance hyperextension that can occur with poor quadriceps control. A significant varus or valgus malalignment may require use of an unloading brace or a lateral or medial heel wedge.

There are primarily two different types of unloading braces: single-hinged and bilateral-hinged. Single-hinged braces are able to create a pulling mechanism through the affected compartment, thereby creating the unloading (e.g., when the brace has a medial hinge, the medial compartment is unloaded). With a double-upright hinged system, the brace will typically have a pushing mechanism of unloading (e.g., when attempting to unload the medial compartment, the lateral hinge mechanism will be adjusted to push through the lateral to the medial joint). In custom unloading braces, a fixed amount of unloading can also be built into the brace. The potential added advantage of double-upright unloading braces is the ability to compensate for cruciate and/ or collateral ligament instability. If a brace or heel wedge is used, the patient is reminded to actively practice the gait retraining techniques and not to solely use the brace/ wedge as a passive limit to hyperextension. These devices also assist in decreasing the medial or lateral pain complaints that can accompany either joint instability or arthritis.

TABLE 29-2 Gait Retraining Program for Abnormal Knee Stance Hyperextension

Anatomic Part	Retraining Program
Trunk-upper body	1. Maintain erect position; avoid forward loading position, which shifts body weight anteriorly to knee joint during stance phase. 2. Avoid excessive medial-lateral sway during stance phase, which induces varus-valgus moments about the knee and hip.
Hip	1. Avoid excessive hip flexion during stance phase, which encourages knee hyperextension and fatigues hip extensors. 2. For valgus lower limb alignment, avoid excessive internal femoral rotation. Encourage external femoral rotation and walking on lateral foot border. Avoid knock-knee position (important for valgus thrusts). 3. For varus lower limb alignment, avoid external femoral rotation. Encourage internal femoral rotation, knock-knee position.
Knee	1. Avoid any knee hyperextension throughout stance phase by always maintaining a knee flexion position. 2. Practice knee flexion-extension control walking in a slow manner; often begin with crutches. Initially use an excessive knee flexion position. 3. Gradually resume a more normal walking speed, after flexion-extension control and a more normal gait pattern are resumed. 4. Look for increase in patellofemoral pain. 5. Look for varus or valgus thrust with knee flexion position. 6. Look for external or internal rotational tibiofemoral subluxations when flexion position resumed.
Ankle	1. Avoid excessive plantar flexion. Maintain dorsiflexion using soleus muscle to induce early heel rise (rocker action) to encourage forward tibial progression and knee flexion. 2. Initially use excessive dorsiflexion and walking aids (elevated heel) to increase early heel off in stance phase.
Foot	1. Encourage push-off against forefoot and toes along with early heel off in stance phase to assist knee flexion during stance phase. 2. With associated varus alignment, encourage toe-out position. For valgus alignment, encourage toe-in position.

From Noyes FR, Dunworth LA, Andriacchi TP, et al. Knee hyperextension gait abnormalities in unstable knees. Recognition and preoperative gait retraining. *Am J Sports Med.* 1996;24:35-45.

Voluntary muscle control is critical to help minimize hyperextension gait mechanisms related to diminished quadriceps function. Normal gait requires adequate push-off from the gastrocnemius-soleus complex, sufficient quadriceps contraction in midstance, hip and knee flexion during swing, and an upright posture. Defects in any of these mechanisms will permit gait alterations, and, when completed with sufficient frequency, become the default gait pattern for the patient. Gait is a learned activity and eventually becomes habitual. Therefore

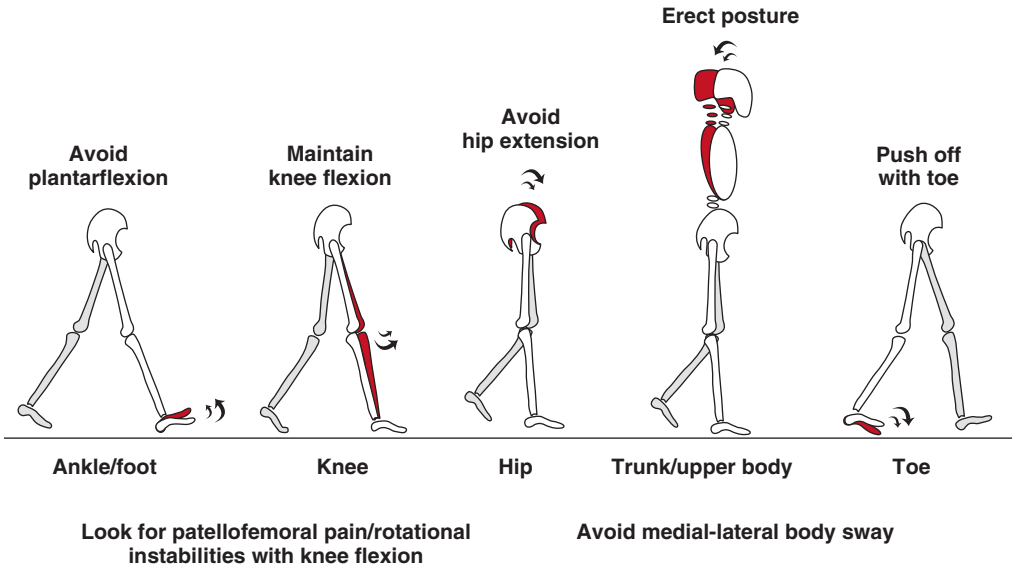

FIG 29-5 Gait abnormalities observed in patients before retraining. *Shaded structures* represent the correct, retrained positions at the trunk, upper body, hip, knee, foot, ankle, and toes. (From Noyes FR, Dunworth LA, Andriacchi TP, et al. Knee hyperextension gait abnormalities in unstable knees. Recognition and preoperative gait retraining. *Am J Sports Med.* 1996;24:35-45.)

gait retraining should include exercises to target the specific muscles during gait, pregait activities to methodically force the patient to think about using these muscles functionally, and then the act to practice the new gait pattern so it eventually becomes the learned default pattern to avoid the hyperextension gait mechanism.

In some knees with varus malalignment, there is an associated internal tibial torsion and toe-in gait. The patient may voluntarily decrease the varus thrust by purposely walking with a toe-out gait; however, when the patient is not practicing, the toe-in gait resumes. The same situation applies to a valgus knee alignment with a pronated toe-out gait. The gait retraining therefore is primarily to address knee hyperextension in which most patients will achieve a beneficial response to the program.

The following sections represent examples of how exercises may be coupled with other activities to assist with gait retraining. An important component of gait retraining is to target exercises for the specific muscles required during the gait cycle. For the gastrocnemius-soleus complex, the patient is instructed on the toe-raise exercise. This exercise can be progressed to move from using double stance to eccentric/negative repetitions (up with two legs/down with a single leg) and eventually to single-ankle plantar flexion lifting. Other options are to move from the floor to the edge of a step or to add additional weight for increasing the workload. The exercise can also be combined with traditional step-up exercises.

Quadriceps control is critical for normal gait and represents the muscle group that demands the most attention. Common exercises that have been shown to be effective in helping with quadriceps reeducation include the straight leg plus raise (Fig. 29-6), performed with the patient in the seated position. The quadriceps is contracted; the leg is lifted approximately 6 inches off the table or chair, held in the lifted position for 15 seconds, and then lowered and relaxed for 45 seconds. This 1-minute cycle is maintained and progressed in ratios (1:3, 1:2, and eventually, 1:1) and then progressed from 5 to 10 repetitions, with additional ankle weight being added to increase the difficulty of the exercise.

FIG 29-6 The straight-leg plus raise exercise.

Isometric wall sits are an excellent method of facilitating quadriceps activation. The desired angle of knee flexion is typically between 45 and 70 degrees. Patients with patellofemoral joint arthritis may need to maintain the angle of flexion between 30 and 45 degrees to decrease patellofemoral pain. Patients who do not have joint damage or pain may perform this exercise in deeper degrees of knee flexion to allow for an increase in quadriceps muscle fiber recruitment. Having the patient keep weight pressures through the heels will also decrease the potential for patellar pain complaints. This exercise is similar to a stationary leg press and is performed as two repetitions, four times a day to a maximum fatigue, experiencing a quadriceps burning sensation. The patient tries each exercise and attempts to reach a 3-minute-total duration for each wall sit repetition.

Active isometric hip adduction during the wall sit by compressing a ball between the knees may assist vastus medialis oblique recruitment. In addition to obtaining adequate quadriceps control, it is

FIG 29-7 The clamshell exercise is performed in either the long-sitting (**A** and **B**) or the side-lying (**C** and **D**) position.

important to improve hip abduction control. A heavy elastic exercise band may be placed proximal to the knee (avoiding patellar pressure) and clamshells are performed in either the hook-sitting (Fig. 29-7, *A* and *B*) or the side-lying (see Fig. 29-7, *C* and *D*) position. Three to five sets of 10 repetitions are performed. Adjustments to either knee flexion or hip flexion angles can make the exercise easier or more difficult depending on what is necessary to challenge the gluteal musculature. The single-leg squat test (Fig. 29-8) may be performed to detect poor hip strength and trunk control, discussed in detail in Chapter 13.

Normal hip abductor and external rotation strength and control of the lower limb are required to prevent the internal hip rotation-valgus lower limb position that is often observed in patients with chronic patellofemoral symptoms.

Balance and proprioception are important components of a gait-retraining program. The patient must be able to maintain single-stance control, as well as move the opposite leg through swing and be ready for the transition into the next stride. Standard progression of balance activities is typically sufficient to allow for return of a normal gait. A sample of these activities includes the following: weight shifting, tandem balance, single-leg balance (stable and unstable), rocker board (front to back and side to side), and Biodex Stabilometer (Biodex Medical Systems) for postural stability (random control and maze control). Focus of balance control is part of both the clinical treatment and home exercise programs.

To create a functional gait retraining program, a blending of the individual exercise programs must progress to include specific gait activities. Patients must overcome a variety of contributing factors including apprehension, muscle weakness, lack of range of motion,

FIG 29-8 A single-leg squat test demonstrating poor hip and knee control.

compensation, and pain. These factors must be resolved for the patient to restore a normal gait cycle. Each of the following factors contributes to a symmetric gait pattern: adequate push off, midstance quadriceps control, hip and knee flexion, and maintenance of an upright posture. Two common gait activities can be used quite successfully to assist in both the early time period after injury or surgery and in later time periods. Initially, an activity known as *cup walking* is used to encourage the patient to break down the actual gait cycle into more manageable tasks. Cups are set up in two staggered rows with symmetric stride lengths (Fig. 29-9). The patient is asked to walk or march over the cups, emphasizing each of the earlier four mentioned tasks. This activity allows the clinician to observe the gait cycle to determine where emphasis needs to be placed. Common compensatory mechanisms that patients exhibit include circumduction of the lower extremity, inadequate push off, midstance hyperextension, lack of coordinated hip and knee flexion, positive Trendelenburg sign, and forward flexed trunk. The clinician must be able to identify the deficiency to teach the patient and her or his support system how to observe the deficiency and to perform the corrective strategy. The normal automatic nature of gait now becomes a thinking activity for the patient. The patient is asked to exaggerate the gait cycle by stepping over the cups. This methodical approach allows the patient to apply a part of the gait cycle to the entire, normal gait pattern. Gait retraining activities such as this must be repeated thousands of cycles over time to create a new default gait pattern.

As time progresses from the injury or surgery, another gait activity may be used that requires the patient to wear a heavy elastic band around the distal thighs (~2 finger widths above the patella) and then produce a marching pattern to provide a resisted-gait cycle. With a central line on the floor, the patient, while marching, must maintain right foot-strike on the right side of the line and left foot-strike on the left side of the line (Fig. 29-10). This movement into swing ensures that adequate hip flexion and hip abduction musculature is used during the gait cycle. In addition, the stance limb requires adequate push off of the gastrocnemius as well as a voluntary quadriceps contraction to prevent a hyperextension episode. This resisted-gait activity can be completed in forward, backward, and lateral directions. Each direction allows the clinician to emphasize what muscle groups

FIG 29-9 Cup walking.

FIG 29-10 Elastic band gait retraining.

are used to allow for adequate voluntary muscle control. Again, these activities require voluntary thought processes to focus on recruiting the quadriceps to avoid the hyperextension mechanism from occurring.

In our experience, after approximately two to four sessions, the patient will understand the abnormal mechanics and recognize when the hyperextension patterns occur. As already discussed, mental reminders, such as "knee bent, toe push-off," are helpful in this stage. After approximately 4 to 6 weeks of training, the patient should convert to a more normal gait pattern. However, it may require 2 to 3 months to complete the training process to the point where a normal gait pattern becomes routine on a subconscious level and the patient does not resume the hyperextension gait pattern when walking quickly.

CLINICAL INVESTIGATION

Methods and Materials

Our gait retraining program[17] was studied in five patients with symptomatic knee hyperextension and deficiency of the posterolateral structures. Computerized gait analysis testing was conducted before and after the retraining program using a two-camera video-based optoelectronic digitizer for measuring motion and a multicomponent force plate for measuring ground reaction force. The force plate was camouflaged under a 10-m walkway. Patients were asked to walk at three speeds (normal, fast, slow), and measurements were obtained over these ranges to enable comparison of similar walking speeds. Data from complete cycles of stance and swing phase were obtained.

Kinematic data in the sagittal plane and kinetic data in the sagittal, coronal, and transverse planes of the hip, knee, and ankle were evaluated. Peak values during stance phase were recorded for each patient. Using a previously described mathematical model,[3,24] joint reaction loads, lateral soft tissue forces, and muscle forces were calculated. The patient data were compared with those obtained from a control group of 11 subjects matched for age and walking speed. All moments, which were expressed as external moments, were normalized to body weight and height.

Analysis of Gait Mechanics before Retraining

Statistically significant differences were found between the pretrained patients and the control subjects in the mean values for knee hyperextension during heel strike and terminal extension (Table 29-3, Fig. 29-11), with the patients demonstrating a range of 5.4 to 18.4 degrees less flexion ($P < .05$). The patients had a significantly higher mean knee midstance extension moment (127%; $P < .01$), knee adduction moment (28%; $P < .05$), and calculated medial tibiofemoral compartment loads (43%; $P < .001$) than the controls. The two knee hyperextension patterns previously discussed were identified; three patients demonstrated pattern I and two patients, pattern II.

Analysis of Gait Mechanics after Retraining

After the program of gait retraining, the patients demonstrated a statistically significant increase in the degrees of knee flexion during heel strike, terminal extension, and toe off (mean, 10 degrees). At terminal extension, an average increase of 18 degrees of flexion was measured compared with the pretraining value ($P < .01$). There were significant decreases in the knee extension moment at heel strike (23%) and terminal extension (80%). The mean adduction moment decreased to a normal value, and a significant reduction (30%) occurred in the predicted medial tibiofemoral load ($P < .05$).

There was a 36% decrease in the hip abduction moment at heel strike ($P < .01$) and an 18% decrease in hip adduction moment during midstance after gait retraining ($P < .01$). The ankle plantar flexion

CRITICAL POINTS Clinical Investigation

Methods

- Gait retraining program studied in five patients with symptomatic knee hyperextension and deficiency of the posterolateral structure
- Computerized gait analysis testing conducted before and after retraining measured motion and ground reaction forces
- Patient data compared with control group of 11 subjects matched for age and walking speed

Results

- Significant differences between pretrained patients and controls. Patients had:
  - Less knee hyperextension during heel strike and terminal extension
  - Greater knee midstance extension moments, knee adduction moments, calculated medial tibiofemoral compartment loads
- After retraining, patients demonstrated:
  - Significant increases in knee flexion during heel strike, terminal extension, and toe off
  - Significant decreases in the knee extension moment at heel strike and terminal extension
  - Significant decreases in the mean adduction moment to normal values
  - Decreases in the hip abduction moment at heel strike
  - Decrease in the hip adduction moment during midstance
  - Decreases in ankle plantar flexion motion

Four of five patients successfully resolved or markedly reduced hyperextension at the knee and abnormal motion patterns at the hip and ankle.

Four of five patients improved from experiencing moderate pain and instability with daily activities before retraining, to walking several hours per day without appreciable symptoms.

motion decreased by 7 degrees ($P < .01$), which was associated with an 8% decrease in the ankle dorsiflexion moment.

Four of the five patients successfully resolved or markedly reduced hyperextension at the knee and abnormal motion patterns at the hip and ankle. These individuals converted the knee flexion-extension moment to a normal biphasic pattern. One patient failed to complete the program and demonstrated continued gait abnormalities.

Effect of Retraining on Patient Symptoms

The patient symptoms before and after gait retraining were evaluated with the symptom rating scale of the Cincinnati Knee Rating System (see Chapter 41). A statistically significant improvement occurred in the pain scale (0 to 10 points) from a mean of 1.6 ± 0.9 points before training to 4.8 ± 2.3 points after training ($P < .05$) and in the partial giving-way scale from a mean of 2.4 ± 0.9 points before training to 5.2 ± 2.3 points after training ($P < .05$). Four of the five patients improved from experiencing moderate pain and instability with daily activities before retraining, to walking several hours per day without appreciable symptoms. Because of this improvement, two patients did not require ligament reconstructive surgery after retraining.

SUMMARY

In patients with chronic deficiency of the posterolateral structures, the use of gait analysis techniques and retraining can successfully change the kinetics and kinematics of the hip, knee, and ankle to more normal levels. The abnormal knee hyperextension can be significantly reduced, along with adduction and extension moments about the knee and medial tibiofemoral compartment loads. Hip abduction and adduction moments may be restored to normal levels.

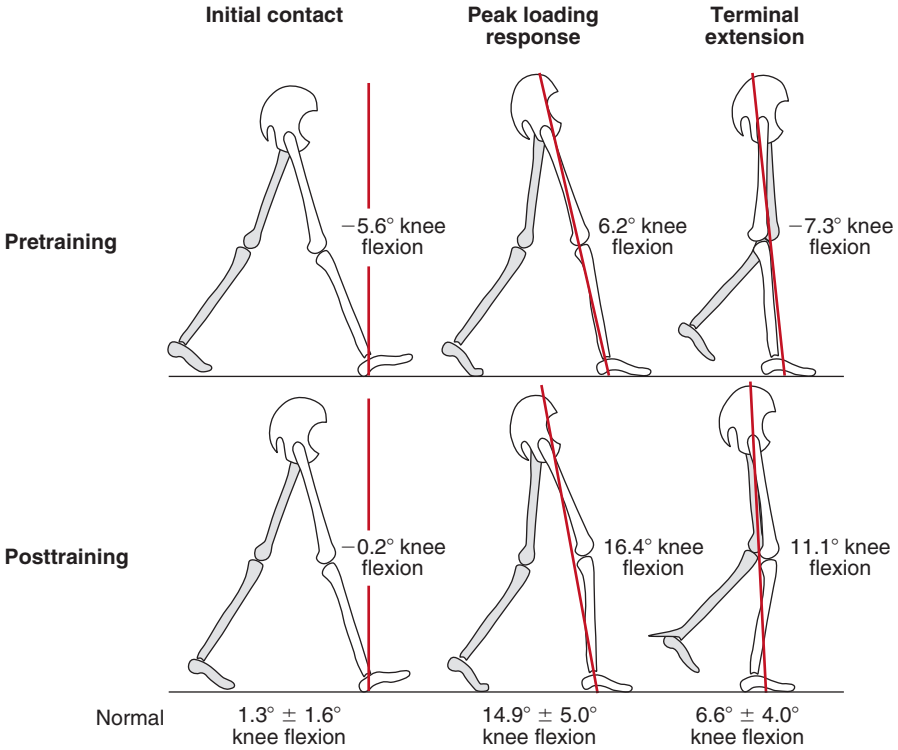

FIG 29-11 An analysis of the pretraining and posttraining knee flexion angles and how the amount of flexion relates to the ground reaction force. Hyperextension tends to place the ground reaction force anterior to the knee, requiring that the posterior structures rather than the quadriceps muscle balance the ground reaction force. (From Noyes FR, Dunworth LA, Andriacchi TP, et al. Knee hyperextension gait abnormalities in unstable knees. Recognition and preoperative gait retraining. *Am J Sports Med.* 1996;24:35-45.)

In addition, ankle plantar flexion and its counterbalancing dorsiflexion moment can be decreased. Gait retraining is indicated in knees with a hyperextension gait abnormality before any ligament reconstructive procedure and may, in some cases, eliminate the requirement for such soft tissue operations. If the gait abnormality is not corrected, cruciate and posterolateral ligament reconstructions may fail from the high tensile forces placed on the grafts postoperatively as the patient resumes an abnormal knee hyperextension gait pattern. These same principles apply to other individuals with knee hyperextension gait patterns[26] such as those that occur with quadriceps muscle weakness from a variety of knee injuries and symptomatic patellofemoral arthritis.

ILLUSTRATIVE CASES

Case 1 A 32-year-old physical therapist with chronic ACL deficiency of the left knee had given up strenuous athletics to avoid ACL reconstruction. She had no pain, swelling, or giving-way for several years. The patient participated in a light recreational volleyball game and experienced a partial giving-way episode. She presented with increasing medial joint line pain and a feeling of knee instability and believed she required ACL reconstruction. The patient had a bilateral standing physiologic varus recurvatum and walked with marked varus recurvatum thrust to the left lower extremity (Fig. 29-12). She was unaware that her gait pattern had changed, but the obvious hyperextension thrust became readily apparent to her after it was revealed under examination. The patient underwent the gait retraining program and adapted to a normal gait pattern. Within 3 weeks, her medial joint pain and instability symptoms resolved. She returned to her preinjury compensated status and had no further symptoms to warrant ACL reconstruction. Because she was a physical therapist and could understand the retraining program, she had a fast response.

Case 2 A 38-year-old woman presented 1 year after a motor vehicle accident with a diagnosis of a PCL rupture. She experienced frequent instability and shifting episodes and severe medial joint line pain. Physical examination revealed marked quadriceps atrophy, 12 mm of increased posterior tibial translation, 10 mm of increased lateral joint opening, 15 degrees of increased external tibial rotation, and a varus alignment. On standing alignment, the patient showed a varus position, but did not demonstrate a varus recurvatum. However, on walking with increased forces, a severe varus recurvatum occurred with every step (Fig. 29-13). The patient first underwent gait retraining to correct the varus thrust and rehabilitation for quadriceps muscle strengthening for 3 months. Then, an opening-wedge osteotomy was performed to correct the varus osseous malalignment, followed 6 months later with a PCL and posterolateral reconstruction.

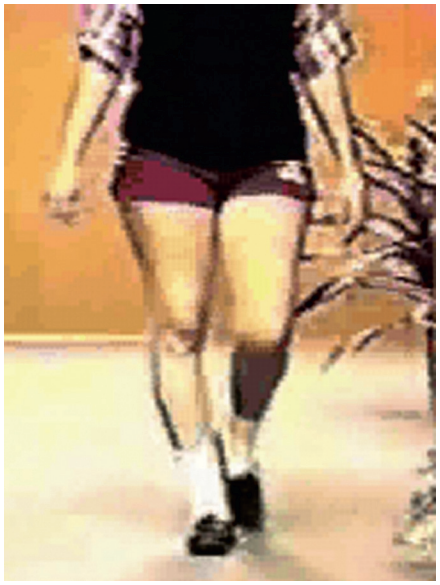

FIG 29-13 Patient who demonstrated a severe varus recurvatum with every step.

FIG 29-12 Patient with bilateral standing physiologic varus recurvatum who walked with marked varus recurvatum thrust to the left lower extremity.

FIG 29-14 Patient who presented 2 years after a motor vehicle accident with a severe gait abnormality and limp on the left lower extremity.

Case 3 A 24-year-old woman presented 2 years after a motor vehicle accident with a severe gait abnormality and limp on the left lower extremity (Fig. 29-14). She had pain throughout knee joint. Physical examination revealed complete deficiency of the PCL and posterolateral structures. The patient had seen three other orthopedic surgeons who were all reluctant to perform surgery owing to the severe gait abnormality and lower extremity muscle atrophy. She required 6 months of gait retraining. Although she was never fully able to control her knee stability, she did experience marked improvement and could consciously control the severe varus recurvatum.

INDICATIONS

Tibiofemoral unicompartmental knee arthroplasty (UKA) is a viable option for patients in whom severe joint damage and complete loss of joint space is present in one tibiofemoral compartment. Although early reports of this procedure were disappointing, improved product materials and design, robotic technology, and a better understanding of patient indications have improved the expected outcome. The advantages of UKA over total knee arthroplasty (TKA) include lower morbidity because of less blood loss, smaller incisions, and decreased soft tissue injury; preservation of bone stock and preservation of normal (or nearly normal) knee kinematics that result in a return to higher levels of function, fewer complications, shortened hospital stays, and an overall faster recovery.[24,26,55,82,91,111,165] A study of surgical trends of UKA and TKA from U.S. Medicare beneficiaries aged 65 years or older found a sixfold increase in the number of patients who underwent UKA from 2000 to 2009, compared with a 1.7-fold increase in the number of patients who had TKA during this same time period.[24] Bicompartmental knee replacements have been described[36,61]; however, this chapter focuses on tibiofemoral UKA. Patellofemoral knee arthroplasty is described in Chapter 37.

The primary indication for UKA is symptomatic isolated painful tibiofemoral arthritis. The procedure is performed in both men and women, with multiple studies demonstrating equivalent results between genders.[85,140] Medial tibiofemoral osteoarthritis (OA) secondary to anterior cruciate ligament (ACL) deficiency is an indication in patients willing to undergo concomitant or staged ACL reconstruction, if instability is problematic.[114,119,150,162] A few investigators reported no difference in outcomes and survivorship between patients who had an intact ACL and patients who had a deficient ACL without instability symptoms.[23,41] Therefore ACL reconstruction may not be required if giving-way does not occur with activity. Lateral UKA is indicated for primary OA, such as that which develops after a lateral meniscectomy, and posttraumatic OA secondary to a tibial plateau fracture.[87,134]

Patient candidates typically have moderate to severe joint line pain and/or stiffness that limits daily activities. Pain and swelling may occur while resting, either during the day or at night. A lengthy course of nonoperative treatment, including nonsteroidal antiinflammatory drugs (NSAIDs), steroid injections, physical therapy, and weight control, fail to alleviate the pain. In our opinion, the patient should be less than 60 years of age, although consideration may be made for those older than 60 years if no contraindications exist and the other knee compartments are not arthritic or symptomatic.

Most patient candidates for UKA will have undergone prior failed surgical procedures such as chondroplasty, meniscectomy, microfracture, autologous chondrocyte implantation (ACI), or osteochondral autograft transfer. In our experience, approximately 60% of the patients who underwent UKA have undergone these types of prior failed procedures. It is important that the patient have realistic expectations regarding what this operation may and may not accomplish. At our center, most patients are able to walk without support within approximately 2 to 3 postoperative weeks, and the majority return to daily activities within 4 to 6 weeks. Light, low-impact activities such as

The senior author (Frank R. Noyes) has no conflict of interest directly or indirectly with the implant or robotic system mentioned in this chapter.

walking, swimming, golfing, light hiking, and bicycling can often be performed by 3 months. However, running and high-impact athletic or occupational activities are not advised and, in fact, should be avoided; and it is essential that the patient understand and accept these limitations. Recent studies have reported that the majority of patients who were participating in sports before UKA were able to return after surgery and that most participated in low-impact activities such as swimming, bicycling, and general fitness training.[43,55,101,125,157]

CONTRAINDICATIONS

The principal contraindication to UKA is preexisting joint arthritis in another compartment of the knee (moderate to advanced articular cartilage deterioration and/or moderate to severe joint space narrowing on standing posteroanterior [PA] radiographs) owing to the evidence that this is one of the leading causes of failure of UKA.[4,33,38,73] Anterior knee pain, without patellofemoral joint narrowing or arthritic damage, is not an absolute contraindication.[10,11,77,99] However, patellofemoral symptoms with stairs, kneeling, and light activity will persist after UKA, and most patients with these problems select TKA. Mild patellofemoral joint deterioration (Outerbridge grade 1-2) also appears not to be deleterious to short-term outcomes of UKA.[14,144]

Other contraindications include uncorrected excessive varus or valgus malalignment (>3 degrees), knee ligament instability, knee hyperextension of 10 degrees or more, inflammatory arthritis, and prior infection. Patients with complex regional pain syndrome, diabetes, knee arthrofibrosis (excessive extension or flexion contracture), chondrocalcinosis, rheumatoid arthritis, or neuromuscular disorders affecting limb control are not considered candidates.

Patients who are obese (body mass index [BMI] >32) are not considered candidates for UKA,[13] although recent reports noted no significant differences in 5- and 10-year survival rates according to BMI subcategories.[28,74,100] Osteopenia (bone mineral density T score between −1.0 and −2.5 standard deviations below normal) or osteoporosis (T score less than −2.5) are contraindications for this operation owing to the potential risk of subsidence of the implants. Other contraindications include failure to treat the patient with all possible conservative measures, noncompliance with rehabilitation, and unrealistic expectations for future activity levels. Although our experience with this operation has usually involved patients younger than 60 years, age alone is not a contraindication to the procedure, assuming no previously mentioned contraindications exist.[73,93,118,162] A few reports have shown poorer results when medial UKA was done in patients with only partial loss of tibiofemoral joint space and articular cartilage.[109,115] Ultimately, the final decision to perform UKA or TKA is made at surgery after all of the joint surfaces have been visualized. The patient should be informed and consent obtained to perform either procedure.

IMPLANT DESIGN

UKAs may be generally categorized according to the bone-cut preparation (resurfacing or inset) and bearing surface (mobile or fixed, Tables 30-1 and 30-2). Resurfacing implants require minimal bone resection, and inset implants require angular cutting similar to TKA. Bearing surfaces are usually all polyethylene or modular and include fixed bearing and mobile bearing. The initial UKA implants, such as the Marmor (Smith & Nephew) and St Georg Sled (Waldemar Link), were fixed bearing with all-polyethylene tibial inserts. Problems with these prostheses included subsidence in both the femoral condyle and tibial plateau, aseptic loosening, and wear caused by suboptimal design.[90] Subsequently, implants were redesigned to distribute loads onto the cortical rim and had a minimum thickness of the tibial insert of more than 6 mm. Metal-backed components were introduced, requiring greater bone resection. The Miller-Galante (Zimmer) is a well-known metal-backed, fixed-bearing implant with a modular polyethylene insert.

Mobil-bearing implant designs were introduced in attempts to reduce the stress exerted on the tibial surface. These implants, such as the Oxford (Biomet), have a metal femoral component that articulates with a polyethylene meniscal component and a flat metal tibial surface. A porous-coated prosthesis was developed to induce bone growth and provide better fixation. For instance, the cementless Oxford Phase 3 has a layer of porous titanium with calcium hydroxyapatite under its components. Mobile-bearing implants are subject to dislocation of the mobile insert from the tibial base.

ROBOTIC TECHNOLOGY

It is well known and documented that early UKA failures were frequently caused by inaccurate positioning of the components, which

led to undercorrection or overcorrection of the final limb alignment. Excessive malalignment of the tibial component (>3 degrees) or posterior tibial slope (>7 degrees) may cause component loosening, fractures, and increased bone stresses.[35,52,63,83,135] Robotic-assisted surgical navigation was introduced in the early 2000s to improve accuracy in UKA (postoperative limb alignment, component positioning, and soft tissue balancing) using less invasive techniques. There are two types of robotic surgery systems: haptic (or tactile) and autonomous. Haptic systems require active participation of the surgeon to complete the entire operation, while autonomous robotic systems complete the operation after the surgeon has performed the approach and set up the machine. Haptic systems constrain the motion of the cutting tool to only the preplanned volume or area of resection. Preoperative 3-dimensional models of the patient's knee (created with computed tomography [CT] scans) are merged with referenced bony surfaces at surgery to form a final model of the actual anatomy of the patient. The component placement and exact cutting zones are determined. As the surgeon resects these areas, the robotic arm provides auditory and tactile feedback, limiting the tip of the rotating burr to just the predefined cutting area. The MAKOplasty Partial Knee Resurfacing System that uses the Robotic Arm Interactive Orthopedic System (RIO) (Stryker) and the Acrobot system (The Acrobot Company) are examples of commercially available haptic systems.

Many studies have compared short-term outcomes between various navigation and conventional UKA techniques (Table 30-3). A systematic review by Nair and associates[103] identified 15 studies published from 2003 to 2011 in which five different navigation systems were used. Overall, the navigation methods improved component alignment and position and reduced radiographic outliers compared with conventional systems. However, there were no differences in clinical outcomes, which is not surprising considering that 14 studies had follow-up of 2 years or less, and just one study had a midterm follow-up of 7 years. A meta-analysis was conducted by Weber and colleagues[159] of 10 studies (level II and III) involving 258 medial UKAs implanted with navigation and 295 medial UKAs implanted with conventional techniques. The study reported that there were more outliers in the conventional group compared with the navigation group for all variables assessed, including mechanics axis (30% and 11%, respectively), femoral anteroposterior (AP) alignment (17% and 5%, respectively), femoral lateral alignment (41% and 18%, respectively), tibial AP alignment (14% and 8%, respectively), and tibial slope (22% and 9%, respectively).

In the largest study to date, Mofidi and coworkers[97] calculated accuracy rates by comparing intraoperative planned and postoperative radiographic measurements in 232 knees that underwent medial UKA using the MAKOplasty system. Accuracy rates of the femoral prosthesis were 2.8 ± 2.5 degrees in the coronal plane and 3.6 ± 3.3 degrees in the sagittal plane. Accuracy rates of the tibial component were 2.2 ± 1.75 degrees in the coronal plane and 2.4 ± 2 degrees in the sagittal plane. The authors concluded there was a high degree of agreement between intraoperatively planned prosthesis alignment and postoperatively measured alignment. Proper cementation technique was considered crucial in achieving accurate alignment.

CLINICAL EXAMINATION

A thorough history, including documentation of prior surgical procedures, conservative treatment measures, and all knee joint injuries, is required. Symptoms are typically experienced most often during stair climbing, walking on uneven ground, and kneeling or squatting.

The comprehensive physical examination includes a complete patellofemoral examination, discussed in detail in Chapter 35, to assess patellar tilt, subluxation, mobility, Q angle, and lower limb rotational alignment (femoral internal torsion, tibial external torsion). The patella and all surrounding tissues are palpated to localize pain. The medial and lateral joint lines are also inspected for any tenderness, indicative of tibiofemoral joint involvement.

All knee ligament tests are conducted as described in Chapters 7 and 17.

The patient's gait, range of knee motion, lower extremity and hip muscle strength, and neurovascular status are evaluated.

Radiographs taken during the initial examination include standing AP at 0 degrees, lateral at 30 degrees of knee flexion, weight-bearing PA at 45 degrees of knee flexion, and patellofemoral axial views. Double-stance full-standing radiographs of both lower extremities, from the femoral heads to the ankle joints, are obtained in knees in which varus or valgus lower extremity alignment is detected on clinical examination. Magnetic resonance imaging (MRI) is required in certain cases to determine the cartilage status of the entire knee joint, along with all other soft-tissue structures.

SURGICAL TECHNIQUE

The UKA operative technique described in this chapter uses an implant that is positioned using 3-dimensional modeling and computer-assisted robotic surgical navigation.[35] Before surgery, customized CT scans are obtained with the patient lying supine with a motion rod attached to the operative leg. Although the senior author (F.R.N.) has used various UKA prostheses, the precision obtained from the RIO UKA system for preoperative planning and surgical implantation appears to offer distinct benefits. It has been incorporated in the senior author's practice since 2008 and provides the surgical experience discussed in this chapter.

A detailed description of the surgical technique for the RIO UKA is available at www.makosurgical.com/physicians/products/rio and is not repeated in this chapter. However, there are technical and operative details that should be stressed. It is important that the surgeon and technician are thoroughly familiar with the detailed procedures and

follow the exact steps, including preoperative planning of the alignment and size of the tibial and femoral implant. The surgeon must perform an adequate surgical exposure, remove bone osteophytes and retained meniscus tissues, place retractors that curve around the posterior tibia to protect the neurovascular structures, perform precise registration of anatomic landmarks for the RIO software, achieve soft tissue balancing of extension and flexion gaps with appropriate adjustment of tibial and femoral implants, and perform meticulous cement fixation of implants.

The usual preoperative planning steps are taken before surgery, including a 5-day scrub with chlorhexidine. A detailed history for prior deep venous thrombosis (DVT) episodes, including personal and family history or other DVT risk factors, is undertaken. In the absence of DVT risk factors, aspirin (325 mg twice a day) is used for 21 days postoperatively. Other chemical forms of anticoagulant therapy are not required unless specific risk factors, such as prior DVT or pulmonary embolism, are present. The patient should be mobilized and active the first day after surgery and thereafter.

The operative limb is signed by the surgeon before the patient receives any medication. A time-out is performed in the operating room with the signed limb signature visible and verbal agreement of patient name, birth date, preoperative antibiotics, allergies, and operative procedure planned by surgeons and operative staff. During the operative procedure, a sequential calf pressure device is used along with antiembolism stockings on the opposite limb.

The patient positioning shown in Figure 30-1 involves the De Mayo Knee Positioner (Innovative Medical Products) to control the knee flexion position. The opposite extremity has a posterior thigh pad that, along with reflex of the hip portion of the surgical bed, maintains 10 degrees of hip flexion and decreases tension on the femoral nerve.

After appropriate draping with the knee at 45 degrees of flexion, a limited medial (or lateral) parapatellar incision is made that extends into the vastus medialis obliquus or vastus lateralis obliquus 3 to 5 cm above the patella to allow sufficient lateral or medial patella glide for exposure. An examination of the knee joint confirms the expected pathology and ensures no unexpected joint arthritis is present in the other knee compartments. There are often reactive and scarred fat pad tissues that require removal along with retained meniscus tissues of the involved compartment. Osteophytes are not removed at this point because they are helpful in identifying tibial and femoral geometry in the registration process. The tibial and femoral arrays are placed a sufficient distance from the knee joint (Fig. 30-2, *A* and *B*) not to obstruct the surgeon's view. The senior author routinely uses a headlight to completely view the interior of the knee joint. The registration process is meticulous and follows the detailed MAKOplasty Partial Knee Application User Guide 206388 Rev 01 and Surgical Technique and Planning Guide #201844 (Stryker).

After removal of osteophytes, the joint balancing step to capture data is completed, providing the tibiofemoral compartment spacing or opening at multiple knee flexion angles under a mild varus or valgus loading (Figs. 30-3 and 30-4). This allows for proper medial or lateral ligament soft tissue tension, with attention directed to prevent overstuffing of the tibiofemoral compartment, particularly at higher angles of joint flexion. The preoperative virtual positioning of the tibiofemoral components in all three planes includes fine tuning of the tibial slope, performed at this point to provide a normal soft tissue balance of extension and numerous knee flexion gaps. The planned operative bone resection is mapped and validated before commencing with the operative procedure. This includes fine tuning of the medial-lateral and internal-external position of the implant using the software to compute and verify that the femoral component tracks in a central position over the tibial component throughout the entire

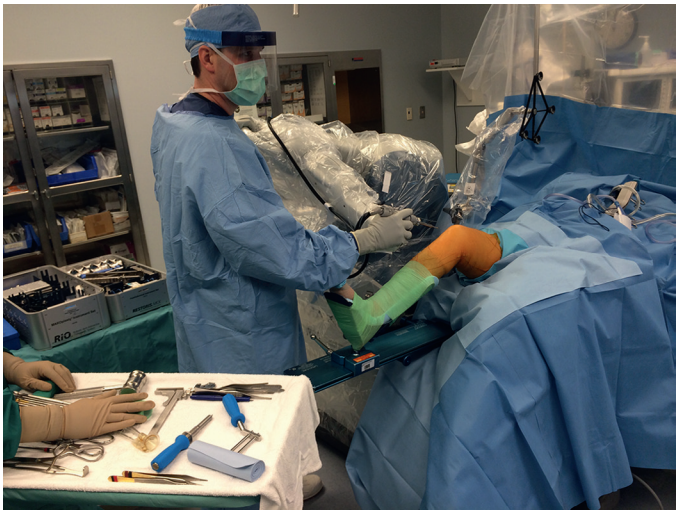

FIG 30-1 The operative positioning of the lower limb, along with the Robotic Arm Interactive Orthopedic System.

FIG 30-2 Operative view (**A**) and illustration (B) of the femoral and tibial arrays and checkpoints. (**B,** Courtesy Stryker Orthopaedics.)

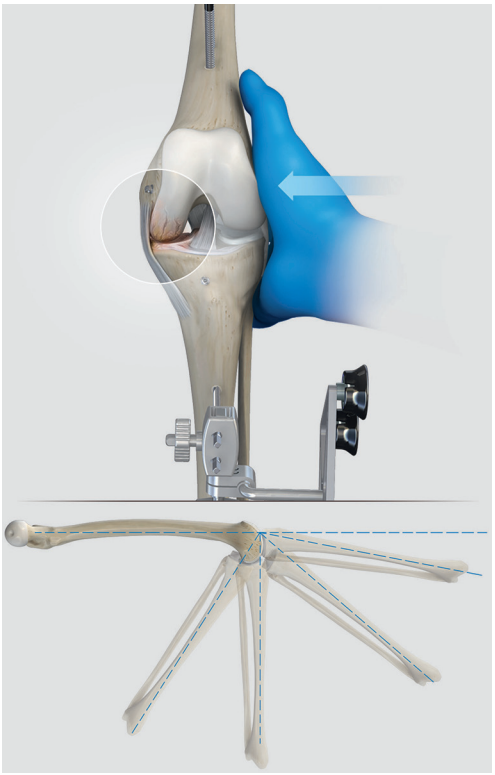

FIG 30-3 Remove overhanging medial osteophytes and then capture a minimum of four poses while applying a valgus stress to passively correct the coronal deformity. The magnitude of the valgus stress must be such that it opens up the collapsed medial compartment and tensions the medial collateral ligament to achieve the desired degree of correction and joint stability. Caution must be exercised to not overcorrect the deformity. In the case of a lateral unicompartmental knee arthroplasty, capture poses while applying a varus stress. The poses captured are in extension, mid flexion, flexion, and full flexion (or approximately 10, 45, 90, and 120 degrees). (Courtesy Stryker Orthopaedics.)

flexion-extension range of knee motion (Fig. 30-5). This step also confirms there is proper sizing of the tibial and femoral implants. The RIO is positioned in the operative field and registered (Fig. 30-6).

The operative plan starts first with the tibial bone resection, followed by femoral bone resection (Fig. 30-7). The trial components are placed with the selected tibial polyethylene trial and determination is made that there is correct anatomic prosthesis alignment during full knee flexion and extension. The surgeon ensures that the anterior femoral tip is flush with the cartilage surface and not proud. Verification of restoration of normal medial or lateral ligament stability and joint opening is performed. The cementing technique follows meticulous steps of irrigation, drying of surfaces, tibial prosthesis placement, and removal of excess cement under direct visualization. Femoral prosthesis cementing and placement of the polyethylene tibial component are done with the joint held under varus or valgus pressure at 30 degree knee flexion. After verification of the soft tissue balance at extension, mid-flexion and high-flexion knee positions, the final polyethylene implant is placed. The extensor mechanism is closed, and the medial or lateral soft tissue structures balanced as described in Chapter 37. The operative steps in closure are designed to prevent excessive medial or lateral soft tissue tension, with the goal of restoring a normal medial or lateral patella glide at 0 and 20 degree knee flexion. A femoral nerve block is commonly performed postoperatively, and the patient either stays overnight for 1 night or remains as an outpatient. The patient is seen by the surgeon and rehabilitation staff the next day to initiate the postoperative rehabilitation protocol.

POSTOPERATIVE MANAGEMENT

The postoperative rehabilitation protocol is shown in Table 30-4. Patients begin immediate knee range of motion (ROM), patellar mobilization, quadriceps strengthening, and balance training with partial weight bearing allowed. A continuous passive motion machine is not required or routinely used by us. Patients perform passive and active ROM exercises in a seated position for 10 minutes a session, approximately 6 times per day. Full passive knee extension must be obtained

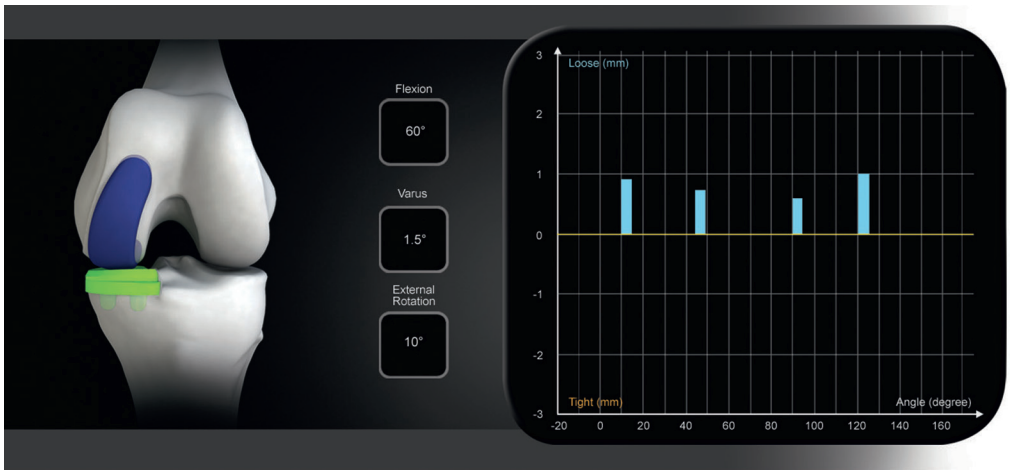

FIG 30-4 Fine tune the femoral and tibial implant placement to ensure joint gaps are 0 to 1.5 mm of looseness through range of motion and good central loading exists between the femoral and tibial components. (Courtesy Stryker Orthopaedics.)

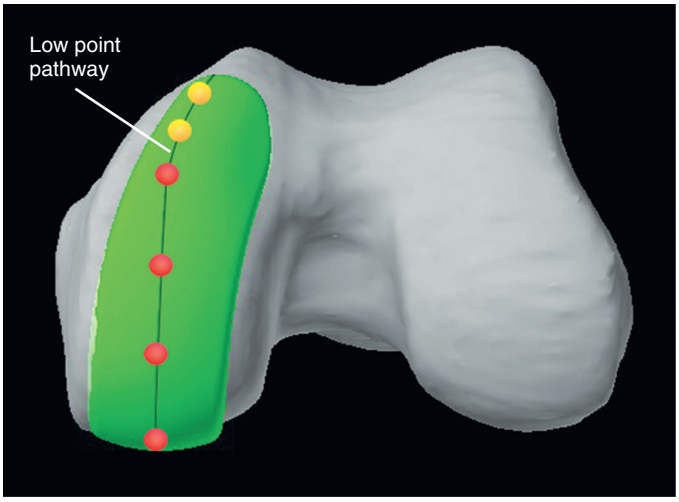

FIG 30-5 Once the joint is balanced, fine tune and medial-lateral position and internal-external rotation of the femoral component to ensure that the femoral component tracks centrally over the tibial component through the patient's range of motion. (Courtesy of Stryker Orthopaedics)

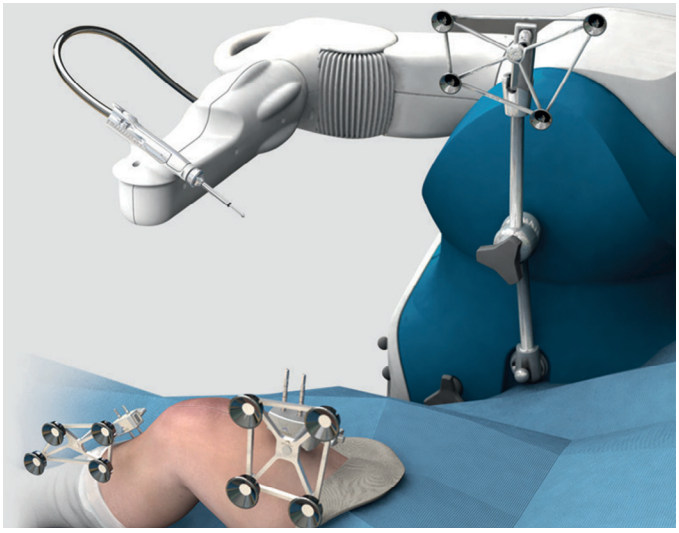

FIG 30-6 Position the RIO in the operative field and perform registration and verification of the robotic arm. (Courtesy Stryker Orthopaedics.)

FIG 30-7 Resect the femoral and tibial surfaces, then create peg holes and keels. (Courtesy Stryker Orthopaedics.)

immediately to avoid excessive scarring. Patellar mobilization is important to restore a normal medial-lateral glide and prevent contracture of soft tissue patellar retinacular structures. If the patient has difficulty regaining at least 0 degrees by the seventh postoperative day, he or she begins an overpressure program. The foot and ankle are propped on a towel or other device to elevate the hamstrings and gastrocnemius, allowing the knee to drop into full extension. This position is maintained for 10 minutes and repeated four to six times per day. A 10- to 20-lb weight may be added to the distal thigh and knee to provide overpressure to stretch the posterior capsule. Knee flexion is gradually increased to 110 degrees by the second postoperative week and 135 degrees by the third to fourth postoperative week. Passive knee flexion exercises are performed initially in the traditional seated position using the opposite lower extremity to provide overpressure. Other methods to assist in achieving flexion greater than 90 degrees include chair rolling, wall slides, knee flexion devices, and passive quadriceps stretching exercises (see Chapter 11).

Patients use a walker or crutches with 50% to 75% weight bearing allowed as tolerated. Full weight bearing is permitted when the patient demonstrates a normal gait pattern, which is usually by the third to fourth postoperative week. Balance, proprioception, and strengthening exercises are gradually increased as supervised by the therapist and shown in Table 30-4 through approximately the twelfth postoperative week. At that time, the patient is encouraged to continue the strengthening and aerobic conditioning program as desired.

COMPLICATIONS AND FACTORS LEADING TO FAILURE

Currently, the progression of tibiofemoral or patellofemoral arthritis and implant loosening are the most common causes of failure or unsatisfactory results (Table 30-5). A study of 418 failed UKAs (requiring any repeat surgery) from the French Hip and Knee Society reported that loosening was the main reason for failure (occurring in 45%) followed by progression of OA (15%) and wear (12%).[42] These findings were similar to those reported in the Swedish, Finnish,[108] and Australian registries. The operations were performed between 1978 and 2009 and included medial UKA in 88%. The majority of bearing designs were fixed (80%) and cement was used for 85% of the femoral components and 70% of the tibial components.

In a study of 1746 UKAs performed in the Kaiser Permanente National Total Joint Registry from 2002 to 2009, Bini and associates[21] reported that implant type, patient age, and yearly surgeon volume were significantly associated with revision rates. Patients younger than 55 years of age had a significantly higher revision rate of 11.7% (39 of 332) compared with those 55 to 65 years of age (4.4%; 28 of 642) and those older than 65 years (2.6%; 20 of 772; $P < .001$). The Preservation All-Poly tibial UKA had a greater risk of revision compared with the Zimmer UKA (9.5% and 1.1%, respectively; $P < .001$). The revision rates for surgeons who performed 12 or fewer UKA per year were significantly higher than those who performed more than 12 per year (6.4% and 3.2%, respectively; $P < .01$).

The incidence of thromboembolic events after UKA with use of a chemoprophylaxis and compression boot protocol is exceedingly low. Berend and associates[15] followed 1000 consecutive UKAs in 828 patients (97% medial, 3% lateral) to determine the incidence of thromboembolic complications. Patients considered to have no risk factors were prescribed aspirin (325 mg, 1-2 times/day) for 6 weeks. Moderate-risk patients received low-molecular-weight-heparin (LMWH) for 2 weeks and aspirin for 4 more weeks. High-risk patients had warfarin

PHASE 1: WEEKS 1 TO 2

General Observation

50%-75% weight bearing with crutches/walker when:
- Pain is controlled
- Hemarthrosis is controlled
- Voluntary quadriceps contraction is achieved

Goals

ROM 0-110 degrees
Adequate quadriceps contraction
Control inflammation, effusion

Factors Evaluated

Pain (controlled)
Hemarthrosis (mild)
Patellar mobility (good)
ROM (minimum 0-110 degrees)
Quadriceps contraction and patella migration (good)
Soft tissue contracture (none)

Continued

TABLE 30-4 Noyes Knee Institute Rehabilitation for Unicompartmental Arthroplasty—cont'd

PHASE 1: WEEKS 1 TO 2

	Frequency	Duration
Range of Motion		
0-110 degrees, hang 10-20 lb of weight if <0 degrees	6 ×/day, 10 min	
Patella mobilization	3 ×/day	
Ankle pumps (plantar flexion with resistance band)	15 min	
Hamstring, gastrocnemius-soleus stretches		5 reps × 30 sec
Strengthening	3 ×/day, 15 min	
Straight-leg raises (flexion, extension, abduction, adduction)		3 sets × 10 reps
Active quadriceps isometrics		10 reps
Knee extension quadriceps, active/active-assisted (range as tolerated)		3 sets × 10 reps
Multi-hip machine (flexion, extension, abduction, adduction)		3 sets × 10 reps
Balance Training	3 ×/day, 5 min	
Weight shift side-side and forward-backward		5 sets × 10 reps
Balance board/two-legged		5 sets × 10 reps
Cup walking		5 sets × 10 reps
Single-leg stance		5 sets × 10 reps
Aerobic Conditioning	2 ×/day, 10 min	
UBC		
Modalities	As required	
EMS		20 min
Cryotherapy		20 min

PHASE 2: WEEKS 3 TO 4

General Observation	Full weight bearing (weeks 2-3) when gait pattern is normal and: • Pain is controlled • Hemarthrosis is controlled • Voluntary quadriceps contraction, full extension, is achieved	
Goals	ROM 0-135 degrees Control inflammation, effusion Muscle control	
Factors Evaluated	Pain (controlled) Effusion (mild) Patellar mobility (good) ROM (minimum 0-135 degrees) Quadriceps contraction and patella migration (good) Soft tissue contracture (none)	
	Frequency	**Duration**
Range of Motion		
Passive (0-135 degrees), hang 10-20 lb weight if <0 degrees; flexion overpressure: stool rolls, wall-slides if <90 degrees	3 ×/day, 15 min	
Patella mobilization	3 ×/day, 15 min	
Ankle pumps (plantar flexion with resistance band)	3 ×/day, 15 min	
Hamstring, gastrocnemius-soleus stretches		5 reps × 30 sec

TABLE 30-4 Noyes Knee Institute Rehabilitation for Unicompartmental Arthroplasty—cont'd

	Frequency	Duration
PHASE 2: WEEKS 3 TO 4		
Strengthening	2-3 ×/day, 20 min	
Straight-leg raises (flexion, extension, abduction, adduction)		3 sets × 10 reps
Isometric training: multiangle (0 and 60 degrees)		1 set × 10 reps
Knee extension quadriceps (resistance, 90-30 degrees)		3 sets × 10 reps
Closed-chain: wall-sits (0-45 degrees)		30-60 sec × 5
Knee flexion hamstring curls (0-90 degrees)		3 sets × 10 reps
Multihip machine (flexion, extension, abduction, adduction)		3 sets × 10 reps
Leg press (70-10 degrees)		3 sets × 10 reps
Balance Training	3 ×/day, 5 min	
Weight shift side-side and forward-backward		5 sets × 10 reps
Balance board/two-legged		
Cup walking		
Single-leg stance		5 reps
Aerobic Conditioning	2 ×/day, 10 min	
UBC		
Stationary bicycling (high seat, low resistance)		
Modalities	As required	
EMS		20 min
Cryotherapy		20 min
PHASE 3: WEEKS 5 TO 6		
General Observation	Full weight bearing when: • Pain is controlled without narcotics • Hemarthrosis is controlled • ROM 0-135 degrees • Muscle control throughout ROM	
Goals	ROM 0-135 degrees Control inflammation, effusion Muscle control Early recognition of complications (motion, RSD, patellofemoral) Full weight bearing	
Factors Evaluated	Pain (mild/no CRPS) Effusion (minimal) Patellar mobility (good) ROM (minimum 0-135 degrees) Muscle control (3+/5) Inflammatory response (none)	
	Frequency	**Duration**
Range of Motion		
Passive (0-135 degrees), continue overpressure program if <0-100 degrees	3 ×/day, 10 min	6 ×/day
Patella mobilization	3 ×/day, 10 min	
Hamstring, gastrocnemius-soleus stretches		5 reps × 30 sec
Strengthening	2 ×/day, 20 min	
Straight-leg raises (ankle weight 2.5-10 lb)		3 sets × 10 reps
Heel raise/toe raise		3 sets × 20 reps
Knee extension (resistance, 90-30 degrees)		3 sets × 10 reps
Knee flexion (active, 0-90 degrees)		3 sets × 10 reps
Leg press (70-10 degrees)		3 sets × 10 reps

Continued

TABLE 30-4 Noyes Knee Institute Rehabilitation for Unicompartmental Arthroplasty—cont'd

PHASE 3: WEEKS 5 TO 6

	Frequency	Duration
Multihip machine (flexion, extension, abduction, adduction)		3 sets × 10 reps
Closed-chain: wall-sits (0-45 degrees)		5 reps
Balance Training	2 ×/day, 5 min	
Balance board, two legged		
Cup walking		
Single-leg stance		5 reps
Aerobic Conditioning	1-2 ×/day, 10 min	
UBC		
Stationary bicycling (high seat, low resistance)		
Water walking (water depth at thigh or waist)		
Modalities	As required	
EMS		20 min
Cryotherapy		20 min

PHASE 4: WEEKS 7 TO 8

General Observation	Independent ambulation ROM 0-135 degrees Can stand and walk for 30 min	
Goals	Full weight bearing Muscle control Control of inflammation, effusion ROM 0-135 degrees	
Factors Evaluated	Pain (mild/no CRPS) Effusion (minimal) Patellar mobility (good) ROM (0-135 degrees) Muscle control (4/5) Inflammatory response (none)	
	Frequency	**Duration**
Range of Motion	2 ×/day, 20 min	
Hamstring, gastrocnemius-soleus stretches		5 reps × 30 sec
Strengthening	2 ×/day, 20 min	
Straight-leg raises (flexion, extension, abduction, adduction) with weights or rubber tubing		3 sets × 10 reps
Closed-chain:		
Wall-sits		5 reps
Minisquats (rubber tubing, 0-30 degrees)		3 sets × 20 reps
Forward step-ups (2- to 4-inch block)		3 sets × 10 reps
Hamstring curls (resistance, 0-90 degrees)		3 sets × 10 reps
Knee extension (resistance, 90-30 degrees)		3 sets × 10 reps
Leg press (70-10 degrees)		3 sets × 10 reps
Multihip machine (flexion, extension, abduction, adduction)		3 sets × 10 reps
Balance Training	2 ×/day, 5 min	
Balance board, single legged (stable vs. unstable surface)		
Single-leg stance		5 reps

TABLE 30-4 Noyes Knee Institute Rehabilitation for Unicompartmental Arthroplasty—cont'd

PHASE 4: WEEKS 7 TO 8

	Frequency	Duration
Aerobic Conditioning	1-2 ×/day, 10-15 min	
UBC		
Water walking		
Swimming (straight-leg kicking)		
Stationary bicycling		
Stair machine (low resistance, low stroke)		
Ski machine (short stride and level, low resistance)		
Modalities	As required	
Cryotherapy		20 min

PHASE 5: WEEKS 9 TO 12

General Observation	Independent ambulation ROM 0-135 degrees	
Goals	Increase strength and endurance Increase balance and coordination ROM 0-135 degrees	
Factors Evaluated	Pain (minimal/no CRPS) Swelling (minimal) Manual muscle test (hamstrings, quadriceps, hip abductors/adductors/flexors/extensors; 4+/5) Patellar mobility (good) Gait (symmetrical)	
	Frequency	**Duration**
Range of Motion	2-3 ×/day, 10 min	
Hamstring, gastrocnemius-soleus, quadriceps, ITB stretches		5 reps × 30 sec
Strengthening	1-2 ×/day, 20 min	
Straight-leg raises		3 sets × 10 reps
Straight-leg raises with weights or rubber tubing		3 sets × 30 reps
Hamstring curls (resistance, 0-90 degrees)		3 sets × 10 reps
Knee extension (resistance, 90-30 degrees)		3 sets × 10 reps
Leg press (70-10 degrees)		3 sets × 10 reps
Closed-chain:		
Wall-sits		To fatigue ×3
Minisquats (with rubber tubing, 0-40 degrees)		3 sets × 20 reps
Lateral step-ups (2- to 4-inch block)		3 sets × 10 reps
Multihip machine (flexion, extension, abduction, adduction)		3 sets × 10 reps
Balance Training	2 ×/day, 5 min	
Balance board, single legged (stable vs. unstable surface)		
Single-leg stance		5 reps
Aerobic Conditioning	1-2 ×/day, 15 min	
Water walking		
Swimming (straight-leg kicking)		
Stationary bicycling		
Walking		
Stair machine (low resistance, low stroke)		
Ski machine (short stride and level, low resistance)		
Modalities	As required	
Cryotherapy		20 min

*After postoperative week 12, patient continues strengthening and conditioning program as desired.
BAPS, Biomechanical Ankle Platform System (Patterson Medical); *BBS*, Biodex Balance System (Biodex Medical Systems); *CRPS*, complex regional pain syndrome; *EMS*, electrical muscle stimulation; *ITB*, iliotibial band; *UBC*, upper body cycle; *ROM*, range of motion.

TABLE 30-5 Effect of Various Factors on Failure of Unicompartmental Knee Arthroplasty

Factor	Studies Associated With Failure (References)	Studies Not Associated With Failure (References)
Progressive arthritis (any compartment)	4, 18, 42, 51, 73, 118, 127, 145, 164	
Component loosening	3, 19, 27, 42, 51, 73, 95, 127, 137, 164, 169	
Bearing dislocation	31, 68, 80, 169	
Polyethylene wear	121	
Tibiofemoral angle 4-6 degrees valgus	66	
Prior HTO	154	
Partial loss medial joint space on x-ray	109	
Patellofemoral joint osteoarthritis (x-ray or arthroscopy)	11, 74	10, 11 (except lateral patellar damage), 118, 144
Body mass index	13, 51, 71	28, 38, 74, 100, 123
Age	74 (<60 yr), 7 (<55 yr)	38, 51, 71, 73, 93, 118, 123, 148, 154
Gender		38, 51, 53, 73, 74, 93
Type tibial implant (full poly, cemented, uncemented metal back)		53, 123
ACL deficiency		23
Concomitant ACL reconstruction		72, 114, 150, 162

ACL, Anterior cruciate ligament; *HTO*, high tibial osteotomy.

supplemented by LMWH. All patients received intermittent pneumatic compression devices and antithrombotic stockings throughout their hospital stays and began full weight bearing and ROM exercises the day of surgery. Only one DVT (0.1%) was reported, and no pulmonary embolism or deaths occurred.

Prosthesis-related bone loss (postoperative decrease in bone mineral density [BMD]) reported after TKA[76,143] has been believed to be related to strain shielding. Strain shielding may promote reduction of bone density and bone resorption, whereas overload promotes excessive formation of bone that causes an increase in bone density and may induce fatigue damage.[46] Loss of bone may lead to periprosthetic fracture or weakening of the implant fixation, resulting in loosening and implant failure.[94,143] To date, only one clinical study assessed BMD after UKA. Richmond and associates[131] followed 50 medial UKAs (Oxford or Genesis) with CT osteodensitometry 1 and 2 years postoperatively. These authors reported mean cancellous BMD decreased only 1.9% on the medial side and 1.1% on the lateral side. Mean cortical BMD decreased 0.4% on the medial side and 0.5% on the lateral side. There were no differences among the implant designs in early BMD changes.

CLINICAL STUDIES

Medial Unicompartmental Knee Arthroplasty

The survivorship rates reported after medial UKA are shown in Table 30-6, and the clinical outcomes are shown in Table 30-7. The rating systems most commonly used to determine clinical outcome to date have been the American Knee Society (AKS) and Oxford Knee Score (OKS), described in detail in Chapter 45. The AKS Function and Knee scores reported in these studies represent the original version of this system because the extensive update was published in 2012.

The Oxford UKA has been the most widely studied of all medial UKA prostheses. Labek and coworkers[75] conducted a systematic review of the literature describing outcomes of the Oxford UKA of articles published from 1988 to 2008. The investigators found that the average results published by the inventor team were significantly better with regard to revision rates than those published by independent studies or worldwide registries. The revision rate from the developing team was 2.7 times lower than the rates published in independent studies and 4.4 times lower than registry data from Sweden and Denmark. These authors cautioned that "the average surgeon should be aware of the fact that the outcome published by the inventing center appears to be hardly reproducible in average patient care and other institutions."[75] The data shown in Table 30-7 represent studies on the Oxford UKA published from 2011 to 2014; only 3 of the 17 studies were from the inventor team. Ten-year survival rates from independent studies ranged from 75% to 95%, although rates from the inventor team ranged from 93% to 95%.

The question of whether individuals with bilateral severe medial OA should undergo simultaneous or staged UKA has been addressed in three studies.[16,29,30] Chen and coworkers[30] followed a group of 171 patients for 2 postoperative years. The patients were invited to choose between the two options, and the majority (72.5%) elected a simultaneous procedure. There were no differences in complications or short-term outcomes with regard to AKS or Oxford scores. The cumulative operating time and length of hospital stay were shorter for simultaneous procedures, and the overall cost for this option was lower. There were no serious complications in either group; all patients received enoxaparin 40 mg once daily and pneumatic calf pumps for prophylaxis of venous thromboembolic events. Chan and associates[29] reported significant differences in major complications between 318 simultaneous and 160 staged medial UKA knees. There were 13 such complications in the simultaneous group and none in the staged group; however, no chemoprophylaxis was used for thromboembolic events that accounted for 10 of the 13 complications. Berend and colleagues[16] reported no major complications in 70 knees that underwent simultaneous UKA and 282 knees that had staged bilateral UKAs. These investigators used chemoprophylaxis (discretion of the medical management providers) and mechanical compression boots to prevent thromboembolic events. The simultaneous group had a shorter cumulative operating room time and hospital stay and a higher AKS function score a mean of 19.4 months postoperatively. There was a selection bias in that patients who received simultaneous procedures were younger and less obese.

Unicompartmental Knee Arthroplasty versus High Tibial Osteotomy

The outcomes of modern UKA and HTO have been compared in several investigations, with most finding little to no differences in postoperative knee function between these operations (Table 30-8).[47]

In 2014, Nwachukwu and associates[112] compared UKA and HTO practice patterns in a large U.S. private payer insurance database that

HTO, High tibial osteotomy; *NA*, not available; *UKA*, unicompartmental knee arthroplasty.

represented 10% of the U.S. population. Between 2007 and 2011, a total of 15,354 UKA and 1047 HTO procedures were performed. The ratio of UKA:HTO was 12:09 in 2007 and increased every year to 17:02 in 2011. Using the age of 30 years as a reference, the likelihood of receiving UKA over HTO became significant when patients reached 50 years of age.

In a unique study, Valenzuela and colleagues[151] compared the outcomes of 22 patients who underwent UKR (Miller-Galante) after a failed closing-wedge HTO with 18 patients who underwent primary UKR (Miller-Galante). The mean ages for the groups were similar (65 and 67 years, respectively), and the follow-up time periods were also similar (6.5 and 7.3 years, respectively). There were no significant differences in AKS Knee and Function scores or in Oxford knee scores between the groups. The authors suggested that a prior HTO did not influence the clinical outcome of a subsequent UKR.

Unicompartmental Knee Arthroplasty versus Total Knee Arthroplasty

Many studies have compared outcomes of UKA with TKA (Table 30-9) even though a direct comparison between these procedures is most likely not realistic because of different implant designs, indications for surgery, duration of follow-up, patient age and postoperative activity levels, and surgeon experience and volume.[55,82,88,108,111,166] In addition, few have matched UKA and TKA cohorts before surgery for age, gender, BMI, and knee function as determined from validated rating scales. Many were retrospective in design.[82,88,147,166]

Many studies have been conducted with national knee joint registry data from outside the United States. For example, Niinimaki and associates[108] reported survivorship data from the Finnish registry on 4713 UKAs and 83,511 TKAs followed a mean of 6 years postoperatively. The majority of UKA prostheses were Oxford Phase III, but 37 different prostheses were used in the TKA patients. The study found that UKA had inferior survivorship rates, even when adjusted for age greater or less than 65 years and gender. Aseptic loosening was the most common cause of failure of both procedures, but it occurred more frequently in UKA. Similar survivorship results have been reported from knee arthroplasty registry data from Australia,[6] the United Kingdom,[110] New Zealand,[113] and Sweden.[156] However, Goodfellow and associates[49] criticized the use of revision rates as outcome measures for national knee joint registry data. In analyzing data from the New Zealand registry, these authors found that the sensitivity of revision rates to clinical failure was different between UKA and TKA. The UKA group had higher Oxford knee scores but nearly three times the revision rate as TKA. In knees with very poor scores (<20 points), only 12% of TKAs were revised compared with 63% of UKRs with similar scores. The conclusion was reached that UKA may be revised more frequently because it is a less invasive intervention and may be converted to TKA without difficulty, whereas revision TKA is a more complicated procedure. This is especially valid in patients with nonspecific knee pain without obvious failure of the implant.

Noticewala and colleagues[111] reported superior knee function outcomes (as determined by Western Ontario and McMaster Universities Osteoarthritis Index [WOMAC] and Short Form [SF]-12 scores) after UKA compared with TKA a mean of 3 years after surgery. Multivariate linear regression analysis that controlled for age, gender, Charlson

AKS, American Knee Society; *SF-12*, Short Form 12; *TKA*, total knee arthroplasty; *UKA*, unicompartmental knee arthroplasty; *WOMAC*, Western Ontario and McMaster Universities Arthritis Index.

Comorbidity Index, diagnosis, and preoperative WOMAC and SF-12 scores found that UKA was significantly associated with higher SF-12 and WOMAC scores than TKA. In addition, the improvements in these scores compared with the preoperative condition were significantly greater in UKA patients.

Wiik and colleagues[165] studied walking speed 1 year after UKA or TKA in 23 and 23 patients, all of whom had high Oxford knee scores (mean, 44 ± 3 and 40 ± 8, respectively) and who were matched for age, gender, height, and BMI. The UKA group was able to walk significantly faster, achieving a mean of 7.0 km/h compared with the TKA group mean of 6.2 km/hr ($P < .05$). The authors attributed the findings to significantly reduced step length, increased stance time, and lower cadence in the TKA group.

Lateral Unicompartmental Knee Arthroplasty

The survivorship rates reported after modern lateral UKA are shown in Table 30-10, and the clinical outcomes are shown in Table 30-11. The largest series reported at the time of writing, from Baker and colleagues,[7] compared survivorship rates between 2052 lateral UKA and 30,795 medial UKA from the National Joint Registry of England and Wales. The 7-year rates were comparable (93% for lateral and 91% for medial) and only age (younger than 55 years) significantly affected the results. Several studies[5,53,79,86,87,124,163] reported 10-year survival rates from 83% to 100%, and three investigations[5,53,87] produced 15-year rates that ranged from 80% to 92%.

In a unique analysis of athletic activity levels before and after surgery, Walker and colleagues[157] reported that 98% of 45 patients were able to return to sports activities a mean of 3 years after undergoing an Oxford Domed (Biomet) UKA. The majority were participating in low-impact activities. There were no significant differences in SF-36 scores between the patients and a matched healthy control population. The remainder of clinical studies used scales that rated activities of daily living and in all but one the cohorts' average age at surgery was 60 years or greater.

Clinical outcomes have been mixed regarding lateral UKA performed for posttraumatic OA secondary to tibial plateau fracture.[87,134] Lustig and associates[87] reported survivorship rates of 100% at 10 years and 80% at 15 years in a small series of 13 patients followed a mean of 10.2 years postoperatively. The mean AKS knee score improved from 51 points before surgery to 88 points at follow-up, with similar improvements noted in the mean AKS function score. However, Sah and Scott[134] found inferior outcomes in AKS scores in 10 patients treated for posttraumatic OA compared with 38 patients who underwent lateral UKA for primary OA. Although none of the knees had been revised a mean of 5.2 years postoperatively (range, 2-15 years), 5 of the 10 patients in the posttraumatic OA group reported only fair satisfaction with their outcome. All 38 patients in the primary OA group reported excellent satisfaction.

As of the time of writing, no study had compared outcomes between lateral UKA and femoral osteotomy or TKA.

ILLUSTRATIVE CASES

Case 1. A 52-year-old man presented with chronic left knee pain in the medial tibiofemoral compartment that occurred with all daily activities and prevented any light recreational sports. He previously underwent a medial meniscectomy and then failed a course of conservative treatment of physical therapy and nonsteroidal antiinflammatory drugs. The physical examination showed an absence of clinical findings related to the patellofemoral and lateral tibiofemoral compartments. Standing 45-degree posteroanterior radiographs showed loss of the medial tibiofemoral compartment space (Fig. 30-8, *A*). The patient underwent a MAKO medial unicompartmental knee arthroplasty, with correction of the varus angulation to neutral. The preoperative planning of the procedure is shown in Figure 30-8, *B* to *D*. An important part of the procedure was the determination of the amount of medial joint opening that allowed the appropriate adjustment of the tibiofemoral gap, avoiding undue compartment loads and balancing the medial soft tissue restraints (Fig. 30-8, *E*). The postoperative radiographs are shown in Figs. 30-8, *F* and *G*.

Case 2. A 46-year-old woman presented with right lateral knee pain and lateral tibiofemoral arthritis. She had a 20-minute walking tolerance. She previously underwent a lateral meniscus transplant that was successful in alleviating her knee pain for 6 years. The patient elected to undergo lateral UKA after the transplant failed and a 45-degree radiograph showed loss of the lateral tibiofemoral compartment space (Fig. 30-9, *A*). A lateral UKA using the MAKOplasty technique was performed. The preoperative planning and placement of the prosthesis are shown in Figure 30-9, *B* to *D*. The postoperative radiographs are shown in Figure 30-9, *E* to *F*.

Clinical Outcomes, 919

INDICATIONS

Management of symptomatic focal chondral and osteochondral defects in the knee is complex and multifactorial. The most salient principle in evaluation of the clinical presentation of patients with focal chondral defects of the knee should focus on "treating the patient" and not the defect. This means avoiding linear reasoning in the presence of a known defect that lacks an inexorable nexus with a patient's clinical presentation. The existence of a lesion on magnetic resonance imaging (MRI) or arthroscopic image should not automatically indicate surgery. It is well known that chondral defects are highly prevalent in both symptomatic and asymptomatic patients (Table 31-1). The incompletely understood natural history of articular cartilage lesions and the predictability of their surgical outcome mandate ensuring that the defect is clinically relevant and a competent source of the patient's symptoms.

Ascribing symptoms to a lesion warrants determination of the exact location of the defect that is tender on exam, if this location of pain is exacerbated by weight bearing, if biologic activity is present via detection of an effusion, and if there is a reduction of pain with intraarticular injection. Articular cartilage is an aneural tissue. Thus, the presence of a defect does not necessarily produce pain. However, patients with full-thickness lesions may demonstrate clinically important limitations in pain, function, sports and recreation, and quality of life as measured by Knee injury and Osteoarthritis Outcome Score (KOOS) subscores.[31] These limitations are not significantly different than those experienced by subjects with arthritis enrolled for osteotomy or arthroplasty and may be worse than those with anterior cruciate ligament (ACL) deficiency.[31] The exact mechanism accounting for pain caused by pathology in an aneural tissue is not completely understood. Stimulation of periarteriolar nociceptive fibers in the subchondral bone is one theory.[38] In addition, the intraarticular biologic inflammatory milieu likely plays a large role with reduced anabolic factors and increased catabolic and nociceptive factors. This leads to synovitis, effusion, capsular distention, and pain.

Once the determination that a defect is symptomatic has been made, conservative treatment options may commence. These include, but are not limited to, rest, activity modification (typically reduction in load, including reductions in body mass index [BMI]), oral antiinflammatory medications, glucosamine, chondroitin, methylsulfonylmethane, injection therapies (steroid [methylprednisolone, triamcinolone, betamethasone], nonsteroid [ketorolac], hyaluronate viscosupplementation, platelet-rich plasma [PRP]), and physical therapy with modalities. Despite the therapeutic effect of injections, the diagnostic effect of added local anesthetic may provide more clinically useful information in determining the severity of symptomatology and may hint at the responsiveness to subsequent treatment.

In the situation of failed conservative treatment, surgical decision making is predicated on the patient's informed consent. This includes recognition of and addressing the patient's preoperative expectations. Complete disclosure of the surgical algorithm (Figs. 31-1 and 31-2) and each technique's advantages, disadvantages, risks, benefits, alternatives, expected outcomes, and postoperative rehabilitation is warranted. The algorithm for selection of the optimal technique is based on multiple patient factors (age, gender, activity level, BMI, symptom duration), limb- and knee-related factors (meniscus, cruciate and collateral ligaments, alignment), and defect-specific factors (location, size, depth, subchondral bone). There are three general categories for surgical procedures designed to address articular cartilage pathology in the knee: (1) palliative (chondroplasty, debridement, lavage, meniscectomy), (2) repair (microfracture, drilling, abrasion, augmented scaffold-supported marrow-stimulation techniques), and (3) restoration (osteochondral autograft, osteochondral allograft, autologous chondrocyte implantation [ACI], and other chondrocyte- and mesenchymal stem cell-based therapies).

In addition to the treatment of the defect, concomitant limb and knee pathology must be addressed in either simultaneously or staged fashion. These entities include meniscal preservation (repair or transplantation),[27] alignment correction (varus or valgus malalignment treatment with proximal tibial or distal femoral unloading osteotomies, respectively, and patellofemoral malalignment treatment with

TABLE 31-1 Prevalence of Chondral Defects in the Knee Based on Unique Subject Populations

Subject Population	Prevalence (%)
All ages: all defect locations, sizes, depths	60-63[5,9,33,45]
All ages: all defect locations, sizes, only full-thickness defects	16[2,9,33,45]
All defect locations: age <40 yr, only full-thickness defects	5-7[9,33,45]
Concomitant anterior cruciate ligament tear	16-46[6]
All locations: amateur and professional athletes, only full-thickness defects	36[15]
All locations: asymptomatic professional basketball players, runners	59-77[15,35,44]

From Harris JD, Brophy RH, Jia G, et al. Sensitivity of magnetic resonance imaging for detection of patellofemoral articular cartilage defects. *Arthroscopy*. 2012;28(11):1728-1737.

CRITICAL POINTS Indications and Contraindications

Indications

- Symptomatic full-thickness chondral defect
- Symptoms such as direct tenderness at lesion, activity-related weight-bearing pain, effusion, and response to injection
- Treat concomitant pathology (meniscus, alignment, ligament)
- Patient selection and addressing expectations are critical

Contraindications

- Asymptomatic
- Patients unwilling or unable to comply with postoperative rehabilitation
- Uncorrected concomitant pathology (meniscus, alignment, ligament)
- Osteoarthritis

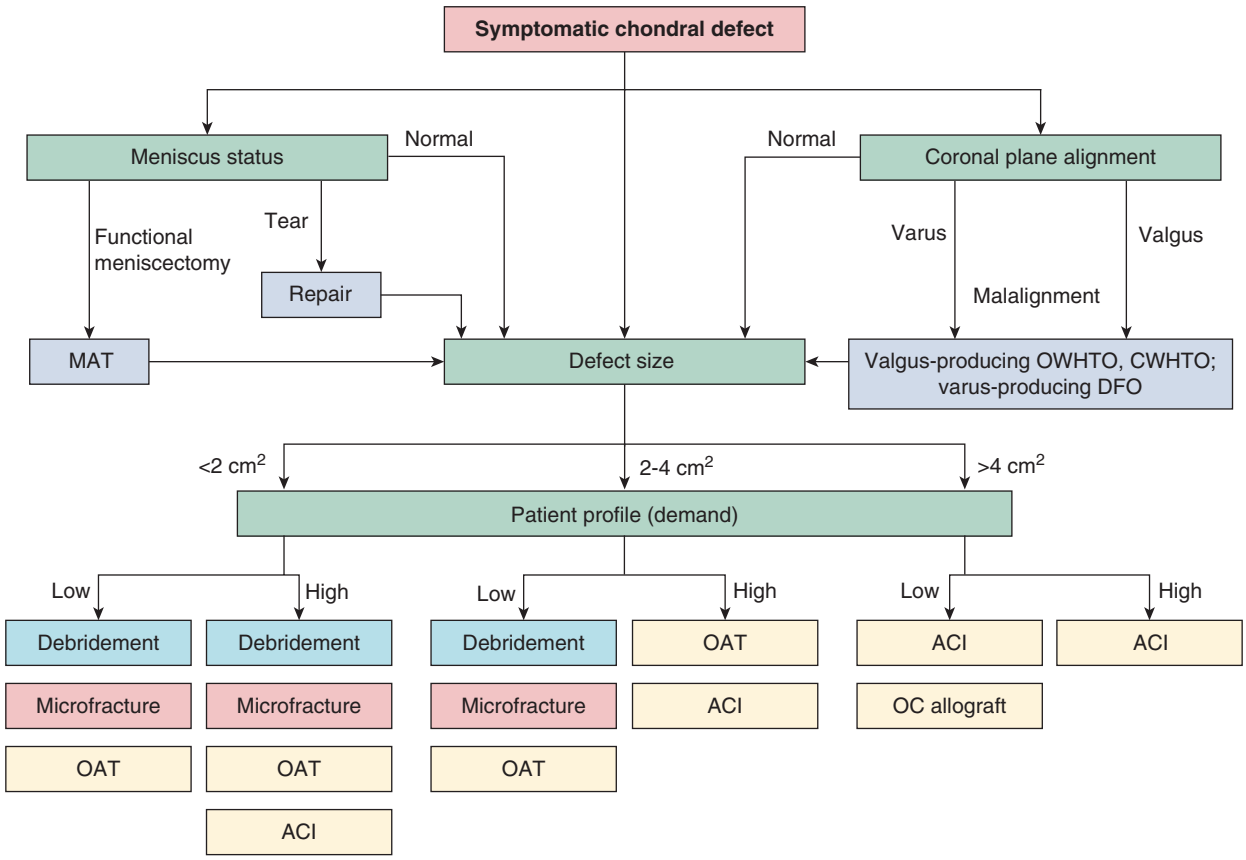

FIG 31-1 Management of symptomatic chondral defect in the tibiofemoral compartment (medial or lateral femoral condyle and/or tibial plateau). Concomitant pathology, such as meniscal deficiency and/or coronal plane malalignment should be addressed simultaneously or in a staged fashion. The most important defect-specific parameter dictating treatment choice is size (cm^2). Yellow shading denotes cartilage restoration, red shading denotes cartilage repair, and purple shading denotes cartilage palliation. *ACI*, Autologous chondrocyte implantation; *CWHTO*, closing-wedge high tibial osteotomy; *DFO*, distal femoral osteotomy; *HTO*, high tibial osteotomy; *MAT*, meniscal allograft transplantation; *OAT*, osteochondral autograft transplantation; *OC*, osteochondral allograft *OWHTO*, opening-wedge high tibial osteotomy.

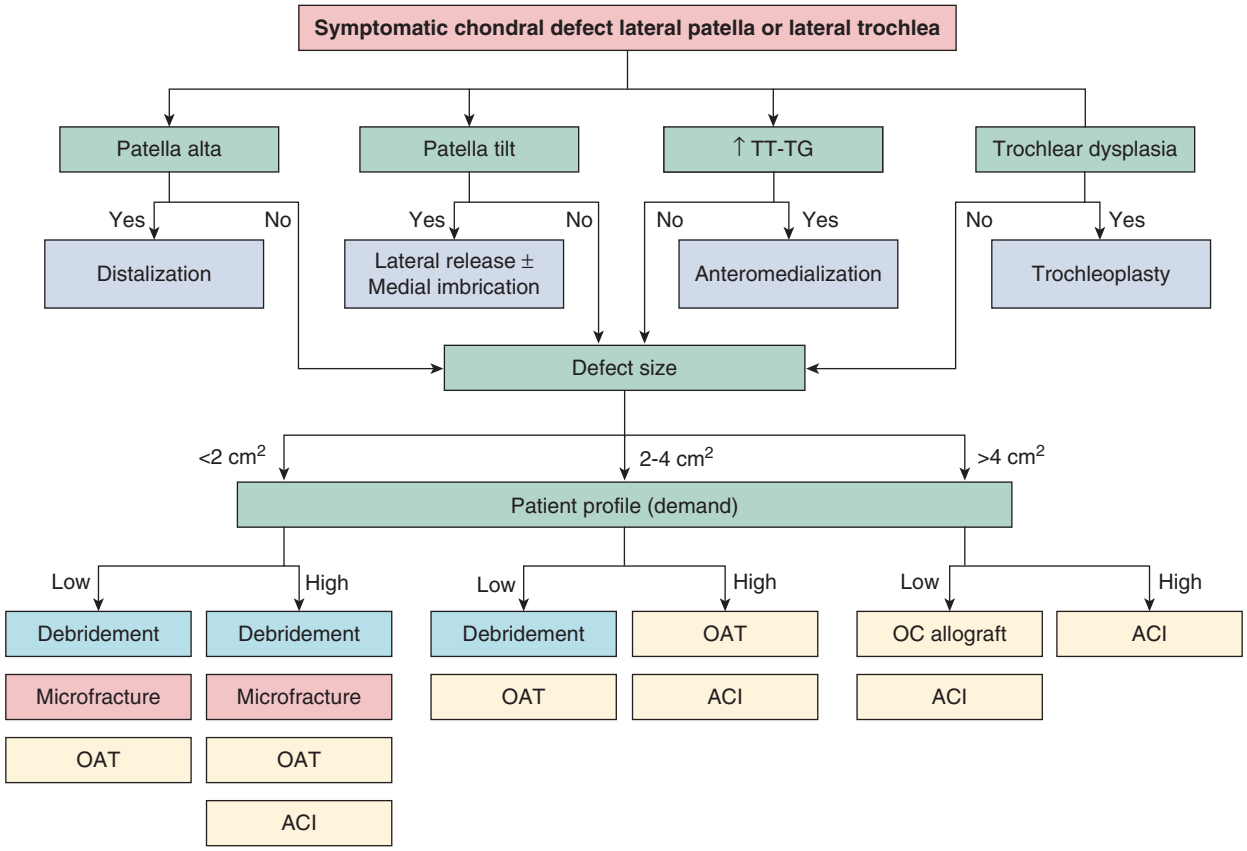

FIG 31-2 Management of symptomatic chondral defect in the patellofemoral compartment (trochlea, patella). Concomitant issues such as patella tilt, alta, increased tibial tubercle-trochlear groove (TT-TG), and trochlear dysplasia should be addressed simultaneously or in a staged manner. Centrally or medially located defects warrant different unloading osteotomy techniques. Medial patellofemoral cartilage pathology is a contraindication to medialization osteotomy. The most important defect-specific parameter dictating treatment choice is size (cm^2). Yellow shading denotes cartilage restoration, red shading denotes cartilage repair, purple shading denotes cartilage palliation. *ACI*, Autologous chondrocyte implantation; *OAT*, osteochondral autograft transplantation; *OC*, osteochondral allograft.

anteromedialization Fulkerson-type tibial tubercle osteotomy),[24,43] and knee ligament reconstruction.[6] The time commitment, intensity, and duration of the postoperative rehabilitation must not be overlooked or underestimated. The time to return to impact activities and return to sport must be discussed. Furthermore, in the setting of competitive athletes, the following factors play a significant role: timing of surgery (in or off season, stage of career); level of sport (high school, collegiate, elite amateur, professional); scholarship, contract, or bonus status; and opinions of stakeholders in the athlete's care (owners, managers, coaches, trainers, agents, teammates, family, friends, spouses). Given the prevalence with which chondral pathology is identified in professional athletes' knees,[15,35,44] the length of time required to rehabilitate following surgery,[22] and the subsequent implications (time lost to team, financial), it is critical to carefully and appropriately select the correct surgical technique in this patient population. As a general consideration, if there is an extraarticular treatment (e.g., osteotomy) that can predictably relieve or improve an athlete's symptoms, strong consideration for delaying an intraarticular procedure (e.g., articular cartilage transplantation) until his or her career is over is a reasonable option.

CONTRAINDICATIONS

There are several groups of subjects that are not candidates for articular cartilage restorative techniques in the knee. There is currently no role for prophylactic cartilage restoration in asymptomatic subjects. However, two exceptions to this contraindication exist: large surface area osteochondritis dissecans lesions and post-lateral meniscectomy in active females with valgus lower extremity alignment. In general, low-level symptoms should drive most early decision making rather than the theoretical risk of progression. There are no clear data showing that neglect leads to inexorable progression or, conversely, that treatment may halt or attenuate progression. Patients with osteoarthritis have an irreversible process illustrated via diffuse degenerative changes of subchondral bone sclerosis, subchondral cyst formation, osteophytes, and joint space narrowing. Patients not willing or unable to comply with the postoperative guidelines and rehabilitation protocols are contraindicated. Other contraindications include uncorrected comorbidities (meniscal deficiency, malalignment, ligamentous insufficiency), malignancy, and infection. Relative contraindications include elevated BMI, tobacco use,[3,4,34] and inflammatory arthritides such as rheumatoid arthritis, psoriatic arthritis, gout, and pseudogout.

CLINICAL BIOMECHANICS

The knee is subjected to high loads during simple tasks such as gait and squatting and even higher forces during sports involving sprinting and jumping.[16,41] These result from external (ground reaction force,

perturbation) and internal (muscle forces, joint reaction force) sources.[40] Small alterations in the direction or angle of a force acting on the knee can significantly influence the magnitude of forces observed.[42] This effect is demonstrated with both ACL injury and focal chondral defects in the knee.

ACL injury leads to translational and rotational disturbances in the knee. These kinematic shifts lead to altered articular cartilage stress in that regions of articular cartilage that were unloaded preinjury are now loaded, and regions of articular cartilage that were loaded preinjury are now unloaded. Because of the mechanosensitivity of chondrocytes and their low level of adaptability and reparability, the knee is susceptible to cartilage degeneration and progression with activity, especially in the setting of previous surgery or excessive BMI. In the presence of a focal chondral defect, the rim of the lesion may bear the load from the opposing articular surface, similar to a car driving over a pothole (Fig. 31-3). This stress concentration has been observed in several biomechanic models. Guettler and associates[21] showed that, for defects larger than 10 mm in diameter, stress concentration occurs around the rim (at 2.2 mm from the rim medially and 3.2 mm from the rim laterally). Eventually, the size (diameter) enlarges enough so that the opposing articular surface contacts and transmits stress to the exposed subchondral bone within the full-thickness defect. This depends on the defect size, location, and shape.

Flanigan and colleagues[14] showed that there were condyle-specific thresholds for contact on exposed subchondral bone within circular defects and stress concentration around the defect at defect sizes greater than 1.61 and 1.99 cm^2, respectively. In a separate investigation, Flanigan and coworkers[13] demonstrated that there were both shape-dependent and condyle-specific thresholds for contact on exposed subchondral bone within oval-shaped defects. Oval-shaped defects with the long axis in the coronal plane (medial to lateral) on the lateral condyle had the lowest size threshold for exposed subchondral bone contact (0.73 cm^2), and oval-shaped defects with the long axis in the sagittal plane (anterior to posterior) on the medial condyle actually had no size threshold (contact not observed). Stress concentration around the defect rim was observed in all defects, regardless of shape, size, or location. The stress dissipated with increasing radius away from the center of the lesion. Harris and associates[26] have also shown that the defect wall geometry (vertical vs. 45-degree beveled; see Fig. 31-3) may play a large role in rim stress concentration, exposed intralesional subchondral bone contact, and subsequent defect progression. These mechanics are all based on condylar/meniscal/plateau geometry, especially coronal and sagittal plane radii of curvature.

The preferential greater lateral-biased defect loading mechanics is based on the unique geometries of the lateral and medial femoral condyles and their interaction with menisci and tibial plateaus. The mean sagittal and coronal plane radii of curvature for the lateral condyle are smaller than the medial condyle. Furthermore, the sagittal radius differs from the coronal radius. This, in effect, creates more "point loading" on the more "convex-on-convex" lateral compartment versus the more congruent "convex-on-concave" medial compartment. Clinically, this may translate to significantly greater risk of subchondral bone changes in full-thickness defects on the lateral condyle, as well as speak to the incrementally greater vulnerability that the lateral compartment has following meniscectomy. This "bone boss" "intralesional osteophyte" effect has been observed in subjects undergoing ACI by Henderson and associates.[32] Patients with a bone boss had a longer duration of symptoms (greater time of subchondral bone experiencing opposing articular surface contact, more microcracks and microfractures).[32] Additionally, Alford and colleagues[1] demonstrated that lateral compartment lesions progress more rapidly than medial and are likely to become symptomatic at smaller sizes. These findings suggest that not only should tibiofemoral lesions be surgically treated differently than patellofemoral, but also lateral femoral condyle lesions should be treated differently than medial condylar lesions. Earlier intervention for lateral lesions may be desirable. The intervention type (entire osteochondral unit [osteochondral autograft, allograft] vs. surface [chondral] treatments) likely also matters.

CRITICAL POINTS Clinical Biomechanics

- Stress concentration occurs around the rim of full-thickness articular cartilage defects in the knee.
- Defects may progress based on several defect specific factors: size, shape, compartment, location.
- Lateral lesions may progress more rapidly than medial because of convex-on-convex mechanics (vs. convex-on-concave medially) between the femoral condyle and tibial plateau.
- With vertical walled lesions, although there is a lower volume of cartilage in the defect and on the exposed subchondral bone by the opposing surface, the stress concentration around the defect rim is greater.

CLINICAL EVALUATION

History

Patients with symptomatic focal chondral defects of the knee experience pain that is reproducibly located at the site of the defect, is primarily activity related (especially with axial load and weight bearing with tibiofemoral lesions, and especially with stairs or prolonged knee flexion with patellofemoral lesions), is associated with effusions (indicative of a biologically active synovitis process and capsular distention), and is often associated with a temporary relief of symptoms with intraarticular local anesthetic injection. Although single-dose intraarticular local anesthetic and corticosteroid injection is effective in significantly reducing pain, we recommend caution with certain anesthetic and corticosteroid injection combinations because of potential articular cartilage chondrotoxicity. These include betamethasone sodium phosphate, betamethasone acetate, triamcinolone acetonide, 0.5% bupivacaine, 1% lidocaine or 0.25% bupivacaine combined with betamethasone acetate or sodium phosphate, and 1% lidocaine combined with methylprednisolone acetate or triamcinolone acetonide.[5,8,10] Because of this potential iatrogenic damage, we recommend 1%

CRITICAL POINTS Clinical Evaluation

- Pain reproducibly located at the site of the defect.
- Pain primarily activity-related (weight bearing with tibiofemoral and stairs or prolonged knee flexion with patellofemoral).
- Associated with intermittent effusions.
- Temporary relief with intraarticular local anesthetic injection.
- Focus on not only the exact location of tenderness (at the defect) but also concomitant pathology, including alignment, meniscal status, ligamentous sufficiency.
- Gait evaluation, proximal and distal musculature (i.e., atrophy), extremity rotational profile, and pedal arch.
- Weight-bearing plain radiographs, including long-leg alignment view, are initial diagnostic evaluation of choice.
- Noncontrast MRI can detail the status of articular cartilage, subchondral bone, effusion, and concomitant pathology.
- Advanced MRI sequences (e.g., dGEMRIC) may characterize collagen and proteoglycan content better than conventional MRI.

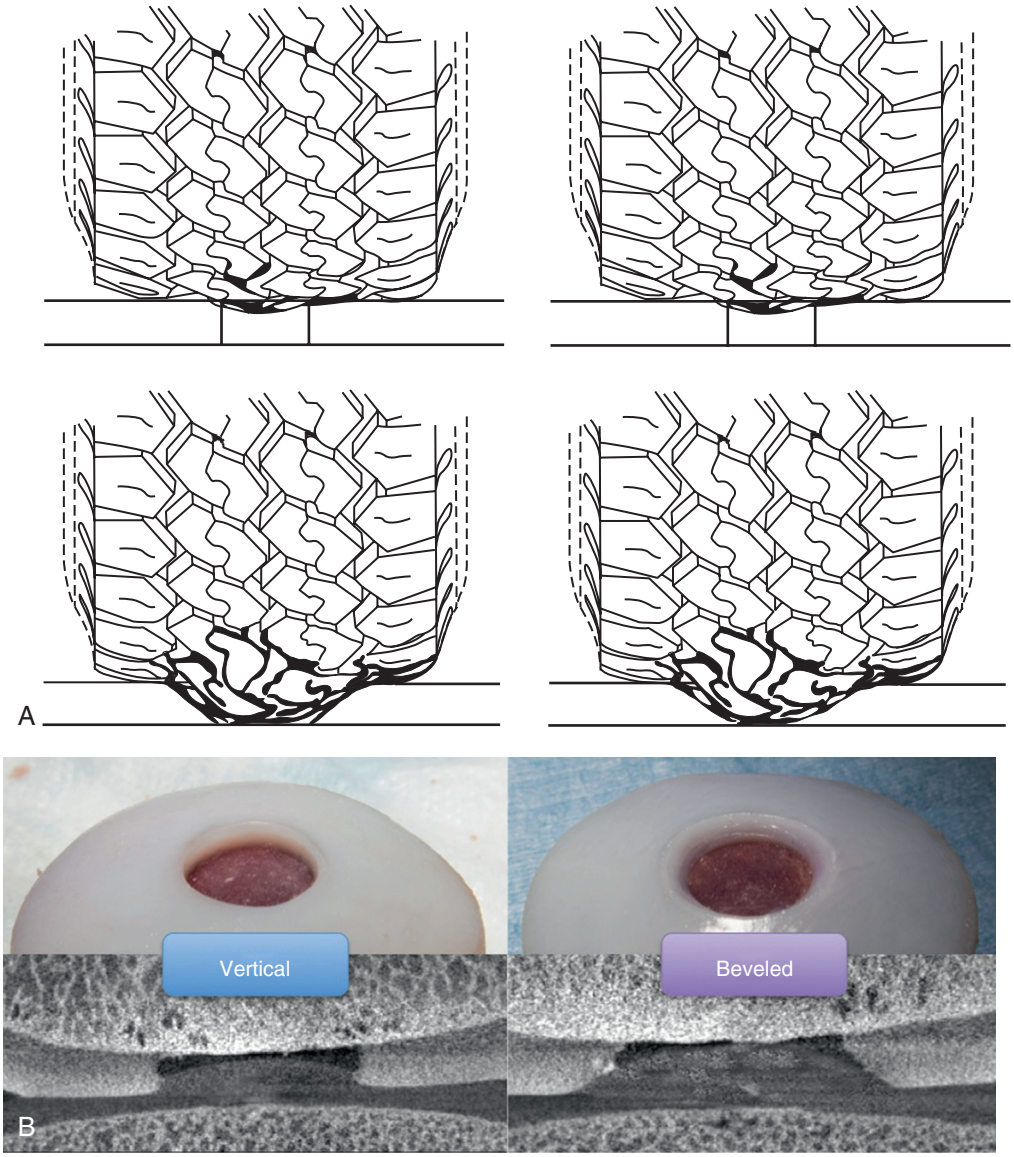

FIG 31-3 **A,** The top images illustrate a full-thickness chondral defect with vertical walls. Although there is greater stress concentration around the rim of the defect, the exposed subchondral bone is more protected. The presence of a defect increases the pressure on the rim of the defect (Pressure = Force/Surface area) because of a smaller surface area of articulating contact areas. The bottom right image illustrates enlargement of the lesion diameter with maintenance of vertical walls so that the exposed intralesional subchondral bone is contacted by the opposing articular surface. The bottom left image illustrates beveling of the lesion so that the exposed subchondral bone is contacted by the opposing articular surface. However, in addition, there is greater surface area of articular cartilage contact distribution with subsequent reduction in stress. We recommend vertical over beveled walls for cartilage repair surgery because it better contains the new cartilage tissue within the defect. **B,** The top two images are vertical and beveled lesions in cadaveric bovine femoral condyles. Upon axial load at the defect by the opposing intact tibial articular surface, visualized on microcomputed tomography, the stress concentration around the defect rim is greater, although there is a lower volume of cartilage in the defect and on the exposed subchondral bone by the opposing surface with the vertical wall lesion.

lidocaine for short- and 0.5% ropivacaine for long-term anesthesia, and dexamethasone as the corticosteroid of choice because these medications have not demonstrated chondrotoxicity in combination in the literature. Preoperative duration of symptoms is highly variable. The mean preoperative duration of symptoms can range from as few as 6 months to more than 15 years, and the number of prior preoperative surgeries can range from none to 30.[22,27,30,43]

Physical Examination

The physical examination of subjects with symptomatic chondral defects should focus not only on the defect itself but also on concomitant pathology. Initial assessment should focus on gait observation. Antalgic patterns indicate pain in the extremity, Trendelenburg gait indicates a contribution of hip abductor weakness to knee pain,

quadriceps avoidance patterns are observed with patellofemoral lesions, and knee flexion contractures are seen with hamstring tightness (from multiple spine, pelvis, hip, and lower extremity sources; patella baja; and patellofemoral pain). Coronal plane alignment should be evaluated during double- and single-leg stance and gait for evaluation of static and dynamic alignment and assessment of thrust.

Lower extremity rotational profiles may be grossly evaluated via inspection for femoral version and tibial torsion via in-toeing or out-toeing. Foot observation examination should be performed during standing and ambulating, and double- and single-heel rises should be done for arch assessment.

Inspection for muscle atrophy at all muscle groups should be performed (this can be quantitatively evaluated with both circumference measurements, manual muscle testing, and isokinetic testing). Palpation is a critical component of the examination, especially focusing on tenderness at the site of the lesion. Although detection of large effusions is straightforward in most subjects, smaller effusions may require milking and ballottement of the patella to detect. Wilson's test may be used to diagnose a classical location osteochondritis dissecans (OCD) lesion on the lateral aspect of the medial femoral condyle. This maneuver is performed by internally rotating the tibia with the knee in a flexed position and then extending the knee while maintaining internal rotation. Pain will reproducibly occur at 30 degrees of flexion as the tibial spine contacts the defect. External tibial rotation will alleviate the pain. The sensitivity and specificity of the physical examination for diagnosis of OCD is 91% and specificity 69%, respectively, which is greater than MRI.[37] In addition to the defect itself, cruciate and collateral ligament stability should be assessed via Lachman, anterior and posterior drawer, sag, and quadriceps active tests and varus/valgus stress tests at 0 and 30 degrees of knee flexion. Posterolateral corner structures may be evaluated via external rotation recurvatum and dial testing, posterolateral drawer, and reverse pivot shift tests.

Diagnostic Tests

Plain radiographs of the knee and full-length alignment radiographs are the initial diagnostic evaluation of choice for evaluation of patients with chondral defects in the knee. Our preferred series includes a weight-bearing anteroposterior view, weight-bearing 45-degree flexion posteroanterior (AP) view, weight-bearing lateral view in 30 degrees of flexion, and patellofemoral view (Merchant or sunrise). A full-length hip-to-ankle weight-bearing AP view allows for determination of the mechanical axis of the lower extremity. All plain radiographs should use a spherical radiographic magnification marker of known size to permit calculation of meniscal or osteochondral allograft sizes (or both).

Noncontrast MRI is useful for evaluation of the articular cartilage, underlying subchondral bone, menisci, ligaments, tendons, and joint fluid. Proton density-weighted, intermediate-weighted, and T2-weighted images provide the best contrast resolution for articular cartilage evaluation. Fluid-sensitive sequences, such as T2 weighted and short-tau inversion recovery (STIR), are able to best differentiate the hyperintense synovial fluid-articular cartilage interface. Thus surface lesions are best evaluated with these sequences. Although fluid-sensitive sequences help to identify subchondral edema, they make it difficult to evaluate the articular cartilage-subchondral bone junction. Acquisitions without fat suppression help to clearly delineate the latter. MRI may be particularly useful in the evaluation of stable delamination injury in which the articular cartilage surface is intact but the underlying cartilage or subchondral bone is damaged. These injury types may be missed by the gold standard articular cartilage evaluation, arthroscopy, because the surface is not breached. Although some types of cartilage lesions are difficult to completely characterize via MRI, this is usually because of the lesion thickness, its orientation and shape, the magnet strength (signal-to-noise ratio spatial resolution), and the imaging plane orientation relative to the defect. Regions of cartilage softening and superficial fibrillation or fissures may be missed by conventional MRI sequences. Advanced sequences, such as T2 mapping, T2*, T1ρ, sodium imaging, and dGEMRIC (delayed gadolinium-enhanced MRI of cartilage) may be useful to evaluate early articular cartilage damage via ultrastructural details of collagen and proteoglycan pathology.

PREOPERATIVE PLANNING

Based on the patient's clinical history, physical examination, imaging work-up, and preoperative discussion with informed consent, a surgical treatment may be recommended. Prior records (operative report and arthroscopic photographs) are an important component of the decision-making algorithm (see Figs. 31-1 and 31-2) because they give the treating surgeon information regarding defect size, defect peripheral walls, subchondral bone appearance, meniscal and ligamentous status, and opposing articular surface ("kissing" lesions). It is critical to recognize and appreciate all patient-, limb-, knee-, and defect-specific factors (Table 31-2) that may influence the surgical outcome.

Each patient and his or her cartilage defect should be approached individually and not always according to a cookbook algorithm. In other words, "treat the patient, not the defect." Algorithms are general guidelines that use various patient and defect factors to help the surgeon and patient select a certain type of surgery. For patients with symptomatic chondral defects in the knee, a prerequisite to cartilage

CRITICAL POINTS Preoperative Planning

- Thorough history and physical examination ("treat the patient, and not the defect"), including prior record review (operative reports, arthroscopic photographs).
- Preoperative informed consent includes a discussion of the intensity, frequency, and duration of postoperative rehabilitation and the patient's ability to comply with it.
- Evaluate and treat all concomitant pathology (meniscus, alignment, ligament) either simultaneously or in a staged fashion.
- Specific surgical techniques are based on patient-, limb-, knee-, and defect-specific factors.
- Defect-specific factors include size, location, depth, shape, and walls.

TABLE 31-2 Patient-, Limb-, Knee-, and Defect-Specific Factors That Influence Outcome of Articular Cartilage Surgery in the Knee

Patient	Limb	Knee	Defect
Age	Coronal alignment	Meniscal status	Size
Body mass index	Patellofemoral "alignment"	Ligament status	Location
Smoking status	Muscle atrophy	Prior surgeries	Depth
Duration symptoms	Contracture	Effusion	Shape
Goals			Subchondral bone
Rehab compliance			Walls
			Single vs. multiple

repair or restoration is the ability to comply with the postoperative protocol in frequency, intensity, and duration. In the tibiofemoral compartment, small lesions (<2 cm^2) are frequently treated with debridement chondroplasty in both low- and high-demand subjects. However, in certain high-demand subjects and subjects who have failed a prior chondroplasty, both microfracture and osteochondral autograft are reliable options. If the subchondral bone plate is disrupted, then osteochondral autograft may be preferred because of the restoration of the entire osteochondral unit. There are several surgical options for medium (between 2 and 4 cm^2) and large (>4 cm^2) lesions. In low-demand subjects, debridement chondroplasty, microfracture, and ACI are viable surface treatment options. The ability to obtain vertical walls (for both microfracture and ACI) is sometimes difficult because of peripheral defect location. This precludes containment of the mesenchymal clot in microfracture or chondrocyte containment in ACI. In the situation of poor lesion containment, osteochondral allograft may be the best surgical choice. In the situation of subchondral bone loss, osteochondral allograft and ACI ("sandwich technique" with bone graft) are both viable options. Failed surface treatments (e.g., microfracture, ACI) may be revised with osteochondral allograft.

In the patellofemoral compartment, the geometry of the articulating surfaces is very different from that of the femoral condyles. In addition to compressive load, a large amount of shear stress is placed on both native and repaired articular cartilage. Thus most articular cartilage repair and restoration procedures are performed in conjunction with a tibial tubercle osteotomy. In the presence of patella alta, a distalization is recommended. If the tibial tubercle to trochlear groove (TT-TG) distance is elevated (>20 mm), then an anteromedialization (Fulkerson-type) osteotomy is recommended. A caveat to anteromedialization is the proximal and/or medial patellar or trochlear lesion, because this defect location would be overloaded with the osteotomy. In the setting of concomitant lateral patellar instability and an incompetent medial patellofemoral ligament (MPFL), an MPFL reconstruction is warranted. As with the tibiofemoral compartment, small (<2 cm^2) defects may be successfully addressed with debridement chondroplasty in both low- and high-demand patients. In certain high-demand subjects and in subjects that have failed a prior debridement, microfracture and osteochondral autograft may be useful for small trochlear lesions. However, in the patella, osteochondral graft (both autograft and allograft) may be difficult because of size, angle, and cartilage thickness mismatch limitations. For medium and large defects on the patella, the only technique able to successfully match the patellar articulating surface geometry is ACI. For medium and large trochlear lesions, both ACI and osteochondral allograft may be used. In the presence of subchondral bone loss, osteochondral allograft is appropriate. Following surface treatment (e.g., microfracture, ACI) failure, just as in the tibiofemoral compartment, lesions may be revised with osteochondral allograft.

In preparation for cartilage palliation techniques (chondroplasty, debridement, lavage, meniscectomy), standard knee arthroscopy equipment should be available. These include arthroscope, video tower, cannula(s), shavers, curettes, gouges, biters, graspers, and radiofrequency devices.

In preparation for cartilage repair (microfracture, drilling, abrasion, augmented scaffold-supported marrow-stimulation techniques), additional equipment should include microfracture awls of various angles, Kirschner wires, small-bore drill bits, other proprietary drills (PowerPick and PowerPick XL [Arthrex], which provides 1.5 mm-diameter drill, with 4- or 6-mm depth, at 30 or 45 degrees angle options, and NanoFx [Arthrosurface], which provides 1 mm-diameter drill, with 9-mm depth), and arthroscopic burs of various sizes. Additional matrix scaffold augmentation may be added to standard marrow-stimulation techniques to stabilize the mesenchymal clot and potentially improve cell differentiation into a more hyaline-like cartilage repair. These include autologous matrix-induced chondrogenesis (AMIC), BioCartilage, and BST-CarGel. AMIC uses a porcine collagen (type I/III) matrix (Chondro-Gide, Geistlich Pharma) with conventional microfracture and fibrin glue. BioCartilage (Arthrex) is a homologous mixture of 1 mL of the patient's PRP and 1 mL of BioCartilage, a dehydrated micronized allograft articular cartilage extracellular matrix, placed on a microfractured defect. BST-CarGel (Primal Healthcare) is a chitosan-based biopolymer mixture of the patient's whole blood and a glycerophosphate buffer placed on a microfractured defect.

Currently, BioCartilage and DeNovo NT (Zimmer) are the only minced articular cartilage technologies commercially available for use in the United States. BioCartilage is an augmented marrow stimulation technique that relies upon the patient's subchondral bone mesenchymal stem cells and PRP, in addition to the dehydrated minced juvenile allograft articular cartilage, to form the cartilage repair tissue. DeNovo NT is different from BioCartilage in that it intentionally does not violate the subchondral bone. DeNovo NT is a chondroconductive, chondroinductive, and chondrogenic product composed of 1 mm^3 fragments of juvenile (<13 years) articular cartilage embedded in fibrin adhesive at the time of implantation. Similar to BioCartilage, DeNovo NT is "minimally manipulated" and thus does not require U.S. Food and Drug Administration (FDA) premarket approval. Also similarly, both BioCartilage and DeNovo NT take advantage of the greater migration and proliferation capacity of juvenile cells (vs. adult cells) without immunogenicity.

In preparation for cartilage restoration (osteochondral autograft, osteochondral allograft, ACI, other chondrocyte and mesenchymal stem cell–based therapies), additional equipment should include instruments and equipment for the open arthrotomy, including defect sizing tools, retractors, scissors, forceps, rongeurs, and scalpel blades. For osteochondral grafts, various sizes of osteochondral graft donor and recipient reamers and cannulated sizing blocks, osteochondral graft preparation back-table workstations, small oscillating saws, and saline pulse lavage are necessary. For ACI and other cell-based therapies, epinephrine-soaked neuropatties, thrombin, fibrin glue, mineral oil, glycerin, small (e.g., 6-0) absorbable suture, tuberculin syringe, 18-gauge plastic Angiocath, type I-III collagen membrane or periosteum, and cells are required.

For all cartilage repair or restoration techniques, the postoperative rehabilitation begins immediately following surgery. This requires preoperative acquisition of the postoperative equipment. These include continuous passive motion (CPM) machines, crutches, brace, ice cryotherapy and/or compression devices, and mechanical thromboembolic disease socks (e.g., thromboembolic hose, compression stockings).

INTRAOPERATIVE EVALUATION AND OPERATIVE TECHNIQUE

Tourniquets are frequently used in knee arthroscopy and arthrotomy. Their use in articular cartilage repair and restoration requires cognizance of their inflation status during surgery. If inflated during marrow-stimulation techniques, the tourniquet should be deflated and the arthroscopic pump turned off to visualize subchondral marrow content (fat and blood) exude to verify sufficient depth of penetration of awl, drill, or wire. In ACI, it is critical to ensure the tourniquet is deflated during defect preparation so that complete hemostasis may be achieved before chondrocyte implantation.

Evaluation of the defect via arthroscopy or arthrotomy is standardized and should include assessment and recording of size (measured

CRITICAL POINTS Intraoperative Evaluation and Operative Technique

- Deflate tourniquet during marrow-stimulation techniques to observe subchondral marrow contents (fat and blood) exuding to ensure sufficient depth of penetration of awl, drill, pick, or wire.
- Deflate tourniquet during autologous chondrocyte implantation during defect preparation so that complete hemostasis can be achieved before chondrocyte implantation.
- Assess and record defect size, depth, location, shape, number, and wall status.
- Ensure complete removal of abnormal, unstable, damaged articular cartilage back to stable rim with vertical walls.
- If unable to obtain vertical walls because of reaching peripheral articular cartilage edge, it is better to leave some damaged cartilage to form a wall for cartilage fill rather than removing it so that no wall would be able to contain cartilage fill.
- Removal of the calcified cartilage zone is important in both microfracture and autologous chondrocyte implantation.
- Avoid excessive subchondral bone removal, as this may stimulate overgrowth and intralesional osteophyte formation.

in anterior to posterior plane and medial to lateral plane), depth (partial thickness, full thickness without subchondral bone loss, full thickness with bone loss), location (femoral condyle, trochlea, patella, tibial plateau), number (single vs. multiple, "kissing" bipolar lesions), shape (defect shape in relation to condyle shape), and wall status (lesion with contained vertical walls or uncontained peripheral lesions). Defect preparation should include sharp removal of unstable loose damaged articular cartilage back to intact healthy articular cartilage with full-thickness vertical walls. In both microfracture and ACI, removal of the zone of calcified cartilage improves repair tissue integration with the underlying subchondral bone. Violation of the subchondral bone should be avoided, especially with ACI, because this causes bleeding and greater proportions of fibrocartilage repair. Excessive removal of subchondral bone also may stimulate subchondral bone overgrowth, intralesional osteophyte formation, and eventual repair breakdown.

Osteochondral allograft is an open single-stage articular cartilage restoration procedure in the knee. The surgical approach and technique vary based on lesion location, with either a medial or lateral parapatellar miniarthrotomy used for exposure. Defect preparation involves recipient site sizing and assurance that the surrounding normal osteochondral unit is stable, with sufficient walls to support the donor plug. The recipient site is reamed to a depth with a healthy subchondral bone bed (typically 6-9 mm). The recipient site articular cartilage thickness is measured at multiple clock-face references (typically 12, 3, 6, and 9 o'clock). The donor allograft is obtained from a qualified tissue bank, with the graft stored at 4° C and used between 14 and 28 days following harvest. It is opened and soaked in cold saline to avoid dramatic temperature changes, which may be chondrotoxic. A surface area– and depth-matched donor plug is then prepared. Before implantation, the donor plug is washed with sterile saline pulse lavage to remove any potential immunogenic subchondral bone marrow elements. The plug is then manually press fit into the recipient site with gentle finger pressure. It is critical to ensure flush placement of the donor plug in the recipient site because proud or recessed plug placement has been shown to significantly increase contact pressure and subsequent articular cartilage degeneration.[11] If secure graft fixation is questionable, then a recessed bioabsorbable screw may be placed in the center of the graft.

ACI is a two-stage cartilage restoration procedure in the knee. Stage one involves a knee arthroscopy, defect assessment, and cartilage biopsy, followed by a chondrocyte culture expansion in vitro. The biopsy may be obtained from multiple locations. However, it is usually taken from the superior lateral (or medial) edge of the intercondylar notch. The biopsy is taken with a sharp curette or gouge, approximately 5 mm wide, 10 to 14 mm long, and is 200 to 300 milligrams and contains approximately 200,000 to 300,000 chondrocytes. This can yield up to four vials of 12 million chondrocytes per vial. The cells are cryopreserved for up to 2 years. After the surgical date is selected, the cells are thawed and cultured for 4 weeks. Upon delivery the day (or the day before) of surgery, the cells expire within 48 hours.

The second stage of ACI involves either a medial or lateral parapatellar miniarthrotomy for exposure. Defect preparation involves removal of all unstable, loose, degenerated articular cartilage with creation of stable normal vertical walls. The calcified cartilage zone should be removed. However, do not be too aggressive in removal of this layer because it will stimulate subchondral bleeding and subsequent fibrocartilage formation. If bleeding is encountered (with the tourniquet down), epinephrine- or thrombin-soaked neuropatties should be used to obtain complete hemostasis. The risk of periosteal hypertrophy precludes use of periosteum for a graft cover.[29] Currently, most surgeons use a type I-III porcine collagen membrane (considered off-label use) for the chondrocyte cover. The porous side of the membrane may or may not (surgeon preference) be seeded with chondrocytes before suturing into the defect. Absorbable 6-0 suture is used (with mineral oil lubrication) in simple interrupted fashion, spaced 2 to 3 mm apart. The needle is initially passed on the patch side then through the articular cartilage. The needle should exit the articular cartilage approximately 3 mm from the edge of the lesion. The suture knot should be placed on the patch side, relatively recessed in relation to the surface of the surrounding articular cartilage. The final one or two suture locations should be at the most superior aspect of the defect, so that none of the chondrocyte solution may leak out (following a watertightness test). The suture line may be reinforced for water tightness with fibrin glue. An 18-gauge Angiocath and a tuberculin syringe are used to aspirate the resuspended cell solution. The solution is injected under the patch, the patch sutured closed, and then fibrin glued. Intraarticular drains should not be used postoperatively to avoid iatrogenic damage to the patch, cells, or both.

Postoperative rehabilitation is similar for both osteochondral allograft and ACI. Defect location (tibiofemoral vs. patellofemoral) dictates the weight bearing and motion restrictions following surgery. For tibiofemoral lesions, a brief (6 weeks) non–weight-bearing period commences following surgery (contrary to patellofemoral, in which weight bearing can begin as long as the knee is locked in extension in a brace). CPM is important in the early postoperative period (first 6 weeks) because the biological properties of articular cartilage and range of motion are significantly improved with CPM.[36] Weight bearing progresses from 6 through 12 weeks, while full symmetric pain-free motion is concurrently achieved. Core and lower extremity strengthening continues beyond 3 months, and functional sport-specific training may begin between 3 and 6 months. However, return to sport is restricted to beyond 9 to 12 months. Concurrent meniscal allograft transplantation or osteotomy may alter weight-bearing and motion limitations in the first 6 to 8 weeks after surgery.

CLINICAL OUTCOMES

Several synthetic systematic reviews and metaanalyses have been published that report on clinical, radiographic, and histologic outcomes after articular cartilage surgery in the knee. Overall, early clinical

reports were small, retrospective case series of levels III and IV evidence. Later publication dates have increasingly yielded larger, high-quality, level I evidence randomized comparative trials. Overall, with time, the level of evidence and methodological quality of knee articular cartilage surgery publications have significantly improved.[28] The rapid proliferation of the number of original research and synthetic review publications prompted the development of a valid and reliable knee articular cartilage condition-specific study methodological quality score.[23]

A systematic review of level I and II evidence studies on clinical outcomes after microfracture identified 15 studies (6 long term and 9 short term) for analysis.[19] These investigations compared microfracture to either ACI or osteochondral graft (autograft or allograft). At short-term follow-up in younger subjects, low-demand subjects, and those with smaller lesion size, microfracture demonstrated good clinical outcomes. However, beyond 5 years after surgery, treatment failures and osteoarthritis were observed, regardless of lesion size. This review parallels the findings of other systematic reviews and meta-analyses. A level IV evidence meta-analysis of articular cartilage repair in athletes revealed that microfracture outcomes deteriorated with time.[22] Significantly better clinical outcomes were observed with either ACI or osteochondral autograft. Results after microfracture were significantly worse with larger defect size (>4 cm^2). Rate of return to sport was significantly lower after microfracture versus ACI or osteochondral autograft. A separate but similar systematic review identified age, level of play, preoperative duration of symptoms, defect size, and repair tissue morphology as significant predictors of return to sport in athletes after microfracture.[39] A significant limitation of these reviews with regard to microfracture is that many fail to address or discuss concomitant pathology.[25] Several investigations compare "cartilage restoration" techniques, such as ACI or osteochondral autograft (which often have simultaneous correction of alignment and meniscus) with microfracture (which is frequently performed in isolation). Thus, this bias remains unaddressed and is a current limitation of the articular cartilage literature.

Just as in microfracture, several systematic reviews and meta-analyses of ACI exist, analyzing short- to long-term outcomes and comparing with osteochondral graft and marrow stimulation procedures. Within these investigations, several compare different generations of ACI, with identification of optimal outcomes and avoidance of complications. A level I and II evidence systematic review demonstrated that a collagen membrane base was significantly better than periosteal cover ACI.[17] Furthermore, matrix-associated had similar outcomes to collagen membrane-based ACI. However, the strength of the evidence in the latter review was weak because of short duration of follow-up, small numbers of subjects, medium-sized lesions, and younger ages of subjects. A separate but similar systematic review of level I and II evidence studies compared ACI with microfracture and osteochondral autograft.[30] Microfracture outcomes deteriorated after 18 to 24 months. ACI and osteochondral autograft demonstrated similar improvements in short-term outcomes. Younger subjects and those with shorter preoperative duration of symptoms and fewer prior surgical interventions had the best outcomes after both microfracture and ACI. Defect size greater than 4 cm^2 was predictive of significantly improved outcomes versus microfracture or osteochondral autograft.

A systematic review of 82 studies (more than 5000 subjects and 6000 defects) analyzed the rate of failures, complications, and reoperations after all generations of ACI.[29] The failure rate was low (1.5%-7.7%) across all generations. Failure rate (7.7%) and unplanned reoperation rate (27%) were highest after periosteal cover ACI. Graft hypertrophy and delamination was most commonly observed after periosteal cover ACI. Arthrofibrosis was most common after arthrotomy-based ACI (vs. all-arthroscopic implantation).

A systematic review of level I and II evidence clinical outcomes after osteochondral cylinder techniques analyzed eight studies (in comparison with microfracture and ACI).[18] Superior clinical outcomes and earlier return to sport was demonstrated after osteochondral autograft versus microfracture. Although mean lesion size was small (<3 cm^2), there was no significant observed difference between osteochondral autograft and ACI. Histologic examination consistently demonstrated hyaline cartilage in the transplanted plugs but no hyaline cartilage between the plugs.

No level I or II evidence exists regarding osteochondral allograft use in the knee. However, for focal and diffuse single-compartment chondral or osteochondral lesions, osteochondral allograft predictably and significantly improves patient-reported outcomes and results in high patient satisfaction.[7] At 5-year follow-up, overall satisfaction approaches 90% and 65% of patients have little or no radiographic osteoarthritis. Short-term complications are infrequent (<3%). Failures, although variably defined (repeat surgery, revision cartilage surgery, osteotomy, or conversion to arthroplasty), are uncommon (<18%). Survival rates decline with time: 91% to 95% at 5 years,[12,20] 76% to 85% at 10 years,[12,20] and 74% to 76% at 15 years.[12,20] Prognostic factors that may negatively influence clinical outcomes include diagnosis of spontaneous osteonecrosis of the knee, bipolar lesions, age greater than 50 years, patellofemoral lesions, Workers' Compensation status, preoperative duration of symptoms greater than 12 months, and failure to address malalignment or meniscal deficiency.[7]

INTRODUCTION

Hyaline articular cartilage is an avascular and insensate tissue that allows low-friction transmission of physiologic loads in diarthrodial joints. Its functional structure ideally is maintained in homeostasis over the lifetime of an individual but remains incapable of mounting an effective repair response when injured in a skeletally mature adult.[9,44] The treatment threshold for surgical intervention is not unequivocal, but patients with symptomatic lesions are generally considered candidates for cartilage restoration procedures.[2]

The use of osteochondral grafts of autologous or allogeneic origin is well supported on a basic science level and has a long successful clinical history as a means of biologic resurfacing.[7,15] Both modalities rely on transplanting mature hyaline cartilage containing viable chondrocytes attached to subchondral bone to restore the architecture and characteristics of native tissue in acquired osteoarticular defects. By transplanting structurally complete osteochondral units with an intact tidemark, the fixation issue is mostly relegated to that of osseous ingrowth.[37] Although both graft sources represent a common cartilage organ transplantation paradigm and are complementary, each has its unique, reciprocal challenges with regard to tissue availability and safety that must be weighed, managed, and communicated whenever the use of osteochondral grafts is being considered.

INDICATIONS

Autografts

Autologous osteochondral grafts are best used to address relatively small, yet symptomatic, focal articular lesions of the femoral condyles, especially if these grafts present with associated subchondral abnormalities such as a bone cyst or an intralesional osteophyte. Autologous plugs are also a potential salvage option as in situ fixation for a delaminating osteochondritis dissecans (OCD) lesion (International Cartilage Repair Society [ICRS] grades II-IV; see Chapter 44).[19,52]

Advantages of autologous grafts are immediate availability, relatively low costs, and their nonantigenic and osteogenic behavior that routinely lead to reliable osteointegration.[10] The possibility of arthroscopic delivery of these smaller grafts is appealing, albeit technically challenging.

One obvious disadvantage of autologous graft sources is that the maximum graft surface area is self-limited by the donor area available to be harvested for small and most medium-sized lesions. This is especially true in the previously injured or operated knee, in which suitability regarding tissue quality and overall joint topography has to be critically assessed. In addition, donor site morbidity can significantly add to the disease burden during intraarticular transfer.[7]

Allografts

Osteochondral allografts are suitable to treat medium to large chondral and osteochondral lesions.[24] In particular, osteochondral allografting may be considered the most appropriate treatment for large and high-grade (ICRS grades III-IV) OCD in the knee. Other specific conditions amenable to allografting include osteonecrosis and posttraumatic defects, such as after periarticular fractures. Further indications for allografting of the knee include treatment of patellofemoral chondrosis or arthrosis and for highly select cases of multifocal or bipolar posttraumatic or degenerative lesions. In a case in which meniscus replacement is also necessary, a composite tibial plateau with attached meniscus can be transplanted. Allografts are also increasingly employed in the salvage of knees that have failed other cartilage resurfacing procedures. Primary treatment may be considered in large chondral defects whose size presents a relative contraindication for other treatments and for which the surgeon believes other procedures may be inadequate.

Osteochondral allografting is the only treatment option that restores mature orthotopic hyaline cartilage and that reproduces the site-appropriate anatomy of the native joint both macroscopically and microscopically, without the risk of inducing donor site morbidity.[25] Osteochondral allografts are versatile when addressing even very large, complex, or multiple lesions in topographically challenging environments, especially if they involve an osseous component.

Obvious drawbacks to the allograft paradigm are the relative scarcity of donor tissue, financial and logistical issues of graft procurement, and residual risk of infection, a discussion that is an essential part of the informed consent process.[24] Although rare allograft-associated bacterial infections have been reported,[69] there are no available published data quantifying this risk or that of viral transmission. Patients are counseled that the risk for disease transmission from a fresh osteochondral allograft is comparable with that associated with banked blood transfusion. In a 35-year experience at our institution using more than 800 fresh allografts, no cases of transmission of disease from donor to recipient have been documented.

Fresh, cold-stored osteochondral allografts have shown to maintain viable chondrocytes and mechanical properties of the matrix many years after transplantation.[2,13-15,36,47,72] These findings have generally supported the use of tissue for small osteochondral allografts in the setting of reconstruction of chondral and osteochondral defects. Chondrocyte viability and structural integrity of the matrix are preserved during hypothermal storage in nutritive culture medium containing human serum, with cell density, viability, and metabolic activity remaining essentially unchanged from baseline for as many as 14 days before deteriorating significantly after 28 days, although the hyaline matrix remains relatively intact.[4,60,63,70,71] The clinical consequences of these storage-induced graft changes have yet to be determined, but 28 days is generally considered the threshold of graft utility in present clinical practice.

CONTRAINDICATIONS

Some of the contraindications to allograft transplantation are uncorrected ligamentous instability, meniscal deficiency, or axial malalignment of the lower extremity, as well as the presence of inflammatory or crystal-induced arthropathy or any unexplained global synovitis of the knee.

Autologous plugs are not advised in lesions presenting with a lack of containment or substantial subchondral bone loss, which might lead to loss of fixation and graft failure. Whereas "kissing" lesions are also widely considered unsuitable for autologous grafting, bipolar and multicompartmental allografting has been modestly successful in the younger individual.[50] However, advanced multicompartmental arthrosis is a relative contraindication to the allografting procedure, and neither osteochondral grafting technique should be considered an alternative to prosthetic arthroplasty in an individual with symptoms and acceptable age and activity level for prosthetic replacement.

CLINICAL EVALUATION

A careful and focused history and a physical examination are essential to determine candidacy for any cartilage restoration procedure. Because articular cartilage itself is insensate, it is important to identify contributory pain generators and to distinguish them from mechanical symptoms. Tools such as the International Cartilage Repair Society (ICRS) Cartilage Injury Evaluation Package,[33] which incorporates several validated outcome measures, can be helpful in systematically documenting the anatomic condition and functional envelope of the knee and in establishing a baseline for therapy.

The clinician should elucidate the location and quality of pain, onset (acute vs. chronic) and duration of symptoms, alleviating and exacerbating events or measures, prior treatment and surgical history (if any), as well as activity at the time of injury and expected future level of occupational and recreational performance. Significant medical factors potentially relating to knee pathology should be sought such as prior trauma, collagen-vascular/inflammatory disorders, or corticosteroid use. It should be noted that the time from the initial cartilage injury and pending disability compensation claims is universally recognized as inversely related to outcome. The onset and character of symptoms are worth noting in an effort to distinguish pain at rest (indicative of an underlying, more advanced degenerative process) from activity-related pain or mechanical symptoms such as catching or locking that suggest meniscal injury, loose bodies, or cartilage flaps associated with acute injury or early degenerative disease.
