Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

PREFACE

I am grateful to all of the contributors to this textbook, *Noyes' Knee Disorders*, which is appropriately subtitled *Surgery, Rehabilitation, Clinical Outcomes*. The chapters reflect the writings and teachings of the scientific and clinical disciplines required for the modern treatment of clinical afflictions of the knee joint. Our goal is to present rational, evidence-based treatment programs based on published basic science and clinical data to achieve the most optimal outcomes for our patients.

The key to understanding the different disorders of the knee joint encountered in clinical practice truly rests on a multidisciplinary approach that includes a comprehensive understanding of knee anatomy, biomechanics, kinematics, and biology of soft tissue healing. Restoration of knee function then requires an accurate diagnosis of the functional abnormality of the involved knee structures, a surgical technique that is precise and successful, and a rehabilitation program directed by skilled professionals to restore function and avoid complications. Each chapter follows a concise outline of indications, contraindications, physical examination and diagnosis, step-by-step open and arthroscopic surgical procedures, clinical outcomes, and analysis of relevant published studies.

The second edition of *Knee Disorders* is the result of complete editing of each chapter, the addition of new chapters on partial knee replacements, updates on anterior cruciate ligament (ACL) and posterior cruciate ligament arthroscopic reconstructions as well as posterolateral reconstructions, the addition of clinical studies on meniscus transplants and meniscus repairs, and the addition of newer concepts on neuromuscular testing and conditioning. Importantly, each rehabilitation postoperative protocol for every surgical procedure has been updated because this textbook serves a readership of surgeons, physical therapists, athletic trainers, and exercise specialists. As a result, this textbook has 45 chapters, 30 authors, 1000 figures, 285 tables, and more than 4500 references, including 1500 new references (1050 clinical studies and 450 articles on biomechanics, anatomy, or basic science).

A special feature of second edition is the video library referenced in the chapters, allowing the reader to both read and see the content being presented. There are 45 videos totaling more than 11 hours of content: 11 surgical videos, 19 patient rounds focusing on surgical procedures and postoperative rehabilitation, and 15 presentations of knee content pertaining to certain selected book chapters.

The first two chapters comprise an anatomic description of the structures of the knee joint. The images and illustrations represent the result of many cadaveric dissections to document knee anatomic structures. It was a pleasure to have four of our fellows (class of 2008-2009) involved in these dissections, which resulted in two superb, award-winning instructional anatomic videos included with this book. Numerous anatomy textbooks and publications were consulted during the course of these dissections to provide, to the best of our ability, accurate anatomic descriptions, with the realization there is still ambiguity in the nomenclature used for certain knee structures.

Special thanks go to Joe Chovan, a wonderful and highly talented professional medical illustrator. Joe attended anatomic dissections and worked hand in hand with us to produce the final anatomic illustrations. Joe and I held weekly to bimonthly long working sessions for more than 2 years, resulting in the unique, highly detailed, and accurate anatomic and medical illustrations throughout this book.

All surgeons appreciate that operative procedures come and go as they are proved inadequate by long-term clinical outcome studies and replaced by newer techniques that are more successful. I am reminded that the basic knowledge of anatomy, biomechanics, kinematics, biology, statistics, and validated clinical outcome instruments always remain our lightposts for patient treatment decisions. For this reason, there is ample space devoted in the text to these scientific disciplines. Equally important are the descriptions of surgical techniques, presented in a step-by-step approach with precise details by experienced surgeons on the critical points for each technique to achieve successful patient outcomes. It is hoped that surgeons in training will appreciate the necessity for the basic science and anatomic approach that, combined with surgical and rehabilitation principles, are required to become a true master of knee surgery and rehabilitation.

There is a special emphasis placed in each of the 13 sections on rehabilitation principles and techniques, including preoperative assessment, postoperative protocols, and functional progression programs to restore lower limb function. The comprehensive rehabilitation protocols in this book have been used and continually modified over many years. My coauthor on these sections, Timothy Heckman, is a superb physical therapist. We have worked together treating patients in a wonderful harmonious relationship for more than 30 years. In addition, there are special programs for the female athlete to reduce the risk of ACL injury. Sportsmetrics, a nonprofit neuromuscular training and conditioning program developed at our Foundation, is one of the largest women's knee injury prevention programs in the world and has been in existence for more than 15 years. A number of scientists, therapists, athletic trainers, and physicians at our Foundation have been involved in the research efforts and publications of this program. All centers treating knee injuries in athletes are reminded of the importance of preventive neuromuscular and conditioning programs, whose need has been well established by many published studies. Recent studies show a high rate of repeat injury to the ACL-reconstructed knee or the opposite knee, approaching 12% to 30% with return to athletics. Our goals are not only to prevent or decrease the incidence of ACL injuries, but (of equal importance) also incorporate Sportsmetrics neuromuscular programs after ACL surgery before return to sports activities.

The entire staff at Cincinnati SportsMedicine and Orthopaedic Center and the Foundation functions as a team, working together in various clinical, research, and rehabilitation programs. The concept of a team approach is given a lot of attention; those who have visited our center have seen the actual programs in place. This team effort is appreciated by all, including patients, staff, surgeons, physical therapists, athletic trainers, administrative staff, and clinical research staff. Our administrative staff has been directed by a superb and highly effective clinical operations manager, Linda Raterman, whom I thank and express my gratitude for her dedication and time. As the President and CEO, I have been freed of many of the operational administrative duties because of this excellent staff, allowing time required for clinical and research responsibilities. I have been blessed to be associated with a highly dedicated group of orthopaedic partners who provide excellent patient care and are a vehicle for lively discussions and debate at our academic meetings and journal clubs.

Nearly all of the patients treated at the Noyes Knee Institute are entered into prospective clinical studies by a dedicated clinical research group directed by Sue Barber-Westin and Cassie Fleckenstein. The staff meticulously tracks patients over many years to obtain a 90% to 100% follow-up rate; I thank Jenny Riccobene for diligently keeping track of all our patients. I invite you to read the Preface by Sue Barber-Westin, who has performed such an admirable and dedicated job in bringing

our clinical outcome studies to publication. It is only through her efforts of more than 30 years that we have been successful in conducting large prospective clinical outcome studies. In each chapter, the results of these outcome studies are rigorously compared with other authors' publications. The research and educational staff work with fellows and students from many different disciplines, including physicians, therapists, trainers, and biomedical students. There have been 147 Orthopaedic and SportsMedicine Fellows who have received training and awarded their certification at our center. The scientific contributions of fellowship research projects working hand-in-hand with our teaching staff are acknowledged numerous times in this text. Our staff enjoys the mentoring process; from a personal perspective, this has been one of my greatest professional joys.

In regard to mentoring, one might ask where the specialty of orthopaedics (or any medical specialty) would be today without the professional mentoring system that trains new surgeons and advances our specialty, providing a continuum of patient treatment approaches and advances. The informal dedication of the teacher to the student, often providing wisdom and guidance over many years, is actually contrary to capitalistic principles because the hours of dedication are rarely (if ever) compensated; it is the gift from one generation to another. I mention this specifically, as I hope that I have been able to repay in part the mentors who provided this instruction and added time and interest for my career. I graduated from the University of Utah with a Philosophy degree, which provided an understanding of the writings and wisdom of the great scientists and thinkers of all time, taught by superb educators in premedical courses and philosophy. I received my medical degree from George Washington University and am thankful to the dedicated teachers who laid a solid medical foundation for their students and taught the serious dedication and obligation that physicians have in treating patients. I was fortunate to be accepted for internship and orthopaedic residency at the University of Michigan and remember the opportunity to be associated with truly outstanding clinicians and surgeons. Under the mentorship of the chairman, William S. Smith, MD, my fellow residents and I received training from one of the finest orthopaedic surgeons and dedicated teachers. Many graduates of this program have continued as orthopaedic educators and researchers, which is a great tribute to Bill Smith and his mentorship. My fellow residents know one of his many favorite sayings that reminded residents of the need for humility: After a particularly enthusiastic lecture or presentation by a prominent visiting surgeon who received glowing statements of admiration, Bill Smith would say with a wink and smile, "He puts his pants on one leg at a time, just like you do."

After orthopaedic residency, I accepted a 4-year combined clinical and research biomechanics position at the Aerospace Medical Research Laboratories with the United States Air Force in Dayton, Ohio. The facilities and veterinary support for biomechanical knee studies were unheralded. It was here that some of the first high-strain-rate experiments on the mechanical properties of knee ligaments were performed. I am indebted to Victor Frankel and Albert Burstein, the true fathers of biomechanics in the United States, who guided me in these formative years of my career. I was particularly fortunate to have a close association with Al Burstein, who mentored me in the discipline of orthopaedic biomechanics. This research effort also included professors and students at the Air Force Institute of Technology. I am grateful to all of them for instructing me in the early years of my research training. As biomechanics was just in its infancy, it was obvious that substantive research was only possible with a combined MD-PhD team approach.

One of the most fortunate blessings in my professional life is the relationship I have had with Edward S. Grood, PhD. I established a close working relationship with Ed, and we currently have the longest active MD-PhD (or PhD-MD) team that I know of, and we are currently conducting the next round of knee ligament function studies using sophisticated three-dimensional robotic methodologies. We worked together to establish one of the first biomechanical and bioengineering programs in the country at the University of Cincinnati College of Engineering, and I greatly appreciated that it was named the Noyes Biomechanics and Tissue Engineering Laboratory. This initial effort expanded with leadership and dedicated faculty and resulted in a separate Bioengineering Department within the College of Engineering, with a complete program for undergraduate and graduate students. Dr. Grood pioneered this effort with other faculty and developed the educational curriculum for the 5-year undergraduate program. Many students of this program have completed important research advances that are referenced in this book. David Butler, PhD, joined this effort in its early years and contributed important and unique research works that are also credited throughout the chapters. This collaborative effort of many scientists and physicians resulted in three Kappa Delta Awards, the Orthopaedic Research and Education Clinical Research Award, American Orthopaedic Society for Sports Medicine Research Awards, and the support of numerous grants from the National Institutes of Health, National Science Foundation, and other organizations. The publications from the clinical and translational research team have been recognized in bibliographic studies as some of the most quoted in the world, as referenced by a recent *Journal of Bone & Joint Surgery* publication of the 100 most quoted knee studies in the past 40 years. Thomas Andriacchi, PhD, collaborated on important clinical studies that provided an understanding of joint kinematics and gait abnormalities. It has been an honor to have Tom associated with our efforts throughout the years.

On a personal note, my finest mentors were my parents, a dedicated and loving father, Marion B. Noyes, MD, who was a true renaissance surgeon entirely comfortable doing thoracic, general surgery, and orthopaedics, and who, as a Chief Surgeon at academic institutions, trained decades of surgical residents. Early in my life, I read through classic Sobotta anatomic textbooks and orthopaedic textbooks that remain in my library with his writings and notations alongside the surgical procedures. Later in my training, I was fortunate to scrub with him on surgical cases. My loving mother, a nurse by training, was truly God's gift to our family. She provided unqualified love and sage and expert advice for generations, with knowledge, wisdom, and our admiration—all the way into her nineties. She expected excellence, performance, and adherence to a rigorous value system. These are also the attributes of the most wonderful gift of all, the opportunity to go through life with a loving and true soulmate, my wife JoAnne Noyes, to whom I remain eternally grateful and devoted. Our family includes a fabulous daughter and two wonderful sons and their families and five wonderful grandchildren. Together with JoAnne and all our brothers and sisters, we enjoy many family events together. As I look back on my career, it is the closeness of family and friends that has provided the greatest enrichment.

In closing, I wish to thank Laura Schmidt, Dolores Meloni, and the other Elsevier staff who are true professionals and were a joy to work with in completing this textbook. Given all the decisions that must be made in bringing a textbook to publication, at the end of the process the Elsevier team made everything work in a harmonious manner, always striving for the highest quality possible.

Frank R. Noyes, MD

PREFACE

Revising and updating *Noyes' Knee Disorders: Surgery, Rehabilitation, Clinical Outcomes* has been a stimulating experience, and I am extremely grateful to the medical community and Elsevier for providing us with this opportunity. Numerous advances have occurred in the treatment and published outcomes of knee injuries and problems in the 7 years since the first edition. This is reflected in the more than 1000 new references that are included in the chapters Dr. Noyes and I completed. Postoperative rehabilitation has also progressed, with more objective and functional measures used to determine when an athlete may safely resume sports participation. Paramount for a successful outcome is the restoration of normal proprioception, balance, coordination, and neuromuscular control for desired activities. These concepts are discussed in detail in chapters Dr. Noyes, Timothy Heckmann, and I revised, as well as in the two chapters contributed by Kevin Wilk.

My interest in conducting clinical research stemmed from my experience of undergoing open knee surgery as a collegiate athlete many years ago. Although the operation was done in an expert manner, it was followed by inadequate rehabilitation and a poor outcome. Three years later, the experience was repeated except that the patient education process was markedly improved, as was the postoperative therapy program, both of which contributed to a successful result. The tremendous contrast between these experiences prompted a lifelong interest in helping patients who face the difficulty of dealing with knee problems. Having undergone arthroscopic surgery more recently on my knee and shoulders, I can personally attest to the incredible advances sports medicine has achieved in the past 3 decades. However, it is important to acknowledge that there is still much to learn and understand regarding the complex knee joint.

My initial experience with research involved collecting and analyzing data from a prospective randomized study on the effect of immediate knee motion after anterior cruciate ligament allograft reconstruction with Dr. Noyes and our rehabilitation staff. The experience was remarkable for the time Dr. Noyes spent mentoring me on all aspects of clinical studies, including critical analysis of the literature, correct study design, basis statistics, and manuscript writing. The scientific methodology adopted by Drs. Noyes and Grood, along with our center's philosophy of the physician-rehabilitation team approach, provided an extraordinary opportunity to learn and work with those on the forefront of orthopaedics and sports medicine. My second major project, used as the thesis for my undergraduate work, involved the analysis of functional hop testing. Dr. Noyes and our statistical consultant at that time, Jack McCloskey, were invaluable in their assistance and efforts to see the investigations through to completion. I remain grateful for these initial stimulating experiences, which provided the basis and motivation for my research career.

The clinical outcomes sections of the chapters of this textbook represent a compilation of knowledge from studies involving thousands of patients from both our center and other published cohorts. We have attempted to justify the recommendations for treatment based in part on the results of our clinical studies, which consistently use rigorous knee rating systems to determine outcome. The development and validation of the Cincinnati Knee Rating System was a major research focus for Dr. Noyes and I for several years. As a result, we have long advocated that "outcome" must be measured by many factors, including patient perception of the knee condition along with valid functional, subjective, and objective measures such as radiographs, knee arthrometer testing, and magnetic resonance imaging when necessary. Simply collecting data from questionnaires does not, in our opinion, provide a scientific basis for treatment recommendations. Even more compelling is the necessity to conduct long-term clinical studies with at least a 10-year follow-up evaluation. These studies must also include these measures to determine the long-term sequelae of various injuries and disorders. At our center, we will continue to conduct clinical research in this manner in our efforts to advance knowledge of the knee joint and provide the best patient care possible.

Another area of particular research interest of mine over the years has been in the field of rehabilitation. In fact, the first clinical study I participated in was initiated while I worked on the physical therapy staff for 2 years. Having been a patient myself, I had a strong interest in studying the effects of different rehabilitation treatment programs on clinical outcomes. At our center, we have always held the belief that postoperative rehabilitation is just as important as the operative procedure for successful resolution of a problem. I have enjoyed working with Tim Heckmann in these studies for many years, as well as many other therapists, assistants, and athletic trainers vital to the success of our rehabilitation research and clinical programs.

Many individuals have contributed to the success of our clinical research program over 30-plus years, but it is not possible to name them all. However, I want to especially recognize Jennifer Riccobene, who for many years has doggedly tracked down and assisted hundreds of patients from all over the United States and beyond with their clinical research visits. Cassie Fleckenstein manages the studies in Cincinnati, keeping track of a multitude of tasks, including fellowship involvement in research, which has been a cornerstone of this program since the early 1980s. We are also very grateful for the statistical expertise provided by Dr. Marty Levy of the University of Cincinnati.

Finally, I'd like to thank my family—my husband Rick and my children Teri and Alex—for their support during this endeavor. I hope this textbook will be of value to many different types of health professionals for many years to come.

Sue D. Barber-Westin

FOREWORD TO THE FIRST EDITION

It has been my observation over the years that Frank Noyes has three fundamental beliefs, or organizing principles, around which he has dedicated his professional life and that explain the contents of this book. These are:

1. Diagnosis and treatment of patient disorders should be strongly informed by knowledge gained from basic science studies.
2. The outcome of surgical treatment is critically dependent on rehabilitation therapy.
3. Advancement of medical care, both surgical and nonsurgical, requires carefully conducted outcomes studies that account for differences in outcome caused by the type and intensity of a patient's activities and avoid bias due to the loss of patients to follow-up.

These core beliefs help explain the many research studies he and his colleagues have conducted. The results of these studies and their clinical correlations, along with the broader base of knowledge developed by numerous investigators, form the foundation of Dr. Noyes' approach to the diagnosis and treatment of knee disorders.

This book details the approaches Dr. Noyes has developed to the diagnosis and treatment of knee disorders, along with the scientific foundations on which his approaches are based. The result is a valuable reference book for both physicians and physical therapists who care for patients with knee disorders. The inclusion of supporting basic science data also makes this book an excellent reference for any investigator or student who is interested in improving the care provided to patients with knee disorders by further advancing knowledge of the normal and pathologic knee.

Although the title *is Noyes' Knee Disorders,* and the content in large part reflects his clinical approaches and research, it also includes the clinical approaches and research results of other leading surgeons and physical therapists. There is, however, a common thread in that the clinical approaches presented include the scientific foundations on which they are based. Furthermore, the reader will find that the chapters that present the research of Dr. Noyes and his colleagues also include results of other leading scientific investigators. The studies included were selected to fill in gaps and provide a broader perspective in areas where a consensus has not yet been developed.

The quality of the content of this book is complemented by the quality of its production. Each chapter has "Critical Points" boxes that focus the reader's attention on the main takeaway messages. There is extensive use of color to enhance readability, particularly in the presentation of data. Great care has been taken to make the anatomic drawings and medical illustrations accurate and to carefully label all illustrations and images. The care put into the production by Elsevier reflects the high standard of care Dr. Noyes brings to those projects he undertakes, including the care delivered to his patients and his dedication to advancing care through carefully conducted basic science and clinical research studies. Although one result of Elsevier's and Dr. Noyes' efforts is the book's visual appeal, it was not the goal. Rather, the visual appeal is a byproduct of their efforts to provide the reader with a useful text in which the content is easily understood and accessible.

This book presents much of the research conducted by Dr. Noyes and his collaborators, including much of my own research. I would like to take this opportunity to express my appreciation and gratitude to Frank Noyes for the opportunity of collaboration, for the time and energy he has devoted to our collaboration, and to the significant financial support he and his partners have provided our research. I first met Frank in 1973 when he was stationed with the 6570th Aerospace Medical Research Laboratory, located at Wright Patterson Air Force Base just outside Dayton, Ohio. I had recently received my PhD and was working at the University of Dayton Research Institute. It was there we met thanks to the efforts of a mutual friend and colleague, George "Bud" Graves. It was also in Dayton we did the first collaborations that led to our paper on the age-related strength of the anterior cruciate ligament. In 1975 we moved to the University of Cincinnati, thanks to the encouragement of Edward Miller, MD, then Head of the Division of Orthopaedics. This move was made possible by the generosity of Nicholas Giannestras, MD, and many other orthopaedic surgeons in the community who provided support to initiate a Biomechanics Laboratory. It was in Cincinnati where we initiated our first study on whole knee biomechanics and designed and initiated our first studies on primary and secondary ligamentous restraints. We were fortunate to have David Butler join our group in late 1976 and complete the study in progress on ACL and PCL restraints, a study for which he later received the Kappa Delta Award.

In addition to working with excellent colleagues, I have been fortunate to work with many engineering students, orthopaedic residents, postdoctoral students, sports medicine fellows, and visiting professors. Without their combined intellectual contributions and hard work, I would not have been able to complete many of the studies that are included in this text. They all have my sincerest appreciation for their support and contributions.

Edward S. Grood, PhD
Director, Biomechanics Research
Cincinnati SportsMedicine Research and Education Foundation
Professor Emeritus, Department of Biomedical Engineering
Colleges of Medicine and Engineering
University of Cincinnati
Cincinnati, Ohio

FOREWORD

The 1970s saw the beginning of dramatic changes in the diagnosis and treatment of knee injuries. Frank Noyes has remained in the forefront of this revolution. Frank Noyes, MD, and Edward Grood, PhD, together with coworkers at the University of Cincinnati and later Cincinnati SportsMedicine and Orthopaedic Center, were the first to perform sophisticated biomechanical studies that changed the way we think about knee instabilities. They were the first to perform three-dimensional analysis of knee motions. They wrote the software that characterized the three axes of knee motion, about which each axis has a rotation and a translation. This concept is used today in all robotic and computerized programs on knee motion analysis.

Noyes and his coworkers studied normal and abnormal knee kinetics and kinematics, specifically anterior and posterior cruciate ligament graft placement sites and tension, as well as strengths of knee ligaments and replacement grafts; they then introduced the flexion-rotation drawer test. They also developed a logical classification of knee ligament injuries. Noyes has published more than 50 articles that have characterized the scientific basis of knee ligament function. His laboratory received a Kappa Delta Award for this research program.

In particular, Dr. Noyes has demanded evidence to support treatments and published the results of many prospective randomized control outcome studies. Dr. Noyes developed and validated the Cincinnati Knee Rating System, considered the gold standard for outcome studies today. He stressed the importance of postoperative rehabilitation and pioneered innovative rehabilitation techniques. Dr. Noyes developed the first program to show that neuromuscular conditioning could decrease the incidence of ACL injuries. This nonprofit program is the largest ACL injury prevention program in the world; it is active at more than 1500 sites in the United States, Europe, Asia, Australia, and elsewhere.

In 1980 the American Orthopaedic Society for Sports Medicine, acting on Dr. Noyes' proposal, created a Research Committee with Dr. Noyes as its Chairman for 10 years. He was appointed the to the National Institutes of Health (NIH) Arthritis Advisory Panel and paved the way for the NIH awarding its first grants in sports medicine.

In "The 100 Classic Papers of Orthopaedic Surgery," Dr. Noyes is listed twice.[1] Only two other orthopaedic surgeons have more citations, none in sports medicine. Several other studies show Dr. Noyes to have the highest number of citations in the published orthopaedic literature.[2-4] Dr. Frank Noyes can unquestionably be called the "father of scientific sports medicine."

In 2010, Dr. Noyes published the culmination of his 40 years of clinical and research experience: *Noyes' Knee Disorders: Surgery, Rehabilitation, and Clinical Outcomes.* He has now prepared an updated and expanded second edition. This new book contains 45 chapters written by 30 authors. The edition also comes with 45 videos lasting 11 hours and has new chapters on unicompartmental knee arthroplasty.

Recently, questions have been raised regarding when athletes may safely return to sports after major knee surgery. The rehabilitation chapters in this new second edition include a detailed progression of exercises and parameters to be met before patients may be released to unrestricted activities.

This edition also contains some of the most comprehensive and advanced chapters on knee arthrofibrosis, complex regional pain syndrome, tibial and femoral osteotomies, and posterolateral reconstructions available in current published literature.

It would be difficult to imagine how the first edition of *Noyes' Knee Disorders* could be made better. But Dr. Noyes has done just that in this new and enhanced second edition.

FOREWORD

I am honored to write this forward for *Noyes' Knee Disorders: Surgery, Rehabilitation, Clinical Outcomes* by Dr. Frank Noyes. I would not have thought that the first edition could have been enhanced, but it certainly was with this edition. My compliments to the editors and authors of this insightful and wonderful textbook. It is truly a wealth of knowledge in one package.

The objective of this book was to produce an all-inclusive text on the knee joint that would include a multidiscipline approach to the evaluation and treatment of knee disorders. The textbook was designed to provide both basic and clinical sciences to enhance the reader's knowledge of the knee joint.

The knee joint continues to be one of the most researched, written about, and talked about subjects in orthopaedics and sports medicine. Even with the extensive literature available, Dr. Noyes and Ms. Barber-Westin have done a masterful job pulling a tremendous amount of information together into over 1200 pages, with over 4600 references and nearly 1000 figures in one comprehensive textbook. There are numerous chapters on the anatomy and biomechanics of various knee structures. There are specific and detailed sections on the evaluation and treatment of specific knee lesions, including the anterior cruciate ligament (ACL), posterior cruciate ligament, articular cartilage, patellofemoral joint, the menisci, and other structures. There are numerous chapters on the rehabilitation for each of the various knee disorders, and even a section on the gender disparity in ACL injuries. Furthermore, there are thorough sections on clinical outcomes—a much-needed area for clinicians to understand and utilize.

I have had the true pleasure of knowing Dr. Noyes for over 25 years, and he has always practiced medicine using several principles. These include a scientific basis (evidence) to support his treatment approach, a team approach to treatment, meticulous surgery, and the attitude to always do what is best for the patient. He has applied these key principles into this outstanding textbook. Dr. Noyes has always been a proponent of a team approach to the evaluation and treatment of patients with knee disorders. This book illustrates this point beautifully, with chapters written by biomechanists, orthopaedic surgeons, and physical therapists. Furthermore, Dr. Noyes has always searched for the best treatments for the patient, seeking clinical evidence to support the treatment.

As they have done more than one hundred times before in published manuscripts and chapters, Dr. Noyes and Ms. Barber-Westin have teamed up to provide us with an outstanding reference book. This text will surely remain on every knee clinician's desk for a very long time. It should be read and studied by physicians, physical therapists, athletic trainers, students, and anyone involved in treating patients with knee disorders. This book will surely be a favorite for all practitioners.

This is a truly great contribution to the literature. Thank you, Dr. Noyes, for the guidance you have given and continue to give us.

MEDIAL ANATOMY OF THE KNEE

The medial anatomy of the knee consists of several layers of structures that work together to provide stability and function.[39,59-61] Authors have used a variety of anatomic terms and descriptions that, unfortunately, have created ambiguity and confusion regarding this area of the knee. Two anatomic classifications or descriptions have been proposed to aid in the understanding of the relationships of the medial knee structures. These include a layered approach,[57] which describes the qualitative relationship of each medial structure, and a more quantitative description,[35] which details the exact attachment site and origin of each structure. In this chapter, both approaches will be presented; however, emphasis is on the precise anatomic relationships that provide a more thorough understanding of the structures compared with the layer approach.

Medial Layers of the Knee

The three-layer description of the medial anatomy of the knee was proposed by Warren and Marshall.[57] In this approach, layer 1 consists of the deep fascia or crural fascia; layer 2 includes the superficial medial collateral ligament (SMCL), medial retinaculum, and the medial patellofemoral ligament (MPFL); and layer 3 is composed of the distal medial collateral ligament (DMCL) and capsule of the knee joint (Fig. 1-1). For this chapter, the term *medial collateral ligament* (MCL) has been used instead of tibial collateral ligament because it represents the term most commonly used in the English language literature. The medial structures identified as important in preventing lateral patellar subluxation are the MPFL[2,19,20] and the medial patellomeniscal ligament, which inserts onto the inferior third of the patella to the anterior portion of the medial meniscus and runs adjacent to the medial fat pad. The medial parapatellar retinaculum and so-called *medial patellotibial ligament* (thickening of the anterior capsule inserting from the inferior aspect of the patella to the anteromedial aspect of the tibia) are retinacular tissues that have been described; however, these structures are not believed important in providing patellar stability.

The layer approach is important because the ligaments and soft tissues on the medial side of the knee are not discrete, individual structures like the SMCL, but rather, fibrous condensations within tissue planes.[57] This qualitative description of anatomy assists in understanding the spatial relationships of these structures and how they function to support the knee.[63] It is equally important to understand the quantitative anatomy from precise measurements of the attachments and origins of each individual structure. The complex medial anatomy of the knee has been illustrated in the past with oversimplification of the soft tissue attachments to bone and other structures, which makes it difficult to compare the origins, insertions, and courses of the many separate structures among studies.[6,7,15,21,37,52,57] LaPrade and coworkers[35] published detailed quantitative measurements that provide a better understanding of the medial knee anatomy (Figs. 1-2 and 1-3).

Layer 1: Deep Fascia

Layer 1 (see Fig. 1-1) consists of the deep fascia that extends proximally to invest the quadriceps, posteriorly to invest the two heads of the gastrocnemius and cover the popliteal fossa, and distally to involve the sartorius muscle and sartorial fascia. Anteriorly, layer 1 blends with the anterior part of layer 2 approximately 2 cm anterior to the SMCL.[57] Inferiorly, the deep fascia continues as the investing fascia of the sartorius and attaches to the periosteum of the tibia. Layers 1 and 2 are always distinct at the level of the SMCL unless extensive scarring has occurred.[57] The gracilis and semitendinosus tendons are discrete structures that lie between layers 1 and 2 and are easily separated from these two layers. However, according to Warren and Marshall,[57] these tendons will occasionally blend with the fibers in layer 1 anteriorly before they insert onto the tibia. As depicted in Figure 1-4, dissections and clinical experience of the authors concur in that there is a blending of layer 1 with a confluence of the semitendinosus and gracilis tendons at their common insertion onto the tibia; however, they are easily

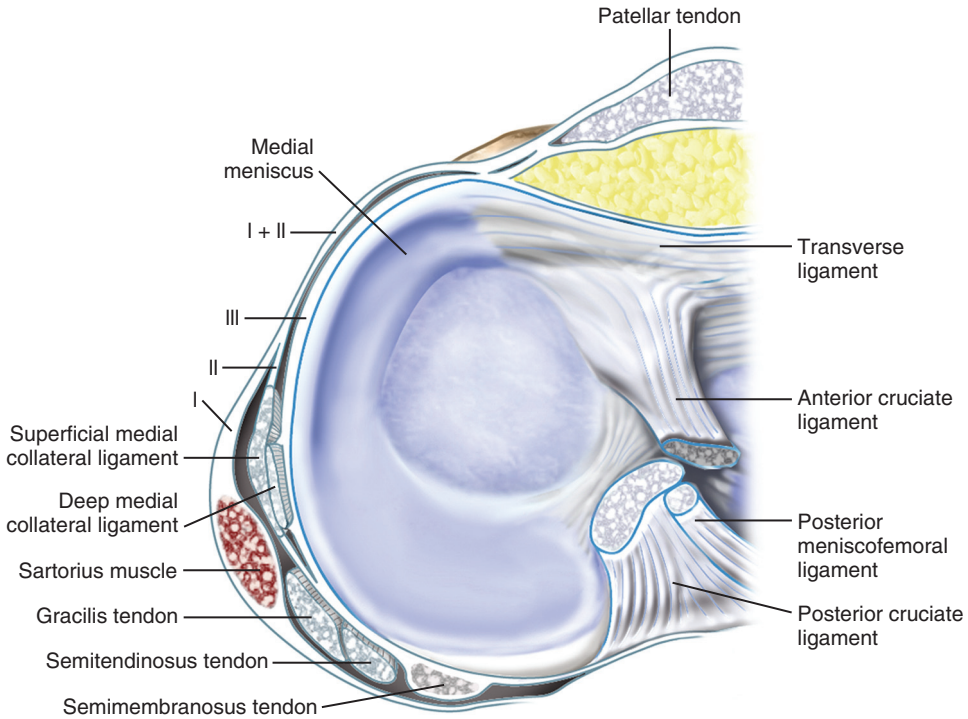

FIG 1-1 Medial layers of the knee. The gracilis and semitendinosus lie between layers 1 and 2.

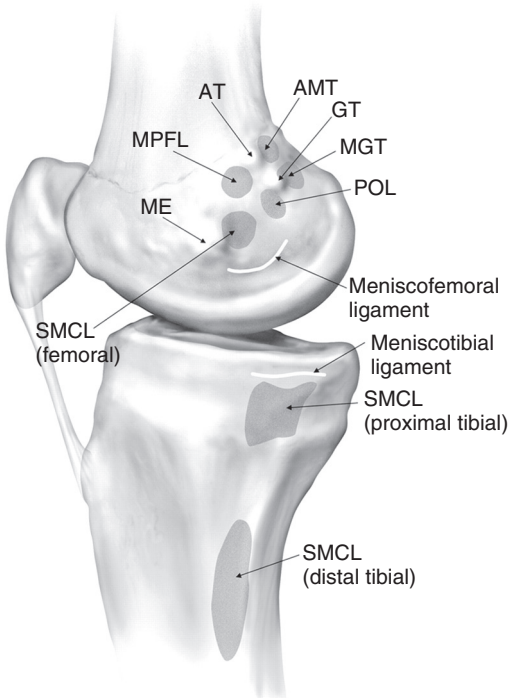

FIG 1-2 The femoral osseous landmarks and attachment sites of the main medial knee structures. *AT,* Adductor tubercle; *AMT*, adductor magnus tendon; *GT*, gastrocnemius tubercle; *ME*, medial epicondyle; *MGT*, medial gastrocnemius tendon; *MPFL*, medial patellofemoral ligament; *POL*, posterior oblique ligament; *SMCL*, superficial medial collateral ligament. (From LaPrade RF, Engebretsen AH, Ly TV, et al. The anatomy of the medial part of the knee. *J Bone Joint Surg.* 2007;89A:2000-2010.)

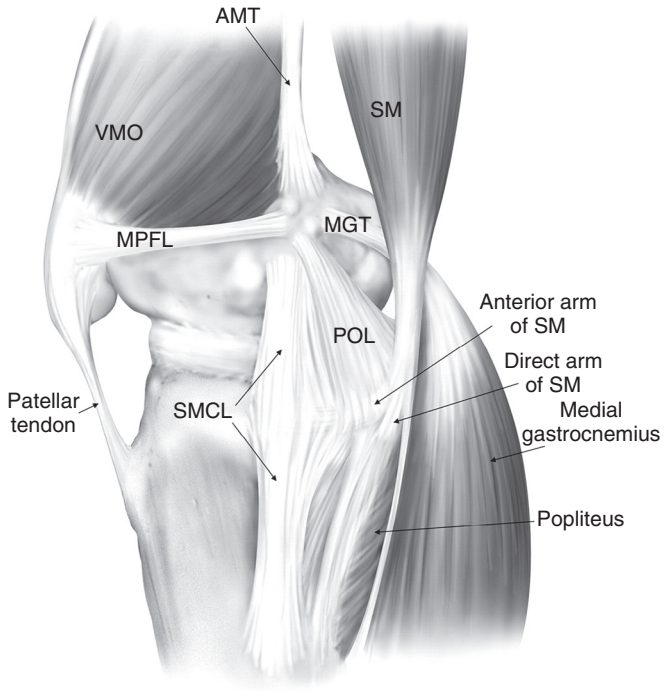

FIG 1-3 The main medial knee structures (right knee). *AMT*, Adductor magnus tendon; *MGT*, medial gastrocnemius tendon; *SM*, semimembranosus muscle; *SMCL*, superficial medial collateral ligament; *MPFL*, medial patellofemoral ligament; *POL*, posterior oblique ligament; *VMO*, vastus medialis obliquus. (From LaPrade RF, Engebretsen AH, Ly TV, et al. The anatomy of the medial part of the knee. *J Bone Joint Surg.* 2007;89A:2000-2010.)

found as discrete structures more posteriorly. Thus, we recommend that when attempting to harvest the semitendinosus and gracilis tendons for an anterior cruciate ligament reconstruction, these tendons initially be identified 2 to 3 cm posterior and medial to the anterior tibial spine. This will allow for easier visualization of the tendons, which can then be traced to their insertions on the anterior tibia to allow for maximal tendon length at the time of harvest.

Layer 2: Superficial Medial Collateral Ligament and Posterior Oblique Ligament

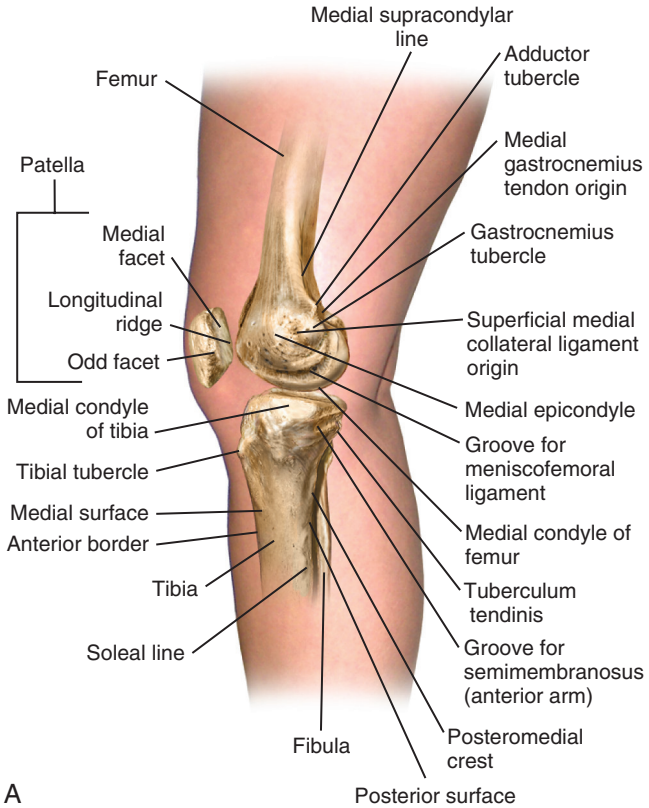
The SMCL is a well-defined structure that spans the medial joint line from the femur to tibia. According to LaPrade and coworkers,[35] the SMCL does not attach directly to the medial epicondyle of the femur, but is centered in a depression 4.8 mm posterior and 3.2 mm proximal to the medial epicondyle center. Other studies have described the MCL attaching directly to the medial epicondyle of the femur.[6,7,29,37,40,42,47,49,55,57] The confusion lies in the confluence of fibers that reside in the area of the medial epicondyle that make it difficult to identify the precise attachment site of the SMCL. As shown in Figure 1-5 the authors agree with LaPrade and coworkers[35] that the main fibers of the SMCL attach to an area just posterior and proximal to the medial epicondyle; but the origin of the SMCL is rather broad and, therefore, there are also superficial fibrous strands attaching anterior on the medial epicondyle and posterior in a depression on the medial femoral condyle.

The posterior fibers of the SMCL overlying the medial joint line, both above and below the joint, change orientation from vertical to a more oblique pattern that forms a triangular structure with its apex posterior,[7,37] eventually blending with the fibers of the posterior oblique ligament (POL) (Fig. 1-6). LaPrade and coworkers[35] described two anatomic attachment sites of the SMCL on the tibia. The first is located proximally at the medial joint line and consists mainly of soft tissue connections over the anterior arm of the semimembranosus. The second attachment site is further distal on the tibia, attaching directly to bone an average of 61.2 mm from the medial joint line. In the authors' experience, there is a consistent attachment of the proximal portion of the SMCL to the soft tissues surrounding the anterior arm of the semimembranosus, but a discrete attachment to bone is found only distally (see Fig. 1-6).

The gracilis and semitendinosus lie between layers 1 and 2 at the knee joint. The sartorius drapes across the anterior thigh and into the medial aspect of the knee invested in the sartorial fascia in layer 1. The insertion of the sartorius, as described by Warren and Marshall,[57] consists of a network of fascial fibers connecting to bone on the medial side of the tibia, but does not appear to have a distinct tendon of insertion such as the underlying gracilis and semitendinosus. However, LaPrade and coworkers[35] located the gracilis and semitendinosus tendons on the deep surface of the superficial fascial layer, with each of the three tendons attaching in a linear orientation at the lateral edge of the pes anserine bursa.

In our experience, the sartorial fascia has a broad insertion onto the anteromedial border of the tibia and, with sharp dissection at its insertion, the underlying distinct tendons of the gracilis and semitendinosus are easily visualized (see Fig. 1-4). At the level of the joint, layers 1 and 2 are easily separated from one another over the SMCL. However, farther anteriorly, layer 1 blends with the anterior part of layer 2 along a vertical line 1 to 2 cm anterior to the SMCL.[57]

Also within layer 2 is the MPFL, which courses from the medial femoral condyle to its attachment onto the medial border of the patella.[5,44,51] This is a flat, fan-shaped structure that is larger at its



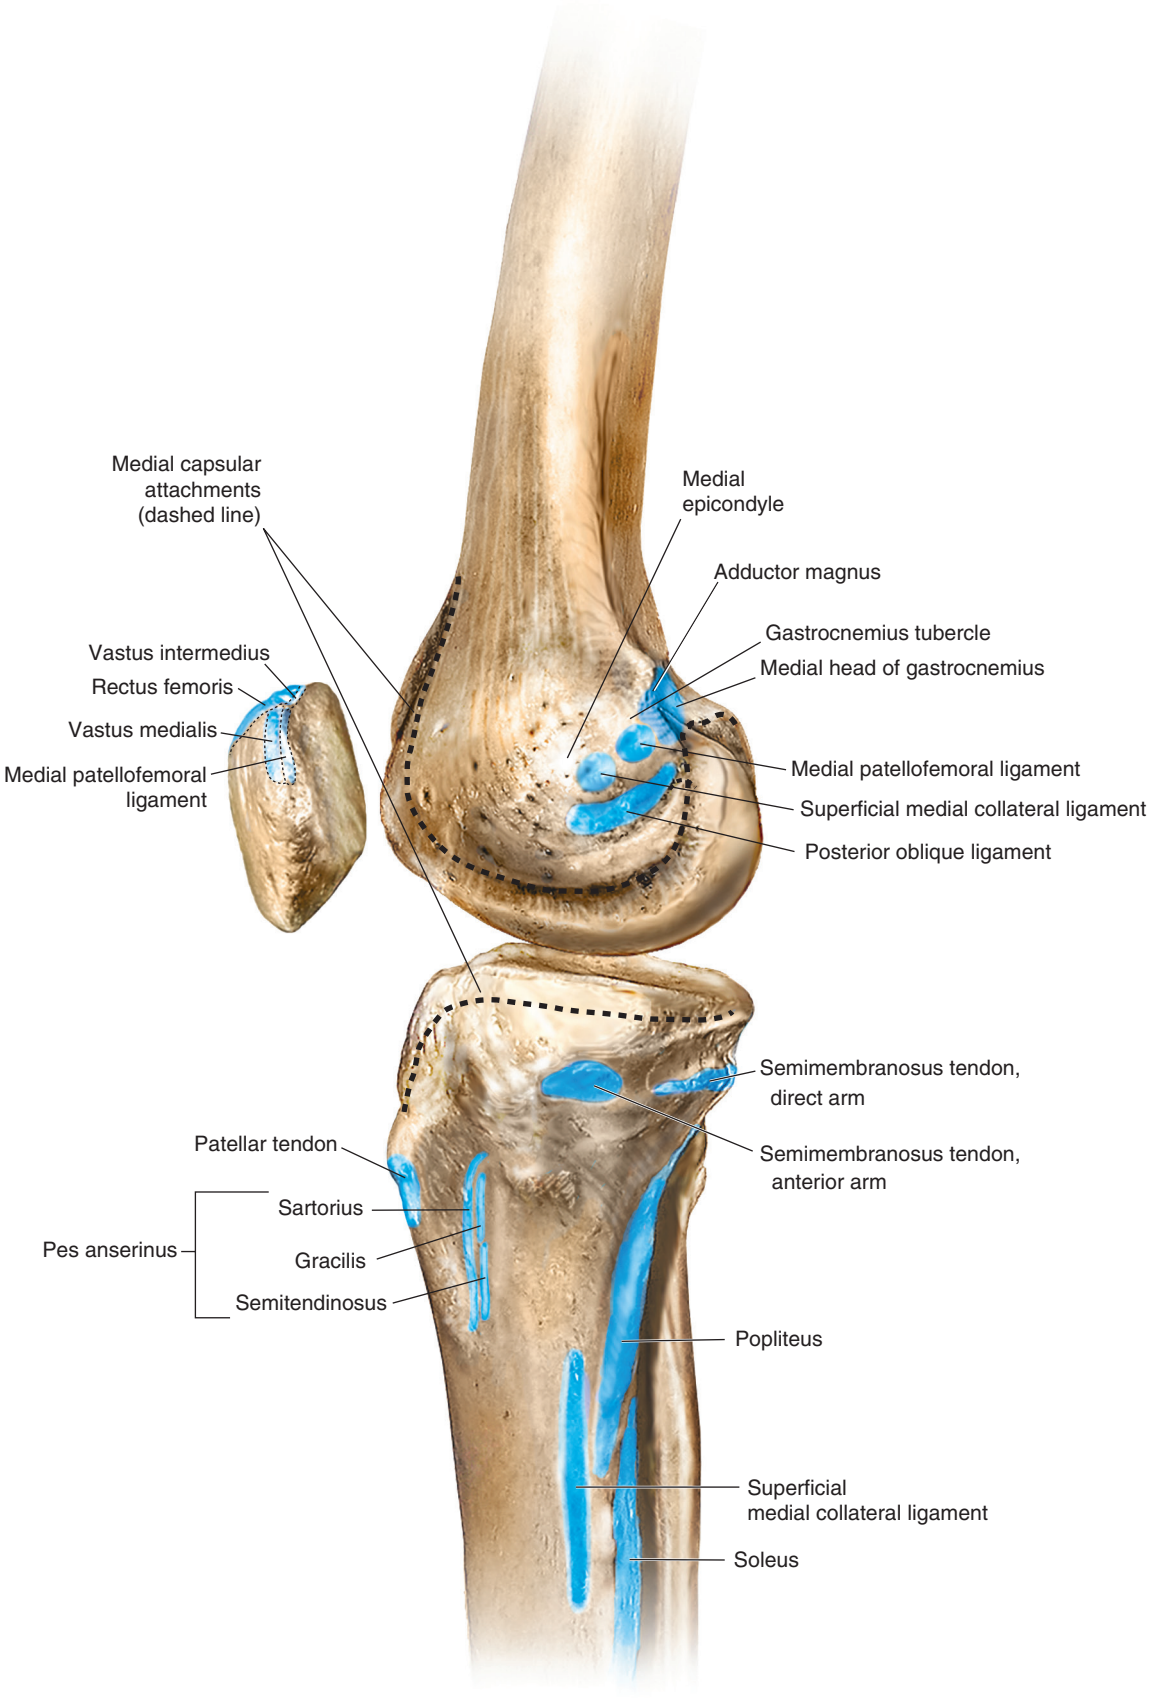


FIG 1-5 A, Osseous landmarks of knee (medial view). *Continued*

B Medial Knee Attachments

FIG 1-5, cont'd B, Soft tissue attachments to bone (medial knee).

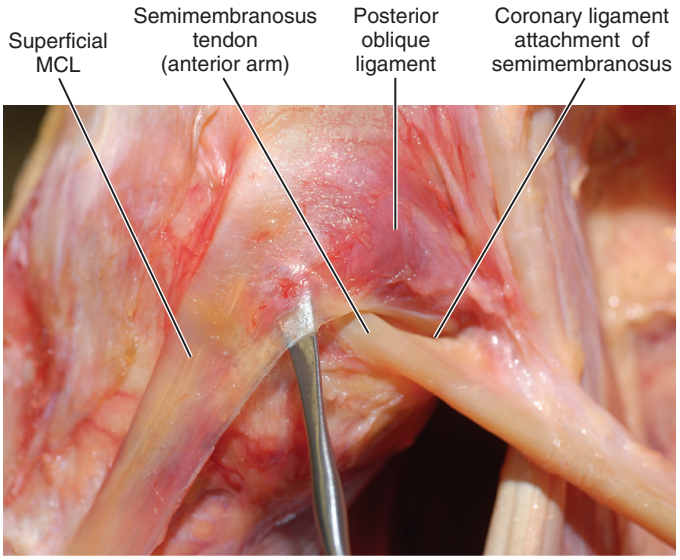

FIG 1-6 Oblique fibers of superficial medial collateral ligament (MCL) blending with the posterior oblique ligament. Note the coronary ligament attachment from the anterior arm of the semimembranosus.

patellar attachment than its femoral origin, with a length averaging 58.3 mm (47.2-70.0 mm).[48] Controversy exists regarding where the MPFL attaches at the medial femoral condyle. Mochizuki and coworkers[41] described the MPFL as a fan-shaped structure with proximal fibers extending to the medial margin of the vastus intermedius, and distal fibers interdigitating with the medial retinaculum without a distinct attachment to the vastus medialis. LaPrade and coworkers[35] noted that the MPFL attaches primarily to soft tissues between the attachments of the adductor magnus tendon and the SMCL, with an attachment to bone 10.6 mm proximal and 8.8 mm posterior to the medial epicondyle. Steensen and associates,[50] from a dissection of 11 knees, believe the MPFL attaches along the entire length of the anterior aspect of the medial epicondyle. Smirk and Morris[48] describe a variable origination of the MPFL on the femur. In dissections of 25 cadavers, the MPFL attached solely to the posterior aspect of the medial epicondyle, approximately 1 cm distal to the adductor tubercle in 44% of specimens. The adductor tubercle was included in the origin in 4%, the adductor magnus tendon in 12%, the area posterior to the adductor magnus tendon in 20%, and a combination of these in 4%. In 16% of the specimens, the MPFL attached anterior to the medial epicondyle. Fulkerson and Edgar[16] described a distinct attachment of the MPFL to the medial quadriceps tendon and named this structure the medial quadriceps tendon–femoral ligament. Kang and associates[30] described the femoral attachment point for MPFL fibers as two "relatively concentrated fiber bundles." The authors identified an "inferior straight" bundle (what is commonly referred to as the *MPFL*) that was the main static soft tissue restraint. The superior-oblique bundle was attached and associated with the vastus medialis obliquus (VMO) and was identified as a dynamic soft tissue restraint. The authors acknowledged that the two bundles were not entirely separable.

In our experience, the MPFL attaches in a depression posterior to the medial epicondyle and blends with the insertion of the SMCL (Fig. 1-7). The anterior attachment of the MPFL consists of both attachments to the undersurface of the VMO and the proximal medial border of the patella. The work of Steensen and associates[50] demonstrated that the VMO does not overlap the MPFL, with the exception in 3 of 11 knees in which only 5% of the width of the MPFL was deep to the VMO. However, LaPrade and coworkers[35] reported that the distal border of the VMO attaches along the majority of the proximal edge of the MPFL before inserting onto the superomedial border of the patella. The midpoint of the MPFL attachment is located 41% of the length from the proximal tip of the patella along the total patellar length. Our experience is that the MPFL attaches to the proximal third of the patella, with the majority of the ligament connected to the distal portion of the VMO with fibrous bands (see Fig. 1-7).

The adductor magnus and medial gastrocnemius tendons also contribute to the medial anatomy of the knee; both attach on the medial femoral condyle. Similar to the SMCL attachment, the confluence of fibers over the medial femoral condyle makes it difficult to precisely identify the exact location of each attachment (Fig. 1-8). The adductor magnus tendon is a well-defined structure attaching just superior and posterior to the medial epicondyle near the adductor tubercle. LaPrade and coworkers[35] reported the adductor magnus does not attach directly to the adductor tubercle, but rather to a depression located an average of 3.0 mm posterior and 2.7 mm proximal to the adductor tubercle. The adductor magnus also has fascial attachments to the capsular portion of the POL and medial head of the gastrocnemius.

The medial gastrocnemius tendon inserts in a confluence of fibers in an area between the adductor magnus insertion and the insertion of the SMCL (Fig. 1-9 *A*). LaPrade and coworkers[35] described a gastrocnemius tubercle on the medial femoral condyle in this region; however, these authors state that the tendon does not attach to the tubercle, but to a depression just proximal and posterior to the tubercle. In addition, fascial expansions from the lateral aspect of the medial gastrocnemius tendon form a confluence of fibers with the distal extent of the adductor magnus tendon in addition to the capsular arm of the POL (see Fig. 1-9 *A*).

Layers 2 and 3 blend together in the posteromedial corner of the knee along with additional fibers that extend from the semimembranosus tendon and sheath that form the posteromedial capsule (see Fig. 1-9). LaPrade and coworkers[35,62] used the term *posterior oblique ligament* (POL) for this same structure and described each of the three fascial attachments similar to Hughston and colleagues' original description.[27,28] The superficial arm of the POL runs parallel to both the more anterior SMCL and the more posterior distal expansion of the semimembranosus. Proximally, the superficial arm blends with the central arm; distally, it blends with the distal expansion of the semimembranosus as it attaches to the tibia.[35]

The central arm is the largest and thickest portion of the POL,[35] running posterior to both the superficial arm of the POL and SMCL. It courses from the distal portion of the semimembranosus and is a fascial reinforcement of the meniscofemoral and meniscotibial portions of the posteromedial capsule. LaPrade and coworkers[35] noted that this structure has a thick attachment to the medial meniscus. As the central arm courses along the posteromedial aspect of the joint, it merges with the posterior fibers of the SMCL and can be differentiated from the SMCL by the different directions of the individual fibers. The distal attachment of the central arm is primarily to the posteromedial portion of the medial meniscus, the meniscotibial portion of the capsule, and the posteromedial tibia.[35]

The capsular portion of the POL is thinner than the other portions of this structure and fans out in the space between the central arm and the distal portions of the semimembranosus tendon. The capsular portion blends posteriorly with the posteromedial capsule of the knee and the medial aspect of the oblique popliteal ligament (OPL).[35] It attaches proximally to the fibrous bands of the medial gastrocnemius tendon and fascial expansions of the adductor magnus tendon, with no osseous attachment identified.

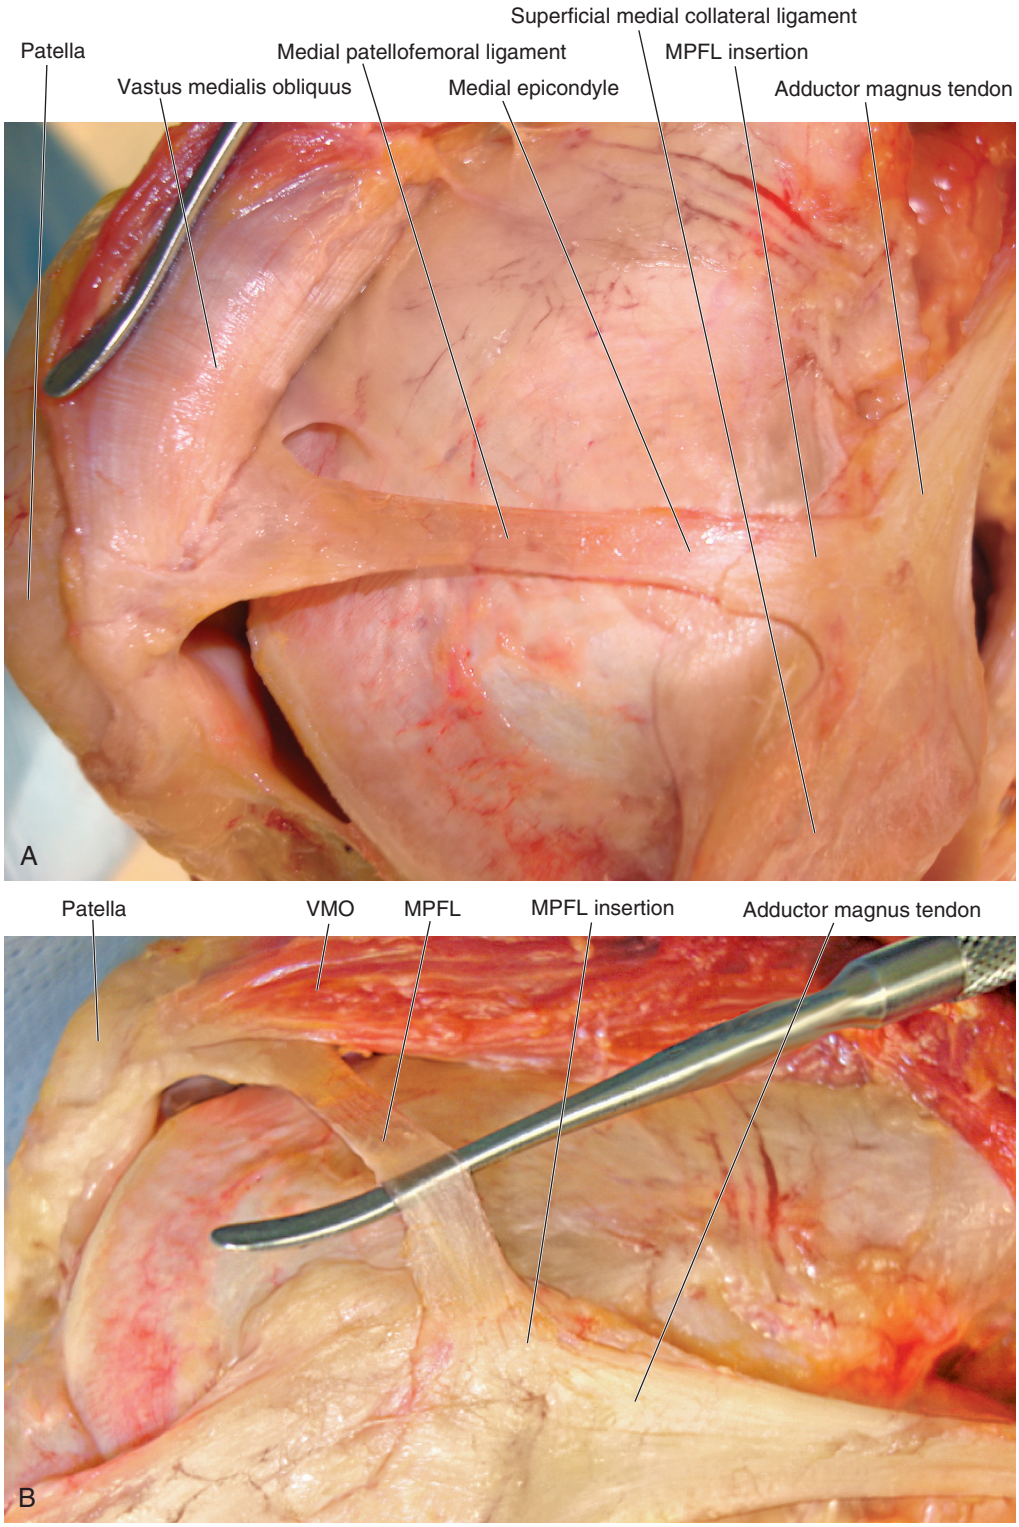

FIG 1-7 **A,** Medial patellofemoral ligament (MPFL) inserts into a depression behind the medial epicondyle and blends with fibers of the superficial medial collateral ligament. **B,** Fibrous bands from the vastus medialis obliquus (VMO) muscle connect to the MPFL before it inserts into the patella.

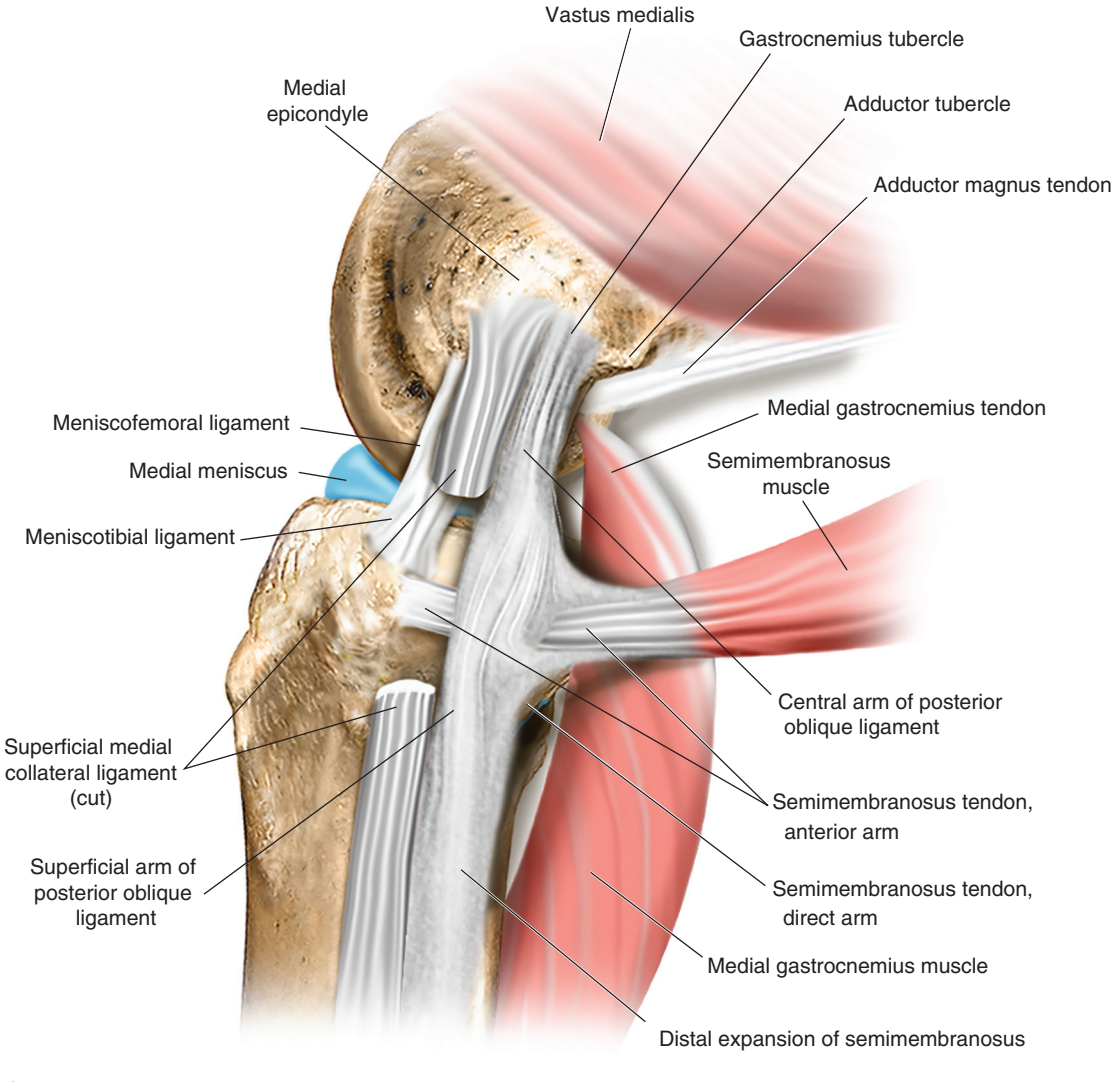

FIG 1-8 A, Insertions onto the medial femoral condyle of the adductor magnus, medial head of gastrocnemius, and the posterior oblique ligament with its three divisions: capsular, central, and superficial arms. **B,** Osseous anatomy of the medial femoral condyle with the medial epicondyle, adductor tubercle, and gastrocnemius tubercle.

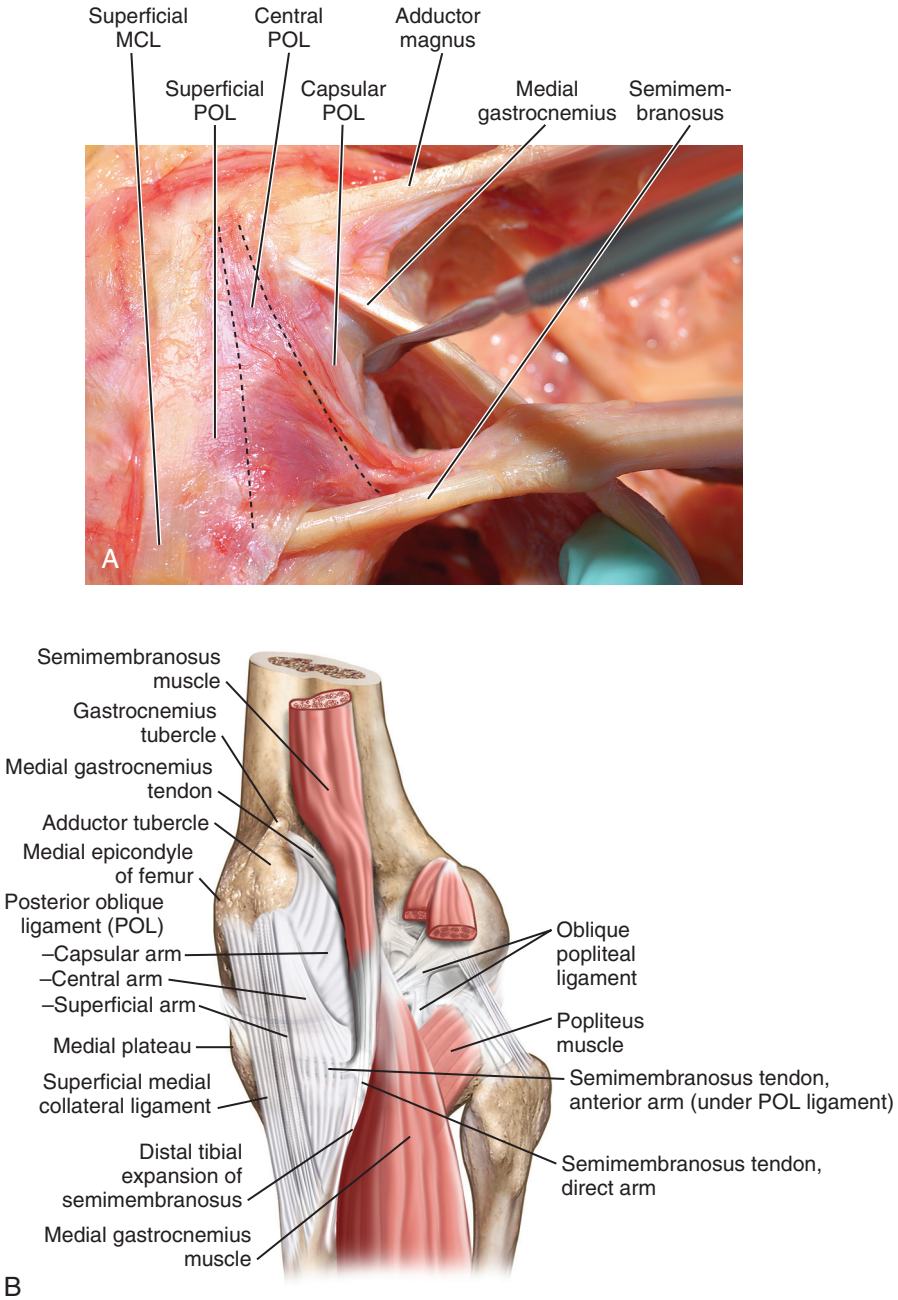

FIG 1-9 **A,** Insertions onto the medial femoral condyle of the adductor magnus, medial head of gastrocnemius, and posterior oblique ligament (POL) with its three divisions: capsular, central, and superficial arms. **B,** Anatomy of the POL with its three divisions. *MCL,* Medial collateral ligament.

The superficial portion of the POL is rather thin and appears to represent a confluence of fibers from the SMCL and the semimembranosus more distally. The capsular portion appears to represent a confluence of fibers from the semimembranosus, adductor magnus, and medial gastrocnemius (see Fig. 1-9). The central arm appears more robust, having contributions from the semimembranosus and medial gastrocnemius.

Controversy remains on whether three separate distinct anatomic structures make up the POL. Other authors[46] have not found three distinct structures and note that with tibial rotation, different portions of the posteromedial capsule appear under tension but are not anatomically separate structures.

Semimembranosus. Controversy exists with respect to the exact number of attachments of the semimembranosus tendon at the knee joint.[8,9,11,28,31,33,34,43,57] However, it appears that three major attachments have been consistently identified. The common semimembranosus tendon bifurcates into a direct and anterior arm just distal to the joint line. LaPrade and coworkers[35,36] described the direct arm attaching to an osseous prominence called the *tuberculum tendinis*, approximately 11 mm distal to the joint line on the posteromedial aspect of the tibia. These authors also note a minor attachment of the direct arm that extends to the medial coronary ligament along the posterior horn of the medial meniscus (see Fig. 1-6). A thinning of the capsule or capsular defect may be identified just distal to the femoral attachment of

the medial head of the gastrocnemius and proximal to the direct arm of the semimembranosus. This is often the site of the formation of a Baker cyst.

Warren and Marshall[57] believed the semimembranosus tendon sheath and not the tendon itself extends distally over the popliteus muscle and inserts directly into the posteromedial aspect of the tibia, with some fibers coalescing with SMCL fibers inserting in the same region. These authors contend that these fibers do not have functional significance, because no change was found in position or tension of the MCL when those fibers were transected. LaPrade and associates[36] separated the distal tibial expansion into a medial and lateral division. Both divisions originating on the coronary ligament of the posterior horn of the medial meniscus are located on either side of the direct arm of the semimembranosus. The divisions then course distally to cover the posterior aspect of the popliteus muscle and insert onto the posteromedial aspect of the tibia, forming an inverted triangle in appearance. These authors noted the medial division attaches just posterior to the SMCL, whose fibers coalesce with the superficial arm of the POL (as previously noted by Hughston and colleagues[28]) rather than the MCL.

In our experience, as shown in Figure 1-10, the semimembranosus tendon sheath and not the tendon itself comprises the distal tibial expansion, which includes a medial and lateral division with a central raphae separating the two. The anterior arm of the semimembranosus courses deep to the SMCL and attaches directly to bone just distal to the medial joint capsule on the tibia (Fig. 1-11). There are fibrous connections between the SMCL and the anterior arm of the semimembranosus, but only the anterior arm of the semimembranosus has an osseous attachment in this region. Because both the direct and anterior arms of the semimembranosus anchor directly to bone and attach distal to the tibial margin of the medial joint capsule, they are not considered part of either layer 2 or layer 3 as described by Warren and Marshall.[57]

The third major attachment of the semimembranosus is the OPL. Warren and Marshall[57] described the semimembranosus tendon sheath forming fiber tracts that make up the OPL, although they admit some collagen fibers may come from the tendon itself. LaPrade and associates[36] described a lateral expansion off the common semimembranosus tendon, just proximal to its bifurcation into the direct and anterior arms, that coalesces to form a portion of the OPL, in addition to the capsular arm of the POL. As shown in Figure 1-12, it is difficult to appreciate distinct structures comprising the origin of the OPL because of the significant confluence of fibers in the region. However, there are fibers originating from both the semimembranosus tendon and its sheath that contribute to its origin.

The OPL is described as a broad fascial band that courses laterally and proximally across the posterior capsule. LaPrade and associates[36] noted two distinct lateral attachments of the OPL (proximal and distal). The proximal attachment is broad, extending to the fabella, the posterolateral capsule, and the plantaris (see Fig. 1-12). It does not attach directly to the lateral femoral condyle. The distal attachment is on the posterolateral aspect of the tibia, just distal to the posterior root of the lateral meniscus, but not directly attaching to the lateral meniscus as described by Kim and coworkers.[34] It is theorized that this may serve a functional role limiting hyperextension, but this has not been demonstrated in any biomechanic study to date.

LaPrade and associates[36] also described a proximal capsular arm of the semimembranosus as a thin aponeurosis that traverses medially to laterally along the superior border of the OPL. As it courses laterally, it blends with the posterolateral capsule and inserts on the distal lateral femur just proximal to the capsular insertion while at the same time extending fibers to the short head of the biceps femoris tendon (see Fig. 1-12 *B* and *C*).

Layer 3: Deep Medial Collateral Ligament and Knee Capsule

The capsule of the knee joint is thin anteriorly and envelops the fat pad. In this area, the capsule is easily separated from the overlying superficial retinaculum until it reaches the margin of the patella, where it is difficult to separate the capsule from the overlying superficial

structures.[57] Under the SMCL lies a vertical thickening of the knee capsule known as the *distal medial collateral ligament* (DMCL). The DMCL crosses the joint from the distal femur to the medial meniscus and inserts into the proximal tibia at sites adjacent to the articular surfaces of the femur and tibia. These separate divisions of the DMCL are named the *meniscofemoral* and *meniscotibial* ligaments. Warren and Marshall[57] noted the meniscofemoral portion of the DMCL had a discrete attachment onto the distal femur at its articular margin. Similarly, the meniscotibial portion of the DMCL, also known as the *coronary ligament*, is easily separated from the overlying SMCL in layer 2 before attaching to the tibia at its articular margin (Fig. 1-13).

The deepest structure on the medial side is the capsule of the knee, which envelops the entire joint and extends proximally up to the suprapatellar pouch and distally to the attachment site of the meniscotibial ligament on the tibia-articular cartilage border.[57]

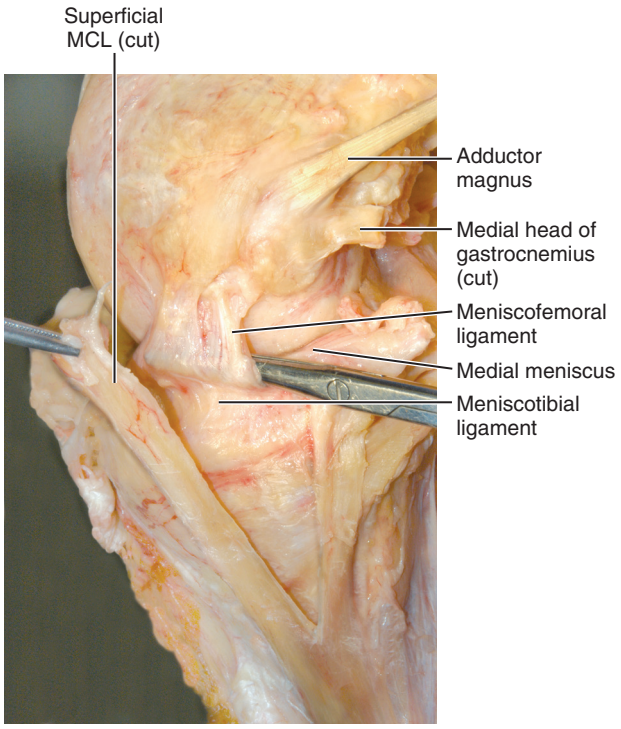

FIG 1-13 Superficial medial collateral ligament (MCL) cut to show deep medial collateral ligament with its two divisions: meniscofemoral and meniscotibial.

ANTERIOR ANATOMY OF THE KNEE

Several anatomic relationships and structures are important to recognize because they are critical to understanding the mechanics of the extensor mechanism and may be involved in several pathologic conditions.

Quadriceps Mechanism

The quadriceps consists of the rectus femoris, adjacent to the vastus medialis and lateralis on either side, and the vastus intermedius deep (Fig. 1-14). The rectus femoris is located centrally and superficially in the quadriceps mechanism and widens distally as is approaches the superior aspect of the patella. Reider and colleagues[45] found the width of the rectus femoris tendon to be 3 to 5 cm at the proximal pole of

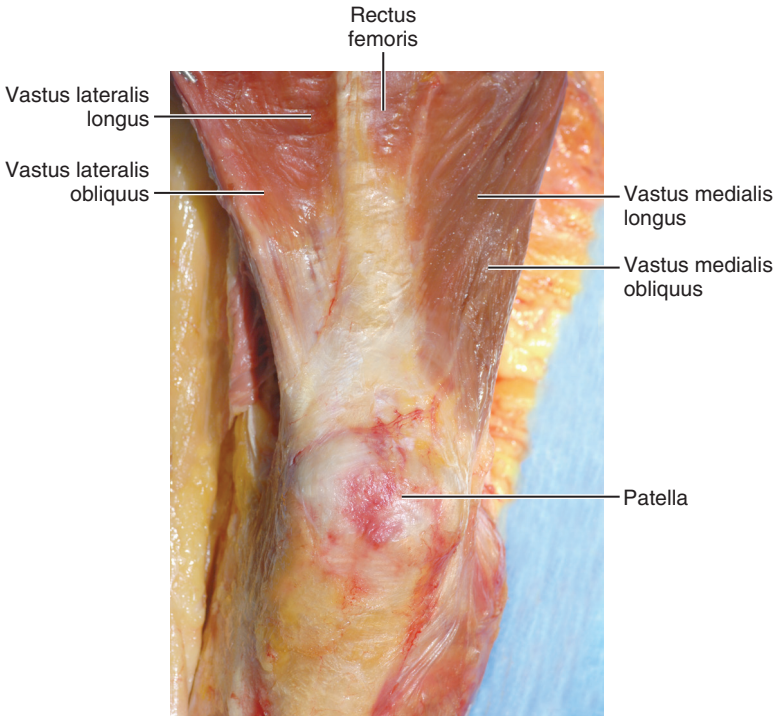

FIG 1-14 Extensor mechanism of knee showing the vastus lateralis, vastus medialis, and rectus femoris. Note the long tendon insertion of the vastus lateralis onto the proximal patella.

the patella. Some of the rectus tendon fibers insert into the superior aspect of the patella, but the majority continue over the anterior surface of the patella and are continuous with the patellar tendon distally. This is in contrast to the other components of the quadriceps mechanism that do not commonly contribute directly to the patellar tendon. The vastus medialis has fibers that run parallel to the rectus femoris fibers, called the *vastus medialis longus*, and others that run obliquely in relation to the rectus, termed the *vastus medialis obliquus* (VMO) according to Lieb and Perry.[38] Conlan and coworkers[10] described the VMO originating from the medial intermuscular septum and the adductor longus tendon proximal to the adductor tubercle. The angle of the obliquity of the VMO fibers varies considerably. Reider and colleagues[45] found a range of 55 degrees to 70 degrees in a cadaveric study. This variability in obliquity has been implicated in patellar maltracking.

The muscle of the vastus medialis extends distally and often becomes tendinous only millimeters from its patellar insertion. Reider and colleagues[45] noted some fibers insert directly into the patella, whereas others course more distally and contribute to the medial retinaculum. Conlan and coworkers[10] contended that some fibers of the VMO extend more distally and actually contribute to the patellar tendon. As shown in Figure 1-14, the vast majority of the VMO fibers either attach directly onto the patella or extend more distally to make up the medial retinaculum. The most medial fibers of the medial retinaculum converge into the medial border of the patellar tendon, but do not provide a significant contribution to the patellar tendon fibers.

The vastus lateralis muscle is divided similarly to the vastus medialis with a longus and obliquus portion. The insertions of the longus and obliquus tendons are quite variable according to Hallisey and associates.[22] These authors contended that the amount of vastus lateralis tendon that travels over the anterior cortex of the patella and contributes to the patellar tendon distally is variable. In some cases, the lateralis tendon fibers remain lateral to the patella and interdigitate with the fibers of the iliopatellar tract without contributing to the patellar tendon (Fig. 1-15). The insertion of the obliquus fibers is also variable according to Hallisey and associates.[22] These authors found that in some specimens, the obliquus tendon fibers insert into the vastus lateralis longus fibers proximal to the patella; in others, they blend into the iliopatellar tract before inserting on the patella. As shown in Figure 1-15, it is our experience that the most medial fibers of the lateralis obliquus tend to coalesce with the fibers of the longus, whereas the most lateral obliquus fibers coalesce with the iliopatellar tract. The vastus lateralis does not provide a significant contribution to the patellar tendon.

The fibers of the lateralis run more parallel to the rectus femoris fibers than the vastus medialis (see Fig. 1-14). The average obliquity of the lateralis fibers is 31 degrees according to Reider and colleagues.[45] The lateralis fibers also become tendinous more proximally than the medialis, an average of 2.8 cm proximal to the patella.[45] The angle of insertion of the obliquus fibers is rather variable, with an average of 48.5 degrees in men and 38.5 degrees in women.[30]

The vastus intermedius is deep to the rectus femoris, inserts directly into the proximal pole of the patella, and blends with the fibers of the medialis and lateralis that insert in similar fashion. Previous descriptions of the quadriceps tendon insertion depict a trilaminar arrangement of fibers, with the rectus femoris contributing the most superficial fibers, the medialis and lateralis contributing the middle layer, and finally, the intermedius contributing the deepest fibers. Reider and colleagues[45] described the inserting fibers as more of a coalescence rather than distinct layers as previously described. It is our experience that the quadriceps tendon is a coalescence of fibers at the proximal pole of the patella, but as one travels a few centimeters proximal, four distinct layers to the quadriceps tendon can be identified and separated from one another (Fig. 1-16). When harvesting a quadriceps tendon graft, it is important that all layers are identified.

Fascial Layers

Confusion arises when attempting to describe the various layers of the anterior knee structures because different nomenclature is used for

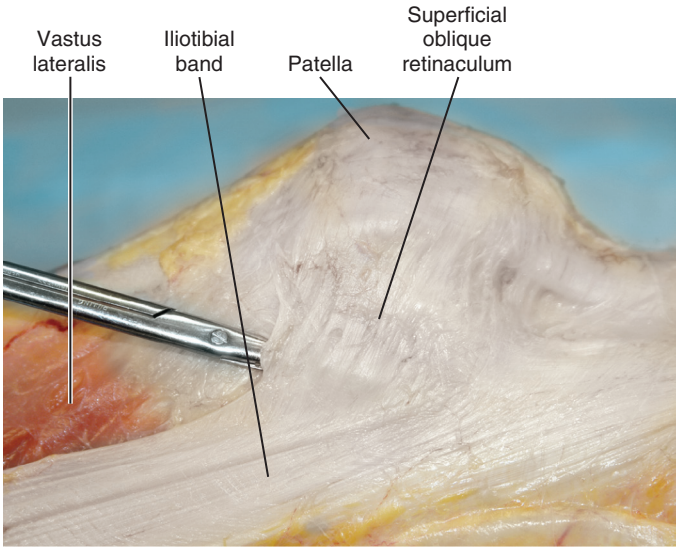

FIG 1-15 Longitudinal fibers of the vastus lateralis blend with fibers of the superficial oblique retinaculum.

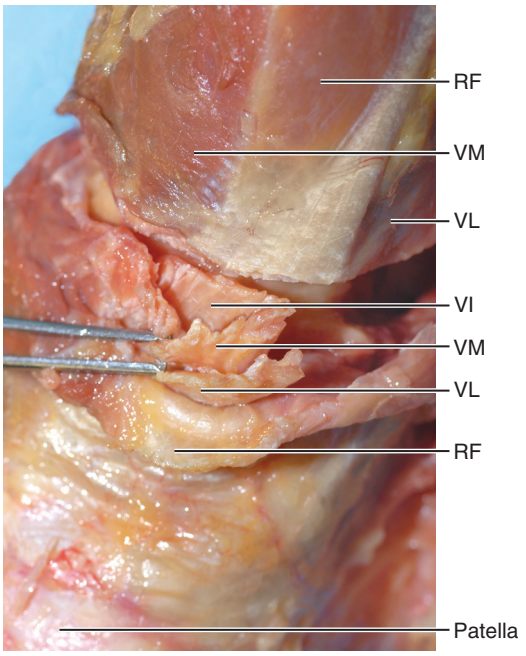

FIG 1-16 Each division of the quadriceps mechanism is dissected proximal to patella. *RF*, Rectus femoris; *VI*, vastus intermedius; *VL*, vastus lateralis; *VM*, vastus medialis.

both the medial and lateral parapatellar tissues. This description will break down the layers both medially and laterally and then attempt to assimilate each as they form a confluence over the anterior aspect of the patella.

Lateral

The most superficial layer laterally, termed the *aponeurotic layer* by Terry and colleagues,[54] is composed of the superficial fascia of the vastus lateralis and biceps femoris. These fibers, termed *arciform fibers*, travel transversely across the anterior aspect of the patella to blend at the midline with the superficial fascia of the sartorius, which begins medially.

The next layer is termed the *superficial layer* by Terry and colleagues.[54] It is made up of the iliopatellar tract, which connects the iliotibial band to the patella.[17,56] The iliopatellar tract has been further subdivided into a superficial and deep layer by Fulkerson and Gossling,[17] who describe two different fiber orientations. The most superficial is termed the *superficial oblique retinaculum* because its fiber orientation is oblique. This tract inserts along the lateral border of the patella (see Fig. 1-15). In addition, there are deep transverse fibers that also connect the iliotibial band with the lateral aspect of the patella (Fig. 1-17). In this deeper, more transverse tract is the patellotibial ligament, which originates just proximal to Gerdy's tubercle on the tibia and inserts on the inferior portion of the lateral aspect of the patella.[17] Just deep to this ligament is the lateral meniscopatellar ligament, which runs between the anterior horn of the lateral meniscus and the inferior aspect of the patella. It is a thickening of the anterolateral capsule. The deepest layer on the lateral side is the capsular-osseous layer, which anchors the iliotibial band to the femur through the lateral intermuscular septum and travels anteriorly to the patella. Some authors[32,54,56] contend that it includes the lateral patellofemoral ligament, but our experience is that a distinct ligament is not present.

As shown in Figure 1-18, the capsular-osseous layer of the iliotibial tract has a femoral attachment proximal to the lateral epicondyle. At the level of the lateral epicondyle is a bursa deep to the iliotibial tract. It is our experience that there commonly is an identifiable nerve, which is named the *lateral retinacular nerve*, within this bursa that may play a role in pain associated with runner's knee. During an iliotibial tract lengthening procedure for recalcitrant runner's knee, we believe that while the iliotibial bursa is excised, the lateral retinacular nerve should be identified and cut posterior to the lateral epicondyle to prevent recurrence of this painful condition.

Medial

The superficial fascia of the vastus medialis and sartorius form the most superficial layer medially. This aponeurotic layer travels laterally over the anterior aspect of the patella to merge with the same layer from the lateral side.

The next layer is considered to be the same as layer 2 as described by Warren and Marshall.[57] This is composed of the MPFL and SMCL. In this layer is the medial retinaculum, which is defined as the VMO fibers running transversely from the anterior border of the SMCL to the medial aspect of the patella. The medial patellotibial ligament is also found in this middle layer (Fig. 1-19). According to Conlan and coworkers,[10] it originates on the inferior portion of the medial aspect of the patella and travels distally and posteriorly to insert on the anteromedial aspect of the tibia. The deepest structure found on the anteromedial aspect of the knee is the medial meniscopatellar ligament, which is a thickening of the capsule that runs between the anterior horn of the medial meniscus and the inferior portion of the medial border of the patella (Fig. 1-20).[10]

Prepatellar

The fascial layer covering the quadriceps is termed the *fascia lata*. Dye and coworkers[14] note that the fascia lata extends distally as the most superficial layer overlying the patella after the skin and subcutaneous tissue. These authors describe the fascia lata as an extremely thin layer with little structural integrity but visible transverse fiber orientation. This is in contrast to the intermediate layer overlying the patella, which has an oblique fiber orientation proximally and becomes more transverse distally over the patellar tendon. Dye and coworkers[14] described the intermediate layer consisting of tendinous fibers from the vastus medialis and lateralis, in addition to the superficial fibers of the rectus femoris that extend over the anterior aspect of the patella.

The deepest layer anterior to the patella is composed of the deeper fibers of the rectus femoris that extend distal to the proximal pole of the patella and are intimately associated with the anterior cortex of the patella as they continue to contribute to the fibers of the patellar tendon (Fig. 1-21).

Dye and coworkers[14] noted these layers form three separate bursae superficial to the patella. The most superficial is termed the *prepatellar subcutaneous bursa* (between the skin and superficial fascia lata). The middle bursa is termed the *prepatellar subfascial bursa* (between the superficial fascia lata and the oblique intermediate layer). Finally, the deepest bursa is called the *prepatellar subaponeurotic bursa* (between the intermediate and deep aponeurotic layers). It should be noted that no bursa exists between the deepest aponeurotic layer and the anterior cortex of the patella, as others have suggested.[1]

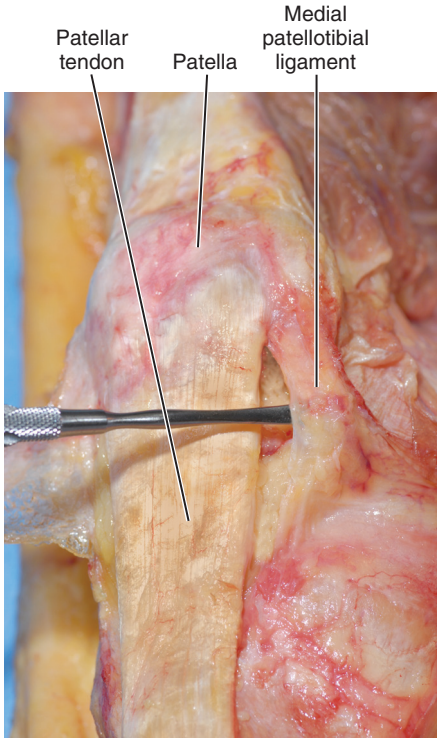

FIG 1-19 The medial patellotibial ligament is adjacent to the patellar tendon.

Patella

The patella is a sesamoid bone deeply associated with the quadriceps tendon, as previously described (Fig. 1-22). The articular surface of the patella is often divided into facets based on longitudinal ridges. The major longitudinal ridge divides the medial and lateral facets of the patella. A second longitudinal ridge near the medial border of the patella separates the medial facet from a thin strip of articular surface known as the *odd facet* (see Fig. 1-20). Wiberg[58] classified the morphology of patellae into three major types based on the position of the longitudinal ridges. Type I patellae have medial and lateral facets that are equal in size. Type II patellae have a medial facet slightly smaller than the lateral facet. Type III patellae have a very small and steeply angled medial facet, whereas the lateral facet is broad and concave. According to Dye and coworkers,[14] type II patellae are the most common (present in 57% of knees) followed by type I (24%) and type III (19%).

Patellar Tendon

The patellar tendon courses between the inferior pole of the patella and the tibial tubercle (see Fig. 1-19). This tendon consists mostly of fibers from the rectus femoris, as previously mentioned. The structure inserts on the proximal tibia, just distal to the most proximal portion of the tibial tubercle. It blends medially and laterally with the fascial expansions of the anterior surface of the tibia and the iliotibial band. Dye and coworkers[14] reported an average length of 46 mm, with a range of 35 to 55 mm.

Infrapatellar Fat Pad

The infrapatellar fat pad is an intracapsular, but extrasynovial structure; the deepest portion is covered by a synovial layer. This structure has been consistently identified to have a thick central body, with

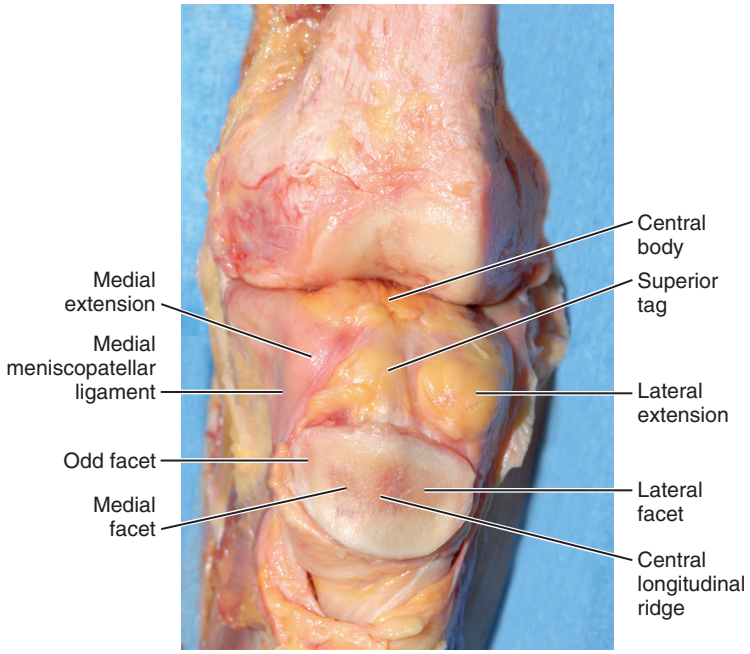

FIG 1-20 Posterior anatomy of the patella with adjacent capsular thickenings and fat pads with medial and lateral meniscopatellar ligaments.

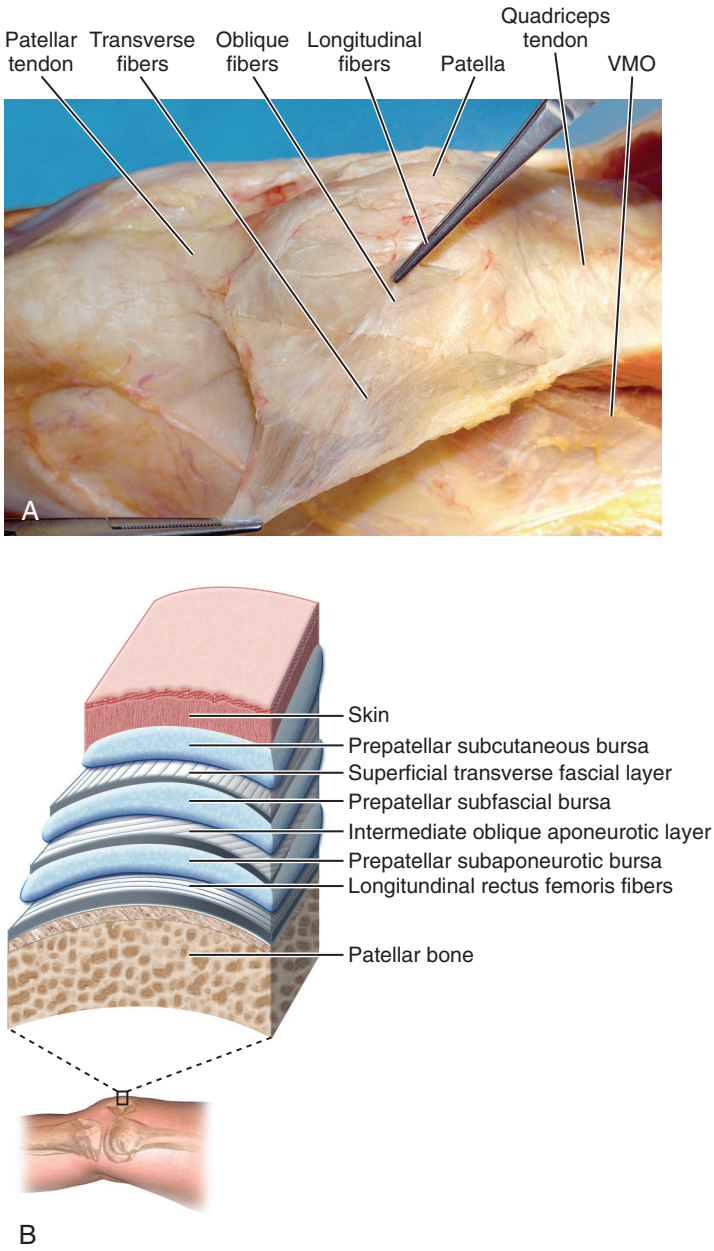

FIG 1-21 A, Fascia layers of the anterior knee. **B,** Layers of the anterior knee. VMO, Vastus medialis obliquus.

thinner medial and lateral extensions (see Fig. 1-20). It has attachments to the inferior pole of the patella proximally, the patellar tendon and anterior capsule anteriorly, the anterior horns of the medial and lateral menisci plus the proximal tibia inferiorly, and the intercondylar notch posteriorly via the ligamentum mucosum.[18] The ligamentum mucosum is an embryonic remnant separating the medial and lateral compartments of the knee. It has two alar folds that attach to the infrapatellar fat pad, allowing it to maintain its position in the joint.[23]

Gallagher and associates[18] identified two clefts in the infrapatellar fat pad: a horizontal cleft found just inferior to the ligamentum mucosum, and a vertical cleft, located anterior to the superior tag of the central body. It has been postulated that these clefts may play a role in reducing the friction between the anterior capsule and the femoral condyles, but they also may be a location for loose bodies to hide.

Inflammation in the infrapatellar fat pad has been implicated as a source of anterior knee pain. Hoffa disease is characterized by inflammation and hypertrophy, with subsequent trapping of the fat pad between the patellar tendon and femoral condyles.[18] The treatment frequently consists of resection of the fat pad, but this has been associated with a decrease in patellar blood supply.[26] The fat pad may also become inflamed after arthroscopic surgery because of portal placement. This may lead to fibrous scarring, which can limit motion and serve as a source for residual pain.[13] Fibrous scars that occur after arthroscopy have a 50% resolution rate after 1 year.[53] It is recommended that portal placement be well medial and lateral to the patellar tendon borders so that damage to the central body and superior tag are minimized to limit this potential complication.[18]

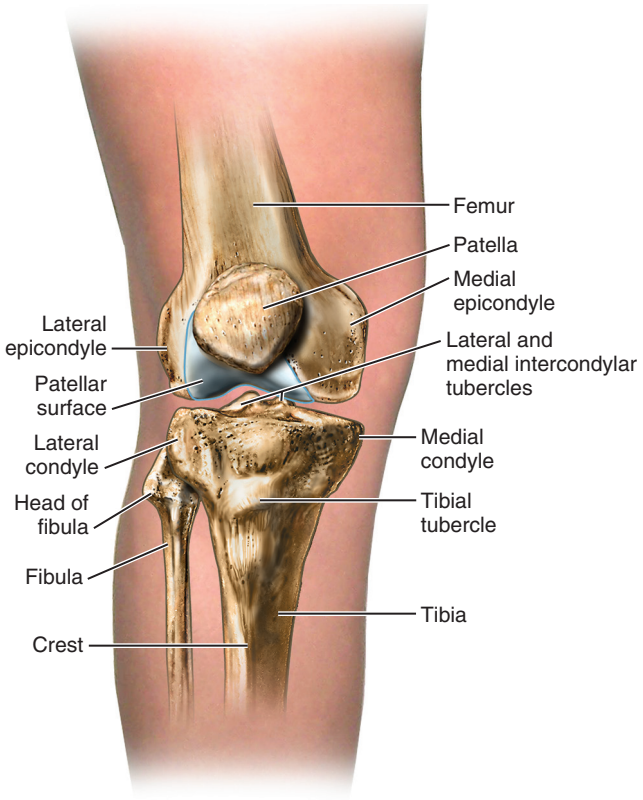

FIG 1-22 Bony landmarks of the anterior knee.

Superficial Neurovascular Structures

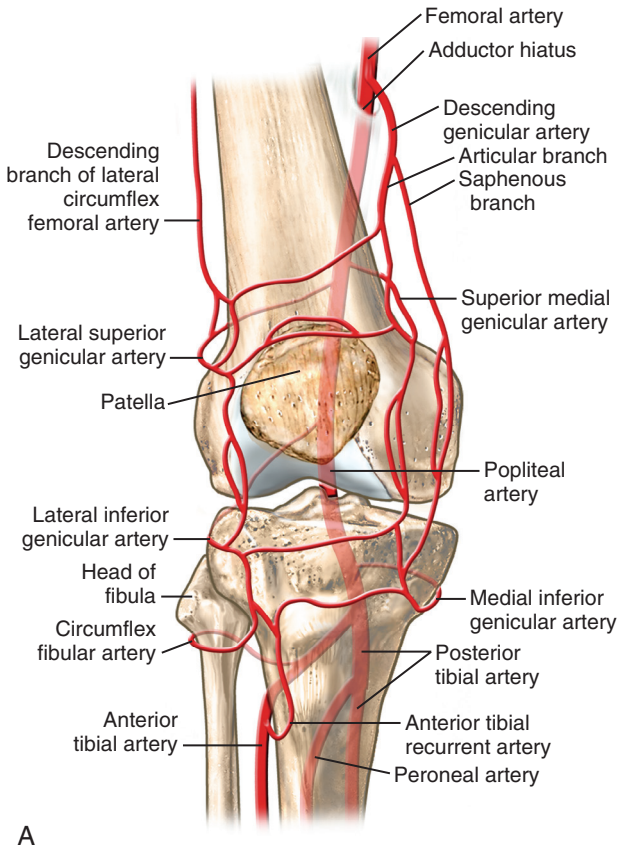
The medial inferior genicular artery traverses beneath the SCML after branching from the popliteal artery (Figs. 1-23 and 1-24). It can be visualized on the anterior border of the SMCL as it courses toward the patellar tendon and medial meniscus. This vascular structure may be encountered during any dissection on the medial aspect of the knee, most notably, during a posteromedial approach for meniscal repair. If identified in the approach, it must be retracted or cauterized to provide a clear approach to the medial meniscus.

Other important structures located on the medial side of the knee are the saphenous nerve with its sartorial and infrapatellar branches, the medial femoral cutaneous nerve, and the medial retinacular nerve (Fig. 1-25). These nerves may be easily injured with medial dissection of the knee. It has been reported that injury to the saphenous nerve occurs in 7% to 22% of patients during arthroscopic meniscal repair.[4] According to Dunaway and colleagues,[12] cadaver dissections in 42 knees revealed that the sartorial branch of the saphenous nerve consistently became extrafascial between the sartorius and gracilis. However, this location varied between 37 mm proximal to the joint line and 30 mm distal to the joint line, with the nerve being extrafascial at the joint only 43% of the time and deep to the sartorius fascia in 66% of specimens. Dunaway and colleagues[12] noted that only 2.8% of the specimens dissected had a sartorial branch anterior to the sartorius fascia. These authors recommend that during an inside-out medial meniscus repair, staying anterior during dissection minimizes risk of injury to the sartorial branch. Horner and Dellon[24] described the sartorial branch as the terminal branch of the saphenous nerve that passes 3 cm posterior to the central point of the medial condyle of the femur and continues to the medial aspect of the foot alongside the saphenous vein.

The infrapatellar branch of the saphenous nerve may also be easily damaged with indiscriminate dissection on the medial aspect of the knee, leading to postoperative pain and paresthesia. Postoperative numbness, paresthesia, or hypersensitivity in the distribution of the infrapatellar branch of the saphenous nerve has been reported in the literature[48]: 21% in the Mayo Clinic series, 51.5% in the Iowa series, and 40% in the Alberta series.[25] The risk of damage is increased by the varying course of the nerve. The infrapatellar branch of the saphenous nerve may have four different courses at the level of the medial joint line, which are described by the nerve's relationship to the sartorius muscle. The nerve may be posterior, penetrating, parallel, and anterior to the sartorius, with the most common type being posterior (62.2%).[3] Arthornthurasook and Gaew-Im[3] reported that the infrapatellar branch of the saphenous nerve is an average distance of 40.6 mm from the medial epicondyle when the nerve exits and travels posterior to the sartorius. Horner and Dellon[24] described the infrapatellar branch separating from the saphenous nerve in the proximal third of the thigh in 17.6% of specimens, in the middle third in 58.8%, and in the distal third of the thigh in 23.5%. This nerve innervates not only the patella but also the anterior-inferior capsule.[24]

Horner and Dellon[24] described the medial femoral cutaneous nerve traveling superficially to the sartorius muscle in 39.1% of knees. However, this nerve often travels in Hunter's canal and perforates the sartorius (30.4% of knees) or continues in Hunter's canal and exits deep to the sartorius (30.4% of knees). The termination of this nerve is the most superficial constant branch that eventually bisects the patella to form a prepatellar plexus before continuing to the lateral aspect of the knee and pairing with the infrapatellar branch of the saphenous nerve proximal the knee joint.

The medial retinacular nerve has also been described as residing on the medial aspect of the knee near the vastus medialis. The vastus medialis is innervated by branches from the femoral nerve. The terminal branch of the nerve to the vastus medialis ends at the medial retinacular nerve. According to Horner and Dellon,[24] this nerve may traverse within the vastus medialis (90% of knees) or lie superficial to its fascia (10% of knees). The nerve enters the knee capsule beneath the medial retinaculum, 1 cm proximal to the adductor tubercle, and sends a branch to the MCL.[24] This nerve was not identified in dissections by us.



Indiscriminate dissection on the medial side of the knee could easily damage any one of these described nerves, leading to the pathology already noted. Painful neuromas and complex regional pain syndrome can turn a successful operation into a complicated pain syndrome. Horner and Dellon[24] advised that the surgeon be aware of these pitfalls and recognize the possibility that symptomatology may result from damage to one or more nerves that require diagnostic nerve blocks at multiple sites to identify the pathology. Unnecessary subsequent surgeries for postoperative pain may be prevented by identifying the true cause of pain, which may very well be the result of nerve damage. A neurectomy may be required when a nerve block provides only temporary relief of pain.[24]

CONCLUSION

The anterior and medial anatomy of the knee has frequently been oversimplified or poorly described in the literature. It is our hope that this chapter has allowed the reader a greater appreciation for the anatomic relationships present and their potential implications in various knee conditions. A key to successful operative repair and reconstruction of the medial side of the knee is detailed knowledge of the anatomy of its structures.

Video 2-1 The Key to the Knee: A Layer-by-Layer Demonstration of Posterior and Posterolateral Knee Anatomy

INTRODUCTION

The posterior and lateral anatomy of the knee joint presents a challenge to even the most experienced knee surgeon. Knowledge of the bony topography will result in a greater number of anatomic ligament reconstructions (Fig. 2-1). A lack of familiarity leads to hesitancy when performing approaches in these areas of the knee. The inherent anatomic complexity of this region is further complicated by variations in terminology found in the orthopedic literature. Recent work by LaPrade and coworkers[16,17,19,20] and others[14] have attempted to clarify the nomenclature used to describe these structures, allowing for better communication among surgeons. These advances also facilitate more accurate biomechanic studies.

In posterolateral reconstructive procedures, the anatomic relationships of the fibular collateral ligament (FCL), popliteus muscle-tendon-ligament complex (PMTL), popliteofibular ligament (PFL), and the posterolateral capsule are particularly important. These structures function together to resist lateral joint opening, posterior subluxation of the lateral tibial plateau with tibial rotation, knee hyperextension, and varus recurvatum (see Chapter 15).[9,32,34]

The goals of this chapter are to (1) accurately describe all relevant structures and their relationships to one another; (2) provide confidence to the knee surgeon when encountering the posterolateral aspect of the knee; and (3) apply knowledge of these structures to provide a base for safe and efficient surgical approaches to the posterolateral aspect of the knee.

ILIOTIBIAL BAND

The iliotibial band (ITB) is a large fascial expansion that originates on the anterior superior iliac spine, covering the tensor fascia lata muscle proximally and extending along the lateral aspect of the thigh. Distally, the ITB has been divided into three separate layers: superficial, deep, and the capsulo-osseous layer.[36,46] A portion of the superficial layer, called the *iliopatellar band*, extends anteriorly to the lateral aspect of the patella (Fig. 2-2).[44] This band is important for proper patellofemoral tracking because it helps resist abnormal medial patella translation (medial glide).[16] The majority of the superficial layer continues distally to insert on Gerdy's tubercle. The deep layer connects the medial portion of the superficial layer to the lateral intermuscular septum of the distal femur. The most distal fibers of the deep layer continue to attach to the posterior aspect of the lateral femoral condyle (Fig. 2-3).[46] The capsulo-osseous layer extends more medial and distal to the deep layer to merge with fibers from the short head of the biceps to form the biceps-capsulo-osseous iliotibial tract confluens.[45] The capsulo-osseous layer continues distally, creating a sling posterior to the lateral femoral condyle to attach posterior and proximal to Gerdy's tubercle.

In knee extension, the ITB is anterior to the axis of rotation and helps maintain extension. When the knee is flexed to 90 degrees, the ITB moves posterior to the axis of rotation. The anteroposterior (AP) position of the ITB with knee flexion contributes to the pivot shift phenomena with an anterior cruciate ligament (ACL) rupture.[10] The posterior portion of the ITB tibiofemoral attachment is re-created in the lateral extraarticular ACL reconstruction.[16,36] During flexion, the ITB moves posteriorly, exerting an external rotational and posteriorly directed force on the lateral tibia, contributing to the reduction in the pivot shift test. The ITB and lateral capsule are important structures that resist internal tibial rotation (see Chapter 3). In extension, the ITB acts as a secondary restraint to varus stress.[4] In severe lateral knee ligament injuries, the ITB may become abnormally lengthened, and at the time of surgery, distal advancement at Gerdy's tubercle is indicated. A bursa between the ITB and the lateral femoral epicondylar region may become inflamed and produce pain. The lateral retinacular nerve courses just posterior to the bursa and may also become symptomatic.

ANTEROLATERAL LIGAMENT

There has been recent interest in the lateral capsule and the so-called *anterolateral ligament* (ALL)[2,14] that, when avulsed from the tibia,

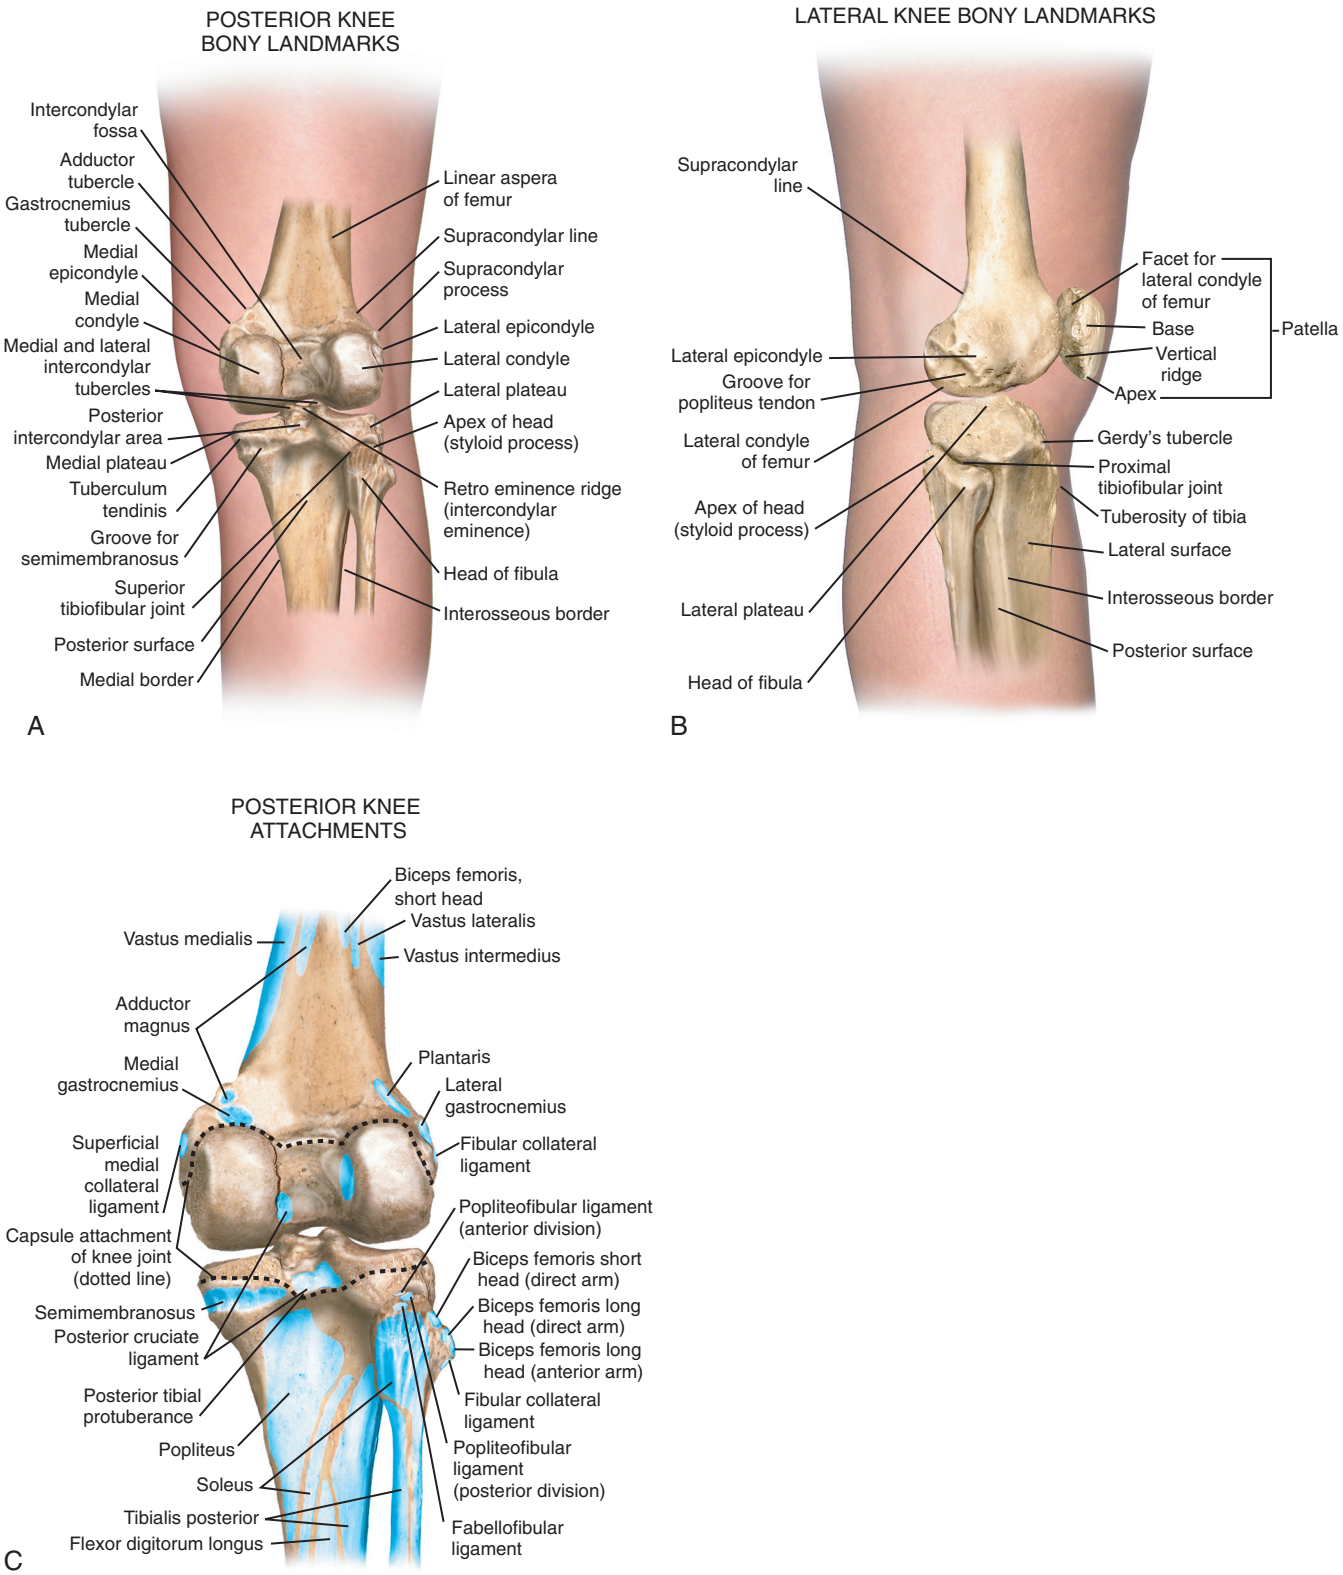

FIG 2-1 **A,** Bony anatomy of the posterior knee joint. **B,** Bony anatomy of the lateral knee joint. **C,** Key anatomic attachments of the posterior aspect of the knee with the joint capsule outlined.

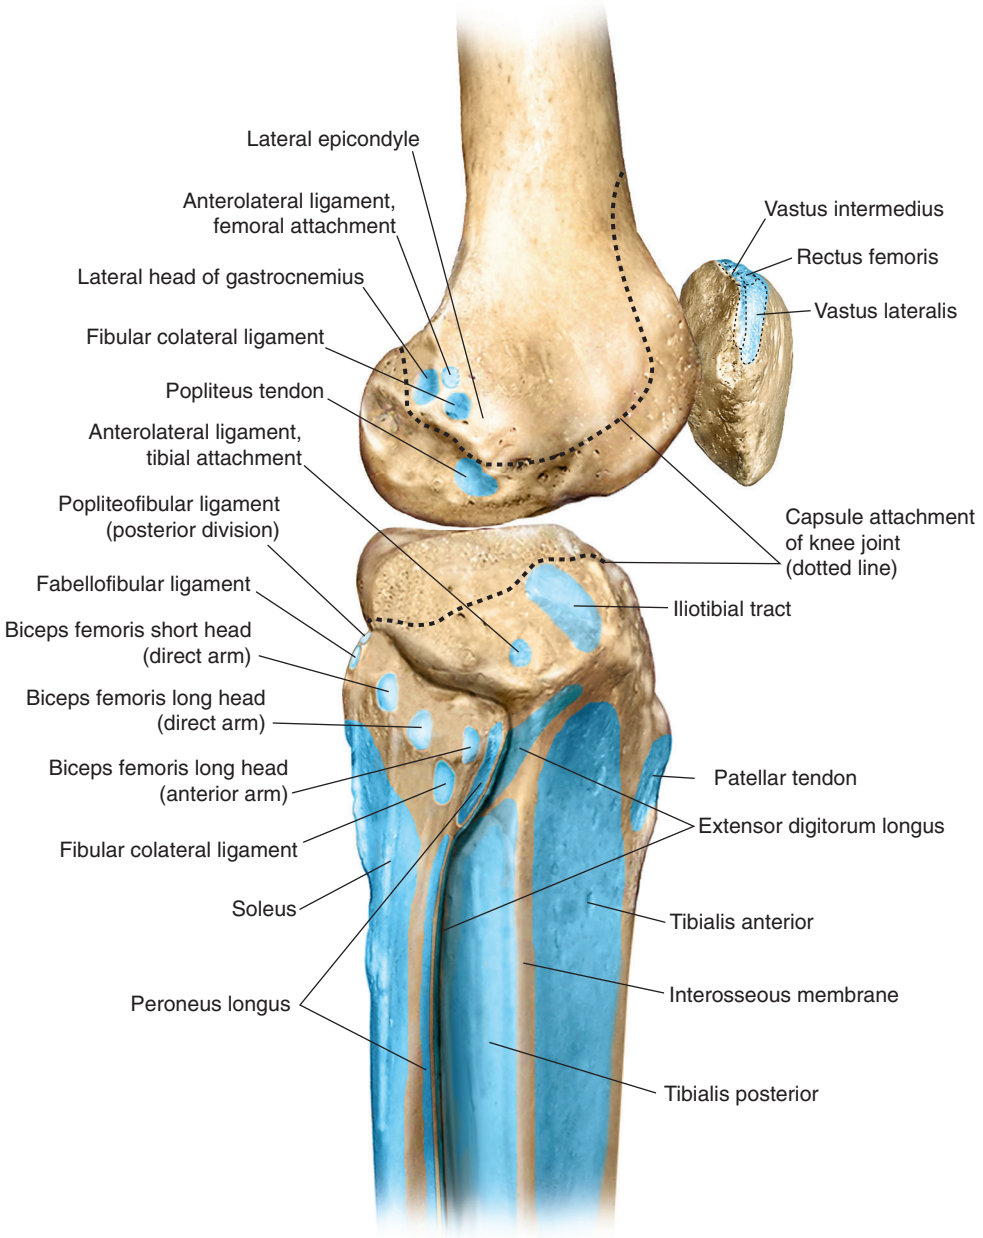

FIG 2-1, cont'd D, Key anatomic attachments of the lateral aspect of the knee with the joint capsule outlined.

produces a Segond fracture. The contribution of the ALL in limiting internal tibial rotation and anterior translation of the lateral tibiofemoral compartment has not been defined. The ALL was first described in 1879 by the French surgeon Paul Segond[38] as a fibrous band at the anterolateral aspect of the human knee attached to the Segond fracture. In 2012, Vincent and associates[47] determined the incidence of this anatomic structure in 30 consecutive patients undergoing total knee arthroplasty. These authors also evaluated the ALL's anatomy and histology in 10 cadaver knees. They found that the ALL was present in all 40 knees.

Claes and associates[2] performed an anatomic dissection on 41 unpaired cadaveric knees and reported the femoral and tibial attachments of the ALL, along with other lateral anatomic structures. These authors reported the ALL was a well-defined ligamentous structure in 40 of 41 knees. In another investigation, Claes and colleagues[1] compared anatomic details of the ALL with radiographic findings from patients with known Segond fractures. These authors found that Segond fractures consistently avulsed where the ALL inserted on the proximal tibia. They suggested that the Segond fracture was not only an indirect sign of ACL injuries, but should be considered a ligamentous avulsion of the ALL.

Dodds and associates[6] reported in an anatomic study that the ALL inserted just proximal and posterior to the lateral femoral epicondyle. The ALL has an oblique course to the anterolateral aspect of the proximal tibia, with attachments to the lateral meniscus, enveloping the inferior lateral geniculate artery and vein. It inserts onto the anterolateral tibia midway between Gerdy's tubercle and the tip of the fibular head, separate from the ITB.

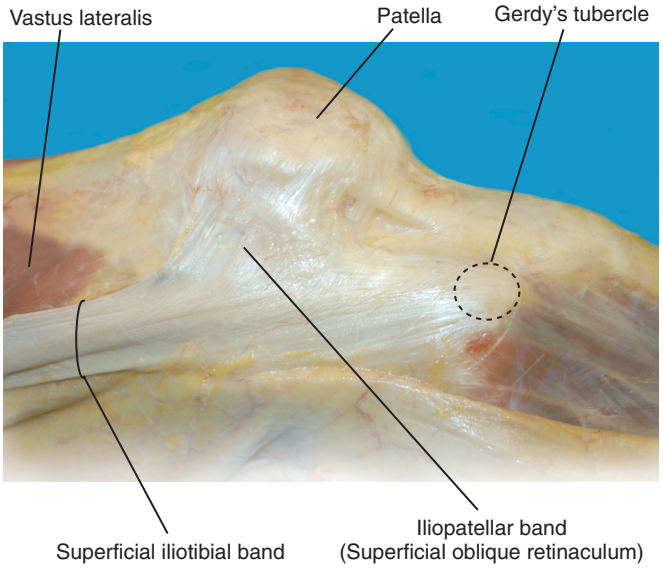

FIG 2-2 Lateral aspect of the knee demonstrates the iliotibial band with its distal insertion on Gerdy's tubercle and the iliopatellar fibers.

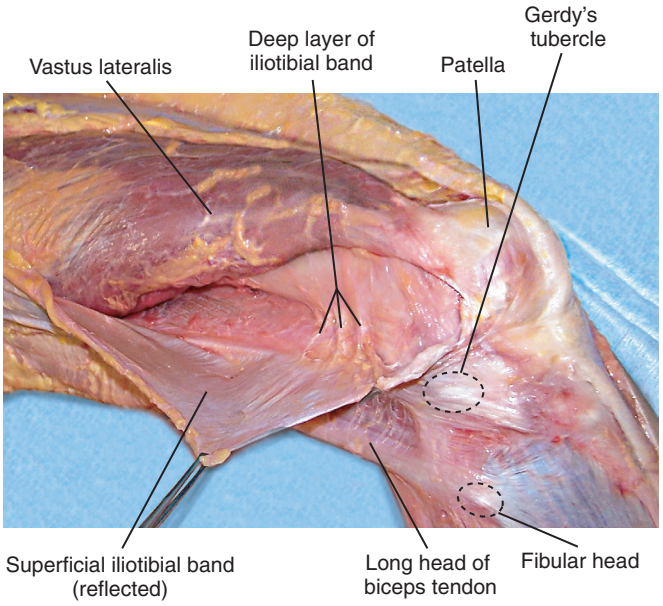

FIG 2-3 Deep fibers of the iliotibial band (ITB) are exposed as the superficial ITB is split and retracted posteriorly.

In an anatomic dissection of 15 cadaver specimens (males, mean age, 58.2 years), Kennedy and colleagues[14] reported that the ALL femoral attachment's area was 67.7 mm^2, which was located a mean of 2.7 mm proximal and 2.8 mm posterior to the FCL's femoral attachment (range, 0.9–6.7 mm proximal and 0.2–7.7 mm posterior; Fig. 2-4). The ALL had fine fascial expansions that extended anterior and distal over the FCL and lateral epicondyle. The ALL attachment was an average of 7.0 mm from the lateral epicondyle and 26.1 mm from the joint line. The tibial attachment was approximately midway between the anterior margin of the fibular head and the center of Gerdy's tubercle (Fig. 2-5). The ALL attachment was a mean of 26.1 mm anterior to the fibular head margin and 24.7 mm posterior to Gerdy's tubercle center, with a mean attachment area of 64.9 mm^2. The respective lengths from 0 to 90 degrees ranged from a mean of 36.8 to 41.6 mm. The mean maximum load to failure was 175 N (confidence interval, 139–211 mm).

It has been hypothesized by some that the ALL, along with the ITB femoral-tibial insertion, is a secondary restraint to internal tibial rotation and anterior translation of the lateral tibial plateau.[51] Wodicka and coworkers[50] found no correlation between the degree of injury to the ALL and the degree of instability after an ACL rupture. They proposed that the ALL in itself plays a minimal role in stability of the knee. Unpublished robotic research in our laboratory has confirmed no statistically significant increases in internal tibial rotation or lateral compartment translation upon sectioning the ALL. Accordingly, these two structures represent secondary restraints to lateral tibiofemoral compartment translation after ACL disruption. In our experience with anatomic dissections, it has been rare to find such a well-defined, robust structure (Fig. 2-6).

FIBULAR COLLATERAL LIGAMENT

For this chapter, the term *fibular collateral ligament* has been selected instead of lateral collateral ligament because it represents the term most commonly used in anatomy textbooks[16,40] and recent studies.[15,19,21,42,52,53] The FCL is a cordlike ligament that runs from the lateral femoral epicondyle to the fibular head (Fig. 2-7). When performing an anatomic FCL reconstruction, it is imperative that the surgeon understands the relationship of the FCL to its surrounding structures. On the femur, the FCL originates approximately 14 mm anterior[19] and slightly distal to the attachment of the lateral gastrocnemius tendon. This tendon is a key landmark during FCL reconstruction because it is frequently spared during a posterolateral corner knee injury.[46] In addition, the FCL attaches proximal and posterior to the popliteus femoral insertion. Distally, it attaches to the lateral aspect of the fibular head just medial to the anterior arm of the long head of the biceps tendon.

In 2003, LaPrade and associates[19] published a quantitative anatomic study that described the FCL and its relationship to osseous landmarks and other posterolateral structures of the knee. These authors reported that the FCL does not originate directly off of the lateral epicondyle, but attaches approximately 1.4 mm proximal and 3.1 mm posterior to the epicondyle, residing in a small bony depression. The average distance between the FCL and popliteus attachments on the femur was 18.5 mm. The ligament travels distally to insert 8.2 mm posterior to the anterior margin of the fibular head and 28.4 mm distal to the tip of the fibular styloid process (Fig. 2-8).[19] The distal 25% of the FCL is surrounded by the FCL–biceps femoris bursa, which has been implicated as a possible source of lateral knee pain.[8] The bursa is covered by the anterior arm of the long head of the biceps.[17]

The FCL is the primary restraint to varus loads at all degrees of flexion.[9] In a cadaveric sectioning study, Grood and colleagues[9] reported that the limit for varus angulation was normal as long as the FCL was intact. In addition, for large changes in external rotation to occur, the popliteus tendon, PFL, posterolateral capsule, and the FCL must all be injured.[51] Thus the FCL provides significant resistance to external rotation. The FCL is a secondary restraint to internal rotation at higher flexion angles (see Chapter 3).

FABELLOFIBULAR LIGAMENT

The fabellofibular ligament begins at the lateral aspect of the fabella (or posterior aspect of the supracondylar process of the lateral femur if a fabella is absent) and inserts distally on the posterolateral edge of

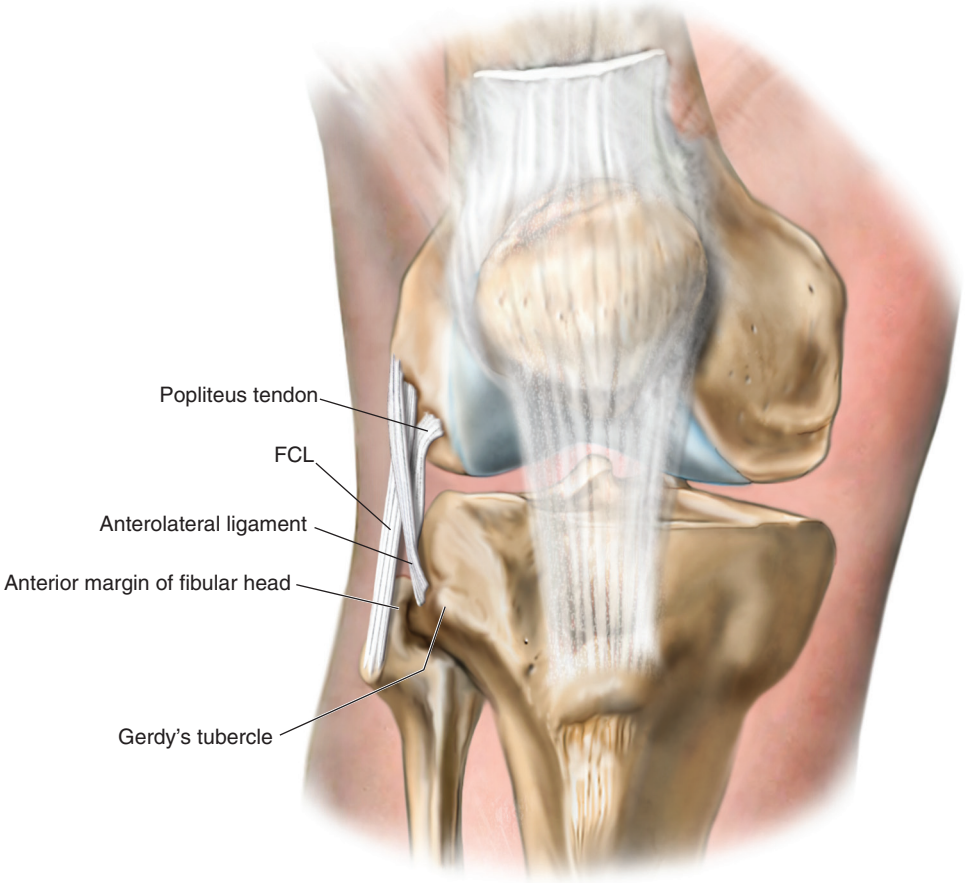

FIG 2-4 The osseous landmarks and attachment sites of the main structures of the lateral knee (iliotibial band and nonanterolateral ligament-related capsule removed, lateral view, right knee). The anterolateral ligament attached posterior and proximal to the fibular collateral ligament femoral attachment and coursed anterodistal to its anterolateral tibial attachment between the center of Gerdy's tubercle and the anterior margin of the fibular head. The short head of the biceps femoris tendon had a direct arm that attached to the fibular head and an anterior arm that attached to the anterolateral tibia. *FCL,* Fibular collateral ligament. (Modified from Kennedy MI, Claes S, Fuso FA, et al. The anterolateral ligament. An anatomic, radiographic, and biomechanical analysis. *Am J Sports Med* 2015;43[7]:1606-1615.)

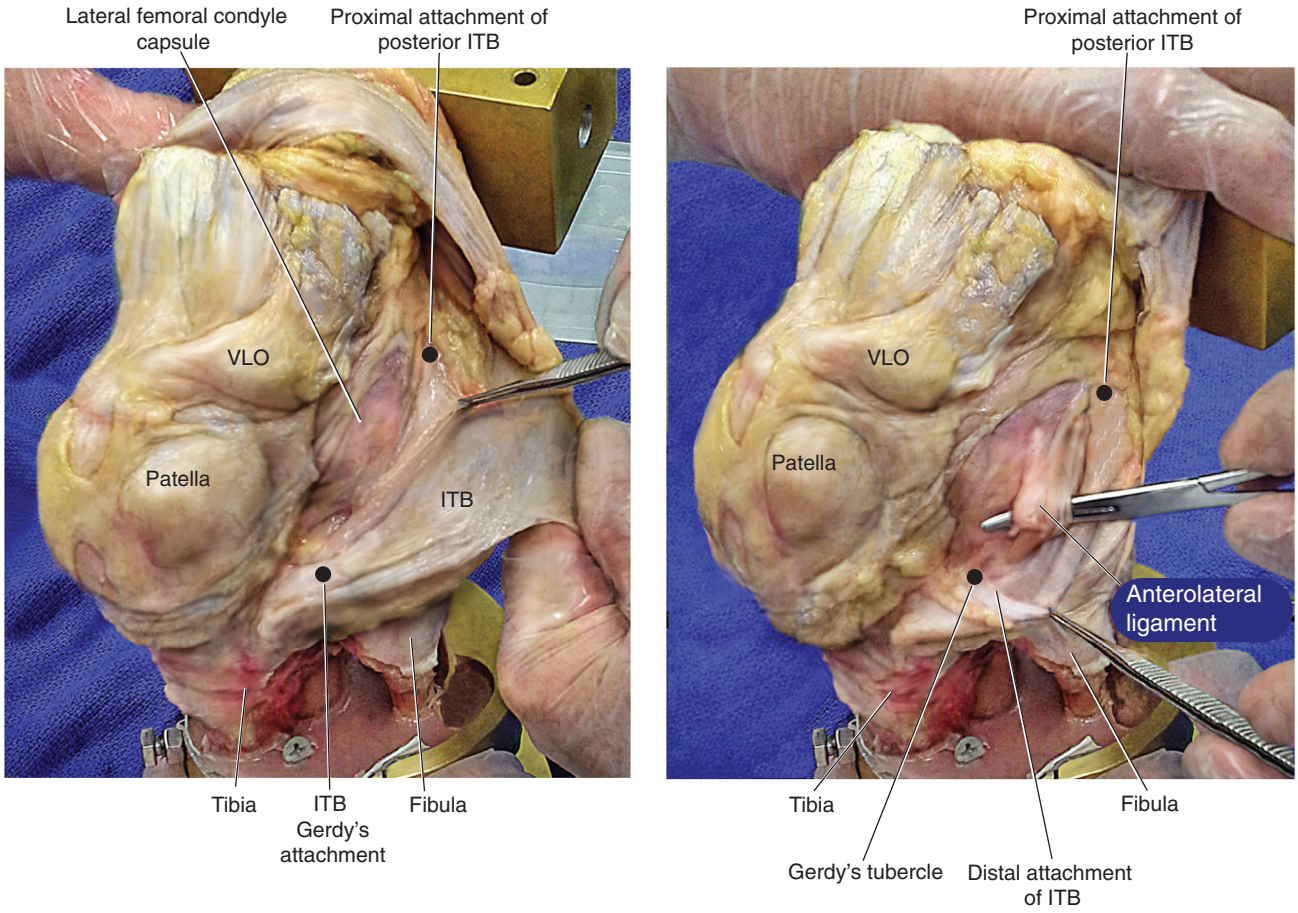

FIG 2-6 The anterolateral ligament (ALL) femoral insertion is just proximal and posterior to the lateral femoral epicondyle. The ALL tibial insertion is on the anterolateral tibia, midway between Gerdy's tubercle and the tip of the fibular head. *ITB,* Iliotibial band; *VLO,* vastus lateralis obliquus.

the fibular styloid (Fig. 2-9).[5] It attaches posterior and lateral to the insertion of the PFL. Proximally, the fabellofibular ligament is a continuation of the capsular arm of the short head of the biceps tendon.[45,46] The fabellofibular ligament is termed the *short lateral ligament* in the absence of a fabella.[13] Throughout this text, this structure is referred to as the *fabellofibular ligament*. The size of the fabellofibular ligament has been directly correlated to the presence of a bony fabella.[16,26,37] When a bony fabella is present, the ligament is more robust, with the opposite being true when the fabella is cartilaginous or absent.

The fabellofibular ligament has been identified in several studies in a variable percentage of patients.[5,19,37,43,48] Sudasna and Harnsiriwattanagit[43] reported the fabellofibular ligament was present in 68% of individuals. Minowa and coworkers[26] identified a fabellofibular ligament in 51.4% of cadaver knees. Diamantopoulos and associates[5] found the fabellofibular ligament in 40% of knees dissected using microsurgical techniques. In contrast, LaPrade[16] believes that the fabellofibular ligament is present in all knees owing to the fact that, by definition, it is the distal extension of the capsular arm of the short head of the biceps. This was confirmed in an article[20] describing these authors' anatomic findings. Functionally, the fabellofibular ligament is taut in extension.[48] Thus it can be inferred that it provides resistance to knee hyperextension. However, to date, there have been no biomechanic studies published that describe the function of the fabellofibular ligament.

FABELLA

The fabella, or little bean, is a bony or cartilaginous structure nestled in the posterolateral aspect of the knee. It is generally believed to reside in the tendon of the lateral head of the gastrocnemius; however, many structures merge at the fabella (Table 2-1). The fabella ranges in size from approximately 5 mm to over 20 mm in diameter, with the majority (70%) being oval in shape.[26,33] There are varying reports on the incidence of the fabella. Earlier radiographic studies appear to underestimate the true prevalence of the fabella compared with more recent cadaveric and histologic studies (Table 2-2). This structure is present bilaterally in approximately 80% of cases. The fabella has been implicated as a cause of posterior knee pain in multiple conditions including chondromalacia fabella, *fabella syndrome*, fracture of the fabella, impingement after total knee arthroplasty, and peroneal nerve irritation.[7,8,22-24,35,49] Thus the fabella and surrounding structures represent a rare but potential source of posterolateral knee pain.

POPLITEUS MUSCLE-TENDON-LIGAMENT COMPLEX

The PMTL is an intricate anatomic conglomerate made up of the popliteus muscle, the PFL, the femoral insertion of the popliteus tendon, the popliteomeniscal fascicles and soft tissue attachments to

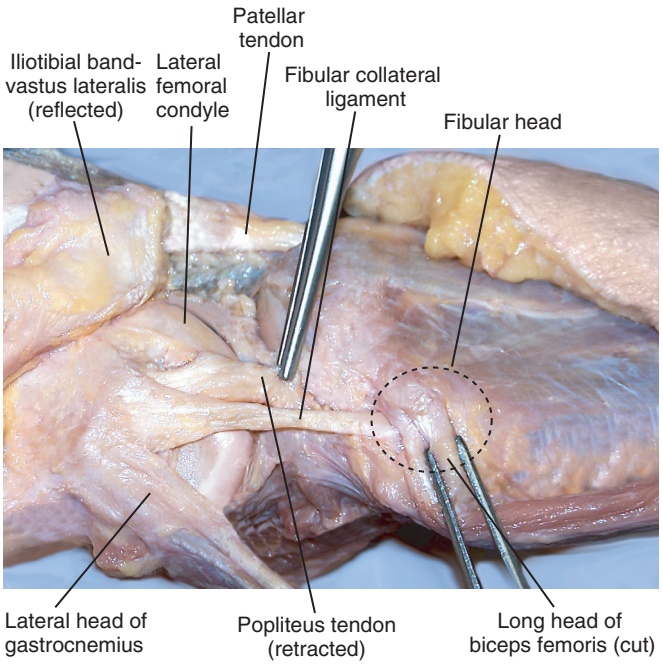

FIG 2-7 **A,** Gross picture of the fibular collateral ligament (FCL) demonstrates its relationship to the popliteus tendon and the lateral head of the gastrocnemius. **B,** The FCL and its relationship to the popliteus tendon and the lateral head of the gastrocnemius.

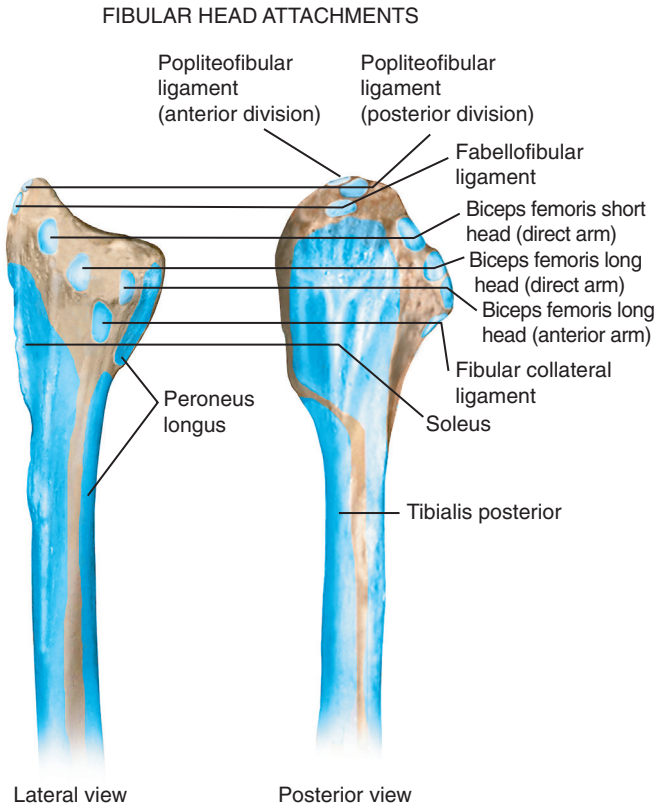

FIG 2-8 Lateral view of the knee demonstrates the fibular collateral ligament insertion onto the proximal fibula distal to the fibular styloid.

OA, Osteoarthritis.

the lateral meniscus, and the proximal tibia. The crucial components for posterolateral stability include the popliteus tendon and the PFL. These structures act in concert with the FCL and posterolateral capsule to prevent excessive external rotation and varus rotation of the knee.[9,32] Restoration of only a portion of these structures may result in residual instability.[31] This is discussed in detail in Chapter 15.[27-30]

The popliteus muscle originates on the posterior tibia just proximal to the soleal line and proceeds lateral and proximal to insert on the lateral femoral condyle (see Fig. 2-8, *B*). The popliteus tendon proceeds proximally through a hiatus in the coronary ligament of the lateral meniscus, then deep to the FCL to ultimately insert anterior and distal to the insertion of the FCL (see Fig. 2-7). As referenced earlier, LaPrade and associates[19] reported that the popliteus inserted an average of 18.5 mm from the FCL on the femur. Staubli and Birrer[41] further described the anatomy of the popliteus tendon at the level of the knee

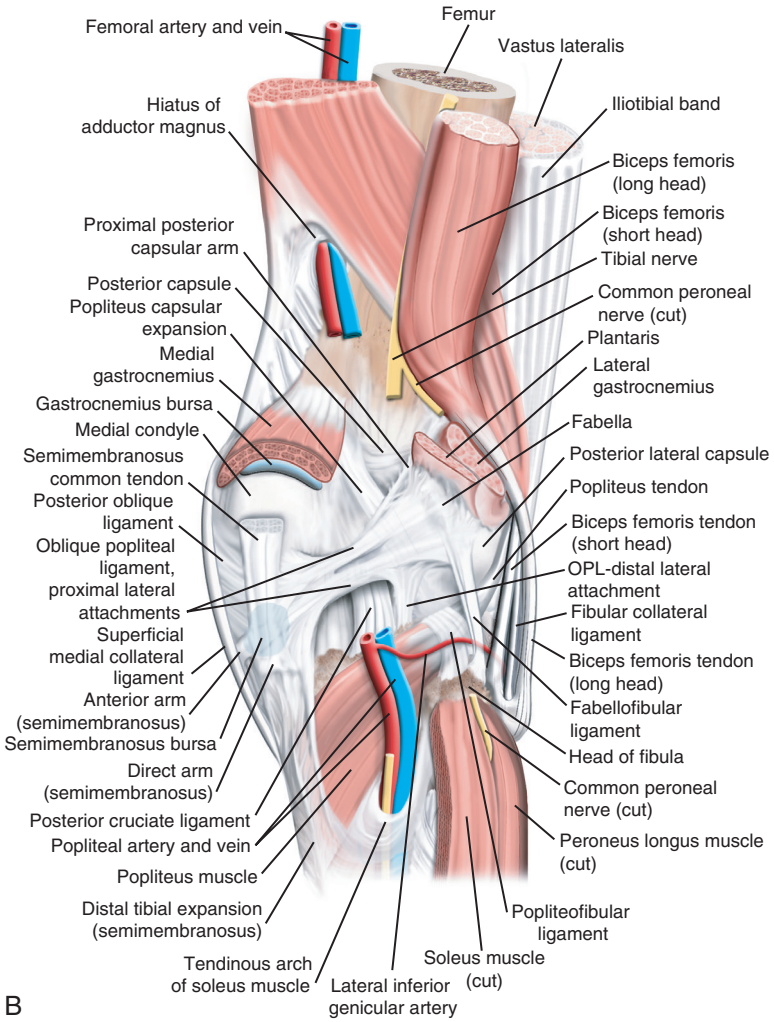

FIG 2-9 **A,** Posterior aspect of the knee with forceps holding the fabellofibular ligament. This ligament originates on the posterior aspect of the lateral femoral condyle and inserts on the fibular head. **B,** The posterior aspect of the knee. *OPL,* Oblique popliteal ligament.

joint. Three attachments of the popliteus tendon to the lateral menisci (termed the *popliteomeniscal fascicles*) were noted that include the anteroinferior, posterosuperior, and posteroinferior fascicles (Fig. 2-10). These fascicles provide stability to the lateral meniscus and, when torn, lead to abnormal translation of the lateral meniscus.[18,39] This may lead to mechanical symptoms and lateral knee pain. In Chapter 23, the repair techniques for the lateral meniscus and popliteomeniscal fascicles are described.

LaPrade and colleagues[20] described a thickening of the posterior joint capsule that extends from the medial aspect of the popliteus musculotendinous junction to the posteromedial aspect of the intercondylar notch of the femur, termed *the proximal popliteus capsular expansion* (see Fig. 2-9, *B*). The study reported this structure to be present in all dissections, and we have also found it to be a constant structure. This structure may provide an additional restraint to knee external tibial rotation and hyperextension.

The PFL originates at the musculotendinous junction of the popliteus and attaches to the medial aspect of the fibular head (Fig. 2-11), where it lies deep to the fabellofibular ligament. Of clinical significance, the inferior lateral geniculate artery courses between these two structures. The artery is frequently encountered during exposure of the posterolateral corner of the knee, especially during the approach for an inside-out lateral meniscus repair (Fig. 2-12). The artery is protected, if possible, and, if injured, requires cauterization to prevent postoperative hematoma formation. The PFL consists of two divisions, an anterior and posterior division.[19] LaPrade and associates[19] found that the average width of the anterior division's attachment at the fibular styloid was 2.6 mm, although the posterior division's width at the fibular styloid attachment was 5.8 mm. Thus the posterior division may contribute more significantly than the anterior division to stability of the posterolateral aspect of the knee.

BICEPS FEMORIS

The biceps femoris is a fusiform muscle comprising two heads: long and short. The long head originates from the ischial tuberosity and is innervated by the tibial division of the sciatic nerve. The short head originates from the lateral aspect of the linea aspera of the femur and is innervated by the peroneal division of the sciatic nerve.[36] Distally, the two heads of the biceps lie just posterior to the ITB (Fig. 2-13). Both heads of the biceps have complex attachments to the posterolateral aspect of the knee. These distinct attachments are described and shown in Tables 2-3 and 2-4. In our experience (in cadaveric dissections and at surgery), many of the attachments blend together distally and are difficult to identify as separate structures. The peroneal nerve lies just distal and posterior to the biceps, curving around the fibular neck. The biceps flexes the knee and also externally rotates the leg when the knee is flexed.[37]

There are varying descriptions of the anatomy of the biceps and the number of attachments.[11,12,25,37,45] Terry and LaPrade[45] described five attachments of the long head of the biceps, including two tendinous and three fascial components (Fig. 2-14; see also Table 2-3). The two tendinous components (direct and anterior arms) and one of the fascial components (lateral aponeurotic expansion) make up the key portion of the long head anatomy. The other fascial components are the reflected arm and the anterior aponeurotic expansion.

The most proximal component is the reflected arm. It originates just proximal to the fibular head and ascends anteriorly to insert on the posterior edge of the ITB. The direct arm inserts onto the posterolateral edge of the fibula just distal to the tip of the styloid (see Fig. 2-8).[16] The anterior arm has a more complex attachment and some important anatomic points. A portion of the anterior arm inserts onto the lateral aspect of the fibular head, and the rest continues distally just lateral to the FCL. Just proximal and at this fibular insertion, portions of the anterior arm ascend anteriorly, forming the lateral aponeurotic expansion that attaches to the posterior and lateral aspect of the FCL. Here, a small bursa separates the anterior arm from the distal fourth of the FCL. The anterior arm thus forms the lateral wall of this bursa.[45]

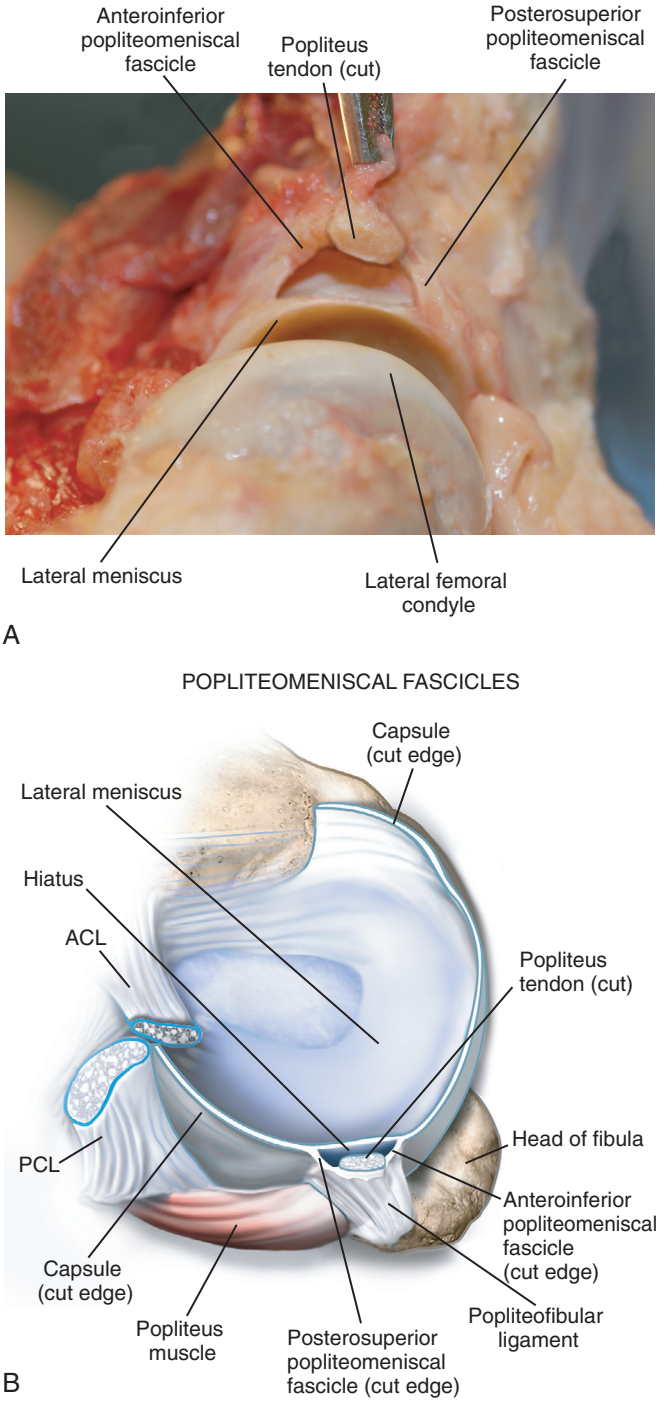

FIG 2-10 A, The popliteus tendon is cut at the level of the joint with its surrounding popliteomeniscal fascicles. The posterosuperior fascicle and anteroinferior fascicle secure the popliteus tendon to the lateral meniscus. The lateral femoral condyle is labeled for reference. **B,** The popliteus tendon and its surrounding popliteomeniscal fascicles. *ACL,* Anterior cruciate ligament; *PCL,* posterior cruciate ligament.

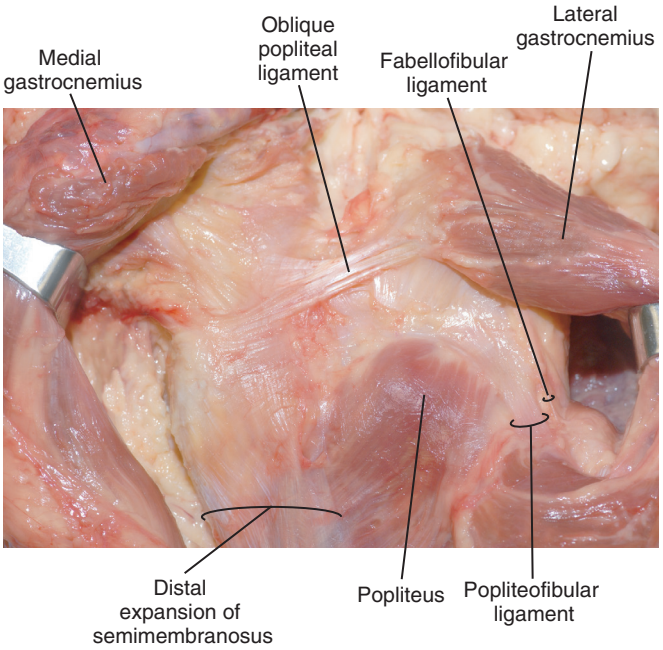

FIG 2-11 The popliteofibular ligament originates from the popliteus muscle and attaches to the medial aspect of the fibula. The lateral head of the gastrocnemius is being retracted proximally.

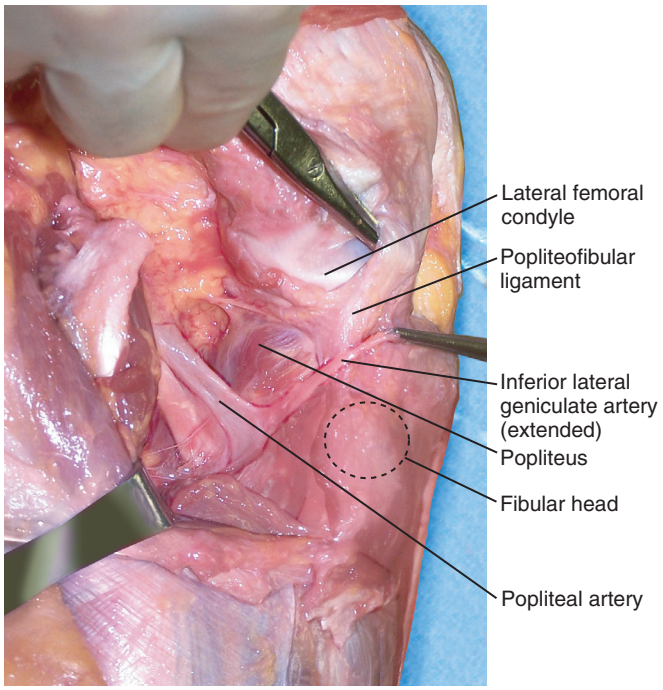

FIG 2-12 The inferior lateral geniculate artery branches off from the popliteal artery and runs superficial to the popliteofibular ligament. The fabellofibular ligament has been removed to better demonstrate the inferior lateral geniculate artery.

This is an important surgical landmark because a small horizontal incision can be made here, 1 cm proximal to the fibular head, to enter this bursa and locate the insertion of the FCL into the fibular head (Fig. 2-15).[16] The anterior arm then continues distally over the FCL, forming the anterior aponeurosis, which covers the anterior compartment of the leg.

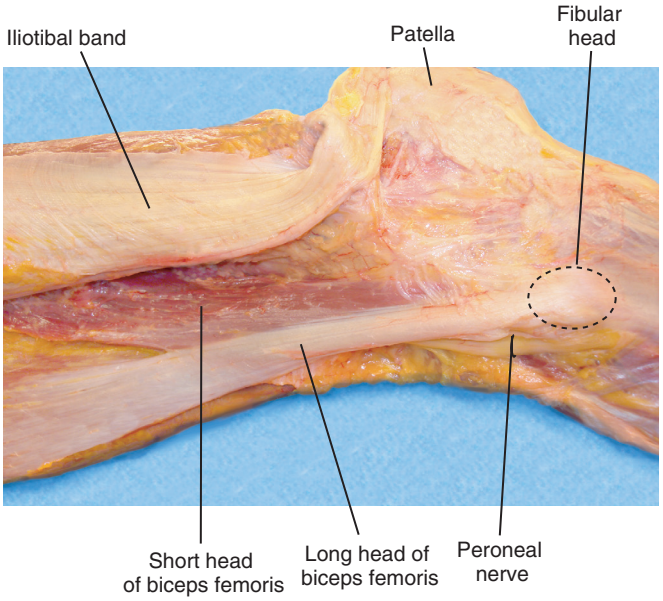

FIG 2-13 The iliotibial band is retracted superiorly demonstrating the short head of the biceps attaching to the long head tendon and inserting onto the fibular head. The peroneal nerve is seen posterior to the biceps.

TABLE 2-3 Five Components of the Long Head of the Biceps Femoris

Component	Attachment
Reflected arm	Posterior edge of ITB

Lateral aponeurotic expansion	FCL
Anterior aponeurotic expansion	Anterior compartment of the leg

FCL, Fibular collateral ligament; *ITB*, iliotibial band.

TABLE 2-4 Six Components of the Short Head of the Biceps Femoris

Component	Attachment
Proximal muscular attachment	Anteromedial aspect of the long head
Capsular arm	Posterolateral knee capsule
Capsulo-osseus layer	Proximolateral tibia
Direct arm	Fibular head
Anterior arm	Proximolateral tibia
Lateral aponeurotic expansion	FCL

FCL, Fibular collateral ligament.

The short head of the biceps courses just deep (or medial) and anterior to the long head tendon, sending a majority of its proximal muscular fibers to the long head tendon itself.[45] It has six distal attachments (Fig. 2-16; see also Table 2-4). The most important attachments are the direct arm, the anterior arm, and the capsular arm.

The capsular arm originates just before the short head reaching the fibula. It then continues deep to the FCL to insert onto the posterolateral knee capsule and fabella. Here, the fibers of the capsular arm continue distally as the fabellofibular ligament.[45] Just distal to the

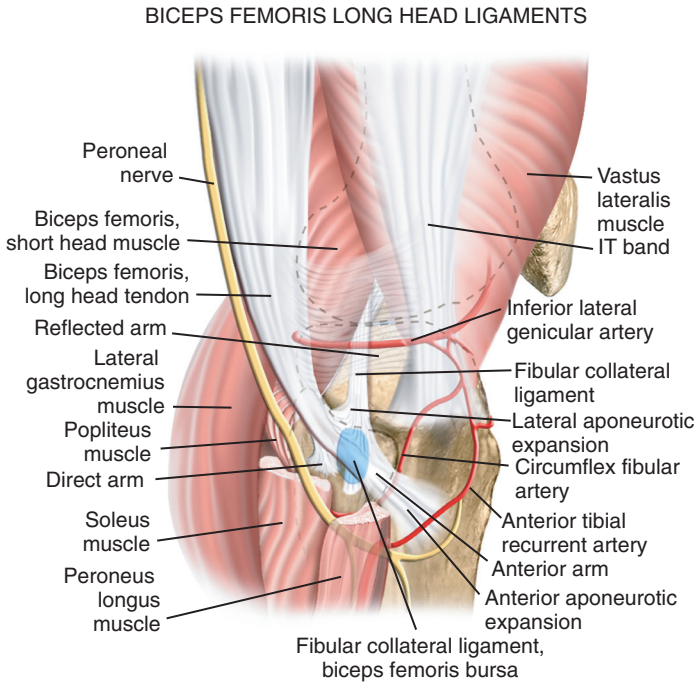

FIG 2-14 The long head of the biceps, multiple insertions.

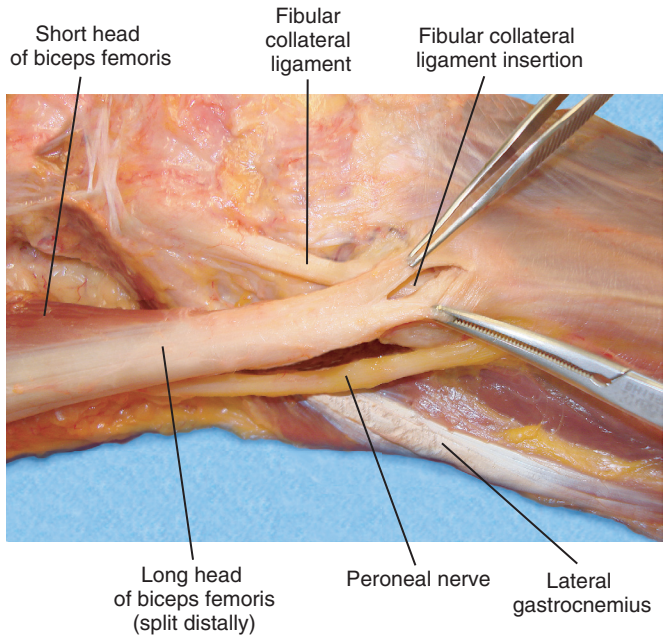

FIG 2-15 An incision in the long head of the biceps tendon reveals the insertion of the fibular collateral ligament as it lies deep to the tendon. The peroneal nerve is in close proximity as it lies superficial to the lateral gastrocnemius.

Fibular collateral ligament	Anterolateral edge (28 mm distal to styloid, 8 mm posterior to anterior edge of fibula)
Fabellofibular ligament	Lateral to the tip of the styloid

LH, Long head; *SH*, short head.

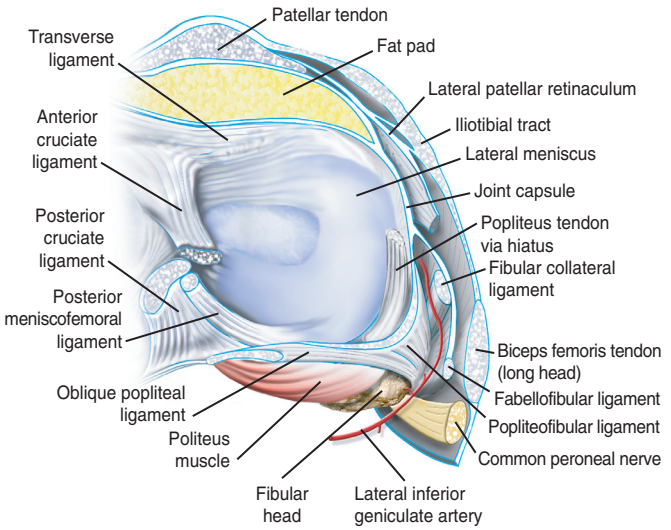

FIG 2-17 Axial view of the lateral knee joint illustrates the trilaminar relationship of the various posterolateral structures.

capsular arm, a capsulo-osseous layer forms a fascial confluence with the ITB (the biceps-capsulo-osseous-iliotibial tract confluens). The direct arm of the short head inserts onto the fibular head just posterior and proximal to the direct arm of the long head tendon. The anterior arm then continues medial or deep to the FCL, partially blends with the anterior tibiofibular ligament, and inserts onto the tibia 1 cm posterior to Gerdy's tubercle. This site is also the attachment of the mid-third lateral knee capsule.[45] It is important clinically because an avulsion fracture can be seen here in ACL injuries, known as a *Segond fracture*.[38,45] Finally, the lateral aponeurotic expansion of the short head inserts onto the medial aspect of the FCL (versus this expansion of the long head that inserts onto the posterior aspect of the FCL).[45]

FIBULAR HEAD

The fibular head is a key anatomic and structural component to the posterolateral knee. It is easily palpable in most patients and is thus an excellent anatomic reference point. In the literature, incomplete descriptions of the anatomy and insertion of structures of the proximal fibula exist. Six key structures attach to the fibular head: three tendons and three ligaments (Table 2-5; see also Fig. 2-8). The PFL attaches to the tip of the fibular styloid. Just distal and lateral, the fabellofibular ligament attaches on the slope of the styloid. The FCL, as mentioned previously, attaches proximally 28 mm distal to the styloid and 8 mm from the anterior cortex of the fibula, depending on the course on specimen size variations.[19] A portion of the anterior arm of the long head of the biceps attaches to the lateral aspect of the fibular head. The direct arms of the long and short head of the biceps attach to the posterior aspect of the fibular head, the long head being just lateral to that of the short head.

KNEE CAPSULE

The knee capsule envelops the joint, extending from the articular margin of the femur to the tibia (see Fig. 2-1, *C* and *D*). On the tibia, it inserts 4 to 14 mm below the articular surface. The most distal attachment at the tibia is located at the posteromedial and posterolateral aspect.[3] Some authors have identified a thickening of the capsule laterally, naming this the *mid-third lateral capsular ligament*.[36] This ligament is divided into two components. The meniscofemoral component and meniscotibial component extend from the femur and tibia, respectively, to attach to the lateral meniscus.[36] The lateral retinacular nerve, a branch of the sciatic nerve, courses along the surface of the lateral capsule (Fig. 2-17).

Video 3-1 Comprehensive Knee Exam: Clinical Rationale and Diagnosis

CLASSIFICATION SYSTEM FOR KNEE LIGAMENT INJURIES

Many different classification systems for knee ligament injuries have been proposed in the sports medicine literature.[28,29,45,47,57] A series of studies we conducted enabled the development of an algorithm for the diagnosis and classification of these injuries based on kinematic and biomechanical data.[6,19-22,50-54,56,57,72,79] The purpose of this chapter is to summarize these studies and provide the clinician with the proper examination techniques that allow precise diagnosis of abnormal knee motions, subluxations, and ligament injuries.

The purposes of a classification system are to (1) make accurate distinctions between separate pathologic conditions in laboratory and clinical studies and (2) provide a common descriptive tool for investigators who wish to present cases and describe the outcome of treatment programs. A system that allows two or more discrete types of injuries to be grouped as a single entity does not allow the association of a unique natural history or surgical result with the anatomic defect on the actual pathologic condition being treated.

The classification scheme developed from our investigations is based on seven concepts:

1. The final diagnosis of knee ligament injuries is based on the specific anatomic defect derived from the abnormal motion limits and joint subluxations.
2. Ligaments have distinct mechanical functions to provide limits to tibiofemoral motions and the types of motions that occur between opposing cartilage surfaces.
3. Although there are six degrees of freedom (DOF), the manual stress examinations are designed to test just one or two limits at a time.
4. Ultimately, the clinical examination must be analyzed by a six-DOF system to detect abnormalities.

CRITICAL POINTS Classification System for Knee Ligament Injuries

Purpose of a Classification System

- Make accurate distinctions between separate pathologic conditions in laboratory and clinical studies.
- Provide a common descriptive tool for investigators who wish to present cases and describe the outcome of treatment programs.

Our Classification System Based on Seven Concepts

1. The final diagnosis of knee ligament injuries is based on the specific anatomic defect derived from the abnormal motion limits and joint subluxations.
2. Ligaments have distinct mechanical functions to provide limits to tibiofemoral motions and the types of motions that occur between opposing cartilage surfaces.
3. Although there are six DOFs, manual stress examinations are designed to test just one or two limits at a time.
4. Ultimately, the clinical examination must be analyzed by a six-DOF system to detect abnormalities.
5. Together, the ligaments and joint geometry provide two limits (opposite directions) for each DOF.
6. Rotatory subluxations are characterized by the separate compartment translations that occur to the medial and lateral tibial plateaus during the clinical test.
7. The damage to each ligament and capsular structure is diagnosed using tests in which the primary and secondary ligament restraints have been experimentally determined.

5. Together, the ligaments and joint geometry provide two limits (opposite directions) for each DOF.
6. Rotatory subluxations are characterized by the separate compartment translations that occur to the medial and lateral tibial plateaus during the clinical test.
7. The damage to each ligament and capsular structure is diagnosed using tests in which the primary and secondary ligament restraints have been experimentally determined.[51]

In this chapter, the studies presented related to the anterior cruciate ligament (ACL), posterior cruciate ligament (PCL), medial collateral ligament (MCL) and posteromedial structures, the iliotibial band (ITB), and the mid-lateral capsule. Studies related to the posterolateral structures (fibular collateral ligament [FCL], popliteus muscle-tendon ligament, and posterolateral capsule) are presented in Chapters 15 and 17.

Concept 1: Final Diagnosis of Knee Ligament Injuries Is Based on the Specific Anatomic Defect Derived From the Abnormal Motion Limit and Joint Subluxation

The term *instability* has been used to describe an abnormal motion or motion limit that exists to the joint because of a ligament injury. This term has also been used to indicate symptomatic giving-way of the knee joint that occurs during activity. Instead, it is recommended to describe the giving-way event and not use the term *instability*. Giving-way may be caused by many factors, including a ligament rupture, poor muscular control of the knee joint, altered neurologic function and control mechanisms, or mechanical problems such as a torn meniscus or loose body. In many cases, giving-way occurs because of multiple factors, and the term *instability* does not precisely indicate the exact cause of the episode. Rather than a diagnosis of anterior instability, it is more appropriate to reduce the abnormality to a precise anatomic diagnosis such as ACL rupture. In addition, other ligament deficiencies, if present, should be identified.

The term *laxity* simply indicates looseness and may be applied to increases in joint motion or increases in ligament elongation. Therefore, the term *laxity* does not provide a diagnosis of a specific abnormality. The knee has a normal amount of laxity (play or motion) required for function. An abnormal amount of laxity may occur as a result of a ligament disruption. Laxity may also indicate a ligament injury in which the ligament has an increase in length or elongation during loading. The finding of abnormal laxity represents a clinical sign that does not provide a precise diagnosis. Instead, the specific anatomic defect of the ruptured ACL and associated injured ligaments or capsular structures should be recorded as the diagnosis. The goal of a comprehensive knee examination is to detect an increase in the amount of motion (translation or rotation) or an abnormal position (subluxation) to determine the specific anatomic defects that are present.

Concept 2: Ligaments Have Distinct Mechanical Functions to Provide Limits to Tibiofemoral Motions and the Types of Motions That Occur Between Opposing Cartilage Surfaces

Ligaments have distinct mechanical functions to provide limits to the amount of tibiofemoral motion that determines the types of motions occurring between opposing cartilage surfaces. The limits of motion are the main focus because loss of this function and the consequent subluxation are the underlying deficits in ligament-injured knees. In addition, the change in limits of motion is the primary basis of diagnosis.

The ability of ligaments to limit tibiofemoral motion provides the geometric parameters within which the neuromuscular system is able to control the position of the knee during activity. Although focus is placed on the mechanical function of the ligaments and capsular structures, the reader should be cognizant of the potentially important role of ligaments in providing sensory feedback to the neuromuscular system.[32,70] Ligaments have three properties that affect their ability to limit joint motion: location of their attachment on the bones, just-taut length, and stiffness.

Tibiofemoral motions are limited along the line that connects the ligament's tibial and femoral attachments in the direction that loads the ligament. Ligaments are not able to limit motions perpendicular to their orientation or motions that cause them to become slack. Just-taut length is a determinant of joint laxity because it controls the amount of motion before the ligament begins to provide a resisting force. Because the two cruciate ligaments are required to limit anteroposterior (AP) translation, total AP translation is determined by the just-taut length of both ligaments.

Ligament stiffness controls how much additional joint movement is required after the ligament has become taut to create a force large enough for the ligament to resist the applied load. Decreased ligament stiffness produces an increase in the motion limit because a greater motion is required before the ligament can develop a sufficient restraining force.

The kinematic and biomechanical concepts required to interpret clinical tests are shown in Figure 3-1. First, the appropriate clinical test must be selected to diagnose a specific ligament structural abnormality. Diagnostic information is obtained based on understanding the primary and secondary ligament restraint system. The results of the tests must be understood and communicated in terms of the six-DOF system that determines the abnormal motion limits. The medial

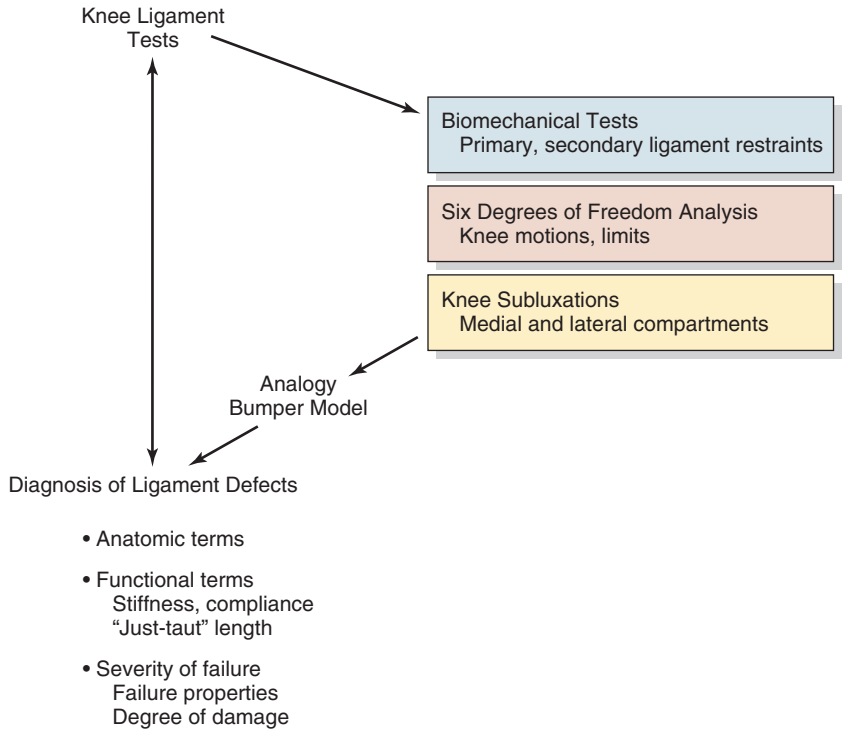

FIG 3-1 The results of clinical tests require specific biomechanical and kinematic principles for correct diagnosis of ligament defects. Ligament defects are defined by anatomic, functional, and severity categories. (From Noyes FR, Grood ES. Classification of ligament injuries: why an anterolateral laxity or anteromedial laxity is not a diagnostic entity. In Griffin P, editor: *AAOS Instructional Course Lectures,* Vol XXXVI. Chicago: American Academy of Orthopaedic Surgeons; 1987:185-200.)

and lateral tibiofemoral compartments are examined separately to determine the different types of subluxation. The final diagnosis of the ligament defect must be made in precise anatomic and functional terms and according to the severity of ligament failure (partial or complete).

Concept 3: Although There Are Six Degrees of Freedom, the Manual Stress Examinations Are Designed to Test Just One or Two Limits at a Time

Although there are six DOF, the knee ligament examination is specifically designed to test just one or two motion limits at a time. Combinations of these motions (coupled motions) are particularly important to the diagnosis of knee ligament injury because they occur during many of the manual stress examinations.

Translation of a rigid body (such as the tibia) is described by the motion of an arbitrarily selected point on the body. Typically, the AP translation is described by the motion of a point located midway between the medial and lateral margins of the tibia. If only translation motions occur, the amount of motion does not depend on which point is chosen—that is, whether the point is at the center of the knee or at the medial or lateral joint margin. This is because all points will move along parallel paths. However, when rotation and translation motions are combined, the amount of translation does depend on which point is used. This can be seen by considering the four cases illustrated in Figure 3-2.

Figure 3-2, *B* shows an anterior translation of 10 mm without associated tibial rotation. All points move anteriorly by the same amount. Figure 3-2, *C* shows an internal rotation of 15 degrees about an axis located midway between the spines of the intercondylar eminence. The point on the rotation axis is stationary while the lateral joint margin (edge) moves anteriorly and the medial margin posteriorly (see Fig. 3-2, *D*). The amount of anterior and posterior motion of the points at the joint margin depends on the amount of rotation and how far they are away from the rotation axis (center of rotation). This illustrates that when translation is measured in the presence of a concurrent rotation, it is important to know at which point the translation was measured.

Concept 4: Ultimately, the Clinical Examination Must Be Analyzed by a Six-DOF System to Detect Abnormalities

The clinician who understands all of the possible motions in the knee joint that are normally limited by the knee ligaments will be able to perform manual stress tests and correctly determine the specific abnormality that is present. However, a diagnosis cannot be based solely on the abnormal motions detected. The diagnosis also requires knowledge of the biomechanical data regarding which ligaments limit each of the possible motions in the knee joint.

The field of science that describes the motions between objects is known as *kinematics*. A fundamental aspect of this field is the recognition that six possible motions may occur in three dimensions. Each of the six motions is discrete and separate from the other five motions. The six motions are referred to as *degrees of freedom*. The three rotational DOF in the knee joint are shown in Figure 3-3. Each rotation occurs about one axis: flexion-extension, internal-external, and abduction-adduction.

The flexion-extension axis is located in the femur and oriented in a pure medial-lateral direction perpendicular to the femoral sagittal

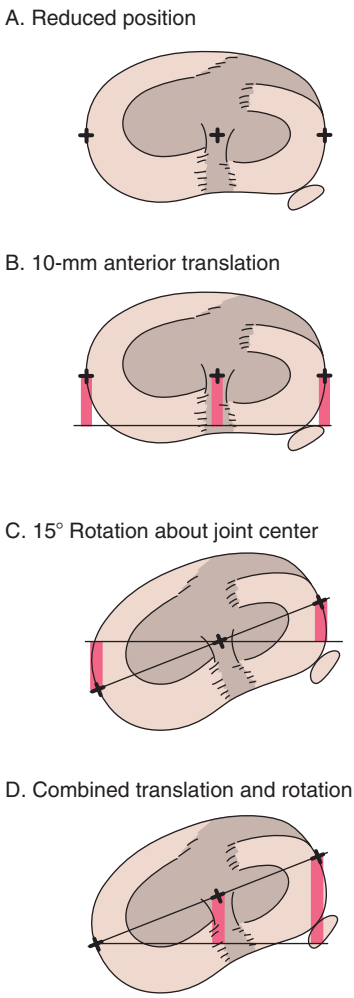

FIG 3-2 Combined anterior translation and tibial rotation. **A,** The tibial plateau is shown along with the contact area on the femur (shaded regions). The tibia is in a reduced position. **B,** Anterior tibial translation of 10 mm. The amount of translation, shown by the vertical bars, is the same at the medial and lateral joint margins as it is at the center of the joint. **C,** Fifteen degrees of internal rotation about the joint center. Tibial contact is anterior on the lateral plateau and posterior on the medial plateau. The bars show the amount and direction of its translation at the medial-lateral joint lines. The amount of translation is approximately 10 mm in an average knee 80 mm wide. There is no translation at the center of the joint where the rotation axis is located. **D,** Combined tibial translation and rotation. A 10-mm anterior translation is combined with 15 degrees of internal rotation at the medial aspect of the tibia. The center of the tibia translates 10 mm anteriorly, while the lateral joint margin translates 20 mm anteriorly. (From Grood ES, Noyes FR. Diagnosis of knee ligament injuries: biomechanical precepts. In Feagin J, editor: *The Crucial Ligaments.* New York: Churchill Livingstone; 1988:245-260.)

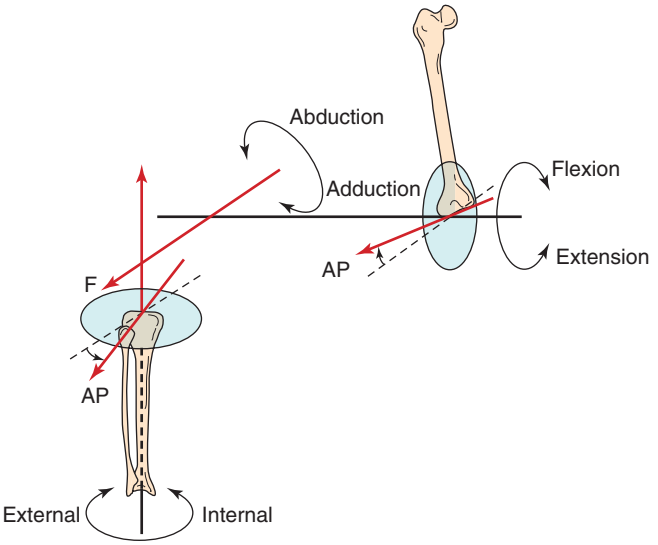

FIG 3-3 The three joint rotations in the knee joint. Flexion/extension occurs about the medially and laterally oriented axis in the femur. Internal and external tibial rotation occurs about an axis parallel to the shaft of the tibia. Abduction occurs about a third axis parallel to the femoral sagittal plane and also through the tibial transverse plane. (From Noyes FR, Grood ES. Classification of ligament injuries: why an anterolateral laxity or anteromedial laxity is not a diagnostic entity. In Griffin P, editor: *AAOS Instructional Course Lectures,* Vol XXXVI. Chicago: American Academy of Orthopaedic Surgeons; 1987:185-200.)

plane. Rotation of the tibia about this axis does not have associated internal-external rotation or abduction-adduction motions.[22] Because these motions occur during flexion, the flexion-extension axis shown in Figure 3-3 does not correspond to the functional flexion axis. The functional flexion axis is skewed in the knee and changes its orientation as the knee is flexed. This skewed orientation accounts for the combined motions of flexion, abduction, and tibial rotation.

The internal-external tibial rotation axis is located in the tibia, parallel to the tibial shaft and perpendicular to the tibial transverse plane. Rotations about this axis are pure internal and external tibial rotation motions without any associated abduction-adduction or flexion-extension.

The abduction-adduction rotation axis is more difficult to visualize because it is not located in either bone and its orientation can change relative to both. This axis is always parallel to the femoral sagittal plane. When the knee is flexed, the orientation of the abduction axis changes relative to the femur as it rotates in the sagittal plane. The abduction axis is perpendicular to the tibial rotation axis and parallel to the tibial transverse plane.

There are three linear DOF in the knee joint, referred to as *translations*. One simple approach to describing translations is to visualize relative sliding between the bones along each of the three rotational axes (Fig. 3-4). The sliding motion along the flexion-extension axis is the medial-lateral translation between the tibia and femur. The sliding motion along the tibial rotation axis results in joint compression and distraction translation. Sliding motions along the abduction-adduction rotation axis produce AP translations. These are also commonly known as *drawer motions*.

Therefore, there are six possible motions that can occur in the knee: three rotations and three translations. Three axes are required to explain these six motions, one fixed in each bone (see Fig. 3-4). Each axis represents two DOF, one a rotation occurring about the axis and the other a translation.

The purpose of the examination is to determine the specific increase in motion (amount and direction) of each clinically relevant DOF. In many cases, coupled motions occur in the knee joint, such as anterior translation combined with internal tibial rotation during Lachman testing, which is further increased on pivot shift testing. First, the examiner must understand the effect that ligament defects have on each of these motions, because one or both may be increased. Second, both the amount of increased motion and resulting subluxation of the tibial plateaus depend on the position of the knee joint, which is

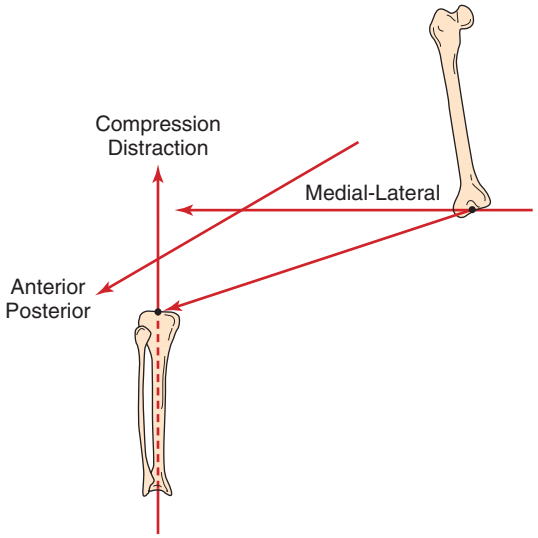

FIG 3-4 The three translations of the knee joint are motions of a point on the tibia parallel to each of the three axes. The point of the tibia used is located midway between the spines of the tibial plateau and is indicated by the arrow originating from the center point of the femur. Medial-lateral translation is motion of the point parallel to the flexion-extension axis. Anterior-posterior translation is motion of the tibial point parallel to the abduction axis, and compression-distraction translation is motion of the point along the internal and external rotation axis. (From Noyes FR, Grood ES. Classification of ligament injuries: why an anterolateral laxity or anteromedial laxity is not a diagnostic entity. In Griffin P, editor: *AAOS Instructional Course Lectures,* Vol XXXVI. Chicago: American Academy of Orthopaedic Surgeons; 1987:185-200.)

defined in terms of six DOF. Third, after a ligament is ruptured, an abnormal position usually is present in the axis of internal-external tibial rotation. This may be detected on examination and is helpful in diagnosing the ligament defect.

To understand the results of the clinical examination, a distinction must be made between abnormalities in joint motion and abnormalities in joint position (subluxation) that occur at the limit of the test. An abnormality in one or more motion limits can cause a subluxation of the knee joint. The subluxation depends on the direction and magnitude of the loads applied. Clinical tests are used to detect the motion limit and the final abnormal joint position. The examination usually detects a subluxation and not a complete knee dislocation, in which contact of the articulating surfaces of both tibiofemoral compartments is lost.

Concept 5: Together, the Ligaments and Joint Geometry Provide Two Limits (Opposite Directions) for Each Degree of Freedom

Together, the ligaments and joint geometry provide two limits (opposite directions) for each DOF. Altogether, there are 12 possible limits of motion of the knee (Table 3-1). Injury to the structures that limit each motion increases joint laxity. The position of the joint at the final limits of motions (reflecting the ligament attachment sites) provides the information required for diagnosis. From a diagnostic standpoint, it would be ideal if each of the 12 limits of motion were controlled by a single ligamentous structure. Differential diagnosis could then be performed by evaluating each of the 12 limits separately. Clearly, this ideal situation does not exist. The ligaments, capsular structures, and joint geometry all work together and each contributes to limiting more than one motion. Thus, the problem of diagnosing knee injuries

TABLE 3-1 Twelve Limits of Knee Joint Motion

Motion Limit	Structures Limiting the Motion
Flexion	Ligaments, leg and thigh shape, joint compression
Extension	Ligaments and joint compression
Abduction	Ligaments and lateral joint compression
Adduction	Ligaments and medial joint compression
Internal rotation	Ligaments and menisci
External rotation	Ligaments and menisci
Medial translation	Bones (spines interlocking with femoral condyles) and ligaments (to prevent distraction)
Lateral translation	Bones (spines interlocking with femoral condyles) and ligaments (to prevent distraction)
Anterior translation*	Ligaments
Posterior translation*	Ligaments
Joint distraction	Ligaments
Joint compression	Bone, menisci, and cartilage

*Menisci, joint compressive effects after injury to primary restraint.

reduces to determining how to apply individual or combination motions to lengthen primarily a single ligament or capsular structure so that structure can be evaluated independently.

The ability to isolate each structure is the key to differential diagnosis of individual ligament injuries. The isolation of a structure is accomplished by placing the knee at the proper joint position (specifically, knee flexion angle and tibial rotation position) before the clinical stress test is performed. For example, the abduction (valgus) stress test is performed both in full extension and at 20 to 30 degrees of flexion. In the flexed position, the posterior capsule becomes slack, which allows the examiner to primarily load the MCL and mid medial capsule. The evaluation of ACL function is performed at 20 degrees of knee flexion[73] as opposed to the 90-degree position[42] commonly used many years ago; the 20-degree position more often results in increased anterior subluxation because secondary restraints are more slack and less able to block this motion. Diagnosis of an injury to a specific ligament is performed at a joint position at which other structures are the most lax and least able to block the abnormal subluxation from the ligament injury. The lax secondary restraints allow an increase in joint motion before they become taut and resist further joint motion. Thus, isolating a ligament so its integrity may be individually tested requires placing the knee in a position in which other supporting structures are slack.

Another example of the importance of selecting the joint position for clinical tests is the diagnosis of PCL injury. Figure 3-5 shows the amount of increased posterior tibial translation that occurs when the PCL is removed.[10,21,22] The increase in posterior translation is two to three times greater at 90 degrees of flexion than at 20 degrees of flexion. This phenomenon is easily understood using a bumper model analogy in which the amount of joint motion after a ligament is injured depends on the role and function of the remaining ligaments that must ultimately limit the joint motion (Fig. 3-6). Thus, the increase in joint motion that occurs when a ligament is injured reflects the amount of additional joint motion required before the remaining intact ligaments become stretched and are able to limit further motion.

Figure 3-7 illustrates the limits to internal tibial rotation in the knee joint.[21] At 30 degrees of flexion (see Fig. 3-7, *A*), the limits to internal rotation are provided by posteromedial structures, lateral structures, and the ACL all working together. Sectioning either the ACL or the

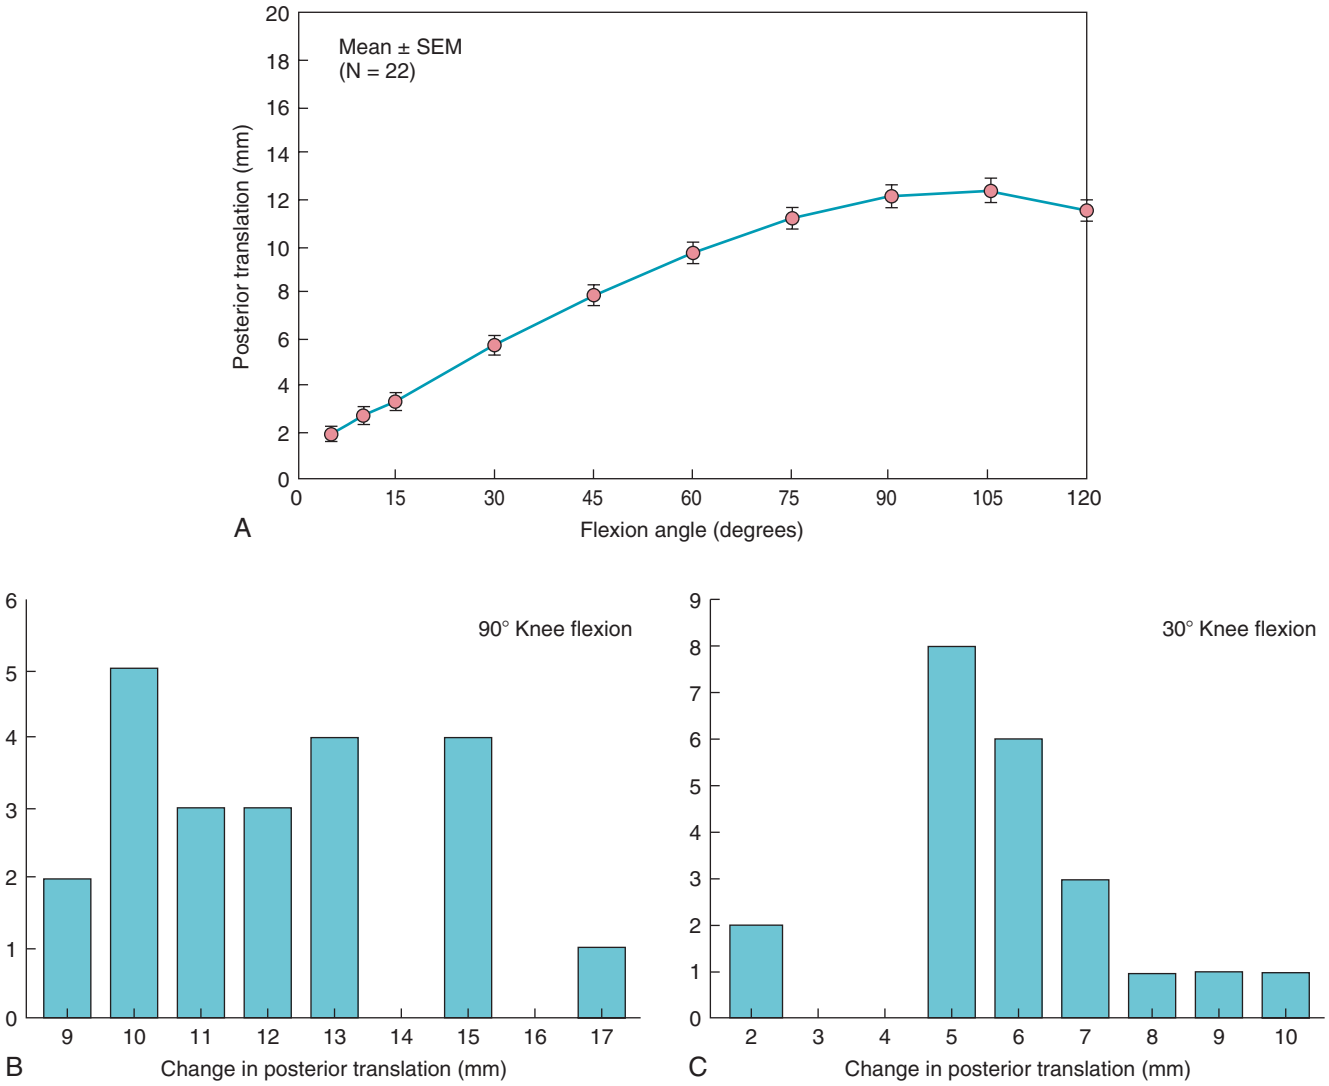

FIG 3-5 **A,** The increase in posterior translation is shown in 22 cadaveric knees under 100 N posterior force applied to the proximal tibia. The posterior force did not constrain the other degrees of freedom. The increase in posterior translation was 5.7 ± 0.4 mm at 30 degrees of flexion (**B**) and 12.1 ± 0.46 at 90 degrees of flexion (**C**). The data show that the majority of knees (15 of 22) that had the posterior cruciate ligament (PCL) sectioned alone had greater than 10 mm of increased posterior translation. This demonstrates the variability in knees in the physiologic tightness or slackness of the secondary restraints in resisting posterior tibial translation after PCL disruption.

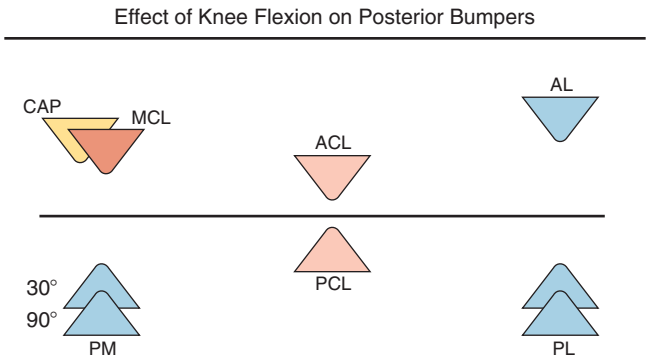

FIG 3-6 Effect of knee flexion on posterior bumpers. After loss of the posterior cruciate ligament (PCL) and as the knee is flexed, the posterior capsular structures become slack, allowing increased tibial displacement before they limit posterior translation. This is shown in the model by the more posterior position of the posteromedial (PM) structures and posterolateral (PL) structures bumpers at 90 degrees compared with 30 degrees of knee flexion. *ACL*, Anterior cruciate ligament; *AL*, anterolateral restraints; *CAP*, capsule; *MCL*, medial collateral ligament; *PM,* posteromedial structures. (From Grood ES, Noyes FR. Diagnosis of knee ligament injuries: biomechanical precepts. In Feagin J, editor: *The Crucial Ligaments.* New York: Churchill Livingstone; 1988:245-260.)

lateral structures produces a small increase in internal rotation. When both of these structures are cut together, a larger increase in internal rotation occurs. The further limit to internal rotation is the FCL, based on its anatomy.

The ACL dominates at flexion angles less than 30 degrees, whereas the lateral structures dominate at flexion angles greater than 30 degrees. This can be explained by considering the changes that occur in ligament slackness with flexion and extension. As the knee is extended past 20 degrees, the amount of AP translation decreases owing to reduction in the combined slackness of both cruciate ligaments. This brings these bumpers closer together. The posteromedial capsule (PMC) also tightens, moving its bumper anteriorly. This combination (see Fig. 3-7, *B*) results in a decreased role of the anterolateral structures because the tibia can no longer rotate to the point where it becomes taut.

With flexion beyond 30 degrees, the lateral structures become progressively tighter and the posteromedial structures become progressively slack. This combination causes internal rotation to be limited first by the extraarticular restraints, and is consistent with laboratory results showing that sectioning the ACL alone does not increase internal rotation when the knee is flexed between 40 and 80 degrees.

Figure 3-8 illustrates the limits to external rotation. At 30 degrees of flexion, external rotation is limited only by the extraarticular restraints. On the lateral side, this includes all of the posterolateral structures, which act as a unit. Large increases in rotation do not occur until all structures are cut. At 90 degrees of flexion, the posterior capsule is slack and the PCL blocks significant increases in external rotation when the posterolateral structures are sectioned. In laboratory studies, external rotation increases an average of only 5.3 ± 2.6 degrees when all of the posterolateral structures are sectioned and the PCL is intact. When the PCL is also sectioned, a large additional increase in external rotation occurs, ranging from 15 to 20 degrees.

An example of the changes in motion limits in ACL ruptures is shown in Figure 3-9. In cadaver knees, cutting the ACL causes an abnormal increase in both anterior tibial translation and internal tibial rotation.[6] The increase in anterior tibial translation is the primary abnormality, because it increases 100% while there is a small increase in internal rotation (approximately 15%). Cutting the ACL alone produced a small but significant increase in internal rotation, greatest at 0 and 15 degrees (Fig. 3-10). Subsequently, sectioning the ITB and lateral capsule produced statistically significant increases at 30 degrees and greater.

Coupled motions (anterior tibial translation, internal tibial rotation) occur in cadaver knees after sectioning the ACL and lateral extraarticular structures. Coupled motions can be caused by factors intrinsic to the knee or by the manner in which the clinical test is performed. For instance, the amount of internal tibial rotation elicited depends on the amount of rotation the clinician applies during the examination. This is why it is difficult to obtain reproducible results with the Lachman and other clinical tests. The KT-2000 (MEDmetric) provides an objective measurement of the amount of tibial translation measured at the center of the tibia. However, the millimeters produced by this device do not include the added millimeters of translation at the lateral tibiofemoral joint with added internal tibial rotation, such as that produced during the pivot shift test.

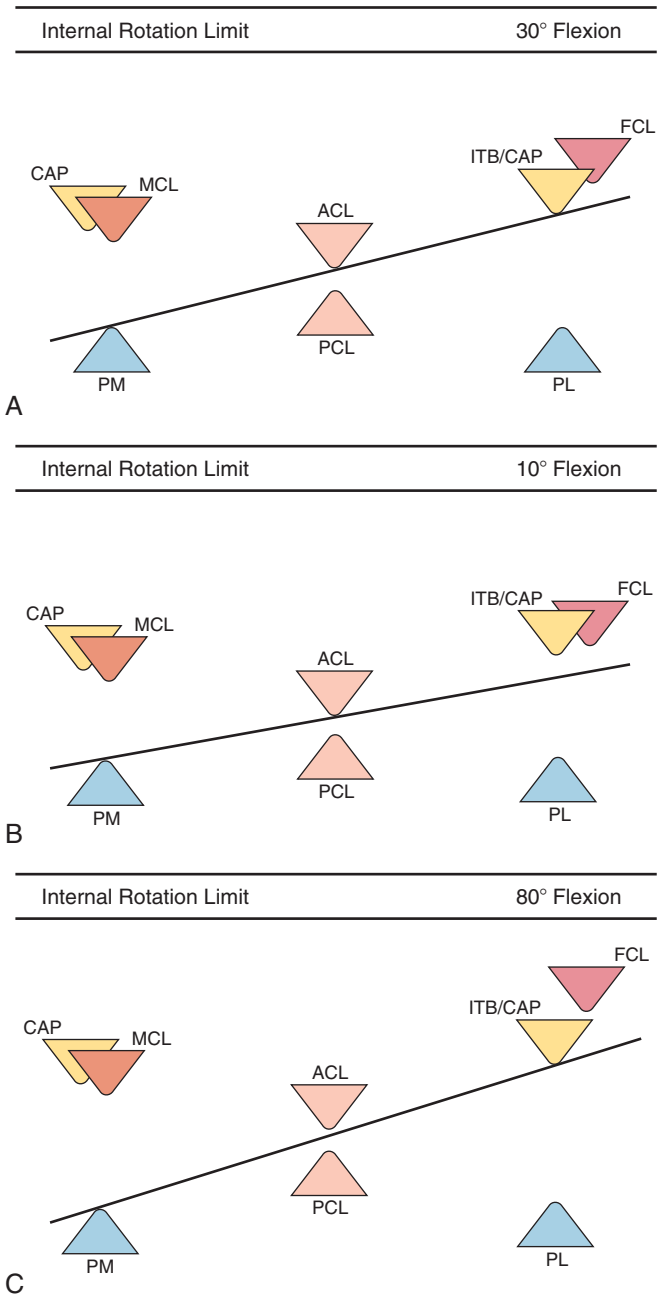

FIG 3-7 Limits to internal rotation. **A,** At 30 degrees of flexion, internal rotation is limited by the anterior cruciate ligament (ACL) centrally and the lateral restraints. These structures limit anterior translation. In addition, the posterior translation of the medial plateau is limited by the posteromedial (PM) restraints. **B,** At 10 degrees of flexion, the posterior bumpers move in closer toward the posterior cruciate ligament (PCL) owing to a reduction in the slackness present in the posterior capsule. In addition, the ACL bumper moves posteriorly as a result of tightening the ACL/PCL complex. Because of this, internal rotation of the tibia is now limited by the ACL centrally and the PM restraints alone. The tibia can no longer rotate far enough to engage the lateral restraints. **C,** At 80 degrees of flexion, the posterior bumpers move further posterior, reflecting the increased slackness in the posterior capsule. In addition, the distance between the ACL and PCL bumpers has increased slightly to reflect the increased laxity of these structures. The medial and lateral structures are now moved posteriorly as a result of tightening of the extraarticular restraints with knee flexion. Internal rotation is now limited by the lateral and PM restraints without direct involvement with the ACL. *CAP,* Capsule; *FCL,* fibular collateral ligament; *ITB,* iliotibial band; *MCL,* medial collateral ligament; *PL,* posterolateral structures. (From Grood ES, Noyes FR. Diagnosis of knee ligament injuries: biomechanical precepts. In Feagin J, editor: *The Crucial Ligaments.* New York: Churchill Livingstone; 1988:245-260.)

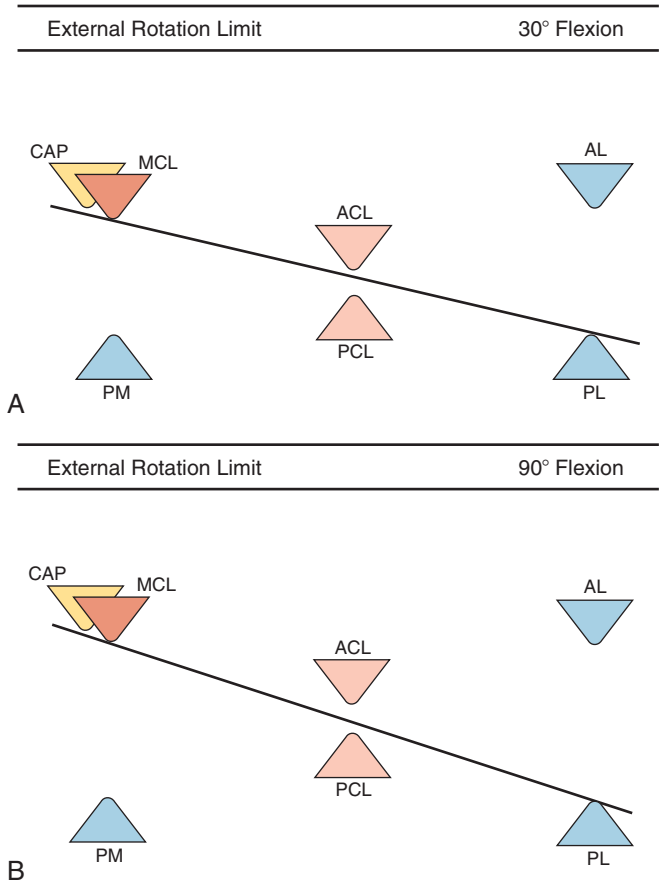

FIG 3-8 Limits to external rotation. **A,** At 30 degrees of flexion, the external rotation of the tibia is limited by the bumpers that stop anterior translation of the medial plateau and posterior translation of the lateral plateau. Owing to the position of the structures, there is no direct involvement of either the anterior cruciate ligament (ACL) or posterior cruciate ligament (PCL) in limiting external rotation. **B,** At 90 degrees of flexion, the posterior bumpers are moved posterior, reflecting the increased slack in the posterior capsule. Because of this, the PCL is nearly taut at the limit of external rotation. After removing the posterolateral (PL) restraints, only a small increase in external rotation occurs at this flexion angle. *AL,* Anterolateral; *CAP,* capsule; *MCL,* medial collateral ligament; PM, posteromedial structures. (From Grood ES, Noyes FR. Diagnosis of knee ligament injuries: biomechanical precepts. In Feagin, J. [ed.]: *The Crucial Ligaments.* New York: Churchill Livingstone; 1988:245-260.)

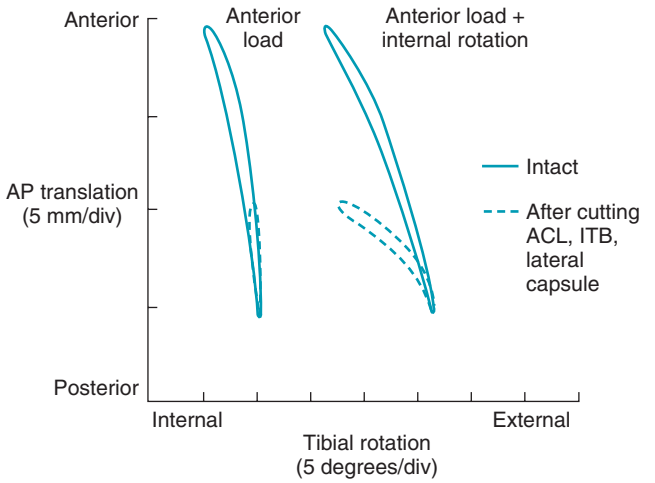

FIG 3-9 Anterior translation versus tibial rotation is shown during the Lachman-type anterior loading test at 15 degrees of knee flexion. The amount of anterior tibial translation is shown vertically and the position of tibial rotation is shown horizontally. *ACL,* Anterior cruciate ligament; *AP,* anteroposterior; div, division; *ITB,* iliotibial band. (From Noyes FR, Grood ES. Classification of ligament injuries: why an anterolateral laxity or anteromedial laxity is not a diagnostic entity. In Griffin P, editor: *AAOS Instructional Course Lectures,* Vol XXXVI. Chicago: American Academy of Orthopaedic Surgeons; 1987:185-200.)

The amount of anterior tibial translation induced during anterior drawer testing is dependent on the amount of internal or external tibial rotation applied at the beginning of the test (Fig. 3-11). The instrumented knee joint is shown for measuring rotations and translation motions during the clinical examination in Figure 3-12. This is because rotation tightens the extraarticular secondary restraints. The greatest amount of anterior or posterior tibial translation will be produced when the tibia is not forcibly rotated internally or externally, tightening extraarticular structures, during the clinical test. If the tibia is internally or externally rotated before the start of testing, the amount of tibial translation elicited will be smaller. Thus the clinician controls the amount of translation by both the initial rotational position of the tibia and by the amount of rotation imposed during the test. There is considerable variation in examination techniques of clinicians that makes all of the clinical tests highly subjective and qualitative, as is discussed.

The pivot shift[14] and flexion-rotation[59] drawer tests involve a complex set of tibial rotations and AP translations (Fig. 3-13). At the beginning of the flexion-rotation drawer test, the lower extremity is simply supported against gravity (Fig. 3-14, position A). After ligament sectioning, both anterior tibial translation and internal rotation increase as the femur drops back and externally rotates into a subluxated position.[57] This position is accentuated as the tibia is lifted anteriorly (Fig. 3-14, position B). At approximately 30 degrees of flexion, the tibia is pushed posteriorly, reducing the tibia into a normal relationship with the femur (Fig. 3-14, position C). This is the limit of posterior tibial translation resisted primarily by the PCL. From position C to position A, the knee is extended to produce the subluxated position again.

The rotational component of the test can be purposely accentuated by the examiner, inducing a rolling motion of the femur. One advantage of the flexion-rotation drawer test is that it is not necessary to produce joint compression or add a lateral abduction force required in the pivot shift test. The rolling motion avoids the sometimes painful "thud/clunk" phenomenon induced in the pivot shift test. A finger may also be placed along the anterior aspect of the lateral and medial plateau and the tibiofemoral step-off palpated to provide a qualitative estimate of the millimeters of anterior tibial subluxation. The examiner can easily visualize the translation and rotation motions. Translation is observed by watching the forward motion of the tibial plateaus. Rotation is observed by watching the patella rotate externally with the femur in the subluxated position and internally in the reduced position.

The pivot shift and flexion-rotation drawer tests are graded only in qualitative terms because it is not possible to determine accurately the actual amount of internal tibial rotation or anterior translation elicited. A fully positive pivot shift test (grade III) indicates a gross subluxation of the lateral tibiofemoral articulation along with an increased anterior displacement of the medial tibial plateau (Table 3-2). The amount of anterior subluxation elicited is indicative of rupture to the ACL and laxity to the secondary extraarticular restraints. The lateral

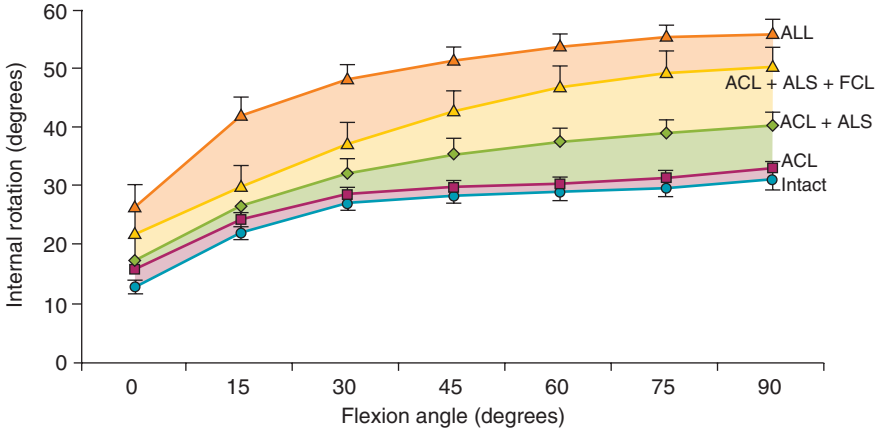

FIG 3-10 Limits of internal rotation with 5 N-m moment for intact specimens and with the anterior cruciate ligament (ACL), ACL/anterolateral structures (ALS), fibular collateral ligament (FCL), and anterolateral ligament (ALL) structures (ACL/ALS/FCL/posterolateral structures [PLS]) cut. Increases in internal rotation with the ACL cut are all statistically significant, but the magnitude of these increases is so small that they are clinically unimportant. With ACL/ALS sectioning, increases in internal rotation are statistically significant at 30 degrees of flexion and above. Statistically significant increases are found at 15 degrees of flexion and above in the ACL/ALS, FCL cut state, and at all flexion angles of the ALL cut state. The effect of the PLS on restraining internal rotation in the extended knee can be seen by comparing the ACL/ALS/FCL curve and the ALL cut curve. The difference between these curves reflects sectioning the PLS. The largest differences are found at 15 and 30 degrees of flexion. (From Wroble RR, Grood ES, Cummings JS, et al. The role of the lateral extraarticular restraints in the anterior cruciate ligament-deficient knee. *Am J Sports Med.* 1993;21:257-263.)

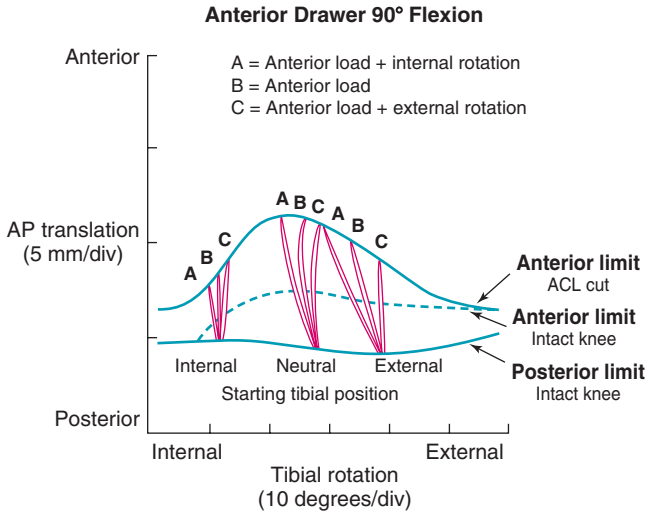

FIG 3-11 The amount of anteroposterior (AP) translation depends on the rotational position of the tibia at the beginning of the anterior drawer test. ACL, Anterior cruciate ligament; div, division. (From Noyes FR, Grood ES. Classification of ligament injuries: Why an anterolateral laxity or anteromedial laxity is not a diagnostic entity. In Griffin P, editor: *AAOS Instructional Course Lectures,* Vol XXXVI. Chicago: American Academy of Orthopaedic Surgeons; 1987:185-200.)

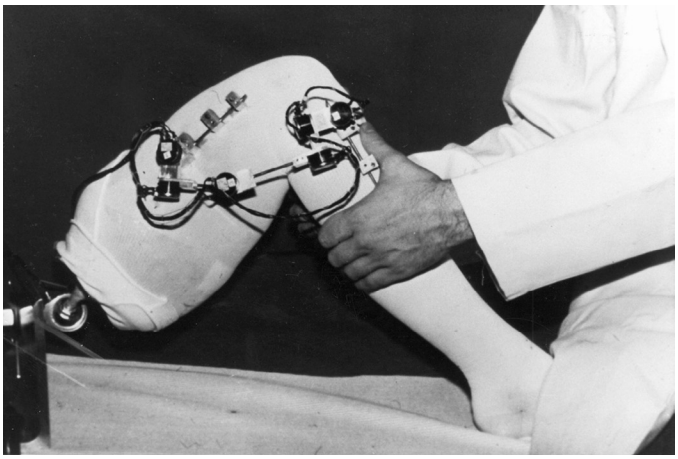

FIG 3-12 The six degrees of freedom electrogoniometer provides the clinician with immediate feedback on the motions induced during the manual drawer tests. (From Noyes FR, Grood ES. Classification of ligament injuries: why an anterolateral laxity or anteromedial laxity is not a diagnostic entity. In Griffin P, editor: *AAOS Instructional Course Lectures,* Vol XXXVI. Chicago: American Academy of Orthopaedic Surgeons; 1987:185-200.)

tibial plateau demonstrates the greater subluxation in a positive pivot shift test, indicating that the lateral restraints (ITB, lateral capsule) are not functionally tight. This does not mean that these restraints are injured because a physiologic slackness of the ITB tibiofemoral attachments is normal at the knee flexion position used in this test. These attachments are tightest at knee flexion angles 45 degrees and higher. Therefore the majority of knees with an isolated ACL tear will have a positive pivot shift phenomenon.

In knees with a grade III pivot shift, the amount of anterior tibial subluxation is so great that the posterior margin of the lateral tibial plateau impinges against the lateral femoral condyle and blocks further knee flexion during the test. The examiner must add both a maximal anterior force and internal tibial rotation force to determine whether the maximum subluxation position can be reached. In revision ACL reconstructions, a combined intraarticular graft and extraarticular ITB surgical approach is often considered.[48]

In a small percentage of knees with ACL ruptures, the classic "thud" or "clunk" will not be elicited during the pivot shift test. An

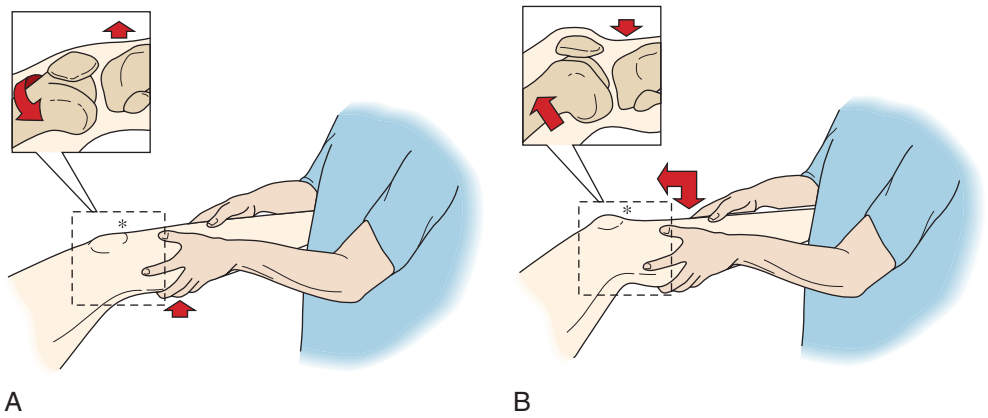

FIG 3-13 A, Flexion-rotation drawer test, subluxated position. With the leg held in neutral rotation, the weight of the thigh causes the femur to drop back posteriorly and rotate externally, producing anterior subluxation of the lateral tibial plateau. **B,** Flexion-rotation drawer test, reduced position. Gentle flexion and a downward push on the leg reduces the subluxation. This test allows the coupled motion of anterior translation-internal rotation to produce anterior subluxation of the lateral tibial condyle. (From Noyes FR, Bassett RW, Grood ES, et al. Arthroscopy in acute traumatic hemarthrosis of the knee. *J Bone Joint Surg Am.* 1980;62:687-695.)

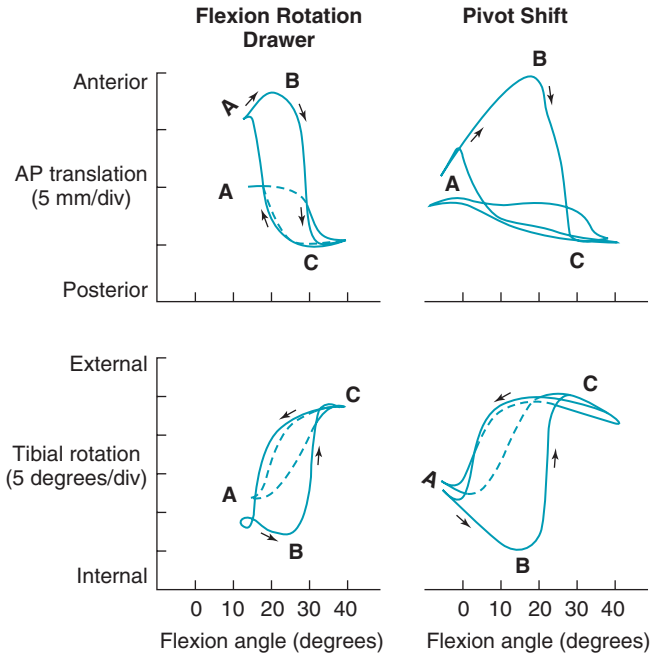

FIG 3-14 The knee motions during the flexion-rotation drawer and pivot shift tests are shown for tibial translation and rotation during knee flexion. The clinical test is shown for the normal knee (*solid-line waveform*) and after ligament sectioning (*dotted-line waveform*). The ligaments sectioned were the anterior cruciate ligament, iliotibial band, and lateral capsule. Position A is the starting position of the test, B is the maximum subluxated position, and C indicates the reduced position. The pivot shift test involves the examiner applying a larger anterior translation load, which increases the motion limits during the test. div, Division. (From Noyes FR, Grood ES, Suntay WJ. Three-dimensional motion analysis of clinical stress tests for anterior knee subluxations. *Acta Orthop Scand.* 1989;60:308-318.)

experienced examiner will detect an increased slipping sensation in the knee (grade I), which indicates that the extraarticular secondary restraints are physiologically tight, limiting the amount of anterior tibial subluxation, or that a partial ACL tear exists.

Concept 6: Rotatory Subluxations Are Characterized by the Separate Compartment Translations That Occur to the Medial and Lateral Tibial Plateaus During the Clinical Test

A simple concept may assist in explaining the abnormal motions that occur after ACL rupture: rotatory subluxations can be classified according to the amount of anterior and posterior translation of each tibiofemoral compartment. Figure 3-15, *A* shows a Lachman test performed on a knee in which the combined motions of anterior tibial translation and internal tibial rotation occur about a medially located rotation axis. In this example, only planar motion occurs; the ACL rupture doubles the amount of anterior tibial translation and slightly increases internal tibial rotation. The rotation axis shifts medially. The ratio of tibial translation to degrees of internal tibial rotation determines how far medially the axis of rotation shifts.

The abnormalities in tibial rotation and translation are easily expressed in terms of the different amounts of anterior translation that occur to the medial and lateral compartments (see Fig. 3-15, *B*) in biomechanical tests. During the clinical tests, the clinician may qualitatively palpate and observe the anterior or posterior translation of each tibial plateau. The AP translation of each plateau is characterized instead of defining the individual components of translation, rotation, and rotation axis location that all lead to the anterior subluxation. The combined effect of the rotation and translation determines the translation of the medial and lateral tibiofemoral compartments.

The type of rotatory subluxations that occur depends on both the ligament injury and the knee flexion position. The subluxations of the medial and lateral compartment are usually recorded at two knee flexion positions, such as 20 and 90 degrees. Described later is the dial test for posterolateral injuries, in which the examiner determines whether increases in external tibial rotation reflect anteromedial or posterolateral tibial subluxations. It should be noted that rotatory

TABLE 3-2 Classification of Pivot Shift Test Grades

	STRUCTURES INVOLVED				
Test Grade	Anterior Cruciate Ligament	Iliotibial Band, Lateral Capsule	Medial Ligaments, Capsule	Positive Tests	Comments
Normal	Intact	Intact	Intact		
I	Intact to slight increase in laxity	Intact	Intact	Lachman, flexion-rotation drawer, pivot shift "slip" but not "jerk"	Either physiologic laxity or partial ACL laxity allow subtle subluxation-reduction phenomena. Secondary ligament restraints limit the amount of joint subluxation. Subluxation is detected as a "slip," indicating increased lateral compartment translation.
II	Ruptured	Intact to slight increase in laxity	Intact	All tests	Hallmark is an obvious "jump," "thud," or "jerk" with the gross subluxation-reduction during the test. There is either a normal physiologic laxity (lateral capsule, iliotibial band) or injured secondary restraints.
III	Ruptured	Significant increase in laxity	May have increase in laxity	All tests	Hallmark is a gross subluxation with impingement of the posterior aspect of the lateral tibial plateau against the femoral condyle. The examiner must decrease internal rotational torque on the leg to allow lateral tibiofemoral reduction and further knee flexion.

ACL, Anterior cruciate ligament.

subluxations are historically based on increases in tibial internal or external rotation, and only in a few studies have the actual medial and lateral tibial subluxations in an AP direction been determined.[21,60] There are complex rotatory subluxations involving increases in translation, but in opposite directions of both the medial and lateral compartments with combined medial and lateral ligament injuries.

Robotic Studies

There have been numerous in vitro and in vivo studies published over the past decade on ACL function in regard to providing rotational knee stability.[12,25,35,38,41,75,81] Based on the results of these studies, recommendations for ACL single- and double-bundle graft reconstructions, graft placement, and tensioning have been published.[12,13,25,34,35,38,41,43,75,80,81] These investigations involved a simulated Lachman test and, more importantly, the pivot shift test, which correlates with patient-subjective giving-way symptoms. In our opinion, there are problematic errors in many studies of which the surgeon should be aware in terms of application of the results to surgical treatment of ACL ruptures. For example, nearly all published studies describe rotational knee stability according to the changes in degrees of internal tibial rotation without measuring the center of tibial rotation or the position or subluxation of the tibiofemoral compartments. We believe that providing only the changes in degrees of tibial rotation, without specification of the medial and lateral tibiofemoral compartment position or subluxation, is an inadequate descriptor of rotational knee stability. In fact, after ACL rupture, there is a change of only a few degrees of internal tibial rotation as long as the lateral extraarticular structures remain intact.[7,54,62,63]

A second problem we have identified in a majority of in vivo and in vitro pivot shift studies is the loading profile used to induce anterior tibial subluxation. Studies commonly report, in the pivot shift simulation, an abnormal anterior tibial translation after ACL sectioning that is only half that obtained in the Lachman test. However, under clinical conditions, a positive pivot shift test produces greater anterior tibial subluxation than the Lachman test. Accordingly, these prior studies were conducted under low knee displacement conditions in which the loading profile involved an internal rotation-valgus condition during knee extension to produce anterior tibial subluxation. There was an absence of a simultaneous combined anterior tibial loading, which is important in the clinical pivot shift test to induce anterior tibial subluxation of both the lateral and medial tibiofemoral compartments.

Bedi and colleagues[3] reported (from in vitro and in vivo pivot shift studies) that the magnitude of lateral compartment translation showed a correlation with the clinical grade of the pivot shift and that a threshold of 6 to 7 mm was necessary to produce a positive pivot shift. This study measured both lateral and medial compartment translations. The mechanized pivot shift involved only small increases in medial tibiofemoral compartment translations, reflecting an internal rotation torque in the absence of anterior tibial loading. ACL sectioning failed to produce a positive pivot shift (grade II) in nearly all specimens, which limits interpretation of these data.

For reasons not apparent, pivot shift loading with a predominant internal rotation-valgus torque, without a coupled anterior tibial loading, has been the typical loading profile in nearly all cadaveric studies on ACL function and surgical reconstructions even though this limits anterior tibial subluxation of the medial compartment. In Figure 3-16, the results of a typical cadaveric knee specimen are shown under two pivot shift loading conditions. Two points are important. In the two simulated pivot shift tests, there is a greater anterior tibial subluxation of the lateral and medial compartment, with the pivot shift subluxation produced by a coupled anterior translation–internal rotation during the valgus loading (pivot shift [PS] 4), compared with an absence of the anterior tibial loading component (PS 3). Second, an analysis of rotational knee stability requires knowledge of the resulting subluxations (translations) of the medial and lateral tibiofemoral compartments. We recommend that future in vitro and in vivo pivot shift studies use loading profiles of coupled anterior tibial translation and

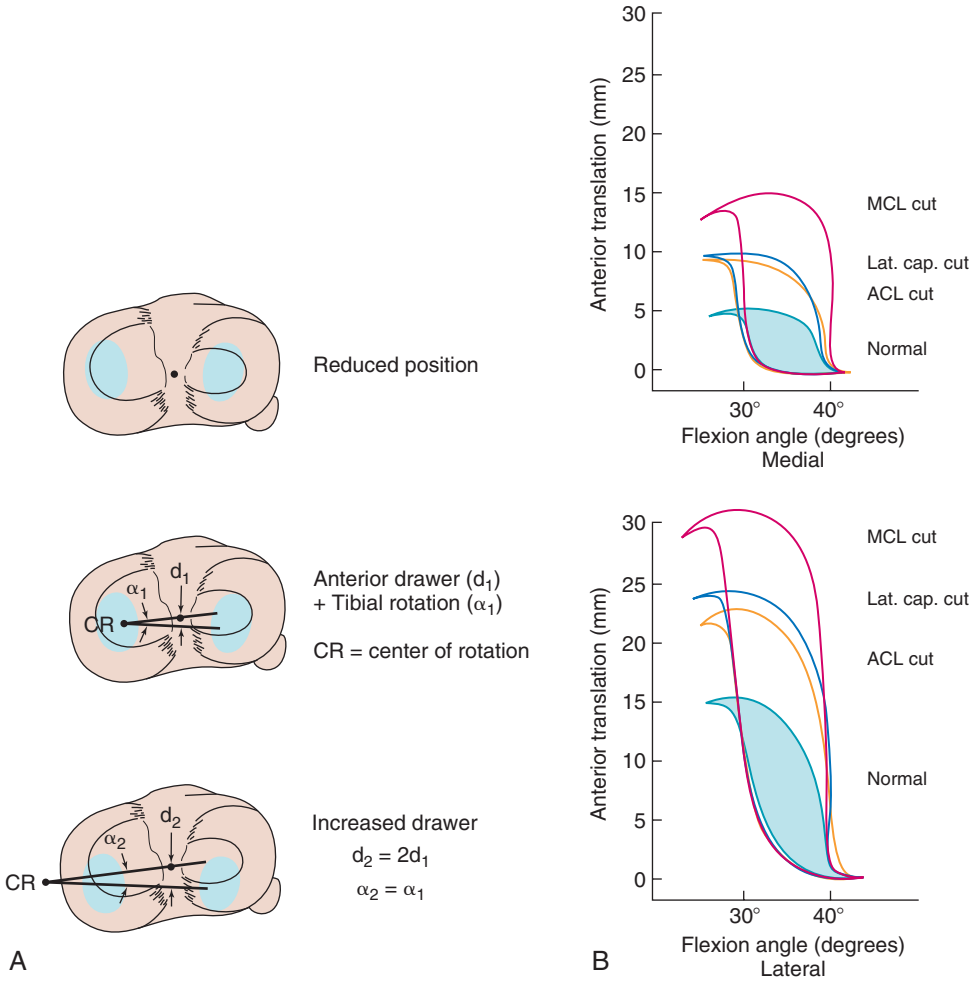

FIG 3-15 **A,** A simplification of the abnormal knee motions after anterior cruciate ligament (ACL) sectioning. An understanding of rotatory subluxations requires specifying changes in (1) position of the vertical axis of rotation and (2) displacement of the medial and lateral tibiofemoral compartments. The normal or subluxated position of the joint is determined by the degrees of rotation and the amount of translation. In the figure, an anterior pull is applied to the knee, which has an intact ACL. There is a normal anterior translation (d_1) and internal tibial rotation (α_1) about the center of rotation (CR). After ACL sectioning, there is a 100% increase in tibial translation (d_2) along with only a slight (15%) increase in internal tibial rotation (α_2). This shifts the axis of rotation medially and produces the subluxation of the lateral compartment and medial compartment as demonstrated. Loss of the medial extraarticular restraints would result in a further medial shift in the axis of rotation. This would increase the anterior subluxation of the medial tibial plateau and lateral tibial plateau. **B,** The amount of anterior tibial translation is shown for the medial and lateral tibiofemoral compartments during the flexion-rotation drawer test in a cadaveric knee preparation using the instrumented spatial linkage and digitization of the tibial and femoral joint geometry. *ACL,* Anterior cruciate ligament; *Lat. cap.,* lateral capsule; *MCL,* medial collateral ligament. (***A,*** From Noyes FR, Grood ES. Classification of ligament injuries: why an anterolateral laxity or anteromedial laxity is not a diagnostic entity. In Griffin P, editor: *AAOS Instructional Course Lectures,* Vol XXXVI. Chicago: American Academy of Orthopaedic Surgeons; 1987:185-200; ***B,*** From Noyes FR, Grood ES, Suntay WJ. Three-dimensional motion analysis of clinical stress tests for anterior knee subluxations. *Acta Orthop Scand.* 1989;60:308-318.)

internal tibial rotation, along with valgus loading, to induce a maximum anterior tibial subluxation of both tibiofemoral compartments. Furthermore, rotational torques should remain low in order not to constrain the maximum subluxation of the medial compartment.

We conducted a series of robotic cadaveric in vitro studies on the kinematic function of the ACL.[15,24,55] The studies involved a six-DOF robotic testing protocol on intact knees, ACL-sectioned knees, and ACL-reconstructed knees. The robotic testing protocol involved, for the first time, the simulation of the pivot shift event using four DOF—namely, anterior tibial translation with internal tibial rotation with valgus loading of the limb during knee flexion-extension to induce maximum anterior tibial subluxation (PS 4). The study also involved, for the first time, digitization of the tibial plateau to determine medial and lateral tibiofemoral compartment translations and centers of tibial rotation in the simulated pivot shift test.

The studies that found a single ACL graft placed into the anatomic center of the femoral and tibial attachment sites restored normal tibiofemoral compartment translations and rotations under simulated Lachman and pivot shift testing conditions. The reconstruction restored rotational stability as defined by normal motion limits and

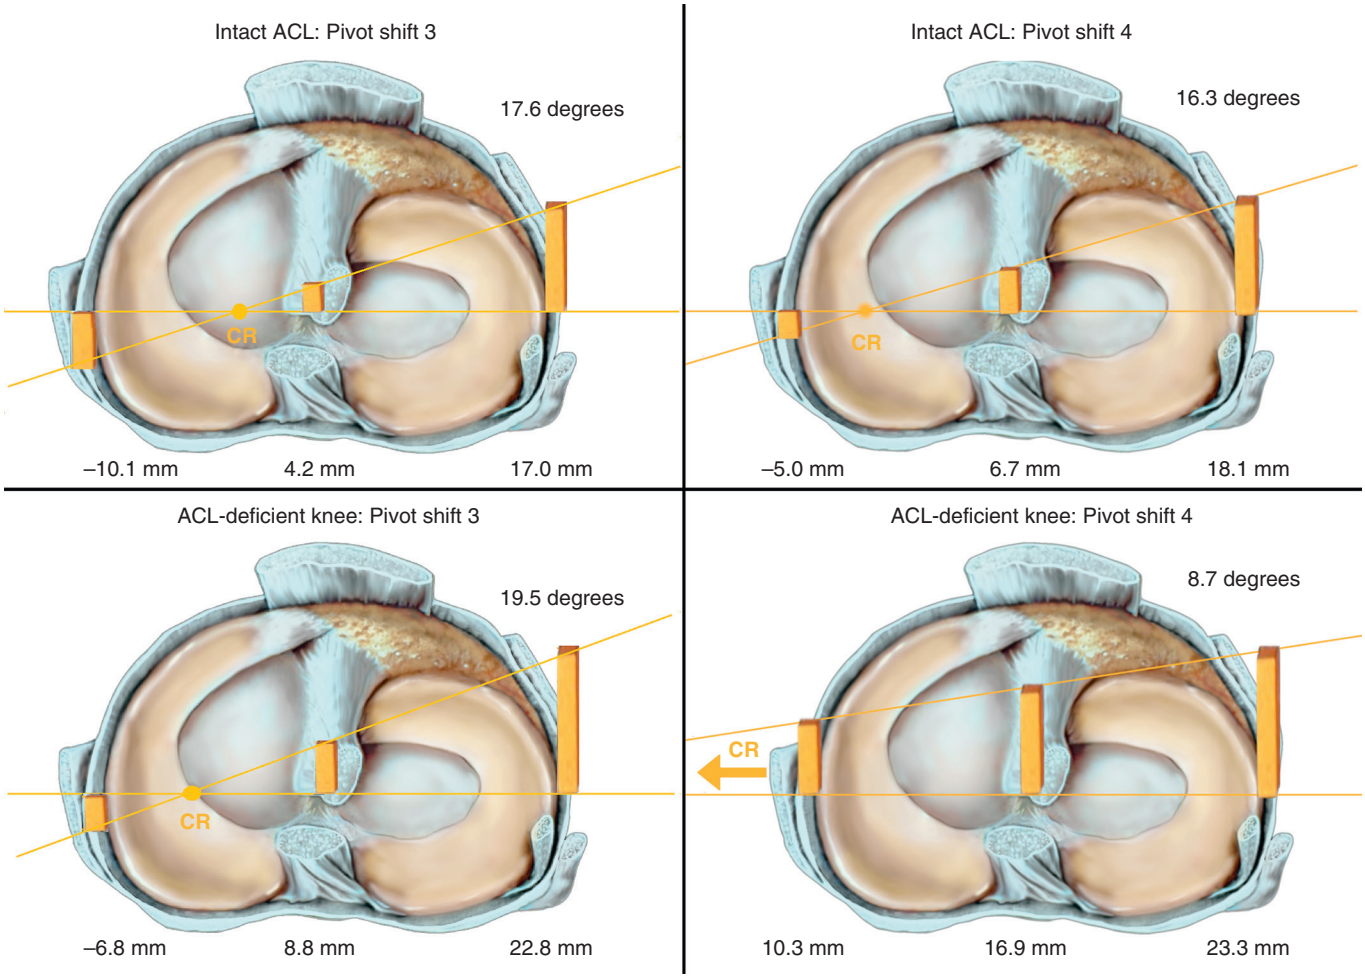

FIG 3-16 A representative right knee specimen showing compartment translations and tibial rotation under two loading conditions: pivot shift 3 and pivot shift 4. In the pivot shift 3 loading, there is no subluxation of the medial tibiofemoral compartment because the anterior tibial loading was of a small magnitude. In contrast, in the pivot shift 4 loading, a major anterior tibial loading is added along with internal rotation-valgus loading. In addition, the internal tibial torque is reduced from 5 to 1 N-m. There is a medial shift in the center of tibial rotation, with subluxation of the medial, center, and lateral tibiofemoral compartments. Loading conditions for pivot shift 3 were 35 N anterior, 5 N-m internal rotation, and 7 N-m valgus. Loading conditions for pivot shift 4 were 100 N anterior, 1 N-m internal rotation, and 7 N-m valgus. *ACL,* Anterior cruciate ligament; *CR,* center of tibial rotation.

normal medial and lateral compartment translations under simulated pivot shift loading conditions (Fig. 3-17). The results support the recommendation for the use of a single ACL graft instead of a double-bundle ACL graft construct (see Chapter 7).

Concept 7: Damage to Each Ligament and Capsular Structure Is Diagnosed Using Tests in Which the Primary and Secondary Ligament Restraints Have Been Experimentally Determined

Tears to the ACL and injury to the extraarticular ligamentous and capsular structures may be diagnosed using the Lachman, pivot shift, and flexion-rotation drawer tests. These tests provide the basic signs that allow the clinician to determine which structures are injured based on abnormal motion limits and resultant joint subluxations. The tests are performed in knee flexion positions in which the secondary restraints are unable to resist abnormal motions so that maximum displacement (subluxation) of the joint is produced. Table 3-3 provides a general summary of the primary and secondary restraints for the major tests used in the clinical examination. Later in this chapter, the specific restraining function of the ligaments is discussed in detail.

The qualitative grading of the pivot shift phenomenon is illustrated in Figure 3-18 to explain how ligament structures resist combined tibiofemoral motions. The cruciate ligaments are represented by a set of central bumpers that limit the amount of AP translation. There are also medial and lateral sets of bumpers that resist medial and lateral tibiofemoral compartment translations. For the medial and lateral bumpers, different ligament structures commonly work together as systems to provide the resistance. The bumpers represent not the anatomic position of the ligament structures, but rather a visual schematic to show the final restraints to tibial motion, summarizing the effect of the ligaments, menisci, and capsular structures. The tension-restraining effect of the ligaments is replaced by an opposite mechanism, a compressive bumper.

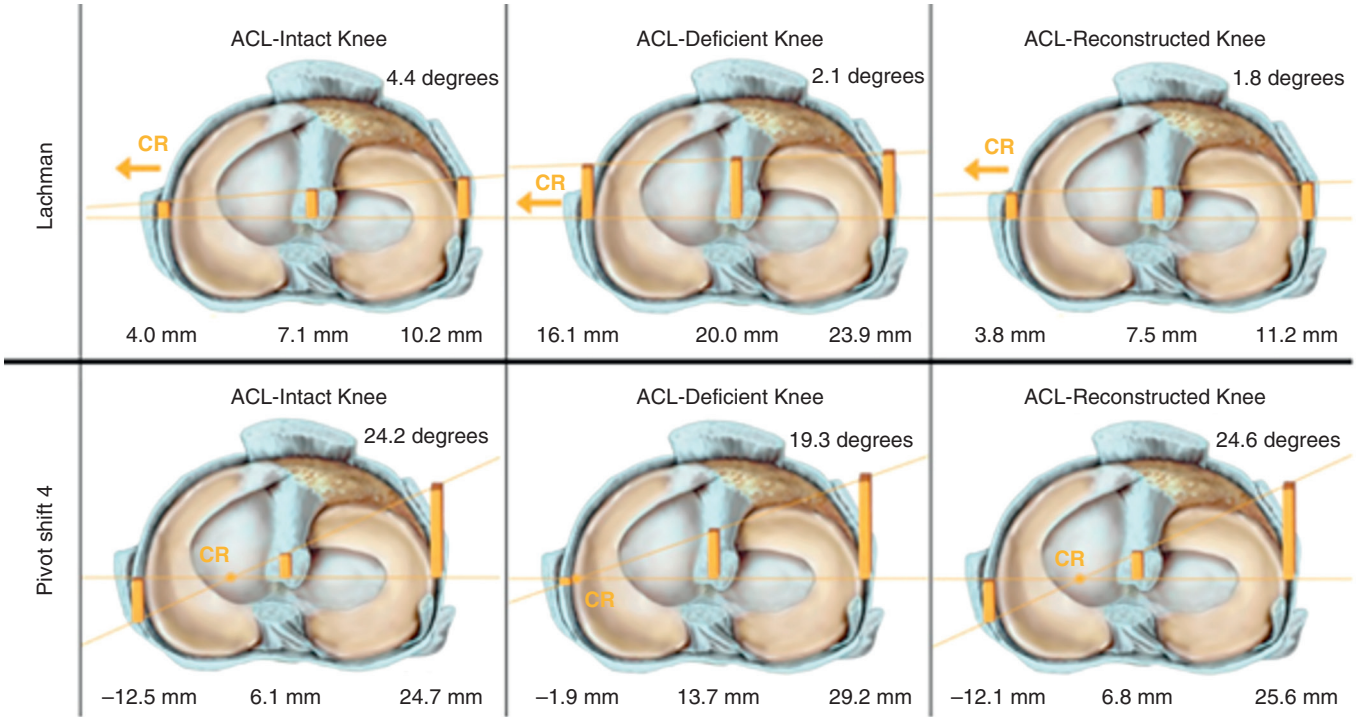

FIG 3-17 Compartment maps of a representative right knee specimen under the Lachman and simulated pivot shift test for intact, anterior cruciate ligament (ACL) deficient, and central anatomic bone-patellar tendon-bone reconstructed conditions. The data from this study showed a restoration of normal tibiofemoral compartment translation after ACL reconstruction. Loading conditions: Lachman anterior translation, 100 N; pivot shift anterior translation, 100 N; internal rotation, 1 N-m; valgus, 7 N-m. *CR*, Center of tibial rotation.

TABLE 3-3 Ligamentous Restraints of the Knee Joint

	PRIMARY RESTRAINT				SECONDARY RESTRAINT

ACL, Anterior cruciate ligament; *ALS*, iliotibial band + anterior + mid lateral capsule; *FCL*, fibular collateral ligament; *Lat*, lateral; LM, lateral meniscus; *MCL*, superficial medial collateral ligament plus middle one-third deep capsule; *MM*, medial meniscus; *PCL*, posterior cruciate ligament; *PLC*, posterolateral capsule (includes fabellofibular ligament); *PMC*, posteromedial capsule (includes posterior oblique ligament); *PMTL*, popliteus muscle-tendon-ligament; *TF*, tibiofemoral.

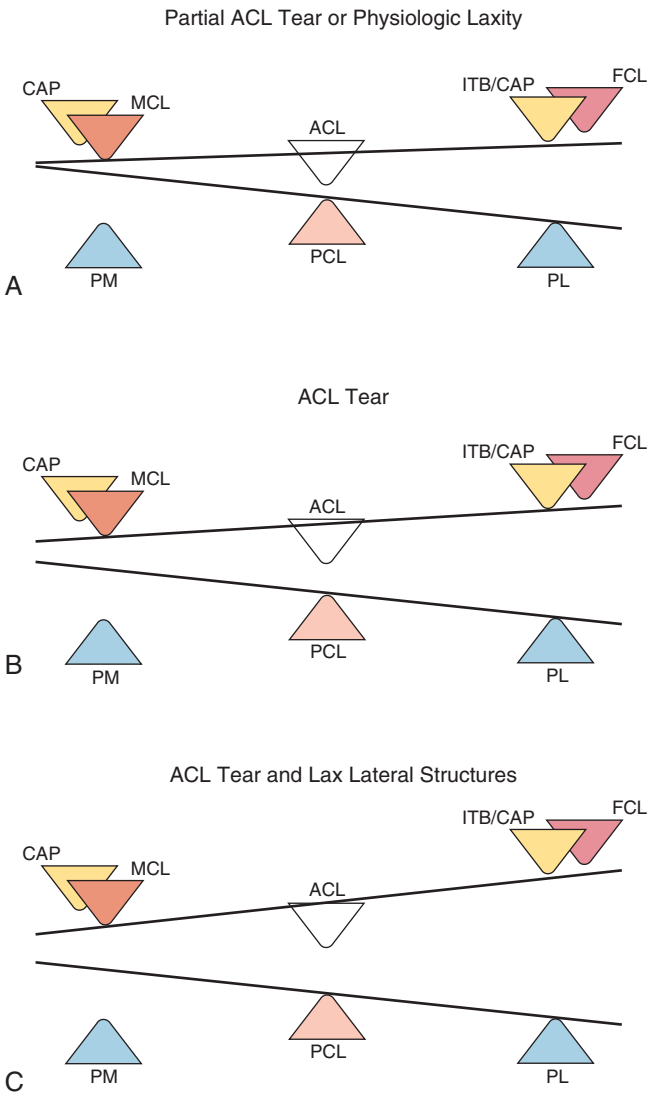

FIG 3-18 **A,** Grade I pivot shift. There is anterior translation of the lateral compartment that is resisted by the anterior cruciate ligament (ACL). There will be a slight increase in anterior translation with a partial ACL tear. Many knees with physiologic ACL laxity have a normal grade I pivot shift. Rarely, a knee will have excessively tight lateral structures that also limit anterior translation, and even with an ACL tear, there is only a grade I pivot shift phenomena. The *lower line* represents the posterior limit of tibial displacement. The *upper line* represents the anterior limit of tibial excursion resisted by the appropriate ligament bumpers. The distance of increased translation to the lateral-central-medial compartments is shown, reflecting the coupled motions of anterior translation and internal rotation. **B,** Grade II pivot shift. This is the usual finding after ACL disruption. The lateral extraarticular structures are physiologically lax between 0 and 45 degrees of knee flexion, allowing for increased anterior translation of the lateral tibiofemoral compartment. The lesion may also involve injury to the lateral structures (iliotibial band [ITB], lateral capsule [CAP]). **C,** Grade III pivot shift. There is associated laxity of the lateral extraarticular restraints. There may also be associated laxity of the medial ligament structures. This allows for a gross subluxation of both the medial and lateral tibial plateaus easily palpable during the pivot shift test, as well as the flexion-rotation drawer and Lachman tests. *ACL,* Anterior cruciate ligament; *CAP,* capsule; *FCL,* fibular collateral ligament; *MCL,* medial collateral ligament; *PCL,* posterior collateral ligament; *PL,* posterolateral structures; *PM,* posteromedial structures. (From Noyes FR, Grood ES. Classification of ligament injuries: why an anterolateral laxity or anteromedial laxity is not a diagnostic entity. In Griffin P, editor: *AAOS Instructional Course Lectures,* Vol XXXVI. Chicago: American Academy of Orthopaedic Surgeons; 1987:185-200.)

In diagnosing abnormal knee motion limits, the Lachman test involves primarily tibial translation without significant tibial rotation, testing the central bumper represented by the ACL. A bumper model representation of a partial ACL tear or an ACL-deficient knee with tight medial and lateral extraarticular restraints that limit the amount of anterior tibial translation is shown in Figure 3-18, *A*. The amount of central and lateral tibial translation is only slightly increased. The bumper model illustrates how the anterior restraints limit motion during the flexion-rotation drawer test, which allows the maximal anterior excursion of the medial and lateral tibiofemoral compartments. In this knee, the pivot shift is qualitatively listed as a grade I.

The most common type of anterior subluxation that occurs after an ACL rupture is shown in Figure 3-18, *B*. The center of rotation shifts medially outside the knee joint, with a resultant increase in translation to both the medial and lateral compartments, with the anterior subluxation of the lateral compartment being the greatest. The anatomic structures include the ACL and the lateral extraarticular restraints. In this knee, the pivot shift is qualitatively listed as a grade II.

A knee with gross anterior subluxation is represented in Figure 3-18, *C*. There is increased translation and subluxation to both the medial and lateral compartments and the rotation axis shifts even further medially outside the knee joint. The pivot shift test is listed as grade III, indicative of gross subluxation with impingement of the posterior aspect of the tibia against the femoral condyle. Partial damage to the medial ligamentous structures may be present.

LIGAMENTOUS RESTRAINTS TO AP TRANSLATION

In a series of biomechanical cadaveric experiments,[6] the ranked order of the importance of each knee ligament and capsular structure in resisting the clinical anterior and posterior drawer tests was determined, providing the primary and secondary restraints to specific knee motions. The ranked order was based on the force provided by each ligament in resisting AP translation.

Before these experiments, investigators performed studies in which selective sectioning of ligaments was conducted and the

CRITICAL POINTS Ligamentous Restraints to Anteroposterior Translation

- This investigation was the first to introduce the concepts of primary and secondary ligament restraints to joint motion.
- A testing method was developed that allowed the restraining force of each individual ligament to be determined.
- A precise displacement was applied and the resultant restraining force measured.
- The reduction in restraining force that occurred after sectioning a ligament defined its contribution.
- The ACL is the primary restraint to anterior translation, providing 86% of the total restraining force.
- Secondary restraints to anterior tibial translation include the iliotibial tract and band, mid medial capsule, mid lateral capsule, MCL, and FCL. No statistical difference exists among these structures in their contribution.
- The PCL provides 94% of the total restraining force of posterior tibial translation at 90 degrees of knee flexion, with similar findings at 30 degrees of flexion.
- The posterolateral capsule, popliteus tendon, and MCL provide the greatest secondary restraint to posterior tibial translation. The posterior medial capsule, FCL, and mid medial capsule provide only modest secondary restraining contribution.

increases in anterior or posterior tibial displacement were measured.[2,4,11,16,27,40,42,64,67] For example, the displacement test was done by applying a force on an intact knee, cutting a ligament, repeating the test, and measuring the increase in displacement. One problem with this experimental design is that the increase in displacement is dependent on the order in which the ligaments are sectioned. If this order is altered, the measured increase in displacement will change. Therefore, it is not possible to define the function of a single ligament in a precise manner. In addition, the amount of residual joint displacement after ligament sectioning is dependent on the just-taut length of the remaining ligaments, which varies between physiologic "tight" and "loose" knee joints.

To solve these problems, a testing method was developed that allowed the restraining force of each individual ligament to be determined. A precise displacement was applied and the resultant restraining force measured. The reduction in restraining force that occurred after sectioning a ligament defined its contribution. Because the joint displacement was controlled, the contributions of the other ligaments and capsular structures of the knee to the resultant tibial displacement were not affected. Controlling and reproducing the joint displacement from test to test eliminated the effect of the cutting order of the structures. This is because the joint displacement controls the amount of ligament stretch and, thereby, its force. Reproducing the displacement reproduces the force in each ligament. This indicates that even after a single ligament is cut, the remaining structures are unaffected. The reader should distinguish the difference between these two testing methods in ligament sectioning studies because the data provide different conclusions on ligament function.

Fourteen cadaver knees were tested from donors aged 18 to 65 years (mean, 42 years). The knee specimens were mounted in an Instron Model 1321 biaxial servo controlled electrohydraulic testing system (Fig. 3-19). A pair of grips was used for the femur and tibia that allowed for their precise position to be adjusted. First, the femur was secured with its shaft aligned along the axis of the load cell. The tibia was placed horizontally, with its weight supported by the lower grip. The output of the load cell was adjusted to zero to compensate for the weight of the upper grip and femur. The tibia was placed in a rotated position halfway between its limits of internal and external rotation. The output of the load cell was monitored while the tibia was secured to avoid preloading the ligaments. Single-plane anterior and posterior drawer tests were conducted by causing the actuator to move up and down without rotation. This is a constrained test in which coupled tibial rotation is purposely blocked. Specific details regarding the tests and data acquisition and statistical analyses are described in detail elsewhere.[6]

An AP drawer test is shown in Figure 3-20. Two curves are present, one for each direction of motion, as a result of the viscoelastic behavior of the knee ligaments. The peak restraining force of this specimen is approximately 500 N (112 lb) at 5 mm of drawer. The general shape of the force-displacement curve for the intact knee is nonlinear. The stiffness of the knee, or slope of the curve, is smallest near the neutral position and increases as the joint is displaced. The average restraining force in the intact knee is approximately 440 N (95 lb) at 90 degrees of flexion and approximately 333 N (75 lb) at 30 degrees of flexion. This is comparable with forces expected during moderate to strenuous activity and is well above the manual force applied during clinical drawer testing.[39,40]

The effect of sectioning the ACL is shown by the decrease in slope of the anterior curve and increase in displacement in Figure 3-18. Note that the anterior curve does not drop to zero owing to the presence of secondary ligament restraints. The ACL is the primary restraint to anterior translation (Fig. 3-21). Its contribution at displacements from

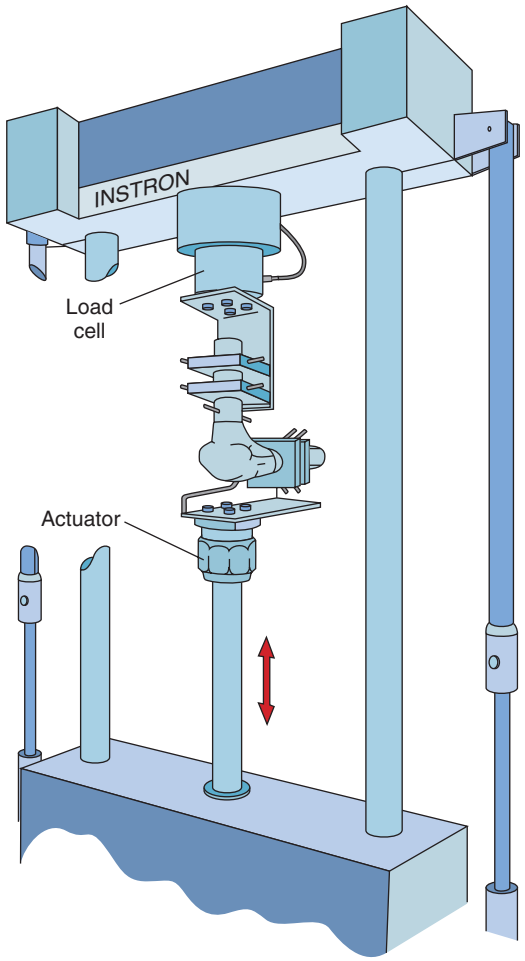

FIG 3-19 Cadaver knee mounted in 90 degrees of flexion. The femur and tibia are potted in aluminum tubes. The femur is secured to the load cell above and the tibia to the moving actuator below. Single-plane anterior and posterior drawer is produced by vertical motion of the actuator. (From Butler DL, Noyes FR, Grood ES. Ligamentous restraints to anterior-posterior drawer in the human knee. A biomechanical study. *J Bone Joint Surg Am.* 1980;62A:259-270.)

1 to 5 mm is shown in Figure 3-22. The percentages given above the bars are for 90 degrees of knee flexion. Nearly identical results are shown at 30 degrees of flexion, which represents the position of the knee during the Lachman test. No significant differences were found between 1 and 5 mm of drawer regardless of the trend toward increasing percentages at larger joint displacements.

The secondary restraints to anterior translation when the ACL is sectioned are shown in Table 3-4. The range in values for each structure demonstrates the large variation in results among specimens. No statistical difference was found among the percentages calculated. The contributions of the PCL, the anterior and posterior capsules, and the popliteal tendon were not included because they provided minimum restraining force.

It is important to characterize the effect of the ACL and secondary restraints on the coupled motions of anterior translation and internal-external tibial rotations. Figure 3-23 shows the effect of the lateral secondary restraints on both anterior translation and internal tibial rotation.

The PCL provides 94.3% ± 2.2% of the total restraining force at 90 degrees of knee flexion, with similar findings at 30 degrees of flexion

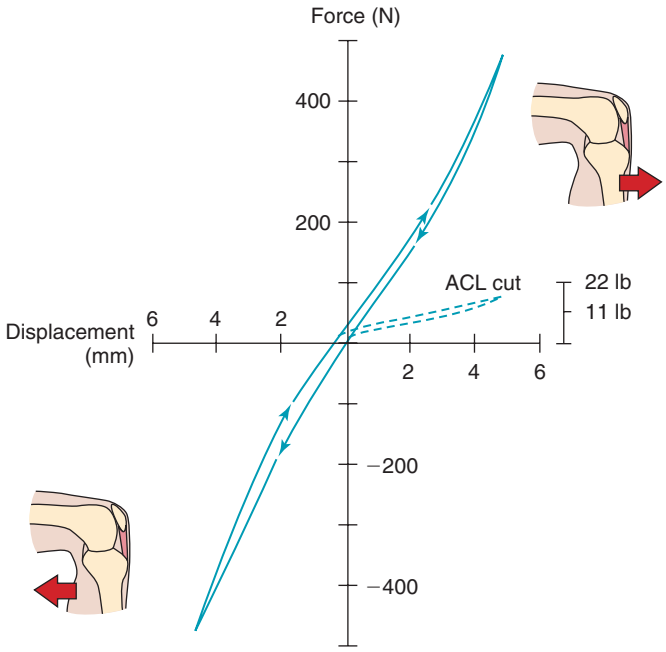

FIG 3-20 A typical force-displacement curve for anterior-posterior drawer in an intact joint (*solid line*) and after cutting the anterior cruciate ligament (ACL) (*dashed line*). The arrows indicate the direction of motion. (From Butler DL, Noyes FR, Grood ES. Ligamentous restraints to anterior-posterior drawer in the human knee. A biomechanical study. *J Bone Joint Surg Am.* 1980;62A:259-270.)

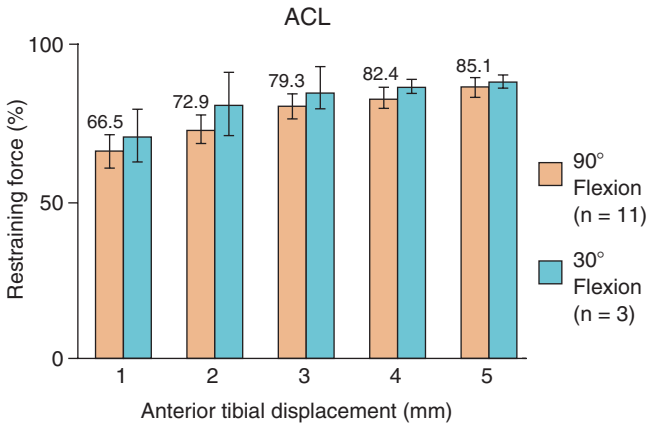

FIG 3-22 Anterior drawer in neutral tibial rotation. The restraining force of the anterior cruciate ligament (ACL) is shown for increasing tibial displacements at 90 and 30 degrees of knee flexion. The mean value ±1 standard error of the mean (SEM) is shown. Percentage values are given for 90 degrees of flexion. No statistical difference was found between 90 and 30 degrees or between 1 and 5 mm of displacement using the Welch modification of the Student t test ($P > .05$). (From Butler DL, Noyes FR, Grood ES. Ligamentous restraints to anterior-posterior drawer in the human knee. A biomechanical study. *J Bone Joint Surg Am.* 1980;62A:259-270.)

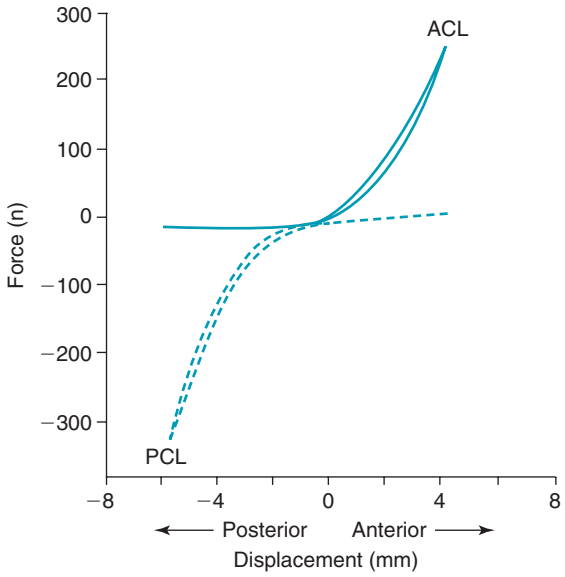

FIG 3-21 Restraining forces of the anterior cruciate ligament (ACL) (*solid line*) and posterior cruciate ligament (PCL) (*dashed line*) during a 5-mm anterior-posterior drawer test on a typical knee specimen. The curves are constructed by taking differences between the curves of the joint before and after cutting the ligament. The ACL resisted nearly all of the force anteriorly with no contribution posteriorly. The PCL restrained posterior joint displacement but had minimum effort anteriorly. Note the hysteresis that is present. (From Butler DL, Noyes FR, Grood ES. Ligamentous restraints to anterior-posterior drawer in the human knee. A biomechanical study. *J Bone Joint Surg Am.* 1980;62A:259-270.)

(Fig. 3-24). No other structure contributes greater than 3% of the total restraint. The secondary restraints to the posterior drawer after the PCL is sectioned (including the lateral meniscofemoral ligament when present) are shown in Table 3-5. The posterolateral capsule and popliteus tendon (combined contribution, 58.2%) and the MCL (15.7%) provided the greatest restraint. The posterior medial capsule, FCL, and mid medial capsule contributed only modest restraints. The combined restraint provided by the posterolateral capsule and popliteus tendon was significantly different from those provided by the other structures.

This investigation was the first to introduce the concepts of primary and secondary ligament restraints to joint motion. The cruciate ligaments are the primary restraints to the AP drawer and provide approximately 90% of the total restraining force at 5 mm of joint displacement. The remaining structures provide only a small contribution. This study also made a distinction between clinical forces, which are small loads applied to the knee during a clinical examination, and functional forces, which are large in vivo loads experienced during moderate or strenuous activities (Fig. 3-25). The increase in joint displacement after the loss of either the ACL or PCL depends on the forces applied to the knee. Although the light forces applied during a clinical test may produce only a slight increase in joint displacement, these increases are expected to be much larger under moderate or strenuous functional forces. Therefore, all clinical ligament examination tests do not predict the magnitude of joint displacement that may occur during functional activities.

LIGAMENTOUS AND CAPSULAR RESTRAINTS RESISTING MEDIAL AND LATERAL JOINT OPENING

We have previously determined the ligaments and capsular structures that resist medial and lateral joint opening in cadaver knees. The ligaments were ranked in order of importance based on the percent of the total restraining force that each provides. The results are independent

of the order in which ligaments are sectioned, allowing all ligaments to be studied in each cadaver knee. Most prior studies of knee ligament function were based on knee motion limits after cutting selected ligaments[4,27,40,76] or on the injury patterns associated with observed clinical pathologies.[2,9,28,29,33,46,61,64,71]

An Instron model 1321 biaxial testing system was used in which the femur was secured to the load cell with two grips that allowed its position to be adjusted.[20] The tibia was attached to the actuator through a plantar hinge mechanism that prevented axial rotation and flexion of the tibia during testing. Each knee was placed to the full-extended (hyperextended) position by applying a 5 N-m extension moment. The tests were performed with the knee flexed 5 and 25 degrees from this position. Single-plane varus and valgus displacements were produced by causing the actuator to move up and down, but not to rotate. The tests were done in a fixed manner that first produced medial and then lateral joint opening. A constant rate was used so that peak opening occurred in 1 second. A series of 25 conditioning tests that produced 6 mm of medial and 6 mm of lateral joint opening were done at the two knee flexion angles. Typically, the peak force changed less than 0.25% per cycle during the last five conditioning tests. Then, baseline

TABLE 3-4 Comparison of Secondary Structures at Increased Anterior Displacement

	Iliotibial Tract and Band	Mid Medial Capsule	Mid Lateral Capsule	Medial Collateral Ligament	Fibular Collateral Ligament
Mean ± SEM (%)	24.8 ± 4.7	22.3 ± 6.9	20.8 ± 5.4	16.3 ± 2.9	12.4 ± 3.3
Minimum (%)	9.8	3.4	1.6	8.1	7
Maximum (%)	44.4	43.6	36.9	29.4	25.2

By Duncan's multiple range test, no statistical difference was found among the percentages for any of the structures shown ($P > .05$). Values are $n = 6$, anterior drawer of 12.2-16.3 mm at 90 degrees of knee flexion.
SEM, Standard error of the mean.

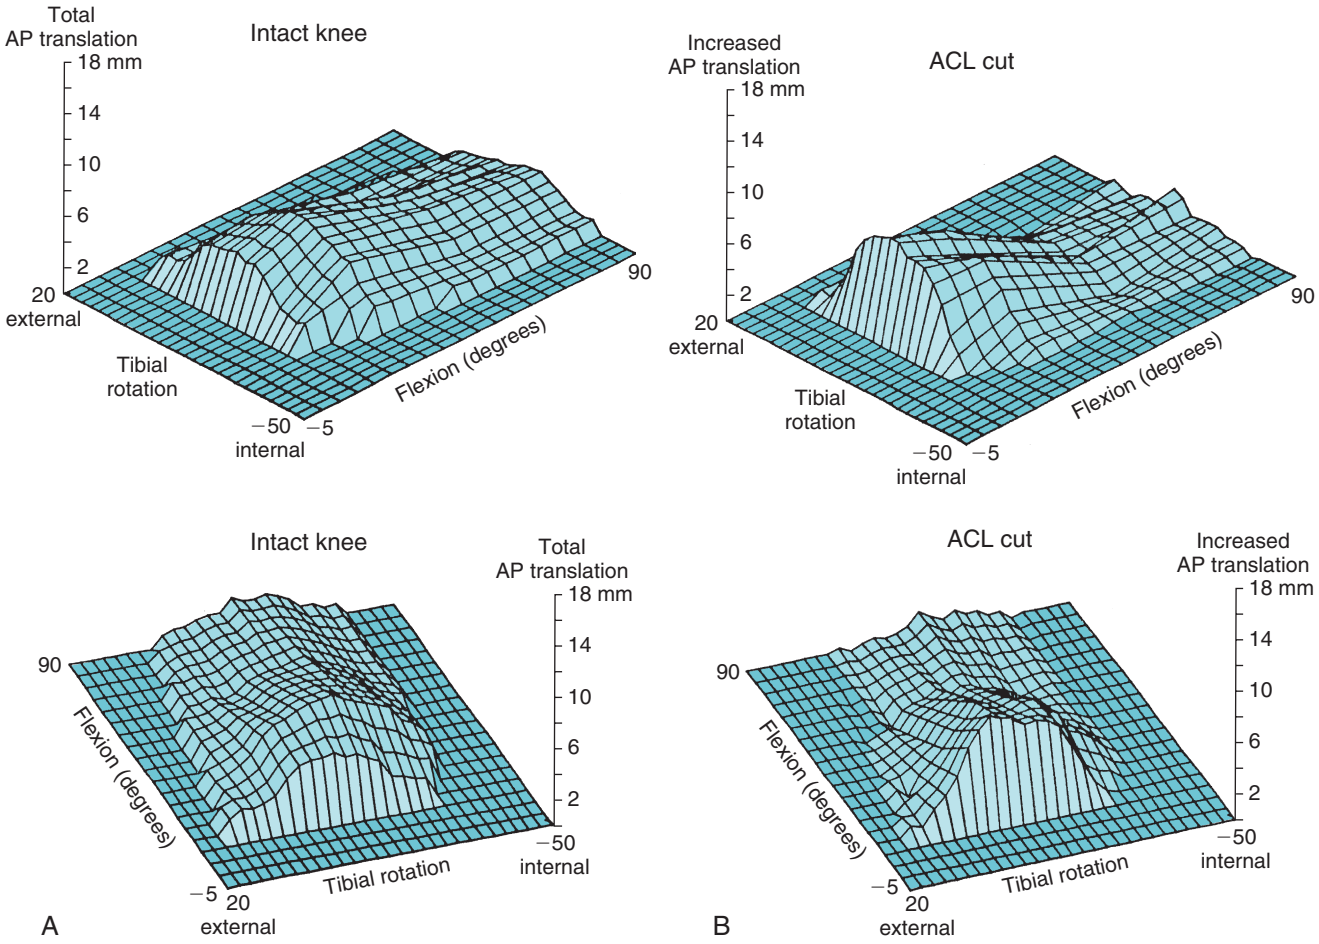

FIG 3-23 Anteroposterior (AP) translation of the human knee joint (100-N load) from 0 to 90 degrees of flexion and under the maximal limits of internal and external tibial rotation (5 N-m torque) before and after selective cutting of ligaments. **A,** Intact knee shows maximum translation at low flexion positions and neutral rotation, two views of the same plot for one knee. **B,** Increased translation caused by anterior cruciate ligament (ACL) sectioning occurs in low flexion positions, indicating other soft tissue restraints are functioning at higher knee flexion positions.

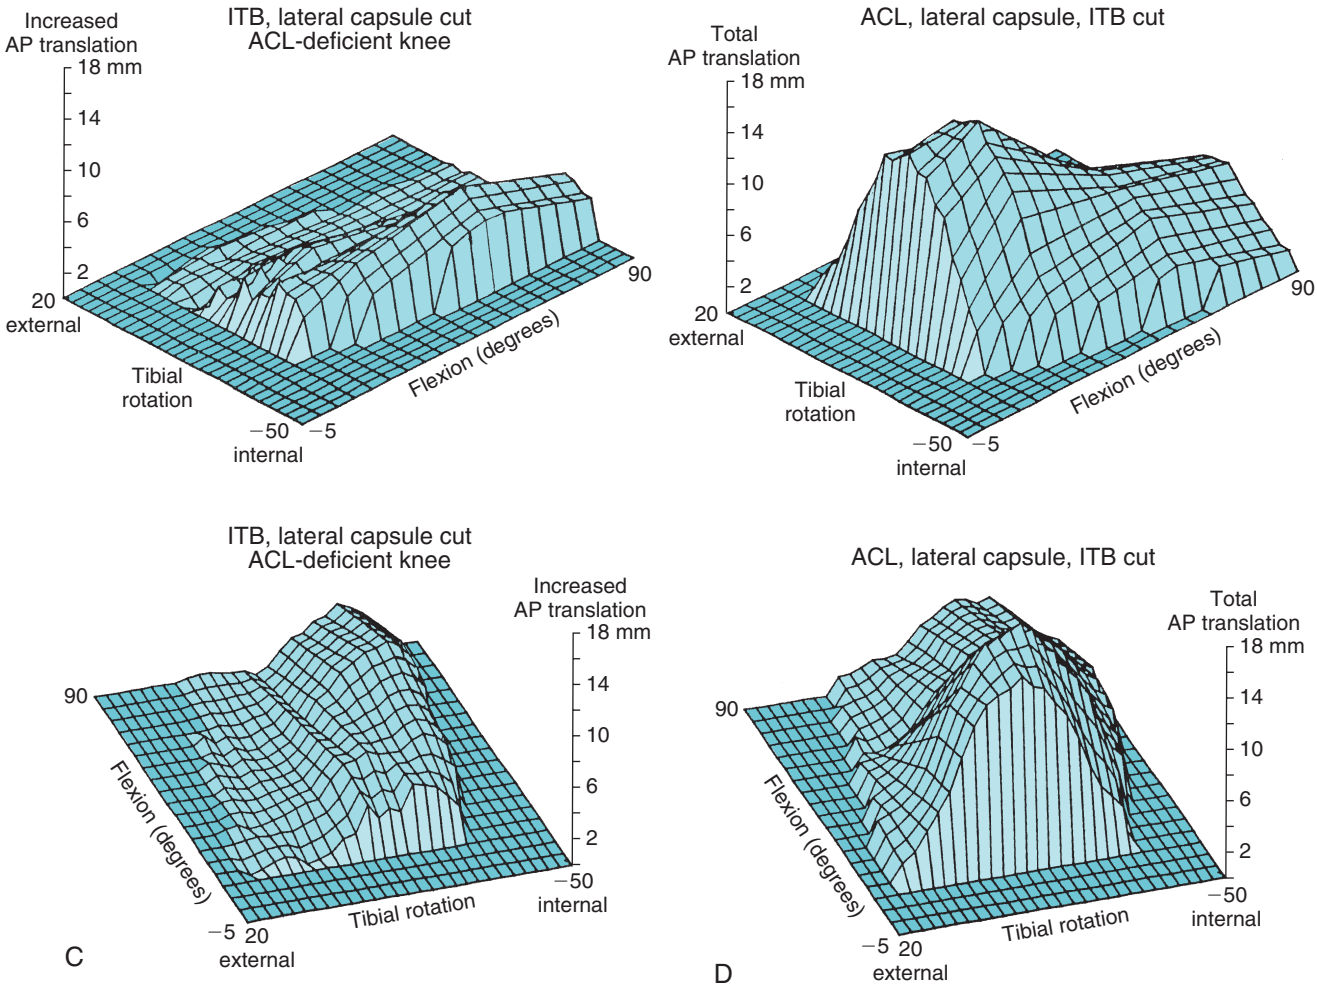

FIG 3-23, cont'd C, Further increased translation after sectioning the iliotibial band (ITB) and lateral capsule. Note the effect of sectioning these restraints is throughout knee flexion but is greatest at the higher flexion positions. This knee shows the effect of tight lateral extraarticular restraints as the initial increased translation after ACL sectioning was modest, and the translation markedly increased after the lateral structures were sectioned. **D,** The final total AP translation is shown for the ACL, lateral capsule, and ITB-sectioned knee, demonstrating major increases in translation throughout knee flexion. Increases in internal rotation of a lesser amount are also shown.

tests were done at both knee flexion angles. A ligament was cut and the test repeated. The restraint caused by the cut ligament was calculated to be the decrease that occurred in the joint restraining moment compared with the moment determined in the test before the ligament sectioning. This process was repeated after cutting other structures until the restraining moments caused by all of the ligamentous and capsular structures had been measured. The medial and lateral tests were performed in 16 knees obtained from 11 cadavers aged 18 to 55 years (mean, 36.8 years).

In six other cadaver lower limbs, the 3-dimensional motion of the knee joint was measured during the clinical examination for medial and lateral joint opening. The motions were determined first in the intact knee and then after a collateral ligament was sectioned to measure the increase in joint opening. The opposite collateral ligament was then sectioned and the increase in joint opening documented. The goal was to determine the actual motions produced in uninjured knees during a clinical examination and to evaluate the change in joint opening that occurred with cutting each collateral ligament. The knee motions were measured using the instrumented kinetic chain (Fig. 3-26),[72] which was positioned across the knee on the lateral side. The leg was positioned over the side of a table. The joint line was palpated with one hand while a force was applied at the ankle with the other hand. The force applied was not measured to conduct the examination in the normal manner. To make these measurements, it was necessary to know the position of the ends of the instrumented chain with respect to the femur and tibia. These positions were established by performing a 3-dimensional analysis using biplane radiographs.[5] Tests for reproducibility demonstrated that translational and rotational motions could be measured within ±0.5 mm and ±0.5 degrees, respectively.

The ligaments and capsular structures studied were the ACL, PCL, superficial parallel fibers of the MCL, the FCL, the popliteus musculotendinous unit (including the popliteofibular ligament [PFL]), the medial and lateral halves of the capsule (subdivided into anterior, middle, and posterior thirds), and the femorotibial portion of the ITB. The middle third of the medial capsule was considered to be the deep fibers of the MCL described by others.[71,77] The posterior third included the complex of capsular structures previously detailed[30,77]

TABLE 3-5 Comparison of Secondary Structures at Increased Posterior Displacement

	Posterolateral Capsule and Popliteus Tendon*	Medial Collateral Ligament	Posterior Medial Capsule	Fibular Collateral Ligament	Mid Medial Capsule
Mean ± SEM (%)	58.2 ± 10.1	15.7 ± 5.2	6.9 ± 3.2	6.3 ± 4.7	6.2 ± 2.4
Minimum (%)	36.7	5.6	0	0	0
Maximum (%)	82.1	29.7	14.5	20.4	11.5

Values are n = 4, posterior drawer of 19.0-25.0 mm at 90 degrees of knee flexion.
*By Duncan's multiple range test, only the posterolateral capsule and popliteus tendon were statistically different from all other structures ($P < .05$). Sectioned from femur; includes popliteofibular ligament.
SEM, Standard error of the mean.

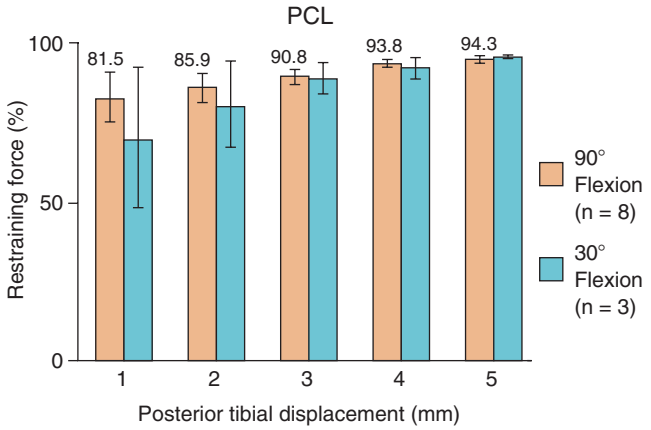

FIG 3-24 For posterior drawer in neutral tibial rotation, the percentage of total restraining force is shown for the posterior cruciate ligament (PCL) for increasing posterior tibial displacement at 90 and 30 degrees of knee flexion. Mean values are shown, ±1 standard error of the mean. Percentage values are given for 90 degrees of flexion. No statistically significant difference was observed between 90 and 30 degrees of flexion, or between 1 and 5 mm of displacement ($P > .05$). (From Butler DL, Noyes FR, Grood ES. Ligamentous restraints to anterior-posterior drawer in the human knee. A biomechanical study. *J Bone Joint Surg Am.* 1980;62A:259-270.)

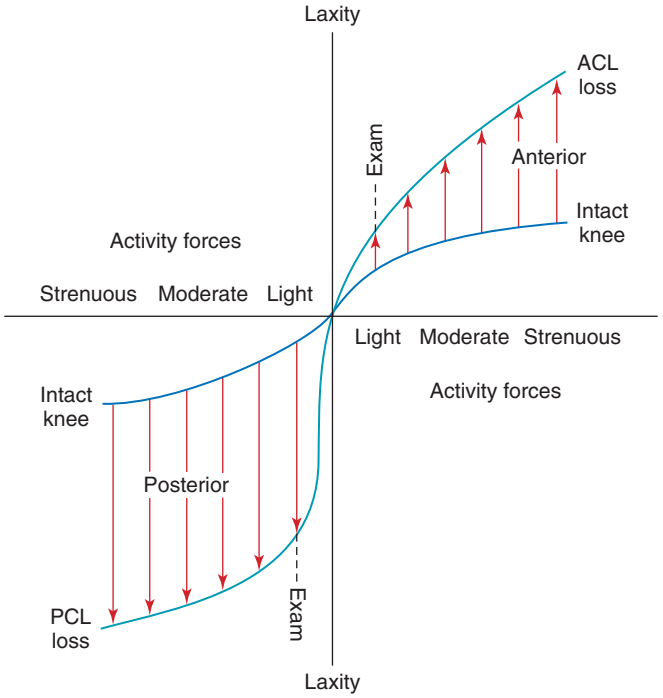

FIG 3-25 Changes in anterior and posterior laxity in one knee specimen before and after loss of the cruciate ligaments. The laxities are shown for increasing activity force. Note the small increase in anterior laxity for a clinical anterior drawer test (examination) performed with a forward pull. A large increase in laxity occurs for posterior drawer when the posterior cruciate ligament (PCL) is cut. *ACL,* Anterior cruciate ligament. (From Butler DL, Noyes FR, Grood ES. Ligamentous restraints to anterior-posterior drawer in the human knee. A biomechanical study. *J Bone Joint Surg Am.* 1980;62A:259-270.)

and the remaining portion of the medial portion of the capsule extending to the mid popliteal region (including the oblique popliteal ligament). The lateral half of the capsule was divided into the anterior third (from the lateral margin of the patellar tendon to Gerdy's tubercle), the middle third (from Gerdy's tubercle to just anterior to the FCL), and the posterior third (the popliteus muscle-tendon-ligament unit and the rest of the capsule extending back to the mid popliteal region).

Results

The results of a typical test on an intact knee and then after sectioning the MCL are shown in Figure 3-27. The curve marked "Intact" represents behavior after conditioning but before ligaments were sectioned. The restraining moment was greater during loading (*upper curve*) than during unloading (*lower curve*) owing to the viscoelastic properties of the ligaments.

During clinical testing in which varus and valgus forces of 45 N are applied at the ankle, a moment of approximately 18 N-m is produced at the knee. These moments produced a medial and lateral joint opening in the knee shown in Figure 3-28**.** When the MCL was cut and a valgus moment applied, the medial opening increased approximately 3 mm. The secondary restraints blocked further joint opening, because they were sufficient to resist the small forces typically induced during a clinical examination. The restraining moment produced by the MCL alone is shown in Figure 3-28.

Medial Restraints

The ligaments and capsular structures resisting 5 mm of medial joint opening are shown for 5 degrees of flexion in Figure 3-29 and for 25 degrees of flexion in Figure 3-30**.** The MCL was the primary restraint at both knee flexion angles, providing 57.4% ± 3.5% of the total restraining moment at 5 degrees and 78.2% ± 3.7% at 25 degrees of flexion. The increase in contribution with flexion was caused primarily by a decrease in the contribution of the posteromedial portion of the

CRITICAL POINTS Ligamentous and Capsular Restraints Resisting Medial and Lateral Joint Opening

- The MCL is the primary restraint to medial joint opening, providing 57% of the total restraining moment at 5 degrees of flexion and 78% at 25 degrees of flexion. The increase in contribution with flexion is caused by a decrease in the contribution of the posteromedial portion of the capsule, which becomes increasingly slack as flexion occurs. The medial restraint provided by the ACL and PCL in combination is 15% of the total at 5 degrees of flexion and 13% at 25 degrees of flexion.
- The FCL is the primary restraint to lateral joint opening, providing 55% of the total restraint at 5 degrees of flexion and 70% at 25 degrees of flexion. The increased contribution of the FCL with knee flexion is because of a marked decrease in the restraint provided by the posterolateral capsule. The cruciate ligaments together provide 22% of the total lateral restraining moment at 5 degrees of flexion and 12% at 25 degrees of flexion.
- The restraints limiting lateral opening caused by the popliteus muscle tendon and ligament and of the femorotibial portion of the ITB are minimal at both knee flexion angles.
- A 5- to 8-mm increase measured clinically after an acute injury indicates significant collateral ligament injury, including the secondary restraints.
- Define the degrees of injury as first, second, or third and then estimate the millimeters of increased joint opening at 5 and 25 degrees of flexion.
- The clinician should place a finger at the joint line to estimate the millimeters of joint opening and compare the finding with the opposite knee. If axial rotation of the tibia occurs caused by inadvertent rotation of the leg during the examination, the examiner may overestimate the amount of joint opening.
- In cases of ACL rupture, the cradled position (holding the lower leg above the table) to induce varus or valgus tests should be avoided. The knee should be examined with the thigh supported by the examination table in a reduced position where the weight of the leg prevents the anterior tibial subluxation.

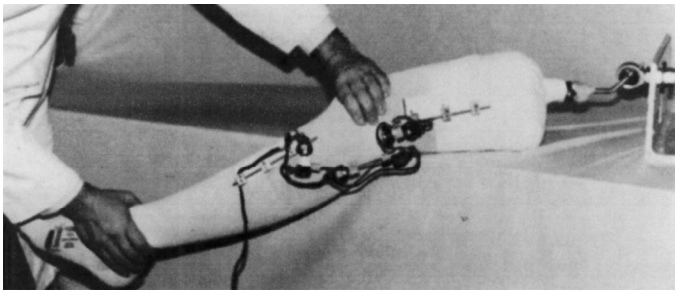

FIG 3-26 The instrumented kinetic chain, used to measure 3-dimensional joint motion, is shown mounted across the knee on a cadaver lower limb. Each end of the chain is attached to a mounting platform made from pins 3.18 mm (⅛ inch) in diameter. The platforms are attached securely to each bone by three pins that pass through the skin, underlying muscle, and bone. The femur is attached to an angle plate by means of a rod cemented in the medullary canal and a mobile ball-and-socket joint that simulates the hip. The angle plate is secured to a table with C-clamps.

capsule, which became increasingly slack as flexion occurred. The anterior and middle parts of the medial half of the capsule provided weak secondary restraint limiting medial joint opening, equivalent to 7.7% ± 1.7% of the total restraint at 5 degrees and to 4.0% ± 0.9% of the total at 25 degrees with 5 mm of opening. The posterior portion of the

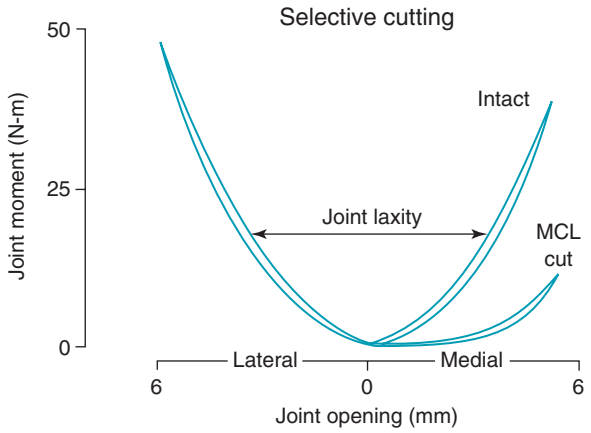

FIG 3-27 The restraining joint moment (in newton-meters) is shown for a typical intact knee and for the same knee after selective cutting of the medial collateral ligament (MCL). The test starts at the neutral position (0) with the knee intact. Six millimeters of medial opening is produced at a constant rate during 1 second. The knee then is returned to neutral and the same amount of lateral opening is produced. When the test is repeated after cutting the MCL, the restraining moment to medial opening is markedly reduced but there is no change during lateral opening. (From Grood ES, Noyes FR, Butler DL, Suntay WJ. Ligamentous and capsular restraints preventing straight medial and lateral laxity in intact human cadaver knees. *J Bone Joint Surg Am.* 1981;63:1257-1269.)

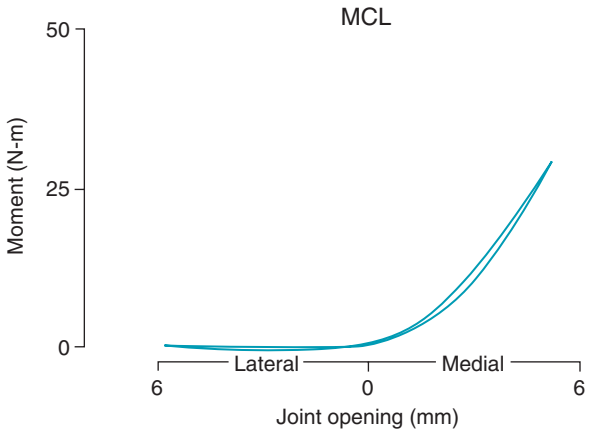

FIG 3-28 The curve for the restraining moment of the medial collateral ligament (MCL) alone versus joint opening. This curve was obtained by subtracting the curve after the ligament was cut from the curve for the intact knee shown in Figure 3-26. (From Grood ES, Noyes FR, Butler DL, Suntay WJ. Ligamentous and capsular restraints preventing straight medial and lateral laxity in intact human cadaver knees. *J Bone Joint Surg Am* 1981;63:1257-69.)

medial half of the capsule provided 17.5% ± 2.0% of the total restraint at 5 degrees and 5 mm of medial opening. At 25 degrees of flexion, the restraint caused by this part of the capsule dropped to 3.6% ± 0.8%. The effect of increasing the medial joint opening on the contribution of the MCL is shown in Figure 3-31**.** At 5 degrees of knee flexion, the contribution of the MCL decreased from 70.0% at 2 mm to 53.2% at 6 mm of opening.

The medial restraint provided by the ACL and PCL in combination was 14.8% ± 2.1% of the total at 5 degrees of flexion and 13.4% ± 2.7% at 25 degrees. In nine specimens, the contribution of one cruciate was separated from that of the other (Table 3-6). At 25 degrees of flexion,

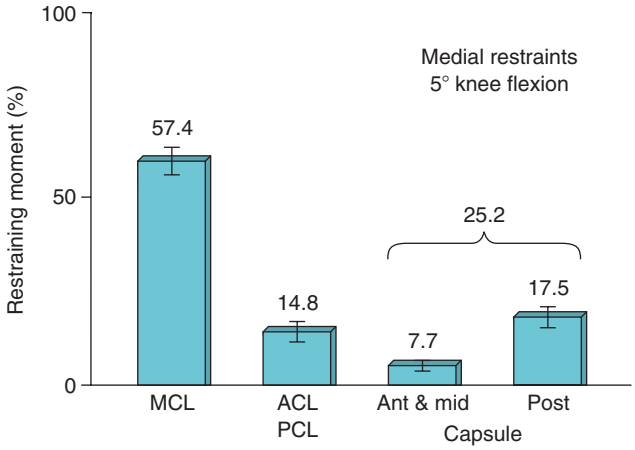

FIG 3-29 The average percent contributions to the medial restraints by the ligaments and capsule at 5 mm of medial joint opening and 5 degrees of flexion. The error bars represent ±1 standard error of the mean. *ACL,* Anterior cruciate ligament; *Ant,* anterior; *MCL,* medial crucial ligament; *PCL,* posterior crucial ligament. (From Grood ES, Noyes FR, Butler DL, Suntay WJ. Ligamentous and capsular restraints preventing straight medial and lateral laxity in intact human cadaver knees. *J Bone Joint Surg Am.* 1981;63:1257-1269.)

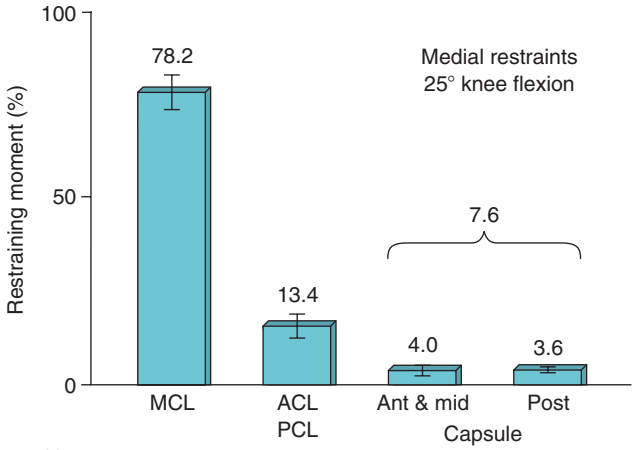

FIG 3-30 The percent restraining contributions of the medial structures at 5 mm of opening and 5 degrees of flexion. *ACL,* Anterior cruciate ligament; *Ant,* anterior; *MCL,* medial crucial ligament; *PCL,* posterior crucial ligament. (From Grood ES, Noyes FR, Butler DL, Suntay WJ. Ligamentous and capsular restraints preventing straight medial and lateral laxity in intact human cadaver knees. *J Bone Joint Surg Am.* 1981;63:1257-1269.)

the PCL accounted for approximately 75% of the combined restraint exerted by the cruciate ligaments to medial opening, and the ACL accounted for 25%. This result did not depend on the order of cruciate ligament sectioning. However, at 5 degrees of flexion, the order of cruciate ligament sectioning affected the results. When the PCL was cut first, it accounted for approximately 70% of their combined restraint. When the PCL was cut after the ACL, its contribution was only 20% of their combined restraint. These findings indicate that the cruciate ligaments do not function independently of each other when the knee is near full extension.

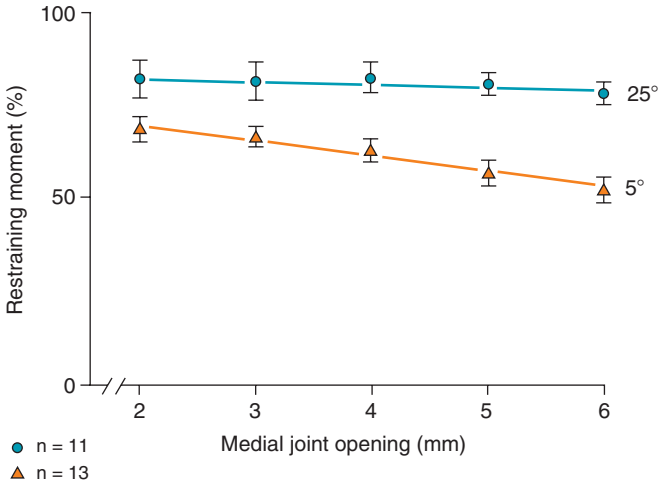

FIG 3-31 The percent contribution of the medial collateral ligament to the restraints limiting medial joint opening in the range of 2 to 6 mm. The decrease with joint opening at 5 degrees is statistically significant ($P < .005$; $r = 0.419$; n = 65). (From Grood ES, Noyes FR, Butler DL, Suntay WJ. Ligamentous and capsular restraints preventing straight medial and lateral laxity in intact human cadaver knees. *J Bone Joint Surg Am.* 1981;63:1257-1269.)

Lateral Restraints

The average contributions of the lateral ligaments, lateral half of the capsule, and cruciate ligaments to the restraining moment at 5 mm of lateral joint opening are shown in Figure 3-32 at 5 degrees of flexion and in Figure 3-33 at 25 degrees of flexion. The FCL was the primary restraint limiting lateral opening of the joint at both knee flexion angles, providing 54.8% ± 3.8% of the total restraint at 5 degrees of flexion and 69.2% ± 5.4% at 25 degrees. The increased contribution of the FCL with knee flexion was caused by a marked decrease in the restraint provided by the posterolateral capsule. There was large variability in the data for the FCL, with its contribution ranging from 34.6% to 8.37% at 5 degrees and from 40.5% to 94.7% at 25 degrees. Still, the FCL provided a restraining moment greater than the combined moments of the entire lateral half of the capsule, the ITB, the popliteus tendon, and the cruciate ligaments.

The entire lateral half of the capsule provided 17.2% of the varus restraint at 5 degrees of flexion (see Fig. 3-30) and 8.8% of this restraint at 25 degrees (see Fig. 3-31). The anterior and middle thirds of the lateral half of the capsule contributed only a small secondary restraint,

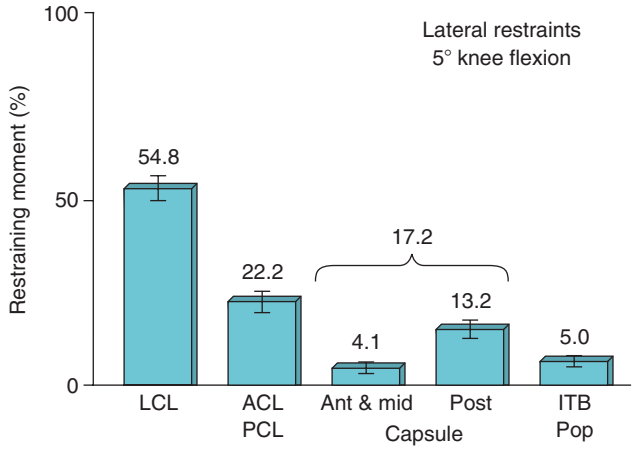

FIG 3-32 The average percent contribution to the lateral restraints by the ligaments and capsule at 5 mm of lateral joint opening and 5 degrees of knee flexion. The error bars indicate ±1 standard error of the mean. There was no tension on the iliotibial band (ITB) proximal to the lateral femoral condyle in these preparations. *ACL,* Anterior cruciate ligament; *LCL,* lateral crucial ligament; *PCL,* posterior crucial ligament; *POP,* popliteal. (From Grood ES, Noyes FR, Butler DL, Suntay WJ. 4.1% ± 1.5% at 5 degrees and 3.7% ± 1.5% at 25 degrees. The posterolateral capsule became slack with flexion and provided only 5.1% ± 1.3% of the total restraint at 25 degrees of flexion.

The cruciate ligaments together provided 22.2% ± 2.6% of the total restraining moment at 5 degrees of flexion and 12.3% ± 4.2% at 25 degrees. There was no effect on the order of cruciate ligament sectioning. However, there was large variation in these data between specimens. The combined restraint of the cruciate ligaments ranged from

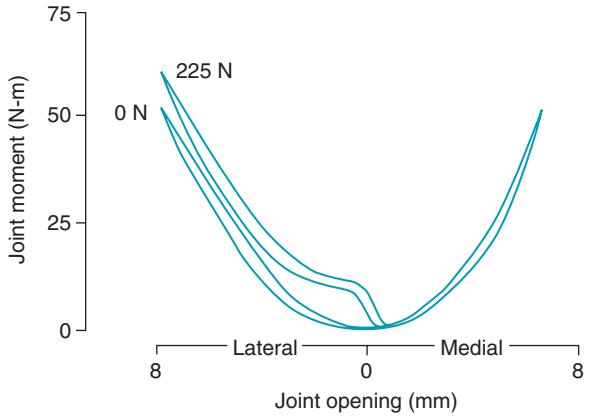

FIG 3-34 The effect of applying a 225-N force to the iliotibial tract. The force increases the lateral restraint (joint moment) and decreases lateral joint opening. (From Grood ES, Noyes FR, Butler DL, Suntay WJ. Ligamentous and capsular restraints preventing straight medial and lateral laxity in intact human cadaver knees. *J Bone Joint Surg Am.* 1981;63:1257-1269.)

TABLE 3-7 Percentage of Restraining Moment Caused by the Cruciate Ligaments for Lateral Joint Opening

Ligament	5 Degrees Knee Flexion	25 Degrees Knee Flexion
ACL	19.7 ± 2.7	10.3 ± 4.1
PCL	2.7 ± 0.7	4.1 ± 1.1
Both	22.4 ± 3.0	14.4 ± 4.7

n = 11. Mean of total lateral restraint ± 1 standard error of the mean. *ACL,* Anterior cruciate ligament; *PCL,* posterior cruciate ligament.

10.7% to 36.7% at 5 degrees of flexion and from 1.9% to 45.7% at 25 degrees of flexion. The ACL provided the greater portion of the combined restraining effects (Table 3-7) at both knee flexion angles.

Iliotibial Tract, Popliteus Tendon, Biceps Tendon

The restraints limiting lateral opening caused by the ligament-like actions of the popliteus muscle tendon and ligament and of the femorotibial portion of the ITB were minimum at both knee flexion angles. Therefore, these structures were combined with the caution that the resulting data do not reflect larger in vivo restraining action of either structure owing to added in vivo muscle forces.

The effect of lateral opening on tension in the ITB and in the biceps tendon was investigated by applying a 225-N (50-lb) force to the ITB with a deadweight and pulley system. A curve of the restraining moment is shown in Figure 3-34 for an intact knee before and after the tension was applied. The tension produced an increase in the lateral restraining moment. The effect of the tension alone (Fig. 3-35) demonstrated that the applied force produced a nearly constant restraining moment, independent of the amount of lateral joint opening.

Location of Rotation Axes

The location of the axes for varus-valgus tests on the femur at 5 degrees of flexion are shown in Figure 3-36. The tibia, which moves during the test, is drawn in the neutral position, corresponding to the beginning of the varus-valgus loading test. The rotation axes are located above the joint contact area on the lateral femoral condyle for valgus displacement and above the medial contact area for varus displacement. The

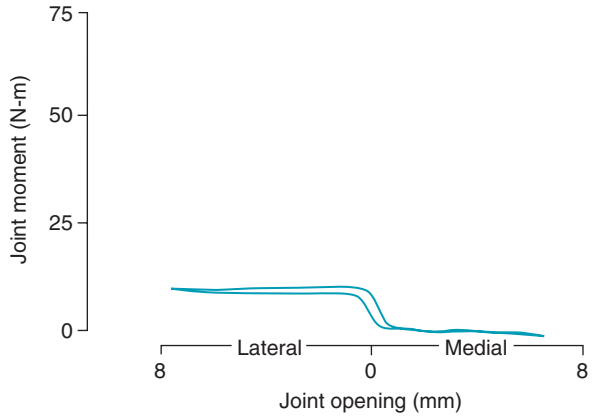

FIG 3-35 Difference curve showing the isolated lateral restraining effect of the force applied to the iliotibial tract. Note that the restraining action is independent of the amount of joint opening. (From Grood ES, Noyes FR, Butler DL, Suntay WJ. Ligamentous and capsular restraints preventing straight medial and lateral laxity in intact human cadaver knees. *J Bone Joint Surg Am.* 1981;63:1257-1269.)

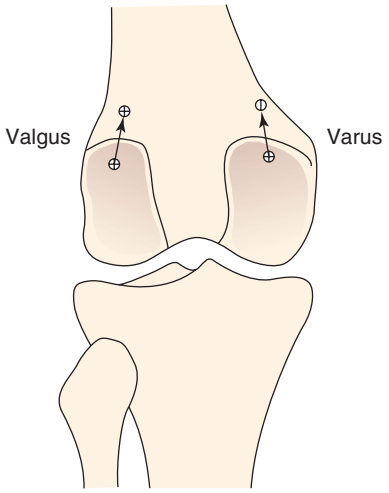

FIG 3-36 The instant centers for one-plane varus and valgus displacements of the knee at 5 degrees of flexion. The instant centers are above the joint line, indicating a sliding motion at the tibiofemoral contact region. During valgus displacement the instant center is on the lateral side and during varus displacement, on the medial side. The arrows indicate that the instant centers move proximally as the medial and lateral joint openings increase. (From Grood ES, Noyes FR, Butler DL, Suntay WJ. Ligamentous and capsular restraints preventing straight medial and lateral laxity in intact human cadaver knees. *J Bone Joint Surg Am* 1981;63:1257-1269.)

lower points represent the rotation axes for the first half of the varus and valgus test (~0-2.5 mm of joint opening). The upper points represent the axes for the last half of each test (2.5-5 mm of opening). For the total varus and valgus motion, the axes are located near the midpoints of the lines connecting the lower and upper points.[20]

The reader should note that the positions of the axes above the joint line indicate that a tibiofemoral sliding motion occurs during the loading test. The tibia slides laterally during a valgus test in the same direction as the applied force. The opposite sliding motion occurs during a varus test as the tibia moves medially. The proximal movement of the instant center reflects an increase in the amount of medial-lateral shear movement for each degree of varus-valgus rotation during the test. The increase in the amount of shear movement per degree of rotation occurs when the rotational stiffness of the joint increases more rapidly than its shear stiffness.[20]

TABLE 3-8 Increase in Joint Opening After Sectioning of the Collateral Ligaments

	Mean ± Standard Deviation (mm)	Range (mm)
Lateral		
5 degrees flexion	0.84 ± 0.46	0.3-1.3
25 degrees flexion	2.56 ± 0.80	1.7-3.7
Medial		
5 degrees flexion	1.24 ± 0.69	1.5-3.7
25 degrees flexion	3.90 ± 1.43	2.0-5.5

n = 5. All numbers are in millimeters of joint opening; 1 mm is equivalent to approximately 1 degree of tibial angulation.

TABLE 3-9 Sprain Classification System of the American Medical Association

Sprain	Symptom	Signs	Tear Fibers
First degree	Mild	None	Minor
Second degree	Moderate	Slight abnormal motion	Partial
Third degree	Severe	Abnormal motion (3-15 mm)	Complete

Increase in medial-lateral joint opening (added by other investigators): grade I (0-5 mm), grade II (6-10 mm), grade III (11-15 mm).

Joint Motions During Clinical Examination

The increases in joint opening after the collateral ligaments were sectioned are shown in Table 3-8. The increases in motion after cutting the FCL during varus testing were 0.84 ± 0.5 mm at 5 degrees of flexion and 2.56 ± 0.8 mm at 25 degrees of flexion. The greater amount of joint opening with flexion was explained by the loss of the restraint provided by the posterior portion of the capsule and the increase in the contribution of the FCL. However, the increases in motion at both knee flexion angles were small owing to the influence of the secondary restraints under the low forces applied during the clinical examination.

The increases in medial joint opening after the MCL was sectioned during valgus testing were larger. This was caused by the larger contribution to varus-valgus restraint provided by the MCL compared with that provided by the FCL. The largest increase measured in medial joint opening was 5.5 mm in one knee at 30 degrees of flexion; however, the average increase was less than 5 mm. Therefore, only small joint openings may be demonstrated on clinical examination even when the medial or lateral primary restraint is ruptured. A 5- to 8-mm increase measured clinically after an acute injury indicates significant collateral ligament injury, including the secondary restraints. The concept of a "grade I laxity" (defined as an up to 5-mm increase in medial or lateral joint opening) as not representing a significant injury is not supported by these data. This raises the need to carefully evaluate any increase in joint opening, because this represents significant damage to the restraining function of a primary collateral ligament. The treatment aspects of acute injuries to the medial and lateral knee ligaments are discussed in Chapter 17 and Chapter 19. Table 3-9 shows the

traditional classification system of the American Medical Association (AMA) of medial and lateral ligament injury. A second-degree injury has only a few millimeters of joint opening, which is barely discernible. An increase up to 5 mm would represent a third-degree injury. Rather than use grades to classify the injury, it is more accurate to define the degrees of injury as first, second, or third and then estimate the millimeters of increased joint opening at 5 and 25 degrees of flexion. Sequential increases of even 3 mm (rather than 5 mm) have important implications of injury to additional ligament structures that, in turn, affect treatment options.

A large amount of out-of-plane tibial rotation occurred during the clinical examination. The amount of axial rotation was typically greater than the total amount of medial-lateral joint opening. In one knee, the joint opening (varus-valgus combined) near full extension was 2.5 mm and was accompanied by 4.5 degrees of axial tibial rotation. At 30 degrees of flexion, the joint opening was 6.5 mm and was accompanied by 8.2 degrees of axial tibial rotation.

The cruciate ligaments act as secondary restraints during medial and lateral opening. If one of the collateral ligaments and associated capsule is ruptured, then the cruciate ligaments become primary restraints. Because the cruciate ligaments are located in the center of the knee, close to the center of rotation, the moment arms are about one third of those of the collateral ligaments. Therefore, to produce restraining moments equal to the collateral ligaments, the cruciate ligaments must provide a force three times larger than that of the collaterals.

The ITB functions as a single unit; when removed from its proximal pelvic attachments, the femorotibial portion becomes slack and incapable of restraining lesser amounts of lateral opening. The major function of the proximal muscle fibers appears to be the transmission of the tension maintaining a tautness of the ITB.[20] There appears to be two main sources of tension in the tract[31]: the passive ligament-like tension between the iliac and femoral insertions of this structure and the active muscle forces transmitted by the tract. The passive ligament-like tension should increase during lateral joint opening. The ilium-to-tibia distance is so long, however, that lateral joint opening of a few millimeters would not be expected to produce much additional tension in the tract.[20]

Conclusion

The amount of medial or lateral joint opening detected on clinical examination is only qualitative. The clinician should place a finger at the joint line to estimate the millimeters of joint opening and compare the finding with the opposite knee. If axial rotation of the tibia occurs because of inadvertent rotation of the leg during the examination, the examiner may overestimate the amount of joint opening. Associated internal or external tibial rotation may be falsely interpreted as additional medial or lateral joint opening. The amount of medial or lateral joint opening should always be measured during arthroscopy with the gap test to verify the preoperative diagnosis.

Recognition of axial rotation is especially important when assessing medial ligament injuries. Two types of tests have been described: one in which only an abduction moment is used for medial joint opening and a second in which external rotation is produced by abducting and externally rotating the leg with the femur held stationary. The first test of medial joint opening more accurately assesses medial ligament damage and allows a diagnosis of ligament and capsular injury because it reproduces the known restraining function of structures proven under in vitro conditions. The second test, which allows a coupled medial joint opening with abduction and anterior tibial translation, may be used when there is an associated ACL rupture. The true millimeters of medial joint opening may be difficult to estimate when a coupled external rotation and anterior translation occurs.

In cases of ACL rupture, the cradled position (holding the lower leg above the table) to induce varus or valgus tests should be avoided. With the leg elevated, an anterior tibial displacement occurs.[49] The joint is partially subluxated, and a medial to lateral rocking motion can be obtained that may be misinterpreted as increased medial or lateral joint opening. To prevent this, the knee should be examined with the thigh supported by the examination table in a reduced position where the weight of the leg prevents the anterior tibial subluxation.

FUNCTION OF MEDIAL AND POSTEROMEDIAL LIGAMENTS IN ACL-DEFICIENT KNEES

The motion limits in normal knees and ACL-deficient cadaveric limbs were studied to define the role of the medial ligamentous structures in limiting anterior translation, abduction (degrees or medial joint opening), and external and internal tibial rotation.[23] The results provide a scientific basis for clinical tests for the diagnosis of combined ACL/MCL ruptures. A six-DOF instrumented spatial linkage at the knee joint was used to measure the motion limits under defined loading conditions using the techniques previously published.[72] The forces and moments in the experiment were: 100 N for anterior and posterior motion limits, 15 N-m for abduction-adduction limits, and

CRITICAL POINTS Function of Medial and Posteromedial Ligaments in ACL-Deficient Knees

- ACL sectioning alone allows small increases in internal tibial rotation and no increases in external tibial rotation. When all medial structures (ACL intact) are sectioned, the abduction limit increases to only about 7 degrees, or 7 to 8 mm of medial joint opening.
- The MCL (and deep medial capsule) limits anterior tibial translation as a secondary restraint after the ACL is ruptured. A combined ACL/MCL injury has equal anterior translation at 30 and 90 degrees, indicating the Lachman and 90-degree anterior drawer will show similar increases in anterior tibial translation.
- In the ACL/MCL-deficient knee, the Lachman test will show an absence of the normal coupled internal tibial rotation in contrast to the coupled rotation in the normal and ACL-deficient knee.
- The MCL is the primary restraint for external tibial rotation; however, the increase is small (4.6 to 8.7 degrees from 30 to 90 degrees of flexion). The increase in external rotation doubles when the PMC is also sectioned. Further increases in external rotation to approximately 15 degrees occur when the ACL is also sectioned. The results validate the importance of performing the dial tibial rotation test to determine anterior subluxation of the medial tibial plateau with medial ligament injuries.
- The combined MCL/PMC injury results in increases in external tibial rotation (9 degrees at 30 degrees of flexion), increases in internal tibial rotation (12 degrees at 30 degrees of flexion), and increases in abduction testing at 0 and 30 degrees of flexion (6 degrees and 9 degrees, respectively).
- The PMC is an important structure for stabilizing the extended knee under valgus loading (32% of the resistance).
- The posterior drawer test is performed in neutral tibial rotation to determine the maximum posterior tibial translation. When the posterior drawer is repeated in maximal internal rotation (in knees with a PCL rupture), the amount of posterior tibial translation will markedly decrease if the PMC is intact.

5 N-m for internal-external tibial rotation limits. After the motion limits were determined in the intact cadaveric knee, the ACL, MCL, and PMC were sectioned in different patterns to determine function when cut alone or after one of the other ligament structures. The ligaments cut were the ACL, superficial long fibers of the MCL (including deep medial one third meniscofemoral but not meniscotibial), and the entire PMC, including the posterior oblique portion.

The increases in motion limits are shown in Table 3-10. The changes in the anterior translation limits following the ligament sectioning procedures are shown in Figure 3-37. The typical pattern of a major increase in anterior translation at low flexion angles compared with high flexion angles was statistically significant ($P < .001$). Note that subsequent sectioning of the MCL resulted in major increases in anterior translation at high flexion angles, with the amount of anterior translation equal at low flexion angles. This means that major increases in anterior translation at 90 degrees of knee flexion indicate that the secondary restraints are also insufficient. When the ACL was intact, there was no increase in anterior translation even when all of the medial ligament structures were sectioned.

The changes in coupled internal and external tibial rotation during the anterior translation and abduction loading tests are shown in Table 3-11. The anterior loading produced a coupled internal tibial rotation, as expected. The coupled internal tibial rotation decreased after the ACL was sectioned, but still remained. However, sectioning the MCL produced a loss of the coupled internal rotation. This indicates the importance of the MCL in maintaining a rotation point for the coupled internal rotation to occur; this is lost with MCL insufficiency, as already discussed. In pivot shift tests with a combined ACL/MCL injury, the magnitude of anterior tibial subluxation results in a grade III pivot shift (tibial impingement). In the abduction (valgus) test for medial joint opening, as long as there is an intact ACL, a coupled internal tibial rotation occurs. However, with an ACL and MCL injury, this internal tibial rotation with abduction is lost and there is an associated increase in external tibial rotation. These subtle changes in internal tibial rotation with combined ACL/MCL injuries are important, because the obligatory coupled rotation of anterior translation-internal tibial rotation is lost, which can be detected on clinical examination.

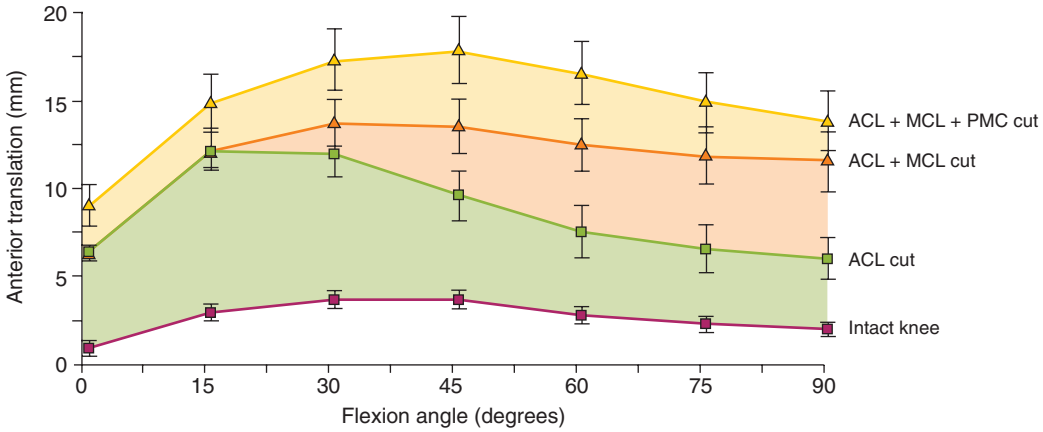

FIG 3-37 The anterior translation limits (*bottom curve*) when a 100-N anterior force was applied to control intact knees (11 donors). Sectioning the anterior cruciate ligament (ACL cut) increased the anterior limits more at 15 and 30 degrees of flexion than at 90 degrees of flexion (six donors). When the superficial medial collateral ligament (MCL) was subsequently cut (ACL + MCL cut), the anterior limit further increased in the flexed knee (six donors). Subsequent cutting of the posteromedial capsule (PMC) (*top curve*) produced an additional 2.4- to 4-mm increase over that for the ACL and MCL injury (nine donors). Error bars show the standard error of the mean. (From Haimes JL, Wroble RR, Grood ES, Noyes FR. Role of the medial structures in the intact and anterior cruciate ligament-deficient knee. Limits of motion in the human knee. *Am J Sports Med.* 1994;22:402-409.)

TABLE 3-11 Mean Degrees of Coupled Rotation During Anterior Translation and Abduction Tests for Intact Knees and After Ligament Sectioning

	ANTERIOR TEST FLEXION ANGLE		ABDUCTION TEST FLEXION ANGLE		
	30 Degrees	90 Degrees	0 Degree	15 Degrees	30 Degrees
Intact	–8.6	–10.6	–2	–4.1	–6.9
ACL	–5.4	–5	–3.2	–7	–9.1
MCL	–11.7	–14.7	1.4	6.4	5.9
ACL + MCL	0.6	0	–0.5	–2.5	–4.2

Negative numbers represent internal rotation and positive numbers represent external rotation. These numbers are the change in tibial rotation from the position of the tibia in the intact knee during passive flexion to the position of the tibia after application of anterior forces or abduction moments. Intact (11 donors); ACL cut (6 donors); MCL cut (6 donors); ACL + MCL cut (6 donors).
ACL, Anterior cruciate ligament; *MCL*, medial collateral ligament.

The increase in the external tibial rotation limit with ligament sectioning is shown in Figure 3-38. Sectioning of the MCL produced major increases in external tibial rotation that increased with each subsequent ligament sectioning. The MCL acted as the primary restraint to external tibial rotation at all flexion angles. Cutting just the PMC (ACL, MCL intact) did not result in any increase in external tibial rotation (see Table 3-10).

The increase in the internal tibial rotation limit is shown in Figure 3-39. Note that the internal tibial rotation limit increases in the intact knee with knee flexion. ACL sectioning produced small increases in internal rotation (<3 degrees) at 0 and 15 degrees of knee flexion (see Table 3-10). Sectioning the PMC alone had no effect on internal tibial rotation; however, PMC sectioning after MCL and ACL sectioning produced a major increase in the internal limit from 0 to 45 degrees of knee flexion.

The changes in the abduction rotation limits in the intact knee and with ligament sectioning are shown in Figure 3-40. The MCL was the primary restraint; however, the data show only small increases in abduction (medial joint opening) with complete MCL sectioning, with further increases in the motion limits after the PMC was sectioned. The ACL cut allowed for even further increases in abduction, indicating that it is a secondary restraint after the medial ligaments (MCL, PMC) are cut.

The conclusions of this cadaveric study on the function of the ACL and medial ligament structures applied to the clinical diagnosis and function of ligament injuries are:

1. ACL sectioning alone allows only small increases in internal tibial rotation and no increases in external tibial rotation. When all medial structures (ACL intact) were sectioned, the abduction limit increased to only about 7 degrees, or 7 to 8 mm of medial joint opening. This suggests that partial to complete ACL tears are required for further increases to occur in medial joint opening (see Table 3-10).
2. The MCL (and deep medial capsule) limits anterior tibial translation as a secondary restraint after the ACL is ruptured. A combined ACL/MCL injury has equal anterior translation at 30 and 90 degrees, indicating the Lachman and 90-degree anterior drawer tests will show similar increases in anterior tibial translation, instead of only the major increase at 30 degrees of knee flexion.
3. In the ACL- and MCL-deficient knee, the Lachman test will show an absence of the normal coupled internal tibial rotation in contrast to the coupled rotation in the normal knee and the ACL-deficient knee.
4. The MCL is the primary restraint for external tibial rotation; however, the increase is small (4.6 degrees to 8.7 degrees from 30 to 90 degrees of flexion). The increase in external rotation doubles when the PMC is also sectioned. Further increases in external rotation to approximately 15 degrees occur when the ACL is also sectioned. The results validate the importance of performing the dial tibial rotation test (see Chapter 15 and Chapter 17) to determine anterior subluxation of the medial tibial plateau with medial ligament injuries.

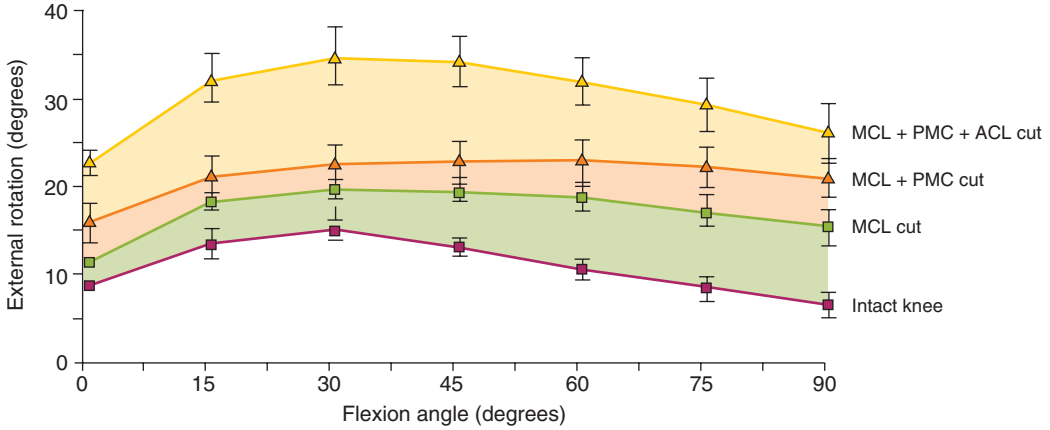

FIG 3-38 The external rotation limits in the intact knee (*bottom curve*) first increased with flexion to 30 degrees and then decreased with further flexion (11 donors). Cutting just the superficial medial collateral ligament (MCL cut) increased the external rotation limits more in flexion than in extension (16 donors). Further cutting of the posteromedial capsule (PMC [MCL + PMC cut]) produced a further increase in the external limit at all flexion angles, but the increase was again greater in flexion than in extension. Cutting the superficial MCL, the PMC, and the anterior cruciate ligament (ACL) allowed for a large increase in the external limit, particularly from 15 to 45 degrees of flexion (*top curve*). (From Haimes JL, Wroble RR, Grood ES, Noyes FR. Role of the medial structures in the intact and anterior cruciate ligament-deficient knee. Limits of motion in the human knee. *Am J Sports Med.* 1994;22:402-409.)

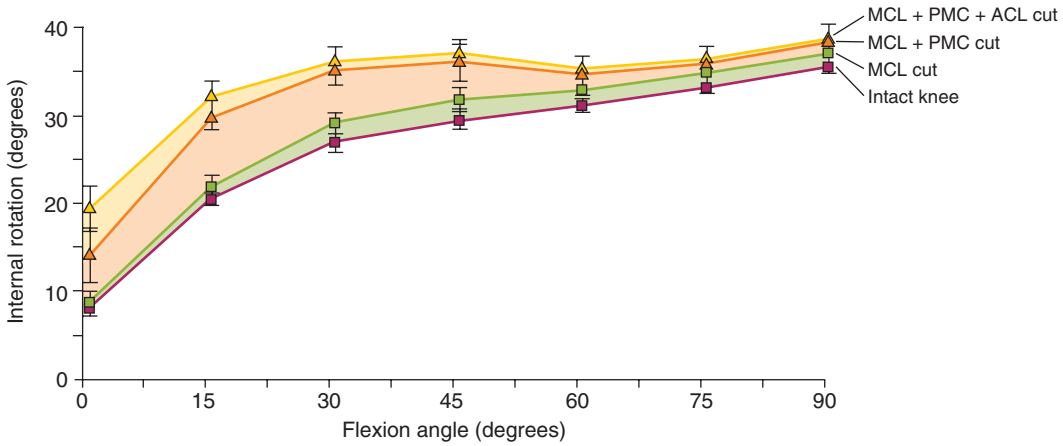

FIG 3-39 The internal rotation limits of the intact knee (*bottom curve*) increased progressively as the knee was passively flexed (11 donors). Cutting the superficial medial collateral ligament (MCL [MCL Cut]) produced only a small increase in the internal rotation limits (six donors). Cutting the MCL and posteromedial capsule (PMC [MCL + PMC Cut]) caused large increases in the internal rotation limits from 0 to 45 degrees of flexion (six donors). Cutting the MCL, the PMC, and the anterior cruciate ligament (ACL) (*top curve*) caused similarly large increases in the internal limits from 0 to 45 degrees of flexion relative to the intact knee (six donors). However, these increases were not significantly different from those seen with the MCL and PMC cut. (From Haimes JL, Wroble RR, Grood ES, Noyes FR. Role of the medial structures in the intact and anterior cruciate ligament-deficient knee. Limits of motion in the human knee. *Am J Sports Med.* 1994;22:402-409.)

5. The combined MCL/PMC injury results in increases in external tibial rotation (9 degrees at 30 degrees of flexion), increases in internal tibial rotation (12 degrees at 30 degrees of flexion), and increases in abduction testing at 0 degrees and 30 degrees of flexion (6 degrees and 9 degrees, respectively). The increase in internal tibial rotation was previously recognized by Mueller[44] and is an interesting finding not commonly reported.

The results of the authors' studies are in agreement with other published data in cadaveric knees. Robinson and coworkers[68] studied the superficial medial collateral ligament (SMCL), the deep medial collateral ligament (DMCL) and the PMC and measured the changes in motion limits under AP drawer, valgus, and internal-external rotation loads by sequential MCL cutting in 18 cadaveric knees. These authors reported that the PMC limited valgus, internal rotation, and posterior drawer in extension, resisting 42% of a 150-N drawer force when the tibia was in internal rotation (Figs. 3-41 to 3-44). The SMCL resisted valgus at all angles and was dominant from 30 to 90 degrees of flexion, plus internal rotation in flexion. The DMCL resisted tibial anterior translation of the flexed and externally rotated knee and was a secondary restraint to valgus.

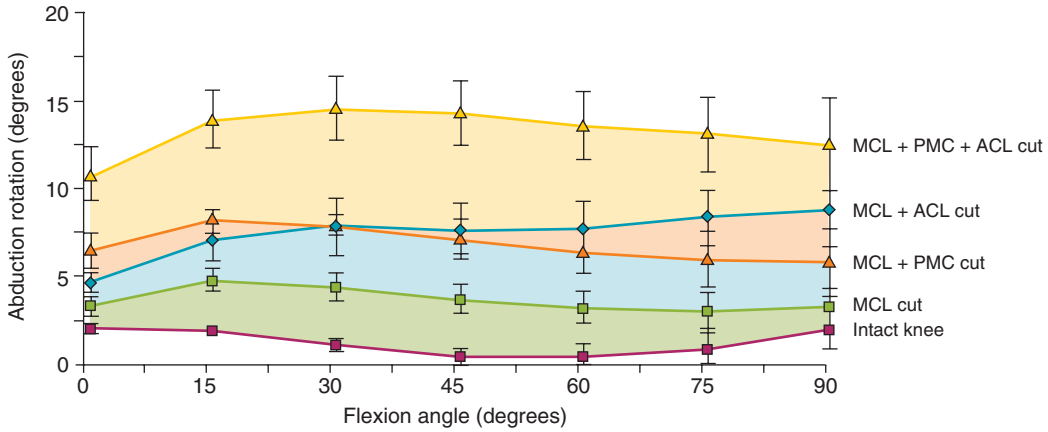

FIG 3-40 The abduction rotation limits (valgus opening) of the intact knee (*bottom curve*; 11 donors). Cutting only the medial collateral ligament (MCL cut) produced a small increase (approximately 2 to 4 degrees) in the abduction limit from 15 to 75 degrees of flexion. Cutting the anterior cruciate ligament (ACL [MCL + ACL cut]) increased the abduction limit (six donors). Cutting the posteromedial capsule (PMC) in addition to the MCL (MCL + PMC cut) with the ACL intact allowed for a further small but consistent increase (2 to 3 degrees) over the superficial MCL alone (six donors). When compared with the intact knee, this injury combination increased the abduction limit approximately 6 to 7 degrees at both 15 and 30 degrees of flexion. Subsequent cutting of the ACL (*top curve*) caused a large increased in the abduction limits at all flexion angles (nine donors). (From Haimes JL, Wroble RR, Grood ES, Noyes FR. Role of the medial structures in the intact and anterior cruciate ligament-deficient knee. Limits of motion in the human knee. *Am J Sports Med.* 1994;22:402-409.)

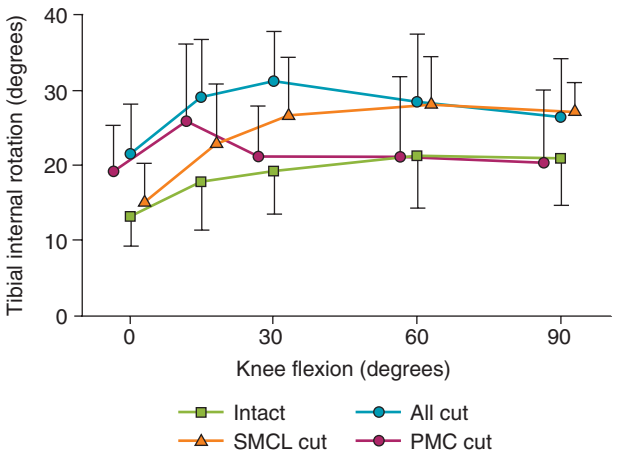

FIG 3-41 Tibial internal rotation motion limits with the knee intact (n = 18) and cutting the superficial medial collateral ligament (SMCL) alone (n = 4), posteromedial capsule (PMC) alone (n = 4), and SMCL, deep medial collateral ligament, and PMC together (n = 14). These data show the reciprocal action of the SMCL and PMC restraining internal rotation at different angles of tibiofemoral flexion. (From Robinson JR, Bull AM, Thomas RR, Amis AA. The role of the medial collateral ligament and posteromedial capsule in controlling knee laxity. *Am J Sports Med.* 2006;34:1815-1823.)

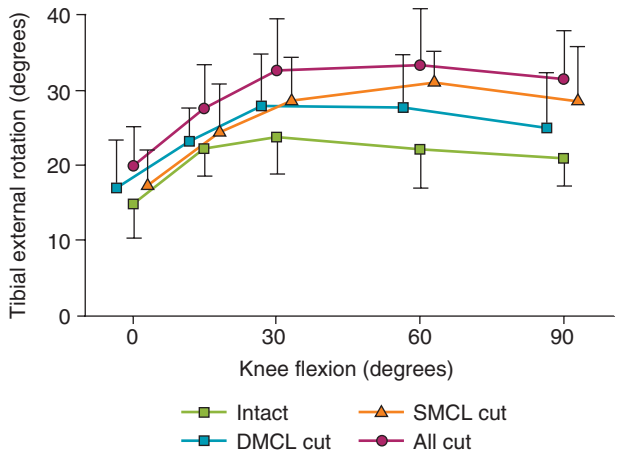

FIG 3-42 Tibial external rotation motion limits with the knee intact (n = 18) as well as changes caused by cutting either the superficial medial collateral ligament (SMCL) alone (n = 4) or the deep medial collateral ligament (DMCL) alone (n = 6) or after cutting both the whole MCL and the posteromedial capsule (n = 14). (From Robinson JR, Bull AM, Thomas RR, Amis AA. The role of the medial collateral ligament and posteromedial capsule in controlling knee laxity. *Am J Sports Med.* 2006;34:1815-1823.)

Robinson and coworkers[68] reaffirmed that the PMC is an important structure for stabilizing the extended knee under valgus loading (32% of the resistance). With knee flexion, the PMC slackens and the MCL becomes the dominant restraint. In the extended knee, with posterior drawer and internal rotation, the PMC tightens based on its attachments at the femur (just posterior to the adductor tubercle) and the posteromedial aspect of the tibia resisting 42% of the posterior load.

In the bumper model of ligament behavior previously discussed, applying an internal tibial rotation tightens the PMC and SMCL, thereby increasing their resistance to posterior tibial displacement. The internal tibial rotation also tightens the ITB and midlateral capsule. In essence, the tibia is placed in a highly constrained position with AP translation blocked by lateral and medial extraarticular structures.

The posterior drawer test for PCL rupture is performed in neutral tibial rotation to determine the maximum posterior tibial translation. When the posterior drawer is repeated in maximal internal rotation (in knees with a PCL rupture), the amount of posterior tibial translation will markedly decrease if the PMC is intact. This can be used as a test to reaffirm that the medial secondary restraints are

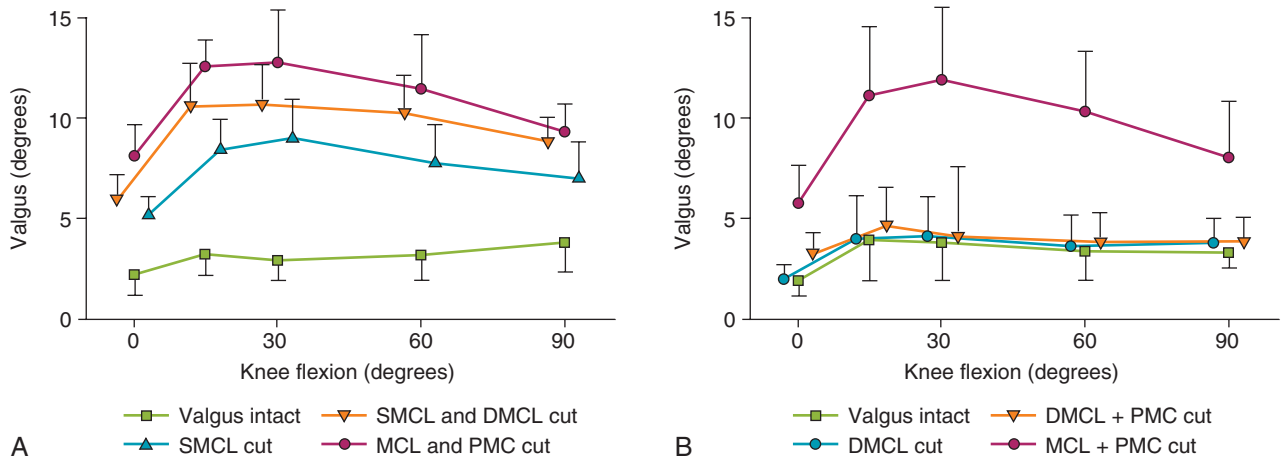

FIG 3-43 A, Valgus rotation produced by a 5 N-m moment of the intact knee and after sequential division of the posteromedial structures, superficial medial collateral ligament (SMCL), then deep medial collateral ligament (DMCL), then posteromedial capsule (PMC; $n = 4$). **B,** Valgus rotation with the knee intact and after sequential division of the posteromedial structures, DMCL, then PMC, then SMCL ($n = 6$). (From Robinson JR, Bull AM, Thomas RR, Amis AA. The role of the medial collateral ligament and posteromedial capsule in controlling knee laxity. *Am J Sports Med.* 2006;34:1815-1823.)

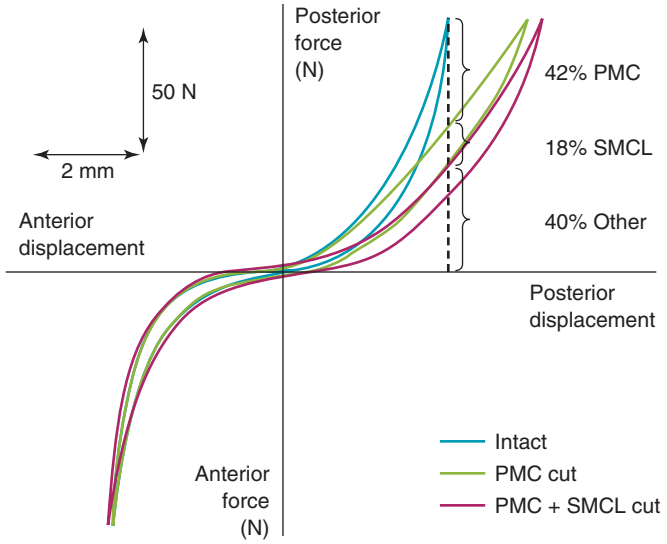

FIG 3-44 Force-displacement test: mean load versus displacement curves for intact, posteromedial capsule (PMC)-deficient, and PMC + superficial medial collateral ligament (SMCL)-deficient knees tested at 0 degrees of flexion with fixed tibial internal rotation. Load share calculated for 100-N posterior displacement force ($n = 4$). (From Robinson JR, Bull AM, Thomas RR, Amis AA. The role of the medial collateral ligament and posteromedial capsule in controlling knee laxity. *Am J Sports Med.* 2006;34:1815-1823.)

disrupted. However, more accurate medial joint opening tests at 5 and 25 degrees of flexion provide the same and frequently more meaningful data.

In regard to the anatomic description in these biomechanical experiments, Robinson and associates[69] dissected the MCL and capsular structures in 20 cadaver knees and reported on the anatomy of the SMCL, DMCL, and PMC. In the PMC, there were oblique fibers referred to as *capsular condensations* that attached at the posterior margin of the SMCL femoral attachment at the femoral epicondyle, proceeding in a distal direction to blend in with the capsule and semimembranosus tendon sheath expansions. These capsular fibers tightened with internal tibial rotation, and the entire PMC tightened with knee extension. The authors reported that the three distinct bands corresponding to the posterior oblique ligament (POL) described by Hughston and Eilers[30] could not be identified, preferring instead to use the nomenclature of the PMC.

Griffith and associates[17] conducted a study on the static function of the medial knee ligament structures in 24 cadaveric knees and emphasized the intricate relationship among the medial ligaments in resisting applied valgus and internal and external rotation torques. A comparison of their results with results of our study[20] show some discrepancies in the magnitude of medial joint opening and degrees of external rotation and internal rotation with ligament sectioning (Fig. 3-45 and Fig. 3-46). It is important to view the results of both studies because they reflect the significant inherent variability from one specimen to another in cadaveric tests. This is further reflected in the bumper model explanations previously described. Overall, both studies are more in agreement than disagreement on the loading relationship of the medial components. Of note, Griffith and associates'[17] study does divide the SMCL into distal and proximal sections in terms of function. These authors reported the proximal division of the SMCL as the primary valgus stabilizer; however, we question this conclusion. Sectioning the distal division also produced major increases in valgus rotation and the proximal SMCL was never sectioned as the first structure. In addition, another study by Griffith and associates[18] on force measurements in the SMCL proximal and distal divisions under valgus loading showed statistically significant resisting forces in the distal SMCL.

EFFECT OF SECTIONING THE MCL AND PMC ON POSTERIOR TIBIAL TRANSLATION

Ritchie and colleagues[66] studied in 14 cadaver knees the contribution of various structures in the PCL-deficient knee in resisting posterior tibial translation. Single-plane posterior drawer tests were performed with the knee in neutral tibial rotation and in 20 degrees of internal tibial rotation. The authors reported that with the knee in internal tibial rotation, posterior displacement was significantly less compared with that in neutral rotation when the SMCL was sectioned. The results showed that the SMCL was responsible for a decrease in posterior tibial

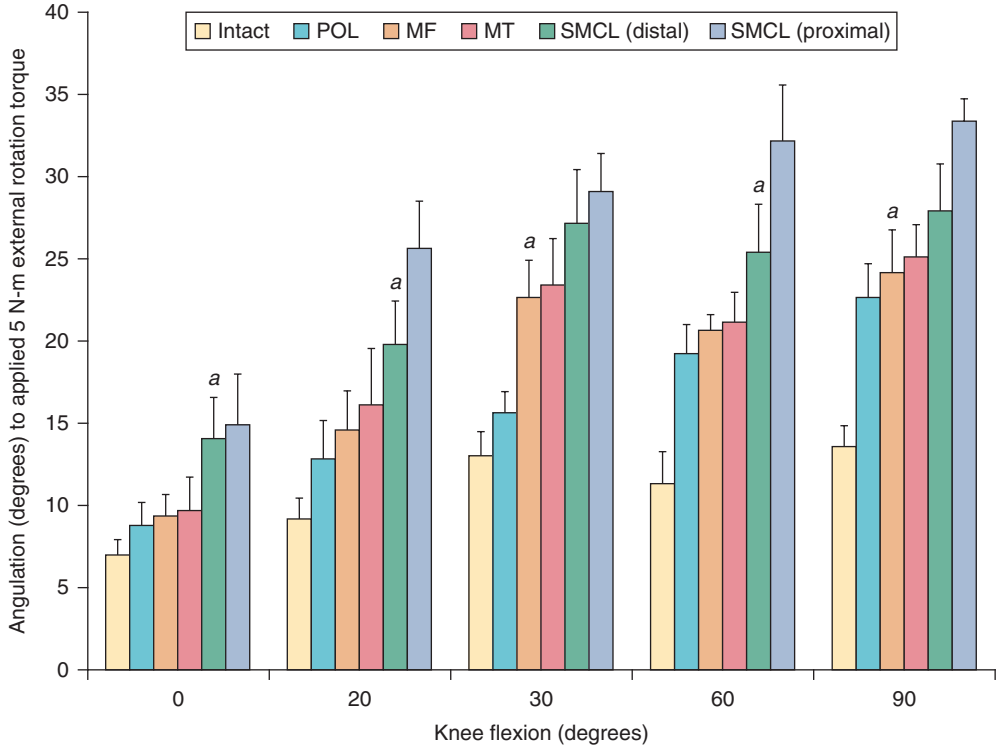

FIG 3-45 Knee angulation changes resulting from an applied external rotation torque (5 N-m) for each group of eight sectioned knees. Testing conditions for group 1 (sectioning of the posterior oblique ligament [POL] first). *a,* Significant difference compared with the intact knee (note that all sequential sectioning states are significantly different compared with the intact knee). Error bars indicate the standard error of the mean. *MF,* Meniscofemoral attachment of deep medial collateral ligament; *MT,* meniscotibial attachment of deep medial collateral ligament; *SMCL,* superficial medial collateral ligament. translation in the PCL-deficient knee and not the PMC, including the POL.

ROLE OF THE POL

In a cadaveric study using a robotic testing system, Petersen and coworkers[65] examined the restraint of the SMCL, the DMCL, the POL, and the PMC in resisting posterior tibial translation after PCL sectioning. The study reported that the POL had a much larger role than the SMCL and DMCL in resisting posterior tibial translation and internal tibial rotation. It should be noted that these two structures were first sectioned; no studies were done when the POL was sectioned first. This indicates there could be a sectioning artifact introduced in the study. Even so, there are posteromedial oblique capsular fibers from the medial femoral condyle to the tibia, just posterior to the SMCL, that resist internal tibial rotation and posterior tibial translation (after PCL sectioning). The study concluded that there are discrete oblique fibers that form the middle arm of the POL described by Hughston and Eilers.[30] Of interest in this cadaveric study was the finding that a valgus loading of the knee joint close to knee extension (with PCL deficiency) produced an increased posterior tibial translation of the medial compartment with absence of the POL and PMC.

Robinson and associates[69] conducted a cadaveric study of the medial and posteromedial structures and could not identify a distinct separate POL structure, but they did identify an oblique portion of the PMC where fibers could be tensioned under internal tibial rotation loading. Robinson and coworkers[68] and Haimes and associates[23] studied the contribution of the PMC, which included the POL. Robinson and coworkers[68] reported that the PMC resisted 28% of the posterior tibial load when the tibia rotated freely in the extended knee, which rose to 42% when the tibia was subjected internal rotation. These authors concluded that the PMC resisted posterior tibial translation close to full extension, and less so with knee flexion, which relaxes the PMC. With knee flexion, the SMCL resisted posterior tibial translation.

The role of the POL (along with the SMCL) in resisting internal and external tibial rotation was further studied by Griffith and colleagues[17,18] and Wijdicks and coworkers[78] and is discussed further in Chapter 19 in reference to the dial test for diagnosis.

In knees with chronic PCL instability and associated medial and posteromedial ligament and capsular injury, the integrity of all the structures should be restored. Specific tests for increased internal tibial rotation using the dial test are performed.

VARIABILITY AMONG CLINICIANS DURING CLINICAL KNEE LIGAMENT TESTING

There is a well-appreciated difficulty in quantifying the amount of tibial displacements and rotations in the clinical knee examination, and the potential exists for considerable variability to occur among examiners. For this reason, any attempt to provide objective

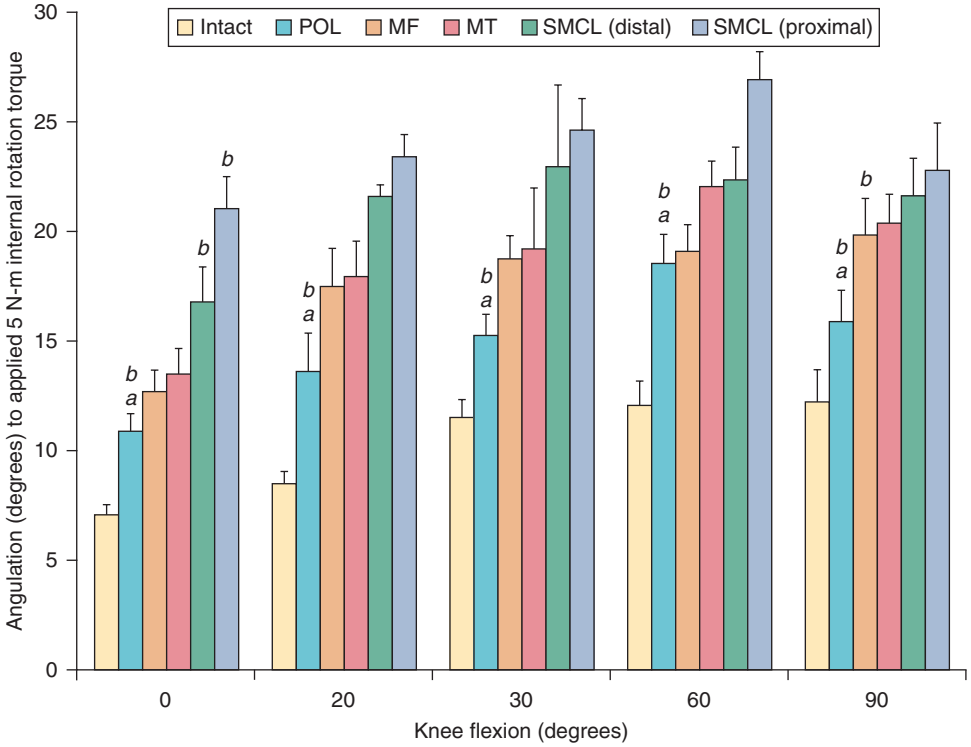

FIG 3-46 Knee angulation changes resulting from an applied internal rotation torque (5 N-m) for each group of eight sectioned knees. CRITICAL POINTS Variability Among Clinicians During Clinical Knee Ligament Testing

- An investigation was conducted with 11 experienced knee surgeons to determine differences in clinical examination testing techniques, accuracy in estimating knee displacements, and skill in diagnosing specific ligament injuries in knees with multiple abnormal motion limits.
- Wide variability existed among examiners in the starting position (knee flexion, tibial rotation) for AP displacement during the Lachman test and in the amount of tibial translation and rotation induced.
- Variability existed in the starting position for the pivot shift test and in the amounts of anterior tibial translation and internal tibial rotation produced. Many examiners induced coupled motions of anterior tibial translation and internal tibial rotation to produce anterior tibial subluxation without constraining or enhancing either motion.
- Most estimates were within 3 mm of the measured values in the laboratory during the medial joint abduction test. The examiners performed the test at a different flexion angle and reached a different final tibiofemoral position in both the intact knee and the ACL/MCL-sectioned knee.
- Large variations were found in the amount of internal and external tibial rotation induced in the ACL/MCL-sectioned knee. Each examiner performed the test at a different knee flexion angle and reached a different final rotation position.
- Seven examiners incorrectly diagnosed an injury to the posterolateral structures after the ACL and MCL were sectioned.
- The pivot shift test is qualitative in nature and imprecise in determining the results of ACL reconstructive procedures.
- Examination test techniques must be standardized regarding the test conditions so that examiners conduct knee examinations in a similar manner.
- The diagnosis of rotatory subluxations is highly subjective and requires a careful assessment of the AP position of the medial and lateral tibial plateaus relative to the femur.

measurements, such as knee arthrometer or stress radiographs (even with these test limitations), is believed to be more accurate than comparing manual examination results among various clinicians.

An investigation was conducted with 11 experienced knee surgeons to determine differences in clinical examination testing techniques, accuracy in estimating knee displacements, and skill in diagnosing specific ligament injuries in knees with multiple abnormal motion limits.[50,54] Knee joint positions and abnormal motions were measured in right-left cadaveric knees by a 3-dimensional instrumented spatial linkage. A comparison was made of the clinicians' estimate of the knee motion limits and subluxations with the actual measured values. The 3-dimensional limits of knee motion were measured in the laboratory

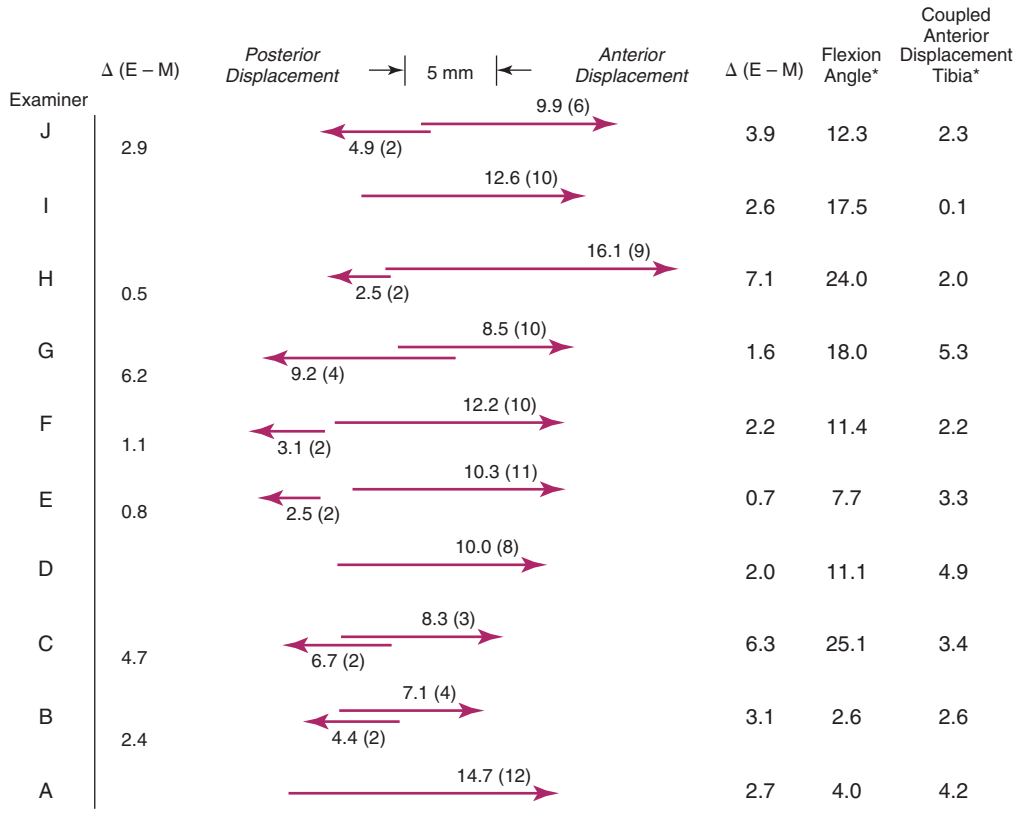

FIG 3-47 The instrumented spatial linkage measured values for anterior and posterior displacement for each examiner. The numbers above and below each bar give the measured displacement; the examiner-estimated values are given in parentheses. Starting position flexion angles and the coupled external rotation for the anterior displacement test are given for each examiner. *Δ (E – M),* Difference between estimated and measured instrumented spatial linkage value (examiner's estimated value). *Measured during anterior displacement test. (From Noyes FR, Cummings JF, Grood ES, et al. The diagnosis of knee motion limits, subluxations, and ligament injuries. *Am J Sports Med.* 1991;19:163-171.)

under defined loading conditions before and after the clinicians' examination.

Anteroposterior Displacement

Wide variability existed among examiners in the starting position of knee flexion and tibial rotation for AP displacement during the Lachman test (Fig. 3-47), and for the amount of tibial translation and rotation induced. Although some of the clinicians displaced the knee to the maximal displacement limits obtained in the laboratory, others failed to do so by a wide margin. The conclusion was reached that there was a wide variation in the loads applied among the examiners during the tests.

Pivot Shift Testing

The starting position for the pivot shift test varied among examiners but was typically close to 5 degrees extension (Fig. 3-48). As the knee was flexed, varying amounts of anterior tibial translation and internal tibial rotation were produced. During flexion, the maximal amount of internal tibial rotation was achieved first, followed by the maximal amount of anterior tibial translation. Although the amount of anterior translation of the lateral tibial plateau was similar among examiners, large differences existed among the clinicians (range, 6-16.9 mm) in the amount of maximum anterior translation of the medial tibial plateau. Examiners who produced the greatest amount of internal tibial rotation during the pivot shift test also significantly limited the amount of anterior translation of the medial tibial plateau ($R = -.79$, $P < .01$).

The maximal amount of anterior tibial translation and the limits to anterior and posterior translation produced by each examiner are shown in Figure 3-49. The normal and abnormal limits of tibial translation are shown before and after combined ACL and MCL ligament sectioning. The maximal amount of anterior translation (central point) ranged from 10 to 18 mm among examiners, and the maximal amount of anterior subluxation of the lateral tibial plateau ranged from 14 to 19.8 mm.

The mean value for maximal internal tibial rotation induced during the pivot shift test was 15.8 degrees ± 3.6 degrees (range, 11-24 degrees). Maximal internal rotation occurred at an average knee flexion angle of 15.6 degrees ± 5.2 degrees (range, 5-23 degrees). The limits to internal and external tibial rotation are shown in Figure 3-50. Two examiners exceeded the normal intact internal tibial rotation limit obtained under 5 N-m of torque. Only a slight increase occurred in the degrees of internal tibial rotation after the ACL and MCL were cut. Increases in external tibial rotation limits were also measured after ACL/MCL sectioning, which occurred during the tibial reduction phase of the pivot shift maneuver.

The tibial reduction phenomenon involved a posterior tibial translation and external tibial rotation. Three examiners (C, F, and I) produced the reduction phase with posterior tibial translation, uncoupling this motion from external tibial rotation. Four examiners (A, B, C, and

F) continued to flex the knee after reduction to about 80 degrees of flexion. Five examiners accentuated the reduction event by producing the maneuver with 20 degrees or less change in knee flexion, which resulted in the steepest decline in the translation and rotation curves.

A few examiners demonstrated variability during the pivot shift test in regard to enhancement of internal tibial rotation (Fig. 3-51 and Fig. 3-52). The millimeters of anterior translation of the medial, central, and lateral points varied depending on how the test was performed.

Medial-Lateral Joint Space Opening

During abduction and adduction rotation testing, the examiners were instructed to begin the tests with the femoral condyle in contact with the tibial plateau. Data from the medial joint space abduction test demonstrated that most of the examiners' estimates were within 3 mm of the actual measured values in the laboratory (Fig. 3-53). The starting flexion angle averaged 11.6 degrees (range, 3.1-21.3 degrees). Each examiner performed the tests at a different flexion angle and reached a different final tibiofemoral position in both the intact knee and the ACL/MCL-sectioned knee (Fig. 3-54).

Internal-External Tibial Rotation

Large variations were found among examiners in the amount of internal and external tibial rotation induced during testing of the ACL/MCL-sectioned knee. Although most of the examiners estimated the total amount of internal tibial rotation to within 5 degrees of that measured in the laboratory, only one examiner provided such an estimate for the total amount of external tibial rotation. The knee flexion angle at the start of the test ranged from 1.9 to 35.3 degrees. Each examiner performed the test at a different knee flexion angle and reached a different final rotation position.

Medial-Lateral Compartment Translations During External Tibial Rotation

After sectioning the ACL and MCL, the amount of external tibial rotation increased from 17.8 degrees (intact knee) to 22.1 degrees. Most of

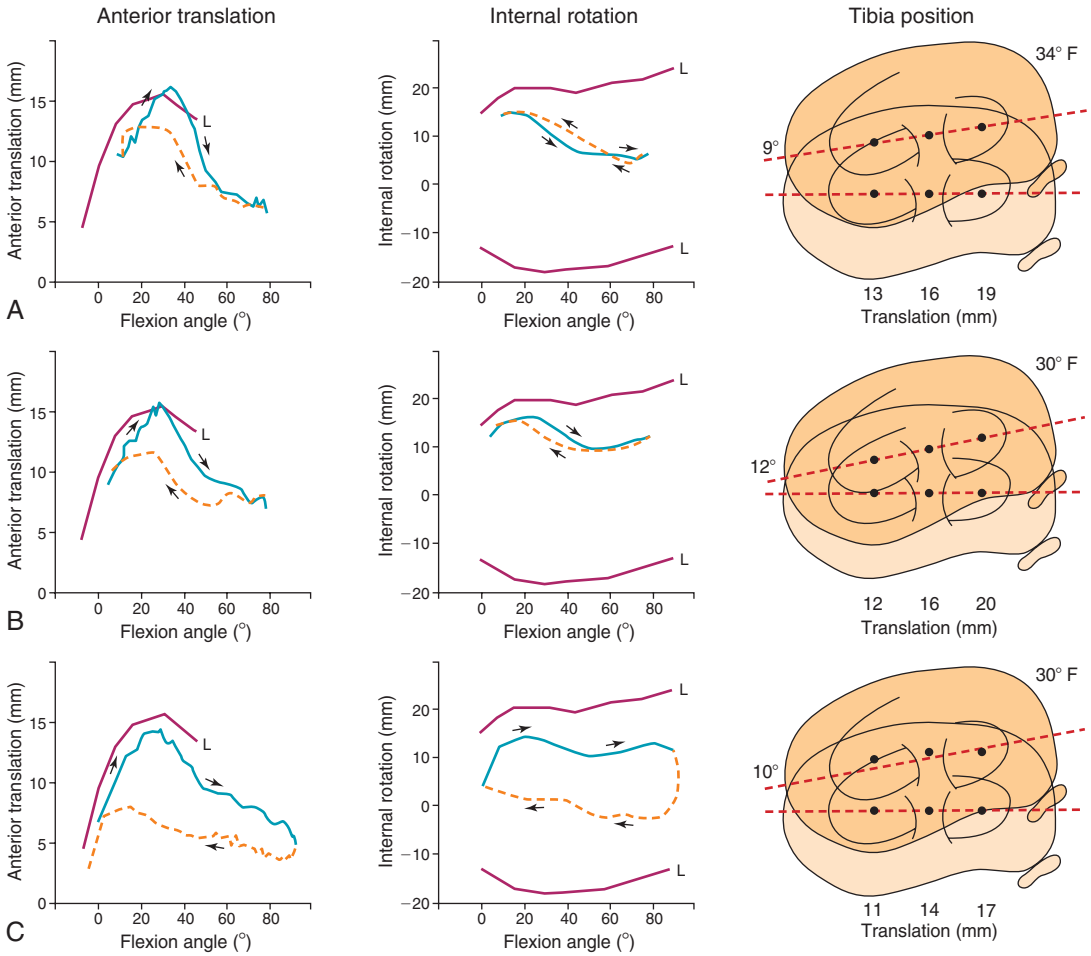

FIG 3-48 The tibial translations and rotations are shown for six examiners (**A** to **F**) during the pivot shift test. The limit curves (L) for 100 N of anterior translation and 5 N-m of the tibial rotation are superimposed on the clinical test results. The test follows the arrow sequence of knee flexion to reach a maximum anterior subluxation, the reduction event, followed by knee extension to return to the starting position of the test. The tibial plateau drawings show the position of maximum anterior subluxation (based on tibial center reference point). The millimeters of anterior translation for the medial, central, and lateral tibial reference points are shown (subluxated position from neutral position). *F,* Flexion. FIG 3-51 Two methods of tibial positioning are shown: (1) by enhancing internal rotation during the pivot shift test and (2) by not enhancing internal tibial rotation. The enhanced internal tibial rotation limited anterior translation of the tibia. *F,* Flexion; *L,* Limit curve. (From Noyes FR, Grood ES, Cummings JF, Wroble RR. An analysis of the pivot shift phenomenon. The knee motions and subluxations induced by different examiners. *Am J Sports Med.* 1991;19:148-155.)

the examiners produced an increase in anterior translation of the medial tibial plateau during the external rotation test. The displacement of the medial and lateral tibial plateaus in both the intact and ACL/MCL-sectioned states are shown in Figure 3-55. The average center of tibial rotation in both states was in the lateral tibiofemoral compartment. The lateral shift in the axis of tibial rotation is demonstrated in Figure 3-55, *B*, along with the increase in anterior displacement (range, 3.0-8.5 mm) of the medial tibial plateau. Seven of the 11 examiners incorrectly diagnosed an injury to the posterolateral structures, even though the lateral tibial plateau did not displace further posteriorly.

Study Limitations and Conclusions

Limitations existed in these studies, including the use of cadaver limbs which do not represent actual clinical conditions. Although whole lower limbs were used, with the hip replaced with a ball- and socket-joint, the muscles and capsular structures of the hip were removed, which may have affected femoral rotations. The forces or torques applied to the limb by each examiner were not directly measured but were inferred by comparing the joint displacements obtained in the clinical tests with those documented in the laboratory under defined loading conditions. The pivot shift test technique used by many examiners more closely replicated that which would be used while patients

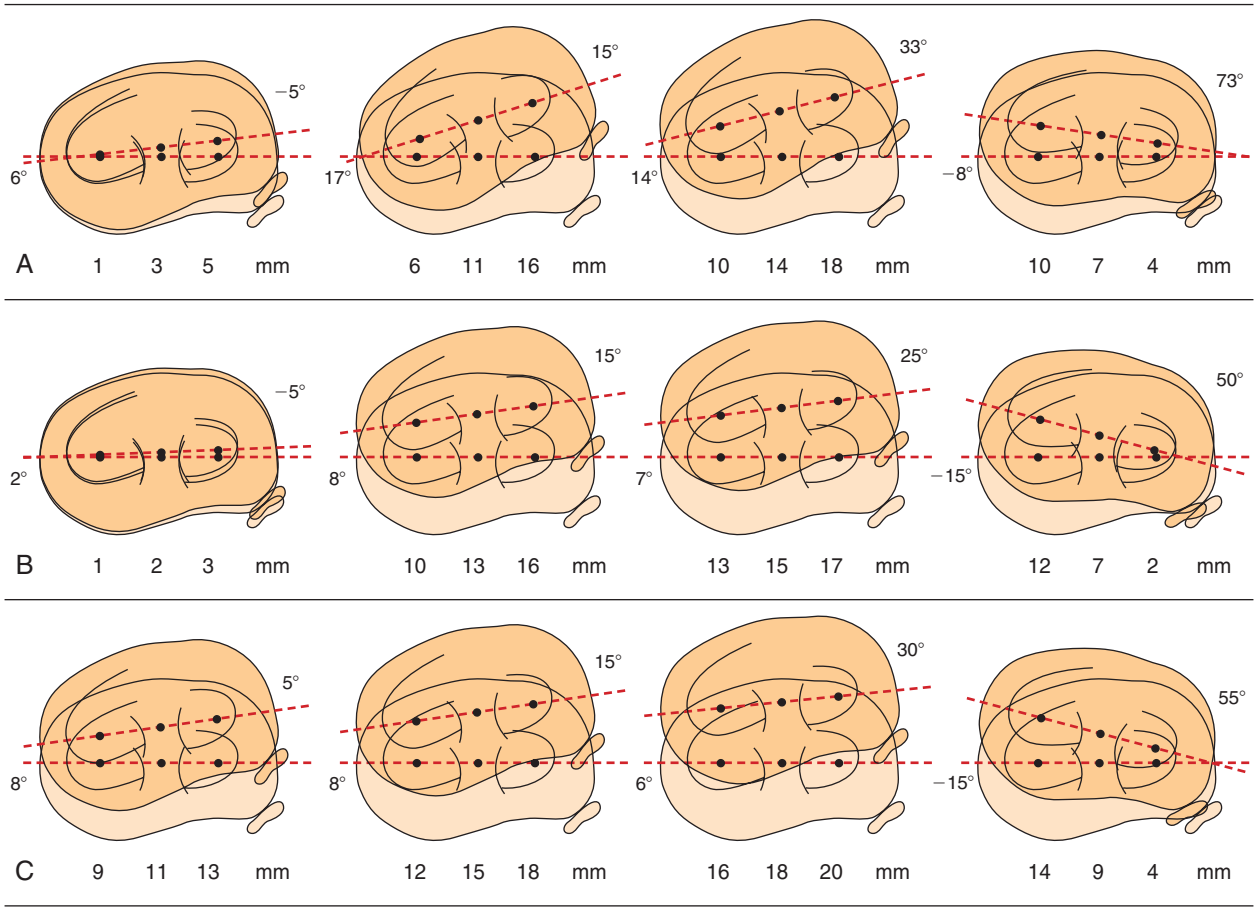

FIG 3-52 **A,** The pivot shift test is performed by first enhancing internal rotation. The test is then repeated in **B,** with the examiner not purposely enhancing internal rotation, and in **C,** with the tibia attempted to be held in a more externally rotated position. In actuality, the tibia is not externally rotated in **B** and **C** until the end of the test. The millimeters of anterior translation of the medial, central, and lateral points vary depending on how the test is performed. (From Noyes FR, Grood ES, Cummings JF, Wroble RR. An analysis of the pivot shift phenomenon. The knee motions and subluxations induced by different examiners. *Am J Sports Med.* 1991;19:148-155.)

are under anesthesia and not during a clinical examination. The gentler techniques, such as those induced during the flexion-rotation drawer test, avoid pain and apprehension although still induce a subluxation-reduction phenomenon.

The investigation demonstrated that many examiners induced coupled motions during the pivot shift test of anterior tibial translation and internal tibial rotation to produce anterior tibial subluxation without constraining or enhancing either motion. These examiners produced a greater anterior subluxation of the medial and lateral tibial plateaus than those who induced greater amounts of internal tibial rotation, which significantly decreased anterior subluxation of the medial tibial plateau ($P < .01$, Fig. 3-56). The recommendation can, therefore, be made to avoid intentional enhancement of internal tibial rotation when performing this test to allow the tibia to subluxate in the least constrained manner.

The variability demonstrated among examiners in the maximal amount of anterior tibial subluxation produced during the pivot shift test may affect the final grade assigned. It is certainly possible that one examiner would rate a knee as a grade II, and another examiner who applied a smaller force would rate the same knee as a grade I. Thus, the pivot shift test must be considered qualitative in nature and imprecise in determining the results of ACL reconstructive procedures. These results determined the need for a clinical testing device that could measure the anterior and posterior subluxations of the medial and lateral tibial plateaus under controlled loading conditions.

The tests for mediolateral joint space opening demonstrated wide variation among examiners in the starting position of the tibiofemoral compartment during abduction-adduction rotation testing. The medial or lateral tibiofemoral compartment must be in the closed position initially in order for the examiner to be able to accurately estimate the amount of joint space opening.

Even though variation existed among examiners in the estimated displacements, 9 of the 11 clinicians correctly diagnosed the ACL/MCL injury. However, numerous errors were made in the diagnosis of other ligament injuries, most notably, to the posterolateral structures. An increase in external tibial rotation was interpreted by many examiners to be a result of a posterior subluxation of the lateral tibial plateau and, therefore, injury to the posterolateral structures. The abnormality was actually an anterior subluxation of the medial tibial plateau, created by sectioning the ACL and MCL. To avoid this misdiagnosis, the examiner should palpate the medial and lateral tibial plateaus and their position relative to the femoral condyle in the maximum position of external and internal tibial rotation.[58,60] Because this provides only a qualitative estimate, the need exists for instrumented or radiographic

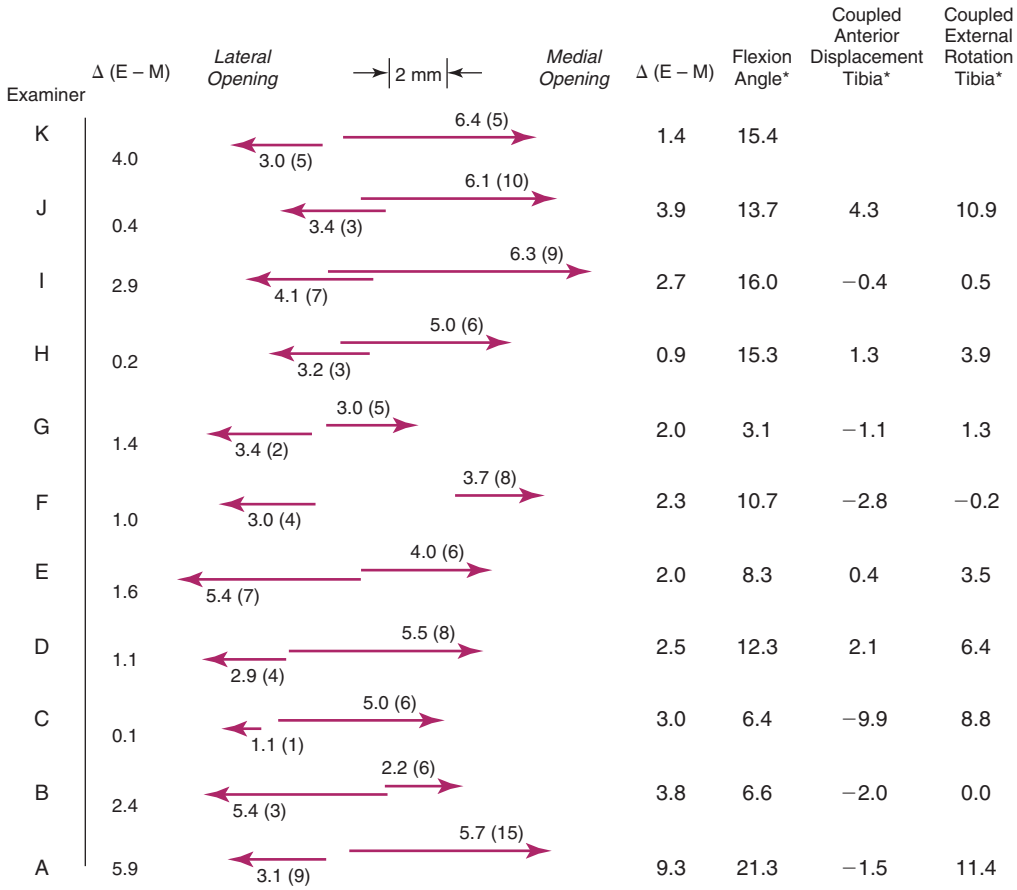

FIG 3-53 Instrumented spatial linkage measured values for the medial and lateral joint space opening in the abduction-adduction rotation test for each examiner (*A* to *K*). The numbers above and below each bar give the measured displacement, and the estimated value for each examiner are in parentheses. Starting position flexion angles, coupled anterior tibial displacement, and the coupled external rotation for the abduction rotation test are given for each examiner. *Δ (E – M),* Difference between estimated and measured instrumented spatial linkage value (examiner's estimated value). *Measured during medial joint space opening test. methods to diagnose more accurately the complex rotatory subluxations of the knee joint.

Based on these investigations, the following conclusions and recommendations were reached: (1) examination test techniques must be standardized regarding the test conditions so that examiners conduct knee examinations in a similar manner; (2) wide variations among clinicians regarding how knee tests are performed may not allow the comparison of knee motion limits; (3) instrumented teaching models should be developed to increase reproducibility among examiners; (4) reliable quantification of clinical testing in the form of knee arthrometry or stress radiography should be required for reporting clinical results; and (5) the diagnosis of rotatory subluxations is highly subjective and requires a careful assessment of the AP position of the medial and lateral tibial plateaus relative to the femur.

DEFINITION OF TERMS FOR KNEE MOTIONS, POSITIONS, AND LIGAMENT INJURIES

Considerable discrepancy exists in the orthopedic literature in the implied meanings of many terms commonly used to describe knee motions, positions, and ligament injuries. As a result, confusion may develop when clinicians communicate or compare the results of studies. In addition, the use of precise terminology is essential in the development of a valid ligament classification system, as described earlier in this chapter. In recognition of this problem, surgeons and scientists from two institutions conducted a study and made recommendations regarding the definitions of medical and engineering terms commonly used to describe the motion and position of the knee observed during clinical testing.[58]

A systematic format was adopted to (1) categorize the terminology used in major articles on knee ligament injuries; (2) compare terms used in the selected articles to determine whether unique definitions had evolved over time through common usage; (3) review and compare definitions of these terms from a variety of primary, secondary, and tertiary sources; and (4) provide a recommendation for use of these terms in the orthopedic literature. Dictionaries were considered primary sources,[26,74] textbooks were considered secondary sources,[37] and published articles were considered tertiary sources. Terms that had controversial or multiple definitions in the orthopedic literature were classified according to the least ambiguous meaning based on simplicity and clarity.

CRITICAL POINTS Definition of Terms for Knee Motions, Positions, and Ligament Injuries

- Considerable discrepancy exists in the orthopedic literature in the implied meanings of many terms commonly used to describe knee motions, positions, and ligament injuries.
- Motion and displacement of the knee are described by the combination of (1) the change in orientation of the tibia and (2) the motion or displacement of some reference or base point on the tibia.
- *Translation* refers to the motion of a rigid body and not of a point. The use of this term to refer to a point has evolved from general usage. The location of the reference point for translation may be chosen arbitrarily. However, the amount of translation depends on which point is selected; any associated rotation could cause the reference points to move differently.
- *Laxity* indicates slackness or lack of tension in a ligament. Laxity may be normal or abnormal; abnormal laxity may be congenital or result from an injury. The adjective *abnormal* should be used to indicate when laxity is pathologic. Because the word *laxity* has many different meanings (in English), more precise terms should be used when possible to describe abnormalities in motion or position of the knee joint.
- *Instability* frequently indicates a condition (physical sign) that is characterized by abnormal displacement of the tibia and describes an anatomic structure, such as ACL instability. It is preferable to describe the specific defect of the ligament or structures and to provide separately the abnormal displacements of the tibia.
- Considerable confusion exists regarding the definition of terms used to describe rotatory instability of the knee, such as anterolateral, posterolateral, anteromedial, and posteromedial. While some authors use these terms to describe abnormal motions, others use them to describe an abnormal position of the knee joint.
- The goal of the examination of the knee joint is to determine the motions, limits of motion, and initial and final positions of the joint that result from specified loading conditions. The outcome of the test should include the motions of the knee that occur, the abnormal motion limits, and the final tibiofemoral position.

The definitions of terms used to describe positions of the knee (position, dislocation, and subluxation) are shown in Table 3-12, and the terms used to describe motion of the knee (motion, displacement, translation, rotation, range of motion, limits of motion, coupled displacement and motion, constrained and unconstrained motion, force, moment, laxity and instability) are shown in Table 3-13. The terms used to describe injury to the knee (sprain, rupture, and deficiency) are shown in Table 3-14.

Note that motion and displacement of the knee are described by the combination of (1) the change in orientation of the tibia and (2) the motion or displacement of some reference or base point on the tibia. The change in orientation is quantified by the rotation of the tibia about the three independent axes (flexion-extension rotation, internal-external rotation, abduction-adduction rotation) and the motion or displacement of the reference point on the tibia. The flexion-extension axis is located in the femur, and its orientation relative to the femur does not change. The internal-external rotation axis is located in the tibia, and its orientation relative to the tibia does not change. The abduction-adduction axis is perpendicular to both the flexion and tibial rotational axes, and its orientation can change relative to both bones. The term *translation* in its purest form refers to the motion of a rigid body and not of a point. Therefore, the use of the term *translation* to refer to a point has evolved from general usage.

The location of the reference point for translation may be chosen arbitrarily. However, the amount of translation depends on which point is selected; any associated rotation could cause the reference points to move differently. The reference point frequently used to describe translation of the knee is located midway between the medial and lateral margins of the joint. Some investigators use a point on the tibial condyle that is midway between the spines of the intercondylar eminence.

The range and limits of knee flexion/extension are commonly defined in the literature by three numbers that denote maximum hyperextension, the zero or neutral point, and maximum flexion. For example, 5-0-145 describes a knee that goes from 5 degrees hyperextension to 145 degrees of flexion. A knee that lacks 15 degrees from full (0 degree) extension would be described as 0-15-145.

Most clinical examination tests are performed in a constrained manner in which the motion of the knee joint is restricted. For instance, in the abduction and adduction tests, the coupled external or internal tibial rotations are blocked by the examiner to determine the medial and lateral joint openings that are caused only by the abduction-adduction motion. An advantage of a constrained test is that the specific motions are known and may be reproduced in the laboratory, allowing the primary and secondary ligamentous restraints to be experimentally determined. During the Lachman test, the examiner may constrain the amount of coupled internal rotation of the tibia. In the pivot shift test, the motions are unconstrained to allow maximal subluxation of the lateral tibiofemoral compartment. The specific ligaments and the importance of each in limiting the final position will depend on how these tests are performed. We described earlier in this chapter the diagnostic information obtained during both constrained and unconstrained tests on the knee joint under known forces, motions, and displacements.

When applied to a ligament, the term *laxity* is used to indicate slackness or lack of tension—a lax ligament. Ligaments may purposely be made slack in an uninjured knee by positioning the tibia so that the distance between the femoral and tibial attachments is shortened. Laxity may be normal or abnormal; abnormal laxity may be congenital or result from an injury. The adjective *abnormal* should be used to indicate when laxity is pathologic. In the orthopedic literature, the term *laxity* is also used to indicate looseness of a joint or some amount of motion that results from the application of forces and moments. One source defines laxity as "either normal free motion or greater than normal free motion, as of a joint."[36] The problem with this term is that the specific type of motion is not stated. For instance, the term *anterior laxity of the knee* may refer to the combined motions of both anterior translation and tibial rotation, or just to the amount of anterior tibial translation. If the latter is true, it is preferable to use the term *anterior translation*, thus avoiding ambiguity and allowing the millimeters of anterior tibial translation that occurred under defined loads to be reported. If the amount of anterior translation reported is the difference between the injured and contralateral knee, this should always be indicated.

Because the word *laxity* has many different meanings, more precise terms should be used, when possible, to describe abnormalities in motion or position of the knee joint. *Laxity* should be used only in a general sense to indicate slackness or lack of tension in a ligament. When referring to motion of the knee, it is preferable to describe the specific motion.

In the orthopedic literature, the term *instability* is commonly used to indicate a condition (physical sign) that is characterized by abnormal displacement of the tibia. This term is also commonly used to describe an anatomic structure, such as ACL instability. It is preferable to describe the specific defect of the ligament or

TABLE 3-12 Definitions of Terms Used to Describe Positions of the Knee

Term	Etymology	Primary Source Definition	Secondary, Tertiary Source Definitions	Comments
Position	From Latin *ponere*, to put, to place	(1) Of the human body: bodily posture or the arrangement of parts of the body (body segment) as used for a particular examination or surgical procedure. (2) Of a point: the location of a point with respect to a reference system. (3) Of a rigid body: the position of a point or particle in the body and the orientation of the body.	The location of a point on the tibia, such as the medial tibial spine, can be described by three translational coordinates: anteroposterior, mediolateral, and proximodistal. These coordinates indicate where the point is located with respect to a reference coordinate system on the femur. The *orientation of a body* refers to how it is rotated relative to other body segments. The orientation of the tibia relative to the femur is described by the angles of flexion-extension, abduction-adduction (or varus-valgus rotation), and internal-external rotation.	The position of the tibia is crucial to correctly diagnose knee ligament injuries. The starting position of the tibia during clinical tests determines the tension in each of the ligamentous and capsular structures. The final position of the tibia when maximum subluxation has been reached determines which ligaments are injured.
Dislocation	From Latin *de*, away from; *locare*, to place	An abnormal position of the osseous structures forming a joint, such that there is no longer contact between the normally opposed, articulating surfaces. Synonym: luxation	The term *dislocation* has been used to indicate a complete noncontact position of either the medial and the lateral tibiofemoral compartments or the patellofemoral joint. This term can also be used to describe a noncontact position of only the medial or lateral tibiofemoral compartment.	Dislocations of the knee joint are typically classified according to the final tibial position: anterior, posterior, medial, lateral, or rotatory.
Subluxation	From Latin *sub*, under, beneath; *luxare*, to put out of joint	A partial dislocation in which there is an abnormal position of the osseous structures forming the joint; however, a portion of the opposing articulating surfaces is still in contact.	*Subluxation* has been used to indicate an incomplete or partial dislocation. This term has been used synonymously with abnormal motion. However, *subluxation* represents a position of the joint and not its motion. It is therefore incorrect to use this term to indicate abnormal motion.	Identifying and quantifying subluxation is difficult because the term does not have units. The clinician must describe a subluxation according to the position of the tibia relative to the femur. Rotatory subluxations are described by the rotation of the tibia and the position of any point on the tibia. Or, the anteroposterior position of a point may be specified on the medial and lateral tibial plateaus.

structures and to provide separately the abnormal displacements of the tibia (including the known loading conditions that lead to the diagnosis).

The term *sprain* is usually defined as an injury to a ligament in which portions of the ligament are torn but not completely disrupted.[1,8,36] The AMA's classification system sorts ligament injuries into three categories: first-, second-, and third-degree sprains, as previously described in Table 3-9.

The goal of the examination of the knee joint is to determine the motions, limits of motion, and initial and final positions of the joint that result from specified loading conditions. The examiner should specify the conditions under which the test is conducted, including the position of the patient and the knee joint and the loads applied. The outcome of the test reported includes the motions of the knee that occur, the abnormal motion limits, and the final tibiofemoral position, as discussed earlier in this chapter. A change in any of the test conditions may alter the interpretation of the outcomes and the final diagnosis of the anatomic structure that is injured.

Considerable confusion exists regarding the definition of terms used to describe rotatory instability of the knee, such as anterolateral, posterolateral, anteromedial, and posteromedial. Although some authors use these terms to describe abnormal motions, others use them to describe an abnormal position of the knee joint. In this textbook the authors use these terms to describe an abnormal position (subluxation) of the medial or lateral compartment with the sense (direction) indicated.

TABLE 3-13 Definitions of Terms Used to Describe Motion of the Knee

Term	Etymology	Primary Source Definition	Secondary, Tertiary Source Definitions	Comments
Motion	From Latin *movere*, to move	The act or process of changing position.	The motion of an object is described by specifying its velocity or the rate and direction with which it is changing position.	The sequential positions of an object in motion compose the path of the motion. The net effect of a motion can be quantified in two ways: (1) by describing the distance that an object travels along its path and (2) by describing the displacement between the starting and the ending points of its path, without regard to the details of the intervening motion.
Displacement	From Old French *des*, away; *placer*, to place	The net effect of a motion. The change in position of a body or particle between two points along its path without regard to the path followed.	The *displacement* of a rigid body is the change in its position regardless of the path it follows. It can be described by the change in position of any particle (also termed *translation*), along with the change in orientation (also termed *rotation*) of the rigid body.	Displacement may be described as a combination of three translations and three rotations, each of which corresponds to a degree of freedom. The standard international unit of translation is the meter; the unit of rotation is the radian or the degree.
Translation	From Latin *trans*, across; *ferre*, to carry	A type of motion or displacement of a rigid body in which all lines attached to it remain parallel to their original orientation. A type of motion by which all points in the body move along paths parallel to each other. All points move with the same speed and in the same direction.	*Translation* describes the motion of the tibia with respect to the femur, which consists of three independent components: mediolateral translation, anteroposterior translation, and proximodistal translation.	A body that follows a curved path undergoes translation if its orientation does not change during the motion. If the direction of motion is constant, the body moves in a straight path. If the direction changes with time, the body follows a curved path. The points of motion should not be referred to as translations; points displace, not translate. The standard international unit of translation is the millimeter.
Rotation	From Latin *rotare*, to turn	A type of motion or displacement in which all points on a body move about an axis as a center or a motion in which one point is fixed. The axis is commonly termed the *axis of rotation*.	During rotation, the points on a body have different directions of motion and different speeds. At each instant, the points move in circles about the axis of rotation. Rotations are composed of three independent degrees of freedom that occur about one of three axes: flexion-extension rotation, internal-external rotation, and abduction-adduction rotation.	Motion and displacement of the knee are described by the combination of (1) the change in orientation of the tibia and (2) the motion or displacement of some reference or base point on the tibia. The change in orientation is quantified by the rotation of the tibia about the three independent axes. The motion is often referred to in the literature as *translation of the tibia*.
Range of motion	From Old French *ranc*, row	The displacement that occurs between the two limits of movement for each degree of freedom.	Common use of *range of motion* in the knee is to describe the amount of rotation that may occur. There is also a *range of motion* for each of the translational and rotational degrees of freedom.	Range of motion depends on the loads applied to the knee. For motions other than flexion-extension, the range of motion generally depends on the angle of flexion of the knee. The range of anteroposterior translation depends on the angle of flexion and the position of tibial rotation in which the knee is placed before a measurement is made.
Limits of motion	From Latin *limes*, boundary	The extreme positions of movement possible for each of the six degrees of freedom.	Two limits, in opposite directions, are required to define range of motion. A total of 12 limits of motion exist in the knee, 2 for each of the 6 independent degrees of freedom.	Specifying the limits of motion provides additional information not provided by the range of motion. The range and limits of knee flexion-extension are commonly defined by three numbers that denote maximum hyperextension, the zero or neutral point, and maximum flexion.

TABLE 3-13 Definitions of Terms Used to Describe Motion of the Knee—cont'd

Term	Etymology	Primary Source Definition	Secondary, Tertiary Source Definitions	Comments
Coupled displacement and motion	From Latin *copula*, bond	A displacement or motion in one or more degrees of freedom that is caused by a load (force or moment) applied in another degree of freedom.	The amount of coupled motion depends on (1) where the force is applied to the tibia, and (2) whether the center of rotation is constrained or allowed to move freely. The type and amount of coupled motion that occur during clinical testing depend on the mechanical properties of the knee and the magnitude and direction of loads applied by the examiner.	An example of coupled motions that occur during clinical testing is external rotation when a posteriorly directed force is applied to the tibia and internal rotation when an anteriorly directed force is applied to the tibia.
Constrained (and unconstrained) motion	From Latin *con*, together; *stringere*, to draw tight	To restrict the motion of a (mechanical) body in a particular mode.	The motion of the knee joint may be allowed to occur freely (*unconstrained*) or it may be restricted (*constrained*). If the motion is unconstrained, the tibia displaces into its maximum position. Constrained tests limit the amount of motion that occurs.	An example of an unconstrained clinical test is the external rotation dial test. Typically, motions of external rotation and posterior translation of the tibia occur. The examiner does not constrain these motions but allows the joint to displace to its maximum subluxation.
Force	From Latin *fortis*, brave, strong	The influence on a body, such as a push or pull, that accelerates (changes either the speed or the direction of motion) or deforms (changes either the size or the shape) the body.	A force has three properties: (1) an orientation or line of action, (2) a sense, forward or backward, along its line of action, and (3) a magnitude, which is expressed in newtons (N).	The effect of a force depends on its three properties and its point of application. If an anteriorly directed force is applied to the tibia, the resulting tibia motion depends on where the force is applied and its magnitude. The direction of the force is the combination of its orientation (along the anteroposterior axis) and its sense (anterior).
Moment	From Latin *momentum*, movement	The influence on a body that causes an angular (rotational) acceleration of the body.	A *moment* has three properties: (1) an orientation, or line of action, (2) a sense, clockwise or counterclockwise, about its line of action, and (3) a magnitude, which is measured in newton-meters. The magnitude of the moment is directly proportional to the magnitude of the force that produces it and to the perpendicular distance to the line of action of the force (moment arm).	When indicating the moment at the knee, it is essential to state the axis about which the moment is determined, because the magnitude of the moment will depend on where the axis is located and on the orientation of the axis.
Laxity	From Latin *laxare*, to relax, slacken	(1) Slackness or lack of tension (a characteristic of a ligament) and (2) looseness, referring to a normal or an abnormal range of motion of a joint.	In the orthopaedic literature, *laxity* has two general meanings: (1) a slackness in a ligament or lack of tension and (2) looseness of a joint. Synonym (as applied to joint motion): play.	The clinical examination for laxity of the knee joint ligaments involves determining the abnormal displacement of the tibia and the position that can be induced by the application of forces and moments. The clinical findings are used to infer the extent of injury to the ligaments and capsular structures (abnormal laxity).
Instability	From Latin *in*, not; *stabilitas*, firmness, steadiness	A condition of a joint characterized by an abnormal increased range of motion (mobility) caused by injury to the ligaments, capsule, menisci, cartilage, or bone.	In the orthopedic literature, *instability* is used to describe (1) an episode of giving-way (symptom) and (2) a condition of abnormal mobility (play) of the joint (physical sign). *Instability* should be used only in a general manner to indicate abnormal displacement of the tibia that occurred owing to an injury.	Functional instability may result in partial collapse of the knee or a subjective sensation. The term *instability* should not be used to indicate a giving-way reinjury or an anatomic structure (e.g., instability of the ACL).

TABLE 3-14 Definitions of Terms Used to Describe an Injury of a Ligament in the Knee

Term	Etymology	Primary Source Definition	Secondary, Tertiary Source Definitions	Comments
Sprain	Possibly from Old French *espreindre*, to squeeze; from Latin *exprimere*, to squeeze or press out	An injury to joint ligaments that stretches or tears ligament fibers but does not completely disrupt the ligament (its continuity remains intact).	Most common definition is an acute injury of a ligament with a partial tear but without a complete rupture or loss of function of the ligament.	If a sprain is classified as a third-degree sprain (according to the classification of the American Medical Association), it is preferable to include the term *third degree* to indicate a complete tear of the ligamentous fibers.
Rupture	From Latin, *rumpere*, to break	A tear or tearing apart.	Usually indicates complete tearing of a ligament and loss of function. Synonym: tear	The term *partial* indicates an incomplete ligament rupture in which some function remains. If the term *partial* is not used, the word *rupture* indicates a complete disruption. It is the loss of function of a ligament that defines a tear, not the property of continuity.
Deficiency	From Latin *deficere*, to fail	The state or condition of lacking a substance, quality, or characteristic essential for completeness.	The term *deficiency* is used to (1) describe a knee in which a ligament is absent and (2) indicate when a loss of function of a ligament has occurred. Synonym: insufficiency	*Deficiency* is a general term that indicates that a defect exists but does not specify the extent of the injury. The clinician or author must therefore specify the extent of the defect. The presence of a positive pivot shift or abnormal anterior tibial displacement defines the deficiency of the ligament.

Video 3-1 Comprehensive Knee Exam: Clinical Rationale and Diagnosis

LIGAMENT FIBER LENGTH-TENSION PROPERTIES

In the early writings of Fick in 1911,[25] the description of ligaments having fibers grouped into bands was presented, along with the concepts that not all fibers of a ligament would be tense at one time. Fick also noted that knee flexion angle played an important role in determining which fibers were under tension and those that were slack. Since then, numerous publications have appeared that demonstrate how ligament fiber tension and function depends on the initial length and attachment site and on the specific joint position of both flexion-extension and tibial rotation.[30,34,35,78] These concepts are important because they form the basis for the placement of knee ligament grafts and provide insight into the concepts of single- and double-bundle anterior cruciate ligament (ACL) and posterior cruciate ligament (PCL) reconstruction. In addition, the ligament fiber length-tension properties form the basis for the tensioning rules regarding knee flexion and load applied for ligament grafts at surgery. Major disagreement still exists among investigators on these points, as is discussed in this chapter.

It is first important to understand the length-tension behavior of individual ligament fibers. The viscoelastic properties of ligament fibers allow them to initially undergo elongation under load in resisting joint displacements. The tension developed in the ligament fibers depends on its tibiofemoral attachment site, initial length, initial joint position, and subsequent joint displacement. In Figure 4-1, a force-versus-length curve is shown for human ACL fibers. The "L0" point describes the initial loading of the ligament fiber; when the ligament bone attachment distance of the fiber is less than L0, the fiber is slack. The fiber functions only when the distance between the fiber attachment sites reaches the length of the fiber to initiate loading. The fiber functions only within a narrow elongation or strain, which has been estimated at strains of 5% or less.[21] Failure of the individual fiber begins in the upper range estimated at the 8% level of strain.

Collagen fibers are not highly elastic and demonstrate failure at relatively low levels of elongation or strain. Because ligament fibers function only within a small range of lengths and the fiber lengths vary with knee rotations and translations, these fiber length patterns can be measured under in vitro conditions. Beynnon and coworkers[5-7] have measured fiber length patterns in vivo (described further in Chapter 10).

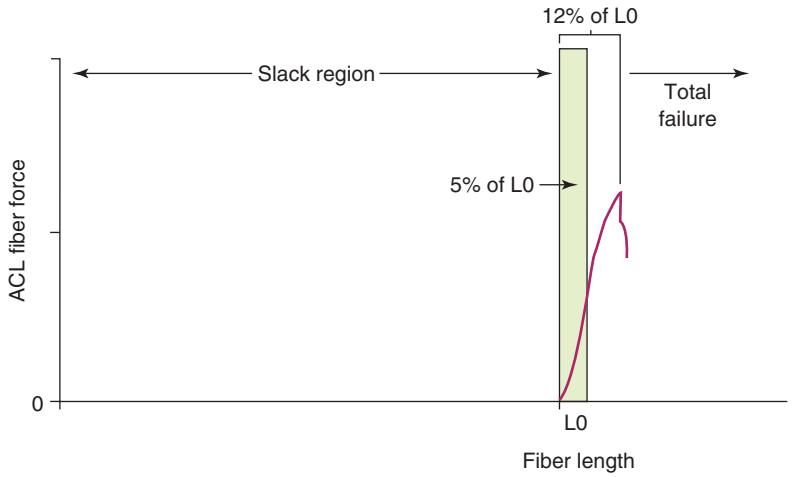

FIG 4-1 Force-length curve for human anterior cruciate ligament (ACL) fibers. Fiber force is shown as a function of the distance between attachments (length). In vivo functional activities are thought to occur within the shaded region, which corresponds to fiber strain of only 5%. (From Grood ES. Placement of knee ligament grafts. In Finerman GA, Noyes FR, eds. *Biology and Biomechanics of the Traumatized Synovial Joint: The Knee as a Model.* Rosemont, IL: American Academy of Orthopaedic Surgeons; 1992-393-417.)

CRITICAL POINTS Ligament Fiber Length-Tension Properties

- Numerous publications demonstrate how ligament fiber function depends on the initial length and attachment site and the specific joint position of both flexion-extension and tibial rotation.
- These concepts form the basis for the placement of knee ligament grafts, provide insight into single- and double-bundle cruciate reconstructions, and form the basis for the tensioning rules regarding knee flexion and load applied for ligament grafts at surgery.
- The tension developed in ligament fibers depends on its tibiofemoral attachment site, initial length, initial joint position, and subsequent joint displacement.
- Fibers function only when the distance between the fiber attachment sites reaches the length of the fiber to initiate loading.
- Collagen fibers are not highly elastic and demonstrate failure at relatively low levels of elongation or strain.

CRITICAL POINTS How Ligament Fiber Microgeometry Determines Ligament Function and Failure

- The 3-dimensional microgeometry of ligament fibers is only partially understood on a macroscopic and ultrastructural level.
- The arrangement of ligament fibers in a parallel manner such as the MCL, FCL, or a tendon provides a structure with a high maximum load to failure because the majority of the fibers are loaded in a symmetrical manner and share the loading profile. The structure will fail at a relatively small displacement.
- The capsular structures are designed to provide a low stiffness, allowing elongation or compliance, which is built into their microgeometry. Failure of capsular structures can be difficult to detect as a microtearing process occurs throughout the entire capsule. Before ultimate failure of the capsule, the microfailure process produces a residual elongation or slackening.
- The length-tension behavior and failure pattern of the ACL and PCL are also dissimilar, with different fiber regions brought into the loading based on the position of the knee.

HOW LIGAMENT FIBER MICROGEOMETRY DETERMINES LIGAMENT FUNCTION AND FAILURE

The 3-dimensional microgeometry of ligament fibers is only partially understood on a macroscopic and ultrastructural level. From a macroscopic level, Figures 4-2 to 4-5 show the concepts of how ligament fibers determine functional properties and the mechanisms of ligament failure. Figure 4-2 shows a stress-strain curve for a typical collagen fiber. The initial toe region involves straightening of the collagen fibers, followed by a linear region. At the end of the linear region, failure of individual collagen fibers occurs, which progresses to final failure of the whole structure. Note that the total fiber strain to failure is only 8% in this illustration. Figure 4-3 shows the effect on the structural properties of a ligament on increasing the cross-sectional area. There is an increase in stiffness and ultimate force to failure. Figure 4-4 shows the effect of different lengths of a collagen structure under load, both having the same cross-sectional area. In the illustration, there is a 50% decrease in stiffness in the ligament that is twice as long. This effect has been noted in ACL semitendinosus-gracilis tendon (STG) reconstructions where aperture fixation of the graft directly at the tunnel site may improve mechanical properties of the graft in addition to decreasing graft-bone tunnel motion. Figure 4-5 shows the effect of fiber microgeometry on structural properties. The finger trap illustration shows a major decrease in stiffness and ultimate strength because the collagen fibers are not loaded in a symmetric manner.

The arrangement of ligament fibers in a parallel manner such as the medial collateral ligament (MCL), fibular collateral ligament (FCL), or a tendon provides a structure with a high maximum load to failure because the majority of the fibers are loaded in a symmetric manner and share the loading profile. The structure will fail at a relatively small displacement, as is true for the MCL and FCL. Alternatively, the capsular structures are designed to provide a low stiffness, allowing elongation or compliance, which is built into the microgeometry, similar to that shown in the illustration of the finger trap in Figure 4-5. Certain portions of the capsule may have an arrangement in which some fibers exist in a more parallel array, such as the posterior oblique ligament of the posteromedial capsule. Failure of capsular structures

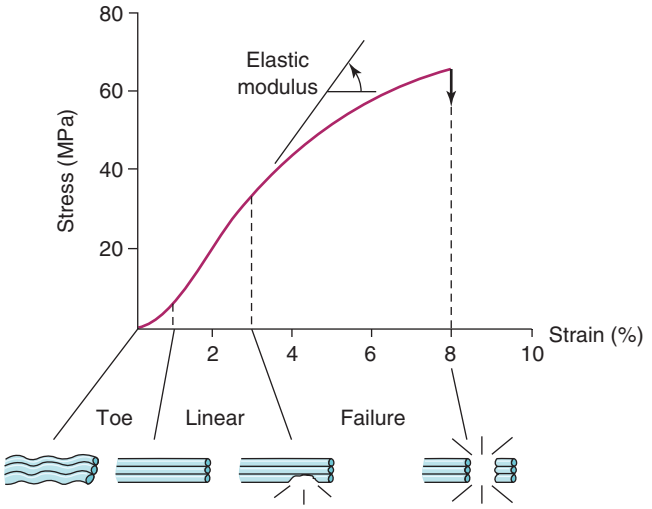

FIG 4-2 Example of a typical normalized stress-strain curve for collagen. The resulting curve provides mechanical (material) parameters that are independent of tissue dimensions. (From Butler DL, Grood ES, Noyes FR, Zernicke RF. Biomechanics of ligaments and tendons. In Hutton R, ed. *Exercise and Sports Science Review,* vol. 6. Philadelphia: Franklin Institute Press; 1978;125-182.)

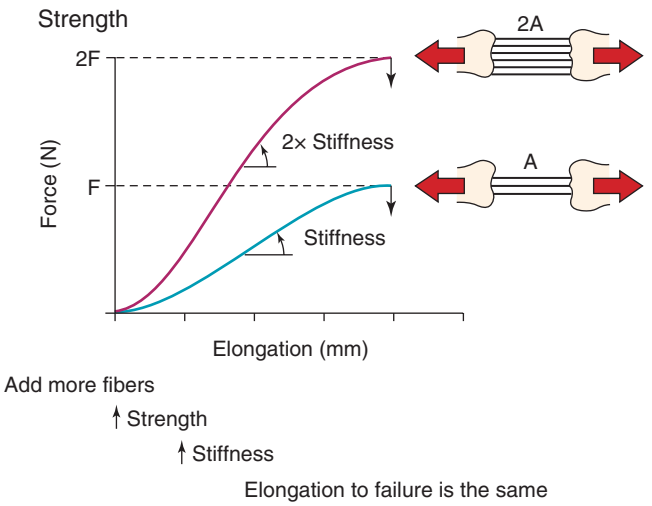

FIG 4-3 The effects of increasing tissue cross-sectional area on the shape of the load-deformation curve. (From Butler DL, Grood ES, Noyes FR, Zernicke RF. Biomechanics of ligaments and tendons. In Hutton R, ed. *Exercise and Sports Science Review,* vol. 6. Philadelphia: Franklin Institute Press; 1978-125-182.)

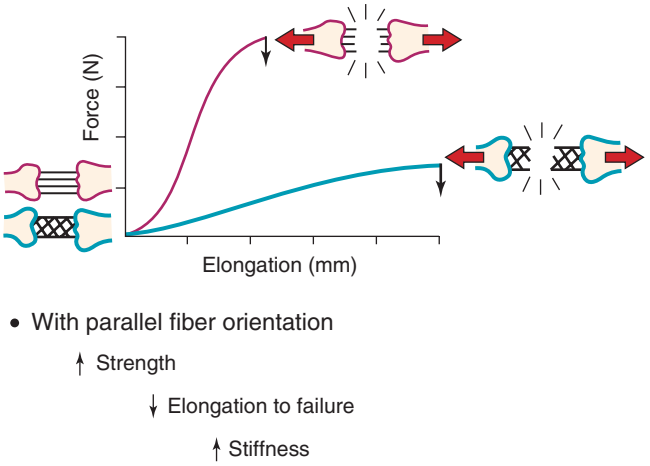

FIG 4-5 The effect of altering the collagen fiber alignment is shown. Parallel collagen fibers are loading uniformly, resulting in structural properties of increased strength, decreased elongation to failure, and increased stiffness in contrast to the oblique fiber orientation representing joint capsular tissues.

can be difficult to detect because a microtearing process occurs throughout the entire capsule. The capsule may appear slack and elongated without an obvious failure or the capsule may be avulsed off its femoral or tibial attachment and the failure site identified and repaired at surgery. Before ultimate failure of the capsule, the microfailure process produces a residual elongation or slackening that, in chronic knee injuries, may require plication procedures to restore tension and function. An example is plication of posteromedial or posterolateral capsular structures so that they will function in full extension and resist knee hyperextension. The length-tension behavior and failure pattern of the ACL and PCL are also dissimilar, with different fiber regions brought into the loading based on the position of the knee.

An example of the force elongation properties of the MCL and medial capsular structures is shown in Figure 4-6. This example is from a rhesus primate knee, in which the medial structures were loaded in uniaxial tension. The high failure load of the MCL compared with the capsular structures is shown. The capsule undergoes a failure process that is somewhat continuous because different portions of the less stiff capsule are brought into the loading sequence and fail, without an abrupt failure.

An example of a scanning electron microscopic analysis of failure of the ACL ligament is shown in Figure 4-7. In this series of experiments, the ACL of a rhesus primate knee was loaded to one half of its expected failure load. Scanning electron microscopic examination showed that some portions of the fiber bundles had separated and had lost some of their normal wavy attachment. This is not an artifact, because normal ACL fibers will show a wavy appearance. In

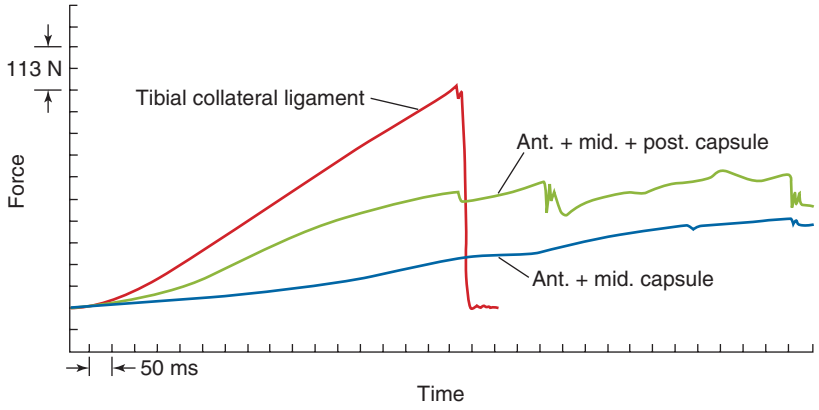

FIG 4-6 Typical oscillograph record of force versus time for failure tests on the medial collateral ligament (MCL) and two capsular preparations. A constant distraction rate was used, so the time axis is proportional to specimen elongation. The MCL supports the largest forces and fails abruptly. This is in contrast to the progressive failure of the ACL. Note the reduction in stiffness that occurs for both the MCL and the capsule before significant failure indicated by the sudden drop in resisting force. This is indicative of a progressive microfailure process, which occurs before macroscopic failure. *Ant.,* Anterior; *mid.,* middle; *post.,* posterior. (From Butler DL, Grood ES, Noyes FR, Zernicke RF. Biomechanics of ligaments and tendons. In Hutton R, ed. *Exercise and Sports Science Review,* vol. 6. Philadelphia: Franklin Institute Press; 1978:125-182.)

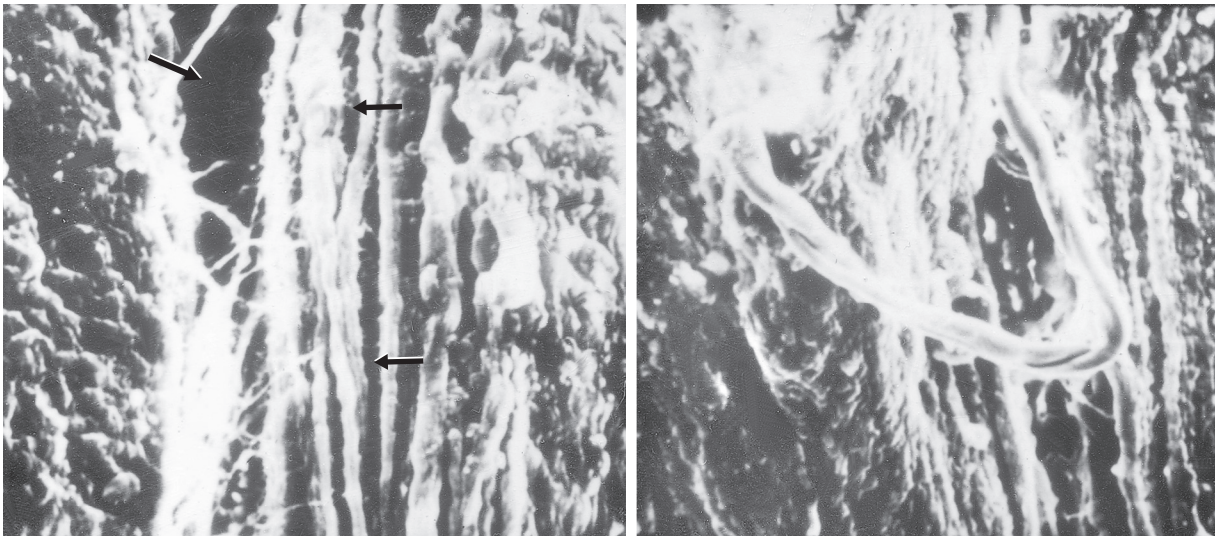

FIG 4-7 Scanning electron microphotographs of an anterior cruciate ligament after it was loaded to one half its anticipated maximum load without evidence of failure. Microfailure occurs. A whole fiber bundle completely ruptured is shown at left (*arrows*). Separation of fibers within a bundle is shown at right. (From Butler DL, Grood ES, Noyes FR, Zernicke RF. Biomechanics of ligaments and tendons. In Hutton R, ed. *Exercise and Sports Science Review,* vol. 6. Philadelphia: Franklin Institute Press; 1978:125-182.)

certain portions of the ACL, there is complete failure of individual fibers that were brought into the loading sequence owing to their fiber length at the knee position selected for the loading test. In Figure 4-8, failure of a major fiber bundle is shown with failure of the individual fibers at different places within the fiber. Note that failure of a small vessel has also occurred at the site of fiber failure, which is unusual given the expected elongation that vessels undergo before ultimate failure.

IMPORTANCE OF FEMORAL ATTACHMENT ON LIGAMENT LENGTH-TENSION PATTERNS

Many factors determine ligament length patterns during knee motion; however, one of the most sensitive factors is the fiber's femoral attachment (even more so than the tibial attachment). This concept is highly important for understanding ACL and PCL ligament fiber function and the location of ligament grafts for reconstruction.

The effect of the femoral attachment described by Grood and associates[30] is illustrated in Figure 4-9. In this model, the tibial attachment is assumed to be stationary, and flexion of the knee occurs about a fixed center of rotation (CR). The location of the CR is at the average rotation center of the human knee joint. A fiber that attaches anterior to the CR, such as fiber F_a, will lengthen with knee flexion up to 90 degrees as it rises up to the top of the circle and thereafter shortens with knee flexion. The opposite effect is shown by fiber F_d, which shortens with knee flexion and, at 90 degrees of flexion, would start to lengthen. The length patterns of the fibers are shown in the accompanying graph. This shows the complex length pattern of cruciate ligament fibers and is in marked contrast to more simplified descriptions that the ACL anteromedial fibers lengthen with knee flexion and the

FIG 4-8 Scanning electron photomicrograph of a collagen fiber bundle at the plane where failure occurred. The failure of collagen fibers at multiple levels within the fiber bundle demonstrates the pull-apart failure process. The *arrows* indicate a rich supply of vessels lying on the surface of the fiber bundle with perpendicular branches supplying the interior of the fiber bundle. (From Noyes FR, Grood ES, Nussbaum NS, Cooper SM. Effect of intra-articular corticosteroids on ligament properties. A biomechanical and histological study in rhesus knees. *Clin Orthop.* 1977;23:197-209.)

CRITICAL POINTS Importance of Femoral Attachment on Ligament Length-Tension Patterns

- Many factors determine ligament length patterns during knee motion; however, one of the most sensitive factors is the fiber's femoral attachment (even more so than the tibial attachment).
- The length-tension pattern of cruciate ligament fibers is complex and is in marked contrast to more simplified descriptions that the ACL anteromedial fibers lengthen with knee flexion and the posterolateral fibers lengthen with knee extension.
- A ligament functions with fibers of different lengths and their loading, which depends on attachment site characteristics.
- There is an approximate region in the ACL and PCL at which one region lengthens with knee flexion, another region shortens, and fibers between these two regions undergo less elongation. However, there are major differences among investigations regarding where these regions are located.
- Our data concluded that the line for the ACL is primarily oriented in a proximal to distal direction and that fibers anterior to the line become longer in flexion and that posterior fibers become shorter.
- The region for the line for the PCL is oriented in an anterior to posterior direction, with distal fibers becoming longer with knee flexion and proximal fibers lengthening with knee extension.
- The effects of changing the tibial attachment of an ACL graft in cadaveric specimens were investigated. Moving the fiber attachment on the tibia in a medial to lateral direction had only a small effect on fiber length and normalized length patterns. In contrast, moving the fiber in an anterior to posterior direction had a strong effect on fiber length.
- The placement of an ACL graft in an anterior to posterior location within its femoral footprint has significant effects in determining the tension and loading conditions of the graft. The placement of a PCL graft in a proximal to distal femoral direction has similar profound effects on its length-tension behaviors.
- The ACL or PCL graft should be tensioned at the knee flexion angle under which the graft will be at its longest length. Tensioning a graft at a flexion range in which the graft is in its shortest position would be expected to produce failure of portions of the graft as it elongates at a different knee flexion position.

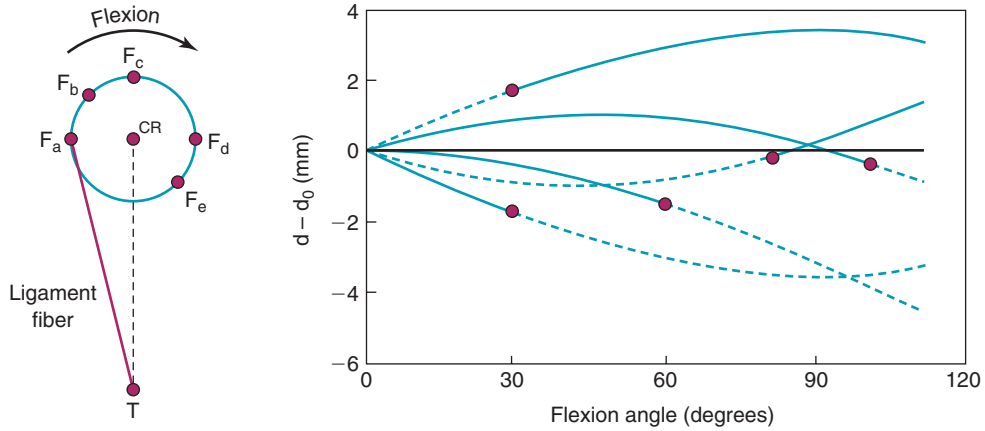

FIG 4-9 Length patterns are determined by the femoral attachment location. A ligament fiber is shown with tibial attachment (T) and femoral attachment (F_a). Other femoral attachments are represented by points F_b through F_e. The femur is assumed to flex about a fixed center of rotation (CR). The graph shows how the distance between attachments (d) referenced to the distance between attachments at 0 degrees (d_o) varies with flexion to 120 degrees. The curves are solid in the region over which the ligament fiber is tense and dotted in the region over which it is slack. The functional region is obtained by assuming the fiber is strained 5% at its maximum length. (From Grood ES. Placement of knee ligament grafts. In Finerman GA, Noyes FR, eds. *Biology and Biomechanics of the Traumatized Synovial Joint: The Knee as a Model.* Rosemont, IL: American Academy of Orthopaedic Surgeons; 1992:393-417.)

posterolateral fibers lengthen with knee extension, which is a gross oversimplification. The circle model is still only an approximation because the knee does not have a fixed CR; this provides an additional complexity in the analysis of ACL and PCL fiber function.

Contour plots are used to simplify the description of ligament length changes; a typical contour map is shown in Figure 4-10.[35] A single contour line expresses all of the attachments that would produce the same maximum fiber strain. The region bound by the contour line with the smallest strain (2% elongation) provides the most isometric femoral attachments. Note in Figure 4-10 that the tibiofemoral separation distance increases dramatically anterior to the contour line, and correspondingly, the length decreases posterior to the line with knee flexion. It should also be noted that the concept of ligament isometricity is a misnomer because it is not expected that a ligament shows this behavior with a set minimal strain or elongation during knee flexion, as already discussed. A ligament functions with fibers of different lengths and their loading, which depends on attachment site characteristics. The disadvantage of the contour map is that the length of the individual native ligament fibers is not represented, and therefore it is unknown at what point the ligament fibers in any region are tense or slack. The contour map is most useful to show the length changes that would occur for ligament grafts placed at certain positions within the ACL and PCL attachment sites at the maximum elongation or strain of the graft. In addition, note the knee position at which the graft is tensioned to not produce excessive graft elongation, which would either overconstrain the joint or result in graft failure.

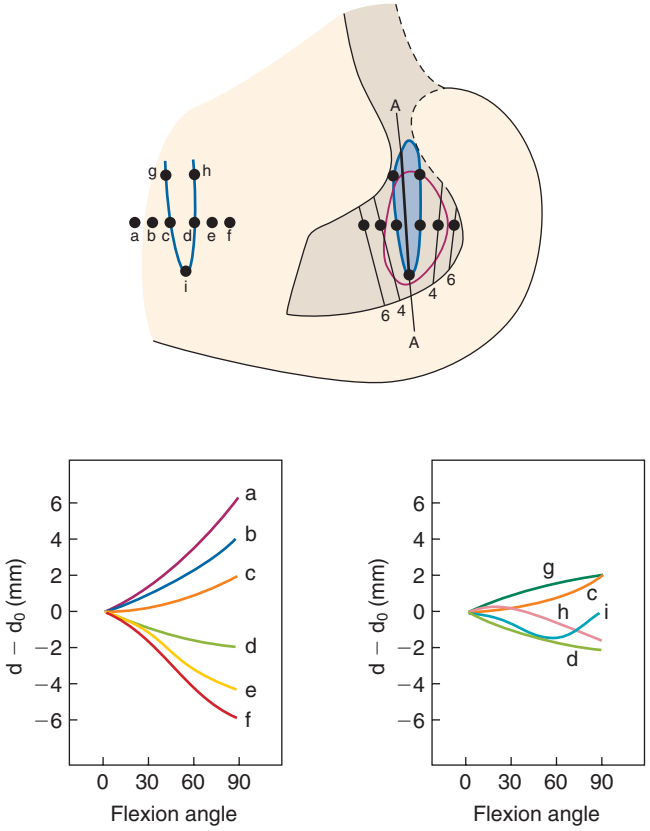

FIG 4-10 Typical contour plot for the anterior cruciate ligament. This figure was determined for knee flexion from 0 to 90 degrees while an anterior force of 100 N was applied to the tibia. The tibial attachment sites used in the analysis were located in the geometric center of the ACL's tibial insertion. (From Hefzy MS, Grood ES, Noyes FR. Factors affecting the region of most isometric femoral attachments: Part II. The anterior cruciate ligament. *Am J Sports Med.* 1989;17:208-216.)

A number of studies show there is an approximate region in the ACL or PCL at which one region lengthens with knee flexion, another region shortens, and fibers between these two regions undergo less elongation.[9,30,32,33,35,68,78] However, there is a major discrepancy in the investigations regarding where the regions are located within the cruciate ligaments. Our data and those of others[78] have concluded that the line for the ACL is primarily oriented in a proximal to distal direction and that fibers anterior to the line become longer in flexion and posterior fibers become shorter (Fig. 4-11; see also Fig. 4-10). The region for the line for the PCL, in contrast, is oriented in an anterior to posterior direction, with distal fibers becoming longer with knee flexion and proximal fibers lengthening with knee extension. Thus, the line that divides the shortening and lengthening regions has a completely different orientation for the ACL than the PCL. This is one of the most basic concepts of how ligament fibers function. Many current illustrations for ACL femoral attachment sites incorrectly show that the proximal fibers lengthen with knee flexion and distal fibers lengthen with knee extension. In fact, there are fibers within the ACL proximal and distal femoral attachment regions, governed by the contour plot behavior (see Fig. 4-10), that do not show this reciprocal tension behavior with knee flexion and extension. The data for these studies are not based on true fiber attachment separation distances, and these differences have rather profound effects on where ACL and PCL grafts are placed and tensioned. The PCL fiber length-tension behaviors under loading are shown in Chapter 15.

It should be noted that both Sidles and colleagues[78] and Hefzy and coworkers[35] reported that the contour maps describing fiber elongation patterns were strongly dependent on whether an anterior or posterior displacement load was applied to the tibia and the contour maps provided were under loading conditions for the respective ACL or PCL. A more complete description of contour maps for the femoral and tibial attachments is provided for the reader,[30,35,78] and the effect of tibial attachment sites is discussed in Chapters 7 and 15.

The effects of changing the tibial attachment of an ACL graft in cadaveric specimens is shown in Figure 4-12. The six ACL fiber locations on the tibia all originate at the approximate center of the ACL femoral attachment. Moving the fiber attachment on the tibia in a medial to lateral direction had only a small effect on fiber length and normalized length patterns. In contrast, moving the fiber in an anterior to posterior direction had a strong effect on fiber length. An anterior shift of the tibial attachment of 7.5 mm increased the fiber length by 5 to 8 mm. An anterior tibial attachment resulted in the fiber length behavior to become tauter in flexion. In Figure 4-13, the strong effect of moving the femoral attachment location in an anterior to posterior location on changing the length with knee flexion is shown. The location of the tibial insertion site is unchanged. The effect of moving the femoral attachment in a proximal to distal direction is shown in Figure 4-14. The more distal attached fibers were markedly shortened and had a concave length pattern, whereas the longer proximal fibers had a slight convex pattern. In summary, these studies show the complex behavior of the cruciate ligaments in which individual fibers and fiber regions are loaded to resist coupled motions of tibial translation and rotation. For the surgeon, the placement of a graft for the ACL in an anterior to posterior location within its footprint has significant effects in determining the tension and loading conditions of the graft as demonstrated. As is discussed in Chapter 15, placing the PCL graft in a proximal to distal direction has similar profound effects on its length-tension behaviors. The surgeon does have the ability to approximately select the range of knee flexion (low flexion, high flexion positions) under which the graft will be at its longest length and, therefore, should

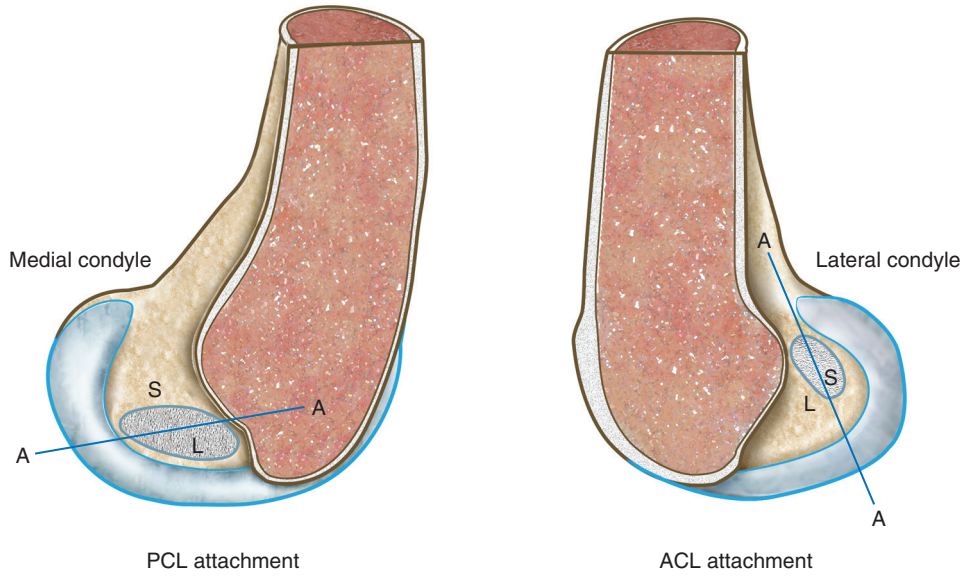

FIG 4-11 The division of the femoral ligament attachment into fibers that shorten (S) and lengthen (L) with knee flexion (reverse with knee extension). The line A to A, dividing the regions, has a different orientation for the two cruciate ligaments. Small errors in placement along the direction of the line have only small effects on length patterns. The approximate location of the line in reference to the posterior cruciate ligament (PCL) and anterior cruciate ligament (ACL) footprint is shown, with the qualification that the line changes its orientation with knee flexion. In contrast, placement errors perpendicular to the line cause large changes in length patterns. (Modified from Grood ES. Placement of knee ligament grafts. In Finerman GA, Noyes FR, editors. *Biology and Biomechanics of the Traumatized Synovial Joint: The Knee as a Model.* Rosemont, IL: American Academy of Orthopaedic Surgeons; 1992:393-417.)

be tensioned at this position. Tensioning a graft at a flexion range at which the graft is in its shortest position would be expected to produce failure of portions of the graft as it elongates at a different knee flexion position. Within each graft, there will be asymmetric loading of the graft fibers. The contour plots show the different fiber elongations of fibers in the center of the graft compared with the fibers at the periphery of the graft. The concept of placing more than one graft is designed to allow adjustments to more closely simulate ligament fiber behaviors, although it is probable that the surgeon is adding collagen fibers to fill the ACL or PCL footprint and that native cruciate fiber behavior is never achieved.

In agreement with Grood and associates' studies, Markolf and colleagues[51] reported in a cadaveric in vitro biomechanical study that positioning the femoral ACL tunnel in an anterior to posterior direction is more critical in terms of graft forces and function than a proximal to distal direction.

LIGAMENT FIBER LENGTH-TENSION PATTERNS AND BURMESTER CURVES

As already discussed, one of the primary scientific bases for ligament fiber function and graft placement is the measurement or computation of fiber length patterns. An alternative approach for determining ligament function proposed by Menschik[54,55] is frequently referenced in the literature. This approach is based on the four-bar model of ACL and PCL ligament function shown in Figure 4-15, first proposed by Strasser,[81] and on the mathematical theory for knee motions developed by Burmester.[10] This mathematical theory was developed to determine all pairs of femoral and tibial attachments that remain the same distance apart (isometric) as the knee is moved through small (infinitesimal) motions. The pairs of attachment points are represented by the two curves shown in Figure 4-16, one for all possible femoral attachments and one for all possible tibial attachments, which are described as a cubic curve because of their mathematical form. A single tibial and femoral attachment of a ligament is obtained by drawing a straight line through the instant center of knee flexion controlled by the four-bar mechanism where the cruciate links cross each other. The MCL tibial and femoral isometric attachments are the points at which a line crosses the tibial and femoral cubics.

CRITICAL POINTS Ligament Fiber Length-Tension Patterns and Burmester Curves

- Mathematical theory developed to determine all pairs of femoral and tibial attachments that remain the same distance apart (isometric) as the knee is moved through small (infinitesimal) motions.
- The pairs of attachment points are represented by a curve for all possible femoral attachments and a second curve for all possible tibial attachments.
- There are important scientific objections to using this model to define ligament function and possible graft attachment locations.
  - Shape of the curves depends on the knee flexion angle that is chosen; different curves can be computed for different flexion angles.
  - The curves are based on small knee motions. There are tibial attachment locations that are as isometric that are not on the Burmester curve when a wider range of knee motion is considered.

The Burmester curves have been used by many authors to explain the attachment locations of the collateral ligaments and capsular structures, and references are available proposing these curves explain ligament function.[59] However, there are important scientific objections to using this model to define ligament function and possible graft attachment locations. The shape of the curves depends on the knee flexion angle chosen, and different curves can be computed for different flexion angles (see Fig. 4-16). Menschik[54,55] published the curves for 43 degrees of flexion without providing the specific criteria used for computing the curves at this particular position of knee flexion. We computed the curves for other flexion angles that differed markedly in shape and had different sites for the attachment of the collateral ligaments that may not be close to their anatomic attachment (see Fig. 4-16). In addition, the Burmester curves are based on small knee motions, and it has been determined that there are tibial attachments locations that are as isometric that are not on the Burmester curve when a wider range of knee motion is considered.

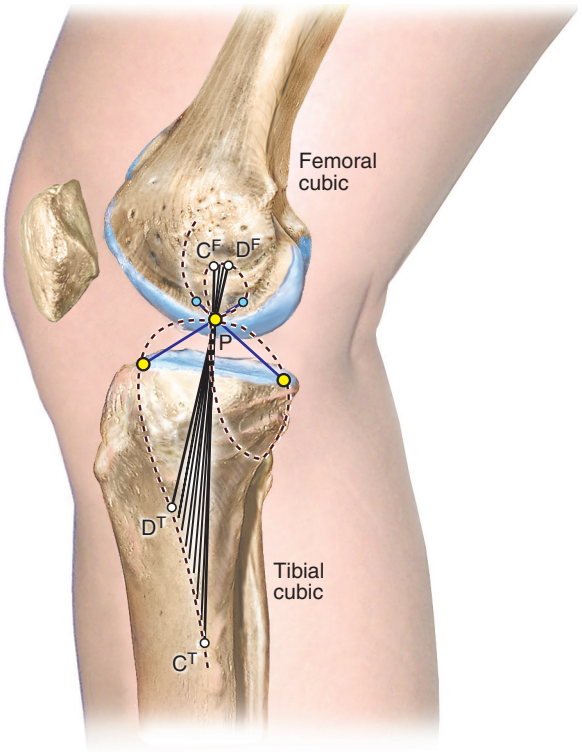

FIG 4-15 Burmester curves for the four-bar mechanism. There are two separate curves, a femoral cubic (C^F) and a tibial cubic (C^T). Pairs of nearly isometric attachments can be obtained by passing a line through instant center (P) and extending the line until it crosses both cubics. The points C^F and C^T where the line crosses the cubics are nearly isometric. Other pairs of nearly isometric attachments, such as D^F and D^T, can be found by rotating the line about the instant center. The lines shown here represent theoretical fibers of the medial collateral ligament.

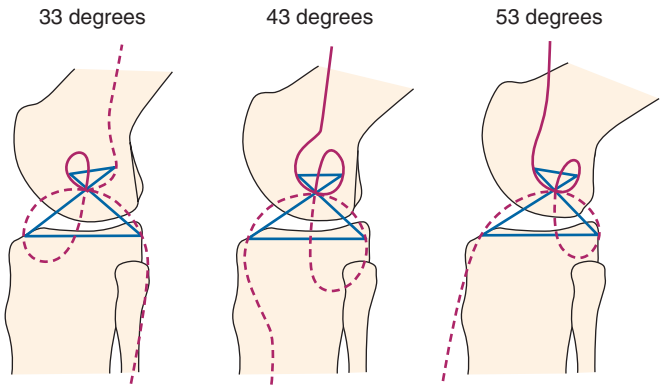

FIG 4-16 Burmester curves computed for flexion angles of 33, 43, and 53 degrees. The curves for 43 degrees of flexion are nearly identical to the curves published by Menschik[54,55] and Mueller.[59] Note that most of the tibial cubic for 33 degrees and 53 degrees of flexion is not on the tibia and thus they are not possible ligament attachments. (From Grood ES. Placement of knee ligament grafts. In Finerman GA, Noyes FR, editors: *Biology and Biomechanics of the Traumatized Synovial Joint: The Knee as a Model*. Rosemont, IL: American Academy of Orthopaedic Surgeons; 1992:393-417.)

MECHANICAL PROPERTIES OF LIGAMENTS

The ligaments of the knee have unique anatomic and mechanical characteristics that cannot be generalized from one ligament to another. The mechanical behavior of ligaments depends on the material properties of the fibers, the geometric arrangement of collagen fibrils[20,23,71] and fiber bundles (as already described), the proportion of different types of fibrous constituents, and the effect of the surrounding ground substance.[20,29,39,58,69] The ligament insertion site and underlying bone are additional portions of the ligament unit that must be considered when evaluating overall mechanical properties.

One approach for investigating each component of a ligament unit is to use a bone-ligament-bone specimen, such as a femur-ACL-tibia complex (FATC) preparation. This allows the mechanical properties of all of the components of the ligament unit to be studied together. The combined interaction of the components determines the properties of the entire structure in vivo. The problem still exists in loading the bone-ligament-bone unit in a manner that allows in vitro data to be

CRITICAL POINTS Mechanical Properties of Ligaments

The mechanical behavior of ligaments varies and depends on the material properties of the fibers, the geometric arrangement of collagen fibrils and fiber bundles, the proportion of different types of fibrous constituents, the effect of the surrounding ground substance, the ligament insertion site, and underlying bone.

Effect of Strain Rate on Mechanical Properties

- Strain rate describes the rate of deformation used in mechanical studies (length change/initial length per unit of time).
- Significant difference in the predominant mode of failure of the specimens tested at the fast strain rate compared with those tested at the slow rate. At the fast rate, two thirds of the specimens demonstrated a ligamentous failure and 28% failed by tibial avulsion fracture. At the slow rate, 57% of the specimens failed by tibial avulsion fracture and 29% failed by ligamentous failure.
- Under slow strain rate conditions, the bone-insertion area of the tibia was the weakest component. At the fast strain rate, representing the more physiologic loading condition, the ligament and bone components were more balanced as to strength properties and failed at a similar maximum load and energy to failure.

Analysis of Failure-Mode Mechanisms

- Mechanism of failure usually involves both the bony and ligamentous components in a progressive manner until complete failure occurs.
- Ligamentous failure occurs by an initial tensile failure of collagen fibers, followed by a pulling-apart shear failure of the disrupted fibers. Rupture of collagen fiber bundles also occurs throughout the ligament.

The study showed for the first time that an ACL-ligament-bone preparation failed at a higher load and at greater elongation, and absorbed significantly more energy, at a fast rate of deformation than at a slow rate, which is important for interpreting in vitro ligament biomechanical studies.

The visual determination of continuity of a ligament at surgery provides an inadequate determination of the extent of ligament damage that has actually occurred and its functional capacity.

The fibrocartilaginous zone at the ligament insertion site is believed to be advantageous in producing a gradual change in mechanical properties, decreasing the stress-concentration effect of the ligament's insertion into the stiffer bone structure.

extrapolated to in vivo loading conditions. This represents a problem because there are so many different in vivo loading conditions at the time of ACL failure; it is simply not possible to reproduce these conditions in the laboratory. There is less of a problem in studying the effect of one factor or variable on the mechanical properties of a ligament-bone unit because the same loading conditions are used throughout the experiment.

Effect of Strain Rate on Mechanical Properties

The strain rate describes the rate of deformation used in mechanical studies (length change/initial length per unit of time). We have conducted a series of fast and slow strain rate tests on ACL bone-ligament-bone specimens in rhesus monkeys.[63] A slow rate of deformation was chosen to represent the strain rates used in many prior in vitro experiments. A fast rate of deformation was chosen to represent the physiologic in vivo loading conditions to which ligaments may be subjected. The ligament units were tested as right-left pairs at the two strain rates to exclude animal variability. The femur and tibia were at an angle that corresponded to 45 degrees of knee flexion to allow as nearly uniform loading of the ligament as possible. In this experiment, a distraction of the joint was produced. An alternative loading sequence would be to induce anterior translation. Both of these loading profiles have been used experimentally.

Dividing the extension rate by the initial length of the ligament produced approximate strain rates of 0.662 sec^{-1} at the fast rate and of 0.00662 sec^{-1} at the slow rate, a 100-fold difference. At the fast rate, the ligament underwent the initial 15% to 20% elongation in approximately 0.25 seconds.

An example of a load-versus-time record from a typical test at the fast strain rate is shown in Figure 4-17. The curve demonstrates an initial concave toe region, followed by a fairly linear region up to the first significant failure. At this point, the load is termed the *linear load* because it denotes the approximate point at which the ligament preparation enters into the major failure region. Minor failures occur first, with a drop in load. Decreases in load after the linear load indicate successive failures until complete failure, at which time the load falls to zero. The maximum load occurs in the major failure region. The time axis is proportional to the relative displacement of the grips and represents elongation of the ligament after the compliance of the testing device and the grips are computed. Because the extension rate is known, specimen elongation at the linear load, maximum load, and zero load (complete failure) is determined. The area under the load-deformation curve indicates the energy absorbed by the specimen up to complete failure. The slope of the curve in the linear region provides the approximate stiffness of the preparation. It was not possible in this experiment to calculate the cross-sectional area of the ACL with any degree of reproducible accuracy. Force values are reported as load rather than stress (force per unit area). Alternative experiments, discussed later, employ other testing configurations in which ligament strain is measured by sensitive optic techniques.

The anterior cruciate bone-ligament-bone specimens showed a complex and varied mode of failure. These included avulsion of minor to major bone fragments from insertion sites, failure at the bone-ligament interface without bone avulsion, and ligament failure that occurred initially by tensile pull-apart failure of fiber bundles and then by shear failure among the disrupted fibers. The predominant mode of failure of each specimen was classified as one of the following: (1) ligamentous failure, (2) tibial avulsion failure, (3) combined ligament failure/tibial avulsion fracture, (4) femoral avulsion fracture, or (5) combined ligament failure/femoral avulsion fracture.

A statistically significant difference was found in the predominant mode of failure of the specimens tested at the fast strain rate compared with those tested at the slow rate ($P < .05$, Fig. 4-18). At the fast rate, two thirds of the specimens demonstrated a ligamentous failure and 28% failed by tibial avulsion fracture. At the slow rate, 57% of the specimens failed by tibial avulsion fracture and 29% failed by ligamentous failure.

The results of the strain rate properties according to the modes of failure are shown in Table 4-1. Under slow strain rate conditions, the bone-insertion area of the tibia was the weakest component, demonstrated by the reduced maximum load and energy absorbed to failure. At the fast strain rate, representing the more physiologic loading condition, the ligament and bone components failed at a similar maximum load and energy. The overall difference in strength properties was

CRITICAL POINTS Effects of Immobilization and Disuse on Ligament Biomechanical Properties

We conducted a study on primates to determine the effect of altered activity levels on the mechanical properties of ligaments.

- The results showed that 8 weeks of immobilization produced a marked decrease of nearly one half of the maximum failure load and significant weakening of a functional ligament unit.
- The decrease in strength properties was associated with resorption of haversian bone and weakening of the cortex beneath the ligament's insertion site at both the tibia and femur.
- An exercise program had little effect in preventing the decline in the strength properties of the ligament unit during immobilization and only partial recovery in strength properties occurred after 20 weeks of resumed activity.
- Following immobility, an extended period of time may be required before the functional capacity of a ligament unit returns to normal.
- Disuse-induced changes following fracture or ligament reconstruction may extend well into the time period after which normal activity has been resumed by the patient

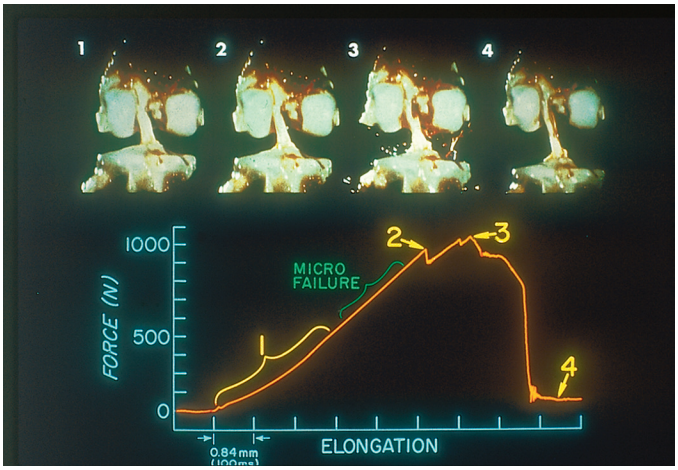

FIG 4-17 Oscillograph record of force versus time for a tension test to failure of a rhesus femur-ACL-tibia preparation. A constant distraction rate was used so that the time axis was proportional to specimen elongation. The images, obtained from high-speed videos taken during the test, show the preparation at four stages of the test. (From Butler DL, Grood ES, Noyes FR, Zernicke RF. Biomechanics of ligaments and tendons. In Hutton R, editor. *Exercise and Sports Science Review,* vol 6. Philadelphia: Franklin Institute Press; 1978-125-182.)

TABLE 4-1 Strain Rate Results by Failure Mode

Strain Rate	*n*	Failure Mode	Maximum Load (kgf)	Strain to Maximum Load (%)	Energy (kgf-cm)	Strain to Failure (%)
Fast	21	Ligamentous	92.8 ± 17.5	51.4 ± 7.5	39.8 ± 8.9	61.0 ± 8.9
	9	Tibial avulsion fx	100.0 ± 19.3*	51.6 ± 7.0*	38.4 ± 13.2	55.0 ± 12.4
Slow	8	Ligamentous	93.0 ± 10.6	47.8 ± 6.0	39.9 ± 9.7†	59.0 ± 9.3†
	16	Tibial avulsion fx	84.1 ± 2*	45.6 ± 7.4*	30.9 ± 9.3†	50.9 ± 8.0†

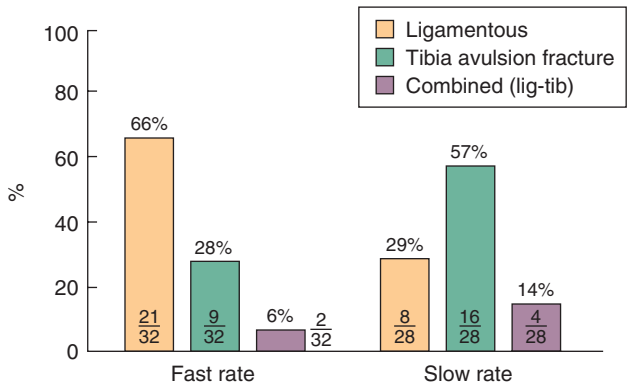

FIG 4-18 The major mechanism of specimen failure is shown for 32 knees tested at the fast strain rate and 28 knees tested at the slow strain rate. The difference in specimen failure at the two strain rates is statistically significant ($P < .05$). (From Noyes FR, DeLucas JL, Torvik PJ. Biomechanics of anterior cruciate ligament failure: an analysis of strain-rate sensitivity and mechanisms of failure in primates. *J Bone Joint Surg Am.* 1974;56:236-253.)

caused in part by increased strength of the bone component at the fast rate. At the slow rate, failure by tibial avulsion fracture was interpreted as premature failure, indicating a decrease in the specimen's potential strength. The size of the animals was not a factor contributing to the predominant mode of failure. The different types of failure were distributed throughout each strain rate group regardless of the weight of the animal. In addition, juvenile animals were not used, which could have biased the results toward a higher frequency of tibial avulsion fractures.

Analysis of Failure-Mode Mechanisms

Macroscopic Analysis

High-speed films of specimen loadings demonstrated that the mechanism of failure usually involved both the bony and ligamentous components in a progressive manner until complete failure occurred. Sequential failure of ligament fibers commonly occurred first, before major tibial avulsion fractures. In other specimens, minor avulsion fractures were associated with major ligamentous failure (Fig. 4-19).

Microscopic Analysis

Microscopic analyses were conducted after the loading tests to define the mechanisms of specimen failure. Resorption changes at the bone-ligament interface, indicative of premature failure, were not visualized in any of the femoral or tibial insertion sites. Polarized light microscopy demonstrated that the ACL inserted at femoral and tibial sites through four well-defined zones of fibrocartilage (see Fig. 4-19).[19] The

FIG 4-19 Photomicrograph after tibial avulsion mode of failure shows that cleavage occurred through cancellous bone below the more dense cortical bone at the site of ligament insertion. The zonal arrangement at the bone-ligament interface is shown. Ligament, zone 1; fibrocartilage, zone 2; mineralized fibrocartilage, zone 3; and bone, zone 4 (hematoxylin and eosin, ×90). (From Noyes FR, DeLucas JL, Torvik PJ. Biomechanics of anterior cruciate ligament failure: an analysis of strain-rate sensitivity and mechanisms of failure in primates. *J Bone Joint Surg Am.* 1974;56:236-253.)

zonal arrangement at the insertion site represents a change in composition of the surrounding medium as the ligament collagen fibers (zone 1) pass through fibrocartilage (zone 2), across a blue line to mineralized fibrocartilage (zone 3), and into the bone (zone 4).

The specimens in this investigation demonstrated three histologic modes of failure, which were consistent with the macroscopic observations. First, ligamentous failure occurred by an initial tensile failure of collagen fibers, followed by a pulling-apart shear failure of the disrupted fibers (Fig. 4-20). Rupture of collagen fiber bundles was also observed throughout the ligament. The ligament fiber microgeometry under the loading conditions in the experiment determined which fibers were subjected to the greatest deformation, leading to the serial

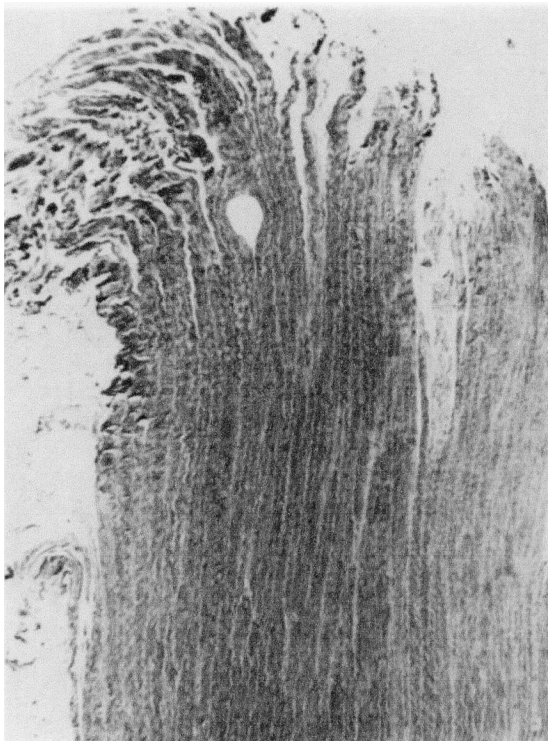

FIG 4-20 Photomicrograph of a portion of the anterior cruciate ligament after failure. The mechanism of failure appeared to be a tensile, pulling-apart type of failure. The collagen fibers are shown to have ruptured at different portions of the ligament, giving an uneven cleavage line corresponding to the common "mop-end" gross appearance (trichrome ×45). (From Noyes FR, DeLucas JL, Torvik PJ. Biomechanics of anterior cruciate ligament failure: an analysis of strain-rate sensitivity and mechanisms of failure in primates. *J Bone Joint Surg Am.* 1974;56:236-253.)

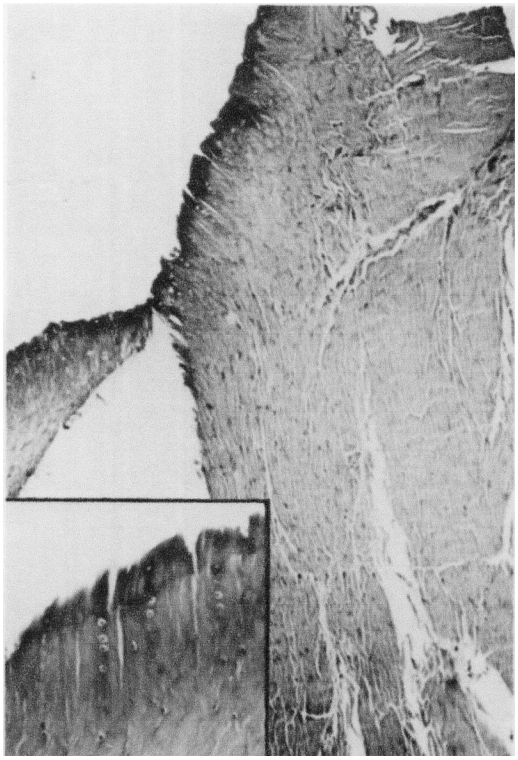

FIG 4-21 Photomicrograph shows predilection for cleavage at the ligament-bone interface to occur through the mineralized fibrocartilage zone. *Inset,* columnar arrangement of chondrocytes (periodic acid–Schiff, ×80). (From Noyes FR, DeLucas JL, Torvik PJ. Biomechanics of anterior cruciate ligament failure: an analysis of strain-rate sensitivity and mechanisms of failure in primates. *J Bone Joint Surg Am.* 1974;56:236-253.)

rupture of fibers and accounted for rupture of fibers in areas adjacent to intact fibers. Although branching among individual collagen fiber bundles was observed, the pulling-apart type of failure suggests that little in the way of cohesive properties exists among the major fiber bundles. A more explicit definition of the mechanism of failure of collagen tissues also involves the ultrastructural changes of fibrils and microfibrils under failure conditions.[63]

Second, avulsion fracture at the attachment site occurred most commonly through the cancellous bone immediately beneath the dense cortical bone (Fig. 4-21). The minute gritty material sometimes just barely palpable on the end of the ligament after failure represented fragments of bone beneath the cartilaginous zone of ligament insertion.[63]

Third, cleavage at the ligament-bone interface showed a predilection for the fracture cleavage line to occur through the zone of mineralized fibrocartilage (zone 3) at or just distal to the blue line. Failure at this interface was the least common mode of failure. It was identified microscopically in 6 of 22 specimens; however, it represented only a minor part of the failure process, the major failure having occurred by either a ligamentous or bone avulsion mode. Failure through the fibrocartilaginous zone was, therefore, never the major mode of specimen failure, but not infrequently accompanied the other two modes of failure.[63]

In summary, it was possible to classify the major mechanism of failure histologically, although minor modes of failure involved to different degrees all portions of the bone-ligament-bone unit. Thus it was not unusual to find microscopic evidence of minor to moderate ligament disruption associated with major bone avulsion failures or vice versa.[63]

This study showed for the first time that an ACL-ligament-bone preparation failed at a higher load and at greater elongation, and absorbed significantly more energy, at a fast rate of deformation rather than at a slow rate. These findings show the time-dependent behavior of bone-ligament-bone preparations and questioned the results of prior ligament failure studies, which often showed premature bone failure at less than expected failure loads. At the slow deformation rate, the bone insertion area of the tibia was the weakest component. At the fast deformation rate, the ligament and tibial osseous component were balanced as to strength properties with an increased frequency of ligamentous failure.[63] The specimen under the fast deformation rate withstood greater loads without premature osseous failure, allowing the ligament to participate in the failure process.[73] Even with expected viscoelastic effects in the ligament as a result of the higher strain rate, the strength of the bone increased faster than did an expected increase in strength of the ligament.[63]

Many cadaveric and experimental animal studies have reported the difficulty of producing ligamentous injuries and have traditionally stated that the bone is the weakest component of the bone-ligament-bone system.[38,57,79,84,85,90,91,100] Other than the difficulty in reproducing in the laboratory the complex loading and displacement conditions that occur in traumatic injuries, the deformation rate of the experimental tests and the effect of disuse-induced bone changes caused by animal caging or aged cadavers are believed to be the major explanation for premature bone avulsion of the ligament-bone unit.[63]

In agreement with these results, Welsh and associates[95] demonstrated that the failure mode of a calcaneal-Achilles tendon unit changed from bone avulsion at low deformation rates to failure at the tendon grip apparatus under high deformation rates. The ultimate load of the specimens in that investigation may not have been obtained because of the difficulty of clamping the tendons; however, the bone insertion site did not fail at the high strain rate despite the specimen reaching a higher load.

In cases of tibial avulsion fracture, the ligament failure component could not be appreciated on gross examination after the test. In view of the demonstrated elongation on the ligament in the region of failure, it is reasonable to expect damage to collagen fibers and blood vessels within the ligament, even though continuity remains. It is well appreciated that the visual determination of continuity of a ligament at surgery provides an inadequate determination of the extent of ligament damage that has actually occurred and its functional capacity. Such factors, among others, may contribute to the occasional unsatisfactory result in cases of partial ligament disruption with continuity and in cases of ligament reinsertion after bone avulsion.[63]

The fibrocartilaginous zone at the ligament insertion site is believed to be advantageous in producing a gradual change in mechanical properties, decreasing the stress-concentration effect of the ligament's insertion into the stiffer bone structure.[19] This zone protects against fatigue and shear failure at the bone-ligament junction, providing a composite structure with the addition of cartilage and mineralized fibrocartilage to the collagen network. The fibrocartilaginous ground substance may provide greater cohesion among fiber bundles and provide a mechanism for diffusion of load over the entire insertion site, avoiding the deleterious effects of stress concentration. Based on the microscopic analysis of specimen failure and the infrequent occurrence of failure through the fibrocartilaginous zone, the zonal insertion arrangement appears to be mechanically advantageous.[63]

EFFECTS OF IMMOBILIZATION AND DISUSE ON LIGAMENT BIOMECHANICAL PROPERTIES

It is well appreciated that immobility may lead to deleterious changes in bone, joint, and soft tissue.[4,18,24,26,28,40,45-47,49,50,82] We conducted a study to determine the effect of altered activity levels on the mechanical properties of ligaments in primates.[67] Although exercise is accepted as beneficial in preventing muscle atrophy and maintaining joint motion, its effect in preventing deterioration or strengthening a bone-ligament-bone unit had not been established. The study simulated certain clinical states of immobility and determined: (1) the effect of immobilization on the mechanical properties of a bone-ligament-bone unit, (2) the effect of an exercise program in preventing changes in these properties, and (3) the extent to which the changes remained after a 20-week reconditioning period. The reader is referred to the publication for the detailed explanation of the study.[67]

The rhesus animals were placed into four groups: (1) group I, control group, 30 knees; (2) group II, nine animals immobilized for 8 weeks in total body plaster casts that included both lower limbs; (3) group III, 11 animals in which one lower limb was immobilized for 8 weeks while the other lower limb was exercised daily; and (4) group IV, 11 animals immobilized as in group II, reconditioned for 5 months in room-sized gang cages that were wide and deep and provided ample room for jumping and other activities.

The animals in the exercise group (group III) performed an active pushing movement against resistance with one free lower extremity in response to a food-reward system. The pushing movement was from 90 degrees of hip and knee flexion to 20 degrees of hip and knee flexion. The foot and ankle were secured by a boot to an exercise apparatus, and with each successful stroke, the animals received a pellet of food. The animals performed the exercise diligently and, on occasion, food had to be restricted. The force required to perform the exercise was minimal initially and then gradually increased over the first 2 weeks so that the animals performed the task at least 600 times daily. The resistance, length of push, and number of repetitions were recorded daily. The animals usually depressed the apparatus 600 to 900 times daily against a resistance of 1.6 to 2.4 kg (about one third body weight).

The average daily work performed by each primate was 11,000 ± 4000 kilogram-force centimeter (kgf-cm) (range, 6600 to 20,200 kgf-cm). The average total work performed by each animal during the 8 weeks of immobilization was $6.19 \times 10^5 \pm 2.4 \times 10^5$ kgf-cm (range, 3.69×10^5 to 1.11×10^6 kgf-cm). There was no significant correlation between the total amount of work each animal performed and the strength of the ligament preparation.

The results showed that 8 weeks of immobilization produced a marked decrease of nearly one half of the maximum failure load ($P < .001$, Table 4-2). No significant differences were found in ultimate failure load between the immobilized or exercised group or between the right and left ligament units from the exercised group. The failure load for the reconditioned animals indicates partial but incomplete recovery at 20 weeks (Fig. 4-22).

The data demonstrate that immobilization leads to significant weakening of a functional ligament unit. The exercise program had little effect in preventing the decline in the strength properties of the ligament unit during immobilization, and only partial recovery in strength properties occurred after 20 weeks of resumed activity. The decrease in strength properties was associated with resorption of haversian bone and weakening of the cortex beneath the ligament's insertion site at both the tibia and femur.

The mechanism of failure of a ligament-bone unit after disuse-induced changes depends on the anatomic characteristics at the ligament-bone insertion site. Most knee ligaments insert into bone through the well-defined zones of fibrocartilage previously described.[19,50,63,74] These zones appear to be protective, because subsynovial and subperiosteal (femoral site) resorption of bone was observed at the peripheral margins of the ligament insertion site but not at the ligament-bone junction. Ultimate failure of the ligament unit occurred through either the underlying cortical bone at the insertion site or through the body of the ligament (or at both of these locations), but not through the ligament-bone junction. This protective effect of the fibrocartilage probably also applies to tendons that have a similar type of attachment[19,74,80] The zone also imposes a barrier to a vascular supply of the ligament from the bone beneath the insertion site.[74] The tibial attachment of the long fibers of the MCL is into the periosteum and Sharpy fibers without a fibrocartilaginous interface. Immobility

CRITICAL POINTS Biomechanical Analysis: Human Ligament Grafts for Reconstruction

We conducted a study on young human cadavers to determine the biomechanical properties of various tissues commonly used to reconstruct knee ligament ruptures.

- Bone-patellar tendon-bone and four-strand semitendinosus-gracilis grafts exceed the percent strength of the ACL.
- Data provide the surgeon with an initial estimate of graft mechanical properties to consider in selection of the appropriate graft for intraarticular and extraarticular ligament reconstructions.

*Mean values and standard deviations for the mechanical test parameters in the control and experimental groups. Statistical comparisons of the mean values among groups are listed for those parameters significantly different from zero on *t* test analysis at $P < .05$ (two-tailed test). Group comparisons not listed are not statistically significant.

C, Control; *I,* immobilized; *ER,* exercise right; *EL,* exercise left (nonexercised limb in exercise group); *R,* reconditioned.

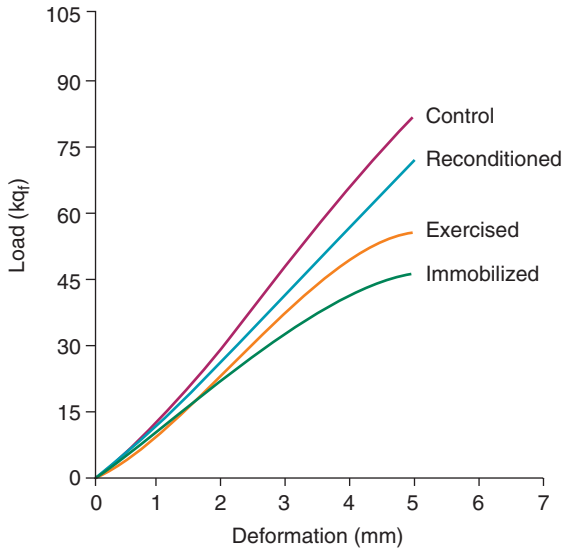

FIG 4-22 Calculated load-deformation curves show ligament behavior under loading for all specimens in each of the animal groups. A significant decrease in stiffness (slope of the load-deformation curve) of the ligament preparation is seen in specimens from the exercised and immobilized group. Partial recovery occurred at 20 weeks. (From Noyes FR, Torvik PJ, Hyde WB, DeLucas JL. Biomechanics of ligament failure. II: An analysis of immobilization, exercise, and reconditioning effects in primates. *J Bone Joint Surg Am.* 1974;56:1406-1418.)

has a pronounced effect in producing subperiosteal bone reabsorption that decreases the tibial MCL attachment site strength, resulting in premature failure before involving the ligament in the failure process.[45,47,50] Because of the premature attachment failure, the use of a MCL bone-ligament unit is not ideal and disuse-induced cage confinement of experimental animals induces this as a variable, affecting the results. We agree with Laros and coworkers[50] that the reported increase in ligament strength above control values, resulting from increased activity in animals, may represent the prevention or reduction of the disuse effect of caging.

The effect of immobility on the ligament itself is of importance to its mechanical function. The change in the relationship between force and ligament elongation (stiffness) after immobilization correlated with the inactivity of the primates. The exercised ligament units were somewhat less affected than the fully immobilized specimens. Both groups were significantly different compared with the control group. The stiffness of the ligament unit in the reconditioned specimens had nearly returned to normal at 20 weeks, although the recovery in strength was incomplete. Other studies have shown a similar correlation between the general level of activity during confinement and the strength of a ligament unit.[1,50,84,86,91,100]

The clinical relevance of this study relates to the suggestion that following immobility, an extended period of time may be required before the functional capacity of a ligament unit returns to normal. Disuse-induced changes after fracture or ligament reconstruction may extend well into the time period after which normal activity has been resumed by the patient.

BIOMECHANICAL ANALYSIS: HUMAN LIGAMENT GRAFTS FOR RECONSTRUCTION

A biomechanical analysis was performed in our laboratory[62] to determine the mechanical properties in human tissues from young donors. Young adult cadaveric tissues were used to exclude age and disuse effects. The overall results of this study are shown in Tables 4-3 and 4-4. The bone-patellar tendon-bone (B-PT-B) grafts exceeded the percent strength of the ACL. However, the specimens used in this study had an increased width of 4 to 5 mm and to apply these results to clinical cases, the conversion of 208 N/mm is provided in Table 4-4. This indicates a 10-mm-wide graft would have a converted value of approximately 2008 N, which still exceeds the approximate strength of a young adult ACL. A single semitendinosus or gracilis tendon has 70% and 49%, respectively, the strength of the ACL, indicating that a four-strand graft would exceed by many times the native ACL strength. In comparison, the distal iliotibial tract has a reduced strength that requires a 45-mm width of fascia to achieve an approximate value equal to the ACL.

Obviously, these maximum load values represent time-zero mechanical properties. Graft fixation and biologic remodeling factors combine to determine the final stabilizing effect of human ligament grafts, as discussed in other sections of this book. Further, the data compare the tissue grafts to human ACL mechanical properties only for uniaxial loading tests. The ACL has a complex fiber microgeometry that none of the graft tissues simulate. Therefore, the data provide the surgeon with an initial estimate of graft mechanical properties to consider in selection of the appropriate graft for intraarticular and extraarticular ligament reconstructions. There is a hypothetical loading curve for the ACL shown in Figure 4-23 that provides a perspective of in vivo ligament function. Although never actually measured, there are safety zones in which the ACL functions for most activities well below its ultimate strength, and the generalization is shown for approximately 454 N (100 lb) for most activities. This represents an approximate built-in safety margin of 4:5:1 ratio of the ultimate in vivo failure strength. Figure 4-23 also shows the slope of the loading curve representing the stiffness (elongation of the ligament per unit load) that determines the stabilizing effect of the ligament in resisting anterior tibial translation that is an equally important property.

CRITICAL POINTS Strength of the ACL: Age-Related and Species-Related Changes

We conducted a study in which the mechanical properties of ACL specimens from humans and rhesus monkeys were determined in tension to failure under high strain rate conditions. The purposes of the study were to determine whether discrepancies in strength and mechanisms of ligament failure between human and animal specimens were caused by size differences, variables in the human specimens such as age or disuse atrophy, or certain experimental testing variables.

- The ligament lengths and areas of the animals were approximately one half and one fourth those in the human donors, respectively.
- Significant differences were found between the older and the younger human specimens in stiffness, strength, and mechanical properties. Preparations from the younger humans failed at a maximum force that was an average of 2.4 times that of the specimens from the older humans.
- Ligaments from the rhesus animals failed at normalized force values (to body mass) over three times higher than those of the younger human specimens.
- The specimens from older humans showed a decrease in cortical thickness and trabecular bone at the insertion of the ligaments. Failure occurred by fracture through the cortical and underlying trabecular bone, owing to both age-related and probably disuse-induced changes.

STRENGTH OF THE ACL: AGE-RELATED AND SPECIES-RELATED CHANGES

Important changes occur in the functional properties of bone-ligament units with age and differences from one animal species to another. We conducted a study in which the mechanical properties of ACL specimens from humans and rhesus monkeys were determined in tension to failure under high strain rate conditions.[64] The age of the cadaver specimens ranged from 16 to 86 years. One of the purposes of the study was to determine whether discrepancies in strength and mechanisms of ligament failure between human and animal specimens were because of size differences, variables in the human specimens such as age or disuse atrophy, or certain experimental testing variables. In addition, human data were required to define the strength properties required for ACL graft replacements.

Comparison of Size Parameters

The mass of the rhesus animals was small compared with that of the human donors (Table 4-5). The ligament lengths and areas of the animals were approximately one half and one fourth those in the human donors, respectively.

TABLE 4-3 Tissue Dimensions

Tissue	No. Specimens	Length (mm)*	Area (mm^2)	Width (mm)

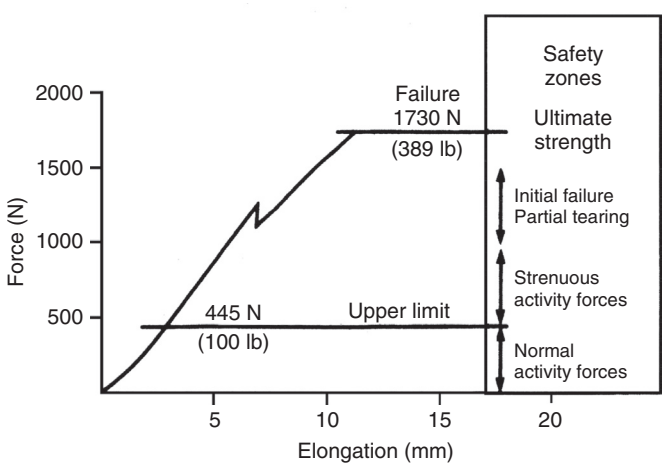

FIG 4-23 A hypothetical load-elongation curve for the anterior cruciate ligament-bone unit is shown along with the idealized safety zones to be considered in evaluating a ligament replacement. The goal is to achieve the highest force zone possible. Some grafts of lesser strength may function as long as lower levels of force are maintained. The cruciate ligament curve does not represent any single failure test that was performed. (From Noyes FR, Butler DL, Grood ES, et al. Biomechanical analysis of human ligament grafts used in knee-ligament repairs and reconstructions. *J Bone Joint Surg Am.* 1984;66:344-352.)

CRITICAL POINTS Effect of Intraarticular Corticosteroids on Ligament Properties

The effect of slightly soluble corticosteroid (methylprednisolone acetate) was investigated on the mechanical properties of a rhesus ACL ligament unit.

- A direct steroid injection into the ligament resulted in statistically significant decreases in maximum load and energy to failure in both the large-dose and small-dose groups.
- The clinical implications are that a single direct injection of a slightly soluble steroid preparation has a marked effect on decreasing ligament functional properties that remained up to 1 year.
- Intraarticular injections resulted in alterations in ligament behavior that were dependent on the dose of the drug and the time that had elapsed after injection.
- In the high-dose group, the maximum failure load of the ligament unit decreased by 11% after 6 weeks and 20% after 15 weeks. In the low-dose group, the maximum failure load of the ligament unit decreased by 9%.
- In the high-dose group, a significant decline in the stiffness of the ligament unit had occurred at 15 weeks. No such decline was detected in the low-dose group.
- The clinical implications suggest that intraarticular, slightly soluble corticosteroids in high and frequent doses have the potential to alter ligament strength and function. The risk associated with such alterations may be minimal if infrequent, low-dose injections are administered.

TABLE 4-5 Anterior Cruciate Ligament Strength: Comparison of Size

	Specimens (*N*)	Donor Mass (kg)	Length (mm)	Area (mm^2)	Volume (mL)
Older human (48-86 yr)	20	72.1 ± 24.6	27.5 ± 2.8	57.5 ± 16.2	1.60 ± 0.53
Younger human (16-26 yr)	6	52.6 ± 0.52	26.9 ± 1.5	44.4 ± 9.7	1.21 ± 0.31
Rhesus monkey	25	7.0 ± 0.6	12.3	12.7 ± 1.71	0.156

Comparison of Structural Parameters

A typical force/elongation curve for one young and one older adult human specimen is shown in Figure 4-24. The mean values for the stiffness and strength parameters of the human and rhesus ligament specimens are shown in Table 4-6. A significant difference was found between the older and younger human specimens. The preparations from the younger humans failed at a maximum force that was an average of 2.4 times that of the specimens from the older humans. The ligaments from the animals failed at force values higher than those of the older human specimens, despite an approximate fivefold difference in the respective cross-sectional area of the ligaments.

Comparison of Material Properties

The data shown in Table 4-7 represent measurements of the mechanical properties of the ligament collagen as a material. They are normalizations of the structural parameters, adjusted for variations in the cross-sectional areas and lengths of the specimens. There were large differences in all parameters shown between ligaments from younger and older humans. The mean value for the elastic modulus of the ligaments from young adult humans was 1.7 times that of the ligaments from the older humans, but was significantly lower than the mean value for the ligaments from the animals.

The maximum stress and the strain energy to failure in the specimens from younger humans were 2.8 and 3.3 times the respective values for the older human group. The maximum stress and the strain energy to failure in the ligaments from the animals were 1.8 and 1.9 times the respective values for the specimens from younger humans.

Age-Related Changes

Statistically significant decreases were found with age in the elastic modulus, maximum stress, and the strain energy for the specimens that failed by a ligamentous mode, in which prior antemortem effects were excluded, but not for the specimens from older humans that failed by premature bone-avulsion fracture, in which significant antemortem effects were suspected.

The regression equation (y) and correlation coefficient (r) for the specimens that failed by a ligamentous mode are shown in Figure 4-25. Maximum stress showed the highest correlation with age ($r = 0.863$, $P < .005$). A low correction was found with strain energy to failure (0.75) and elastic modulus (0.712), but all correlations were statistically significant.

Histologic Findings

The change in mechanism of specimen failure with age from a ligamentous mode to bone-avulsion fracture correlated with histologic findings. The specimens from older humans showed a decrease in cortical thickness and trabecular bone at the insertion of the ligaments. Failure occurred by fracture through the cortical and underlying trabecular bone. The fibrocartilage junctional zone remained intact with normal straining characteristics and only rarely did the fracture plane extend through it.

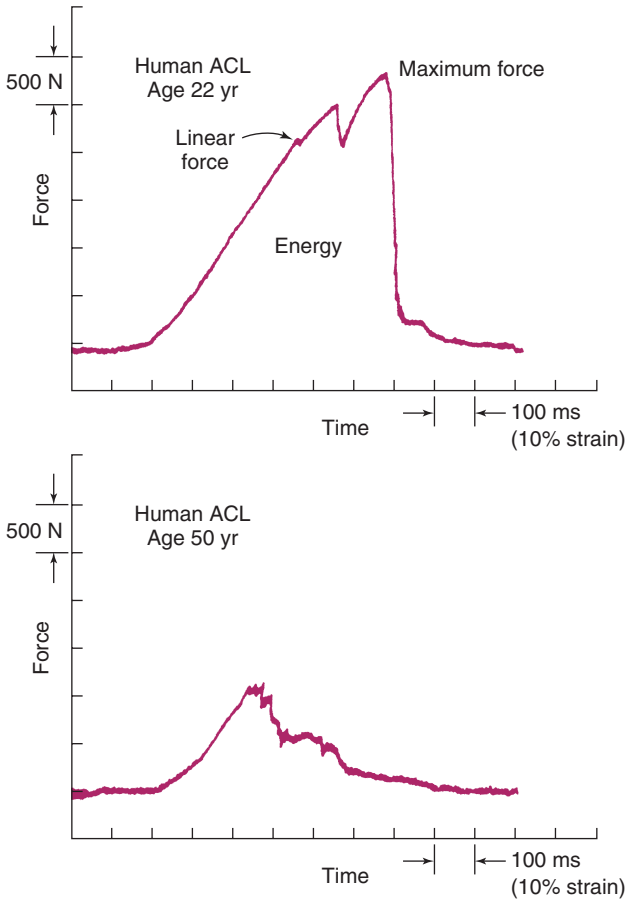

FIG 4-24 Typical oscillograph force versus time records for a younger and an older human specimen show behavior of the anterior cruciate ligament (ACL) preparation in the mechanical test. The specimen from the older human demonstrates a decrease in stiffness (slope of the curve) and failure at lower force and strain values. Failure in the specimen from the older human occurred by femoral avulsion fracture just beneath the ligament attachment site in contrast to the ligamentous mode of failure in the preparation from the younger human. (From Noyes FR, Grood ES. The strength of the anterior cruciate ligament in humans and rhesus monkeys. Age-related and species-related changes. *J Bone Joint Surg Am.* 1976;58:1074-1082.)

The histologic findings frequently included other minor modes of failure involving all other portions of the ACL unit, as previously described.[63,67]

Comparison of Ligament Structural Properties

Alm and colleagues[2] conducted a study on the tensile strength of the canine cruciate ligament in which the data were normalized by calculating the ratio between ligament separation force and animal mass.

TABLE 4-6 Anterior Cruciate Ligament Strength: Comparison of Structural Properties

	Specimens (n)	Stiffness (kN/m)	Linear Force (kN)	Maximum Force (k/N)	Energy to Failure (N-m)
Older human (48-86 yr)	20	129 ± 39	0.622 ± 0.283	0.734 ± 0.266	4.89 ± 2.36
Younger human (16-26 yr)	6	182 ± 56	1.17 ± 0.75	1.73 ± 0.66	12.8 ± 5.5
Rhesus monkey	25	194 ± 28	0.71 ± 0.12	0.83 ± 0.11	3.0 ± 0.6

Statistical comparison of the Welch modification of the Student *t* test (two-tailed) of each value on each line compared with that on the line below it is indicated as follows: **P* > .01, †*P* > .005, ‡*P* > .001.

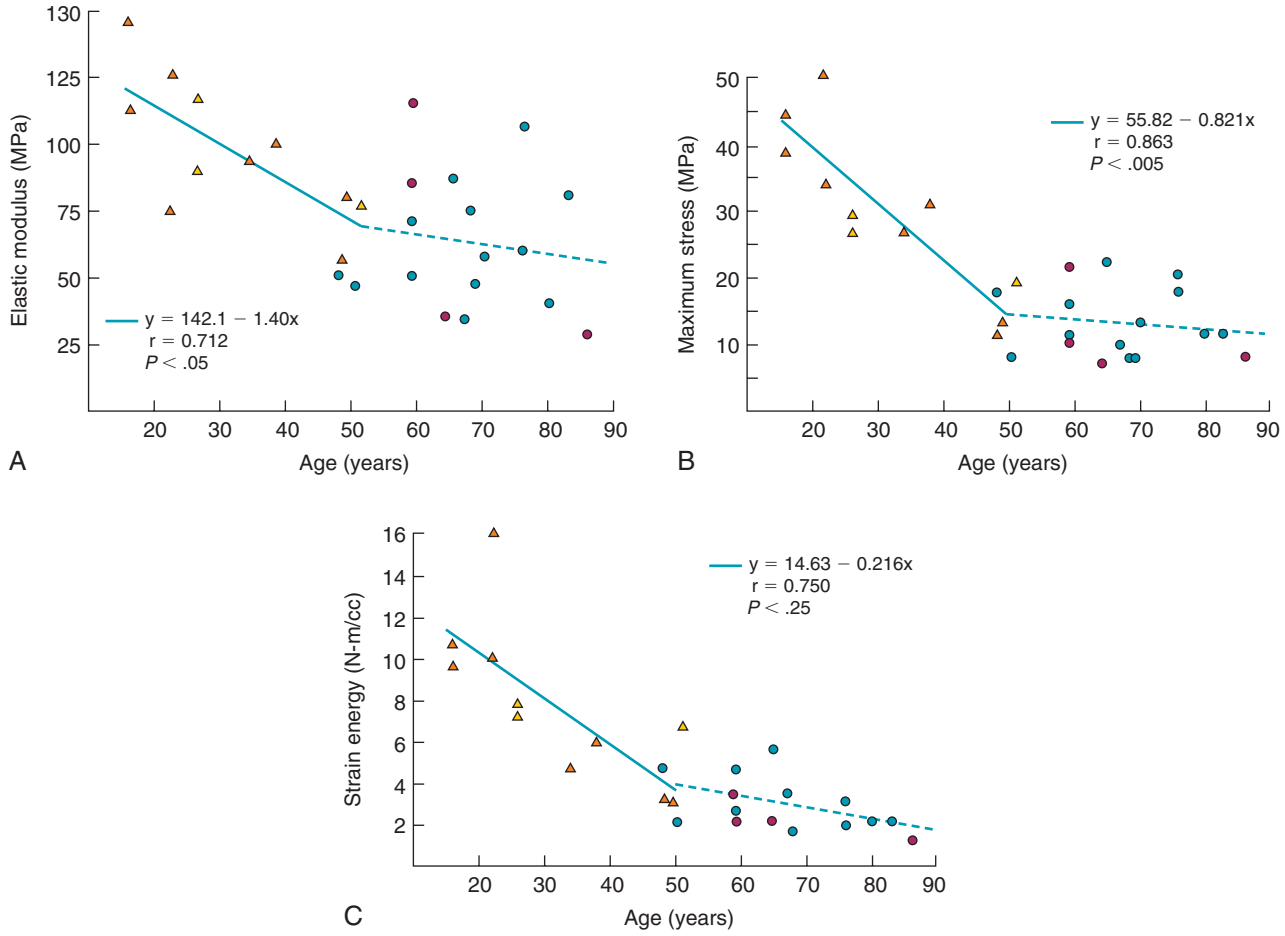

FIG 4-25 Correlation of ligament strength with age. The *solid line* represents the statistically significant correlation with age found in the trauma specimens (*orange triangles*) and younger cadaver preparations (*yellow triangles*), all of which failed through the body of the ligament. The *dashed line* represents the correlation (not statistically significant) found in the amputation (*blue circles*) and older cadaver (*red circles*) preparations, which failed by avulsion fracture of the bone underneath the ligament insertion site. (From Noyes FR, Grood ES. The strength of the anterior cruciate ligament in humans and rhesus monkeys. Age-related and species-related changes. *J Bone Joint Surg Am.* 1976;58:1074-1082.)

Ratios were reported ranging from 80 to 95 N/kg of body mass. Similar ratios ranging from 80 to 118 N/kg of body mass may be calculated from data reported by Viidik[90,91] in the rabbit model. Smith[79] reported a ratio that ranged from 40 to 80 N/kg of body mass in rabbits. A ratio of 119 N/kg of body mass was found in the rhesus monkey preparations in our study,[64] and the specimens from older and younger humans had ratios of 10 and 33 N/kg of body mass, respectively. The human maximum force ratios were markedly low in comparison with those of the rhesus animals as well as other animal models.

It may be invalid, however, to conduct such comparisons based on body mass. The functional demands placed on ligaments vary according to the mode of locomotion, and one cannot compare the stresses of the bipedal gait of humans with the gaits of rabbits, monkeys, or dogs. In addition, the normalization of ligament strength as a function of body mass does not show parallel findings with respect to the variations in size of the ligaments, regardless of which scaling rule is applied. Differences in experimental protocol and testing procedures, such as strain rates, angles of knee flexion, and methods used in gripping the specimens, also make comparisons among studies difficult.

Age-Related Changes

Although it is reasonable to expect an alteration in ligament strength properties with age, our data found greater than expected declines in strength from the younger human specimens compared with the older human preparations (ultimate failure means, 1730 N and 734 N, respectively). The mean body mass of the younger donors was 53 kg; even higher values would be expected for individuals of greater body mass. In the failed specimens from the older humans, there was a decrease in thickness of the cortical and trabecular bone beneath the fibrocartilaginous ligament-bone attachment site. The underlying trabecular bone had wider spaces between trabeculae, and the individual trabeculae appeared thinner than in the specimens from the younger humans. Failure of the ligament-bone unit occurred by an osseous failure owing to both age-related and probably disuse-induced changes.

Kennedy and colleagues[48] reported an ultimate tensile strength of 626 N for human specimens obtained from donors with a mean age of 62 years. Trent and coworkers[87] reported a range of 285 to 1718 N in five cadaver specimens with a donor age of 29 to 55 years. Woo and associates[97] evaluated the structural properties of 27 pairs of human cadaver knees to determine effects of specimen age on the tensile properties of the FATC. Tensile tests of the bone-ligament unit were performed at 30 degrees of knee flexion with the ACL aligned vertically along the direction of applied tension load. One knee from each pair was oriented anatomically, and the second knee was oriented with the tibial aligned vertically. Specimen age did not affect anteroposterior (AP) displacement tests in intact knees at 30 and 90 degrees of flexion. Structural properties of linear stiffness, ultimate load, and energy absorbed significantly decreased with specimen age (Fig. 4-26). Specimen orientation affected these properties because higher values were found in specimens tested in the anatomic orientation (Table 4-8).

It is well known that humans begin to lose bone mass beginning in the fourth decade of life. This phenomenon has important implications in the strength of the osseous components of ligament units for individuals in whom the process is advanced or when it occurs in association with other disuse or disease states in the presence of osteopenia.

Other studies of age-related changes in the mechanical properties of collagenous soft tissues have shown increases in tensile strength and stiffness and decreases in elongation properties with aging.[92,93] However, these studies involved young animals, and the results reflect a maturation process rather than aging, which were probably related to changes in insoluble collagen, increased intermolecular and intramolecular cross-linking, and increases in the collagen/glycosaminoglycan and collagen/water ratios.[79] The physiochemical and mechanical changes that occur in collagen after completion of maturation, which can be ascribed to an aging process in the absence of adverse environmental or disease factors, have not been defined.

Murray and colleagues,[60] in an experimental healing model of ACL in Yucatan minipigs, concluded that the level of skeletal maturity of the animal affected healing properties because immature animals showed higher maximum loads to failure compared with mature animals after suture repair with a collagen platelet composite. However, the data also showed that the immature healing ACL was only an approximate one third of normal ACL load values.

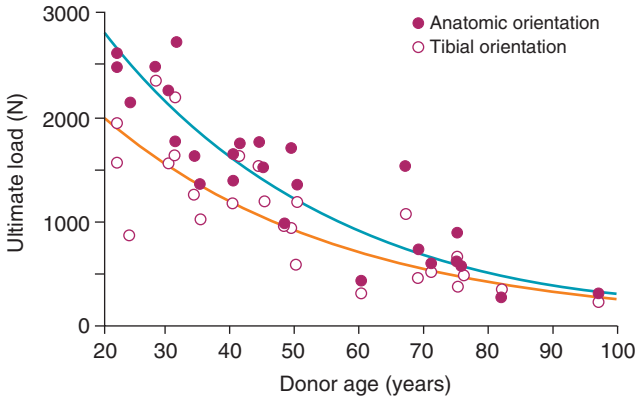

FIG 4-26 The effect of specimen age on femur-anterior cruciate ligament-tibia complex (FATC) ultimate load. Data on ultimate load as a function of specimen age and orientation using a least squares curve fit demonstrated that the strength of FATC decreases in an exponential manner. (From Woo SL-Y, Hollis JM, Adams DJ, et al. Tensile properties of the human femur-anterior cruciate ligament-tibia complex. The effects of specimen age and orientation. *Am J Sports Med.* 1991;19:217-225.)

TABLE 4-8 Effects of Specimen Age and Orientation on the Structural Properties of the Femur-Anterior Cruciate Ligament-Tibia Complex

Age (yr)	Specimen Orientation	Stiffness* (N/mm)	Ultimate load* (N)	Energy Absorbed* (N-m)
Younger (22-35)	Anatomic	242 ± 28	2160 ± 157	11.6 ± 1.7
	Tibial	218 ± 27	1602 ± 167	8.3 ± 2.0
Middle (40-60)	Anatomic	220 ± 24	1503 ± 83	6.1 ± 0.5
	Tibial	192 ± 17	1160 ± 104	4.3 ± 0.5
Older (60-97)	Anatomic	180 ± 25	658 ± 129	1.8 ± 0.5
	Tibial	124 ± 16	495 ± 85	1.4 ± 0.3

*Younger specimens had significantly higher values than older specimens ($P < .001$).

Gender-Related Anterior Cruciate Ligament Tensile Properties

Chandrashekar and associates[15] determined the tensile properties of the human ACL in 10 male and 10 female unpaired cadaveric knees. The comparison of ACL anthropometry indicated a significant decrease in the female specimens compared with the male specimens in minimum area (72.91 and 57.32 mm^2, respectively; $P = .04$) and volume (2722 and 1996 mm^3, respectively; $P = .04$). The maximum load to failure of the female ACL specimens was 1266 ± 627 N compared with the male value of 1818 ± 699 N ($P = .04$). Similar decreases in stiffness, stress at failure, and modulus of elasticity were also reported. Pairwise correlations between male and female specimens provided a strong relationship among body mass index, ACL volume, and minimum area. The authors suggested the need for further research to explain the difference in ACL mechanical properties, ultrastructural differences, and the impact these differences may have on higher ACL failure rates in women.

EFFECT OF INTRAARTICULAR CORTICOSTEROIDS ON LIGAMENT PROPERTIES

The effect of an intraarticular, slightly soluble corticosteroid (methylprednisolone acetate) was investigated on the mechanical properties of a ligament unit.[65,66] ACL preparations from wild rhesus animals were used to determine the effect of corticosteroid dosage and time duration after administration.

Direct Steroid Injection Into Ligament

In the first study, animals were divided into a control group, a sham control group (saline injection), a 20-mg large-dosage group, and a 4-mg small-dosage group (methylprednisolone acetate).[13,65] The large-dosage group was studied at 6 and 15 weeks after injection, and the small-dosage group was studied at 15 and 52 weeks after injection. The FATC specimens were tested in tension to failure using a procedure previously described.[63]

Statistically significant decreases occurred in maximum load in the large-dosage (21% and 39% declines at 6 and 15 weeks, respectively) and the small-dosage groups (27% at 15 weeks, which remained comparable at 52 weeks). In the large-dosage group, minimal decreases in energy to failure were found at 6 weeks, but significant declines (43%) were present at 15 weeks. In the small-dosage group, decreases occurred in energy to failure of 27% at both time intervals.

Haraldsson and associates[31] showed that corticosteroid administration significantly reduced tensile yield strength by 16% and Young's modulus by 14% compared with controls in a rat tail tendon model. Mikolyzk and colleagues,[56] in a rat rotator cuff tendon model, reported that a single corticosteroid dose produced significant short-term biomechanical effects (decreased maximum load, maximum stress, and stiffness) in injured and uninjured tendons. However, these biomechanical properties returned to control levels by 3 weeks.

Intraarticular Steroid Injection

In our second investigation, two animal groups were studied.[59] The first group (high corticosteroid dosage) comprised 10 animals that received a total of three intraarticular injections of methylprednisolone acetate (6.0 mg/kg) into one knee. The injections were spaced 1 week apart. A sham procedure was performed on the opposite knee that consisted of an intraarticular saline injection in equal volume to that of the drug. These animals were sacrificed 6 weeks after the first injection. The second group (low corticosteroid dosage) consisted of 12 animals that received two injections of a dosage one tenth of that used in the other animal group (methylprednisolone acetate 0.6 mg/kg). The two injections were given 2 weeks apart, with a sham saline injection administered into the opposite knee. The animals were sacrificed 15 weeks after the first injection.

A load-versus-time record from a typical right and left specimen pair in an animal from the high corticosteroid dosage group is shown in Figure 4-27. The strain parameters are approximated because of inherent errors in measuring ligament length and in using the tibiafemur separation distance as a measure of ligament elongation during testing.

The histologic analysis of the failed ligament units showed no detectable corticosteroid effect in that the fibrocartilage zones at the ligament insertion sites were intact. There were no bone resorptive changes at the ligament attachment sites. On scanning electron microscopy, no alterations were found in the surface appearance of collagen fibers and fibrils in the ligaments that received the corticosteroid.[66]

The alterations in ligament behavior were dependent on the dosage of the drug and the time that had elapsed after injection. In the higher-dosage group, the maximum failure load of the ligament unit decreased by 11% after 6 weeks and 20% after 15 weeks. The stiffness of the ligament preparation showed a minimal decrease 6 weeks after injection; however, at 15 weeks, a significant decline had occurred. In the lower-dosage group, the maximum failure load of the ligament unit decreased by 9% and the energy absorbed before failure decreased by 8%. The decreases were found when the right-left specimen pairs were compared and were statistically significant. No significant change occurred in the stiffness of the ligament unit. These small changes suggest only slight alterations in the projected functional capacity of the ligament unit.

The specific ultrastructural mechanisms responsible for the alterations in ligament mechanical properties following administration of corticosteroid are unknown. There are known inhibitory effects of corticosteroids on the synthesis of glycosaminoglycans, proteins, and collagen. Whether decreased collagen synthesis occurs owing to the drugs' effect on specific collagen precursors and enzymes or from a general inhibitory effect on overall protein synthesis is unknown. Corticosteroid preparations are known to alter fibroblast proliferation and metabolism. The cellular and subcellular effects are highly complex and beyond the scope of this chapter. The end result of these drugs is generally antianabolic and responsible for the adverse effect on wound and soft tissue healing.

The clinical implications of this study are suggestive that intraarticular, slightly soluble corticosteroids in high and frequent doses have the potential to alter ligament strength and function. The risk associated with such alterations may be minimal if infrequent, low-dose injections are administered. Alternatively, a single direct injection of a slightly soluble steroid preparation has a marked effect on decreasing ligament functional properties, which remained up to 1 year.

Wiggins and colleagues[96] and Walsh and coworkers[94] have reported extensive studies on the effect of a steroid injection in human equivalent doses on the healing of a rabbit MCL model. Their data show statistically significant reductions in maximum failure loads and alteration in histologic properties compared with appropriate controls. The authors concluded that a single steroid injection at the site of a healing ligament would decrease or retard healing properties; however, they suggested that the effect was probably reversible. The authors reviewed a number of mechanisms for the deleterious effects. It should be noted that the studies were performed on a rabbit model that exhibits a known hypersensitivity to steroids that is more pronounced than that expected in other animals and humans.

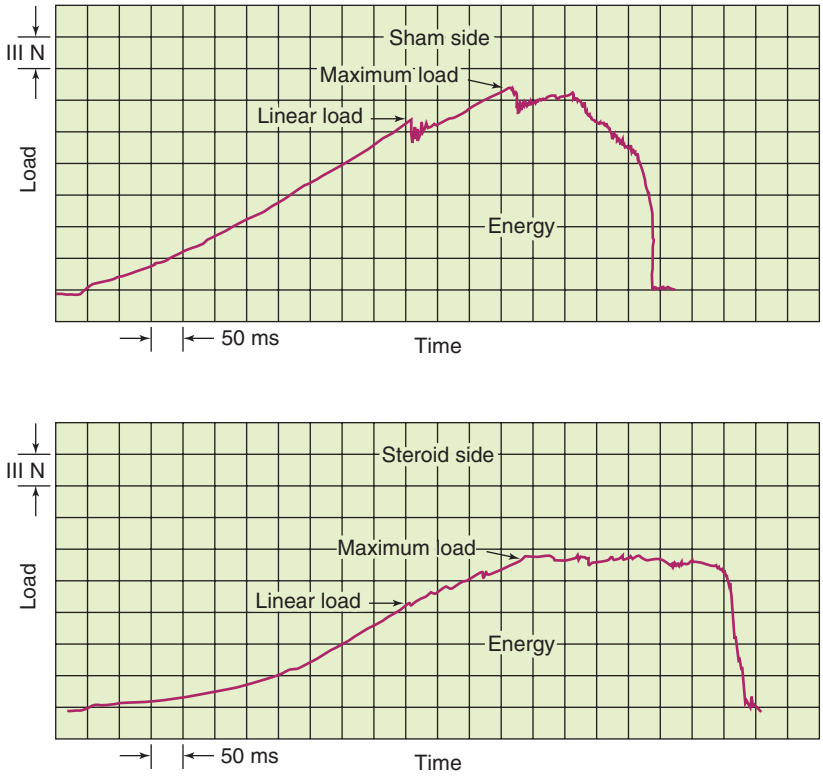

FIG 4-27 Typical load-versus-time records for a right-left pair of specimens. The sham specimen demonstrates normal behavior under loading. The steroid side demonstrates a decrease in stiffness (initial slope of the curve), failure at lower loads, and an increase in ligament elongation at complete failure. (From Noyes FR, Grood ES, Nussbaum NS, Cooper SM. Effect of intra-articular corticosteroids on ligament properties. A biomechanical and histological study in rhesus knees. *Clin Orthop.* 1977;23:197-209.)

EFFECT OF VASCULARIZED AND NONVASCULARIZED ACL GRAFTS ON BIOMECHANICAL PROPERTIES

After ACL graft reconstruction, there is a marked cellular invasion that removes necrotic collagenous tissues with replacement collagenous fibers that are a ligament in a parallel fashion, but do not resemble the native microgeometry of the ACL. The question that has been posed is whether maintaining a vascular supply (and any concomitant neural innervation) of an ACL graft would limit the so-called necrotic phase of ligament remodeling and retain more normal ligament functional properties. An investigation was conducted to measure the mechanical properties of patellar tendon autografts used to replace the ACL in the cynomolgus monkey at four time periods up to 1 year.[12] The ACL was replaced with the medial half of the patellar tendon as a vascularized graft in one knee and as a nonvascularized (or free) graft in the contralateral knee. The 5-mm–wide medial patellar tendon free grafts were prepared through a standard medial parapatellar exposure. The vascularized grafts were prepared in a similar manner, except the medial retinacular vascular supply and a portion of the fat pad were preserved. The tibial attachment sites were prepared by producing a thin bony trough in the anteromedial aspect of the tibia to the site of the ACL attachment, and the ACL grafts with the vascularized pedicle were transposed into a bony trough. An identical tibial and femoral placement was used for the free grafts. Standard graft fixation methods were used. The knees were immobilized for 4 weeks at 30 degrees of flexion followed by unrestricted activity in large cages.

CRITICAL POINTS Effect of Vascularized and Nonvascularized ACL Grafts on Biomechanical Properties

An investigation was conducted to determine whether maintaining a vascular supply (and any concomitant neural innervation) of an ACL graft would limit the so-called necrotic phase of ligament remodeling and retain more normal ligament functional properties.

- The ACL was replaced with the medial half of the patellar tendon as a vascularized graft in one knee and as a nonvascularized (or free) graft in the contralateral knee in cynomolgus monkeys.
- Both the vascularized and nonvascularized grafts underwent significant reductions in structural mechanical and material properties as early as 7 weeks after surgery.
- Retention of a portion of the blood supply to the ligament is not sufficient to avoid a major reduction in ligament mechanical properties that occur in vivo following implantation.

Both the vascularized and nonvascularized grafts underwent significant reductions in structural mechanical and material properties as early as 7 weeks after surgery. Stiffness values were as low as 24% to 28% of control ACL and medial patellar tendon values. Maximum force at 7 weeks was 16% of control ACL values, increasing to 39% of control maximum force by 1 year (Fig. 4-28, *A*). Modulus and maximum stress showed even greater reductions and were only 34% and 26%, respectively, of control ACL values at 1 year (Fig. 4-28, *B*). The rate of return was slow up to 1 year for all variables studied. The

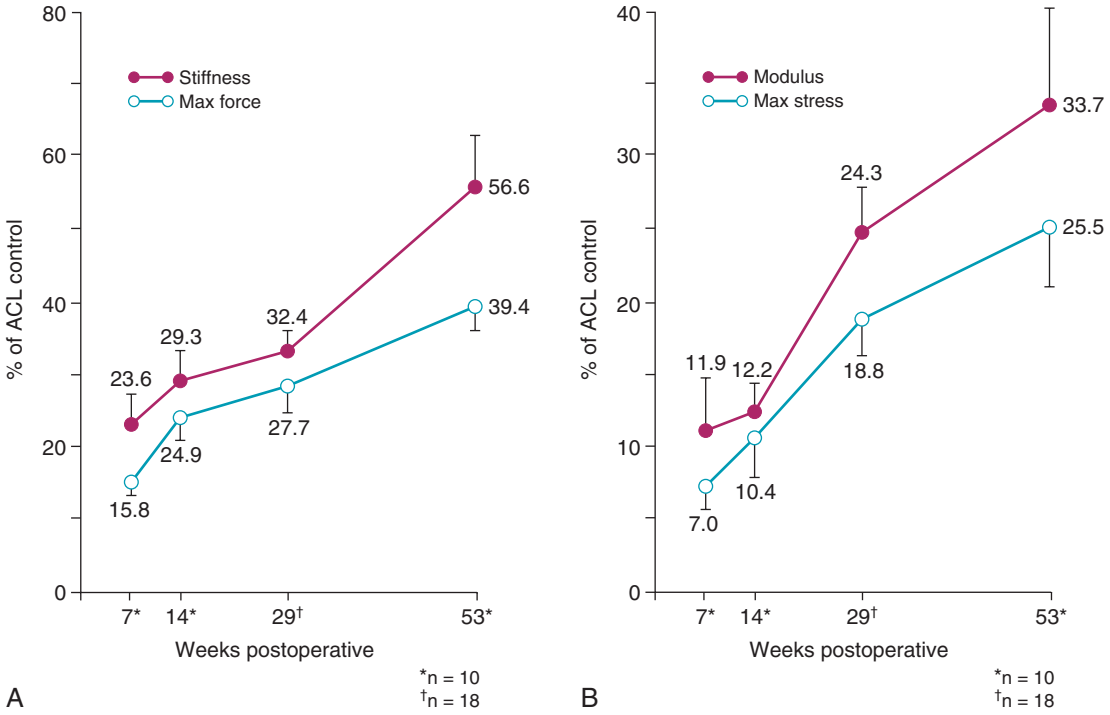

FIG 4-28 **A,** Normalized graft stiffness and maximum force (standard error of the mean) are plotted against weeks postoperative. Note the more rapid increase in the stiffness values over time. By 1 year, stiffness and maximum force were 57% and 39% of control, respectively. **B,** Normalized graft modulus and maximum stress are plotted against weeks postoperative. No significant differences are present among the parameters at any time period. Modulus and maximum stress are lower than corresponding stiffness and maximum force in **A,** suggesting that the collagen material is both very compliant and weak. (From Butler DL, Grood ES, Noyes FR, et al. Mechanical properties of primate vascularized vs. nonvascularized patellar tendon grafts: changes over time. *J Orthop Res.* 1989;7:68-79.)

changes in maximum force over time were generally consistent with other studies that used free grafts, showing on a mechanical basis that an extended period of time is required for ACL graft remodeling and partial return of strength. The study concluded that retention of a portion of the blood supply to the ligament is not sufficient to avoid a major reduction in ligament mechanical properties that occur in vivo following implantation.

EFFECT OF CELLULAR NECROSIS AND STRESS-SHIELDING ON ACL HEALING AND RETENTION OF NATIVE ACL FIBER MICROARCHITECTURE

Jackson and associates[41-43] performed a series of landmark studies in a goat model in which the ACL was frozen in situ, producing cellular necrosis while retaining the normal fiber microarchitecture. Mechanical loading tests of the ACL bone-ligament-bone preparation at 6 months showed no difference in the maximum failure load, stiffness, or AP translation compared with those in untreated controls. The authors theorized that the large decreases in ACL mechanical properties and strength in experimental animals after ACL reconstruction could not be explained by cell death and devascularization.

To provide additional experimental information, a study was conducted in our laboratory in which the previously described devitalized frozen model in the goat ACL was used and two conditions were added.[11] In one group of knees, the ACL tibial attachment was elevated by osteotomy and then replaced in its normal anatomic position. In a second group of knees, the ACL tibial attachment was osteotomized and replaced on the tibia 5 mm posterior to its normal attachment to study the effects of an altered loading state (stress-shielding) on ligament remodeling properties. The results of the ACL mechanical failure tests are summarized in Table 4-9. The stiffness, maximum force, and stress and modulus were greater in the anatomic placement group than in the posterior ACL placement group; however, they were still less than historic controls. Increased failures were noted at the tibial attachment site in the posterior ACL placement group.

CRITICAL POINTS Effect of Cellular Necrosis and Stress-Shielding on ACL Healing and Retention of Native ACL Fiber Microarchitecture

- Based on a series of studies,[41-43] Jackson and associates concluded that large decreases in ACL mechanical properties and strength in experimental animals after ACL reconstruction could not be explained by cell death and devascularization.
- Other experimental studies strongly suggest that the use of ACL ligament grafts, which have no similarity to the native ACL fiber organization and in vivo microstrains, results in replacement of the ACL graft with a scarlike disorganized collagen framework with marked loss of mechanical strength and stiffness.
- Clinically, ACL grafts are limited in their ability to truly restore native ACL fiber microgeometry and therefore never function similar to a normal ligament. The grafts function to provide a gross checkrein to abnormal knee displacements.

The results of all of the studies[12,14,16,17,37,43,52,53,61,77,83,88,99] are summarized in Figure 4-29, which compares historic maximum failure loads in experimental animals with the frozen devitalized specimens in Jackson and associates' study[42] and the anatomic- and posterior-placed ACL preparations.[11] Although the anatomic-placed ACL (after tibial osteotomy) had a reduction in strength compared with the native frozen ACL, the strength was still greater than ACL graft reconstructions. The presumed loss of the normal stress and fiber loading in the posterior-placed ACL, in addition to tibial healing effects, produced marked reductions in all mechanical properties.

The results of these experimental studies strongly suggest that retaining the complex native microgeometry of the ACL provides a necessary stimulus for ligament remodeling. In addition, the use of ACL ligament grafts, which have no similarity to the native ACL fiber organization and in vivo microstrains, results in replacement of the ACL graft with a scarlike disorganized collagen framework with marked loss of mechanical strength and stiffness. Insofar as the results apply to clinical ACL reconstructions, the suggestion is that ACL grafts are limited in their ability to truly restore native ACL fiber microgeometry and, therefore, never function similar to a normal ligament. The authors hypothesized that ACL grafts function to provide a gross checkrein to abnormal knee displacements in contrast to the so-called fine-tuning of joint motions by a ligament fiber guiding microarchitecture mechanism. It is probable that even two-bundle graft constructs behave in a similar manner, replacing the collagen fiber mass of the ligament at tibial and femoral attachments. However, with remodeling, even two-bundle constructs have altered mechanical properties and function that does not approximate native ligament function.

ALLOGRAFTS AND AUTOGRAFTS: BIOMECHANICAL PROPERTIES AFTER IMPLANTATION AND EFFECT OF IRRADIATION

Multiple studies have been published on the biomechanical properties of autografts and allografts in experimental animal models.[3,11,22,41-44,76,77,83,89] The majority demonstrate that allografts have inferior results compared with those of autografts (and contralateral controls) in regard to mechanical strength properties. In 1989, Thorson and colleagues[83] studied the 4-month postoperative mechanical properties of adult canines that received either bone-tendon-bone allografts or autografts. The allograft group showed a mean load to failure of only 17% of the contralateral control ligament, compared with 41% in the autograft group. Shino and coworkers,[76,77] in two studies using the canine model, reported that allografts had a mean maximum tensile load of approximately 30% that of contralateral controls 1 year postimplantation. Jackson and associates[43] reported in 1993, in a goat model, that the strength of fresh frozen patellar tendon allografts was only 27% of controls at 6 months postimplantation. In contrast, the strength of patellar tendon autografts was 62% of control ACLs. The

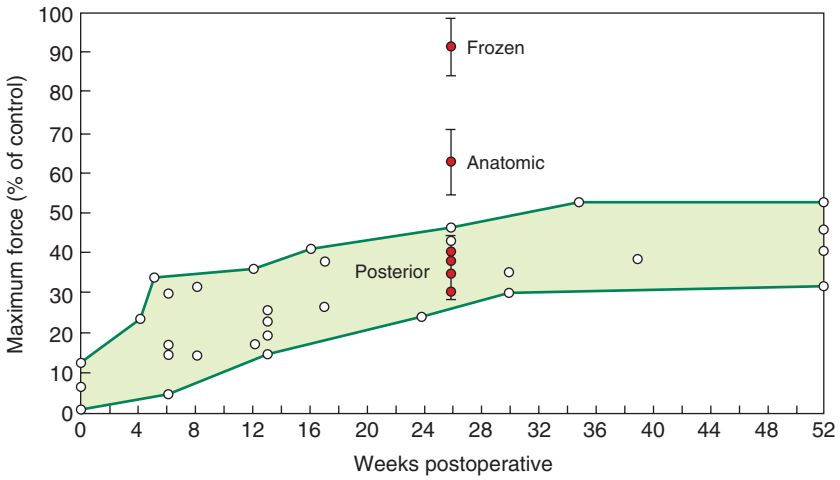

FIG 4-29 Maximum load to failure versus postoperative time. The range (*shaded region*) of means for allograft reconstructions (*open circles*) are from previously published studies. The mean (± standard error of the mean) for frozen ligaments and their tibial insertion moved 5 mm posterior lie within this range. Ligaments frozen and replaced in the anatomic position have greater maximum loads but still less than for in situ freezing alone as reported by Jackson et al.[42] (From Bush-Joseph CA, Cummings JF, Buseck M., et al. Effect of tibial attachment location on the healing of the anterior cruciate ligament freeze model. *J Orthop Res.* 1996;14:534-554.)

authors concluded that allograft remodeling is much slower than autograft and suggested that patients who receive allografts should probably be protected against maximum activities for a longer period of time than those who receive autografts.

In another study in which freeze-dried bone-ACL-bone allografts were implanted, Jackson and associates[41] reported that the maximum load of the allografts was only 25% of the contralateral ACL controls at 1 year postimplantation. Figure 4-30 summarizes a number of allograft ACL reconstruction studies and demonstrates that all had mechanical properties in low ranges from 4 to 52 weeks postoperative. The healing effects of autografts and allografts are covered in greater detail in Chapter 5.

Our laboratory[27,70,72] has studied the effects of gamma irradiation on the mechanical and material properties of allografts in the goat model and in human cadavers. In the first study, Gibbons and colleagues[27] reported on the effects of 2 and 3 mrad of gamma irradiation on goat ACL B-PT-B in vitro properties. The study reported that the maximum stress, maximum strain, and strain energy were significantly reduced after 3 mrad; however, there were no significant reductions after 2 mrad of irradiation (Table 4-10).

In a second study, the effects of a higher level of irradiation (4 mrad) were studied on human cadaver donor (aged 18 to 59 years) frozen patellar tendon-bone allografts and were compared with a frozen control graft (0 mrad).[70] Irradiation produced a small, but significant, decrease in graft length (0.6 mm, $P < .01$; Table 4-11). The irradiated grafts showed significant reductions in stiffness ($P < .025$) and maximum force ($P < .001$).

In a third study, Salehpour and associates[72] studied the effects of 4, 6, and 8 mrad (40,000, 60,000, or 80,000 Gy) of gamma irradiation on the in vitro properties of a B-PT-B allograft unit retrieved from mature female goats. On average, stiffness decreased by 18%, 40%, and 42% at 4, 6, and 8 mrad, respectively ($P < .05$ for all comparisons). The data

CRITICAL POINTS Allografts and Autografts: Biomechanical Properties After Implantation and Effect of Irradiation

The majority of experimental studies demonstrate that allografts have inferior results compared with autografts (and contralateral controls) in regard to mechanical strength properties. The effects of gamma irradiation on the mechanical and material properties of allografts have been studied in the goat model and human cadavers for many years.

- Effects of 2 and 3 mrad of gamma irradiation on goat ACL bone-patellar tendon-bone in vitro properties showed maximum stress, maximum strain, and strain energy were significantly reduced following 3 mrad; however, there were no significant reductions following 2 mrad of irradiation.
- Effects of 0 versus 4 mrad of gamma irradiation on human cadavers: irradiation produced a small, but significant, decrease in graft length (0.6 mm). Irradiated grafts showed significant reductions in stiffness and maximum force.
- Effects of 4, 6, and 8 mrad on goat ACL bone-patellar tendon-bone units: data showed the overall dose-dependent effects of irradiation on ligament mechanical properties; doses less than 2 mrad had minimal effects.
- In vivo effect of 4 mrad of gamma irradiation on bone-patellar tendon-bone units in goats at time 0 and 6 months postimplantation: irradiation significantly altered structural but not material properties.

At present, there are no experimental data to show that the low-dose irradiation as used to secondarily sterilize allografts has a deleterious effect on graft mechanical properties.

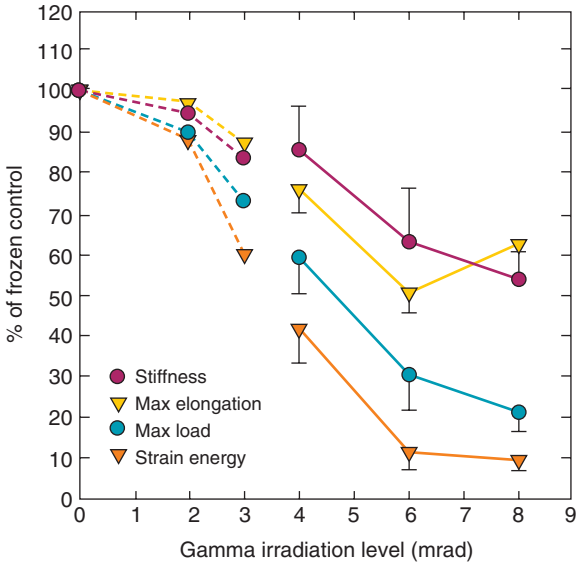

FIG 4-30 Average dose-dependent response curves for all four mechanical properties (*solid lines*), expressed as percentages of values for contralateral frozen controls. Normalized data for 2 and 3 mrad (*dashed lines*) from earlier studies are also shown. Those studies used different testing conditions. Note the nearly linear declines in all curves between 2 and 6 mrad. (From Salehpour A. Butler DL. Proch FS, et al. Dose-dependent response of gamma irradiation on mechanical properties and related biochemical composition of goat bone-patellar tendon-bone allografts. *J Orthop Res.* 1995;13:898-906.)

†Mean values for normal ACL based on prior published literature.

as a whole showed the overall dose-dependent effects of irradiation on ligament mechanical properties. Doses less than 2 mrad have minimal effects. Schwartz and coworkers[75] examined the in vivo effect of 4 mrad of gamma irradiation on B-PT-B units in adult goats at time 0 and 6 months postimplantation. The irradiation significantly altered structural but not material properties. Stiffness was reduced by 30% and maximum force by 21%, resulting in these parameters averaging 12% to 20% of normal ACL values (Table 4-12).

We concluded that 4 mrad of gamma irradiation affect ACL allograft subfailure viscoelastic and structural properties but not material or biochemical properties over time.[70,72,75] The ACL allografts of the 0 mrad failed at 497 N (see Table 4-9), which in comparison with the first study of Gibbons and associates[27] showed a control graft of 1400-N maximum force. This suggests that the effects of the remodeling process, resulting in a weakened graft with altered mechanical properties as previously described, produced even more profound deleterious effects than the irradiation treatment.

Bhatia and colleagues[8] reported that maximal load and stiffness in a rabbit ACL model, using tendon allografts and autografts, were unaltered by low-dose (1.2 mrad) gamma irradiation. They concluded that low-dose gamma irradiation was safe for sterilization of soft tissue ACL allografts. Yanke and colleagues[98] studied cyclic and failure properties of human B-PT-B allografts treated with 1.0 to 1.2 mrad compared with paired untreated specimens and found no significant difference in biomechanical properties except for decreased in graft stiffness of 20%. They concluded that low-dose irradiation was not deleterious to preimplantation mechanical properties. Recent interest in electron-beam irradiation, rather than gamma irradiation, is noted in Hoburg and associates' investigation.[36] This sterilization process demonstrated a minimal effect on B-PT-B ACL allograft strain, cyclic elongation, stiffness, and failure and may provide a higher level of safety.

The published results of studies showing the delayed healing of allografts and low ultimate strength properties even at 1 year in the animal model are consistent with clinical observation in humans of the higher failure rate of ACL allografts, and we recommend to use autograft tissues whenever possible in ACL surgery. These concepts are further discussed in Chapters 7 and 8. We prefer to obtain allografts for patients from tissue banks that use secondary chemical sterilization for bacterial contamination.

INTRODUCTION

Traumatic rupture of the anterior cruciate ligament (ACL) can be a common source of knee instability and dysfunction in athletes. Reconstruction of a torn ACL, to restore function and limit injury to the menisci, has become a common orthopedic procedure. Despite advances in surgical techniques and the ability to implant an isometric graft that restores knee stability, ACL reconstruction is not always a universally efficacious procedure. Rates of recurrent laxity, 1 year postoperatively, have been reported to be as high as 17%.[101]

Graft integration failure and inadequate tendon-to-bone healing may be an important cause of recurrent knee instability following ACL reconstruction. The healing of tendon to bone is the basic requirement for successful long-term survival of the graft.[17,32] Whether an autograft or allograft tendon is used, biomechanical testing has shown that the initial strength of the graft material is superior to the intact ACL.[17,32] Therefore, the weakest link after reconstruction is not the graft itself, but rather the fixation points until graft osteointegration occurs. The intraarticular portion of the graft must ultimately undergo remodeling and the process of *ligamentization* to form an organized structure that resembles a native ligament.[5,6,41,47,49]

Current techniques of ACL reconstruction require tendon-to-bone healing in a surgically created bone tunnel. No native human tendons pass through an osseous tunnel; therefore, this type of healing environment is inherently unusual. When a bone-tendon-bone graft is used for ACL reconstruction, graft fixation initially depends on bone-to-bone healing. However, tendon-to-bone healing still remains critical regardless of whether an all soft-tissue graft or a graft with a bony plug is selected. The length of the tendinous portion of the bone-tendon-bone graft is greater than the intraarticular length of the native ACL, resulting in a substantial amount of tendon within the bony tunnel. Aperture healing to minimize graft micromotion and tunnel widening requires tendon-to-bone healing with any graft.[49]

Because all grafts depend on tendon-to-bone healing, this chapter focuses on graft osteointegration and the process by which structural and functional continuity between the tendinous portion of the graft and bone is achieved. Both the biologic milieu and the biomechanical environment occurring at the bone tunnel result in formation of an attachment site that differs from the native ligament-bone insertion. The biology of this healing remains incompletely understood and is exposed to a number of biomechanical and physiologic influences. The current understanding of the biology of graft reconstruction is reviewed and potential strategies to enhance early graft integration are discussed.

NATIVE TENDON-BONE INSERTION

The ACL is an intraarticular, extrasynovial structure that acts to control anterior translation and rotational movements of the femur on a fixed tibia. It is composed of multiple fascicular collagen bundles enveloped in a sheath that contains vascular and neural elements.[2] The ACL inserts to bone via a direct type of insertion, similar to the transition seen from tendon to bone. Microscopic examination of the sites of bony attachment shows interdigitation of the collagen fibers with bone though four distinct transition zones: tendon, unmineralized fibrocartilage, mineralized fibrocartilage, and bone (Fig. 5-1).[2,24,75,92] This graduated change in stiffness allows for transmission of complex mechanical loads from soft tissue to bone while minimizing peak stresses at any single point along the ligament. Cartilage-specific collagens including types II, IX, X, and XI are found in the fibrocartilage insertion site. Collagen X plays a key role in maintaining the interface between the mineralized and unmineralized zones.[2,24,75,92] Recently, it was noted that both the femoral origin and tibial insertion of the ACL contain discrete regions of both direct and indirect ligamentous insertions.[37,94] The theoretical biomechanical advantages of recreating the direct fibers have been explored; however, few clinical data support targeted surgical reconstruction of these discrete tissue attachments.[86]

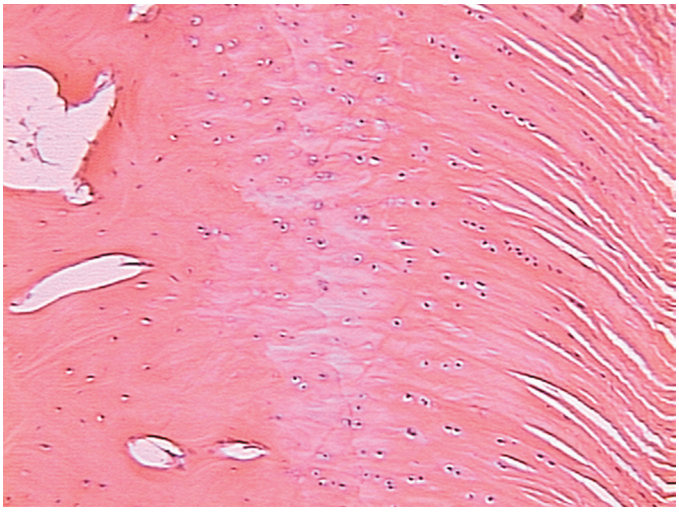

FIG 5-1 Histology of native anterior cruciate ligament insertion to bone. Examination shows interdigitation of the collagen fibers with bone through four distinct transition zones: tendon, unmineralized fibrocartilage, mineralized fibrocartilage, and bone.

CRITICAL POINTS Native ACL Insertion

- The native ACL inserts via a direct type of insertion to bone, with distinct transition zones of ligament, unmineralized fibrocartilage, mineralized fibrocartilage, and bone.
- Insertion site provides gradual transition in material properties, thereby minimizing stress concentration at the interface.
- All ACL reconstruction procedures require tendon-to-bone healing in a surgically created bone tunnel, to which there is no analogous situation in the native human body.
- Regardless of ACL graft choice, some degree of tendon-bone healing must take place for successful ligament reconstruction.

TENDON-BONE INSERTION AFTER ACL RECONSTRUCTION

The overall structure, composition, and organization of the native ACL attachments sites are not reproduced after surgical reconstruction of the ACL. This disparity reflects an inability to recapitulate the events that occur during embryonic development with current surgical strategies. Rather than regenerating the four organized zones of direct insertion, the graft heals with an interposed zone of vascular, highly cellular granulation tissue between the graft and tunnel wall (Fig. 5-2).[28,29,87] The healing process of a tendon graft in a bone tunnel has been defined in rabbit and dog models.[45,87] In the initial postoperative period, the graft-tunnel interface is filled with vascular granulation tissue containing an abundance of type III collagen. Vascular endothelial growth factor (VEGF) and fibroblast growth factor (FGF) are expressed, stimulating an influx of macrophages and enlarged fibroblasts. Chondroid cells accumulate along the walls of the bone tunnel and deposit type II collagen as part of the endochondral process of new bone formation. After 3 to 4 weeks, this interface tissue undergoes a maturation process until its matrix consists of oriented Sharpey-like collagen fibers that bridge the bone to the graft (Fig. 5-3). The chondroid cells are gradually replaced with lamellar bone in a process similar to endochondral ossification.[45] The Sharpey-like fibers are composed of type III collagen and extend into the surrounding bone to resist shear stresses. The number and size of these collagen fibers positively correlate with the pull-out strength of the graft (Fig. 5-4). The time interval for this process to occur has been variably reported in the literature, ranging from 8 to 30 weeks.[45] Graft attachment strength further improves as bone grows into the interface tissue and outer portion of the graft.[28,29,87]

CRITICAL POINTS Tendon-Bone Insertion After ACL Reconstruction

- A native ACL insertion is not reproduced after ACL reconstruction and reflects an inability to recapitulate the events of embryonic development.
- Graft-to-bone healing occurs via an interposed zone of vascular granulation tissue between the graft and tunnel wall that matures with time.
- Attachment strength is proportional to the magnitude of bony ingrowth into the interface tissue and anchoring Sharpey-like collagen fibers that bridge the tendon to bone.

CHALLENGES OF TENDON-BONE HEALING AFTER ACL RECONSTRUCTION

The biologic cascade of healing between a grafted tendon and bone tunnel remains incompletely understood. The biologic and biomechanic environments result in the formation of an inferior attachment site that is different from the organized, direct-type ACL insertion. Current work suggests a number of fundamental challenges responsible for the suboptimal healing response between tendon and bone instead of regeneration of the insertion site.[31] These factors include:

1. The presence of inflammatory cells at the graft-tunnel interface that precipitates scar formation.
2. Slow and limited bony ingrowth into the graft from the tunnel walls, resulting in a biomechanically weaker attachment.
3. Insufficient number of undifferentiated stem cells at the healing tendon-bone interface.
4. Graft-tunnel micromotion that precludes the formation of a firm attachment at the tunnel aperture.
5. Lack of a coordinated gene-signaling cascade that directs healing toward regeneration rather than scar tissue formation in the postnatal organism.

Strategies to promote tendon-to-bone healing in ACL reconstruction focus on overcoming these challenges through modification of the biologic and biomechanical environment.

MODULATION OF TENDON-BONE HEALING

Technical Factors

Adjustments can be made in the surgical technique of reconstruction to optimize tendon-to-bone healing. The fundamental principle is to maximize the surface area of the tendon-bone interface. Animal studies have shown that increasing the length of the bone tunnel positively correlates with the quality and strength of the reconstruction.[105] Minimizing graft tunnel mismatch by effectively achieving a press fit of the graft into the bony tunnel improves healing.[30] Additionally, maximizing circumferential contact area of the graft and tunnel (i.e., avoiding use of an interference screw) may improve healing.[96] However, this final factor must be ultimately balanced with the increased stiffness from decreased fixation-to-fixation construct length that aperture fixation provides to the healing graft environment.

Mechanical Factors

Relative graft-tunnel micromotion may preclude the formation of a firm attachment to the tunnel wall. Yu and Paessler[108] compared

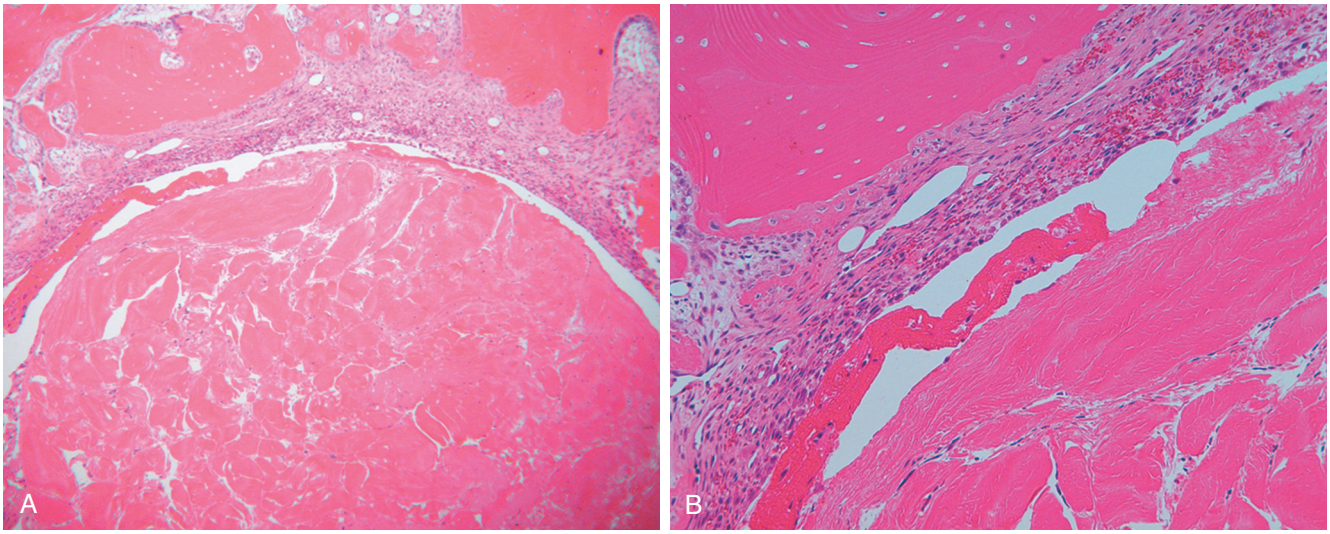

FIG 5-2 Insertion site histology 1 to 2 weeks after anterior cruciate ligament reconstruction. Shown are low-power **(A)** and high-power magnification **(B)**. Vascular, highly cellular granulation tissue is interposed as a layer between the graft and tunnel wall.

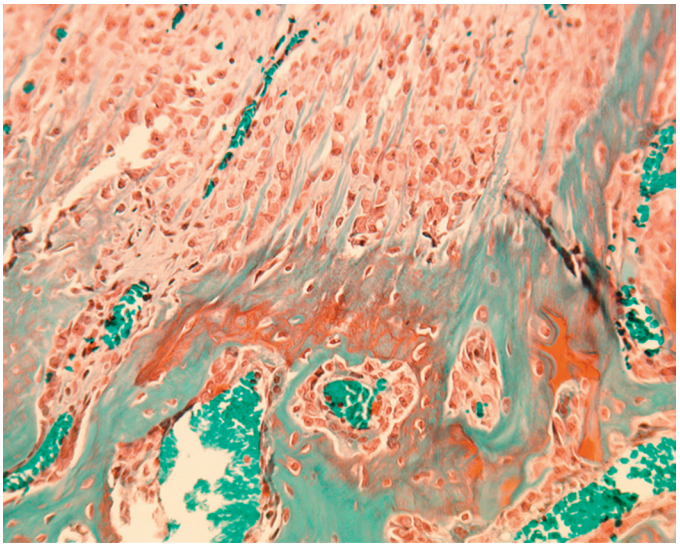

FIG 5-3 Insertion site histology 3 to 4 weeks after anterior cruciate ligament reconstruction. The interposed tissue has matured with oriented, Sharpey-like collagen fibers bridging the tendon to bone.

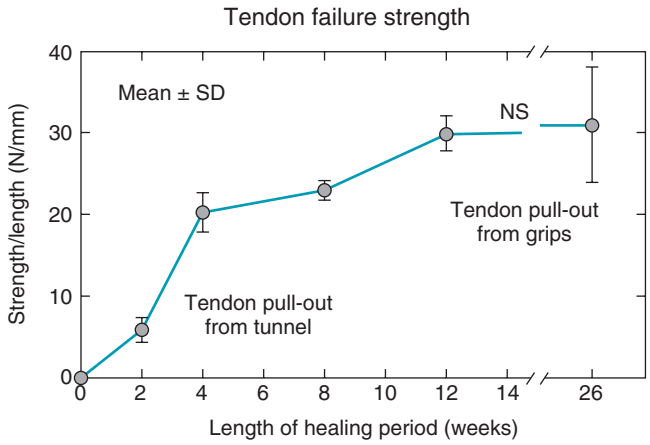

FIG 5-4 Pull-out strength of graft correlates with the number and size of bridging, Sharpey-like collagen fibers. *NS,* Not significant. (From Rodeo SA, Arnoczky SP; Torzilli PA, et al. Tendon-healing in a bone tunnel. A biomechanical and histological study in the dog. *J Bone Joint Surg Am.* 1993;75:1795-1803.)

"aggressive" versus "conservative" rehabilitation protocols in patients after ACL reconstruction with quadrupled hamstring grafts. Significantly greater tunnel widening was reported in the aggressive rehabilitation group, supporting the view that graft-tunnel micromotion is a cause of tunnel widening and that the mechanical environment in the bone tunnel influences tendon-bone healing.

Animal studies have corroborated these clinical observations. Sakai and associates[93] compared immediate motion with varying periods of immobilization for up to 6 weeks after ACL reconstruction in a rabbit model. Biomechanical analysis demonstrated a greater load to failure of the graft in immobilized animals, and histologic studies demonstrated closer tendon-bone apposition with less fibrovascular interface scar tissue. Rodeo and colleagues[88] evaluated the effect of graft-tunnel motion on tendon-to-bone healing in a rabbit ACL reconstruction model. ACL reconstruction was performed in five cadaveric rabbit limbs with aluminum beads fixed to the tendon and bone tunnel. Three-dimensional graft-tunnel motion was quantified using micro-computed tomography (microCT) analysis. Motion was observed to be greatest at the tunnel apertures and least at the tunnel exits, adjacent to the graft fixation at the tunnel exit (Fig. 5-5). Histomorphometric analysis demonstrated healing to be slowest at the apertures, with a wider fibrovascular interface tissue present between tendon and bone. An inverse relationship between graft-tunnel motion and healing in the femoral tunnel was demonstrated. In addition, osteoclasts were preferentially observed at the tunnel aperture, supporting the hypothesis that graft-tunnel motion may stimulate osteoclast-mediated bone resorption and secondary tunnel widening.[88]

These findings have been further investigated in rodent models. We developed a rat ACL reconstruction model that permits application of controlled cyclic axial loading postsurgery. We found that low-magnitude cyclic axial loading of the ACL graft for a short period of time each day, postoperatively, was associated with greater

CRITICAL POINTS Modulation of Tendon-Bone Healing

- Maximizing the surface area of the tendon-bone interface by minimizing graft tunnel mismatch and using long bone tunnels can help to improve the chances of secure graft-bone healing.
- ACL graft-tunnel micromotion, often seen with suspensory fixation techniques, can preclude the formation of a secure attachment to the tunnel wall and is associated with osteoclast-mediated bone resorption and tunnel widening.
- The rapid inflammatory response after ACL reconstruction is highly complex and may trigger a cascade of events that favors fibrosis and scar formation over tissue regeneration, resulting in an inferior tendon-bone attachment site.
- Ingrowth of bone from the surrounding tunnel wall into the interface zone and graft is ultimately responsible for the improved biomechanical properties of the attachment site after healing is complete.
- Use of undifferentiated stem cells and/or cytokines at the tendon-bone interface may have a future role in promoting tissue regeneration and the restoration of native insertion site morphology after ACL reconstruction.

inflammation and less bone formation in the tunnel when compared with animals that underwent continuous immobilization; however, this loading regimen was not detrimental to the strength of the healing tendon-bone interface.[13] Delayed application of cyclic axial load after ACL reconstruction in the same model resulted in improved mechanical and biologic parameters of tendon-to-bone healing compared with those associated with immediate loading or prolonged postoperative immobilization of the knee.[9] Higher strain levels applied to the healing ACL graft in this model had deleterious effects during the early time periods of graft healing.[83] However, stress deprivation to the graft can also have negative consequences on the biomechanical properties of the healing graft.[25]

Modulation of the mechanical environment may have profound effects on the cellular and molecular events at the tendon-bone interface. An improved understanding of these mechanisms may help to develop a postoperative rehabilitation program that provides an optimal environment for tissue regeneration and tendon-bone healing. The delicate balance that must be achieved will need to be explored with larger animal models, along with well-designed clinical trials to improve our understanding of the mechanobiology of healing.

Biologic Factors

Modulation of the Inflammatory Response

The normal response to surgery involves an acute inflammatory response marked by influx of neutrophils, macrophages, and mesenchymal cells. Important insights about the effect of this inflammatory response on tissue healing can be learned from the study of fetal wound healing. Wounds in the embryo and early fetus heal by tissue regeneration and result in "scarless healing." These healing events are characterized by the absence of an acute inflammatory response. Inflammation after trauma, although essential for healing in adults, is also responsible for healing by scar rather than regeneration of native tissue. The rapid inflammatory response that ensues after ACL reconstruction may trigger a cascade of events that ultimately leads to fibrosis rather than tissue regeneration and restoration of the native tendon-to-bone insertion.[27,51,95]

The fibrin clot that forms after surgery allows for a controlled release of cytokines that drive the early response. Transforming growth

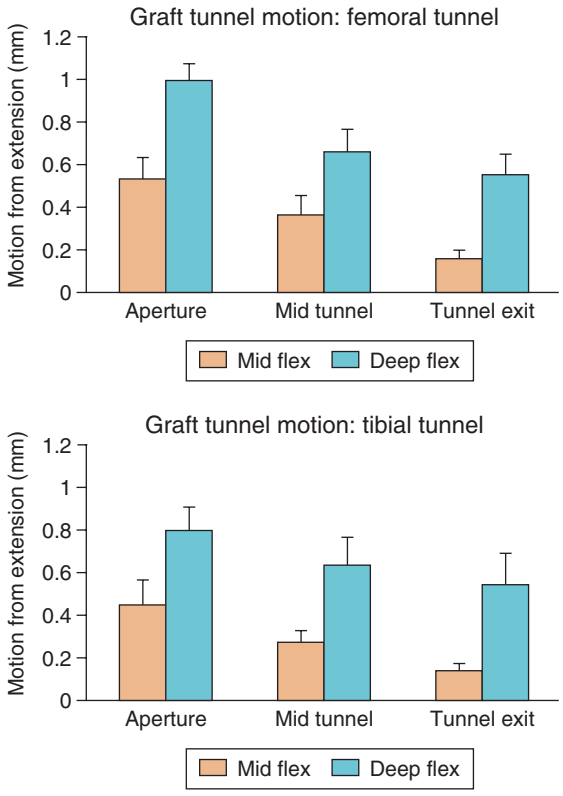

FIG 5-5 Relative motion between the tendon and bone tunnel in the femoral and tibial tunnels. Anterior cruciate ligament reconstruction was performed in five cadaveric rabbit limbs, and graft tunnel motion was measured by microcomputed tomography. Graft tunnel motion was greatest at the tunnel apertures and least at the tunnel exit in cadaveric testing. Healing of the graft was slowest at the tunnel apertures. (From Rodeo SA, Kawamura S, Kim HJ, et al. Tendon healing in a bone tunnel differs at the tunnel entrance versus the tunnel exit: an effect of graft-tunnel motion? *Am J Sports Med.* 2006;34:1790-1800.)

factor-β (TGF-β) and platelet-derived growth factor (PDGF) act together to modulate tissue healing and matrix deposition by recruiting neutrophils and macrophages to the local tissue.[27,51,95] Neutrophil influx peaks at about 2 days after the operation and is followed by an influx of macrophages. These monocytes are essential to the early formation of granulation tissue from the clot, initiating the process of soft tissue adherence to bone.[46] They also drive the angiogenic phase, providing nutrients and oxygen for the prolonged period of matrix synthesis and remodeling that ensues over the next several weeks. TGF-β secreted by macrophages recruits and stimulates fibroblasts to degrade matrix through matrix metalloproteinases (MMPs). Simultaneously, these fibroblasts synthesize new matrix proteins to replace the early granulation tissue with scar tissue. Tissue inhibitors of MMPs (TIMPs) inhibit MMPs and provide a check-and-balance regulation to this complex process of matrix degradation, synthesis, and remodeling.[26]

The accumulation of macrophages around the tendon graft in bone has been further characterized in a rat ACL reconstruction model.[46] Two distinct subpopulations of macrophages were identified at the tendon-bone interface. ED1+ macrophages derived from the circulation act in a proinflammatory fashion in the early response with neutrophils to migrate into the tissues and remove debris after surgery. This is followed by the accumulation of proregenerative ED2+ macrophages from the local tissues, which promote anabolic tissue healing and scar formation by fibroblasts via TGF-β secretion (Fig. 5-6).[46]

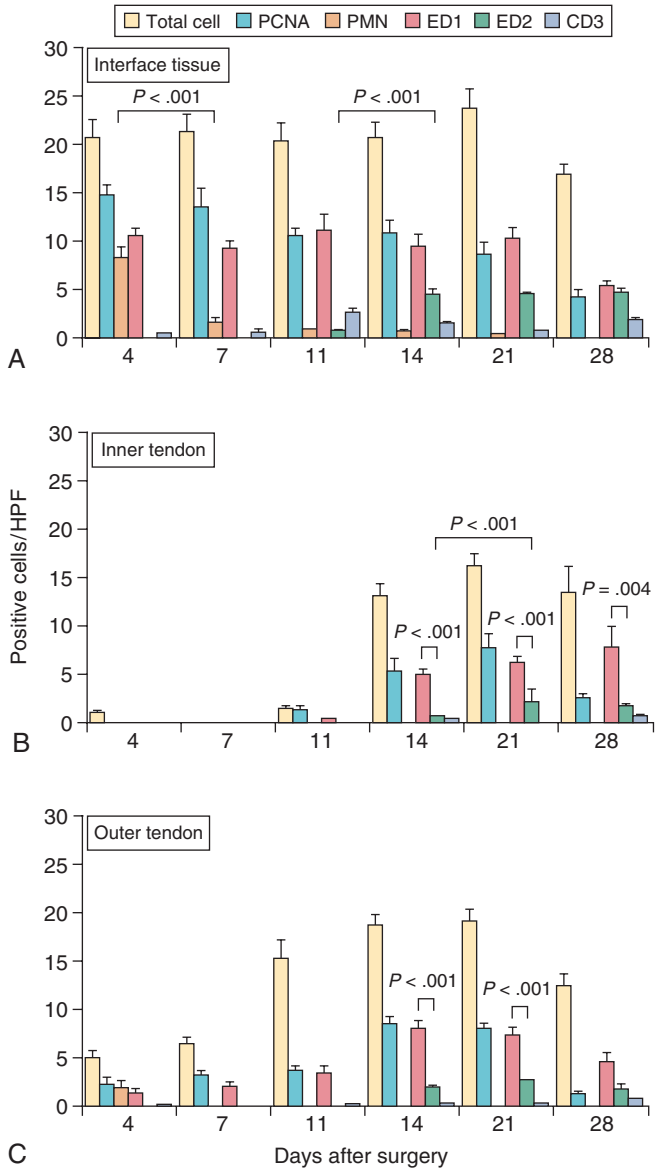

FIG 5-6 Time course of inflammatory cell accumulation in the tendon-bone interface **(A)**, inner tendon **(B)**, and outer tendon **(C)**. The number of positively stained cells for PCNA, PMN, ED1, ED2, and T-lymphocytes were counted in 15 randomly chosen high-power fields 50 µm × 50 µm at ×400 for each area. **A,** There was a significant decrease in the number of neutrophils between 4 and 7 days ($P < .001$). ED2+ macrophages were not present until 11 days after surgery, with a significant increase in positive staining by 14 days after surgery ($P < .001$). **B,** There were significantly more ED1+ macrophages than PCNA+ cells at 28 days after surgery ($P = .014$). There were significantly more ED1+ macrophages than ED2+ macrophages at 14 days and 21 days after surgery ($P < .001$) and at 28 days after surgery ($P = .004$). There were significantly more ED2+ macrophages 21 days compared with 14 days after surgery ($P < .001$). There were no significant differences in the number of CD3-positive cells at all time points. *HPF,* High-power field; *PCNA,* proliferating cell nuclear antigen; *PMN,* polymorphonuclear cells. (Modified from Kawamura S, Ying L, Kim HJ, et al. Macrophages accumulate in the early phase of tendon-bone healing. *J Orthop Res.* 2005;23:1425-1432.)

Given the critical role of macrophages in scar tissue formation, animal studies have investigated the role of macrophage depletion on tendon-bone healing to test the hypothesis that macrophage depletion could promote a "scarless" regenerative healing process at the healing insertion site. Hays and colleagues[34] demonstrated less scar tissue formation, improved collagen organization, and superior biomechanical strength in a rat ACL reconstruction model when macrophages were depleted by administration of liposomal clodronate, a selective inducer of macrophage apoptosis. Other studies have identified gastric pentadecapeptide BPC 157, a novel antiinflammatory used in the treatment of inflammatory bowel disease, to improve Achilles tendon-to-surface bone healing and tissue regeneration in a rat Achilles tendon model.[48]

The impact of inflammatory response suppression, however, has not been uniformly favorable for tendon-bone healing. Cohen and associates[16] evaluated the effect of antiinflammatory medications indomethacin and celecoxib, selective cyclooxygenase 2 (COX-2) inhibitors, on tendon-bone healing in a rat rotator cuff model. The treated group was found to have histologic and biomechanically inferior tendon-bone interfaces at both 4 and 8 weeks relative to controls (Fig. 5-7).

These studies indicate that the acute inflammatory response that ensues after ACL reconstruction is highly complex and remains to be further defined. Selective reduction in inflammatory mediator expression, improved angiogenesis, and improved tissue regeneration may promote formation of a native tendon-bone insertion over scar tissue formation. However, a dichotomy exists because other elements of the inflammatory response are necessary in the postnatal organism to initiate the tissue healing response and allow for an efficient graft interface remodeling process.

Modulation of Bone Ingrowth

Bone ingrowth plays a critical role in the later stages of tendon-bone healing after ACL reconstruction and is ultimately responsible for the improved biomechanical properties after healing is complete. Animal studies have provided strong evidence to support that increased bone ingrowth positively correlates with graft-bone fixation strength.[89] The primary strategies that have been employed include use of osteoinductive agents, osteoconductive agents, and modulation of osteoclast activity.

Osteoinductive agents, particularly from the bone morphogenic protein (BMP) family, have been shown to promote ingrowth of bone from the tunnel into the soft tissue graft. Rodeo and coworkers[89] delivered recombinant human BMP-2 (rh-BMP-2) on an absorbable type I collagen sponge in a canine tendon-bone model. At all time points, the rh-BMP–2 treated limbs healed with increased bone formation around the tendon. Biomechanical testing demonstrated higher tendon pull-out strength in the treated limbs relative to controls at 2 weeks. Ma and colleagues[53] delivered rh-BMP-2 in an injectable calcium phosphate matrix to the bone tunnel in a rabbit ACL reconstruction model. Histologic analysis revealed a dose-dependent increase in bone formation at the tendon-bone interface and significantly narrower tunnel diameters (15% to 45%) relative to the control group. Increased construct stiffness was also seen in the treatment group at 8 weeks postoperatively.[53] Martinek and associates[56] transected semitendinosus grafts in vitro with adenovirus-BMP-2 (Ad-BMP-2) and compared them with untreated controls in a rabbit ACL reconstruction model. These investigators demonstrated the formation of a fibrocartilaginous interface at the tendon-bone junction in the experimental group that was absent in the controls. Both stiffness and load-to-failure parameters were superior in the treatment group at 8 weeks. BMP-7 has also been shown to improve bone formation at the tendon-bone interface

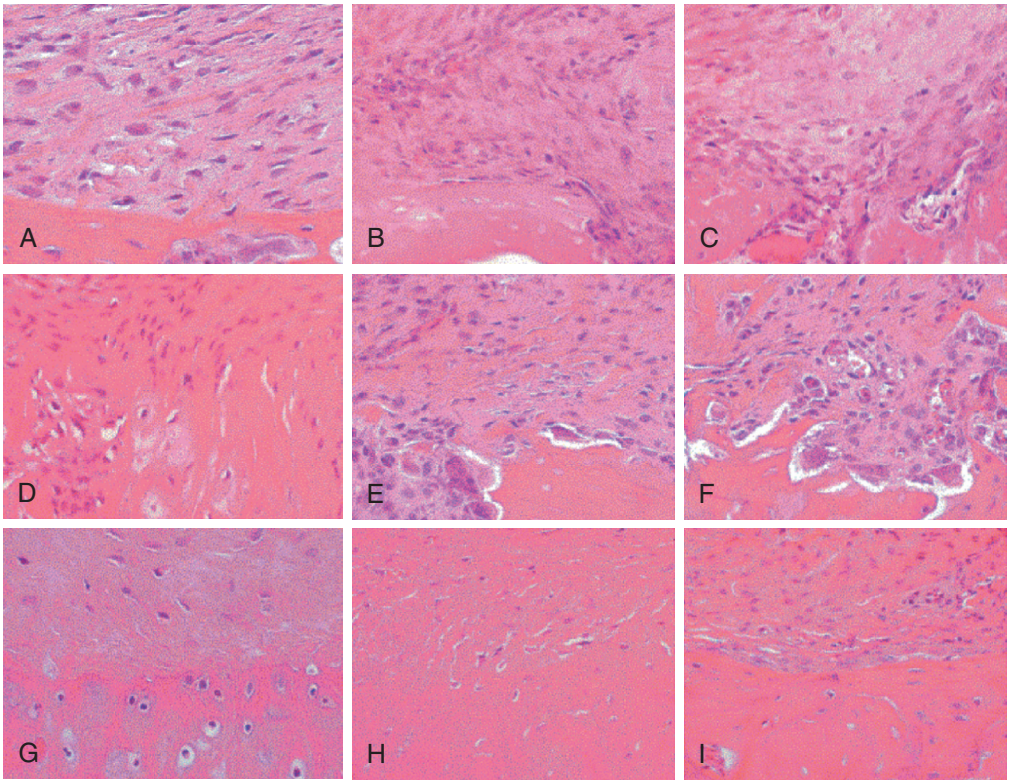

FIG 5-7 Photomicrograph demonstrating tendon-bone insertion site at 2 weeks (**A,** control group; **B,** celecoxib group; **C,** indomethacin group), 4 weeks (**D,** control group; **E,** celecoxib group; **F,** indomethacin group), and 8 weeks (**G,** control group; **H,** celecoxib group; **I,** indomethacin group) after surgery (hematoxylin-eosin, ×320). and load-to-failure at both 3 and 6 weeks postoperatively in an ovine reconstruction model.[1,61]

Further support for the role of BMPs in bone ingrowth around tendon graft comes from studies of BMP inhibition. Ma and colleagues[53] delivered noggin, a potent inhibitor of all BMP activity, to the healing tendon-bone interface using an injectable calcium phosphate matrix in a rabbit ACL reconstruction model. Noggin significantly inhibited new bone formation at the tendon-bone interface. Furthermore, a significant increase in the width of the fibrous tissue interface between tendon and bone was found in the noggin-treated animals (Fig. 5-8).

The favorable effect of osteoinductive agents on tendon-bone healing in a tunnel is further supported by studies that have used tendons wrapped in periosteum. Transplantation of a long digital extensor tendon wrapped in periosteum into a tunnel in the proximal tibia were compared with controls in a rabbit model.[14,80] Improved biomechanical strength, along with bone and fibrocartilage formation at the tendon-bone interface, was ultimately demonstrated in the treated animals at 8 and 12 weeks. Ohtera and colleagues[80] completed further studies comparing fresh and frozen periosteum and demonstrated better histologic and biomechanical outcomes using fresh periosteal wraps. These findings support the hypothesis that the viable osteoinductive factors in the periosteum may contribute to the improved outcomes.

Osteoconductive agents have also produced favorable outcomes in animal models. Calcium-phosphate (CaP)-hybridized grafts used in a rabbit ACL reconstruction model demonstrated improved fibrocartilage and bone formation relative to animals treated with unhybridized

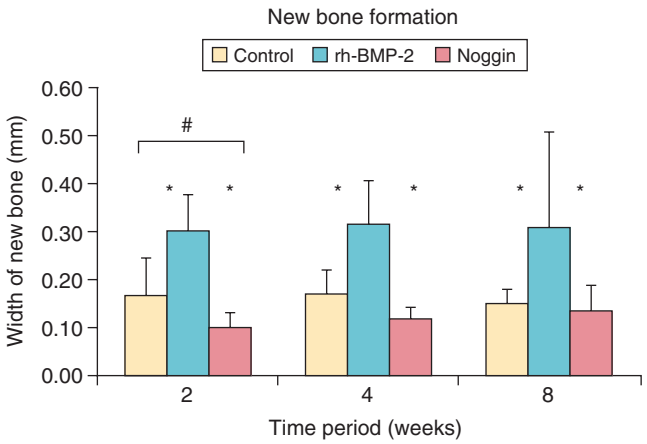

FIG 5-8 The width of new bone formation (mm ± standard deviation) at the tunnel-graft interface after anterior cruciate ligament reconstruction in a rabbit model. *Asterisks* represent significant differences compared with the rh-BMP-2 group ($P < .05$). #Represents significant differences compared with the control group ($P < .05$). For each dosage of rh-BMP-2 and noggin test, 4 rabbit limbs were used for histomorphometric analysis. (Modified from Ma C, Kawamura S, Deng X, et al. BMP-signaling plays a role in tendon-to-bone healing: A study of rhBMP-2 and noggin. *Am J Sports Med.* 2007;35:597-604.)

grafts at 3 weeks postoperatively.[73] Furthermore, Tien and coworkers[99] used injectable CaP cement in the femoral tunnel of a rabbit ACL reconstruction model and reported improved bone formation and biomechanical strengths relative to controls at 1 and 2 weeks postoperatively.

Modulation of osteoclast activity in the bone tunnel is another technique of promoting bone formation at the tendon-bone interface. Furthermore, inhibition of osteoclast-mediated bone resorption offers a potential means by which to limit the bone tunnel expansion commonly seen after ACL reconstruction. One study demonstrated that increased knee laxity correlated with radiographic tunnel widening after ACL reconstruction using hamstring tendon.[33] The role of osteoclastic bone resorption on tendon-bone healing has been evaluated in a rabbit ACL reconstruction model.[20] Osteoprotegerin (OPG), a potent inhibitor of osteoclast activity, or receptor activator of nuclear factor κB ligand (RANKL), a potent stimulant of osteoclast formation, were delivered to the bone tunnels around a tendon graft using a CaP carrier matrix. A significantly greater amount of bone surrounding the tendon at the interface was seen in the OPG-treated limbs relative to controls and RANKL-treated limbs at all time points (Fig. 5-9).[20] Furthermore, biomechanical testing at 8 weeks demonstrated significantly increased stiffness of the femur-graft-tibia complex in the OPG-treated limbs compared with the RANKL-treated limbs.

Stem Cells

Undifferentiated, pluripotent mesenchymal cells (MSC), also termed *stem cells,* may be critical to stimulate tissue regeneration rather than scar formation at the tendon-bone interface. These cells retain the capacity to differentiate into various specialized cell types based on biologic signals in the local environment. Therapeutic use of these cells has been investigated for numerous clinical conditions in the field of orthopedics, and cell lines can be derived from various sources (bone marrow, adipose tissue, synovium, etc.). Animal studies have tested the effects of local stem cell delivery on tendon-bone healing. Rabbit bone marrow stromal cells placed in a fibrin glue carrier were delivered to the tendon-bone interface of the hallucis longus tendon in a calcaneal tunnel.[82] Histologic analysis revealed improved healing with fibrocartilaginous attachment between tendon and bone in the experimental group. Lim and associates[52] performed bilateral ACL reconstructions in a rabbit model and evaluated the role of mesenchymal stem cells on the tendon-bone interface. The grafts coated with MSC demonstrated cartilage at the tendon-bone interface, whereas only fibrous tissue was observed at the interface in the contralateral control limbs. The interface stained positively for type II collagen in the MSC-treated grafts, and was similar in organization to a native, direct ligament insertion. Furthermore, biomechanical testing at 8 weeks demonstrated higher loads to failure and stiffness relative to controls. More recent studies have demonstrated improved efficiency in collagen organization with the use of MSCs, and have even demonstrated the presence of pluripotent-like ($CD34^+$) cells in the substance of the ruptured ligament.[44,60]

Further work is required to determine the mechanism by which pluripotent stem cells enhance tendon-bone healing. It is unknown whether these cells differentiate into fibrochondrocytes (i.e., the ultimate fate of these cells) or if they produce cytokines that improve insertion site organization and tissue regeneration. It is likely that optimal use of cellular therapy will require concomitant delivery of growth factors to produce a regenerative healing response at the tendon-bone interface.

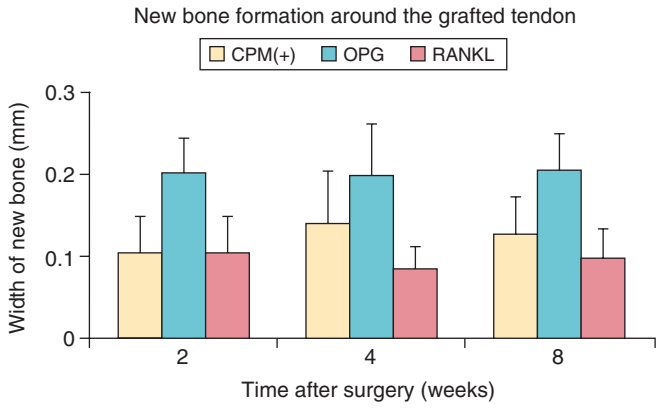

FIG 5-9 Fifteen New Zealand white rabbits underwent unilateral anterior cruciate ligament reconstruction using an autologous semitendinosus tendon graft. Animals treated with 100 μg osteoprotegerin (OPG) had a significant ($P = .007$) increase in newly formed bone around the graft compared with the control group (0.16 ± 0.01 mm^2 vs. 0.06 ± 0.02 mm^2). *CPM,* Calcium phosphate matrix; *RANKL,* receptor activator of nuclear factor κB ligand. (Modified from Rodeo SA, Kawamura S, Ma CB, et al. The effect of osteoclastic activity on tendon-to-bone healing: an experimental study in rabbits. *J Bone Joint Surg Am* 2007;89: 2250-2259.)

Modulation of Vascularity

Whereas vascularity is critical for the efficient delivery of oxygen and nutrients to support tissue healing, the precise role of local vascularity at the tendon-bone interface remains to be defined. Krivic and colleagues[48] demonstrated improved vascularity at the healing Achilles tendon-bone interface after treatment with gastric pentadecapeptide BPC 157 in a rat model. This improved vascularity correlated with favorable histologic and biomechanical properties of the tendon-bone interface. In contrast, a recent study examined the effect of VEGF on graft healing in an ovine ACL reconstruction model.[107] Although vascularity and cellularity were increased in the VEGF-soaked grafts relative to controls, the stiffness of the femur-graft-tibia complex was significantly inferior to controls at 3 months. Even though only a single concentration of VEGF was used, the results suggest the possibility that excessive vascularity may adversely affect healing and the biomechanical properties of the tendon-bone interface.[107]

Modulation of Matrix Metalloproteinases

The MMPs are a family of zinc-dependent endoproteinases that play a critical role in tissue degradation, healing, and normal remodeling. They function in both an extracellular environment and through transmembrane and intracytoplasmic domains.[19] Inflammatory cytokines such as interleukin-1 (IL-1) and tumor necrosis factor (TNF) initiate the transcription and activation of MMPs from their zymogen form. Their catabolic, destructive activity is balanced, however, by tissue inhibitors of TIMPs. TIMPs provide a check-and-balance mechanism to control the activity of these degradative enzymes and thereby maintain homeostasis of extracellular matrix formation and degradation that occurs with tissue remodeling.[26]

Synovial fluid tracking between the graft and tunnel walls after ACL reconstruction is known to contain large amounts of collagenase and stromelysin. It has been theorized that MMPs may have adverse effects on the tendon-bone interface, perhaps by limiting the formation of Sharpey-like collagen fibers. Demirag and coworkers[19] used α_2-macroglobulin (A2 M), an endogenous inhibitor of matrix metalloproteinases, to study this hypothesis in a rabbit ACL reconstruction model. Each rabbit underwent bilateral ACL reconstruction with hamstring autograft. A2 M was injected into one knee postoperatively and was compared with the contralateral control limb. The interface tissue

in treated specimens was more mature with significantly greater Sharpey-like fibers. Biomechanical studies demonstrated greater load to failure compared with controls at 2 and 5 weeks (Fig. 5-10).[19] This work was further substantiated by Bedi and colleagues,[10] who demonstrated A2 M improved fibrocartilage formation at the site of healing tendon. The answer is likely somewhere in the middle ground as the importance of MMP-2 mediation has been recently elucidated as a reason for in vitro cell migration in the ruptured ACL.[103] Further studies are necessary to characterize the precise mechanism of action of MMPs at the tendon-bone interface. Nonetheless, this work provides preliminary evidence that modulation of MMP activity may improve graft-bone healing in a bone tunnel.

Modulation of Nitric Oxide

Nitric oxide is a free radical agent synthesized by nitric oxide synthase from L-arginine. It acts as a regulatory molecule both in cells and in the extracellular matrix. Studies have shown that it is induced during tendon healing in vitro, with a dose-dependent effect on fibroblast collagen production.[71,72] ACL ligament fibroblasts are uniquely able to produce more nitric oxide compared with other local fibroblasts, including those derived from the medial collateral ligament (MCL).[62] Limited research exists defining the exact role behind the potential beneficial effects of nitric oxide. Therapeutic delivery of nitric oxide has demonstrated improved collagen organization in the healing tendon, with improved biomechanical properties compared with controls, and likely works via improving blood flow to the healing site.[12] The influence of nitric oxide levels, specifically in regard to tendon-bone healing after ACL reconstruction, remains to be defined.

Effect of Hyperbaric Oxygen

Yeh and associates[106] studied the influence of hyperbaric oxygen (HBO) therapy on the graft-bone tunnel interface in a rabbit model. The HBO group was exposed to 100% oxygen at 2.5-atm pressure for 2 hours daily, 5 consecutive days a week. The control group was exposed to normal air. The HBO group demonstrated increased neovascularization and an increased number of Sharpey fibers relative to controls. Furthermore, the HBO group achieved higher maximal pull-out strengths at 12 and 18 weeks relative to control specimens.[106] Although the mechanism of action is unclear, these preliminary results suggest that HBO therapy may improve tendon-bone healing after ACL reconstruction.

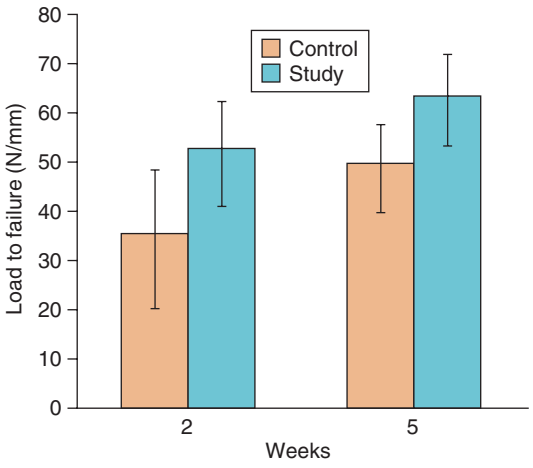

FIG 5-10 The ultimate load to failure was significantly greater in the α_2-macroglobulin–treated specimens than in the untreated control specimens at both 2 and 5 weeks ($P = .007$ and $P = .006$, respectively). (Modified from Demirag B, Sarisozen B, Durak K, et al. The effect of alpha-2 macroglobulin on the healing of ruptured anterior cruciate ligament in rabbits. *Connect Tissue Res.* 2004;45[1]:23-27.)

Modulation of Other Biologic Mediators

Future techniques to enhance tendon-bone healing after ACL reconstruction will be directed by an improved understanding of the biology of this healing process. Use of cytokines to provide important signals for tissue formation and differentiation, gene therapy techniques to provide sustained cytokine delivery, the use of stem cells, or transcription factors to modulate endogenous gene expression represent some of these possibilities. *Scleraxis*, a transcription factor expressed in mesenchymal tendon progenitor cells, Indian hedgehog, a factor involved in growth plate and limb development, and *Sox-9*, a transcription factor that is critical for chondrogenesis, are examples of proteins that may play key roles in native tendon insertion site formation.

BONE-TO-BONE HEALING IN ACL AUTOGRAFT RECONSTRUCTION

Healing of a bone plug to the osseous tunnel walls after autograft ACL reconstruction is unique and unlike anywhere else in the body. The biomechanic and biologic environment in the graft tunnels present significant challenges to union.

The sequence of bone-tendon-bone autograft incorporation has been defined in animal models. Tomita and colleagues[100] compared healing of a soft tissue graft to a bone-patellar tendon-bone (B-PT-B) autograft in a canine model. The bone plug undergoes osteonecrosis and is gradually replaced by a process of creeping substitution (Fig. 5-11). Newly formed bone surrounding the plug is seen at 3 weeks. These investigators found pull-out strength of the B-PT-B graft to be superior to the soft tissue graft at 3 weeks, but not significantly different at 6 weeks. At 6 weeks, a change in the point of failure was noted from the graft-tunnel interface to the tendon-bone plug interface. Papageorgiou and coworkers[85] directly compared tendon-bone to bone-bone healing in a goat model. Bone-patellar tendon autografts were harvested; the soft tissue graft was placed in the tibial tunnel while the bone plug was secured in the femoral tunnel. Biomechanical testing at 3 weeks demonstrated universal failure of the tendon-bone interface with pull-out from the tibial tunnel. At 6 weeks, however, approximately 20% of cases demonstrated mid substance failures. The remaining cases continued to be tibial tunnel graft pull-out. Histologic evaluation at 3 weeks confirmed creeping substitution with a necrotic bone plug surrounded by granulation tissue. Evaluation at 6 weeks revealed complete plug incorporation with bridging cancellous bone.[85]

Synovial fluid flows from the joint into the tunnels and can interfere with healing at the tendon-bone interface. The high quantities of MMPs and other proteolytic enzymes in synovial fluid can slow bone tendon-bone and bone-bone healing. Berg and associates[11] evaluated

CRITICAL POINTS Bone-to-Bone Healing After ACL Autograft Reconstruction

- The process of bone plug incorporation after ACL reconstruction is complex and is characterized by osteonecrosis followed by creeping substitution and new host bone formation.
- Synovial fluid flow into the bone tunnels may interfere with healing at the tendon-bone interface.
- Regardless of whether a soft tissue or bone-tendon-bone graft is used, the critical healing at the intraarticular aperture that must occur to minimize graft micromotion usually requires tendon-bone healing.

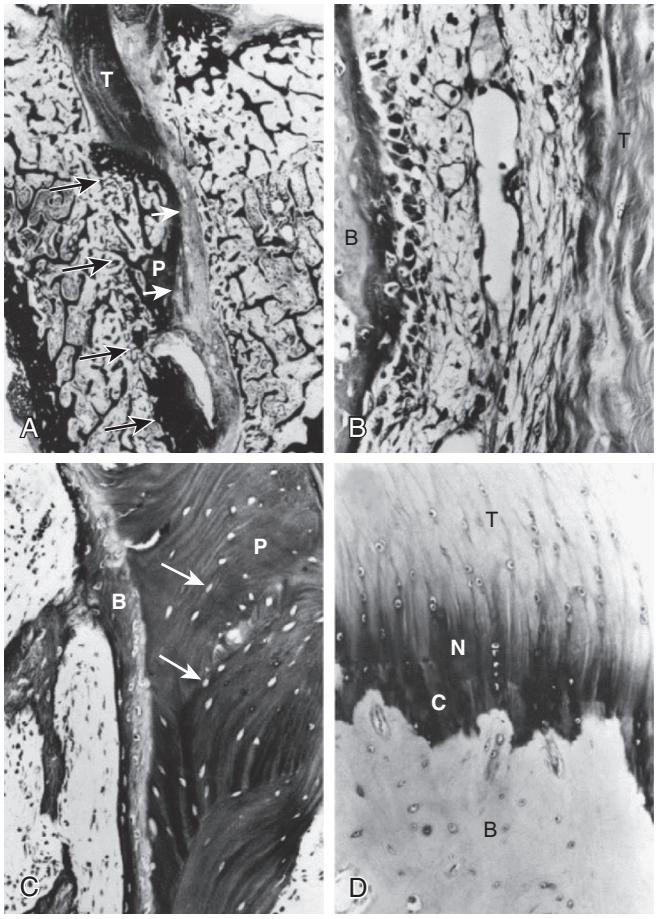

FIG 5-11 Healing of a bone-patellar tendon-bone (B-PT-B) autograft in a canine model. The bone plug undergoes osteonecrosis and is gradually replaced by a process of creeping substitution. In the bone plug of the B-PT-B graft, a number of empty lacunae (*white arrows*) indicate bone necrosis, except at the superficial portion of the plug. *B,* Bone wall; *C,* calcified fibrocartilage; *N,* noncalcified fibrocartilage; *P,* bone plug of the B-PT-B graft; *T,* patellar tendon. (From Tomita F, Yasuda K, Mikami S, et al. Comparisons of intraosseous graft healing between the doubled flexor tendon graft and the bone-patellar tendon-bone graft in anterior cruciate ligament reconstruction. *Arthroscopy.* 2001;17: 461-476.)

the role of synovial fluid by drilling femoral and tibial tunnels and leaving them empty in a rabbit ACL model. These authors found that healing occurred most rapidly at points farthest away from the joint, whereas the slowest and most incomplete regions of healing were at the tunnel apertures. These findings are suggestive of a possible inhibitory effect of synovial fluid on healing in the tunnel.

It is critical to remember that regardless of whether a soft tissue or bone-tendon-bone graft is used, the critical aperture fixation will usually require tendon-bone healing. The tendon length of a B-PT-B graft exceeds the native ACL length, such that a substantial portion of the tunnel, including the aperture zone, will contain tendon. Tendon-bone healing at the aperture, regardless of graft choice, is essential to minimize graft micromotion and subsequent risk of tunnel widening.

INTRAARTICULAR GRAFT HEALING IN ACL AUTOGRAFT RECONSTRUCTION

Ligamentization refers to the complex process of biologic incorporation and remodeling of the tendon graft that occurs after ACL

CRITICAL POINTS Intraarticular Graft Healing in ACL Autograft Reconstruction

- Intraarticular graft healing occurs by a process of remodeling that is dependent on revascularization and cellular repopulation from the host synovium.
- The incorporated graft does not achieve the organization or vascularity of the native ACL.

reconstruction. Animal studies have attempted to define the phases of intraarticular graft healing that occur postoperatively. The graft goes through an initial phase of avascular necrosis. At 2 weeks, the graft demonstrates patches of necrosis, although the collagen architecture and scaffold remain intact.[3,5,47,84] By 4 weeks, the graft is almost entirely avascular and acellular. This phase, however, is followed by cellular repopulation from the host synovial cells. Biopsy at 3 months reveals extensive vascular proliferation and cellular repopulation. By 9 months, the graft histologically resembles the native ligament.[3,5,47,84]

However, it should be noted that our understanding of the process of revascularization and graft incorporation is based on animal models, which have distinct limitations. For various reasons, it is very difficult to stabilize the animal knee with ACL reconstruction. Consequently, most animal models of ACL reconstruction have graft laxity, which may affect graft biology. It is known that stress deprivation in fibrous connective tissue (which would occur in a lax, unstressed graft) leads to upregulation of MMPs, which adversely affect the matrix. It is clear that further studies are required to fully elucidate the process of graft revascularization, incorporation, and remodeling.

Intraarticular healing has been studied in other animal models. Oaks and colleagues[79] demonstrated remodeling occurred from the periphery toward the graft center. This was associated with a change from large-diameter to small-diameter collagen fibrils. This pattern of remodeling supports the hypothesis that healing is dependent on gradual revascularization and cellular repopulation from the host synovium. Arnoczky and coworkers[5] evaluated patellar tendon graft revascularization in a canine model. Initially the grafts were avascular, but by 6 weeks they were completely ensheathed in a vascular synovial envelope. The soft tissues of the infrapatellar fat pad, the tibial remnant of the ACL, and the posterior synovial tissues contributed to this synovial vasculature. Intrinsic revascularization of the patellar tendon graft progressed from the proximal and distal portions of the graft centrally.[5] The tibial attachment of the patellar tendon graft did not contribute any vessels to the revascularization process. The contribution of the soft tissues of the knee to the revascularization process of the graft emphasized the importance of their preservation in maintaining the graft's viability. Recent advanced imaging studies in humans have confirmed that graft revascularization occurs in a gradual fashion. Ntoulia and coworkers[78] demonstrated with contrast-enhanced magnetic resonance imaging that the intraarticular portion of the graft successfully revascularized before the attachment sites, which was still displaying uptake at the 12-month postoperative mark.

Although animal models have provided insight into the process of ligamentization, the process has not been fully characterized in humans. Jackson and associates[41] concluded that an incorporated graft never replicates the native ACL, but rather functions like a checkrein of organized scar tissue. Delay and colleagues[18] described a case report of a B-PT-B autograft with avascular, acellular regions in the deep, distal graft, 18 months after reconstruction. Rougraff and Shelbourne[91] performed patellar tendon graft biopsies on nine subjects 3 to 8 weeks after autogenous ACL reconstruction. Graft vascularity was present at 3 weeks and increased over the 8-week interval.

PRIMARY ACL HEALING AND REPAIR

Primary repair of the ACL after traumatic rupture was historically considered to be a viable surgical option. Outcome studies, however, reported unacceptable rates of failure after primary surgical repair.[21] In their classic study, Feagin and Curl[21] reported a 94% rate of instability in patients at 5-year follow-up after primary suture and drill hole ACL repair. Marshall and coworkers[55] reported a 20% to 40% failure rate despite repair using a sophisticated, multiple-depth suture technique. Zysk and Refior[110] also reported modest outcomes in a study of middle-aged patients who underwent primary ACL repair and recommended that open primary repair be abandoned in favor of autogenous tissue reconstruction or augmentation. These results were further corroborated by a Norwegian study that assessed long-term outcomes in a large series of patients who underwent primary ACL repair.[98] An open procedure using the original Palmer technique with nonabsorbable Bunnell sutures was performed in all cases. At 15 to 23 years postoperatively, 57% had greater than 3 mm of anterior translation on KT-1000 testing. The estimated rate of total failure was 27%. These results are in sharp contradistinction to the MCL, in which failure to primarily heal is the exception rather than the rule.

The poor rate of primary healing that is observed after ACL rupture is believed to be multifactorial in nature. One of the most salient factors is the intraarticular environment and synovial fluid that surrounds the ACL.[63,65-70,97] Studies by Murray and associates[63,65-70,97] demonstrated the differences in intraarticular (i.e., ACL) versus extraarticular (i.e., MCL) healing in a canine, central ACL wound model. An empty wound persists at the defect of an intraarticular ligament wound, whereas these wounds are rapidly filled with a fibrin-platelet scaffold in an extraarticular injury. This scaffold is critical to allow subsequent cellular repopulation, revascularization, and ligament remodeling into mature scar tissue. The presence of fibrinolysates in the joint prevents the formation of a stable fibrin clot that could serve as a provisional scaffold. The lack of a scaffold in the intraarticular ligament wounds was associated with decreased inflammatory cytokines needed for the healing response, including fibrinogen, PDGF, TGF-β, and FGF.[63,65-70,97] Studies by Murray and associates[63,65-70,97] demonstrated that replacement of the central intraarticular ligament void with a collagen-platelet-rich plasma scaffold resulted in increased filling of the wound with repair tissue that had similar profiles of protein expression to matched, extraarticular ligament wounds. Biomechanical studies of suture ACL repair augmented with a collagen-platelet–rich scaffold in a porcine model have shown significant improvement in load to failure and linear stiffness at 4 weeks compared with unaugmented, control repairs.[63,65-70,97] These studies support the concept of a bioenhanced repair, and a recent large animal model randomized trial demonstrated equivalent functional results in pigs treated with repair versus reconstruction. Importantly, 80% of those knees treated with reconstruction developed posttraumatic osteoarthritis, whereas none of the knees in the bioenhanced repair group developed osteoarthritis in the same time period.[102]

Other factors implicated in the poor ACL healing response included alterations in cellular metabolism after injury, cellular loss within the tissues after injury, and intrinsic differences in ACL fibroblasts compared with fibroblasts in extraarticular ligaments. Murray and associates[63,65-70,97] defined the histologic changes that occur after ACL rupture. The human ACL undergoes four histologic phases, consisting of inflammation, epiligamentous regeneration, proliferation, and remodeling (Fig. 5-12). Although similar to the response to injury in other dense connective tissues, major exceptions include (1) formation of an α-smooth muscle actin–expressing synovial cell layer on the surface of the ruptured ends, (2) the lack of any tissue bridging the rupture site, and (3) the presence of an epiligamentous reparative phase that lasts 8 to 12 weeks.[63,65-70,97] The biology involved in intraarticular ligament healing will need to be further defined to overcome the obstacles to long-term success with primary ACL repair.

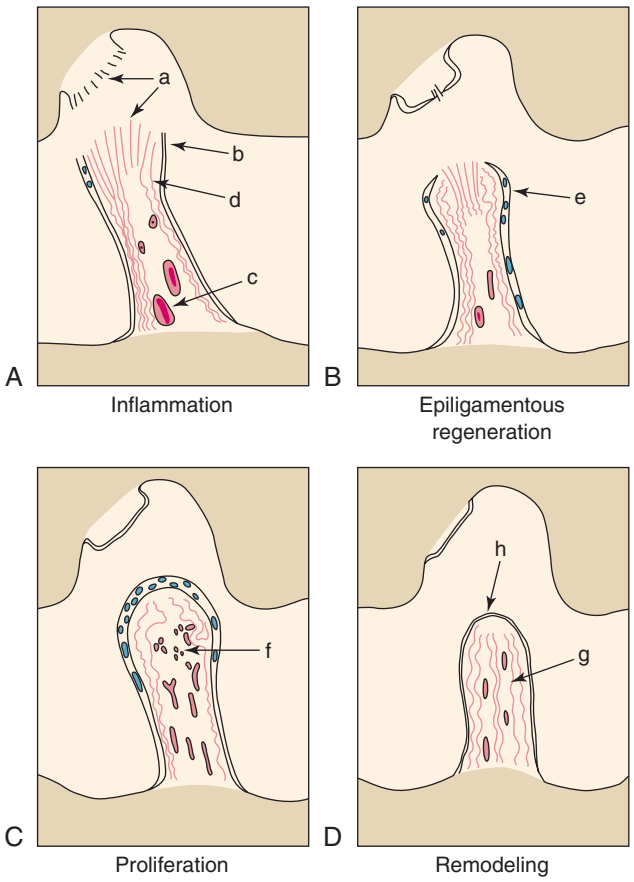

FIG 5-12 Schematic of the gross and histologic appearance of the four phases of the healing response in the human anterior cruciate ligament. **A,** The inflammatory phase, showing mop ends of the remnants *(a)*, disruption of the epiligament and synovial covering of the ligament *(b)*, intimal hyperplasia of the vessels *(c)*, and loss of the regular crimp structure near the site of injury *(d)*. **B,** The epiligamentous regeneration phase, involving a gradual recovery of the ligament remnant by vascularized, epiligamentous tissue and synovial tissue *(e)*. **C,** The proliferative phase, with revascularization of the remnant with groups of capillaries *(f)*. **D,** The remodeling and maturation phase, characterized by a decrease in cell number density and blood vessel density *(g)* and by retraction of the ligament remnant *(h)*. (Modified from Murray MM, Martin SD, Martin TL, Spector M. Histological changes in the human anterior cruciate ligament after rupture. *J Bone Joint Surg Am.* 2000;82-A:1387-1397.)

CRITICAL POINTS Primary ACL Healing and Repair

- Clinical outcomes studies have shown unacceptable rates of failure after primary ACL repair.
- The poor healing rate is believed to be multifactorial in nature, including an unfavorable, intraarticular biologic environment and altered cellular metabolism and function after injury.
- Augmentation with a collagen-platelet-rich plasma scaffold may offer future promise to improve healing after primary ligament repair.

ALLOGRAFT HEALING IN ACL RECONSTRUCTION

An increasing desire to avoid the morbidity of graft harvest and to reduce operative times has led to a dramatic increase in the use of allografts as an alternative graft source in primary ACL reconstruction.[7] Allografts are also frequently used in revision procedures or multiligament reconstruction procedures. Good clinical outcomes have been reported with allograft reconstructions at 2- to 5-year follow-up, and multiple studies have found no significant subjective or objective difference in knee function after allograft versus autograft ACL reconstructions.[8] However, other studies have reported less favorable results after allograft reconstruction, particularly in the setting of chronic or revision knee surgery,[76,77] and larger multicenter cohorts have echoed these observations.[35] A recent systematic review of overlapping metaanalyses reviewed eight studies with a total of 15,819 patients.[57] Approximately one half of the metaanalyses found no differences in patient outcomes between autograft and allograft, whereas the other half concluded autografts produced better outcomes. Because the first half included studies with higher level of evidence, the authors concluded that the current evidence shows no differences in rupture rate and clinical outcomes between autograft and allograft.[57] Important considerations regarding allograft preparation and processing are germane for the surgeon, as nonirradiated, nonchemically treated allografts have shown equivocal outcomes to autografts in regards to stability and function.[50] See also Chapters 7 and 8 for further discussion on clinical outcomes of ACL allograft and autograft reconstructions.

Despite compatible clinical outcomes, animal studies have shown that allografts have a slower rate of incorporation, prolonged inflammatory response, and greater initial decrease in biomechanical properties compared with autografts.[2-6,38-40,42,43,109] The phases of healing, although delayed, resemble those of the autograft. The tendon-bone interface develops a fibrovascular granulation tissue interface that eventually undergoes bone ingrowth and develops Sharpey-like anchoring fibers.[2-6,38,43,109] The intraarticular graft undergoes ligamentization with a phase of avascular necrosis followed by cellular repopulation and vascular proliferation from host synovium. Donor DNA was entirely replaced by host DNA within 4 weeks in a goat reconstruction model. Revascularization starts at 3 weeks and progresses gradually over the next several weeks. Jackson and colleagues compared healing of patellar tendon autografts with fresh allografts in a goat ACL reconstruction model.[2-6,38,43,109] Although graft structural properties were similar at time 0, the allografts healed at a much slower rate. At 6 months, the autografts demonstrated a superior load to failure, larger increase in graft cross-sectional area, and better restraint to anteroposterior displacement. The allografts demonstrated a significantly greater decrease in their preimplantation structural properties.

Human studies have supported these findings of slower allograft incorporation. At 2 years postoperatively, biopsy studies have shown that the central portion of allografts can be acellular.[36] Cellular repopulation of the entire graft was often seen only after 3 years or more after allograft reconstruction.[54]

Because of the relatively hypocellularity of tendon allografts and current sterilization techniques, the host immune response is relatively limited. Major histocompatibility complex antigens that incite a potent immune response are largely depleted. Matrix antigens, however, persist and can elicit an immune response that may contribute to the delayed incorporation and the pronounced alteration in structural properties after surgery.[90,104] The specific influences of such an immune response on the biology of ACL graft healing remains to be defined.

CRITICAL POINTS Allograft Healing in ACL Reconstruction

- Allografts demonstrate a slower rate of host incorporation, prolonged inflammatory response, and greater decrease in initial biomechanical properties than those of autograft in ACL reconstruction.
- Allografts have greater variability in clinical outcomes compared with autograft ACL reconstruction.
- Allografts have a higher failure rate when used for revision ACL reconstruction.

PLATELET-RICH PLASMA AS AN ADJUNCT TO IMPROVED HEALING

Platelet-rich plasma (PRP) has been evaluated as an adjunct to improve healing after primary repair of the ACL and after ACL graft reconstruction. Growth factors present in PRP have been found to stimulate proliferation and migration of ACL fibroblasts.[59] PRP alone does not improve healing of the ACL after primary repair, likely because of rapid degradation of fibrin in the PRP from the presence of plasmin in the joint. However, the combination of PRP with collagen to form a scaffold is resistant to degradation by plasmin, and the use of a composite collagen-platelet concentrate has been reported to improve healing after primary repair of the ACL in a porcine model.[64] In this model, Murray and associates[64] performed primary ACL repair that was augmented with whole blood containing a physiologic concentration of platelets in a collagen-based scaffold. There was no significant difference in mechanical properties when the "bioenhanced" ACL repair was compared with ACL reconstruction using an allograft tendon at 3 months and 1 year after surgery. A notable finding was less cartilage degeneration at 1 year in the animals that underwent enhanced repair compared with animals that underwent ACL graft reconstruction. Further study is required to determine the optimal PRP formulation to stimulate primary healing of the ACL. In vitro and in vivo data currently suggest that the use of concentrations of platelets greater than 1X within extracellular matrix scaffolds may not be as effective at stimulating ACL healing at physiologic concentrations.[58] However, the inclusion of plasma with platelets has been found to improve ACL fibroblast collagen gene expression.[15]

PRP has also been evaluated for augmentation of ACL graft healing in animal models. Treatment of an ACL graft with a collagen-platelet composite resulted in improvement in graft tensile properties and reduced laxity in a porcine model.[23] Several studies have evaluated the use of PRP in ACL reconstruction in humans, using magnetic resonance imaging (MRI) to directly evaluate the ACL graft. In general, these clinical studies show that platelet concentrates may improve the rate at which grafts achieve low signal intensity on MRI or an improved ligament maturity index on histology[81]; however, no study showed an improvement in clinical or patient-oriented outcome at 2 years[74] or significantly improved bone-tendon healing.[22] Further study is necessary to determine the optimal platelet preparation and method of delivery in an effort to further explore the potential of PRP and blood products to improve ACL graft healing, revascularization, and incorporation.

CONCLUSION

This chapter presents the basic principles of the biology behind ACL reconstruction and reviews several potential techniques to improve graft healing. A sound understanding of the complex mechanism of tendon-to-bone healing offers new and exciting ways to manipulate

the chemical and molecular mediators of the inflammatory response and to ultimately improve on the quality of surgical and postoperative interventions.

Summary, 133

INTRODUCTION

The anterior cruciate ligament (ACL) plays an important role in stability of the knee primarily through its passive constraint to anterior tibial translation and tibial rotation. In addition, the ACL influences the dynamic function of the knee. For example, ambulatory changes have been associated with functional adaptations after loss of ACL function and after ACL reconstruction. The nature of these functional adaptations may be considered a potential functional marker for the ability to return to vigorous activities,[3,36,37] as well as for secondary degenerative cartilage changes after ACL injury.[7]

CRITICAL POINTS Introduction

The purpose of this chapter is:

- To develop some fundamental gait analysis principles.
- To illustrate the application of gait analysis to the issues related to the evaluation and treatment of ACL injury.
- To describe the cause and implications of a change in muscle-generated moments after ACL injury.
- To describe kinematic changes at the knee during walking and the association of kinematics changes with emergence of premature osteoarthritis after ACL injury.
- To describe the influence of the adduction moment on the progression of knee OA and its implication for ACL-deficient patients with concomitant varus knee alignment and lateral ligament laxity.

Differences in the manner in which patients adapt their gait characteristics to the loss of the ACL provide a possible explanation for the variable outcome after this injury. It is likely that some patients can dynamically adapt to the loss of an ACL, whereas others will not. The large variation in treatment selection and outcome[9,10] suggests a need for better methods of assessing the clinical and functional status of the patient after ACL rupture. Diagnostic methods for identifying a torn ACL have improved substantially; however, prognostic methods for assessing the probability of successful treatment are not yet available. Even quantitative laxity measurements obtained from devices such as the KT-1000 (MEDmetric) have not been predictive of clinical outcome.[51] Thus variability in dynamic adaptations achieved through alteration in the patterns of muscle firing[1,26,48] during a particular activity provides a possible explanation for the differences in outcome of patients after ACL injury.

The variable natural history in the progression of degenerative joint disease suggests that some patients make appropriate functional adaptations for the loss of the ACL. The nature of these functional adaptations can differ substantially among patients who present with the same clinical status. Thus, the ability to identify and understand the nature and cause of changes in ambulatory function, or specifically gait characteristics, is an important consideration in the evaluation and treatment of ACL injury.

This chapter discusses fundamental gait analysis principles and illustrates the application of gait analysis to the issues related to the evaluation and treatment of ACL injury. Specific examples are provided on the interaction between the passive function of the ACL and the change in muscle-generated moments, kinematics, and

the relationship between kinematic changes and the emergence of premature osteoarthritis (OA). In addition, the influence of specific characteristics of gait in ACL-deficient patients with concomitant varus lower limb malalignment and lateral and posterolateral ligament deficiency are described.

JOINT KINETICS DURING GAIT AND THE ACL-DEFICIENT KNEE

An analysis of the kinetics (forces and moments) that act at the knee during walking provides useful insight into the functional changes associated with the ACL-deficient knee. In particular, the moments that act at the knee suggest the cause and potential effect of gait changes after ACL injury. For example, a reduction in the intersegmental moment tending to flex the knee (balanced by net quadriceps contraction) during walking was among the first changes in walking mechanics reported in the ACL-deficient knee.[11] The reduction of the net internal quadriceps moment is consistent with quadriceps muscle atrophy, which is frequently reported after ACL injury[22] and helps to explain why it is difficult to restore quadriceps strength in these knees. Thus it is useful to examine the physical meaning and relevance of the intersegmental moment at the knee during walking. This section provides a summary of the methods used to determine the joint moments, an example of how to interpret the magnitude and pattern of the flexion-extension moment at the knee in context of the function of the knee flexors and extensors during ambulation, and an example of how an analysis of the flexion-extension moment during walking can provide insight into the functional role of the ACL.

When interpreting the findings presented in this chapter, it is important to first discuss the limitations of joint kinetic and kinematic measures made with marker-based optoelectronic gait analysis. All skin-based marker systems suffer from the fact that bony landmarks are typically identified via manual palpation; ultimately what is being measured is the motion of the skin and soft tissue overlying the bone rather than the bones themselves. Errors in palpation of anatomic landmarks propagate into incorrectly defined anatomic coordinate systems and can consequently cause substantial errors in the reported kinetic and kinematic measures. Further, motion of the skin relative to the bones during movement can also result in substantial errors; therefore strategies are often employed such as the use of redundant cluster marker sets and computational postprocessing techniques to minimize error caused by skin motion artifact.[15] Other techniques that can image the bones directly, such as fluoroscopy and high-speed radiography,[52] have the potential to be more accurate at examining tibiofemoral motion, but currently cannot capture the full gait cycle during overground walking and can encumber natural motion. Because studying tibiofemoral motion and loading during unencumbered walking is critical for understanding the function of the knee joint,[6] the error associated with skin markers has been considered an acceptable compromise for many applications.[4,6,7,41] The validity of using skin markers with robust correction techniques[15] is supported by studies that show associations between gait kinematics and other physical characteristics of the joint.[4,7,42]

CRITICAL POINTS Joint Kinetics During Gait and the ACL-Injured Knee

- The magnitude and phasing of the intersegmental flexion-extension moment during walking can be used to characterize normal gait.
- The intersegmental flexion moment is balanced by a net quadriceps muscle–generated moment.
- A reduction in the maximum external flexion moment during walking is common to patients after ACL injury and has been interpreted as a tendency to reduce the net internal quadriceps moment during walking.
- A reduction in the maximum quadriceps moment during walking is consistent with quadriceps muscle atrophy after ACL injury.
- Reduction in quadriceps contraction during walking can reduce the anterior force on the tibia generated by muscle contraction because the anterior angulation of the patellar ligament insertion angle (PLIA) causes an anterior force to be applied to the tibia when the quadriceps contracts.
- The anterior component of force produced by quadriceps muscle contraction during running and stair climbing is lower than during walking because the high quadriceps forces occur at higher knee flexion angles than those occurring during walking.
- Anatomic differences in the angle of insertion of the patellar ligament with the knee at full extension can explain individual differences in the magnitude of the reduction in the net quadriceps moment during walking after ACL injury.
- A reduction in the maximum external flexion moment during walking persists after ACL reconstruction and has been associated with a more vertical orientation of the ACL graft.

Definition of Intersegmental Moment

A *moment* is a vector quantity that can be considered a rotational force (lever arm × force) in the sense that it tends to produce a rotation about a specific point. Although moments can be calculated at any point, it is useful to use the joints between adjacent limb segments to define the moments that act on the body during walking. For example, the moment acting at the knee would be the intersegmental moment between the thigh and the shank. The external moment tending to flex or extend the joint is illustrated in Figure 6-1. The intersegmental moments are typically calculated from measurement of the foot-ground reaction forces (using a force platform) and the motion of markers placed on the limbs using an optoelectronic system for motion capture. The weight and inertial forces are often approximated by modeling the leg as a collection of rigid segments representing the

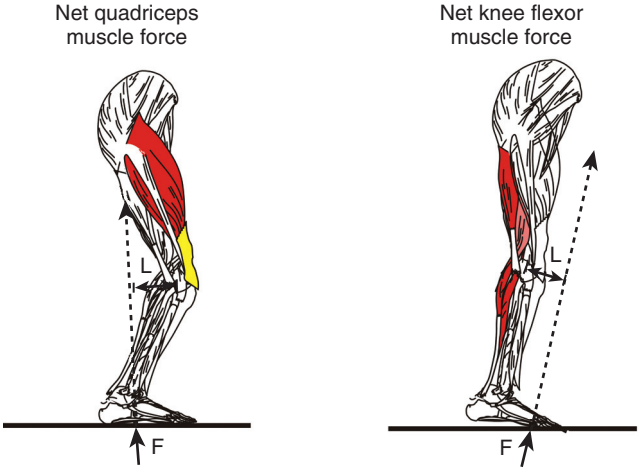

FIG 6-1 The intersegmental flexion-extension moment can be visualized by considering a ground reaction force vector that passes posterior to the knee will produce an external flexion moment that is balanced by a net internal quadriceps moment. When the vector passes anterior to the knee, an external extension moment is produced that must be balanced by a net internal flexor muscle moment. *F,* Ground reaction force; *L,* lever arm.

thigh, shank, and foot. The reader should be aware of the assumptions used in performing these calculations.[5] Finally, the units of a moment are force and length. Therefore, it is useful when comparing different-sized subjects to express the intersegmental moments in nondimensional units by dividing the moment by the subject's height (Ht) and body weight (BW). Thus moments measured during gait are often expressed in units of percentage of the product of the body weight and height (% BW × Ht), so that moments can be compared among subjects of different heights and weights.

Interpretation of Intersegmental Moment

The moment can be visualized in the context of the direction of the ground reaction vector relative to the position of the knee joint center (see Fig. 6-1). If the vector passes anterior to the knee, the moment will tend to extend the knee, whereas if the vector passes posterior to the knee, the moment will tend to flex the knee. As noted previously, the direction of the moment can be used to infer the net muscular moment. Thus an external moment tending to flex the knee will be balanced by a net quadriceps moment. Previous studies have demonstrated that the external moments measured can be interpreted in terms of the loads on muscles, passive soft tissue, and joint surfaces.[44] In addition, the joint moments have been shown to be sensitive indicators of differences between normal and abnormal function.[3,11,40]

It is useful to examine the assumptions used as the basis for the interpretation of the joint moments during function. Mechanical equilibrium dictates that external forces and moments must be balanced by internal forces and moments. Internal forces generated by muscle, passive soft tissue, and joint contact force create these internal moments. If muscles act only synergistically when balancing the external moments, one could directly infer the internal muscle force in synergistic muscle groups. For example, the total force in the quadriceps needed to balance an external moment tending to flex the knee joint could be determined.[44] However, if antagonistic muscle activity is present, the external moment reflects the net balance between agonist and antagonist muscles. The force in the synergistic muscle group would be greater under these conditions. The external moment can, however, be used to obtain a conservative estimate or lower bound on the synergist muscle force. Throughout this chapter, external moments are described from the measurements taken in the laboratory and inferences are made in terms of the net muscular moment (see Fig. 6-1).

Flexion-Extension Moment and the ACL-Deficient Knee

The normal temporal pattern of the flexion-extension moment during stance phase of walking can be interpreted in terms of the net quadriceps moment or net knee flexor muscle moment (hamstrings and/or gastrocnemius) during stance phase (Fig. 6-2). Typically, at heel strike, there is an external moment that tends to extend the knee joint, demanding a net knee flexor force. As the knee moves into mid stance, the external moment reverses its direction, demanding a net quadriceps force. As the knee passes midstance, the moment again reverses its direction, demanding net flexor muscle force. Finally, in the preswing phase, the moment tends to flex the knee, demanding a net quadriceps muscle force. As previously noted, a reduction of the net quadriceps moment relative to normal is frequently seen in ACL-deficient subjects during level walking (see Fig. 6-2). Specifically, ACL-deficient subjects walk in a manner that has been interpreted as a tendency to avoid or reduce the demand on the quadriceps muscle.[11] Although the reduction in net quadriceps moment can be interpreted as either a reduction in the quadriceps or an increase in the knee flexor muscle moment, the fact that quadriceps atrophy is a common finding after ACL injury[22] supports the conclusion of a reduction in quadriceps contraction during walking.

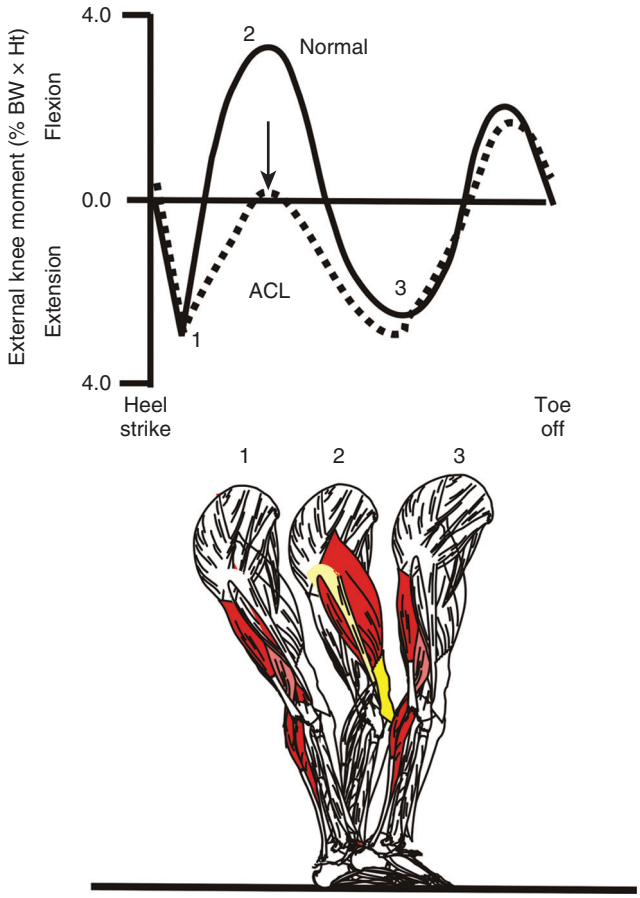

FIG 6-2 The pattern of the external flexion-extension moment during normal walking for anterior cruciate ligament (ACL)-deficient (*dashed line*) and normal (*solid line*) knees. Typically, patients with ACL-deficient knees have a reduced moment, tending to flex the knee (net quadriceps moment) during midstance. The figure of the leg indicates the position of the knee joint and the net muscular activation (*shaded area*) required to balance the external moment shown in the graph. *BW,* Body weight; *Ht,* height.

The mechanics of the knee extensor mechanism suggest a possible cause for the inhibition of quadriceps contraction during walking. As illustrated in Figure 6-3, the anterior angulation of the patellar ligament insertion angle (PLIA) causes an anterior force to be applied to the tibia when the quadriceps contracts. In the absence of the ACL, the tibia moves forward when the quadriceps contracts until the force is balanced by other secondary restraints to anterior tibial displacement, such as the medial collateral ligament, meniscus, or a hamstring contraction. Thus, more anterior tibial translation could occur in ACL-deficient knees than in uninjured knees when the quadriceps contracts. The amount of anterior force is greatest at full extension because the PLIA has the largest anterior angle at full extension and this angle reduces as the knee flexes.[18,32] Thus, walking would produce a substantial component of anterior force owing to quadriceps contraction because the knee remains near full extension throughout stance phase, with maximum flexion angles less than 30 degrees. A reduction in quadriceps contraction could eliminate large anterior tibial translations near full extension and prevent sensations of joint instability by the patient.

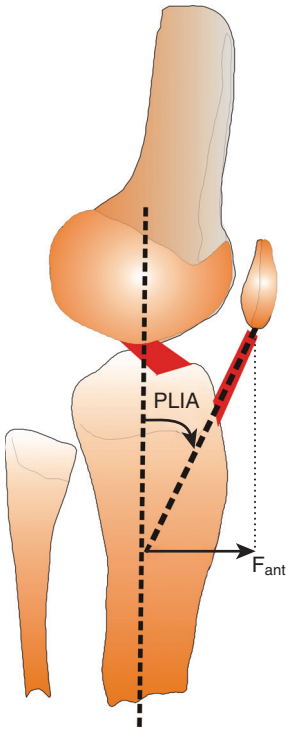

FIG 6-3 The line of action of the patellar ligament running from the posterior pole of the patella to the tibial tuberosity. The patellar ligament insertion angle *(PLIA)* is measured as the angle between the midshaft of the tibia and the line of action of the patellar ligament. With the knee in an extended position as shown, contraction of the quadriceps would transmit a relatively large anterior force *(F_{ant})* to the proximal tibia.

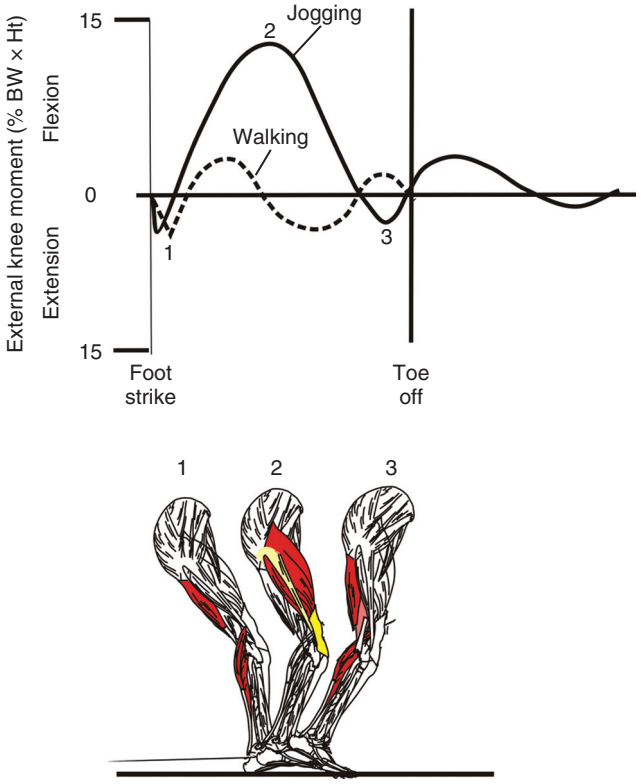

FIG 6-4 A comparison of the flexion-extension moments occurring during normal walking (*dashed line*) and jogging (*solid line*). The magnitude of the moment tending to flex the knee (net quadriceps moment) can be 5 times greater during jogging than during normal walking. *BW,* Body weight; *Ht,* height.

Interestingly, the magnitude of the net quadriceps moment can increase by more than a factor of 5 during jogging as compared with level walking (Fig. 6-4), yet the percentage change in the net quadriceps moment between ACL-deficient and normal subjects is substantially less during jogging than during walking.[11] The fact that the maximum net quadriceps moment during jogging occurs when the knee is at approximately 40 degrees of flexion, as compared with 20 degrees during level walking, might provide an explanation for the fact that patients with an ACL-deficient knee do not show a similar reduction in the net quadriceps moment during jogging compared with walking. Similarly, while ascending stairs, the maximum net quadriceps moment occurs at approximately 60 degrees of flexion and thus the amount of reduction in the net quadriceps moment is small compared with that during level walking. The adaptations during activities of daily living appear to be dependent on the angle of knee flexion when the greatest net quadriceps moment occurs. These observations suggest an interaction between the direction of pull of the patella ligament and the functional role of the ACL (Fig. 6-5). When the knee is near full extension, the patellar ligament places an anterior pull on the tibia. As the knee flexes beyond approximately 45 degrees, the orientation of the patellar ligament reverses direction during the quadriceps contraction and places a posterior pull on the tibia. At deeper flexion angles, the contraction of the quadriceps acts to compensate for an absent ACL.

Thus, during level walking, when the maximum net quadriceps moment occurs between 0 degrees and approximately 20 degrees, there is a greater tendency for the quadriceps contraction to produce an anterior pull on the tibia. The adaptation to avoid quadriceps contraction eliminates this anterior force component when the knee is near full extension (see Fig. 6-3).

Activity	Knee flexion angle	Patellar ligament orientation
	Angle at maximum quadriceps moment	AP component on tibia
Walking	20°	Anterior
Jogging	40°	Anterior
Stair climbing	60°	Posterior

FIG 6-5 The relationship between the knee flexion angle at which the maximum net quadriceps moment occurs during activities of daily living and the orientation of the patellar ligament relative to the tibia. As the knee moves from a relatively extended position (walking) to a more flexed position (stair climbing), the anteroposterior *(AP)* component of the patellar ligament shifts from an anterior orientation to a posterior orientation relative to the tibia.

Anatomy of the Extensor Mechanism and Quadriceps Inhibition

The variation in the amount of reduction in the net quadriceps moment during walking can be explained by anatomic differences in the anatomy of the extensor mechanism as defined by the PLIA (see Fig. 6-3). As noted previously, the PLIA is of particular importance to the knee extensor mechanism because it determines the decomposition of quadriceps force into anterior and superior directions (see Fig. 6-3) while transferring the quadriceps contraction to the tibia. Previous studies confirmed this relationship by showing that the patellar ligament pulls the tibia anteriorly when the knee is near full extension and also that anatomic variations exist between individuals in both PLIA and the moment arm of the patellar ligament.[18] Thus knees with larger PLIAs generate larger anterior forces on the tibia with the same level of quadriceps contraction.

More importantly, it has been shown that the PLIA negatively correlates to the peak knee flexion moment (balanced by net quadriceps moment) during walking in ACL-deficient knees,[49] whereas no correlation exists in uninjured contralateral knees of ACL-deficient patients (Fig. 6-6). The negative correlation between PLIA and the peak external knee flexion moment indicates that ACL-deficient knees with higher PLIAs significantly reduce usage of the quadriceps during walking. These results suggest that the subject-specific anatomy of the knee extensor mechanism provides a possible explanation for the variability[16] previously observed in adaptation of a quadriceps reduction strategy after ACL injury. This mechanism may explain the reduction in the external knee flexion moment, which is balanced by net quadriceps force, among ACL-deficient knees. This mechanism is further supported by the clinical observation of quadriceps atrophy in ACL-deficient subjects,[22] because reduced use of the quadriceps during walking should lead to muscle atrophy. However, the variability between individuals' adaptations to ACL injury suggests that other factors, such as PLIA, may influence which subjects adopt a strategy of quadriceps reduction.[14,36]

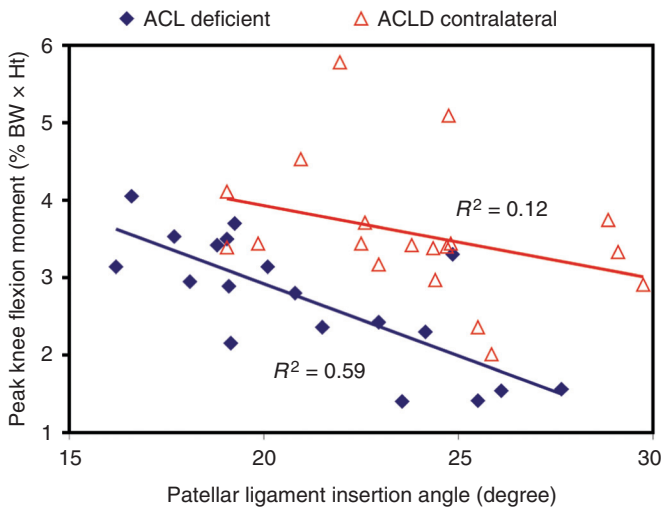

FIG 6-6 Anterior cruciate ligament (ACL)-deficient knees show a significant negative correlation between peak external knee flexion moment (net quadriceps moment) and patellar ligament insertion angle during normal walking. However, uninjured contralateral knees do not show a significant correlation. *ACLD,* Anterior cruciate ligament deficient; *BW,* body weight; *Ht,* height.

Flexion-Extension Moment and the ACL-Reconstructed Knee

Surgical reconstruction of the ACL has become well established as the standard of care for the ACL-injured knee. Given the primary function of the ACL as the passive restraint to anterior tibial translation, ACL reconstruction has been traditionally assessed based on its ability to restore anterior knee stability on static laxity tests and ultimately on its ability to return patients to high-performance activities.[8,47] However, considering the functional changes that commonly occur after ACL injury, it is important to also evaluate the surgical procedure based on its ability to successfully restore the salient features of normal ambulatory knee mechanics. As discussed previously, the knee flexion moment during walking (balanced by an internal quadriceps moment) represents a sensitive measure of joint function as it has been demonstrated to provide important insight into joint anatomy (i.e., PLIA), neuromuscular function, and dynamic tibiofemoral stability after ACL injury.[4,11,31] ACL reconstruction thus presents a unique subject population to reexamine this interaction among ACL anatomy, the knee extensor mechanism, and the adaptation of the net quadriceps moment during walking.

Differing from the ACL-deficient knee, the variation in the amount of reduction in the net quadriceps moment during walking in the ACL reconstructed knee was not related to differences in the anatomy of the extensor mechanism as defined by the PLIA.[50] The lack of relationship indicates that ACL-reconstructed knees with higher PLIAs do not significantly reduce usage of the quadriceps during walking. This finding agrees with the static laxity testing and suggests that the ACL reconstruction has restored the restraint to anterior translation because subjects no longer adapt their gait to reduce quadriceps usage in proportion to the anterior pull of the tibia through the patellar ligament. However, it has been shown that the magnitude of the knee flexion moment still remained significantly reduced in the ACL-reconstructed knees relative to the contralateral, though the reduction was no longer associated with the PLIA.[50] This indicates that there are other factors associated with the ACL reconstructed knee that prevent the full restoration of the quadriceps function during ambulation.

Although the PLIA was no longer directly related to the knee flexion moment, it is important to examine other structural factors in the ACL reconstructed knee that can have a significant influence on knee joint stability. Specifically, in vitro biomechanical investigations have demonstrated that postoperative tibiofemoral stability is sensitive to the 3-dimensional obliquity of the ACL graft.[27,45] Grafts that are placed with more vertical orientation relative to the orientation of the native ACL, particularly in the coronal plane, have reduced ability to resist the complex 3-dimensional loads that occur during dynamic activities such as walking. Thus, when the variability in knee flexion moment during walking after ACL reconstruction was investigated relative to the coronal obliquity of the single-bundle ACL graft in 17 subjects, a statistically significant relationship was observed (Fig. 6-7).[41] The relationship indicated that reconstructed knees with more vertical coronal graft orientation (less anatomic) were associated with a greater reduction in the knee flexion moment (balanced by internal quadriceps moment) during walking (1.0 m/s, $r = -0.866$, $P < .001$; 1.3 m/s, $r = -0.657$, $P = .004$). This finding suggests that as the ACL graft is placed in a more vertical coronal orientation, the capacity of the reconstruction to replicate the function of the native ACL is diminished, and the patient subconsciously adapts his or her gait to avoid joint instability in a manner consistent with complete ACL deficiency. Complete restoration of the 3-dimensional anatomy and function of the ACL during the ACL reconstruction procedure plays a critical role in the

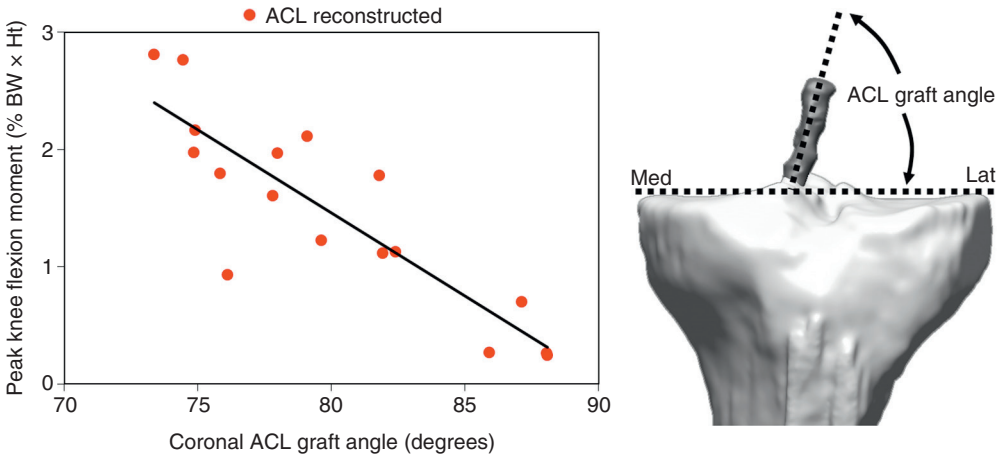

FIG 6-7 Anterior cruciate ligament *(ACL)*-reconstructed knees show a significant negative correlation between peak external knee flexion moment (net quadriceps moment) and coronal ACL graft angle during walking. ACL-reconstructed knees with a more vertical coronal orientation of the graft had a greater reduction in the peak external knee flexion moment. *BW,* Body weight; *Ht,* height.

return of normal ambulatory mechanics in the ACL-reconstructed knee.

KNEE KINEMATICS DURING WALKING AND ACL INJURY

The anatomy of the ACL suggests its potential role in determining the motion (kinematics) of the knee during ambulation. Clearly, passive function of the ACL for guiding motion and stabilizing the knee has been well documented. However, the analysis of the functional role of the ACL during dynamic in vivo ambulatory activities is more complex than for passive movements. The force generated by the ACL during passive stretch is relatively small compared with the magnitude of the muscle forces and extrinsic forces (load bearing) that occur during ambulation. Further, the ability to capture the movement of the knee under conditions that reflect natural movement remains a challenge. The kinematic role of the ACL during functional activities has been described for several weight-bearing activities.[4,17,25,52] The knee kinematics presented in this chapter focus primarily on walking. The kinematics of walking can provide valuable insights into the functional role of the ACL during locomotion.[6] Functional adaptation to the loss of the ACL can be detected during walking, because it has been suggested that patients can adapt patterns of locomotion that compensate for the loss of the ACL. In addition, walking is the most frequent ambulatory activity of daily living, and specific characteristics of this activity have been associated with cartilage thinning.[7,34] ACL rupture, regardless of whether it is reconstructed or not, has been identified as a significant risk factor for premature knee OA. This chapter focuses on the internal-external (IE) rotation and anteroposterior (AP) translation that occur at the knee during walking. These secondary movements (IE, AP) of the knee are directly related to the function of the ACL and have been shown to be altered in patients with ACL-deficient and ACL-reconstructed knees during walking for the reasons described previously.

Methods for Defining and Measuring Knee Kinematics During Walking

The kinematics of human movement during walking is normally described in terms of relative motion between adjacent limb segments (Fig. 6-8). In practice, human gait is most often described in terms of the sagittal plane motion (flexion-extension). This practice has come as a consequence of the much larger motions in this plane, making these motions relatively easy to measure and perhaps most relevant to function. However, the motion at the knee is more complex than other major joints of the lower extremity, involving all six degrees of freedom (three rotations and three translations). The complexity of the kinematic analysis substantially increases when going from a sagittal plane analysis to a complete 3-dimensional analysis. The appropriate interpretation of in vivo kinematic measurements requires a precise and physically meaningful definition of anatomic references. For the

CRITICAL POINTS Knee Kinematics During Walking and ACL Injury

- The motion (kinematics) of the knee is complex, and normal motion requires critical secondary movements of AP and IE rotation.
- The characteristics of the AP translation and IE rotation during walking provide a useful basis for understanding the pathomechanics of kinematic changes associated with the loss of the ACL.
- The swing phase of repetitive activities such as walking can provide useful insight into the functional role of the ACL because the passive force capacity of the ACL can have a substantial influence on the knee motion during non–weight-bearing, whereas extrinsic forces and muscle forces dominate knee motion during the stance phase.
- The tibia translates forward and externally rotates as it extends during the terminal portion of swing phase in preparation for heel-strike positioning the tibia at an anterior position and in external rotation at heel strike.
- The normal external rotation and anterior translation of the tibia that occur as the knee extends during terminal swing is reduced in the absence of the ACL, and the tibia maintains this offset relative to normal throughout the stance phase of the walking cycle.
- Following ACL reconstruction, alterations in rotational motion of the knee remain, with the tibia tending to be more externally rotated throughout the stance phase of the walking cycle.
- The kinematic changes at the knee after ACL injury have been implicated as a factor in the cause of premature OA by shifting joint contact to regions in the cartilage that cannot adapt to the changes in the repetitive loads that occur during walking.

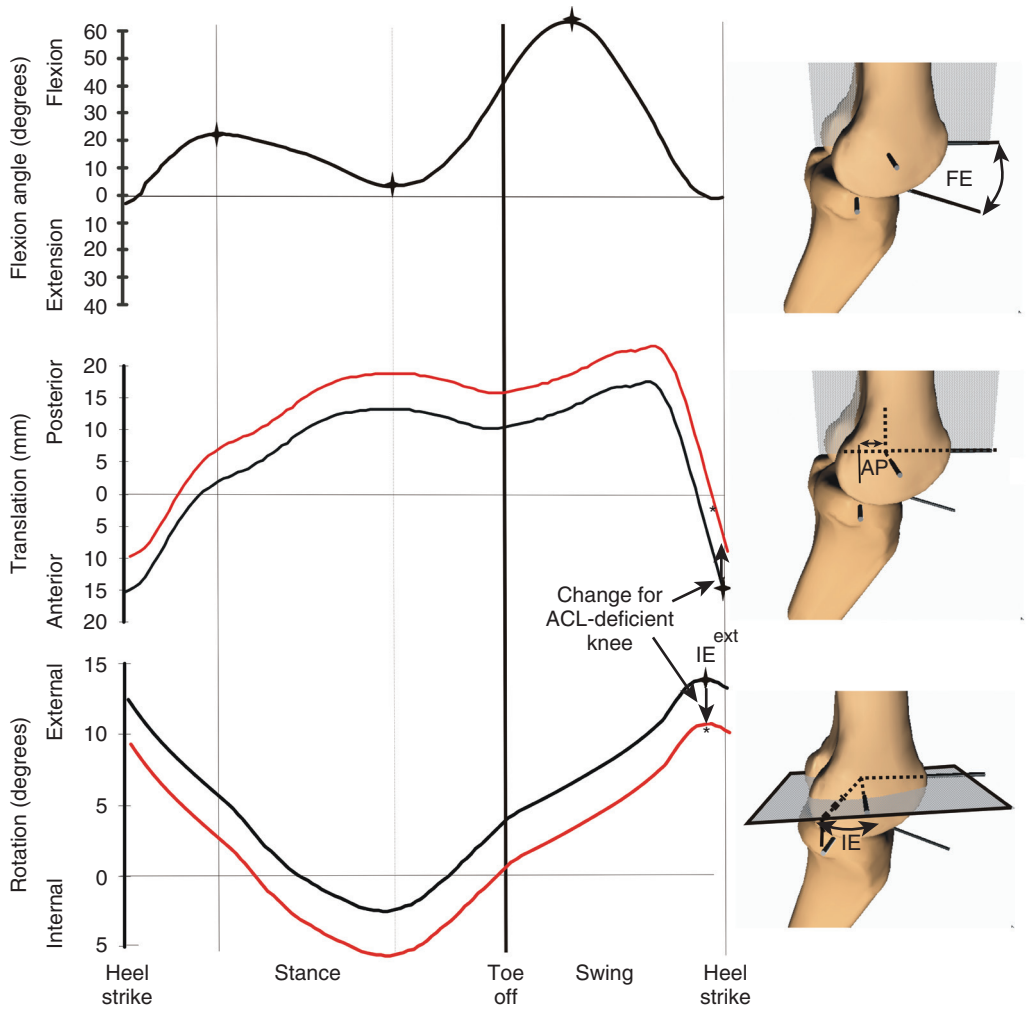

FIG 6-8 The flexion-extension, anterior-posterior, and internal-external motions of the knee that occur during normal walking (expressed as the position of the tibia relative to the femur) for normal (*black line*) and anterior cruciate ligament *(ACL)*-deficient (*red line*) knees. The kinematic changes in the ACL-deficient knee are characterized by a posterior translation offset and an internal rotation offset.

kinematics described in this chapter, the anatomic femoral coordinate system was located at the midpoint of the transepicondylar line of the distal femur, and the anatomic tibial coordinate system was set at the midpoint of a line connecting the medial and the lateral points of the tibial plateau. The AP translation was determined by calculating the displacement between the origins of the tibial coordinate system relative to a femoral coordinate system projected onto the AP axis of the tibia (see Fig. 6-8). IE rotations were measured by projecting the mediolateral femoral axis onto a plane created by the AP and mediolateral axes fixed in the tibia. Additional details of defining the system used in this chapter can be found in Andriacchi and Dyrby,[4] Andriacchi and coworkers,[5] and Dyrby and Andriacchi.[15]

Anterior-Posterior Translation and Internal-External Rotation of the Knee During Normal Walking

The flexion-extension motion of the knee is the primary motion of the joint because this movement is required for most ambulatory activities. However, AP translation and IE rotation are important secondary movements of the knee because these movements can influence the moment-generating capacity of the muscles,[2] as well as the movement of the position of the tibiofemoral contact, all important for normal function. The AP translation and IE rotation of knee have been previously described for normal walking based on the coordinate system.[4,15]

The characteristics of AP translation and IE rotation (see Fig. 6-8) provide a useful basis for understanding the pathomechanics of kinematic changes associated with the loss of the ACL. During normal walking, the tibia is in an anterior position at heel strike that is the result of anterior tibial translation during the terminal portion of swing phase (see Fig. 6-8). During the major portion of stance phase, the tibia translates to a posterior direction. Finally, during the later portion of swing phase, the tibia moves in an anterior direction relative to the femur, reaching a maximum anterior position at or just before heel strike. In addition, at heel strike, the tibia is externally rotated and internally rotates through the major portion of stance phase. The tibia begins to externally rotate during swing phase as the knee extends before heel strike and reaches a maximum external rotation at or just before heel strike. The motion of the tibia during the terminal portion of swing phase reflects the natural screw-home motion[19] of the knee in which the tibia externally rotates as the knee extends. This natural screw-home movement occurs during the non–weight-bearing portion of the gait cycle in which the passive structure and joint surface drive the movement of the knee. As previously noted, during the

weight-bearing stance phase of the walking cycle, the kinematics are driven by the extrinsic forces that act at the knee rather than the internal passive structures such as the ligaments. Thus, the swing phase of repetitive activities such as walking can provide useful insight into the functional role of the ACL because the passive force capacity can have a substantial influence on the knee motion during non–weight-bearing activities.

Kinematic Changes After Anterior Cruciate Ligament Injury

Kinematic changes at the knee during ambulation have been reported for patients with ACL-deficient knees.[4,17] In particular, the normal external rotation and anterior translation of the tibia that occur as the knee extends during terminal swing are reduced in the absence of the ACL. The tibia maintains this offset relative to normal throughout the stance phase of the walking cycle. These observations indicate that the ACL plays a critical role in the positioning of the knee at the end of swing phase[4] in preparation for heel strike during walking (see Fig. 6-8), suggesting a loss of the normal screw-home movement.[19] The loss of the screw-home movement at the end of swing phase produces an offset toward internal rotation in the average position of the tibia relative to the healthy knee that is maintained through stance phase. The reduced anterior displacement of the ACL-deficient knee at heel strike also appears to be related to modified kinematics during terminal swing phase. Thus, the transition between swing phase and stance is an important consideration in evaluating the ACL-deficient knee.[12,30]

ACL injury is associated with premature OA of the knee.[21-23,35] Numerous pathogenic factors have been associated with the initiation of OA in the ACL-injured knee, including meniscectomy, severe bone marrow edema, articular cartilage injury, lower limb malalignment, and associated injuries to other knee ligaments.[24,28,31,38,39] The kinematic changes at the knee after ACL injury have been implicated as a factor in the cause of premature OA in this population.[7] A shift in the rotational alignment near heel strike can shift the load-bearing contact to regions in the cartilage that have not adapted to the high loads occurring at heel strike. Typically, the thickest regions of the femoral and tibial load-bearing articular cartilage are aligned when the knee is at full extension.

The change in the rotational characteristics at the knee could cause specific regions of the cartilage to be loaded that were not loaded before the ACL injury. It has been suggested that the altered contact mechanics in the newly loaded regions could produce local degenerative changes to the articular cartilage.[13,56] As previously reported, cartilage in highly loaded areas is mechanically adapted relative to underused areas where signs of fibrillation can be observed in healthy knees in relatively young subjects.[13,54] Thus a spatial shift in the contact region could place loads on a region of cartilage that may not adapt to the rapidly increased load initiating degenerative changes.[55]

Kinematics of the Anterior Cruciate Ligament-Reconstructed Knee

Kinematic alterations at the knee have also been reported for patients who undergo ACL reconstruction during walking and other dynamic activities.[42,52,53] In particular, the tibia tends to be more externally rotated in the ACL-reconstructed knee, differing from the shift toward internal rotation in the ACL-deficient knee. In the ACL-reconstructed knee, the tibia maintains the external rotation offset (mean, 2.3 degrees; 95% CI, 1.0-3.7 degrees) relative to normal throughout the stance phase of the walking cycle (Fig. 6-9).[42] These observations further support the assertion that the ACL plays a critical role in guiding the secondary motions of the knee and that conventional ACL reconstruction is not effective in replicating the complex anatomy and function of the native ligament. This is consistent with previously reported in vitro biomechanical studies that have demonstrated that conventional ACL reconstruction techniques often place grafts in a nonanatomic orientation that cannot replicate the rotary stability provided by the native ACL.[27,45]

Interestingly, reconstruction of the ACL has not been shown to reduce the increased incidence of premature knee OA following ACL injury.[29,33] Based on the kinematic findings and natural history of the ACL-deficient knee, many researchers have also implicated altered tibiofemoral kinematics as a precipitating factor in the degenerative process in the ACL-reconstructed knee.[6,7,20,42,43] In a similar manner, the shift in the rotational alignment of the ACL-reconstructed knee during walking would also shift the load bearing to regions of the tibiofemoral cartilage that cannot adapt to the high loads experienced during ambulation. Although the shift in contact caused by the change in rotational position may appear to be relatively small at first, it represents a fairly substantial change when considering the overall range of rotational motion that normally occurs during walking (~10 degrees).[42] It is hypothesized that, when combined with the chronic repetitive nature of walking, the cumulative effect over time of even a minor kinematic change could ultimately play an important role in the early onset of OA in this population. Taken together, these studies further support the importance of assessing the success of new ACL reconstruction techniques based on their ability to replicate the normal 3-dimensional joint anatomy, restore ambulatory mechanics, and prevent long-term degenerative changes.

THE ADDUCTION MOMENT AT THE KNEE AND ANTERIOR CRUCIATE LIGAMENT INJURY

The external adduction moment during walking is a result of the line of action of the ground reaction force passing medial to the center of the knee (Fig. 6-10). The offset or lever arm of this force causes a moment that tends to adduct the knee during walking (Fig. 6-11). The adduction moment will influence the relative distribution of load (see Fig. 6-10) between the medial and the lateral compartments of the knee,[44] causing a higher force on the medial compartment relative to the lateral compartment. The adduction moment has become an ambulatory biomechanical marker for risk of progression of medial compartment OA at the knee.[7,34] In general, patients with a higher adduction moment have worse treatment outcome after high tibial osteotomy,[40] more severe disease,[46] and a higher rate of progression of OA.[34]

Adduction Moment and Osteoarthritis at the Knee

The adduction moment during walking can be an important consideration in patients with ACL-deficient knees because OA in this group occurs most frequently in the medial compartment. It has been shown that patients with a varus angulation at the knee and ACL injury introduce additional problems that should be considered when making treatment decisions.[38] Varus angulation in conjunction with clinical indication of medial compartment OA, cartilage damage, or loss of medial meniscus function is a potential indication for high tibial osteotomy. Gait analysis can provide useful insight into those patients who are at greater risk for medial compartment OA.

The adduction moment during walking makes the knee vulnerable to lateral joint opening in the absence of stabilizing muscle forces. As illustrated in Figure 6-12, muscle contraction can dynamically stabilize the knee to resist a varus thrust and can compensate for lateral joint laxity. Therefore, there is a potential interaction between the reduced

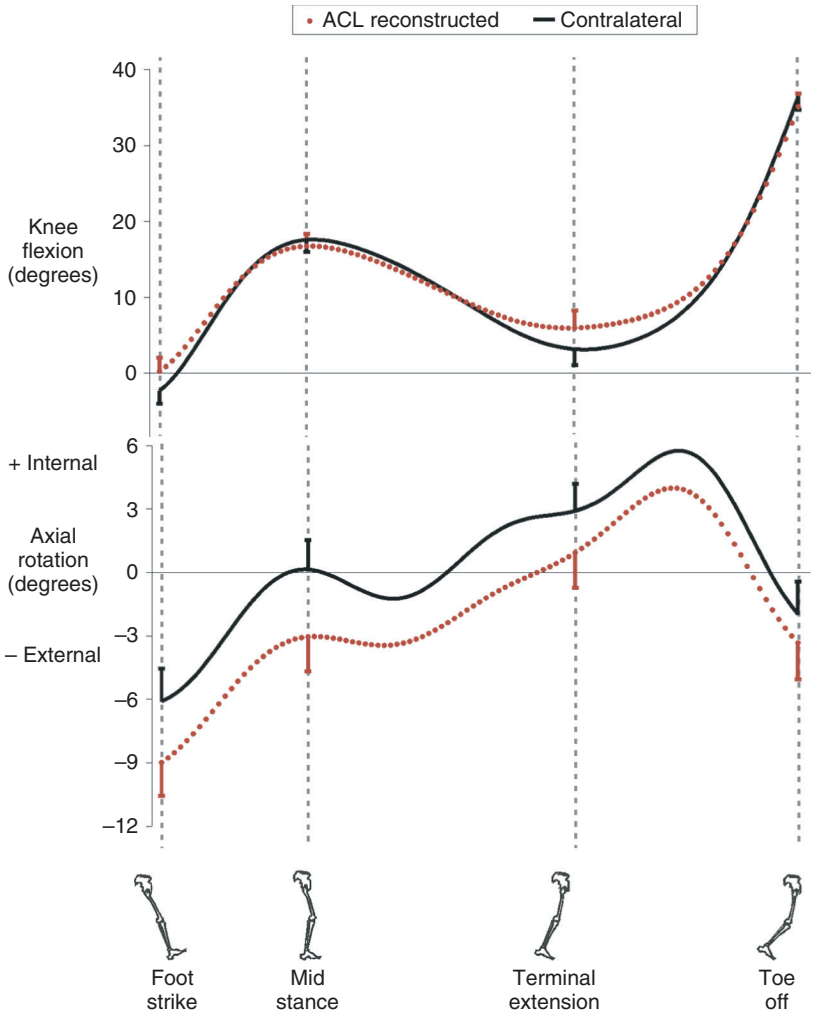

FIG 6-9 The flexion-extension *(FE)* and internal-external *(IE)* motions of the knee that occur during normal walking (expressed as the position of the tibia relative to the femur) for normal (*black line*) and anterior cruciate ligament *(ACL)*-reconstructed (*red line*) knees. The kinematic alterations in the ACL-reconstructed knee are characterized by an internal rotation offset. *AP*, Anterior-posterior.

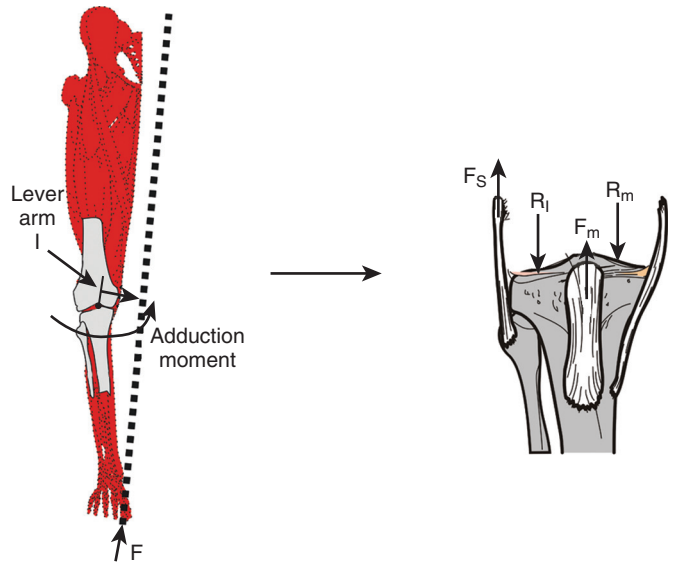
CRITICAL POINTS **Adduction Moment at the Knee and ACL Injury**

- The external adduction moment during walking causes higher force on the medial compartment relative to the lateral compartment of the knee.
- The adduction moment has become an ambulatory biomechanical marker for risk of progression of medial compartment OA at the knee.
- The adduction moment is an important consideration in patients with ACL-deficient knees because OA in this group occurs most frequently in the medial compartment.
- In ACL-deficient patients with lateral joint laxity, a high adduction moment during walking makes the knee vulnerable to lateral joint opening in the absence of stabilizing muscle forces and can cause the entire force across the knee to be transmitted to the medial compartment.
- Varus angulation in conjunction with clinical indication of medial compartment OA, cartilage damage, or loss of medial meniscus function and a high adduction moment during walking is a potential indication for a high tibial osteotomy in patients with ACL-deficient knees.

quadriceps contraction, a high adduction moment, and lateral laxity[38] because a high adduction moment can produce a tendency to open the joint laterally in the absence of the stabilizing forces of muscle contraction (see Fig. 6-11). Based on the mechanics of walking, lateral laxity presents an additional risk in the presence of a varus malaligned knee, a high adduction moment, and reduced quadriceps activity because this combination of conditions can cause the entire force across the knee to be transmitted to the medial compartment. This combination of conditions places the medial compartment of the joint at greater risk for breakdown and should be considered in the overall clinical evaluation of patients with ACL injury.

SUMMARY

The ambulatory characteristics of patients after ACL injury provide unique insight into the functional role of the ACL and provide information that can be helpful in treatment evaluation and planning. The nature and cause of the reduction of quadriceps muscle strength after ACL injury can be explained in part by the reduction of the moment sustained by the quadriceps during walking. The anatomy of the PLIA and the fact that quadriceps contraction creates the greatest anterior pull on the tibia when the knee is near full extension (as during



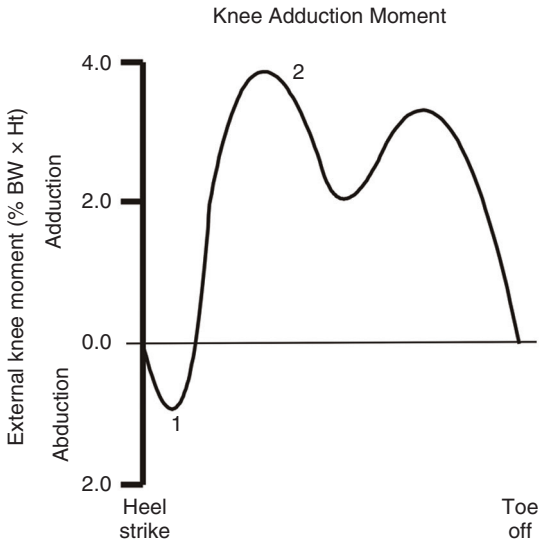


FIG 6-10 An external knee adduction moment occurs during walking when the ground reaction force vector passes medial to the knee joint center in the frontal plane. The adduction moment will influence the relative distribution of load between the medial and the lateral compartments of the knee, with a high adduction moment resulting in a greater compressive load passing through the medial compartment relative to the lateral compartment. *F,* Ground reaction force; F_s, force in lateral soft tissues; F_m, muscles (quadriceps) force; R_l, lateral joint reaction force; R_m, medial joint reaction force.

CRITICAL POINTS Summary

- Gait characteristics of patients after ACL injury provide unique insight into the functional role of the ACL and provide information that can be helpful in treatment evaluation and planning.
- The reduction of quadriceps muscle strength after ACL injury can be explained in part by the reduction of the moment sustained by the quadriceps during walking.
- The anatomy of the patellar insertion angle provides a functional explanation for quadriceps reduction during level walking.
- Kinematic changes have been implicated in the premature OA frequently reported in patients after ACL injury.
- Gait mechanics can provide insight into the treatment of the varus-aligned knee with ACL injury.

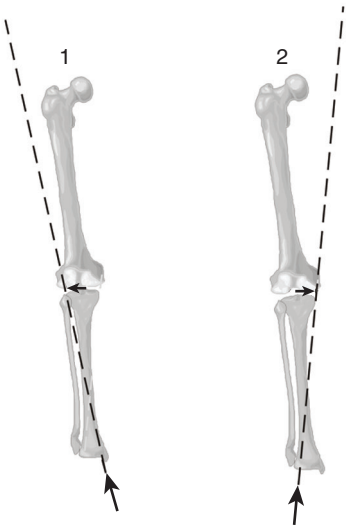

FIG 6-11 The pattern of the external adduction-abduction moment during normal walking. Typically, an abduction moment occurs just after heel strike, and then an adduction moment is maintained throughout the rest of stance phase. The figure of the legs indicates the line of action of the ground reaction force vector relative to the frontal plane position of the knee joint. An external abduction moment is produced when the ground reaction force vector passes lateral to the knee joint center, and an adduction moment is produced when the vector passes medial to the knee joint center. *1,* Peak abduction moment (just after heel strike); *2,* peak adduction moment (mid stance).

walking) provide a functional explanation for quadriceps reduction during level walking. Because the knee is more flexed during activities such as stair climbing or jogging, the PLIA has less anterior pull and there is a reduced need to adapt a pattern of movement to reduce quadriceps contraction unless there is secondary quadriceps weakness and the adaptation is to a weak quadriceps.

The kinematic changes at the knee during walking after ACL injury suggest that the ACL provides an important role in positioning the knee during the swing phase of walking. In particular, patients with ACL injury or ACL reconstruction demonstrate a rotational offset in the position of the tibia that is maintained during the stance phase of walking. It is hypothesized that this rotational offset could play a role in the premature OA frequently reported in patients after ACL injury. The rotational offset can cause a shift in the position of the articular cartilage contact between the femur and the tibia, and it has been suggested that the cartilage cannot adapt to this change in the local mechanical environment, causing the initiation of a degenerative process leading to OA.

Gait mechanics can also provide insight into the treatment of the varus malaligned knee with ACL injury. A high adduction moment during walking in patients with ACL deficiency and varus malaligned knees has been suggested as a consideration for high tibial osteotomy when symptoms of cartilage degradation are present.

Finally, this chapter has discussed how an analysis of ambulatory mechanics can provide insight into the pathomechanics of knee OA after ACL injury that cannot be obtained from other methods. Restoration of function and prevention of long-term comorbidities, such as OA and meniscus degeneration, are among the primary goals of

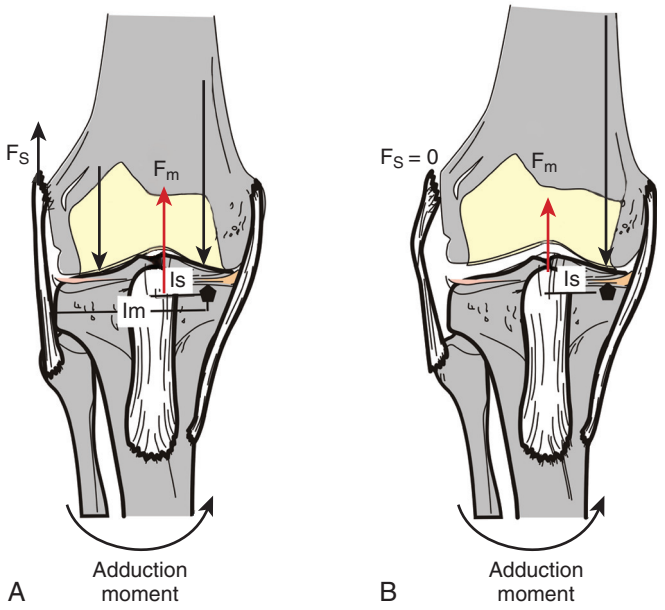

FIG 6-12 **A,** Muscle contraction (F_m) acting through the lever arm (lm) and competent lateral soft tissue structures (F_s) acting through the lever arm (ls) are capable of dynamically stabilizing the knee joint in the presence of a large moment, tending to adduct the knee (such as occurs during walking in the varus malaligned knee). **B,** However, the combination of weak extensor muscles and lateral joint laxity (Fs = 0) in the anterior cruciate ligament–deficient knee can be potentially insufficient to resist a large adduction moment, resulting in opening of the lateral compartment and a concentration of the load across the medial compartment of the knee.

treatment. Thus quantitative analysis of function should be considered in the evaluation of new treatment modalities.

CRITICAL POINTS Indications

- Complete ACL rupture: >5 mm of increased anterior tibial translation, positive pivot shift test.
- Profile patient for desired future activity level.
- High-risk activities (pivoting, cutting, twisting, and turning): reconstruct.
- Acute ACL rupture and concomitant displaced bucket-handle meniscus tear: surgery within 2 to 3 weeks to repair meniscus, usually concurrent ACL reconstruction.
- Low-risk activities, willing to avoid strenuous activities that place the knee at increased risk for giving-way episodes: conservative treatment.
- Successful ACL reconstruction reduces risk of subsequent injuries.
- Partial ACL tears: <50% fibers torn: conservative treatment; >50% torn in athlete: consider graft augmentation.

INDICATIONS

Patients presenting with acute complete ruptures of the anterior cruciate ligament (ACL) (>5 mm of increased anterior tibial translation and positive pivot shift test) are treated with rehabilitation until pain and swelling subside and joint motion and muscle function are restored. This delay markedly reduces the incidence of postoperative complications of knee motion limitations and muscle weakness. All patients with acute ruptures are profiled with regard to their desired future activity level to determine whether ACL reconstruction is warranted.[212] Those who are highly motivated to return to high-risk activities, including strenuous athletics or occupations involving pivoting, cutting, twisting, and turning, are considered for reconstruction.[64] In patients with acute ACL ruptures and a concomitant displaced bucket-handle meniscus tear, surgery within 7 to 10 days is required to reduce the meniscus to a normal location and repair the tear. The ACL reconstruction may be performed at the same setting; however, knees with excessive swelling and pain undergo a staged meniscus repair first. After an appropriate period of rehabilitation, ACL reconstruction is then performed.

Patients involved in low-risk activities or who are willing to avoid strenuous athletic and occupational activities that place the knee at increased risk for giving-way episodes may not require ACL reconstruction. These patients are placed into a conservative treatment program that includes rehabilitation to regain muscle strength and neuromuscular function and counseling on the risk of future giving-way reinjuries and potential damage to the joint. Even with surgical reconstruction, patients are informed that an ACL rupture is a serious injury and it is unlikely that they will ever have a truly normal knee joint. The injury may also involve a bone bruise and chondral damage, with sequelae for future joint symptoms. The goal of conservative management is to prevent recurrent giving-way reinjuries that are deleterious to the joint because they frequently result in meniscus tears and subsequent meniscectomy. It is important to categorize the knee joint regarding the extent of the injury that occurred. Repairable meniscus tears almost always indicate a concurrent ACL reconstruction. Otherwise, the success of the meniscus repair may be compromised.[52,181,246] DeHaven and coworkers[52] documented higher failure rates of meniscus repairs in knees with ACL deficiency than in knees with normal ACL function (46% and 5%, respectively) in a 10-year follow-up study. A grade III pivot shift and grossly positive Lachman test results (increased ≥10 mm anterior tibial translation) indicate involvement of the secondary ligamentous restraints and, in our experience, an increased risk of giving-way reinjuries with recreational activities. Patients with physiologic laxity of other ligaments or partial tears (second-degree) of medial or lateral ligaments frequently have a grossly positive pivot shift, as discussed in Chapter 3.

The rationale for the indications for ACL reconstruction is based on a study of 103 patients with chronic ACL ruptures.[214] These knees had no other ligament injuries and had not undergone reconstruction. The patients were evaluated for a mean of 5.5 years after the initial knee injury; a subgroup of 39 patients presented an average of 11 years postinjury. This study was not a natural history study, because all patients sought treatment because of symptoms. After the initial injury, 82% of the patients returned to sports activities, which gave an initial false impression of the seriousness of the ACL disruption. After 5 years only 35% were continuing athletics, often with recurrent symptoms of pain or swelling. A significant reinjury occurred in 36 patients within 6 months and in 53 patients within the first year following the initial injury. Moderate to severe symptoms of pain, swelling, and/or giving-way were reported in 32 patients during walking, in 45 patients during activities of daily living, and in 73 patients during turning or twisting athletic activities. Giving-way occurred in 22 patients during walking, in 34 patients during recreational sports, and in 66 patients during strenuous sports. Patients who had undergone meniscectomy had a twofold to fourfold increase in pain and swelling symptoms. Radiographic findings lagged behind clinical symptoms. Forty-four percent of patients in the subgroup 11 years from injury had moderate to severe arthritic changes. The "ring" sign was noted, which represents an osteophyte (Fig. 7-1) that forms around the circumference of the lateral tibial plateau. This is associated with an absence of a pivot shift phenomena because the lateral femoral condyle translation is restrained by the osteophytes and increased concavity of the lateral tibial plateau.

In a follow-up study, 84 of the initial 103 patients underwent a repeat evaluation 3 years after initiating a conservative and activity modification treatment program.[212] The frequently quoted "rule of thirds" represents the outcome of this study regarding the effects of an ACL injury on subsequent functional activities. Approximately one third of the patients showed improvement in symptoms and functional limitations with daily or recreational activities, one third did not improve, and one third became worse with continuing symptoms and limitations. Thirty percent of the patients (labeled "knee abusers") were noncompliant with the activity modification recommendations and stated they would continue athletics despite symptoms and the increased risk for future arthritis. These patients had the poorest overall prognosis with conservative management. This general rule of

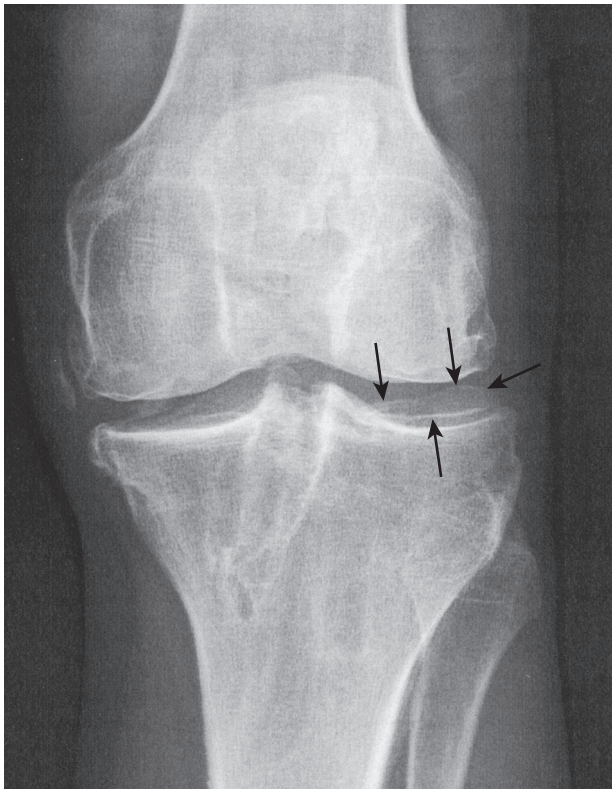

FIG 7-1 The "ring" sign (*arrows*) represents an osteophyte that forms around the circumference of the lateral tibial plateau with degenerative arthritis and meniscectomy, which commonly reduces the pivot shift phenomena caused by increased plateau concavity that limits anteroposterior (AP) translation.

thirds may not always be specific to individual patients with chronic ACL insufficiency because it does not take into account the presence of meniscus and arthritis grading, compliance with activity modification, and maintenance of a muscle strengthening program. The frequency of giving-way episodes correlated with chronic pain, swelling, and functional limitations. The conclusion was reached that any giving-way episode with athletics, even if followed by periods of no giving-way or other symptoms, was to be absolutely avoided because meniscus tears and joint deterioration may occur. The results of this program show the importance of counseling the patient on the possible expected levels of athletic activity and following closely those who do not initially choose to have surgery to lessen the chance of significant arthritis in future years.

Recent systematic reviews have demonstrated that ACL reconstruction reduces the incidence of subsequent meniscus injuries, reduces the need for further operations, and results in greater improvements in activity levels.[40] In patients who undergo reconstruction and in whom the menisci are retained, there is a lower incidence of knee osteoarthritis (OA).[42,154] Mather and associates[170] reported that, in the short term, ACL reconstruction was less costly (cost reduction of $4503) and more effective compared with rehabilitation. In the long term, the mean lifetime cost to society for a patient undergoing ACL reconstruction was calculated to be $38,121 compared with $88,538 for nonoperative treatment with rehabilitation.

Partial ACL tears occur more frequently than suspected and present in a manner similar to complete ACL ruptures. These injuries frequently occur from a noncontact giving-way episode during jumping or pivoting and are often accompanied by a popping sensation and acute hemarthrosis. There is a limitation of full extension with pain on even gentle attempts to passively achieve 0 degrees, mimicking a torn displaced meniscus, which requires magnetic resonance imaging (MRI) to exclude a mechanical block to knee extension. In a study reported by the senior author (F.R.N.) and associates,[213] of 32 knees with a partial ACL tear verified arthroscopically, a tear to one or both menisci occurred in 53% of the knees. In an average of 67 months postinjury (range, 24-110 months), 38% had progressed to complete ACL deficiency. The arthroscopic evaluation of the extent of ACL disruption was related to the prognosis and progression to complete ACL deficiency. Even though the arthroscopic evaluation does not define the true extent of ligament injury on a microscopic or functional basis,[207] 86% of knees in which three fourths of the ACL was torn progressed to ACL deficiency. One half of the knees with an estimated injury involving half of the ligament progressed to ACL deficiency, even though major portions of the ACL were still intact, preventing a pivot shift phenomena. Only 12% of knees that had an estimated one fourth or less of the ligament torn progressed to complete ACL deficiency; therefore these knees had a reasonably good prognosis for return to athletics.

Messner and Maletius[175] followed 22 consecutive patients with partial ACL ruptures (no more than 50% of the ACL fibers torn) a mean of 12 years postinjury; all but one were also reexamined for a mean of 20 years postinjury. No patient required ACL reconstruction. Patients decreased their level of activity from contact sports to recreational activities. Few had an increase in anterior translation or improvement in the pivot shift test, and few differences were noted in symptoms between follow-up evaluations.

Based on these data, the following rules apply for the management of partial ACL tears. Knees with tears of 50% or less of the ACL fibers are not candidates for reconstructive surgery. The patients are advised that they need to be followed yearly. The chance for progression to complete ACL deficiency in the more than 50% tear group is at least one in two knees. In the athletic individual, a hamstring graft augmentation is a consideration (made on a case-by-case basis) to provide stability and retain the remaining function of the ACL. In the more sedentary patient who may wish to choose a nonoperative treatment of a complete ACL rupture, a reconstruction is not warranted.

CONTRAINDICATIONS

Patients who are sedentary and do not experience giving-way or swelling episodes with daily activities and have little exposure to strenuous or high-risk activities are treated conservatively. These patients are advised to maintain an ideal body weight and have periodic knee examinations. In addition, patients who are willing to modify their activity level to avoid high-risk knee motions such as pivoting and cutting are placed in a conservative treatment program. Patients who are unable to participate or be compliant with postoperative rehabilitation are not surgical candidates.

The presence of symptomatic patellofemoral or tibiofemoral arthritis is a general contraindication to ACL surgery because pain symptoms remain postoperatively. Although pain symptoms may be lessened by restoring knee stability, the joint damage will still limit daily activities. Weight-bearing 45-degree posteroanterior (PA) views are important to determine the millimeters of remaining medial or lateral tibiofemoral joint space. In chronic ACL injuries, patients are frequently surprised to learn that the joint space is absent or nearly absent, because their symptoms have not yet limited daily activities. In these knees, conservative measures are instituted until such time that partial or total joint replacement is warranted.

CRITICAL POINTS Contraindications

- Sedentary patients, no symptoms, little exposure to high-risk activities
- Patients unable to participate in postoperative rehabilitation program
- Patients with preexisting severe loss of patellofemoral or tibiofemoral compartment joint space
- Marked muscle atrophy
- Complex regional pain syndrome
- Obesity
- Prior joint infection

Patients with ACL deficiency, symptomatic mild or moderate medial tibiofemoral arthritis, and varus malalignment require corrective valgus-producing high tibial osteotomy (HTO). These patients often do not require subsequent ACL surgery because there are limitations in activities owing to the joint damage. This principle applies to both ACL-deficient knees and those who had a prior failed ACL reconstruction. These patients often report improved joint instability because the varus thrust gait pattern is eliminated with osteotomy.

Patients with marked lower extremity muscle atrophy require a delay in surgery for many months until adequate muscle function has been restored. These patients have an increased risk for postoperative complications, including quadriceps muscle shutdown, patella infera, and arthrofibrosis. In some cases, the restoration of muscle function may lead to increased knee stability, avoiding ACL revision.

The presence of residual signs and symptoms of a complex regional pain syndrome (CRPS) requires careful examination and questioning regarding the presence of burning pain, abnormal skin hypersensitivity, extremity discoloration, and intolerance to cold and ice. Even after resolution of a prior CRPS, there is an increased frequency for return of the syndrome in these knees that must be promptly recognized in the postoperative period (see Chapter 40).

Patients with a body mass index of 30 or greater are usually not surgical candidates. A history of prior infection with subsequent joint arthritis often contraindicates ACL surgery. There may be associated medical conditions contraindicating surgery. The use of nicotine products is strongly discouraged and absolutely contraindicated if osteotomy alignment procedures are required.

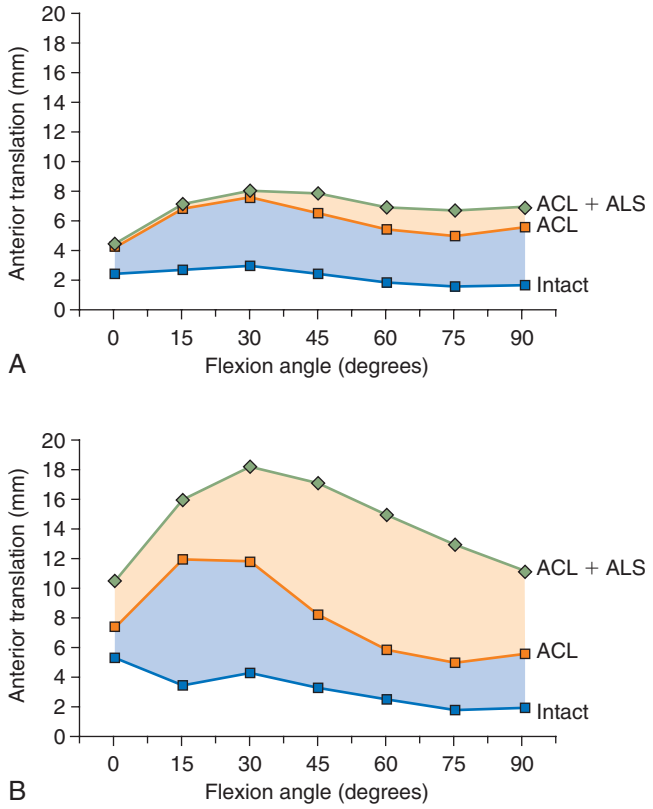

FIG 7-2 Limits of anterior translation (100 N) for intact specimens and with the anterior cruciate ligament (ACL) and ACL/iliotibial band lateral capsule (ALS) cut. **A,** In these specimens, anterior translation in the intact state was low and, with sectioning of the ACL, moderate increases were found throughout the range of motion. Further sectioning of the ALS produced less than 3 mm of an increase in anterior translation, predominantly in the flexed knee. **B,** In this group of specimens, anterior translation in the intact state was higher than in the prior group of specimens at low flexion angles. After cutting the ACL, anterior translation was markedly increased in the 15 to 30 degrees of flexion range. After further sectioning of the ALS, large anterior translation increases were found at all flexion angles, indicating the ALS is a secondary restraint. (**A** and **B**, From Wroble RR, Grood ES, Cummings JS, et al. The role of the lateral extraarticular restraints in the anterior cruciate ligament-deficient knee. *Am J Sports Med.* 1993;21: 257-262.)

CLINICAL BIOMECHANICS

Effect of Anterior Cruciate Ligament and Lateral Structures on Anterior Tibial Translation and Internal Tibial Rotation Limits

The function of the ACL is discussed in Chapter 3. Additional information regarding the restoration of ACL function related to surgical techniques and graft placement issues are discussed in this section. The ACL is the primary restraint to anterior tibial translation, providing 87% of the total restraining force at 30 degrees of knee flexion and 85% at 90 degrees of flexion.[38] The iliotibial band (ITB), mid medial capsule, mid lateral capsule, medial collateral ligament (MCL), and fibular collateral ligament (FCL) provide a combined secondary restraint to anterior tibial translation. The posteromedial (PM) and posterolateral (PL) capsule structures provide added resistance with knee extension. The secondary restraints may become deficient after an ACL injury or repeat giving-way episodes resulting in increased symptoms.

The ACL resists the coupled motions of anterior tibial translation and internal tibial rotation along with the lateral structures. In our laboratory, Wroble and colleagues[297] measured in ACL-deficient knees the simulated effect of lateral soft tissue injuries on internal tibial rotation and anterior tibial translation. The experimental design consisted of a six degrees of freedom (DOF)-instrumented spatial linkage and loading of the knee joint under defined loads of 100-N anteroposterior (AP), 15 N-m varus-valgus, and 5 N-m internal-external tibial rotation torque. The limits of knee motions were determined in the intact knee and then after sectioning the ACL, ITB, lateral capsule (anterolateral ligament),[44] popliteus tendon, popliteofibular ligament, and PL capsule.

The effect of sectioning the ACL first, followed by the ITB and lateral capsule, is shown in Figure 7-2. Two distinct responses were measured. In the first set of knees (see Fig. 7-2, *A*), there were only moderate increases in anterior tibial translation after ACL sectioning and negligible further increases after sectioning the ITB and lateral

CRITICAL POINTS Clinical Biomechanics

- ACL primary restraint anterior tibial translation.
- ITB, mid medial capsule, mid lateral capsule, MCL, FCL combined secondary restraint.
- ACL resists coupled motions anterior tibial translation and internal tibial rotation along with the lateral structures.
- Secondary restraints may become lax after reinjuries, may be physiologically loose or tight.
- Loss of ACL and lateral structures increases anterior tibial translation and internal tibial rotation.
- Increase in coupled motions shifts center of rotation to medial compartment.
- Concurrent injury to medial structures causes center of rotation to shift outside medial compartment, gross anterior subluxation of both compartments.
- Some authors provide evidence of two-bundle division of ACL, others argue that ACL fiber function is too complex to be artificially divided into two bundles.
- Characterization of ACL into two bundles represents gross oversimplification not supported by laboratory studies.
- With substantial anterior tibial loading or coupled motions, majority of ACL fibers are in a load-sharing configuration with different percentages as to fiber tensile loads.
- ACL is not isometric, all ACL fibers anterior to transitional zone lengthen with knee flexion, and posterior fibers lengthen with knee extension.
- Function ACL fibers determined primarily by anterior-to-posterior direction (knee at extension), and secondarily by proximal-to-distal femoral attachment and anterior-to-posterior tibial attachment.
- Placement of graft too far in an anterior or posterior femoral position has a large effect on deleterious lengthening and graft failure.
- Several studies report transtibial drilling techniques select a posterior tibial position, resulting in a vertical ACL graft orientation.
- Variation in ACL anatomy requires surgeon to outline the size and shape of the ACL attachment in each patient, if possible.
- Landmarks for ACL tibial attachment: medial tibial spine, posterior interspinous ridge (RER), attachment of lateral meniscus. PCL is poor landmark.
- Place guide pin eccentric and 2 to 3 mm anterior and medial to ACL center, avoiding posterior tibial attachment location.
- Anterior notchplasty often required with central ACL graft placement.
- Landmarks for ACL femoral attachment: posterior articular cartilage, Blumenstaat line, ACL attachment on lateral femoral wall.
- Central anatomic ACL placement: femoral guide pin 2 to 3 mm above the midpoint of the proximal-to-distal length of the ACL attachment, 8 mm from the posterior articular cartilage edge. Define anatomic attachment with knee 20 to 30 degrees of flexion.
- Majority in vitro robotic studies compare double-bundle graft to a less than ideal vertically placed single graft in a high femoral and posterior tibial location. This graft placement is not recommended.
- Studies of single ACL grafts in the more ideal central tibial and femoral anatomic attachment show restoration of rotational knee stability.
- There appears to be no distinct advantage of the more complex double-bundle technique in comparison to a well-placed central anatomic single graft technique.
- Both ACL bundles function synergistically to resist medial and lateral compartment subluxations during Lachman and pivot shift tests.
- Assessment of ACL graft function takes into account restoration of normal coupled motion limits of anterior tibial translation and internal tibial rotation. No current reliable measuring system is available to measure pivot shift test.
- Important landmarks for the ACL tibial attachments are the medial tibial spine, posterior interspinous ridge of the proximal PCL fossa, and the attachment of the lateral meniscus. ACL tibial attachment location that we recommended for a single graft is directly adjacent to the lateral meniscus anterior horn attachment.
- Important landmarks for the femoral attachment are the posterior articular cartilage, Blumenstaat line, and identification of the ACL attachment on the lateral femoral wall of the notch.
- For single grafts, we recommend a central anatomic ACL placement with the femoral guide pin 2 to 3 mm above the midpoint of the proximal-to-distal length of the ACL attachment (30 degrees of knee flexion) and 8 mm from the posterior articular cartilage edge.

capsule. However, in the second set of knees (see Fig. 7-2, *B*), much larger increases were noted in anterior tibial translation after sectioning the ACL, and even greater increases were found after sectioning the ITB and lateral capsule.

These findings are compatible with clinical tests after ACL injury in which some knees have only moderate increases in anterior tibial translation, whereas other knees have much larger increases. This concept is discussed in Chapter 3, using the analogy of the bumper model to simulate the resistance of the secondary restraints on motion limits once the ACL is removed. Clinically, an ACL graft would be expected to be subjected to greater in vivo forces in the second set of knees without the unloading provided by relatively "tight" secondary restraints. The increase in the magnitude of anterior translation and internal rotation in these physiologically loose knees after loss of the anterolateral structures results in a grade III pivot shift phenomena. These knees require a high-strength, securely fixated ACL graft to resist these major displacements, and autografts are highly recommended in these grossly unstable knees, with preference for a bone-patellar tendon-bone (B-PT-B) graft.

The effect of sectioning the lateral and posterolateral structures (PLS) is shown in Figure 7-3.[297] Sectioning of the FCL or PLS (popliteus tendon, popliteofibular ligament, PL capsule) produced small but statistically significant increases in anterior tibial translation at low flexion angles. The combined ACL-ALS-FCL (where ALS are the anterolateral structures comprising the ITB and anterior and middle portions of the lateral capsule) sectioned knee had large increases in anterior tibial translation, with the greatest changes occurring at higher flexion angles.

The effect of sectioning the ACL and lateral structures on the limits of internal tibial rotation are shown in Figure 7-4. Sectioning of the ACL produced only a small increase in the final internal rotation limit. Sectioning of the ALS and the FCL produced sequentially larger increases in internal tibial rotation. In select revision knees that have large increases in internal tibial rotation, the data support the role of a lateral extraarticular procedure discussed later to unload the ACL graft and restore stability.

The conclusions from this study support the ACL as the primary restraint to anterior tibial translation. The data show that the ultimate limit for internal tibial rotation is resisted by the lateral extraarticular structures that are tightened by the internal tibial rotation. This is an important concept because clinical and biomechanical studies frequently attempt to measure increases in internal tibial rotation after

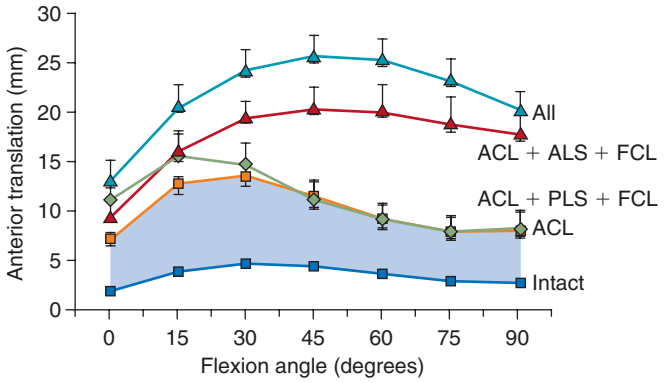

FIG 7-3 Limits of anterior translation (100 N) for intact specimens and with serial sectioning of the anterior cruciate ligament (ACL) and lateral structures. Increases in anterior translation with sectioning of the ACL are statistically significant at all flexion angles. For the ACL/PLS/FCL cut state, the only statistically significant increase was at 0 degrees of flexion. For the ACL/ALS/FCL cut state, increases were statistically significant at 15 degrees of flexion and above. Increases for the all cut state were statistically significant at all flexion angles. Anterior translation at 30 degrees and 90 degrees of flexion is approximately equal when the secondary lateral restraints are removed. *ALS*, iliotibial band, lateral capsule; *FCL*, fibular collateral ligament; *PLS*, posterolateral structures (popliteus tendon and popliteofibular ligament, posterolateral capsule). (From Wroble RR, Grood ES, Cummings JS, et al. The role of the lateral extraarticular restraints in the anterior cruciate ligament-deficient knee. *Am J Sports Med.* 1993;21:257-262.)

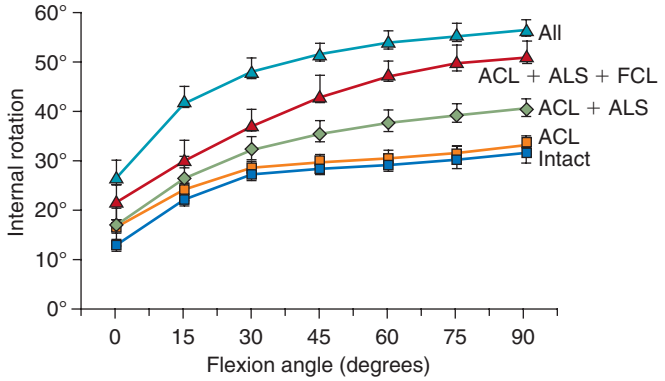

FIG 7-4 Limits of internal rotation (5 N-m) for intact specimens and with the anterior cruciate ligament (ACL), ACL/ALS, ACL/ALS/FCL, and ALL structures (ACL/ALS/FCL/PLS) cut. Increases in internal rotation with the ACL cut (statistically significant) state are so small that they are clinically unimportant. With ACL/ALS sectioning, increases in internal rotation are statistically significant at 30 degrees of flexion and above. Statistically significant increases are found at 15 degrees of flexion and above in the ACL/ALS/FCL cut state, and at all flexion angles for the all cut state. The effect of the PLS on restraining internal rotation in the extended knee can be seen by comparing the ACL/ALS/FCL curve and the ALL cut curve. The differences between these curves reflects sectioning the PLS. The largest differences are found at 15 degrees and 30 degrees of flexion. *ALS*, iliotibial band, lateral capsule; *FCL*, fibular collateral ligament; *PLS*, posterolateral structures (popliteus tendon and popliteofibular ligament, posterolateral capsule). (From Wroble RR, Grood ES, Cummings JS, et al. The role of the lateral extraarticular restraints in the anterior cruciate ligament-deficient knee. *Am J Sports Med.* 1993;21:257-262.)

ACL surgery in an effort to quantify ACL graft function. Accordingly, this approach would not be expected to be successful. When the ITB and lateral capsule are physiologically slack, the FCL and ACL assume increased importance in limiting internal rotation. In summary, ACL function is ideally described by the restraining effect of lateral and medial tibial plateau translation and not by internal rotation limits. A positive pivot shift test represents the effect of abnormal compartment translations and anterior subluxation of both tibiofemoral compartments.

The motions that occur during the pivot shift maneuver are shown in Figure 7-5. At the beginning of the tests, the lower extremity is simply supported against gravity. After ACL disruption, both anterior tibial translation and internal tibial rotation occur as the femur drops back and externally rotates with subluxation of the lateral tibiofemoral compartment. This position is accentuated as the tibia is lifted anteriorly. At approximately 30 degrees of knee flexion, the tibia is pushed posteriorly, reducing the tibia into a normal position with the femur. From position C to position A (see Fig. 7-5, *B*), the knee is extended to again produce the subluxated position.

The effect of the ACL in providing rotational stability is shown in Figure 7-6. After ACL sectioning, there is an increase in medial and lateral compartment translation as the center of rotation shifts from inside the knee joint to outside the medial compartment. The medial ligamentous structures influence the new center of rotation. With injury to the medial ligament structures, the center of rotation shifts so far medially that a tibial rotational displacement is essentially lost, resulting in a gross anterior subluxation of both compartments. The data show the important surgical concept of restoring injured medial and lateral ligament structures to restore anterior knee stability in conjunction with the ACL.

There have been numerous in vitro and in vivo studies published over the past decade on ACL function in regard to providing rotational knee stability.[76,100,134,151,166,285,303] Based on the results of these studies, authors have provided recommendations for ACL single- and double-bundle graft reconstructions, graft placement, and tensioning.[76,77,100,133,134,151,166,174,285,298,303] These investigations involved a simulated Lachman test and, more importantly, the pivot shift test, which correlates with patient subjective giving-way symptoms. In our opinion, there are problematic errors in many studies that the surgeon should be aware of in terms of application of the results to surgical treatment of ACL ruptures. For example, nearly all published studies describe rotational knee stability according to the changes in degrees of internal tibial rotation, without measuring the center of tibial rotation or the position or subluxation of the tibiofemoral compartments. We believe that providing only the changes in degrees of tibial rotation, without specification of the medial and lateral tibiofemoral compartment position or subluxation, is an inadequate descriptor of rotational knee stability. In fact, after ACL rupture, there is a change of only a few degrees of internal tibial rotation as long as the lateral extraarticular structures remain intact as already described.[54,208,219,220]

A second problem we have identified in a majority of in vivo and in vitro pivot shift studies is the loading profile used to induce anterior tibial subluxation. Studies commonly report, in the pivot shift simulation, an abnormal anterior tibial translation after ACL sectioning that is only half that obtained in the Lachman test. However, under clinical conditions, a positive pivot shift test produces greater anterior tibial subluxation than the Lachman test. Accordingly, these prior studies were conducted under low knee displacement conditions in which the loading profile involved an internal rotation-valgus condition. There was an absence of a simultaneous combined anterior tibial loading, which is the major reason the clinical pivot

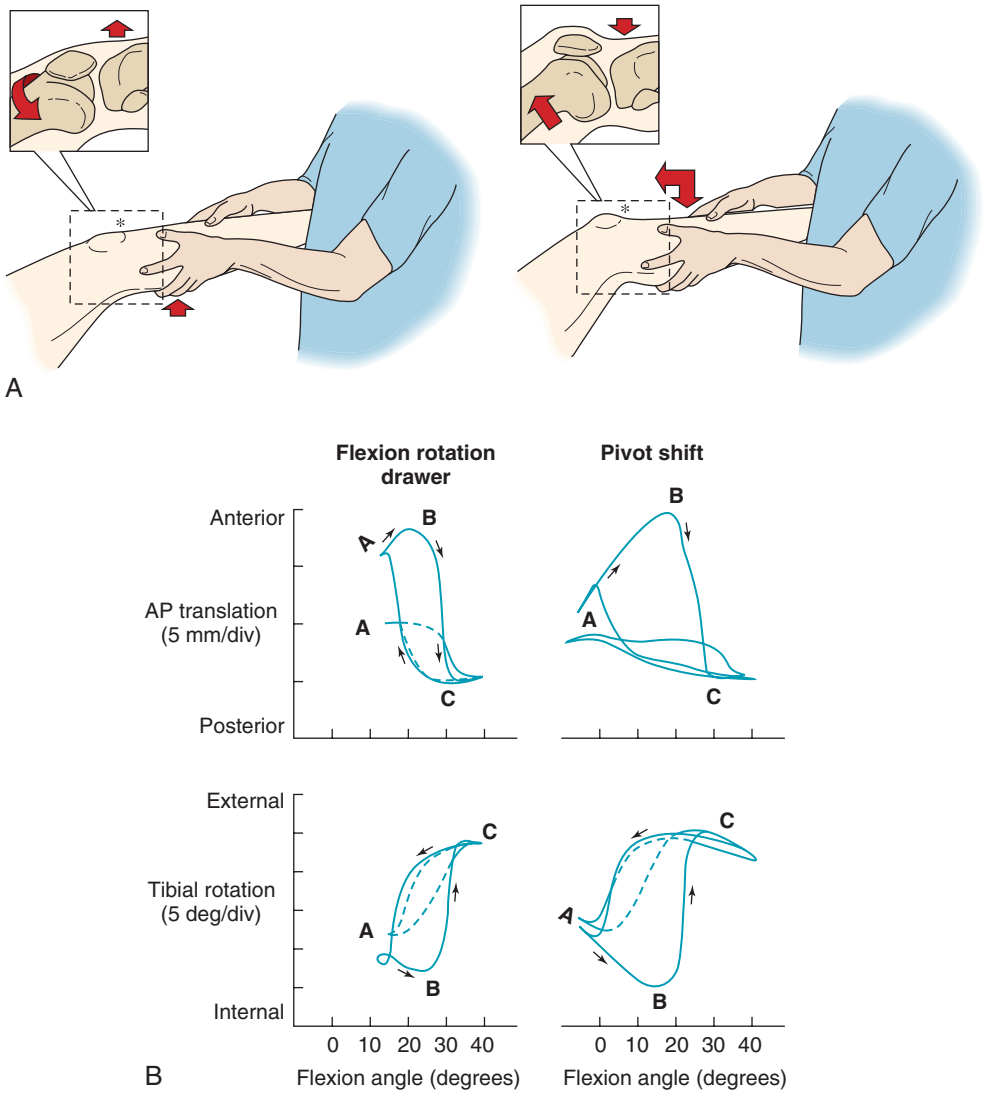

FIG 7-5 Flexion-rotation drawer and pivot shift tests. **A,** With the leg held in neutral rotation, the weight of the thigh causes the femur to drop back posteriorly and rotate externally, producing anterior subluxation of the tibial plateau. Gentle flexion and a downward push on the leg reduce the subluxation. This test allows the coupled motion of anterior translation-internal rotation to produce anterior subluxation of the lateral and medial tibial plateau. **B,** The knee motions during the tests are shown for tibial translation and rotation during knee flexion. The clinical test is shown for the normal knee (*dotted line*) and after ligament sectioning (*solid line*). The ligaments sectioned were the anterior cruciate ligament (ACL), iliotibial band, and lateral capsule. Position A equals the starting position of the test, B is the maximum subluxated position, and C indicates the reduced position. The pivot shift test involves the examiner applying anterior translation and rotational loading to produce the tibial subluxation. The actual changes in the motion limits are shown later where there are major increases in lateral and medial tibiofemoral compartment translations and only small changes in degrees of internal tibial rotation. *AP,* Anteroposterior; *div,* division. Three-dimensional motion analysis of clinical stress tests for anterior knee subluxations. *Acta Orthop Scand.* 1989;60:308-318.)

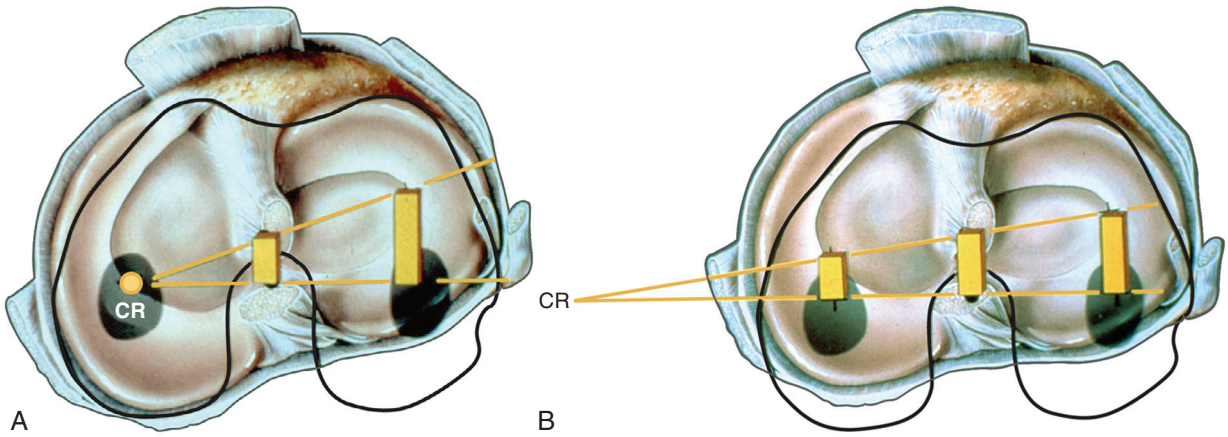

FIG 7-6 Intact knee and after anterior cruciate ligament (ACL) sectioning: response to coupled motions of anterior tibial translation and internal tibial rotation. **A,** Intact knee. The center of rotation (CR) may vary between the medial aspect of the posterior cruciate ligament and meniscus border, based on the loads applied and physiologic laxity of the ligaments. **B,** ACL sectioned; note shift in center of tibial rotation medially. The effect of the increase in tibial translation and internal tibial rotation produces an increase in medial and lateral tibiofemoral compartment translation (anterior subluxation). The millimeters of anterior translation of the tibiofemoral compartments represents the most ideal method to define knee rotational stability (see Chapter 3). The center of rotation under a pivot shift type of test shifts to the intact medial ligament structures. If these are deficient, the center of rotation shifts outside the knee joint.

shift test induces anterior tibial subluxation. A prior published study from our institution[208] that studied orthopedic surgeons performing a pivot shift test on an instrumented lower extremity reported that two types of clinical pivot shift loadings were induced: (1) a predominant internal rotational-valgus torque; and (2) a combined anterior tibial loading with internal rotation-valgus torque. The combined pivot shift loading test produced the greatest amount of anterior tibial subluxation of both tibiofemoral compartments. The predominant internal rotational-valgus torque loading constrained anterior tibial subluxation by reducing the medial tibiofemoral compartment translation.

For reasons not apparent, pivot shift loading with a predominant internal rotation-valgus torque, but without a coupled anterior tibial loading, has been the typical loading profile in nearly all cadaveric studies on ACL function and surgical reconstructions even though this limits anterior tibial subluxation of the medial compartment. In Figure 7-7, the results of a typical cadaveric knee specimen are shown under two pivot shift loading conditions. Three points are important. In the two simulated pivot shift tests, there is a greater anterior tibial subluxation of the lateral and medial compartment, with the pivot shift subluxation produced by a coupled anterior translation-internal rotation during the valgus loading as the knee approaches extension (pivot shift [PS] 4), compared with an absence of the anterior tibial loading component (PS3). Secondly, high tibial internal rotation torques in the pivot shift reduces the medial tibiofemoral compartment (see Fig. 7-7), constraining the amount of medial and central compartment translation. Third, an analysis of rotational knee stability requires knowledge of the resulting subluxations (translations) of the medial and lateral tibiofemoral compartments (see Chapter 3). We recommend that future in vitro and in vivo pivot shift studies use loading profiles of coupled anterior tibial translation and internal tibial rotation, along with valgus loading, to induce a maximum anterior tibial subluxation of both tibiofemoral compartments. Further, rotational torques should remain low to not constrain the maximum subluxation of the medial compartment.

Division of Anterior Cruciate Ligament Into Anteromedial and Posterolateral Bundles

Controversy exists in published studies on the division of the ACL into two distinct fiber bundles. Some authors provide evidence of both an anatomic and functional division, whereas others doubt this division exists and argue that ACL fiber function is too complex to be artificially divided into two bundles. In some studies,[7,47] the anteromedial (AM) bundle is identified functionally at its femoral location as the proximal half of the attachment (knee in extension) that tightens with knee flexion. The PL bundle is identified as the distal half of the ACL femoral attachment that tightens with knee extension. The PL bundle is described to relax with knee flexion, as the ACL femoral attachment changes from a vertical to a horizontal structure. The problem is that this classical description of a reciprocal tightening and relaxation of the AM and PL bundles occurs only under low anterior loading conditions. With substantial anterior tibial loading, and particularly with a coupled motion of anterior translation and internal tibial rotation, the majority of the ACL fibers are brought into a load-sharing configuration to a differing percentage as is presented later.

We believe the characterization of the ACL into two fiber bundles represents a gross oversimplification not supported by biomechanical length-tension laboratory studies.[93,264] Zavras and coworkers[309] published a comparative study on previously published isometric points for the ACL and concluded that the ACL isometric zone was high and proximal in the ACL attachment, close to the posterior end of the Blumensaat line. These data, along with other studies, focused on placing grafts in the proximal aspect of the ACL attachment, in a so-called isometric position. The problem with applying published isometric data to the clinical situation is that the data are valid only for knee flexion-extension and do not indicate the most effective ACL graft position for controlling knee rotational loading as occurs during the pivot shift test.

The length-tension behavior of ACL fibers is primarily controlled by the femoral attachment in reference to the center of femoral

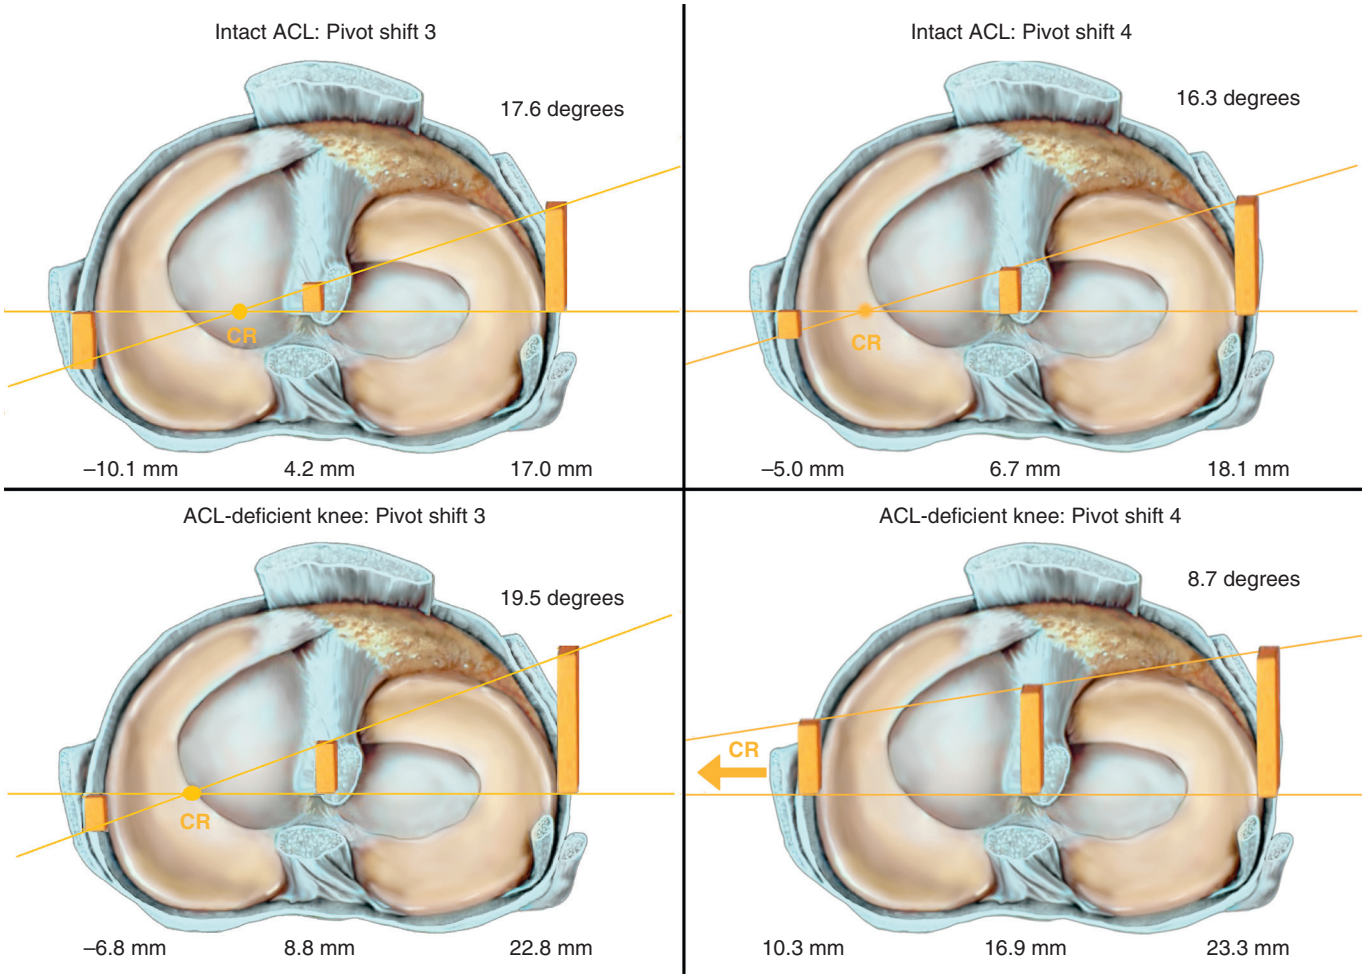

FIG 7-7 A representative right knee specimen showing compartment translations and tibial rotation under two loading conditions: *pivot shift 3* and *pivot shift 4*. In the pivot shift 3 loading, there is a coupled internal rotation-valgus loading with a high internal rotation torque. There is no subluxation of the medial tibiofemoral compartment. In contrast, in the pivot shift 4 loading, there is a coupled anterior tibial translation-internal rotation (low) and valgus loading. There is a medial shift in the center of tibial rotation, with subluxation of the medial, center, and lateral tibiofemoral compartments. Loading conditions for pivot shift 3 were 35 N anterior, 5 N-m internal rotation, and 7 N-m valgus. Loading conditions for pivot shift 4 were 100 N anterior, 1 N-m internal rotation, and 7 N-m valgus. *CR*, Center of tibial rotation.

rotation, the coupled motions applied, the resting length of ACL fibers, and tibial attachment locations. In Chapter 3, the concept of an isometric transition zone or contour plot is presented. The zone represents a central transition zone in which fibers undergo 2 mm of length change during knee flexion and extension. This zone is not an isometric zone because the length change is not zero. All ACL fibers anterior to the zone lengthen with knee flexion, whereas the posterior fibers lengthen with knee extension. Under loading conditions, fibers in both the AM and PL divisions contribute to resist tibial displacements. ACL fibers in the PL division attach in part posterior to the transitional zone and lengthen with knee extension. Note that the function of the ACL fibers is determined by the anterior-to-posterior direction (knee at extension) as well as the proximal-to-distal femoral attachment. Placement of a graft in an anterior or posterior position has a large effect in producing deleterious lengthening and graft failure. The obvious example is a graft placed anterior to the "resident's ridge," which is anterior to the femoral ACL attachment. The femoral proximal-to-distal division of the ACL used in two-bundle descriptions of fiber length in knee flexion and extension oversimplifies the functional behavior of the ACL fibers, which are more dependent on their anterior and posterior femoral attachments.

The division of the ACL into two bundles was historically based on the tibial attachment site and not on a corresponding femoral attachment site. Recent studies project the tibial bundles onto two corresponding femoral sites. In these studies, to be described later, we usually divide the ACL femoral attachment site at a midpoint into a corresponding AM and PL bundle. In our opinion, there is not at present convincing anatomic data to support a division of the ACL into two separate bundles, although one study[68] reported a bony ridge between the two femoral attachment bundles. Because of the lack of a clear anatomic division of the ACL into two bundles, there is discrepancy among authors on anatomic descriptions of the ACL bundles and

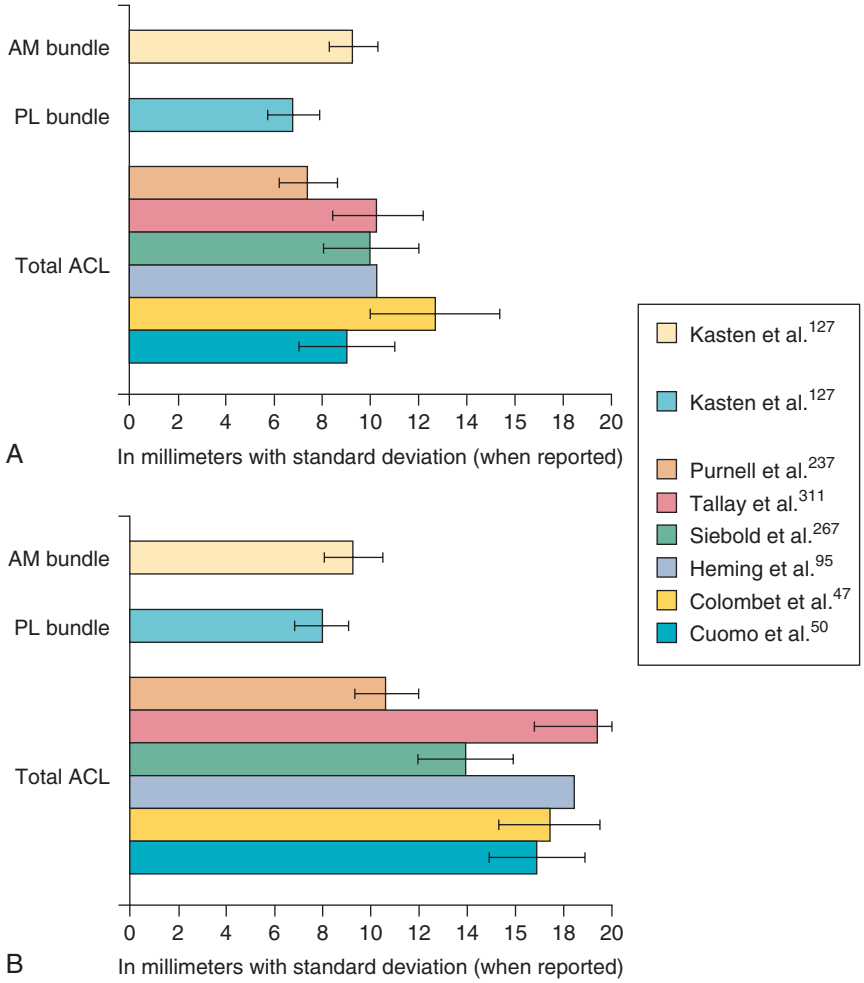

FIG 7-8 Anterior cruciate ligament (ACL) tibial insertion size width **(A)** and length **(B)** by publication, bundle, or footprint as a whole (total ACL). *AM,* Anteromedial; *PL,* posterolateral. recommendations for the surgical technique on tibial and femoral tunnels for two bundle graft reconstructions.

Tibial and Femoral Footprint Anatomy

Hwang and associates[112] performed a systematic review of the ACL tibial footprint in which 19 studies were analyzed. The authors noted wide variability in the reported size and shape of the native tibial footprint (Fig. 7-8). As a general guideline, on a lateral radiograph, the AM bundle was located at one third the anterior-to-posterior distance, the PL bundle was located at one half this distance, and the ACL center was located midway between (Fig. 7-9 and 7-10). The authors mentioned that although the line described by Amis and Jakob[8] was parallel to the medial plateau and the line described by Staubli and Rauschning[270] was perpendicular to the tibial axis, both lines yielded approximately the same results (Table 7-1). The approximate arthroscopic landmarks of the reviewed studies are shown in Table 7-2. These measurements need to be adjusted according to the relative size of the knee joint and potential anatomic variations. Even so, these measurements allow identification of the anterior two thirds of the ACL footprint for a 10-mm tunnel that avoids any portion of the tunnel occupying the posterior one third (PL bundle portion), ensuring that the tunnel remains anterior to the posterior lateral meniscus attachment.

Edwards and coworkers[59] defined the ACL tibial attachment in 55 cadaveric specimens. In Figure 7-11, the tibial bony landmarks are depicted. The "over-the-back" ridge (posterior interspinous ridge [RER]) corresponds to the interspinous ridge just anterior and proximal to the posterior cruciate ligament (PCL) attachment. Figure 7-12 presents these authors' recommendations for best-fit central and two-tunnel positions. The center of the ACL attachment was 15 ± 2 mm (range, 11-18 mm) from the RER at 36% of the anteroposterior (AP) depth of the tibia. The center of the PL bundle anterior from the RER was 10 ± 1 mm (range, 8-13 mm) and the AM bundle was 17 ± 2 mm (range, 13-19 mm), corresponding to 29% and 46% of the tibial depth, respectively. These authors were not able to define two separate anatomic ACL bundles. Instead, they defined two functional bundles by observing the tightening and slackening behavior of the ACL fibers during flexion and extension.

Stabuli and Rauschning[270] reported the center of the ACL tibial attachment at 43% of the AP depth, which extended from 25% to 62% of the tibial width. These important landmarks provide a reference to measure lateral radiographs before and after ACL graft

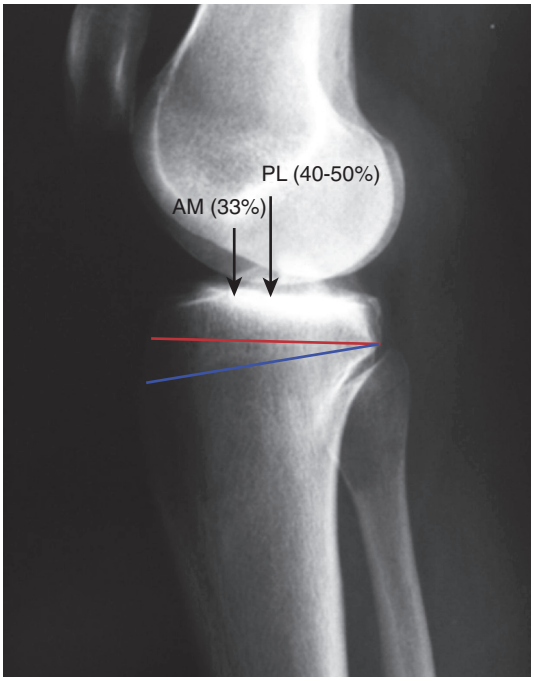

FIG 7-9 Lateral knee radiograph centered on the proximal tibia illustrates two anterior-to-posterior (AP) lines that may be used to identify the anatomic centrum of the anterior cruciate ligament (ACL) anteromedial (AM) and posterolateral (PL) bundles. The line (red) described by Amis and Jakob[8] is parallel to the medial tibial plateau. The line described (blue) by Stäubli and Rauschning[33] is perpendicular to the tibial axis. Systematic review of the literature shows that both lines yield similar results: the center of the AM bundle of the ACL is approximately one third of the AP distance along either line, and the center of the PL bundle is approximately 50% of the AP distance along either line. (From Hwang MD, Piefer JW, Lubowitz JH. Anterior cruciate ligament tibial footprint anatomy: systematic review of the 21st century literature. *Arthroscopy*. 2012;28:728-734.)

placement to avoid a posterior and vertical graft placement (Fig. 7-13). Siebold and associates[267] performed a cadaveric study in 50 knees and documented the ACL tibial insertion using a digital image analysis system and divided the ACL into AM and PL bundles. The average AP length of the ACL tibial attachment was 14 mm (range, 9-18 mm). The average male ACL tibial insertion area was 130 mm^2 versus the average female knee of 106 mm^2. The average AP length of the ACL footprint in females was 14 mm (range, 9-18 mm) and in males, 15 mm (range, 12-18 mm). The average width of the ACL in all knees was 10 mm. The study concluded that two tibial bone tunnels cannot be placed at the anatomic centers of the AM and PL bundles because the space is too narrow and the tunnels would overlap. This highlights the difficulty of the ACL double-bundle technique in recreating the native ACL fiber attachment.

Forsythe and colleagues[71] quantified the position of AM and PL bone tunnels in ACL reconstruction using arthroscopic dissection and computed tomography (CT) images in cadaveric knees (Figs. 7-14 and 7-15). Three-dimensional models were created from the CT scans and aligned into an anatomic coordinate system. The tibial and femoral measurements were similar to those published by other studies (Table 7-3).

In 2012, Piefer and associates[230] conducted a systematic review of studies that described the location of the ACL femoral footprint. Using the 20 articles selected for analysis, the authors provided general

The lateral knee radiograph method for describing the anatomic centrum of the anterior cruciate ligament (ACL) and its anteromedial (AM) and posterolateral (PL) bundles may be based on either the proximal tibial line described by Amis and Jakob[8] or the line described by Staubli and Rauschning[270] (see Fig. 7-13). The findings described by one of these two methods are summarized by published articles, with regard to the center of each bundle (and range when reported), as the percent distance along the line from anterior to posterior. In sum, both lines yield similar results; the center of the AM bundle of the ACL is approximately one third of the anterior-to-posterior distance along either line, and the center of the PL bundle is approximately 40% to 50% of the anterior-to-posterior distance along either line.

NA, not available; *SD*, standard deviation.

TABLE 7-2 Arthroscopically Useful Landmarks for Identifying ACL Tibial Footprint or Centrum of ACL Tibial AM or PL Bundles

Reference	Key Findings
Iriuchishima et al.[116] (2010)	Distance between center of AM and PL footprints and anterior margin of PCL is 23 ± 4 mm and 12 ± 3 mm, respectively.
Purnell et al.[237] (2008)	Distance from posterior fibers of ACL to anterior margin of PCL is 16.5 ± 2 mm (range, 12.7-19.1 mm).
Siebold et al.[267] (2008)	Posterior horn of lateral meniscus is adjacent to posterior border of PL footprint; centrum of PL footprint is 5 mm anterior.
Heming et al.[95] (2007)	Centrum of tibial footprint is 15.0 mm anterior to tibial notch of PCL.
Edwards et al.[59] (2007)	Centrum of tibial footprint is 15 ± 2 mm (range, 11-18 mm) from anterior PCL; center of PL bundle is 10 ± 1 mm (range, 8-13 mm) and AM is 17 ± 2 mm (range, 13-19 mm) from anterior PCL.
Luites et al.[156] (2007)	Centrum of AM bundle is one fourth interspinous distance from ML intercondylar eminence; PL bundle centrum is 4 mm more lateral, approximately halfway between spines; tibial footprint centrum as a whole is two fifths ML (interspinous distance).
Cuomo et al.[50] (2006)	Anterior border of ACL tibial footprint is 22 ± 3 mm (range, 16-27 mm) anterior to "over the back position" (ridge just anterior to PCL); posterior border is 6 ± 2 mm (range, 2-8 mm) anterior to ridge.
Colombet et al.[47] (2006)	Mean distance between AM bundle and anterior border of PCL is 17.5 ± 1.7 mm.

recommendations regarding the arthroscopic identification of the femoral footprint (Table 7-4). Already appreciated was the ACL location, which was noted to be in the posterior third of the lateral wall, posterior to the lateral intercondylar ridge (resident's ridge). The anatomic centrum of the ACL femoral footprint was 43% of the proximal-to-distal length of the lateral femoral intercondylar notch wall and femoral socket radius plus 2.5 mm anterior to the posterior articular cartilage margin. There is a well-known anatomic variability of size and shape in the majority of knees in which the ACL fibers can be visualized (Table 7-5 and Fig. 7-16).

The Bernard-Hertel method describes the centrum as the percent distance along the Blumensaat line (from proximal and posterior to distal and anterior) by the percent distance along a line perpendicular to the Blumensaat line (from proximal and anterior to distal and posterior). The Mochizuki method describes the centrum as the percent distance from proximal to distal by the percent from anterior to posterior (referencing the roof of the intercondylar notch). The Edward method describes the centrum as the percent distance from shallow (proximal and posterior) to deep (distal and anterior) by the percent from proximal and anterior to distal and posterior (referencing the roof of the intercondylar notch). The Takahashi method describes the centrum as the percent distance from proximal to distal by the percent from anterior to posterior (referencing the roof of the intercondylar notch).

ACL, Anterior cruciate ligament; *NA,* not available.

These data indicate that a 10-mm drill would produce a central point at the 43% proximal-to-distal line (just proximal to the midpoint). Assuming a 5-mm radius, plus a 3-mm back wall (to the articular cartilage bone margin), there would be an 8-mm point for the posterior articular cartilage margin. We prefer arthroscopic identification of the ACL femoral footprint compared with the various radiographic techniques shown in Table 7-6. The goal is to avoid a distal ACL footprint location (thereby producing a short graft) but to place the ACL graft into the proximal two thirds of the native footprint. This means the surgeon should select a point just proximal to the 43% line. We recommended the use of standard anatomic descriptions (anterior, posterior, proximal, and distal), rather than terms such as shallow, deep, high, and low.

Edwards and coworkers[59] described the anatomic locations of the ACL femoral attachments of the AM and PL bundles in a companion study in 22 cadaveric knees using a measurement grid system shown in Figure 7-17. The authors reported a wide variation in the size and shape of the ACL attachment and bundle arrangement that was selected (Fig. 7-18). The femoral attachment was oriented at 37 degrees to the long axis of the femur. The authors reported that the AM bundle extended to the posterior proximal limit of the femoral notch between the 10:30 and 11:30 o'clock positions. The PL bundle was located between the 9:00 and 10:30 o'clock positions. They reported that a 6-mm graft tunnel had the best fit if the AM bundle was located at 11 o'clock, 6 mm from the posterior outlet, and the PL bundle was located at 10 o'clock, 9 mm from the posterior outlet. They noted that other studies had different recommendations for the placement of two femoral tunnels in the double-bundle technique.

Zantop and colleagues[308] performed a cadaveric study in 20 knees that outlined the AM and PL bundle locations at the tibial and femoral sites. The authors arrived at different conclusions from those of Siebold and associates.[267] The tibia ACL division into the AM bundle was oriented from medial lateral, occupied the anterior one half of the ACL footprint, and was aligned with the anterior horn of the lateral meniscus. The center of the PL bundle was located 11 mm posterior and 4 mm medial to the anterior insertion of the lateral meniscus. The center of the AM bundle was located at 30% and the PL bundle was located at 40% on the lateral transtibial line.

Rue and associates,[248] in a cadaveric study, used a transtibial-drilled femoral tunnel, placed at the 10:30 position, and determined the location of a single-graft femoral tunnel in relation to the AM and PL bundles. The authors placed the guide pin for the tibial tunnel approximately 7 mm anterior to the PCL, which would represent a posterior one-third tibial attachment. They reported that the transtibial drilling of the femoral tunnel resulted in the AM bundle occupying an average of 32% (range, 3%-49%) of the ACL attachment and the PL bundle occupying an average of 26% (range, 7%-41%) of the ACL attachment. In addition, the remainder of the area of the 10-mm tunnel did not overlap the ACL footprint. The wide ranges reported in this study for the location of the femoral tunnel in terms of the native ACL femoral attachment highlight the problems of using the tibial tunnel to drill the femoral tunnel.

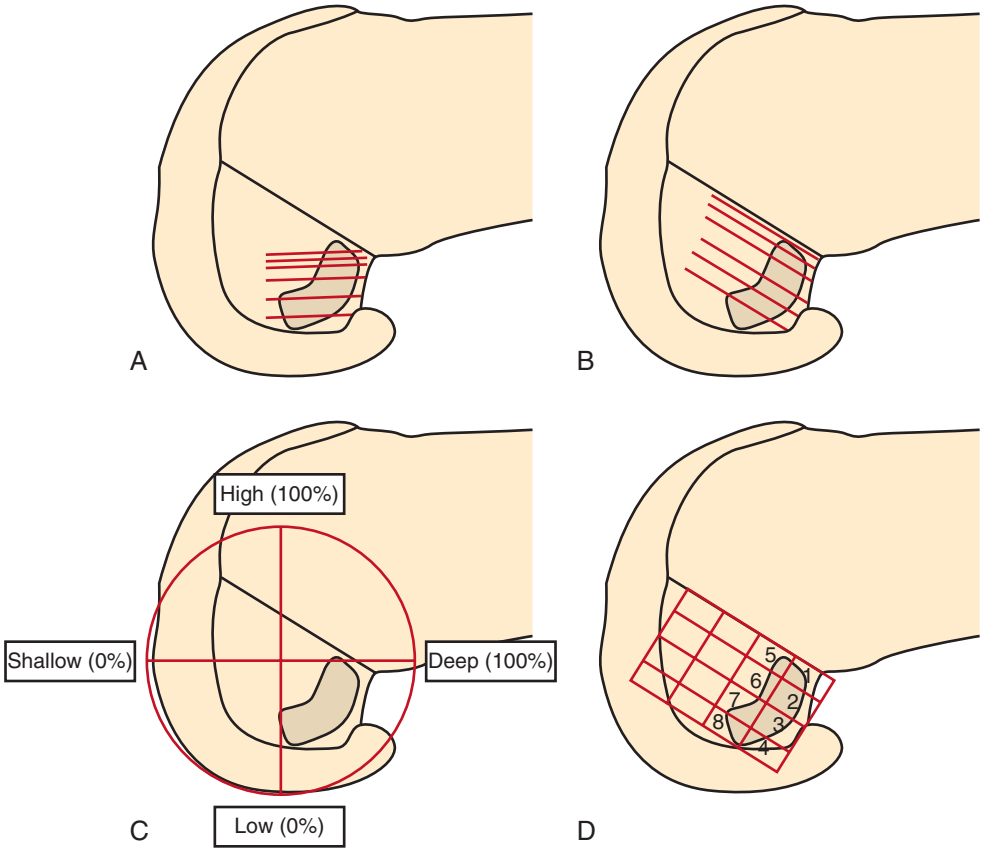

FIG 7-17 **A,** Measurement lines drawn parallel to the femoral shaft at clock-face positions. **B,** Measurement lines drawn parallel to the femoral notch roof from clock-face positions. **C,** The posterior condyle circle reference system. **D,** Measurement grid for describing the position of the centers of the two functional anterior cruciate ligament bundle attachments, with numbered zones. (From Edwards A, Bull AM, Amis AA. The attachments of the anteromedial and posterolateral fibre bundles of the anterior cruciate ligament: part 2: femoral attachment. *Knee Surg Sports Traumatol Arthrosc.* 2007;16:29-36.)

Heming and colleagues[95] reported the ACL tibial and femoral footprints in 12 cadaveric knees (Fig. 7-19). Note in Figure 7-19, *C*, the orientation of the clock face places the 9 to 3 o'clock horizontal line at the base of the femoral condyles and not within the center of the notch, which is typically used by other authors. A guide pin placed between the ACL anatomic femoral and tibial attachment centers (as in a transtibial drilling technique) was only possible if the tibial tunnel started in a medial position close to the joint line that would be too short to be functional for ACL grafts. The study concluded that transtibial drilling techniques resulted in a more vertical graft orientation.

Anterior Cruciate Ligament Function Defined by the Role of Anteromedial and Posterolateral Divisions

Biomechanical studies have reported marked differences in the function of the AM and PL bundles. Sakane and coworkers,[251] in one of the first cadaveric robotic studies, reported the PL bundle provided the primary restraint to anterior tibial translation at low flexion angles. Increasing forces were reported in the AM bundle with knee flexion; these remained lower than the calculated in situ forces of the PL bundle. However, subsequent studies have shown an increased role of the AM bundle and decreased role of the PL bundle in limiting anterior tibial translation.

The role of the ACL bundles in restraining rotational motions was examined by Zantop and associates[307] in a robotic study. A 134-N anterior tibial load or a combined 10 N-m valgus and 4 N-m internal tibial torque were applied to cadaveric knees. Sectioning the PL bundle at 30 degrees of flexion resulted in an approximate 7-mm increase in anterior tibial translation, whereas sectioning the AM bundle produced at 60 degrees an approximate 9-mm increase in anterior translation. Similar data were reported at low flexion angles for the combined rotational loads. These data imply a near-absence of function of the remaining "intact" bundle that is not supported by other studies. For example, Markolf and colleagues,[164] in a cadaveric study, reported that cutting the PL bundle resulted in an increase of only 1.1 mm at 10 degrees of flexion and 0.5 mm at 30 degrees of flexion. These authors questioned the need to reconstruct the PL bundle in ACL reconstructions.

Gabriel and coworkers,[74] in a robotic cadaveric experiment, removed all of the soft tissues to produce a femur-ACL-tibia specimen. For anterior tibial loading (Fig. 7-20), the AM bundle was reported to be nearly equal to the PL bundle at 15 degrees of flexion, with increasing AM forces with knee flexion. Under the rotation loads of valgus and internal tibial rotation, the forces in the AM bundle exceeded those of the PL bundle (Fig. 7-21).

Li and associates[145] used MRI and fluoroscopic images of subjects performing a lunge to create 3-dimensional models in which the AM and PL attachments were outlined. The study reported that the AM and PL bundles reached their maximum elongation between full extension and 30 degrees of flexion and did not demonstrate a reciprocal behavior with knee flexion-extension.

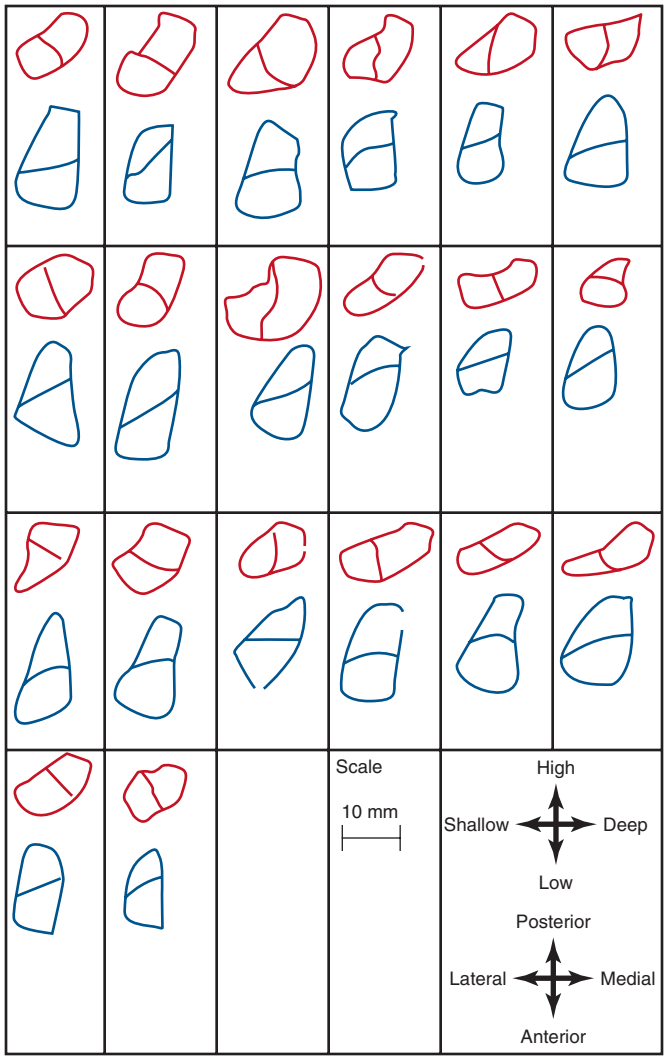

FIG 7-18 Anterior cruciate ligament attachment outlines on the femur and the corresponding outlines on the tibia; femur above tibia in each case; all shown for the right knee. (From Edwards A, Bull AM, Amis AA. The attachments of the anteromedial and posterolateral fibre bundles of the anterior cruciate ligament: part 2: Femoral attachment. *Knee Surg Sports Traumatol Arthrosc.* 2007;16:29-36.)

Giron and colleagues,[84] in a cadaveric experiment, determined that a "deep" (proximal) femoral tunnel position could be achieved with either one of three techniques (double incision, transtibial, or AM portal). However, Arnold and coworkers[15] showed in cadaveric experiments that the ACL is entirely attached to the lateral femoral wall and that this attachment position was not able to be accessed through a transtibial tunnel (40% AP tibial tunnel measurement). The transtibial tunnel method resulted in the guide pin and drill hole placed at the junction of the proximal ACL attachment and femoral roof (Fig. 7-22).

Mae and associates,[158] in a cadaveric knee study, used a robotic simulator to study the effect of single- versus two-femoral tunnel ACL graft reconstruction. A single tibial tunnel was placed in the center of the ACL tibial attachment. The locations of the single and two tunnels were described at the 1 o'clock and 2:30 positions. The data for AP translation and in situ graft forces at 44-N graft pretension showed little difference between the single- and double-bundle grafts, both of which produced a mild to moderate overconstraint that limited anterior tibial translation. The study reported on the load-sharing between the normal ACL bundles (Fig. 7-23), which demonstrated the PL bundle functioned more at low flexion angles, equal to the AM at 10 degrees of flexion, with a further increase in AM bundle function with increasing knee flexion. A study of load-sharing between the two bundles of a simulated pivot shift type of loading was not performed.

Yagi and colleagues[303] compared single- and double-bundle ACL hamstring reconstructions. A double-looped single-bundle hamstring graft was placed at approximately the 11 o'clock position and tensioned to 44 N, whereas each bundle of the double-bundle graft was tensioned to 44 N. The double-bundle graft had a total of 88 N of tension versus 44 N for the single-graft reconstruction. In response to a 134-N anterior load at 30 degrees of flexion, the data showed an unexplained residual anterior tibial translation (intact, 6.4 mm ± 2.4 mm: single bundle, 10.2 ± 2.5 mm), which would not be anticipated from a single graft in terms of resisting translation. The finding of a lax single graft most likely explains the reported decreased ability of the single graft to resist the combined rotation-translation motions.

Petersen and coworkers[229] concluded that the location of the ACL double-bundle grafts in clinical studies varied markedly at both the femoral and tibial sites. In a cadaveric study, Petersen et al.[229] found that a two-tunnel tibial technique provided an advantage in resisting combined rotatory loads, simulating the pivot shift (anterior tibial translation, 7.5 mm versus 9.5 mm, 30 degrees of flexion, 5 N-m internal rotation, 10 N-m valgus torque). Of note, the single tibial tunnel and graft were placed 7 to 8 mm anterior to the PCL; the authors stated that this was a position recommended by some surgeons.[106,180] As previously discussed, the posterior tibial tunnel position results in a more vertical ACL graft, with portions of the graft possibly even posterior to the native ACL tibial attachment. The addition of a second graft placed in a more anterior tibial position within the ACL footprint would be expected to provide better resistance to the loading conditions. Although the data do not provide evidence for a double-bundle ACL procedure, it does provide evidence to avoid placement of a single ACL graft in the posterior one third of the ACL tibial attachment.

Yamamoto and associates[304] conducted a cadaveric robotic study that compared a single ACL graft placed in the 10 o'clock position on the lateral wall with an anatomic double-bundle reconstruction. This is one of the few published studies in which a single-graft lateral wall placement was used, avoiding a more proximal graft placement. Similar loading conditions were used as in the other robotic studies (anterior tibial load 134 N, combined rotatory load 10 N-m valgus and 5 N-m internal tibial torque). There was no statistical difference in the anterior tibial translation or in situ force at 30 degrees of knee flexion between the intact ACL, the single bundle, or the anatomic double-bundle reconstructions. Under the combined rotatory loading conditions, there were no differences in anterior tibial translation, internal tibial rotation, and ACL in situ graft forces, which is in direct contrast to other robotic experiments.

Markolf and colleagues[165] measured in cadaver knees a simulated pivot shift in the intact knee and then after single-bundle and double-bundle ACL reconstruction. The single-bundle reconstruction (placed at the anatomic AM bundle site) restored mean tibial rotations and lateral plateau displacements to levels similar to those of the intact knee, whereas the double-bundle reconstructions reduced coupled rotations and displacements to levels less than those in the intact knee. The authors concluded that the overconstraint induced by the double-bundle reconstructions has unknown clinical consequences and that the need for the added complexity of this procedure is questionable.

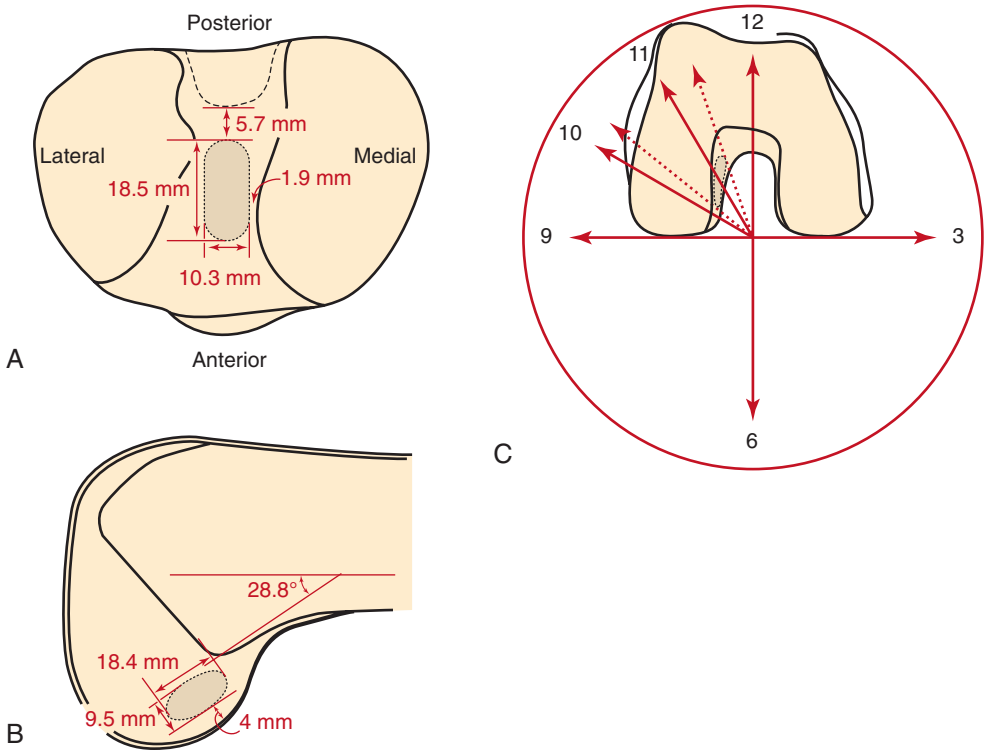

FIG 7-19 **A,** Right knee anterior cruciate ligament (ACL) tibial insertion. Measurements are the mean for the anterior-posterior length, medial-lateral width 10 mm from the posterior margin, distance from the posterolateral cruciate ligament notch, and distance to the medial plateau articular cartilage. **B,** Right knee ACL femoral insertion. Measurements are the mean for the length, width 10 mm from the proximal margin, distance to the articular cartilage, and angle to the long axis of the femur in the sagittal plane. **C,** Right knee ACL femoral insertion in the coronal plane with the knee flexed 90 degrees. The ACL insertion spanned the clock face from 10:14 to 11:23. The vertical 12 o'clock axis was perpendicular to the 3 to 9 o'clock axis drawn between the posterior femoral condyles. The vertical axis extended superiorly from a point midway between the walls of the notch to the apex of the notch. (From Heming JF, Rand J, Steiner ME. Anatomical limitations of transtibial drilling in anterior cruciate ligament reconstruction. *Am J Sports Med.* 2007;35:1708-1715.)

Cuomo and coworkers[51] reported on the effects of tensioning single- and double-bundle ACL reconstructions in cadaveric knees instrumented with a six-DOF system under defined loading conditions (anterior translation, 90 N; 5 N-m internal rotation torque). Different flexion positions were used for tensioning each of the grafts in the double-bundle construct. The single graft was tensioned at 20 degrees of knee flexion. All grafts had sufficient tension applied to restore normal intact knee translation. Tensioning each of the grafts individually (AM bundle at 90 degrees, PL bundle at 20 degrees, varying which was tensioned first) resulted in overconstraining AP translation. In contrast, tensioning both the AM and PL grafts simultaneously at 20 degrees provided the best match for the intact knee AP translation throughout knee flexion. The data show the difficulty in tensioning two ACL grafts at the time of surgery in terms of matching the intact ACL load-sharing among fibers. With anterior loading, both the AM and PL fibers participate in load-sharing, but at different percentages as already discussed. For single-bundle ACL grafts placed within the center of the femoral and tibial attachments, higher overall graft tension occurred under anterior loading compared with the two graft bundles tensioned at 20 degrees of flexion. Importantly, the data show that tensioning of the AM and PL grafts under low tensions (20 N) provided the best results. The single graft required 38 ± 27 N to restore the native knee laxity.

Scopp and associates,[257] in cadaveric experiments, reported that a more oblique femoral tunnel placement (60 degrees from vertical) was more effective in resisting internal rotational torques (difference 4.4 degrees, 6.5 N-m) than a "standard" tunnel placement (30 degrees from vertical). The femoral tunnel was drilled using a transtibial technique and, most likely, a posterior tibial tunnel placement. Anterior tibial translation values were not restored to normal (increased 2.5 mm and 2.2 mm, standard and oblique femoral tunnels).

Simmons and colleagues,[268] in cadaver experiments, showed the deleterious effects of a more vertical tibial tunnel (70 degrees and 80 degrees) with impingement against the PCL and higher graft tension. A more oblique tibial tunnel and femoral tunnel in the 60-degree coronal plane did not impinge against the PCL. The study recommended a posterior tibial tunnel placement and more proximal ACL femoral attachment with use of a transtibial drilling technique, again showing from a historical perspective the studies in the literature in which a more vertical graft orientation results.

Arnold and coworkers[16] showed in cadavers that the passive ACL tension flexion-extension tension curve was not reproduced by femoral tunnels placed at the 10 and 11 o'clock positions, but was reproduced by grafts in the 9 o'clock positioned tunnels. However, a less ideal posterior ACL tibial tunnel was used in this experiment.

In summary, a majority of in vitro robotic studies compare a double-bundle graft construct with a hybrid proximal femoral and posterior tibial orientation of a more vertical single-bundle graft construct and not a centrally placed femoral and tibial graft construct. Therefore, the published data apply specifically to this type of single-graft construct and show as expected that a vertical single graft is not positioned to resist rotational loading. It may be concluded that there is sufficient experimental data to recommend this hybrid graft orientation be avoided in clinical practice.

There are incomplete in vitro data on the comparison of an anatomic single-graft construct (within central tibial and femoral tunnels) with a double-bundle construct.[153] There are also incomplete experimental data on the function of individual regions of ACL fibers in resisting coupled motions as occurs in the pivot shift phenomena, which is an important area for future study (Fig. 7-24). Other biomechanical studies reviewed show that a single ACL graft placed within the anatomic femoral and tibial attachments (avoiding a high femoral and posterior tibial position) restore rotatory stability and question the need for a double-bundle procedure.[165]

One theoretical advantage of a double-graft construct tensioned appropriately is that there is initially less graft tension in each of the graft strands compared with the overall tension in a single graft. Stated differently, a single graft will always exhibit much higher graft tension to resist anterior loading than two graft arms in which load-sharing occurs. There is also the theoretical advantage of tensioning the two graft strands at different knee flexion positions to exhibit a different percent sharing of the overall tension than a single graft. From an experimental standpoint, either a single-graft or double-graft construct can be tensioned to restore normal motion limits; however, this may occur at the expense of high graft tensions,

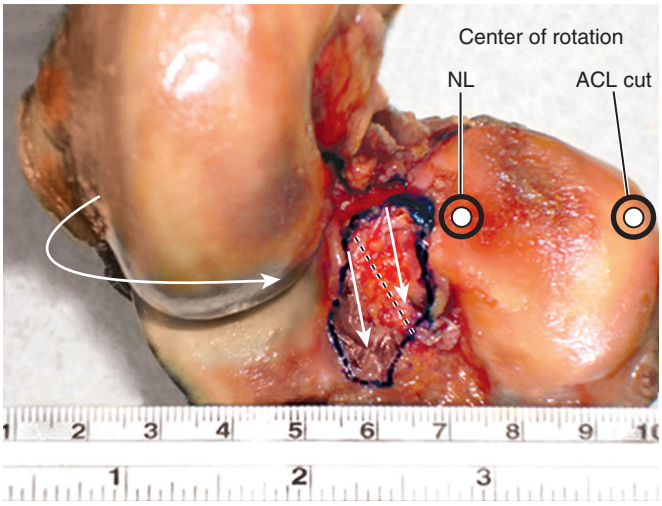

FIG 7-24 The anterior cruciate ligament (ACL) attachment on the tibia is outlined, along with an approximated center of tibial rotation. After ACL sectioning, the center of tibial rotation shifts medially, restrained in part by the medial ligament structures. The ACL tibial fibers are divided into anteromedial and posterolateral bundles. It should be noted that the anteromedial bundle is anatomically positioned to limit the coupled motions of internal tibial rotation and anterior translation under loading conditions; this effect has been frequently underestimated in biomechanical studies. *NL,* Normal.

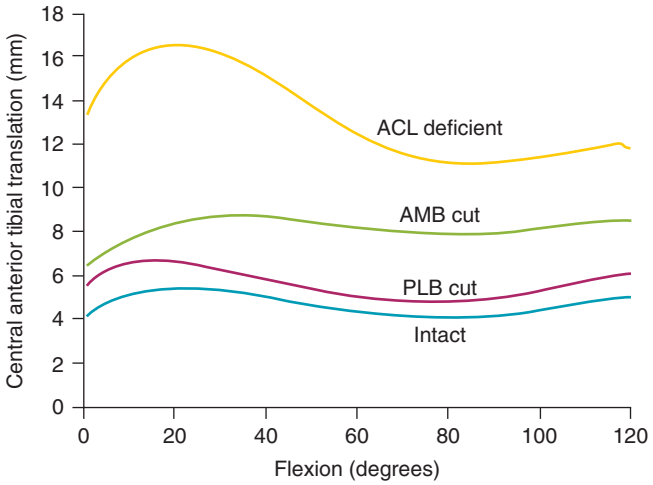

FIG 7-25 Anterior tibial translation of the central tibiofemoral compartment under a 100-N anterior load test from 0 to 120 degrees of flexion for intact, posterolateral bundle (PLB) cut, anteromedial bundle (AMB) cut and anterior cruciate ligament (ACL) deficient conditions. (From Gardner EJ, Noyes FR, Jetter AW, et al. *Effect of anteromedial and posterolateral ACL bundles on resisting medial and lateral tibiofemoral compartment subluxations. Arthroscopy.* 2015;31(5):901-910.)

particularly in a single-graft construct. Thus, the advantage of a double-graft construct (either ACL or PCL) is to restore normal knee motion limits under the lowest graft tensile loads, which is advantageous during graft healing and remodeling. A graft under lower loads has the theoretical advantage of less risk in stretching out with return of the abnormal motion limits. In addition, an ACL or PCL graft under higher tension, under cyclic loading conditions, is at high risk of graft stretching and failure.[261] Again, it should be noted that either one or two ACL grafts does not restore native ACL fiber length-tension properties.

Our Robotic Studies on Anterior Cruciate Ligament Anteromedial Bundle and Posterolateral Bundle Function and Single Anterior Cruciate Ligament Graft Reconstruction

We conducted a series of robotic cadaveric in vitro studies on the kinematic function of the AM and PL bundles of the ACL.[78,91,209] The studies involved a six-DOF robotic testing protocol on intact knees, knees in which either the AM or PL bundle was sectioned, and knees in which complete ACL sectioning was performed. As previously described, the robotic testing protocol involved, for the first time, the simulation of the pivot shift event using four DOF; namely, anterior tibial translation with internal tibial rotation with valgus loading of the limb during knee flexion-extension to induce maximum anterior tibial subluxation. The studies also involved, for the first time, digitization of the tibial plateau to determine medial and lateral tibiofemoral compartment translations and centers of tibial rotation in the simulated pivot shift test.

The results showed both ACL bundles functioned synergistically to resist medial and lateral compartment subluxations during the simulated Lachman and pivot shift tests. The AM bundle provided more restraint to anterior tibial translation under both tests than the PL bundle. Both ACL bundles had to be sectioned to produce tibiofemoral compartment subluxations during pivot shift loading (Figs. 7-25, 7-26, and 7-27). Neither bundle contributed to resisting internal rotation during pivot shift loading tests. We concluded that an ACL graft designed to duplicate the AM bundle restores medial and lateral compartment translations under multiple loading conditions; however, the PL bundle only provides a back-up restraint at low flexion angles. Neither ACL bundle resists internal tibial rotation or, in its absence, allows a positive pivot shift subluxation. Furthermore, the PL bundle is not the primary restraint for providing rotational knee stability, as has been quoted in the literature.[110,120,124]

We conducted a robotic cadaveric in vitro study that found that a single ACL graft placed into the anatomic center of the femoral and tibial attachment sites restored normal tibiofemoral compartment translations and rotations under simulated Lachman and pivot shift testing conditions. The study involved a six-DOF robotic testing protocol on intact knees, ACL-sectioned knees, and ACL-reconstructed knees. The reconstruction restored rotational stability as defined by normal motion limits and normal medial and lateral compartment translations under simulated pivot shift loading conditions (Fig. 7-28).

The results of this study support the recommendations in this chapter on the use of a single ACL graft instead of a double-bundle ACL graft construct. This finding is supported by Markolf and associates[166] who studied the effect of single- and double-bundle ACL grafts in cadaveric knees. As described in this chapter, prior robotic pivot shift studies on double-bundle ACL reconstructions used loading profiles that did not involve a coupled anterior tibial translation and internal rotation to induce maximum anterior tibial subluxations, and, in addition, did not measure resulting tibiofemoral compartment translations or subluxations. We question the validity of these studies in terms of the conclusions that a single ACL graft does not restore knee rotational stability or that a double-bundle ACL construct is required.

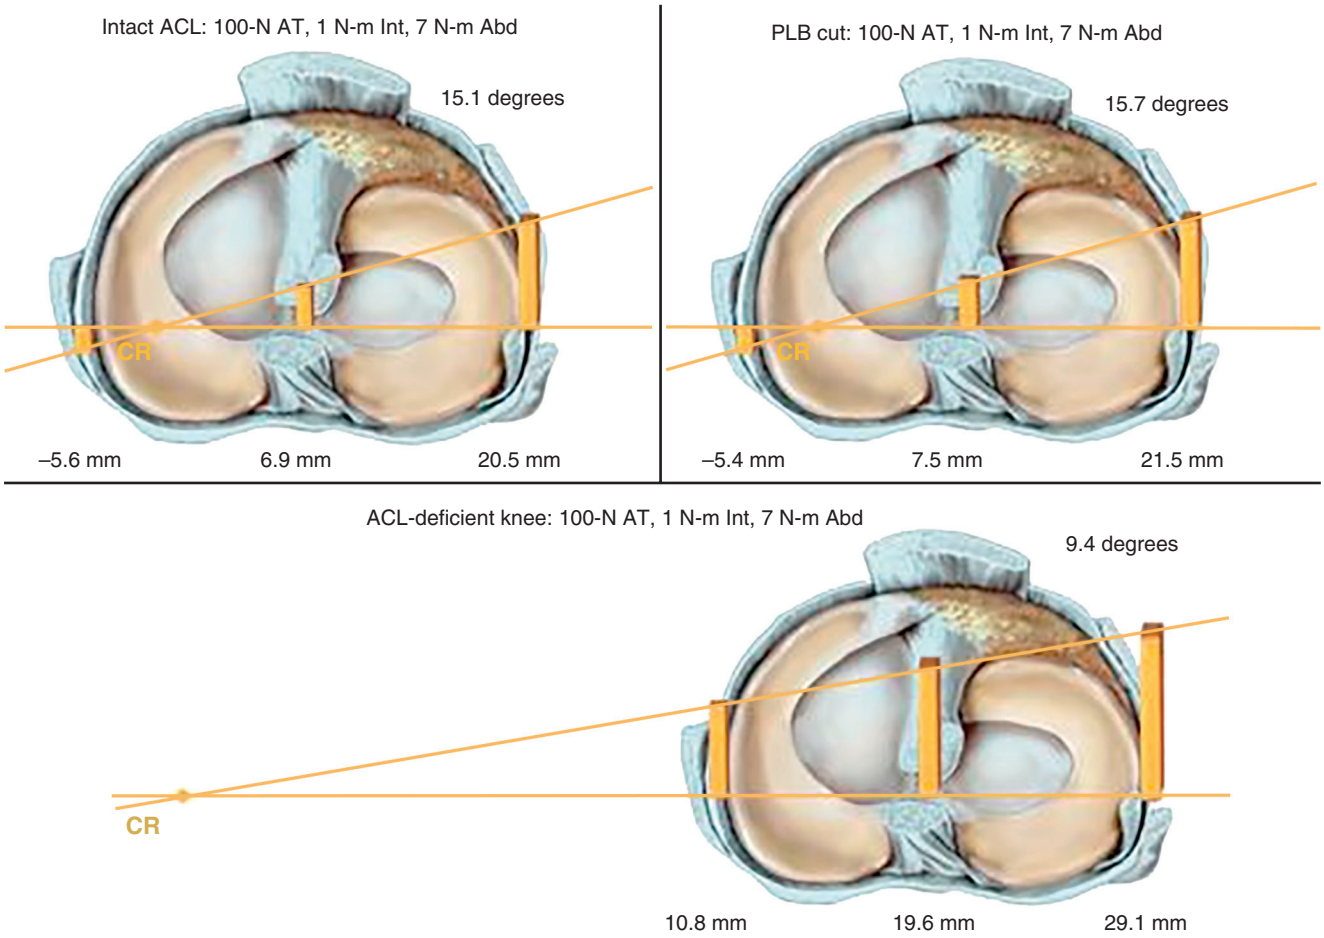

FIG 7-26 A representative right knee specimen showing compartment translations and tibial rotation under pivot shift 4 loading conditions (100-N anterior, 1 N-m internal rotation, 7 N-m valgus) for intact, posterolateral bundle (PLB) cut, and anterior cruciate ligament (ACL)-deficient states. PLB sectioning alone resulted in no statistically significant change in tibiofemoral compartment translations. *Abd*, Abduction; *AT*, anterior translation; *CR*, center of tibial rotation; *Int*, internal. (From Gardner EJ, Noyes FR, Jetter AW, et al. Effect of anteromedial and posterolateral ACL bundles on resisting medial and lateral tibiofemoral compartment subluxations: *Arthroscopy*. 2015;31(5):901-910.)

Clinical Measurement of Anterior Cruciate Ligament Graft Function During and After Anterior Cruciate Ligament Surgery

The assessment of ACL graft function must take into account the restoration of the normal coupled motion limits of anterior tibial translation and internal tibial rotation during the pivot shift phenomenon, which strongly correlates with patient giving-way symptoms. During KT-2000 (MEDmetric) testing, only anterior tibial translation is assessed. If the knee joint has a 3-mm or lower increase in central anterior tibial translation over the opposite knee, it can be assumed that there is no positive pivot shift because this amount of constraint to anterior tibial translation also limits anterior subluxation of the lateral tibial plateau. Conversely, if a greater than 5-mm increased anterior tibial translation exists, there may occur a positive pivot shift test and patient complaints of giving-way. The problem is in knees that demonstrate 3 to 5 mm of increased anterior tibial translation, which may represent 20% to 30% of patients in clinical investigations,[1,14,218,259,260] especially when allografts are used.[203] This mild to moderate increase in anterior tibial translation results in a mildly positive Lachman test with a hard endpoint. However, these knees may demonstrate a positive pivot shift and giving-way symptoms. Since the pivot shift test is highly subjective and variable among examiners (see Chapter 3), an author may report a successful result based on the KT-2000 (anterior tibial translation) or a pivot shift test, whereas another examiner may grade the knee as a failure, based on the method in which the pivot shift test is performed. There is a pressing need for clinical examination methods that simulate the pivot shift phenomenon and the resultant subluxations (in millimeters) of the medial and lateral tibiofemoral compartments.

Bull and associates[35] were among the first authors to report intraoperative measurement of tibial translations and rotations using a 3-dimensional motion analysis system. In the operative setting, there was a marked variability in knees in the amount of medial and lateral tibial plateau displacements during the pivot shift test. Robinson and colleagues[245] performed an ACL double-bundle reconstruction using computerized navigation techniques in 22 patients. The exact location of ACL grafts and the loads applied by the examiner are variables still to be determined.

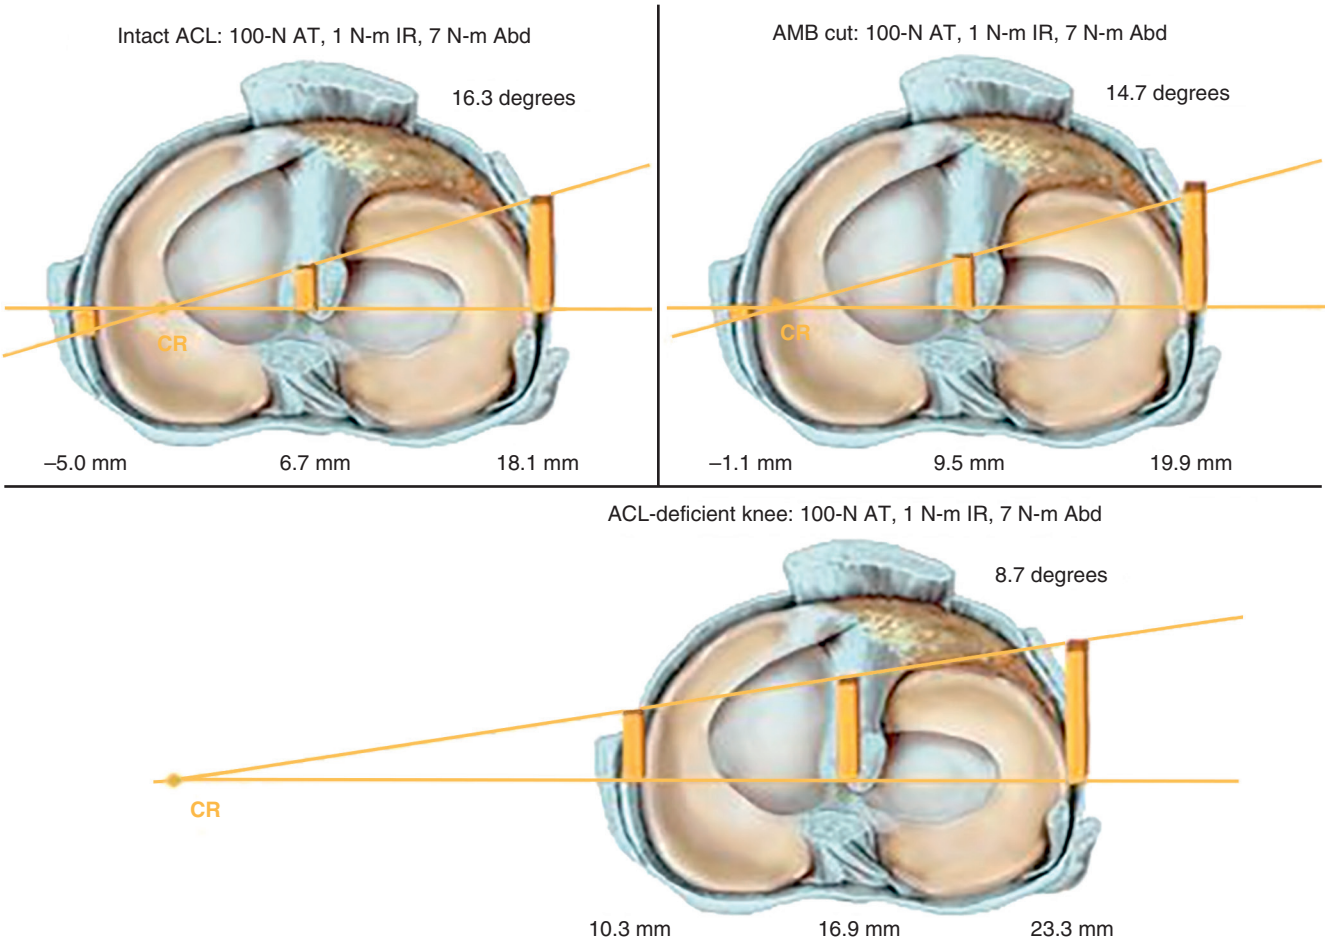

FIG 7-27 A representative right knee specimen showing compartment translations and tibial rotation under pivot shift 4 loading conditions (100-N anterior, 1 N-m internal rotation, 7 N-m valgus) for intact, anteromedial bundle (AMB) cut and anterior cruciate ligament (ACL)-deficient states. AMB sectioning alone resulted in a small but statistically significant change in tibiofemoral compartment translations. *Abd*, Abduction; *AT*, anterior translation; *CR*, center of tibial rotation; *Int*, internal. (From Gardner EJ, Noyes FR, Jetter AW, et al. Effect of anteromedial and posterolateral ACL bundles on resisting medial and lateral tibiofemoral compartment subluxations: *Arthroscopy*. 2015;31(5):901-910.)

In a frequently quoted study, Tashman and coworkers[282] devised a unique methodology of dynamic in vivo measurements of patients who had undergone ACL reconstruction. The investigators used a biplanar radiographic system to measure tibiofemoral displacements while the patients ran downhill on a treadmill. The reconstructed knees showed an increase in mean values of external tibial rotation (3.8 ± 2.3 degrees) and adduction (2.8 ± 1.6 degrees). The effect of these small differences from a clinical standpoint is unknown and future studies are required that involve more dynamic rotational movements in comparison to straight-ahead running to measure the rotational kinematics of the knee joint. The specific ACL graft femoral and tibial tunnel placement was not identified in this study.

Ristanis and associates[244] assessed 11 patients who had undergone B-PT-B reconstruction using kinematic data from a six-camera optoelectronic system obtained during a jump landing and pivoting maneuver. The ACL reconstruction did not restore tibial rotation to normal values of the opposite uninvolved extremity or controls. The femoral tunnel was placed through an AM approach with the knee joint flexed to 120 degrees to achieve a 10 to 11 o'clock lateral wall position. The tibial tunnel was placed into the center of the ACL footprint. The authors noted that a limitation of the study was the movement of skin markers that may not have accurately represented true tibiofemoral joint translations.

Monaco and colleagues[179] evaluated the effect, on internal tibial rotation, of a single-bundle ACL reconstruction combined with an extraarticular procedure compared with a double-bundle ACL reconstruction. Computerized navigation instrumentation was used in the operating room before and after the ACL procedures. The addition of the PL bundle after the AM bundle did not have an effect in reducing AP translation or the limit of internal tibial rotation, and there were no significant differences between the single- and double-bundle reconstructions. The extraarticular reconstruction significantly reduced the internal tibial rotation limit, as would be expected. The tibial placement of the graft was performed with the guide pin 7 mm anterior to the PCL insertion into the posterior ACL attachment. The authors did not determine the effect of either graft configuration on the coupled motions of the pivot shift test but only on the limit of internal tibial rotation alone.

Our conclusions of single-graft versus double-bundle graft ACL studies are summarized in Table 7-7. The hypothesis presented is that an ideally placed single-graft construct (central femoral and tibial ACL attachments, avoiding a vertical graft orientation) provides control of

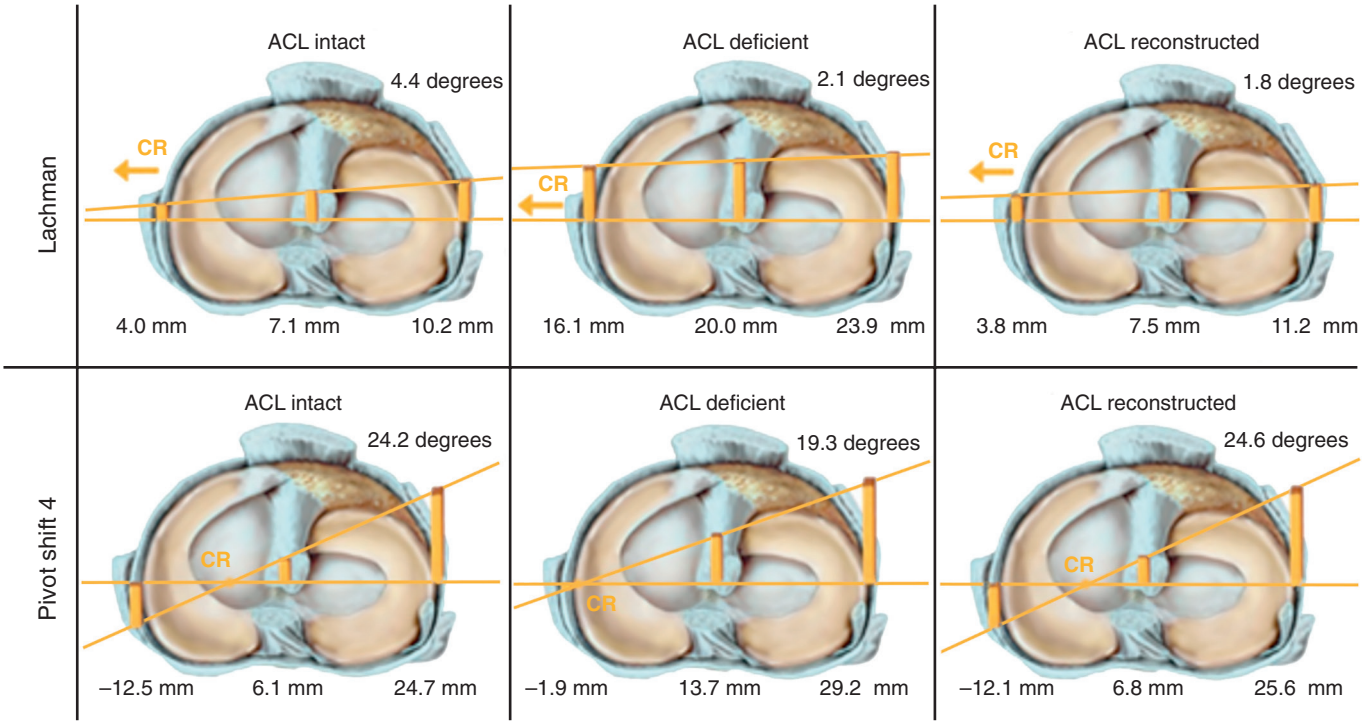

FIG 7-28 Compartment maps of a representative right knee specimen under the Lachman (100 N) and pivot shift 4 loading conditions (100-N anterior, 1 N-m internal rotation, 7 N-m valgus) for intact, anterior cruciate ligament (ACL)-deficient, and ACL-reconstructed conditions. A single bone-patellar tendon-bone graft placed in the central tibial and femoral ACL attachment sites restored translational and rotational stability, as measured by tibiofemoral compartment translations. *CR*, Center of tibial rotation.

TABLE 7-7 Our Conclusions of Single- vs. Double-Bundle Anterior Cruciate Ligament Reconstructions

1. The anterior cruciate ligament (ACL) is not an isometric structure and the length-tension behavior of its fibers cannot be represented by a functional division into two fiber bundles. Native ACL function cannot be replicated by either single- or double-bundle grafts. Oversimplification of ACL anatomy into two bundles is firmly established in the orthopedic literature. However, some studies suggest that there is no true anatomic division. In the future, a better understanding of which ACL femoral and tibial attachment regions represent the most ideal graft placement sites (and their appropriate tensioning) and the surgeon's ability to reproduce these conditions at surgery will result in a distinct advance for ACL surgery.
2. A common recommendation for placement of a single ACL graft into the proximal femoral attachment and posterior one-third tibial attachment (7-8 mm from the posterior cruciate ligament [PCL] fossa) produces a vertically oriented graft that does not provide adequate control of the coupled motions of the pivot shift.
3. Arthroscopic transtibial techniques commonly result in ACL grafts placed into a proximal femoral position through a tibial tunnel that is too posterior. Grafts in this location may decrease anterior tibial translation, but not the rotational motions of the pivot shift phenomena, and are not recommended.
4. A single ACL graft appears to be most ideally placed in the central femoral and tibial attachments, using an anteromedial (AM) portal with the knee in hyperflexion (or flexible guide pin, drill) or a two-incision technique (retrograde drill, flip drill) for the femoral tunnel. Transtibial arthroscopic drilling techniques are not recommended.
5. The double-bundle ACL technique has the theoretical advantage of locating grafts and collagen fibers throughout the entire ACL anatomic attachment sites (in contrast to single grafts). Robotic laboratory and clinical studies supporting ACL double-bundle grafts appear to reference the results to a hybrid single-bundle (proximal femoral, posterior tibial location), which is less ideal in resisting rotational loading.
6. It has not been experimentally proven from robotic or clinical studies that there is any difference (resisting the abnormal motions of the pivot shift phenomenon) between a central anatomic single ACL graft and a double-bundle graft.
7. The concepts of ACL double-bundle grafts have prompted a worthwhile reevaluation of ACL anatomy and study of the ideal location for both single- and double-bundle grafts. The added operative complexity of a double-bundle graft is not required compared with a well-placed single centrally located anatomic graft. In addition, revision procedures for failed double-bundle ACL reconstructions may represent an added and unnecessary complexity.
8. ACL double-bundle techniques often use soft tissue allografts to achieve the desired graft cross-sectional area. Allografts pose the added problem of a higher failure rate owing to delayed graft incorporation and healing compared with autografts. Prospective, randomized Level I clinical studies comparing anatomic single- and double-bundle autografts are required to provide clinical data without the added variables related to allografts.
9. Further clinical studies and objective clinical testing methods to measure rotational knee stability are required. Measurements of the coupled motions in the pivot shift test are required. The limits of anterior tibial translation of the lateral and medial tibiofemoral compartments with these coupled motions provide the best description of the anterior joint subluxations and rotational stability.

the abnormal pivot shift motions, avoiding the necessity and added complexity of a double-bundle graft reconstruction.

Recommended Tibial and Femoral Anterior Cruciate Ligament Graft Locations

Given the variation in ACL anatomic shapes among specimens, it is important during surgery to outline the individual size and shape of the ACL attachment for each knee. This can be done in a primary ACL reconstruction, but usually not in revisions. The cadaveric studies provide important anatomic reference landmarks. Because of the variation in ACL attachment shapes, it would be expected that there would exist variation among surgeons on the locations chosen for both single- and double-bundle ACL graft locations. Newer computer navigation techniques have been studied to aid in the placement of ACL grafts; however, it is still unknown at present which anatomic points to select for graft tunnels that would correlate with clinical stability results.

The important landmarks for the ACL tibial attachments are the medial tibial spine, RER of the proximal PCL fossa, and the attachment of the lateral meniscus. The PCL is a poor soft tissue landmark for the posterior extent of the native ACL attachment. It should be noted that some authors[107] have advocated a guide pin and tibial tunnel placement 6 to 8 mm from the PCL, which would place the tibial tunnel in the posterior portion of the ACL. In some knees, the tibial tunnel would be posterior to the native ACL attachment and just a few millimeters from the RER or interspinous ridge. This posterior tibial tunnel produces a near-vertical ACL graft that would not be expected to resist rotational loads in obliterating the pivot shift phenomenon, as already discussed.

The ACL tibial attachment location we recommend for a single graft is directly adjacent to the lateral meniscus anterior horn attachment as shown in Figure 7-29. The ACL attachment can be easily mapped at surgery based on the anatomic references provided. In some knees, the anterior extent of the ACL attachment may be obscured by soft tissues, and in these cases, the RER or posterior interspinous ridge of the PCL fossa is an important landmark. The center of the ACL will be 16 to 20 mm anterior to the RER. The guide pin is most ideally placed eccentric and 2 to 3 mm anterior and medial to the true ACL center, because the ACL graft displaces to the posterior and lateral aspect of the tibial tunnel.[45] The tunnel places the majority of the graft within the central tibial attachment and avoids the posterior attachment location. It is important that graft impingement against the anterior intercondylar notch does not occur because the circular graft may occupy a portion of the native flattened ACL tibial attachment. An anterior notchplasty is required, particularly in knees with an A-shaped notch. In many ACL revision knees, the bony ridge posterior to the ACL attachment ("no-man's land," Fig. 7-30) has been disrupted with a prior graft tunnel that extends 1 to 2 mm from the RER and requires a bone graft before the revision procedure. To avoid a vertical graft orientation, it is important that during the ACL tibial tunnel preparation (primary or revision surgery), the tibial drill does not inadvertently penetrate into or beyond the posterior one-third ACL attachment and adjacent RER.

Important landmarks for the femoral attachment are the posterior articular cartilage, the Blumenstaat line, and identification of the ACL attachment on the lateral femoral wall of the notch (in the regions outlined on the grid systems). The goal is to locate the tunnel in the central to proximal thirds to maintain ACL graft length, and within the central direct ACL native insertion that occurs through fibrocartilage and not within the posterior indirect insertion of fibers adjacent to the femoral articular cartilage edge. A tunnel distance (posterior or deep) from the femoral condyle articular cartilage of 3 mm prevents an excessive posterior graft placement that would be slightly lax with increasing knee flexion (flexion laxity). Again, the emphasis is made that no ACL fibers extend to the intercondylar roof; all of the fibers are on the lateral wall. Tsukada and coworkers[290] reported that the osseous ridge on the lateral femoral wall of the intercondylar notch (resident's ridge) had major positional and dimensional variations and should not be used as a reference for femoral tunnel creation.

Bird and associates[28] reported in a cadaveric study that, with the knee at 90 degrees of flexion, the central location of the ACL attachment was 50% of the AP depth of the femoral condyle (junction articular cartilage) along the lateral bifurcate ridge. The possible error in this technique is the distance that the central point is measured along the bifurcate ridge to avoid a tunnel adjacent to the femoral articular cartilage. Piefer and colleagues,[230] in a systematic review of 20 ACL femoral footprint publication, noted differences in techniques among studies; however, these investigators arrived at recommended arthroscopic osseous landmarks on the lateral wall of the intercondylar notch (Fig. 7-31) which are very useful for the arthroscopic surgeon. These include, when possible, identification of the native ACL attachment, the resident's ridge or intercondylar ridge, the bifurcate ridge, the notch roof where no ACL fibers attach, and the articular cartilage junction of the lateral femoral condyle. We first place the knee at 30 degrees (see Fig. 7-30), making sure the radius of the tunnel plus 3 mm is followed. For example, a 10 mm drill hole would have a radius of 5 mm plus 3 mm, or 8 mm from the articular cartilage. We measure tunnel placement at both 30 degrees and 90 degrees of knee flexion and each method is different in terms of measurements as discussed. The question regarding the ideal femoral graft placement at time zero (for example, proximal two thirds, central two thirds) and its effects on subsequent biologic remodeling cannot be answered and still requires more kinematic and clinical studies. It is our impression based on current knowledge that there would be no difference between these two femoral placements that would affect final clinical results. With femoral tunnel placement try to ensure the placement is not too anterior or posterior or distal in the femoral footprint.

Hensler and associates[97] conducted a study on the ACL femoral tunnel morphology induced by use of an AM portal drilling technique with knee hyperflexion. From a review of the literature, the authors determined that the average femoral ACL insertion size was 8.9 mm wide, 16.3 mm long, and 136 mm^2 in area. The femoral tunnel aperture was influenced by drill-bit diameter, transverse drill angle, and knee flexion angle (Fig. 7-32). The femoral tunnel aperture best matched the native ACL footprint at 102 degrees of knee flexion, whereas at 130 degrees of flexion, a mismatch in area of 13.5% was calculated (Fig. 7-33). Even so, the higher knee flexion angle of 115 degrees to 120 degrees lessens the chance of a posterior femoral wall blow-out. This study shows how the AM accessory portal drilling of the femoral ACL tunnel requires clinical experience and precise guide pin placement. The surgeon must determine that the exiting guide pin position is in the midlateral plane, above the femoral epicondyle, and maintain a 3- to 4-mm osseous posterior rim from the tunnel wall to the femoral articular cartilage. An angled flexible guide pin and drill are useful in larger patients when the AM portal drilling technique is selected because it is difficult to achieve 120 degrees of knee hyperflexion.

For single grafts, we recommend a central anatomic ACL placement with the femoral guide pin 2 to 3 mm above the midpoint of the proximal-to-distal length of the ACL attachment (30 degrees of knee flexion) and 8 mm from the posterior articular cartilage edge (see Fig. 7-30). This will produce a 10-mm tunnel, leaving a 3-mm thick posterior tunnel wall. The senior author prefers to define the ACL

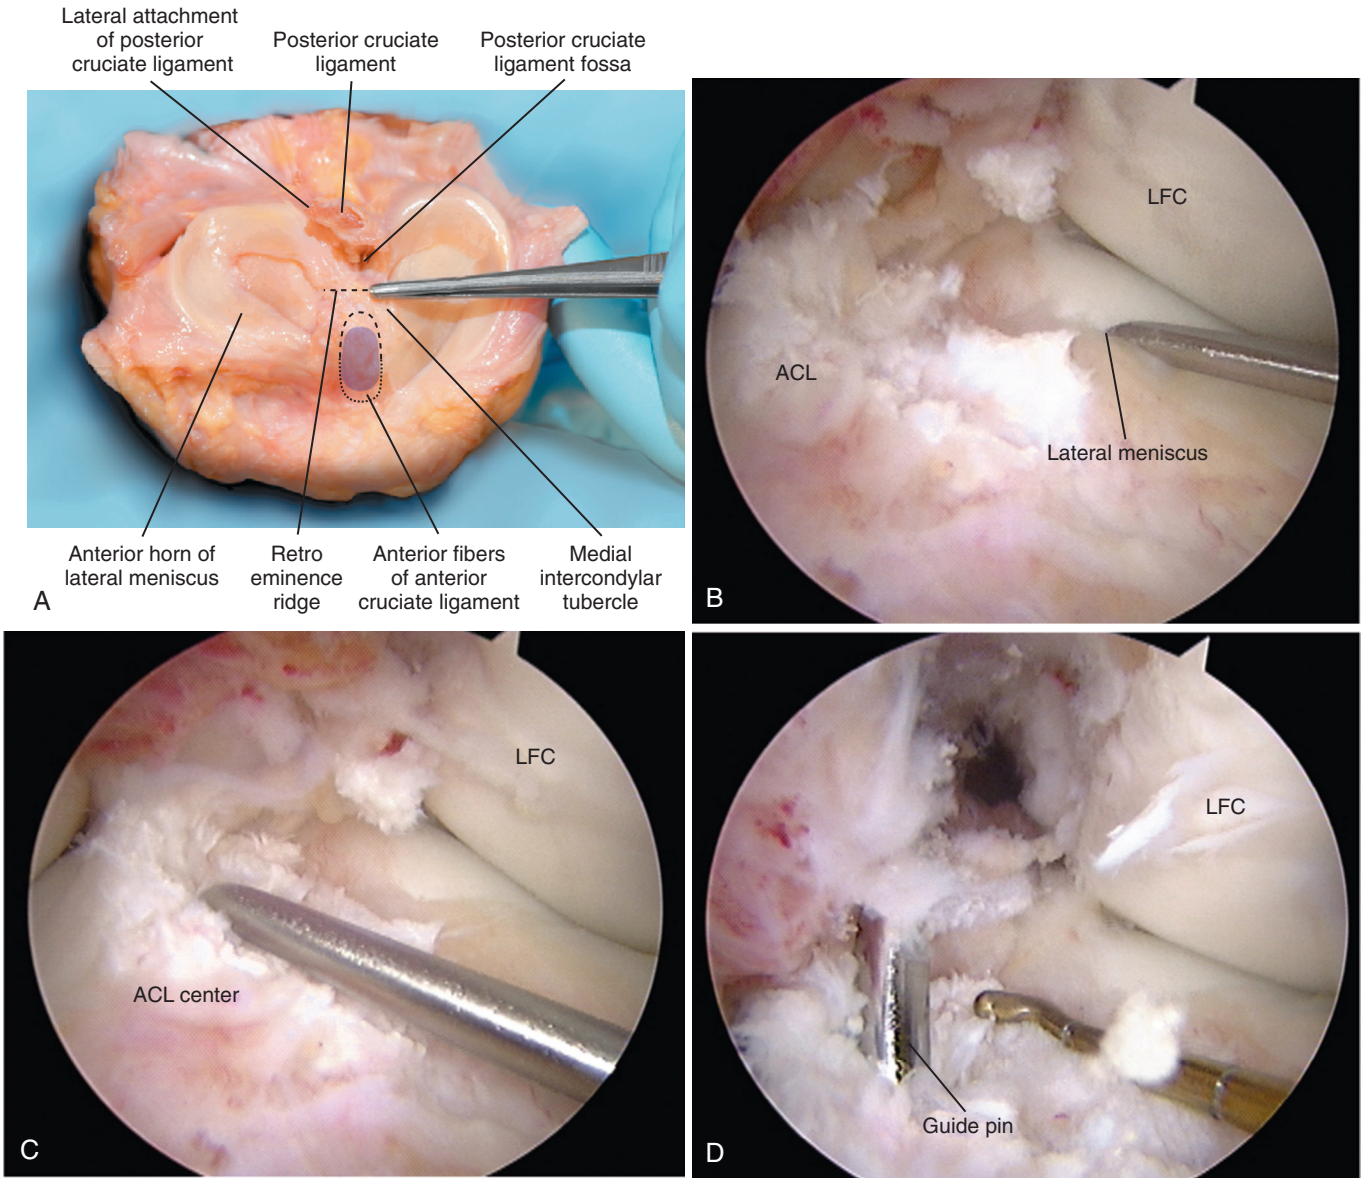

FIG 7-29 **A,** Anterior cruciate ligament (ACL) tibial attachment is outlined along with the shaded region, indicating a central placement of an ACL graft and tibial tunnel. **B,** Arthroscopic ACL attachment anterior to the posterior edge of the lateral meniscus. **C,** Center of ACL attachment is marked and is anterior to the lateral meniscus posterior edge. **D,** Placement of central guide pin for single-tunnel ACL reconstruction. *LFC,* Lateral femoral condyle.

attachment at 20 degrees to 30 degrees of flexion with the arthroscope in the AM portal. After the femoral site is marked, the knee can be placed in 120 degrees of flexion if an AM portal arthroscopic drilling technique is selected. A 9- to 10-mm diameter tunnel occupies the central ACL attachment, leaving only the most proximal and distal few millimeters of the attachment not occupied by a graft. It is important that the ACL femoral tunnel not be placed too far posteriorly because this produces excessive graft tension with knee extension. In addition, the graft should not be too distal at its femoral attachment because this shortens the intraarticular graft tibiofemoral length. The location for a single-tunnel ACL reconstruction is more distal than recommendations for a 1 o'clock tunnel that replaces only the proximal portion of the ACL femoral attachment. However, it has not been determined in clinical studies if a difference exists between the 1 o'clock and central femoral graft placement sites.

In Figure 7-34, *A*, the hybrid graft position of a proximal femoral and posterior tibial position is shown, which we do not recommend. The preferred central anatomic tibial and femoral position is presented in Figure 7-34, *B*, and the femoral position is presented in Figure 7-34, *C*. In our opinion, it would not be possible from a clinical standpoint to examine the difference in knee stability (pivot shift and Lachman tests and subjective symptoms) between a central femoral ACL graft location (that occupies the central two thirds, single graft) and a proximal femoral ACL graft location (that occupies the proximal two thirds, single graft). Both graft locations are described as anatomic and avoid placing the graft in the distal two thirds that would represent a shortened ACL construct. A recent study[242] suggested that a central femoral anatomic placement, achieved using an AM approach, was associated with a higher failure rate compared with grafts placed through a transtibial approach (5.16% and 3.20%, respectively).

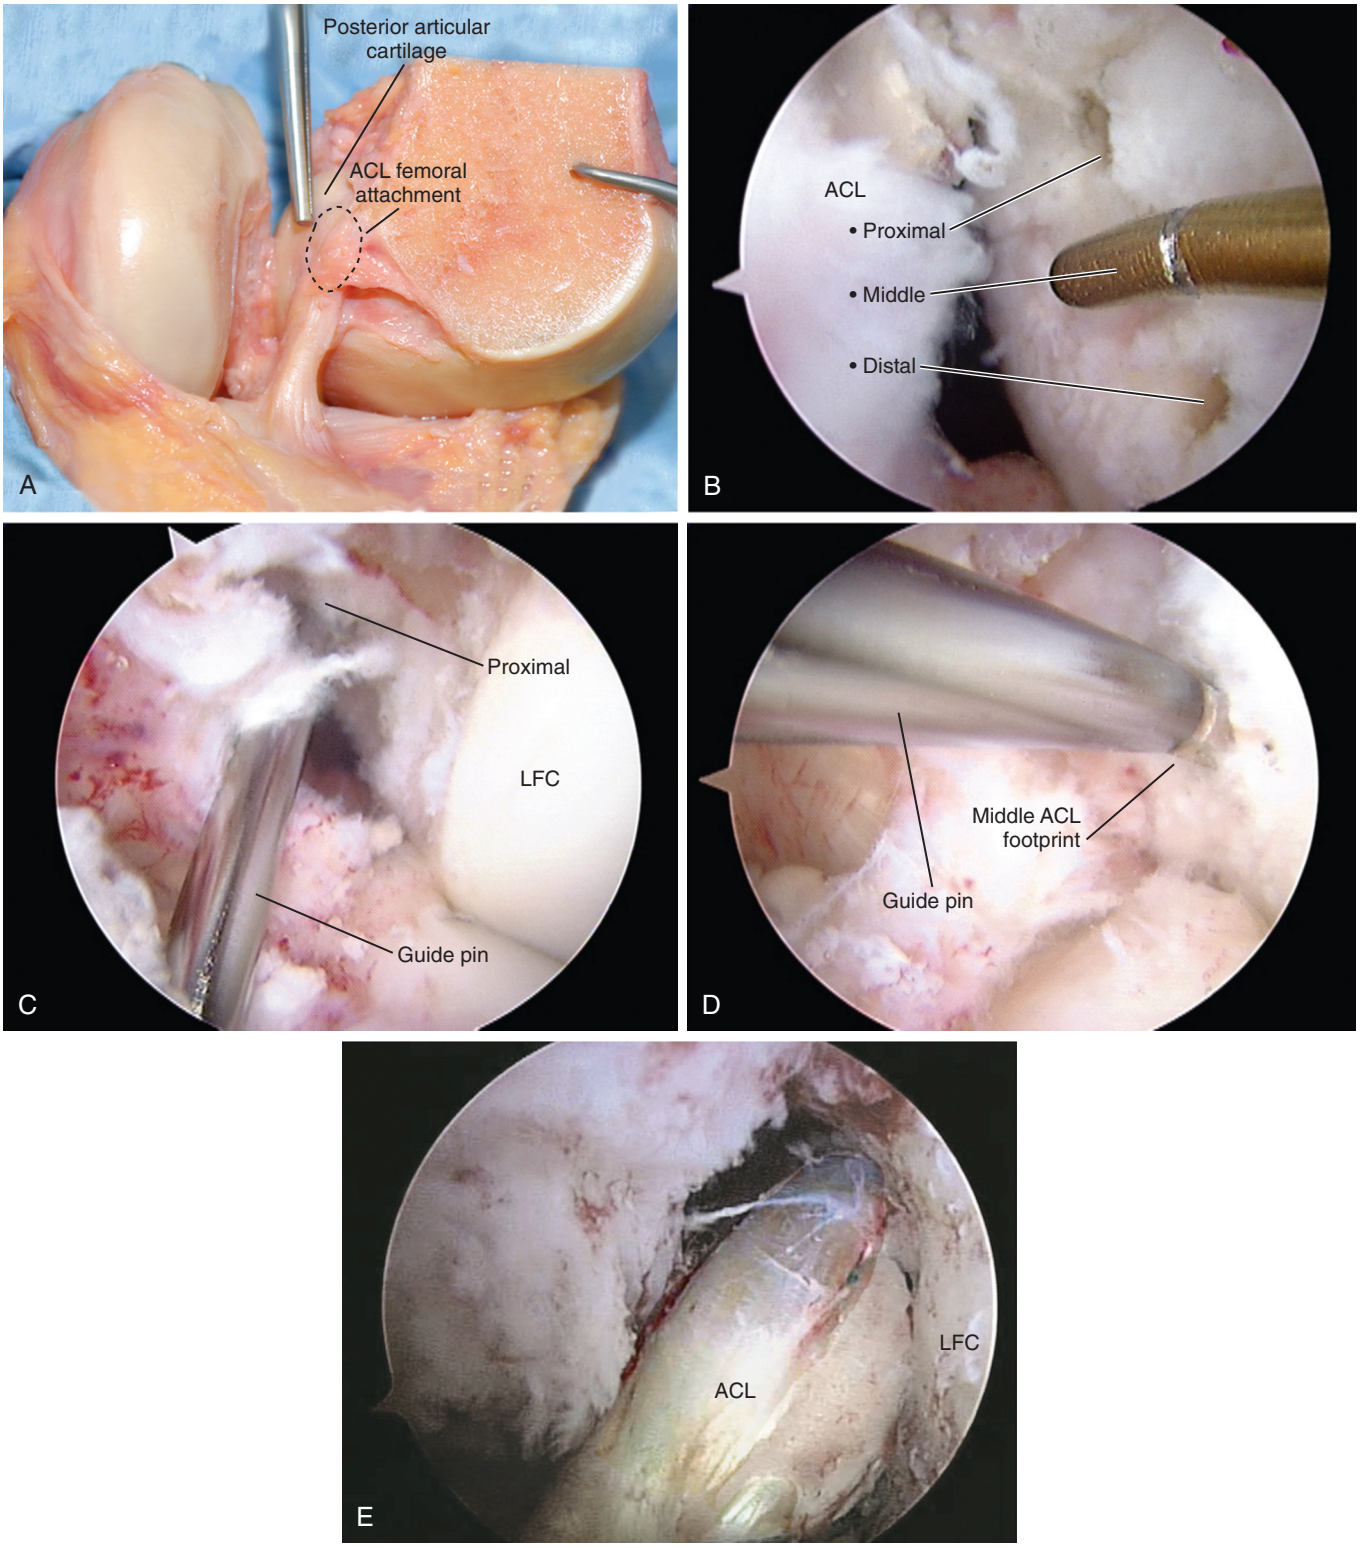

FIG 7-30 **A,** Anterior cruciate ligament (ACL) femoral attachment at 30 degrees of knee flexion (our preference rather than 90 degrees) shows the entire attachment on lateral wall of notch. **B,** Three points identified in proximal, middle, and distal portions of ACL attachment. **C,** Transtibial guide pin placement reaches only proximal one third of ACL attachment with a portion of the femoral tunnel extending onto the notch roof when a central ACL tibial tunnel is used. **D,** ACL central point reached with knee hyperflexion and anteromedial portal or with two-incision rear-entry technique. **E,** Final graft appearance on lateral wall. *LFC,* Lateral femoral condyle.

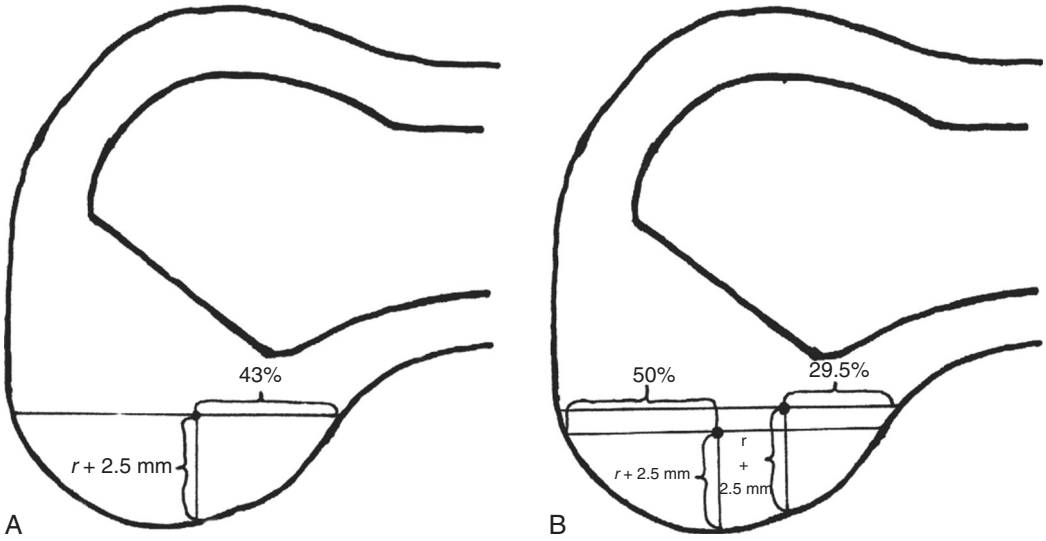

FIG 7-31 **A,** Sagittal section drawings representing the lateral wall of the intercondylar notch, right femur, with mean anatomic centrum of the anterior cruciate ligament (ACL) femoral footprint marked. **A,** The anatomic centrum of the ACL femoral footprint is 43% of the proximal to distal length of the lateral, femoral intercondylar notch wall and femoral socket radius (r) plus 2.5 mm anterior to the posterior articular margin. **B,** The anatomic centrum of the ACL femoral footprint anteromedial bundle (point on right) is 29.5% of the proximal to distal length of the lateral, femoral intercondylar notch wall. The anatomic centrum of the ACL femoral footprint posterolateral bundle (point on left) is 50% of the proximal to distal length of the lateral, femoral intercondylar notch wall. From posterior to anterior, the anteromedial bundle appears slightly anterior to the posterolateral bundle, and both bundles appear as r (socket radius) + 2.5 mm anterior to the posterior cartilage margin. (From Piefer JS, Pflugner TR, Hwang MD, Lubowitz JH. Anterior cruciate ligament femoral footprint anatomy: systematic review of the 21st century literature. *Arthroscopy.* 2012;28:872-881.)

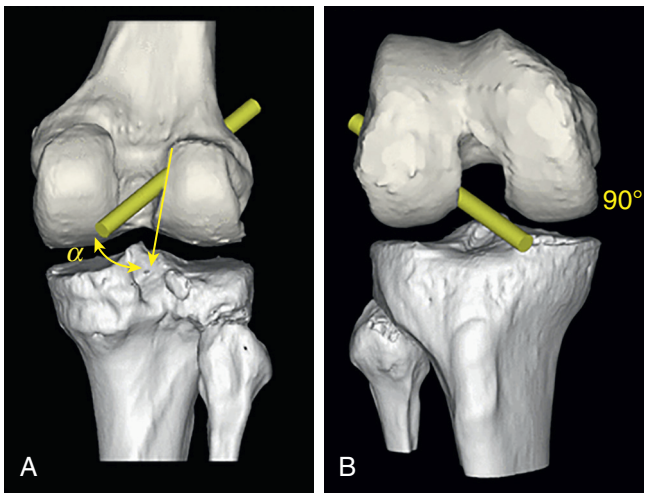

FIG 7-32 Three-dimensional model showing different transverse drill angles. **A,** Posterior view. **B,** Anterior view. α, angle at which the drill bit intersects the bone. (From Hensler D, Working ZM, Illingworth KE, et al. Medial portal drilling: effects on the femoral tunnel aperture morphology during anterior cruciate ligament reconstruction. *J Bone Joint Surg Am.* 2011;93:2063-2071.)

However, this study only used revision surgery in the calculation of failure and patients were followed only for a mean period of 22 months postoperatively.

ANTERIOR CRUCIATE LIGAMENT GRAFT HEALING

The process of biologic healing of ACL grafts is discussed in detail in Chapter 5. The potential use of MRI to document healing of the collagenous portion of the graft, the osseous tunnels, and the bone-ligament insertion sites after surgery is well known. However, standard MRI techniques that use echo times longer than a few milliseconds acquire very low signal from the tendon graft, which is subsequently viewed through negative contrast with surrounding tissues.[240] In addition, fixation materials cause local signal loss that results in low contrast between the graft and hardware.

In an effort to improve these problems, contrast-enhanced MRI was used to evaluate ACL grafts serially over the first postoperative year by Muramatsu and colleagues[182] and Ntoulia and associates.[216] In 2008, Muramatsu and colleagues[182] compared the signal/noise quotient (SNQ) of 20 ACL B-PT-B autografts with 24 fresh-frozen B-PT-B allografts at 1, 4, 6, and 12 months postoperatively. The center of the intraarticular portion of the ACL graft was evaluated before and after contrast enhancement. The authors reported statistically significant differences at all time periods, with the autografts demonstrating higher SNQ values. They did not provide any clinical data in regard to knee stability or sports activities resumed postoperatively.

In 2011, Ntoulia and associates[216] described the use of contrast-enhanced MRI to study changes in signal intensity in three distinct graft sites over time. The sites were (1) the intraarticular portion of the graft, (2) the site of the graft location inside the osseous tunnels, and (3) site of the graft that was adjacent to the fixation material inside the tunnels. The cohort included 32 males who underwent ACL B-PT-B reconstruction and MRI evaluations at the third postoperative day and 6 and 12 months postoperatively. All patients had a clinically stable knee postoperatively (negative Lachman and pivot shift tests) and resumed their preinjury sports activity level by 12 months. Distinct signal changes were noted between 3 days postoperative and 6 and 12 months later. The intraarticular site was the first and fastest to achieve satisfactory contrast medium uptake, which was noted at the 6-month test with no further alteration found at the 12-month test.

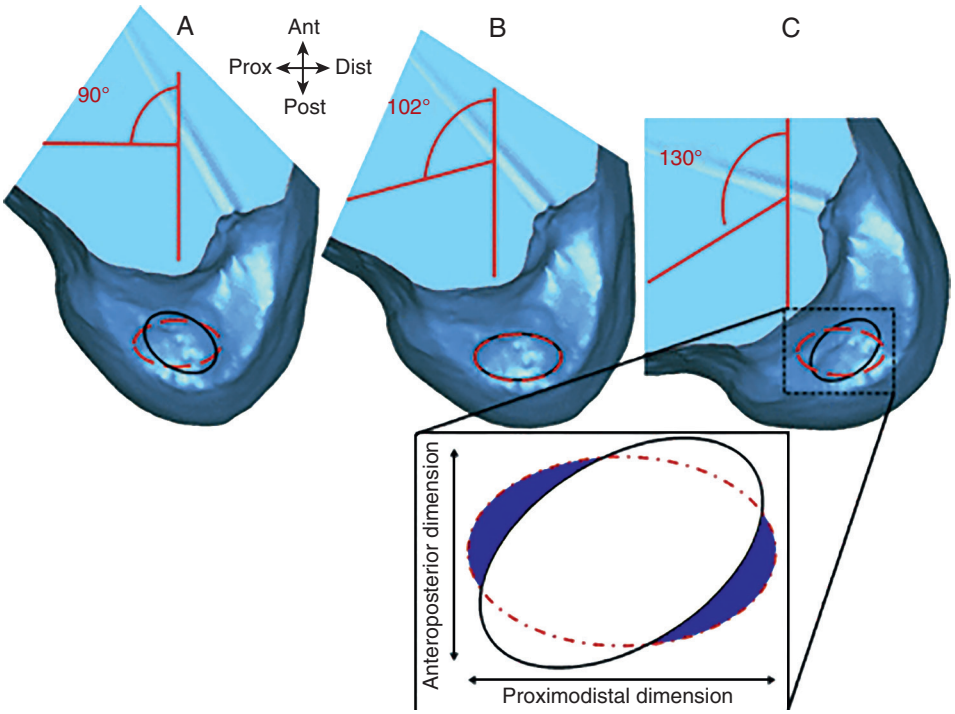

FIG 7-33 Examples of different knee flexion angles, where the anterior cruciate ligament (ACL) footprint is shown by the black oval lines and the tunnel aperture is shown by the red dotted lines. **B,** Overlapping ACL footprint and tunnel aperture at a knee flexion angle of 102 degrees. **A** and **C,** Mismatch between the ACL footprint and tunnel aperture in different knee flexion angles. The inset for **C** shows the resulting nonanatomic aperture area. *Ant,* anterior; *Dist,* distal; *Prox,* proximal. (From Hensler D, Working ZM, Illingworth KE, et al. Medial portal drilling: effects on the femoral tunnel aperture morphology during anterior cruciate ligament reconstruction. *J Bone Joint Surg Am.* 2011;93:2063-2071.)

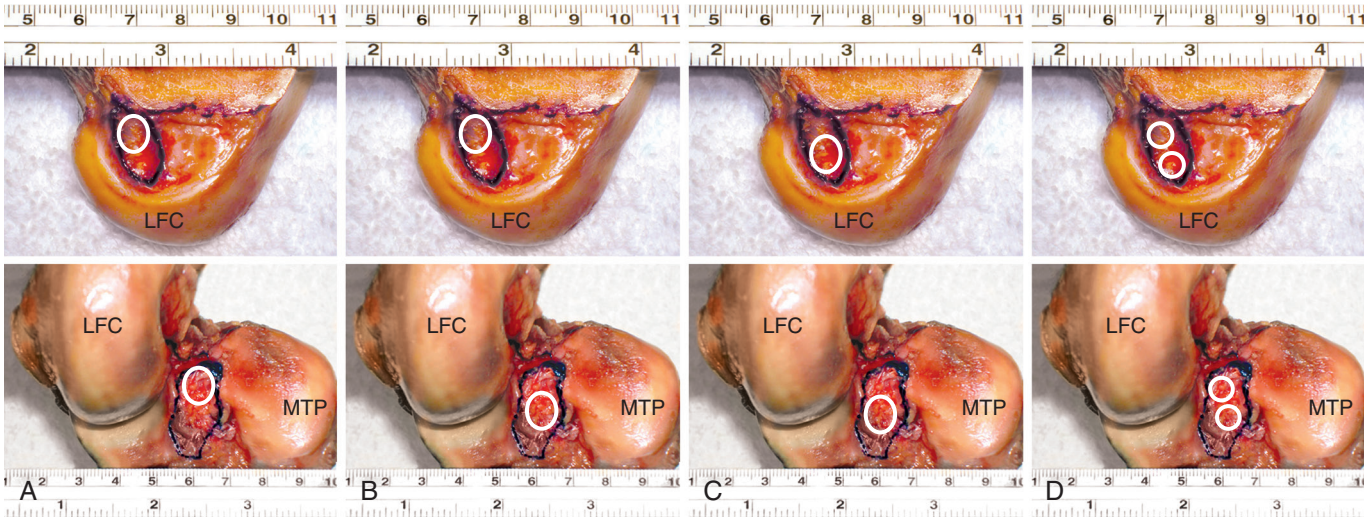

FIG 7-34 Summary of different femoral and tibial graft positions that are possible using anteromedial (AM) and posterolateral (PL) bundle terminology. **A,** Classic AM femur to PL tibia results in a vertical graft with a tibial tunnel placed too far posteriorly. **B,** A more central tibial tunnel is advantageous for control of rotational stability. **C,** The ideal central femoral-tibial tunnel locations for a single graft reconstruction. **D,** The placement of a two-bundle anterior cruciate ligament reconstruction. *LFC,* Lateral femoral condyle; *MTP,* medial tibial plateau.

The other sites showed a slower progression of remodeling that was still in progress at the 12-month test.

Other studies have more recently advocated the use of ultrashort echo-time (UTE) MRI techniques to study ACL grafts after implantation.[240] Three-dimensional UTE techniques allow visualization of short-T_2 components in tendons, ligaments, and menisci that provide superior contrast between ACL grafts and fixation material.[26,27,41,69,132,238-240,295] At the time of writing, only one in vivo study documented the use of 3-dimensional UTE in three asymptomatic men who had undergone semitendinosus-gracilis (STG) autograft

reconstruction 3 to 8 years previously.[240] The tests demonstrated a high graft signal that allowed visualization of the graft's internal structure (allowing homogeneity of the graft to be judged) and superior depiction of the fixation material. The authors commented that the addition of contrast agents may even further enhance the image contrast.

In 2014, Biercevicz and colleagues[27] further improved UTE MRI techniques by using high-resolution 3-dimensional images with no slice gap, volume and relaxation time (instead of signal intensity), and T_2 mapping in a porcine model. The authors reported that a multiple regression model based on ligament volume and its corresponding T_2 values significantly predicted the ligament's maximum load, yield load, and linear stiffness (that were determined with tensile testing) after 52 weeks of healing ($R^2 = 0.92, 0.82, 0.33$, respectively; $P < .001$). The T_2 relaxation time was believed to represent an MRI parameter that would be applicable across scanners of the same strength and among institutions. Further studies are required to evaluate the efficacy of using this method to predict structural ACL properties in vivo for longitudinal analysis.

In 2015, Ge and associates[79] used MRI to obtain 3-dimensional dual-echo steady-state images that were imported into solid modeling software that created 3-dimensional model reconstructions of bone tunnels in 36 patients. Eighteen patients had autograft and 18 had allograft ACL reconstructions and all were at least 2 years postoperative at the time of the study. The study found SNQs of the allograft group were consistently higher than those in the autograft group in the tibial tunnel. The authors concluded that the allograft tendons may have inferior remodeling in the bone tunnel; however, all knees had bone tunnel enlargement at the femoral aperture most likely because of the biomechanical effect of graft motion (sagittal and longitudinal graft-tunnel motion).

CLINICAL EVALUATION

A thorough history is performed, including a detailed account of all knee injuries and the operative procedures that have been performed. A comprehensive physical examination involving assessment of knee flexion and extension, patellofemoral indices, tibiofemoral crepitus, tibiofemoral joint line pain, muscle strength, and gait abnormalities is also completed. The surgeon must determine all of the abnormal translations and rotations in the knee joint. The medial posterior tibiofemoral step-off on the posterior drawer test is done at 90 degrees of flexion. Quantification of posterior tibial translation may be performed using stress radiography in knees with PCL ruptures to determine if the rupture is partial or complete (see Chapter 16).[99] The appropriate tests to determine the integrity of the ACL are performed, including KT-2000 arthrometer testing at 20 degrees of flexion (134-N force) to quantify total AP displacement. The pivot shift test is recorded on a scale of 0 to III, with a grade of 0 indicating no pivot shift; grade I, a slip or glide; grade II, a jerk with gross subluxation or clunk; and grade III, gross subluxation with impingement of the posterior aspect of the lateral side of the tibial plateau against the femoral condyle.

Insufficiency of the PLS and medial ligament structures are determined by varus and valgus stress testing at 0 and 30 degrees of knee flexion. The surgeon estimates the amount of joint opening (in millimeters) between the initial closed contact position of each tibiofemoral compartment, performed in a constrained manner avoiding internal or external tibial rotation, to the maximal opened position. The result is recorded according to the increase in the tibiofemoral compartment of the affected knee compared with that of the opposite normal knee. Abnormal medial or lateral joint opening may be measured with stress radiographs. The tibiofemoral rotation dial test at 30 and 90 degrees detects increases in external tibial rotation with posterior subluxation of the lateral tibial plateau or anterior subluxation of the medial tibial plateau because of medial ligament injury. A word of caution is necessary; it is possible to confuse increased external tibial rotation for a PL injury and miss the medial side ligament injury that requires correction.[206] The presence of a varus recurvatum in both the supine and standing positions is carefully assessed. Gait analysis is performed to detect a varus or valgus thrust or hyperextension thrust. Patients can often demonstrate their knee instability on standing, with a few degrees of knee flexion, by producing an external femoral rotation, which reproduces the pivot shift phenomena. Abnormal varus or valgus tibiofemoral joint opening may also be demonstrated by the patient.

Radiographs taken during the initial examination include standing AP at 0 degrees, lateral at 30 degrees of knee flexion, weight-bearing physical activity (PA) at 45 degrees of knee flexion, and patellofemoral axial views. Double-stance full-standing radiographs of both lower extremities, from the femoral heads to the ankle joints, are obtained in knees in which varus or valgus lower extremity alignment is detected on clinical examination. The mechanical axis and weight-bearing line are measured as discussed in Chapter 26. MRI is performed to provide further details of the condition of the articular cartilage and menisci. Fast-spin-echo techniques and 3-Telsa articular cartilage T_2 mapping are available when deemed necessary to obtain superior-quality articular cartilage images.[205,234]

At our center, patients complete questionnaires and are interviewed for the assessment of symptoms, functional limitations, sports and occupational activity levels, and patient perception of the overall knee condition according to the Cincinnati Knee Rating System (see Chapter 41).[22] The forms are available online for the patient to obtain before their consultation.

CRITICAL POINTS Clinical Evaluation

- Perform thorough history.
- Comprehensive physical examination assesses knee flexion and extension, patellofemoral indices, tibiofemoral crepitus, tibiofemoral joint line pain, muscle strength, gait abnormalities.
- Perform all stability tests to document abnormal tibial translation, rotations, and tibiofemoral compartment translation.
- Knee arthrometer test: 134 N.
- Radiographs: standing anteroposterior at 0 degree, lateral at 30 degrees; weight-bearing posteroanterior at 45 degrees; patellofemoral axial views; double-stance hip-knee-ankle alignment; lateral and posterior stress views as indicated.
- MRI, including articular cartilage image techniques.
- Cincinnati Knee Rating System for subjective, objective, functional scoring.

PREOPERATIVE PLANNING

All abnormalities or potential problems are addressed preoperatively, including patient expectation issues, muscular weakness, painful

CRITICAL POINTS Preoperative Planning

- Obtain full knee motion, muscle reeducation, and return of function before surgery.
- Address patient expectation and goals of surgery.
- Determine need for concomitant procedures, extraarticular procedures, and other ligament reconstructions to correct all instabilities.

neuromas, residual CRPS, and anterior knee pain caused by patellofemoral cartilage damage. A loss of full knee extension creates problems. It is important to obtain full knee motion before surgery. The exception is a bucket-handle meniscus tear that produces a mechanical block to full extension or flexion.

Considerable counseling and patient education are required on the expected results and outcomes from the reconstruction, as previously discussed. This is especially important in knees with preexisting arthritis or loss of meniscal function or those that require additional major operative procedures. A surgeon-rehabilitation team is required to provide instruction on rehabilitation to ensure that the postoperative exercise program will be successfully followed by the patient. The patient and family consult with the physical therapy team before surgery to ensure that the postoperative rehabilitation requirements are thoroughly understood. We have written specific patient-oriented electronic books (eBooks) for ACL surgery that provide extensive preoperative information and counseling.

Knees with grossly positive clinical laxity tests have involvement of the secondary ligament restraints, primarily the lateral structures. Associated medial or lateral ligament laxity is an indication for medial or lateral ligament reconstruction. In the ACL Reconstruction Clinical Studies section that follows, the results of autografts and allografts are discussed in further detail.

INTRAOPERATIVE EVALUATION

All knee ligament subluxation tests are performed after the induction of anesthesia in both the injured and contralateral limbs. The amount of increased anterior tibial translation, posterior tibial translation, lateral and medial joint opening, and external tibial rotation are documented. A thorough arthroscopic examination is conducted, noting articular cartilage surface abnormalities and the condition of the menisci. Appropriate debridement and meniscus repair or partial excision are performed as necessary.

The lateral and medial gap tests are done during the arthroscopic examination (see Chapter 17).[202] The knee is flexed to 30 degrees and a varus load of approximately 89 N applied. A calibrated nerve hook is used to measure the amount of tibiofemoral compartment opening. Knees that have 12 mm or more of joint opening at the periphery or 10 mm at the midpoint of the tibiofemoral compartment require a PL or medial ligament reconstructive procedure.

OPERATIVE TECHNIQUES

Graft Selection

The principles of ACL surgery are summarized in Table 7-8. Currently, there is no standard graft choice for ACL reconstruction. Autograft

CRITICAL POINTS Operative Techniques: Graft Selection, Patient Setup and Positioning, Graft Harvest

Graft Selection
- Primary knees: Prefer B-PT-B autograft in athletes, STG in recreational, more sedentary patients or those with patellofemoral problems.
- Allografts reserved for multiligament procedures, special cases where graft harvest is to be avoided.

Patient Set up and Positioning
- Patient uses chlorhexidine wash operative limb three days before surgery.
- Antibiotic infusion 1 hour before surgery.
- Nonsteroidal antiinflammatory medication morning of surgery, continued 72 hours postoperative.
- Knee to be reconstructed initialed by surgeon, time-out in operating room.
- Patient supine, place tourniquet middle thigh for use only as necessary.
- Use leg holder for initial arthroscopy, meniscus repairs.
- Knee portion bed flexed 60 to 90 degrees, bed midportion retroflexed 15 degrees.
- Uninvolved extremity placed in well-cushioned padded holder.
- After initial arthroscopy, adjust bed to allow 120 degrees of knee flexion.

Graft Harvest, B-PT-B Autograft
- Inflate tourniquet 275-mm pressure.
- 3- to 4-cm incision adjacent medial border patellar tendon, medial to inferior pole of patella, mobilize skin flaps for cosmetic approach.
- Retinaculum middle patellar tendon incised, limited dissection only for width of graft to be removed.
- 50% of patients will have small area of numbness just lateral to the patellar tendon counsel preoperatively.
- Use precut 10-mm and 22-mm paper ruler to define graft dimensions.
- Patellar tendon incised in midportion.
- Trapezoidal bone block graft from patella removed with fine saw cuts, osteotome, and similar procedure for tibial bone block.
- Sutures placed each bone block, prepared for passage.
- Graft wrapped in blood-soaked sponge.
- Diameter of tunnels 1 mm larger than diameter of bone block.
- End of procedure, loosely approximate tendon graft harvest site with sutures.
- Meticulous bone graft from core reamer patella, tibia defects. Place two horizontal mattress sutures inferior pole patella, superior tibial tendon attachment to hold bone grafts in defects, close anterior tissues.

Graft Harvest: Quadriceps Tendon-Patellar Tendon Autograft
- 5- to 6-cm longitudinal incision from superior pole patella, extending proximally.
- Graft harvest: 10 mm wide through all 3 layers, length 60 to 70 cm.
- Bone graft sized 9- to 10-mm diameter.
- Close quadriceps tendon defect with sutures.
- Meticulous bone grafting patellar defect, closure soft tissues

Graft Harvest: STG Autograft
- 3- to 4-cm oblique incision over pes tendons.
- Identify, palpate STG tendons.
- Turn down confluent tibial attachment.
- Grasp each tendon 90-degree angle distal end, roll two to three times about straight hemostat.
- Superficial tissues removed, overlying sartorius fascia protected.
- Proximal fascia bluntly dissected, ST tendon attachment medial gastrocnemius fascia incised, avoid saphenous nerve.
- Displace each tendon 10 cm in push-pull maneuver.
- Pass graft harvester, transect each tendon 20 cm for a four-strand graft or 24 cm for a six-strand graft.
- Prepare, wrap in blood-soaked sponge.
- Six-strand graft used in women and patients of small stature.

Iliotibial Band Extraarticular Tenodesis
- Goal is to reconstruct the posterior femoral tibial ITB attachment, which is an important restraint to abnormal internal tibial rotation.
- Procedure is described in detail in Chapter 8.

TABLE 7-8 Principles of Anterior Cruciate Ligament Surgery

1. The principles for successful anterior cruciate ligament (ACL) reconstruction are the same for both primary and revision ACL procedures. The goal is to obtain a stable knee joint with improved function without a complication.
2. The indications for ACL surgery involve profiling the patient's future athletic pursuits, as discussed. Athletic patients participating in turning, twisting, and jumping activities are candidates for ACL reconstruction, whereas sedentary patients are treated conservatively. The recreational athlete has time to choose; however, it would be incorrect to return this patient to strenuous athletic pursuits with an ACL-deficient knee. A primary goal is to prevent a meniscus tear occurring from a repeat giving-way injury. All studies show that the loss of meniscus function results in a high rate of future joint arthritis.
3. ACL grafts should be placed in an anatomic position within the femoral and tibial footprint (single- or double-bundle graft). In single ACL grafts, the central portion of the femoral and tibial attachment site is recommended. The graft should not be placed in a femoral tunnel located solely in the proximal one third of the ACL footprint. This results in an orientation that is not effective in controlling anterior tibial translation and internal tibial rotation. This proximal placement may also occur in double-bundle techniques, such as smaller knees in which a more proximal femoral tunnel is selected to make room for the second femoral tunnel. The native ACL femoral attachment is located entirely on the lateral wall; no fiber attachments extend to the intercondylar roof.
4. A less than ideal graft placement may also occur at the ACL tibial attachment when the tibial tunnel location is in the posterior one third of the ACL footprint. A commonly used ACL tibial guide system references the tibial tunnel 6 to 8 mm from the posterior cruciate ligament (PCL) at the tibia. This places the tibial tunnel in the posterior one third of the ACL attachment and, in some knees, posterior to the native ACL attachment, resulting in a vertical graft orientation.
5. A limited notchplasty is usually required during ACL primary and revision surgery, with an anatomic central tibial ACL placement to prevent roof impingement in extension and to have an adequate graft space between the lateral notch and the PCL.
6. Associated ligament injuries overload an ACL graft and require diagnosis and correction to prevent failure of the ACL reconstruction. Abnormal medial or lateral gap tests during arthroscopy indicate that the ACL graft alone will not correct the instability. There exists a select group of knees with significant physiologic laxity of associated knee ligaments that should be treated as a concurrent pathologic instability. An abnormal lateral tibiofemoral gap of 12 mm on varus testing at arthroscopy requires surgical correction regardless of whether the gap resulted from injury, physiologic laxity, or a combination of both problems.
7. Abnormal knee hyperextension of 12 to 15 degrees may overload an ACL graft and requires operative correction. The recommended posterolateral graft reconstructive procedures for a severe hyperextension varus recurvatum deformity are described in Chapter 17. Certain ACL revision knees with stretching or injury to the secondary ligament restraints and a gross grade III pivot shift have a higher revision failure rate, and a lateral extraarticular procedure is warranted.
8. The selection of an autograft or allograft to provide the highest success remains controversial. We recommend autografts (ipsilateral or contralateral) for both primary and ACL revision surgery owing to the superior healing, graft incorporation, overall higher success rates in clinical studies, and avoidance of transmission of disease (even though of rare incidence). Allografts are reserved for multioperated revision knees with concurrent instability where suitable graft sources are not available or special clinical cases in which a graft harvest is to be avoided. Use of extraarticular allografts is discussed in subsequent chapters for medial and lateral ligament reconstructions.
9. During revision surgery, a variety of instruments and techniques are required for graft placement and fixation when the tibial or femoral tunnels are enlarged. If anatomic graft placement cannot be achieved using existing tunnels, staged bone grafting is required. The integrity and quality of the surrounding bone must be restored to allow a close approximation between the tunnel and graft interface for graft incorporation and a successful healing process.
10. Proper rehabilitation supervised by professionals trained in problems related to complex knee surgery is essential for success and the return of lower extremity function and avoidance of arthrofibrosis. Rehabilitation principles and protocols are addressed in Chapters 10 to 12.
11. Patient education is required regarding expected outcomes and return to athletic activities. A primary ACL patient may have sustained articular cartilage damage or loss of meniscus function that will affect future athletic activities. A majority of revision knees have associated articular cartilage damage and partial or total loss of meniscus function. Many patients who have joint stability restored believe their preinjury athletic activities may be possible without modification. Counseling on the associated damage to other joint structures and need for activity modification allows for an active lifestyle over the long-term.

tissue sources include B-PT-B, quadriceps tendon-patellar bone (QT-PB),[157] and STG tendons. We prefer B-PT-B autogenous grafts in athletes, a recommendation supported by several long-term studies[56,92,98,142,224] and in investigations showing a higher rate of ACL primary reconstruction failure after allografts compared with autografts, especially in younger patients.[24,62,122,137,224] A B-PT-B autograft is not recommended if there is associated patellofemoral arthritis (grade 2B classification, see Chapter 44), anterior knee pain, or history of patellar subluxation or dislocation. A B-PT-B autograft is not performed when patient issues suggest a decreased ability to follow the more involved rehabilitation program and cope with the initial pain related to this graft. In recreational athletes and more sedentary patients, a four-strand or six-strand STG autograft is recommended. Modern STG graft fixation methods have increased the success rate, and the rehabilitation postoperatively is easier on the patient. There is a suggestion in the literature of increased STG failure rates with associated physiologic posterolateral laxity. Although allografts offer technical ease and reduced donor site pain, there are risks of disease transmission, a biomechanically inferior graft, and biologic reaction to irradiation and chemical sterilization processing.[81] A recent meta-analysis demonstrated that, when compared with low-dose irradiated allografts (<2.5 mrad), nonirradiated allografts produced superior stability (Lachman, pivot shift, KT-2000 tests), had a lower risk of revision, and higher Lysholm scores.[226] The orthopedic surgeon should understand the sterilization techniques used by the tissue bank and use grafts supplied by banks accredited by the American Association of Tissue Banks.

Patient Setup and Positioning

The patient is instructed to use a chlorhexidine wash of the operative limb ("toes to groin") 3 days before surgery, including the evening before and morning of surgery. Lower extremity hair is removed by

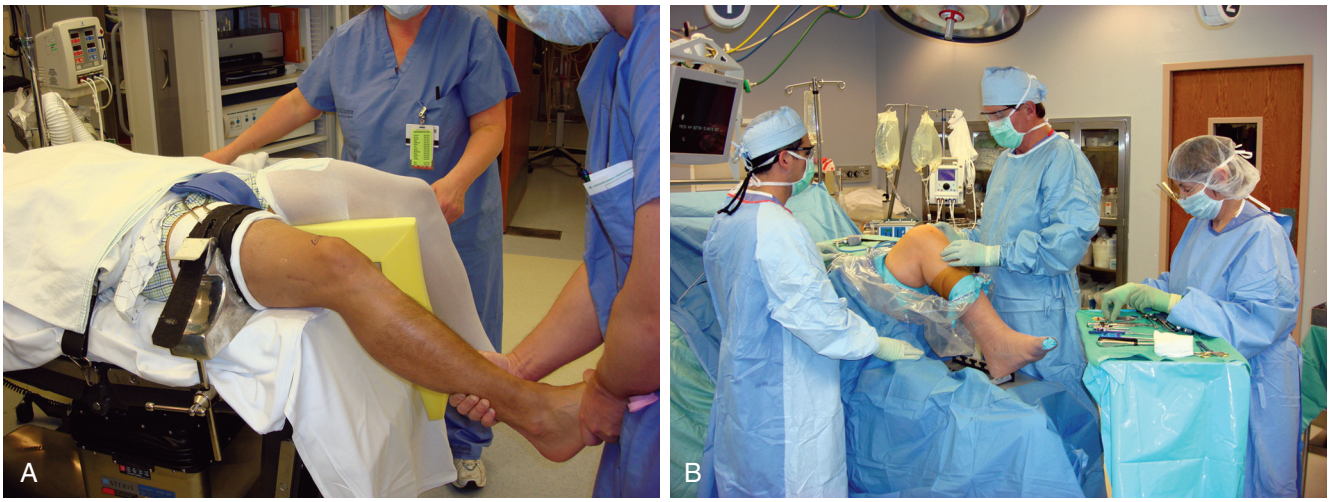

FIG 7-35 Initial operating room setup and patient positioning. **A,** Use of thigh holder to achieve maximum medial/lateral joint opening, particularly for meniscus repairs, that may be removed for the anterior cruciate ligament procedure (our preference). **B,** Patient in supine position with leg holder used to allow selected knee flexion positions, particularly hyperflexed position with anteromedial portal pin placement for femoral tunnels.

clippers, not a shaver. Antibiotic infusion is begun 1 hour before surgery. The use of a nonsteroidal antiinflammatory drug (NSAID) and a postoperative firm double-cotton, double-Ace compression dressing for 72 hours (cotton, Ace, cotton, Ace layered dressing) has proven effective in diminishing soft tissue swelling in knee surgery cases. In complex multiligament surgery, the antibiotic is repeated at 4 hours and continued for 24 hours. A urinary indwelling catheter is not used unless there are specific indications. The patient's urinary output and total fluids are carefully monitored during the procedure and in the recovery room. The knee skin area is initialized by the surgeon before entering the operating room, with a nurse observing the procedure. The identification process is repeated with all operative personnel with a "time out" before surgery to verify the knee undergoing surgery, procedure, allergies, antibiotic infusion, and special precautions that apply. All personnel provide verbal agreement.

A single femoral nerve block is administered preoperatively or in the recovery room, which markedly decreases the need for analgesic medication. The patient is instructed to use crutches with limited weight bearing for 24 hours owing to decreased quadriceps function. Bupivacaine (Marcaine) or lidocaine joint installation is contraindicated because high local doses may alter chondrocyte function and viability.[88,126,291] A fluid inflow-pressure-regulated pump is recommended over gravity infusion because hemostasis can be controlled and tourniquet use limited in most cases. An electrocautery device is always available to control bleeding points.

With the patient in a supine position on the operative table and all extremities well padded, a tourniquet is placed on the middle to proximal thigh (Fig. 7-35, *A*). A leg holder is used for the initial arthroscopic examination to provide for maximum opening of the medial and lateral tibiofemoral compartments during the gap tests and to provide necessary distraction for a meniscus repair or partial resection. A leg holder provides better visualization of the posterior meniscus regions over a lateral post. A low-profile leg holder is used, which is pressed into the operative bed mattress to decrease posterior thigh pressure; this is removed following the initial diagnostic arthroscopic procedure. The knee portion of the bed is flexed 60 to 90 degrees and the bed midportion is retroflexed 15 degrees to allow flexion of the hips to relieve undue tension on the femoral neurovascular structures. The uninvolved extremity is placed in a well-cushioned padded holder. An alternative approach described in the literature is to place the uninvolved extremity in an abducted and flexed position with a thigh and leg holder. However, this position does not make it possible to perform inside-out meniscus repairs when indicated.

After the arthroscopic procedures and removal of the leg holder, two positions may be used for the lower limb. The first is to adjust the operative bed to allow 90 degrees of knee flexion. The knee can be flexed to 120 degrees or more during the procedure, if necessary, by having the operative assistants flex the hip joint and knee joint. The second option is to position the operative bed flat and use an Alvarado foot and leg holder or sandbag taped to the table to allow the knee joint to be flexed to the desired position (see Fig. 7-35, *B*). The senior author prefers the first position that allows medial, lateral, or PCL procedures to be performed. With concurrent medial or lateral reconstructions, the surgical procedure is performed at 20 to 30 degrees of flexion with a roll placed beneath the thigh. The knee joint can also be brought to full extension to determine that posterior capsular reconstructions do not constrain full knee extension.

Graft Harvest: Bone-Patellar Tendon-Bone Autograft

A tourniquet is inflated to 275 mm of pressure. This is usually the only time the tourniquet is inflated in the reconstructive procedure. A 3- to 4-cm vertical medial incision is made just adjacent to the medial border of the patella tendon, avoiding the tibial tubercle (Fig. 7-36). The incision is located just medial to the inferior pole of the patella. A proximal skin incision over the patella is not required because the patella is easily displaced distally during removal of the patella bone portion of the graft.

A cosmetic approach is used where the plane beneath the subcutaneous tissues is dissected to allow for a limited skin incision. The skin incision is displaced proximally and distally as required for the graft harvest. Four vein retractors are placed into the proximal, distal, medial, and lateral aspects of the skin incision to allow for a rectangular skin opening for the graft harvest. An alternative technique is to use a proximal and distal skin incision, avoiding a vertical skin incision, which has less chance of a sensory skin loss but a greater chance of skin hypertrophic scar formation.

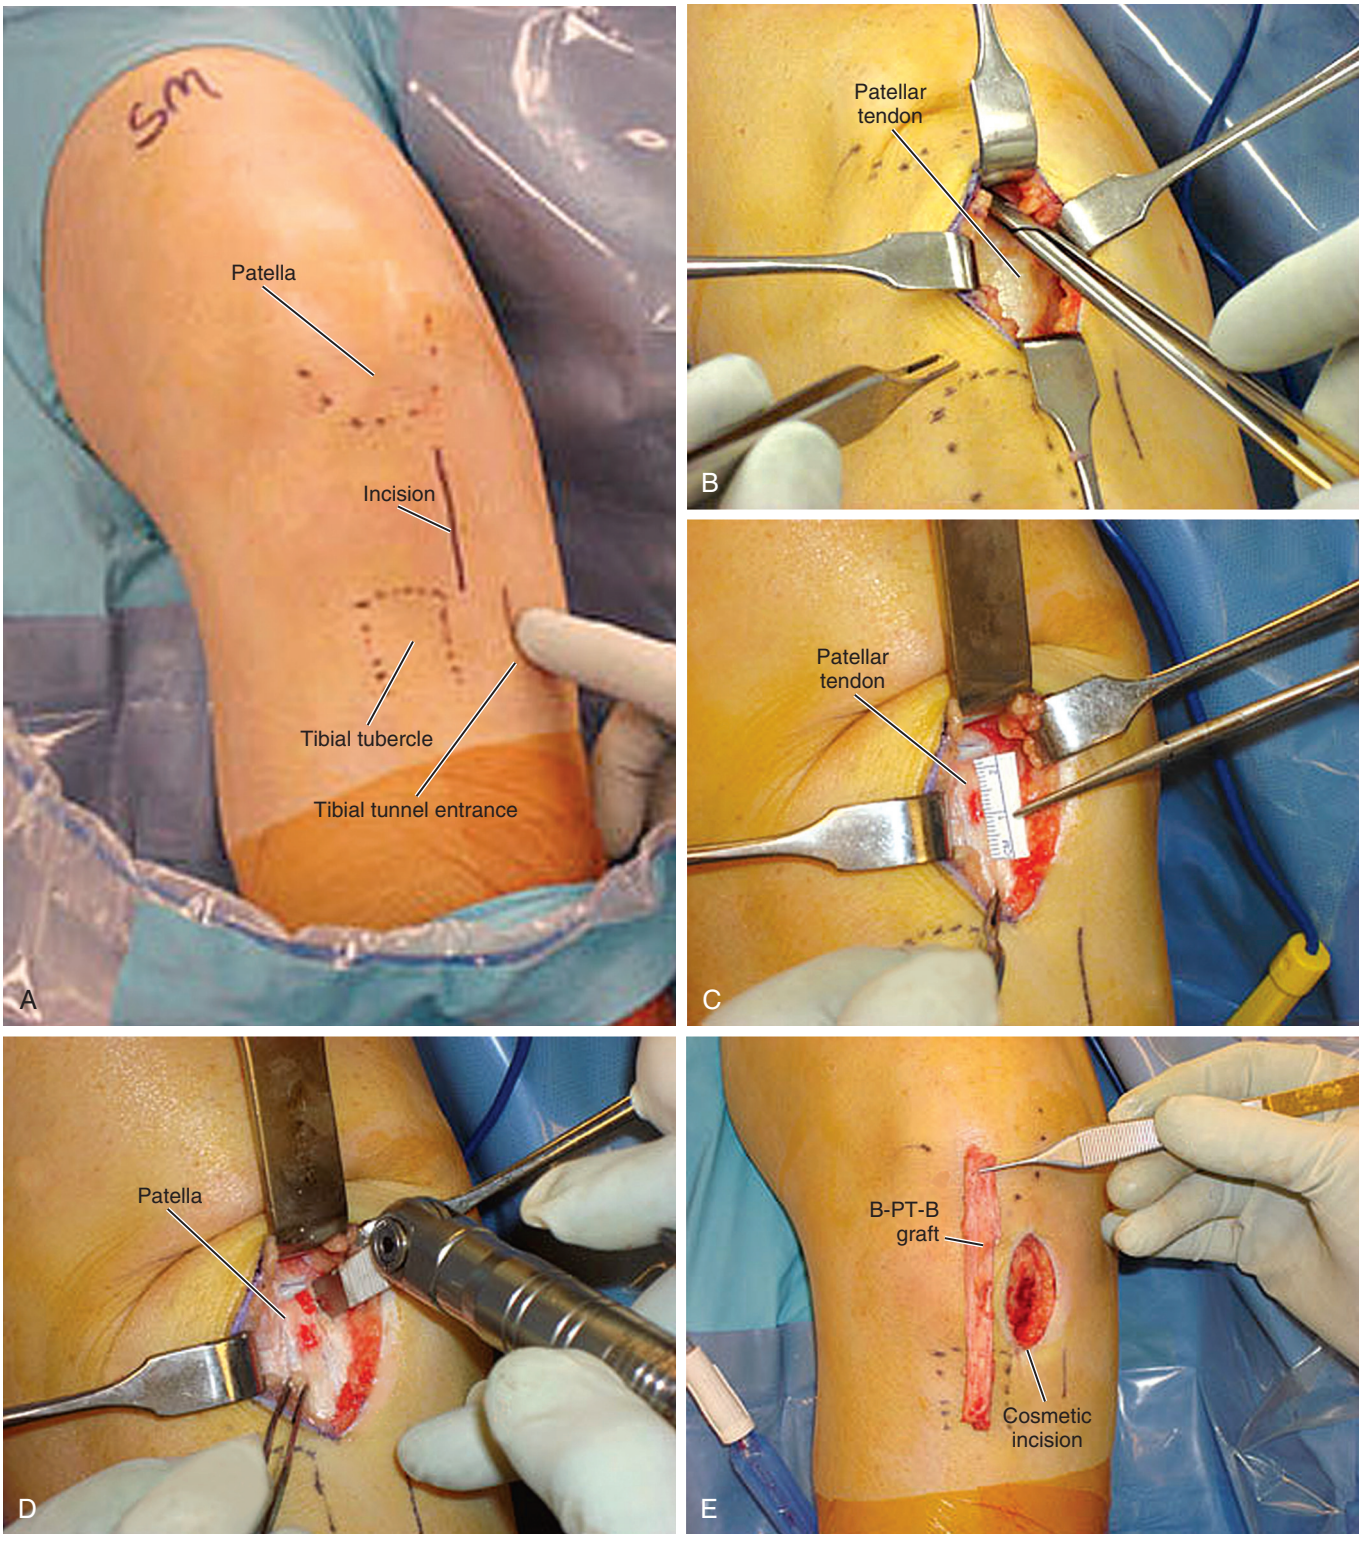

FIG 7-36 The technique we recommends for harvest of a bone-patellar tendon-bone (B-PT-B) autograft is shown. **A,** A 3- to 4-cm skin incision, just medial to the patellar tendon, is made to avoid the bony prominence of the patella and tibial tubercle. The index finger points to the planned tibial tunnel, which can be reached through this cosmetic incision. **B,** Mobilization of subcutaneous tissues to allow the cosmetically placed incision to be moved in a proximal-distal and medial fashion. Infrapatellar nerves when present are protected. **C,** A ruler measures the length of the patellar tendon and a 10 mm wide patellar tendon graft is marked by two or three ink dots. **D,** The patella is displaced distally and the patellar bone block removed. Note the saw has a tape marking a 9-mm depth to prevent from cutting too deep into the patella. The saw is angled 10 to 15 degrees to produce a trapezoidal bone block. The saw carefully cuts the medial and lateral borders, making sure the bone beneath the tendon insertion has been cut to prevent a fracture of the graft. A similar technique is used for the tibial tubercle. **E,** Appearance of the graft after harvest.

Continued

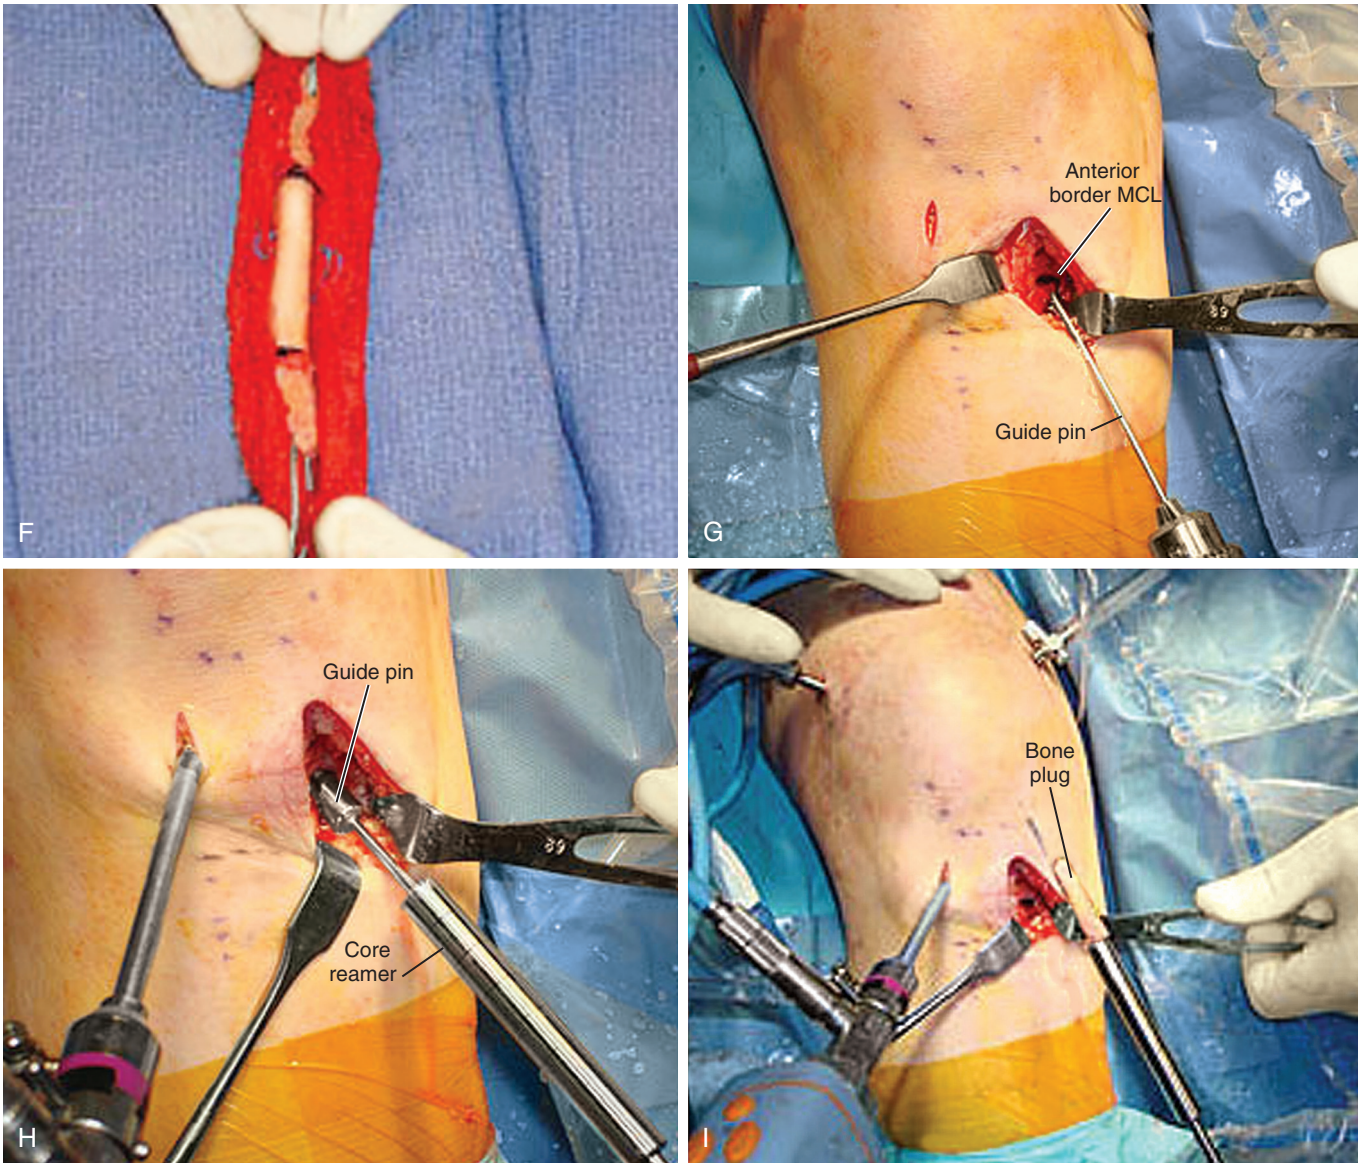

FIG 7-36, cont'd **F,** Preparation of the graft is shown. Two nonabsorbable No. 2 sutures are placed in a distal drill hole in each bone plug. The bone tendon junction is marked. The graft is wrapped in a blood-soaked sponge with the goal of maintaining viability of some tendon cells. **G,** The skin incision is displaced distally to reach the desired position for the coronal tibial tunnel, as described in the text. **H,** The core reamer is placed in the tibial tunnel for the graft harvest. **I,** The bone plug removed by the core reamer. *MCL,* Medial collateral ligament.

The retinaculum in the middle of the patellar tendon is incised and the dissection limited only to the midportion of the patellar tendon. The parapatellar tissues and blood supply to the tendon are not disturbed. The tendon should not be dissected to its edges because this damages the blood supply, particularly to the major vein and artery on the medial side of the tendon. In some knees, a branch of the infrapatellar nerve will cross the middle of the patellar tendon and should be preserved. In these knees, the nerve provides a large area of cutaneous sensation over the lateral aspect of the knee. It should be noted that up to one half of patients will have a 2-cm area of numbness just lateral to the patellar tendon from incision of small cutaneous nerve branches not visible during the procedure. Patients are warned of the potential loss of sensation preoperatively. The numbness may be avoided by use of a lateral incision adjacent to the patellar tendon; however, this requires a second tibial incision for the tibial tunnel that could be avoided if an all-inside ACL technique is performed. The patellar retinaculum is carefully incised and reflected medially and laterally only for the width of the graft to be removed. The retinaculum is protected to allow for closure over the bone-grafted patellar defect. A similar procedure is used at the tibial tuberosity.

It is useful to have a precut 10-mm and 22-mm paper ruler held on a hemostat to place over the tendon and bone harvest sites to allow fine marks to be placed on the tissues to define graft dimensions.

The patellar tendon is incised in the midportion to the appropriate size, 9 to 10 mm. The patella is displaced distally into the wound using

a forked retractor placed at the superior patellar margin. A powered handheld saw with a thin-width blade is marked with a Steri-Strip 9 to 10 mm from the tip to prevent too deep a cut, which would weaken the patella. A trapezoidal bone block graft from the patella is removed by angling the fine saw 15 degrees at each side of the cut. The bone cut extends to the inferior pole and care is taken to protect the insertion site of the patellar tendon. A 4-mm osteotome gently removes the patellar bone block without wedging the sidewalls, which could induce a fracture. A similar procedure is followed in the harvest of the tibial bone block.

The tourniquet is deflated, and a cotton sponge is placed in the wound. The graft is later wrapped in the blood-soaked sponge, which provides for protection of the graft, maintains a moist blood environment, and may allow cells to survive in the graft-remodeling process. It would be incorrect to have the graft openly exposed on the back table, which would allow drying, cell death, and possible air contamination. A first assistant prepares the graft to decrease operative time.

The bone blocks are prepared to easily pass through the selected diameter tunnels. The diameter of the tunnels will be configured 1 mm larger than the diameter of the bone block. The bone-tendon junction of each graft is marked for later identification. The graft preparation involves a 2-mm drill hole placed one third of the way from the end of each bone block for sutures. The end sutures allow the graft to be passed into the tunnel. A suture placed into the midportion of the graft would tilt the bone block, making passage into the tunnels difficult. The tibial portion of the graft is identified and will be later passed in a retrograde manner through the tibial tunnel into the femoral tunnel. The bone block tip is fashioned into a bullet tip configuration for tibial tunnel passage. Two No. 2 nonabsorbable FiberWire (Arthrex) sutures are passed into the distal one third tibial bone block. The graft is wrapped in a blood-soaked sponge.

At the conclusion of the ACL reconstruction, closure of the patellar tendon graft harvest site is performed. The patellar tendon is loosely approximated with 2-0 absorbable sutures. A coring reamer used for the tibial tunnel provides a large dowel of cancellous bone to completely fill the patella and tibia defects. The bone-grafted sites are smoothed to remove any pressure points. It is important to place two horizontal mattress sutures at the inferior pole of the patella and at the superior tendon attachment at the tibia to create a pocket to maintain the position of the core bone graft at each site. Otherwise, the bone graft may displace and be a source of pain because it is located in the tendon rather than the bony defect. The patella retinaculum is carefully closed to provide a soft tissue covering over the patella defect. The retinaculum over the tibial tuberosity is not as well defined; however, the soft tissues are closed using 2-0 absorbable horizontal mattress sutures.

The meticulous technique described for the B-PT-B graft procedure is an important part of the operative procedure. The skin incision is medial to any bone prominences and does not extend over the patella. The dissection is limited entirely to the central portion of the patellar tendon where the graft is removed, protecting nerves and the parapatellar vascular supply. The surgeon is seated, with the patient's foot in the surgeon's lap to directly visualize the wound and carefully control the saw blade. A headlight is always used to see the fine neural and vascular structures.

The use of the coring reamer at the tibial site provides ample bone graft to completely fill the tibia and patella bone defects. The use of shavings or small amounts of bone obtained in the procedure is insufficient to completely fill these defects and has led to complaints of kneeling pain in some studies.[87,157] If the tibial tuberosity defect is left partially unfilled, there will be ridges on either side of the defect that will prevent the patient from kneeling because of pain with pressure at this site. If the defects are closed as described, then kneeling with little to no discomfort is to be expected, equal to the opposite knee. In our opinion, this point has not been sufficiently stressed in the literature. A completely filled graft harvest site at the patella and tibial tubercle is required. Saving bone chips during the ACL tunnel preparation usually results in insufficient bone for both harvest sites. The added time to use the coring reamer bone-graft harvesting instruments provides the benefit of a quality bone graft for both the patellar and tibial sites. Commercially sold bone allografts are available; however, we prefer to use the patient's bone. The length of the bone block is 22 to 24 mm to facilitate passage.

In cases where a patella alta (and exceedingly long patellar tendon) is present, a problem arises when harvesting the patellar tendon, which is often 60 mm in length, to use for an ACL reconstruction. There are two techniques that may be used to prevent the bone portion of the graft from protruding at the tibial and femoral sites. The most ideal is to use a 2-incision technique in which the tibial and femoral tunnels are devised to be approximately 35 mm in length to accommodate the abnormally long B-PT-B graft. A second, less ideal option that may be selected when required, involves rotating the bone portion of the graft back onto the patellar tendon and suturing it to the tendon over a FiberLoop (Arthrex), which is usually placed at the femoral tunnel site.

Graft Harvest: Quadriceps Tendon-Patellar Bone Autograft

A 5- to 6-cm longitudinal incision is made from the superior pole of the patella that extends proximally. The prepatellar retinaculum is reflected and protected for later closure over the grafted patellar defect. The quadriceps tendon and its junction with the vastus medialis obliquus and vastus lateralis obliquus (VLO) are identified. The proximal portion of the quadriceps tendon is identified and the graft harvest is carried 10 mm distal to the rectus femoris muscle-tendon attachment in order not to weaken this site. A 10-mm wide tendon graft, through all three layers, is removed to a length of 60 to 70 cm (Fig. 7-37). In large patients, the 10-mm graft may prevent the deeper third layer from being removed. The tendon attachment to the anterior superior pole of the patella is carefully identified and the synovial attachment protected. A power saw with the cutting blade marked with paper tape to a depth of 10 mm is used to cut the anterior cortex. It is necessary to place the thin saw blade at the superior pole immediately posterior to the quadriceps tendon patella attachment to saw through the patellar bone at this location. The goal is to produce a patellar bone graft 22 to 24 mm long by 9 to 10 mm wide. The bone graft is sized to 9 to 10 mm in diameter. The quadriceps tendon defect is closed with interrupted 0-Ethibond suture (Ethicon). Two sutures of 0-nonabsorbable material are placed just proximal to the proximal patellar bone defect to create a pocket for the bone graft obtained from the coring tibial reamer. The core bone graft completely obliterates the patellar defect, and a meticulous closure of anterior tissues over the graft is performed, as already described. Even though techniques have been described for quadriceps tendon graft harvest without removing the patellar bone, the senior author believes this technique to be less desirable. The patellar bone fixation is superior to tendon fixation and adds length of the tendon portion of the graft within the tibial tunnel, which is advantageous for healing.

Graft Harvest: Semitendinosus-Gracilis Autograft

The STG graft harvest procedure is shown in Figure 7-38. A 3- to 4-cm oblique incision is made over the palpated pes tendons. The incision

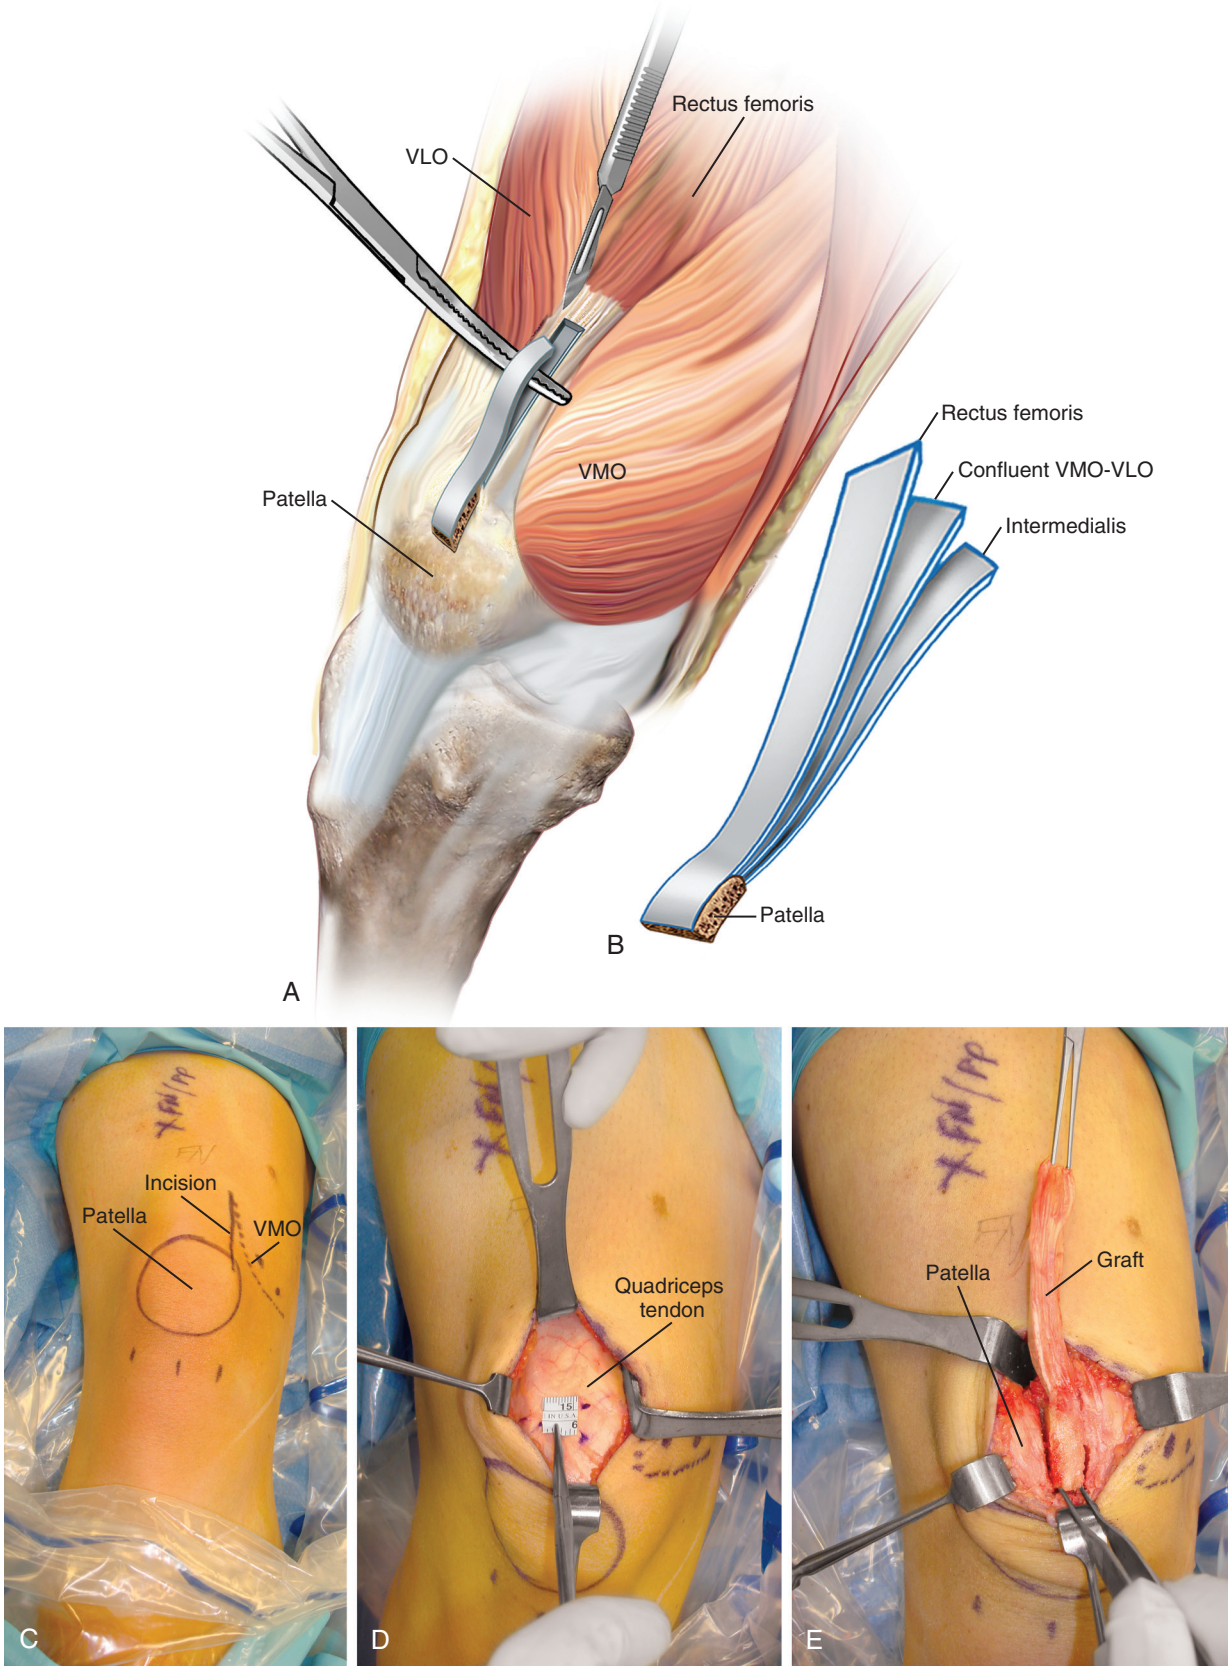

FIG 7-37 **A,** The quadriceps tendon and vastus medialis oblique and vastus lateralis oblique muscles are identified proximally. A 9- to 10-mm wide tendon graft, through all three layers, which has a length of 60 to 70 cm, is removed. The graft harvest does not extend to the muscle tendon junction. A patellar bone graft is fashioned to be approximately 22 to 24 mm long by 9 to 10 mm wide by 9 to 10 mm in diameter. **B,** Usually, all three layers are sutured together at the end of the graft (2-0 nonabsorbable suture) with a running suture on both sides of the graft. **C,** Surgical case, initial skin incision. **D,** Measurement of graft width. **E,** Final harvest. *VLO,* Vastus lateralis obliquus; *VMO,* vastus medialis obliquus.

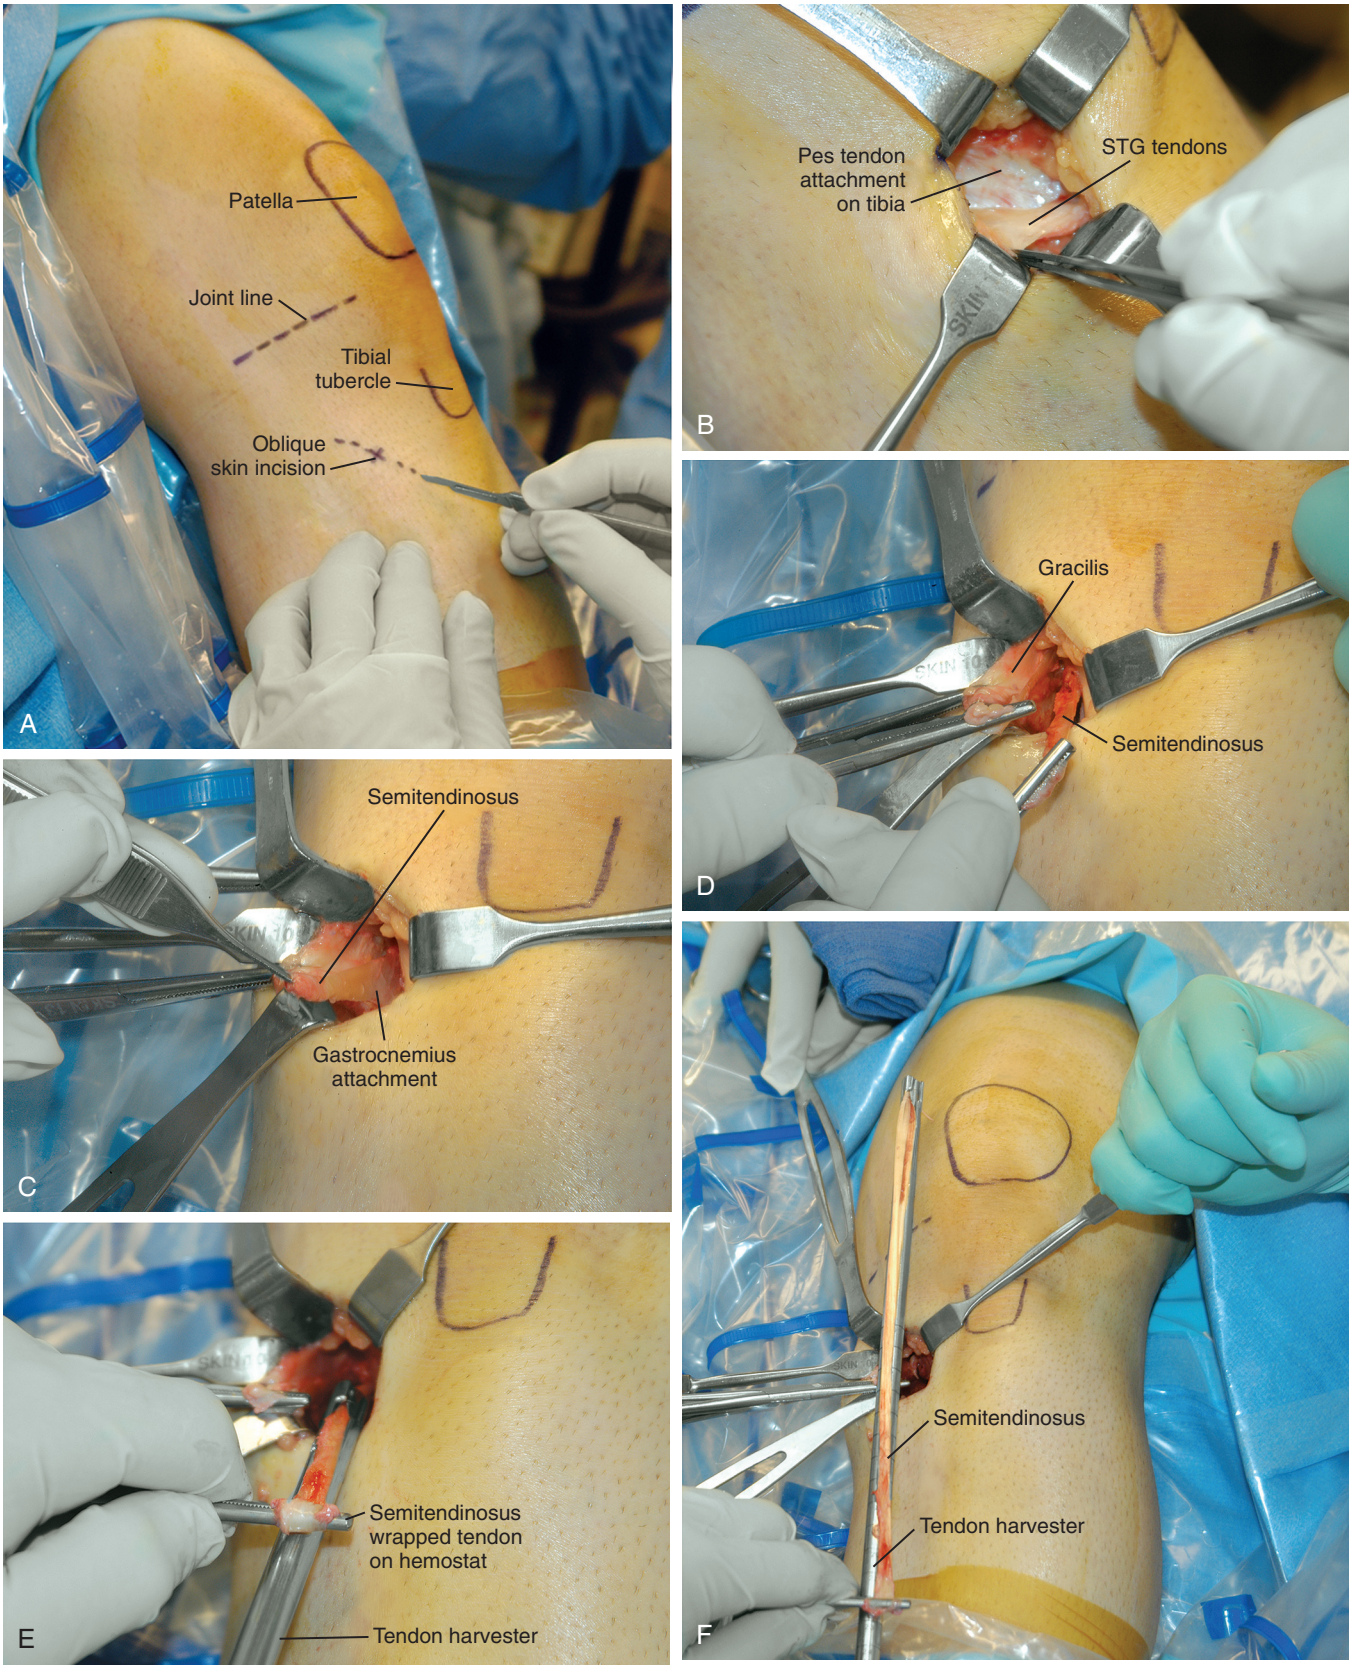

FIG 7-38 **A,** A 2-cm longitudinal or oblique incision at the anteromedial tibial region. **B,** An L-shaped incision at the pes tendon tibial attachment is performed and the tendon flap is reflected to identify the semitendinosus-gracilis (STG) tendons. **C,** Dissection of soft tissue to identify the STG and remove the gastrocnemius secondary attachment. **D,** "Push-pull" test to confirm that the STG tendons are free of attachments. **E,** Harvest of STG using closed-end harvester to prevent premature transection of STG. **F,** Appearance of long semitendinosus tendon obtained at harvest.

Continued

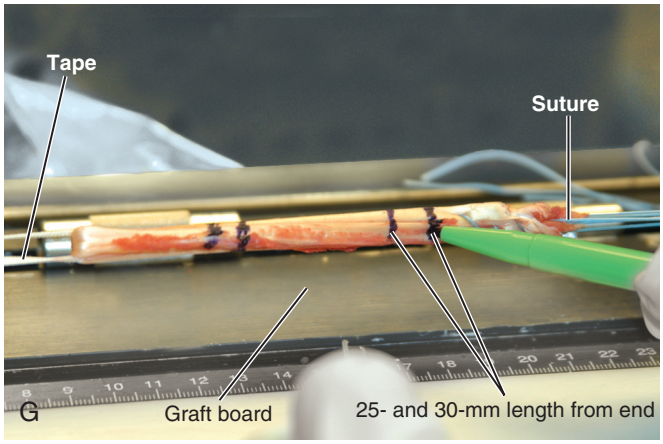

FIG 7-38, cont'd **G,** Graft preparation with graft board. Nonabsorbable 3-mm tape at the proximal end and three 2-0 FiberWire fixation at the distal end. (An alternative is a TightRope [Arthrex] fixation device.) Running suture is used on each side of the STG graft.

is cosmetic and the plane beneath the subcutaneous tissues is carefully dissected. The senior author prefers an AM incision over a popliteal-based incision to gain maximum length of the tendons at the tibial confluent attachment. The surgeon is seated, the bed is flexed 60 degrees, and a headlight is routinely used. The sartorius fascia is incised directly proximal to the semitendinosus and gracilis palpated tendons over the distal superficial medial collateral ligament (SMCL) attachment. This provides a window and opening to protect the SMCL. The overlying fascia is incised proximally in the same oblique plane of the STG tendons.

It is worthwhile in the initial dissection to identify the STG tendons to protect them and not inadvertently section the tendons. This is best performed by extending the fascia, incising just above the gracilis tendon over its tibial insertion, and then at a 90-degree angle, laying back the insertion site distally. This allows the STG tendons to be viewed throughout their distal course to their tibial attachment. In most knees, the STG tendons are confluent and blend to make one tendinosis structure. Each tendon is identified and incised through the confluent distal tendon region. Each tendon is grasped at a 90-degree angle at its distal end and rolled two to three times around a straight hemostat, which allows tension to be placed on the tendon without producing damage.

The proximal extent of each tendon is palpated and superficial tissues removed, protecting the overlying sartorius fascia. The dissection plane is never carried close to the inferior sartorius or posterior semitendinosus muscles to avoid injury to the saphenous nerve. The headlight provides excellent illumination in the proximal portion of the incision to protect any neurovascular structures. The proximal fascia about each tendon is bluntly dissected and the semitendinosus tendon attachment to the medial gastrocnemius fascia is incised. With tension on each tendon and a repetitive pulling motion, each tendon will freely displace 10 cm. It is important to determine that each tendon is completely free of tissues to allow the tendon harvester to pass freely. The anesthesiologist is asked to provide muscle relaxation sedation to facilitate this step. The closed-end graft harvester is passed along the trajectory of each tendon and each tendon is transected at 20 cm for a four-strand graft or 24 cm for a six-strand graft described later. There is a commercially available tendon harvester with a blunt tip that protects against inadvertent tendon transection that has a tendon cutter in its distal tip activated by the mechanism at the handle. The STG tendons are prepared (see Fig. 7-38). In the four-strand graft, each tendon is looped about a 3-mm tape and the tendon end sutured to itself with a No. 2 nonabsorbable suture. A third suture (FiberLoop) is added at both graft tendon ends. A running 0-nonabsorbable suture is used to produce a tubed structure running from proximal to distal and then back to the proximal starting point. A metal graft tensioning board (25- to 30-N tension) is used rather than a graft preparation board with plastic holders because the latter is difficult to sterilize to avoid a graft contamination problem. The graft is marked 25 mm from each end, wrapped in a blood-soaked sponge, and placed in a secure place on the back table. The overall length is approximately 80 to 85 mm.

The six-strand graft is used in women and patients of small stature in which the STG tendon diameter is decreased and to provide added tendon substance for a 9- to 10-mm graft diameter. This avoids a 6- to 7-mm graft, which has a known increased failure rate (see "Other Authors' Clinical Studies"). The six-strand graft technique is described in Table 7-9 and is shown in Figure 7-39.

Iliotibial Band Extraarticular Tenodesis

Two clinical studies (Noyes and Barber[185] and Ferretti and coworkers[66]) have shown significant improvements in knees with gross instability and loss of secondary lateral restraints that had an extraarticular tenodesis procedure for additional restraint of abnormal tibial internal rotation. The goal is to reconstruct the function of the anterolateral ligament and posterior femoral tibial ITB attachment, which restrains abnormal internal tibial rotation. The lateral capsule fibers (referred to as the anterolateral ligament) are plicated at surgery; however, it is not necessary to add a graft reconstruction for this structure. The procedure is described in detail in Chapter 8.

Anterior Cruciate Ligament Bone-Patellar Tendon-Bone Graft Anatomic Tibial and Femoral Technique

A single-graft procedure is described in which the graft is located into the central anatomic tibial and femoral attachment locations, as already discussed. The graft placement specifically avoids the proximal ACL femoral attachment site and the posterior ACL tibial attachment site to avoid a vertical graft and allow the graft to resist rotational motions in addition to anterior tibial translation (Fig. 7-40). This

TABLE 7-9 Preparation of Six-Strand Semitendinosus-Gracilis Autograft

Indications: Harvest of a semitendinosus-gracilis (STG) autograft of narrow diameter, where a final 6- to 7-mm diameter graft would be produced, which is less than ideal and associated with a high failure rate.

Surgical Steps:

1. Based on patient size, anterior cruciate ligament (ACL) length, and tunnel lengths, a final 75- to 85-mm length graft is prepared.
2. Place tibial and femoral ACL tunnels in center of attachment sites as already discussed.
3. Measure the length of the tibial and femoral tunnels and ACL graft distance to tunnels. To compute ideal final graft length, add tunnel lengths and intraarticular length, then subtract 10 mm for positioning and tensioning. For example:
   - 30-mm tibial and femoral tunnels (60 mm) + 35-mm intraarticular length = maximum graft length of 95 mm – 10 mm = maximum graft length of 85 mm.
   - In a smaller patient, a 25-mm femoral tunnel and a 35-mm tibial tunnel and an intraarticular length of 30 mm = maximum graft length of 80 mm – 10 mm = ideal graft length of 70 mm.
4. Harvest STG graft to 24 cm for 80 mm triple semitendinosus (ST) and gracilis (G) six-strand graft.
5. Place zero FiberWire at the end of both tendons and mark the graft into thirds. Lead the sutured tendon end around TightRope at both ends, ending up at the one-third graft length and tie the tendon end onto the looped tendon at this one third site.
6. Place the six-strand graft on a tensioning board, tension at 40 N, and tie each end suture onto the TightRope. Place a single FiberLoop at each end of six-strand graft and tie over TightRope. The final construct is FiberWire plus FiberLoop tied to TightRope at each end of the graft construct. Consider adding additional FiberLoop as necessary.
7. Use as a running suture zero FiberWire looped up one side and back the other side of the six-strand graft to approximate all six tendon loops into one single-graft strand.

CRITICAL POINTS Operative Techniques: ACL Bone-Patellar Tendon-Bone Graft Anatomic Tibial and Femoral Technique

Placement of Tibial Tunnel

- Define center ACL, usually 16 to 20 mm anterior to RER or interspinous ridge.
- Mark ACL center, usually adjacent and always anterior to posterior edge of lateral meniscus anterior horn attachment.
- Place guide pin eccentric and 2 to 3 mm anterior and medial to true ACL center.
- Determine graft length of patellar tendon on MRI.
- Two-incision technique allows graft length to be adjusted by proximal advancement of femoral tunnel.
- Place tibial tunnel in coronal manner, 55- to 60-degree angle, tunnel length 35 to 40 mm.
- Begin tunnel anterior and adjacent to superficial MCL, 15 mm medial to tibial tubercle medial border, 10 mm distal to proximal patellar tendon insertion.
- Use core reamer to obtain good-quality bone to fill bone defects.
- Drill tunnel, chamfer edges.

Placement of Femoral Tunnel

- Use either two-incision technique (open or flip drill) or AM portal with knee hyperflexed 120 degrees.
- Two-incision technique: Drill tunnel retrograde through lateral incision 2 to 3 cm at distal lateral femoral condyle.
- Perform femoral notchplasty to avoid graft impingement.
- Identify ACL attachment with knee in 20 to 30 degrees of flexion, scope in AM portal.
- Place guide pin within central ACL attachment. Always preserve 3 to 4 mm of posterior back wall of the tunnel so that the graft is not placed too far posteriorly. A guide pin placed 8 mm from the posterior articular cartilage at the central ACL attachment will have a 4-mm posterior back wall for an 8-mm graft.
- Drill tunnel, chamfer edges.

Graft Tunnel Passage, Conditioning, and Fixation

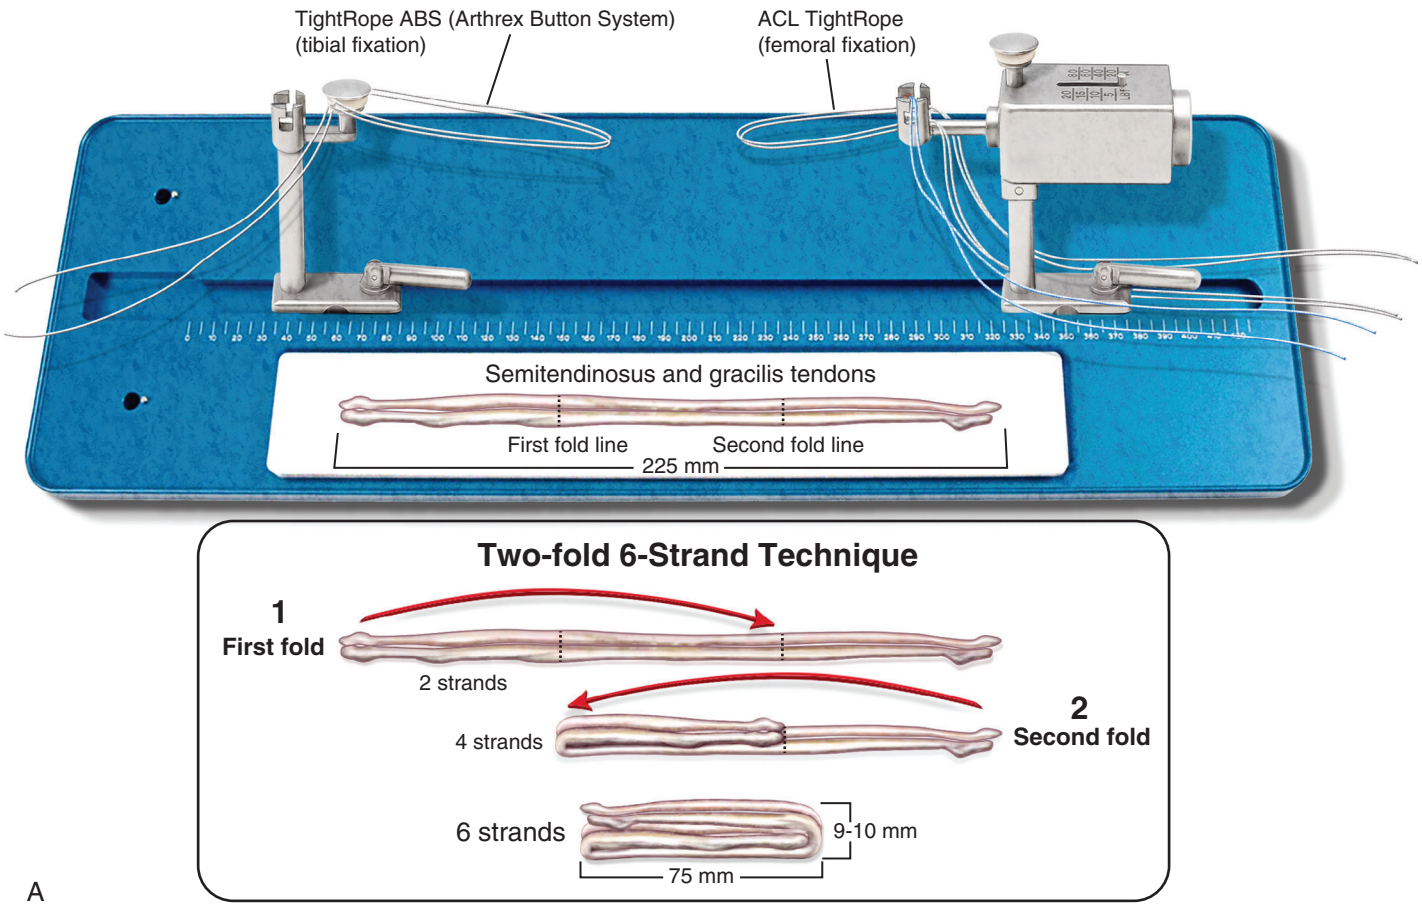
- Pass graft gently in retrograde arthroscopically assisted.
- Bring graft proximally until bone is flush with tibia.
- Femoral position of graft at or just proximal to inside femoral tunnel.
- Fix femoral bone graft plug with interference screw.
- Condition graft, 44-N tension, flex knee 0 to 135 degrees 40 cycles.
- Verify position arthroscopically, no impingement.
- Place knee in 20 degrees of flexion, reduce tension to 10 to 15 N.
- Place interference screw tibia. Use additional sutures tied over suture post if required.
- Perform Lachman test, ensure no overconstraint.
- For STG graft, femoral fixation: Post with sutures and absorbable interference screw if necessary. Tibial fixation: Interference screw plus suture post.

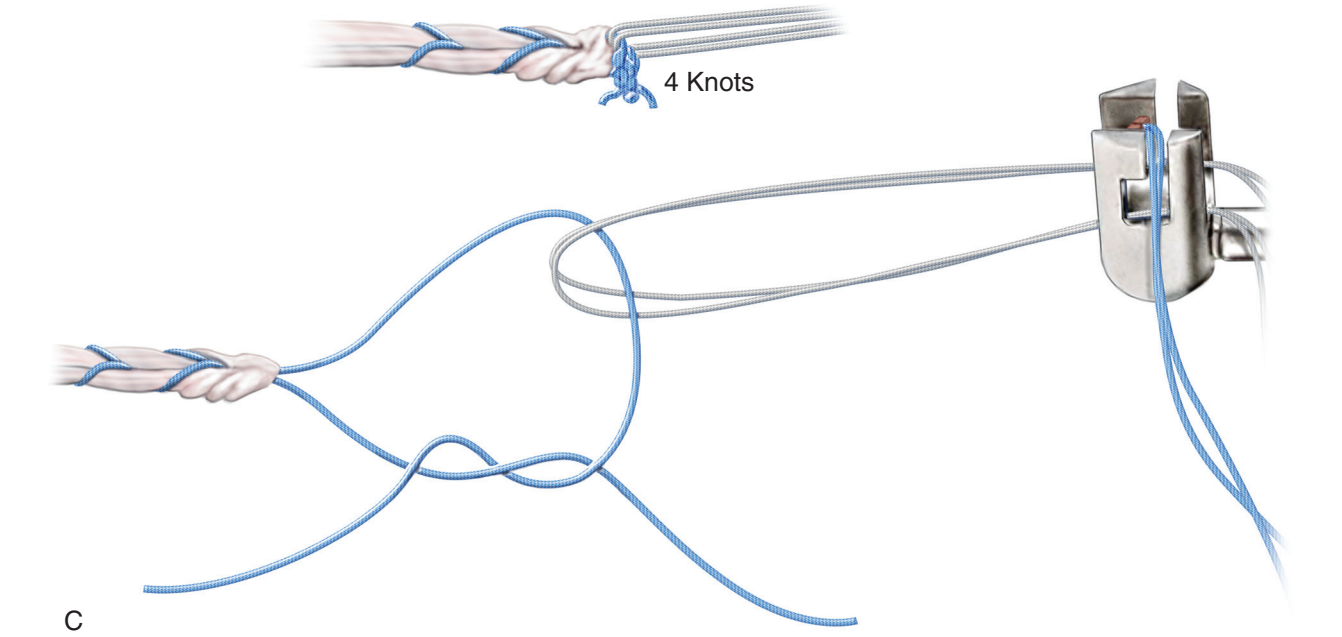
section describes using a single B-PT-B autograft that is preferred compared with an allograft procedure. Our clinical studies described later support the concept of a single-graft technique for primary ACL reconstruction.

Placement of Tibial Tunnel

As previously described, the ideal central ACL tibial attachment location is directly adjacent and anterior to the posterior edge of the lateral meniscus anterior horn attachment (see Fig. 7-29). The ACL attachment can be easily mapped at surgery based on the anatomic reference maps previously provided, with the ACL center location based on the anterior-to-posterior and medial-to-lateral attachments. The anterior extent of the ACL attachment may be obscured by soft tissues, and the RER or posterior interspinous ridge of the PCL fossa is an important landmark. The center of the ACL will be 16 to 20 mm anterior to the RER or interspinous ridge. No portion of the tibial tunnel is posterior to the posterior edge of the lateral meniscus attachment, which represents the posterior one third of the ACL attachment. The guide pin is placed eccentric and 2 to 3 mm anterior and medial to the true ACL center as the ACL graft displaces to the posterior and medial aspects of the tibial tunnel.[45] This eccentric tunnel places the majority of the graft within the ideal central tibial attachment.

It is important to determine the graft length of the autograft or allograft to ensure a mismatch does not occur between intraarticular length of the tunnel and the length of the graft. The most common problem is with a relative patella alta and a B-PT-B length greater than 90 mm based on the patient's body habitus. The length of the patellar





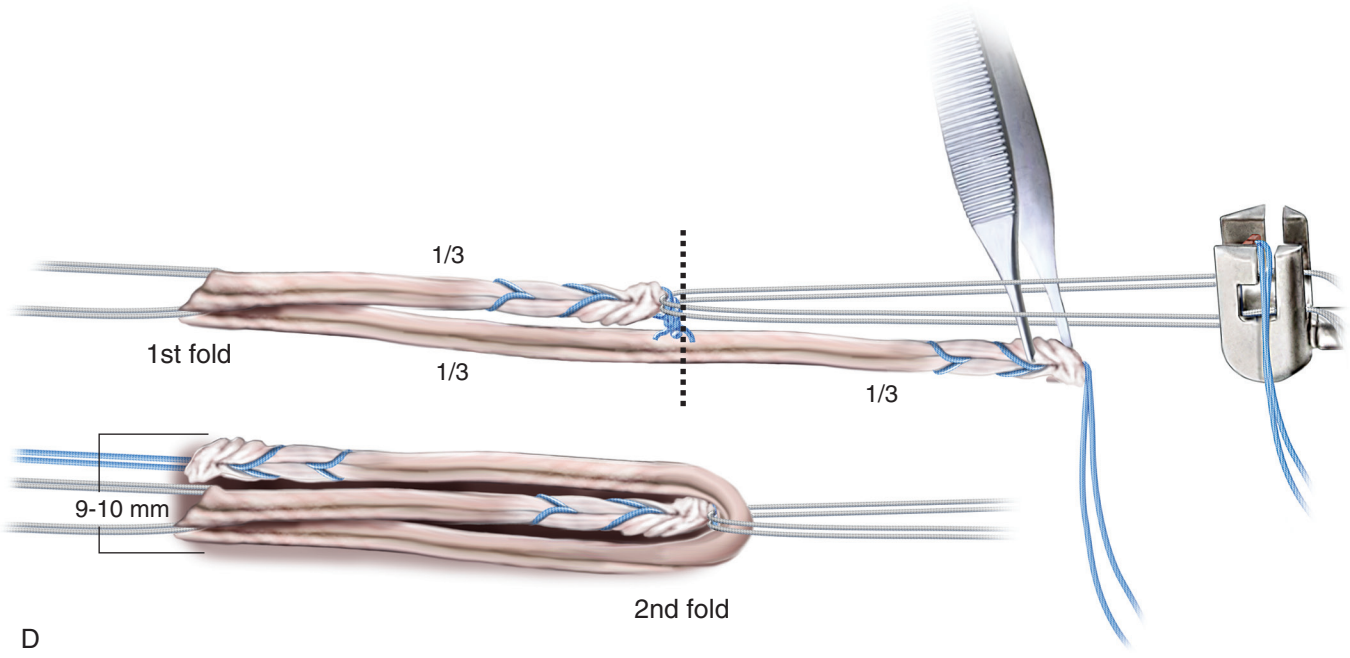


FIG 7-39 Anterior cruciate ligament six-strand semitendinosus-gracilis (STG) autograft technique. **A,** A 70- to 80-mm length graft is prepared. The STG tendons are folded two times to obtain a six-strand graft. **B,** The semitendinosus and gracilis tendons are sutured together at either end with two to three locking-type sutures (0 or No. 2 FiberWire) to stabilize the end.

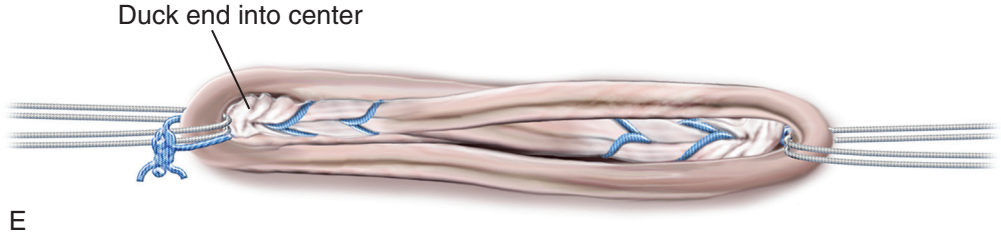

FIG 7-39, cont'd **C,** One end of the STG graft is tied to the TightRope. **D,** The other end of the STG graft is folded through one end of the TightRope loop and folded back to the second TightRope loop. **E,** The end of the STG is placed into the center of the folded graft and tied to the second TightRope loop.

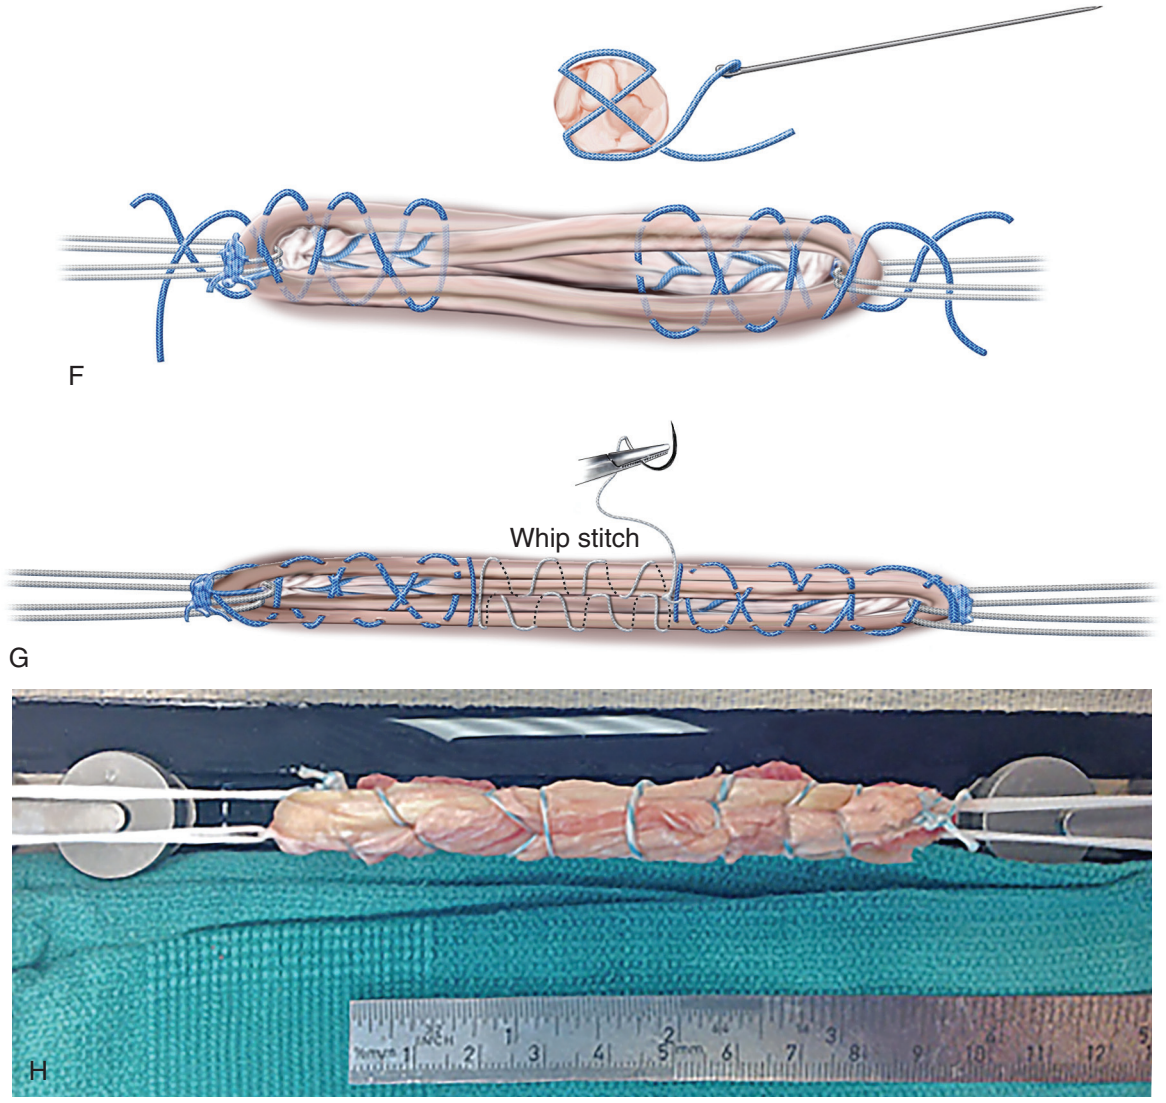

FIG 7-39, cont'd **F,** Two FiberLoop sutures (No. 2) are passed in a criss-cross fashion to secure each end of the six-strand graft. **G,** Place the construct under 40-N force to precondition the fibers. A whipstitch suture is placed along the top of the graft and then brought back on the bottom of the graft to secure the STG tendons together. **H,** Final six-strand graft construct.

tendon is determined on preoperative lateral radiographs. The normal patellar length based on the Linclau technique[152] (see Chapter 38) is a 1:1 ratio with the patellar tendon in the 35-mm range. The intraarticular ACL length is measured on the lateral MRI, and this length is matched with the autograft. It is possible to accommodate a shorter length patellar tendon by adjusting the proximity of the tibial tunnel. A total B-PT-B tendon length greater than 90 to 95 mm is usable with the bone portion of the graft adjusted in the tibial and femoral tunnels. A two-incision technique allows adjustment of graft length by proximal advancement in the femoral tunnel and is ideal when there is graft mismatch caused by an excessively long patellar tendon. There is a technique with a long B-PT-B graft in which the tibial bone plug may be rotated 180 degrees onto the tendon, sutured to the bone plug, and the tibial tunnel resized. However, the senior author recommends a two-incision technique to manage this problem. The bone plug sutures are tied to a tibial post. With a graft length mismatch, we do not recommend removal of the bone plug to shorten overall graft length or multiple twisting of the graft to shorten its length.

The ideal tibial tunnel is placed in a coronal manner, at a 55- to 60-degree angle, allowing a tunnel length of 35 to 40 mm. The tunnel is begun just anterior and adjacent to the SMCL and is usually 15 mm medial to the tibial tubercle medial border and 10 mm distal to the most proximal point of the patellar tendon tibial tubercle insertion.

A core reamer is placed over the guide pin to remove a tibial bone plug when a B-PT-B or QT-PB autograft is used to obtain a core of bone to fill the bone defects. As already described, the core reamer provides a more suitable graft material than drill reamings, and the bone defects are filled in an anatomic manner that results in the patient able to kneel on the tibial bone harvest site.

The tunnel is drilled to the desired graft diameter and the joint tunnel edges chamfered to prevent graft abrasion.

Placement of Femoral Tunnel

As previously described, a two-incision technique (open or FlipCutter [Arthrex]), an AM portal femoral tunnel placement with knee hyperflexion technique, or a flexible reamer is used. Baer and associates[17]

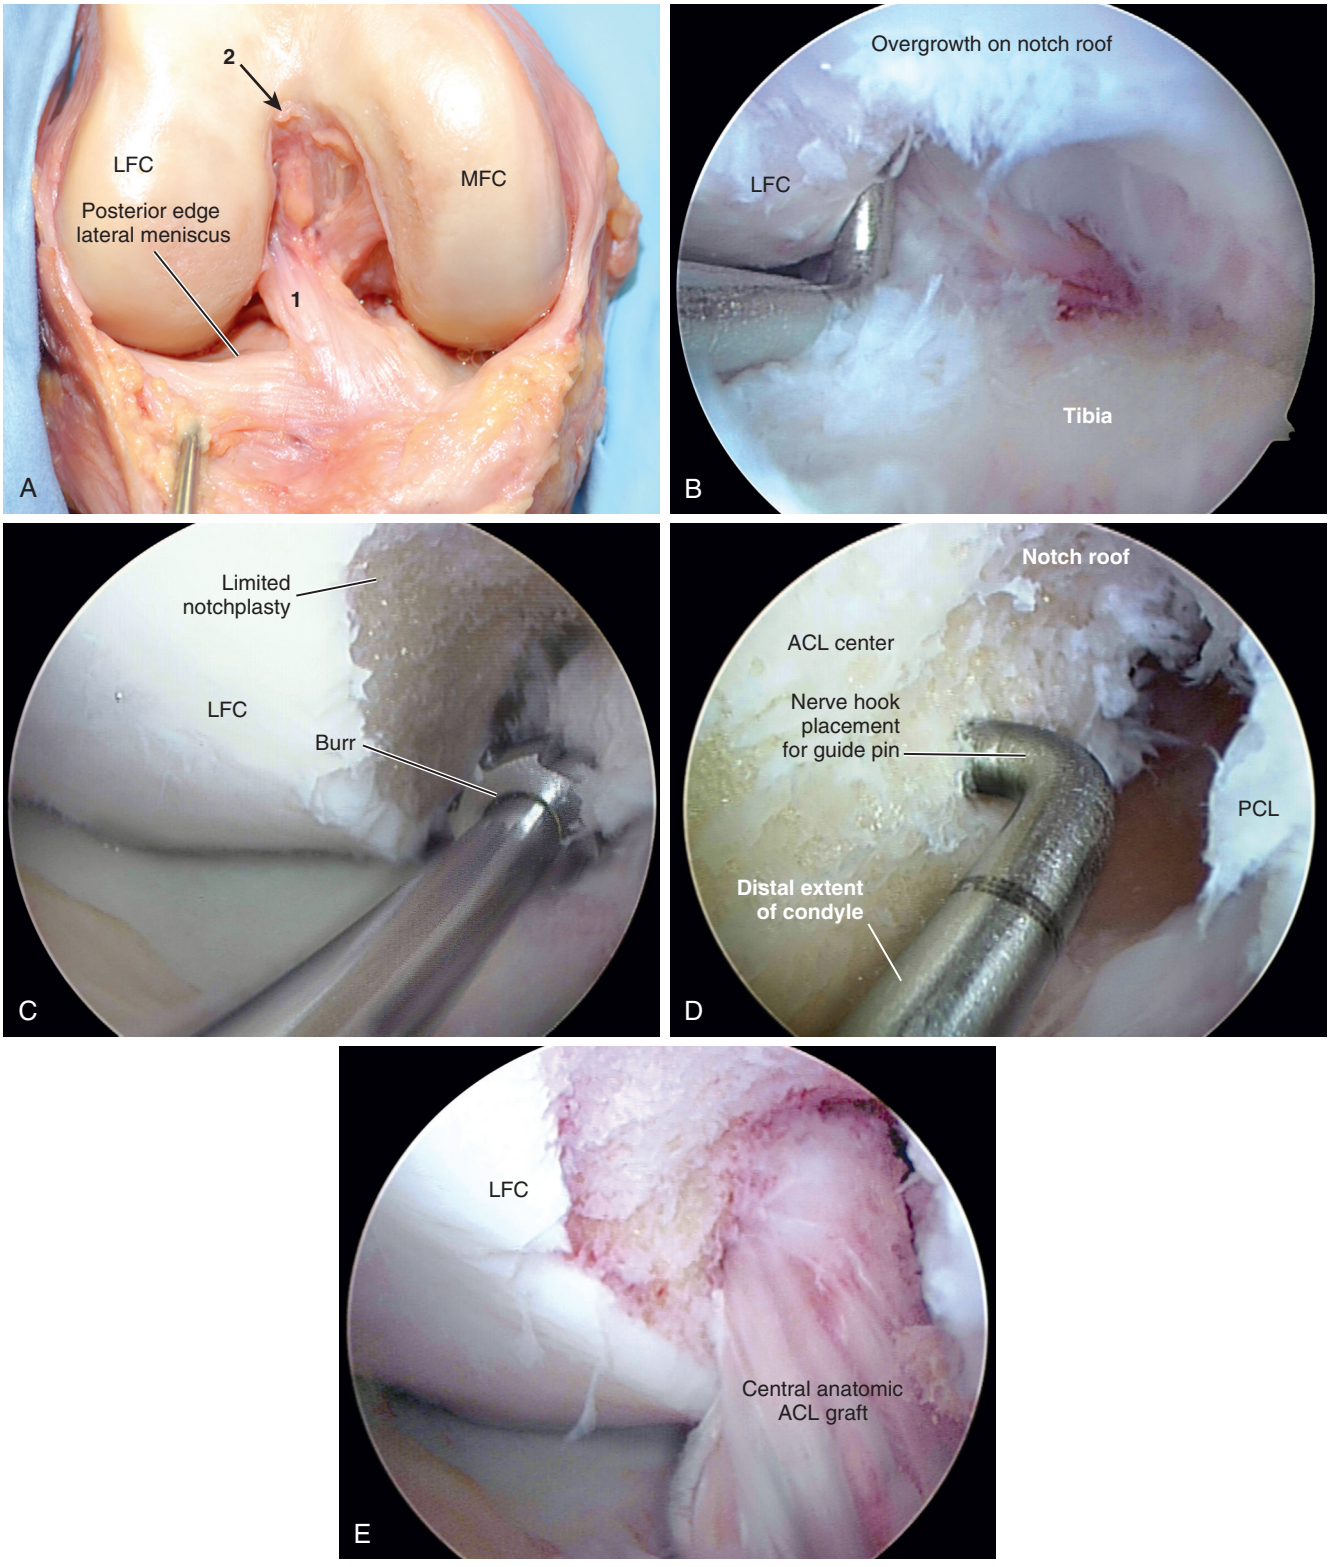

FIG 7-40 **A,** A normal femoral notch, which is viewed at arthroscopy by using the anteromedial portal. Label *1* shows the normal space between the medial femoral condyle and the posterior cruciate ligament (PCL), which is occupied by the anterior cruciate ligament (ACL). Label *2* shows the normal anterior notch that should not impinge on the graft. **B,** Revision ACL with failed ACL graft shows overgrowth of the lateral notch and notch roof, requiring a limited notchplasty. **C,** The lateral notch wall is visualized entirely posteriorly to the articular cartilage of the femoral condyle. **D,** The ACL femoral attachment is mapped out and a central small hole is made for placement of the guide pin. The resident's ridge has been removed. The anterior notch region has not been disturbed. **E,** Final placement of a single-bundle graft within a central anatomic tibial and femoral placement that occupies over 75% of the attachment site. *LFC*, Lateral femoral condyle; *MFC*, medial femoral condyle.

reported in a cadaver study that at least 110 degrees of knee flexion is required for femoral tunnel drilling through the AM portal to avoid potential injury to the peroneal nerve, the lateral condylar articular surface, the FCL, and the popliteus tendon. The use of the AM portal or more medial accessory portal to place the femoral tunnel has the problems in some knees of difficulty with visualization at 100 to 120 degrees of flexion, the potential for the drill to damage the medial femoral condyle, and a shorter femoral socket. As with any of the ACL techniques, surgeon experience is necessary to achieve a successful result. There is an advantage of using the flexible guide pin and reamers in larger patients where 110 degrees of knee flexion is easily achieved, avoiding greater knee hyperflexion.

The two-incision technique retrograde-drilling procedure (Fig. 7-41) involves a lateral incision of 2 to 3 cm in length at the distal lateral femoral condyle. The posterior one third of the ITB is incised for 4 to 6 cm to allow exposure. The interval posterior to the vastus lateralis is entered and the muscle protected. An S retractor is placed beneath the VLO to gently lift the muscle anteriorly, avoiding entering the proximal joint capsule. The proximal edge of the lateral femoral condyle is bluntly palpated with an instrument (over-the-top location), with the goal of locating the tunnel entrance just anterior and not distal to this point. A 15-mm periosteal incision is made and an elevator used to remove soft tissues from the site for the tunnel proximal entrance. With a B-PT-B graft length of 80 to 85 mm, a FlipCutter procedure may be selected to create a femoral socket rather than a tunnel.

As already described, the placement of the tibial tunnel in the central tibial ACL attachment in almost all cases requires a femoral notchplasty to avoid graft impingement with knee hyperextension. In most chronic ACL-deficient knees, there is an overgrowth of cartilage and spur formation in the femoral notch, requiring a notchplasty. The notchplasty rules taught by the senior author and used in all the clinical studies reported are described in Table 7-10. A lateral notchplasty is performed as required when there is insufficient width (9-10 mm) between the PCL and the lateral femoral notch wall to accommodate the ACL graft.

The ACL femoral attachment is mapped based on the bony landmarks already described. The location of the guide pin for an ACL central femoral tunnel is shown in Figures 7-31, 7-34, 7-40, and 7-42, *C* to *E*. The guide pin is placed within the central ACL attachment, which is midway between the lateral notch roof and the distal articular cartilage edge, 8 mm from the posterior articular cartilage edge. Clock locations are actually an inaccurate description of the tunnel location.[59,60] With the central femoral tunnel, the posterior back wall is 3 to 4 mm thick and the graft occupies approximately two thirds to three fourths of the ACL footprint. Always preserve 3 to 4 mm of the posterior back wall of the tunnel so that the graft is not placed too far posteriorly. Grafts placed too far posteriorly will have increased tension with knee extension and may potentially block full extension. In these cases, the graft will be observed to shorten with knee hyperextension and piston into the tibial tunnel. A guide pin placed 8 mm from the posterior articular cartilage at the central ACL attachment will have a 4-mm posterior back wall for an 8-mm graft and 3-mm wall for a 10-mm graft. One key to define the ACL attachment is to place the knee in 20 to 30 degrees of flexion viewed through the AM portal and map out the oval attachment and center point, measuring the distance to the posterior articular cartilage. It is often easier to mark out the ACL femoral attachment when it is viewed in a vertical plane rather than the horizontal attachment plane with knee flexion. The tunnel is drilled to the appropriate diameter, which is usually 1 mm greater than the bone portion that allows a snug graft fit in the tunnel. The edges of the tunnel are chamfered to prevent graft abrasion. The technique with a rear-entry guide drill is shown in Figure 7-42.

Graft Tunnel Passage, Conditioning, and Fixation

The graft is passed in a retrograde manner either with a Beath pin in the arthroscopic technique (placed through the accessory AM portal) or in the two-incision technique with a 20-gauge looped wire passed from the femur to the tibial tunnel. The graft is gently lifted up through the tibia and guided into the femoral tunnels with a nerve hook. The graft is marked at the bone-tendon junction to adjust its length in each tunnel. The graft is brought proximally until the bone is flush with the tibia. In most knees, the femoral portion of the graft is at or just proximal to the inside femoral tunnel. The femoral bone-graft plug is fixed with an interference screw of a metallic or absorbable type. Graft conditioning is performed by placing approximately 44-N tension on the distal graft sutures and flexing the knee from 0 to 135 degrees for 30 to 40 flexion-extension cycles. The arthroscope is placed to verify that the graft position is ideal and there is no impingement against the lateral femoral condyle or notch with full hyperextension. Appropriate notchplasty is performed when necessary.

The knee is placed at 20 degrees of flexion, and the tension on the graft is reduced to approximately 10 to 15 N to avoid overconstraining AP tibial translation. A finger is placed on the anterior tibia to maintain the posterior gravity position of the tibia. An alternative procedure is to fixate the graft with a larger graft tension at 0 degrees; however, the senior author believes there is more control of graft tension at the partially flexed position. An interference screw is placed. In cases where the interference screw fixation is not ideal or the screw resistance on placement is not acceptable, the sutures are tied over a suture post. The arthroscope is placed into the joint and final graft inspection performed. A Lachman test is performed and there should be total AP translation motion of 3 mm, indicating that the graft has not been over tightened. If the graft has a "bowstring," tight appearance with little to no anterior tibial translation on testing, the distal tensioning and fixation procedure is repeated with less tension placed on the graft.

Li and associates[145] reported the ACL 3-dimensional morphological changes in humans during weight-bearing flexion using a fluoroscopic and MRI-based system. The ACL tibial insertion twisted internally relative to the femoral insertion. The ACL internal twist amounted to approximately 10 degrees at full extension to 44 degrees at 90 degrees of flexion. The data were based on insertion site measurements and not actual ACL fiber microgeometry. Even though some authors[8] have recommended an ACL graft orientation to reproduce an internal twist of the ACL fibers, this effect on clinical outcomes is unknown. The B-PT-B orientation is usually placed in the sagittal plane on the femur and tibia with the cancellous surface lateral in the femoral tunnel to lessen abrasion of the tendon against the femoral condyle.

Techniques Using Other Grafts

With all other grafts, the same procedure is used with the following exception. In the two-incision technique with a STG graft, a femoral post is used with the sutures tied first at the femoral site about the post (35-mm, 4.0-mm cancellous self-cutting screw with washer). An absorbable interference screw is added. At the tibia, the interference screw is first placed, followed by the suture post fixation. Using the combined interference screw and suture post provides sufficient graft strength fixation for rehabilitation to proceed equal to the B-PT-B graft. An alternative technique for a four-strand STG graft using a FlipCutter and EndoButton (Smith & Nephew) or TightRope (Arthrex) technique is shown later in this chapter. The bone portion of the QT-PB is usually placed into the femoral tunnel; however, the graft can be reversed with the bone plug placed into the tibial tunnel and located appropriately to make up for an enlarged tibial tunnel that requires the bone portion of the graft.

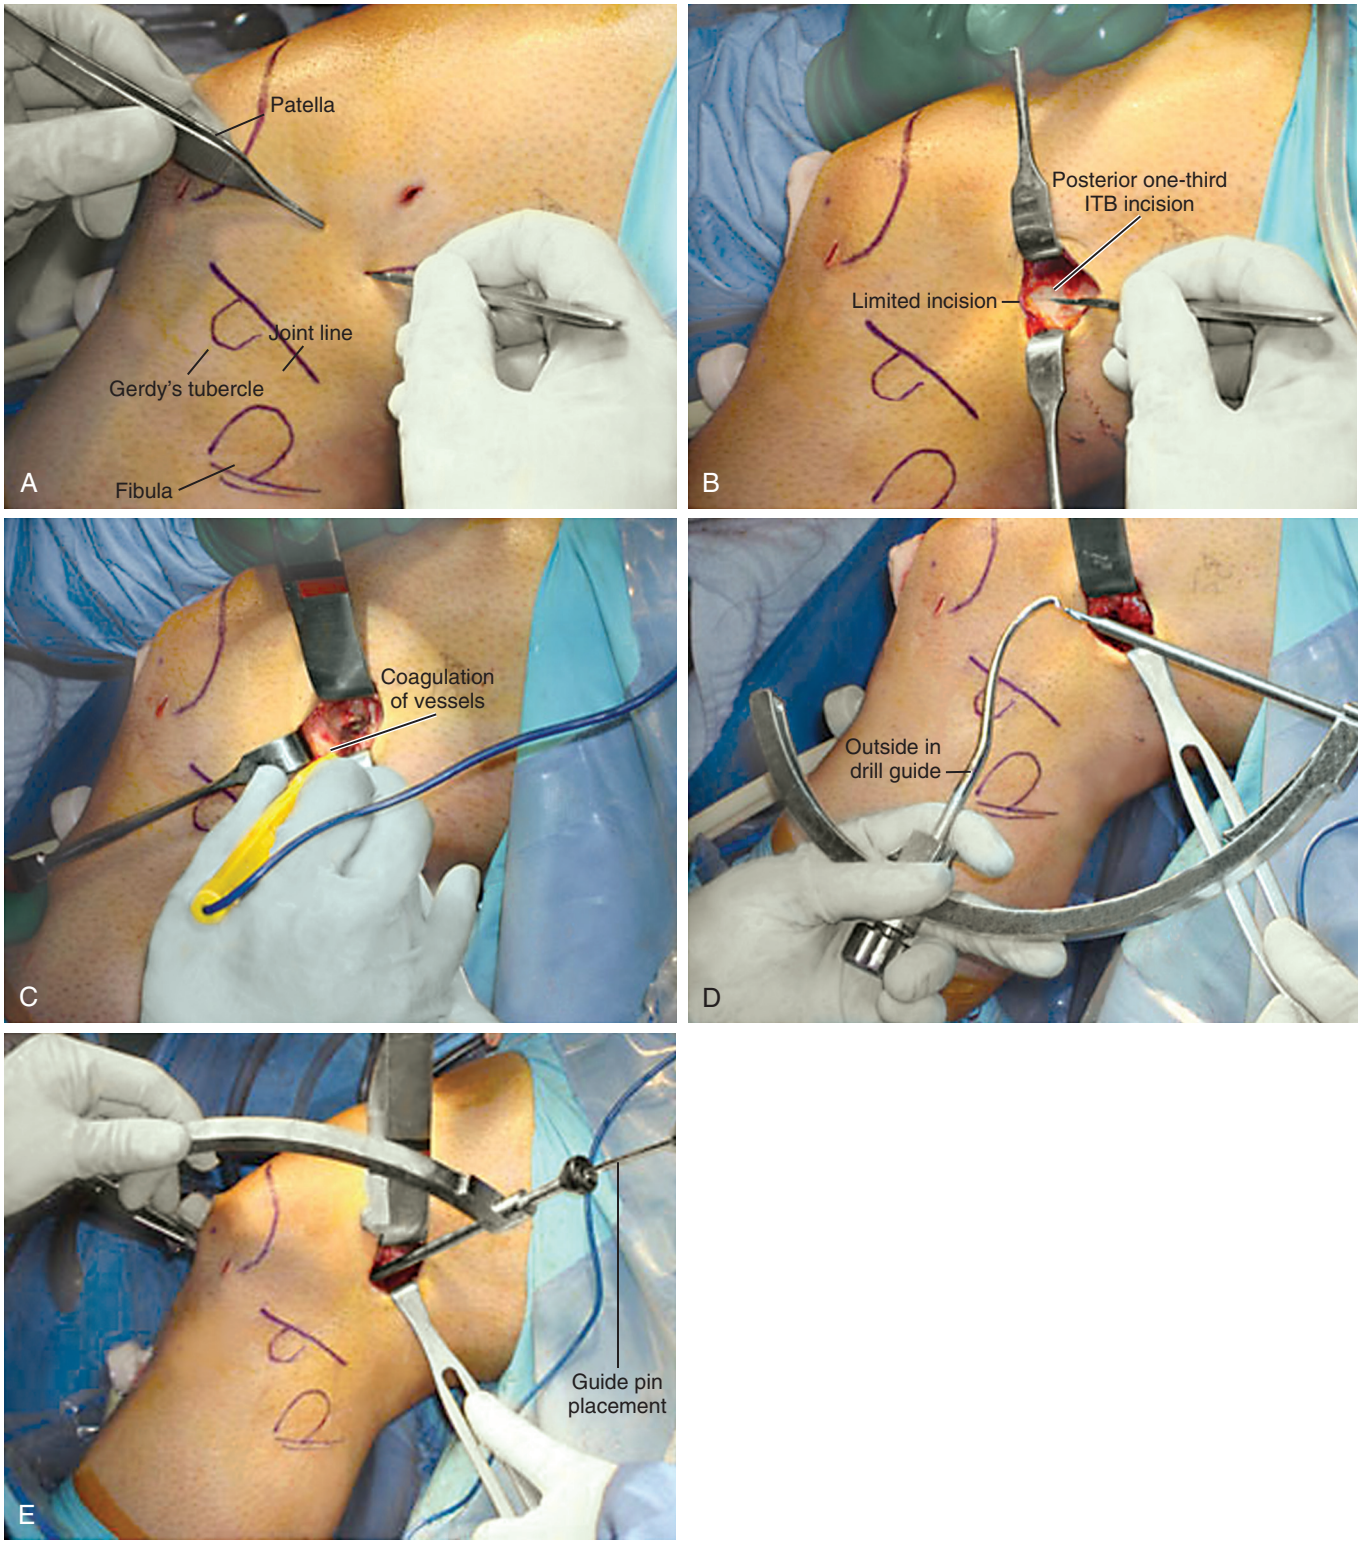

FIG 7-41 The anterior cruciate ligament procedure for a two-incision technique is shown. **A,** The anatomic landmarks are shown. The joint line, tibial tubercle, and fibula are marked. **B,** The 2-cm incision is made in the posterior one third of the iliotibial band (ITB), as described in the text. **C,** Electrocoagulation of vessels. **D,** Commercially available drill guide. **E,** Placement of guide pin. Antegrade drilling is viewed arthroscopically.

TABLE 7-10 Notchplasty Techniques and Rules

1. The arthroscope is placed in the anteromedial (AM) portal with instruments passed through a central portal (patellar tendon graft site or central patellar tendon portal). Place the knee at 20 to 30 degrees of flexion to view the anterior cruciate ligament (ACL) attachment, not a high flexion angle where the ACL is in a horizontal plane. A mistake is to view the lateral wall of the notch through an anterolateral (AL) portal, which provides suboptimal visualization. In the presence of a prominent lateral resident's ridge, it is often difficult if not impossible to view or identify with accuracy the ACL femoral attachment though the AL portal.
2. Measure the clearance of the lateral notch wall to the posterior cruciate ligament (PCL) to ensure there is 9- to 10-mm clearance for the graft. Remove the shallow notch to obtain this clearance, starting distally and progressing proximally up to the top of the notch entrance. This ensures an adequate lateral graft notch clearance throughout knee flexion, preventing graft abrasion from a stenotic lateral notch wall. Usually only 2 to 3 mm of the lateral notch is removed; aggressive resection of the lateral wall beyond this should be avoided.
3. To ensure that the height of the notch is sufficient and will not impinge, place the notchplasty burr at the central ACL tibial attachment and gently bring the knee into full hyperextension. The burr should not impinge into the anterior notch. This defines the millimeters of the anterior and lateral aspect of the notch that are removed to prevent graft impingement. Normally, this is 4 to 6 mm; more is removed when there is excessive hyperextension.
4. The anterior notch is gently curved, removing an A-shaped notch if present. Before graft passage, the arthroscope is placed within the tibial tunnel "worm's-eye view" and the knee taken to full hyperextension, observing whether any portion of the anterior notch comes into view which would require removal. This provides for direct arthroscopic confirmation that there is no ACL graft impingement and intraoperative fluoroscopy is not required.
5. Avoid use of a commercially available "tunnel smoother" because this is too aggressive. When placed in an intraarticular location within both femoral and tibial tunnels and moved proximally and distally, this instrument may remove the anterior aspect of the femoral tunnel and posterior aspect of the tibial tunnel, producing a vertical graft.
6. Once the anterior and lateral aspects of the femoral notch (shallow portion) are prepared, it is possible to completely view the deep portion of the notch, identify the appropriate place for the ACL graft on the lateral wall, and remove an anterior bone buttress in front of the ACL attachment (resident's ridge). Maintain the knee at 20 to 30 degrees of flexion rather than 90 degrees of flexion.
7. The deep roof portion of the notch represents the Blumenstaat line, and it is important not to elevate the notch because this would change the anatomic reference points for the native femoral ACL attachment. In addition, the lateral deep wall of the notch is not changed or removed to maintain the native ACL attachment location for the ACL graft. Remaining ACL fibers are helpful to define the femoral footprint. Only in rare instances is there overgrowth in this region and insufficient clearance between the lateral notch and the PCL. The tissue in this region is gently removed and the PCL synovium is protected. A sharp curette is used to remove soft tissues on the lateral wall to the femoral condyle articular cartilage edge, which is the required reference for ACL graft placement. The mistake is made not to go deep enough in the notch on the lateral wall to view "around the corner" because sometimes the notch wall will have a gentle deep lateral slope of a few degrees.

A variety of techniques for femoral fixation (Fig. 7-43) and tibial fixation (Fig. 7-44) are available, based on the preference of the surgeon. Interference screw fixation alone of an STG or soft tissue allograft is not recommended either. A suture post is commonly required to achieve higher strength graft fixation.

Alternative Procedures

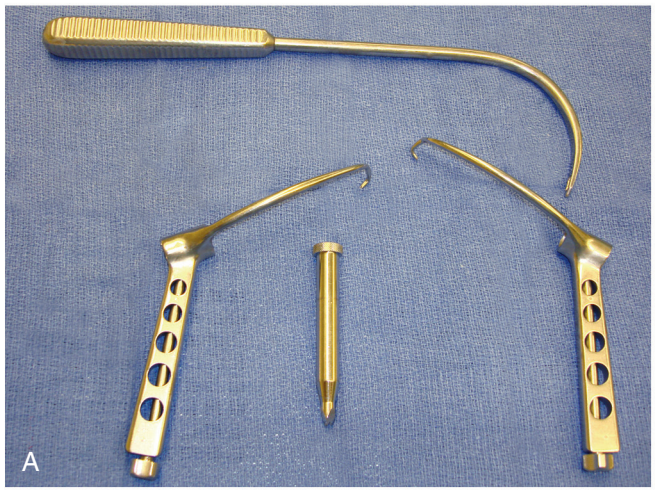
FlipCutter for Femoral Tunnel

An alternative approach to the two-incision technique is the FlipCutter technique that may be used to locate and drill the tunnel from inside out (Fig. 7-45). This procedure provides a long femoral tunnel for graft healing and incorporation. It also allows control of the guide pin for the femoral tunnel to be oriented into the most ideal position to achieve good-quality bone for interference screw fixation. This technique avoids the necessity for tunnel drilling in a hyperflexed knee position.

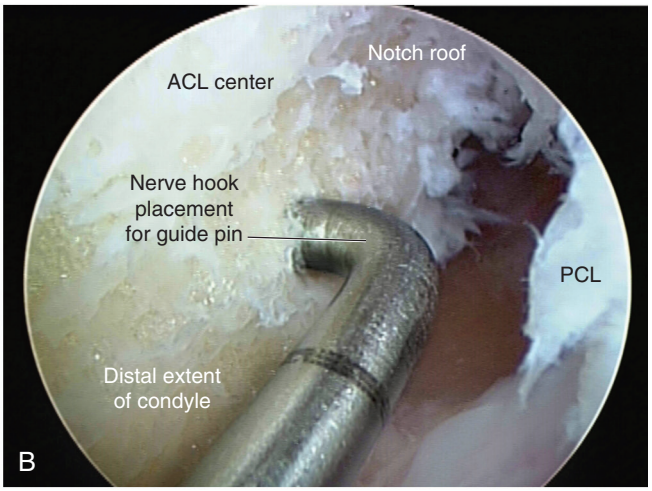
The steps for this technique are shown in Figure 7-45. The steps already described for locating the central femoral ACL guide pin placement are performed. A 10-mm incision is made at the posterior one third of the thigh and at the proximal margin of the lateral femoral condyle. The drill guide is placed and the blunt proximal guide sleeve bluntly advanced to the femur. The guide pin FlipCutter is advanced and the position and entrance determined with the arthroscope in the AM portal. The drill socket is created. The tunnel joint entrance is chamfered to prevent graft abrasion. The graft is passed in a retrograde manner and fixed by an EndoButton, the TightRope technique, or with an interference screw (B-PT-B) using the AM portal in a retrograde manner. In rare cases where the bone quality on the femur is not ideal and a femoral suture post is desired, it is easy to enlarge the incision for visualization, extend the femoral tunnel to exit proximally, and provide a graft suture post.

CRITICAL POINTS Operative Techniques: Alternative Procedures

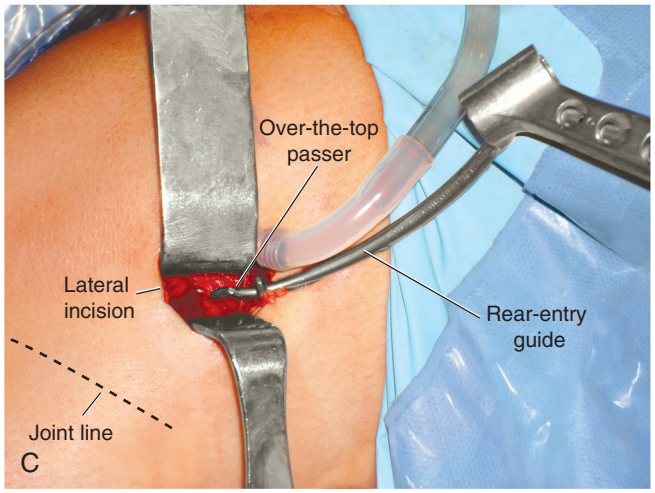
FlipCutter for Femoral Tunnel



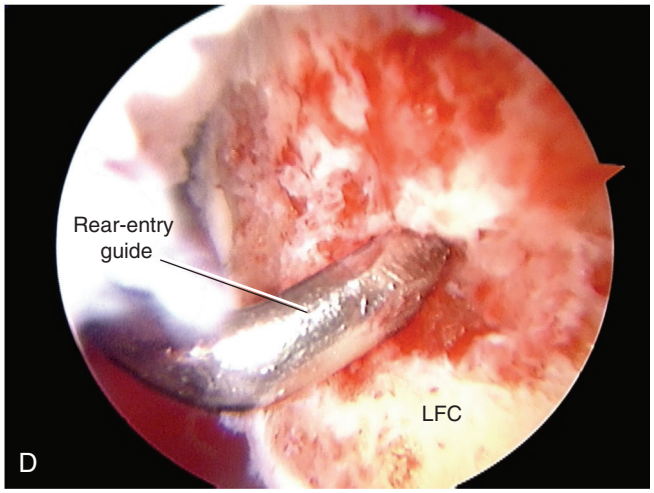
- Used to locate and drill tunnel from inside out.
- Provides long femoral tunnel.
- Guide pin control to orient tunnel in best position to achieve good-quality bone for fixation.
- Avoids necessity for drilling tunnel in hyperflexed knee position.



All-Inside ACL Graft-Link Technique Using Second-Generation FlipCutter and TightRope Devices



- Advantages include the ability to measure femoral and tibial tunnel length, preparation of the graft to match the sum of tunnel length and intraarticular length (usually 75 mm), and a suture-based graft tensioning that allows the graft to fill the tunnels.



Management of Graft Malposition

- Excessive anterior femoral tunnel: two-incision reorientation of the femoral tunnel is indicated, and a femoral suture post is added to provide a combined interference screw and suture post fixation.
- Excessive posterior femoral tunnel: requires an anterior adjustment in the tunnel.
- Tibial tunnel malposition: small adjustments may be made in medial or lateral graft position by placing the interference screw in a medial or lateral direction.
- Fracture of the bone portion of the graft: place two additional sutures in the tendon portion of the graft and two sutures in the bone portion.
- B-PT-B fixation problems with interference screws are usually solvable by upsizing the screw diameter and adding a suture fixation post.
- Enlarged tibial or femoral tunnel: place absorbable interference screw to compress one side of the graft into the tunnel.

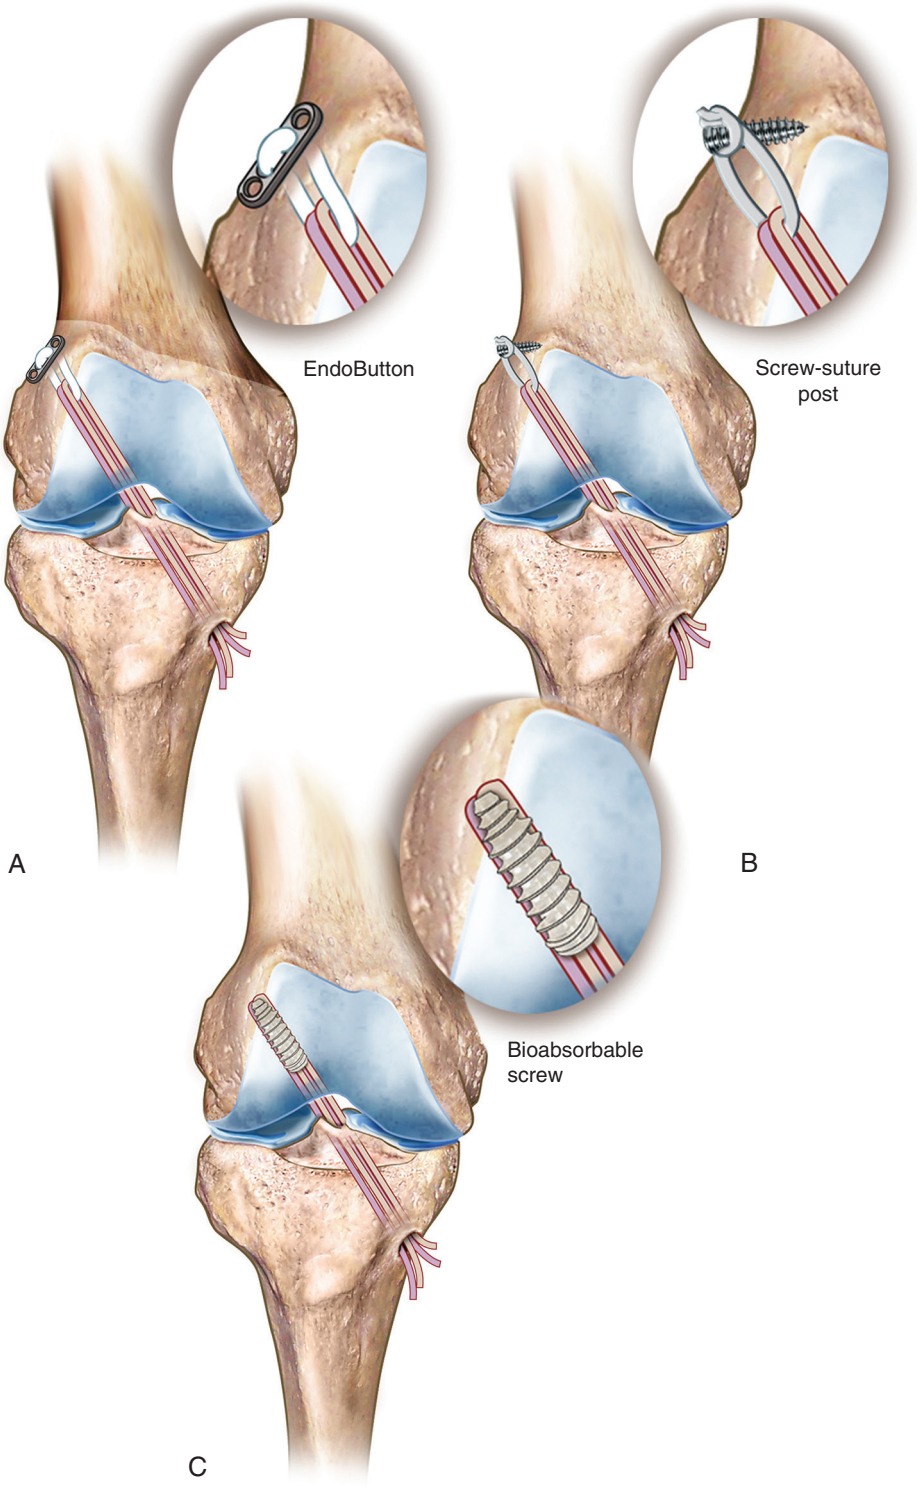

FIG 7-43 A variety of anterior cruciate ligament femoral fixation techniques for semitendinosus-gracilis grafts. The interference screw alone **(C)** is not recommended because it produces the lowest graft tensile strength to pullout.

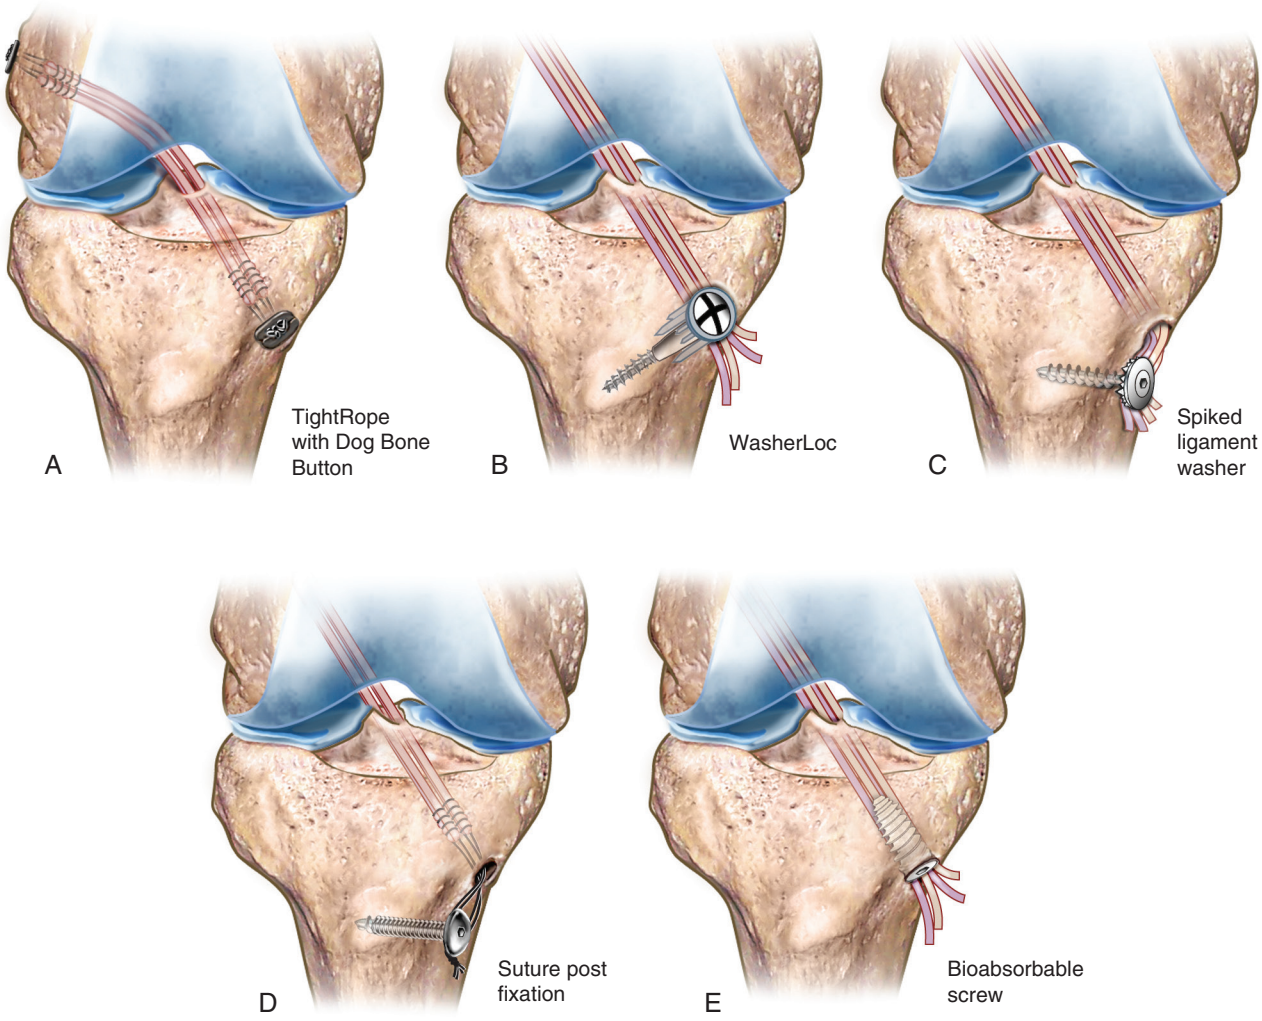

FIG 7-44 Various tibial fixation techniques for semitendinosus-gracilis grafts. An interference screw alone **(D)** is not recommended.

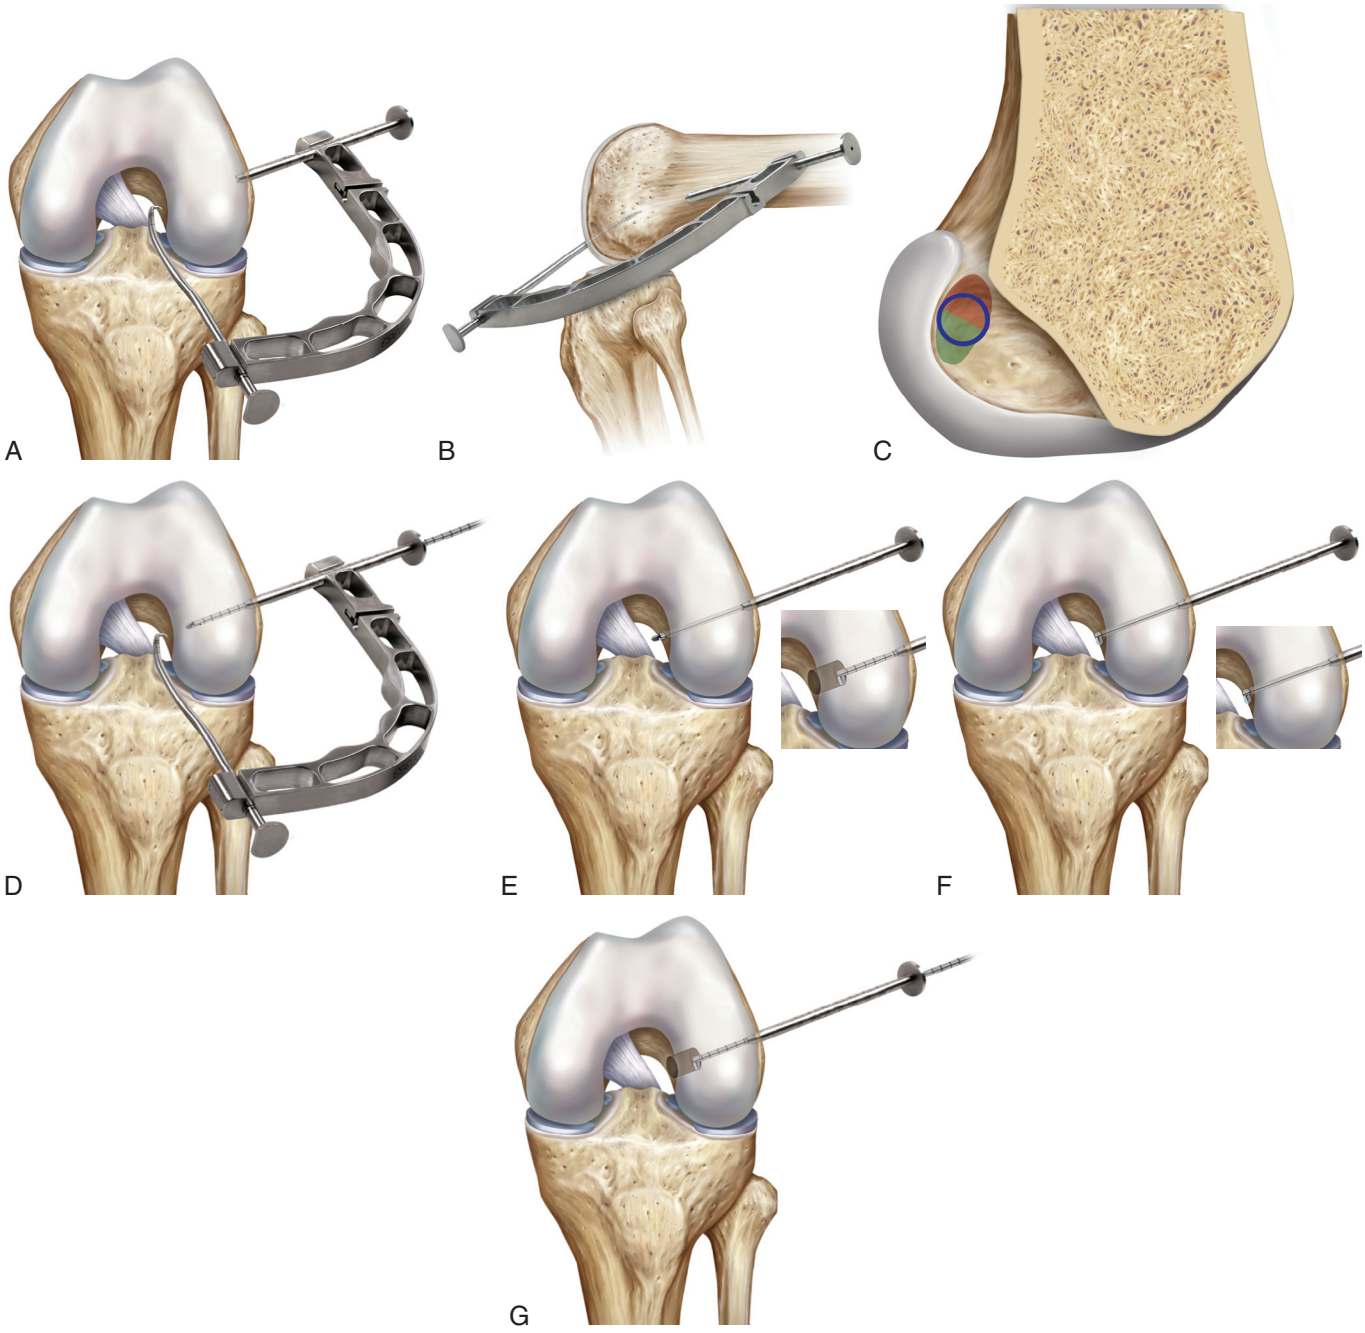

FIG 7-45 Demonstration of FlipCutter technique for femoral socket or tunnel. **A** and **B,** Placement and location of drill guide. **C,** Central anterior cruciate ligament anatomic tunnel placement. **D,** Placement of the FlipCutter. **E,** The FlipCutter is advanced at the femoral attachment. **F,** The drill end is "flipped" at a right angle to the pin. **G,** Creation of a femoral socket that can extend completely as a tunnel if desired. (Courtesy Arthrex, Inc., Naples, FL.)

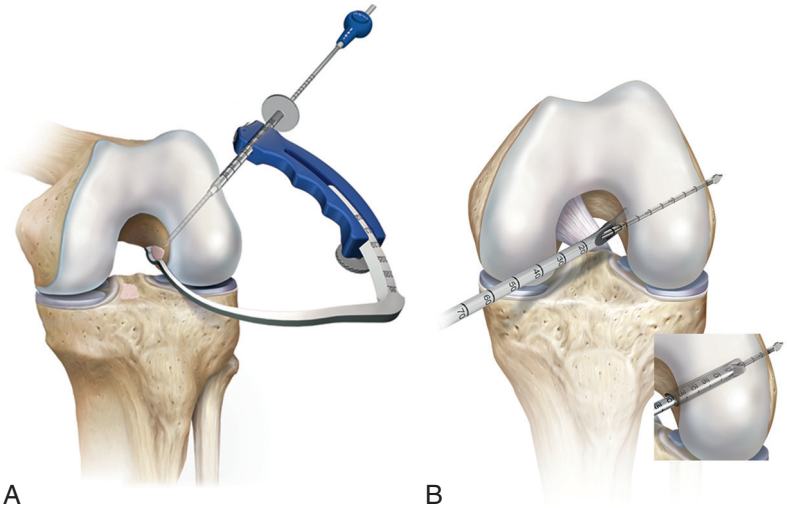

FIG 7-46 The femoral socket can also be prepared in a retrograde fashion using the FlipCutter and the RetroConstruction Drill Guide System **(A)** or an antegrade fashion with a RetroButton Pin II and Low Profile Reamers **(B)**. Note intraosseous length during tunnel preparation and mark that distance on the anterior cruciate ligament TightRope RT implant. (Courtesy Arthrex, Inc., Naples, FL.)

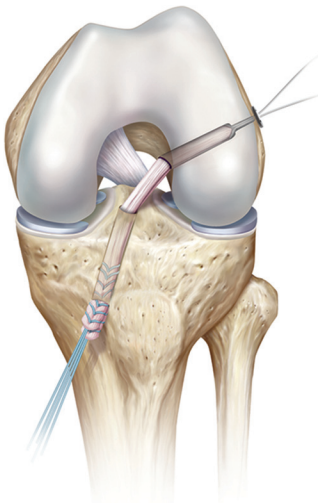

FIG 7-47 Hold slight tension on the tibial tails of the graft during graft advancement. To advance the graft, pull on the tensioning strands one at a time, alternating approximately 1 cm on each side. A mark on the graft made at a distance of the femoral socket is helpful in signaling that the graft is fully seated. Once the graft is fully seated, pull firmly back on the graft to check fixation. If desired, advance the graft just shy of the full length of the socket. This will allow retensioning of the graft after tibial fixation has been completed. (Courtesy Arthrex, Inc., Naples, FL.)

All-Inside Anterior Cruciate Ligament Graft-Link Technique Using Second-Generation FlipCutter and TightRope Devices

Lubowitz and colleagues[155] described the surgical technique in detail for an all-inside ACL reconstruction using a hamstring graft, second-generation FlipCutter guide pins (Arthrex) to create femoral and tibial sockets, and TightRope (Arthrex) for fixation (Figs. 7-46 to 7-52). The advantages of this technique include the ability to measure femoral and tibial tunnel length, preparation of the graft to match the sum of tunnel length and intraarticular length (usually 75 mm), and a suture-based graft tensioning that allows the graft to fill the tunnels. The central femoral and tibial native insertion sites are carefully marked as previously described. Placement of the femoral FlipCutter guide pin is accomplished through a small stab wound 25 mm above the lateral femoral epicondyle in the mid lateral plane. The guide sleeve is advanced 7 mm in the femur (also tibial cortex) to avoid the FlipCutter breaching the cortex. The FlipCutter guide pin is placed at an approximate 45-degree angle at the AM tibial cortex adjacent to the tibial tubercle. A flexible silicone cannula in the AM arthroscopic portal aids in intraarticular graft passage. A recent modification of this technique for tibial fixation of the graft is shown in Figure 7-51.

Flexible Guide Pin and Drill for Femoral Tunnel

The VersiTomic Flexible Reaming System (Stryker), composed of flexible reamers and guide pins, may be used for creating independent bone tunnels during ACL reconstruction (Fig. 7-53).

Management of Graft Malposition

In the operative technique it is important to recognize whether or not an improper graft position has occurred so that steps may be taken to address the problem. An excessive anterior femoral tunnel results when all of the soft tissues have not been removed from the lateral femoral wall and the "around-the-corner" view posteriorly of the femoral condyle has not been achieved. It is important that the AM portal be used to view the entire lateral sidewall in selecting the ideal femoral tunnel position. Excessive posterior placement of a femoral tunnel with a back-wall blow-out would provide a compromise to interference screw fixation. In these cases, a two-incision reorientation of the femoral tunnel is indicated, and a femoral suture post is added to provide a combined interference screw and suture post fixation.

An excessively placed posterior femoral tunnel results in shortening of the graft in extension; this requires an anterior adjustment in the tunnel. When the guide pin is placed in the femoral ACL attachment from either an inside-out or outside-in approach, it is possible to start with a 6-mm acorn-shaped reamer to readjust the tunnel and subsequent tunnel entrance with a stepwise progression in the reamers. In this manner, the most ideal placement of the femoral tunnel may be achieved. A distal femoral tunnel past the 9 o'clock position may result

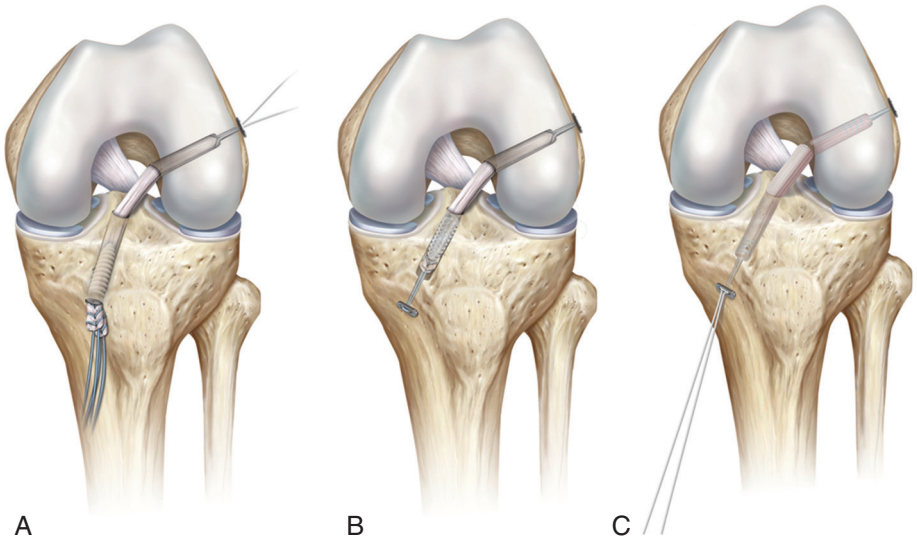

FIG 7-48 **A,** Fix the tibial side of the graft. If desired, and space has been left on the femoral side, retention shortening strands on the femur. Cut shortening strands with a closed-end TightRope Suture Cutter. **B,** Anterior cruciate ligament (ACL) TightRope RT is also ideal for all-inside ACL reconstruction because it facilitates incremental graft advancement and tensioning after tibial fixation has been completed. **C,** ACL TightRope RT may also be used on the tibial side with the GraftLink procedure. See Arthrex technique guide LT0157 for details. (Courtesy Arthrex, Inc., Naples, FL.)

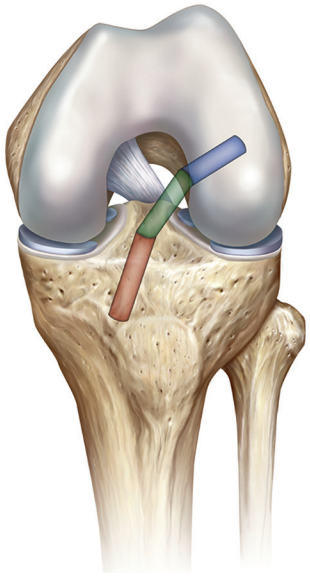

FIG 7-49 GraftLink all-inside anterior cruciate ligament reconstruction with TightRope: Socket creation. The length from the end of the femoral socket to the end of the tibial socket should be at least 10 mm longer than the graft to ensure that the graft can be tensioned fully. For example, with a 70-mm graft length and assuming a maximum intraarticular length of 30 mm (green shading), there will be approximately 20 mm of graft in the femoral and tibial socket. Drill the femoral 20 to 25 mm deep (blue shading) and the tibia approximately 30 mm deep (red shading) to allow an extra 10 mm for tensioning. (Courtesy Arthrex, Inc., Naples, FL.)

in a graft impinging on the lateral femoral condyle, requiring excessive notchplasty. The final graft length is short and not ideal.

A tibial tunnel malposition posteriorly produces a vertical graft. A tibial tunnel placed too far anteriorly may result in anterior graft impingement or loss of the anterior tibial cortex for adequate interference screw fixation. A tibial tunnel placed too far medially or laterally may impinge on the PCL or lateral femoral condyle, respectively. Small adjustments may be made in medial or lateral graft position by placing the interference screw in a medial or lateral direction. The principle is never to accept a misplaced tibial or femoral tunnel and risk of a graft failure and revision knee problem.

A fracture of the bone portion of the graft, in which 15 mm of bone remains, may be managed by placing two additional sutures in the tendon portion of the graft and two sutures in the bone portion. An interference screw is used along with a suture post. In the rare instance of disruption of a B-PT-B graft at the bone-tendon junction, the senior author prefers to harvest an STG autograft instead of adding sutures to the tendon portion because the diameter of the patellar tendon is not ideal in the absence of the bone portion.

In cases of Osgood-Schlatter disease or an accessory ossification of the patellar tendon at the patella attachment (that is not appreciated until the graft is harvested), it is possible to remove the excess bone that will not affect the length or integrity of the graft. However, it is best to avoid a graft from these locations in these disease states and inform the patient that an alternative graft source will be used. The problem is that it may be necessary in a large Osgood-Schlatter lesion to dissect intact tendon adjacent to the graft harvest site to remove the bony lesion entirely, which results in weakening of the tendon attachment site. This problem requires added postoperative protection and modification of the immediate rehabilitation program. B-PT-B fixation problems with interference screws are usually solvable by upsizing the screw diameter and adding a suture fixation post. Never compromise the final graft fixation strength and accept a less than ideal

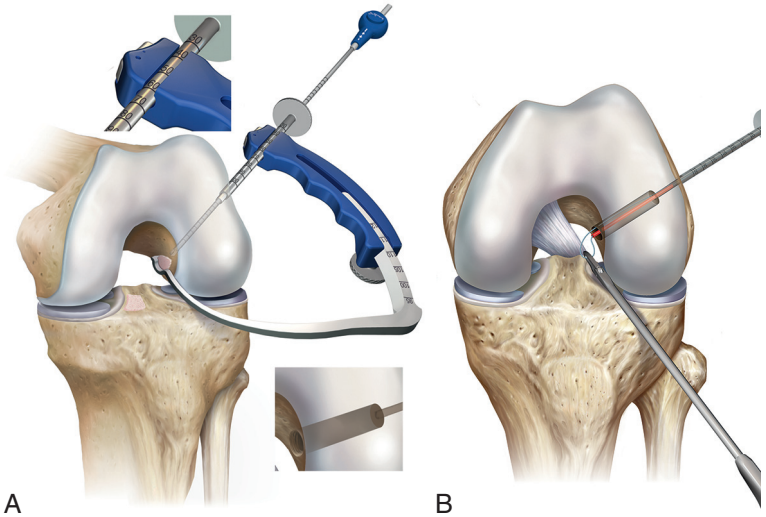

FIG 7-50 **A,** The FlipCutter may be used to create the femoral socket. fixation because this would potentially result in graft loosening in the early postoperative period.

It is more difficult to manage an enlarged tibial or femoral tunnel with an STG graft because the technique requires that a snug-diameter tunnel be placed to achieve a graft-tunnel interface to allow graft incorporation and avoid excessive tunnel widening. An absorbable interference screw may be necessary to compress one side of the graft into the tunnel, which would require modification of the postoperative rehabilitation to protect the graft during the initial healing stages. EndoButton or TightRope techniques are frequently used with STG grafts, and problems may be encountered with inadvertent reaming of the femoral cortex and loss of fixation strength. Fixation with an interference screw provides a weaker graft fixation, and consideration of a two-incision technique with a suture post is warranted. There is a concern regarding STG tendons looped over a 3-mm loop in the Endobutton or TightRope fixation.

OUR ANTERIOR CRUCIATE LIGAMENT RECONSTRUCTION CLINICAL STUDIES

We have published a series of prospective clinical studies on ACL primary reconstruction in over 650 knees with acute, subacute, and chronic ruptures.* The data from these investigations provide information regarding the following variables on clinical outcome: (1) type of graft, (2) sterilization of allografts, (3) gender, (4) chronicity of injury, (5) concomitant operative procedures, (6) preexisting joint arthritis, (7) varus osseous malalignment, (8) the rehabilitation program, and (9) type of insurance (workers' compensation versus private). This chapter provides summaries of these investigations and the reader is encouraged to refer to the original publications for further

*References 11, 18, 20, 21, 37, 185-188, 190, 191, 193-198, 202, 210.

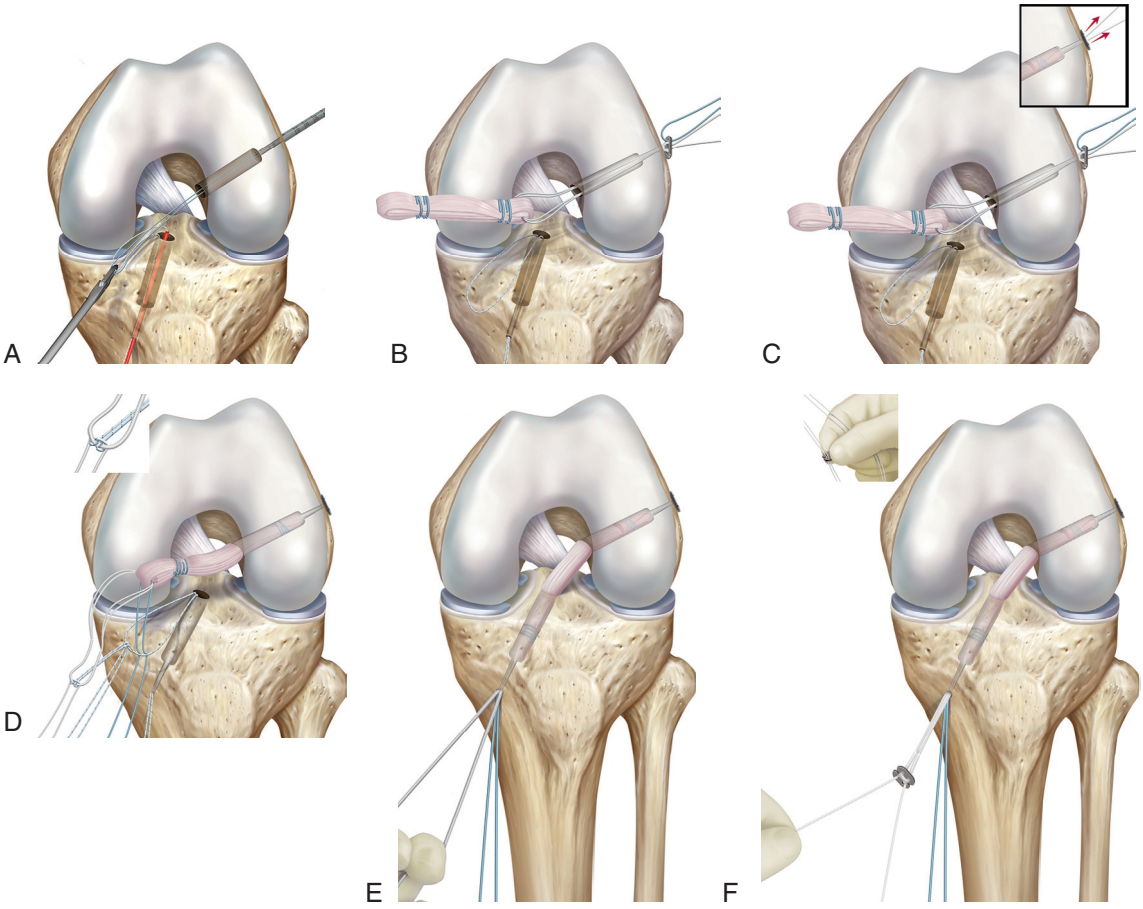

FIG 7-52 Graft passing. **A,** Straighten the FlipCutter blade and remove from the joint. Pass a TigerStick into the joint and retrieve both the tibial TigerStick and the femoral FiberStick out the medial portal together with an open suture retriever. Retrieving both sutures at the same time will help avoid tissue interposition that can complicate graft passing. **B,** Pass the blue button suture and the white shortening strands through the femur. Remove slack from sutures and ensure equal tension. Clamp or hold both blue and white sutures together and pull them together to advance the button out of the femur. Use markings on the loop and arthroscopic visualization of the button to confirm exit from the femoral cortex. Pull back on the graft to confirm the button is seated. **C,** While holding slight tension on the graft, pull the shortening strands proximally, one at a time to advance the graft. Pull on each strand in 1-cm increments. **D,** Cinch a suture around the end of the TightRope ABS loop to use for passing (inset). Load the cinch suture and the whipstitch tails from the graft into the tibial passing suture. Pull distally on the tibial passing suture to deliver both the TightRope ABS loop and the whipstitch sutures out of the tibia distally. **E,** Advance the graft into the tibia by pulling on the inside of the ABS loop and whipstitch sutures. **F,** Load the TightRope ABS button onto the loop. Pull on the white shortening strands to advance the button to bone and tension graft. Ensure the button has a clear path to bone, as to not entrap soft tissue under the button. detail. The grafts studied included freeze-dried fascia lata and fresh-frozen or irradiated (2.5 mrad) B-PT-B allografts and B-PT-B autografts. An ACL reconstruction was considered failed if more than 5 mm of increased AP tibial displacement was measured on knee arthrometer testing or if a grade II or III pivot shift was elicited on clinical examination (International Knee Documentation Committee [IKDC] knee categories of abnormal and severely abnormal combined).

Type of Graft

A higher rate of ACL graft failure was noted in knees with chronic ACL ruptures that received fresh-frozen or irradiated allografts (16%-30%)[185,186] compared with those that received autografts (3%-8%[195]; Table 7-11). Accordingly, the senior author advised against the use of allografts in 1997[195] because of these differences. The only exception was in a group of knees that underwent a combined allograft and ITB extraarticular procedure in which a failure rate of only 3% was found.[185]

In knees that underwent ACL reconstruction for acute or subacute ruptures, there was no difference in the overall failure rate among B-PT-B allografts (7%)[191] and autografts (3%).[195] However, a greater percentage of knees that received allografts had 3 to 5 mm of increased AP displacement, indicating partial graft function, compared to autografts (Fig. 7-54). The knees in this category typically demonstrate a grade I pivot shift and may be at increased risk for progression to a fully positive pivot shift in the future. As a result of these findings, we recommended in 1997 to use arthroscopically assisted B-PT-B autogenous grafts as the first choice for acute and chronic ACL ruptures.[195]

Augmentation Procedures for Allografts (Iliotibial Band Extraarticular, Ligament Augmentation Device)

We conducted a prospective study (Level II) on the use of an extraarticular ITB tenodesis procedure combined with a B-PT-B allograft for chronic ACL ruptures.[185] This was the first study that compared the outcomes of this combined procedure (64 patients) with those of an allograft alone (40 patients). The knees in this study had a high grade of instability before surgery because 50% or more had a grade III pivot shift, indicating deficiency of the extraarticular lateral restraints.

At follow-up, a mean of 2.9 years postoperatively, the rate of graft failure was 16% in the allograft-alone subgroup compared with 3% in the combined allograft-ITB subgroup ($P < .05$, see Table 7-11). The difference in AP displacements measured on KT-1000 testing was also statistically significant (Fig. 7-55, $P < .01$). The difference in the rate of failure was not caused by an irradiation effect because only 10 patients in the allograft-alone group and 2 patients in the combined allograft-ITB group received irradiated grafts. The combined subgroup returned to significantly higher levels of sports activity ($P < .05$) and had higher overall rating scores on the Cincinnati Knee Rating System (CKRS) ($P < .01$). There were no differences among the subgroups in isokinetic muscle test scores, functional limitations, symptoms, or patellofemoral crepitus.

We hypothesized that the ITB tenodesis provided support to the intraarticular allograft by restoring the secondary lateral restraints to anterior translation and internal rotation. Therefore, the procedure may be useful in knees with a grade III pivot shift. However, the study cohort is not large enough to provide definitive recommendations and further study is indicated. The results of this study may have implications in the treatment of ACL revision knees in which an allograft approach is selected (see Chapter 8).

From a historical perspective, we conducted a prospective, randomized clinical trial (Level I) on the effect of a ligament augmentation device (LAD) combined with an irradiated B-PT-B allograft for chronic ACL ruptures.[186] The results of the combined procedure in 49 knees were compared with those of a fresh-frozen B-PT-B allograft used alone in 66 knees. At an average of 2.8 years postoperatively, there was no difference in overall graft failure rates (20% and 16%, respectively; see Table 7-11) or in the individual symptom, functional limitation, or overall rating scores. The LAD did not improve the efficacy of the reconstruction and was therefore not recommended for use with an allograft for ACL reconstruction.

Secondary Sterilization Process Used for Allografts

Based on the two studies in the chronic ACL groups shown in Table 7-11, a higher rate of ACL graft failure was measured in knees that

received allografts sterilized with 2.5 mrad of gamma irradiation (23%; 14 of 61 knees) compared with those that were fresh frozen (11%; 10 of 92 knees, $P < .05$).[185,186] We prefer and recommend other methods of secondary sterilization that have been discussed in detail by others elsewhere.[171,292,293]

Gender

We conducted a prospective study (Level II) on 94 patients (47 males, 47 females) who received B-PT-B autografts to determine whether or not a difference existed in outcome between men and women.[20] This was the first study of its kind to conduct this type of comparison. The patient groups were stratified according to chronicity of the injury to determine whether this factor affected the results. Patients in the acute subgroup received the operation within 14 weeks of the original injury; all others were placed in the chronic subgroup. The patients were matched for age, preoperative sports activity levels, condition of the articular cartilage, and months of follow-up.

At a mean of 2.2 years postoperatively, there were no significant differences in outcome between the men and the women. Although the women demonstrated greater mean AP displacements before surgery than the men (14.3 ± 5 mm and 11.2 ± 4 mm, respectively; $P = .05$), these data were similar at follow-up (0.90 ± 2.69 mm for men, 0.70 ± 3.49 mm for women), as were the percentages of patients with less than 3 mm, 3 to 5.5 mm, and 6 mm or more of increased AP displacement (Fig. 7-56). The overall failure rate was 4% for men and 6% for women. There was no difference between genders for range of knee motion, patellofemoral crepitus, anterior knee pain, muscle strength deficits (Table 7-12), or complications. In addition, there was no significant difference between men and women for symptoms, functional limitations with daily or sports activities, or the overall rating scores. The conclusion was reached that equal consideration should be given to active patients for ACL reconstruction regardless of gender. Subsequently, other authors conducted similar analysis and reached the same conclusions for men and women receiving B-PT-B autografts[65] and STG autografts.[252]

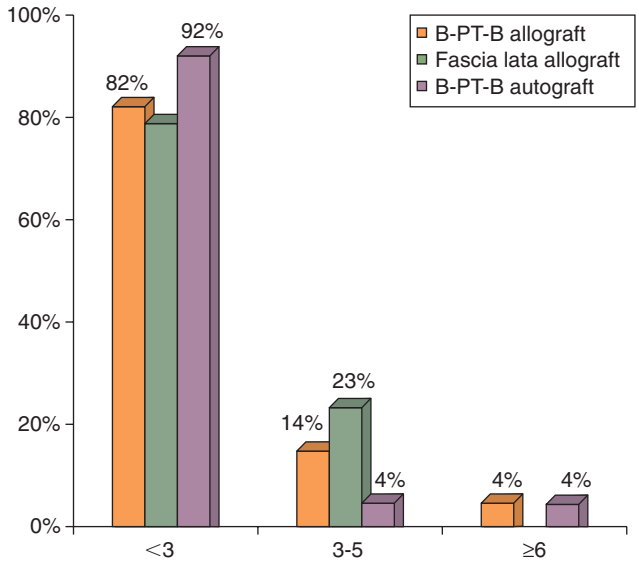

FIG 7-54 Knee arthrometer results from our clinical studies in patients who received ACL reconstruction for acute or subacute ruptures with either bone-patellar tendon-bone (B-PT-B) allograft, fascia lata allograft, or B-PT-B autograft tissue.

Chronicity of Injury

We prospectively followed 94 consecutive patients who received B-PT-B autografts to determine whether a difference existed in objective or subjective outcome between acute and chronic ACL ruptures.[195] Eighty-seven patients (93%) returned for follow-up evaluations from 2 to 3.7 years postoperatively. The acute subgroup comprised 30 patients who underwent reconstruction, a mean of 6 weeks (range, 2-14 weeks) after the injury. The chronic subgroup comprised 57 patients who underwent reconstruction, a mean of 4.5 years (range, 3 months to 29 years) after the original knee injury. All of these patients had symptoms or functional limitations that failed to improve with rehabilitation or activity modification. A total of 94 operative procedures had been done in 34 of these patients before the ACL reconstruction, including 20 medial meniscectomies and 9 lateral meniscectomies (partial or total).

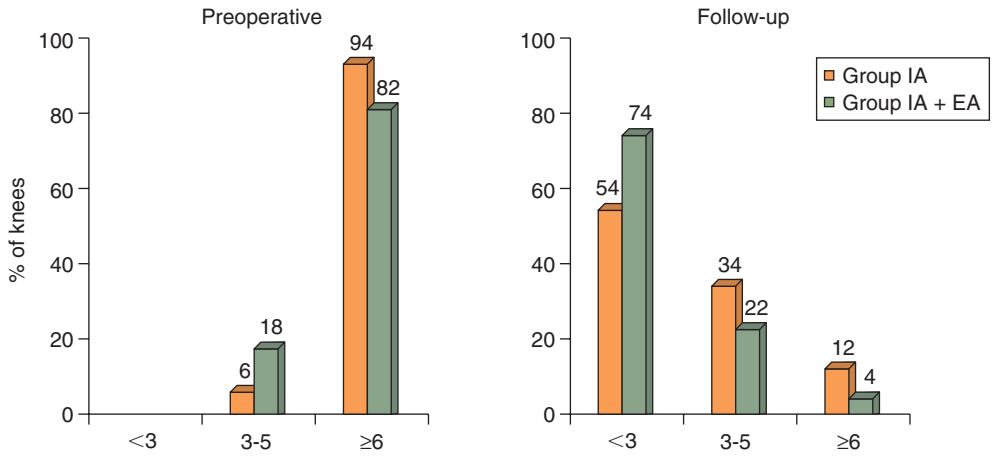

FIG 7-55 Preoperative and follow-up results of testing with the KT-1000 arthrometer for anterior-posterior displacement at 89 N of total force for group IA (allograft alone) and group IA + EA (allograft and extraarticular procedure). At the latest follow-up evaluation, the difference in the displacement between the two groups was statistically significant ($P < .01$). (From Noyes FR, Barber SD. The effect of an extra-articular procedure on allograft reconstructions for chronic ruptures of the anterior cruciate ligament. *J Bone Joint Surg Am.* 1991;73:882-892.)

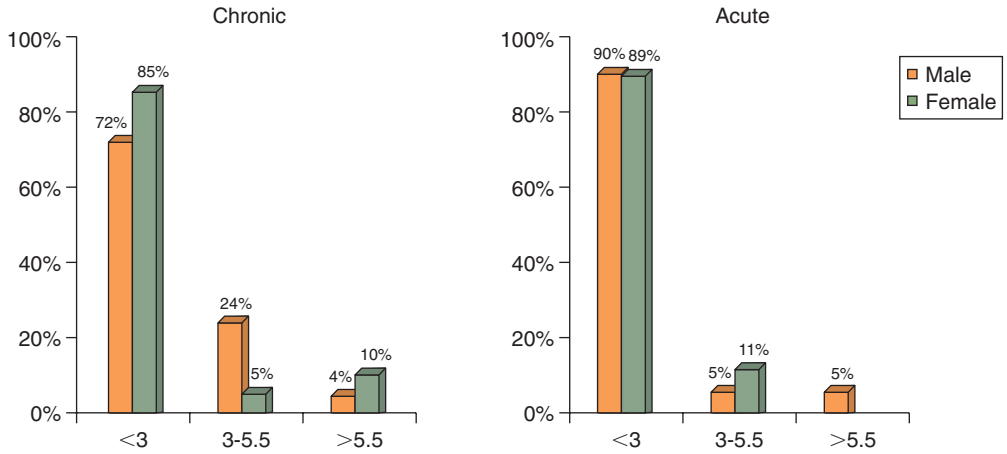

FIG 7-56 The results of KT-2000 arthrometer testing at 134-N (involved vs. noninvolved limb) at follow-up. There was no statistically significant difference found between men and women in the percentage of patients in the three anterior-posterior displacement categories. (From Barber-Westin SD, Noyes FR, Andrews MA. A rigorous comparison between the sexes of results and complications after anterior cruciate ligament reconstruction. *Am J Sports Med.* 1997;25:514-526.)

Functional analysis	S: squatting, running, jumping, twisting NS: walking, stairs	Cincinnati Knee Rating System
Symptoms	S: pain NS: swelling, giving-way	Cincinnati Knee Rating System
Overall rating score	S	Cincinnati Knee Rating System
Patient rating outcome	S	Cincinnati Knee Rating System

For all significant values, the acute subgroup had better results than the chronic subgroup.
ACL, Anterior cruciate ligament; *B-PT-B,* bone-patellar tendon-bone; *NS,* difference not statistically significant; *S,* difference statistically significant.

The results of the comparisons are shown in Table 7-13. There was no difference among the subgroups in mean AP displacements (chronic group, 0.4 ± 2.7 mm; acute group, –0.3 ± 2.6 mm), pivot shift testing, knee motion complications, or overall rate of graft failure (chronic group, 8%; acute subgroup, 3%). A total of 46 menisci had been repaired during the ACL reconstruction. At follow-up, there was no evidence of retears in 41 of these knees, indicating the importance of meniscus repairs in acute and chronic knees.

There were significant differences among the subgroups for pain ($P = .04$), squatting/kneeling ($P = .03$), running ($P = .02$), jumping ($P = .04$), twisting/turning ($P = .01$), the patient rating of the overall condition of the knee ($P = .007$), and sports activity levels ($P = .05$). Patients in the acute subgroup had less pain and limitations with sports functions and returned to more strenuous activities than those with chronic deficiency. The conclusion was reached that joint stabilization should be performed early in active patients before reinjuries and loss of meniscus tissue. In addition, investigations that assess the results of ACL reconstruction should separately assess the outcome of acute/subacute and chronic ruptures with rigorous knee rating systems.

Concomitant Operative Procedures

We conducted several studies on patients who received concomitant procedures with an ACL reconstruction, including complex meniscus repair for tears that extended into the central third region,[37,198,199,205,247] HTO,[188,202] PL reconstructions,[189,190,192,197,200,201] MCL repairs,[190] and multiligament procedures.[197]

In a series of 177 patients who underwent repair of 198 meniscus tears that extended into the central third region, the ACL was also

TABLE 7-14 Reoperation Rates of Meniscus Repairs According to ACL Function

ACL Function	Repaired Menisci That Required Follow-up Arthroscopy for Tibiofemoral Joint Symptoms
Functional ($n = 166$)	32 (19%)
Not functional ($n = 32$)	7 (22%)
Total ($n = 198$)	39

Functional = <5 mm of increased anteroposterior displacement on arthrometer testing or pivot shift grade 0 or I; not functional = >5 mm of increased anteroposterior displacement on arthrometer testing or pivot shift grade II or III.
ACL, Anterior cruciate ligament.

reconstructed in 126 (71%) knees with either irradiated allografts (72 knees) or B-PT-B autografts (54 knees).[247] At a mean of 3.5 years postoperatively, the failure rates were 4% for the autografts and 15% for the allografts. The increased failure rate for the allografts may have been related to the irradiation sterilization process. The study found that 159 of the meniscus repairs (80%) were successful, with no tibiofemoral joint symptoms. Thirty-nine patients (20%) required repeat arthroscopy for symptoms. No statistical relationship was found between ACL function at follow-up and the reoperation rate for a symptomatic meniscus repair (Table 7-14).

A separate investigation was performed for 28 complex meniscus repairs for tears that extended into the central third region in 27 patients aged 40 to 58 years.[198] The ACL was reconstructed in 21 patients with B-PT-B autografts in all but five knees. At a mean of 2.8 years postoperatively, none of the ACL grafts had failed. Twenty-six of the meniscus repairs (87%) were asymptomatic and considered successful. Concomitant ACL reconstruction appeared to increase the healing rate of meniscus repairs. This older group of patients was physically active and w believed it was important to stabilize the knee and preserve the meniscus, as all desired to return to athletics.

A third investigation followed 61 knees in 58 patients under the age of 20, who underwent a total of 71 complex meniscus repairs that extended into the central third region.[199] Forty-seven knees had a concurrent ACL reconstruction with either irradiated B-PT-B allografts (20 knees) or B-PT-B autografts (27 knees).[199] At a mean of 4.2 years postoperatively, none of the autografts had failed, whereas five of the allografts (25%) had failed, which was most likely related to the irradiation sterilization process. As a footnote, irradiated allografts were used from a historical perspective when tissue banking was still undergoing certification procedures. We abandoned irradiated allografts in the late 1990s after publishing in vitro and in vivo studies on the deleterious effects of high-dose irradiation on allografts.

Fifty-three of the meniscus repairs (75%) were asymptomatic and had not required further surgery. None of the patients in whom the allografts failed had tibiofemoral symptoms. A long-term investigation was conducted on a subgroup of 31 of these patients who had a single longitudinal meniscus tear.[205] The study included 18 patients who underwent ACL reconstruction (8 allografts and 10 autografts) and who were evaluated a mean of 17.3 years postoperative (range, 10.1-22.9 years). All of these knees had an IKDC ACL rating of either A or B, indicating normal or nearly normal graft function. The success rates of these three investigations warrants repair of complex meniscus tears that extend into the central third region in active individuals, along with stabilization of ACL deficiency (see Chapter 23).

FIG 7-57 An example of a two-incision anterior cruciate ligament bone-patellar tendon-bone autograft technique combined with a proximal advancement of the posterolateral (PL) complex for abnormal lateral tibiofemoral joint opening. The PL insufficiency represented an interstitial stretching and not a traumatic rupture, which was an ideal indication for the proximal advancement, avoiding a more complex posterolateral graft reconstruction.

In our experience, the majority of patients who require PL reconstructions also require ACL or PCL reconstruction. Four investigations determined the outcome of PL reconstructions that consisted of a proximal advancement of the PLS,[192] a femoral-fibular allograft reconstruction,[189,201] and an anatomic B-PT-B FCL reconstruction,[200] all of which are described in detail in Chapter 17. In one study, 21 patients were followed who received a proximal advancement of the PLS; 12 patients also had an ACL B-PT-B reconstruction (allograft in 10, autograft in 2).[192] These patients all had a definitive FCL, although lax, which did not require graft reconstruction (Fig. 7-57). At follow-up, a mean of 3.5 years postoperatively, only one of the ACL reconstructions had failed. The PL procedure was successful in restoring function or partial function in all but two knees.

In another study, we followed 21 patients who received an allograft femoral-fibular PL reconstruction, of whom 13 also had a B-PT-B ACL reconstruction (11 allografts, 2 autografts).[189] All of the allograft tissues were irradiated. At follow-up a mean of 3.5 years postoperatively, only one ACL reconstruction had failed. The PL procedure restored function or partial function in all but five knees. The patients in whom the PL procedure was rated as functional were followed in a long-term investigation (mean, 14 years); the study included 10 patients who had received ACL allografts. The IKDC ACL ratings were A to B in seven knees, C in one knee, and D in one knee. All of the PL reconstructions were rated as A or B.

In another investigation, 13 patients who underwent 14 anatomic FCL B-PT-B reconstructions were followed 2 to 13.7 years postoperatively.[200] In this group, 12 patients underwent concomitant ACL reconstruction with irradiated B-PT-B allografts, B-PT-B autografts, or quadriceps tendon-PT autografts. At follow-up, all but two of the ACL

reconstructions were rated as IKDC normal or nearly normal, and all but one of the posterolateral reconstructions were rated normal or nearly normal. These studies emphasize the importance of surgically restoring all deficient knee ligamentous structures concomitantly. The selection criteria for the appropriate posterolateral procedure are described in Chapter 17.

We followed a series of 46 patients who had combined ACL and MCL deficiency to determine the appropriate treatment (operative or conservative) for MCL ruptures, described in detail in Chapter 19.[190] All patients underwent ACL allograft reconstruction. In 34 patients in whom all of the medial structures were ruptured, an MCL repair was performed. In 12 patients, only the superficial MCL fibers were torn and these did not undergo surgery. At follow-up, a mean of 5.3 years postoperatively, seven of the ACL allografts (15%) had failed. All of the knees had less than 3 mm of increased medial joint opening at 5 degrees and 25 degrees of flexion. The study found that knee motion problems and patellofemoral symptoms were more common in patients who received the MCL repair. Therefore, the recommendation was made for knees with combined ACL-MCL ruptures to treat the MCL injury with appropriate conservative measures first, followed by a staged ACL reconstruction (see Chapter 20). An exception is a displaced medial meniscus tear, which requires early operative intervention.

Preexisting Joint Arthritis and Prior Meniscectomy

We studied the effect of preexisting advanced articular cartilage damage in knees undergoing ACL reconstruction for giving-way symptoms to determine whether the operation was effective in improving the overall quality of life. In one investigation,[193] 53 patients received autogenous B-PT-B ACL reconstructions an average of 7.5 years after the original injury. A total of 90 prior operative procedures had been performed in these knees, including 10 ACL reconstructions that had failed, 27 medial meniscectomies, and 10 lateral meniscectomies (partial or total). During the reconstruction, a total of 84 advanced lesions were found; subchondral bone exposure was noted in 20 knees and extensive fissuring and fragmentation (extending greater than half of the depth of the surface) was found in 33 knees. Eighty-seven percent of the knees that had lesions in the tibiofemoral compartment had undergone prior meniscectomy. At follow-up a mean of 27 months postoperatively, 40 ACL reconstructions (75%) were rated as normal; 10 (19%), as nearly normal; and 3 (6%), as failed. Statistically significant improvements were found for pain, swelling, giving-way (Table 7-15), functional limitations with daily and sports activities, the patient perception of the overall knee condition (Fig. 7-58), and the overall CKRS score. The conclusion of the study is that ACL reconstruction, even in cases of moderate arthrosis, may provide a benefit to select patients.

In a second study, 40 patients with advanced articular cartilage deterioration underwent ACL B-PT-B allograft reconstruction an average of 7 years after the original knee injury. Thirty-two of the allografts (80%) had received 2.5 mrad of gamma irradiation before implantation. A total of 102 prior operative procedures had been done, including 16 prior failed ACL procedures in 12 patients, 24 medial meniscectomies, and 18 lateral meniscectomies. A total of 64 noteworthy articular cartilage lesions were identified at surgery, including subchondral bone exposure in 15 knees (38%) and extensive fissuring and fragmentation in 25 knees (62%). Seventy-nine percent of knees with damage in a tibiofemoral compartment had undergone a prior meniscectomy. At follow-up, a mean of 3.1 years postoperatively, 70% of the ACL reconstructions were rated as normal or nearly normal and 30% as failed. The failure rate was most likely related to the irradiation of the grafts. Statistically significant improvements were found for pain, partial giving-way, and full giving-way ($P < .01$). Significant improvements were also found for squatting, running, jumping, twisting/turning, and the overall rating score. In the patient rating of the overall knee condition, 42% rated the knee as normal or very good, 24% as good, 21% as fair, and 13% as poor.

These investigations demonstrated that ACL reconstruction is effective in reducing symptoms and functional limitations and increasing activity levels in approximately two thirds of patients with advanced articular cartilage damage. Many patients return to low-impact activities based on the advice to avoid sports involving jumping, cutting, twisting, and pivoting. This is especially true in those in whom prior meniscectomy has been performed. It is important to note that these patients suffered giving-way symptoms and, therefore, the requirement for stabilization was justified. A trial of function is frequently attempted in patients who have advanced arthritis, pain, and giving-way that includes muscle strengthening and a functional knee brace. If this trial is unsuccessful in resolving these symptoms, ACL surgery is warranted. These studies do not answer the question of the ability of an ACL reconstruction to prevent or delay worsening of the preexisting articular cartilage damage.

TABLE 7-15 Change in Symptom Scores From the Preoperative to the Follow-up Evaluation in 53 Patients With Advanced Joint Arthrosis After ACL B-PT-B Autograft Reconstruction

Symptom	Improved	Same	Worse
Pain	37 (70%)	14 (26%)	2 (4%)
Swelling	38 (72%)	14 (26%)	1 (2%)
Partial giving-way	47 (89%)	6 (11%)	0
Full giving-way	42 (79%)	8 (15%)	3 (6%)

All values are *n* (%).

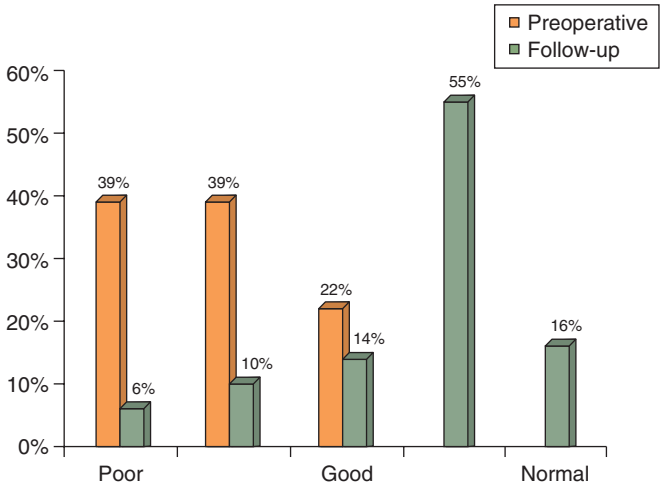

FIG 7-58 The patients' own ratings of the overall knee condition showed significant improvement from the preoperative condition to that recorded at the follow-up evaluation ($P = .0001$). (From Noyes FR, Barber-Westin SD. Anterior cruciate ligament reconstruction with autogenous patellar tendon graft in patients with articular cartilage damage. *Am J Sports Med.* 1997;25:626-634.)

Varus Osseous Malalignment

Two investigations assessed the outcome of treatment of varus-angulated, ACL-deficient knees[188,202]; both are described in detail in Chapter 26. In one study[202] 41 patients were treated with HTO and an ACL reconstruction with a B-PT-B allograft or autograft, which was staged after the HTO in the majority a mean of 6 months later. In addition, PL reconstructions were done in 18 triple varus knees along with the ACL reconstruction, which were all staged after the HTO. At follow-up, a mean of 49 months after the ACL reconstruction, a decrease was noted in the mean AP displacement measurement of the autografts compared with the allografts (autograft mean preoperative, 12.8 ± 5.5 mm and mean follow-up, 1.4 ± 5.4 mm; allograft mean preoperative, 12.2 ± 3.9 mm and mean follow-up, 4.1 ± 5.8 mm; P = not significant). From a historical standpoint, irradiated allografts were no longer used because of this trend. The failure rates were 43% for the allografts and 23% for the autografts. Owing to the small numbers in each graft subgroup (21 allografts [73% irradiated], and 20 autografts), no conclusion could be reached regarding the effect of each type of graft on the failure rate. However, before referral to our center, 15 of these patients had undergone ACL reconstructions that had failed, and there was a significant difference in the failure rate between the revision and primary cases (67% and 33%, respectively, $P < .05$).

In a second investigation, 41 patients underwent HTO, 16 of whom also had a staged ACL allograft reconstruction.[188] This investigation demonstrated that not all varus-angulated, ACL-deficient knees require both procedures, but that ACL reconstruction is warranted when giving-way symptoms continue after osteotomy. Patients who do not experience such symptoms and who have advanced arthritis may avoid ACL surgery by activity modification. Staging these two operative procedures allows the patient and clinician to determine whether joint stabilization is required. Indications for concurrent ACL reconstruction or staged after HTO are discussed in detail in Chapter 26.

Rehabilitation Program

Our rehabilitation protocols are described in detail in Chapter 11. Several investigations assessed the effects of these programs on knee motion complications and graft failure rates.[18,21,204,210,211] The use of immediate knee motion after both ACL allograft and autograft reconstruction was proven to be effective in reducing the risk of arthrofibrosis and was not deleterious to the healing graft (see Chapter 10). In a series of 207 patients who received ACL allograft reconstruction, 189 (91%) achieved a full range of motion without additional treatment measures.[211] The remaining 19 patients were placed into a phased program that included serial extension casting (six knees), early gentle manipulation under anesthesia (nine knees), and arthroscopic lysis of adhesions and scar tissue (three knees). At follow-up, two patients had a loss of 5 degrees of full extension and two others had a permanent and significant limitation of motion. The incidence of knee motion problems was 4% in patients who had only an ACL reconstruction, 10% in knees in which an ITB extraarticular procedure had also been done, and 12% in knees in which a meniscus repair had been performed, and 23% in knees that also had a MCL repair.

In a second investigation, we followed 443 patients who had a B-PT-B autogenous reconstruction for either an isolated rupture (219 knees) or combined with other procedures (224 knees).[204] At follow-up, a normal range of motion was detected in 436 knees (98%) and a mild loss of extension (≤5 degrees) was found in 7 knees. Twenty-three knees required a treatment intervention for an early postoperative limitation of knee motion, including extension casting (9 knees), gentle manipulation under anesthesia (9 knees), arthroscopic debridement (3 knees), and continuous epidural anesthetic and inpatient physical therapy (2 knees). At follow-up, 87% had less than 3 mm of increased AP displacement on arthrometer testing, 9% had 3 to 5.5 mm, and 4% had 6 mm or greater. There was no effect of gender, injury chronicity, articular cartilage condition, location of physical therapy, prior surgery performed, or prior ACL reconstruction performed on the risk of a motion problem (Table 7-16). Although not statistically significant owing to the small number present, a concurrent MCL repair was believed to be a clinically significant risk factor for a knee motion problem.

TABLE 7-16 Assessment of Possible Risk Factors for Knee Motion Limitation After ACL B-PT-B Autogenous Reconstruction in 443 Knees

Risk Factor	No. in Study	Motion Limitations, n (%)

ACL, Anterior cruciate ligament; *B-PT-B,* bone-patellar tendon-bone.
*Fissuring and fragmentation greater than half depth of the surface or subchondral bone exposed.

Two investigations were performed in which serial knee arthrometer measurements were done postoperatively to determine whether any phase of the rehabilitation program or the amount of time that elapsed after surgery was associated with increased AP displacement (> 3 mm) or graft failure.[18,21] In the first study, 84 patients who received a fresh-frozen B-PT-B ACL allograft reconstruction were followed a mean of 3.1 years postoperatively.[18] The clinical outcome of these patients had been described in another report on the effectiveness of an ITB extraarticular procedure with allograft tissue.[185] This study included 52 patients who had the allograft alone and 32 who also had the ITB extraarticular procedure. Knee arthrometer measurements were taken at postoperative weeks 4, 8, 12, 16, 24, 52, and 128 for the majority of patients. The rehabilitation program was divided into four phases: assisted ambulatory, early strength training, intensive strength training, and return to sports activities.

There were a total of 28 patients in the allograft-alone group and 9 patients in the allograft-ITB procedure group with abnormal displacements detected postoperatively. The abnormal displacements were first identified a mean of 83 weeks following surgery in both groups. The majority of abnormal displacements (86%) were detected during the intensive strength training or return to sports activities

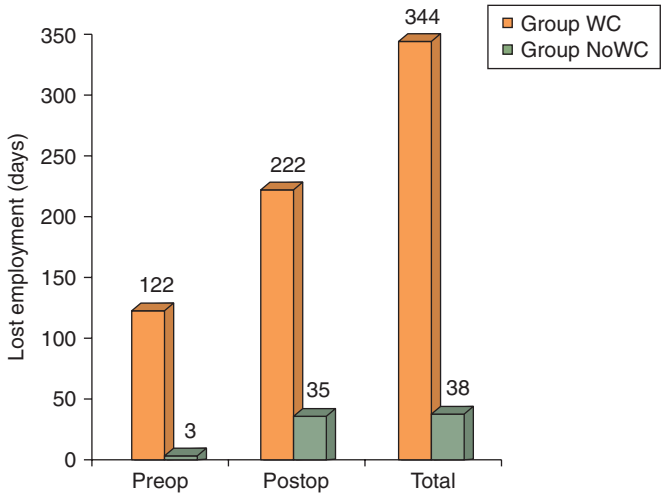

FIG 7-59 The mean number of days of lost employment for patients who did (WC) and did not (NoWC) receive workers' compensation benefits before and after anterior cruciate ligament reconstruction. The difference between the groups was statistically significant for all time periods analyzed ($P < .001$). (From Noyes FR, Barber-Westin SD. A comparison of results of arthroscopic-assisted anterior cruciate ligament reconstruction between workers' compensation and noncompensation patients. *Arthroscopy.* 1997;13:474-484.)

phases. The rehabilitation program did not result in early stretching or failure of the allografts in this cohort.

A similar investigation was done in a group of 142 patients who underwent ACL B-PT-B autograft reconstruction.[21] A total of 938 serial KT-2000 measurements were collected the first 2 years postoperative. Twenty-one knees had abnormal displacements detected after surgery. No association was found between the initial onset of the abnormal displacements and either the amount of time after surgery or the rehabilitation program. The failure rate was an acceptable 5%.

Insurance (Workers' Compensation)

A study was conducted to determine if differences existed after B-PT-B autograft ACL reconstruction between patients who received workers' compensation (WC) benefits and patients who received private insurance benefits (NoWC).[196] Nineteen patients from each group were matched for age, injury chronicity, number of prior operations, and months of follow-up. The only significant difference in outcome was the mean days of lost employment (Fig. 7-59) before surgery (WC, 122 days; NoWC, 3 days; $P < .0001$) and after surgery (WC, 222 days; NoWC, 37 days; $P < .001$). At a mean of 2.2 years postoperatively, 17 patients in the WC group had returned to work (6 with symptoms) and 2 were disabled. In the NoWC group, all patients had returned to work, 2 with symptoms. There were no differences between the groups in AP displacements, functional limitations with sports or daily activities, patient perception of the knee condition, the overall rating score, or complications. None of the autografts failed in the WC group, and only 1 graft failed in the NoWC group. In the WC group, 13 patients rated their knee condition as normal or very good, 3 as good, and 3 as fair. In the NoWC group, 15 rated their knee condition as normal or very good, 4 as good, and 1 as poor. The hypothesis proposed was that the difference in the days of lost employment was caused by wage systems that support WC injuries for long periods of time, the lack of a case-management system that closely follows injured workers, the inability of workers to modify existing job requirements, and/or improper early diagnosis and treatment of the injury. After this study, Wexler and coworkers[294] conducted an investigation on 22 WC patients who underwent ACL B-PT-B reconstruction. All patients returned to work and none of the grafts failed. We concluded that the outcomes were similar to historical controls and that WC did not compromise the results of ACL reconstruction.

A summary of the outcomes from our primary ACL reconstruction investigations is shown in Table 7-17.

OTHER AUTHORS' CLINICAL STUDIES

It is not the purpose of this chapter to conduct an exhaustive review of the outcome of ACL primary reconstructions reported in the English literature. Rather, the reader is encouraged to review recent metaanalysis and systematic reviews on this topic.* A summary of some of the most relevant and current topics is provided below. A recent review of the incidence and trends of ACL reconstruction in the United States between 1994 and 2006 found a significant increase in the number of procedures performed (from 32.9/100,000 in 1994 to 43.5/100,000 in 2006; $P = .01$). The increase was especially noted in women, patients younger than 20 years of age, and patients older than 40 years of age.[161] The investigators concluded that this is one of the most common orthopedic procedures performed and prevention strategies are justified in these groups.

Allografts Versus Autografts

Many studies have compared the outcomes of ACL allografts with ACL autografts and the results and conclusions have varied widely (Table 7-18). Problems related to study design, surgeon bias in graft selection, length of follow-up, failure to account for the factors of patient age and activity level, and failure to account for allograft sterilization processing account for some of the discrepancies among investigations. Importantly, recent studies have shown significant and deleterious effects of high levels (2.0-2.5 mrad) of irradiation, patient age younger than 25 years, and high activity levels on outcomes of ACL allograft reconstructions.

In 2013, the largest metaanalysis of ACL B-PT-B allograft and autograft reconstruction studies to date was published by Kraeutler and associates.[137] Encompassing 76 studies (4276 B-PT-B autografts and 906 B-PT-B allografts) that followed patients 4.3 years postoperatively or more, the authors found that allografts had a threefold increase in rerupture rates compared with autografts (12.7% and 4.3%, respectively). Autografts had significantly better outcomes for subjective IKDC, Lysholm, Tegner, single-leg hop, and KT-1000 scores.

Prodromos and coworkers[235] analyzed data from 20 allograft studies and compared stability findings with previously published data of B-PT-B and STG autografts. Allografts had a significantly greater percent of knees with abnormal stability, defined as more than 5 mm of increased AP displacement, compared with all autografts (14% vs. 5.3%, $P < .001$). In addition, a significantly greater abnormal stability rate was found in irradiated allografts compared with nonirradiated allografts (31% vs. 12%; $P < .001$). Sun and associates[276] also reported significantly higher failure rates in irradiated B-PT-B allografts compared with B-PT-B autografts (34.4% vs. 6.1%) in 102 patients followed 2 to 4 years postoperatively. In this investigation, nonirradiated allografts had a failure rate that was comparable to autografts (8.8%).

Pallis and associates[224] analyzed the survival of ACL reconstructions that had been performed in 120 cadets aged 18 to 23 years before

*References 9, 10, 25, 29, 34, 39, 40, 42, 49, 53, 63, 72, 136, 137, 139, 147, 163, 221, 236, 243, 249, 254, 283.

TABLE 7-17 Summary of Conclusions From Our Primary Anterior Cruciate Ligament Reconstruction Clinical Studies

Factor	Conclusions
Type of graft	B-PT-B autografts preferred whenever possible, decreased failure rate in chronic knees, more rapid graft healing. Autografts provide higher success rate in subjective, objective, and functional parameters. Allografts reserved for multiligament surgery, knee dislocations, and special situations.
Augmentation procedures for allografts	ITB extraarticular procedure decreases allograft failure rate in chronic knees, recommended in grossly unstable knees (grade III pivot shift).
Secondary sterilization of allografts	Irradiation most likely deleterious, increase in failure rate; not recommended.
Gender	No difference in outcomes between males and females. No scientific basis to use gender as selection criteria for reconstruction.
Chronicity of injury	No difference between acute and chronic knee injuries in objective stability after B-PT-B autograft reconstruction. Significantly poorer results in chronic knees for symptoms, limitations with sports and daily activities, and patient rating of knee condition owing to loss of meniscus tissue, preexisting joint damage. Reconstruct ACL early after injury in active patients.
Concomitant operative procedures	Meniscus repairs frequent, results may be improved by concomitant ACL reconstruction. High success rates, even in complex tears extending into central third region, regardless of patient age. Posterolateral injuries frequently accompanied by ACL ruptures; reconstruct all ligamentous ruptures concurrently. MCL injuries usually do not require surgical treatment unless gross instability exists.
Preexisting joint arthrosis	Symptomatic unstable knees can be improved by ACL reconstruction. Advise return to low-impact activities.
Varus osseous malalignment	ACL reconstruction usually staged after osteotomy in symptomatic unstable knees. ACL reconstruction not required after osteotomy in knees that are asymptomatic, patient willing to modify activities.
Rehabilitation program	Immediate motion and rehabilitation safe, not deleterious to healing graft, low incidence (<1%) of arthrofibrosis. Identify and immediately treat limitation of knee motion with overpressure program. Full motion regained within weeks of surgery (with exception of PCL reconstructions in which hyperflexion is delayed).
Insurance	No difference in outcome between workers' compensation and privately insured patients except days of lost employment. Reconstruct knees of workers' compensation patients earlier after injury.

entering the U.S. Military Academy. All participated in intramural, club, or intercollegiate athletics, as well as military training. Those who had received an allograft were 7.7 times more likely to experience a subsequent graft failure compared with those who had received a bone-to-bone autograft.

Kaeding and associates[122] found that patients who received allografts were more likely to experience graft failure than those who received autografts (8.9% and 3.5%, respectively; $P < .01$), and that age influenced the odds. The differences in absolute failure rates between autografts ($n = 691$) and allografts ($n = 234$) according to age were as follows: 14 years, 15%; 18 years, 13%; 22 years, 9%; 30 years, 4%; and 40 years, 2%.

Carey and associates[39] analyzed data from nine studies (746 patients) that followed patients a mean of 4.1 years postoperatively who had received either allografts or autografts. The majority of grafts were B-PT-B and both irradiated and fresh-frozen allografts were included. No significant differences were found in any of the outcome measures among graft types. The authors stressed that none of the studies stratified outcomes according to age or activity level, which (in addition to the irradiation factor) limited the investigation's conclusions.

Bone-Patellar Tendon-Bone Versus Semitendinosus-Gracilis Tendon Autograft

Many studies have reported few differences in the outcomes of B-PT-B and STG autografts.* However, a recent registry study from Scandinavia reported a significantly greater revision rate in patients who underwent STG reconstruction (1042 of 38,666 patients) compared with B-PT-B procedures (156 of 6736 patients; hazard rate ratio, 0.63).[82] Another study reported a higher percentage of STG knees with grade II pivot shift test results compared with B-PT-B knees at 2 years postoperatively (24% vs. 10%; $P = .02$).[94] Two studies that pooled data from previously published trials also found significantly poorer results in STG knees for pivot shift test results.[25,147] An investigation that assessed 13,647 ACL reconstructions a mean of 3 years postoperatively reported a higher relative risk of revision surgery (1.41) after STG compared with B-PT-B.[241] Increased anterior knee pain and kneeling pain has been reported following B-PT-B reconstruction compared with STG reconstruction in several studies,[23,57,94,131,144,147,160,232,299] although others have refuted these findings.[83,104,141,250,283]

Leys and associates[144] followed 94 patients (43 B-PT-B and 51 STG) for 15 years postoperatively and found better outcomes in STG recipients in several parameters. These authors specifically noted a decline in outcomes in the B-PT-B knees from 10 to 15 years postoperative, including loss of knee extension, decreased performance in the single-leg hop test, and higher rate of radiologic OA. There was a high rate of reinjury to either knee in both groups (29% STG and 32% B-PT-B).

Effects of Age and Anterior Cruciate Ligament Graft Size

Authors have performed subset analysis comparing failure rates of B-PT-B and STG autografts according to age. Kamien and associates[123] followed 98 patients who received STG reconstructions for 2 years postoperatively and found a significantly higher percentage of patients 25 years of age or younger had failed (12 of 48, 25%) compared with patients older than 25 years (3 of 50, 6%; $P = .009$). Magnussen and

ACL, Anterior cruciate ligament; *B-PT-B*, bone-patellar tendon-bone; *NA*, not available; *NS*, not significant; *STG*, semitendinosus-gracilis.

colleagues[159] followed 136 men and 120 women who underwent ACL STG autograft reconstruction a mean of 14 months (range, 6-47 months) postoperatively and noted a significant difference in the rate of revisions between patients aged 20 years or older and those younger than 20 years (0.7% vs. 14.3%; $P < .0001$). Bourke and associates[31] in a 15 year follow-up study of 186 patients found that those aged 18 years or younger had a threefold increase in the risk of rupturing the STG graft ($P = .002$). Shelbourne and coworkers[263] reported, at a minimum 5-year postoperative follow-up in 1415 patients, a higher risk of reinjury to either the BTB autograft-reconstructed knee or contralateral knee in patients younger than 18 years of age (17%) compared with those aged 18 to 25 years (7%) and those older than 25 years (4%).

Krych and associates[138] reported that age and body mass index (BMI) were associated with superior 6-month isokinetic muscle strength and single-leg hop test results in a cohort of 224 patients who underwent primary isolated transtibial ACL reconstruction. Multivariate analysis demonstrated that younger age (odds ratio [OR] 0.95 per 1-year increase, $P = .02$) and lower BMI (OR 0.90 per 1-unit increase, $P = .01$) were associated with superior outcomes. Graft selection was not associated with superior outcomes in the entire cohort; however, the use of allografts correlated with improved functional testing in patients over 30 years of age.

In Magnussen and colleagues' series[159] previously described, STG graft size was related to failure and subsequent ACL revision. Revision ACL reconstruction was required in just 1 of 58 patients (1.7%) whose grafts were greater than 8 mm in diameter. However, revision was done in 9 of 139 patients (6.5%) whose grafts were 7.5 to 8 mm, and in 8 of 59 patients (13.5%) whose grafts were 7 mm or less in diameter. In combining the factors of age and graft size, the authors reported that 16 of the 18 revisions were done in patients who were less than 20 years old and whose ACL grafts were 8 mm or smaller in diameter. This high revision rate represents a major problem to be addressed in the future in this younger athletic population. Limitations of this study addressed by the authors were the potential effect of an "accelerated rehabilitation" program that was done to return patients to sports at 6 months after surgery, unknown mechanisms for the repeat injury episode (such as noncontact versus contact), and the inability to examine the effect of gender on noncontact repeat ACL injuries. In our opinion, before accepting the conclusions of this study it would be necessary to determine if an ACL STG graft larger than 8 mm in diameter, or a B-PT-B graft would decrease the high revision rate in this younger athletic population that returned to sports at 6 months after surgery. In general, the data is concerning for grafts diameters smaller than 8 mm and attention is directed to the techniques described in this chapter to prepare a six-strand STG graft when necessary to achieve larger STG graft diameters.

Mariscalco and associates[162] studied the effect of STG autograft size on patient outcomes and revision in a Multicenter Orthopaedic Outcomes Network (MOON) study on 263 of 320 consecutive primary ACL reconstructions (82%). The authors concluded that hamstring grafts greater than 8 mm in diameter had a statistically significant higher Knee Injury and Osteoarthritis Outcome Score (KOOS) function score and lower revision rate. For patients aged 18 years or younger, grafts greater than 8 mm in diameter had 0 revisions (0 of 14 patients), although grafts 8 mm in diameter or less had a 7% revision rate (14 of 199 patients). The authors reported an ACL revision rate of 15.3% in patients younger than 19 years who had grafts that were 8 mm or smaller in diameter. The study had significant limitations, including using the revision rate rather than the actual failure rate, no data regarding return to sports or type of sports participation, no information on the type of repeat injury (contact versus noncontact), and a small sample size.

Park and colleagues[227] followed 296 patients who underwent ACL STG reconstruction a mean of 4.5 years (range, 2-5.9 years) postoperatively and reported a statistically significant difference in failure rates between those with grafts that were less than 8 mm compared with those whose grafts were 8 mm or greater in diameter (5.2% and 0%, respectively; $P < .05$).

These results point to the need to do everything possible in younger athletic populations undergoing ACL reconstruction to avoid an ACL graft failure and need for revision. Although all variables to lessen revision are still not known at present, possible potential effects of maximizing STG graft diameter, using objective criteria to allow athletes to return to sports,[19] conducting neuromuscular retraining in female athletes before return to sports, and critically examining all other risk factors (including gender and associated instabilities) have most likely have beneficial effects in reducing the need for ACL revision surgery.

Single- Versus Double-Bundle Anterior Cruciate Ligament Reconstruction

Multiple studies have compared outcomes of single- and double-bundle ACL reconstructions; in fact, more than 30 have been published since 2009.* It should be noted that, in many studies that compared outcomes of these ACL reconstruction techniques, the single graft represented a vertical ACL graft orientation as described previously in this chapter (posterior tibial attachment, high femoral attachment). A vertical graft placement has been shown in a number of in vivo and in vitro studies previously discussed to result in an inferior control of rotatory loading of the knee joint and the pivot shift phenomena.

Five metaanalyses published from 2012 to 2014 are summarized in Table 7-19.[136,148,149,284,300] There are limitations to these studies. First, the investigators did not take the potential problem of the single-graft being in a vertical position into account when conducting their reviews (although it is acknowledged that this may not always be possible to ascertain). Second, the follow-up of the studies analyzed was short, with most providing data 2 to 3 years postoperatively. Overall, the results favored double-bundle reconstructions in regard to the presence of a negative pivot shift and a higher IKDC objective score. However, there are limitations in the pivot shift test because the manner in which it is performed may affect the results,[208] the outcome is graded in qualitative terms, and the forces or torques applied do not replicate those that occur during athletic or strenuous activities. Therefore, caution is warranted in using these data to definitely determine "rotational" knee stability. Finally, results were either mixed or showed no significant difference among procedures for all other variables including KT-2000, IKDC subjective score, Lysholm score, Tegner score, and complications. The ability of either individual comparative studies or metaanalyses to provide a definitive conclusion regarding which procedure is superior is limited at best.

Three studies conducted a different type of analysis of single- and double-bundle ACL reconstructions that may have more meaningful application to actual knee function under high loading conditions. Misonoo and colleagues,[176] Claes and associates,[43] and Tsarouhas and coworkers[286] evaluated in vivo tibial rotation that occurred during pivoting and cutting tasks in healthy controls and knees that had undergone single- or double-bundle reconstruction 6 to 12 months previously. None of these studies found a significant difference between the two types of ACL reconstructive procedures in the amount of tibial

rotation that occurred during the tasks. The investigators agreed that the results do not support the more complex double-bundle reconstruction. A note of caution is warranted in the interpretation of these studies because the ACL is not a primary restraint for controlling internal tibial rotation; rather, the lateral extraarticular structures (ITB, lateral capsule, anterolateral ligament) resist rotation.

Osteoarthritis Rates in Long-Term Studies

Published rates of radiographically documented OA following ACL reconstruction vary tremendously (Table 7-20). Investigators typically used weight-bearing AP and PA radiographs, as well as lateral and Merchant views, to determine the presence and severity of OA, although a few investigators also used MRI[89,102] or CT.[92] The two most commonly used rating systems to classify OA in recent studies were the Kellgren-Lawrence and IKDC. One conclusive association with future joint OA is loss of meniscus tissue. Nearly every long-term study reported a statistically significant correlation between meniscectomy performed either concurrently or after the ACL reconstruction and radiographic OA. Preexisting chondral damage was the second most frequently cited factor.

Determining the risk of developing future OA after ACL reconstruction is difficult for many reasons. There are several factors that may influence the development of articular cartilage deterioration, including the effects of the initial impact injury on the subchondral bone (bone bruising),[48,103] loss of meniscus tissue (either before, during, or after the ACL reconstruction), patient age, time from injury to reconstruction, number of reinjuries before reconstruction, failure of the reconstruction to restore normal AP displacement and knee kinematics, the rehabilitation program, complications (such as infection, arthrofibrosis), final knee motion achieved, and the activity level the patient resumes after surgery. In many studies, these variables are not controlled for, making reaching conclusions on this topic difficult. In addition, most long-term studies have an unfortunate high rate of transfer bias (patients lost to follow-up) and do not compare the radiographic findings of the reconstructed knee with the contralateral normal knee.

PREVENTION AND MANAGEMENT OF COMPLICATIONS

Arthrofibrosis and Limitation of Knee Motion

The postoperative complication of arthrofibrosis (either primary or secondary) or a limitation of knee flexion and extension resulting from other factors such as a cyclops lesion are frequently reported problems after ACL reconstruction. The causes, risk factors, preventative measures, and effective treatment strategies for knee motion complications are discussed in detail in Chapter 38. In addition, the reader is referred to our postoperative rehabilitation protocols provided in Chapter 11 for comprehensive exercises and modalities used after ACL reconstruction.

Infection

Deep joint infection after ACL reconstruction is a rare problem, occurring in approximately 0.8 to 1.70% of patients.[33,36,70,114,121,258]

Matava and colleagues[169] conducted a survey in which 61 orthopedic surgeons participated to determine the preferred treatment recommendations for postoperative infection. The infecting organism and systemic signs of sepsis were viewed as the most important factors in determining the initial treatment. Arthroscopic debridement and irrigation as early as possible were recommended and this protocol is also supported by other studies.[36,172,256,291,296] The majority of surgeons in Matava and colleagues' survey (85%) used culture-specific intravenous antibiotics and attempted to retain the ACL graft when possible. Graft excision and hardware removal were reserved for resistant infections that require further debridement procedures. Immediate graft removal was recommended by only 6% of surgeons treating infected autografts and 33% of those treating infected allografts. Only one half of the surgeons surveyed routinely used a drain after ACL reconstruction. The infection rate was twice as high for these surgeons compared with those who did not use a drain (0.27% and 0.10%, respectively; $P = .04$). The authors stressed that although obtaining a stable knee is the primary goal of ACL reconstruction, eradication of infection supersedes graft preservation to avoid the deleterious consequences of a chronic infection.

CRITICAL POINTS Prevention and Management of Complications

- Rules to prevent and treat infection summarized in Table 7-21.
- Graft contamination: Prefer to harvest second autograft. In allograft procedure, discard and use second allograft.
- Fluid extravasation: Be constantly aware of joint pressure, fluid inflow and outflow, increased thigh tension, any lack of joint distention during arthroscopic procedures. Palpate popliteal and calf region during procedure.

Brophy and associates (representing the MOON Knee Group)[33] reviewed incidence rates and potential risk factors of infection after ACL reconstruction. Of 2198 patients who underwent surgery from 2002 to 2005, 17 (0.8%) developed a postoperative infection. Diabetes was found to be a significant risk factor (OR, 18.8; $P < .001$). Use of a hamstring autograft (OR, 4.6; $P = .03$) and other graft choices (allografts, OR, 4.3; $P < .05$) were also associated with an increased odds of infection compared with B-PT-B autografts. Patient age, BMI, and smoking status were not associated with an increased infection risk.

Schulz and coworkers[256] treated 24 patients who developed postoperative septic arthritis after ACL reconstruction. The treatment protocol was based on the classification of the grade of infection proposed by Gachter[75] and included arthroscopic debridement, irrigation, partial to total synovectomy, and placement of intraarticular gentamicin-containing polymethylmethacrylate (PMMA) beads. The mean time from the ACL reconstruction to the first arthroscopic debridement was 62 days (range, 5-196 days). The ACL grafts had autodigested in 8 knees and were removed in 9 others. The infection resolved in all cases. Van Tongel and associates[291] described a series of 15 patients who underwent arthroscopic management of this complication, followed by intravenous antibiotics and then oral antibiotics. The infection resolved in all patients and the ACL grafts were retained in all but one knee.

Burks and colleagues[36] described a small series of 4 knees in whom graft removal was required during arthroscopic debridement and irrigation for septic arthritis. The patients developed the infection an average of 24 days postoperatively. The autografts had a fibrinous coating that led the authors to be concerned about the potentially deleterious effects of persistent infection or a delay in resolving the joint infection. All four patients had a revision ACL reconstruction between 1 and 6 weeks following completion of 6 weeks of antibiotics. At an average of 21 months postrevision, the patients had a normal range of knee motion and a mean of 3.0 mm (range, 1.9-4.0 mm) of increased anterior tibial displacement on KT-1000 testing.

The senior author has followed a series of operative rules over many years to prevent and treat operative infections; these are summarized in Table 7-21.

Table 7-20 Rates of Radiographic Osteoarthritis After ACL Reconstructions in Mid- and Long-Term Clinical Studies

Study	Graft†	Knees (n)	Follow-up, yr (Mean ± SD)	MODERATE OA (%)*					SEVERE OA (%)*					Factors Associated With Development of OA

TABLE 7-21 Rules to Prevent and Treat Postoperative Infection

1. Obtain a preoperative history of the patient's health and diet, perform a general assessment of nutritional status and the need for vitamin supplementation (including vitamin C). A history of prior infections, methicillin-resistant *Staphylococcus aureus* requires infectious disease consultation (e.g., preoperative nasal swab).
2. Preoperative preparation to avoid postoperative anemia with low hemoglobin values, menstruation issues. Consider appropriate serum iron, iron-binding capacity studies, and others.
3. Conduct a skin evaluation, avoid skin rashes or sores. Patient uses a chlorhexidine body wash 3 days before surgery and a preoperative antibacterial wash from the toes to groin the evening before and the morning of surgery. Use hair clippers (instead of a razor) in preanesthetic room.
4. Administer antibiotics 1 hour before surgery, confirm at "time-out" (when the limb to be reconstructed is signed by the surgeon), repeat antibiotics for longer cases based on half-life (usually 4 hours for most cephalosporins). Repeat intravenous antibiotics in recovery room and over 24 hours if admitted.
5. Skin preparation agent of choice in meticulous manner following manufacturer's recommendations, occlusive skin dressing.
6. Careful planning of skin incision in knees with prior incisions to avoid flap necrosis or delayed healing. Perform a meticulous dissection of skin flaps beneath the fascial plane and not directly in the subcutaneous plane to protect the blood supply. Avoid undue skin tension and retraction, avoid grasping the skin with forceps, use blunt retractors instead of sharp rakes, and observe skin viability after the tourniquet has been deflated. Use tourniquet only as required. Perform a meticulous closure, do not place tension on skin Steri-Strips to prevent blister formation with postoperative edema.
7. Operative technique issues: Perform sharp dissection and a meticulous gentle handling of soft tissues, avoid a "blunt finger" or "sponge" dissection. Limit the number of times that fingers are "poked" into the wound by using instruments instead of fingers. Debride devitalized soft tissues, limit the dissection to only the operative site. Use meticulous hemostasis, maintain the blood supply to tissues, and limit electrocoagulation to direct operative site. Use the least number of nonabsorbable sutures possible, limit suture load to that which is required, and close all dead spaces. Deflate the tourniquet before closure, and limit operative time with trained staff.
8. Operating room staff issues: Staff double-checks operative instrument pack sterility markers, avoid operating rooms used for general surgery and infectious cases (even though assured clean room reestablished in the "perfect world"). Conduct a monthly check of the incidence of infections or undue occurrence of infections within operating room. Document hospital procedures to detect remote infections, share information with surgeons and hospital infectious committee. Limit traffic in and out of the operating room. Cover all hair on head, use long operative gowns when the knee is flexed over bed, closely monitor for any break in sterility.
9. Postoperative dressing: Double cotton-double elastic bandage (Robert Jones dressing) to provide firm uniform compression, avoid rewrap unless a problem occurs. If the dressing becomes loose, rewrap, maintain for 48 to 72 hours, and then replace with elastic stocking and supplemental elastic bandage for added compression. The goal is to prevent hematoma and soft tissue swelling without compromise of skin circulation. Use commercial ice delivery systems, maintain limb elevation, and avoid limb-dependent conditions. Avoid use of drains unless specifically indicated. Recheck for calf tenderness, perform deep venous thrombosis assessment.
10. Intraoperative meticulous coagulation of any intraarticular bleeding sites during procedure. Aspirate knee joint hematoma first postoperative day, or subsequently if tense, painful, or over approximately 50 mL.
11. First postoperative day: Patient performs active quadriceps cocontraction with hamstrings, must show active muscle contraction, which is repeated every hour. The patient places a hand on the thigh to monitor quadriceps firmness and turgor. Ankle pumps are performed every hour while awake.
12. Patient takes oral temperature during day and importantly at night and records results. The surgeon is notified immediately if temperature reaches 101° F. The surgeon is also notified if the patient maintains a low-grade temperature or experiences persistent joint pain, redness, warmth, and increased swelling.
13. Conduct a careful weekly assessment of the wound for redness, swelling, or any other signs of infection. Maintain a low tolerance for knee joint aspiration and fluid analysis (cells, Gram stain, sugar, cultures) for any abnormal signs suggesting infection such as low-grade temperature, persistent joint swelling, redness or warmth; failure to achieve dry knee within first 2 to 3 weeks of surgery. Repeat blood studies as necessary (use sedimentation rate, C-reactive protein studies, although often not helpful 4 to 6 weeks postoperative owing to elevation from surgery). Clinical findings alone are sufficient to proceed with emergent arthroscopic washout and soft tissue cultures as described below.
14. Occurrence of postoperative infection:
    a. Immediate emergent arthroscopic washout and arthroscopic debridement of devitalized tissues, intravenous antibiotics switched to culture-specific antibiotics when tissue cultures and Gram stain are available. Obtain tissue specimens for culture and fluid aspirate. Magnetic resonance imaging (MRI) obtained before washout to assess soft tissue abscess, sinus tracks, and Baker's cysts, which may represent a closed abscess.
    b. First time washout and debridement: Grafts and hardware left in place, consider removal if subsequent arthroscopic washout is required or highly virulent organism cultured.
    c. Recognize frequent need to repeat washout after 48 hours.
    d. Do not stop gentle flexion and extension overpressure program, including patellar mobilization, to maintain knee motion; otherwise, a joint fibrosis will rapidly develop.
    e. Open graft harvest wound or meniscus repair wound: If any local signs of infection are noted, opening of these wounds is not required in majority of cases.
    f. Recognize that cause of recurrent infection may be presence of Baker's cyst or other soft tissue abscess requiring open drainage. Repeat MRI is beneficial in resistant cases.
    g. When major concurrent medial or lateral reconstructive procedure is involved, determine the need to open the wounds and perform debridement if any signs of infection. Proceed with secondary closure rules, allow granulation tissue formation, consider skin tension sutures (to prevent abnormal skin contracture) and wound drainage systems.
    h. Closely inspect any soft tissues areas that are involved that would allow open drainage into joint. These require urgent treatment and soft tissue joint closure, including necessary muscle flaps in severe cases.
    i. Close follow-up of infectious disease team to monitor progress, use appropriate blood studies, repeat aspiration as necessary, and monitor for recurrence. Monitor carefully for osteomyelitis with residual hardware in osseous tunnels as shown by increasing edema signal intensity on repeat MRI.
    j. Length of time of intravenous antibiotics is usually 4 to 6 weeks based on organism and cultures, with a subsequent 6 weeks of oral antibiotics. These programs are often empiric and based on surgeon and infectious disease team assessments.

Graft Contamination

In 2014, Khan and associates[29] conducted a systematic review of the management of contaminated ACL grafts. The authors' search found six laboratory studies that contained a total of 495 graft samples. The most successful sterilization protocols used chlorhexidine or mechanical agitation with a polymyxin B-bacitracin solution, which achieved sterility in 100% of tissues. Also effective was a chlorhexidine soak and plain bacitracin soak, which achieved sterility in 97.5% and 97% of samples, respectively. Povidone-iodine and an antibiotic soak of polymyxin-bacitracin were the least effective protocols.

Plante and associates[233] recently investigated bacterial contamination of STG grafts dropped onto the operating room floor and methods of graft decontamination. There was no significant difference in positive culture rates between grafts retrieved in less than 5 seconds (33%) and those retrieved 15 seconds after being dropped (23%). Control grafts (not dropped) tested positive in 23%, although none of the patients developed clinical infections postoperatively. Sixteen unique organisms were identified, with *Staphylococcus aureus* being the most common. Grafts rinsed in either bacitracin solution or 4% chlorhexidine solutions had only one of 30 cultures that were positive.

In 2005, Izquierdo and coworkers[118] reported the results of a survey of 196 orthopedic surgeons on the management of contaminated ACL grafts. Fifty-seven surgeons had managed at least one contaminated graft in their career. The majority (75%) cleaned the graft and proceeded with the reconstruction. Others (18%) harvested a different graft or used an allograft. No infections were reported. The grafts that underwent cleansing were cleaned with either Hibiclens (Regent Medical) or chlorhexidine gluconate, using different protocols. The authors cautioned that potential side effects of graft cleansing should be considered, including increased polymorphonuclear granulocyte toxicity and impaired phagocytic efficiency, intraarticular reactive synovitis and chondrolysis, and increased postoperative morbidity.

Molina and associates[178] measured the incidence of positive cultures resulting from ACL specimens that were dropped on the operating room floor and then treated by soaking in one of three antimicrobial solutions: an antibiotic solution of neomycin and polymyxin B, a 10% povidone-iodine solution, or a chlorhexidine gluconate solution. Sixty percent of the dropped specimens cultured positive, although the majority grew nonvirulent species. The incidence of specimens that tested positive following the treatment protocols was 24% for povidone-iodine solution; 6% for antibiotic solution; and 2% for chlorhexidine gluconate solution. The authors recommended sterilization with chlorhexidine gluconate, although there was no significant difference in the incidence of positive cultures with this method compared with the antibiotic solution.

In our experience, harvest of a second autograft may be preferred to graft cleansing. With an allograft procedure, the contaminated allograft is always discarded and substituted with another allograft.

Fluid Extravasation

The senior author and Spievack[215] conducted a cadaver study many years ago that determined a subtle mechanism for extraarticular fluid extravasation during arthroscopy. Weak tissues in the suprapatellar pouch or semimembranosus bursa ruptured at only moderate intraarticular pressures, with flexion of the knee markedly increasing these pressures. The recommendation was made that the surgeon be constantly aware of the joint pressure, fluid inflow and outflow, increased thigh tension, and any lack of joint distention during arthroscopic procedures. Intermittent palpation of the popliteal and calf region is performed during the operative procedure to detect fluid extravasation caused by an inadvertent rupture of a Baker's cyst.[215]

ILLUSTRATIVE CASES

Case 1. A 47-year-old man presented 6 weeks after a left knee injury sustained during skiing. Physical examination revealed a moderate effusion, a severe restriction in knee motion of 0 to 30 degrees, and moderate quadriceps atrophy. Radiographs demonstrated normal tibiofemoral joint space (Fig. 7-60, *A*). The patient underwent 2 months of physical therapy to improve his knee motion and muscle strength. The patient desired to return to his active lifestyle and was treated with an ACL B-PT-B autograft reconstruction. Under anesthesia, he had 5 mm of increased medial joint opening at 25 degrees of flexion, no increase of medial joint opening at 0 degrees, and a grade III pivot shift. A repair of a complex double longitudinal lateral meniscus tear was also performed. The patient had an extensive area of grade 2B articular cartilage damage on the undersurface of the patella.

The patient recovered with no problems and resumed tennis, squash, and skiing. At 11 years postoperatively, physical examination revealed a normal range of motion, no lateral compartment pain, a negative pivot shift, 2-mm increase in medial joint opening at 25 degrees of flexion, and no increase in AP displacement on KT-2000 testing. However, radiographs demonstrated severe loss of lateral tibiofemoral joint space (see Fig. 7-60, *B*).

He did well until 14 years postoperative, when he slipped and fell onto his left knee. MRI revealed bilateral meniscus tears and the patient underwent a partial medial and lateral meniscectomy. At that time, extensive grade 3A damage (exposed bone) was noted on the lateral femoral condyle.

Comment: This patient required 2 months of rehabilitation owing to muscle atrophy and limitation of motion before the initial ACL surgery. Because he had a grade III pivot shift, a B-PT-B autograft was selected instead of an STG autograft or allograft. Unfortunately, the lateral meniscus repair did not provide a long-term chondroprotective effect.

Case 2. A 44-year-old woman presented 5 weeks after a twisting injury sustained to her right knee while playing badminton. She had a mild effusion, 0 to 120 degrees of knee motion, severe medial joint line pain, a grade II pivot shift, and 8 mm of increase in AP displacement on KT-2000 testing. The patient was treated conservatively for 1 month and wished to remain active in recreational softball and volleyball. She underwent an endoscopic ACL B-PT-B autograft reconstruction. There were no meniscal tears; however, fissuring and fragmentation were noted on the undersurface of the patella.

One year postoperatively, the patient complained of pain over the tibial hardware and saphenous nerve. She underwent removal of the tibial interference screw and scar tissue resection. No neuroma was identified. This procedure successfully resolved her pain and she returned to softball without problems.

At the most recent follow-up evaluation, 11 years postoperatively, the patient had a normal range of knee motion, no effusion, no joint line pain, a negative pivot shift, and 3 mm of increase in AP displacement on KT-2000 testing. Radiographs demonstrated preservation of the medial and lateral tibiofemoral joint spaces (Fig. 7-61). She had no

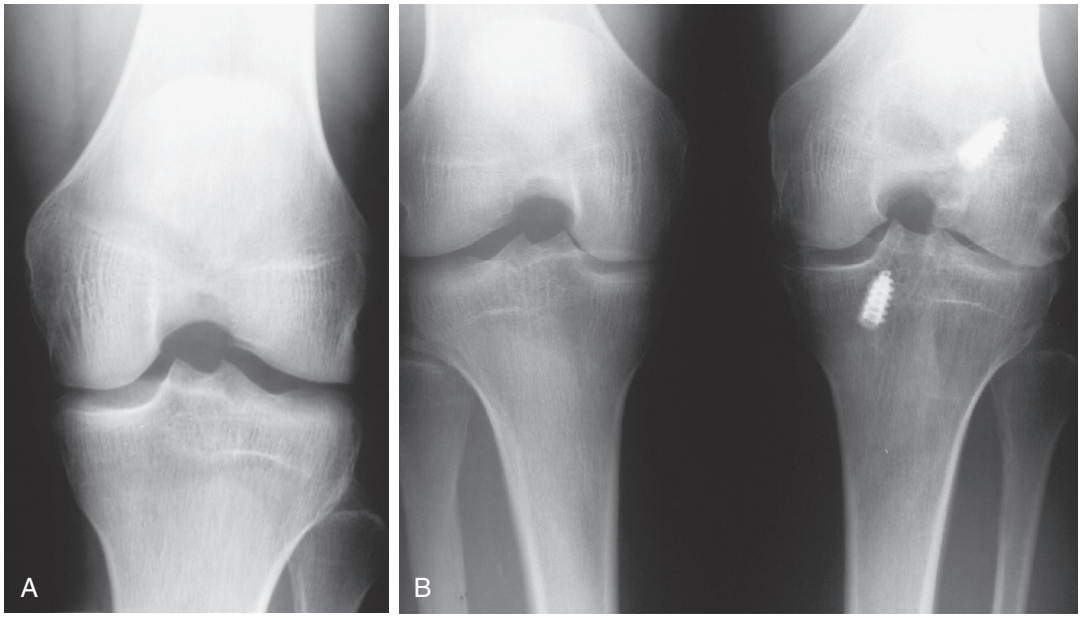

FIG 7-60 Case 1.

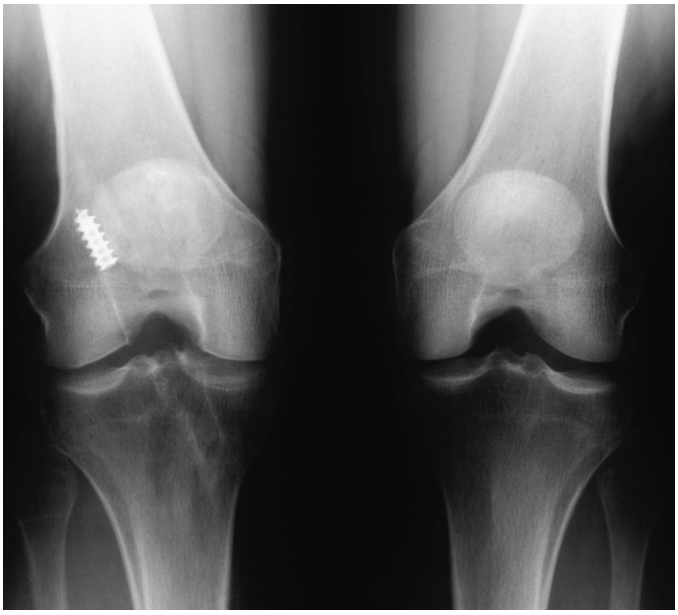

FIG 7-61 Case 2.

symptoms with low-impact activities and rated the overall condition of her knee as good.

Comment: This case, 11 years post ACL reconstruction with intact menisci and no evidence of arthritis, is in marked contrast to the frequent occurrence of arthritis that develops over the long term in patients who undergo meniscectomy.

Case 3. An 18-year-old male collegiate athlete presented 2 weeks after an acute twisting injury sustained to his right knee while playing basketball. He had a mild effusion, medial and lateral joint line pain, a grade II pivot shift, and 13.5 mm of increased AP displacement on KT-2000 testing. He was treated 4 months later with an ACL B-PT-B autograft, and bilateral meniscus repairs for double longitudinal tears. Extensive fissuring and fragmentation on the medial femoral condyle was noted at surgery. The patient had a normal postoperative course and returned to recreational basketball without problems.

Five years later, he injured the left ACL and medial meniscus and underwent an ACL B-PT-B autograft reconstruction and medial meniscectomy elsewhere. The patient then returned to our center 10 years later with complaints of left medial tibiofemoral compartment pain with daily activities. Standing PA radiographs at 45 degrees of flexion demonstrated a weight-bearing line of 28%. AP radiographs showed moderate loss of medial tibiofemoral compartment joint space in both the right (Fig. 7-62, *A*) and left (Fig. 7-62, *B*) knees. The right knee was entirely asymptomatic. The patient underwent a left opening wedge osteotomy with an iliac crest autograft and a locking plate (see Fig. 7-62, *C*). During the procedure, the ACL graft was noted as absent (see Fig. 7-62, *D*). The varus malalignment was corrected to a 60% weight-bearing line (see Fig. 7-62, *E*).

At the most recent follow-up evaluation, 14 years after the right ACL reconstruction and 7 months after the left HTO, the patient had a normal range of knee motion bilaterally. The right knee had a negative Lachman and pivot shift examination. The left knee had a grade II pivot shift and 5 mm of increased anterior drawer. There was no medial or lateral compartment pain in either knee. The patient was asymptomatic with daily activities and had elected not to return to strenuous athletics; therefore, a left ACL revision reconstruction was not performed.

Case 4. A 43-year-old man presented 4 months after a noncontact injury sustained to his left knee while playing basketball. The patient had experienced three additional giving-way episodes during daily activities. Physical examination demonstrated a mild joint effusion, 0 to 120 degrees of knee motion, moderate medial joint line pain, a grade II pivot shift, no increase in lateral or medial joint opening, and 7 mm of increased anterior tibial translation on Lachman testing. Radiographs revealed a weight-bearing line of 32% and moderate narrowing of the medial tibiofemoral compartment (Fig. 7-63, *A*). The patient had pain with daily activities and a walking tolerance of only 20 minutes.

The patient was treated with an opening wedge osteotomy, an ACL STG reconstruction, and a repair of a horizontal medial meniscus tear.

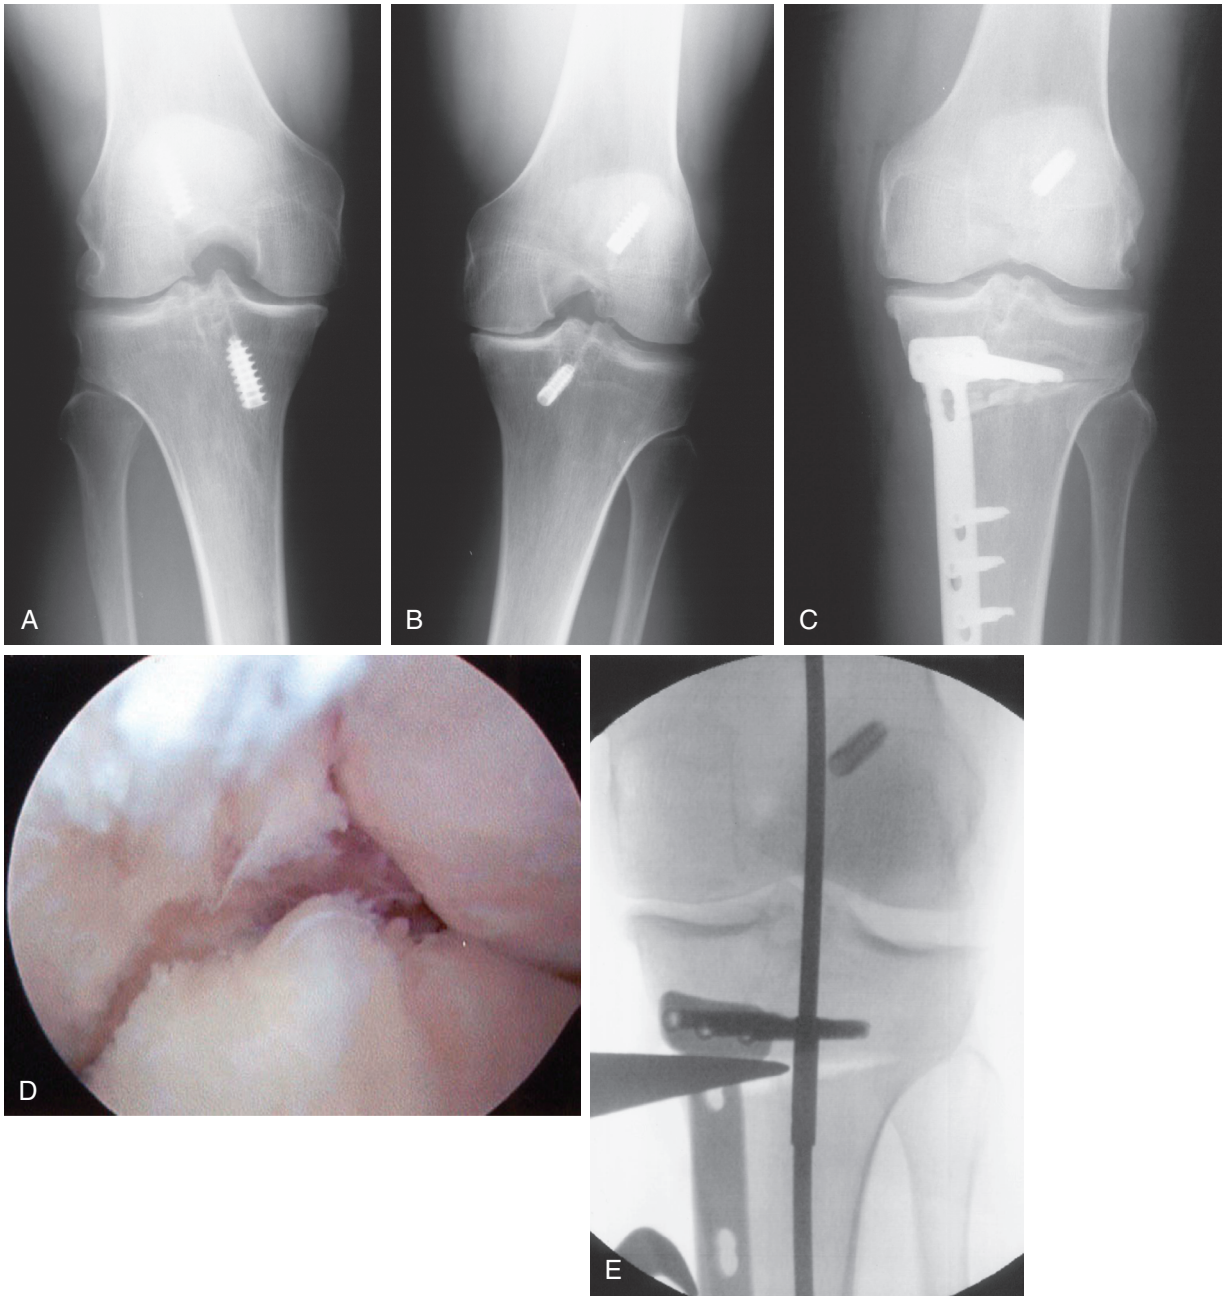

FIG 7-62 Case 3.

Grade 3A damage was noted on the medial femoral condyle and 2B damage was found on the undersurface of the patella during the procedure. No PL procedure was required owing to a normal lateral tibiofemoral opening gap test.

At follow-up 2 years postoperatively, the patient had a normal range of motion, no effusion, a grade I pivot shift, and 4.5 mm of increased displacement on KT-2000 testing. His weight-bearing line was 52% (Fig. 7-63, *B*). He had no problems with daily activities and rated the overall condition of his knee as very good.

Comment: There was no abnormal lateral joint opening in this varus-angulated knee (representing primary varus). Therefore, concurrent ACL reconstruction at the time of osteotomy was performed. The medial meniscus horizontal tear, commonly not amenable to suture repair, was in this case repaired in an attempt to save some meniscus function. The senior author prefers to use a locking plate and screws for fixation of opening wedge osteotomy (see Chapter 26). A two-incision ACL STG procedure was performed to achieve an ideal central tibial and femoral graft location.

Case 5. A 54-year-old woman presented 1 week following a hyperextension injury sustained to her left knee during snow skiing. She had a moderate effusion, mild medial tibiofemoral compartment pain, and a normal range of knee motion. The patient demonstrated 13.5 mm of increased AP displacement on KT-2000 testing, a grade III pivot shift, 12 mm of increase in lateral joint opening at 25 degrees of flexion, no increase in lateral joint opening at 0 degrees of flexion, and 15 degrees of increase in external tibial rotation. The patient attempted conservative treatment for 5 months, but was not satisfied with the

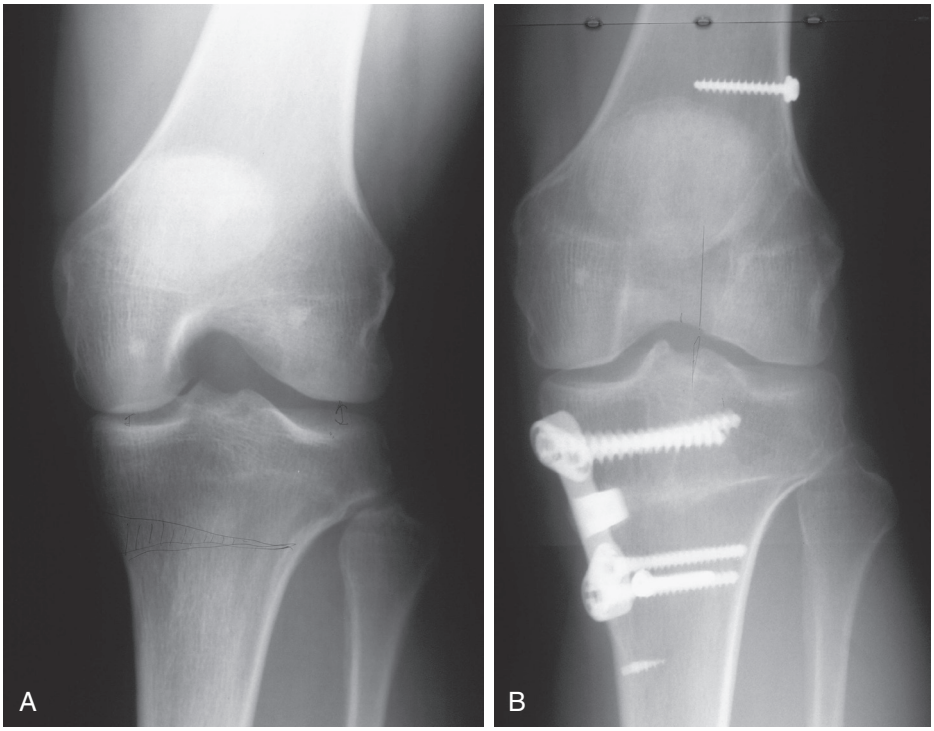

FIG 7-63 Case 4.

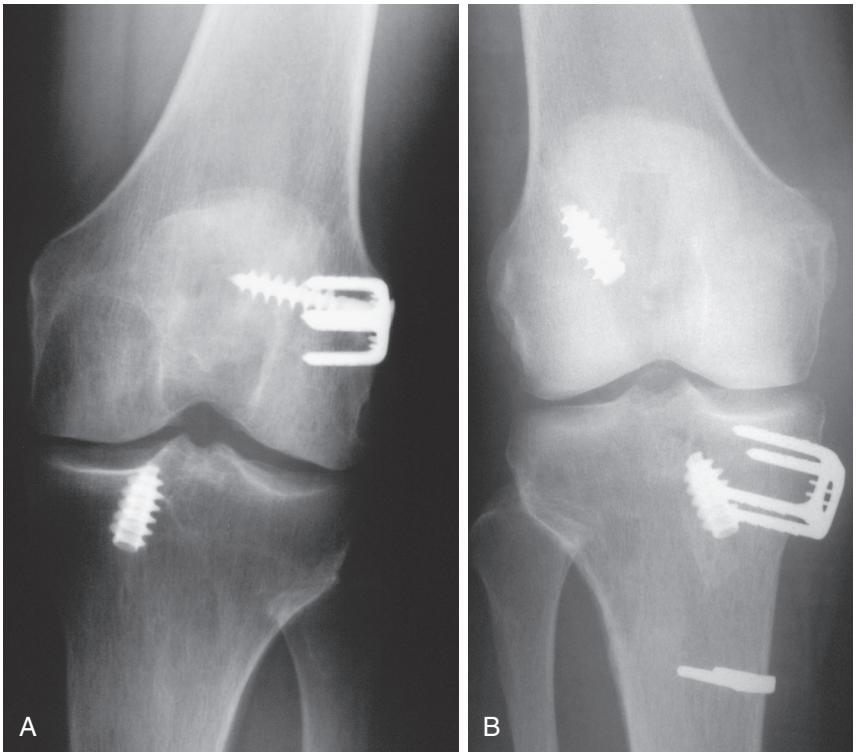

FIG 7-64 Case 5.

function of her knee because she experienced giving-way with daily activities and wished to return to skiing.

The patient was treated with an ACL B-PT-B autograft and a proximal advancement of the PL complex to her left knee (Fig. 7-64, *A*). The lateral exploration showed intact but elongated PL structures and, therefore, a lateral graft reconstruction was not required (see Chapter 17). There were no meniscus tears or noteworthy articular cartilage damage noted. The patient recovered and did well for 9 years, returning to snow skiing without problems.

The patient, now 63 years of age, returned after an injury sustained to her right knee during skiing. Physical examination revealed no effusion, moderate lateral and medial joint line pain, 5 mm of increased

medial joint opening at 25 degrees of flexion, a positive pivot shift test, and 7 mm of increased AP translation. The patient was treated conservatively for 3 months, but continued to experience pain and giving-way symptoms. Owing to her active lifestyle and continued giving-way problems, she was treated with an ACL B-PT-B autograft (see Fig. 7-64, *B*). At surgery, the medial gap test showed 12 mm of tibiofemoral opening; therefore a concurrent MCL STG reconstruction was performed. The articular surfaces and menisci were intact.

At follow-up, 10 years after the left ACL reconstruction and 1 year after the right ACL reconstruction, the patient had a normal range of motion bilaterally, no joint line pain or crepitus, no effusion, and a grade I pivot shift in both knees. She had no symptoms with daily activities.

Comment: This patient shows the successful treatment of ACL rupture combined with PL and medial ligament injuries. Immediate range of motion and closely supervised rehabilitation is the key to avoiding complications after multiple-ligament surgery. A B-PT-B autograft is preferred in grossly unstable knees, particularly with concurrent ligament reconstruction as occurred in this patient. An STG autograft would be a second choice and preferred over an allograft in a grossly unstable knee.

Case 6. A 19-year-old male presented 5 years after a right knee injury sustained during high school football. He had undergone arthroscopy and partial lateral meniscectomy elsewhere. He did well initially but suffered two episodes of giving-way and a recent hyperextension injury. Physical examination revealed no effusion, a mild loss of extension, a grade II pivot shift, and 7 mm of increase in lateral joint opening at 25 degrees of flexion.

The patient was treated with an ACL B-PT-B reconstruction, a proximal advancement of the PL complex (Fig. 7-65), a repair of a complex medial meniscus tear, and a repair of a peripheral lateral meniscus tear. There was grade 2B articular cartilage damage noted on the medial femoral condyle and medial tibial plateau.

At follow-up 3 years postoperatively, the patient had no effusion, a normal range of motion, no tibiofemoral compartment pain, no crepitus, a negative pivot shift, 2 mm of increase in lateral joint opening at 25 degrees of flexion, and no increase in AP displacement on KT-2000 testing. He had no problems with basketball and rated the overall condition of his knee as normal.

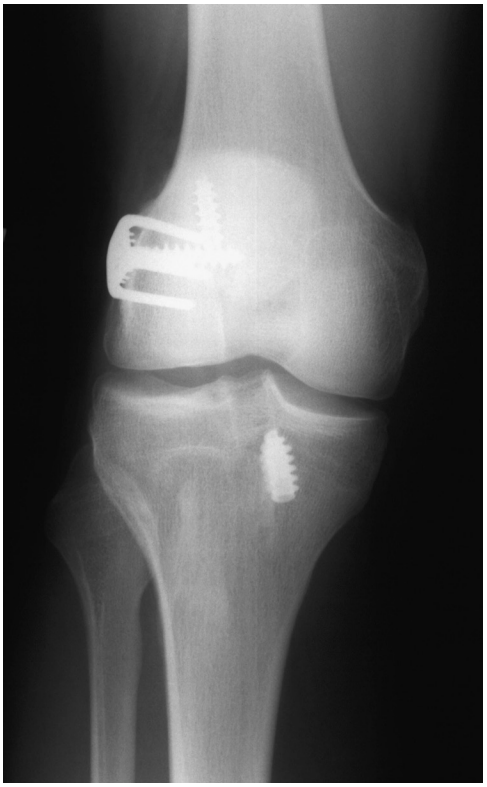

FIG 7-65 Case 6.

Comment: The treatment of a concurrent PL ligament injury with an ACL rupture requires different procedures, described in Chapter 17. In this case, the FCL and PL structures appeared normal, representing a prior interstitial tear with subsequent healing. Therefore, a more simplified proximal advancement procedure restored PL stability.

INDICATIONS

Many factors influence failure of anterior cruciate ligament (ACL) surgery.[3,26,47,60,66,73-75,77,78,84,86,100,101,103] A failed ACL reconstruction is noted by a return of knee instability and increased lateral and medial tibiofemoral compartment anterior translation and subluxation as demonstrated by positive Lachman and pivot shift tests. The surgeon must determine the factors that caused the prior reconstruction to fail, which may include a misplaced vertical ACL graft, inadequate healing and maturation of the graft, associated lateral or medial ligament insufficiency, varus or valgus malalignment, or inadequate postoperative rehabilitation with residual weakness and neuromuscular control (Table 8-1). In many cases, other associated major knee problems are present. These include limitation of knee motion with pain and stiffness, muscle atrophy from inadequate rehabilitation, articular cartilage damage, meniscectomy and its effects on joint symptoms and function, undiagnosed lower limb malalignment, and posterolateral (PL) or medial ligament deficiency. When present, each of these pathologies

TABLE 8-1 Possible Causes of Failure of ACL Reconstructions

- Misplaced femoral and/or tibial tunnel.
- Uncorrected medial, lateral, and/or posterior cruciate ligament insufficiency.
- Uncorrected varus or valgus osseous malalignment.
- Traumatic contact reinjury.
- Inadequate rehabilitation, poor muscle strength and neuromuscular control leading to noncontact reinjury upon return to athletics.
- Inadequate healing, maturation of allograft tissues.
- Family history of anterior cruciate ligament injuries.
- Prior anterior cruciate ligament injury on contralateral leg.
- Small-sized semitendinosus autograft.
- Obesity.
- Inadequate healing, maturation of autograft tissues, uncorrected hyperextension gait abnormality.

ACL, Anterior cruciate ligament.

CRITICAL POINTS Indications

- Determine factors that caused the prior ACL reconstruction to fail
- Address all pathologies before surgery: lower limb malalignment, muscle atrophy, limitation knee motion, gait abnormalities, misplaced tunnels.
- Goals, outcome of surgery depend on preexisting joint damage, associated procedures required.
  - Knees with misplaced tunnels with intact menisci and articular cartilage: most ideal outcome expected.
  - Knees with prior meniscectomy, articular cartilage damage, other ligament insufficiency, or varus malalignment: salvage procedure.
  - Select cases with concomitant articular cartilage restoration procedure, meniscus transplantation

must be addressed and resolved before or during ACL revision. The goal of rehabilitation is to restore the best possible function to the lower extremity before ACL revision to minimize the possibility of failure of the revision procedure.

Importantly, the patient and surgeon must address the expectations and goals of the revision because often associated cartilage damage or meniscectomy requires modification or elimination of strenuous, high-impact activities. In many cases, patients have undergone multiple prior surgical procedures that did not achieve the desired outcome.[74,75,77] The expectation of the revision operation to accomplish the patient's goals must be realistically discussed.[29]

A number of preoperative and operative issues must be addressed in a methodical manner to salvage knee function and obtain a reasonable result after prior ACL procedures have failed. These may include the necessity to perform staged procedures to correct lower limb malalignment with an osteotomy or fill enlarged or misplaced tibial and femoral tunnels with a bone graft. Patients may require extensive rehabilitation before surgery to restore normal joint motion and neuromuscular control. The approach taken is to maximize every aspect of the patient's knee condition and not accept any abnormality, such as a slightly misplaced tunnel or concurrent knee instability, in planning the revision procedure.

Other chapters in this book address issues related to correction of lower limb malalignment, arthrofibrosis, and muscle atrophy; procedures for articular cartilage defects; meniscus transplantation; and PL and medial ligament reconstructions. Although the timing of these procedures will be addressed in this chapter, the principal focus relates to surgical planning and technique decisions that, in our experience, will improve the success of the ACL revision.

Patients presenting for ACL revision fall into one of three categories, each of which has a different prognosis. In the most ideal category are knees with a misplaced tibial or femoral tunnel that have intact menisci and articular cartilage and no associated ligament instability. In these cases, the revision procedure is similar to a primary ACL reconstruction in terms of an expected good functional outcome. In the most severe category are knees that had a previous meniscectomy, articular cartilage damage, associated ligament instabilities, or lower limb malalignment. These patients will have a less than ideal outcome and the revision represents a salvage situation. In the middle of these two categories are patients who have partial or complete loss of meniscus function, associated cartilage damage, and a residual pivot shift from a failed ACL procedure, but no associated lower limb malalignment or other ligament instability. The outcome for providing stability in these cases is good; however, further joint deterioration will occur over time and counseling must be undertaken for activity modification. In select cases, indications exist for an articular cartilage restoration procedure and meniscus transplantation. Clinical studies on ACL revision usually contain a selection bias regarding the inclusion of patients from these three categories, which accounts for the differences in reported outcomes among investigations. The majority of studies report that the outcome of ACL revision is inferior to that of primary reconstruction. Usually, the revision procedures are performed many months or years after the failure of the primary reconstruction, during which time further giving-way episodes and joint deterioration have occurred that compromise the final outcome.

A frequent clinical presentation after an ACL reconstruction with a vertical ACL graft is a negative or mildly positive Lachman test with a positive pivot shift test that reproduces the patient's complaints of residual giving-way with activities. These patients are candidates for an ACL revision in which the entire ACL graft is removed and an anatomic ACL graft replacement is performed. In rare instances, the primary ACL graft may be retained and a second graft is placed in a more suitable anatomic location to provide rotational stability, as is discussed later.

CONTRAINDICATIONS

Patients who are sedentary and do not experience giving-way or swelling episodes with daily activities and have little exposure to strenuous or high-risk activities are treated conservatively. These patients are advised to maintain an ideal body weight and have periodic knee examinations. In addition, patients who are willing to modify their activity level to avoid high-risk knee motions such as pivoting and cutting are placed into a conservative treatment program. Patients who are unable to participate or be compliant with postoperative rehabilitation are not surgical candidates.

The presence of symptomatic patellofemoral or tibiofemoral arthritis is a general contraindication to ACL surgery, because pain symptoms remain postoperatively. Although pain symptoms may be lessened by restoring knee stability, significant joint damage may still limit daily activities. Weight-bearing 45-degree posteroanterior (PA) views are important to determine the millimeters of remaining medial or lateral tibiofemoral joint space. Patients are frequently surprised to learn that the joint space is absent or nearly absent because their symptoms have not yet limited daily activities. In these knees, conservative measures are instituted until such time that unicompartmental or total joint replacement is warranted.

CRITICAL POINTS Contraindications

- Sedentary patient with no symptoms with daily activities.
- Patient willing to modify activity level, avoid high-risk knee motions.
- Patient not able to participate or comply with rehabilitation program.
- Presence of symptomatic arthritis in knees with major loss of joint space.
- Varus-malaligned knees undergo high tibial osteotomy first, may not require subsequent ACL revision.
- Patients with marked muscle atrophy undergo extensive rehabilitation first, restoration of muscle function may avoid ACL revision.
- Complex regional pain syndrome.
- Unrealistic expectations for future athletic activities.
- Obesity, prior joint infection.

CRITICAL POINTS Clinical Evaluation

- Perform thorough history, review prior medical and operative records.
- Comprehensive physical examination assesses knee flexion and extension, patellofemoral indices, tibiofemoral crepitus, tibiofemoral joint line pain, muscle strength, gait abnormalities.
- Perform all stability tests to document abnormal tibial translation, rotations, and tibiofemoral compartment translation.
- Knee arthrometer test: 134 N.
- Radiographs: standing anteroposterior at 0 degree, lateral at 30 degrees; weight-bearing PA at 45 degrees; patellofemoral axial views; double-stance hip-knee-ankle alignment; lateral and posterior stress views as indicated.
- MRI, including articular cartilage image techniques.
- Cincinnati Knee Rating System for subjective, objective, functional scoring.

Patients with ACL deficiency, symptomatic medial tibiofemoral arthritis, and varus malalignment require corrective valgus-producing high tibial osteotomy (HTO). These patients often do not require subsequent ACL surgery, because there are limitations in activities owing to the joint damage.[71] These patients often report improved joint instability because the varus thrust gait pattern is eliminated with osteotomy.

Patients with marked lower extremity muscle atrophy often require a delay in surgery for many months until adequate muscle function has been restored. These patients have an increased risk for postoperative complications, including quadriceps muscle shutdown, patella infera, and arthrofibrosis. In some cases, the restoration of muscle function may lead to increased knee stability, avoiding ACL revision.

The presence of residual signs and symptoms of a complex regional pain syndrome (CRPS) requires careful examination and questioning regarding the presence of burning pain, abnormal skin hypersensitivity, extremity discoloration, and intolerance to cold and ice. Even after resolution of a prior CRPS, there is an increased frequency for return of the syndrome in these knees that must be promptly recognized in the postoperative period (see Chapter 40).

It is not unusual for patients who require ACL revision to have unrealistic expectations of future athletic activities. The goals of the revision procedure are reviewed in detail, and the patient educational process involves recommendation of recreational and low-impact activities only, avoiding strenuous activities in knees with associated joint cartilage damage.

Patients with a body mass index of 30 or greater are usually not surgical candidates. A history of prior infection with subsequent joint arthritis often contraindicates ACL revision. There may be associated medical conditions contraindicating surgery. The use of nicotine products is strongly discouraged and absolutely contraindicated if osteotomy alignment procedures are required.

CLINICAL EVALUATION

A thorough history is performed, including a detailed account of all knee injuries and the operative procedures that have been performed. In revision knees, prior operative records are obtained to verify the surgical findings, condition of the articular cartilage and menisci, and graft placement. A comprehensive physical examination is performed, including assessment of knee flexion and extension, patellofemoral indices, tibiofemoral crepitus, tibiofemoral joint line pain, muscle strength, and gait abnormalities. The surgeon must determine all of the abnormal translations and rotations in the knee joint. The medial posterior tibiofemoral step-off on the posterior drawer test is done at 90 degrees of flexion. Quantification of posterior tibial translation may be performed using stress radiography in knees with posterior cruciate ligament (PCL) ruptures to determine if the rupture is partial or complete (see Chapter 16).[41] The appropriate tests to determine the integrity of the ACL are performed, including KT-2000 (MEDmetric) arthrometer testing at 20 degrees of flexion (134-N force) to quantify total anteroposterior (AP) displacement. The pivot shift test is recorded on a scale of 0 to III, with a grade of 0 indicating no pivot shift; grade I, a slip or glide; grade II, a jerk with gross subluxation or clunk; and grade III, gross subluxation with impingement of the posterior aspect of the lateral side of the tibial plateau against the femoral condyle.

Insufficiency of the PL and medial ligament structures are determined by varus and valgus stress testing at 0 and 30 degrees of knee flexion. The surgeon estimates the amount of joint opening (in millimeters) between the initial closed contact position of each tibiofemoral compartment, performed in a constrained manner avoiding internal or external tibial rotation, to the maximal opened position. The result is recorded according to the approximate millimeters of increase in the tibiofemoral compartment opening of the affected knee compared with that of the opposite normal knee. Abnormal medial or lateral joint opening may be measured with stress radiographs. The results are always confirmed at arthroscopy by the gap test. The tibiofemoral rotation dial test at 30 and 90 degrees detects increases in external tibial rotation with posterior subluxation of the lateral tibial plateau or anterior subluxation of the medial tibial plateau caused by medial ligament injury. A word of caution is necessary, because it is possible to confuse increased external tibial rotation for a PL injury and miss the medial side ligament injury that requires correction.[79] The presence of a varus recurvatum in both the supine and standing positions is carefully assessed. Gait analysis is performed to detect a varus or valgus thrust or hyperextension thrust. Patients can often demonstrate their knee instability on standing, with a few degrees of knee flexion, by producing an external femoral rotation that reproduces the pivot shift phenomena. Abnormal varus or valgus tibiofemoral joint opening may also be demonstrated by the patient.

Radiographs taken during the initial examination include standing AP at 0 degree, lateral at 30 degrees of knee flexion, weight-bearing PA at 45 degrees of knee flexion, and patellofemoral axial views. Double-stance full-standing radiographs of both lower extremities, from the femoral heads to the ankle joints, are obtained in knees in which varus or valgus lower extremity alignment is detected on clinical examination. The mechanical axis and weight-bearing line are measured as discussed in Chapter 26. Magnetic resonance imaging (MRI) is

performed to provide further details of tunnel placement and the condition of the articular cartilage and menisci. Fast-spin-echo and other MRI protocols (T2 mapping) are available to obtain superior quality articular cartilage images.[85] The tibial tunnel placement is visualized on sagittal views and measurements made to determine if the tunnel is too posterior, which often requires a staged bone graft procedure.

At our center, patients complete questionnaires and are interviewed for the assessment of symptoms, functional limitations, sports and occupational activity levels, and patient perception of the overall knee condition according to the Cincinnati Knee Rating System (CKRS; see Chapter 41).[6] The forms are available online for the patient to obtain before their consultation.

PREOPERATIVE PLANNING

The factors that may have been related to or directly caused the failure of the prior ACL reconstruction must be identified and addressed either before or during the revision procedure. A meticulous physical examination, previously discussed, is performed to detect associated ligament deficiencies, valgus or varus lower limb malalignment, or gait abnormalities. The type of hardware used previously is identified to ensure that the proper equipment is available for removal during the revision procedure, if required. If existing hardware does not interfere with new tunnel placement and is in a difficult location to reach, it may be left alone.

All abnormalities or potential problems are addressed preoperatively, including patient expectation issues, muscular weakness, painful neuromas, residual CRPS, and anterior knee pain caused by patellofemoral cartilage damage. A loss of full knee extension creates problems. It is important to obtain full knee motion before revision surgery. The exceptions are grafts placed too far anteriorly or cyclops lesions that produce a mechanical block to full extension or flexion. During the revision procedure, anterior intercondylar blockage is eliminated by adequate notchplasty and correct graft placement. In these knees, there may also be associated tightness to the posterior capsular structures, which have shortened, requiring a vigorous postoperative program. If the lack of extension is greater than 5 degrees, the procedures are staged by first performing an arthroscopic debridement and cyclops lesion excision, followed by rigorous rehabilitation to regain full motion, and then ACL revision reconstruction.

Knees with grossly positive clinical laxity tests have involvement of the secondary ligament restraints, primarily the PL structures. Associated medial or lateral ligament laxity is an indication for medial or lateral ligament reconstruction.

Considerable counseling and patient education are required on the expected results and outcomes from the revision procedure. This is especially important in knees with preexisting arthritis or loss of meniscal function or those that require additional major operative procedures. In nearly one half of revision knees, a major concomitant procedure will be required.[74] Patients need to understand the technical difficulties inherent in the operative procedures and that the results are typically not as favorable as primary ACL reconstruction. A surgeon-rehabilitation team is required to provide instruction on rehabilitation to ensure that the postoperative exercise program will be successfully followed by the patient.

GRAFT SELECTION

Currently, there is no standard graft choice for ACL revision reconstruction.[46,107] Autograft tissue sources include bone-patellar tendon-bone (B-PT-B), quadriceps tendon-patellar bone (QT-PB), and semitendinosus-gracilis (STG) tendons. We prefer B-PT-B autogenous grafts. If the ipsilateral patellar tendon was previously harvested, the contralateral patellar tendon is a potential graft source. Ipsilateral patellar tendon graft reharvest is not recommended because of persistent changes on MRI and graft morphology reported in these knees 7 to 10 years postoperatively.[9,49,53-55,58] A B-PT-B autograft is not recommended if there is associated patellofemoral arthritis (Grade 2B or 3A classification; see Chapter 44), anterior knee pain, or history of patellar subluxation or dislocation. A B-PT-B autograft is not performed when patient issues suggest a decreased ability to follow the more involved rehabilitation program and initial pain related to this graft.

A second option is a QT-PB graft taken from the same or opposite knee, with grafting of any residual patellar bone defect. The quadriceps tendon has the greatest cross-sectional area (100 mm^2) and is ideal in revision knees if the prior tunnels are in the desired anatomic ACL site, but are slightly expanded.

A third option in knees with good bone quality and normal-sized tunnels is an STG autograft, which may be either a four-strand or six-strand graft (see Chapter 7). In recreational athletes and more sedentary patients, a four- or six-strand STG autograft is recommended. Newer fixation methods have increased the success rate and the rehabilitation postoperatively is easier on the patient.

If autograft tissues are not available or the patient refuses a contralateral autograft harvest, then a B-PT-B or Achilles tendon-bone allograft is recommended. A lateral extraarticular iliotibial band (ITB) procedure[18] is recommended with ACL allografts in knees that demonstrate a grade III pivot shift test or greater than 10 mm of increased AP translation on KT-2000 testing to reduce the high failure rate noted after revision ACL allograft reconstruction[45,77,94] and the delay in allograft healing and maturation.[4,43,44,110] A posterior or anterior tibialis allograft is not recommended.[91] It is desirable to have one portion of

CRITICAL POINTS Preoperative Planning

- Determine all factors related to failure index ACL procedure for treatment plan.
- Identify tibial and femoral tunnel location and necessity for bone graft.
- Identify hardware previously used.
- Obtain full knee motion, muscle strength, return of adequate neuromuscular function.
- Determine need for concomitant cartilage/meniscus procedures, extraarticular procedures, and other ligament reconstructions to correct all instabilities.
- Address patient expectation and goals of surgery.

CRITICAL POINTS Graft Selection

- We prefer B-PT-B autograft; use contralateral knee if previously harvested.
- QT-PB autograft second option.
- STG autograft (four- or six-strand) option for recreational athletes, more sedentary patients.
- B-PT-B or Achilles tendon-bone allograft reserved for multiligament procedures, special cases where graft harvest to be avoided, or patient refuses contralateral autograft harvest.
- Graft harvest: See Chapter 7.

the graft with a bone plug for increased rate of graft healing in one of the tunnels.

OPERATIVE TECHNIQUES

Patient Setup

The patient is instructed to use a chlorhexidine wash of the operative limb ("toes to groin") three days before surgery, including the evening before and morning of surgery. Lower extremity hair is removed by clippers, not a shaver. Antibiotic infusion is begun 1 hour before surgery. The use of a nonsteroidal antiinflammatory drug (NSAID) and a postoperative firm double-cotton, double-Ace compression dressing for 72 hours (cotton, Ace, cotton, Ace layered dressing) has proven effective in diminishing soft tissue swelling in knee surgery cases. In complex multiligament surgery, the antibiotic is repeated at 4 hours and continued for 24 hours. A urinary indwelling catheter is not used unless there are specific indications. The patient's urinary output and total fluids are carefully monitored during the procedure and in the recovery room. The knee skin area is initialized by the surgeon before entering the operating room, with a nurse observing the procedure. The identification process is repeated with all operative personnel with a "time out" before surgery to verify the knee undergoing surgery, procedure, allergies, antibiotic infusion, and special precautions that apply. All personnel provide verbal agreement.

The patient setup and positioning and graft harvest techniques for B-PT-B, STG, and QT-PB autografts are done as described in detail in Chapter 7.

All knee ligament subluxation tests are performed after the induction of anesthesia in both the injured and contralateral limbs. The amount of increased anterior tibial translation, posterior tibial translation, lateral and medial joint opening, and external tibial rotation are documented. A thorough arthroscopic examination is conducted, noting articular cartilage surface abnormalities and the condition of the menisci. Appropriate debridement and meniscus repair or partial excision are performed as necessary.

The lateral and medial gap tests are done during the arthroscopic examination (see Chapter 17).[76] The knee is flexed from 25 to 30 degrees and a varus load of approximately 89 N applied. A calibrated nerve hook is used to measure the amount of tibiofemoral compartment opening (Fig. 8-1). Knees that have 12 mm or more of joint opening at the periphery or 10 mm at the midpoint of the tibiofemoral compartment require a PL or medial ligament reconstructive procedure.

The general principles the senior author (F.R.N.) applies to ACL reconstruction are discussed in Chapter 7 (see Table 7-8).

CRITICAL POINTS Operative Techniques: Patient Setup

- Patient uses chlorhexidine wash operative limb three days before surgery.
- Antibiotic infusion 1 hour before surgery.
- Nonsteroidal antiinflammatory medication morning of surgery, continued 5 days postoperative.
- Knee to be reconstructed initialed by surgeon, time-out in operating room.
- Lateral and medial gap test done during arthroscopic examination to determine need for concurrent ligament reconstructive procedures.

Identification of Tibial Tunnel Problems in Revision Knees and Need for Staged Bone Grafting

It is next important to determine that the tibial and femoral tunnels can be placed into the ideal position before the selected graft is harvested and prepared. The selection and preparation of autografts is performed only after the tibial and femoral tunnels have been determined to be adequate or have been bone grafted previously.

It is usually not difficult to identify the prior tibial tunnel entrance into the joint after removal of the soft tissues and graft material at the ACL attachment location. The adjacent lateral meniscus attachment

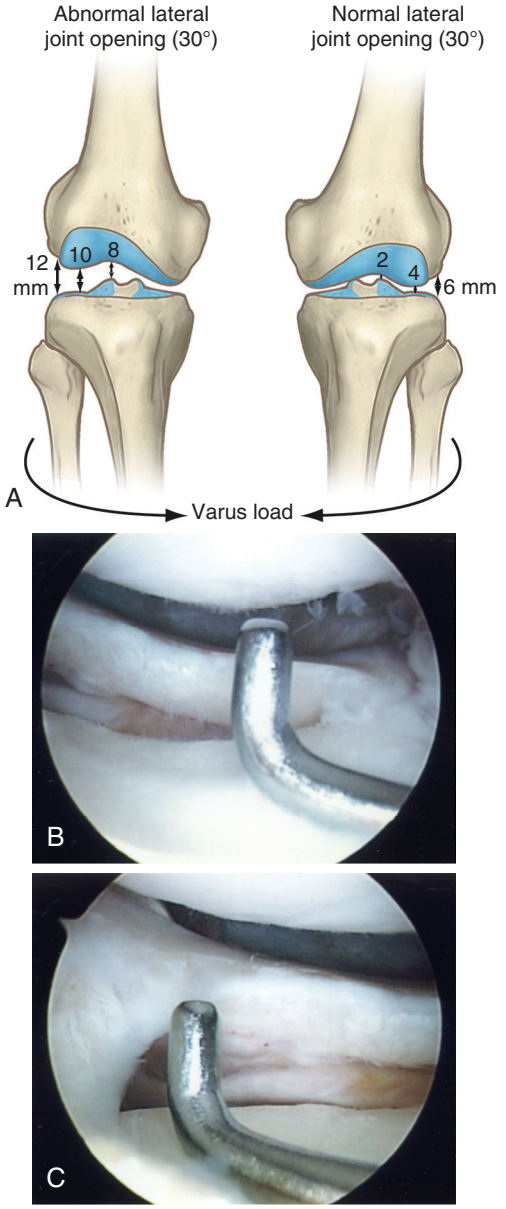

FIG 8-1 The gap test. **A,** The amount of lateral tibiofemoral joint opening is measured with the knee at 25 degrees of flexion. Knees with insufficiency of the posterolateral structures will demonstrate 12 mm of joint opening at the periphery of the lateral tibiofemoral compartment, 10 mm at the midportion of the compartment, and 8 mm at the innermost medial edge. **B,** Normal gap test. **C,** Abnormal gap test.

CRITICAL POINTS Operative Techniques: Identification of Tibial Tunnel Problems in Revision Knees and Need for Staged Bone Grafting

Tibial Tunnel

- Identify prior tibial tunnel entrance after removal of soft tissues and graft material at the ACL attachment location.
- Identify lateral meniscus attachment, PCL, posterior ridge, medial tibial spine, medial articular cartilage.
- Posterior expanded tibial tunnel extending all the way to the RER is not acceptable for revision graft, requires staged bone grafting with autogenous bone.
- Posterior tibial tunnel located in posterior one third of the native ACL attachment, with 5-mm bridge between the tunnel and RER, if not dilated, may be relocated anteriorly.
- Use cortical allograft dowel to fill posterior one third of tunnel.
- Or perform double-bundle reconstruction. Posterior tibial tunnel used for PM bundle, second anterior tibial tunnel used for AM bundle when two femoral tunnels possible.

Femoral Tunnel

- Place arthroscope in AM portal, view entire lateral notch and notch roof.
- Remove all soft tissues and graft material.
- Perform limited notchplasty to view furthest posterior aspect of lateral notch.
- Map out central anatomic ACL; position knee 20 to 30 degrees of flexion.
- Majority knees will have vertical grafts on roof of notch, allowing new lateral wall tunnel to be placed.
- For dilated and slightly misplaced femoral tunnel, use two stacked interference screws to provide a buttress against one side of the tunnel. Only possible if tunnel is close to ideal anatomic position. Otherwise, staged bone graft required.

may be encased in scar tissue and is preserved. The PCL, posterior ridge, medial tibial spine, and medial articular cartilage are all identified. The furthest extent of the posterior ACL tibial attachment is approximately 8 mm anterior to the posterior ridge (RER). This is a critical measurement because many primary ACL operative procedures place the ACL graft into the posterior one third of the ACL attachment. It is often the case that during the drilling procedure for the posterior tibial tunnel, or in using this tunnel for the femoral tunnel placement that the tunnel is enlarged posteriorly out of the native ACL footprint and extends to the RER. This situation results in a vertical ACL graft. Often, the preoperative MRI will allow measurements of the tunnel location relative to the AP width and the surgeon is already aware of this problem (Fig. 8-2).

It may initially appear that the tibial tunnel is acceptable; however, after removing all of the soft tissues or when the tibial tunnel drilling is performed, the surgeon may discover that a posterior tibial tunnel exists that extends all the way to or through the RER, which is not acceptable for the revision graft. These cases require staged bone grafting (Fig. 8-3). On occasion, the posterior tibial tunnel is located in the posterior one third of the native ACL attachment, with only a 5-mm bridge between the tunnel and RER. If the tibial tunnel is not dilated requiring grafting, it is possible to drill and relocate the tibial tunnel approximately 8 mm anteriorly into a more advantageous central ACL attachment position. A cortical allograft dowel is positioned to occupy and fill the posterior one third of the tunnel, maintaining the graft in the ideal central position. Another technique is to fashion the bone plug of a revision allograft, maintaining an enlarged bone block to fill the posterior portion of the tibial tunnel and prevent the collagen portion of the graft displacing posteriorly. A third technique is to perform a double-bundle reconstruction with the posterior tibial tunnel used for the PL bundle (assuming the graft is placed into the native ACL tibial footprint and not located in an abnormal posterior position). A second anterior tibial tunnel is used for the anteromedial (AM) bundle. Use of double-bundle grafts in a revision procedure requires that the femoral tunnel location also be ideal, which is often a problem. A misplaced femoral tunnel may prevent two additional tunnels to be adequately placed because these tunnels could possibly weaken the femoral condyle.

In our opinion, the mistake that is possible at ACL revision is to accept a posterior tibial tunnel position for a single-graft procedure. It is preferable to proceed with the staged bone grafting if there is any question that the bone quality is not ideal and that the revision graft would be placed into the posterior one third of the native tibial attachment and result in a windshield effect on weakened bone posteriorly eroding through to the RER. The alternatives listed previously to relocate the graft tunnel are indicated only when good bone quality exists and the prior tibial tunnel does not extend beyond the native ACL attachment. In our experience, in the majority of revision cases involving a posteriorly placed tibial tunnel, the tunnel is frequently dilated and expanded. This is not suitable for bone incorporation into the revision graft, and there is little question that staged bone grafting is necessary.

Identification of Prior Femoral Tunnel in Revision Knees and Need for Staged Bone Grafting

The arthroscope is placed in the AM portal to view the entire lateral notch and notch roof, and all soft tissues and graft material are removed. An angled curette, suction cutting device, and occasionally a radiofrequency probe are used. Any spurs or overgrowth of the notch are removed and a limited notchplasty performed to view the furthest posterior aspect of the lateral notch. A mistake is to not remove all of the lateral soft tissues adjacent to the lateral femoral condyle articular cartilage edge because this is the landmark for identification of the correct location of the revision graft. With a prior vertical tunnel or anterior tunnel, it is often possible to outline the native ACL attachment, which provides important identification landmarks for graft location. The ACL footprint is mapped out and the determination is made whether an ideal anatomic central tunnel is possible, as described.

In a majority of revision cases, the index graft is placed in a vertical, nonanatomic position on the roof of the intercondylar notch (Fig. 8-4) and it is possible to place the revision tunnel in the ideal central ACL anatomic attachment. We use the two-incision approach to reorient the femoral tunnel entirely away from the index tunnel. It is sometimes possible to perform an endoscopic approach using an AM portal to drill the femoral tunnel with a hyperflexed knee; however, the two-incision technique is preferable in most revision procedures. In posterior wall femoral blowout situations, a reoriented tunnel wall can often be used and the bone portion of the graft fashioned so that the bone is placed in the posterior portion of the tunnel to maintain the collagen portion of the graft within the native ACL femoral footprint.

The more difficult problem is the management of a dilated and slightly misplaced femoral tunnel that is at the native ACL attachment or perhaps extends a few millimeters beyond the native ACL attachment onto the intercondylar roof. The new tunnel will overlap and produce an enlarged dilated tunnel with portions extending proximal and beyond the native ACL footprint. There is a technique in which two stacked interference screws (absorbable or metallic) are used to

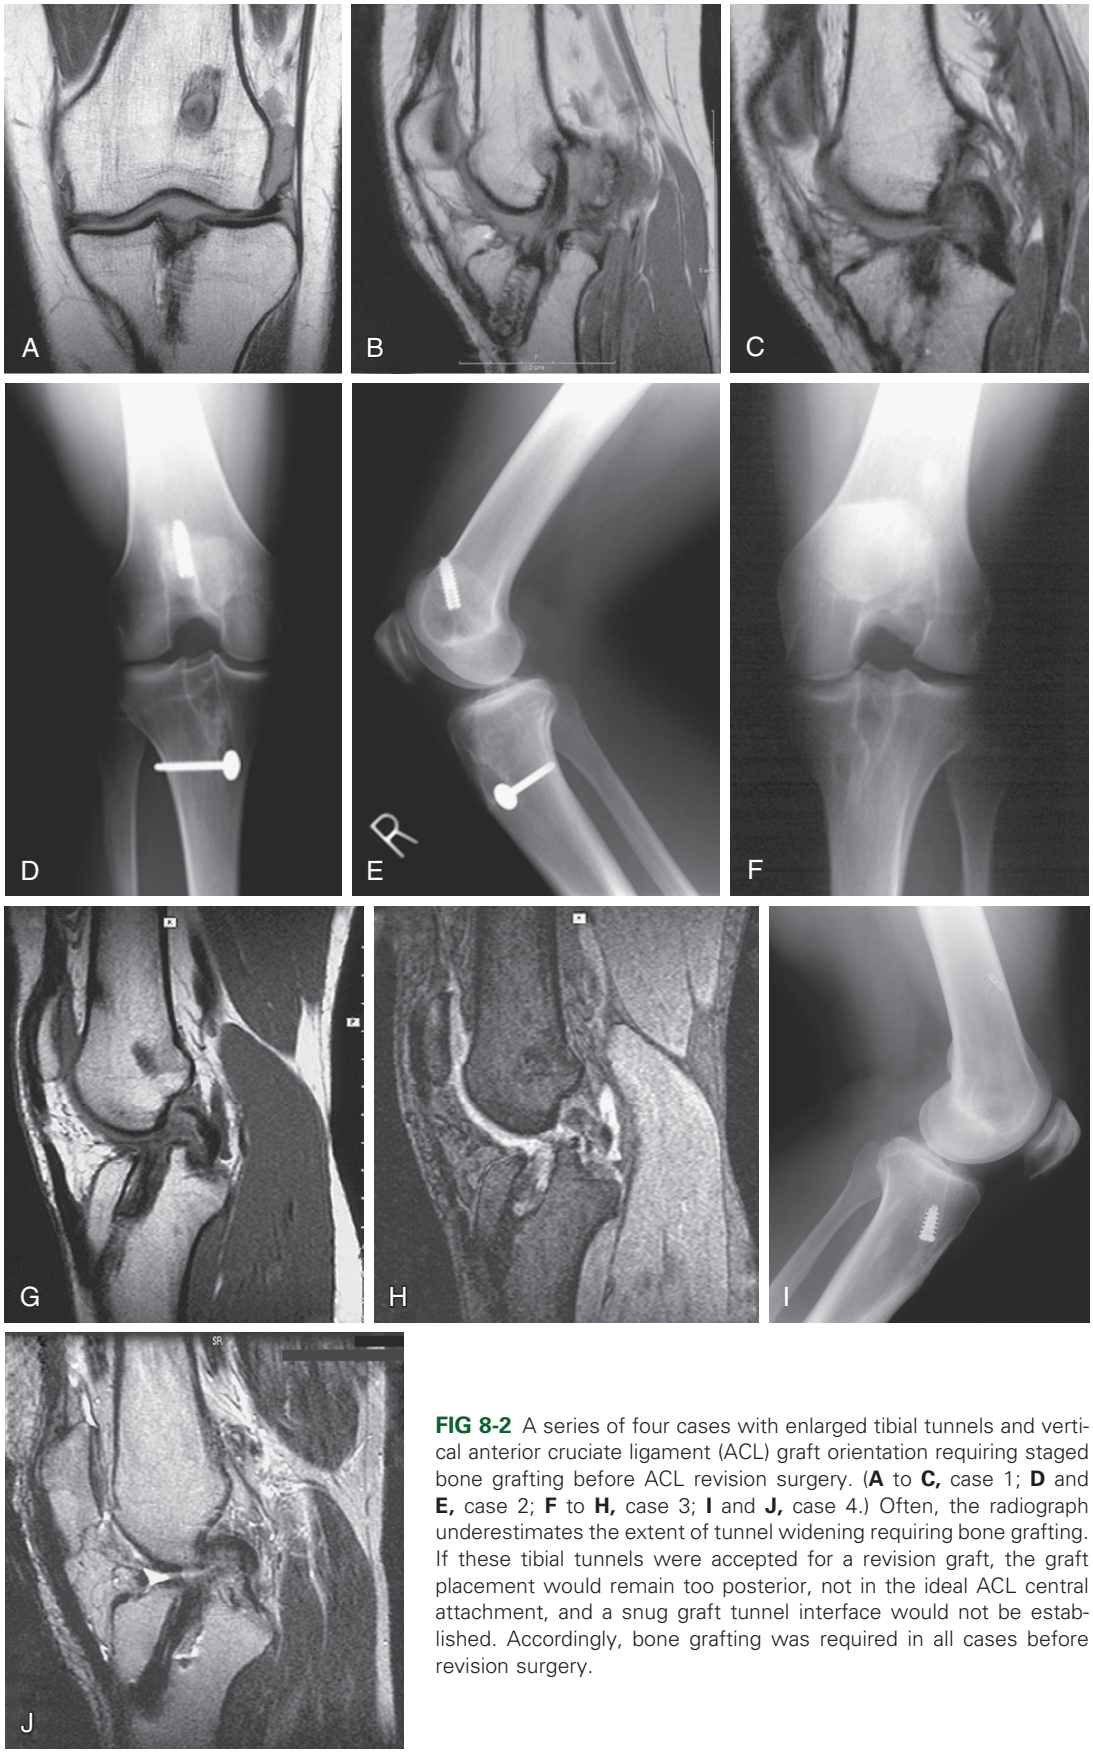

FIG 8-2 A series of four cases with enlarged tibial tunnels and vertical anterior cruciate ligament (ACL) graft orientation requiring staged bone grafting before ACL revision surgery. (**A** to **C,** case 1; **D** and **E,** case 2; **F** to **H,** case 3; **I** and **J,** case 4.) Often, the radiograph underestimates the extent of tunnel widening requiring bone grafting. If these tibial tunnels were accepted for a revision graft, the graft placement would remain too posterior, not in the ideal ACL central attachment, and a snug graft tunnel interface would not be established. Accordingly, bone grafting was required in all cases before revision surgery.

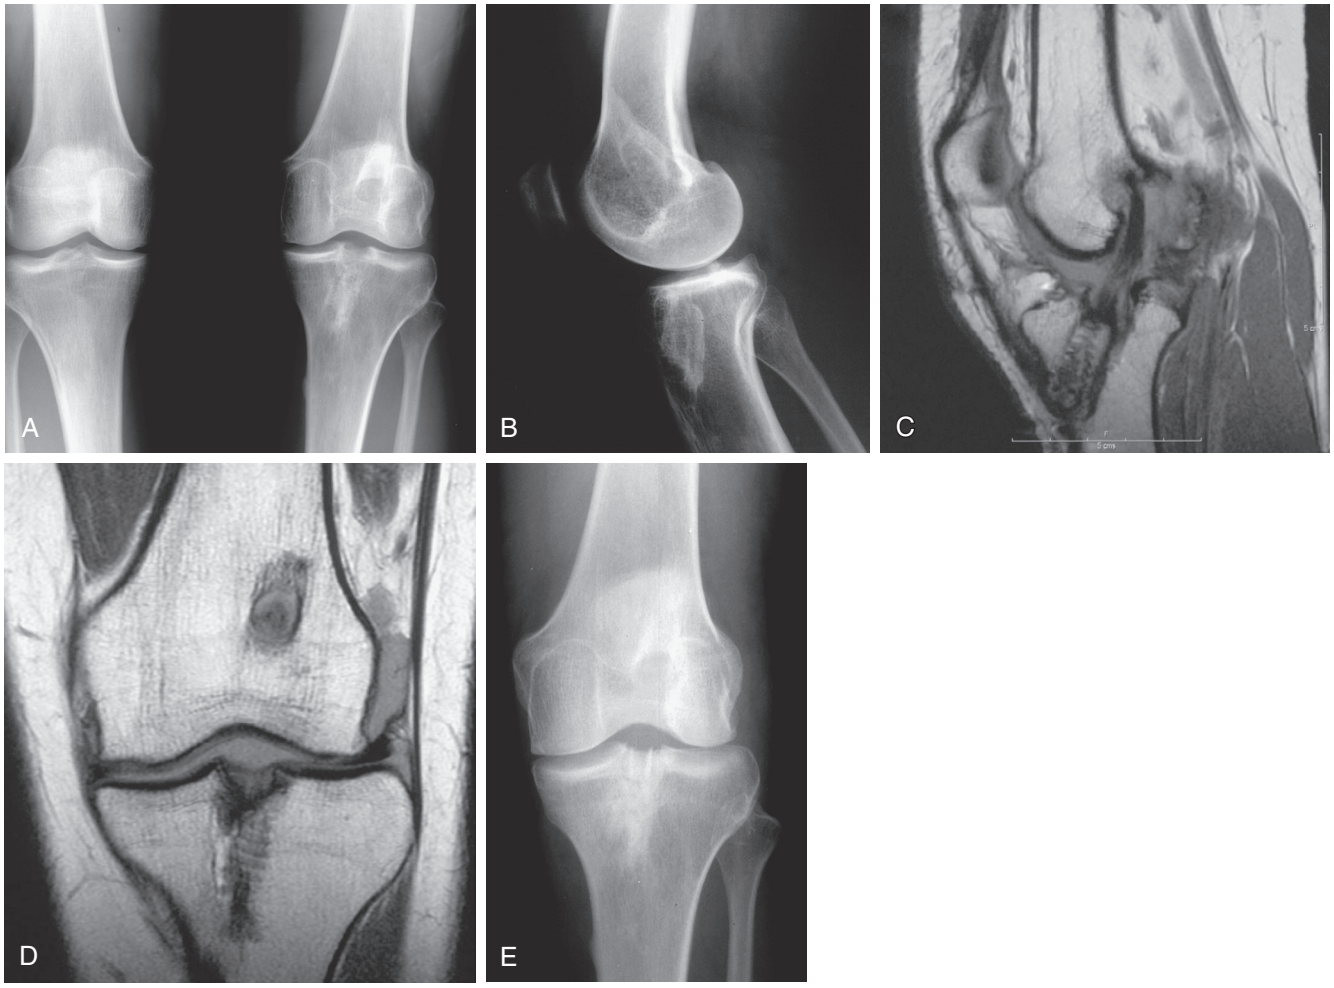

FIG 8-3 **A,** A 31-year-old woman with failure of a primary anterior cruciate ligament (ACL) semitendinosus-gracilis autograft and revision anterior tibial allograft of the left knee. **B,** A bone graft of a large tibial tunnel was performed with allograft. **C** and **D,** The allograft procedure did not provide a restitution of the tibial tunnel and a residual widening was present. **E,** A repeat bone graft using autogenous iliac crest was required to obtain bone of sufficient quality for an ACL revision.

provide a buttress against one side of a dilated tunnel to locate the graft within the ideal femoral attachment. However, this technique is possible only when the femoral tunnel is close to ideal and the stacked interference screw is truly used as a buttress screw against one side of the tunnel wall. The remainder of the femoral tunnel cannot be dilated or enlarged, and the bone quality about the femoral tunnel is not osteopenic and allows for graft fixation. The femoral tunnel for the graft does not extend to the roof of the notch or to the edge of the femoral articular cartilage.

The mistake that may be made is to accept a "slightly enlarged" femoral tunnel in which the graft placement is not ideal, such as too proximal or anterior on the lateral femoral wall. If there is any question, a bone grafting procedure is performed and the revision reconstruction done 5 to 6 months later. Meniscus repairs may be done with the bone grafting procedure to protect the meniscus, and a functional brace used until the revision procedure is performed.

Bone Grafting Procedure for Tibial and Femoral Enlarged Tunnels

There are available principles to follow when performing bone grafting of enlarged tunnels (Table 8-2). The first is to adequately prepare the graft site by removing all soft tissues, curette, and place small drill holes into the cortical tunnel walls to provide the most ideal surface for bone graft healing. Cultures of the removed soft tissues are obtained. Rarely, a Gram stain and frozen section are necessary to exclude an occult infectious process within a tibial or femoral tunnel, particularly when an allograft was used.

CRITICAL POINTS Operative Techniques: Bone Grafting Procedure for Tibial and Femoral Enlarged Tunnel

- Prepare graft site by removing all soft tissues, curette, and place small drill holes into the cortical tunnel walls.
- Culture removed soft tissues, possible Gram stain, cell count.
- Freeze-dried dense cancellous allograft core used in tunnel or to replace posterior tibial RER when deficient.
- Rare cases, minimally invasive iliac crest autograft procedure, remove only the superior and outer portions, do not disturb the inner table and muscle attachments.
- Major defects: cancellous allograft bone in 5- to 8-mm fragments packed between cortical-cancellous strips.

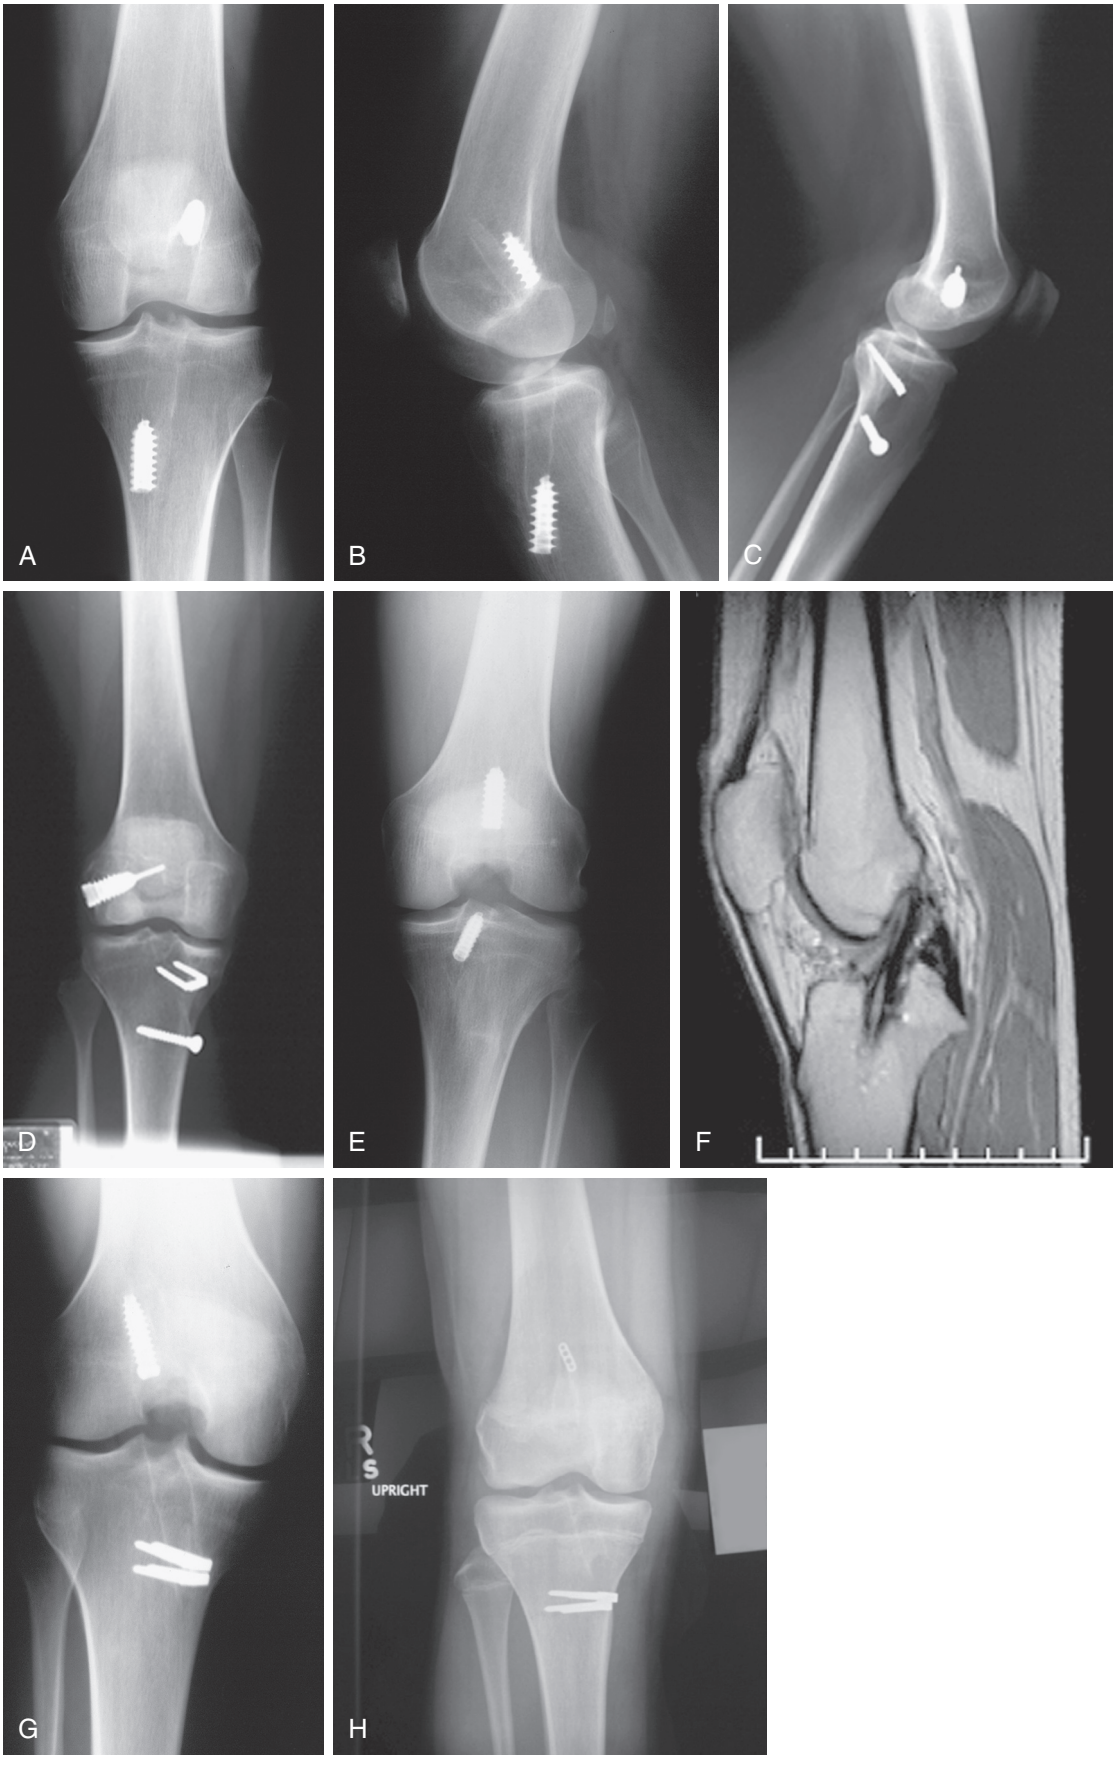

FIG 8-4 Patients who presented to our center for anterior cruciate ligament (ACL) revision with a vertical ACL graft, easily detected on anteroposterior and lateral radiographs and magnetic resonance imaging. The femoral graft location is primarily on the notch roof. In our experience, this vertical graft orientation is the primary cause for ACL failure.

TABLE 8-2 Rules to Follow for Bone Grafting Tibial and Femoral Tunnels in ACL Revision Surgery

1. The goal of bone grafting is to restore good-quality bone for a subsequent staged ACL revision reconstruction. The rule is to never accept a compromised tunnel caused by either malposition or enlargement.
2. In rare instances, a bone graft or interference screw may be used at the time of ACL revision to slightly adjust a graft tunnel; however, the surgeon must ensure that the remaining tunnel is in the correct position and not dilated because this would interfere with good bone healing and graft incorporation. In most ACL revision knees, and in particular, those in which an allograft was previously used, the tunnels are dilated throughout their length and bone grafting of the entire tunnel is required to restore adequate bone quality for the staged ACL revision (see Fig. 8-2). In short, it is not worth taking the chance that the ACL revision procedure will fail (thus requiring another ACL revision operation) because of marginal bone quality.
3. In terms of bone graft selection criteria, a dowel bone allograft that entirely fills the tunnel has the advantage of providing a complete substrate for creeping substitution and tunnel healing (see Fig. 8-5). Packing of cortical-cancellous allograft into a dilated tibial or femoral tunnel is a second option, although the senior author uses this technique only for pockets of bone loss adjacent to the dowel allograft. The freeze-dried dowel is among the safest preparation of all bone allografts owing to its processing and is advantageous because it avoids (in almost all cases) the necessity of harvesting an iliac crest autograft.
4. Approach the tibial tunnel first, remove all graft material, observe for any signs of infection, and send specimens for pathology. Enlarge the tunnel as required so that the diameter is fairly uniform throughout. Use a fully threaded drill and not an acorn drill, which will wander in the tunnel and not provide a symmetric diameter.
5. Follow the same steps described above for the femoral tunnel, which can be reamed in the same orientation as the primary ACL surgery (transtibial, anteromedial portal, or two-incision).
6. Use the arthroscope to examine the interior of the tunnels to be sure all material is removed. For sclerotic tunnel walls, the straight drill provides an abrasion effect to facilitate healing of allografts.
7. Select a dowel bone graft that is 1 mm smaller in diameter than the drill diameter (see Fig. 8-6, *A*). If there is any question that a snug fit will not be obtained, use a drill that is ½ mm larger than the dowel to prevent migration of the dowel out of the tunnel into the joint. Fill the femoral hole first.
8. A core reamer provides an ideal instrument for the bone dowel center hole to secure it for passage in the tunnel (see Fig. 8-6, *B*). Use only gentle pressure to impact the dowel into the tunnels because the freeze-dried allograft is brittle. Determine by arthroscopy that the bone dowel is flush with the tibial and femoral intraarticular tunnels.
9. Preserve tissue over the tibial tunnel on the initial exploration by subperiosteal exposure, which can be sutured to close the tibial tunnel external entrance and prevent graft extrusion.
10. Postoperative rehabilitation involves 50% weight bearing for 3 weeks to prevent undue activity that may cause migration of the bone graft. Then, full weight bearing is resumed, but no strenuous activities are allowed. Radiographs are taken postoperatively and then 6 weeks later to confirm that the allograft dowel is in the correct location. In our experience, at 20 weeks postoperatively, there is very good incorporation of the bone graft that will allow drilling of anatomically correct tunnels in the staged ACL revision procedure.

ACL, Anterior cruciate ligament.

Second, a freeze-dried dense cancellous allograft core that may be fashioned to fit snuggly into the remaining tunnel provides an ideal graft for bony incorporation (Figs. 8-5 and 8-6). Third, the posterior tibial RER, when deficient, may also be replaced with a core allograft. The goal is to prevent the revision graft in the newly placed tunnel from enlarging the tunnel posteriorly by a windshield-wiper effect against poor-quality bone. The same situation applies to an enlarged dilated femoral tunnel where the anterior shallow portion of the tunnel is grafted with a core allograft to obtain a good-quality bone construct. It is rare that an autogenous iliac crest autograft is required. However, in such instances, the outer iliac crest can be fashioned into a rectangular or circular dowel that is wedged into the enlarged tibial or femoral tunnel, providing a near-complete filling of the expanded tunnel and likelihood of the revision procedure being performed in 3 to 6 months. Strips of cortical cancellous bone are packed into any remaining defects. In major defects, cancellous allograft bone in the range of 5- to 8-mm fragments are packed between the cortical-cancellous strips. The bone grafting procedure is easily performed in an arthroscopically assisted manner, enlarging the portals as necessary to deliver the bone graft into the femoral tunnel. The tibial tunnel is packed in a retrograde manner, observing the final position of the graft from an appropriate arthroscopic portal. Bone graft substitutes are commercially available; however, their role instead of autogenous or allograft bone has not been established in clinical studies.

Anterior Cruciate Ligament Bone-Patellar Tendon-Bone Graft Anatomic Tibial and Femoral Technique

A single graft procedure is described in which the graft is located into the central anatomic tibial and femoral attachment locations; the reader is referred to Chapter 7. The graft placement for revision knees specifically avoids the proximal ACL femoral attachment site and the posterior ACL tibial attachment site to circumvent a vertical graft and allow the graft to resist rotational coupled motions in addition to anterior tibial translation (Fig. 8-7). This section describes using a single B-PT-B autograft or allograft procedure; other techniques are described in Chapter 7. Our clinical studies support the concept of a single graft technique for revision procedures. One exception is where a double-bundle procedure may be used in a knee in which a prior vertical ACL graft placement was performed, which limits anterior tibial translation, and a second coronal graft is added to provide added control.

Placement of Tibial Tunnel

The ideal central ACL tibial attachment location is directly adjacent and anterior to the posterior edge of the lateral meniscus anterior horn attachment. The ACL attachment can be easily mapped at surgery based on the anatomic reference maps provided, with the ACL center location based on the anterior-to-posterior and medial-to-lateral attachments. The anterior extent of the ACL attachment may be

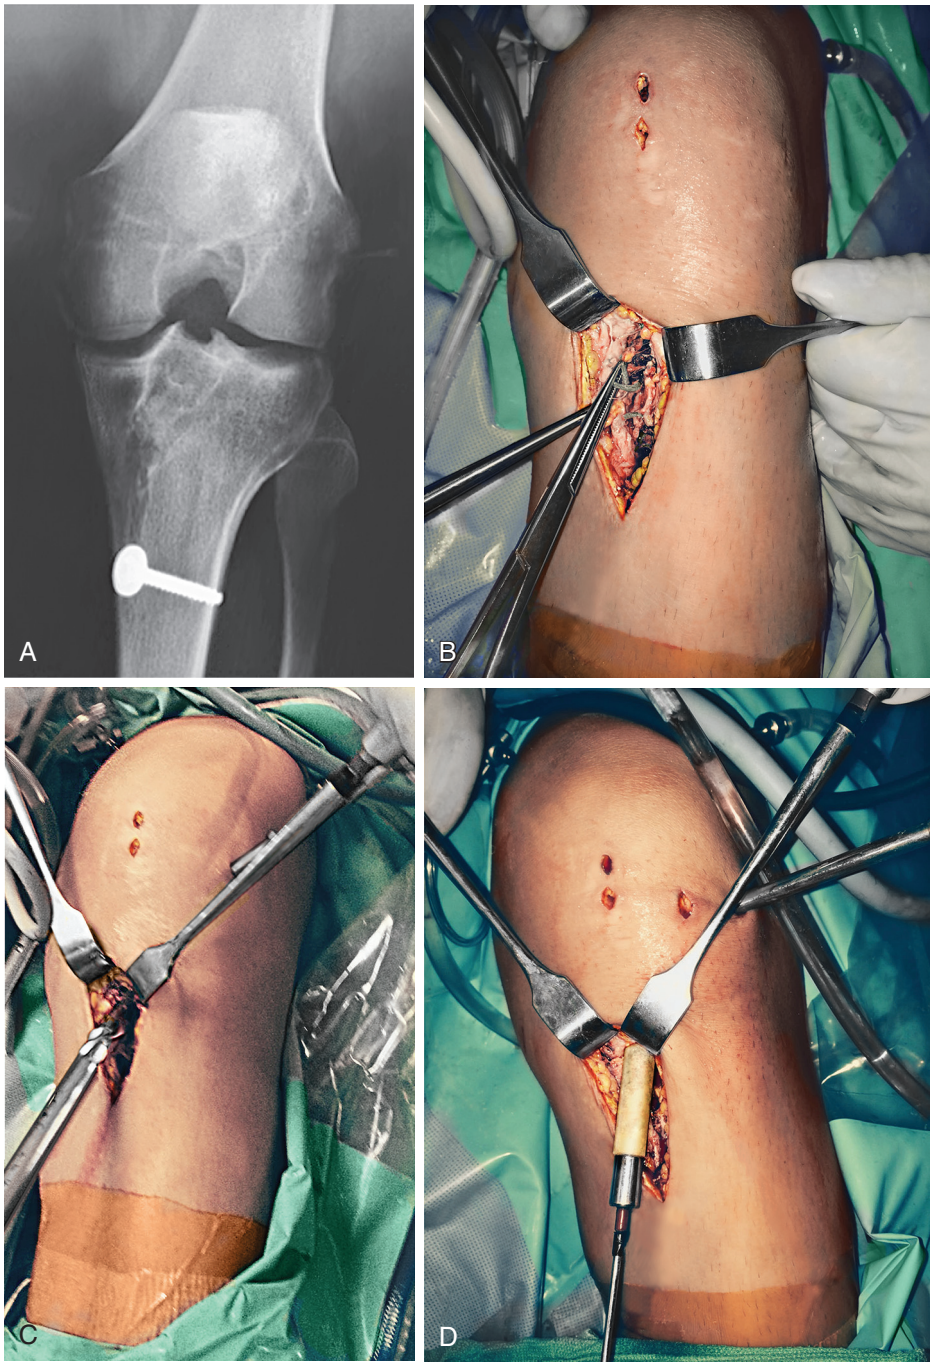

FIG 8-5 A 21-year-old soccer player with a failed anterior cruciate ligament (ACL) semitendinosus-gracilis allograft reconstruction and marked dilation and widening of the tibial and femoral tunnels **(A)** required a staged bone graft. **B,** Debridement of the tibial tunnel. **C,** Drilling of the tibial tunnel over a guide pin placed in the prior tunnel. Instead of an acorn drill, a regular drill was used with complete cutting threads throughout the shaft to provide a constant-diameter tunnel for the core bone graft to be inserted and fit snugly into the tunnel. The femoral tunnel was also debrided and a guide pin placed through the tibial tunnel for a similar drilling procedure. The majority of these cases involve transtibial drilling techniques. If an accessory anteromedial portal is used for the femoral tunnel, then a similar technique is used to bone graft the femoral tunnel. **D,** Insertion of a 12-mm freeze-dried core allograft under arthroscopic control, performed after the femoral tunnel has been grafted.

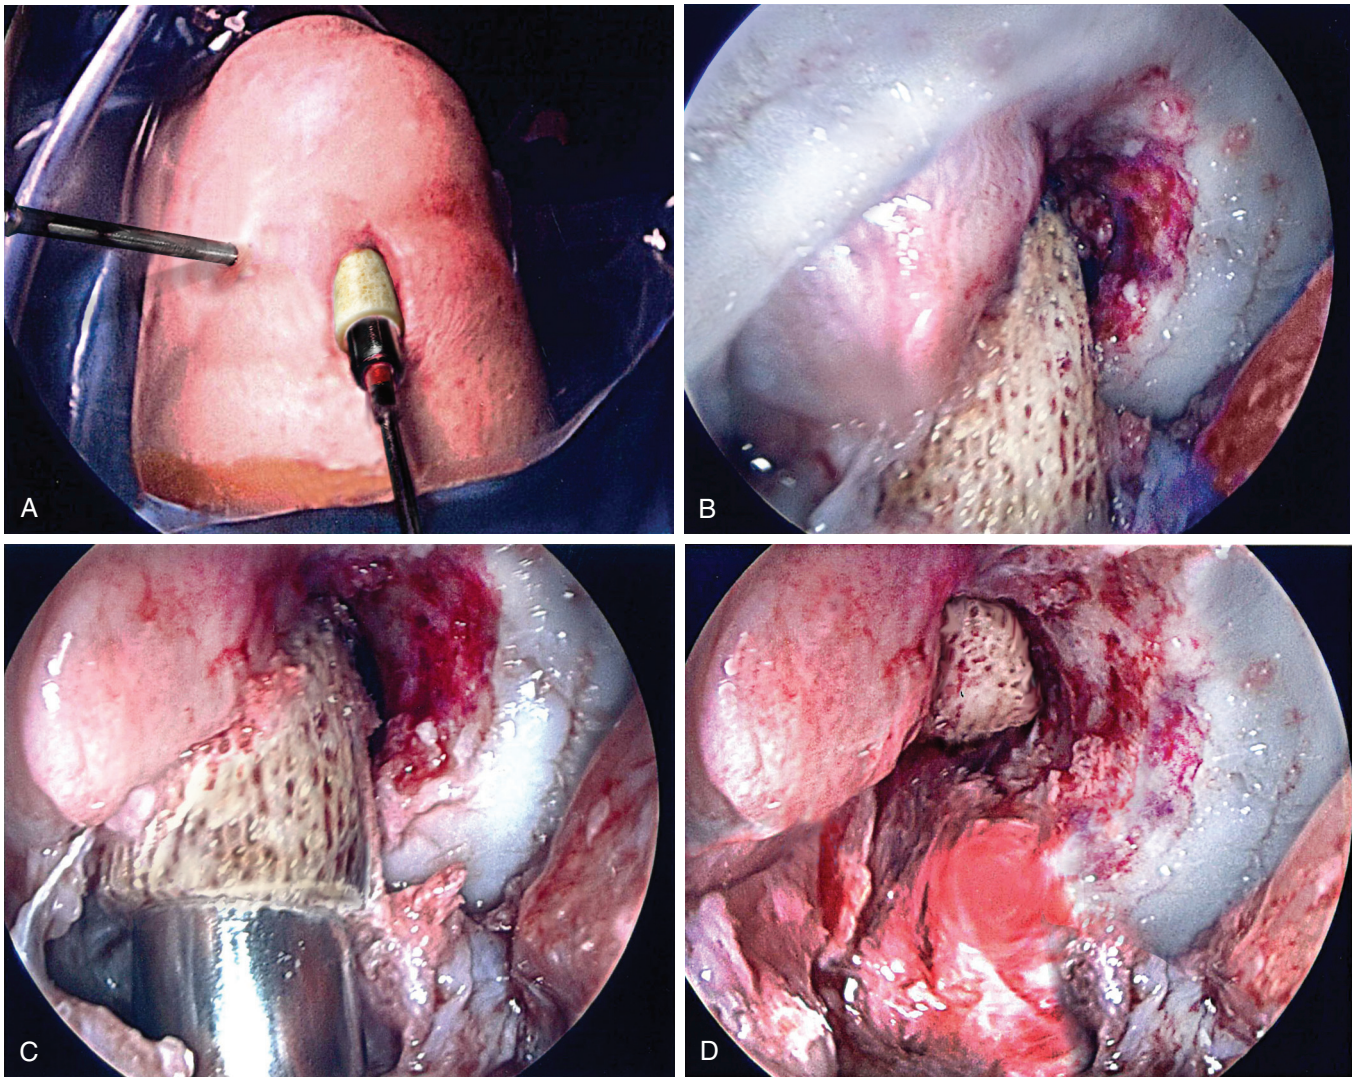

FIG 8-6 Demonstration of bone grafting with core (freeze-dried) allograft of a large vertical femoral tunnel for staged anterior cruciate ligament (ACL) revision reconstruction. First, the tibial and femoral tunnels are debrided and drilled to a constant diameter. **A,** Insertion of core bone graft through existing tibial tunnel. **B,** Careful technique is used as the bone graft enters the femoral tunnel under arthroscopic control. **C,** Impaction of the femoral bone graft into the tunnel. **D,** Final appearance of bone grafted femoral tunnel.

obscured by soft tissues, and the RER or posterior interspinous ridge of the PCL fossa is an important landmark. The center of the ACL will be 16 to 20 mm anterior to the RER or interspinous ridge. The guide pin is placed eccentric and 2 to 3 mm anterior and medial to the true ACL center as the ACL graft displaces to the posterior and medial aspects of the tibial tunnel.[13] This eccentric tunnel places the majority of the graft within the ideal central tibial attachment.

It is important to determine the graft length of the autograft or allograft to ensure a mismatch does not occur between intraarticular length of the tunnel and the length of the graft. The most common problem is with a patella alta and a B-PT-B length greater than 100 mm. The length of the patellar tendon is determined on preoperative lateral radiographs. The normal patellar length based on the Linclau technique[56] (patellar cartilage length to anterior vertical tibial prominence; see Chapter 38) is a 1:1 ratio with the patellar tendon in the 35- to 45-mm range. The intraarticular ACL length is measured on the lateral MRI, and this length is matched with an autograft or allograft. It is possible to accommodate a shorter length patellar tendon by adjusting the proximity of the tibial tunnel. A patella alta with a tendon length greater than 50 mm is usable with the bone portion of the graft adjusted in the tibia and femoral tunnels. A two-incision technique allows adjustment of graft length by proximal advancement in the femoral tunnel and is ideal when there is graft mismatch caused by an excessively long patellar tendon. In rare instances, with a long B-PT-B graft, the tibial bone plug is rotated 180 degrees onto the tendon, sutured to the bone plug, and the tibial tunnel resized. The bone plug sutures are tied to a tibial post. With a graft length mismatch, we do not recommend removal of the bone plug to shorten overall graft length or multiple twisting of the graft.

The ideal tibial tunnel is placed in a coronal manner, at a 55- to 60-degree angle, allowing a tunnel length of 35 to 40 mm. The tunnel is usually 15 mm medial to the tibial tubercle and 10 mm distal to the most proximal point of the patellar tendon tibial tubercle insertion.

A core reamer is used to remove a tibial bone plug when a B-PT-B or QT-PB autograft is used to obtain a core of bone to fill the graft bone defects. As already described, the core reamer provides a more

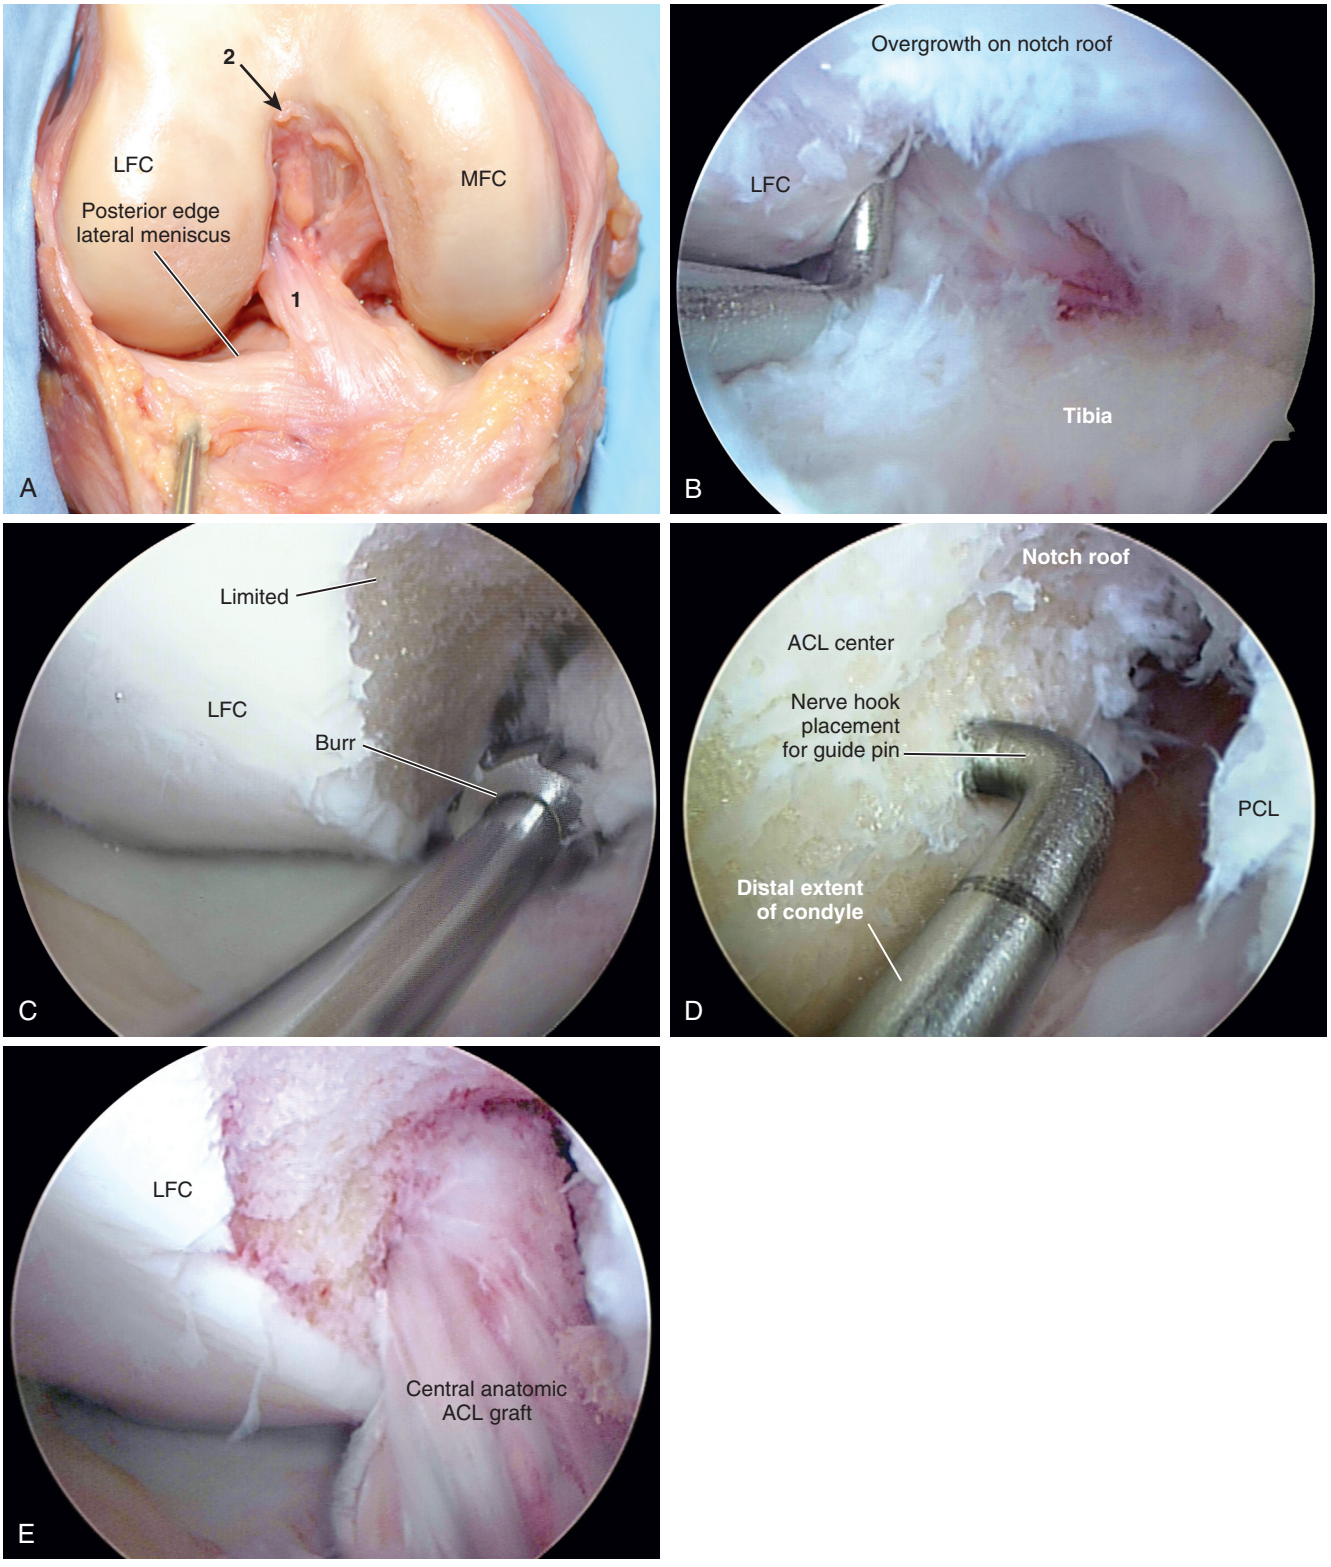

FIG 8-7 **A,** A normal femoral notch is shown, which is viewed at arthroscopy by using the anteromedial portal. *1* shows the normal space between the medial femoral condyle and the posterior cruciate ligament (PCL) which is occupied by the anterior cruciate ligament (ACL). *2* shows the normal anterior notch that should not impinge on the graft. **B,** Revision ACL with failed ACL graft shows overgrowth of the lateral notch and notch roof, requiring a limited notchplasty. **C,** The lateral notch wall is visualized entirely posteriorly to the articular cartilage of the femoral condyle. **D,** The ACL femoral attachment is mapped out and a central small hole is made for placement of the guide pin. The resident's ridge has been removed. The anterior notch region has not been disturbed. **E,** Final placement of a single-bundle graft within a central anatomic tibial and femoral placement that occupies over 75% of the attachment site. *LFC*, Lateral femoral condyle; *MFC*, medial femoral condyle.

CRITICAL POINTS Operative Techniques: ACL Bone-Patellar Tendon-Bone Graft Anatomic Tibial and Femoral Technique

Placement of Tibial Tunnel

- Define center ACL, usually 16 to 20 mm anterior to tibial RER or interspinous ridge.
- Mark ACL center, usually adjacent and always anterior to posterior edge of lateral meniscus anterior horn attachment.
- Place guide pin eccentric and 2 to 3 mm anterior and medial to true ACL center.
- Determine graft length of patellar tendon on MRI.
- Two-incision technique allows graft length to be adjusted by proximal advancement of femoral tunnel.
- Place tibial tunnel in coronal manner, 55- to 60-degree angle, tunnel length 35 to 40 mm.
- Begin tunnel adjacent to superficial MCL, 15 mm medial to tibial tubercle medial border, 10-mm distal proximal patellar tendon insertion.
- Use core reamer to obtain good-quality bone to fill bone defects.
- Drill tunnel, chamfer edges.

Placement of Femoral Tunnel

- Use either two-incision technique (open or flip drill) or anteromedial portal with knee hyperflexed 120 degrees.
- Two-incision technique: Drill tunnel retrograde or antegrade procedure.
- Perform femoral notchplasty to avoid graft impingement.
- Identify ACL attachment with knee in 20 to 30 degrees of flexion, scope in anteromedial portal.
- Place guide pin within central ACL attachment. Always preserve 3 to 4 mm of posterior back wall of the tunnel so that the graft is not placed too far posteriorly. A guide pin placed 8 mm from the posterior articular cartilage at the central ACL attachment will have a 4-mm posterior back wall for an 8-mm graft.
- Drill tunnel, chamfer edges.

Graft Tunnel Passage, Conditioning, and Fixation

- Pass graft gently in retrograde arthroscopically assisted.
- Bring graft proximally until bone is flush with tibia.
- Femoral position of graft at or just proximal to inside femoral tunnel.
- Fix femoral bone graft plug with interference screw.
- Condition graft, 44-N tension, flex knee 0 to 135 degrees, 40 cycles.
- Verify position arthroscopically, no impingement.
- Place knee in 20 degrees of flexion, reduce tension to 10 to 15 N.
- Place interference screw tibia. Use additional sutures tied over suture post if required.
- Perform Lachman test, ensure no overconstraint.
- For STG graft, femoral fixation: Post with sutures and absorbable interference screw if necessary. Tibial fixation: Interference screw plus suture post.

suitable graft material than drill reamings, and the bone defects are filled in an anatomic manner that results in the patient able to kneel on the tibial bone harvest site.

The tunnel is drilled to the desired graft diameter and the joint tunnel edges chamfered to prevent graft abrasion.

Placement of Femoral Tunnel

As previously described, either a two-incision technique, FlipCutter (Arthrex), or AM portal femoral tunnel placement (or flexible drill system) with knee hyperflexion technique is used. These techniques are illustrated in Chapter 7. Baer and associates[5] reported in a cadaver study that at least 110 degrees of knee flexion is required for femoral tunnel drilling through the AM portal (with nonflexible drills) to avoid potential injury to the peroneal nerve, the lateral condylar articular surface, the fibular collateral ligament (FCL), and the popliteus tendon. The use of the AM portal to place the femoral tunnel has the problem in some knees of difficulty with visualization at 100 to 120 degrees of flexion, the potential for the drill to damage the medial femoral condyle, and a shorter femoral socket, which may be a problem with a B-PT-B autograft. The flexible guide system is the senior author's preferred technique. As with any of the ACL techniques, surgeon experience is necessary to achieve a successful result.

In revision knees when the femoral tunnel is close to a prior tunnel, the two-incision procedure allows the guide pin to be more accurately placed and the tunnel divergence angle to be controlled more accurately than the endoscopic procedure. Importantly, the two-incision procedure carries a smaller risk of placing a less than ideal femoral tunnel, as there have been cases where endoscopic revision is performed and the tunnel breaks into the old tunnel, producing a more complex problem.

In the two-incision technique, a lateral incision 2 to 3 cm in length is made at the distal femoral metaphysis and posterior third of the ITB. The posterior third of the ITB is incised for 4 to 6 cm to allow exposure. The interval posterior to the vastus lateralis is entered and the muscle protected. An S retractor is placed beneath the vastus lateralis obliquus (VLO) to gently lift the muscle anteriorly, avoiding entering the proximal joint capsule. The proximal edge of the lateral femoral condyle is bluntly palpated with an instrument (over-the-top location), with the goal of locating the tunnel entrance just anterior and not distal to this point. A 15-mm periosteal incision is made and an elevator used to remove soft tissues from the site for the tunnel proximal entrance. An alternative procedure is to use a FlipDrill to create a femoral socket, as when the TightRope (Arthrex) technique is used (see Chapter 7).

In most revision knees, there is an overgrowth of cartilage and spur formation in the femoral notch, requiring a notchplasty to prevent ACL graft impingement. The notchplasty rules taught by the senior author since the mid-1980s are described in detail in Chapter 7. The ACL femoral attachment is mapped based on the bony landmarks already described. The location of the guide pin for an ACL central femoral tunnel is shown in Chapter 7. The guidewire is placed within the central ACL attachment, which is midway between the lateral notch roof and the distal articular cartilage edge (2:00 to 2:30 o'clock position), 8 mm from the posterior articular cartilage edge. Clock locations are actually an inaccurate description of the tunnel location.[22,23] With the central femoral tunnel, the posterior back wall is 3 to 4 mm thick and the graft occupies approximately two thirds to three fourths of the ACL footprint. Always preserve 3 to 4 mm of the posterior back wall of the tunnel so that the graft is not placed too far posteriorly. Grafts placed too far posteriorly will have increased tension with knee extension of the graft into the tibial tunnel and may potentially block full extension. A guide pin placed 8 mm from the posterior articular cartilage at the central ACL attachment will have a 4-mm posterior back wall for an 8-mm graft. A guide pin placed 10 mm from the posterior articular cartilage at the central ACL attachment would have a 5-mm posterior back wall for a 10-mm graft. One key to define the ACL attachment is to place the knee in 20 to 30 degrees of flexion viewed through the AM portal and map out the oval attachment and center point, measuring the distance to the posterior articular cartilage. The senior author prefers this mapping technique with partial knee flexion rather than at 90 degrees of flexion. Once the ideal center point is selected, the knee is flexed to the position desired. It is easier to mark out the ACL femoral attachment when it is viewed in a vertical plane

rather than the horizontal attachment plane with knee flexion. The tunnel is drilled to the appropriate diameter for a snug graft fit in the tunnel. The edges of the tunnel are chamfered to prevent graft abrasion.

Graft Tunnel Passage, Conditioning, and Fixation

The graft is passed in a retrograde manner either with a Beath pin in the endoscopic technique (placed through the AM portal) or in the two-incision technique with a 20-gauge looped wire passed from the femur to the tibial tunnel. The graft is gently lifted up through the tibia and guided into the femoral tunnels with a nerve hook. It is marked at the bone-tendon junction to adjust its length in each tunnel, and is brought proximally until the bone is flush with the tibia. In most knees, the femoral portion of the graft is at or just proximal to the inside femoral tunnel. The femoral bone graft plug is fixed with an interference screw of a metallic or absorbable type. Graft conditioning is performed by placing approximately 44 N tension on the distal graft sutures and flexing the knee from 0 to 135 degrees for 30 to 40 flexion-extension cycles. The arthroscope is placed to verify that the graft position is ideal and there is no impingement against the lateral femoral condyle or notch with full hyperextension. Appropriate notchplasty is performed when necessary. The knee is placed at 20 degrees of flexion, and the tension on the graft is reduced to approximately 10 to 15 N to avoid overconstraining AP tibial translation. A finger is placed on the anterior tibia to maintain the posterior gravity position of the tibia. An alternative procedure is to fixate the graft with a larger graft tension at 0 degree; however, the senior author believes there is more control of graft tension at the partially flexed position. An interference screw is placed. In cases where the interference screw fixation is not ideal or the screw resistance on placement is not acceptable, the sutures are tied over a suture post. The arthroscope is placed into the joint and final graft inspection performed. A Lachman test is performed and there should be total AP translation motion of 3 mm, indicating that the graft has not been over tightened. If the graft has a "bowstring," tight appearance with little to no anterior tibial translation on testing, the distal tensioning and fixation procedure is repeated with less tension placed on the graft.

Techniques Using Other Grafts

With all other grafts, the same procedure is used with the following exception. In the two-incision technique with a STG graft, a femoral post is always used with the sutures tied first at the femoral site about the post (35 mm, 4.0 mm cancellous self-cutting screw with washer). An absorbable interference screw is added if the graft tunnel interface is not tight. At the tibia, the interference screw is first placed, followed by the suture post fixation. Using the combined interference screw and suture post provides sufficient graft strength fixation for rehabilitation to proceed equal to the B-PT-B graft. The bone portion of the QT-PB is usually placed into the femoral tunnel; however, the graft can be reversed with the bone plug placed into the tibial tunnel and located appropriately to make up for an enlarged tibial tunnel that requires the bone portion of the graft.

A variety of techniques for femoral and tibial fixation are available, based on the preference of the surgeon and have been described in detail (see Chapter 7). The tibial fixation is usually the weakest and a suture post may be required. Interference screw fixation alone of an STG or soft tissue allograft is not recommended.

The postoperative rehabilitation program is described in Chapter 11. We do not administer preoperative or intraoperative intraarticular anesthetic injections because of the known adverse effects on articular cartilage.[39,48,87]

Alternative Procedures

Alternative approaches to ACL reconstruction, including use of the FlipCutter or flexible reamers and guide pins to drill the femoral tunnel, and the all-inside ACL Graft-Link technique that uses the FlipCutter and TightRope devices are described in detail in Chapter 7.

Iliotibial Band Extraarticular Reconstruction

Clinical studies (Noyes and Barber[70] and Ferretti and coworkers[27]) have shown significant improvements in the pivot shift test in chronic and revision knees with gross instability and loss of secondary lateral restraints that had a concomitant extraarticular reconstructive procedure for additional restraint of abnormal tibial internal rotation.[18] The goal is to reconstruct the posterior femorotibial ITB attachment that is an important restraint to abnormal internal tibial rotation. The lateral capsular fibers (referred to as the anterolateral ligament [ALL][12]) may be plicated at surgery. The ALL graft reconstructive procedure is discussed (see Anterolateral Ligament Reconstruction).

The primary indication for a lateral extraarticular reconstruction is a grade III pivot shift on knee examination, indicating loss of the ALL and ITB tibiofemoral osseous fibers (described in Chapter 3). The senior author has successfully used this procedure in grossly unstable revision knees in which an added lateral restraint resists abnormal lateral compartment anterior translation and reduces forces on the ACL graft reconstruction. The extraarticular reconstruction is also of benefit in certain situations where an allograft or STG autograft is used and viewed as a weaker ACL construct, whereby the extraarticular reconstruction provides an added measure of graft protection. In our study,[70] an ITB extraarticular reconstruction significantly reduced the rate of failure of ACL allograft reconstructions compared with a group of knees that did not have this concomitant procedure (3% and 16%, respectively; $P < .05$). It is important to note that involvement of the FCL along with the other lateral extraarticular structures indicates an insufficiency of the posterolateral complex and the operative procedure would involve a posterolateral reconstruction (see Chapter 17). Although extraarticular reconstructions may be indicated more frequently in chronic, grossly unstable revision knees, the roles of an ITB tendosis and ALL graft reconstruction have not

CRITICAL POINTS Operative Techniques: ITB Extraarticular Tenodesis

- Lateral incision 8 to 10 cm in length at the mid-lateral aspect of the knee extending from Gerdy's tubercle proximally.
- Strip of ITB incised, 12 mm wide, 18 to 20 cm long, tibial attachment kept intact.
- Identify femoral attachment ITB: deep fiber insertion to femur, confirm isometric femoral point for screw placement.
- Knee 30 degrees of flexion, neutral tibial rotation.
- Loop ITB strip around soft tissue washer and screw and back to Gerdy's tubercle. Fixate graft at femoral site.
- Suture ITB strip to itself under only mild tension, including posterior ITB fibers.
- Take knee through internal-external tibial rotation to ensure no constraint to normal rotation.
- Close ITB absorbable sutures.
- Examine medial patellar medial glide for normal mobility, do not close or overtension lateral iliopatellar tissues.

been clinically determined and are not yet recommended in acute, first-time ACL reconstructions.

A lateral incision 8 to 10 cm in length is made at the mid lateral aspect of the knee extending from Gerdy's tubercle to the lateral femoral condyle proximally. The skin incision is undermined by subcutaneous dissection to increase the skin mobility and shorten the incision for cosmetic purposes. A strip of ITB is incised proximal to distal from the posterior one third of the band, which is 12 mm wide and 18 to 20 cm long with the tibial attachment intact (Fig. 8-8).

The most isometric point for the femoral attachment of the graft, proximal and posterior to the lateral femoral condyle, is located (see Fig. 8-8, *D*) and tested by using a guide pin placed at this site. This location is usually just distal to the lateral intramuscular septum, posterior and proximal to the lateral epicondyle, and anterior to the gastrocnemius tubercle lateral attachment. The error is to place the ITB graft too anterior, which blocks knee flexion and constrains internal tibial rotation. The posterior placement allows the ITB graft to undergo increasing tension with knee extension. This area is curetted to remove soft tissues to allow for the ITB strip to be in contact with the overlying bone.

The extraarticular graft attachment points have also been reported by Kittl and associates.[52] These authors found that a graft that was attached proximal to the lateral femoral epicondyle and passed deep to the FCL also provided desirable graft behavior. In addition, a graft placed anterior to the lateral femoral epicondyle showed undesirable tension and lengthening with knee flexion. Unfortunately, this study reported graft length changes only with knee flexion and extension and the effect of internal-external tibial rotation was not assessed.

When tensioning the ITB graft, do not overconstrain the joint and block normal internal tibial rotation. After the ACL procedure is completed, the extraarticular tensioning and fixation are performed. The knee is placed at 30 degrees of flexion and neutral rotation. The ITB strip is fixated around a soft tissue washer (Fig. 8-9) and cancellous screw and brought back upon itself to Gerdy's tubercle. The screw is angulated anteriorly away from the ACL tunnel. The ITB graft is then sutured to itself with only slight tension. Sutures are also placed through the graft and posterior third of the remaining intact ITB. This produces a strong restraint to abnormal internal tibial translation and anterior tibial translation. The knee is taken through normal internal-external tibial rotation to ensure that there is no abnormal constraint to internal tibial rotation. The knee is flexed to 135 degrees; usually, increasing knee flexion will provide for increased tension in the graft. There is no true isometric point for the femoral attachment of the graft for flexion-extension and tibial rotation motions. It is probable that even with precautions taken to not overconstrain knee motion, regaining full knee flexion may be more difficult when the extraarticular procedure is performed.

The ITB is closed with absorbable sutures throughout the site where the graft was harvested. The patellar medial glide is examined at 30 degrees of knee flexion to ensure that closing the ITB does not limit the normal patellar mobility. The patella should have at least 10 mm of medial glide with a medially directed manual translation. If there is an abnormal restraint to medial patella mobility, a small lateral release is performed. The anterior fibers of the ITB, which comprise the lateral retinaculum adjacent to the patella, are incised the required length to relieve the undue tension on these soft tissues from closing the ITB defect, thereby avoiding a release of the vastus lateralis tendon.

In the 1980s when extraarticular procedures were used, it was common for the ITB graft to be routed underneath the FCL and then sutured to itself at Gerdy's tubercle (Cooker-Arnold procedure). However, this represents a nonanatomic placement of the ITB graft. In addition, there is concern that a soft tissue structure wrapped around the FCL could induce stretching of the FCL and allow for an increase in lateral joint opening. It is recommended to secure the ITB graft to the femoral attachment as discussed and to avoid looping the graft around the FCL.

Recent robotic studies have been conducted at our laboratory on the effect of the extraarticular reconstruction in limiting anterior tibial translation of the lateral tibiofemoral compartment (Fig. 8-10). The reconstruction had a statistically significant effect in reducing the magnitude of lateral compartment translation in the simulated pivot shift test (loading conditions, anterior translation 100 N, internal rotation 1 N-m, valgus 5 N-m).

In summary, our clinical studies have shown that the surgical technique of the ITB tenodesis has proven successful, particularly in grossly unstable chronic and revision knees with a grade III pivot shift.

Anterolateral Ligament Reconstruction

Sonnery-Cottet and associates[93] described a reconstructive procedure for a deficient ALL. The procedure uses two small incisions and is less invasive compared with the open ITB tenodesis procedure previously described. There are insufficient clinical data on the indications and outcomes of this technique; however, it would appear to fulfill similar conditions and indications that we have used for the open ITB tenodesis procedure. Sonnery-Cottet and associates[93] described further indications of a high level of sporting activity, participation in pivoting sports, chronic ACL rupture, an associated Segond fracture, and a lateral femoral notch sign on radiographs in patients with a grade I or II pivot shift. These authors reported short-term outcomes of a combined ALL and a single-bundle ACL reconstruction in 92 patients. The procedure failed in one knee and seven others sustained a contralateral ACL rupture. In 83 patients followed a mean of 32 ± 4 months postoperatively, 76 had a grade 0 and 7 had a grade I pivot shift. All returned to sports, although 24 did so at a lower level. The authors acknowledged that longer term and comparative clinical studies are required to determine if this combined reconstruction is warranted to improve the results of ACL reconstruction.

Dodds and associates[19] and Kennedy and coworkers[50] reported in anatomic studies that the ALL inserts just proximal and posterior to the lateral femoral epicondyle. The ALL has an oblique course to the anterolateral aspect of the proximal tibia, with attachments to the lateral meniscus, enveloping the inferior lateral geniculate artery and vein. It inserts onto the anterolateral tibia midway between Gerdy's tubercle and the tip of the fibular head, separate from the ITB.

A semitendinosus autograft is used for ALL reconstruction because the cross-sectional area, length, and ultimate loads provide sufficient anatomic and mechanical properties. The minimum graft length is 8 to 9 cm, and the graft is whipstitched 15 mm at one end with a zero or 2-0 FiberWire loop suture. The graft should be tapered at the whipstiched end to facilitate insertion of the graft into the femur. The description of the procedure is shown in Figure 8-11.

The senior author's suggestions and modifications of this technique are as follows. It is important that the femoral guide pin (see Fig. 8-11, *C*) is located 6 to 8 mm posterior and 4 mm proximal to the center of the femoral epicondyle to obtain a graft location that does not have abnormal tension with knee flexion. If the pin is anterior to this location, the graft will undergo large tensile loads with flexion that will risk graft pull-out with early knee motion postoperatively. The senior author determines the isometricity of the graft at this point, using a suture passed over the pin and placed at the

Text continued on p. 241

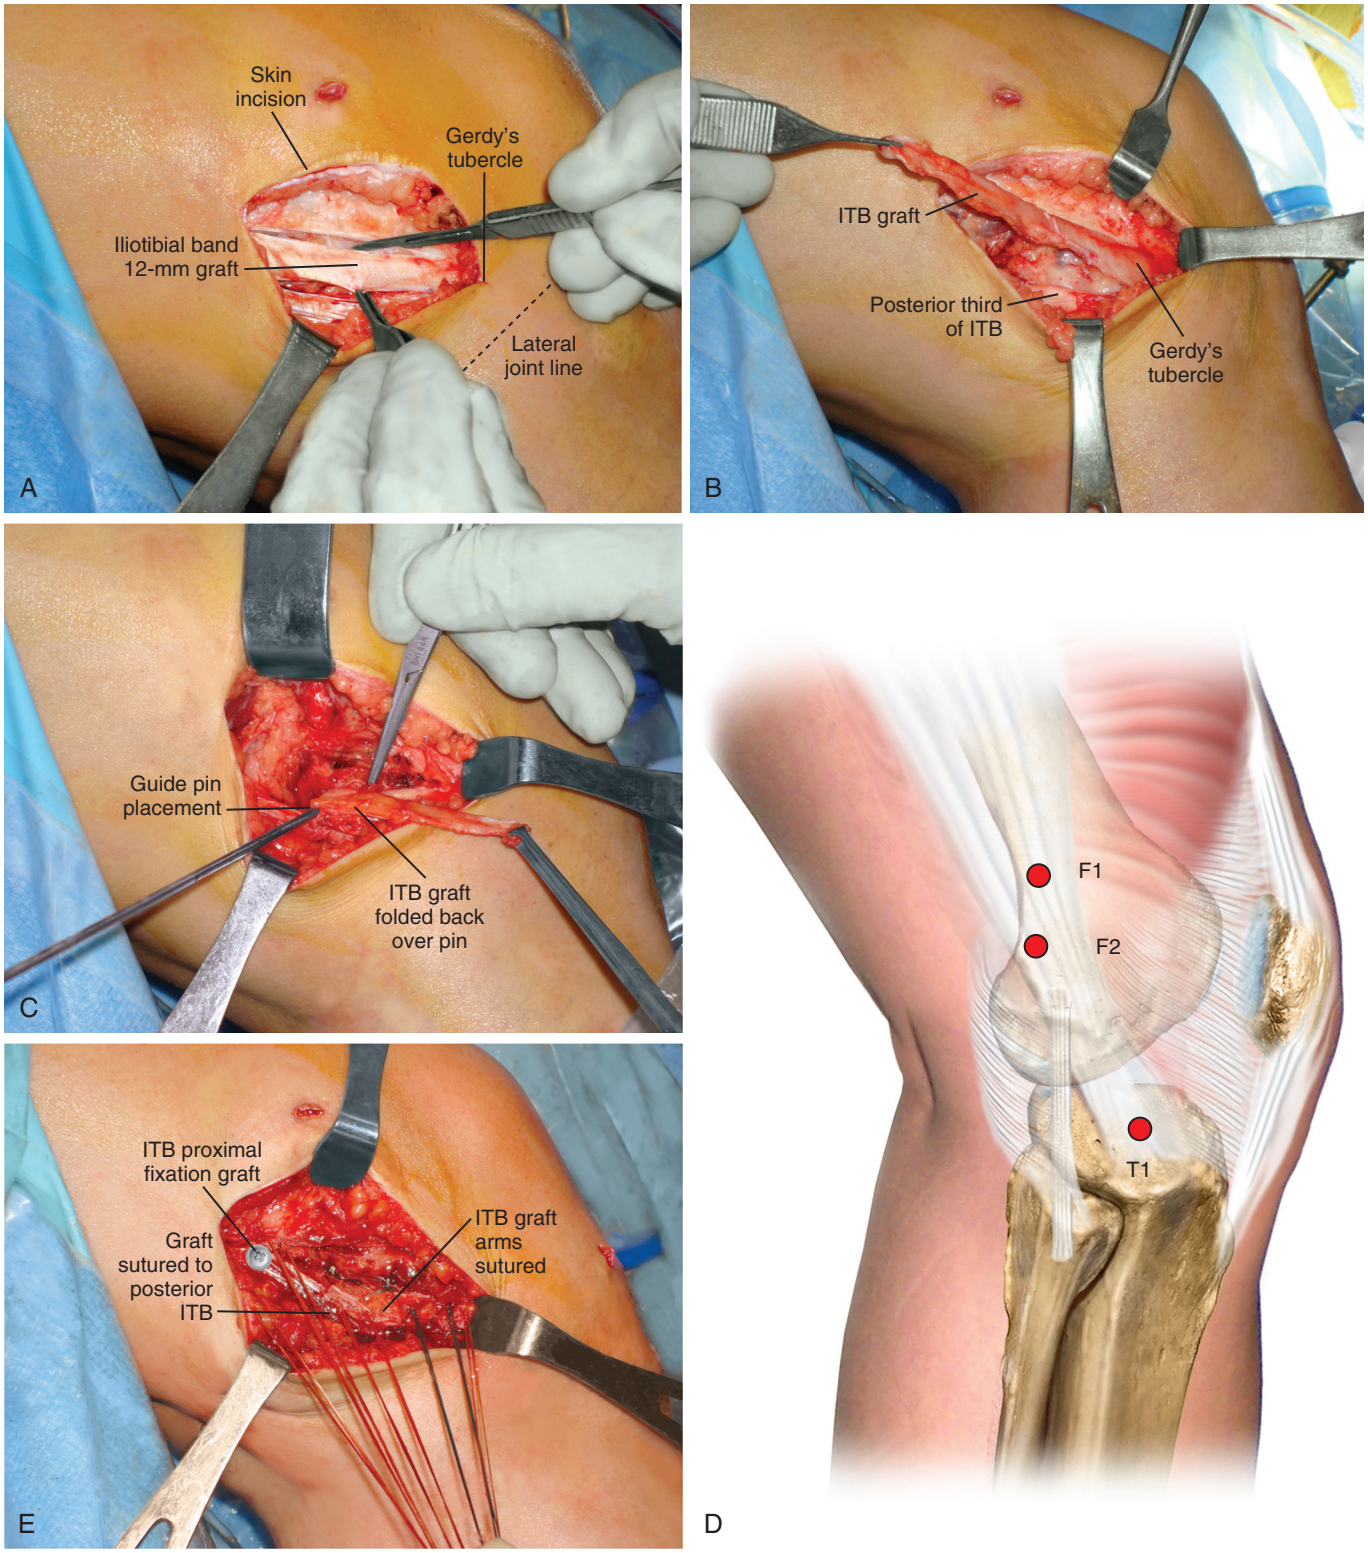

FIG 8-8 **A,** Cosmetic lateral incision is made just proximal to Gerdy's tubercle. A 10-mm strip along the posterior half of the iliotibial band (ITB) is harvested. The proximal skin flap is undermined to obtain a 20-mm long graft. **B,** The ITB graft (10 mm wide) is dissected distally to Gerdy's tubercle where the tibial attachment is left intact. **C,** The ITB graft is looped around a guide pin placed just distal to the lateral intermuscular and proximal to the fibular collateral ligament attachment. The knee is flexed from 0 to 135 degrees, neutral tibial rotation. **D,** The "isometric points" graft attachment sites for an extraarticular reconstruction as measured by Kurosawa et al. The points *T1-F1* provided the least change in length with knee flexion (maximum percentage of strain, 11.6% ± 3.0%). The points *T1-F2* offer a second choice, except that there is an increase in the percentage of strain with knee flexion compared with *T1-F1*. **E,** The graft is looped around a soft tissue screw and washer and both graft ends are sutured to each other and the remaining posterior ITB. This forms a strong femoral-tibial structure that both incorporates the graft and reproduces the normal posterior ITB femoral tibial attachments. The knee is in neutral tibial rotation and graft overtensioning is avoided.

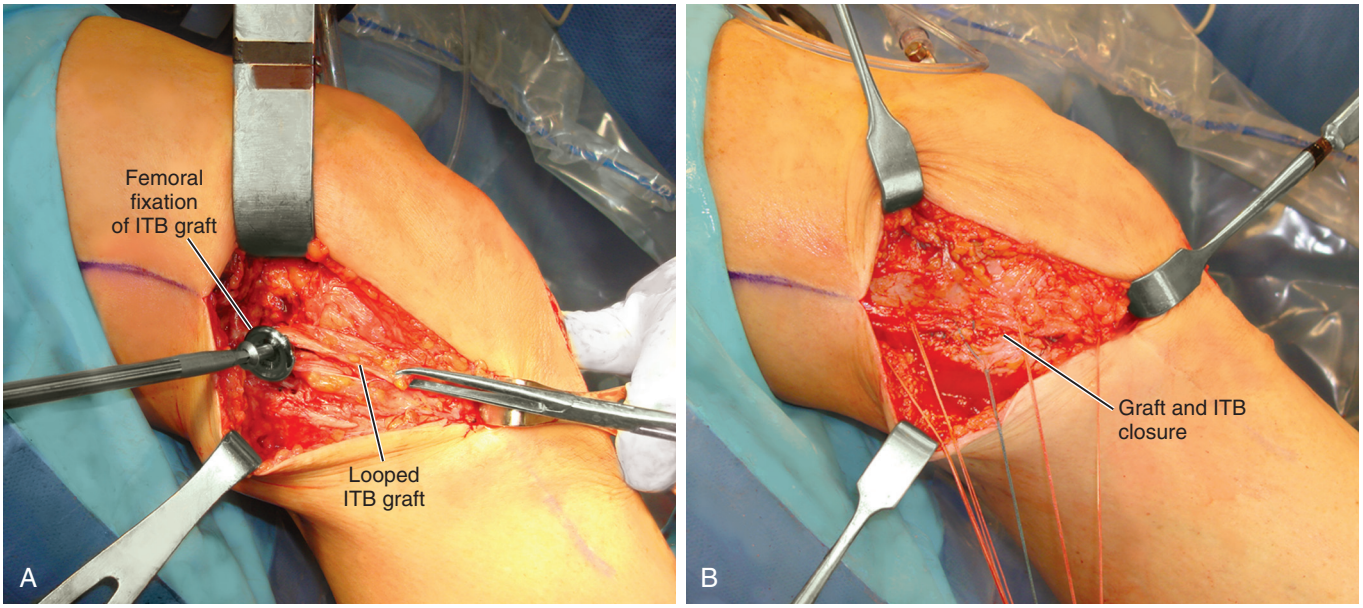

FIG 8-9 **A,** Extraarticular iliotibial band (ITB) graft is shown looped around a soft tissue screw and anchor in a second patient. **B,** Final closure of the overall remaining ITB to the looped ITB graft.

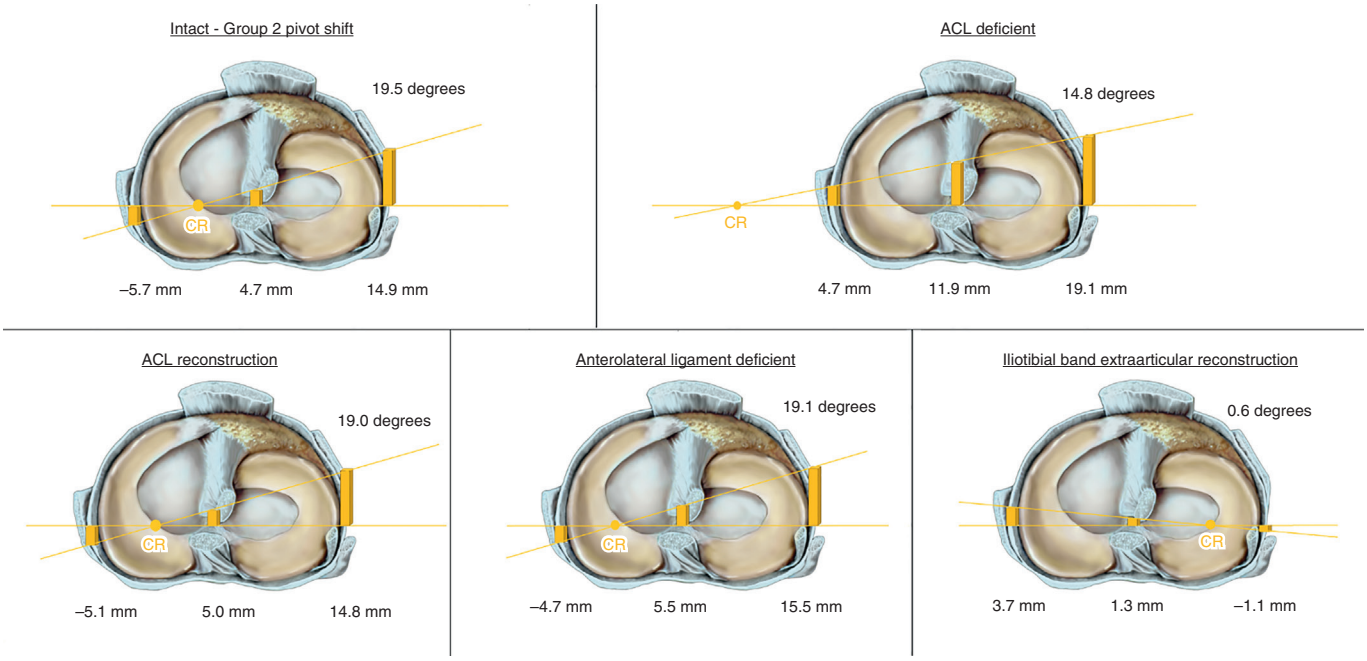

FIG 8-10 A representative right knee specimen in an in vitro robotic study showing compartment translations and tibial rotation under pivot shift loading conditions (100-N anterior, 1 N-m internal rotation, 7 N-m valgus). Note the difference in the intact and anterior cruciate ligament (ACL)-deficient states, which shows major increases in all three compartment translations. The ACL reconstruction with a bone-patellar tendon-bone graft placed in the center anatomic ACL tibial and femoral native sites restored compartment translations to the intact condition. Sectioning the anterolateral ligament produced no differences in compartment translation. The operative procedure of an iliotibial band reconstruction (see Fig. 8-9) does have a marked effect in limiting anterior translation of the lateral compartment. The indications for this procedure are discussed in greater detail in the text. *ALL*, Anterolateral ligament; *CR*, center of tibial rotation.

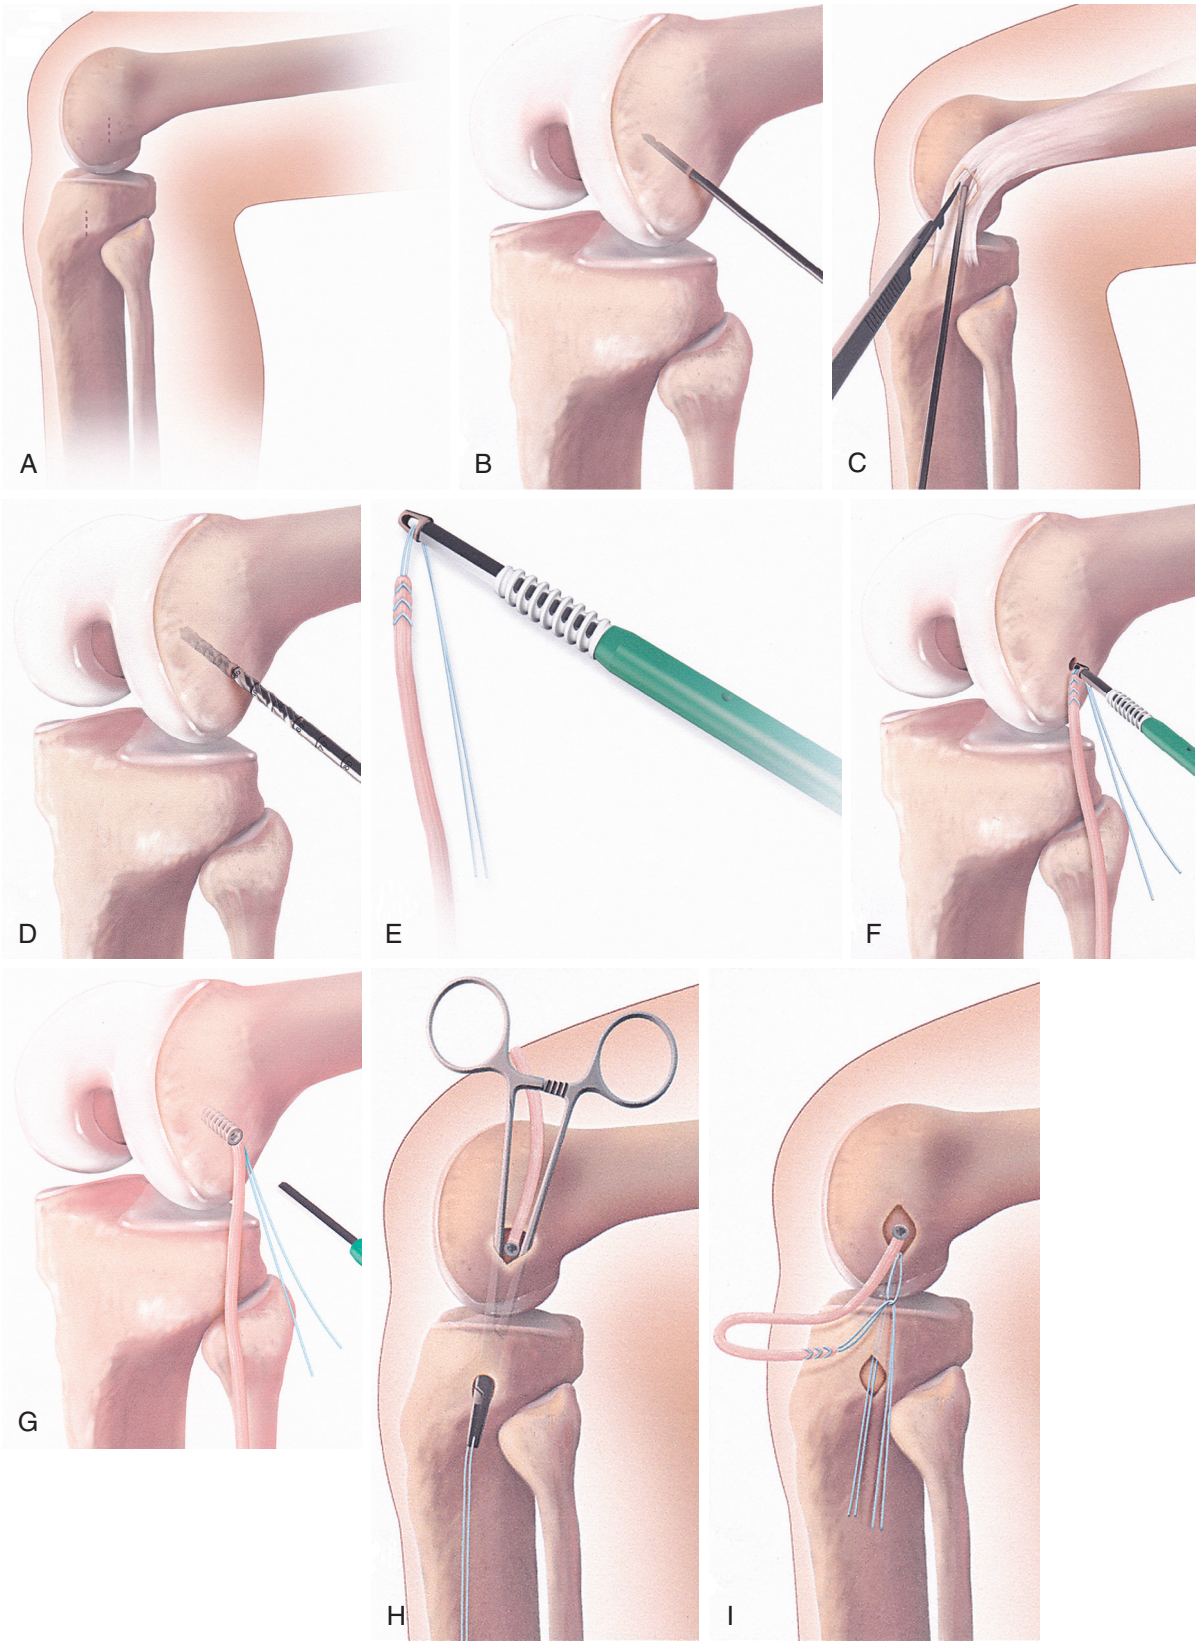

FIG 8-11 The anterolateral ligament (ALL) reconstruction, as described by Steven Claes, MD. **A,** The femoral stab incision is made just posterior to the lateral epicondyle and the tibial stab incision is made midway between Gerdy's tubercle and the center of the fibular head. **B** and **C,** On the femur, drill the 2.4-mm guide pin for the 4.75-mm SwiveLock (Arthrex) slightly proximal and approximately 6 to 8 mm posterior to the lateral epicondyle. Aim slightly anterior and proximal to avoid drilling into the femoral socket of the anterior cruciate ligament reconstruction. After the pin is drilled, split the iliotibial band (ITB) around it with a scalpel to facilitate the insertion of the SwiveLock. **D,** Overdrill the guide pin with a 4.5-mm drill to drill to a depth of 20 mm. **E,** Load the whipstitched sutures of the graft through the PEEK eyelet of the 4.75-mm SwiveLock. **F** and **G,** Insert the SwiveLock into the drilled hole. Ensure the eyelet is fully seated so that the threads of the SwiveLock anchor have started to touch the bone. Hold the paddle of the SwiveLock and turn the knob to insert the anchor. The SwiveLock sutures are removed. **H** to **J,** Use a curved hemostat to dissect underneath the ITB to create a plane from the femoral incision to the tibial incision. Place a passing suture from distal to proximal with the hemostat. Use the passing suture to pass the graft to the tibial side. *Continued*

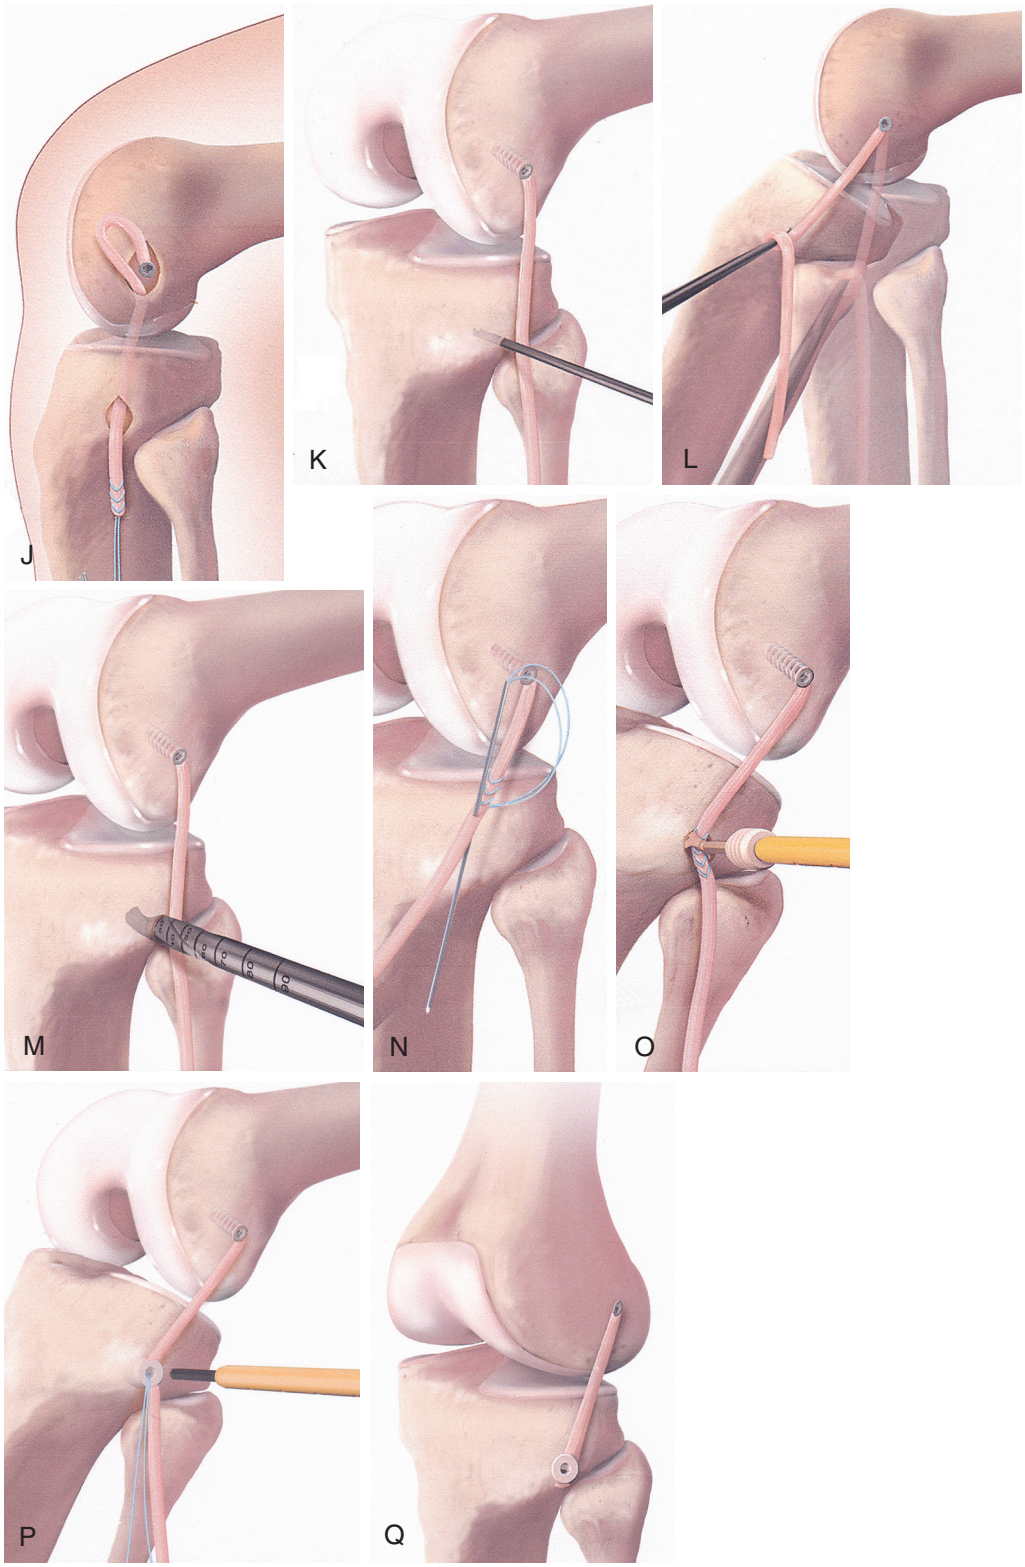

FIG 8-11, cont'd **K,** Drill a 2.4-mm guide pin 22 mm posterior to Gerdy's tubercle and 10 mm distal to the joint line. This should also be the approximate midpoint between Gerdy's tubercle and the center of the fibular head. **L,** Test the isometry of the graft by wrapping it around the pin and moving the leg through the range of motion. The graft should be isometric between 30 and 90 degrees of flexion. The graft should become slightly looser as the knee reaches full extension. **M,** Overdrill the guide pin with a 7-mm cannulated drill to a depth of 20 mm. **N,** Hold the graft to the drilled hole and mark it at that location. Whipstitch the graft distally from the mark, using a No. 2 FiberLoop. This will allow the whipstitches to enter the drilled hole with the SwiveLock and increase the pull-out strength of the graft. **O,** Place the 7-mm forked Tenodesis SwiveLock over the graft. Push the forked end into the tunnel and adjust the tension by pulling on the graft. It is important not to overconstrain the ALL. **P,** Fix the anchor with the knee in 60 degrees of flexion and neutral rotation. Once the anchor is in place, remove the sutures. Cut the end of the graft exiting the tibial socket. **Q,** Final appearance of the ALL reconstruction. (Courtesy Arthrex, Inc., Naples, Florida.)

selected tibial insertion point shown in Figure 8-11, *L*. This allows the femoral graft fixation site to be relocated if necessary. In select knees where there is osteopenia from disuse, or in revision knees, a larger diameter SwiveLock (Arthrex; 8 mm) may be required for adequate fixation. The drill would accordingly be larger in size as required. A modification of the tibial preparation and fixation may be required in osteopenic knees in which the sutures are placed in a transtibial beef pin that allows tensioning of the graft, along using a fully threaded interference screw. The senior author tensions the graft under very low loads (approximately 8-10 N) at 60 degrees of knee flexion and neutral tibial rotation. The knee is taken through a range of motion from 0 to 120 degrees at surgery with neutral rotation under very low tension. Accordingly, the graft will be under increased tension with internal rotation and under no tension with external tibial rotation.

OUR ANTERIOR CRUCIATE LIGAMENT REVISION CLINICAL STUDIES

We conducted three prospective studies on ACL revision reconstruction to determine the causes of failure of the previous operations and effects of revision graft type, concurrent ligament reconstructive procedures, and joint damage on patient outcome.[74,75,77] A total of 145 patients were entered into these investigations, of whom 141 (97%) were followed with formal research visits at our center 2 to 7 years postoperatively. In all patients, the grafts were placed within the ACL anatomic footprint of the femur and the anterior-central portion of the ACL tibial footprint. Patient outcome was assessed using the CKRS and KT-2000 testing. A fourth investigation was conducted to determine the causes of ACL reconstruction failure in a large cohort of patients who presented to our center for consideration of a revision procedure.[61]

Anterior Cruciate Ligament Revision Using Quadriceps Tendon-Patellar Bone Autografts

In 2006, we reported the results of a prospective study of 22 consecutive patients who received a QT-PB autograft ACL revision reconstruction.[75] Twenty-one patients (95% follow-up) were followed for a mean of 4.1 years (range, 2.1 to 6.9 years) postoperatively. Sixty operative procedures had been done before the revision operation, including 32 ACL procedures. Six PL procedures had been done in five knees, of all but one of which had failed. An HTO was done in four knees at our center and in one knee elsewhere a mean of 4.1 years (range, 4 months to 13 years) before the revision. Concomitant operative procedures were done in 15 knees, including a PL reconstructive procedure in five knees and a HTO in two knees. Ten knees had abnormal articular cartilage surfaces.

Multiple factors were involved in the failure of the prior ACL reconstructions, including misplaced femoral or tibial tunnels, vertical ACL graft placement, untreated or failed PL procedures, and untreated varus osseous malalignment. An endoscopic revision procedure was performed in seven knees (Fig. 8-12) and a two-incision in 14 knees (Fig. 8-13).

Statistically significant improvements were found in the mean scores for pain, swelling, and giving-way (Table 8-3; $P < .0001$). Before the revision, 14 knees (67%) had moderate or severe pain with activities of daily living, whereas only 4 knees (19%) had such pain at follow-up. The mean score of the patient rating of the overall knee condition improved from 2.7 ± 1.3 points before the operation to 6.2 ± 2.6 points (scale of 1 to 10 points) at follow-up ($P < .0001$). Eighteen patients (86%) rated the condition of the knee as improved and three rated the condition as the same as before the operation (Fig. 8-14).

CRITICAL POINTS Our Anterior Cruciate Ligament Revision Clinical Studies

Quadriceps Tendon-Patellar Bone Autograft

- 21 patients (95% follow-up) followed mean 4.1 years (range, 2.1-6.9 years) postoperatively.
- 32 prior failed ACL procedures.
- Significant improvements in mean scores for pain, swelling, giving-way.
- 86% rated condition of the knee as improved.
- 81% grafts rated as normal or nearly normal, 19% as failed.
- QT-PB autograft viable for ACL revision

B-PT-B Autograft

- 54 patients (96% follow-up) followed for a mean of 2.8 years (range, 2-6.2 years) postoperatively.
- 60 prior failed ACL procedures
- Significant improvements in mean scores for pain, functions of activities of daily living and sports, patient perception of the overall knee condition, overall rating score.
- 94% patients rated condition of the knee as improved.
- 76% grafts rated normal or nearly normal, 24% failed.
- Graft failure rates: ACL revision reconstruction only: 16%; HTO before revision: 22%; additional ligament procedures: 43%.
- Significant effect of articular cartilage damage on functional scores, symptoms.

B-PT-B Allograft

- 65 patients (98% follow-up) followed up for a mean of 3.5 years (range, 2-6.5 years) postoperatively.
- Significant improvements in mean scores for pain, functions of activities of daily living and sports, overall rating score.
- 64% grafts rated normal or nearly normal, 36% failed.
- Allografts reserved for knees that do not have suitable autogenous tissues or require multiple grafts.
- Consider using ITB extraarticular procedure with allograft to improve success rate.

Prevalence of Nonanatomic Graft Placement in Failed ACL Reconstructions

- 122 consecutive patients referred after failed ACL reconstruction.
- Patients evaluated mean 8.3 years after failed procedure.
- Nonanatomic graft placement in 107 knees (83%).
- Transtibial technique used in 83%.
- 92 underwent revision; 73 required two-incision technique, 18 staged bone grafting.

The mean AP displacement value decreased from 8.4 ± 3.1 mm (range, 4.0-15.0 mm) preoperatively to 2.1 ± 2.2 mm (range, −4.0 to +5.0 mm) at follow-up ($P < .001$). At follow-up, 8 of 21 grafts were rated as normal; 9 as nearly normal; and 4 as failed (Table 8-4).

This study contains too small of a cohort to form definitive conclusions; however, these published data and our subsequent experience in other revision knees demonstrate that the QT-PB graft is an important autograft to consider for this operation. The QT-PB is a large cross-sectional area graft, nearly double that of a B-PT-B, and provides the surgeon with the ability to use the bone portion of the graft at either the femoral or the tibial site, based on any perceived deficiency in bone at one of these sites. However, the overall results of these revision knees were inferior to those previously reported by us for primary ACL reconstructions.[72] Ninety percent of the knees had one or

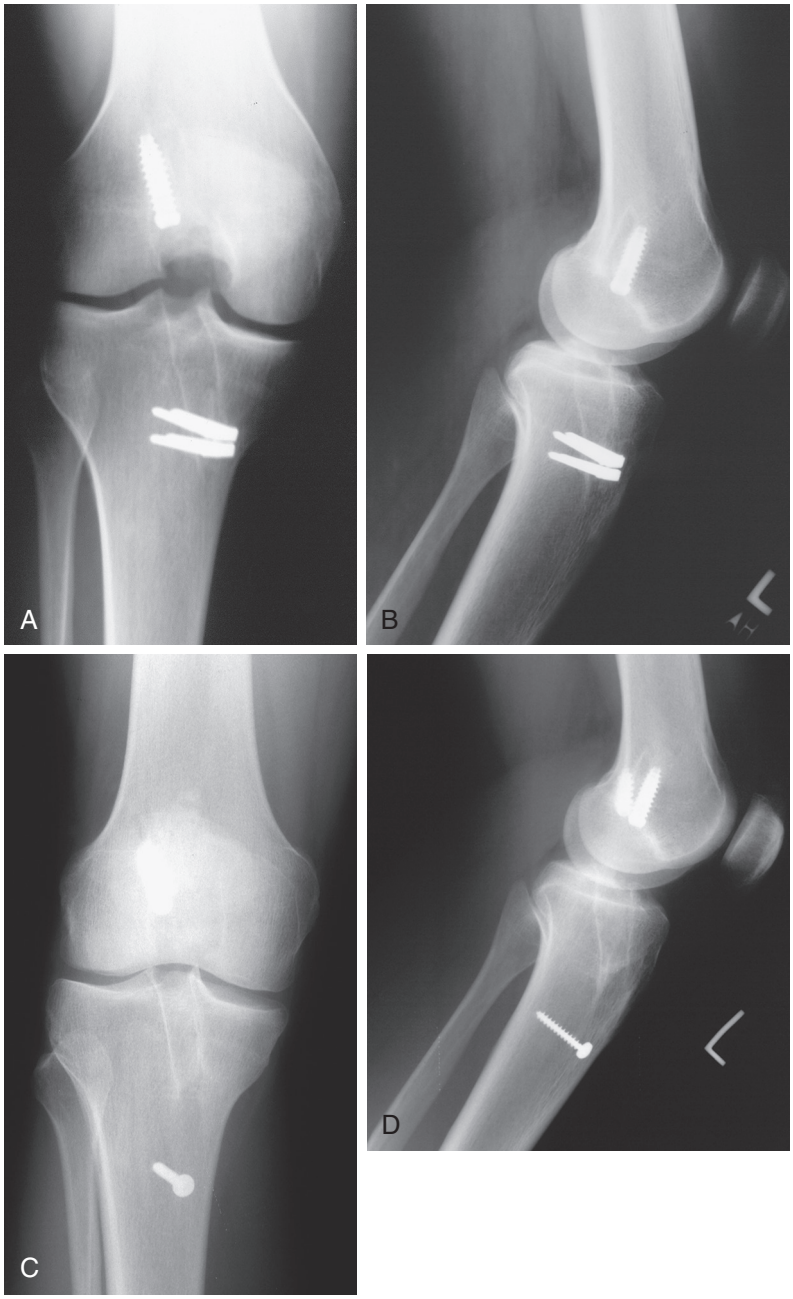

FIG 8-12 Anteroposterior (AP) **(A)** and lateral **(B)** radiographs of the right knee of an 18-year-old woman 26 months after a failed anterior cruciate ligament (ACL) Achilles tendon allograft reconstruction. Note the anterior orientation of the femoral tunnel. AP **(C)** and lateral **(D)** radiographs 50 months postoperatively demonstrate the quadriceps tendon-patellar bone (QT-PB) autograft revision. The femoral cancellous screw was retained from the primary reconstruction to avoid creating an excessively large femoral tunnel. The placement of the new femoral tunnel was accomplished using an endoscopic technique. (From Noyes FR, Barber-Westin S.D. Anterior cruciate ligament revision reconstruction: results using a quadriceps tendon-patellar bone autograft. *Am J Sports Med.* 2006;34:553-564.)

more compounding problems, including articular cartilage damage, meniscectomy, varus malalignment, and additional ligamentous injuries, which affected the outcome.

Anterior Cruciate Ligament Revision Using Bone-Patellar Tendon-Bone Autografts

We reported a prospective consecutive study of 57 ACL revision reconstruction using a B-PT-B autograft.[74] Fifty-five knees (96% follow-up) were followed a mean of 2.8 years (range, 2-6.2 years) postoperatively. A total of 218 prior operative procedures had been done in these knees, including 60 ACL procedures. A two-incision technique was used for the revision procedure in 35 knees (64%). Concurrent operative procedures were common and included reconstructive procedures for PL or medial collateral ligament deficiency in 17 knees (31%). During the revision operation, 28 knees (57%) had noteworthy damage of the articular cartilage.

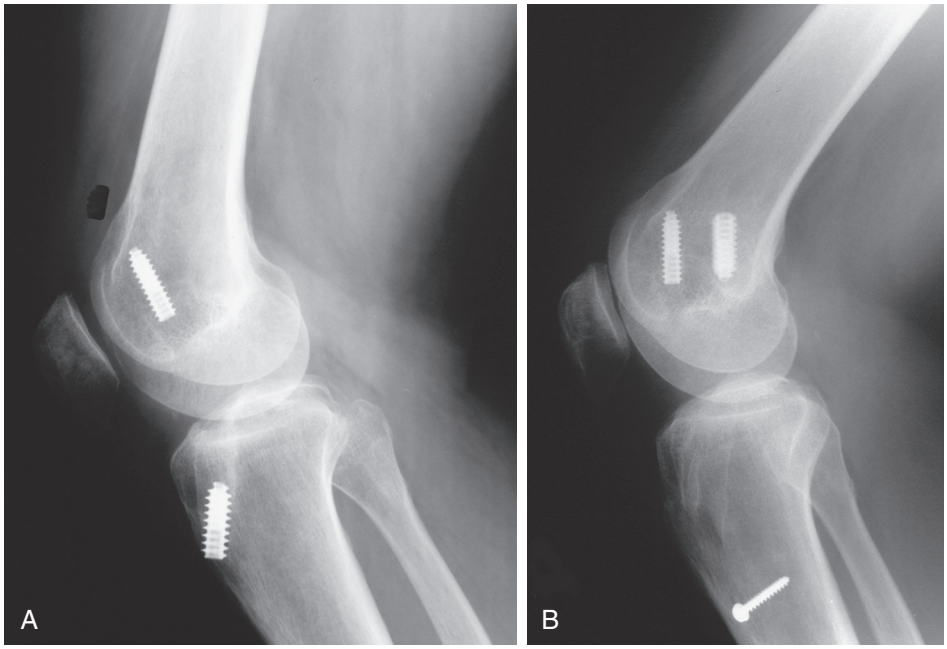

FIG 8-13 A, Lateral radiographs of the right knee of a 46-year-old man 12 months after a failed anterior cruciate ligament (ACL) reconstruction with a patellar tendon autograft demonstrates anterior placement of the femoral and tibial tunnels. **B,** Lateral radiograph 18 months after the quadriceps tendon-patellar bone autograft revision that reestablished the correct anatomic placement of the tibial and femoral attachment sites. The patellar bone was placed in the femoral tunnel, and the quadriceps tendon was placed in a new tibial tunnel located in the central ACL attachment position. The femoral screw from the primary reconstruction was deeply placed and therefore not removed. (From Noyes FR, Barber-Westin SD. Anterior cruciate ligament revision reconstruction: results using a quadriceps tendon-patellar bone autograft. *Am J Sports Med.* 2006;34:553-564.)

TABLE 8-3 Symptoms and Functional Limitations Before and After QT-PB ACL Revision Reconstruction

Factor	Point Scale	Preoperative (Mean ± SD)	Follow-up (Mean ± SD)	*P* Value
Pain	0-10	2.8 ± 1.5	5.6 ± 2.7	<.001
Swelling	0-10	2.9 ± 1.4	6.1 ± 2.7	<.001
Giving-way	0-10	4.3 ± 2.6	7.3 ± 2.9	<.001
Patient perception	1-10	2.7 ± 1.3	6.2 ± 2.6	<.001
Walking	0-40	30 ± 10	34 ± 10	.02
Stair climbing	0-40	24 ± 14	31 ± 12	.002
Squatting	0-40	9 ± 15	19 ± 16	.05
Running	40-100	49 ± 14	70 ± 24	.003
Jumping	40-100	46 ± 11	59 ± 22	.007
Twisting	40-100	48 ± 13	65 ± 24	.003

ACL, Anterior cruciate ligament; *QT-PB,* quadriceps tendon-patellar bone.

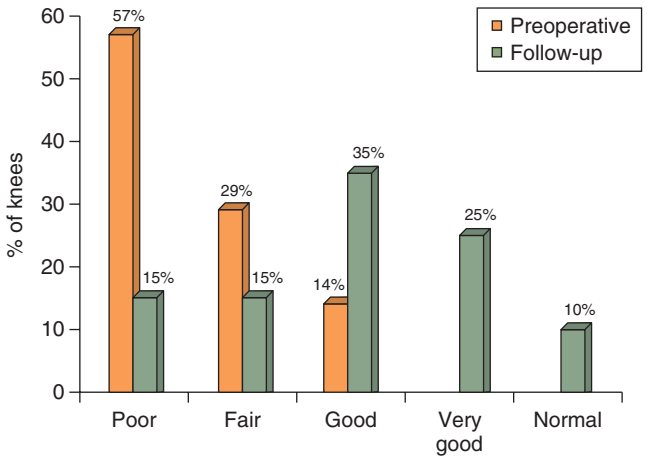

FIG 8-14 The distribution of patient ratings of the knee condition before surgery and at follow-up. The difference among evaluations was significant ($P < .0001$). (From Noyes FR, Barber-Westin SD. Anterior cruciate ligament revision reconstruction: results using a quadriceps tendon-patellar bone autograft. *Am J Sports Med.* 2006;34:553-564.)

There were significant improvements in pain (Fig. 8-15; $P < .0001$), functions of activities of daily living ($P < .05$) and sports ($P < .001$), the patient perception of the overall knee condition ($P = .0001$), and the overall rating score ($P = .0001$). Preoperatively, 19 patients (39%) participated in sports activities, all with symptoms or limitations. At follow-up, 30 patients (61%) had returned to athletics without symptoms. Seven other patients were participating in sporting activities with symptoms against our advice.

The mean preoperative patient perception score of 4.2 ± 2.8 points significantly improved to 6.4 ± 2.0 points at follow-up ($P = .0001$). Forty-six knees (94%) indicated that the overall condition had improved by circling at least one point higher on the scale at follow-up compared with the preoperative questionnaire (Fig. 8-16). Two patients

*Failed: >5-mm increase total AP displacement or grade II or III pivot shift.
ACL, Anterior cruciate ligament; *AP*, anteroposterior; *B-PT-B*, bone-patellar tendon-bone; *HTO*, high tibial osteotomy; *I-N*, involved knee-noninvolved knee; *QT-PB*, quadriceps tendon-patellar bone.

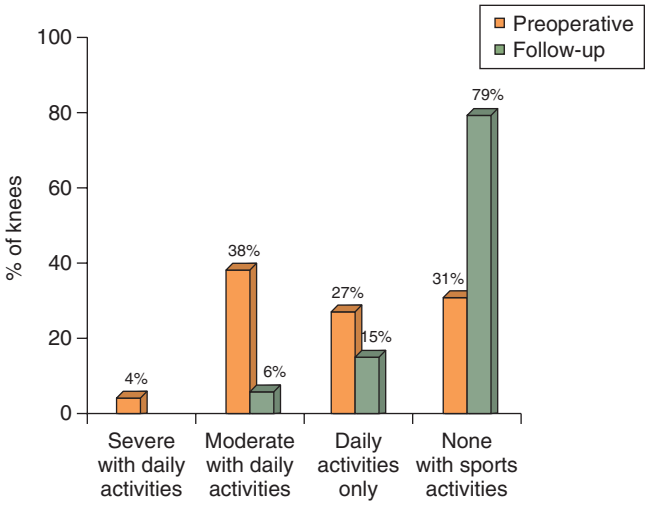

FIG 8-15 The preoperative and follow-up distribution of patient responses on the rating scale for pain. The improvement was significant (P = .0001). The scale shows the highest level of activity possible without the patient experiencing pain. (From Noyes FR, Barber-Westin SD. Revision anterior cruciate ligament surgery with use of bone-patellar tendon-bone autogenous grafts. *J Bone Joint Surg Am.* 2001;83:1131-1143.)

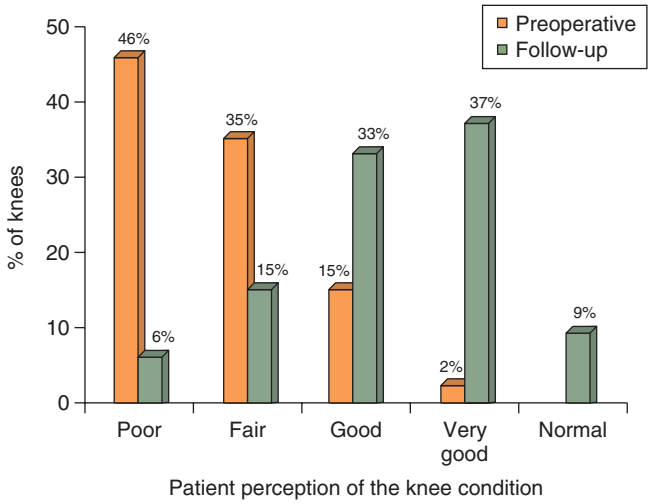

FIG 8-16 The preoperative and follow-up distribution of patient responses on the rating scale for perception of the overall knee condition. The improvement was significant (P = .0001). (From Noyes FR, Barber-Westin SD. Revision anterior cruciate ligament surgery with use of bone-patellar tendon-bone autogenous grafts. *J Bone Joint Surg Am.* 2001;83:1131-1143.)

rated the overall condition as the same, and one rated the knee condition as worse at follow-up.

AP displacements significantly decreased from a mean of 11.6 ± 3.9 mm preoperatively to a mean of 1.2 ± 4.0 mm at follow-up (P = .0001). At follow-up, 60% of the grafts were rated as normal, 16% as nearly normal, and 24% as failed.

The population was sorted according to concurrent operative procedures performed with the ACL revision reconstruction to determine the effect of these procedures on outcome (Table 8-5). In regard to graft failure, 5 of the 32 knees (16%) that had only the ACL revision reconstruction failed, 2 of the 9 knees (22%) that had an HTO before the revision procedure failed, and 6 of the 14 knees (43%) that had additional ligament procedures failed. There were statistically significant differences among the knees that had the revision reconstruction

TABLE 8-5 Effect of Additional Operative Procedures on Outcome of ACL B-PT-B Revision Reconstruction

	PAIN (POINTS)			PATIENT PERCEPTION (POINTS)			Graft Failure	OVERALL RATING SCORE (POINTS)		
Procedure	Preop	Follow-up	*P* Value	Preop	Follow-up	*P* Value	Rate (%)	Preop	Follow-up	*P* Value
Revision with no other major operative procedures ($n = 32$)	4.1 ± 1.7	5.7 ± 0.7	.0001	3.2 ± 1.6	7.1 ± 1.6	.0001	16	64 ± 10	64 ± 10	.0001
Revision staged after HTO ($n = 9$†)	2.9 ± 1.4*	4.9 ± 2.0	.05	2.0 ± 1.4	4.3 ± 1.9*	.03	22	53 ± 9*	81 ± 10*	.0004
Revision and other ligament procedure ($n = 17$†)	3.5 ± 1.7	4.7 ± 2.3	.05	3.2 ± 1.9	4.8 ± 2.2	.02	35*	56 ± 9*	84 ± 12*	.0001

*The value was significantly different from that in the subgroup with revision and no other major procedure ($P < .05$).

ACL, Anterior cruciate ligament; *B-PT-B,* bone-patellar tendon-bone; *preop,* preoperative.

only and those that had HTO before the revision procedure. Patients who underwent HTO (usually indicating more advanced medial arthrosis) had poorer mean patient perception scores and overall rating scores at follow-up ($P < .05$).

There were no complications related to the graft harvest procedure. There was a statistically significant difference between the 31 knees (56%) that had abnormal articular cartilage surfaces and the knees with normal surfaces in the scores for twisting and turning activities and the ability to return to strenuous activities ($P < .05$). The study concluded that B-PT-B autograft knees had improved knee stability and avoided the added risk of infection and expense of the allograft.

Anterior Cruciate Ligament Revision Using Bone-Patellar Tendon-Bone Allografts

We conducted a prospective study on 66 consecutive patients who received a B-PT-B allograft ACL revision reconstruction, of whom 65 (98% follow-up) were followed an average of 3.5 years (range, 2-6.5 years) postoperatively.[77] Concomitant procedures were common and included reconstruction of the FCL (seven knees), advancement of the PL complex (11 knees), reconstruction of the MCL (four knees), and reconstruction of the PCL (two knees). Forty of the allografts had been sterilized with gamma irradiation (25,000 Gy) and 26 were fresh frozen.

At follow-up, significant improvements were found for pain, swelling, giving-way, walking, stair climbing, kneeling, running, jumping, and twisting/turning ($P < .0001$). Forty-two patients (65%) returned to mostly low-impact sports without problems.

Thirty-seven knees (56%) had noteworthy deterioration of the articular cartilage surfaces. At follow-up, significant differences were found between these knees and those with normal cartilage surfaces for the variables of pain (Fig. 8-17), stair climbing, kneeling, running, jumping, twisting/turning, sports activity level, and the overall rating score (Table 8-6).

The preoperative CKRS overall rating score for all 65 knees of 54 ± 10 points significantly improved to 77 ± 13 points at follow-up ($P < .0001$). All patients except one had an improvement in this score; the average increase was 23 ± 11 points.

At follow-up, 43% of the grafts were rated as normal; 21%, as nearly normal; and 36% failed. There appeared to be an effect of irradiation on the failure rate of this study, because 40 of the 66 allografts had undergone irradiation (2.5 mrad). The increased failure rate in allograft studies (excluding irradiation effects), the cost of allograft tissue, and risk of disease transmission (even though rare) led us to recommend in 1997[72] that autografts be used as the primary graft source for ACL revision reconstruction. Allografts are reserved for knees lacking suitable autogenous tissues or that required multiple ligament reconstructive procedures.

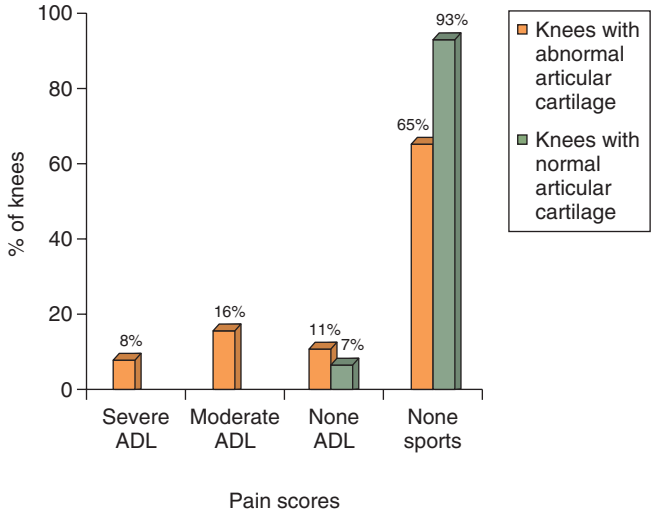

FIG 8-17 Comparison of the pain scores at the most recent follow-up evaluation among 28 knees with normal articular cartilage and 37 knees with abnormal articular cartilage. The difference between groups was significant ($P < .05$). Severe activities of daily living (ADLs), severe pain (constant, not relieved) with ADLs; moderate ADLs, moderate pain (frequent, limiting) with ADLs; no ADLs, no pain with ADLs but pain with any sports activity; and no sports, no pain with sports activity. (From Noyes FR, Barber-Westin SD, Roberts CS. Use of allografts after failed treatment of rupture of the anterior cruciate ligament. *J Bone Joint Surg Am.* 1994;76:1019-1031.)

Prevalence of Nonanatomic Graft Placement in Failed Anterior Cruciate Ligament Reconstructions

A consecutive series of 122 patients who presented to our center for treatment of one or more failed ACL reconstructions was analyzed to

TABLE 8-6 Effect of the Condition of the Articular Cartilage at the ACL Allograft Revision Reconstruction on the Subjective Scores and Overall Rating at the Latest Follow-up Examination

Variable	Point Scale	Patients With Normal Articular Cartilage* (Mean ± SD)	Patients With Abnormal Articular Cartilage (Mean ± SD)	*P* Value
Pain	0-6	5.9 ± 0.5	4.6 ± 2.1	.03
Swelling	0-6	5.8 ± 0.6	5.2 ± 1.4	NS
Partial giving-way	0-6	5.9 ± 0.4	5.2 ± 1.5	NS
Full giving-way	0-6	6.0	5.5 ± 1.4	NS
Walking	0-40	38 ± 4	34 ± 8	NS
Stair climbing	0-40	36 ± 5	29 ± 11	.01
Kneeling	0-40	28 ± 14	21 ± 14	.01
Running	40-100	84 ± 18	61 ± 21	.001
Jumping	40-100	78 ± 21	57 ± 22	.01
Twisting and turning	40-100	73 ± 21	55 ± 20	.01
Overall rating	0-100			
Follow-up		85 ± 9	71 ± 12	.0001
Improvement from preoperative		26 ± 10	21 ± 11	NS

*Abnormal was defined as fissuring and fragmentation of 15 mm or more in diameter that extended into more than one half of the involved surface or any exposed subchondral bone.
ACL, Anterior cruciate ligament; *NS,* not significant; *SD,* standard deviation.

determine the prevalence of a nonanatomic ACL graft placement.[61] The cohort included 63 patients who had undergone both a primary and failed revision procedure elsewhere. Radiographs, MRI, and operative reports were used to determine graft placement, which was considered nonanatomic when 50% or more of the graft was outside of the native femoral and tibial insertions. The patients were evaluated a mean of 8.3 years after the failed ACL reconstruction. All patients had a grade II or III pivot shift and 77% rated their overall knee condition as fair or poor.

A nonanatomic graft placement was found in 107 knees (83%). A transtibial technique had been used in 83% of the failed primary ACL procedures and in 70% of the failed revision ACL procedures. The mean values for the coronal and sagittal graft placement showed a significantly increased vertical orientation when compared with a control group ($P < .01$). Forty-two of these 107 knees had undergone one or more ACL revision without correction of the misplaced graft tunnels, and these procedures also failed.

A total of 92 knees underwent anatomic revision at our center. Of these, 73 were done with a two-incision independent-drilling technique for the femoral and tibial tunnels. Staged bone grafting was required in 18 patients. The conclusion was reached that the transtibial tunnel drilling technique may result in a vertical graft orientation and eventual failure. In revision knees, the new graft tunnels should be placed at the native ACL attachments with independent drilling of each tunnel using either a two-incision or anteromedial portal technique (see Chapter 7).

OTHER AUTHORS' CLINICAL STUDIES

Risk Factors for Failure of Anterior Cruciate Ligament Reconstruction

Many investigations have been conducted to determine factors that are associated with failure of ACL reconstructions (Table 8-7). The majority of studies showed age to be a significant risk factor, especially in patients younger than 20 years old.[47,57,59,60,84,89,91,99-101] When compared with B-PT-B autografts, STG autografts, particularly those less than 8 mm in diameter, were shown to have higher failure rates.[37,60,62,83,84] Allograft tissue was noted to have a higher failure rate than autografts,[10,24,25,40,57,82,100] with irradiation possibly having an additional deleterious effect.[65] (This issue was also discussed in Chapter 7.) Poor graft placement from femoral tunnels placed too far anteriorly and/or tibial tunnels placed posteromedially relative to the native ACL position was noted in several studies to be a major factor for graft failure.[42,67,86,97]

Most studies found that gender was not a significant risk factor for failure of ACL reconstruction.[57,59,60,62,83,84,86,100,101] In addition, most agreed that height, weight, BMI, cartilage damage, and meniscal damage were not risk factors.[3,57,59,60,83,86,100,101] Disagreement existed in regard to the effect of the activity level patients returned to postoperatively and the timing of return to sports.

As studies become more sophisticated, all possible factors from large cohorts (such as the Multicenter Orthopaedic Outcome Network study) may be assessed in multivariate statistical models to determine which factors (alone and in combination) are most likely to cause failure of this operation. We avoid the use of allografts in younger, active patients and do not allow a return to unrestricted athletic activities until the patient demonstrates return of normal neuromuscular indices and other factors that are discussed in detail in Chapter 11.

Bone-Patellar Tendon-Bone Autograft

A common autograft source for ACL revision reconstruction is the B-PT-B (Table 8-8). Failure rates range from 0% to 15% and subjective outcomes tend to be somewhat inferior when compared with primary ACL reconstructions. However, this is frequently because of the preexisting meniscal and chondral damage in revision knees. The contralateral patellar tendon has been used in knees in which the ipsilateral patellar tendon had previously been harvested, although few clinical outcomes have been published after this procedure.[38,49,90]

Reharvested Bone-Patellar Tendon-Bone Autograft

Although authors of early studies[8,14,15,81,105] postulated that reharvest of the ipsilateral patellar tendon was feasible for revision reconstruction, others disagreed.[9,49,53-55,58] Liden and associates[54] followed 11 patients who underwent ACL revision surgery using reharvested ipsilateral patellar tendon grafts. At 10 years postoperatively, MRI demonstrated a significant increase in the thickness of the tendon at the donor site compared with the contralateral side (6.4 ± 1.3 mm and 4.5 ± 1.3 mm, respectively; $P = .02$) and a visible donor site gap. Nine patients were rated as abnormal or severely abnormal on IKDC scores.

Kartus and colleagues[49] compared the results of 12 knees in whom the ipsilateral patellar tendon was reharvested with 12 knees that received contralateral patellar tendon grafts for ACL revision reconstruction. Two years postoperatively, no differences were found among the subgroups on MRI for patellar ligament length, width, thickness, or donor site gap measurements. However, the knees that received the reharvested grafts had lower functional scores and a higher rate of complications, including one patellar fracture and one patellar ligament rupture postoperatively.

Semitendinosus-Gracilis Autograft

Multiple investigations have documented acceptable outcomes following STG revision reconstructions.[16,27,28,31,32,63,68,80,88,94,95,102,109] Ferretti and associates[27] followed a group of 30 knees that received an ACL revision STG autograft that was combined with an extraarticular ITB tenodesis. The failure rate was 10%. In another investigation, Ferretti and coworkers[28] harvested the contralateral STG after failure of the primary ACL reconstruction using the ipsilateral STG had occurred in 12 patients. A mean of 3 years postoperative, 1 patient had experienced graft failure. The other patients were rated as A or B on the IKDC objective evaluation.

Salmon and associates[88] followed 50 patients who received this operation and documented a 10% failure rate. However, only 56% of the knees were rated as normal or nearly normal according to the IKDC rating. The poor subjective and functional outcomes were related to the degree of joint (articular cartilage) damage. Weiler and colleagues[102] reported a 6.5% graft failure in 62 patients who underwent four-strand STG ACL revision. However, compared with a group of knees that had primary ACL STG reconstruction, the revision patients had inferior subjective knee function results. A greater percent of the revision knees had undergone prior meniscectomy, which may have led to the poorer outcome.

Muneta and associates[68] studied the outcome of primary and revision ACL reconstruction using a double-bundle technique with a multistrand semitendinosus graft. Twenty-one patients who had a revision procedure were followed a mean of 3.3 years, and 86 patients who had a primary reconstruction were followed a mean of 2.7 years postoperatively. There was a significant difference in pivot shift test because 22% of revision and 10% of primary knees had a positive result ($P < .05$). However, there was no difference in the mean KT-1000 measurements or the Lachman test. The revision knees had a poorer mean Lysholm knee score ($P < .0001$).

Staged Bone Grafting

Thomas and associates[95] reported the outcome of a staged ACL revision procedure in 49 patients who required bone grafting of the tibial tunnel first to achieve an anatomic ACL reconstruction. Thirty-four patients received a STG autograft and 15 had a B-PT-B autograft; all were followed a mean of 6.2 years postoperatively. The results were compared with a group of patients who underwent primary ACL reconstruction matched for age, gender, type of graft used, and follow-up time period. The revision patients demonstrated a greater number of meniscus tears, a significantly greater number of chondral lesions in the patellofemoral ($P = .015$) and lateral tibiofemoral compartments ($P < .001$), and had significantly lower IKDC subjective ($P = .006$) and objective ($P = .035$) scores than the primary ACL reconstruction group. There was no difference in instrumented laxity measurements. The results demonstrated that revision ACL knees without major associated instability, with abnormal bone tunnels grafted and bone quality restored, have a good success rate in terms of achieving postoperative stability. There were two failures in the revision group and one in the primary ACL reconstruction group. The results apply to knees that have intact secondary restraints, as knees requiring an additional medial or lateral ligament reconstruction were excluded and 9 of the 49 knees (18%) had only 3 to 4 mm of increased anterior tibial displacement before the operative procedure.

Franceschi and colleagues[31] performed staged ACL STG revision reconstruction in 30 patients who first underwent a bone graft of the femoral tunnel. All patients had posttraumatic knee instability after a prior B-PT-B autograft reconstruction. Although the femoral and tibial tunnels were deemed to be in the correct location, the authors removed the femoral fixation and filled the large defect (8-11 mm in diameter; 20 to 30 mm in length) with autologous bone grafts harvested from the anterior tibial metaphysis in an attempt to "restore the integrity of the femoral condyle." At a mean of 6.7 years postoperatively, no patient had experienced a graft failure and 27 patients were rated as normal or nearly normal on the overall IKDC score.

Quadriceps Tendon-Patellar Bone Autograft

Fewer investigators[17,33,96,104] have reported outcomes using the QT-PB autograft for ACL revision reconstruction. Garofalo and associates[33] followed 28 patients 3.3 to 5.6 years postoperatively at which time 25% had a grade I+ pivot shift and only one graft failed. Patient satisfaction was high, with 93% grading their knee condition as normal or nearly normal. Trojani and colleagues[96] used the QT-PB autograft in 16 revision knees that were followed a mean of 3.6 years postoperatively. The investigators reported that 73% were rated as normal or nearly normal on IKDC overall grading, and that 12% had failed. This graft is preferred after failure of a STG or B-PT-B autograft by these authors owing to donor-site morbidity incurred after B-PT-B harvest.

Allografts

Although historically allograft tissue was used in several studies for ACL revision reconstruction,[30,35,38,45,92,94,98] fewer reports have been published in more recent years[7,11,51,64] because surgeons appear to now favor autograft tissue for this procedure.[63] The issue of graft irradiation has been addressed by a few studies, with those using fresh-frozen tissue usually showing better stability outcomes compared with those using irradiated tissue. For instance, Mayr and associates[64] retrospectively compared the outcome of 15 patients who received fresh-frozen B-PT-B allografts with 14 patients who received B-PT-B autografts, a mean of 5.7 years postoperatively. There were no significant differences in mean IKDC subjective, Tegner, or Lysholm scores. There was also no difference in mean KT-1000 scores and no patient had more than 5 mm of increased anterior tibial translation. The authors attributed the results to the lack of irradiation or chemical sterilization of the allografts. Fox et al[30] followed 32 patients who received fresh-frozen B-PT-B allografts from 2 to 12 years postoperatively. Preoperatively, only 9% of these patients had more than 5-mm increased anterior tibial translation on knee arthrometer testing. At follow-up, 84% had a functional reconstruction, 9% had partial function, and 6% failed.

In contrast, Kievit and colleagues[51] followed 25 patients who received revision fresh-frozen allografts (13 tibialis tendon, 15 Achilles tendon, 2 B-PT-B) a mean of 5 years postoperatively. Compared with a group of primary STG reconstructions, the revision group had significantly worse pivot shift scores because 16% had 2+ test result compared with 4% of primary knees ($P = .007$). The revision knees also had significantly worse Knee injury and Osteoarthritis Outcome Score (KOOS) for pain, symptoms, and activities of daily living, sports, and quality of life.

Johnson and coworkers[45] reported that 36% of patients had greater than 5 mm of increased anterior tibial translation and 88% were rated as abnormal by IKDC guidelines a mean of 2.5 years after revision ACL reconstruction that was performed with irradiated allografts.

Conclusion

Most authors agree that the outcomes of ACL revision reconstruction are inferior to those of primary ACL procedures, usually because of preexisting articular cartilage damage and loss of meniscal tissue.[7,34,106,107] A recent systematic review by Wright and associates[107] that included 863 patients from 21 studies found that the failure rate of revision ACL reconstructions (13.7%) was nearly three to four times the failure rate of previously published primary ACL procedures (2.9%-5.8%).[106,108]

Problems with published studies include small cohorts, heterogeneous populations with regard to grafts used and/or concomitant procedures required,[1,7,17,95] and lack of concurrent control groups as issues preventing definitive conclusions on the optimal treatment for these knees.

Irradiated allografts and small-sized STG autografts appear to have higher failure rates than B-PT-B autografts. Although the QT-PB autograft seems to be a reasonable graft choice, few data have been published on the outcome after ACL revision reconstruction.

ILLUSTRATIVE CASES

Case 1. A 19-year-old male presented two years following a failed ACL B-PT-B autograft reconstruction. The procedure had been done 16 months following a left knee injury sustained during a hockey game for symptoms of full giving-way and pain. Although the patient completed a rigorous postoperative rehabilitation program, his giving-way symptoms persisted. He had given up all sports activities and noted generalized pain with daily activities. Physical examination demonstrated no effusion, a full range of knee motion, a grade III pivot shift, and 16.5 mm of increased AP displacement on KT-2000 testing. The patient also had 5 mm of increased lateral joint opening at 25 degrees of flexion, but no increase in external tibial rotation. He had a bilateral varus thrust on ambulation and increased recurvatum of the left knee. Full standing radiographs revealed bilateral varus malalignment, with a weight bearing line of 20% on the involved left knee (Fig. 8-18, *A*) and 40% on the contralateral right knee.

The patient underwent an HTO, followed 4 months later with a two-incision ACL B-PT-B autogenous reconstruction. During the procedure, the lateral tibiofemoral gap test was normal, indicating that a posterolateral procedure was not required. The B-PT-B graft was harvested from the contralateral knee. A new femoral tunnel, required to achieve anatomic graft placement on the lateral wall, was positioned adjacent to the previous tunnel. Fixation was achieved with interference screws proximally and distally. The patient had grade 2-A articular cartilage damage on the medial femoral condyle, and a stable lateral meniscus tear that did not require treatment.

At the most recent follow-up evaluation, 10 years postoperatively, the patient had no effusion, a normal range of knee motion, a grade 0 pivot shift, and 1 mm of increase in AP displacement on KT-2000 testing. He had no symptoms with light recreational activities and rated the overall condition of his knee as good. Standing PA radiographs at 45 degrees of flexion showed no difference between the noninvolved (Fig. 8-18, *B*) and involved knees (Fig. 8-18, *C*), with only mild narrowing of the medial tibiofemoral joint space.

Our comment: In revision knees, we prefer autogenous grafts because of the higher success rate compared with allografts. Contralateral graft harvest carries low postoperative morbidity, with careful attention to handling of soft tissue and bone grafting of the patellar and tibial defects. In this case, a closing wedge osteotomy of the tibia and fibular neck was performed, protecting the proximal tibiofibular joint and proximal fibular ligament attachments. We favor opening wedge osteotomy, which does not require fibular osteotomy and is described in Chapter 27.

Case 2. A 40-year-old male presented five years following a failed ACL allograft reconstruction on the right knee. The operative procedure had included a primary repair of the medial collateral ligament, a lateral meniscus repair, a medial meniscus repair, and a proximal patellar realignment. The patient had also undergone an ACL allograft reconstruction on the left knee two years following the right knee procedure. At the initial evaluation, he described a feeling of looseness in the right knee that began gradually but had recently become more symptomatic, although he had not experienced full giving-way episodes. He had given up all sports activities and desired an active lifestyle. Physical examination demonstrated a full range of knee motion, a grade III pivot shift test, and moderate crepitus in the lateral

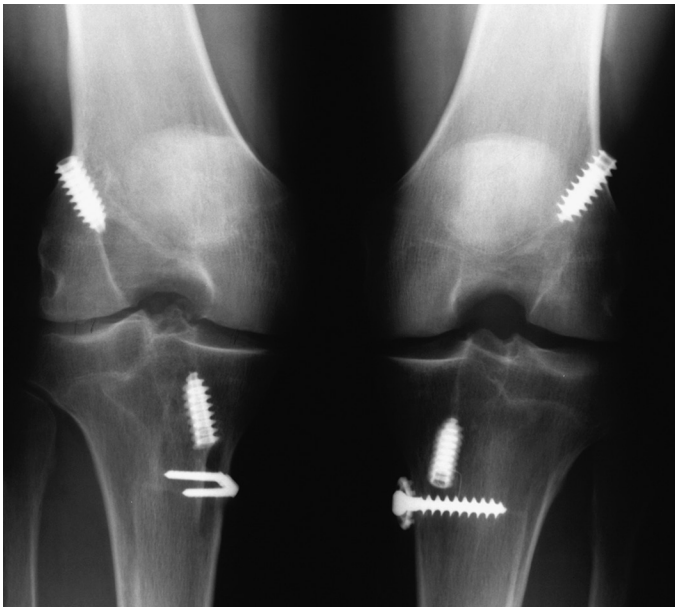

FIG 8-19 Case 2.

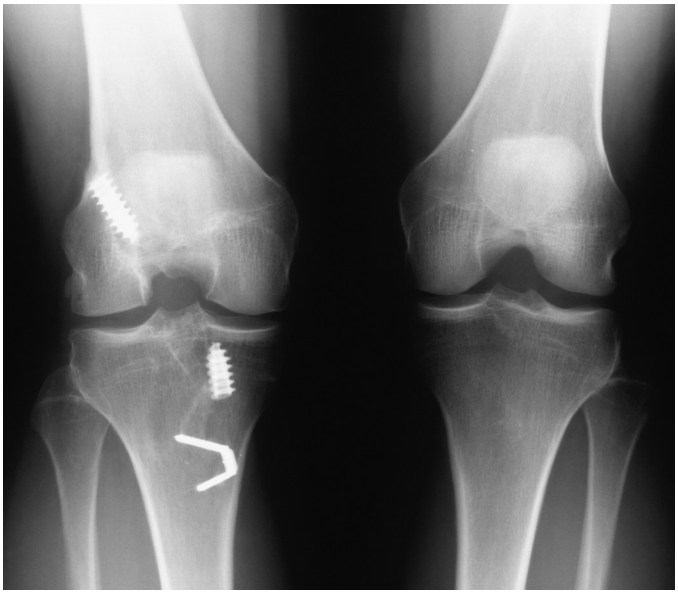

FIG 8-20 Case 3.

tibiofemoral compartment. There was normal axial alignment and no valgus alignment requiring corrective osteotomy.

The patient was treated with a revision ACL B-PT-B autogenous reconstruction of the right knee and a repair of a complex longitudinal medial meniscus tear located at the red-white junction. The allograft and ligament augmentation device were removed and the autogenous graft placed in the previous bone tunnels, as they were in an anatomically correct position. Fixation was achieved with an interference screw proximally (two-incision technique) and distally with an interference screw and a small staple over which the sutures from the bone plug were tied. Noteworthy articular cartilage damage (grade 2-B) was noted on the lateral femoral condyle.

At the most recent follow-up evaluation, 11 years postoperatively, the patient had no knee pain or complaints of giving-way. He participated in low-impact activities and rated the overall condition of his right knee as good. Physical examination demonstrated a grade I pivot shift with a solid endpoint, a normal range of knee motion, mild lateral joint line tenderness, and no effusion. Radiographs revealed 2 mm of lateral joint space narrowing and tunnel enlargement (Fig. 8-19). The patient was advised to continue low-impact activities and return if the lateral tibiofemoral symptoms worsened.

Our comment: This case demonstrates the probable long-term function of the medial meniscus repair, as preservation of the medial joint space is evident on radiographs.

Case 3. A 27-year-old female physician presented after two failed ACL reconstructions, including a primary repair and an allograft with a ligament augmentation device. The allograft failed in a low-energy trauma reinjury. Physical examination demonstrated a grade III pivot shift with no endpoint, 16 mm of increased AP displacement on KT-1000 testing, and a full range of knee motion. She had no symptoms with daily activities but had given up all sports and was having pain and giving-way symptoms at work.

The patient underwent a revision ACL B-PT-B autograft reconstruction using a two-incision outside-in approach. The allograft and ligament augmentation device were removed and the graft placed in the previous bone tunnels, which were in an anatomically correct position. Fixation was achieved with an interference screw proximally and an interference screw and a post (sutures in the bone plug) distally. Mild articular cartilage damage (grade 2-A) was noted on the undersurface of the patella and medial femoral condyle. The menisci were intact.

At the most recent follow-up evaluation, 12 years postoperative, the patient was doing well with low-impact activities and had no symptoms at work. She rated the overall condition of her knee as very good. Physical examination showed no effusion, a normal range of knee motion, no joint line tenderness, a grade I pivot shift, and 4 mm of increase in AP displacement on KT-2000 testing. Radiographs demonstrated no loss of joint space (Fig. 8-20).

Our comment: A two-incision, outside-in femoral approach is favored in most revision knees to place the graft entirely on the sidewall of the lateral femoral condyle at the anatomic footprint. An endoscopic technique drilling of the femoral tunnel through an anteromedial portal in knee hyperflexion is an alternative technique, based on the location of the prior femoral tunnel.

Case 4. A 21-year-old female presented with a history of two failed left ACL procedures, including an ITB extraarticular procedure and a B-PT-B autograft. The patient experienced recurrent giving-way symptoms following both reconstructions. She had also undergone a total medial meniscectomy following the first ACL operation. The patient's chief complaints were pain and giving-way with daily activities. She had given up all sports activities and rated the overall condition of her knee as poor. Physical examination revealed a full range of knee motion, a grade III pivot shift, 9 mm of increased AP displacement on KT-2000 testing, 8 mm of increase in lateral joint opening, and 10 degrees of increase in external tibial rotation.

The patient was treated with an ACL B-PT-B autograft reconstruction and a proximal advancement of the posterolateral complex. A new femoral tunnel was placed on the lateral wall with an outside-in technique to achieve anatomic graft placement. The prior interference screw was removed and a new screw inserted into the prior tunnel to prevent collapse into the new tunnel. Fixation of the ACL graft was

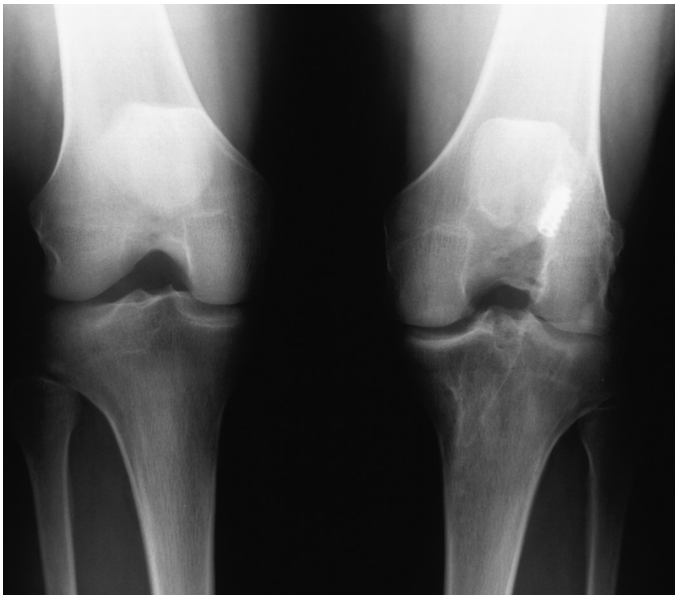

FIG 8-21 Case 4.

achieved with interference screws proximally and distally. The patient had grade 2-A articular cartilage damage on the undersurface of the patella, medial femoral condyle, and medial tibial plateau. The lateral meniscus was intact.

At the most recent follow-up evaluation, 13 years postoperatively, the patient had no symptoms with strenuous activities including motorcycle racing. She rated the overall condition of her knee as good. Physical examination demonstrated a negative pivot shift, no increase in lateral joint opening on stress radiographs, 4 mm of increase in AP displacement on KT-2000 testing, a normal range of knee motion, and moderate patellofemoral and lateral tibiofemoral crepitus. Radiographs demonstrated moderate narrowing of the medial tibiofemoral compartment and severe narrowing of the lateral tibiofemoral compartment (Fig. 8-21). The patient was advised to avoid high-impact activities and to monitor the patellofemoral and tibiofemoral joints for future pain.

Our comment: This case demonstrates the progression of arthritis frequently reported after prior meniscectomy in ACL revision knees. The lateral compartment has progressed past the point of considering a meniscus allograft, but fortunately, the patient is functioning well. She is following a nonoperative arthritis protocol designed to buy time and remain recreationally active.

Case 5. A 32-year-old female physical therapist presented after undergoing a total of 22 operative procedures on her right knee elsewhere. The operative history included four failed ACL procedures (an extraarticular ITB procedure, two B-PT-B autografts, and an STG autograft), seven failed posterolateral procedures (four proximal advancements of the posterolateral complex, an FCL allograft, an FCL B-PT-B autograft, a biceps tendon transposition), two failed HTOs, and a derotational osteotomy performed distal to the prior osteotomy site. The patient had moderate pain, swelling, and giving-way with daily activities. Physical examination demonstrated a grade III pivot shift with no endpoint, 15 mm of increased lateral joint opening at 25 degrees of flexion with no endpoint, 10 degrees of increased external tibial rotation, 15 degrees of hyperextension, a varus thrust on ambulation, varus recurvatum, and 12 mm of increased AP displacement on KT-2000 testing. Full-length radiographs revealed a 75% weight-bearing line on the right limb compared with a 56% weight-bearing line on the left limb.

The patient was treated with an ACL B-PT-B autogenous reconstruction using the contralateral patellar tendon. New femoral and tibial tunnels were required to achieve anatomic graft placement. Fixation was accomplished with interference screws proximally and distally. In addition, an anatomic reconstruction of the posterolateral structures (see Chapter 17) was done using a B-PT-B autograft to replace the FCL, a semitendinosus tendon autograft to replace the popliteus tendon and popliteofibular ligament, and a proximal advancement of the posterolateral capsule (Fig. 8-22, *A* and *B*). Advancement of the ITB and posteromedial capsule were also required. The patient had noteworthy articular cartilage damage (grade 2-B) on the undersurface of the patella, the trochlea, and the medial femoral condyle.

At the most recent follow-up evaluation, 10 years postoperative, the patient reported no problems with low-impact activities. She rated the overall condition of her knee as very good and was able to ski with minimal complaints. Physical examination demonstrated a negative pivot shift, no increase in lateral joint opening on stress radiographs (Fig. 8-22, *C* and *D*), 5 mm of increased AP displacement on KT-2000 testing, no increase in external tibial rotation, and an overall valgus lower limb alignment. Weight-bearing PA radiographs at 45 degrees of flexion demonstrated early narrowing of the lateral compartment (Fig. 8-22, *E*). An unloader brace and continued avoidance of impact activities were advised.

Case 6. A 27-year-old male presented following three failed ACL reconstructions, including an ipsilateral B-PT-B autograft, a contralateral B-PT-B autograft, and an ipsilateral (reharvested) B-PT-B autograft. The patient had also undergone a total medial meniscectomy. The history and medical records revealed that the causes of failure of the reconstructions were anterior graft placement on the femur, uncorrected varus osseous malalignment, and uncorrected deficiency of the posterolateral structures. Physical examination demonstrated a grade III pivot shift, 15 mm of increased AP displacement on KT-2000 testing, 5 mm of increase in lateral joint opening, and a weight-bearing line of 15%. The patient complained of symptoms with all activities and ambulated with a varus thrust.

The patient underwent a closing wedge HTO and proximal advancement of the posterolateral structures, followed later with a QT-PB autogenous ACL reconstruction. A new femoral tunnel to achieve a central ACL graft placement was required and the previously placed vertical femoral tunnel screw was left intact. Fixation was achieved with an interference screw proximally, and an interference screw and graft suture post. Noteworthy articular cartilage damage (grade 2-B) was evident on the undersurface of the patella and on the medial femoral condyle.

At the most recent follow-up evaluation, 6 years later, the patient had a grade I pivot shift bilaterally, 1.0 mm of increased AP displacement on KT-2000 testing, no increase in lateral joint or external tibial rotation, a normal range of knee motion, and correction to a valgus alignment. Radiographs demonstrated medial compartment joint space narrowing (Fig. 8-23). The patient declined further surgery such as a meniscus transplant. He was able to participate in low-impact activities and had only minimal problems in his occupation as a flooring installer. He rated the overall condition of the knee as good. The patient was advised that the long-term prognosis of the knee joint was poor.

Our note: This case demonstrates a protracted course of treatment that included two prior ACL revision procedures that failed, in part, because of vertical graft placement. In addition, the varus

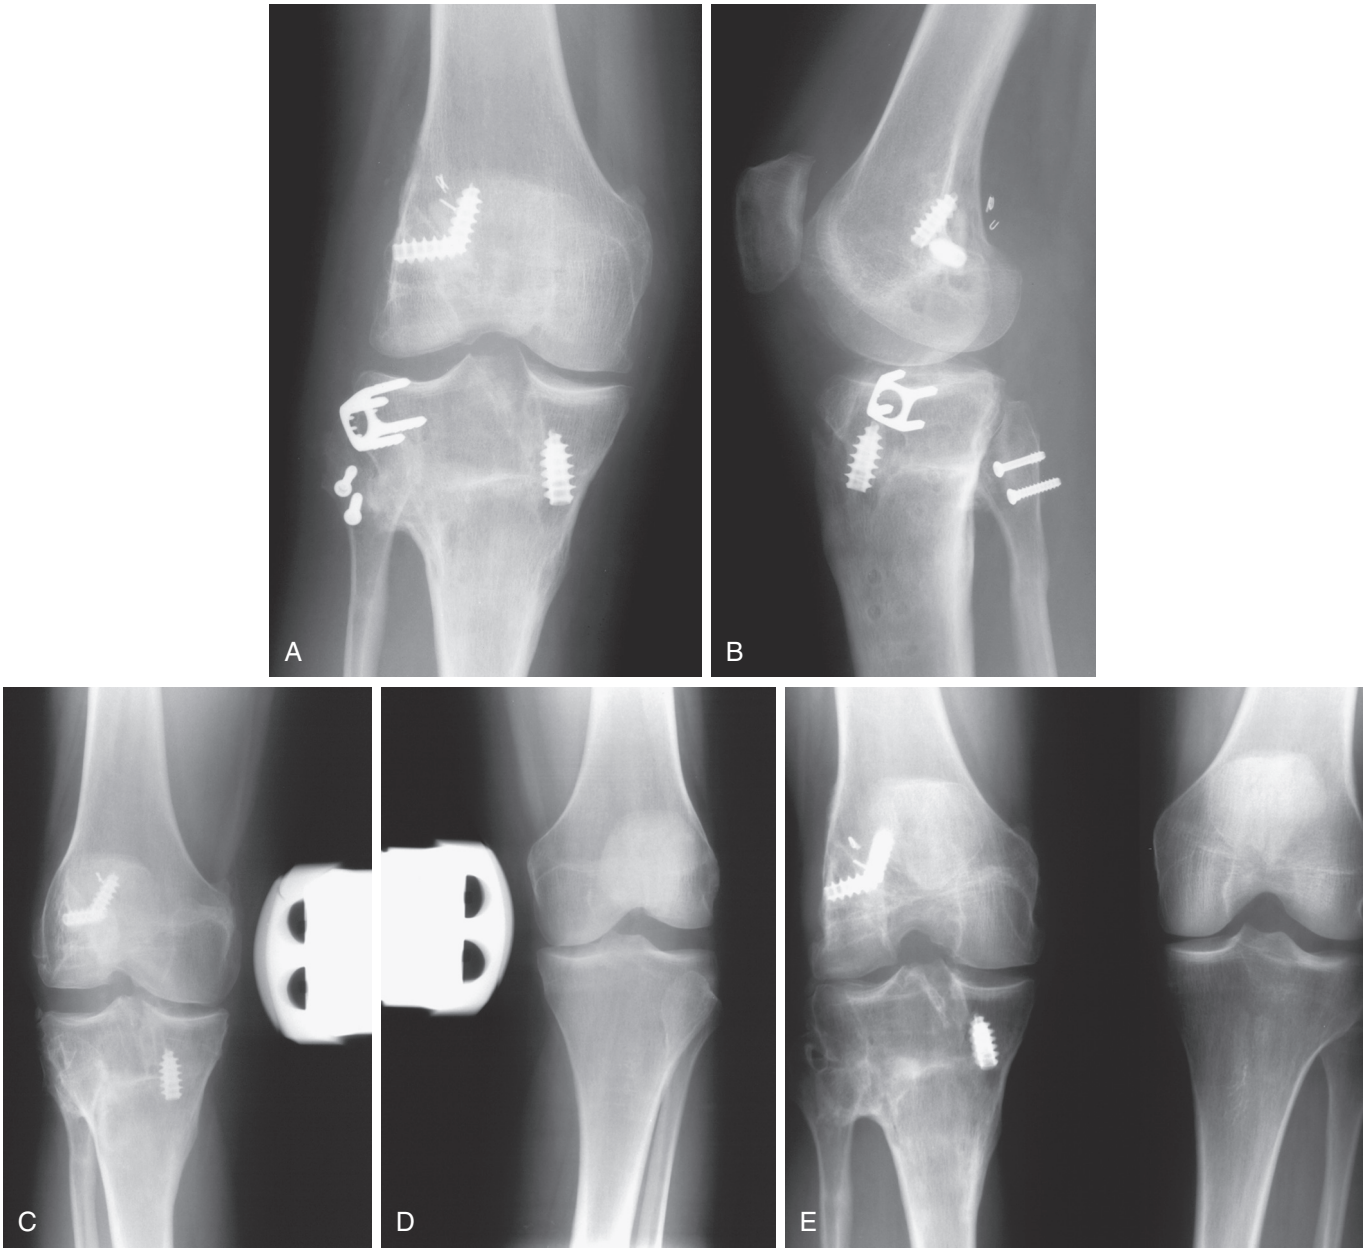

FIG 8-22 Case 5.

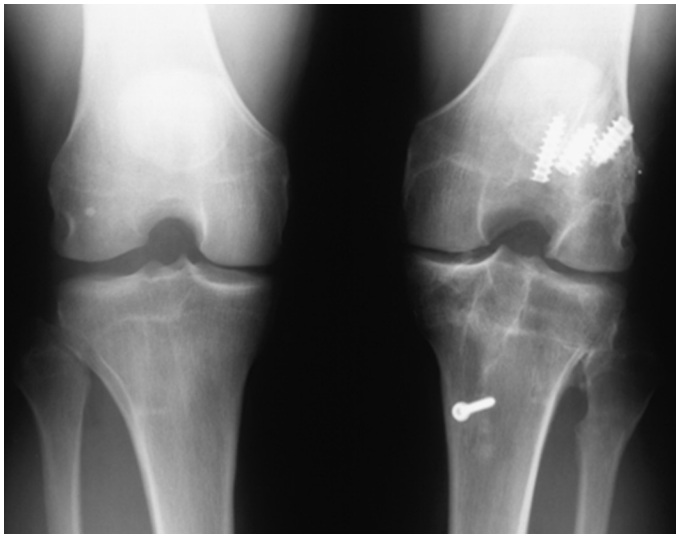

FIG 8-23 Case 6.

malalignment was not corrected, which produced pain and an obvious varus thrust with walking. Following the valgus-producing osteotomy and posterolateral reconstruction, a QT-PT autograft was favored over an allograft to decrease the possibility of failure of the third ACL revision procedure. Tibial tunnel dilation does occur in a small percentage of cases when the QT-PT graft is selected. In this case, the collagenous tendon portion was placed in the tibial tunnel and the patellar bone plug was placed in the femoral tunnel. The QT-PT graft provides the option of placing the bone plug at either the tibial or femoral location, based on the best graft fit at surgery.

INTRODUCTION

Mid-substance anterior cruciate ligament (ACL) injuries in the skeletally immature athlete are being recognized with increasing frequency. ACL injury has been reported in 10% to 65% of pediatric knee injuries with acute hemarthroses. This increased incidence is largely attributed to changes in the activity patterns of young athletes. Participation in sports is on the rise, with young athletes training year-round and specializing at earlier ages. Increased demand for peak performance at an age of major physiologic change and neuromuscular deficits may also contribute to an increase in ACL injuries in young athletes.

Ongoing debate regarding the optimal treatment for ACL injuries in children has not resulted in a clear consensus for initial nonoperative treatment or operative reconstruction. The age and relative skeletal maturity of the child influence management. Although nonoperative treatment avoids iatrogenic injury to open physes, the current literature supports the trend toward early operative treatment to restore knee stability and prevent meniscal and chondral damage that is irreversible.

The optimal surgical approach to ACL reconstruction in this age group also continues to be debated. The concern regarding iatrogenic growth disturbance in children prevents the routine use of anatomic ACL reconstruction that has proved successful in adults. The armamentarium of operative techniques for treating ACL injuries in skeletally immature patients has expanded over the past decade. Alternative surgical treatment options include primary repair, extraarticular reconstruction, and all-epiphyseal and transphyseal intraarticular reconstruction. Although these injuries are occurring with increasing frequency, long-term studies to help guide optimal management approach are still lacking.

INDICATIONS

Historical recommendations for nonsurgical management of ACL insufficiency in the skeletally immature patient were based primarily on the concern for complications related to physeal injury. However, the majority of active patients treated nonsurgically were unable to return to sports, developed symptomatic instability, sustained meniscal tears, and experienced long-term sequelae of articular cartilage damage. Unfortunately, the options for the young patient who develops traumatic osteoarthritis are very limited. Therefore, instability (giving-way) must be controlled. If activity modification can successfully eliminate episodes of instability, nonoperative treatment is an option.

CRITICAL POINTS **Indications**

- Historically, recommendations for nonsurgical treatment were based on concerns about physeal injury.
- A majority of active patients who are treated nonsurgically are unable to return to sports, develop symptomatic instability, sustain meniscal tears, and experience long-term sequelae of articular cartilage damage.
- If instability persists, the permanent sequelae of nonoperative treatment can be more difficult to manage than growth plate injury.

If instability persists, the permanent sequelae of nonoperative treatment are seemingly more difficult to deal with than physeal injury.

Graf and associates[9] reported poor results at 15 months after ACL injury, with new meniscal tears and episodes of instability in seven of eight skeletally immature patients who did not undergo reconstruction. Similarly, in a series of 18 skeletally immature patients examined an average of 51 months after complete ACL tear, Mizuta and colleagues[31] found that all patients had symptoms, 6 had meniscal tears, and 11 had developed radiographic changes. McCarroll and associates[26] reported superior results with surgical management of complete ACL tears in prepubescent and junior high school patients compared with patients receiving conservative treatment. Of 16 prepubescent patients treated nonoperatively, 9 stopped all sports participation, 4 sustained at least one reinjury, and only 3 were able to return to sport.[26] In their study of a separate group of 75 junior high school athletes with mid-substance tears, McCarroll and colleagues[27] reported that 37 of 38 patients who were initially treated nonoperatively had instability and 27 (71%) developed meniscal tears. Overall, 92% (55 of 60) of those treated with reconstruction were able to return to play.[27] Prolonged delay between injury and reconstruction has been associated with irreparable meniscal injury. Lawrence and colleagues[21] reported on a cohort of 29 patients who underwent ACL reconstruction more than 12 weeks from the time of injury. There was a significant association between time to reconstruction and severity of both chondral lesions and medial meniscal tears.[21] Henry and colleagues[13] compared two treatment strategies for the management of ACL rupture in skeletally immature patients. Group 1 patients were treated at a children's hospital with physeal-sparing reconstruction. Group 2 participants underwent delayed reconstruction at an adult hospital once skeletally mature. Patients in group 2 had a higher rate of medial meniscal tears (41% vs 16%) and a higher rate of meniscectomy.[13]

In a recent metaanalysis of nonoperative versus operative treatment, Ramski and colleagues revealed multiple trends that favored early surgical stabilization over nonoperative or delayed treatment. Patients treated nonoperatively or with delayed reconstruction experienced more instability and inability to return to previous activity levels.[33]

Similarly, in a systematic review of 48 studies[41] that included both surgical and conservative treatment of complete ACL tears in immature individuals, Vavken and Murray found that conservative treatment resulted in poor clinical outcomes as well as a high incidence of secondary meniscal and chondral injuries. They concluded that surgical stabilization should be considered the preferred treatment.[41]

CONTRAINDICATIONS

Nonoperative treatment is contraindicated in patients with giving-way episodes that produce meniscal tears or articular cartilage damage. If surgical intervention is chosen, the patellar tendon autograft should not be harvested in a skeletally immature individual, because it violates the proximal tibial apophysis and may result in tibial recurvatum. The placement of bone blocks into tunnels drilled across the femoral or tibial physis reliably causes growth arrest and must be avoided. Similarly, disruption of the periosteum surrounding a growth plate (perichondrial ring) can alter growth. In the pubescent patient in whom a final growth spurt is anticipated, a soft tissue graft can be used.

Clinical reports of growth disturbance following ACL reconstruction in the skeletally immature athlete are rare. A survey of the Herodicus Society noted 15 cases of growth disturbance.[17] Associated risk factors included fixation hardware across the physis, large tunnels (≥12 mm), lateral extraarticular tenodesis, dissection in proximity to the perichondrial ring of LaCroix, and suturing near the tibial tubercle.[17] Yoo and associates[42] reported a retrospective review of 43 patients who underwent transphyseal reconstruction of the ACL using a soft tissue graft with postoperative magnetic resonance imaging (MRI) at a mean of 16 months. A focal bone bridge was observed in five patients, four involving the tibial physis and one at the femoral physis. Despite this, physeal angles did not change significantly during follow-up in either the coronal or sagittal plane.[42] The risk of physeal arrest following trauma with fractures involving the distal femoral and proximal tibial growth plates is much higher (30%-50%). If parents are unwilling to accept the risk of growth plate injury to their child, reconstruction should be delayed until the physes are closed.

CLINICAL EVALUATION

History

A tear of the ACL can result from a direct impact to the knee, but more commonly it is the result of a noncontact twisting or landing injury. The timing of injury, either acute or chronic, and any prior knee injury should be noted. Knee effusion, pain, and ability to bear weight are important factors in diagnosing an ACL tear. An audible pop heard at the time of injury may be reported. An acute hemarthrosis, particularly in the first 6 to 12 hours after injury, should raise concern for ACL injury. Stanitski and coworkers[37] found that 47% of preadolescents with a knee effusion had an ACL injury. Acute patellar dislocations may present with a similar mechanism and symptoms. Children with congenital limb deficiencies, such as tibial and fibular hemimelia, congenital short femur, or proximal femoral focal deficiencies, are a subset of patients with ACL insufficiency. These children may develop knee instability at a much younger age and without any history of trauma to the knee. These cases are more complex and must be evaluated on an individual basis.

Risk Factors for Injury

Notch volume. Prior studies have demonstrated a correlation between femoral intercondylar notch stenosis and ACL injuries in collegiate athletes.[20] In a recent study, Swami and associates[38] used MRI to compare notch volumes in skeletally immature patients with or without a torn ACL ligament. Their study results showed that notch volumes were significantly lower in knees with ACL tears than in control knees. Notch volumes were also significantly smaller in girls than in boys.[38] A decrease in notch volume implies a smaller ACL that has decreased strength on a congenital basis.

Landing mechanics. Existing studies have demonstrated that frontal knee motions and torques are strong predictors of noncontact ACL injury risk in female athletes. Video analysis studies also indicate a frontal plane "valgus collapse" mechanism of injury in females. Females have typically been found to land with greater peak knee abduction angles compared with males. Because the load-sharing among the knee ligaments is complex, coronal as well as sagittal plane loading mechanisms likely contribute to noncontact ACL injury. Risk factors are discussed in detail in Chapter 13.

CRITICAL POINTS Clinical Evaluation

- The most important component of diagnosing pediatric knee injuries is the physical examination.
- MRI can assist in detection of anterior cruciate ligament tears, as well as associated meniscal pathology and chondral injury. However, MRI does not quantify abnormal translation or rotation.
- An examination of the contralateral knee and generalized laxity is essential.

Physical Examination

The most important component of diagnosing pediatric knee injuries is the physical examination. The presence of an effusion should be noted. Palpation of the joint line as well as the distal femoral and proximal tibial physes should be performed. Active and passive motion should be documented. Varus and valgus laxity should be checked in full extension and at 30 degrees of flexion. A Lachman test should be performed and graded. Pivot shifting may be unreliable in the acute setting if the child is guarding. If the Lachman test is positive acutely, the pivot shift test can be deferred until the examination while the patient is under anesthesia if surgical intervention is chosen. Findings should always be compared with those in the contralateral uninjured knee. The patient should also be assessed for generalized ligamentous laxity, with the degree of knee hyperextension and tibial translation on the uninjured side noted.

Diagnostic Tests

Routine anteroposterior (AP) and lateral radiographic series should be obtained. The formation of the tibial spine and femoral notch should be assessed. Children with congenital limb deficiencies often have a deficient tibial eminence and hypoplastic lateral femoral condyle. In addition, a decrease in the size of the femoral notch has been implicated in ACL injury.[7] Comparison views and stress views may be selectively needed if physeal injury is suspected. MRI can assist in detection of ACL tears as well as associated meniscal pathology and chondral injury in those individuals who are difficult to examine. However, physical examination is more sensitive and specific than MRI in the evaluation of young patients. MRI may also be helpful in assessing for other intraarticular pathology in the young patient, including tibial eminence fractures, periarticular (physeal) fractures, and congenital absence of the ACL.

PREOPERATIVE PLANNING

Skeletal Maturity

The patient's level of skeletal maturity should be defined preoperatively. It is generally assumed that girls grow until 14 years of age and boys grow until age 16. However, age is not the only indicator of potential growth. Peak growth velocity occurs in girls aged 10 to 11 years and boys aged 13 to 14 years. Closure of the triradiate cartilage, which can be seen on a standard radiograph of the pelvis (Fig. 9-1), typically marks the end of peak growth velocity. The patient can be assessed physiologically for signs of development, as noted by Tanner and Davies.[39] A study by Slough and colleagues[36] suggested that preoperative Tanner staging performed by orthopedic surgeons has large interobserver variability and may not be reliable. The child can be classified as either prepubescent or pubescent. The prepubescent patient has physiologic findings consistent with Tanner stages 1 and 2 and a bone age younger than 12 years in boys and younger than 11 years in girls. The pubescent patient has physiologic findings consistent with Tanner stages 3 and 4 and a bone age of 13 to 16 years in boys and 12 to 14 years in girls. In girls, age at onset of menses can be useful. After menarche, girls enter a deceleration phase of growth and typically reach skeletal maturity 18 months later. Familial height can also be used as an approximate estimate of growth potential.

The patient can be assessed radiographically to determine skeletal maturity using the Risser sign on the pelvis. The Risser sign is a radiographic measurement based on ossification of the iliac apophysis, beginning on the lateral aspect and progressing medially (Fig. 9-2). Divided into four quadrants, the Risser sign proceeds from 0 (no ossification) to Risser 4, in which all four quadrants show ossification

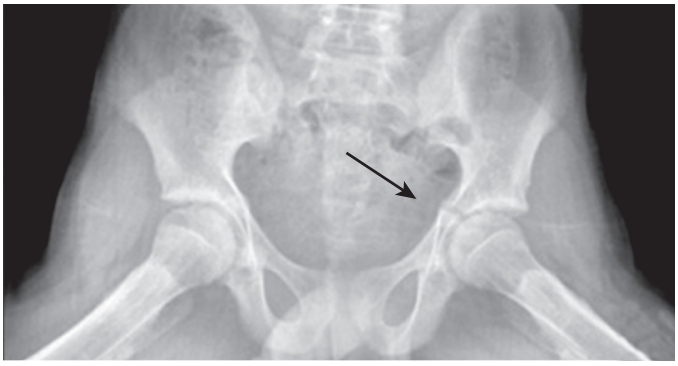

FIG 9-1 Radiograph of pelvis showing closure of the triradiate cartilage (*arrow*).

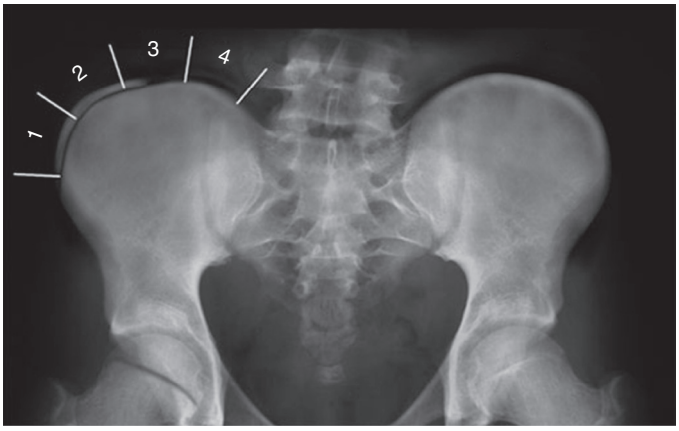

FIG 9-2 Skeletal maturity can be evaluated radiographically using the Risser sign on the pelvis, a measure of ossification of the iliac apophysis along four quadrants as shown. A Risser sign of 0 indicates little or no ossification (skeletal immaturity), whereas Risser 4 shows full ossification of the apophysis (skeletal maturity).

CRITICAL POINTS Preoperative Planning

- The patient's skeletal maturity should be defined preoperatively.
- The patient can be assessed both physiologically (Tanner stage) and radiographically to determine skeletal maturity using the Risser sign or bone age.

of the apophysis. Patients with Risser 0 or 1 have significant growth remaining, and the Risser 4 patient is skeletally mature. Bone age can be determined on the basis of examining a radiograph of the hand and wrist and comparing it with the standards in the Greulich and Pyle atlas.[10] The "rule of thirds" suggests that the distal femur and proximal tibia grow an average of 0.9 cm and 0.6 cm, respectively, per year of growth remaining. Limb lengths and bilateral lower-extremity alignment can be measured objectively using a mechanical axis radiograph. Genu valgum, more common in adolescent females, has been associated with ACL injury.

Associated Intraarticular Pathology

Previous studies have shown that 20% to 100% of pediatric patients who sustain ACL injuries have a concomitant meniscal injury. Although lateral meniscal tears are more common with acute injury, Millett and coworkers[30] found that the incidence of medial meniscal tears increases significantly with chronic ACL insufficiency. Of the 22 patients who

underwent surgery more than 6 weeks after injury, 72% had associated meniscal tears. If unstable meniscal tears exist, more aggressive management to salvage the meniscus in children may be indicated. Meniscectomy in this age group carries an even more ominous prognosis. Manzione and associates[25] evaluated the results of partial and total meniscectomy in 20 patients with a mean age of 15 years (range, 5-15 years). At 6-year follow-up, 16 knees had grade I osteoarthritis and 4 had grade II or III changes. Osteochondral injuries may also require debridement, drilling, and/or stabilization at the time of ACL reconstruction.

INTRAOPERATIVE EVALUATION

A complete physical examination of the affected knee should be repeated with the patient under anesthesia for laxity, including Lachman and pivot shift tests, and again compared with the contralateral side. Before ligament reconstruction, arthroscopic visualization of the knee may be needed to assess for the partial or complete nature of the ACL tear if the examination done while the patient was under anesthesia is inconclusive. Partial tear decisions should be based on the functioning of the remaining intact ligament and the degree of instability. Kocher and associates[16] performed a study on 45 adolescents with partial ACL tears. One third of patients underwent subsequent ACL reconstruction. The risk factors associated with failed nonsurgical management included tears involving more than 50% of the ACL, a positive pivot shift test, and older chronologic and skeletal age.[16]

OPERATIVE TECHNIQUES AND CLINICAL OUTCOMES

Treatment strategies for the ACL-deficient knee have evolved as recent studies have identified unique considerations specific to the skeletally immature patient. The current literature now supports a trend toward operative treatment to restore knee stability and prevent meniscal and/or articular cartilage injury, but the optimal approach to ACL reconstruction in the skeletally immature patient remains controversial. Conventional surgical ACL reconstruction techniques used in adults, when used in children, risk potential iatrogenic growth disturbances caused by physeal injury. The spectrum of surgical techniques used in skeletally immature patients includes primary repair, extraarticular tenodesis, physeal sparing, and partial or complete transphyseal reconstruction. Skeletal age, activity level, associated injuries, reported success, and expected graft longevity are among the factors to consider when selecting a technique.

CRITICAL POINTS Operative Techniques and Clinical Outcomes

- Conventional techniques used in adults risk potential iatrogenic growth disturbances in children, owing to physeal injury.
- Surgical techniques used in children include
  - Primary repair
  - Physeal sparing techniques
  - Transepiphyseal reconstruction
  - Partial transphyseal reconstruction (tibia only)
  - Transphyseal reconstruction
- Graft selection controversial; there are no prospective, randomized studies comparing the clinical success of graft type, graft placement, or graft fixation in skeletally immature patients.

Primary Repair

DeLee and Curtis[6] reported on three patients who underwent primary ACL repair through sutures tied across the physis. At 21 months of follow-up, all had clinical laxity and two of the three had episodes of giving-way. Engebretsen and colleagues[8] reviewed eight patients between 3 and 8 years of age following primary repair; they found that all experienced a decrease in activity level, and five of the eight demonstrated instability on clinical examination. Grontvedt and associates[11] also noted that primary repair of the ACL in the skeletally immature patient had poor results, similar to those in adults.

Although primary repair is not considered a treatment option, basic science studies suggesting that it may be a viable option in the future continue to emerge. A recent study of ACL repair in large animal models has indicated promising results with the use of a bioactive and biocompatible scaffold in the form of a clot to enhance cellular proliferation and biosynthesis at the torn ACL edges. Human clinical studies are necessary before any clinical application of this technique is undertaken.[40]

Physeal-Sparing Techniques

Early reports of physeal-sparing intraarticular reconstruction describe use of a hamstring autograft left attached distally, passed into the knee under the medial meniscus, and fixed to the lateral femoral condyle with staples in the over-the-top position on the femur (Fig. 9-3). This technique is nonanatomic and therefore does not reproduce the normal knee and ligament kinematics. In a report of nine patients at 36.5 months of follow-up, all had a 1+ Lachman test result and 1+ anterior drawer test score.[4] Six of nine patients had returned to sports, but with bracing and precautions. No growth disturbances were reported.[4]

More recently, Chicorell and colleagues[5] described the Micheli technique, which is a combined intraarticular and extraarticular reconstruction using autogenous iliotibial band (ITB) without violation of the physes. An incision is made obliquely from the lateral joint line to the superior border of the ITB. The ITB graft is harvested free proximally and left attached to the Gerdy tubercle distally, and it is tubularized with a whipstitch. Arthroscopy of the knee is then performed

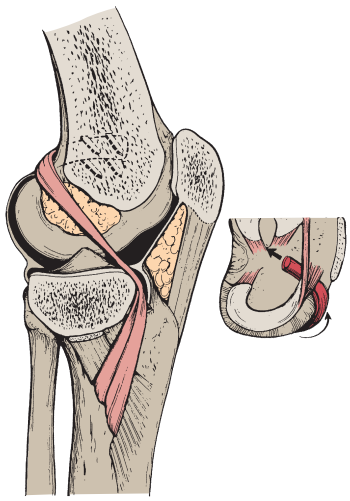

FIG 9-3 Cross section of the left knee shows the trajectory of the graft. The *inset* shows the tibial plateau with the graft coursing under the anterior horn of the medial meniscus. (Modified from Brief LP. Anterior cruciate ligament reconstruction without drill holes. *Arthroscopy*. 1991;7:350-357.)

through standard portals. The free end of the graft is brought into the knee in the over-the-top position of the femur posteriorly. A second incision is made over the proximal medial tibia. Dissection is carried down to the periosteum, and a curved clamp is placed into the joint under the intermeniscal ligament. The graft is then brought through the knee, under the intermeniscal ligament anteriorly, and out through the tibial incision. The graft is secured to the lateral femoral condyle using sutures placed at the insertion of the lateral intermuscular septum with the knee in 90 degrees of flexion and external rotation. On the tibial side, the graft is sutured to the periosteum of the proximal tibia just distal to the physis with the knee flexed 20 degrees while tension is applied to the graft (Fig. 9-4).

Postoperatively, the patient ambulates with crutches and toe-touch weight-bearing for 6 weeks. A hinged knee brace is set to allow 0 to 90 degrees of flexion initially, followed by progression to full motion after 2 weeks.

Micheli and coworkers[29] reported the results of 17 patients with an average chronologic age of 11 years and mean bone age of 10 years (range, 2-13 years) who underwent the physeal-sparing reconstruction described above. The mean follow-up was 66 months. All knees were subjectively stable and objectively stable by KT-1000 (MEDmetric) arthrometer testing. No child developed a growth disturbance. Although this was initially thought to be a temporizing procedure until adult-type reconstruction could be performed after skeletal maturity, a follow-up study of 44 skeletally immature patients (Tanner stage 1 or 2) with a mean chronologic age of 10.3 years (mean skeletal age, 10.1 years) by Kocher and associates[18] showed excellent results. Functional outcome, graft survival, and growth disturbance were evaluated at a mean of 5.3 years (range, 2-15.1 years) after surgery. Lachman test results were normal in 23 patients, nearly normal in 18 patients, and abnormal in 1 patient. Only two patients required revision reconstruction for graft failure, at 4.7 and 8.3 years postoperatively, respectively. No patient had an angular deformity or limb-length discrepancy clinically or radiographically. We strongly recommend this technique for prepubescent (Tanner stages 1 and 2) patients requiring ACL reconstruction.

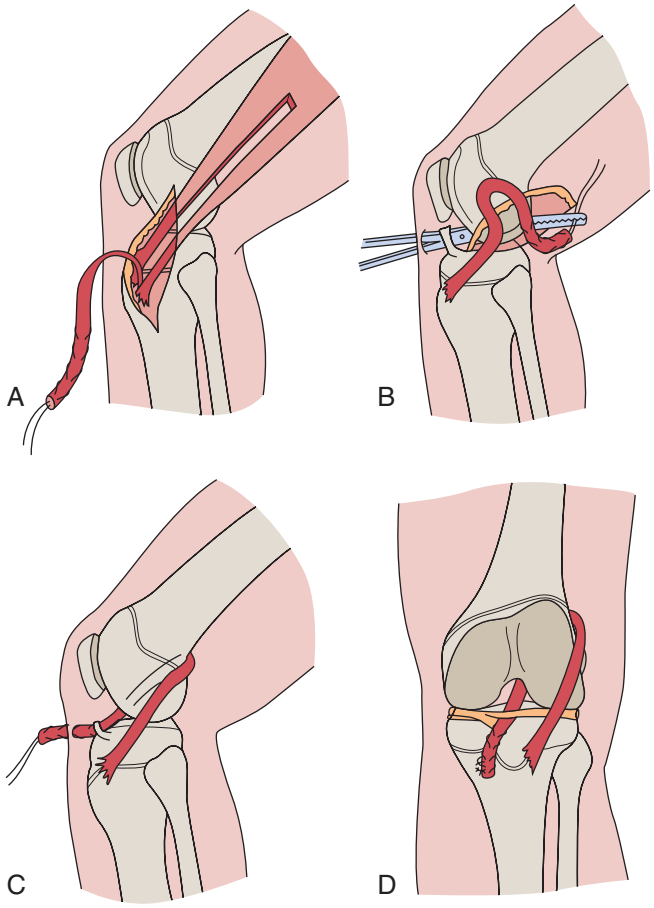

FIG 9-4 Physeal sparing combined with intraarticular and extraarticular reconstruction using an autogenous iliotibial band for prepubescent patients. **A,** The iliotibial band graft is harvested free proximally and left attached to the Gerdy tubercle distally. **B,** The graft is brought through the knee in the over-the-top position posteriorly. **C,** The graft is brought through the knee and under the intermeniscal ligament anteriorly. **D,** The graft is fixed to the intermuscular septum on the femoral side and to the periosteum of the proximal part of the tibia on the tibial side. (Modified from Kocher MS, Garg S, Micheli LJ. Physeal sparing reconstruction of the anterior cruciate ligament in skeletally immature prepubescent children and adolescents. Surgical technique. *J Bone Joint Surg Am.* 2006;88[suppl 1 pt 2]:283-293.)

Transepiphyseal Reconstruction

The nonanatomic, nonisometric positioning of physeal-sparing ACL reconstruction techniques creates concern for the biomechanics of the graft and, consequently, its longevity. Transepiphyseal ACL reconstruction generally follows the principles of ACL reconstruction in adults, but it minimizes the risk of physeal injury by not crossing the tibial or femoral physis.

The affected leg is positioned with the hip flexed approximately 20 degrees. A fluoroscope is positioned on the side of the table opposite the injured knee, and the femoral and tibial growth plates are visualized in both planes before prepping and draping the patient. An oblique incision is made over the hamstring tendons. The semitendinosus and gracilis tendons are harvested and then doubled. Arthroscopy of the knee is accomplished in a standard fashion. With the C-arm in the lateral position, the point of the guidewire is positioned on the skin over the lateral femoral condyle, corresponding to the location of the footprint of the ACL. A small lateral incision is made, and the ITB is split longitudinally. The guidewire is advanced across the femoral epiphysis, and the C-arm is used to confirm that the guidewire is not angulated in the AP or inferosuperior planes. The guidewire is visualized in the intercondylar notch arthroscopically, entering the joint at the proximal femoral footprint. A second guidewire is then inserted into the anteromedial tibia at the level of the epiphysis. The guidewire is advanced, clearing the tubercle anteriorly and entering the joint at the free edge of the lateral meniscus on the tibia (center of the footprint of the ACL). Tendon sizers are used to measure the diameter of the tendon graft and the smallest appropriate reamer and the appropriate EndoButton (Smith & Nephew) fixation device are chosen. The EndoButton and tendons are pulled up through the tibia and out the femoral tunnel with a suture. An EndoButton washer is placed over the EndoButton and the graft is placed under tension, pulling the EndoButton and washer to the surface of the lateral femoral condyle. With the knee in 10 degrees of flexion, the graft is secured distally over a screw and post placed medial to the tubercle and distal to the tibial physis (Fig. 9-5).

Two series in which transepiphyseal ACL reconstruction was performed in skeletally immature patients have been reported. Guzzanti and coworkers[12] reported the results of using this technique in five preadolescent patients (Tanner stage 1) with ACL injuries. The hamstring graft was left attached to the tibia, a transepiphyseal tibial tunnel was used, and the graft was looped over a staple placed at the femoral attachment of the ACL. At a minimum follow-up of 4 years, KT-1000 arthrometer testing revealed an average side-to-side difference of

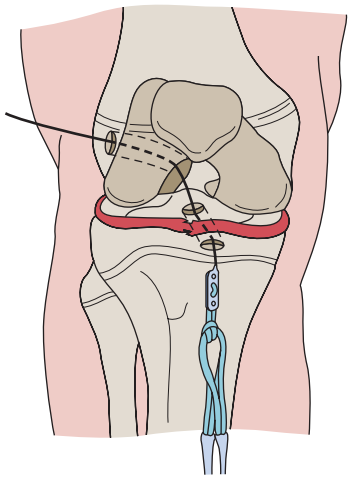

FIG 9-5 The semitendinosus and gracilis tendons are pulled up through the tibia and out the lateral femoral condyle with use of a No. 5 suture in the EndoButton fixation device. (Modified from Anderson AF. Transepiphyseal replacement of the anterior cruciate ligament in skeletally immature patients. A preliminary report. *J Bone Joint Surg Am.* 2003;85:1255-1263.)

1.8 mm. Anderson[1] reported his results of using the technique described above in a series of 12 patients (Tanner stages 1-3). At a mean follow-up of 4.1 years (range, 2-8.2 years), KT-1000 arthrometer testing revealed a mean side-to-side difference of 1.5 mm. In both series, there were no reported growth abnormalities and no subjective or objective evidence of recurrent instability in a minimum of 4 years of follow-up.

Lawrence and associates[22] reported a modification of this technique using an intraoperative O-arm (Medtronic) for tunnel placement in prepubescent, skeletally immature patients. With their method, intraoperative computed tomographic scanning with 3-dimensional reconstruction is used to confirm the precise localization of the all-epiphyseal femoral and tibial tunnels. The femoral tunnel is drilled entirely in the epiphysis of the lateral femoral condyle. The tibial tunnel is drilled from inside out to the level of the tibial physis using a retrograde drill. Fixation of the soft tissue graft is achieved with a retrograde interference screw in the tibia and an interference screw in the femur. Lawrence and associates[22] reported results for three boys ages 10 to 12 years (Tanner stage 1) with a minimum follow-up of 1 year. All three patients objectively had stable knees based on Lachman and KT-1000 testing. There was no evidence of growth disturbance in any of these patients, and all three returned to sports activity using a custom ACL brace.

Partial Transphyseal Reconstruction

The partial transphyseal technique is a hybrid technique in which the graft is placed through a transphyseal tibial tunnel and fixed to the femur in the over-the-top position. A soft tissue graft is passed through a 6- to 8-mm drill hole that crosses the tibial physis. The tunnel is placed more vertically to decrease the risk of damage to the physis. The graft is secured in the over-the-top position on the femur, with care taken not to damage the distal femoral physis during fixation.

Lipscomb and Anderson[23] reported a series of 24 patients (21 males, 3 females) aged 12 to 15 years who underwent partial transphyseal reconstruction. Eleven patients had a completely open physis, and 13 had a partially open physis. Skeletal age was not recorded. A hamstring autograft was placed across the tibial physis (6.4-mm tunnel) and exited through a femoral epiphysis. In addition, an extraarticular reconstruction of the lateral side was routinely added for rotational stability. At an average follow-up of 35 months, the side-to-side difference found in Lachman tests averaged 1.8 mm, and all patients denied swelling or giving-way. One patient developed a 2-cm limb-length inequality as a result of stapling across the femoral and tibial physes.[23]

Andrews and colleagues[2] performed ACL reconstruction in eight adolescents using either a 7-mm fascia lata or Achilles tendon allograft placed centrally across the tibial physis and secured to the femur in the over-the-top position. At skeletal maturity, there were no detected limb-length discrepancies (Figs. 9-6 and 9-7).

Lo and coworkers[24] reported on five patients with an average age of 12.9 years (range, 8-14 years) who underwent partial transphyseal reconstruction with either a hamstring or patella tendon autograft passed centrally through the tibial physis (6 mm) to an over-the-top position on the femur. At an average follow-up of 7.4 years, scanograms revealed no angular deformities or leg-length discrepancies.

Kennedy and associates[15] performed a biomechanical comparison of three different physeal-sparing techniques to determine which most closely restored native knee kinematics. Displacement and rotation of the tibia with respect to the femur were measured after ACL reconstruction using all-epiphyseal, partial transphyseal (transtibial over-the-top), and ITB physeal-sparing techniques. Although all physeal-sparing reconstruction techniques restored some stability to the knee, the ITB reconstruction best restored both AP and rotational stability.[15]

Transphyseal Reconstruction

Complete transphyseal reconstruction is performed with standard bone tunnels that traverse the physes of both the tibia and the femur. This technique is equivalent to conventional ACL reconstruction in adults, with the use of either autograft or allograft tissue. Aronowitz and associates[3] reported on 19 skeletally immature patients ages 11 to 15 years who underwent allograft reconstruction through tunnels in the distal femur and proximal tibia (Fig. 9-8). All patients had a skeletal age of at least 14 years. At an average of 25 months after surgery (range, 12-60 months), there were no significant leg-length discrepancies or angular deformities, as determined by scanograms and AP and lateral radiographs of the femur and tibia. The mean Lysholm knee score was 97 (range, 94-100), and the mean KT-1000 side-to-side difference was 1.7 mm (range, 0.0-3.0 mm). All patients were satisfied with the results of surgery, and 16 of 19 patients returned to the same sport they participated in before the injury.[3]

McIntosh and colleagues[28] reported on 16 patients (11 male and 5 female) who underwent transphyseal ACL reconstruction. Each patient was followed until skeletal maturity, with a mean clinical follow-up of 41.1 months (range, 24-112 months). At last follow-up, the mean leg-length discrepancy was 0.62 cm (range, 0.2-1.5 cm). Clinical or radiographic evidence of malalignment was not present in any patient. At follow-up, the mean modified Lysholm knee score was 98.8 (range, 94-100), and the majority of patients (87.5%) had returned to their previous level of activity.[28]

Shelbourne and coworkers[35] reported a series of 16 patients with open growth plates who underwent transphyseal ACL reconstruction with a patellar tendon autograft. At the time of surgery, seven patients were Tanner stage 3 and nine were Tanner stage 4. The surgical technique was meticulous for placing the bone plugs proximal to the physes and not overtensioning the graft. Clinical follow-up (mean, 3.4 years after surgery) showed that no patients had growth plate disturbances, angular deformities, or leg-length discrepancies. All patients returned to competitive sports after surgery.[35]

Most recently, Kocher and associates[18] reported on 61 knees in 59 skeletally immature pubescent adolescents (Tanner stage 3) who underwent transphyseal ACL reconstruction using hamstring

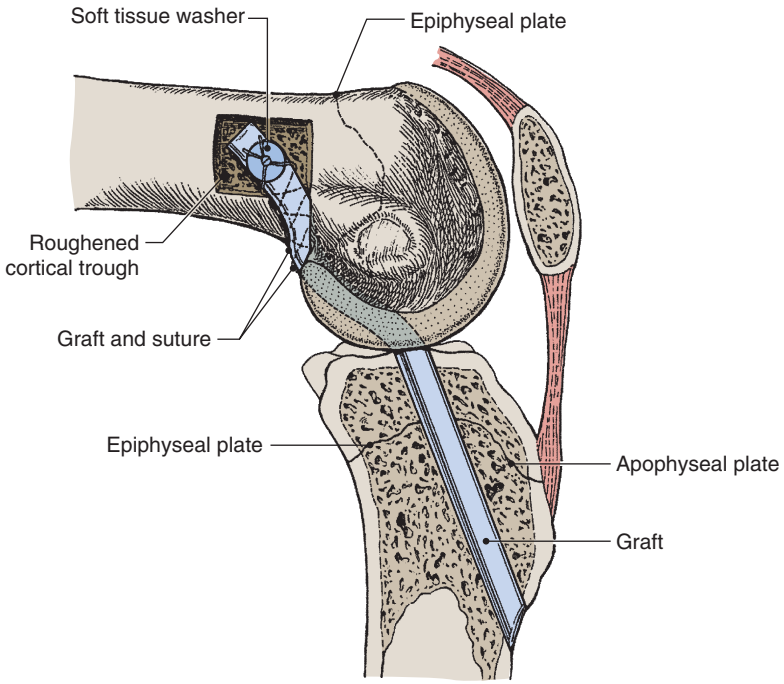

FIG 9-6 Over-the-top position in the lateral femoral condyle with elevation of periosteal H-flaps and roughening of the femoral cortical trough. (Modified from Andrews M, Noyes FR, Barber-Westin SD. Anterior cruciate ligament allograft reconstruction in the skeletally immature athlete. *Am J Sports Med.* 1994;22:48-54.)

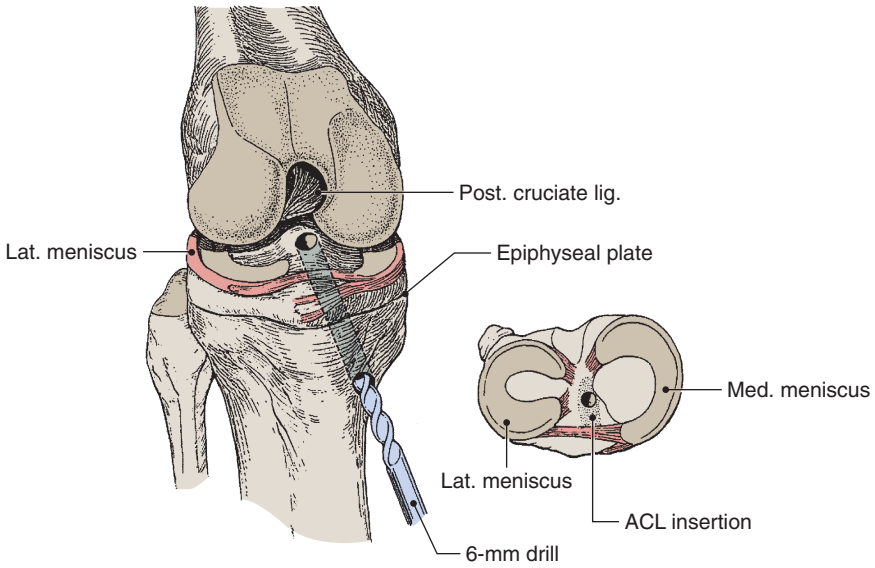

FIG 9-7 A 7-mm drill hole is made through the anteromedial aspect of the tibia (~3 cm), passing proximal to the epiphyseal plate in the center of the growth plate in a perpendicular fashion slightly posterior to the anatomic anterior cruciate ligament (ACL) insertion. (Modified from Andrews M, Noyes FR, Barber-Westin SD. Anterior cruciate ligament allograft reconstruction in the skeletally immature athlete. *Am J Sports Med.* 1994;22:48-54.)

autograft and metaphyseal fixation. Functional outcome, graft survival, and growth disturbances were evaluated at a mean of 3.6 years after surgery. Two patients required revision surgery for graft failure. The Lachman test results were normal in 51 knees and nearly normal in 8 knees, and no patient had an abnormal pivot shift test. The mean increase in height from the time of surgery was 8.2 cm (range, 1.2-25.4 cm), and no angular deformities or limb-length inequalities were detected clinically.[18]

These and other reports consistently support the use of transphyseal ACL reconstruction in pubescent (Tanner stages 3 and 4) adolescents. Overall, few growth disturbances have been reported following transphyseal reconstruction. Koman and Sanders[19] reported a case of 14-year-old boy who developed a distal femoral valgus deformity requiring osteotomy and contralateral epiphysiodesis following transphyseal reconstruction with a semitendinosus autograft. The skeletal age of the patient was unknown. The tibial tunnel diameter was

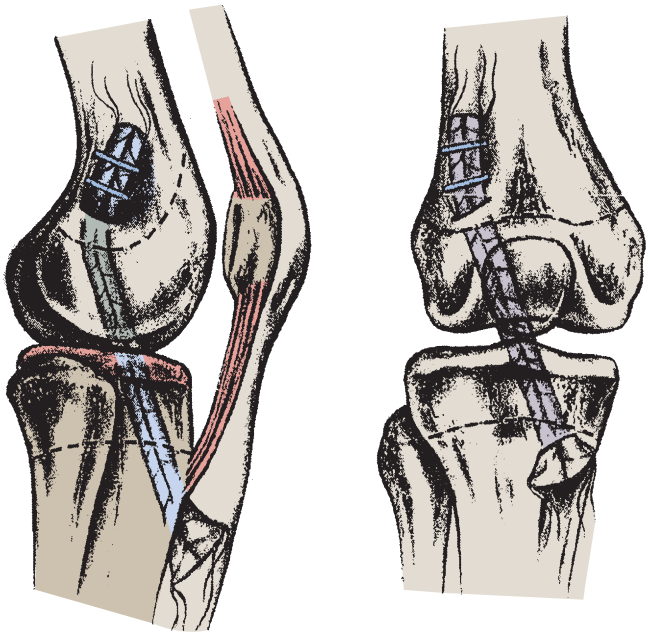

FIG 9-8 Lateral (*left*) and anteroposterior (*right*) views illustrating the technique of passing an Achilles tendon allograft through drill holes across the open physis of both the proximal tibia and distal femur. The graft is press-fitted on the tibial side before fixation with two staples on the femoral side. (From Aronowitz, E, Ganley TJ, Goode JR, et al. Anterior cruciate ligament reconstruction in adolescents with open physes. *Am J Sports Med.* 2000;28:168-175.)

unknown, but a 9-mm femoral tunnel was drilled. Cancellous bone plugs were inserted into both tunnels, and the tendon was fixed with a cannulated screw across the lateral femoral condyle.[19]

Transphyseal tunnels in the skeletally immature patient are more vertical, particularly on the femoral side. Shea and colleagues[34] used a computer-aided 3-dimensional model to incorporate the drilling of an anatomic ACL femoral tunnel in 10 pediatric knees using a variety of drill-hole diameters. They demonstrated that, with this technique, the average physeal volume removed was between 3.7% and 6.5%. Anatomic tunnel placement during ACL reconstruction produces an unacceptably large zone of physeal injury to the distal femoral physis.[34]

Graft Selection

The use of autograft versus allograft tissue in ACL reconstruction remains a source of controversy. A recent study was conducted to evaluate graft choice as well as the risks associated with graft failure.[14] Patients between ages 10 and 19 years had the highest rate of graft failure, regardless of whether autograft or allograft was used. In addition, the rate of graft failure was four times higher with allograft than with autograft reconstruction.[14]

Despite the numerous reports describing ACL reconstruction using extraarticular techniques, intraarticular physeal-sparing surgery, and transphyseal reconstruction of the ACL, there are no prospective, randomized studies comparing the clinical success of graft type, graft placement, or graft fixation in skeletally immature patients. The existing literature includes studies with relatively small sample sizes and use of a variety of outcome measures, making comparisons among studies difficult. Unfortunately, some of the reports do not clearly note the patients' sex, chronologic or skeletal age, or the level of skeletal maturity at the time of surgery. These studies also combine patients in different age groups (i.e., 8-15 years), making it difficult to interpret the results. Despite these limitations, the available studies in the literature do not support any trend or significant pattern of growth disturbance (leg-length inequality or angular deformity) following ACL reconstruction with or without physeal violation in patients with open physes.

RECOMMENDATIONS

A recent systematic review confirms the benefits and safety profile of ACL reconstruction in the skeletally immature patient.[41] The current treatment algorithm is predicated on the patient's skeletal, chronologic, and physiologic age, as well as on the extent of the ACL tear. Patients with partial tears involving less than 50% of the entire ACL diameter are treated nonsurgically with activity modification, physical therapy, and bracing. A patient with a clinically stable knee on examination and stress maneuvers typically can return to sports activity approximately 3 to 6 months following the initial injury. Complete ACL ruptures are managed surgically even in the very young patient. In prepubescent patients (i.e., Tanner stages 1 and 2) (bone age: boys, ≤12 years; girls, ≤11 years), a physeal-sparing combined intraarticular and extraarticular reconstruction using an autogenous ITB graft is preferred.[29] In the pubescent patient with open growth plates and more than 1 year of growth remaining, a partial transphyseal reconstruction (vertical tibial tunnel across the physis and over the top on the femur) using a hamstring autograft is preferred. Adolescent patients with minimal growth remaining (i.e., Tanner stages 3 and 4; bone age: boys, 13-16 years; girls, 12-14 years) are treated with complete transphyseal reconstruction using autogenous quadrupled hamstring or quadriceps tendons with smaller, more vertical tunnels and metaphyseal fixation. In older adolescent patients with closing physes (i.e., Tanner stage 5) (bone age: males, >16 years; females, >14 years), an anatomic adult-type ACL reconstruction with an autogenous quadrupled hamstring or bone-patellar tendon graft and interference screw or aperture fixation is preferred.

Patients are placed in a range-of-motion (ROM) brace for 6 weeks postoperatively. Patients treated with ITB ACL reconstruction are restricted to toe-touch weight-bearing for 6 weeks, whereas patients treated with a transphyseal technique are restricted to toe-touch weight-bearing until muscle control of the limb is achieved. Progressive rehabilitation consisting of ROM, closed-chain quadriceps and hamstring strengthening, patellar mobilization, and modalities are used for the first 3 months postoperatively. Initiation of straight-line jogging and plyometrics may begin as early as 3 to 5 months after reconstruction, depending on ROM and strength or functional progression. A full return to cutting and pivoting activities and sports is considered at 6 to 8 months postoperatively if all strength and functional parameters, including symmetry, are met.

CRITICAL POINTS Recommendations

- Prepubescent patients: physeal sparing, combined intraarticular and extraarticular reconstruction of autogenous ITB
- Pubescent patients, open growth plates, more than 1 year of growth remaining: partial transphyseal reconstruction hamstring autograft
- Adolescents, minimal growth remaining: complete transphyseal reconstruction autogenous quadrupled hamstring or quadriceps tendon graft with smaller, more vertical tunnels and metaphyseal fixation
- Older adolescents with closing physes: anatomic adult-type ACL reconstruction with autogenous quadrupled hamstring or bone–patellar tendon graft and interference screw or aperture fixation

INJURY PREVENTION

Neuromuscular Training

Well-designed injury prevention programs reduce the risk of ACL injuries for athletes, particularly females. These programs attempt to alter dynamic loading of the tibiofemoral joint through neuromuscular and proprioceptive training. They emphasize proper landing and cutting techniques. This includes landing softly on the forefoot and rolling back to the rearfoot, engaging knee and hip flexion, and, whenever possible, landing on two feet. Players are also trained to avoid excessive dynamic valgus of the knee and to focus on the "knee-over-toe position" when cutting.

Studies have shown reductions in lower-extremity injury rates with the use of training protocols that focus on landing mechanics, balance training, strength training, and/or agility training. Implementation of injury prevention training was effective in limiting the loss of knee control in female athletes during puberty, suggesting that it might be possible to lower the risk of ACL injury in this population.[32] Preventive programs should be implemented during ACL rehabilitation, followed by a maintenance program.

INTRODUCTION

Considerable advances have been made in the treatment of complete anterior cruciate ligament (ACL) ruptures and reconstruction methods. These include the appropriate selection of patient candidates and criteria for goals that should be achieved before surgery, such as resolving limitations of knee motion, muscle atrophy, gait abnormalities, pain, and joint effusion.[24,58,65,66,170,171,229,244,255,284] Appropriate graft selection, harvest, implantation, tensioning, and fixation are all paramount to achieving a reliable and desirable outcome.[8,181,286] The main goals of rehabilitation after surgery are to prevent complications such as arthrofibrosis and reinjury and eventually achieve normal knee function. Patients must regain full knee motion; normal patellar mobility; normal gait mechanics; and adequate lower-extremity muscle strength, coordination, proprioception, and neuromuscular function for their desired activities. Importantly, the exercise program should not produce undue forces on the healing ACL graft, patellofemoral or tibiofemoral compartments, or precipitate chronic joint effusions. The opposite extremity must be rehabilitated as well so that symmetries in strength and neuromuscular function are restored.

There are many factors that may impact both the initial and long-term recovery after ACL reconstruction (Table 10-1).[58] Few ACL ruptures are truly isolated in nature because approximately 80% of patients sustain concomitant bone bruises[78,138] and 60% sustain meniscus tears.[204,207] Investigators have noted no benefit[34,187] and, in some cases, deleterious outcomes[229,248,285] when ACL reconstruction is performed before the resolution of limitations in knee motion, muscle atrophy, swelling, and pain. Investigators have heavily emphasized the need to restore normal knee motion when possible before surgical intervention.[229,238,249,291] The exception is the presence of a mechanical block to extension, such as a bucket-handle meniscus tear.[246] In these cases, early surgical intervention is warranted to repair the meniscus tear, rehabilitate the knee to regain full extension and flexion, and then proceed with ACL reconstruction. In certain cases, the ACL reconstruction may be performed at the same time as the meniscus repair. Communication between the surgeon and therapist is essential so that the therapist understands what was done at surgery (especially any concomitant procedures) and the condition of the menisci and articular cartilage surfaces.

An important issue is whether the postoperative rehabilitation process should be governed and progressed according to the amount of time that has elapsed or by well-defined and measurable criteria. Although some programs allow a return to full activities according to a certain amount of time, such as 6 months postsurgery, others (including these authors) will not release patients until specific muscle and function objectives have been achieved, regardless of the amount of time that has passed since surgery.[11,12] There is no consensus among investigators regarding which factors are the most important to measure to determine when patients may safely return to athletic

TABLE 10-1 Factors Affecting Recovery After Anterior Cruciate Ligament Reconstruction

- Resolution of limitations in knee motion, muscle atrophy, gait abnormalities, pain, and knee joint effusion *before* surgery
- Anterior cruciate ligament (ACL) graft selection, harvest, placement, fixation, healing, and remodeling
- Initial patient response to surgery, including pain, effusion, and muscle inhibition
- Patient psychological factors, such as motivation, beliefs, compliance, self-efficacy, and fear of reinjury
- The condition of the articular cartilage
- The presence and severity of bone bruising
- Concomitant major operative procedures: meniscus repairs or transplants, other ligament reconstructions, patellofemoral realignment procedures, and articular cartilage restorative procedures
- Lingering postoperative deficits in muscle strength and neuromuscular function
- Patellofemoral pain or tendinitis
- Restoration of normal knee stability
- Previous ACL reconstruction that failed

activities.[246] This is concerning when one understands the risks of reinjury to either the ACL-reconstructed knee or contralateral ACL.[12]

Modern studies of ACL autograft reconstruction typically report failure rates ranging from 5% to 15%.[35,47,126,152,203] Failure is defined as an increase in anteroposterior (AP) displacement of 6 mm or more compared with the normal contralateral limb or a fully positive (grade 2 or 3) pivot shift test. However, the percentage of grafts that undergo some amount of elongation, resulting in 3 to 5 mm of increased AP displacement or a mildly positive (grade 1) pivot shift test, is quite variable and ranges from 5% to 50%.[80,89,106,110,142,267] Therefore although the overall rate of failure is usually acceptable, some authors express concern that any amount of abnormal anterior tibial translation may be detrimental to the knee joint over the long term.[26,222] Graft elongation may occur as a result of technical aspects of the operative procedure, inconsistencies in maturation of the collagenous and bony components of the construct, the rehabilitation program, or a combination of these factors.

Many modern studies have identified problems with altered gait biomechanics, muscle strength, and neuromuscular function many months or years following ACL reconstruction.* Although deficits in proprioception following ACL reconstruction were reported by investigators several years ago,[15,31,166,174] several recent studies refuted these findings.[4,28,123,168,194,218,232] Even so, altered muscle and neuromuscular function are especially concerning when patients resume sports activities, and investigators have hypothesized that these problems may result in serious reinjuries.[11,240,289]

The purpose of this chapter is to review the current knowledge regarding rehabilitation after ACL autogenous reconstruction. The scientific basis for immediate knee motion, early weight bearing, methods to regain muscle strength and neuromuscular function, and evaluation criteria for return to activity are reviewed. Our ACL postoperative rehabilitation programs, formulated from the scientific literature and over 3 decades of empirical clinical experience, are detailed in Chapter 11.

CRITICAL POINTS Immediate Knee Motion, Early Weight Bearing, Bracing

- Scientific basis supporting immediate range of motion exercises after ACL reconstruction is well established. Include patellar mobilization.
- Treat limitations of knee motion early postoperatively with overpressure program.
- Immediate partial weight bearing safe, not harmful to ACL graft.
- No high-quality evidence supports postoperative bracing. Helpful in select patients for protection and comfort.

IMMEDIATE KNEE MOTION, EARLY WEIGHT BEARING, AND BRACING

The scientific basis supporting immediate range-of-motion (ROM) exercises after ACL reconstruction is well established.[25,118,131,132,154,205] Early knee joint motion decreases pain and postoperative joint effusions, aids in the prevention of scar tissue formation and capsular contractions that can result in arthrofibrosis, decreases muscle disuse effects, maintains articular cartilage nutrition, and benefits the healing ACL graft.[46,229,257] There is a consensus in the medical community that immobilization is detrimental to the knee joint structures and may result in a permanent limitation of knee motion, prolonged muscle atrophy, patella infera, and articular cartilage deterioration.[46,208-210,224] Failure to achieve full knee motion may cause abnormal joint arthrokinematics, increased contact pressures in the patellofemoral and/or tibiofemoral joints, patellofemoral osteoarthritis, and a poor outcome.[48,199,250,291] Shelbourne and Gray[250] noted a significant association between the loss of 3 to 5 degrees of knee extension and radiographic arthritis (abnormal or severely abnormal International Knee Documentation Committee [IKDC] rating).

The use of an immediate postoperative knee motion program (in the range of 0-90 degrees) after ACL reconstruction was initiated in our center in 1981.[206] Patellar mobilization is an important component of this program to help prevent the formation of excessive scar tissues around the patella, the medial and lateral retinaculum, and the fat pad. An investigation was later conducted in our center on 443 knees that had an arthroscopy-assisted ACL bone-patellar tendon-bone (B-PT-B) autograft reconstruction to determine the effectiveness of this program in restoring normal knee motion.[205] The protocol included the early recognition and treatment of limitations of flexion and extension according to goals established before surgery. Patients who did not achieve 0 to 90 degrees of flexion by the end of the first postoperative week were placed into an overpressure protocol initially (Fig. 10-1). This was followed, if required, by a serial extension cast program (Fig. 10-2) and, in rare instances, by arthroscopic debridement of scar tissues (Fig. 10-3). Treatment intervention was performed in 23 knees, all of which achieved normal knee motion. At follow-up (mean, 25 months postoperatively), a normal ROM was detected in 436 knees (98%) and a mild limitation of extension of 5 degrees was found in 7 patients who refused additional treatment intervention. Only three knees required an arthroscopic lysis of adhesions that, combined with an inpatient epidural program, resulted in successful resolution of the motion limitations. The incidence of knee motion problems based on concomitant surgical procedures with the ACL reconstruction was 22% for medial collateral ligament repairs, 18% for patellar realignment procedures, 8% for meniscus repairs, and 6% for isolated ACL reconstructions.

Although many authors have recommended early partial or full weight bearing immediately following ACL reconstruction, few studies have examined this factor and its potential effect on both short- and

FIG 10-1 Knee overpressure exercises for limitation of extension **(A)** and flexion (**B** to **D**).

long-term recovery.[282,295] The effect of immediate full weight bearing on the outcome in knees with noteworthy articular cartilage damage or those in which major concomitant operative procedures were required is unknown. In addition, gait abnormalities that may ensue from immediate full weight bearing owing to pain, knee joint effusion, and muscle weakness have not been examined. It does appear, based on the literature[28,90,107,243] and our experience,[14] that immediate partial weight bearing is safe and not deleterious to the healing ACL graft.

Ohkoshi and associates[212] recommended early weight bearing after ACL reconstruction many years ago. These investigators used an analytical model to calculate shear forces placed on the tibia during standing at various trunk and knee flexion angles (Fig. 10-4). The shear forces were posteriorly directed in all positions, which increased as trunk flexion angles increased (at knee flexion angles of 30 and 60 degrees). Cocontraction of the quadriceps and hamstrings was observed at all knee and trunk flexion angle positions, with increasing hamstring activity measured with increasing trunk flexion angles. Exercises performed in the standing position with the knees flexed and the trunk anteriorly flexed, such as half-squatting, were believed to not only be safe but also to have the potential advantages of increasing muscle strength, endurance, and proprioception and decreasing bone atrophy.

The effects of postoperative and functional braces on pain, return of normal knee motion, complications, sports activity performance, balance, and proprioception have been assessed by many investigators.[154,169,183,294] Most studies report that braces do not provide significant benefit in achievement of normal (1) knee motion, (2) isokinetic lower-extremity muscle strength, (3) stability, (4) lower limb symmetry on single-leg hop tests, and (5) functional knee rating and activity level scores.[30,107,119,131,132,185,237,294] In addition, in systematic reviews[24,154,169,183,294]

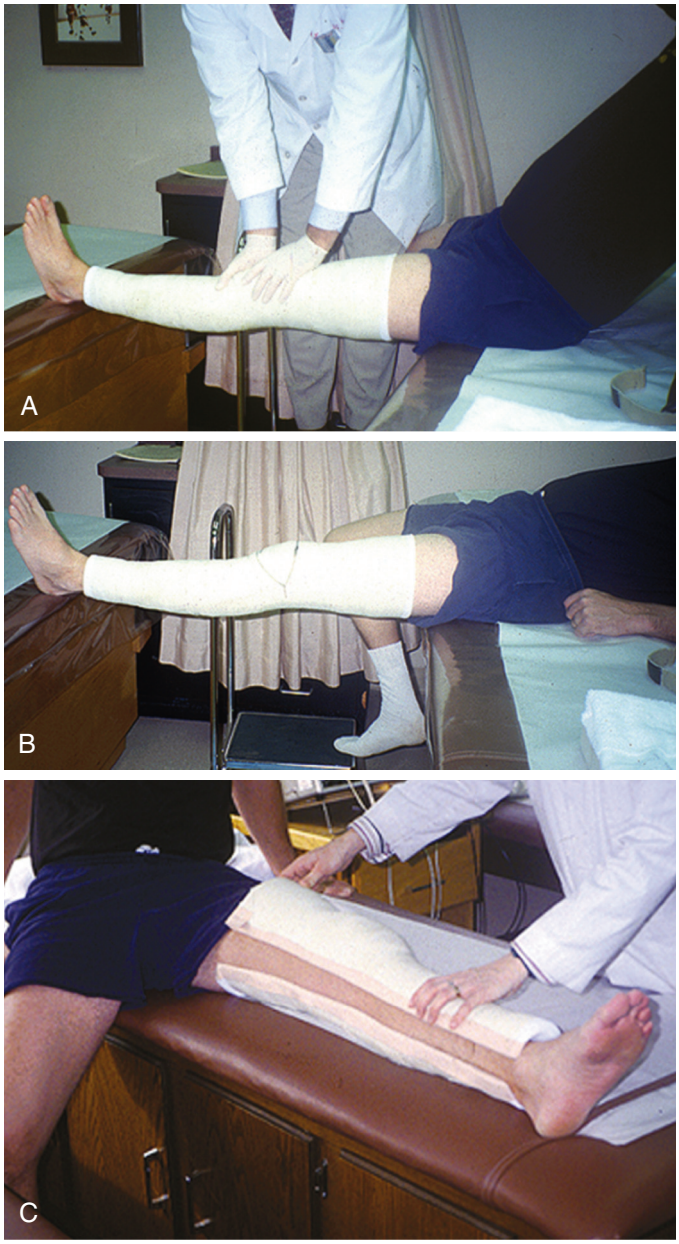

FIG 10-2 Extension cast application requires overpressure initially **(A)**. The cast is worn for 48 hours **(B)** and is then split **(C)** and converted into a night splint.

and consensus statements,[246] high-quality evidence has not been found to support the routine use of functional or rehabilitative bracing after ACL reconstruction. In our experience, a postoperative brace is beneficial in select patients early after surgery for protection and comfort, as discussed in Chapter 11.

LOWER-EXTREMITY MUSCLE ATROPHY AND WEAKNESS AFTER SURGERY

Lower-extremity muscle atrophy and weakness after ACL reconstruction represents a difficult and unresolved problem.[54,109,125,144,221,242,273] Investigators have reported postoperative strength deficits ranging from 5% to 40% for the quadriceps[54,63,120,141,148,150,191,273] and from 9% to 27% for the hamstrings.[54,120,141,146] Unresolved postoperative muscle strength deficits may be associated with knee osteoarthritis that is present either at baseline or years after surgery.[49,145,214,220,279] A recent study[227] found that quadriceps strength predicted 61% the variance in self-reported disability (according to the IKDC Subjective Knee Form) an average of 4.5 years postoperatively in a small group of 15 patients.

CRITICAL POINTS Lower-Extremity Muscle Atrophy and Weakness After Surgery

- Unresolved problem, studies report deficits ranging from 5%-40% for quadriceps, 9%-27% for hamstrings.
- Several theories for atrophy and strength deficits; may occur bilaterally.
- Changes in muscle fiber composition, abnormal gamma loop function; arthrogenic muscle inhibition commonly cited.

The factors related to the loss of muscle size and strength after ACL reconstruction remain unclear. Studies vary considerably in terms of patient age, preoperative and postoperative activity levels, time elapsed since surgery, ACL grafts, rehabilitation programs, concurrent operative procedures, and methods used to determine muscle size and function. For instance, in one recent study, researchers compared 15 patients who underwent ACL reconstruction (who were 2-15 years postreconstruction) with 15 controls, all of whom were "active" people (Tegner activity scale score ≥4), between 19 and 38 years of age.[153] Problems with muscle atrophy appear to occur regardless of the type of graft used to reconstruct the ACL and frequently occur bilaterally.[221] The proposed reasons for quadriceps muscle strength deficits that persist after surgery include:

- Selective atrophy of type 1 fibers.[105]
- A reduction in muscle fiber size.[299]
- Hypertrophy of fast-twitch muscle fibers.[17,68]
- Nonoptimal activation of muscles during voluntary contractions.[172]
- Loss of native ACL mechanoreceptors that result in abnormal (decreased) gamma loop function.[135-137,147,149,259,263,264]
- Arthrogenic muscle inhibition: Inhibition of muscle tissue from joint effusion and soft tissue damage leads to altered afferent output from knee joint and muscle atrophy.[109,122,221,261]
- Peripheral changes in muscle-tendon units of the quadriceps muscle, including chronic atrophy, changes in the compliance of the series elastic components of the muscle-tendon units, and alterations in structure and fiber type.[153]
- Elevated levels of atrophy-inducing signaling cytokines such as myostatin and transforming growth factor-β.[188]
- Alterations in neural pathways.[167]
- A combination of the above.

Regardless of the cause of muscle atrophy and weakness, it is paramount that the rehabilitation program correct the deficits in a controlled, effective, and safe manner. There are several principles the therapist must use to achieve this goal, which change as the patient progresses through the program. Modifications will be required based on the factors addressed in Table 10-1. Adequate muscle strength is required to initiate more advanced neuromuscular exercises and, eventually, sports-specific activities. At our center, patients are seen 24 hours after surgery to begin initial muscle-strengthening and knee motion exercises.

OPTIONS TO REGAIN MUSCLE STRENGTH

Patellofemoral Joint Protection

It is critical as one attempts to make gains in strength to avoid placing high forces on the patellofemoral joint throughout the rehabilitation process. Anterior knee pain that develops after ACL reconstruction is a difficult complication,[91,142] and it is essential that the therapist

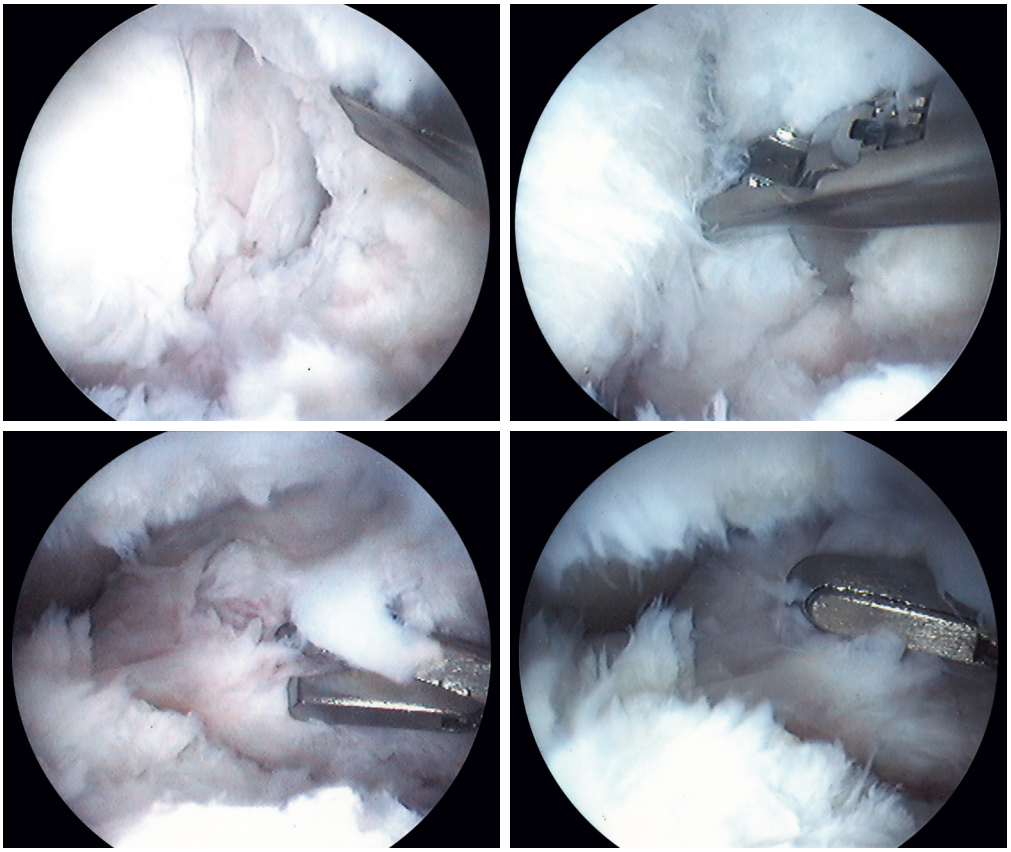

FIG 10-3 Arthroscopic debridement of scar tissues.

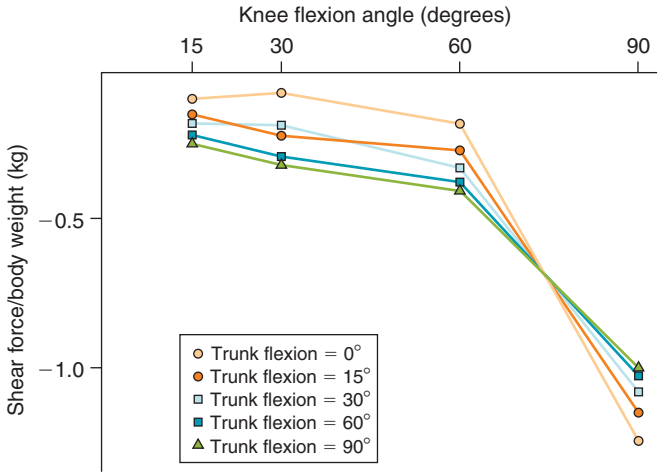

FIG 10-4 Shear force (kilograms) per body weight (kilograms) while standing on both legs at various flexion angles of the knee and the trunk. (From Ohkoshi Y, Yasuda K, Kaneda K, et al. Biomechanical analysis of rehabilitation in the standing position. *Am J Sports Med.* 1991;19:605–611.)

CRITICAL POINTS Options to Regain Muscle Strength

- Protect patellofemoral joint, avoid leg extension 0-30 degrees, exercises involving high knee flexion angles (deep squats, stairs).
- Prefer closed kinetic chain exercises 0- to 50-degree range to minimize patellofemoral forces.
- Control joint effusion to prevent reflex inhibition of quadriceps.
- Electrical muscle stimulation, biofeedback are good adjuncts early postoperatively.
- Use knee extension 50-100 degrees, single-leg and two-legged squats, wall squats, lunges, leg press machine, stationary bicycle initial postoperative phase.
- Single-leg squat, straight-leg raise, heel raises, single-leg stance safe for healing anterior cruciate ligament graft.
- Eccentric training appears advantageous, further studies required to determine safety.
- Motor imagery should be explored early postoperatively to enhance muscle activation.

understand the impact that exercises have on the patellofemoral joint. Patients who develop patellofemoral symptoms postoperatively must be carefully followed and the rehabilitation program altered as required to avoid activities that place high forces on the patella. We recommend avoidance of the leg extension machine (an open kinetic chain [OKC] exercise) in the range of 30 to 0 degrees of knee flexion, as well as exercises that involve high knee flexion angles such as deep squatting, kneeling (past 50 degrees) and extensive stair climbing, in the first 3 months after surgery. The advice to avoid leg extensions in low knee flexion angles was first given many years ago in a cadaveric study conducted in our laboratory that measured the forces incurred on the extensor mechanism that developed during an OKC knee extension simulated exercise.[104] The investigation demonstrated that the quadriceps force required to extend the knee remained at a constant value between 60 and 15 degrees of knee flexion and then rose rapidly. The addition of a small amount of resistance (31 N) doubled the quadriceps force that was required to extend the knee, resulting in large forces on the patellofemoral joint.

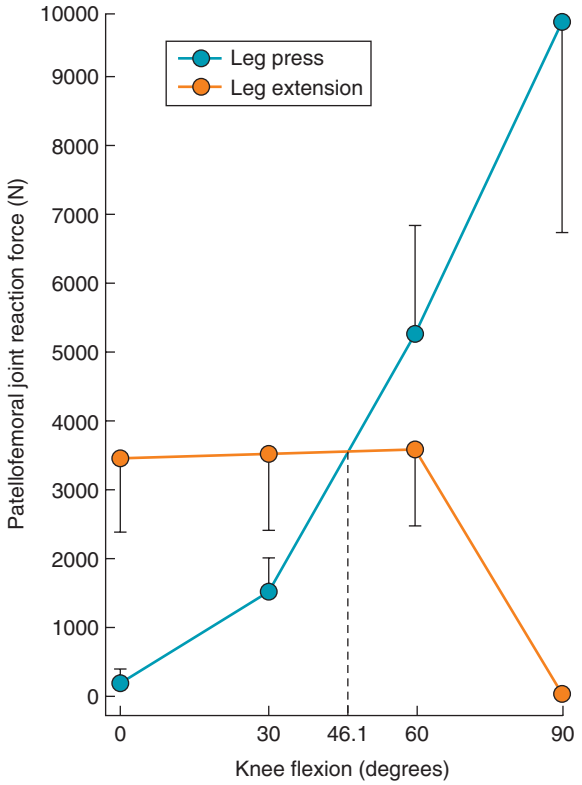

FIG 10-5 Mean ± standard deviation of patellofemoral joint reaction force at four flexion angles. (From Steinkamp LA, Dillingham MF, Markel MD, et al. Biomechanical considerations in patellofemoral joint rehabilitation. *Am J Sports Med.* 1993;21:438–444.)

Steinkamp and associates[266] calculated patellofemoral joint reaction forces in 20 healthy subjects at 0, 30, 60, and 90 degrees of knee flexion during a closed kinetic chain (CKC) leg press exercise and an OKC leg extension exercise. Reaction forces were significantly greater ($P < .001$) at 0 and 30 degrees in the OKC leg extension exercise than during the leg press exercise (Fig. 10-5). The opposite was true at the high knee flexion angles, for which forces were significantly greater in the leg press exercise. The authors concluded that the leg press placed minimal stress on the patellofemoral joint in the functional ROM (low knee flexion angles).

The stress on the patellofemoral joint depends not only on the load applied but also on the surface areas of the patella and femur that may be in contact at any given point in time. At 0 degrees of knee flexion, no or only minimal contact occurs between the patella and trochlear groove (Fig. 10-6).[33,88] With small amounts of knee flexion (20 degrees), contact occurs first on the distal portion of the patella with the proximal trochlea. As the knee flexes, the contact area moves proximally on the patella, whereas at 45 degrees, contact is on the central portion of the patella. Borotikar and Sheehan[33] measured the in vivo contact area between the femur and patella using dynamic magnetic resonance imaging during knee flexion-extension and reported a mean of 125 mm^2 at 10 degrees of flexion, which increased to 229 mm^2 at 40 degrees of flexion. At 90 degrees, the superior portion of the patella is in contact with the trochlea. The greatest compressive forces occur in 60 to 90 degrees of flexion.[103,300] Investigators have estimated that the loads on the patellofemoral joint range from 3 times body weight (BW) with stair climbing to 7 times BW with squatting to up to 20 times BW with jumping.[233,258]

In regard to stair climbing, Goudakos and colleagues[100] reported that, compared with level walking, this activity resulted in greater

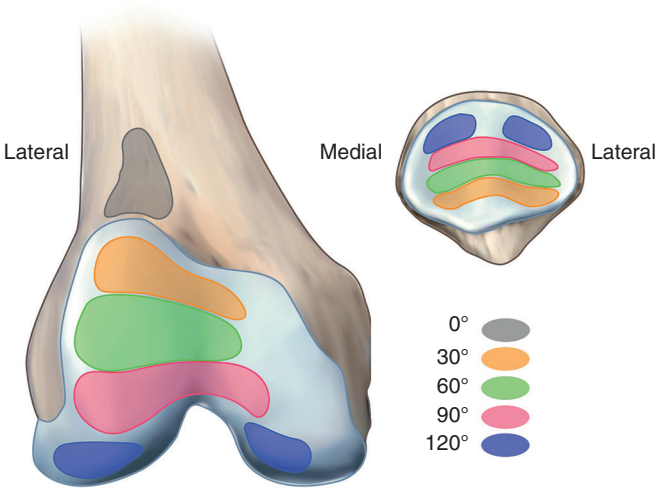

FIG 10-6 Contact surface areas on the patella and trochlea/femoral condyles at various degrees of knee flexion.

patellofemoral mean and peak pressures ($P = .01$), patellar contact area ($P = .02$), and patellar tilt ($P = .02$). These differences were recorded when the knee reached 30 degrees of flexion. At a lower knee flexion angle of 12 degrees, stair climbing resulted in a significantly higher peak patellofemoral pressure, lateral patellar tilt, and amount of lateral force distribution on the trochlea ($P = .01$). These authors concluded that their findings explained the association of stair climbing with patellofemoral pain.

Doucette and Child[60] measured patellar congruence in patients with symptomatic lateral patellar compression syndrome with the lower extremity relaxed, holding an OKC knee extension position, and holding a CKC exercise position. During all three conditions, patellar congruence progressively improved with knee flexion. The authors concluded that a quadriceps contraction had less influence on patellar tracking at 30 degrees of flexion than at 0 degrees of flexion owing to the increased stability of the patella as it moved into the intercondylar groove as the knee was flexed. In low ranges of knee motion, CKC exercises were recommended owing to the improved patellar positioning and decreased joint irritation in symptomatic patellofemoral patients. This advice was more recently supported in a systematic review of exercises for patellofemoral pain by Harvie and associates.[113] Some examples include minisquats (to 45 degrees of knee flexion), wall sits (to 50 degrees of flexion), lateral step-ups, and forward step-ups.[42] Escamilla and associates[74] measured patellofemoral compressive forces during a CKC wall squat exercise in healthy subjects. The forces ranged from approximately 75 to 1400 N between 0 and 50 degrees of knee flexion and then rose to approximately 2100 to 3650 N between 60 and 90 degrees of knee flexion. This compares to compressive forces incurred on the patellofemoral joint during walking of approximately 900 N. A series of studies led Escamilla and colleagues[70,71] to recommend CKC training within 0 to 50 degrees of knee flexion to minimize patellofemoral and cruciate ligament forces.

Control Effusion

A knee joint effusion may precipitate reflex inhibition of the quadriceps, leading to weakness and atrophy.[53] Several investigators documented that quadriceps muscle inhibition occurred following an experimentally induced knee joint effusion and produced alterations in normal function during walking, jogging, and landing from a jump.[134,219,277,278] Therefore it is imperative that knee joint effusions be avoided or treated immediately to lessen deleterious impact on

quadriceps function. Joint aspiration, cryotherapy, transcutaneous electrical nerve stimulation, and compression are effective therapeutic measures.[155,221] Prudent, short-term use of nonsteroidal antiinflammatory medications may also be required.

Electrical Muscle Stimulation and Biofeedback

Neuromuscular electrical muscle stimulation (EMS) and biofeedback are recommended early after surgery in modern ACL rehabilitation protocols (see Chapter 11).[114,221,291] Studies conducted several years ago demonstrated that EMS combined with active exercise was more effective than active exercise alone in recovery of quadriceps strength and normal gait mechanics.[56,260,262] Fitzgerald and associates[82] reported modest (effect size, 0.48) improvements in quadriceps isometric peak torque 16 weeks after ACL reconstruction when an EMS training protocol was incorporated into the postoperative rehabilitation program of 21 patients. Twelve weeks postoperatively, the experimental group demonstrated significantly greater quadriceps isometric peak torque index compared with that of a matched group of patients who did not receive EMS training (75.9 ± 16.8 and 67.0 ± 19.9, respectively; $P < .05$). However, no significant differences were measured at 16 weeks postoperatively between these groups. A greater proportion of the EMS-trained subjects initiated agility training at 16 weeks compared with the control group (62% and 32%, respectively; $P < .05$). Although high-level modern quality studies are lacking, Wright and associates[296] concluded on the basis of a systematic review that high-intensity EMS may help achieve improved quadriceps strength after ACL reconstruction. In a more recent review, Imoto and colleagues[128] concluded that EMS added to conventional exercises may be effective in improving muscle strength and recovery 2 months after surgery.

Biofeedback therapy has been suggested as a useful therapeutic technique in overcoming muscle inhibition early postoperatively.[221] This therapy helps patients develop and increase their voluntary control over muscle contractions.[45,61,62] However, no high-level studies have been conducted to ascertain the effectiveness of biofeedback following ACL reconstruction in regard to increases in muscle strength and/or reduced quadriceps atrophy.

Open Versus Closed Kinetic Chain Exercises

The process of ACL graft maturation and healing is assumed to be influenced by strains and forces applied to the lower limb during weight bearing and exercises. Although a general consensus exists that some strain is necessary to promote the process of ligamentization,[26] questions remain regarding the amount of load that is safe and the amount that may produce graft elongation. Over the past two decades, investigations have attempted to measure, through either analytical or direct means, force and strain incurred on the ACL during common OKC and CKC exercises used in rehabilitation. During CKC exercises, the foot is fixed to a platform or surface, the motion at the knee joint is accompanied by predictable motions at the hip and ankle joints, and the entire limb is loaded such as during a leg press or squat. In OKC exercises, the foot is mobile and not fixed to a surface, and motion at the knee joint occurs independent of motion at the hip and ankle joints. Common examples include the leg extension and hamstring curl exercises.

Calculated ACL Forces, in Vivo ACL Strain

Several years ago, 2-dimensional mathematical models were used to calculate muscle forces, tibiofemoral shear, and compressive forces during isometric and isokinetic exercises.[10,129,143,173,200,201,212,280,297] These analytical models did not allow the authors to determine the magnitude of the ligament forces incurred during various exercises. Experimental biomechanical models have also been used to estimate ACL strain or tensile forces during a variety of OKC and CKC exercises.[70,71,73,75,76,79,226,252,253,290]

Direct in vivo measurement of ACL strain incurred during activities in human subjects has been conducted by several investigators.[21-23,27,84,85,87,117] Beynnon and associates[23,27,84,86,115] conducted a series of studies in which a Hall effect transducer was arthroscopically implanted into the anteromedial fibers of the normal ACL in volunteers undergoing surgical procedures under local anesthesia. Patients performed several OKC and CKC exercises at different knee flexion angles, including isometric contractions,[23] squatting,[27] bicycling,[85] stair climbing,[84] and lunging.[115] The mean peak ACL strains reported in these studies are shown in Table 10-2.[26] The magnitude of ACL strain produced by the exercises assessed in these studies was *lowest* in those that involved (1) isometric contractions of the hamstring muscles; (2) cocontractions of the quadriceps and hamstrings at 30, 60, and 90 degrees of knee flexion; (3) isometric quadriceps contractions at 60 and 90 degrees of knee flexion; and (4) passive flexion and extension of the knee. The activities that produced the *highest* ACL strain included (1) isometric quadriceps contractions at 15 degrees of knee flexion with 30 N-m of extension torque, (2) squatting without and with resistance, and (3) active flexion and extension of the knee with a 45-N weight boot. The authors emphasized that the limits of ACL strain that are safe and not deleterious to healing ACL grafts remain unknown. Although excessive loading must be avoided early postoperatively, controlled loading is required to enhance graft healing and ligamentization.

Escamilla and associates[72] recently summarized data from multiple experimental biomechanical models and in vivo measurements of ACL strain and tensile forces. These investigators concluded that the OKC knee extension exercise performed between 50 and 100 degrees of knee flexion, as well as isometric and isokinetic knee flexion exercises, appear to be safe to the healing graft early postoperatively. In addition, CKC exercises of single-leg and two-legged squats (with and without resistance), forward and side lunges, leg press machine, and stationary bicycle were recommended in the initial recovery phase after surgery.

Anterior Tibial Translation

Studies have reported that the early incorporation of certain OKC exercises after surgery does not adversely affect anterior tibial translation compared with the later initiation of these exercises.[28,29,90,131,225] These exercises include (1) leg extensions in the range of 45 to 90 degrees,[28,29,90,116,189] (2) short arc quadriceps sets from 0 to 30 degrees,[29] (3) quadriceps isometrics at 0 degrees,[28,29,245] and (4) quadriceps-hamstrings cocontraction isometrics at 0 degrees.[28,29,131,245] Beynnon and associates[28] performed a roentgen stereophotogrammetric analysis of tibiofemoral joint displacements and rotations that occurred in 24 patients who began early OKC exercises and compared them with 18 patients who participated in a nonaccelerated program. Significant increases in anterior tibial displacement ($P < .0001$) and internal-external and varus-valgus rotations ($P = .03$) were measured in both groups between the baseline (immediately after surgery) and at the 2-year follow-up evaluation. The investigators concluded that "the entire envelope of knee laxity increases for participants of both rehabilitation programs" and that these increases occur over the first 6 months of graft healing.

Tagesson and colleagues[271] conducted analyses of dynamic anterior tibial translation that occurred during the Lachman test and seven exercises done 5 weeks after ACL reconstruction with a computerized electrogoniometric measuring system. Exercises performed with a straight knee (heel raises, single-leg stance, straight-leg raises) produced significantly less anterior tibial translation than those that

TABLE 10-2 Rank Comparison of Mean Peak Anterior Cruciate Ligament Strain Values Measured in Vivo in Subjects With Uninjured Knees

Exercise	OKC or CKC	Peak ACL Strain (%)
Isometric quadriceps contraction at 15 degrees (30 N-m extension torque)	OKC	4.4
Squat with SportCord	CKC	4
Active flexion and extension (45 N weight boot)	OKC	3.8
Lachman test at 30 degrees (150 N anterior shear load)		3.7
Squat, no resistance	CKC	3.6
Isometric gastrocnemius contraction at 15 degrees (15 N-m plantar flexion torque)	OKC	3.5
Active flexion and extension, no resistance	OKC	2.8
Cocontraction quadriceps and hamstrings at 15 degrees	OKC	2.8
Isometric gastrocnemius contraction at 5 degrees (15 N-m plantar flexion torque)	OKC	2.8
Single-legged sit-to-stand exercise	CKC	2.8
Isometric quadriceps contraction at 30 degrees (30 N-m extension torque)	OKC	2.7
Stair climbing	CKC	2.7
Step-up and step-down	CKC	2.5
Weight bearing at 20 degrees		2.1
Leg press at 20 degrees (40% body weight)	CKC	2.1
Anterior drawer test at 90 degrees (150-N anterior shear load)		1.8
Lunge	CKC	1.8
Stationary bicycling	CKC	1.7
Isometric hamstrings contraction at 15 degrees (10 N-m flexion torque)	OKC	<1.0
Cocontraction quadriceps and hamstrings at 30 degrees	OKC	<1.0
Isometric gastrocnemius contraction at 30 degrees (15 N-m plantar flexion torque)	OKC	<1.0
Passive flexion and extension	OKC	<1.0
Isometric quadriceps contraction at 60 and 90 degrees (30 N-m extension torque)	OKC	0
Isometric gastrocnemius contraction at 45 degrees (15 N-m plantar flexion torque)	OKC	0
Cocontraction quadriceps and hamstrings at 60 and 90 degrees	OKC	0
Isometric hamstrings contraction at 30, 60, and 90 degrees (10 N-m flexion torque)	OKC	0

ACL, Anterior cruciate ligament; *CKC,* closed kinetic chain; *OKC,* open kinetic chain.

required greater motion in the knee joint (Table 10-3). However, when these exercises were evaluated only at the same knee flexion angle as that performed in the Lachman test, they produced less anterior tibial translation ($P < .001$). The authors concluded that all exercises evaluated could be recommended early after ACL reconstruction, but they believed the single-leg squat and straight-leg raise were the safest in terms of ACL graft forces. It is important to note that the cyclic effect on anterior tibial displacement produced from OKC or CKC exercises after ACL reconstruction in the usually prescribed manner performed (e.g., 30-50 sets of an exercise) has not been explored in clinical studies.

Muscle Activation Patterns

Muscle electromyographic (EMG) activation patterns that occur during OKC and CKC exercises have been measured in several studies in uninjured subjects (Table 10-4).[9,19,20,67,79,158,159,184,268,271,290] Notable findings included (1) high and balanced levels of quadriceps activation occurred during CKC single-leg squat, step-ups, and leg press tasks[20,268,271] (see also Table 10-5); (2) the single-leg wall squat had the highest muscle efficiency compared with other single-leg CKC exercises[9]; (3) trunk position affected muscle activity patterns during the forward lunge exercise[79]; and (4) balanced quadriceps-hamstrings cocontractions occurred during the single-leg dead lift, single-leg transverse (rotational) hop, single-leg lateral hop, and lateral band walking exercises (Table 10-6).[19]

The issue of muscle activation patterns that occur after ACL reconstruction was addressed by Tagesson and associates[271] in 11 men and 8 women who underwent preoperative and postoperative (5-week) EMG testing during several exercises. None of the patients had knee pain before the postoperative test; however, there were deficits in knee flexion (mean, 16 degrees; range, 3-55 degrees) and extension (mean, 6 degrees; range, 0-13 degrees). Compared with the preoperative values of the uninjured legs, EMG activation in the reconstructed extremity's hamstrings and gastrocnemius was greater during many of the activities evaluated (Table 10-7). The investigators concluded that patients incorporated greater hamstring muscle activity to enhance joint stiffness to protect the ACL graft.

There are conflicting data regarding the effect of early OKC exercises on the time to restore quadriceps and hamstrings strength. In addition, some studies showed no beneficial effect of early OKC exercises for limb symmetry on hop tests, final muscle strength, proprioception, and functional knee outcome rating scores.[28,29,90,116,131,225] Even so, some investigators recommend the use of early OKC exercises owing to the potential for early postoperative increases in quadriceps strength.[28,90]

Eccentric Muscle Training

Eccentric training has been proposed to enhance increases in muscle cross-sectional area (CSA), volume, and strength after ACL reconstruction.[37,93-96,161] This type of training is believed by some to be superior to concentric training owing to its potential to overload the muscle and produce greater increases in muscle size and strength. Gerber and colleagues[93] used a progressive, gradual eccentric training protocol from 3 to 15 weeks after ACL reconstruction in 16 patients. These investigators reported that patients who completed this program had

a twofold greater increase in quadriceps CSA, volume, and strength compared with patients who followed a standard rehabilitation program only. There were no significant differences between groups in the improvement in volume and CSA of the hamstring muscles. Brasileiro and associates[37] reported significant improvement in isokinetic peak torque and quadriceps CSA following 6 weeks of eccentric training in nine subjects who underwent ACL reconstruction. The training was conducted on an isokinetic dynamometer 9 to 10 months postoperatively. There are concerns with high-force eccentric training after ACL reconstruction, including the potential for inducing damage to the muscle and healing graft. Further high-level research is required to determine the efficacy of this type of training.

Motor Imagery

A few investigators have explored the potential efficacy of the use of motor imagery (MI) as a part of the rehabilitation process early after ACL reconstruction.[50,163] MI is a cognitive process whereby the patient is asked to mentally visualize certain motions, but not to actually perform them, thus not resulting in any measurable outflow from spinal motor neurons. The primary motor cortex is engaged, which may involve contralateral as well as bilateral cortex activity. MI strategies are classified as either kinesthetic motor imagery (KMI) or visual motor imagery (VMI).[269] KMI indicates imaging the *feeling* that the task indicated produces, whereas VMI involves mentally *visualizing* performing the task. In a study involving these concepts in the upper extremity, researchers found that KMI, not VMI, modulated corticomotor excitability.[269]

Cupal and Brewer[50] conducted a randomized trial in which 10 patients were treated with standard physical therapy and a program involving relaxation and MI beginning approximately 2 weeks after ACL reconstruction. This group participated in 10 sessions, each 2 weeks apart, all of which began with breath-assisted relaxation techniques and then progressed to VI. At 24 weeks postsurgery, the treatment group had significantly greater knee isokinetic strength and less reinjury anxiety and pain ($P < .001$) than the placebo and control groups. Lebon and associates[163] studied the effectiveness of MI in a group of seven patients with ACL reconstruction who completed 12 MI sessions beginning 7 to 12 days postoperatively. The sessions were conducted every 2 days and were done along with traditional rehabilitation. At the conclusion of the last session, EMG analysis of the quadriceps showed that, compared with a control group, the MI group elicited greater muscle activation ($P < .05$). There were no significant differences between groups in pain or range of knee motion. In addition, quadriceps muscle size decreased in a similar manner in both groups. These findings led the authors to conclude that MI influences neural, but not structural, modulations and should be considered as a reliable and cost-effective adjunct to standard rehabilitation. Further research is required to determine the short- and long-term potential effects of MI.

RESTORATION OF NEUROMUSCULAR FUNCTION

Proprioception and Postural Stability

Restoration of normal neuromuscular function after ACL reconstruction is paramount for the eventual implementation of sports-specific exercises and release to full activities. Knee joint proprioception is considered by many to be a crucial element of neuromuscular function and its recovery essential for a successful outcome.[194,291] Proprioception is altered after ACL rupture owing to damage incurred to the joint mechanoreceptors and muscle afferents and may be further impaired with a concurrent meniscus tear.[178,180] Years ago, several investigators reported deficits in proprioception 1 to 2 years after ACL reconstruction.[15,31,166,174]

Interestingly, more recent studies[4,28,142,168,194,218,254] have refuted previous findings regarding deficits in proprioception after ACL reconstruction. The authors of a recent systematic review questioned the tests commonly used to measure proprioception and the clinical relevance of prior studies.[98] Littmann and associates[168] found no difference in dynamic position sense accuracy and central nervous system processing time between ACL-reconstructed knees (that were at least 1 year postoperative) and healthy controls. These results conflicted with the patients' perception of knee function and impairment, which was significantly inferior compared with controls. These and other authors[98,174] have suggested that variables other than proprioception

CRITICAL POINTS Restoration of Neuromuscular Function

- Knee joint proprioception and dynamic postural control may be altered from ACL rupture and require restoration early after surgery.
- Joint repositioning, weight shifting, cup and/or cone walking, mini-squats, single-leg stance, lunges, progress from stable to unstable surfaces.
- Normal neuromuscular function may not be restored many months or years postoperatively.
- Front step-downs, lateral step-downs, single-leg balance drills, progressive perturbation training with the therapist, lunge exercises in various directions using a resistance cord onto an unstable surface. Progress to running, plyometrics.
- Patient must be taught correct form and posture during all exercises.

TABLE 10-4 Muscle Activation and Recruitment During Open and Closed Kinetic Chain Exercises

Study	No. of Healthy Subjects	Methods, Muscles Tested	Results	Comments
Wilk et al[290] (1996)	10 men	Knee extension, leg press, squat RF, VMO, VL, BF, ST, SM, gastrocnemius	Maximum quadriceps activation occurred during knee extension from 56-70 degrees. Cocontraction of quadriceps-hamstrings was greatest during squat from 0-30 degrees	Squat best exercise evaluated for quadriceps: hamstring cocontraction; leg press: quadriceps activation 39%-52% MVC, minimal hamstring activity
Beutler et al[20] (2002)	11 men, 7 women	Single-leg squat, step-up RF, VMO, VL	Peak quadriceps activation of MVC: 201 ± 66% squats, 207 ± 50% step-ups	High, sustained levels of quadriceps activation indicated these exercises would be effective for strengthening
Stensdotter et al[262] (2003)	3 men, 7 women	Isometric knee extension at 30 degrees flexion, simulated OKC, CKC activities RF, VMO, VML, VL	Onset activity for all quadriceps muscles was simultaneous during CKC exercise; OKC, onset of VL occurred before all other muscles	CKC more balanced initial quadriceps activation
Ayotte et al[9] (2007)	16 men, 7 women	Single-leg wall squat, single-leg minisquat; forward step-up, lateral step-up, retro step-up GMAX, GMED, VMO, BF	Statistically significant differences in mean normalized EMG signal for 4 muscles among all exercises; wall squat had highest levels of activation	All exercises sufficient for strengthening; wall squat most efficient
Ekstrom et al[67] (2007)	19 men, 11 women	Lateral step-up, lunge VMO, ST, SM, GMAX, GMED	Both exercises >75% MVC of VMO	Both exercises sufficient for quadriceps strengthening
Farrokhi et al[79] (2008)	5 men, 5 women	Forward lunge: trunk erect, trunk forward, trunk extended GMAX, BF, VL, gastrocnemius	Trunk forward position produced significant increases in peak hip flexion angle, hip extensor and ankle plantar flexor impulse, % MVC of GMAX and BF	Trunk position affected exercise; forward position increased hip extensor muscle actions; other positions did not change EMG findings
Tagesson et al[271] (2010)	11 men, 8 women	7 exercises VMO, VL, hamstrings, gastrocnemius, soleus	Highest quadriceps activation: single-leg squat, seated knee extension; no exercise produced enough hamstring activation to promote strengthening	Seated knee extension also produced greatest amount of anterior tibial translation compared with other exercises
Begalle et al[19] (2012)	12 men, 15 women	9 CKC exercises VMO, VL, ST, SM, BF	Most balanced coactivation ratios: single-leg dead lift, single-leg transverse hop, single-leg lateral hop, lateral band walk; no exercise produced enough hamstring activation to promote strengthening	Quadriceps-dominant exercises: single-limb squat, transverse lunge, lateral lunge, forward lunge (see also Table 10-4)

affect the perception of knee function after ACL reconstruction. Gokeler and colleagues,[98] in a review of 24 studies, found no association between proprioception and (1) quadriceps isokinetic muscle strength, (2) knee joint laxity, (3) limb symmetry on single-leg hop tests, and (4) patient-reported outcome. It may be that modern rehabilitation programs are effective in eliminating proprioceptive deficits as measured by the standard joint position sense and threshold to detect passive motion tests.

Dynamic postural control or stability is another important neuromuscular factor that must be restored after ACL reconstruction. Balance requires constant adjustment to the body's muscular activity and positioning and is influenced by the integration of sensorimotor information into the central nervous system and the resultant motor response. Impairment in postural stability is believed to be related, in part, to deficiencies in proprioception.[1,97] Postural control may be measured using a *static* test on a fixed force platform by assessing the displacement (in centimeters) of the patient's center of gravity in the sagittal and frontal planes. A *dynamic* test may also be used with a tilting or translating platform in which the deviation from the level position is indicated in degrees, or with an even simpler clinical method such as the Star Excursion Balance Test (SEBT). The SEBT requires a patient to maintain a stable base by balancing on one leg

while reaching out with the other leg and touching the ground as far as possible in various directions.[13]

Howells and associates[124] reviewed 10 studies of ACL reconstruction and concluded that subjects appeared to have impaired postural control, especially in dynamic tasks that were more relevant to actual sports activities. Subsequently, other studies demonstrated impairments in dynamic postural stability in athletes.[55,190,198,287] The clinical significance of these deficits in regard to risk of reinjury and poor outcomes is unclear and requires further study. Even so, investigators encouraged the continuation of supervised neuromuscular training before[190,198] and after[55] the patient has returned to athletics in an effort to correct this problem.

A general consensus exists that the ACL postoperative rehabilitation program should include exercises believed to improve proprioception and postural stability as soon as possible after surgery and gradually progress in difficulty. Some examples of these exercises are joint repositioning (with the therapist),[139] weight shifting, cup and/or cone walking, mini-squats (to 25 to 30 degrees of knee flexion) on a stable and unstable surface, single-leg stance on even and then unstable surfaces,[90] and lateral and/or diagonal lunge drills. Recently, Cappellino and associates[40] devised a unique neurocognitive exercise protocol that included MI initially to assist in recovery of motor skills. A pilot study showed promise in improvements in gait and lower limb symmetry while standing. Brunetti and associates[39] conducted vibration muscle stimulation (low amplitude, high frequency with simultaneous muscle voluntary contraction) to the quadriceps 1 month postoperatively in 15 patients. When compared with 15 other patients who did not receive the therapy, single-leg standing balance and

extensor muscle torque of the treated subjects was significantly improved immediately after the 3-day treatment and remained so 9 months later ($P < .05$).

Advanced Neuromuscular Activities

The restoration of normal neuromuscular function and correction of limb-to-limb asymmetry during complex athletic tasks is the final goal of ACL reconstruction and postoperative rehabilitation. Unfortunately, several recent investigations demonstrated this goal was not achieved in young athletic populations before or after sports were resumed (Table 10-8).[41,52,55,57,99,176,211,216,217,235,272,298] Because of these relatively new findings, we can only speculate on rehabilitation concepts that may correct continued neuromuscular impairments. For instance, Delahunt and colleagues[55] concluded, "Based on our findings, we would advocate the use of dynamic stabilization training, with emphasis placed on the correct execution of sports applicable techniques incorporating tri-planar hip and knee joint control." Nyland and associates[211] demonstrated long-term (5 years postoperatively) compensatory neuromuscular and biomechanical adaptations in 70 patients during a single-leg countermovement jump, even though knee extensor muscle strength and limb symmetry on a single-leg hop test were within normal limits. The findings included decreased lower-extremity landing forces, decreased vastus medialis activation, and increased gluteus maximus activation. The investigators suggested the need to continue neuromuscular training for as long as patients continue to participate in high-risk athletic activities.

Exercises to promote neuromuscular function are detailed in Chapters 11 and 12. Examples include front step-downs, lateral step-downs, single-leg balance drills, progressive perturbation training with the therapist, and lunge exercises in various directions using a resistance cord onto an unstable surface. It is crucial that the patient be taught correct posture and form while performing these exercises. This includes avoiding varus or valgus lower limb alignment, maintaining knee flexion to prevent knee hyperextension, avoiding hip adduction and internal rotation, maintaining balance and control throughout the exercise, and landing softly to decrease ground reaction forces. The progression of exercises to running, pivoting and/or cutting, plyometrics, and return to full activities is based on specific criteria to be discussed next.

CRITERIA TO BEGIN SPORTS TRAINING, RETURN TO FULL ACTIVITIES

Published Criteria

A lack of consensus exists among medical professionals regarding the objective and subjective criteria patients should achieve before clearance is given to progress to strenuous training and, eventually, release to full sports activities.[51,69,133,246,276] We conducted a systematic review to determine when return to unrestricted athletics was deemed appropriate following ACL reconstruction.[11] Literature published between

CRITICAL POINTS Criteria to Begin Sports Training, Return to Full Activities

- Systematic review of 264 articles revealed only 13% listed objective criteria for return to activities.
- Use knee examination, isokinetic muscle test, single-leg hop test, knee arthrometer test, completion of each phase before progression to next phase allowed (see Table 10-9).
- Most of the rehabilitation program is done at home, but therapist must be actively involved during all phases.

2001 and 2011 was searched, and 264 articles were identified that were original research reports (all levels of evidence) involving primary ACL reconstructions in skeletally mature patients who had a minimum of 12 months of follow-up. Of these, 105 (40%) failed to provide any criteria for return to sports postoperatively. In 84 studies (32%), the amount of time postoperatively that patients were allowed to return to sports activities was the only criterion provided. In 40 other studies (15%), the amount of time along with subjective criteria (that could not be measured) were provided.

Only 35 studies (13%) in the review listed objective criteria required for return to athletics. These included muscle strength (25 studies), knee effusion and/or ROM (15 studies), limb symmetry on single-leg

TABLE 10-8 Impairments in Advanced Neuromuscular Activities After Anterior Cruciate Ligament Reconstruction

Study	Subjects	Testing Protocol	Results	Comments
Dai et al[52] (2013)	23 ACLR adolescents, 5-7.6 mo postoperative before return to sports	Vertical approach jump, preplanned side-cut 35 degrees, involved-noninvolved limb GRF, knee kinetics in sagittal plane	24%-34% asymmetries in peak knee extension moment, average knee moment, total knee work 11%-23% asymmetries in GRF on vertical jump, <11% on side-cut Asymmetry index of peak knee moments correlated with GRF asymmetry indexes	Asymmetries in vertical GRF significantly predicted knee kinetic asymmetries (11%-19% estimation errors) during both tasks No control group
Roos et al[235] (2014)	21 ACLD, 3-240 mo postinjury 23 ACLR, 7-36 mo postoperative 20 controls	Single-leg hop, involved leg only onto force platform, isokinetic knee extension-flexor 90 degrees/sec, hip abductor-adductor 45 degrees/sec	ACLR significantly reduced hop distance, peak knee extensor moment compared with controls ($P < .001$) Hop distance correlated with strength ($P < .01$).	Fluency (mediolateral knee control) in coronal plane was reduced in ACLR and ACLD
Delahunt et al[55] (2012)	14 ACLR, avg. 4.4 yr postoperative 14 controls, all female athletes	Vertical two-legged drop-jump 35 cm	ACLR increased peak hip adduction ($P = .01$) and internal rotation ($P < .05$), decreased peak knee adduction ($P < .05$) and flexion ($P < .01$) angles At IC, ACLR valgus knee position, controls varus knee position	ACLR multiplanar kinematic deficits
Castanharo et al[41] (2011)	12 ACLR, avg. 37 mo postoperative 12 controls, all male, all participating in sports	Countermovement jump, squats	ACLR 13% lower peak knee joint power involved-noninvolved side on jump task ($P < .05$) ACLR 15% greater hip/knee power ratio on involved side on squat task ($P < .05$)	ACLR asymmetries suggest need for improved rehabilitation
Madhavan et al[176] (2011)	12 ACLR, avg. 3.7 yr postoperative 12 physically active controls, all female	LLRs in quadriceps-hamstrings in response to unexpected perturbation during single-leg squat to 30 degrees flexion	ACLR greater overshoot error, knee velocity, increased LLR responses, reduced absolute anticipatory, short-latency reflex, voluntary quadriceps activity	ACLR impaired response of decreased quadriceps activity and enhanced LLR
Ortiz et al[217] (2011)	13 ACLR, 1-16 yr postoperative 15 physically active controls, all female	Single-leg side-to-side hop, hip and knee joint angles/moments, EMG quadriceps/hamstrings	ACLR greater knee abduction moments	Landing mechanics, muscle activation similar with exception of knee abduction moments
Yosmaoglu et al[298] (2011)	20 ACLR, 6 and 12 mo postoperative	Target-tracking ability, isokinetic strength 60 degrees/sec, 180 degrees/sec, single-leg hop	Significant deficits in isokinetic strength and hop test 6 mo postoperative improved 12 mo postoperative Significant deficits in concentric and eccentric motor coordination tracking ability 6 and 12 mo postoperative	Significant coordination deficits remained at 12 months postoperative, even though muscle and hop performance improved
Deneweth et al[57] (2010)	9 ACLR (6 male, 3 female), 4 mo postoperative	Single-leg forward hop landing	At IC, reconstructed side had significantly greater knee extension, external tibial rotation, and medial tibial translation than contralateral side ($P < .05$)	Patients had different tibiofemoral joint motion on reconstructed knee; caution warranted in performing this task 4 mo postoperative

TABLE 10-8 Impairments in Advanced Neuromuscular Activities After Anterior Cruciate Ligament Reconstruction—cont'd

Study	Subjects	Testing Protocol	Results	Comments
Gokeler et al[99] (2010)	9 ACLR (6 male, 3 female), 6 mo postoperative 11 controls	Single-leg hop, EMG	ACLR significantly earlier onset times for all muscles except vastus medialis compared with noninvolved side ($P < .05$) Significantly reduced knee flexion during takeoff, increased plantar flexion at IC ($P < .05$) Significantly lower knee extension moment ($P < .05$)	Muscle onset times earlier and movements patterns altered on ACLR side compared with contralateral side 6 mo postoperative
Nyland et al[211] (2010)	70 ACLR (35 male, 35 female), avg. 5.3 yr postoperative	Single-leg countermovement vertical jump	ACLR decreased lower-extremity landing forces ($P < .01$), decreased vastus medialis activation ($P = .01$), increased gluteus maximus ($P < .0001$) and gastrocnemius activation ($P < .0001$)	Patients demonstrated protective mechanisms to minimize knee loads
Orishimo et al[216] (2010)	13 ACLR (9 male, 4 female), 4-12 mo postoperative	Single-leg hop	Takeoff: degrees of knee motion of reconstructed side significantly smaller than noninvolved side ($P < .01$), peak knee extensor moment 40% lower ($P = .01$), peak power generated at knee 38% lower ($P < .01$)	During takeoff, decreased knee moment and power production compensated for by higher moments and power at the hip During landing, decreased knee power compensated for by greater power absorption at the ankle

hop tests (10 studies), and knee stability (8 studies). In regard to muscle strength, recommendations ranged from more than 80% to more than 90% for isokinetic testing of the quadriceps and hamstrings compared with the contralateral side. There were no data regarding requirements for the hamstring/quadriceps ratio or other muscle groups.

A multifactorial analysis of knee function was determined by two studies[111,182] in which three to four categories were included for release to sports activities. Hartigan and associates[111] required 90% or greater scores on the quadriceps strength index, four single-leg hop tests (single hop, triple hop, triple crossover hop, time hop), the Knee Outcome Survey activities of daily living scale, and a global rating of overall knee function. Mascarenhas and colleagues[182] proposed at least 90% on a weighted leg extension test and hop and/or jump tests (although the specific tests were not provided), full knee motion, and no effusion for return to athletics.

Van Grinsven and coworkers[284] conducted a systematic review of the rehabilitation literature to develop an evidence-based postoperative ACL program that would allow a return to athletics within 6 months. These authors recommended the following for return to sports criteria: full knee motion, at least 85% on strength (quadriceps and hamstrings) and single-leg hop tests compared with the opposite leg, no more than a 15% deficit on the hamstrings/quadriceps strength ratio, no pain or swelling with sport-specific activities, and a stable knee in active situations.

Our Recommendations

We recommend the criteria shown in Table 10-9 for progression to advanced training and release to unrestricted sports activities.[114] Other tests to consider include the multistage fitness test to determine maximal oxygen consumption[230] and the 60-second sit-up test or other core strength measures.[215] If isokinetic test equipment is not available, a one-repetition maximum bench press and leg press is recommended if weight room equipment is available, along with an experienced test administrator and a sufficient amount of time to safely conduct these tests.[151,234] If the athlete desires to return to high-risk activities, the medical professional should watch the athlete's pivoting and cutting techniques, which should demonstrate the ability to maintain the upper body over the knees and toes, adequate knee and hip flexion, and symmetry with the technique compared with the uninvolved leg.

Home-Based Versus Supervised Therapy

In several investigations, researchers have compared home-based rehabilitation with supervised clinic-based physical therapy programs.[18,81,101,102,121,241] The studies found similar outcomes among programs, and most authors agree that essential components required for a successful home-based protocol are preoperative patient education sessions, a comprehensive written and visual description of the exercises, and periodic monitoring of the patient's progress by a therapist. However, the investigations did not provide a rigorous analysis of the sports activities to which patients returned (both asymptomatically and symptomatically), details regarding the end-stage functional progression of their programs (e.g., plyometric training), or long-term outcomes. There were several methodologic problems, such as small sample sizes and inadequate randomization, making conclusions difficult.[3] It remains unclear if patients participating in a home-based program are able to achieve the same final goals as those in a supervised situation in terms of restoration of normal neuromuscular

TABLE 10-9 Recommendations for Progression of Advanced Training and Return to Sports After Anterior Cruciate Ligament Autogenous Reconstruction

Approximate Time Postoperative	Activity Permitted	Requirements
Weeks 9-12	Straight running	Isokinetic test isometric mode quadriceps, hamstrings: ≤30% deficit No pain, swelling, patellofemoral crepitus Lachman, KT-2000 (MEDmetric) arthrometer test: <3-mm increase over opposite side
Weeks 13-26	Cutting, basic plyometrics	Isokinetic test 300 degrees/sec quadriceps, hamstrings: ≤25% deficit No pain, swelling, patellofemoral crepitus Lachman, KT-2000 arthrometer test: <3-mm increase over opposite side Single-leg hop tests: ≤25% deficit
Week 27 and beyond	Advanced plyometrics	Isokinetic test 180 degrees/sec and 300 degrees/sec quadriceps, hamstrings: <15% deficit No pain, swelling, patellofemoral crepitus Lachman, KT-2000 arthrometer test: <3-mm increase over opposite side Single-leg hop tests: <15% deficit Successful completion of running program Successful completion beginning plyometric training with therapist
As indicated	Release unrestricted to sports	Isokinetic test 180 degrees/sec and 300 degrees/sec quadriceps, hamstrings: ≤10% deficit No pain, swelling, patellofemoral crepitus Lachman, KT-2000 arthrometer test: <3-mm increase over opposite side Single-leg hop tests: <15% deficit Successful completion of advanced plyometric training >60% normalized knee separation distance on video drop-jump test No valgus motion or mediolateral movement of knee on single-leg squat test

indices. One recent study found that although patient compliance in completing home exercises after ACL reconstruction was acceptable, it was affected by fluctuations in pain, negative mood, and stress.[38] In addition, the term *home-based* may be misleading because the therapists in the investigations were actively involved in the patients' care. We acknowledge that a great deal of the rehabilitation program must be done outside the clinic setting owing to insurance and financial issues. However, in light of the potential for reinjury in younger, highly active patients, to be discussed next, it is believed critical that the therapist remain actively involved in the patient's care throughout advanced neuromuscular and plyometric training.

REINJURY RISK FACTORS

An important component of the surgery and rehabilitation process is an understanding of the risks of reinjury upon return to activity. In both long-term[35,64,126,130,144,162,196,213,228,240,292] and short-term investigations,[140,177,223] researchers have reported concern regarding reinjury rates after ACL reconstruction (Table 10-10); however, the factors most responsible for this problem remain unclear. The contralateral knee is also at risk for ACL rupture, and many studies have documented a higher rate of this injury than that to the ACL-reconstructed knee.[35,126,162,196,213,223,228,240,270]

CRITICAL POINTS Reinjury Risk Factors

- Concerning reinjury rates published, involve both knees.
- Factors that may influence reinjury rates: patient age, activity level, family history, use of allografts.
- Possibility exists that many athletes have not regained normal neuromuscular indices in both lower limbs, and premature release to unrestricted activities is a potential factor for reinjuries.

Investigators have analyzed potential risk factors for reinjury rates, including patient age, sex, sports activity level, type of graft, and genetic predisposition.[32,35,126,140,177,197,228,240,251,283] Younger patient age is the factor most frequently associated with an increased risk of reinjury.[126,140,177,228,240,251,283] Shelbourne and colleagues[251] reported a reinjury rate (to either knee) of 17% for patients younger than 18 years of age, 7% for those aged 18 to 25 years, and 4% for those older than 25 years of age. A total of 72% of patients younger than 18 years of age returned to sports and did so an average of 4.6 months postoperatively. Although not always related to patient age, return to high-level[239] or high-risk sports such as soccer,[251] basketball,[251] and team handball[197] has also been associated with increased injury rates.

Bourke and colleagues[35] reported that female sex and a family history of ACL ruptures (to either sex) were significantly associated with subsequent ACL reinjuries. Borchers and associates,[32] in a case-control study, reported that the use of allografts and a return to high levels of sports activities were significant risk factors for ACL graft failure in 21 of 322 patients followed 2 years postoperatively. High failure rates and an increased risk for revision after ACL allograft reconstruction have been reported by other investigators, especially in young active cohorts.[16,186,231,256,286] Paterno and colleagues[223] reported that alterations in neuromuscular control of the hip and knee on a drop-jump task and postural stability predicted ACL injury upon return to activities after reconstruction in 43 athletes followed for 1 year postoperatively. In this investigation, 10 of the 13 patients who sustained a reinjury did so to the contralateral knee. Studies in which researchers have specifically analyzed patients who sustained contralateral ACL rupture have noted return to high activity levels, age younger than 21 years, small intercondylar notch width, generalized joint laxity, and a family history of ACL injuries as potential risk factors for this problem.[2,108,193,228,239,247,265]

Unfortunately, studies in which investigators assessed factors that might have been responsible for reinjury rates did not always take into

TABLE 10-10 Rates of Reinjury/Graft Failure in the Reconstructed Knee and Injury to the Contralateral Anterior Cruciate Ligament

account the status of the athletes' strength, stability, neuromuscular control, and general knee condition upon return to sports. The possibility exists that many athletes had not regained normal indices in both lower limbs and that the premature release to unrestricted activities may have been a factor in the subsequent reinjuries. The effect of advanced neuromuscular retraining following ACL reconstruction on the reduction of reinjury rates remains unknown.

Note that ACL grafts may fail for reasons other than obvious reinjuries. These include improper graft placement,[181] failure of the graft to complete the healing (revascularization) process, failure to correct lower-limb malalignment, and failure to restore deficiency to other ligaments in the knee joint. These problems are discussed in detail in Chapter 8.

PSYCHOLOGICAL FACTORS THAT MAY AFFECT OUTCOMES

An important consideration regarding factors that may affect patient outcomes for the rehabilitation team are patient psychological traits

Critical Points Psychological Factors That May Affect Outcomes

- Fear of reinjury one of most common reasons for failure to return to preinjury activity levels.
- Measures of self-motivation, self-efficacy, and optimism predict compliance with rehabilitation, return to sport, and self-rated knee function.
- Self-efficacy influenced by patient's preinjury activity level, age, chronicity of injury, and sex.
- Modeling techniques may be effective in increasing early postoperative levels of self-efficacy and motivation to comply with rehabilitation.
- Further work highly warranted to improve postoperative self-efficacy and investigate appropriate preoperative psychological screening methods to determine patients who require additional support and counseling.

TABLE 10-11 Knee Self-Efficacy Scale

Category	Items
Daily activities	*Right now, despite pain or discomfort, how certain are you about:* • Walking in the forest • Climbing up and down a hill/stairs • Going out dancing • Jumping ashore from a boat • Running after small children • Running for the tram/bus • Working in the garden
Sports and leisure activities	• Cycling a long distance • Cross-country skiing • Riding a horse • Swimming • Hiking in the mountains
Physical activities	• Squatting • Jumping sideways from one leg to the other • Working out hard • Doing one-leg hops on the injured leg • Moving around in a rocking small boat • Doing fast twisting
Knee function in the future	*How certain are you that:* • You can return to the same physical activity level as before the injury? • You would not suffer any new injuries to your knee? • Your knee will not "break"? • Your knee will not get worse than before surgery?

From Thomee P, Wahrborg P, Borjesson M, Thomee R, Eriksson BI, Karlsson J. A new instrument for measuring self-efficacy in patients with an anterior cruciate ligament injury. *Scand J Med Sci Sports*. 2006;16(3):181-187.
Responses to all items are done on an 11-grade Likert scale from 0 (not at all certain) to 10 (very certain).

TABLE 10-12 Tampa Scale of Kinesiophobia for Anterior Cruciate Ligament Injury Studies

1. I'm afraid that I might injure myself if I exercise.
2. If I were to overcome it, my pain would increase.
3. My body is telling me I have something dangerously wrong.
4. My knee trouble would probably be relieved if I were to exercise.
5. People aren't taking my medical condition seriously enough.
6. My accident has put my body at risk for the rest of my life.
7. Pain always means I have injured my body.
8. Just because something aggravates my knee trouble does not mean it is dangerous.
9. I am afraid that I might injure myself accidentally.
10. Simply being careful that I do not make any unnecessary movements is the safest thing I can do to prevent my injured leg from worsening.
11. I wouldn't have this much knee trouble if there wasn't something potentially dangerous going on in my body.
12. Although my knee condition is painful, I would be better off if I were physically active.
13. Pain lets me know when to stop exercising so that I don't injure myself.
14. It's really not safe for a person with a condition like mine to be physically active.
15. I can't do all the things normal people do because it's too easy for me to get injured again.
16. Even though my injured knee is causing me a lot of pain, I don't think it's actually dangerous.
17. No one should have to exercise when he/she is gets injured.

From Kvist J, Ek A, Sporrstedt K, Good L. Fear of re-injury: a hindrance for returning to sports after anterior cruciate ligament reconstruction. *Knee Surg Sports Traumatol Arthrosc.* 2005;13(5):393-397.
Responses to all items are done on a 4-point Likert scale from 1 (strongly disagree) to 4 (strongly agree). On a scale from 0 to 51, a higher score indicates more fear.

and behavioral responses to injury and pain.[6,7,36,59,77,83,112,157,160,165,179] Researchers have tested basic psychological theories of the fear-avoidance model and self-efficacy. Fear of reinjury is one of the most common reasons patients fail to return to preinjury sports activity levels.[5,7,43,59,83,157,281] *Self-efficacy* refers to the judgment of one's potential ability to complete a task. Following ACL surgery, an individual with a high level of self-efficacy will devote considerable effort and have greater resolve to return to their desired level of activity than will a patient with low self-efficacy.

Available scales for ACL studies related to psychology include (1) the Anterior Cruciate Ligament-Return to Sport After Injury scale (12 items)[288]; (2) the Knee Self-Efficacy Scale (22 items, Table 10-11)[274]; (3) the Tampa Scale of Kinesiophobia, adapted by Kvist and associates[157] for ACL injury studies (17 items, Table 10-12); (4) the shortened version of the Tampa Scale of Kinesiophobia[92,293]; (5) the Emotional Responses of Athletes to Injury Questionnaire (28 items)[192]; and (6) the Sport Rehabilitation Locus of Control scale (9 items).[195]

A recent systematic review by Everhart and associates[77] noted that measures of self-motivation, self-efficacy, and optimism were predictive of compliance with rehabilitation, return to sport, and self-rated knee function. Ardern and colleagues[6] found that preoperative psychological responses predicted return to preinjury sports by 12 months after surgery. Factors included readiness to return to sport, the subject's estimate of how long it would take to return, and locus of control. Locus of control indicates whether patients believe their health is controlled by their own behavior and beliefs or by fate or chance.[36] Chmielewski and coworkers[44] studied longitudinal changes in the psychosocial factors of self-efficacy and fear of movement or reinjury during the first 12 weeks after ACL reconstruction in 77 patients. Compared with baseline, all factors improved in a positive manner. Importantly, an association was found between high self-efficacy scores for rehabilitation exercises and higher knee pain improvements. High self-efficacy scores combined with low scores for fear of movement or reinjury were associated with improved knee function.

Brand and Nyland[36] suggested that self-efficacy is one of the most important psychological factors affecting outcomes of ACL reconstruction. This trait is influenced by the patient's preinjury activity level, age, chronicity of injury, and sex. Men, younger patients, patients with acute injuries, and patients with high activity levels tend to have higher self-efficacy levels.[275] Modeling techniques may be effective in increasing early postoperative levels of self-efficacy and motivation to comply with rehabilitation.[175] Maddison and associates[175] successfully used two modeling videos in an effort to reduce preoperative anxiety and pain and increase postoperative self-efficacy and functional outcomes after ACL surgery. The first video was watched preoperatively and addressed the first 2-week rehabilitation period. The second video focused on the 2- to 6-week time period and consisted of interviews and various action sequences of models performing the same time-matched rehabilitation

exercises that the patient was currently performing. Further work is highly warranted in this area to improve postoperative self-efficacy in patients with (measured) low levels and to investigate appropriate preoperative psychological screening methods to determine patients who require additional support and counseling.

CLINICAL CONCEPTS

The two anterior cruciate ligament (ACL) postoperative rehabilitation protocols described in this chapter consist of a careful incorporation of exercise concepts supported by the scientific data presented in Chapter 10. The protocols are evaluation based; that is, progression through the program is based on continual evaluation using the principles of anatomy, physiology, biomechanics, and surgery,[4,5,20,44,55] with an understanding that the overall goals of the reconstruction and rehabilitation are to:

- Regain normal knee stability: less than 3 mm of increased anteroposterior (AP) displacement on knee arthrometer testing, negative or trace pivot shift
- Control joint pain, swelling, and hemarthrosis
- Regain a normal range of knee motion
- Restore a normal gait pattern and neuromuscular control for ambulation
- Recover normal lower limb muscle strength
- Regain normal proprioception, balance, coordination, and neuromuscular control for desired activities
- Achieve optimal functional outcome based on orthopedic and patient goals

Each patient is taken through the appropriate program at a rate that takes into account sports and occupational goals; the condition of the articular surfaces, menisci, and other knee ligaments; concomitant operative procedures performed with the ACL reconstruction; the type of graft used; postoperative healing and response to surgery; and biologic principles of graft healing and remodeling. The protocols are divided into seven phases according to the time period postoperatively (e.g., phase I comprises postoperative weeks 1 and 2). Each phase has

CRITICAL POINTS Clinical Concepts

Protocols are evaluation based: Progression is based on continual evaluation using the principles of anatomy, physiology, biomechanics, and surgery.

Goals

- Regain normal knee stability
- Control joint pain, swelling, and hemarthrosis
- Regain normal range of knee motion
- Restore normal gait pattern
- Recover normal lower limb muscle strength
- Regain normal proprioception, balance, coordination, and neuromuscular control
- Achieve optimal functional outcome based on orthopedic and patient goals

The protocols are divided into seven phases according to the time period postoperatively. Each phase has four categories:

- General observation of the patient's condition
- Evaluation and measurement of specific variables, with goals identified for each variable
- Treatment and exercise program according to frequency and duration
- Rehabilitation goals that must be achieved to enter into the next phase

One protocol for patients who undergo primary ACL bone-patellar tendon-bone (autogenous reconstruction and desire to return to strenuous sports or work activities as soon as possible after surgery)

Second protocol for ACL revision reconstruction, primary ACL allograft or semitendinosus-gracilis autograft reconstruction, complex reconstruction in which major concomitant operative procedures were performed, or in whom significant articular cartilage lesions were found during the operation

Both protocols incorporate home self-management program.

Neuromuscular retraining program (e.g., Sportsmetrics) advocated for all patients returning to high-risk activities

First postoperative week critical for all patients: control pain and swelling, demonstrate adequate quadriceps muscle contraction, immediate knee motion, and adequate limb elevation

four main categories that describe the factors evaluated by the therapist and exercises performed by the patient:

- General observation of the patient's condition
- Evaluation and measurement of specific variables, with goals identified for each variable
- Treatment and exercise program according to frequency and duration
- Rehabilitation goals that must be achieved to enter into the next phase

The first protocol is designed for patients who undergo primary ACL bone-patellar tendon-bone (B-PT-B) autogenous reconstruction and desire to return to strenuous sports or work activities as soon as possible after surgery. All patients are warned that the return to strenuous activities early postoperatively carries a risk of either a reinjury to the ACL-reconstructed knee or a new injury to the contralateral knee. These risks cannot be scientifically predicted, and patients are cautioned to return to strenuous activities carefully and avoid any activity in which pain, swelling, or a feeling of instability develops. Patients who develop postoperative problems, such as knee motion complications, chronic effusion, patellofemoral pain, or patellar tendinitis, are advised to slow the rate of progression until the problems are resolved. The following criteria exclude a patient from this protocol:

- Concomitant major operative procedures, such as complex meniscal repair or transplantation,[19] other ligament reconstruction, patellofemoral realignment, articular cartilage restorative procedure, and osteotomy

TABLE 11-1 Estimated Supervised Physical Therapy Visits After Anterior Cruciate Ligament Reconstruction

Phase	Postoperative Weeks	Minimum Visits (*n*)	Maximum Visits (*n*)
1	1-2	2	4
2	3-4	2	4
3	5-6	1	2
4	7-8	1	2
5	9-12	1	2
6	13-26	2	3
7	27-52	2	4
Total		11	21

- Prior ACL reconstruction that failed
- Residual muscular atrophy with chronic instability
- Magnetic resonance imaging (MRI) or arthroscopic evidence of major bone bruising or articular cartilage damage

A second protocol, designed to delay or diminish knee joint and graft loading, is used for patients who undergo ACL revision reconstruction (with either allogeneic or autogenic tissue), primary ACL allograft or semitendinosus and gracilis autograft reconstruction, or complex B-PT-B autogenous reconstruction in which major concomitant operative procedures were performed or in whom significant articular cartilage lesions were found during the operation. Delays in return of full weight bearing, initiation of certain strengthening and conditioning exercises, initiation of running and agility drills, and return to full sports activities are incorporated. This protocol is designed to protect healing concomitant meniscal or ligament repairs or allograft tissues and avoid exacerbating articular cartilage deterioration or symptoms.

Specific criteria are evaluated throughout both rehabilitation programs to determine if the patient is ready to progress from one phase to the next. Both protocols incorporate a home self-management program, along with an estimated number of formal physical therapy visits (Table 11-1). For most patients, a total of 11 to 21 postoperative visits is expected to produce a desirable result. A few more supervised sessions may be required between the sixth and twelfth postoperative months for patients who undergo advanced training to return to strenuous activities. A specific neuromuscular retraining program (e.g., Sportsmetrics) is advocated for all patients returning to high-risk activities (see Chapter 14). For all patients, the following signs are continually monitored postoperatively: joint swelling, pain, gait pattern, knee motion, patellar mobility, muscle strength, flexibility, and AP displacement. Any individual who experiences difficulty progressing through the protocol or who develops a complication is expected to require additional supervision in the formal clinic setting.

The first postoperative week represents a critical time period for all patients in regard to control of knee joint pain and swelling, demonstration of adequate quadriceps muscle contraction, initiation of immediate knee motion exercises, and maintenance of adequate limb elevation. A bulky compression dressing is used for 48 hours and then converted to compression stockings with an additional Ace bandage if necessary. Patients are encouraged to remain recumbent and elevate the limb above the heart for the first 5 to 7 days, rising only to perform exercises and attend to personal bathing issues. Prophylaxis against deep venous thrombosis includes one aspirin daily for 10 days, ambulation (with crutch support) six to eight times daily for short periods of time, ankle-pumping every hour that the patient is awake, and close observation of the lower limb by the therapist and surgeon. Knee joint

hemarthroses require aspiration. Nonsteroidal antiinflammatory drugs are used for at least 5 days postoperatively. Appropriate pain medication is prescribed to provide relief and allow the immediate exercise protocol described below to be performed.

REHABILITATION PROTOCOL FOR PRIMARY ACL B-PT-B AUTOGENOUS RECONSTRUCTION: EARLY RETURN TO STRENUOUS ACTIVITIES

Modalities

In the immediate postoperative period (1-3 days), knee effusion must be controlled to avoid the quadriceps inhibition phenomenon.[14] Electrogalvanic stimulation or high-voltage electrical muscle stimulation (EMS) may be used to augment the ice, compression, and elevation program to control swelling.[31,59,75] This treatment uses the concept of like charges repelling. The effusion or swelling has a negative electrical charge, so using the negative electrodes at the knee and the positive (dispersive) electrode on either the low back or opposite thigh will assist the body in removing the fluid from the joint to be reabsorbed. The treatment duration is approximately 30 minutes; the intensity is set to patient tolerance; and the treatment frequency is three to six times per day. Once the joint effusion is controlled, functional EMS is begun for muscle reeducation and quadriceps facilitation (Table 11-2).

The use of EMS to facilitate and enhance an adequate quadriceps contraction is based on the evaluation of quadriceps and vastus medialis oblique (VMO) muscle tone. One electrode is placed over the VMO, and the second electrode is placed on the central to lateral aspect of the upper third of the quadriceps muscle belly (Fig. 11-1). The treatment duration is 15 to 20 minutes. The patient actively contracts the quadriceps muscle simultaneously with the machine's stimulation. A portable EMS machine for home use may be required in individuals whose muscle rating is poor. EMS is continued until the muscle grade is rated as good.[10,59] Biofeedback is also useful in enhancing hamstring relaxation if the patient experiences difficulty achieving full knee extension secondary to knee pain or muscle spasm. The surface electrode may be placed over the selected muscle component to provide positive feedback to the patient and clinician regarding the quality of active or voluntary quadriceps contraction (Fig. 11-2). The electrode may also be placed over the belly of the hamstring muscle while the patient performs range-of-motion (ROM) exercises.

FIG 11-1 Electrical muscle stimulation is used to facilitate and enhance an adequate quadriceps contraction early postoperatively.

The most widely used modality after ACL reconstruction is cryotherapy, which is begun in the recovery room after surgery. The cost of various cryotherapy options and patient compliance are two major factors in the successful control of postoperative pain and swelling. The standard method of cold therapy is an ice bag or commercial cold pack, which is kept in the freezer until required. Empirically, patients prefer motorized cooler units (Fig. 11-3). These units maintain a constant temperature and circulation of ice water through a pad, which provides excellent pain control. Gravity flow units are also effective; however, temperature maintenance is more difficult with these devices than with the motorized cooler units. The temperature can be controlled by using gravity to backflow and drain the water, refilling the cuff with fresh ice water as required. Cryotherapy is used for 20 minutes at a time from three times per day to every waking hour, depending upon the extent of pain and swelling. In some cases, the treatment time is extended owing to the thickness of the buffer used between the skin and the device. The motorized units contain a thermostat, which is

Text continued on p. 304

FIG 11-2 Biofeedback therapy is implemented to facilitate an adequate quadriceps muscle contraction early postoperatively.

FIG 11-3 A motorized cooler unit is used to provide cryotherapy.

PHASE 1: WEEKS 1-2

General Observation

50% weight bearing with two crutches when:

- Postoperative pain controlled
- Hemarthrosis controlled
- Voluntary quadriceps contraction achieved

Factors Evaluated (Goal)

Pain (controlled)
Hemarthrosis (mild)
Patellar mobility (good)
ROM (minimum, 0-110 degrees)
Quadriceps contraction and patella migration (good)
Soft tissue contracture (none)
Joint arthrometry day 14 (<3 mm)

TABLE 11-2 Cincinnati SportsMedicine & Orthopaedic Center Rehabilitation Protocol for Primary Anterior Cruciate Ligament Reconstruction: Early Return to Strenuous Activities—cont'd

PHASE 1: WEEKS 1-2

Activity	Frequency	Duration
ROM	3-4 ×/day, 10 min	
Passive (0-90 degrees)		
Patella mobilization		
Ankle pumps (plantar flexion with resistance band)		
Hamstring, gastrocnemius-soleus stretches		5 reps × 30 sec each
Strengthening	3 ×/day, 15 min	
Straight-leg raises (flexion, extension, abduction, adduction)		3 sets × 10 reps
Active quadriceps isometrics (full extension)		1 set × 10 reps
Knee flexion (active, 0-90 degrees)		3 sets × 10 reps
Knee extension (active assisted, 90-30 degrees)		3 sets × 10 reps
Multihip machine (flexion, extension, abduction, adduction)		3 sets × 10 reps
Leg press (70-10 degrees)		3 sets × 10 reps
Closed-chain: minisquats (0-45 degrees, 50% weight bearing)		3 sets × 20 reps
Balance Training	3 ×/day, 5 min	
Weight shift side-side and forward-back		5 sets × 10 reps
Aerobic Conditioning		
UBC	1-2 ×/day, 5 min	
Modalities	As required	
EMS		20 min
Cryotherapy		20 min
Goals	• ROM 0-110 degrees • Adequate quadriceps contraction • Control inflammation and effusion • 50% weight bearing	

PHASE 2: WEEKS 3-4

General Observation	Full weight bearing with one crutch when: • Pain controlled without narcotics • Effusion controlled • ROM 0-100 degrees • Muscle control throughout ROM
Factors Evaluated (Goal)	Pain (mild) Effusion (mild) Patellar mobility (good) ROM (minimum, 0-120 degrees) Muscle control (3/5) Inflammatory response (none) Joint arthrometry, day 28, 20 lb (<3 mm)

Activity	Frequency	Duration
ROM	3-4 ×/day, 10 min	
Passive (0-120 degrees)		
Patella mobilization		
Ankle pumps (plantar flexion with resistance band)		
Hamstring, gastrocnemius-soleus stretches		5 reps × 30 sec each

Continued

TABLE 11-2 Cincinnati SportsMedicine & Orthopaedic Center Rehabilitation Protocol for Primary Anterior Cruciate Ligament Reconstruction: Early Return to Strenuous Activities—cont'd

PHASE 2: WEEKS 3-4

Activity	Frequency	Duration
Strengthening	2-3 ×/day, 20 min	
Straight-leg raises (flexion, extension, adduction, abduction)		3 sets × 10 reps
Isometric training, multiangle (90, 60, 30 degrees)		1 set × 10 reps
Heel raise/toe raise		3 sets × 10 reps
Hamstring curls (active, 0-90 degrees)		3 sets × 10 reps
Knee extension (active, 90-30 degrees)		3 sets × 10 reps
Closed-chain:		
Wall-sits		5 reps
Minisquats		3 sets × 20 reps
Multihip machine (flexion, extension, abduction, adduction)		3 sets × 10 reps
Leg press (70-10 degrees)		3 sets × 10 reps
Balance Training	3×/day, 5 min	
Weight shift side-side, forward-back		5 sets × 10 reps
Balance board, two legged		
Cup walking		
Single-leg stance (level surface)		5 reps
Aerobic Conditioning	2×/day, 5 min	
UBC		
Water walking		
Stationary bicycling (patellofemoral precautions)		
Modalities	As required	
EMS		20 min
Cryotherapy		20 min
Goals	• ROM 0-125 degrees • Muscle control • Arthrometer within 3 mm • Control inflammation, effusion • 100% weight bearing	

PHASE 3: WEEKS 5-6

General Observation	Independent ambulation when: • Pain controlled • Effusion controlled • ROM 0-120 degrees • Muscle control throughout ROM
Factors Evaluated (Goal)	Pain (no CRPS) Effusion (minimal) Patellar mobility (good) ROM (0-135 degrees) Muscle control (4/5) Inflammatory response (none) Gait, symmetric

Activity	Frequency	Duration
ROM	3 ×/day, 10 min	
ROM passive (0-135 degrees)		
Patella mobilization		
Hamstring, gastrocnemius-soleus stretches		5 reps × 30 sec

TABLE 11-2 Cincinnati SportsMedicine & Orthopaedic Center Rehabilitation Protocol for Primary Anterior Cruciate Ligament Reconstruction: Early Return to Strenuous Activities—cont'd

PHASE 3: WEEKS 5-6

Activity	Frequency	Duration
Strengthening	1-2 ×/day, 20 min	
Straight-leg raises (ankle weight, <10% of body weight)		3 sets × 10 reps
Straight-leg raises with rubber tubing		3 sets × 10 reps
Isometric training, multiangle (90, 60, 30 degrees)		2 sets × 10 reps
Heel raise/toe raise		3 sets × 20 reps
Hamstring curls (active, 0-90 degrees)		3 sets × 10 reps
Knee extension (90-30 degrees, with resistance)		3 sets × 10 reps
Closed-chain:		
Wall-sits		5 reps
Minisquats		3 sets × 20 reps
Multihip machine (flexion, extension, abduction, adduction)		3 sets × 10 reps
Leg press (70-10 degrees)		3 sets × 10 reps
Balance Training	3 ×/day, 5 min	
Balance board, two legged		
Lateral step-ups, 2- to 4-inch block		
Aerobic Conditioning (Patellofemoral Precautions)	2 ×/day, 10 min	
UBC		
Water walking		
Stationary bicycling		
Stair machine (low resistance and stroke)		
Ski machine (short strike and level, low resistance)		
Modalities	As required	
EMS		20 min
Cryotherapy		20 min
Goals	• ROM 0-135 degrees • Control inflammation and effusion • Recognition of complications (motion loss, CRPS, increased anteroposterior displacement) • Muscle endurance • Recognition of patellofemoral changes • Full weight bearing, normal gait	

PHASE 4: WEEKS 7-8

General Observation	• No effusion • Painless ROM (0-135 degrees) • Joint stability • Performs activities of daily living • Full weight bearing • Can walk 20 min without pain
Factors Evaluated (Goal)	Manual muscle test (hamstrings, quadriceps, all hip muscles; 4/5) Swelling (none) Joint arthrometry, 8 weeks (<3 mm) Patellar mobility (good) Crepitus (none/slight)

Continued

PHASE 4: WEEKS 7-8

Activity	Frequency	Duration
ROM	2 ×/day, 10 min	
Hamstring, gastrocnemius-soleus stretches		5 reps × 30 sec
Strengthening	1-2 ×/day, 20 min	
Straight-leg raises, rubber tubing		3 sets × 30 reps
Hamstring curls (active, 0-90 degrees)		3 sets × 10 reps
Knee extension with resistance (90-30 degrees)		3 sets × 10 reps
Leg press (70-10 degrees)		3 sets × 10 reps
Multihip machine (flexion, extension, abduction, adduction)		3 sets × 10 reps
Closed-chain:		
Wall-sits		5 reps
Minisquats		3 sets × 20 reps
Dynamic hip and core program		
Balance Training	3 ×/day, 5 min	
Balance board, two legged		
Single-leg stance		
Resistance band walking		
PlyoBack ball toss		
Perturbation training		
Aerobic Conditioning (Patellofemoral Precautions)	1-2 ×/day, 15-20 min	
Stationary bicycling		
Water walking		
Swimming (straight-leg kicking)		
Walking		
Stair machine (low resistance and stroke)		
Ski machine (short stride and level, low resistance)		
Elliptical machine (low resistance)		
Modalities	As required	
Cryotherapy		20 min
Goals	Increase strength and endurance	

PHASE 5: WEEKS 9-12

General Observation	• No effusion, painless ROM (0-135 degrees), joint stability • Performs ADLs, can walk 20 min without pain • Full weight bearing
Factors Evaluated (Goal)	Manual muscle test (4/5) Isometric test, 12 weeks, mean average torque/% deficit in quadriceps and hamstrings (30%) Swelling (none) Joint arthrometry, 12 weeks (<3 mm) Patellar mobility (good) Crepitus (none/slight)

TABLE 11-2 Cincinnati SportsMedicine & Orthopaedic Center Rehabilitation Protocol for Primary Anterior Cruciate Ligament Reconstruction: Early Return to Strenuous Activities—cont'd

PHASE 5: WEEKS 9-12

Activity	Frequency	Duration
ROM	2 ×/day, 10 min	
Hamstring, gastrocnemius-soleus, quadriceps, ITB stretches		5 reps × 30 sec
Strengthening	2 ×/day, 20 min	
Straight-leg raises with rubber tubing		3 sets × 30 reps
Hamstring curls (active, 0-90 degrees)		3 sets × 10 reps
Knee extension with resistance (90-30 degrees)		3 sets × 10 reps
Leg press (70-10 degrees)		3 sets × 10 reps
Multihip machine (flexion, extension, abduction, adduction)		3 sets × 10 reps
Closed-chain:		
Wall-sits		5 reps
Minisquats		3 sets × 20 reps
Lateral step-ups (2- to 4-inch block)		3 sets × 10 reps
Dynamic hip and core program		
Balance Training	3 ×/day, 5 min	
Balance board, two legged		
Single-leg stance		
Resistance band walking		
PlyoBack ball toss		
Perturbation training		
Aerobic Conditioning (Patellofemoral Precautions)	3 ×/wk, 15-20 min	
Stationary bicycling		
Walter walking		
Swimming (kicking)		
Walking		
Stair machine (low resistance and stroke)		
Ski machine (short stride and level, low resistance)		
Elliptical machine (low resistance)		
Running Program (Straight)	3 ×/wk, 10 min	
Jog		¼ mile
Walk		⅛ mile
Backward walk		20 yards
Modalities	As required	
Cryotherapy		20 min
Goals	Increase strength and resistance	

PHASE 6: WEEKS 13-26

General Observation	• No effusion • Painless ROM • Joint stability • Performs ADLs • Can walk 20 min without pain

Continued

TABLE 11-2 Cincinnati SportsMedicine & Orthopaedic Center Rehabilitation Protocol for Primary Anterior Cruciate Ligament Reconstruction: Early Return to Strenuous Activities—cont'd

PHASE 6: WEEKS 13-26

Factors Evaluated (Goal)	Isokinetic test (isometric + torque 300 degrees/sec, % difference in quadriceps and hamstrings, tested monthly) Swelling (none) Joint arthrometry (<3 mm) Patellar mobility (good) Crepitus (none/slight) Single-leg function tests (hop distance, timed hop, % difference between involved and noninvolved side)

Activity	Frequency	Duration
ROM	2 ×/day, 10 min	
Hamstring, gastrocnemius-soleus, quadriceps, ITB stretches		5 reps × 30 sec
Strengthening	1 ×/day, 20-30 min	
Straight-leg raises, rubber tubing (high speed)		3 sets × 30 reps
Hamstring curls (active, 0-90 degrees)		3 sets × 10 reps
Knee extension with resistance (90-30 degrees)		3 sets × 10 reps
Leg press (70-10 degrees)		3 sets × 10 reps
Multihip machine (flexion, extension, abduction, adduction)		
Dynamic hip and core program		
Balance Training	3 ×/day, 5 min	
Balance board, two legged to single legged		
Single-leg stance on unstable platform		
Aerobic Conditioning (Patellofemoral Cautions)	3 ×/wk, 20-30 min	
Stationary bicycling		
Water walking		
Swimming (kicking)		
Walking		
Stair machine (low resistance and stroke)		
Ski machine (short stride and level, low resistance)		
Elliptical machine (low resistance)		
Running Program (Straight)	3 ×/wk, 15-20 min	
Jog (progress speed from ½ to ¾ to full)		¼ to 1 mile
Walk		⅛ mile
Backward run		20 yards
Cutting Program (Lateral, Carioca, Figure-Eights)	3 ×/wk	20 yards
Functional Training	3 ×/wk	
Plyometric training (box hops, level, double leg)		15 sec, 4-6 sets
Sport-specific drills		
Modalities	As required	
Cryotherapy		20 min
Goals	Increase strength and endurance	

PHASE 7: WEEKS 27-52

General Observation	• No effusion • Painless ROM • Joint stability • Performs ADLs • Can walk 20 min without pain

TABLE 11-2 Cincinnati SportsMedicine & Orthopaedic Center Rehabilitation Protocol for Primary Anterior Cruciate Ligament Reconstruction: Early Return to Strenuous Activities—cont'd

PHASE 7: WEEKS 27-52

Factors Evaluated (Goal)	Isokinetic test (torque at 180 and 300 degrees/sec, % difference in quadriceps and hamstrings, tested quarterly; isometric if symptomatic patellofemoral joint) (10%-15%) Swelling (none) Joint arthrometry (<3 mm) Patellar mobility (good) Crepitus (none/slight) Single-leg functional test (hop distance, timed hop, % difference between noninvolved and involved side) (≤15%)	
Activity	**Frequency**	**Duration**
ROM	2 ×/day, 10 min	
Hamstring, gastrocnemius-soleus, quadriceps, ITB stretches		5 reps × 30 sec
Strengthening		
Straight-leg raises, rubber tubing (high speed)	3-4 ×/wk, 20-30 min	3 sets × 30 reps
Hamstring curls (active, 0-90 degrees)		1-2 sets × 8-12 reps
Knee extension with resistance (90-30 degrees)		1-2 sets × 8-12 reps
Leg press (70-10 degrees)		1-2 sets × 8-12 reps
Multihip machine (flexion, extension, abduction, adduction)		1-2 sets × 8-12 reps
Dynamic hip and core program		
Balance Training	3 ×/day, 5 min	
Balance board, two legged to single legged

helpful when cold therapy is used for an extended treatment time. Vasopneumatic devices offer another option for cold therapy. The Game Ready device (Game Ready) allows the clinician to set the temperature as well as one of four different compression levels, depending on patient tolerance. Although this is primarily a clinical treatment tool, it may be used at home. Cryotherapy is typically done after exercise or when required for pain and swelling control and is maintained throughout the entire postoperative rehabilitation protocol.

Postoperative Bracing

The use of postoperative braces after ACL reconstruction is controversial.[7,30,34,37,74] Screening patients for personality type, pain tolerance, and program compliance may provide insight into the individual who will require brace protection postoperatively. The primary indication for the use of a brace, in our opinion, is protection of the patient during weight bearing in the event of a fall and to initiate early, more comfortable weight bearing during the first few postoperative weeks. The brace should be rigid in nature and the knee held initially at 0 degrees (Fig. 11-4). The brace is opened based on the protocol to allow normal knee flexion during ambulation. Periodic evaluation of the brace and its position on the leg must be done to ensure maximal benefit is achieved. We do not routinely prescribe a derotation or functional knee brace upon return to full activities after ACL reconstruction for patients treated according to this protocol.

Range of Knee Motion

The goal in the first postoperative week is to obtain a ROM of 0 to 90 degrees. We do not require or routinely use continuous passive motion machines. Patients perform passive and active ROM exercises in a seated position for 10 minutes per session, approximately four to six times per day (Fig. 11-5).

FIG 11-4 A long-leg postoperative brace protects the patient during weight bearing in the event of a fall and promotes early, comfortable weight bearing during the first few postoperative weeks.

FIG 11-5 Passive (**A**) and active (**B**) range-of-motion exercises in a seated position.

Full passive knee extension must be obtained immediately to avoid excessive scarring in the intercondylar notch and posterior capsular tissues. If the patient has difficulty regaining at least 0 degrees ROM by the seventh postoperative day, he or she begins an overpressure program. The foot and ankle are propped on a towel or other device to elevate the hamstrings and gastrocnemius that allows the knee to drop into full extension (Fig. 11-6, *A*). This position is maintained for 10 minutes and repeated four to six times per day. A 10-pound weight may be added to the distal thigh and knee to provide overpressure to stretch the posterior capsule. Full knee extension should be obtained by the second postoperative week. If this is not accomplished, or if the clinician notes a firm end feel, then an extension board (see Fig. 11-6, *B*) or additional weight of 15 to 20 pounds is used six times per day. If this is still not effective, a dropout cast (see Fig. 11-6, *C*) is implemented for 24 to 36 hours for continuous extension overpressure. The goal is to obtain 0 to 2 to 3 degrees of hyperextension, which is within the normal knee motion limit. In patients with physiologic bilateral knee hyperextension, we recommend the gradual return of 3 to 5 degrees of hyperextension in the reconstructed knee to more closely resemble the amount of hyperextension present in the contralateral knee. However, we do not recommend that the patient regain more than 5 degrees of hyperextension, owing to potentially deleterious forces that may be placed on the healing graft.

Knee flexion is gradually increased to 120 degrees by the third to fourth postoperative week and 135 degrees by the fifth to sixth postoperative week. Passive knee flexion exercises are performed initially in the traditional seated position, using the opposite lower extremity to provide overpressure. Other methods to assist in achieving flexion greater than 90 degrees include chair-rolling (Fig. 11-7, *A*), wall slides (see Fig. 11-7, *B,* and 11-7, *C*), knee flexion devices (see Fig. 11-7, *D*), and passive quadriceps-stretching exercises. Patients who have difficulty achieving 0 to 90 degrees of flexion by the fourth week require additional treatment interventions to relieve pain during joint motion, such as appropriate medications, local nerve blocks, and possibly a gentle ranging of the knee under anesthesia (not a forceful manipulation), as described in Chapter 38, Prevention and Treatment of Knee Arthrofibrosis.

Patellar Mobilization

Restoring normal patellar mobility is critical to regain a normal range of knee motion. The loss of patellar mobility is often associated with arthrofibrosis and, in extreme cases, the development of patella infera.[56,57,60] Patellar glides are begun the first postoperative day in all four planes (superior, inferior, medial, and lateral) with sustained pressure applied to the appropriate patellar border for at least 10 seconds (Fig. 11-8). This exercise is performed for 5 minutes before ROM exercises. Caution is warranted if an extensor lag is detected, because this may be associated with poor superior migration of the patella, indicating the need for additional emphasis on this exercise. Patellar mobilization is performed for approximately 6 weeks postoperatively.

Weight Bearing

Partial weight bearing is permitted immediately postoperatively as long as pain and swelling are controlled and a voluntary quadriceps contraction is demonstrated. Initially, bilateral crutches may be used, and 50% body weight is placed on the involved foot. The amount of weight the patient is allowed to place on the involved limb is progressed as tolerated to allow full weight by the third to fourth postoperative week. Importantly, a normal gait pattern is advocated that avoids a locked knee position and encourages normal knee flexion throughout the gait cycle. This technique allows for normal patterning of heel-to-toe ambulation, quadriceps contraction during midstance, and hip and knee flexion during the gait cycle. The locked-knee position is avoided owing to the potential of the development of a quadriceps-avoidance gait pattern.

FIG 11-6 Overpressure program for extension. **A,** Hanging-weight exercise. **B,** Extension board (ERMI Knee Extensionater). **C,** Dropout cast.

Flexibility

Hamstring and gastrocnemius-soleus flexibility exercises are begun the first day after ACL reconstruction. A sustained static stretch is held for 30 seconds and repeated five times. The most common hamstring stretch is the modified hurdler stretch (Fig. 11-9), whereas the most common gastrocnemius-soleus stretch is the towel pull (Fig. 11-10). These exercises help control pain owing to the reflex response created in the hamstrings when the knee is kept in the flexed position. As well,

FIG 11-7 Overpressure program for flexion. **A,** Rolling-stool exercise. **B** and **C,** Wall slides. **D,** Overpressure flexion device (E Knee Flexionater).

the towel-pulling exercise can help lessen discomfort in the calf, Achilles tendon, and ankle. These stretches represent critical components of the knee extension ROM program, because the ability to relax these two muscle groups is imperative to achieve full passive knee extension.

Quadriceps (Fig. 11-11) and iliotibial band (Fig. 11-12) flexibility exercises are performed to assist in achieving full knee flexion and controlling lateral hip and thigh tightness. A complete evaluation of the lower extremity will reveal deficit areas in flexibility that should be corrected. When designing a flexibility program, the therapist should take into account the particular sport or activity to which the patient wishes to return, as well as the position or physical requirements of that activity. Flexibility is incorporated in the maintenance program the patient performs once discharged.

Strengthening

Lower extremity muscle atrophy and weakness after ACL reconstruction represents a difficult and unresolved problem.[15,17,23,28,59,67,70] Therefore our strengthening program begins at the first postoperative visit. Early emphasis on the generation of a good voluntary quadriceps contraction is critical for a successful and safe return to functional activity. Isometric quadriceps contractions are completed on an hourly basis following the repetition rules of 10-second holds, 10 repetitions, 10 times per day. Adequate evaluation of the quadriceps contraction by both the therapist and patient is critical. The patient can monitor contractions by visual or manual means, comparing the quality of the contractions with those achieved by the contralateral limb. The patient can also assess the superior migration of the patella during the contraction, which should be approximately 1 cm, and the inferior migration of the patella during the initial relaxation of the contraction. The patient must not let the knee go into hyperextension during isometric contractions but instead hold the knee flexion position throughout the exercise. If necessary, biofeedback can also be used to reinforce a good quadriceps contraction.

Straight-leg raises are initiated on the first postoperative day in the four planes of hip movement. The adduction straight-leg raise has a beneficial effect on the VMO. Supine straight-leg raises must include a sufficient isometric quadriceps contraction to benefit the quadriceps. Straight-leg raises in the other two planes are also important for proximal stabilization. As these exercises become easy to perform, ankle weights are added to progress muscle strengthening. Initially, 1 to 2 pounds of weight are used, and eventually up to 10 pounds is added

FIG 11-8 Patellar glides are begun on the first postoperative day in all four planes. **A,** Superior and inferior. **B,** Medial and lateral.

FIG 11-9 Hamstring modified hurdler stretch.

as long as this is not more than 10% of the patient's body weight. Active assisted ROM can also be used to facilitate the quadriceps muscle if poor tone is observed during isometric contractions. These exercises are used primarily during the first 8 postoperative weeks, when emphasis is placed on controlling pain and swelling, regaining full ROM,

FIG 11-10 Gastrocnemius-soleus towel-pull stretch.

FIG 11-11 Quadriceps stretch.

achieving early quadriceps control and proximal stabilization, and resuming a normal gait pattern.

Closed kinetic chain exercises are initiated in the first postoperative week. Minisquats from 0 to 45 degrees (Fig. 11-13, *A*) are begun when tolerated by the patient. Initially, the patient's body weight is used as resistance, and TheraBand (see Fig. 11-13, *B*) or surgical tubing is gradually used as resistance mechanisms. Quick, smooth, rhythmic squats are performed to a high-set/high-repetition cadence to promote muscle fatigue. Hip position should be monitored to promote a quadriceps contraction.

Toe raises for gastrocnemius-soleus strengthening and wall-sitting isometrics for quadriceps control are begun in the second postoperative week. The goal of wall-sitting is to improve quadriceps contraction by performing the exercise to muscle exhaustion (Fig. 11-14, *A*). If anterior knee pain is experienced, it may be decreased by either altering the knee flexion angle of the sit or by subtly changing the toe-out/toe-in angle by no more than 10 degrees. The exercise may also be modified to produce greater challenge to the quadriceps. The patient may voluntarily set the quadriceps muscle once he or she reaches the maximum knee flexion angle, which is typically between 30 and 45 degrees. This contraction and knee flexion position is held until muscle fatigue occurs, and the exercise is repeated three to five times. The patient may squeeze a ball between the distal thighs, inducing a hip adduction contraction and a stronger VMO contraction (see Fig. 11-14, *B*). In a third variation, the patient holds dumbbell weights in the hands to increase body weight, which promotes an even stronger quadriceps contraction (see Fig. 11-14, *C*). Finally, the patient can shift the body weight over the involved side to stimulate a single-leg contraction. This exercise is promoted as an excellent one for the patient to perform at home four to six times daily to achieve quadriceps fatigue in a safe knee flexion angle that does not induce an abnormal anterior tibial translation.

FIG 11-12 Iliotibial band stretch.

Lateral step-ups are begun when the patient has achieved full weight bearing (Fig. 11-15). The height of the step is gradually increased based on patient tolerance.

Hamstring curls are begun with Velcro ankle weights within the first few weeks and eventually advanced to weight machines (Fig. 11-16). Weight machines are advantageous owing to the muscle isolation obtained, as the machine provides stability to the knee joint. The patient exercises the involved limb alone as well as both limbs together. If the lightest amount of weight on the machine is too heavy to be lifted by the involved limb alone, the exercise may be performed as an eccentric contraction in which the patient lifts the weight with both legs and lowers the weight with the involved side. Eccentric contractions may also be used in the advanced stages of strength training. Hamstring strength is critical to the overall success of the rehabilitation program because of the role that this musculature plays in the dynamic stabilization of the knee joint. Weight training is used throughout the advanced program and continues in the return-to-activity and maintenance phases of rehabilitation.

Open kinetic chain extension exercises are incorporated within the first few weeks to further develop quadriceps muscle strength. Caution is warranted because of the potential problems these exercises may create for the healing graft and the patellofemoral joint. Resisted knee extension is begun with Velcro ankle weights in the first week from 90 to 30 degrees. The terminal phase of extension is avoided because of the forces placed on the patellofemoral joint and ACL graft. The patellofemoral joint must be monitored for changes in pain, swelling, and

FIG 11-16 Hamstring curls.

crepitus to avoid a patellar conversion in which painful patellofemoral crepitus develops with articular cartilage damage. The surgeon should advise the therapist if there are abnormal patellofemoral findings of joint damage.

A full lower extremity–strengthening program is critical for the early and long-term success of the rehabilitation program. Other muscle groups included in this routine are the hip abductors, hip adductors, hip flexors, and hip extensors. These muscle groups can be exercised on either a multihip or cable system machine (Fig. 11-17) or a hip abductor/adductor machine. Gastrocnemius-soleus strength is a key component for both early ambulation and the running program. In addition, upper extremity and core strengthening are important for a safe and effective return to work or sports. Sport and position specificity are taken into account when devising the strengthening program to maximize its benefits. In 2009, the American College of Sports Medicine (ACSM)[2] updated their recommendations for progression of muscle strength, hypertrophy, power, and endurance training (Tables 11-3 to 11-6). Specific strengthening and sport-specific timing drills are beyond the scope of this chapter; the therapist should work with the patient and appropriate coaches to determine the individual patient's program.

Balance, Proprioceptive, and Perturbation Training

Restoration of normal neuromuscular function after ACL reconstruction is paramount for the eventual implementation of sport-specific exercises and release to full activities. Knee joint proprioception is a crucial element of neuromuscular function, and its recovery is essential for a successful outcome.[16,22,38,40,42,73] Balance and proprioceptive training are begun the first postoperative week. Initially, the patient simply stands and shifts weight from side to side and from front to back. This activity encourages confidence in the leg's ability to withstand the pressures of weight bearing and initiates the stimulus to knee joint position sense.

Cup walking is begun when the patient achieves full weight bearing (Fig. 11-18) to promote symmetry between the surgical and uninvolved limbs. This exercise helps develop hip and knee flexion and quadriceps control during midstance of gait to prevent knee hyperextension. In addition, cup walking controls hip and pelvic motion during midstance, gastrocnemius-soleus activity during push-off, and excessive hip hiking. These components of gait control are critical in the early phases of rehabilitation to decrease forces on the healing graft.

Double- and single-leg balance exercises in the stance position are beneficial early postoperatively. During the single-leg exercise, the foot is pointed straight ahead, the knee flexed 20 to 30 degrees, the arms extended outward to horizontal, and the torso positioned upright with the shoulders above the hips and the hips above the ankles (Fig. 11-19, *A*). The objective is to remain in this position until balance is disturbed. A minitrampoline or unstable platform may be used to make this exercise more challenging, because these devices promote greater dynamic limb control than that required to stand on a stable surface (see Fig. 11-19B). To provide a greater challenge, patients may assume the single-leg stance position and throw and catch a weighted ball against an inverted minitrampoline (Fig. 11-20) until fatigue occurs.

Perturbation training techniques are initiated at approximately the seventh to eighth postoperative week during balance exercises. The therapist stands behind the patient and disrupts her or his body posture and position periodically to enhance dynamic knee

stability. The techniques involve either direct contact with the patient (Fig. 11-21, *A*) or disruption of the platform the patient is standing on (Fig. 11-21, *B*).

Half round foam rolls are also used in this time period as part of the gait retraining and balance program (Fig. 11-22). This exercise helps the patient develop balance and dynamic muscular control required to maintain an upright position and be able to walk from one end of the roll to the other. Developing a center of balance, limb symmetry, quadriceps control in midstance, and postural positioning are benefits developed from this type of training. Use of the Biomechanical Ankle Platform System (BAPS [AliMed]) in double-leg and single-leg stances is another effective balance and proprioceptive exercise (Fig. 11-23).

The use of more expensive devices adds another dimension to the proprioception program, because certain units objectively attempt to document balance and dynamic control. Two of the more common units include balance systems from Biodex Medical Systems (Fig. 11-24) and NeuroCom (Natus Balance & Mobility).

FIG 11-22 Gait and balance retraining using half round foam rolls.

FIG 11-24 The Biodex Balance System (Biodex Medical Systems) may be used for balance training and to objectively measure balance and dynamic control.

FIG 11-23 The Biomechanical Ankle Platform System (BAPS [AliMed]) is used in double-leg and single-leg stances.

Conditioning

The primary consideration for a conditioning program throughout the rehabilitation period is to stress the cardiovascular system without compromising the knee joint. Depending on accessibility, a cardiovascular program is begun as soon as the patient can sufficiently tolerate the upright position with an upper extremity ergometer. The surgical limb should be elevated to minimize lower extremity swelling. This exercise is performed as tolerated. Stationary bicycling is begun in the third postoperative week. Water walking may be initiated when the surgical wound has healed. Early goals of these programs include facilitation of full ROM, gait retraining, and cardiovascular reconditioning. To improve cardiovascular endurance, the program should be performed at least three times per week for 20 to 30 minutes, and the exercise should be performed to at least 60% to 85% of maximal heart rate. It is generally regarded that performing in the higher levels of percentage of maximal heart rate achieves greater cardiovascular efficiency and endurance.

Use of cross-country skiing and stair-climbing machines is permitted during the fifth to sixth postoperative weeks. Protection against high stresses to the patellofemoral joint is strongly advocated. During bicycling, the seat height is adjusted to its highest level based on patient body size, and a low resistance level is used initially. Stair-climbing machines are adjusted to produce a short step and low resistance.

An effective cardiovascular exercise program is an important component of the latter phases of rehabilitation. In addition to the previously described exercises, an aquatic program that includes lap work using freestyle or flutter kicking, water walking, water aerobics, and deep-water running is encouraged. The determination of which cardiovascular exercises are appropriate is based on each patient's access to and preference for specific equipment.

Running and Agility Program

To initiate the running program, the patient must demonstrate no more than a 30% deficit in average torque for the quadriceps and hamstrings on isokinetic testing, have no more than a 3-mm increase in AP displacement on arthrometer testing, and be at least 9 weeks postoperative. It is important to note that the majority of patients initiate running at approximately 16 to 20 weeks after surgery. Only in exceptional cases does this program begin before this time period when muscle strength has returned to normal, no pain of joint effusion is present, and no concurrent operative procedures were performed, such as a complex meniscus repair or other ligament reconstruction.

The running program is designed based on the patient's athletic goals, particularly the position or physical requirements of the activity. For instance, an individual returning to short-duration, high-intensity activities should participate in a sprinting program rather than a long-distance endurance program. The running program is performed three times per week on opposite days of the strength program. Because the running program may not reach aerobic levels initially, a cross-training program is used to facilitate cardiovascular fitness. The cross-training program is performed on the same day as the strength workout.

The first level consists of straight-ahead walk-run combinations. Running distances are 20, 40, 60, and 100 yards (18, 37, 55, and 91 m) in both forward and backward directions. The initial running speed is approximately one-fourth to one-half of the patient's normal speed, which gradually progresses to three-fourths to full speed. An interval training-rest approach is applied in which the rest phase is two to three times the length of the training phase. After the patient is able to run straight ahead at full speed, lateral running and crossover maneuvers are begun. Short distances, such as 20 yards (18 m), are used to work on speed and agility. Side-to-side running over cups may be used to facilitate proprioception. At this time, sport-specific equipment is introduced to enhance skill development (e.g., a soccer ball for a soccer player to work on dribbling and passing activities). These variations are useful to motivate the patient and minimize training boredom.

The third level of the running program incorporates figure-eight running drills. Long and wide movement patterns over 20 yards (18 m) are initially used to encourage subtle cutting. As speed and confidence improve, the distance is decreased to approximately 10 yards (9 m). Progression through this phase is similar to that used in the lateral side-to-side program just described. Speed and agility are emphasized and equipment is introduced to develop sport-specific skills.

The fourth phase in the running program introduces cutting patterns. These patterns include directional changes at 45- and 90-degree angles, which allow the patient to progress from subtle to sharp cuts.

Plyometric Training

Plyometric training is begun upon successful completion of the running program to minimize bilateral alterations in neuromuscular function and proprioception. Plyometric training in combination with resistance training is recommended by the ACSM to improve vertical jump height.[2] Important parameters to consider when performing plyometric exercises include surface, footwear, and warmup. The jump training should be done on a firm yet forgiving surface such as a wooden gym floor. Very hard surfaces such as concrete should be avoided. A cross-training or running shoe should be worn to provide adequate shock absorption as well as adequate stability to the foot. Checking wear patterns and outer sole wear will help avoid overuse injuries. Beginning plyometric training is done in individual sessions performed in a manner similar to interval training. Initially, a rest period is incorporated that lasts two to three times the length of the exercise period; this is gradually decreased to one to two times the length of the exercise period. As well, plyometrics are performed two to three times each week, along with strength and cardiovascular endurance exercises.

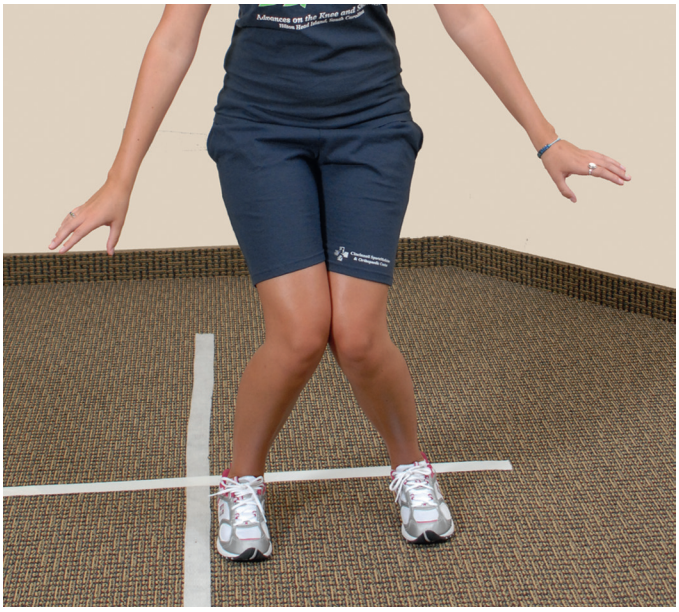

FIG 11-25 During plyometric training, the patient is instructed to keep the body weight on the balls of the feet and to jump and land with the knees flexed and shoulder-width apart to avoid knee hyperextension and an overall valgus lower limb position, as shown here.

During the various jumps, the patient is instructed to keep the body weight on the balls of the feet and to jump and land with the knees flexed and shoulder-width apart to avoid knee hyperextension and an overall valgus lower limb position (Fig. 11-25). The patient should understand that the exercises are reaction and agility drills and that, though speed is emphasized, correct body posture must be maintained throughout the drills.

The first exercise is level-surface box-hopping using both legs. A four-square grid of four equally sized boxes is created with tape on the floor. The patient is instructed to first hop from box 1 to box 3 (front to back) and then from box 1 box 2 (side to side) (Fig. 11-26). The second level incorporates both of these directions into one sequence and also includes hopping in both right and left directions (e.g., box 1 to box 2 to box 4 to box 2 to box 1). Level three progresses to diagonal hops (Fig. 11-27), and level four includes pivot hops in 90- and 180-degree directions (Fig. 11-28). Once the patient can perform level four double-leg hops, the same exercises are done on a single leg. The next phase incorporates vertical box hops.

Improvement is measured by counting the number of hops in a defined time period. The initial exercise time period is 15 seconds. The patient is asked to complete as many hops between the squares as possible in 15 seconds. Three sets are performed for both directions, and the number of hops is recorded. The program is progressed as the number of hops increases, as does the patient's confidence.

We recommend that patients complete a course of Sportsmetrics training to reduce the risk of a noncontact reinjury before return to strenuous athletics.[53] This training program teaches athletes to control the upper body, trunk, and lower body position; lower the center of gravity by increasing hip and knee flexion during activities; and develop muscular strength and techniques to land with decreased ground reaction forces. In addition, athletes are instructed to preposition the body and lower extremity before initial ground contact to

FIG 11-26 Initial plyometric training involves jumping front to back (**A** to **C**) and side to side (**D** to **F**) on a level surface using both legs.

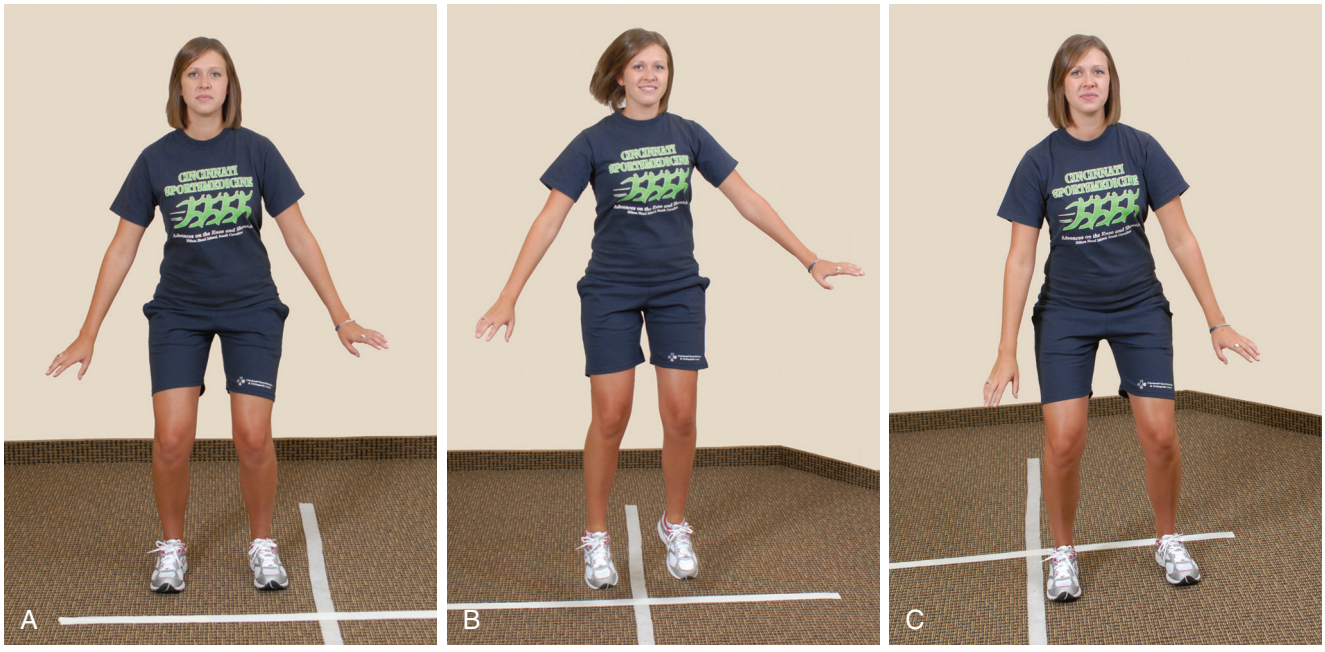

FIG 11-27 Plyometric training using diagonal hops forward and backward.

FIG 11-28 Plyometric training using pivot hops in 90- and 180-degree directions.

obtain the position of greatest knee joint stability and stiffness. The program consists of a dynamic warmup, plyometric jump training, strengthening exercises, aerobic conditioning, agility, and risk awareness training. The training is conducted three times per week on alternating days for 6 weeks. It is described in detail in Chapter 14.

Return to Sports Activities

Return to sports activities is based on successful completion of the running and functional training and plyometric programs as well as the following criteria:[4,5]

1. Knee examination
   - ROM: International Knee Documentation Committee (IKDC) rating of normal or nearly normal
   - Lachman test: IKDC rating of normal or nearly normal
   - Pivot shift test: IKDC rating of normal or nearly normal
   - Patella pain: none
   - Effusion: none
2. KT-2000 (MEDmetric)[13,76]
   - Less than 3-mm reconstructed compared with contralateral knee (if normal), 134-N total AP displacement.
3. Quadriceps and hamstrings muscle strength and endurance tests: less than 10% deficit compared with contralateral side, based on equipment available:
   - Isokinetic 180 degrees/sec and 300 degrees/sec[8,9,18,21,26,32,33,39,61,66,77]
   - Isometric portable fixed or hand-held dynamometer: quadriceps 60-degree flexion, hamstrings 60- or 90-degree flexion, three repetitions each, use average[69,71,72]
   - If isokinetic or isometric equipment is not available, a one-repetition maximum bench press and leg press is recommended if weight room equipment is available, along with an experienced test administrator and a sufficient amount of time to safely conduct these tests.[29,65]
4. Single-leg hop tests: 15% or less deficit lower limb symmetry on single-hop and triple crossover hop tests[3,6,18,33,35,36,45,77] (may videotape to provide subjective analysis of balance and landing position)
3. Video drop-jump[43,54,63,68]
   - If software is available, 60% or greater normalized knee separation distance
   - If software is not available, use video for subjective analysis of landing position (varus, valgus, neutral): no valgus, knees flexed for controlled landing
5. Single-leg squat, five repetitions: no knee valgus, mediolateral movement, or pelvic tilt[1,11,24,25]
6. Video plant-and-cut drill: subjective rating of high hip and knee flexion, upright posture, and no valgus collapse[12,27,41] (This test should be done in the manner described by Pollard and associates,[62] in which the patient runs 5 meters to a spot designated on the floor with tape, plants on the reconstructed leg, and then performs a 45-degree cut. If the right leg was reconstructed, the cut should be to the left. Cones may be set up to direct the patient to perform the angle of 45 degrees.)

Other tests to consider before the patient is released to unrestricted athletic activities include the multistage fitness test to determine maximal aerobic capacity[64] and the 60-second sit-up test or other core strength measures.[58] A single-leg vertical jump test may be conducted to determine whether a deficit exists between the reconstructed and the contralateral leg.

A trial of function is encouraged in which the patient is monitored for knee swelling, pain, overuse symptoms, and giving-way episodes. Some athletes will experience transient knee swelling upon return to strenuous activities and should be educated on how to recognize this problem and the importance of reducing activities until the swelling subsides. If swelling persists, the athlete is advised to reduce athletic activities for 2 to 6 weeks, consider use of nonsteroidal antiinflammatory drugs, and use ice and elevation. Upon successful return to activity, the patient is encouraged to continue with a maintenance program. During the in-season, a conditioning program of two workouts per week is recommended. In the off-season or preseason, this program should be performed three times per week to maximize gains in flexibility, strength, and cardiovascular endurance.

REHABILITATION PROTOCOL WITH DELAYED PARAMETERS FOR REVISION ACL RECONSTRUCTION, ALLOGRAFTS, AND COMPLEX KNEES

This protocol incorporates delays in return of full weight bearing and knee flexion; initiation of certain strengthening, conditioning, running, and agility drills; and return to unrestricted activities (Table 11-7) for knees undergoing ACL revision,[48,52] allograft reconstruction,[51] major concomitant operative procedures (complex meniscus repairs or transplants, other ligament reconstructions, articular cartilage restorative procedures, patellofemoral realignment procedures, or osteotomies), or that have noteworthy articular cartilage damage.[47,49] Toe touch–only weight bearing is allowed for the first 2 postoperative weeks. The amount of weight patients are allowed after this time depends on the concomitant operative procedures performed as well as on evaluation of postoperative pain and swelling, quadriceps muscle control, and ROM. The majority of patients are weaned from crutch support between the sixth and eighth postoperative weeks.

Allowance of knee flexion of at least 135 degrees is delayed according to the concomitant procedure performed. Knees that undergo a posterolateral reconstructive procedure are placed into a bivalved long-leg cast for the first 4 weeks[50] (see Chapter 18). The patient removes the cast to perform ROM exercises several times each day and is instructed to reach 0 degrees of extension, but to avoid hyperextension. Patients who undergo a concomitant proximal patellar realignment are allowed 0 to 75 degrees of flexion for the first 2 postoperative weeks. Flexion is slowly advanced to 135 degrees by the eighth week. Knee flexion is also initially limited in knees that undergo a concomitant posterior cruciate ligament reconstruction[46] (see Chapter 18) and or complex meniscus repair (see Chapter 25).[19]

Knee extension is limited in individuals who have abnormal hyperextension (≥10 degrees) with physiologic laxity to 0 to 5 degrees for approximately 3 weeks to allow for sufficient healing before stress is applied to push for 0 degrees.

A postoperative long-leg hinged knee brace is used for approximately the first 8 weeks in patients placed in this protocol, except those who undergo a posterolateral procedure. The brace provides protection and support to the healing tissues and assists with patient comfort during this time period.

Modifications in strengthening, conditioning, and strenuous training are based on the concomitant procedures performed. Return to activity is delayed until at least the sixth postoperative month to allow for healing of all repaired and reconstructed tissues and return of joint and muscle function. It is our opinion that allografts have a delay in maturation compared with autografts (see Chapter 5) and that the resultant time constraints postoperatively in terms of release to full activity are empirical at present. Evaluation is a key component to allow initiation of the functional program, which includes the

PHASE 1: WEEKS 1 TO 2

General Observation

Toe-touch weight bearing to 25% body weight when:

- Pain is controlled
- Hemarthrosis is controlled
- Voluntary quadriceps contraction is achieved
- 0 degrees extension

TABLE 11-7 Cincinnati Sportsmedicine & Orthopaedic Center Rehabilitation Protocol for Anterior Cruciate Ligament Reconstruction: Revision Knees, Allografts, and Complex Knees—cont'd

PHASE 1: WEEKS 1 TO 2		
Evaluation (Goal)	Pain (controlled) Hemarthrosis (mild) Patellar mobility (good) ROM (minimum 10-80 degrees) Quadriceps contraction and patella migration (good) Soft tissue contracture (none)	
Goals	ROM (depends on procedure) Adequate quadriceps contraction Control of inflammation, effusion	
	Frequency	**Duration**
ROM	3-4 ×/day, 10 min	
ROM passive Meniscus repair (complex), MCL, revision, EA = 0-90 degrees Patellar realignment = 0-75 degrees Posterolateral procedure = 0-90 degrees (unless examination shows hyperelastic tissue type, then hold 15-70 degrees for 2 wk postoperative) Patella mobilization Ankle pumps (plantar flexion with resistance band) Hamstring, gastrocnemius-soleus stretches		5 reps × 30 sec
Strengthening	3 ×/day, 15 min	
Straight-leg raises (flexion)		3 sets × 10 reps
Active quadriceps isometrics (based on ROM limits)		1 set × 10 reps
Knee extension (active assisted)		3 sets × 10 reps
Modalities	As required	
EMS		20 min
Cryotherapy		20 min
PHASE 2: WEEKS 3 TO 4		
General Observation	50% weight bearing when: • Pain is controlled • Hemarthrosis is controlled • Voluntary quadriceps contraction is achieved	
Evaluation (Goal)	Pain (controlled) Effusion (mild) Patellar mobility (good) ROM (minimum 0-90 degrees) Quadriceps contraction and patella migration (good) Soft tissue contracture (none) Joint arthrometry, 3 wk, 20 lb (<3 mm)	
Goals	ROM (0-110 degrees) Control of inflammation, effusion Adequate quadriceps contraction 50% weight bearing	
	Frequency	**Duration**
ROM	3-4 ×/day, 10 min	
ROM passive (0-90 degrees) Patella mobilization Ankle pumps (plantar flexion with resistance band) Hamstring, gastrocnemius-soleus stretches		5 reps × 30 sec

PHASE 3: WEEKS 5 TO 6

	Frequency	Duration
Strengthening	1-2 ×/day, 20 min	
Straight-leg raises (ankle weight, <10% body weight)		3 sets × 10 reps
Isometric training: multiangle (90, 60, 30 degrees)		2 sets × 10 reps
Heel raise/toe raise		3 sets × 20 reps
Hamstring curls (active, 0-90 degrees)		3 sets × 10 reps
Knee extension (90-45 degrees, with resistance)		3 sets × 10 reps
Closed-chain:		
Wall-sits		To fatigue, 5 sets
Minisquats		3 sets × 20 reps
Lunge (no resistance)		
Multihip machine (flexion, extension, abduction, adduction)		3 sets × 10 reps
Leg press (70-10 degrees)		3 sets × 10 reps
Balance Training	3 ×/day, 5 min	
Weight shift side-side and forward-backward		5 sets × 10 reps
Balance board, two legged		
Cup walking	1-2 ×/day, 5 min	
Single-leg stance on stable platform		5 reps
Aerobic Conditioning	2 ×/day, 10 min	
UBC		
Water walking		
Stationary bicycling (patellofemoral precautions)		
Modalities	As required	
EMS		20 min
Cryotherapy		20 min

PHASE 4: WEEKS 7 TO 8

General Observation	Independent ambulation when: • Pain is controlled • Effusion is controlled • ROM 0-120 degrees • Muscle control throughout ROM • Dynamic control of varus/valgus
Evaluation (Goal)	Pain (no CRPS) Effusion (minimal) Patellar mobility (good) ROM (0-135 degrees) Muscle control (4/5) Inflammatory response (none) Gait (symmetric) Joint arthrometry, 8 wk (<3 mm)
Goals	ROM (0-135 degrees) Full weight bearing, normal gait Control of inflammation, effusion Muscle endurance Recognition of complications (motion loss, CRPS, increased anteroposterior displacement, patellofemoral changes)

assessment of symptoms and examination of knee motion, muscle strength, and ligament stability. The sum of the evaluation, not just one parameter, should determine return to function. In patients following this protocol, return to full activity is not usually expected to occur until the ninth to twelfth month postoperatively. It should also be noted that return to full activity does not guarantee return to preinjury activity levels. Consideration of use of a derotation or functional brace includes patients who have undergone ACL revision or multiligament reconstruction or who demonstrate an increase in AP displacement postoperatively of 3 mm or more compared with the contralateral limb. In addition, patients who are apprehensive about returning to strenuous activities or who experience a subjective sensation of instability are candidates for functional bracing.

Video 12-1 Proprioception and Neuromuscular Control: Drills for the ACL Patient

INTRODUCTION

Rehabilitation after anterior cruciate ligament (ACL) injury and surgery has evolved in the past 2 decades from programs that recommended 6 to 8 weeks of immobilization, restricted range of motion (ROM) and strengthening exercises, and a delay in return to sports activities for 9 to 12 months postoperatively. Current therapeutic programs implement immediate knee motion,[53,54] weight bearing, and functional exercises, as well as proprioception and neuromuscular control drills[43,66] aimed at improving the patient's overall outcome, thereby promoting an earlier restoration of functional dynamic stability and return to sports activities.

Although there have been numerous advances in surgery and rehabilitation after ACL injury and surgery, the rate of return to preinjury levels of activity is alarmingly low. Arden and associates[2] reported in a meta-analysis of 5770 patients that 63% returned to preinjury sports levels and only 44% returned to competitive sports. The most common reason reported for not returning to preinjury sport levels was fear of reinjury. These investigators found that 19% of all patients had a fear of reinjury and 13% stated they had structural integrity issues with the knee. This concept of fear of reinjury is referred to as *kinesophobia*, as described by Chmielewski and colleagues.[16] Lentz and coworkers[41] recently reported that 45% of the patients with ACL reconstructions did not return to preinjury sport levels. Of those patients not returning to sports, 45% reported kinesophobia and 68% had a feeling of knee instability. We believe a rehabilitation program that has a significant focus on proprioception and neuromuscular control exercises and drills will assist in preventing the development of kinesophobia and will ensure that patients develop confidence in their knee and improved function.

Fitzgerald and associates[24] reported improved outcomes in ACL-deficient patients who participated in a rehabilitation program that emphasized proprioception and perturbation training. Shelbourne and Nitz[61] first reported improved clinical outcomes in patients who participated in earlier functional activities after ACL reconstruction. The results of these studies increased the emphasis on neuromuscular training in postoperative programs. In this chapter, proprioception and neuromuscular control are defined, the implications after ACL surgery are discussed, and techniques commonly used to restore functional dynamic stability to allow a return to a prior level of function are described.

TERMINOLOGY

Proprioception, *kinesthesia*, and *neuromuscular control* are terms that are often used interchangeably to describe exercises and techniques implemented in treatment; however, these terms have distinctive definitions. *Proprioception* is the awareness of joint position, whereas *kinesthesia* is the cognizance of joint movement.[43] *Neuromuscular control* has been defined as the efferent response to an afferent input,[65] thus providing the functional component to movement and athletic activities that is referred to as dynamic stability.

Mechanoreceptors (pacinian corpuscles, Ruffini endings, muscle spindle, and Golgi tendon organs [GTO]) located in muscles, capsules, and ligaments provide sensory input into the central nervous system (CNS). These mechanoreceptors act together to give sensory awareness of joint position, movement, acceleration, and strain via afferent pathways to the CNS. The CNS provides an efferent response to the surrounding joint musculature to elicit the desired response.

Several proposed mechanisms have been described for the joint mechanoreceptors' influence for joint stability. Extrinsic muscle stiffness is mediated through two mechanisms: (1) force feedback, which is provided by the GTO,[34] and (2) length feedback, which is stimulated by the muscle spindle pathway that facilitates motor activity.[47,48]

Additionally, the joint mechanoreceptors contribute to joint stability through two possible mechanisms. The direct ligamentous-muscular protective reflex, a reflex between the ACL and hamstring muscles, causes reflex inhibition of the quadriceps and facilitation of the hamstrings when stimulated that is aimed at minimizing strain on the ACL. Another proposed mechanism for added joint stability is the receptors' indirect contribution to dynamic joint stability through what is termed *presetting*.[36] The receptors contribute to preparatory adjustments of muscle stiffness and dynamic stability that are essential in preparation for deceleration and cutting activities.

EFFECTS OF INJURY ON PROPRIOCEPTION

Normal recruitment and timing patterns of the surrounding musculature are impeded after an injury because of changes that occur within the joint. Two theories are proposed for this mechanism, including an alteration occurring in the ratio of muscle spindle-to-GTO activity that causes an interference of the proprioceptive pathway. Joint effusion has also been credited with a diminished ability of the musculature to contract, thereby decreasing proprioception. A significantly decreased activation of the vastus medialis and lateralis muscles during a single-leg drop landing has been demonstrated with a 30-mL knee joint effusion.[56]

After injury, the interactions within the neuromuscular system are disturbed as deafferentation of peripheral sensory receptors occurs, resulting in diminished proprioception and kinesthesia, abnormal patterns of muscle activity,[19] and reduced joint dynamic stability.[6,7,42] Changes in proprioception have been reported to occur within 24 hours following injury[43] and may persist for as long as 6 years.[22] Additionally, Hooks and coworkers[33] reported that within 24 to 48 hours after ACL injury, the contralateral extremity had diminished proprioceptive sense. Therefore the rehabilitation program should consist of bilateral motor and proprioceptive training to minimize proprioceptive loss after injury.

A significant decrease in muscle activation timing and recruitment order of the quadriceps, hamstrings, and gastrocnemius in response to anterior tibial translation in the ACL-deficient knee compared with the intact-ACL knee has been reported.[71] The delay in muscle recruitment may lead to decreased knee joint stability owing to the stabilization effect of the musculature. A reflexive activation of the hamstring musculature has been reported with the application of 100 N of anterior shear force on ACL-deficient knees.[7] Paterno and colleagues[57] reported a significant difference in force production 27 months after ACL reconstruction during a vertical jump in the involved knee compared with the contralateral knee.

Gait abnormalities are common after ACL injury because patients frequently demonstrate a "quadriceps avoidance gait pattern."[1,8] This altered pattern occurs because patients ambulate with a flexed knee gait as a result of increased hamstring activity and minimal or no quadriceps electromyography activity (EMG). This altered gait pattern can persist for several months because the patient will develop a protective neuromuscular adaptation if not addressed during rehabilitation.

The reported time frame varies regarding the length of time proprioceptive and neuromuscular control deficits persist after surgery. Harrison and coworkers[29] found no significant differences in postural sway (eyes open and closed) of the involved and uninvolved lower extremity during single-leg stance 10 to 18 months after surgery. However, other examiners have reported more extended periods of deficits after ACL injury. Fremerey and coauthors[27] measured joint position sense preoperatively and serially after surgery, and noted that restoration of joint position sense was virtually restored at near-end range of flexion and extension 6 months postoperatively. However, proprioception was impaired at the mid range of knee motion 6 months after surgery and persisted up to 3.5 years for some patients. Long-term deficits in proprioceptive awareness may influence the athlete's functional ability and/or likelihood of reinjury because dynamic stability is critical in the mid range position where the majority of activities occur.

Long-term follow-up studies after ACL injury have reported a 10-times greater incidence rate of knee osteoarthritis (OA), with a 40% to 90% occurrence 7 to 12 years after surgery.[25,44,59] Carey and colleagues[14] reported that although 80% of running backs and wide receivers returned to play in the National Football League, the performance was reduced by a third. Likewise, Busfield and associates[13] reported a 44% decrease in the performance of National Basketball Association players who returned to play after ACL reconstruction as measured with statistical and efficiency ratings. Barber-Westin and Noyes[5] conducted a systematic review with a minimum 2-year follow-up and reported reinjury rates of the ACL-reconstructed knee ranged from 0% to 24%, and injury to the contralateral knee ranged from 2% to 15%. Arden and coworkers[2] reported that 63% of athletes were able to return to preinjury levels and only 44% were able to return to competitive sports. The authors reported a fear of reinjury (19%) as the number one reason athletes did not return to sports participation, with 13% reporting structural/functional problems. As discussed previously, the fear of movement and/or reinjury (kinesophobia) is a common problem and appropriate interventions to improve self-efficacy should be implemented to improve knee function.[17,21,70]

CLINICAL IMPLICATIONS

The rehabilitation program after ACL injury should ensure the restoration of neuromuscular control beginning immediately after ACL reconstruction to prevent deafferentation of the joint. The therapist should safeguard against deleterious stresses that neuromuscular training may place on the healing structures, while ensuring a proper progression into advanced techniques. Therefore the clinician throughout the rehabilitation program monitors the progression of volume and advanced techniques.

MOTOR SKILL DEVELOPMENT STAGES

Three stages of motor skill development have been described: cognitive, associative, and autonomous.[15] The cognitive stage occurs when a new task or drill is introduced because increased movement errors occur, movement is stiff and/or rigid, and extended training is required as the individual learns the movement. This is followed by the associate stage where less time is spent processing the drill with improved movement; however, it is still not automatic. The final stage, autonomous, occurs as the movement becomes automatic, efficient, and more skilled. These stages of motor skill development are required in skilled sporting activities such as swinging a golf club or hitting a baseball. Additionally, a refining stage occurs as the individual refines the task/drill to an increased level of perfection.

When learning a new motor skill, patients will progress through four stages: mobility, stability, controlled mobility, and skill.[64] *Mobility* refers to the individual having both adequate ROM to assume a posture or position and motor recruitment to initiate the movement. *Stability* is the capability to produce a cocontraction to provide tonic holding. Controlled mobility occurs as movement is added to a stable posture. *Skill*, the highest level of motor control, refers to function and the

ability to perform tasks in an unstable environment such as football or soccer.

NEUROMUSCULAR TRAINING PROGRAM

Neuromuscular training, like any other form of treatment, should be adapted and prescribed based on the patient's neuromuscular status, desired goals, and current phase of healing and rehabilitation (acute, subacute, advanced, and return to activity). Although the neuromuscular techniques incorporated into the training program are numerous, the clinician should ensure an appropriate progression is implemented, including the required skill level and use of both isolated and combined movements. Additionally, the clinician should ensure an adequate level of difficulty is imparted into the training because studies have shown a 50% to 60% failure rate of a task is required for an individual to learn a new skill.[23,50] Therefore the clinician should carefully monitor these drills to ensure adequate training without preventing undue stresses and strains on healing tissues.

The clinician can impart various exercises depending on the current phase of treatment that are patient specific. These exercises are categorized into joint repositioning, balance training, perturbation training, plyometric drills, and technique training. Throughout the training, feedback is given to the patient using verbal instructions, technique guidance, and visual feedback such as a mirror or a force platform. These techniques and cueing may aid in modification and mastering a movement drill.

Lephart and colleagues[42,43] described joint repositioning drills in which the clinician passively positions the affected joint to a predetermined joint angle and then passively returns the knee to the starting position. The clinician then instructs the patient to actively reposition the prescribed knee joint angle. This drill can be performed as either a test or as a rehabilitation-training technique.

Balance-training exercises are used to incorporate postural control into the training program aimed at reducing postural sway. The patient performs exercises on various training surfaces based on level of difficulty. In the acute phase, a force platform can be used to determine weight acceptance and distribution with exercise (Fig. 12-1). Balance training can be initiated on flat ground incorporating upper and/or lower extremity movements (Fig. 12-2). Unstable surfaces such as foam, air mattresses, and wobble boards (Fig. 12-3) are included in the training program to promote further challenge. Furthermore, balance-training devices (Fig. 12-4) can be included to further challenge the neuromuscular system and provide the patient with visual feedback.

Perturbation training is performed by the clinician applying an external force to create a postural disturbance that initiates a reactive motor response. Wilk and coworkers[66] emphasized the importance of perturbation training in the female ACL patient and highlighted these drills as a critical component necessary for athletes to master to ensure a successful return to sports. Fitzgerald and associates[24] examined the efficacy of perturbation drills in the rehabilitation of ACL-deficient knees and reported increased satisfactory outcomes and decreased frequency of giving-way episodes. Chmielewski and coworkers[16,18] noted a restoration of knee joint kinematics and an increase in quadriceps-hamstring muscle coactivation after perturbation training in patients with ACL-deficient knees. Wilk and colleagues[66,67,69] and Snyder-Mackler and coworkers[62] highly recommended the incorporation of perturbation training in ACL rehabilitation.

Plyometric training drills can be performed to facilitate dynamic stabilization and neuromuscular control of the knee joint. These drills are used to train the lower extremity to produce and dissipate forces to avoid injury by using the muscle's stretch-shortening capabilities to produce maximal concentric contraction that is immediately followed by a rapid eccentric loading of the muscle tissues.[68,69] Hewett and associates[32] examined the effects of a 6-week plyometric training program on the strength and landing mechanics in female athletes. They reported a 22% decrease in peak ground reaction forces and a 50% decrease in frontal plane movement of the knee during landing. Significant increases in hamstring isokinetic strength, hamstring-to-quadriceps ratio, and vertical jump height were also noted. Furthermore, Hewett and coworkers[31] prospectively analyzed the effects of this plyometric training program in the prevention of ACL injuries and noted a statistically significant decrease in the knee ligament injury rate compared with a control group.

Wilk and associates[69] referred to plyometric training as "reactive neuromuscular training" that is initiated in the advanced phases of

FIG 12-1 Balance training performed while standing on a force gauge to give the patient feedback regarding the weight distribution.

FIG 12-2 Incorporating upper and lower extremity movements into single-limb stance for greater postural disturbance.

FIG 12-3 Mini-squats performed on a wobble board.

FIG 12-4 Stabilization training on the Biodex Stability System.

FIG 12-5 The patient begins jumping off one box, landing on the floor with both knees slightly flexed **(A)**, and then jumps to the second box, again landing with both knees slightly flexed **(B)**.

rehabilitation to increase performance. Plyometric training is implemented to increase performance and reduce the incidence of injury; therefore the patient should focus on proper technique and body mechanics throughout the exercise. These exercises are progressed from double-leg drills to single-leg drills, and from level-ground jumps to box jumps (Fig. 12-5).

The final stage of training is technique training and involves sports-specific and performance training. The patient performs drills such as running and cutting, deceleration training, and landing from a jump. The inclusion of technique training has been reported to reduce ACL injury.[49] Mandelbaum and coworkers[45] reported a reduction in ACL injuries in soccer players with an ACL prevention program that focused on proper technique. The Sportsmetrics program (see Chapter 14) emphasizes proper landing technique from plyometric jumps by instructing the patient to repeat an exercise if it is not performed appropriately after the technique has been corrected.[32,52]

TABLE 12-1 Rehabilitation After Anterior Cruciate Ligament Injury

Goals	Brace	Weight Bearing	Exercises	Electrical Muscle Stimulation	Neuromuscular, Proprioception Training	Cryotherapy	Patient Education
Diminish inflammation, swelling, pain	Elastic wrap or knee sleeve to reduce swelling	As tolerated, with or without crutches	Ankle pumps, passive knee extension to 0 degrees	To quadriceps during voluntary quadriceps exercises (4-6 h/day)	Eliminate quadriceps-avoidance gait	Apply ice 20 min/hr	Review postoperative rehabilitation program
Restore normal knee ROM, especially extension			Passive knee flexion to tolerance		Retro-stepping drills	Elevate leg with knee in full extension	Review instructional video (optional); select appropriate surgery date
Restore voluntary muscle activation			Straight leg raises (flexion, abduction, adduction).		Joint repositioning	Knee must be above heart	
Provide patient education to prepare for surgery			Quadriceps setting CKC: minisquats, lunges, step-ups		Passive/active reposition at 90, 60, and 30 degrees CKC: squat/lunge repositioning on screen		

CKC, Closed kinetic chain; *ROM*, range of motion.

POSTOPERATIVE REHABILITATION PROGRAM

The rehabilitation program after ACL reconstruction has undergone an evolution since the middle of the 1990s. Previously, crutches were recommended for 8 to 12 weeks with the knee immobilized for 6 to 8 weeks.[11,12,58,63] The avoidance of early isolated quadriceps activity was recommended to protect the reconstructed knee.[11,12,30,37,38,73,74] However, many complications were reported in the literature such as arthrofibrosis, quadriceps weakness, and extensor mechanism dysfunction as a result of a conservative program.[28,35,37,58,60] Shelbourne and Nitz[61] first reported improved clinical outcomes in patients who followed an accelerated program compared with patients who followed a conservative approach. Current programs emphasize immediate motion, full passive knee extension, immediate weight bearing, immediate muscular training, closed-chain exercises, and functional exercises to improve the patient's overall outcome. This rehabilitation program following ACL reconstruction using a bone-patellar tendon-bone autograft is outlined in Table 12-1.

Phase I: Acute Phase

Immediately following surgery, basic proprioceptive training is initiated based on adequate normalization of pain, swelling, and quadriceps recruitment. Passive ROM can be performed in the early acute phases of rehabilitation and is beneficial to stimulate joint mechanoreceptors. This exercise can be progressed to passive/active reproduction sense techniques to further improve proprioceptive sense (Fig. 12-6).

Weight-bearing exercises can be safely initiated in the early stages of rehabilitation. Weight shifts are performed in the medial-lateral and diagonal directions, as well as minisquats (0-40 degrees of knee flexion). These exercises can be performed on a force platform, which

FIG 12-6 Passive/active joint reproduction. The patient's lower extremity is placed at a prescribed range of motion by the clinician. The clinician then returns the lower extremity to the resting position and asks the patient to actively reposition the lower extremity in the clinician-placed position originally set.

measures the amount of weight distribution between the involved and noninvolved extremities. An elastic bandage worn postoperatively has been shown to improve joint position sense and proprioception and can be worn to provide sensory input.[9,10,39]

In addition, one of the primary goals during the first 5 to 7 days postoperative is to establish weight-bearing dynamic stability. This is accomplished using an exercise in which the patient stands with the knee at 30 to 45 degrees of flexion and attempts to maintain stability. The progression of this drill is first, static stability, then static stability with ball catches, and then stability with arm movements.

The patient may be progressed with minisquats onto an unstable surface such as a tilt board or foam. The patient squats to approximately 30 degrees and holds the position for 2 to 3 seconds while stabilizing the tilt board. Wilk and colleagues[67] reported that, during the squat exercise, the greatest amount of quadriceps and hamstring cocontraction occurred at approximately 30 degrees of knee flexion. Baratta and coworkers[3] reported an increased risk of ligamentous injury in knees with quadriceps-to-hamstring strength imbalances. Markolf and associates[46] demonstrated that contraction of the surrounding musculature can decrease the varus and valgus laxity in the knee joint threefold.

Gait activities such as stepping over cones are initiated during the second week after surgery. These drills can be performed either laterally (Fig. 12-7) or forward and backward (Fig. 12-8) to facilitate gait training, enhance dynamic stability, and to train the hip to control and dissipate forces at the knee. The patient is instructed to raise the thigh to the level of the hip and step over a series of cones to facilitate a heel/toe gait. These cone drills may be performed at various speeds to improve lower extremity stabilization and control momentum.

FIG 12-7 Lateral cone walking to facilitate hip stabilization. In addition, the patient can perform the exercise three times each way: (1) at normal speed, (2) at a faster speed, and (3) at a slower speed to emphasize knee and hip flexion.

Lateral lunges are initiated without resistance on a stable surface. The patient is instructed to land with a slight flexed knee (30 degrees) to improve dynamic stability through cocontraction of the hamstrings and quadriceps (Fig. 12-9). Gait activities can be performed with an elastic band around the patient's thighs to improve hip muscular strength (Fig. 12-10).

FIG 12-8 Forward and backward cone walking. The patient is instructed to facilitate a heel/toe gait with the exercise. The patient can also perform the three variations as performed with lateral cone walking.

FIG 12-9 Lateral lunge performed in a straight plane with the resistance of a SportCord as the patient lands unilaterally and pauses in single-leg stance to promote balance and stability.

FIG 12-10 Ambulation performed with a TheraBand (The Hygenic Corporation) around the hips to create a greater contraction of the hip musculature and emphasize stability of the hip muscles.

FIG 12-11 SportCord lateral lunges performed in the diagonal plane landing onto a foam pad.

Phase II: Dynamic Stability Drills

Phase II allows a progression in the degree of difficulty and complexity of the previous activities and a transition to more combined movement patterns. Ensure that the patient has mastered specific techniques and movements of the previous phase.

Lateral lunges are progressed in a functional manner, beginning with straight-plane lateral lunges, progressing to multiple-plane/diagonal lunges, lateral lunges with rotation, and finally, lateral lunges onto a foam surface (Fig. 12-11). As the patient progresses through the exercises, a ball toss can be added to further challenge the preparatory stabilization of the lower extremity with lessened conscious awareness.

Front step-downs and lateral step-ups are included into the treatment program. These exercises can be progressed to include ankle strategies by having the patient stand on half-circle foam and/or while catching a ball (Fig. 12-12). Chmielewski and associates[20] compared several weight-bearing activities in ACL-deficient and ACL-reconstructed knees and reported a strong correlation between functional outcome scores and patient satisfaction and the ability to perform the front step-down exercise. Squats on an unstable surface such as a BOSU ball (Fig. 12-13) can be performed during this phase to provide neuromuscular cocontraction of the quadriceps and hamstrings. Local muscular endurance exercises can be gradually implemented. Local muscular endurance is important because proprioception has been shown to significantly decrease as much as 75% once a joint is fatigued.[40,55,72] Wojtys and coworkers[72] reported that, after fatigue, a significantly slower response time occurred in the quadriceps, hamstrings, and gastrocnemius.

Single-leg balance exercises are progressed by incorporating movement of the upper extremity and uninvolved lower extremity aimed at altering the patient's center of gravity. The patient stands on a stable surface, progressing to foam, (Fig. 12-14) with the knee slightly flexed and performs flexion, extension, abduction, adduction, and diagonal movements of the upper extremity while holding a weighted ball (Fig. 12-15). Alternately, the patient can perform movements of the uninvolved lower extremity while performing single-leg stance. These drills can be progressed to incorporate combined upper and lower extremity movements during single-limb stance (Fig. 12-16), and are intended

FIG 12-12 Front step-down exercise performed while standing on half-circle foam and catching a ball.

FIG 12-13 Squatting exercise performed on a BOSU ball.

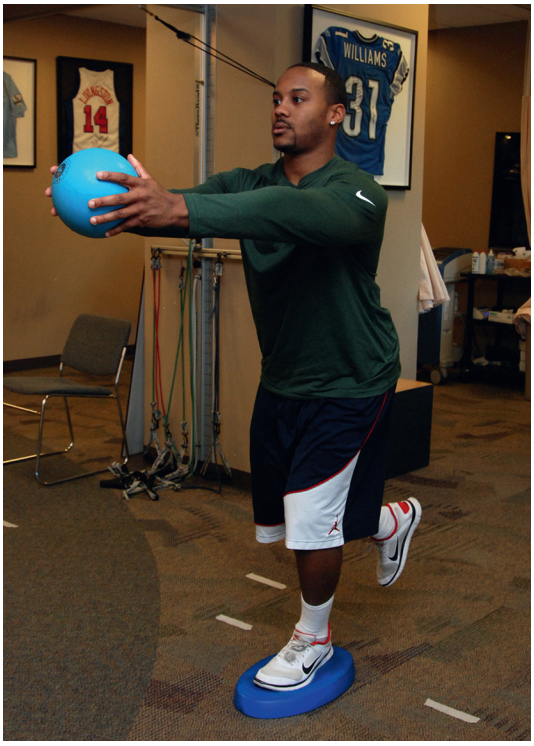

FIG 12-14 Single-limb stance on a foam pad while performing upper extremity movements with a weighted ball.

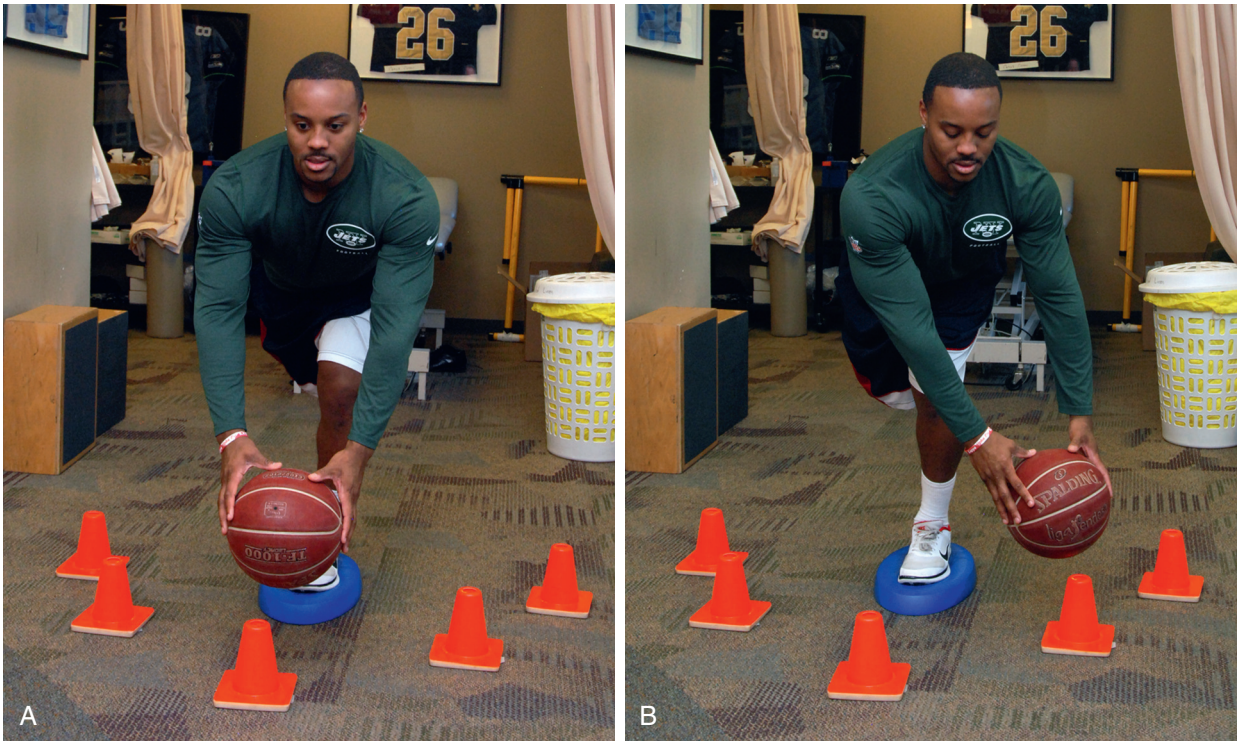

FIG 12-15 Single-limb stance on a foam pad with the knee flexed while performing diagonal movements of the upper extremity with a weighted ball.

FIG 12-16 PlyoBack (Exertools) ball toss while standing on a tilt board.

FIG 12-18 Single-limb stance on a foam pad while performing upper and lower extremity movements with a weighted ball as the clinician creates perturbations to the upper extremity.

FIG 12-19 Perturbation training as the patient performs single-limb stance on a tilt board with ball toss.

to create alterations in the patient's center of gravity to increase the demands of the dynamic stabilizers.

Phase III: Neuromuscular Control Drills

The third phase of the program combines knee stabilizations with sports-specific drills by performing random designed movements in combined functional movement planes. Perturbation training is initiated on a tilt board and is progressed from a bilateral squat (Fig. 12-17) to single-leg holds at 30 degrees knee flexion, to single-leg squats, to single-leg stance at 30 degrees knee flexion with a ball toss using a 1- to 2-kg medicine ball (Fig. 12-18). The patient is instructed to stabilize the tilt board in a reaction to the sudden momentum forces produced by catching the weighted ball. Additionally, the clinician may provide manual perturbations by tapping the tilt board with his or her foot to impart a sudden postural disturbance, thus requiring the patient to stabilize the tilt board by using dynamic muscular contractions (Fig. 12-19). Furthermore, perturbations may be simultaneously performed as the clinician taps the patient at their hips or trunk to facilitate both proximal and distal perturbation forces. Neuromuscular training can be performed as the patient

FIG 12-20 Lunges performed on a tremor board.

performs lunges onto stability devices such as the tremor device (Fig. 12-20). Plyometrics is instituted during this phase and begins by having the patient perform plyometrics on the leg press with bilateral lower extremities. The patient is instructed to perform corner drills with plyometric leg press exercise to incorporate coordination and proprioception training (Fig. 12-21). Jump training has been shown[31] to reduce ACL injury rates in athletes and should be incorporated into the rehabilitation program after ACL injury or surgery. A word of caution is stressed in that, after ACL injury, the clinician should delay plyometric jump training until bone bruises resolve and the knee returns to the normal state. This is done to ensure the prevention of further deterioration of existing articular cartilage lesions or the early development of knee joint OA.

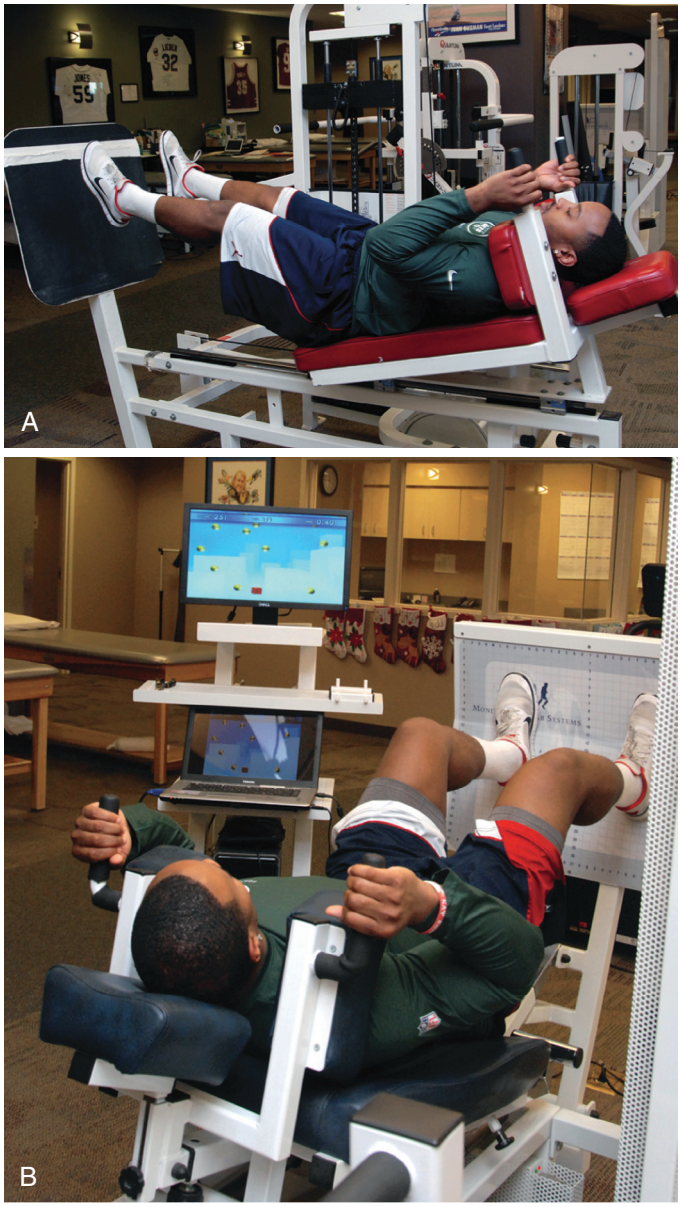

FIG 12-21 Plyometrics performed using bilateral lower extremities on the leg press.

Phase IV: Functional Activities and Skill Training

The final stage in the rehabilitation program is the functional skill and return to activity phase. During this phase, all four types of neuromuscular-training drills are incorporated: perturbations, plyometrics, technique, and progression of sports-specific drills. Plyometric activities are progressed from the leg press to flat ground (Fig. 12-22), to jumping over a hurdle, and then to box jumps. Box jumps begin using one box, then progress to two boxes, and finally, to four boxes.

A running program is initiated with backward running to facilitate knee flexion and muscle coactivation. Backward running also produces higher EMG activity of the quadriceps and hamstrings than that of running forward.[26] The patient progresses to lateral movements, including side shuffles and cariocas, before beginning forward running. The patient advances to running and deceleration drills, and finally to running and cutting once forward running is performed with a normal pattern.

Following the successful completion of the running program, the patient may begin a sports-specific training program. The patient should be carefully monitored throughout these activities, with the clinician ensuring protection of motor skill development and promote proper technique. Additionally single-leg hop functional tests may be implemented to determine limb symmetry.[4,51]

CONCLUSION

Significant deficits of the static and dynamic stabilizers exist at the knee after ACL injury because of changes in the muscular activation pattern of the muscles around the knee joint. The rehabilitation program after ACL surgery must restore normal knee motion, joint stability, and muscular strength while protecting the regeneration of the ACL graft. In addition, the therapy program must incorporate neuromuscular training to facilitate a full functional return to activities without compromise. The neuromuscular system is a vital

FIG 12-22 Scissor plyometric jumps performed on level ground.

component to the rehabilitation program of a patient with an ACL injury to the knee.

Video 11-4 Sportsmetrics Neuromuscular Conditioning Programs to Prevent ACL Injuries in Female Athletes

INTRODUCTION

It is well recognized that female athletes and military recruits have a higher incidence of noncontact anterior cruciate ligament (ACL) injuries than males participating in the same activity. A study done at our institution and published in 1994[144] was the first to recognize this gender disparity in female soccer players, who had nearly six times the rate of serious knee ligament injuries of male players ($P < .01$) during indoor games. In 2007, Prodromos and colleagues[212] conducted a meta-analysis of 33 articles and reported that the average ACL injury rate for females was significantly greater than that for males in basketball, soccer, and handball ($P < .0001$ for all comparisons). Several studies that compiled data from the National Collegiate Athletic Association (NCAA) were in agreement with these findings.[3,10,110] For instance, Hootman and colleagues[110] analyzed 16 years of NCAA data and reported that female basketball and soccer players had a threefold higher ACL injury incidence compared with male players. Recently, Beynnon and associates[25] compiled first-time noncontact ACL injury data from 8 colleges and 18 high schools and found that female collegiate athletes had the highest risk among the groups studied. The incidence rates were generally higher for females than for males (relative risk, 2.10) and for collegiate athletes compared with high school athletes (relative risk, 2.38).

In regard to ACL injuries that occur in the U.S. military, Gwinn and associates[89] reported that female midshipmen at the U.S. Naval Academy from 1991 to 1997 had a fourfold increase compared with their male counterparts in intercollegiate-level soccer, basketball, and rugby collectively ($P = .006$). In addition, women had nearly 11 times the incidence of ACL ruptures as men during obstacle course running ($P = .004$). Mountcastle and coworkers[171] reported female/male incidence ratios for noncontact ACL injuries of 4.95 for gymnastics, 3.72 for the obstacle course test, 3.01 for basketball, 1.71 for handball, and 1.27 for soccer at the U.S. Military Academy at West Point over a 10-year period.

A few investigators have noted that, although ACL ruptures represent a serious injury that results in months of lost playing time, the overall incidence in female athletes compared with other injuries, such as ankle sprains, is low.[3,110] Hootman and associates[110] concluded, "using the standard of <.05 as rare, the actual probability of ACL injury would be considered a rare event." We recently systematically reviewed eight studies of the effect of ACL injury prevention programs[179] found noteworthy differences in the ACL injury rates in female adolescent athletes, ranging from .03 to .08 per 1000 athlete-exposures to 0.21 to 0.49 per 1000 athlete-exposures. Three neuromuscular retraining intervention programs significantly reduced the noncontact ACL injury incidence rates: the Sportsmetrics, Prevent Injury and Enhance Performance, and Knee Injury Prevention programs. The number of athletes who needed to train to prevent one ACL injury in these three programs ranged from 70 to 98, and the

relative risk reduction ranged from 75% to 100%. Although the number of athletes needed to treat appeared somewhat high, in our experience many individuals participate in sports year-round with very little time off. They achieve within a few years a high number of exposures (in both practice and games) that place them at risk for ACL injury. This is especially true for athletes who begin competition at a very young age. For these athletes, by the time they are in high school, they will already have been exposed to well over 1000 hours of participation. These high rates of cumulative exposures validate ACL neuromuscular intervention programs.

Despite the many investigations that have been conducted on potential risk factors for noncontact ACL ruptures, definitive conclusions cannot be reached for either males or females regarding which factors may predispose an athlete to this serious injury. Investigators have attempted to develop risk-screening models using knee valgus motion, range of motion, body mass, tibial length, and quadriceps/hamstring ratio[100]; however, others have refuted their findings.[83] In one investigation, researchers found that the Landing Error Scoring System failed to predict ACL injuries in a cohort of 5047 high school and collegiate athletes.[248] This system rates body mechanics and technique of a vertical drop-jump on a 17-point scale, with a higher score indicating poor landing technique, and it has been shown in other studies to correlate with several measures of ACL loading and injury risk.[186,191]

The reasons for the increased incidence of this injury in female athletes over that in male athletes cannot be scientifically defined at present.[240] In many studies published to date, investigators examined a small sample size of each gender (and therefore the studies had insufficient power to avoid a type II statistical error[86]), focused on one or just a few of the possible risk factors, or examined neuromuscular characteristics in a controlled laboratory environment instead of more realistic playing conditions. Controlled laboratory experiments have variations that may influence results, such as performing a task with or without shoes or with arm movements controlled or uncontrolled. The major potential risk factors that have been proposed for this injury are shown in Table 13-1. This chapter reviews investigations related to these risk factors and emphasizes findings that may have a role in the gender disparity in noncontact ACL injury rates. We note that Elliot and associates[71] proposed other potential risk factors that should be explored in future studies. These include lifestyle habits and psychosocial influences on female athletes, such as fatigue from chronic sleep deprivation, poor nutrition and eating disorders, substance use and abuse, overtraining, stress, and depression.

TABLE 13-1 Hypothesized Risk Factors for ACL Injury in Female Athletes

Category	Risk Factor	Comment
Genetics	Family history, genotypic variants in collagen genes	Gender effect not determined to date; association may exist regardless of gender
Extrinsic	Footwear, climate conditions, playing surface, prophylactic knee braces	Gender effect not determined to date; majority of studies conducted in males
Anatomic	Intercondylar notch geometry, ACL size, tibial plateau geometry, foot pronation, pelvic tilt, quadriceps femoris angle, body mass index, generalized joint laxity, anterior knee laxity	No proven gender effect or results too diverse for conclusions
Hormonal	Phase of menstrual cycle, effect of hormonal cycling on ligament biomechanical properties, muscle strength, neuromuscular indices	No strong association proven, owing to difficulty in accurately identifying phase when ACL injuries occurred
Neuromuscular/ biomechanical	Muscle strength, knee joint stiffness Movement patterns during landing, cutting, agility tasks resulting in altered knee and hip joint angles and moments, muscle activation	Many gender differences exist (see Table 13-2)

ACL, Anterior cruciate ligament.

GENETICS

Regardless of gender, a question has been raised for many years about a potential genetic predisposition for ACL rupture. At the time of this writing, five studies had examined family history of ACL injuries. Webster and associates[275] noted a significant association among both ACL semitendinosus-gracilis graft rupture and contralateral ACL tears and a family history (first-degree relative) of ACL injury. In their cohort of 561 knees that had undergone ACL reconstruction, 26 procedures failed. Of these patients, 8% had a family history and 4% did not (odds ratio, 2.4; 95% confidence interval [CI], 1.1-5.3; $P = .04$). Forty-one patients tore their contralateral ACL; of these, 13% had a family history and 7% did not (odds ratio, 2.2; CI, 1.2-4.4; $P = .02$).

Bourke and associates[30] assessed the survival rate of 755 ACL reconstructions followed for a minimum of 15 years postoperatively. A positive family history of ACL rupture doubled the odds of tearing either the ACL graft or the contralateral ACL ($P = .003$). This occurred regardless of gender or graft type (patellar tendon or hamstring tendon autograft).

CRITICAL POINTS Genetics

- Possible evidence exists for familial predisposition for ACL injury.
- Potential exists for genotypic variants in collagen genes as an inherent risk factor for ACL injury.
- Variants may alter mechanical properties of ligaments and may be associated with increased genu recurvatum, anterior knee laxity, and general joint laxity.
- Important need for continued study in this area.

Flynn and associates[76] conducted a questionnaire-based study of 171 patients who sustained either contact or noncontact ACL ruptures to determine whether a familial predisposition existed for their injuries. The patients were matched with 171 uninjured control subjects according to age, gender, and primary sport. Patients who had sustained ACL ruptures were twice as likely as the control subjects to have a first-, second-, or third-degree relative who also had an ACL tear. Posthumus and associates[210] noted a significant difference in the self-reported family history of ligament injuries among 38 females who sustained ACL injuries and 84 controls (incidence rates of 50% and 21.5%, respectively; $P = .01$). In their investigation, there was no

significant difference in this factor between males with ACL injuries and controls. Harner and coworkers,[92] in a small series of 31 patients with noncontact bilateral ACL ruptures, found the patients had a significant increase in the incidence rate of immediate family members who had sustained an ACL injury compared with a control group (35% and 4%, respectively; $P < .01$).

More recently, investigators have examined the potential of genotypic variants in collagen genes as an inherent risk factor for knee ligament injuries.[18,54,75,128,153,182,209,210,213,214] The genes *COL1A1*, *COL5A1*, and *COL12A1* encode for the major α-chains that make up collagen types I, V, and XII, respectively.[208] Studies have identified sequence variants within these genes that are believed to be associated with ACL injuries in Caucasian South African patients,[209,210] Swedish patients,[128] and Polish/Eastern European patients.[75] The variants have been hypothesized to alter the structure and behavior (mechanical properties) of ligaments and other musculoskeletal soft tissues.[18,53,135] In addition, they may be associated with increased genu recurvatum, anterior knee laxity, and general joint laxity.[18] Posthumus and associates[208] recommended that further work be conducted in this area before genetic testing for ACL injury risk is initiated.

EXTRINSIC: FOOTWEAR, PLAYING SURFACE, CLIMATE CONDITIONS

Extrinsic risk factors for ACL injuries include footwear, playing surface, and climate conditions. The effect of footwear is assessed by calculating shoe-surface interaction, which is defined by the force of the friction between the athlete's shoe and the surface it comes into contact with during movement (quantified by the coefficient of friction [COF]).[66] Changing the COF of the shoe-surface interaction causes athletes to change their movement techniques, essentially their biomechanics, to accommodate for the change in COF. The type of shoe, playing surface, and climate conditions all affect the COF of the shoe-surface interaction. To date, all major studies on shoe characteristics and weather conditions and their association with ACL injuries have been conducted only in male athletes.

There are many different types of playing surfaces, including natural grasses, artificial turfs (first, second, third, and fourth generation), wood floors, and artificial rubberized floors. In general, artificial turfs have higher COF than natural grasses, and artificial rubberized floors have a higher COF than wooden floors.[66] Investigators have reported no differences in ACL injury rates in female soccer players who played on third- and fourth-generation artificial turfs compared with those who played on natural grass.[79,80,251,256] However, researchers in two studies[185,200] reported significantly higher ACL injury rates in female athletes who played floorball or handball on artificial rubberized floors compared with those who played on wooden floors. Dowling and Andriacchi hypothesized that it is "highly likely that the COF of the rubberized floor is high and may be the cause of the observed increase in ACL injury among female athletes on this surface."[66]

One other extrinsic risk factor is the use of a prophylactic knee brace to prevent ACL injuries. However, only a few investigations have been published on this topic, all of which involved male football players,[5,202,246] and no conclusions are possible regarding a potential benefit of the use of these braces for reducing the ACL injury rate in female athletes. It is important to note that no investigation to date has taken into account other risk factors (such as hormonal or neuromuscular factors) along with extrinsic factors that could confound possible conclusions.

CRITICAL POINTS Extrinsic: Footwear, Playing Surface, Climate Conditions

- To date, all studies on shoe characteristics and weather conditions and their association with ACL injuries have been conducted only in male athletes.
- Playing surface: higher ACL injury rates on artificial rubberized floors than wooden floors in female athletes.
- No study available on potential effect prophylactic knee brace in female athletes.
- No investigation has taken into account other risk factors (such as hormonal or neuromuscular) along with extrinsic factors that could confound possible conclusions.

ANATOMIC

Many authors have proposed that inherent anatomic differences between women and men are responsible or partially responsible for the disparity in noncontact ACL injury rates. Proposed anatomic risk factors include quadriceps femoris angle (Q-angle), foot pronation, intercondylar notch size, ACL size, tibial slope and surface geometry, anterior and generalized joint laxity, and body mass index (BMI).[40,41,45,64,164] However, no investigation has demonstrated that any anatomic factor alone is responsible for the increased risk of noncontact ACL injuries in female athletes. The major problem is that no study to date has entered anatomic indices along with hormonal and neuromuscular factors into an appropriate statistical model to determine the effects of all of these potentially important risk factors on ACL injury rates.

Geometry of the Intercondylar Notch and Anterior Cruciate Ligament

A correlation exists between the width and volume of the intercondylar notch and the cross-sectional area and volume of the ACL.[45,57,64,254] An association between a narrow intercondylar notch or a stenotic notch and an increased incidence of ACL ruptures has been reported or suggested by many authors.[72,111,138,149,233,245,252,253,257,269,289] In a meta-analysis of this topic published in 2013, Zeng and associates[289] found statistically significant differences in the intercondylar notch width index (pooled data from 16 studies, 0.02; CI, –0.04 to –0.01; $P < .001$) and

CRITICAL POINTS Anatomic

- No investigation has demonstrated that any anatomic factor alone is responsible for the increased risk of noncontact ACL injuries in female athletes.
- Association exists between a narrow intercondylar or stenotic notch and an increased incidence of ACL rupture, regardless of gender.
- Female ACL has smaller cross-sectional area, mass, volume, and material properties.
- Association may exist between ACL noncontact injuries and increased posterior slope of the lateral proximal aspect of the tibia, regardless of gender.
- Excessive foot pronation, anterior pelvic tilt may be risk factors for ACL injuries, regardless of gender.
- Women have greater inherent joint laxity, but no evidence exists that this factor increases their risk of ACL injury.
- No evidence that body mass index or quadriceps femoris angle are risk factors for ACL tears.

notch width (–2.15; CI, –3.09 to –1.21; $P < .001$) among subjects with ACL injuries and control groups. These results were found regardless of measurement methods. A few investigations[99,147,226,259] have refuted these findings. This is most likely because of variations among studies with regard to techniques used to determine notch size (plain non-weight-bearing and weight-bearing radiographs, magnetic resonance imaging [MRI], computed tomography [CT], and photographic techniques), notch indices studied (lateral condylar width, total condylar width, notch width, notch width at two-thirds notch height, notch width index, and notch angle), and the statistical methods used to determine results. When measured on radiographs, the notch width index does not necessarily correlate with the notch volume (overall notch size), a finding that has led some authors[8,269] to caution against using radiographs to predict risk of ACL rupture. Newer MRI techniques are preferred over plain radiographs for measuring interchondral notch and ACL size and geometric indices.[49,64,72,245]

The association between notch area or shape and ACL injury appears to be unrelated to gender.[7,49,65,72,120,138,233,245,253,267,289] A general speculation has been raised[9,45,64,87,172] that a small notch will contain a small ACL that is vulnerable to rupture owing to decreased strength properties. In addition, a narrow or stenotic notch may increase the risk of ACL impingement and subsequent rupture.[7,64,81,172] Hoteya and coworkers[111] measured the notch width index near the femoral ACL attachment on coronal MRI scans in 25 patients with bilateral ACL injuries, 30 patients with unilateral ACL injuries, and 20 healthy subjects. The notch was significantly narrower in the subjects with bilateral ACL injuries compared with those with unilateral injuries and controls. The authors concluded that the risk for ACL injuries is "very high" when the notch width is less than 0.25 (odds ratio, 22.667 for risk of bilateral ACL tears). A gender comparison was not conducted. Other authors have proposed different values for notch width that may be associated with increased risk of ACL injury regardless of gender, including 0.18,[267] 0.19,[138] and 0.24.[65]

Many investigators have reported that a gender difference exists in the cross-sectional area, mass, and volume of the ACL in uninjured subjects on the basis of MRI[9,45,57,64,254,282] evidence and cadaveric specimens.[40,41,145,172] Dienst and colleagues[64] reported significant differences between women and men in mean ACL cross-sectional area (45.4 ± 10 mm^2 and 68.4 ± 20 mm^2, respectively; $P = .003$), mean notch area (537 mm^2 and 634 mm^2, respectively; $P = .008$), and mean ACL notch area index (0.33 and 0.45, respectively; $P = .02$) measured using MRI. A significant correlation was found between ACL cross-sectional area and notch areas in three planes. Staeubli and associates[254] reported a significant difference between men and women in the absolute width of the ACL at the cruciate intersection on MRI (6.1 ± 1.1 mm and 5.2 ± 1.0 mm, respectively; $P < .01$). The intercondylar notch widths were also significantly greater in males, as were height, weight, and bicondylar femoral width.

Chandrashekar and colleagues[40,41] studied the length, area, mass, volume, and material properties of the ACL in 20 cadaveric knees (10 male, 10 female, aged 17-50 years). The male specimens had significantly greater values than the females for ACL length (29.82 ± 2.51 mm and 26.85 ± 2.82 mm, respectively; $P = .01$), mid substance area (83.54 ± 24.89 mm^2 and 58.29 ± 15.32 mm^2, respectively; $P = .007$), mass (2.04 ± 0.26 g and 1.58 ± 0.42 g, respectively; $P = .009$), and volume (2967 ± 886 mm^3 and 1954 ± 516 mm^3, respectively; $P = .003$). The female specimens had significantly lower mechanical properties than the male specimens, including 30% load to failure, 22.49% modulus of elasticity, 14.3% stress at failure, 9.43% strain energy density at failure, and 8.3% strain at failure. The authors concluded that the smaller ligament size and mechanical properties in women may contribute to their increased rate of noncontact ACL rupture. It is important to recognize that the mechanical properties reported, including load at failure (1818 ± 699 for male and 1266 ± 527 for female; $P < .05$), may underestimate the expected higher values in young athletes. Lipps and coworkers[145] in a recent cadaveric study, simulated strain of the distal third of the anteromedial region of the ACL incurred during a pivot landing in height- and weight-matched specimens. These investigators concluded that this region of the female ACL will develop greater strain than the male ACL upon landing, owing to its smaller cross-sectional area and lateral tibial slope.

Tibial Plateau Geometry

A potential association between the surface geometry of the tibial plateau (e.g., convexity in its lateral aspect) and clinical instability in ACL-deficient knees was speculated years ago by a few investigators.[60,132,155] Studies conducted more recently have measured a multitude of anatomic indices, including the relative length, width, concavity, and depth of the tibial surface, using radiography, CT, and MRI. Several investigations have indicated that an association may exist between ACL noncontact injuries and increased posterior slope of the lateral proximal aspect of the tibia,[23,26,32,94,95,127,154,160,245,258,264] although a few have refuted these findings.[114,165] In healthy subjects, gender differences have been found in the slopes of both the medial and lateral proximal aspects of the tibia.[94,114] However, many studies have failed to identify gender differences in the posterior tibial slope in ACL-injured knees.[32,95,127,258,264,268] One recent study in which researchers examined the radial geometry of the articular surfaces of the lateral compartment of the knee[272] indicated that ACL-injured male patients and all female subjects (ACL-injured and control) had a common lateral tibiofemoral geometry of a relatively short and steeply convex tibial articular surface and increased convexity of the femoral surface. In another investigation, Beynnon and coworkers[23] found a 21.7% increased risk of noncontact ACL injury with each degree of increase of the lateral tibial plateau slope in women, but not in men. Other investigators[105,260,268] also found that the increased posterior tibial slope was a risk factor only in women.

Recent work in this area involves the in vivo assessment of the effect of variations in knee joint anatomy on knee joint forces and moments during dynamic activities such as landing from a jump. McLean and associates[159] examined six anatomic indices in 20 female athletes during single-leg land-and-cut tasks. Of interest among several findings was that increases in lateral tibial slope were associated with increased peak anterior knee joint reaction force on landing. The observed force magnitudes ranged between 100 N and 130 N, well below loads required for ACL rupture. Even so, the authors speculated that increases in tibial slope may impact other joint mechanics that contribute to ACL injury. Shultz and Schmitz[239] conducted a similar study of 23 female subjects who performed double-legged drop-jumps. An association was noted between increased lateral tibial slope and increased hip internal rotation upon landing, as well as decreased mediolateral tibial slope and increased knee internal rotation on landing. Tibial plateau geometry was not a predictor of hip adduction, hip external rotation, knee varus, or knee internal rotation joint moments. To date, no investigators have examined the influence of knee joint anatomic indices on dynamic activities in male athletes, and therefore a gender comparison is not currently available.

Foot Pronation, Pelvic Tilt

Excessive foot pronation (hyperpronation)[6,16,98,148,283] and anterior pelvic tilt[98,148,266] have been suggested as potential risk factors for ACL injuries. However, even if these factors do increase risk, gender does not appear to play a role. Authors have speculated that hyperpronation

leads to increased internal tibial rotation,[16,55,263] and an anterior pelvic tilt may be associated with increased hip internal rotation, both of which could place the ACL at risk for injury.[98]

Foot pronation is measured by the navicular drop test.[34] In four investigations, researchers reported significantly higher navicular drop values in patients who sustained ACL ruptures than in matched control subjects: a mean of 6 mm in one study,[16] 2 to 2.5 mm in two studies,[6,283] and 1.6 mm in another.[98] Woodford-Rogers and associates[283] reported that navicular drop, calcaneal alignment, and anterior tibial translation (when combined) were predictors of classification of athletes into the ACL-injured and ACL non-injured groups, because 87.5% of the female athletes and 70.5% of the male athletes in their investigation were correctly classified. Hertel and coworkers[98] reported that increased navicular drop and anterior pelvic tilt were predictors of ACL injury history, regardless of gender. These investigators measured navicular drop, Q-angle, leg length, hip internal and external rotation, and pelvic tilt in 20 patients with a history of ACL injuries and 20 control subjects. Patients with a greater than 8-mm navicular drop were 20 times more likely to have torn their ACL than were subjects with less than 6.3 cm ($P = .01$).

In a study composed of only female athletes, a combination of postural "faults" was found to have a greater predictive value for ACL injury than a single problem (such as excessive pronation).[148] The combination of excessive knee hyperextension, navicular drop, and subtalar joint pronation significantly identified the patients compared with 20 control subjects ($P = .0001$).

It is important to note that other studies failed to find an association between foot hyperpronation and ACL injury risk. Jenkins and coworkers[122] did not find an association between subtalar joint neutral position and navicular drop and ACL injury in a group of 16 athletes with ACL injuries. Smith and colleagues[250] were also unable to find an association between excessive pronation and noncontact ACL injuries. These authors cautioned that static measurements of pronation may not be representative of dynamic conditions and that future research should include not only dynamic analyses, but other anatomic risk factors as well.

Joint Laxity

Some authors have reported that women appear to have greater inherent joint laxity and/or anterior tibial translation than men.[22,216,217,225,237,265,267] Huston and Wojtys[119] reported that females had significantly greater anterior tibial translation than males (6.5 and 5.8 mm, respectively; $P < .05$), as did Rozzi and associates[219] (6.05 ± 1.46 and 4.80 ± 1.53 mm, respectively; $P = .02$). Seckin and colleagues[230] reported a significantly greater prevalence of generalized joint hypermobility in female high school students compared with male students (16.2% and 7.2%, respectively; $P < .0001$). Remvig and coworkers[216] found considerable evidence in the literature of an increased prevalence of hypermobility among women. A few studies have examined gender differences in tibial rotation and varus-valgus angles, with mixed results.[113,197,238]

Even though women may have inherently greater joint laxity than men, there is no strong evidence that this factor plays a role in their increased risk of noncontact ACL injury.[267,270] Uhorchak and associates[267] reported that, regardless of gender, generalized joint laxity was a significant risk factor of ACL injury, because subjects who had at least five regions classified as lax according to the Beighton score were 2.8 times more likely to sustain an ACL rupture. Ramesh and colleagues[215] reported a prevalence of generalized joint laxity (>6 Beighton score) in 169 ACL-deficient knees (137 men and 32 women) compared with a control group of 65 subjects (42.6% and 21.5%, respectively; $P < .01$). Knee hyperextension was present in 78.7% of the ACL-deficient knees compared with 37% of the control knees ($P < .001$), but a gender comparison was not performed. Two studies in which researchers assessed only female athletes found an association between increased knee hyperextension and ACL injury.[148,173]

Body Mass Index, Q-Angle

There is no evidence to support that an excessive BMI alone is a risk factor for noncontact ACL injuries. Ostenberg and Roos[189] found that BMI was not a risk factor for knee injuries in female soccer players, as did Knapik and coworkers[130] in military training–related injuries in female recruits. When combined with a narrow femoral notch and generalized joint laxity, a BMI greater than 1 standard deviation above the mean did contribute to a high prediction of noncontact ACL injuries in Uhorchak and coworkers' series.[267] Although the Q-angle has been commonly cited as a potential independent risk factor for ACL injuries, there is no clinical evidence supporting this belief.[98,117,148]

HORMONAL

The presence of female sex hormones (namely, estrogen, progesterone, and relaxin) and their fluctuations during the menstrual cycle have been proposed by several investigators to affect muscle and neuromuscular indices, as well as the material and mechanical properties of the female ACL.* Some researchers have hypothesized that hormonal influences may increase the risk of ACL injury in female athletes.[1,24,146,279,285] However, several problems have been identified with the methods of published studies that preclude drawing definitive conclusions.[208,249,271] These include difficulty in accurately identifying the phase of the cycle at the time of injury and inconsistent classifications of the various phases of the cycle.[208,249]

Two basic methods have historically been used to identify the phase of the cycle at the time of ACL injury. These include the analysis of a single biologic sample on the day of or a few days after an ACL injury and/or the collection of retrospective self-reported menstrual history questionnaires. These methods do not accurately verify current cycle length for several reasons.[249,271] There is no validated outcome measure that uses a biological sample (serum, urine, or saliva) concentration alone or in combination with cycle history that accurately predicts cycle phase at the time of an ACL injury.[249] Substantial variability exists in menstrual cycle length and hormone profiles among and within women, as summarized by Vescovi.[271] Vescovi recommended against assuming a 28-day cycle exists in all women and that consistent cycle lengths exist within women. There are wide variations in the lengths of the follicular and luteal phases (9-23 days and 8-17 days, respectively), as well as the length of the total cycle (22-36 days). This is especially true in physically active women. Vescovi[271] also remarked that female athletes who appear to be eumenorrheic, with regularly occurring menses, may not necessarily have normal sex steroid hormone profiles. This fact negates the assumption that normal ovarian endocrine function is closely associated with regularly occurring menses.

Several studies have shown no influence of the phase of the menstrual cycle on passive knee anterior tibial translation.[17,38,97,104,204] These findings bring into question the role of sex hormone concentrations on knee joint laxity. Hormonal cycling that occurs throughout the menstrual cycle did not appear to affect loading on the knee (hip and/or knee moments or knee flexion angles) during high-risk tasks in one investigation[48]; however, another study[241] found that intersubject

Table 13-2 Hypothesized Neuromuscular and Biomechanical Risk Factors for Noncontact ACL Injury in the Female Athlete

Category	Risk Factor	Hypothesized Gender Difference
Muscle strength, activation, recruitment patterns	Lower extremity muscle strength and activity Hip muscle strength Lower extremity muscle recruitment patterns Fatigue Core stability	Compared with males, females have: • Weaker quadriceps and hamstring muscle peak torques • Slower times to reach lower extremity muscle peak torques • Higher quadriceps activity and reduced hamstring activity during athletic maneuvers • Weaker hip muscles • Poor core stability • Different muscle activation patterns during preplanned and unplanned athletic tasks • Faster time to fatigue • Different muscle recruitment patterns in response to a passive anterior tibial translation force
Knee stiffness		Compared with males, females have: • Decreased inherent passive and active knee joint stiffness
Movement patterns	Knee and hip flexion Tibial rotation Knee abduction Hip internal rotation, abduction Knee abduction and/or adduction moments	During high-risk activities, compared with males, females have: • Smaller knee and hip flexion angles • Less internal tibial rotation • Larger knee abduction angles • Smaller hip abduction angles • Greater hip adduction and knee abduction and/or adduction moments • Smaller hip extensor and flexor and knee flexor moments

ACL, Anterior cruciate ligament.

CRITICAL POINTS Hormonal

- Researchers have hypothesized that hormonal influences may increase the risk of ACL injury in female athletes.
- Problems identified with methods of published studies preclude definitive conclusions.
- Analysis of single biological sample after an ACL injury and/or the collection of retrospective self-reported menstrual history questionnaires are not accurate in predicting cycle phase.
- No influence exists of the phase of the menstrual cycle on passive knee anterior tibial translation.
- Use of oral contraceptives has not been found to protect against ACL injury.

CRITICAL POINTS Neuromuscular/Biomechanics

- Differences between female and male athletes in muscle strength and stiffness, movement patterns, and body positions that occur during various athletic activities have been demonstrated in the laboratory and during videotape analysis of game injuries.
- Women tend to perform athletic maneuvers (landing from a jump, cutting) with less knee and hip flexion, greater quadriceps activity, reduced hamstring activity, higher knee extensor moments, increased knee valgus angles, and increased hip adduction and knee abduction/adduction moments compared with men.
- Women have less lower extremity strength and knee stiffness than men.
- Fatigue appears to affect landing mechanics regardless of gender.

variability in multiplanar knee laxity (anterior, genu recurvatum, varus-valgus, and internal-external rotation) changes during the cycle did affect kinematic patterns on a drop-jump. The use of oral contraceptives has not been found to protect against ACL injury.[4,220] More research is required in this area to determine whether a link exists between menstrual cycle phase, hormone concentrations, and risk of ACL injury.

NEUROMUSCULAR/BIOMECHANICS

Muscular Protection of the Knee: Lower Extremity, Hip, Core

Several neuromuscular and biomechanical factors have been hypothesized by various investigators to play a major role in the disparity between genders in noncontact ACL injury rates (Table 13-2). Differences between female and male athletes in muscle strength and stiffness, as well as movement patterns and body positions that occur during various athletic activities, have been demonstrated under controlled preplanned and reactive conditions in the laboratory. Videotape analyses of noncontact ACL injuries demonstrate certain lower extremity positions and characteristics in female athletes that lend support to the theory that movement pattern differences during athletics may likely play a role in this problem.[29,131,184] Women tend to perform athletic maneuvers with less knee and hip flexion, greater quadriceps activity, reduced hamstring activity, higher knee extensor moments, and increased knee valgus angles and moments compared with men. Several studies have found that men have greater strength[9,12,31,101,108,119,142,170,203,232] and knee stiffness[84,85,278,280] than women. The sagittal plane shear stiffness of the knee represents the resistance exerted by soft tissues (passive and active) in response to an anterior tibial translation force.[175] It is technically defined as the ratio of change in force in a muscle to its change in length.[162] A higher degree of muscle stiffness prevents muscle lengthening in response to an anterior tibial translation, thereby theoretically decreasing the likelihood of ACL injury.[27] Blackburn and colleagues[27] reported that individuals with greater hamstring stiffness displayed smaller frontal plane knee moments, smaller anterior tibial shear forces, and greater knee flexion upon landing from a drop-jump compared with athletes with lower hamstring stiffness. In this investigation, hamstring stiffness was quantified using a damped oscillatory technique and normalized to body mass. The high-stiffness group (25.81 ± 4.61 N-m $\times$ kg^{-1}) was

composed of 5 men and 7 women, and the low-stiffness group (14.52 ± 1.51 N-m × kg^{-1}) contained 7 men and 5 women.

It is important to briefly review the role of the muscles in the lower extremity, hip, and core in protecting athletes from noncontact ACL injuries. The major lower extremity muscles are the quadriceps, hamstring, and gastrocnemius-soleus. Many investigators have described the association between high quadriceps forces and noncontact ACL injuries.[52,61,88,273] High quadriceps forces produce anterior shear force during the last 30 degrees of knee extension. Grood and associates[88] reported that, during the knee extension exercise, the quadriceps force required to extend the knee remained at a constant value of 177 N between 50 and 15 degrees, but then rose rapidly to reach 350 N at 0 degrees (Fig. 13-1). The addition of resistance doubled the quadriceps force required to extend the knee, resulting in large forces on the ACL and patellofemoral joint.

DeMorat and colleagues[61] reported that a high quadriceps load (4500 N) simulated in cadaveric knees at 20 degrees of flexion produced significant anterior tibial translation (mean, 19.5 mm). The authors concluded that the quadriceps can serve as a major intrinsic force in noncontact ACL injuries. Wall and associates[273] showed in cadaveric knees that, although an axial compressive force (such as that incurred when landing from a jump) to the knee can injure the ACL, the addition of a quadriceps force significantly lowers the axial compressive force threshold required to disrupt the ligament.

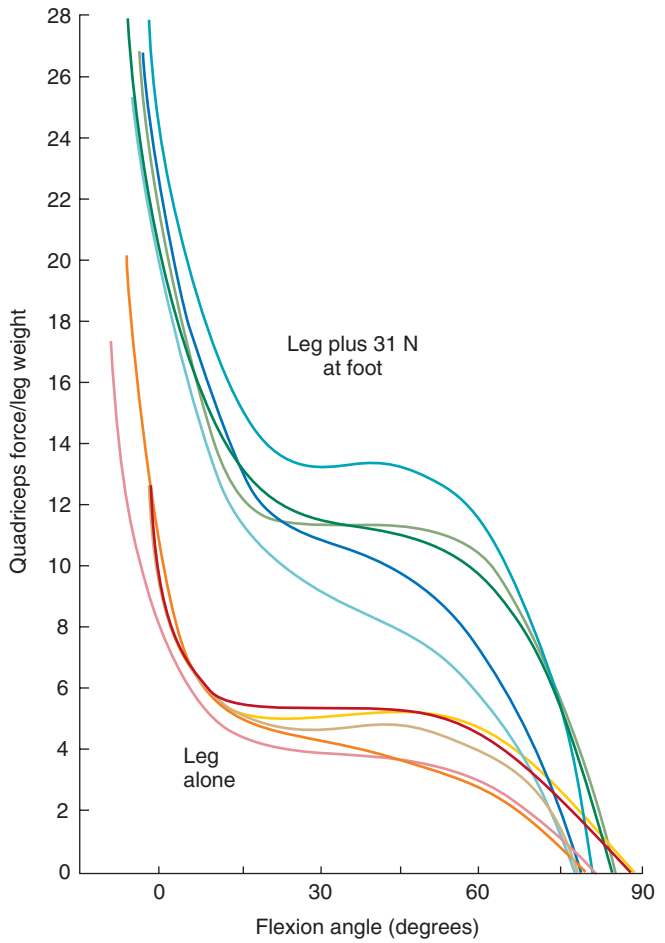

FIG 13-1 The ratio of quadriceps force to leg weight is shown for five specimens as a function of flexion angle. The *lower group of curves* demonstrates the force measured when extending the leg against its own weight. The *upper group of curves* shows the forces measured when 31 N was placed at the foot.

Colby and coworkers[52] measured hamstring and quadriceps muscle activation and knee flexion angles during sidestep cutting, cross-cutting, stopping, and landing in nine male and six female collegiate athletes. A high-level quadriceps muscle activation occurred just before foot-strike and peaked in mideccentric motion. Hamstring muscle activation was submaximal at and after foot-strike. Colby and coworkers concluded that the combination of the high level of quadriceps activity, low level of hamstring activity, and low angle of knee flexion during eccentric contractions in these maneuvers could produce significant anterior translation of the tibia.

The hamstring musculature is important in stabilizing the knee joint because it functions as a joint compressor and restrains anterior tibial translation.[151,169] The biomechanical function of the sartorius, gracilis, and semitendinosus muscles was assessed many years ago when investigators found these muscles had a marked functional dependence on the angle of knee flexion and degrees of external tibial rotation.[181] For instance, the flexion force of the hamstrings was greatest at 90 degrees of knee flexion (Fig. 13-2). As the knee was extended, the tendon insertion angle became more acute relative to the tibia, resulting in a decrease in the mechanical advantage of the muscle and a subsequent decrease in the flexion moment about the knee joint. At 0 degrees of extension, the flexion force was reduced to 49% of that measured at 90 degrees of flexion. The rotation force of the hamstrings was also reported to be greatest at 90 degrees of knee flexion (Fig. 13-3). The rotation force of the hamstrings (under the same muscle load) increased with increasing external tibial rotation at the four knee flexion positions shown in Figure 13-4. The rotation force produced at 15 degrees of external tibial rotation was approximately double that measured at 0 degrees of external tibial rotation. The conclusion reached was that the hamstrings actively oppose extension by stabilizing the knee posteriorly and preventing knee hyperextension and anterior subluxation of the tibia. In addition, these muscles actively oppose external tibial rotation.

The major antigravity hip muscles are the gluteus maximus (GMAX, hip extensor) and the gluteus medius (GMED, hip abductor). The GMAX has a large cross-sectional area and long muscle fibers that allow it to produce a large amount of force at high velocities. It also has the ability to act as a hip abductor and external rotator at small degrees of hip flexion. The GMED works to stabilize the pelvis and limit hip adduction during single-leg stance. Both of these muscles contribute significantly to total power generation and absorption during jumping and landing. Insufficient use of GMED (owing to either inherent muscle weakness or poor landing strategies) may predispose an athlete to land in greater hip adduction or internal rotation during athletic activities, which may in turn lead to increased knee abduction angles and moments that place the ACL at risk for injury.[106,121,140] However, data from studies that have examined the relationship between hip muscle strength and knee joint biomechanics are not in agreement.[109,168,201,242,261] Powers[211] suggested that factors other than hip strength, such as impaired motor control, may be associated with movement patterns that may increase the risk of ACL injury. Walsh and associates[274] reported that a high level of both quadriceps and GMAX activation, along with low levels of hamstring and gastrocnemius activation, led to smaller knee flexion angles upon landing from a drop-jump. Homan and coworkers[109] found that individuals with poor hip abductor and external rotator muscle strength activated their GMED and GMAX muscles at higher levels than subjects with high hip strength during a drop-jump task. There were no differences in frontal plane hip or knee kinematics between subjects with high and low hip strength. They hypothesized that weaker athletes use greater

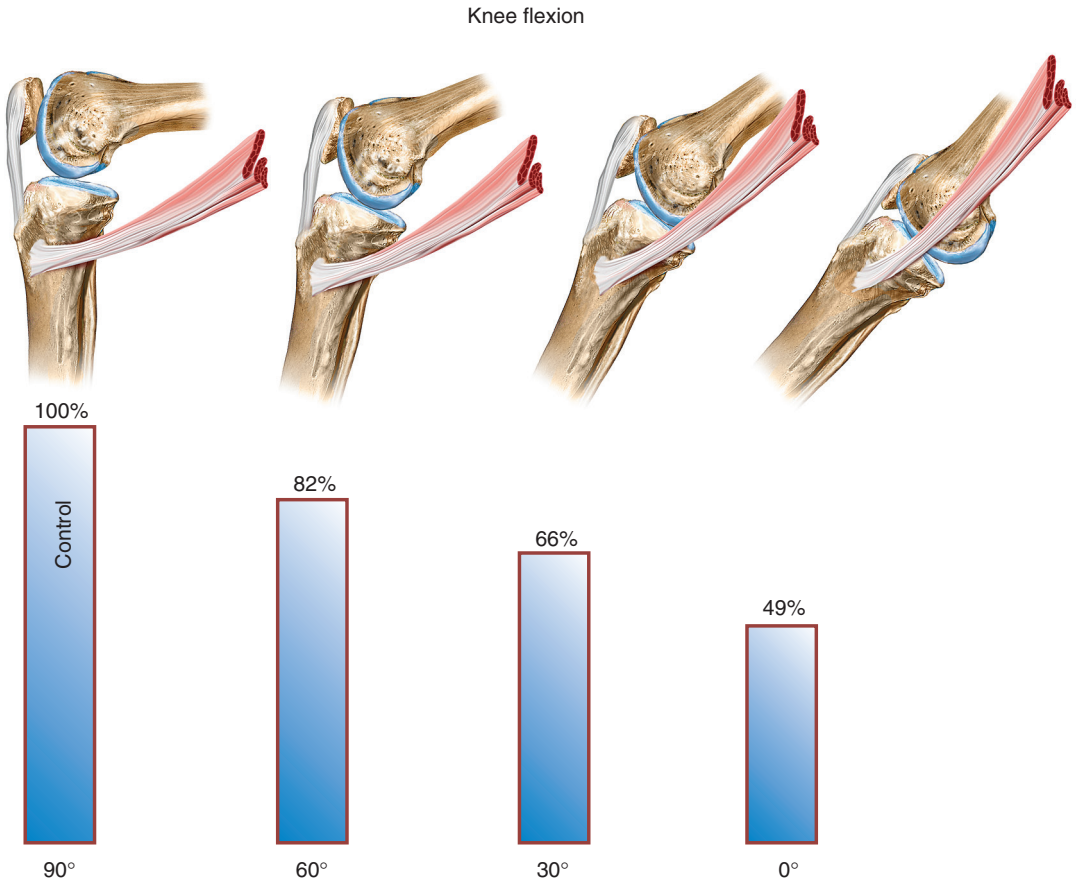

FIG 13-2 Pes anserine flexion forces. Knee extension yields a decrease in insertion course angles with respect to the tibia. The resulting loss in mechanical advantage is indicated by reduced flexion forces with extension ($P < .05$).

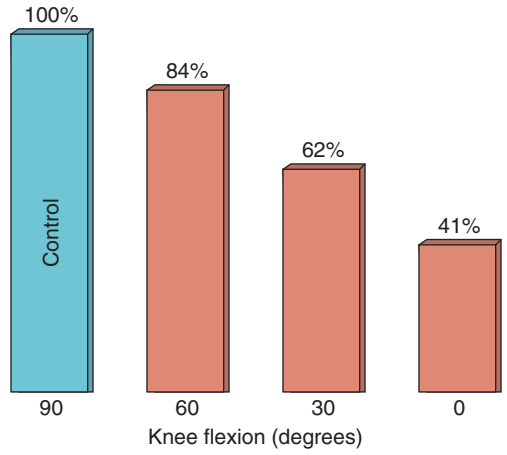

FIG 13-3 Pes anserine rotation forces. Reduction in mechanical advantage with knee extension is accompanied by corresponding decreases in rotation forces ($P < .05$).

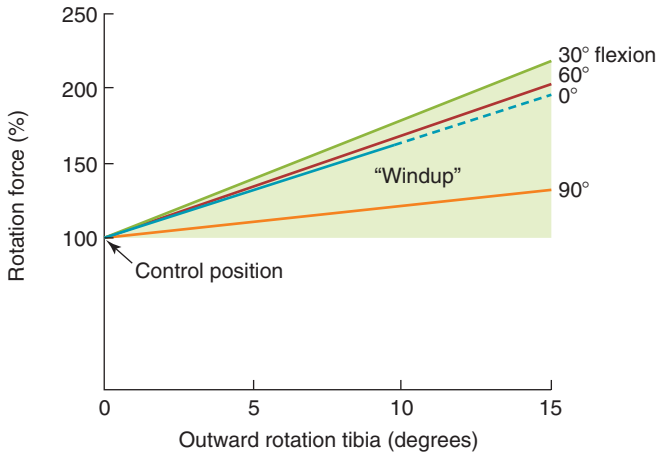

FIG 13-4 Rotation windup forces. The rotation forces under the same muscle loading increase significantly with external tibial rotation at each knee flexion position tested ($P < .05$).

neural drive to the gluteal muscles to achieve the same landing position as stronger individuals.

The "core" of the body includes all of the muscles of the trunk and pelvis required to stabilize the spine and pelvis during activities. *Core stability* may be defined as the "ability of the core, or the muscles of the abdomen and lower back, to maintain or resume a relative position (or trajectory) of the trunk after a perturbation."[47] The core provides a stable base for enhanced lower extremity control, leading to the belief that poor core strength or trunk position (e.g., excessive anterior pelvic tilt) may place the ACL at risk for injury.[133,134,286] However, further research is required to understand the relationship between core strength and stability and ACL injury.

TABLE 13-3 Significant Gender Differences in Isokinetic Quadriceps and Hamstring Strength

Gender Differences in Lower Extremity Muscle Strength and Stiffness

Marked differences among adolescent and adult male and female athletes in quadriceps and hamstring isokinetic peak torques (Table 13-3), hamstring/quadriceps ratios (Table 13-4), time to reach peak torque,[119,178] and internal-external tibial rotation[178] have been documented in numerous investigations. Huston and Wojtys[119] reported several years ago that collegiate female athletes had significantly weaker quadriceps and hamstring strength and endurance, as well as slower time-to-peak torque values for knee flexors, than male athletes. They also reported gender differences in muscle recruitment order in response to an anterior tibial translation force. The female athletes tended to recruit the quadriceps first, followed by the hamstrings and gastrocnemius. The male athletes tended to recruit the hamstrings first, followed by the quadriceps and gastrocnemius.

One of the largest studies conducted to date, on 853 females and 177 males aged 9 to 17 years, demonstrated that significant gender differences in lower extremity strength become evident at age 14 years (Fig. 13-5).[12] This investigation revealed that females appear to reach peak hamstring strength at age 11 years, with no significant difference found in this factor between girls 11 years of age and those up to 17 years (Fig. 13-6). No difference in isokinetic muscle strength values between boys and girls younger than 14 years has been reported by many laboratories.[62,63,107,231]

Several investigators have reported gender differences in knee stiffness (Table 13-5). Wojtys and colleagues[278] measured passive and active anterior shear stiffness of the knee joint with a testing apparatus that recorded anterior tibial translation and muscle activity with surface electromyography (EMG). Although there was no significant difference between genders in passive shear stiffness, men produced significantly higher active stiffness values during a maximum cocontraction.

TABLE 13-4 Significant Gender Differences in Isokinetic Hamstring/Quadriceps Ratio

Study	Subjects	Testing Protocol	Male (mean ± SD)	Female (mean ± SD)	*P* Value
Holm & Vollestad[108] (2008)	165 female, 144 male athletes	8 yr, 240 degrees/sec	65 ± 14	54 ± 12	<.01
		9 yr, 60 degrees/sec	61 ± 12	55 ± 11	<.05

BW, Body weight; *SD,* standard deviation.

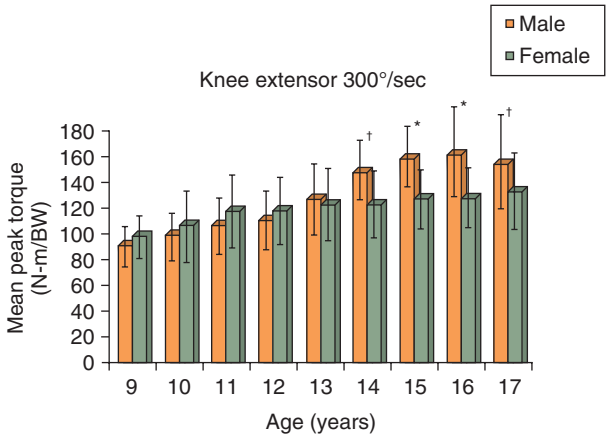

FIG 13-5 No significant difference was found in the mean extensor peak torque ratio values between females and males in the 9- to 13-year-old age groups. However, from the ages of 14 to 17 years, males had significantly greater mean extensor peak torque ratio values than females. *$P < .0001$; †$P = .001$. *BW,* Body weight.

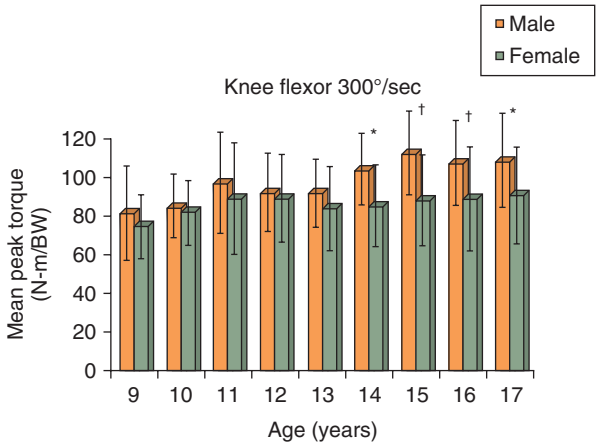

FIG 13-6 No significant difference was found in the mean flexor peak torque ratio values between females and males in the 9- to 13-year-old age groups. However, from the ages of 14 to 17 years, males had significantly greater mean flexor peak torque ratio values than females. *$P < .001$; †$P = .0001$. *BW,* Body weight.

In a separate investigation, Wojtys and coworkers[280] reported that female athletes involved in pivoting sports had significantly smaller increases in torsional stiffness of the knee under internal rotation loading conditions than male athletes. The athletes were matched for age, height, weight, BMI, shoe size, and activity level. A significant reduction in active muscle stiffness in females compared with males during isometric knee flexion and extension and hopping tasks was reported by Granata and associates.[84,85] The gender difference was amplified at higher loads, leading the investigators to conclude that this finding had implications for potential injury during functional loading tasks.

Data published to date on hip strength are conflicting in regard to gender differences. Studies have assessed hip strength either isometrically with dynamometers under non-weight-bearing conditions or with surface EMG under passive or active conditions. Leetun and associates[141] measured hip abduction and external rotation isometric strength, abdominal muscle function, and back extensor and quadratus lumborum endurance in 79 female and 60 male collegiate athletes. The male athletes had greater hip isometric abduction and external rotation strength, as well as lateral core strength, than the female athletes (Table 13-6). However, Brophy and coworkers[35] measured isometric hip abduction and found no gender-based differences between 54 male and 44 female soccer players when the values were adjusted for limb length, weight, and height. The women had significantly weaker hip abductors in their nondominant hip, which was not present in the male players. In the majority of studies in which hip and core strength have been measured, the measurements were done during activities such as a single-leg squat and a single-leg land from a jump, described next.

Gender Differences in Strength, Lower Extremity Function and Alignment During Single-Leg Tasks

Several investigators have reported gender differences in muscle strength and frontal lower extremity alignment during a single-leg

squat (Fig. 13-7).[11,51,277,288] Zeller and associates[288] reported that female athletes had significantly greater angles of ankle dorsiflexion, ankle pronation, hip adduction, and hip flexion, as well as greater quadriceps femoris activation, than males (Table 13-6). The women began the movement in a greater amount of valgus alignment and remained in this position throughout the squat. Clairborne and coworkers[51] found that men had greater hip and lower extremity strength than women; however, there were no gender differences noted for frontal plane kinematic values, including peak knee valgus angle. Hip abduction, hip internal rotation, knee flexion, and knee extension strength were predictors of frontal plane knee motion. These authors speculated that the single-leg squat may not produce the magnitude of external moments required to produce a significant difference in frontal plane knee motion. Willson and colleagues[277] reported that, at the deepest angle of the squat, women assumed a greater valgus position than men. Hip external rotation strength was associated with frontal plane position angle. Baldon and associates[11] found that women had greater contralateral pelvic depression, femur adduction, and knee abduction than men. A relationship was found in female subjects between eccentric hip abduction strength and femoral adduction and knee abduction movements. These authors concluded that weakness of this muscle group may play a greater role in altering overall lower limb alignment in women than in men.

Muscle activation patterns and lower extremity alignment have been studied extensively in single-leg landings from a drop-jump* and from a forward hop.[93,112,121,192,193] Significant gender differences have been noted for various phases of these maneuvers, including preland-ing, landing, and postlanding (Table 13-7), although the conclusions drawn in the studies vary because of differences in study methods. Shimokochi and associates[234] found few differences between 10 male and 10 female recreational athletes in lower extremity alignment upon landing. However, the authors noted that individuals who landed in an "upright" position had increased vertical ground reaction forces (GRF), peak knee extensor moments, and quadriceps muscle activation compared with those who landed in a forward-leaning position. Generally, authors have found muscular weaknesses and/or imbalances in women compared with men during single-leg tasks. Female athletes appear to have higher levels of quadriceps activity upon landing, tend to land in an overall valgus position, land with greater vertical GRF, and have reduced hip and knee flexion angles compared with male athletes. The authors of a systematic review[39] of 27 studies that measured gender differences in landing found that 45% of females landed from a single-leg task with increased knee abduction angles compared with males.

Gender Differences in Strength, Lower Extremity Function, and Alignment During Two-Legged Landings

Many investigators have reported gender differences in two-legged landings similar to those just described for single-leg landings (Table 13-8). A study conducted at our laboratory[101] many years ago was one of the first to demonstrate gender differences in muscle strength and movement patterns upon two-legged landings from a volleyball block jump. The hypothesis was advanced that male athletes most likely use different mechanisms from those used by female athletes to compensate for high landing forces and moments at the knee.

Researchers in several studies have assessed gender differences in two-legged landing from a drop-jump (Fig. 13-8). Huston and associates[118] believed that GRF were likely to be greater in women per unit body weight than in men because women landed from a drop-jump with a straighter knee. Decker and colleagues[58] found that females landed in a more erect posture upon initial impact compared with males. More recently, Joseph and coworkers[124] concluded on the basis of their investigation that female and male athletes use a "completely different kinematic landing/jumping strategy" because females landed and collapsed into a valgus alignment more rapidly than males. Sigward and colleagues[243] found gender differences across prepubertal, pubertal, postpubertal, and young adult athletes. The female athletes had significantly higher knee adductor moments and used their knee extensors to a greater extent than the hip extensors (knee/hip extensor moment ratio) during the deceleration phase of landing. Stearns and associates[255] agreed and also found that women displayed lower knee and hip flexion angles and increased knee adduction angles and knee abductor moments during this phase. The authors of a systematic review[39] of 27 studies that measured gender differences in landing found that 72% of females landed in a double-leg task with increased knee abduction angles compared with males.

In contrast, some studies have not found gender differences during two-legged tasks or have refuted earlier findings in regard to the relationship between quadriceps muscle activation and lower limb alignment landing position.[37,56,73,96,187,190,222] For instance, Shultz and associates[236] found no association in female subjects between high levels of quadriceps activation on landing and lower hip and knee flexion angles or greater peak knee extensor moments. Afifi and Hinrichs[2] reported several differences in mechanics when a two-legged drop jump was compared with a countermovement jump for both genders and cautioned that "stepping off a box onto the ground may not be the best way to study landings if the purpose is to generalize to real-world landings from a jump." More realistic athletic tasks have

Butler et al[36] (2013)	14 female, 14 male recreational soccer players, age 18-30 yr	Two landings: forward stop-jump, countermovement vertical	Both genders showed differences in peak vertical GRF between two landings. Males had greater increases from first to second landing ($P < .01$).	Males had 19% decrease in peak hip flexion compared with females ($P < .05$).	Males had 20% increase in peak knee extension moment compared with females ($P < .01$).
Stearns et al[255] (2013)	20 female, 20 male recreational athletes	Drop-jump 36 cm, isometric strength testing	Females had higher knee/hip extensor ratio ($P < .001$).	Females had lower peak knee and hip flexion angles and higher peak knee abduction angles ($P < .001$).	Females had higher knee adductor moments ($P < .001$), lower knee and hip extensor moments ($P < .001$), and higher knee/hip extensor moment ratios ($P < .001$).
Norcross et al[176,177] (2013)	41 female, 41 male physically active subjects	Drop-jump 30 cm	Females had greater peak posterior GRF and greater peak anterior tibial shear force ($P < .05$). Females were 3.6 times more likely than males to use landing strategy with greater frontal plane initial impact phase energy absorption.	Females had greater knee valgus angles ($P < .05$).	Females had greater peak knee extension moments and greater peak knee varus moments ($P < .05$).
Sigward et al[243] (2012)	60 female, 59 male athletes, age 9-22 yr	Drop-jump 36 cm	Females had greater knee/hip energy absorption ratio ($P < .001$).	NA	Females had greater knee adductor moments ($P < .005$) and knee/hip extensor moment ratios ($P = .001$).
Joseph et al[124] (2011)	10 female, 10 male collegiate athletes	Drop-jump 31 cm	Frontal plane motion of hip, knee, ankle in females occurred earlier in stance phase than in males. Females had increased angular velocity knee valgus excursion.	Females decelerated with hip adduction, knee valgus, and ankle eversion before maximum knee flexion.

Hughes et al[116] (2010)	6 female, 6 male collegiate athletes	Volleyball block jumps (unopposed and opposed)	None	Females had greater valgus position on initial contact and maximum position on opposed jumps ($P < .05$). Females had greater knee flexion on opposed jumps ($P < .05$).	NA
Beutler et al[21] (2009)	1046 female, 1707 male cadets	Drop-jump 30 cm, LESS score, isometric strength testing with handheld dynamometer and normalized body mass	Females had weaker quadriceps, hamstrings, hip IR and ER, gluteus maximum and minimum ($P < .001$). Females had lower LESS scores ($P < .001$).	Females more likely to land with less hip and knee flexion at initial contact, more knee valgus, and less flexion displacement over entire landing phase ($P < .001$).	NA
Shultz et al[236] (2009)	39 female, 39 male adults	Drop-jump 45 cm, surface EMG, isometric strength dynamometer	Females had weaker quadriceps and hamstring peak torque ($P < .001$).	Females had smaller knee and hip flexion excursion angles ($P < .05$).	NA
Hughes et al[115] (2008)	6 female, 6 male collegiate athletes	Volleyball block jump	NA	Females had greater maximum knee valgus angle and greater valgus ROM ($P < .01$)	NA
Pappas et al[196] (2007)	16 female, 16 male recreational athletes	Drop-jump 40 cm, surface EMG	Females landed with increased vertical GRF ($P < .001$).	Females had increased knee valgus on landing ($P < .001$)	None
Kernozek et al[126] (2005)	15 female, 15 male recreational athletes	Drop-jump 60 cm	Females had greater peak vertical and posterior GRF ($P < .05$).	Females had greater peak ankle dorsiflexion, foot pronation, and knee valgus angles on landing ($P < .05$) as well as greater ankle dorsiflexion, foot pronation ROM, and varus-valgus ROM frontal plane ($P < .05$).	Females had lower peak knee varus moments on landing ($P < .05$).
Salci et al[223] (2004)	8 female, 8 male collegiate athletes	Spike and block landings 40 cm, 60 cm	Females had greater normalized vertical GRF ($P < .05$) and weaker quadriceps and hamstring peak torques normalized to BW.	Females had lower knee and hip flexion angles ($P < .05$).	
Decker et al[58] (2003)	9 female, 12 male recreational athletes	Drop-jump 60 cm	Females had greater energy absorption from knee and ankle compared with hip ($P < .05$). Males had equal amounts of energy absorption from all joints. Females had 34% less negative hip work, 30% more negative knee work, 52% more negative ankle work than males ($P < .05$).	Females had greater knee extension and ankle plantar flexion angles at initial ground contact ($P < .05$)	NA
Ford et al[77] (2003)	47 female, 34 male high school athletes	Drop-jump 31 cm	NA	Females had greater valgus limb alignment on landing ($P < .01$).	NA

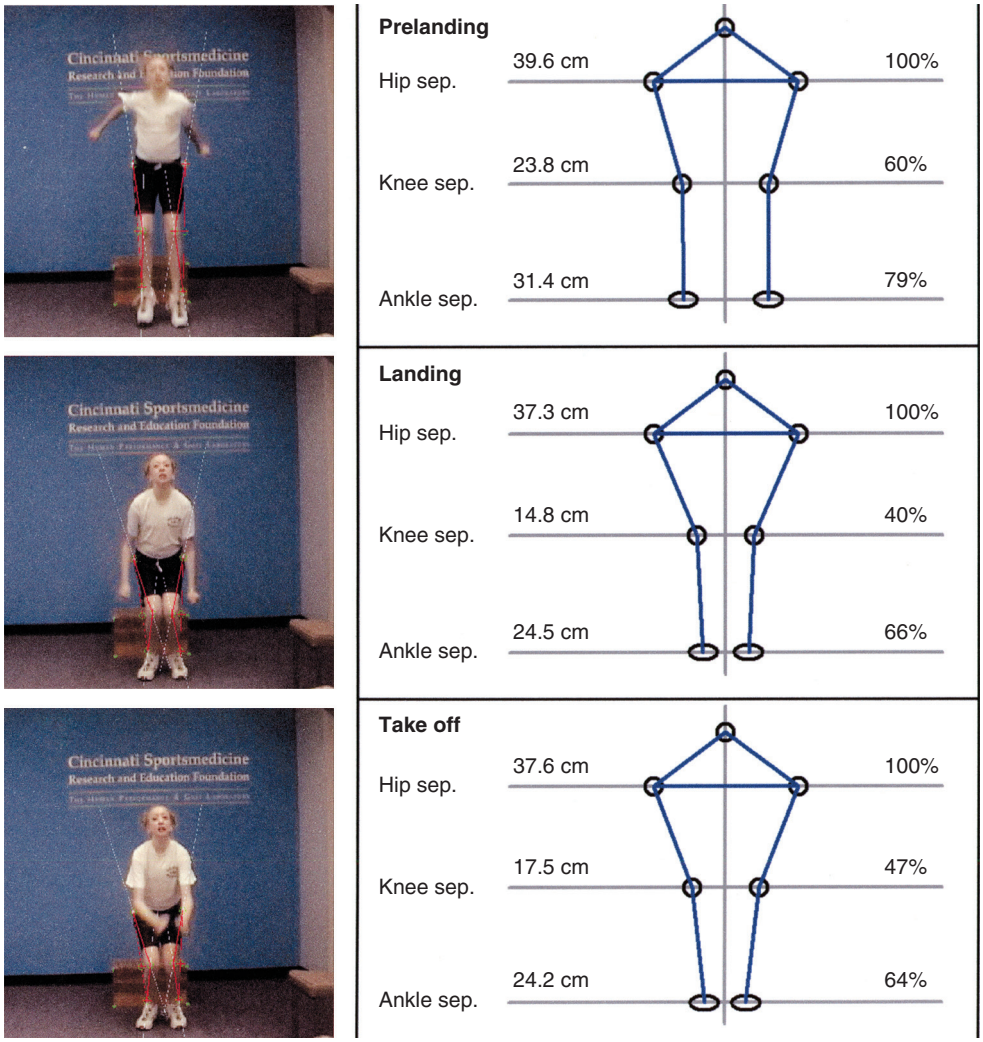

FIG 13-8 The three phases of the two-legged drop-jump test as conducted at our laboratory. The distance between the hips, knees, and ankles is calculated in centimeters with normalized knee and ankle separation *(sep.)* distances (according to the hip separation distance). Shown are the results of a 14-year-old female.

been studied, such as running, cutting, and agility maneuvers, discussed next.

Gender Differences in Strength, Lower Extremity Function, and Alignment During Running, Cutting, Stop-Jump Tasks

Gender differences during straight running have been found in regard to activation of the peroneus longus, tibialis anterior, hamstring, gastrocnemius, GMED, GMAX, and vastus lateralis muscles.[13,50,68,137,152] Comparisons of hip and knee joint angles and moments have also revealed differences between female and male athletes (Table 13-9). The relationship of these gender differences during straight running in regard to ACL injury risk remains unclear.

Many different types of cutting maneuvers have been studied with respect to gender differences in 3-dimensional kinematics and kinetics in male and female athletes (Table 13-10). These include preplanned side cuts,[19,69,91,152,157,158,161,183,207,244] preplanned box-jump cut maneuvers,[183] randomly cued or unanticipated 45-degree cuts,[14,15,78,183,205,206] unanticipated cross-cuts,[136] and unanticipated side cuts.[137] The majority of studies reported gender differences in muscle activation patterns, hip and knee flexion angles, and moments about the hip and knee. For instance, Beaulieu and colleagues[14,15] reported that female athletes had increased hip external rotation, knee abduction angles, and ankle pronation compared with male athletes on a randomly cued 45-degree cut. In addition, female subjects performed the task with greater lateral gastrocnemius activity than males and contracted their vastus lateralis more than their vastus medialis muscles. The authors concluded this muscular imbalance may be the reason the females struck the ground with a more abducted knee position compared with the males. Chaudhari and coworkers[46] observed a correlation between frontal plane lower limb alignment and knee moments, because subjects who assumed a valgus lower limb position during a 90-degree lateral run-to-cut maneuver had significantly higher knee abduction moments than those who had a neutral or varus lower limb position ($P < .01$). Of the 21 subjects tested, 67% of females assumed a lower limb valgus alignment, compared with 22% of males.

In a gender comparison of knee kinetics in three stop-jump tasks (Fig. 13-9), investigators found that women had significantly greater proximal anterior shear forces, extension moments, and valgus

TABLE 13-9 Significant Gender Differences During Running

Study	Subjects	Testing Protocol	Muscle Activation/ Timing	Knee, Hip Flexion Angles	Knee, Hip Moments
Chumanov et al[50] (2008)	17 female, 17 male recreational athletes	Straight run 1.2, 1.5, 1.8 m/s with surface inclinations of 0%, 10%, 15% grade Surface EMG	Females had greater gluteus maximus activity ($P < .001$) for all conditions.	Females had greater peak hip internal rotation ($P < .05$), adduction ($P < .001$), and lateral pelvic tilt excursion ($P < .001$) during stance for all conditions.	NA
Landry et al[136] (2007)	21 female, 21 male elite adolescent athletes	Straight run 0.5 s before planting and cutting Surface EMG	Females had lower lateral hamstring activity, higher quadriceps activity ($P < .01$), and greater lateral gastrocnemius activity ($P < .002$) than males. Females had greater lateral gastrocnemius activity than medial gastrocnemius activity ($P = .02$).	Females landed with greater hip adduction angles ($P = .01$).	Females landed with greater hip external rotation moments ($P < .05$) and knee extension moments ($P = .01$).
Ferber et al[74] (2003)	20 female, 20 male recreational athletes	Straight run	NA	Females had higher hip adduction ($P < .05$), knee abduction ($P < .05$), and hip internal rotation ($P = .01$) angles.	NA
Malinzak et al[152] (2001)	9 female, 11 male recreational athletes	Straight run Surface EMG	Females had greater quadriceps activation and lower hamstring activation during stance phase ($P < .001$).	Females had smaller knee flexion angles and greater knee valgus angles during stance phase ($P < .001$).	NA

Study	Subjects	Testing Protocol	Muscle Activation/ Timing	Knee, Hip Flexion Angles	Knee, Hip Moments
Beaulieu et al[15] (2009)	15 female, 15 male collegiate athletes	Randomly cued 45-degree cut Surface EMG	Females had greater lateral gastrocnemius activity than males and greater vastus lateralis activity than vastus medialis.	Females had increased hip external rotation ($P = .01$), knee abduction angles ($P = .05$), and ankle pronation ($P < .05$).	NA
Hanson et al[91] (2008)	20 female, 20 male collegiate athletes	Side-cut 60 degrees onto nondominant leg Surface EMG	Females had greater vastus lateralis activation before contact and stance phase ($P = .001$) and greater gluteus medius activation stance phase ($P = .01$).	NA	NA
Beaulieu et al[14] (2008)	15 female, 15 male collegiate athletes	Randomly cued 45-degree cut Surface EMG	Males had higher quadriceps activation at initial contact ($P = .01$) and at stance phase of cutting cycle ($P < .05$). Females had lower frequency lateral hamstring at initial contact ($P < .05$).	Females had greater knee valgus angles at initial contact ($P = .04$) and peak knee valgus angles ($P = .01$).	NA
Landry et al[136] (2007)	21 female, 21 male elite adolescent athletes	Unanticipated crosscut (cut to the right), 35- to 60-degree angle Surface EMG	Females had greater lateral gastrocnemius activity ($P < .001$), rectus femoris activity ($P < .001$), and reduced hamstring activity ($P = .05$).	Females had reduced hip flexion angles ($P = .01$) and increased ankle eversion angles ($P = .002$).	Females had reduced hip flexion moments ($P = .003$) and increased knee extension moments ($P < .05$) and knee adduction moments ($P < .05$) throughout stance.
Landry et al[137] (2007)	21 female, 21 male elite adolescent athletes	Unanticipated side-cut (cut to the right), 35- to 60-degree angle Surface EMG	Females had greater gastrocnemius ($P < .01$) and rectus femoris activity ($P = .05$).	Females had reduced hip flexion ($P = .01$) and greater hip external rotation ($P < .05$).	Females had smaller hip flexion moments ($P < .05$).
Pollard et al[207] (2007)	15 female, 15 male collegiate athletes	Side-cut from right onto left leg, 45 degrees	NA	Females had greater hip IR ($P = .01$) and decreased hip flexion ($P = .05$) during early deceleration.	Females had greater hip adductor moments ($P < .05$) and decreased hip extensor moments ($P = .04$).
Sigward & Powers[244] (2006)	15 female, 15 male collegiate athletes	Side-cut from right onto left leg, 45 degrees Surface EMG	Females had greater quadriceps activity ($P = .02$).	None	Females had smaller peak knee flexor moments ($P = .05$) and greater knee adductor moments ($P < .01$) during early deceleration.
McLean et al[157] (2005)	10 female, 10 male collegiate athletes	Side-cut, 35-55 degrees	NA	Females had larger hip IR and knee valgus angles ($P < .05$).	Females had larger peak knee valgus moments ($P < .05$).

Study	Subjects	Testing Protocol	Muscle Activation/ Timing	Knee, Hip Flexion Angles	Knee, Hip Moments
McLean et al[158] (2004)	8 female, 8 male subjects	Side-cut from right onto left leg, 30-40 degrees, with and without simulated defensive opponent	None	Females had larger peak knee valgus and rearfoot pronation angles and smaller peak hip flexion, hip abduction, hip IR, and knee flexion and IR angles ($P < .01$).	NA
Pollard et al[205] (2004)	12 female, 12 male collegiate athletes	Randomly cued 45-degree cut	NA	Females had less peak hip abduction ($P = .03$) during first 40 degrees of knee flexion of stance phase.	None
Malinzak et al[152] (2001)	9 female, 11 male recreational athletes	Side-cut (8-m approach run, dominant to nondominant leg) 45 degrees Cross-cut (8-m approach run, dominant leg only) 45 degrees Surface EMG	Females had greater quadriceps activation and lower hamstring activation during stance phase ($P < .001$).	Females had smaller knee flexion angles and greater knee valgus angles during stance phase ($P < .001$).	NA

EMG, Electromyography; *IR,* internal rotation; *NA,* not available.

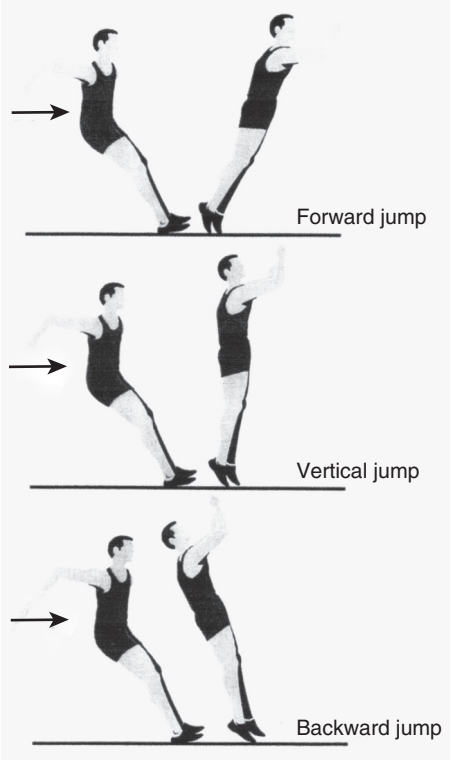

FIG 13-9 Three stop-jump tasks.

moments upon landing compared with men (Fig. 13-10).[44] Chappell and colleagues[44] believed that the observed increased proximal shear force was because of a high quadriceps muscle force, a low hamstring muscle force, a straight knee upon landing, or a combination of all of these factors. Chappell and associates[43] also assessed the effect of fatigue on knee kinetics in stop-jump tasks. Female subjects had significantly greater peak proximal tibial anterior shear forces than males, greater knee extension moments at peak proximal tibial anterior shear force, and smaller knee flexion angles ($P = .001$, all comparisons) in both unfatigued and fatigued states. The mean valgus moment at the peak proximal tibial anterior shear force of female subjects increased 96% from the unfatigued to fatigued condition. Male subjects decreased their mean valgus moments by 43% between test conditions. Chappell and colleagues concluded that fatigue increased the risk of ACL injury more in females than in males. In a third investigation by Chappell and colleagues,[42] female recreational athletes displayed less knee and hip flexion, less hip external rotation, and increased hip abduction than male athletes upon preparation for landing. The authors hypothesized that the athletes "preprogrammed" these lower extremity motions during the flight phase of the last step of the approach run in this task.

Yu and coworkers[284] studied lower extremity kinematics during a stop-jump task in soccer players aged 11 to 16 years. Female players older than 12 years of age had decreased knee and hip flexion angles than the male athletes on landing. Female players increased the amount of knee valgus motion as their age increased. However, male players older than 12 years of age demonstrated a varus knee angle at initial contact. The authors acknowledged the small sample size as a limitation of the study.

Sell and associates[232] conducted an investigation involving high school basketball players in which both planned and reactive stop-jump tasks were performed vertically, horizontally to the left, and

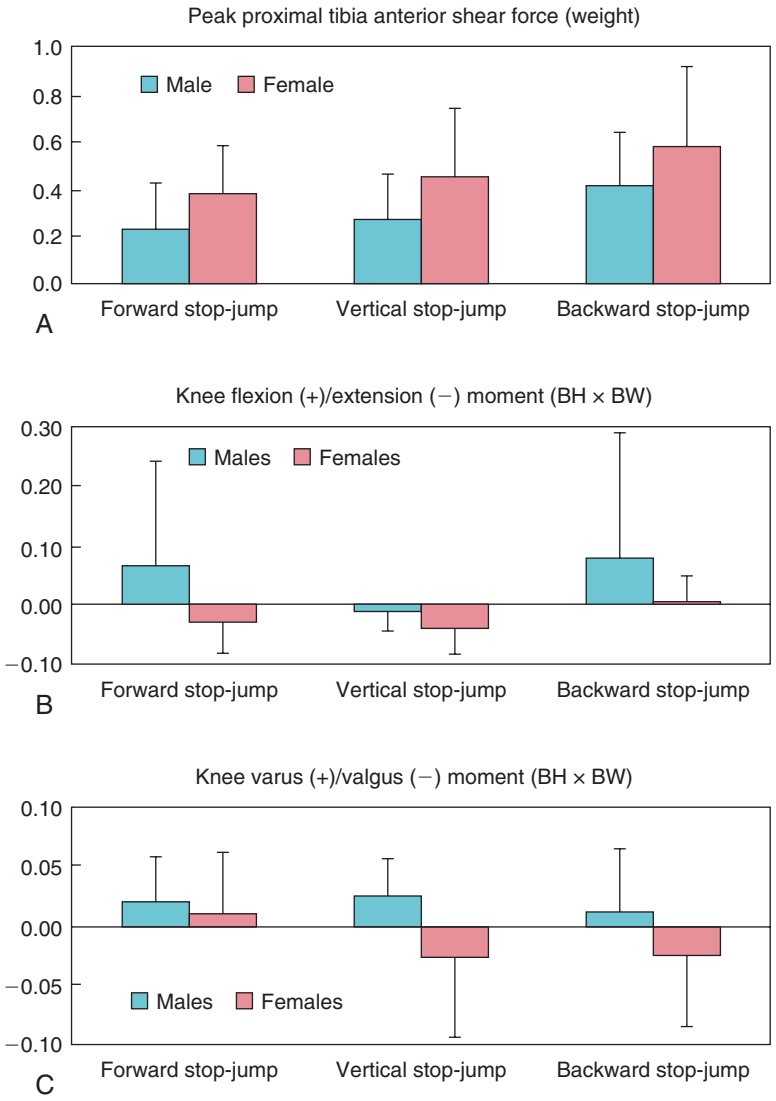

FIG 13-10 Comparisons of peak proximal tibia anterior shear force **(A),** knee flexion-extension moment **(B),** and knee varus-valgus moment **(C)** during the landing phase of three stop-jump tasks. The results are normalized by body weight (BW) (peak shear force) or by body height × body weight (BH × BW) (knee flexion-extension moment and varus-valgus moment). (Modified from Chappell JD, Yu B, Kirkendall DR, Garrett WE. A comparison of knee kinetics between male and female recreational athletes in stop-jump tasks. *Am J Sports Med.* 2002;30: 261-267.)

horizontally to the right. During the reactive tasks, females had lower maximum knee flexion angles than males ($P = .001$), greater maximum knee valgus angles ($P < .05$), greater anterior shear force at peak posterior GRF ($P < .05$), and greater knee flexion moment at peak posterior GRF ($P < .05$). During the horizontal jump to the left, females had significantly lower maximum knee flexion angles than males ($P = .007$), lower knee flexion at posterior GRF ($P = .006$), and greater knee valgus at posterior GRF ($P < .05$). The authors hypothesized that these differences could place greater strain on the female ACL.

FATIGUE

Many ACL injuries occur in the later stages of competition, and several investigators have examined the effects of fatigue on factors such as motor control performance,[123,281] neuromuscular control,[281] knee joint laxity,[218,281] and proprioception.[103,139,167,247] Some investigators found gender differences following fatigue protocols in muscle activation patterns, joint angles, and joint moments (Table 13-11). However, several other studies have failed to identify gender differences in terms of changes in muscle strength or body mechanics.[20,33,43,143,262] Overall, it appears that most fatigue protocols affect landing biomechanics regardless of gender.[20,33,43,143] In a systematic review of fatigue investigations, Santamaria and Webster[224] recommended development of a standardized fatigue protocol, confirmation that fatigue has been reached in all subjects, use of unanticipated single-leg landing tasks, and assessment of all joints of the limb and core before and after fatigue.

CONCLUSION

To determine which risk factors for noncontact ACL ruptures are significant and which may play a more negligible role, future investigations must include greater sample sizes, include analyses of factors in all of the major categories (anatomic, environmental, hormonal, and neuromuscular), and follow athletes for at least one entire athletic

TABLE 13-11 Significant Gender Differences Following Fatigue Protocols

Study	Subjects	Testing Protocol	Muscle Activation/ Timing	Knee, Hip Flexion Angles	Knee, Hip Moments
Liederbach et al[143] (2014)	40 female, 40 male, ballet dancers and team sport athletes	Single-leg drop-jump 30 cm; sets of stepping and jumping protocol until 10% decrease in maximum vertical jump height	Female ballet dancers took significantly longer to reach fatigue ($P = .02$) than athletes did.	All subjects had decreased hip external rotation angle ($P < .01$) and increased knee flexion angle ($P < .001$).	All subjects increased peak knee valgus moments ($P < .05$), decreased peak hip adduction moments ($P < .05$), and increased hip internal rotation moments ($P = .001$).
Thomas et al[262] (2010)	12 female, 13 male, collegiate recreational athletes	Single-leg forward hop, dominant side; reps of five alternating quadriceps-hamstring maximum voluntary concentric contractions until torque dropped <50% of baseline	Quadriceps and hamstring decreased torque production 15%. No effect of gender. Women had larger peak vertical GRF ($P < .05$).	All subjects had increased hip internal rotation at initial contact. Females landed with greater hip flexion; males had greater hip abduction. All subjects increased knee extension and external rotation. Females landed with greater hip and knee flexion.	All subjects had increased knee extension moments and decreased knee flexion and external rotation moments. Females landed with less hip abduction.
Brazen et al[33] (2010)	12 female, 12 male collegiate athletes	Single-leg drop landings 0.36 m; course consisting of 4 ladder drills, side-to-side bounds, minitrampoline jumps, minihurdle hops, and vertical jumps	Anterior-posterior and vertical time to stabilization increased in all subjects, demonstrating reduced postural stability. All subjects landed with greater peak vertical GRF ($P = .002$).	All subjects increased knee flexion and ankle plantar flexion angles ($P = .01$). No change in knee valgus angles.	NA
Gehring et al[82] (2009)	13 female, 13 male recreational athletes	Two-leg drop-jump 52 cm; reps in leg press at 50% of their 1-rep maximum until unable to achieve this load	Females landed with increased knee flexion velocities ($P < .01$) and had delayed activation lateral hamstring and vastus lateralis ($P < .05$) preparatory phase.	Females landed with greater knee abduction angles ($P < .01$).	NA
Benjaminse et al[20] (2008)	15 female, 15 male physically active, age 18-30 yr	Single-leg stop-jump; treadmill run maximum effort to exhaustion	No gender difference in time to fatigue.	All subjects had decreased maximal knee valgus and knee flexion angles on initial contact.	NA
Kernozek et al[125] (2008)	14 female, 16 male recreational athletes	Single-leg drop-jump 50 cm; reps in parallel squat; Smith machine at 60% of their 1-rep maximum until unable 4 times	Females landed with greater anterior knee shear force than men did ($P = .01$).	Men landed with higher knee flexion angles than women ($P < .05$).	None
McLean et al[156] (2007)	10 female, 10 male collegiate athletes	Two-leg drop-jump 50 cm; series of continuous jump drills for 4 minutes	NA	Females landed with increased ankle plantar flexion initially, then peak stance knee abduction, knee internal rotation, and ankle supination angles ($P < .001$).	Females had increased knee abduction and internal rotation moments ($P < .01$). Females had smaller ankle dorsiflexion moments ($P = .001$).

TABLE 13-11 Significant Gender Differences Following Fatigue Protocols—cont'd

Study	Subjects	Testing Protocol	Muscle Activation/ Timing	Knee, Hip Flexion Angles	Knee, Hip Moments
Pappas et al[196] (2007)	16 female, 16 male recreational athletes	Two-leg drop-jump 40 cm; 100 consecutive jumps over obstacles and 50 maximal vertical jumps	Females landed with higher normalized vertical GRF ($P = .003$).	Females landed with greater knee valgus ($P = .001$).	NA
Chappell et al[43] (2005)	10 female, 10 male recreational athletes	3 stop-jump tasks; unlimited reps of 5 vertical jumps followed by 30-m sprint until exhaustion	Peak proximal anterior tibial shear force increased in all ($P < .01$). Women had greater shear force than men across fatigue states and tasks.	Knee flexion angle decreased in all subjects ($P = .03$). Women had smaller knee flexion angles across fatigue states and tasks.	Knee valgus moment increased in all subjects ($P = .03$). Knee valgus moment increased 96% in women. No effect of knee extension moment.

GRF, Ground reaction forces; *NA,* not available.

season for injury. Epidemiologically sound study methodology must be followed, including tracking injury exposures and conducting power analyses to avoid a type II statistical error. Athletes from multiple sports should be included to determine whether certain factors are sport specific in terms of injury risk. Future studies need to incorporate reactive tasks because there appear to be significant differences in movement and muscle activation patterns under these conditions versus those of controlled preplanned maneuvers. As technology improves, these studies may be able to move from the laboratory and measure neuromuscular indices under actual playing conditions.

SCIENTIFIC RATIONALE AND SUPPORTING INVESTIGATIONS FOR SPORTSMETRICS NEUROMUSCULAR RETRAINING PROGRAM

This chapter presents the scientific rationale, supporting data, and specific strategies for the implementation of Sportsmetrics, a neuromuscular knee ligament injury prevention training program. Since Sportsmetrics was first introduced to the medical community by the senior author (F.R.N.) and associates in 1996,[25] at least 50 other so-called *anterior cruciate ligament (ACL) injury prevention programs* have followed that are focused on female athletes.[5] Many investigations have been conducted to determine the effectiveness of these programs in reducing ACL injury rates,[16,24,31,33,38,43,54-56,63,68] improving knee kinematic and kinetic factors,* and enhancing athletic performance indicators.†

There exist differences in opinion among investigators regarding the frequency, intensity, duration, and components that should comprise an ACL intervention training program. One issue is whether a true reduction in the injury rate can be accomplished with *warmup programs* that are relatively short in session duration (10-20 minutes) but long in total training duration (for instance, one season). This is in contrast to *preseason programs* that last 6 to 8 weeks but require 60 to 120 minutes of training per session. A second issue is whether ACL intervention training should be modified according to the athlete's age and sport. A third issue is whether athletes may be identified as having a high risk of sustaining a noncontact ACL injury and thus whether they should undergo a different training program than those who are at a lower risk for this injury. There does not exist to date an accurate prediction model for ACL injury according to all of the potential risk factors discussed in Chapter 13.

We recently reviewed all published ACL neuromuscular retraining programs to determine those that significantly reduce the incidence of noncontact ACL injuries in female adolescent athletes (Table 14-1).[46] Only eight studies were found that assessed noncontact ACL injury rates in these athletes according to athlete exposures (AEs).[24,31,33,38,53,56,63,68] Three programs—Sportsmetrics, Prevent Injury and Enhance Performance,[38] and Knee Injury Prevention[33]—were found to be effective in reducing noncontact ACL injuries. Unfortunately, several programs[16,31,43,53-56,63,68] failed to have an effect on reducing the ACL injury rate. Issues related to poor compliance with training and too few ACL injuries to avoid a type II statistical error were commonly cited as the reasons for the outcomes of these investigations. In general, ACL intervention programs published to date have had methodologic problems that preclude definitive answers regarding which programs are effective and which are ineffective. These include lack of randomization and control, limited statistical power because of the small number of exposures and ACL injuries, failure to determine ACL injury incidence according to AEs, poor compliance with training, poor documentation of contact versus noncontact ACL injuries, and changes in study protocols over the course of the investigations.

The Sportsmetrics program is proven effective in inducing changes in neuromuscular indices in female athletes because studies have

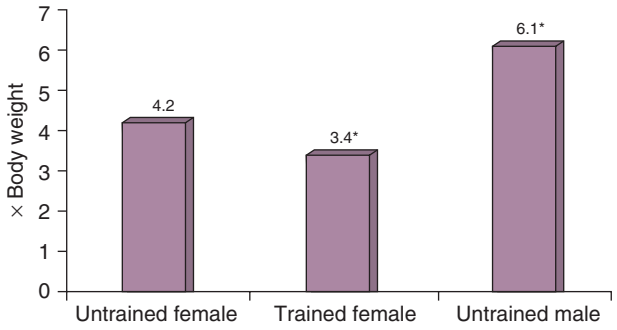

FIG 14-1 Decrease in peak landing forces with training in female subjects before and after training and relative to age- and weight-matched male athletes. *$P < .01$. (From Hewett TE, Stroupe AL, Nance TA, Noyes FR. Plyometric training in female athletes: decreased impact forces and increased hamstring torques. *Am J Sports Med.* 1996; 24:765-773.)

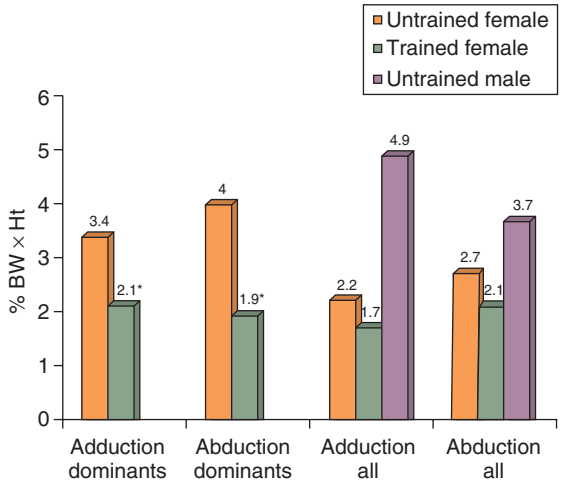

FIG 14-2 Peak knee adduction and abduction moment data at landing before and after training. The female subjects were grouped according to the dominant moment (adduction or abduction) and all the female subjects grouped together (all). *$P < .05$ compared with untrained females. *BW,* Body weight; *Ht,* height. (From Hewett TE, Stroupe AL, Nance TA, Noyes FR. Plyometric training in female athletes: decreased impact forces and increased hamstring torques. *Am J Sports Med.* 1996;24:765-773.)

shown improved overall lower limb alignment on a drop-jump test,[7,47-50] increased hamstring strength,[25,47,70] increased knee flexion angles on landing,[25,58] and reduced deleterious abduction and adduction moments and ground reaction forces.[25] Sportsmetrics significantly reduces the risk of noncontact ACL injuries in female athletes participating in basketball and soccer.[24,46] In addition, this program enhances athletic performance indicators in female soccer,[50] basketball,[49] volleyball,[48] and tennis[4] players.

A pilot laboratory study was conducted at our institution using 11 high school female volleyball players to determine the effect of Sportsmetrics training on landing mechanics and lower extremity strength.[25] The control group consisted of nine male subjects matched for height, weight, and age. Training was performed three times per week for 6 weeks. Before and after the training program, the athletes completed isokinetic muscle testing at 360 degrees/sec and force analysis testing to measure motions and ground reaction forces during volleyball jumping and landing maneuvers.

After 6 weeks of training, peak landing forces from a volleyball block jump decreased 22% ($P = .006$), or an average of 456 N (103 lb) (Fig. 14-1). Knee adduction and abduction moments decreased approximately 50% (Fig. 14-2). Decreased abduction or abduction moments may lessen the risk of liftoff of the medial or lateral femoral condyle, improve tibiofemoral contact stabilizing forces,[39] and reduce the risk of knee ligament injury. In addition, the female athletes demonstrated lower landing forces than male athletes and lesser adduction and abduction moments compared with pretraining values. Hamstring-to-quadriceps muscle peak torque ratios increased 26% on the nondominant side and 13% on the dominant side, correcting side-to-side imbalances.

A second study was conducted in 62 high school female athletes to determine whether Sportsmetrics training altered lower limb alignment on a drop-jump task and improved isokinetic lower limb muscle strength.[47] Before training, 80% of the female athletes had a valgus overall lower limb alignment on landing from a drop-jump. After training, 34% of the females demonstrated this alignment ($P < .0001$).

Significant increases were noted after training in knee flexion peak torque in both the dominant and nondominant limbs ($P < .0001$).

Sportsmetrics training has been shown to significantly reduce the incidence of noncontact ACL injuries in female adolescent athletes. Our research institution[24,46] followed 700 females who underwent Sportsmetrics training, as well as 1120 female controls and 434 male control athletes. All athletes were followed throughout their sports seasons for injury documentation. The total numbers of AEs were 36,724 for the trained group, 61,244 for the control female group, and 21,390 for the control male group. Noncontact ACL injuries were sustained in 1 trained female athlete, 13 control female athletes, and 1 control male athlete. The knee injury incidence per 1000 AEs was 0.03 in trained female athletes, 0.49 in control female athletes, and 0.09 in male athletes ($P = .03$).

We recently reviewed the effectiveness of Sportsmetrics training in 1000 female athletes 13 to 18 years of age who participated in a variety of sports activities. There were statistically significant improvements and large effect sizes (ESs) in overall lower leg alignment in the coronal plane on the drop-jump test ($P < .0001$; ES = 0.97). Before training, 79% had a valgus alignment appearance on landing. The program markedly improved the alignment in 75% of these athletes. There were significant improvements in the single-leg triple-crossover hop in the mean distance hopped (33 cm; $P < .0001$; ES = 0.47). In addition, 13% had abnormal limb symmetry on this test before training, whereas only 2% were rated as having abnormal symmetry after completing the program. There were significant improvements in the agility *t* test ($P < .0001$; ES = 0.64) and the multistage fitness test (MSFT) ($P < .0001$; ES = 0.57). Isokinetic hamstring strength significantly improved ($P < .0001$; ES = 0.57 dominant, ES = 0.61 nondominant), as did quadriceps strength ($P < .01$; ES = 0.27 dominant, ES = 0.35 nondominant). Significant improvements, but low ESs, were found in the vertical jump and sit-up tests.

We also compared the difference in noncontact ACL injury rates between a subset of 700 trained athletes with that of 700 untrained athletes matched for age, sport, and body mass index. The subgroup of 700 trained athletes had a significant reduction in the noncontact ACL injury incidence rate (according to AEs) compared with the control group. The trained group had 36,724 AEs and 1 ACL injury, whereas the control group had 61,244 AEs and 13 ACL injuries (incidence rates, 0.03 and 0.21 per 1000 AEs, respectively; $P = .03$).

The risk factors that have been hypothesized to increase the potential for an ACL injury are discussed in Chapter 13. The final position of the knee joint on landing, pivoting, and cutting is influenced by the center of gravity of the upper body and the trunk over the lower extremity. Equally important are the factors of trunk-hip adduction or abduction, foot-ankle pronation-supination, and foot separation distance. These effects additively produce either a varus or valgus moment about the knee joint that must be balanced by the lower limb musculature. If the athlete is off balance or contacts another player, a loss of trunk and lower limb control and position may occur and the knee joint may go into a hyperextended or valgus position. Although there are many potential mechanisms for ACL injury, it has been postulated that excessive valgus moments about the knee joint, with subsequent high anterior tibial shear forces, may be one of the most common to occur in females.[18,27,37] Excessive valgus loading may result in decreased tibiofemoral contact, or condylar liftoff,[39] and a reduction in the normal joint contact geometry that contributes to knee joint stability. This position, coupled with a highly activated quadriceps muscle that produces maximum anterior shear forces with the knee joint at low flexion angles (0-30 degrees)[10,20,52] and a relatively inactive hamstring musculature, could potentially lead to ACL rupture. The function of the hamstrings is dependent on the angle of knee flexion and degrees of external tibial rotation.[51] The mechanical advantage of these muscles increases as the knee is flexed because at 0 degrees of extension, the flexion force is only 49% of that generated at 90 degrees of flexion. Withrow et al.[71] speculated that it may be possible to limit ACL strain by accentuating hip flexion during the knee flexion phase of jump landings because this increases the tension in the active hamstring muscles.

The time within which an ACL rupture occurs has been estimated to range from 17 to 50 milliseconds after initial ground contact.[32] It is evident that there is not enough time for an athlete, upon sensing a knee injury about to occur, to alter the body's or lower extremity's position to prevent this injury. To have a significant impact on reducing the incidence rate of noncontact ACL tears, the goals of a training program are to teach athletes to control the upper body, trunk, and lower body position; lower the center of gravity by increasing hip and knee flexion during activities; and develop muscular strength and techniques to land with decreased ground reaction forces. Athletes should be taught to pre-position the body and lower extremity before initial ground contact to obtain the position of greatest knee joint stability and stiffness. This includes avoidance of sudden deceleration and cutting and pivoting with an extended knee that induces a large quadriceps contraction. The program should consist of a dynamic warmup, plyometric jump training, strengthening exercises, agility and aerobic conditioning, and risk awareness training.[19]

SPORTS INJURY TEST

We developed a sports injury test (SIT) to obtain a profile of each athlete before and after Sportsmetrics training. Before testing begins, a history is collected regarding prior injuries to the knees and ankles. The SIT is completed just before training begins and then again within 1 week after the program is completed. The SIT measures (1) knee and ankle position on landing and takeoff from a drop-jump during a video test, (2) lower limb symmetry[2,45] and a general assessment of lower limb control on single-leg hop tasks (Fig. 14-3), (3) hamstring flexibility, and (4) vertical jump height (countermovement and two-step approach). Athletes participating in sport-specific Sportsmetrics programs, discussed later in this chapter, also undergo additional agility, speed, and aerobic tests as required for their sport. These may include a *t* test, 37-meter sprint, 18-meter sprint, MSFT, sit-up test, and 1-mile run.[48-50] Tennis players perform a series of tests on the court, including a suicide sprint, service box and baseline speed and agility tests, and a medicine ball toss described elsewhere.[4]

SPORTSMETRICS ESSENTIAL COMPONENTS

There are four essential components of Sportsmetrics: dynamic warmup, plyometric jump training, strengthening, and flexibility. It is recommended that training be conducted either during the off-season or just before the start of the athlete's sport season. The training is conducted three times per week on alternating days for 6 weeks. As described later in this chapter, sport-specific speed and agility components may be added to the training program if desired by an athlete or team. A maintenance training program (Sportsmetrics Warm-up for Injury Prevention and Performance [WIPP]) may be performed upon completion of the formal Sportsmetrics program to continue to instill the skills and techniques learned during the athlete's sports season. Training may be accomplished either in classes led by an instructor who has completed certification training from our foundation or by following an instructional step-by-step DVD series. Athletes who do not train with a certified instructor are encouraged to perform training either in front of a mirror or with a partner so that mistakes in technique, form, and body alignment may be detected and

FIG 14-3 Single hop for distance video screening allows a qualitative assessment of an athlete's ability to control the upper and lower extremities upon landing, which may be rated as either good (**A**), fair (**B**), or complete failure, fall to ground (**C**).

corrected. A list of certified instructors and sites is available at www.sportsmetrics.org.

Dynamic Warmup

The dynamic warmup prepares the body using function-based activities that incorporate sport-specific motions. The goals are to raise core body temperature, increase heart rate, increase blood flow to the muscles, and improve flexibility, balance, and coordination. Upon completion of this warmup, the athlete will be physically prepared for training. All of these exercises should be performed across the width of a court or field or for approximately 20 to 30 seconds.

1. **Toe walk.** The athlete walks up on the toes with the legs straight. The heel of the foot should not touch the ground, and the hips should remain neutral throughout.
2. **Heel walk.** The athlete walks on the heels with the legs straight. The toes should not touch the ground; the knees should not lock; and the hips should remain neutral.
3. **Straight-leg march**. The athlete walks with both legs straight, alternating lifting up each leg as high as possible without compromising form. The knees are kept straight and posture is erect, and the body should not lean backward. The arms are swung in opposition.
4. **Leg cradle** (Fig. 14-4). The athlete walks forward, keeping the entire body straight and neutrally aligned. One leg is lifted in front of the body, bent at the knee. The knee is rotated outward and the foot inward. The foot is held with both hands while standing on one leg, and this position is held for 3 seconds. The foot is placed back down, and the exercise is repeated with the opposite leg.
5. **Dog and bush (hip rotator) walk** (Fig. 14-5). The athlete is instructed to pretend that there is an obstacle directly in front of her or him. The athlete faces forward and keeps the shoulders and hips square. One leg is extended at the hip, and the knee is kept softly bent. The leg is externally rotated out at the hip, and the knee is bent to approximately 90 degrees. The leg is rotated and brought up and over the obstacle and then placed back on the ground. The exercise is repeated with the opposite leg.
6. **High-knee skip.** The athlete begins to skip. One knee is driven up in the air as high as possible while the other leg is used to hop off the ground. As the athlete lands, the exercise is immediately repeated on the opposite side. The opposite arm of the high knee is swung up in the air to help gain height.
7. **High knees.** The athlete begins to jog forward. With each step, the knees are driven up as high as possible using short, choppy steps. The athlete remains facing forward, keeping the shoulders and hips square throughout the exercise.
8. **Glute kicks.** The athlete begins to jog forward. With each step, the athlete kicks the feet back as if trying to reach the glutes with the heel, using short, choppy steps. The athlete remains facing forward, keeping the shoulder and hips square throughout the exercise.
9. **Stride out.** The athlete begins jogging forward with an exaggerated running form. The knees are driven as high as possible and the feet are kicked back, as if trying to make a large complete circle

FIG 14-4 Leg cradle.

with the legs. The athlete should stay up on the balls of the feet throughout the exercise.

10. **All-out sprint.** The athlete sprints forward as fast as possible while maintaining proper technique and running form.

Plyometrics/Jump Training

Plyometrics help develop the muscle control and strength considered critical to reducing the risk of knee ligament injuries. These exercises are well known to increase muscular power, vertical jump height, acceleration speed, and running speed.[29,36,59,60,65] However, if done improperly, plyometrics would not be expected to have a beneficial effect in reducing the risk of a noncontact ACL injury. Therefore the philosophy of the plyometric and jump-training component in the Sportsmetrics program is to place a major emphasis on correct jumping and techniques throughout the 6 weeks of training. Specific drills and instruction are used to teach the athlete to pre-position the entire body safely when accelerating or decelerating on landing. The selection and progression of the exercises entail neuromuscular retraining and proceed from simple two-legged jumping drills (to instill correct form) to multidirectional single-foot hops and plyometrics with an emphasis on quick turnover (to add movements that mimic sport-specific motions). The jump training is divided into three 2-week phases. Each 2-week phase has a different training focus, and the exercises change correspondingly (Table 14-2).

The aim of phase 1, termed the *technique development phase,* is to teach the athlete proper form and technique for eight different jumps. Four basic techniques are stressed: correct posture and body alignment throughout the jump (spine erect, shoulders back, chest over knees); jumping straight up with no excessive side-to-side or forward-backward movement; soft landings, including toe-to-midfoot rocking and bent knees; and instant recoil preparation for the next jump. The athletes are taught these techniques through verbal queues from instructors, such as "On your toes," "Straight as an arrow," "Light as a feather," "Shock absorber," and "Recoil like a spring." Constant feedback is offered by instructors, and mirrors are used in the training sessions to provide direct visual feedback if possible. Throughout each session, exercises are increased by duration or repetition. If the athlete becomes fatigued and cannot perform the jumps with the proper technique, he or she is encouraged to stop and rest. Approximately 30 seconds of recovery time is allowed between each exercise.

In phase 2, called the *fundamentals phase,* emphasis continues to be on proper technique and quality jumping form. Five jumps from phase 1 are continued, but these are performed for longer periods of time. In addition, four new jumps of increased difficulty are incorporated.

In phase 3, the *performance phase,* the quantity and speed of the jumps are increased to develop a truly plyometric exercise routine. The athlete is encouraged to complete as many jumps as possible with proper form and to concentrate on the height achieved in each jump.

1. **Wall jump** (weeks 1-6). Also known as *ankle bounces,* these jumps are performed with the knees slightly bent and both arms raised over the head (Fig. 14-6, *A*). From this position, the athlete bounces up and down off his or her toes (Fig. 14-6, *B*). The knees should be soft and the hips, knees, and ankles in neutral alignment. This jump is performed first to prepare the athlete mentally and physically for plyometric training. This also provides the trainer with an opportunity to observe and begin positive feedback and instruction.

   Mistakes to correct include slouched posture, too much knee flexion, and eyes watching the feet with the head down. The athlete should be told to keep the eyes and head focused upward, bend the knees slightly, and maintain neutral alignment.

2. **Tuck jump** (weeks 1-6). The athlete begins in an upright neutral stance with the feet shoulder width apart (Fig. 14-7, *A*). The athlete jumps up, bending the knees together to bring the thighs up toward the chest as high as possible (Fig. 14-7, *B*).

   Mistakes to correct include lowering the chest to the knees rather than lifting the knees to the chest, bringing the knees together during takeoff or landing, double-bouncing between jumps, and producing a loud landing with a lack of muscle control. The athlete should be told to lift the knees up to the chest, control and keep the landing quiet, land on the balls of the feet,

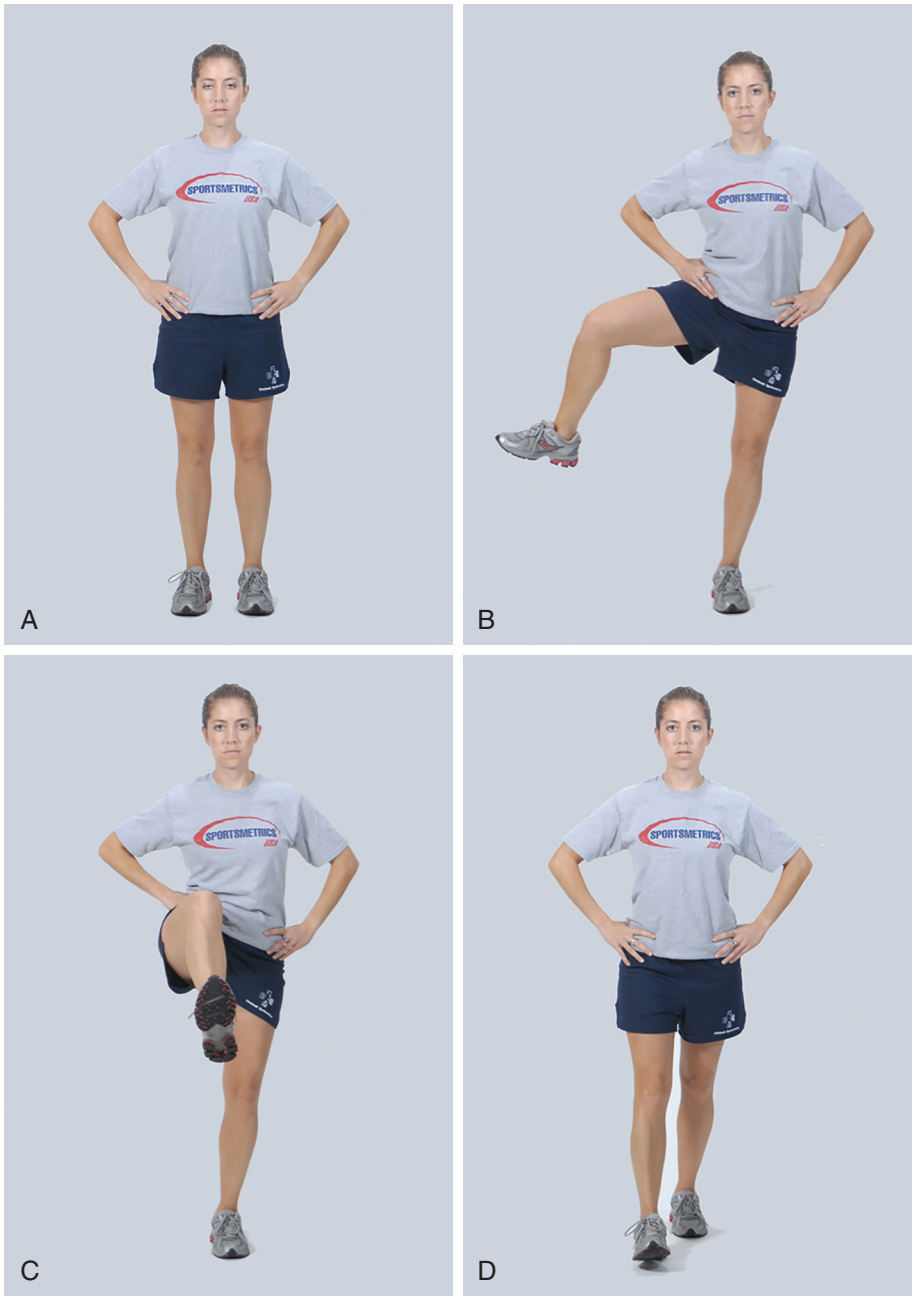

FIG 14-5 Dog and bush walk.

keep the knees bent when landing to go immediately into the next jump, keep the knees and ankles at shoulder and hip width at all times, keep the back straight and shoulders back, and keep the head and eyes up with each jump.

3. **Squat jump** (weeks 1-6). The athlete begins in a fully crouched position as deep as comfortable (Fig. 14-8, *A*). The knees and feet are directed forward and are in alignment with the hips. The upper body is upright with the chest open. The hands touch or reach toward the ground on the outside of the heels. The athlete jumps up, reaching as high as possible (see Fig. 14-8, *B*), and then returns to the crouched position with hands reaching back toward the heels (see Fig. 14-8, *C*).

   Mistakes to correct include landing with body and/or knees forward and/or off-balance, bringing the knees together during takeoff or landing, and producing a loud landing with a lack of muscle control. The athlete should be told to keep the hands reaching back toward the heels (not forward), keep the knees tracking under the hips on takeoff and landing, maintain the knees and ankles at shoulder and hip width at all times, keep the back straight and the shoulders back, and keep the head and eyes up with each jump.

4. **Barrier jump side to side** (weeks 1 and 2). A cone or barrier approximately 6 to 8 inches in height is used. The athlete stands in a modified squat position (Fig. 14-9, *A*). The athlete then jumps from one side of the barrier to the other side with the feet kept together (Fig. 14-9, *B*) and lands in the same amount of knee flexion as the starting position (Fig. 14-9, *C*).

   Mistakes to correct include landing or taking off with stiff, straight, or wobbly knees; jumping side to side quickly without bringing the entire body over the barrier; double-bouncing on landing

TABLE 14-2 Sportsmetrics Neuromuscular Training Program: Jump Training Component

Phase	Jumps	Duration		Emphasis, Goals
1: Technique Development		Week 1	Week 2	Proper form and technique for each jump
	Wall jump	20 seconds	25 seconds	Correct posture, body alignment throughout each jump
	Tuck jump	20 seconds	25 seconds	Jump straight up with no excessive side-to-side or forward-backward movement
	Squat jump	10 seconds	15 seconds	Soft landings that include toe-to-midfoot rocking and bent knees
	Barrier jump (side to side)	20 seconds	25 seconds	Deep knee flexion
	Barrier jump (forward and back)	20 seconds	25 seconds	Instant recoil preparation for the next jump, no double-bouncing
	180-degree jump	20 seconds	25 seconds	
	Broad jump (stick 5 seconds)	5 reps	10 reps	
	Bounding in place	20 seconds	25 seconds	
2: Fundamentals		Week 3	Week 4	Proper technique to build a base of strength, power, agility
	Wall jump	25 seconds	30 seconds	Focus on well-performed, quality jumps
	Tuck jump	25 seconds	30 seconds	Same jumps from phase 1 done for longer duration
	Jump, jump, jump, vertical jump	5 total	8 total	New, more difficult jumps introduced to build on skills mastered from phase 1
	Squat jump	15 seconds	20 seconds	
	Barrier hop side to side	25 seconds	30 seconds	
	Barrier hop forward and back	25 seconds	30 seconds	
	Scissors jump	25 seconds	30 seconds	
	Single-leg hop (stick)	5 reps	5 reps	
	Bounding for distance	1 run	2 runs	
3: Performance		Week 5	Week 6	Enhance basic skill and muscle control learned in first two phases
	Wall jump	20 seconds	20 seconds	Increase quantity, speed of jumps with well-performed, quality jumping technique
	Jump up, down, 180 degrees, vertical	5 total	10 total	
	Squat jump	25 seconds	25 seconds	
	Mattress jump side-side	30 seconds	30 seconds	
	Mattress jump forward-back	30 seconds	30 seconds	
	Hop, hop, hop, stick	5 reps	5 reps	
	Jump into bounding	3 runs	4 runs	

FIG 14-6 Wall jump.

FIG 14-7 Tuck jump.

FIG 14-8 Squat jump.

and takeoff; and not landing with the feet together. The athlete should be told to bend the knees up to clear the barrier, land quietly on the balls of the feet and rock back to the heels, control the landing to be able to immediately take off again, keep the back straight with the shoulders back, keep head and eyes up with each jump, keep the knees tracking under the hips and toes pointed forward on takeoff and landing, and keep the feet parallel to each other.

5. **Barrier jump forward-backward** (weeks 1 and 2). A cone or barrier approximately 6 to 8 inches in height is used. The athlete stands facing the barrier in a modified squat position (Fig. 14-10, *A*). The athlete jumps forward and backward with the feet kept together (Fig. 14-10, *B*) and lands in the same amount of knee flexion as the starting position (Fig. 14-10, *C*).
   Mistakes to correct include landing or taking off with stiff, straight, or wobbly knees; jumping forward and backward quickly

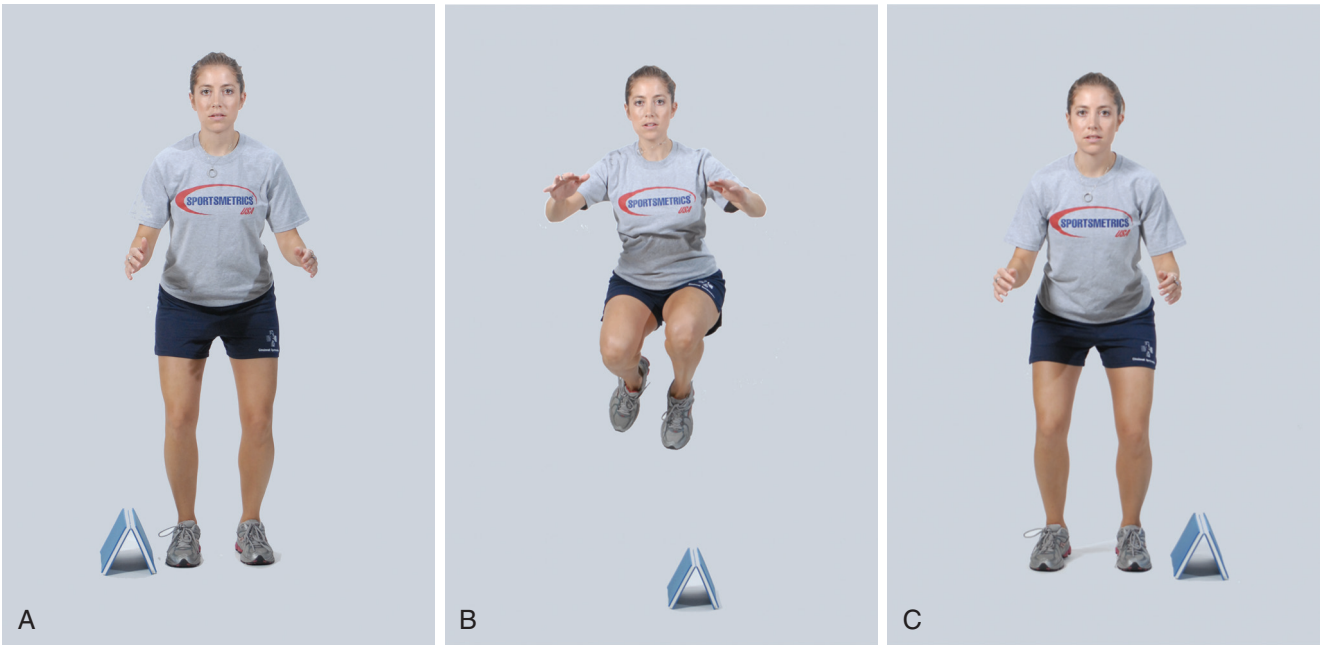

FIG 14-9 Barrier jump side to side.

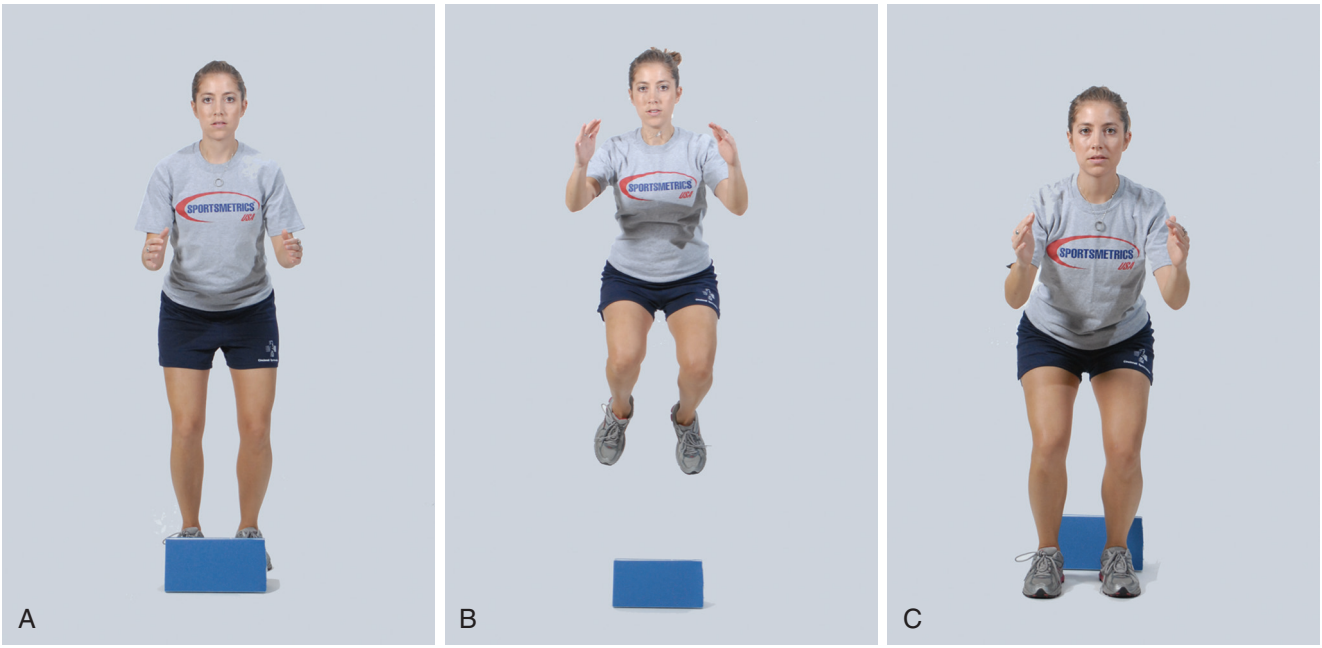

FIG 14-10 Barrier jump forward and backward.

without bringing the entire body over the barrier; double-bouncing on landing and takeoff; and separating the feet to clear the barrier. The athlete should be told to lift the knees up to the chest to clear the barrier, land quietly on the balls of the feet and rock back to the heels, control the landing to be able to immediately take off again, keep the back straight with the shoulders back, keep the head and eyes up with each jump, and keep the knees tracking under the hips and the toes pointed forward on takeoff and landing.

6. **180-degree jump** (weeks 1 and 2). The athlete begins from an upright neutral stance with the feet shoulder width apart (Fig. 14-11, *A*). The athlete jumps straight up into the air with both feet and makes a 180-degree turn in midair (Fig. 14-11, *B*) before landing (Fig. 14-11, *C*). The landing is held for 2 seconds, and then the direction is reversed and the jump repeated.

Mistakes to correct include overrotating or underrotating; not turning the body 180 degrees; not rotating the body as a unit; landing loud, straight, and stiff-legged, with staggered feet or one foot landing before the other; always jumping in the same direction (in a circle); rotating back and forth with minimal height during the jump; and separating the feet beyond the desired "feet, shoulder, and/or hip width" distance.

The athlete should be told to jump straight upward and rotate the body as a unit from the head to the toes; land with soft, slightly

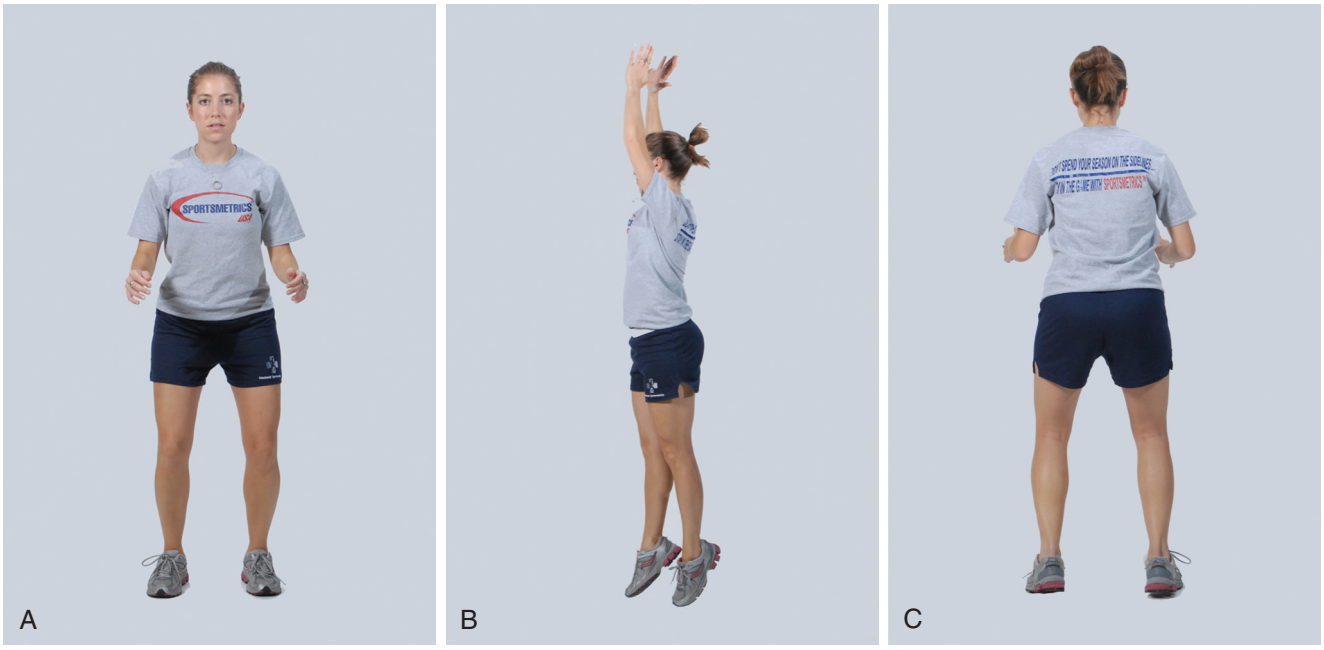

FIG 14-11 A 180-degree jump.

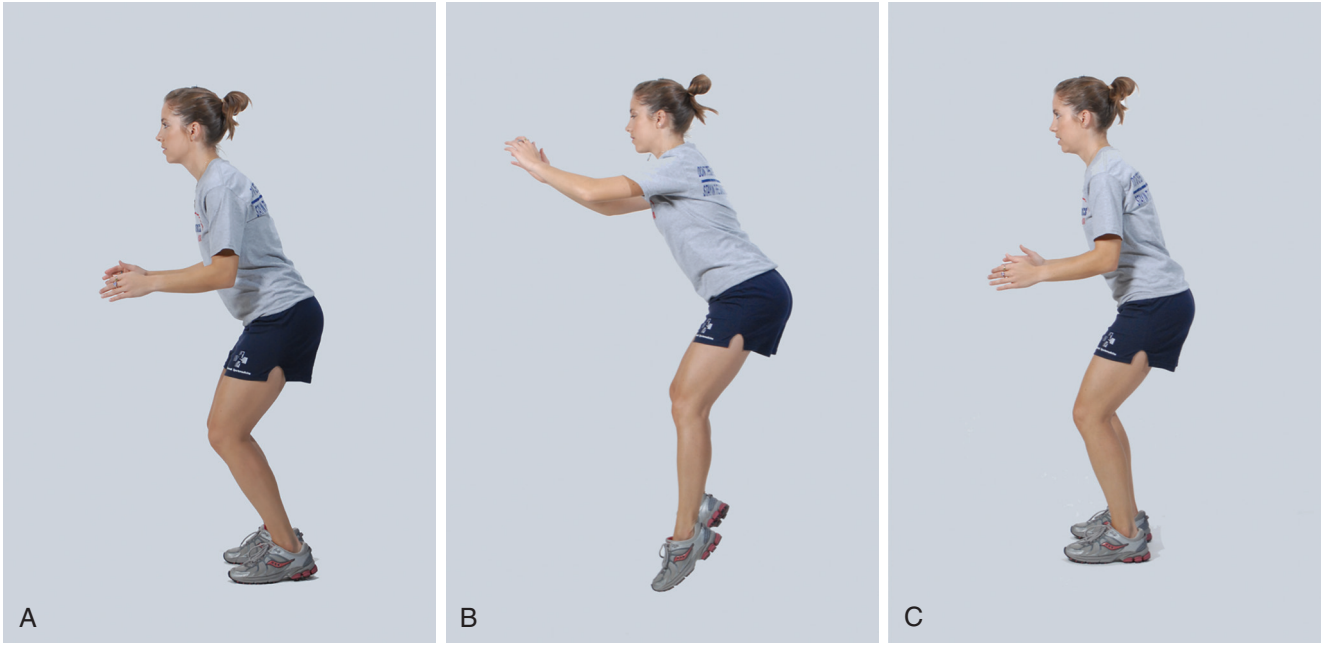

FIG 14-12 Broad jump.

flexed knees; always jump in opposing directions (one jump over the right shoulder, the next over the left); keep the knees tracking under the hips on takeoff and landing; maintain the knees and ankles at shoulder and/or hip width at all times; keep the back straight with the shoulders back; and keep the head and eyes up with each jump.

7. **Broad jump** (weeks 1 and 2). The athlete starts from an upright neutral stance (Fig. 14-12, *A*) and jumps forward as far as possible (see Fig. 14-12, *B*), taking off with both feet. The athlete lands on both feet, remains in a deep crouch position (see Fig. 14-12, *C*) for 5 seconds, and then repeats the jump.

   Mistakes to correct include not holding or sticking the landing, pointing the knees inward during landing and takeoff, and landing in a straight-legged or upright position. The athlete should be told to track the knees over the heels and under the hips on takeoff and landing, land with a soft toe-ball-heel rock with the knees flexed, and hold the landing for 5 seconds.

8. **Bounding in place** (weeks 1 and 2). The athlete begins this jump on a single leg, with the opposite leg bent behind. While the athlete stays in one place, the leg positions are alternated by driving the back leg forward and upward. The rhythm and height are progressively increased throughout the exercise (Fig. 14-13).

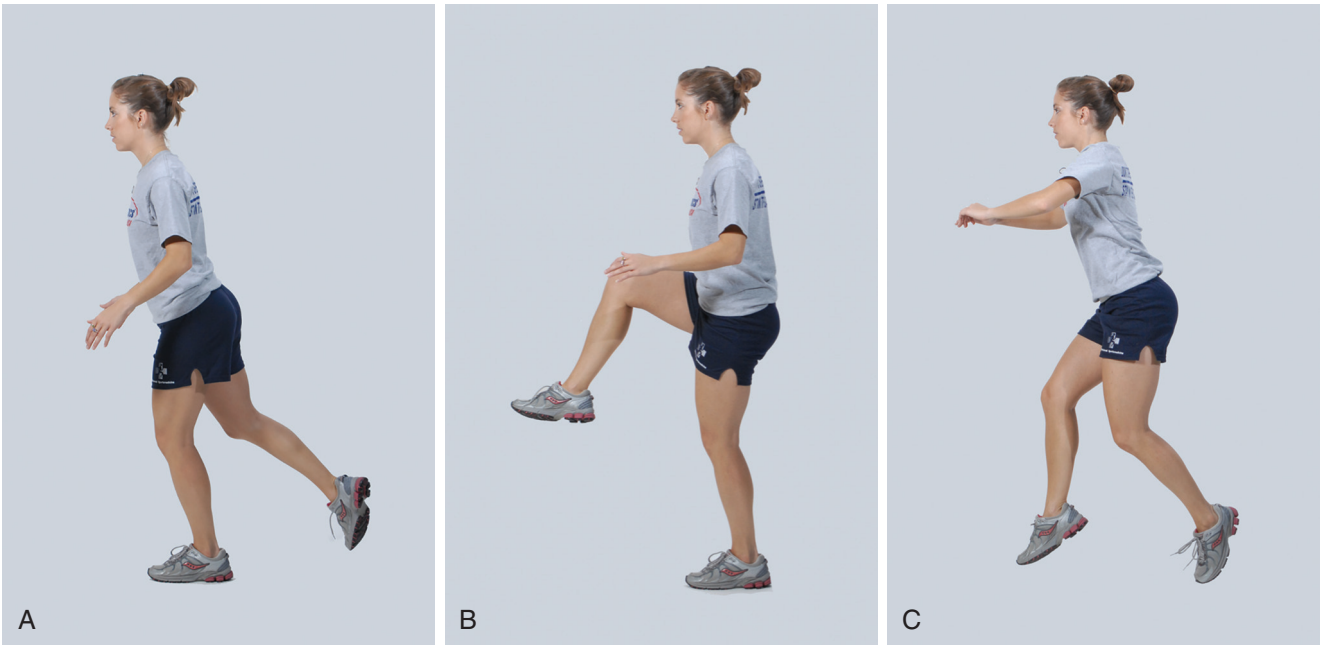

FIG 14-13 Bounding in place.

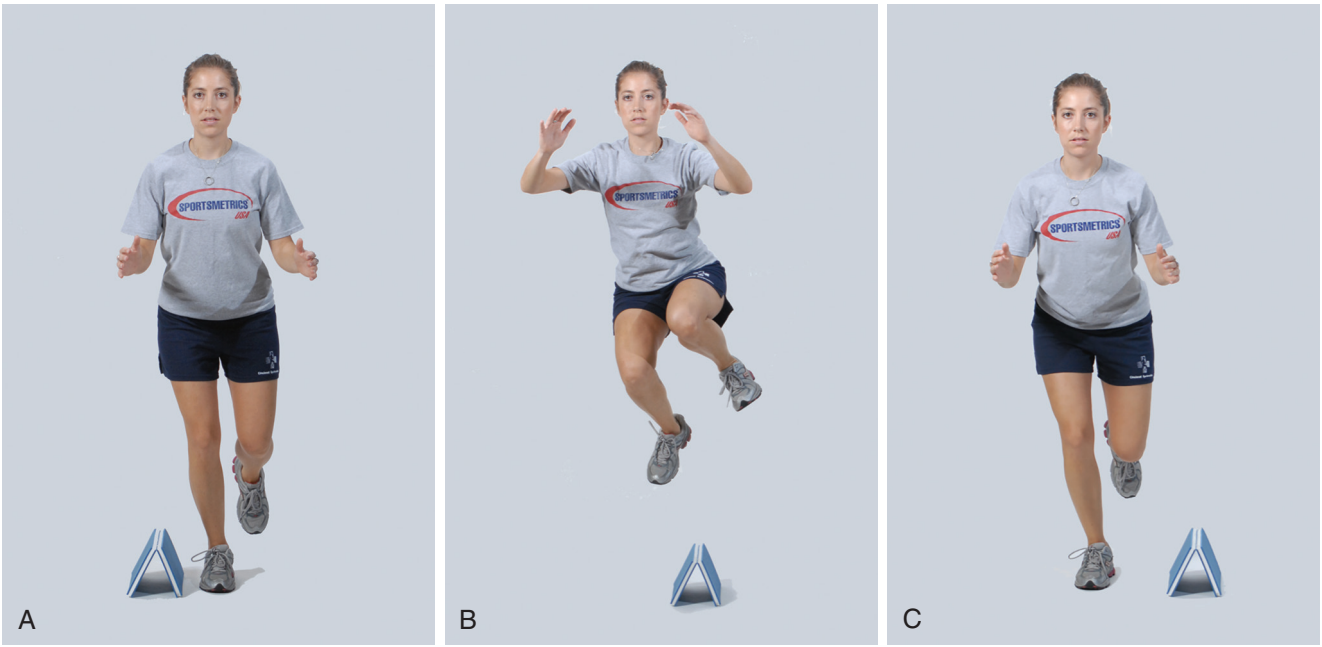

FIG 14-14 Barrier hop side to side.

Mistakes to correct are simply alternating the knees or jogging in place and landing loudly or with wobbly knees. The athlete should be told to use the arms as a countermovement to progress to increasing height and power, drive the knees upward, and land with soft knees and a toe-ball-heel rock landing pattern.

9. **Jump, jump, jump, vertical jump** (weeks 3 and 4). The athlete performs three broad jumps with each takeoff and landing in a deep crouch position. Then, the athlete finishes with a maximum vertical jump and returns to the deep crouch position and holds the position for 5 seconds.

   Mistakes to correct include pointing the knees inward during landing and takeoff and carrying the body forward rather than upward on the vertical jump. The athlete should be told to keep the knees over the heels and under the hips on takeoff and landing, land with the toe-ball-heel rock with the knees flexed, and go straight up on the vertical jump.

10. **Barrier hop side to side** (weeks 3 and 4). Using the same cone or barrier from phase 1, the athlete performs a single-leg hop rather than a double-leg jump side to side over the barrier (Fig. 14-14).

    Mistakes to correct are landing or taking off with stiff, straight, or wobbly knees; hopping side to side quickly without bringing the entire body over the barrier; and double-bouncing on landing. The athlete should be told to bend the knee to clear the barrier; land quietly on the ball of the foot and rock back to the heel; control the landing to be able to immediately take

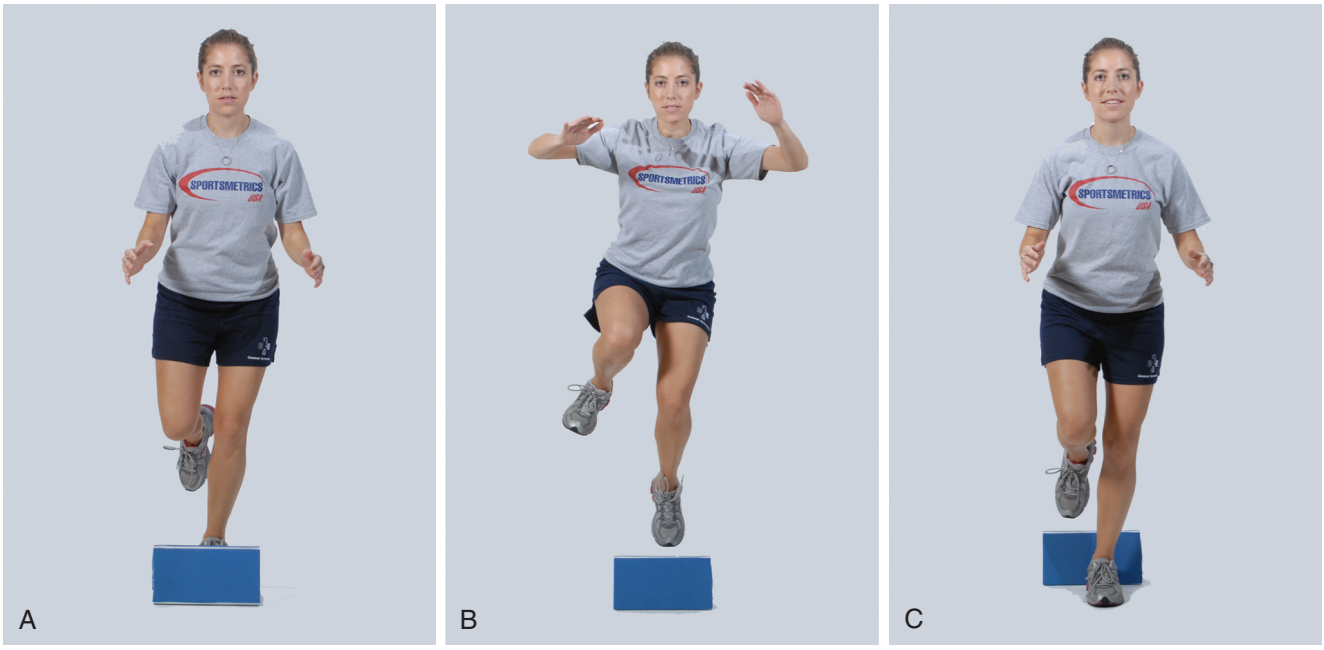

FIG 14-15 Barrier hop forward and backward.

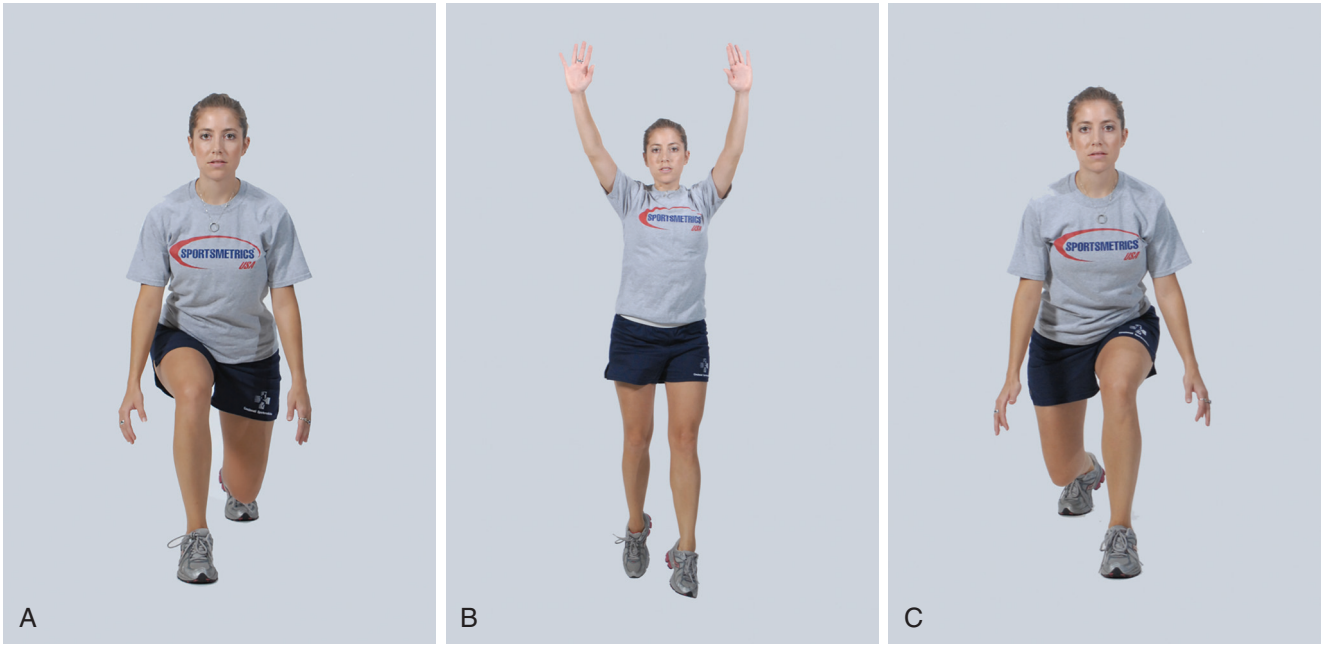

FIG 14-16 Scissors jump.

off again; keep the back straight, shoulders back, and head and eyes up with each hop; keep the knee tracking under the hips; and keep the toes pointed forward on takeoff and landing.

11. **Barrier hop forward and backward** (weeks 3 and 4). Using the same cone or barrier from phase 1, the athlete performs a single-leg hop rather than a double-leg jump forward and backward over the barrier (Fig. 14-15).

    Mistakes to correct are landing or taking off with stiff, straight, or wobbly knees; hopping forward and backward quickly without bringing the entire body over the barrier; and double-bouncing on landing. The athlete should be told to bend the knee to clear the barrier; land quietly on the ball of the foot and rock back to the heel; control the landing to be able to immediately take off again; keep the back straight, shoulders back, and head and eyes up with each hop; keep the knee tracking under the hips; and keep the toes pointed forward on takeoff and landing.

12. **Scissors jump** (weeks 3 and 4). The athlete begins in a long lunge position with the front knee bent directly over the ankle (Fig. 14-16, *A*). The athlete pushes off the front leg, jumps straight up in the air (see Fig. 14-16, *B*), lands with the opposite leg bent in front (see Fig. 14-16, *C*), and then alternates legs.

    Mistakes to correct are landing with wobbly knees or knees extended past the front ankle, jumping up to alternate legs with minimal height, not switching legs directly under the body, simply switching legs without power, landing loudly, landing with a straight or stiff leg, landing with staggered feet, or

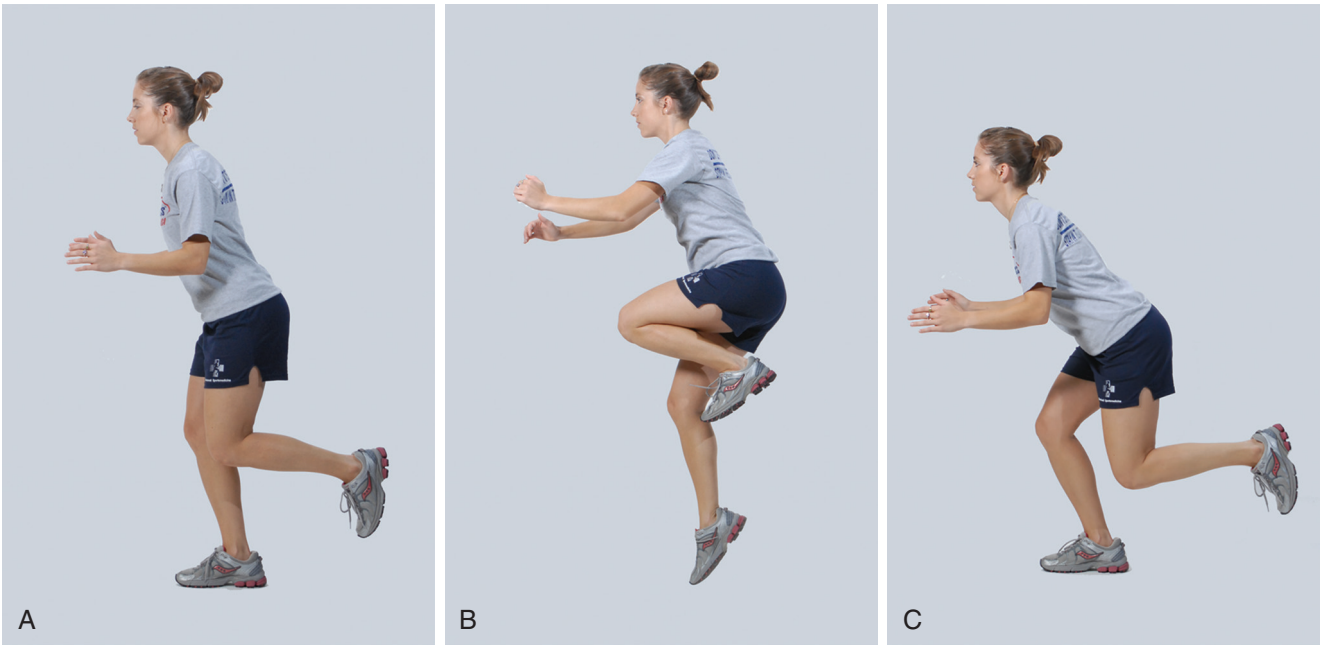

FIG 14-17 Single-leg hop.

landing with one foot before the other. The athlete should be told to push off with power from the front leg, obtain maximum height on the leg switch, land in control with the legs bent and the front knee directly over the ankle, keep the back straight, keep the shoulders back, keep the head and eyes up with each jump, and keep the toes pointed forward with each takeoff and landing.

13. **Single-leg hop** (weeks 3 and 4). This hop is performed just like the broad jump, except the athlete starts and lands on the same leg. The athlete lands in a deep crouched position, which is held for 5 seconds, and then repeats the hop on the opposite leg (Fig. 14-17).
    Mistakes to correct include landing with a wobbly knee, landing upright with the knee straight, and landing in deep knee flexion but standing up immediately. The athlete should be told to keep the knees over the heels and under the hips on takeoff and landing, land with the toe-ball-heel rock and the knees and ankles flexed, and hold the landing for 5 seconds (more important than distance).
14. **Bounding for distance** (weeks 3 and 4). The athlete begins bounding in place and progresses forward, increasing the distance with each step while keeping the knees high.
    Mistakes to correct include performing alternating knee lifts or a high knee jog, landing loudly or with wobbly knees, and keeping the knee low instead of lifting it up. The athlete should be told to use the arms as a countermovement to progress and increase height and power, and also to drive the knee upward and forward.
15. **Jump up, jump down, 180 degrees, vertical** (weeks 5 and 6). This is a double-foot jump onto a 6- to 8-inch box or stacked mat. The athlete lands in a deep crouched position and immediately performs a double-foot jump-down (a depth jump) off the box or mat. The athlete lands again in a deep crouched position and immediately performs a 180-degree jump. Upon landing, the athlete jumps right into a maximum vertical jump, landing once again in the deep crouched position, which is held for 5 seconds.
    Mistakes to correct are landing each jump in an upright straight- or stiff-legged stance or landing with one foot. The athlete should be told to land every jump in a deep crouch with the knees and ankles flexed and to have the feet land at the same time.
16. **Mattress jump side to side** (weeks 5 and 6). The cone or barrier is placed on a cushioned surface approximately 2 to 3 inches deep. The athlete performs a double-foot jump from side to side (Fig. 14-18).
    Mistakes to correct are landing with wobbly knees or knees pointed inward, double-bouncing on landing, landing with the feet staggered, or landing with one foot in front of the other. The athlete should be told to land and take off with both feet together, control the landing to be able to immediately take off back over the barrier, and keep the feet parallel to each other.
17. **Mattress jump forward and backward** (weeks 5 and 6). The cone or barrier is placed on a cushioned surface approximately 2 to 3 inches deep. The athlete performs a double-foot jump forward and backward (**Fig. 14-19**).
    Mistakes to correct include landing with wobbly knees or knees pointed inward, double-bouncing on landing, landing with the feet staggered, or landing with one foot in front of the other. The athlete should be told to land and take off with both feet together, control the landing to be able to immediately take off back over the barrier, and to keep the feet parallel to each other.
18. **Hop, hop, hop, stick** (weeks 5 and 6). The athlete performs three single-leg hops for distance, holding and sticking the final landing for 5 seconds.
    Mistakes to correct include landing with wobbly knees or knees pointed inward, landing upright with poor knee and ankle flexion, and landing in keep knee flexion but immediately standing up. The athlete should be told to keep the knees over the heels and under the hips on takeoff and landing, land with a toe-ball-heel rock and keep the knees flexed, and hold the landing for 5 seconds (more important than distance).

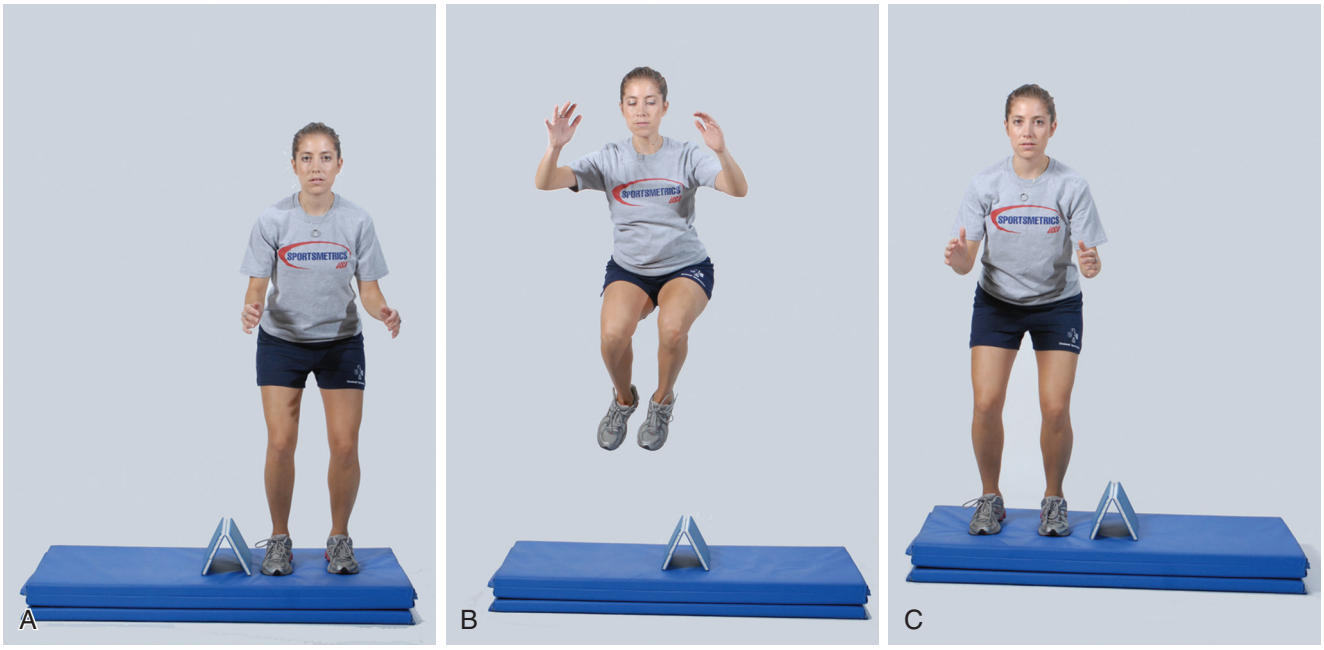

FIG 14-18 Mattress jump side to side.

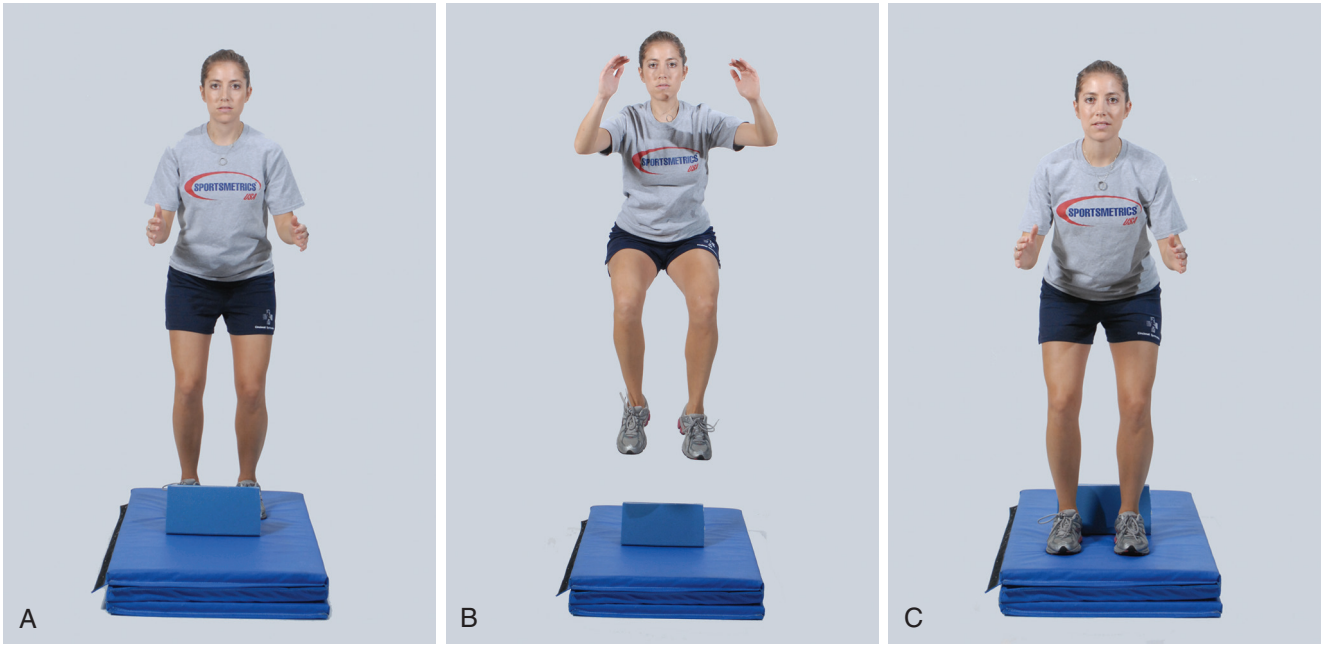

FIG 14-19 Mattress jump forward and backward.

19. **Jump into bounding** (weeks 5 and 6). The athlete jumps forward off both feet, landing on one leg with the other bent behind, and immediately begins bounding for distance.
    Mistakes to correct are performing alternating knee lifts or a simple high-knee jog, landing loudly or with wobbly knees, and keeping the knees low instead of lifting them high. The athlete should be told to land with control off the jump and immediately begin bounding, use the arms as a countermovement to progress and increase height and power, and to drive the knees upward and forward as if going for an approach vertical jump.

Strength Training

A combination of strength-training options is used to focus on the development of core strength and the improvement of overall muscular efficiency. Either isokinetic equipment or free weights may be used by the athlete, based on their availability. The lower extremity muscle groups targeted are the quadriceps, hamstrings, gluteals, and gastrocnemius. The athlete begins with 12 to 15 repetitions for each muscle group. When the athlete can perform 15 repetitions, the amount of weight is increased. The upper body muscle groups include the deltoids, pectorals, triceps, latissimus dorsi and low back, and abdominals.

FIG 14-20 Minisquat with TheraBand.

Ten to twelve repetitions are recommended initially; when the athlete can perform twelve repetitions, the amount of weight is increased. Athletes are encouraged to use 70% of their one-repetition maximum upon initiation of strength training. The overload principle is stressed. For athletes who do not have access to isokinetic equipment or free weights, exercises for strength training using body weight and a resistance band may be used, as described next.

1. **Minisquats with resistance band.** The athlete stands on the center of a strip of a resistance band with the feet shoulder width apart (Fig. 14-20, *A*). While gripping each end of the band, the athlete pulls both hands up to waist level to make the band taut. The athlete squats down into a modified 70-degree bend at the hips and knees, lowering the body against the resistance of the band (Fig. 14-20, *B*). The knees are kept over the ankles. The athlete rises back up, pushing through the heels to the starting position. This exercise is done for 30 seconds during weeks 1 to 3 and for 60 seconds during weeks 4 to 6.
   Mistakes to correct are body weight and/or knees shifting forward, slouched posture, and maintaining too much slack in the band. The athlete should be told to wiggle the toes throughout the movement and to keep the back straight, the head up, and the knees centered over the ankles.
2. **Walking lunges forward.** This exercise is similar to the lunges performed during the dynamic warmup, but a larger range of motion and slower movements are used. While keeping the entire body facing forward, the athlete steps out with one leg as far as possible. Bending the knees, the athlete lowers the back leg toward the ground, stopping just before the knee touches the ground. The front knee should stay directly over the ankle. The athlete lifts the body up to standing position by initiating the lift-up with the front leg. The back leg is brought alongside the front leg, followed by a pause, and then repeating with the opposite leg. This exercise is done for 30 seconds during weeks 1 to 3 and for 60 seconds in weeks 4 to 6.
   Mistakes to correct are bending the knee past the front toe, wobbly knees or lack of upper body control, moving fast, and pushing off from the back leg for leverage. The athlete should be told to maintain an upright posture, lift with the gluteal and quadriceps muscles on the front leg, and move slowly and deliberately.
3. **Prone hamstrings with partner resistance.** The athlete lies flat on the stomach, tightening the abdominal and gluteal muscles to press the hips into the floor. A partner places even, downward pressure on the lower calf as the athlete resists, bending at the knee so the heel comes toward the gluteal muscles without raising the hips off the floor. The athlete continues to bend and straighten the leg with control as the partner applies even, downward pressure. This exercise is repeated on each leg for 30 seconds during weeks 1 to 3 and for 60 seconds during weeks 4 to 6.
   Mistakes to correct include lifting the upper body, lifting the working hip off the ground, and the partner not resisting to create eccentric contractions. The athlete should be told to keep the hips pressed into the ground, keep the upper body relaxed, and move the leg through the full range of motion.
4. **Supine hamstring bridge.** While lying flat on the back, the athlete bends one knee and places the heel of the foot as close to the gluteus maximus as possible. The other leg is extended straight up into the air (Fig. 14-21, *A*). Pushing through the heel that is on the ground, the athlete performs small lifts, raising the gluteus maximus off the ground and taking the extended leg higher in the air with each push (see Fig. 14-21, *B*). The abdominals should be tight and the upper back in neutral position. The arms should be relaxed above the head. This exercise is repeated on each leg for 30 seconds during phase 1.
   Mistakes to correct include simply swinging the leg in the air back and forth, not raising the gluteus maximus off the ground into a bridge position, bending the leg in the air, pushing up through the toe instead of the heel, and holding the body up off the ground with the arms or hands. The athlete should be told to press the heel into the ground, keep the abdominal muscles tight and the lower back in neutral position, lift the leg straight up in the air and push the foot up toward the ceiling, keep the heel close to the gluteus maximus, and raise and lower the leg slowly and under control.

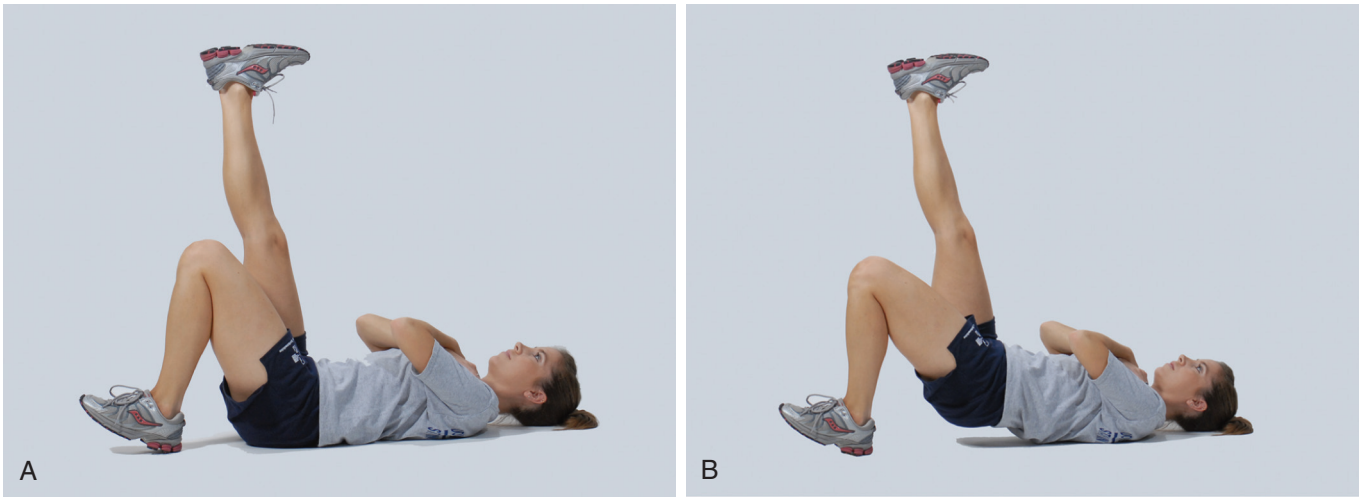

FIG 14-21 Supine hamstring bridge.

FIG 14-22 Arm swing with TheraBand.

5. **Bridge with alternating-leg hamstring glide.** This exercise is similar to the supine hamstring bridge; however, instead of extending one leg directly up from the hip, the athlete places both heels as close as possible to the gluteus maximus. The athlete slides one leg to nearly full extension, keeping the heel on the ground. The leg is returned to the starting position and repeated. This exercise is repeated on each leg for 30 seconds in phase 2.
   Mistakes to correct are not lifting and holding the hips off the ground, not moving the leg through the full range of motion, and locking the knee. The athlete should be told to relax the shoulders and keep the head on the ground, move in a slow and controlled pattern, and keep the abdominals tight.
6. **Bridge with double-leg hamstring glide.** This exercise is similar to the alternating-leg hamstring glide. The athlete begins with both heels as close to the gluteus maximus as possible. Both legs are slid to nearly full extension and then back up to the starting position. This exercise is repeated for 30 seconds in phase 3.
   Mistakes to correct include not lifting and holding the hips off the ground, not moving the legs to nearly full extension, and locking the knee. The athlete should be told to relax the shoulders and keep the head on the ground, move in a slow and controlled pattern, and keep the abdominals tight.
7. **Arm swing with resistance band.** The athlete stands on the center of a strip of a resistance band with the feet shoulder width apart. While gripping each end of the band, the athlete pulls it up to waist level so the band is taut and the elbows are at a 90-degree angle (Fig. 14-22, *A*). The arms are kept at a 90-degree angle (see Fig. 14-22, *B*) while alternatively swung from the hip to the ear, mimicking a running pattern (see Fig. 14-22, *C*). This exercise is done for 30 seconds during weeks 1 to 3 and for 60 seconds during weeks 4 to 6.

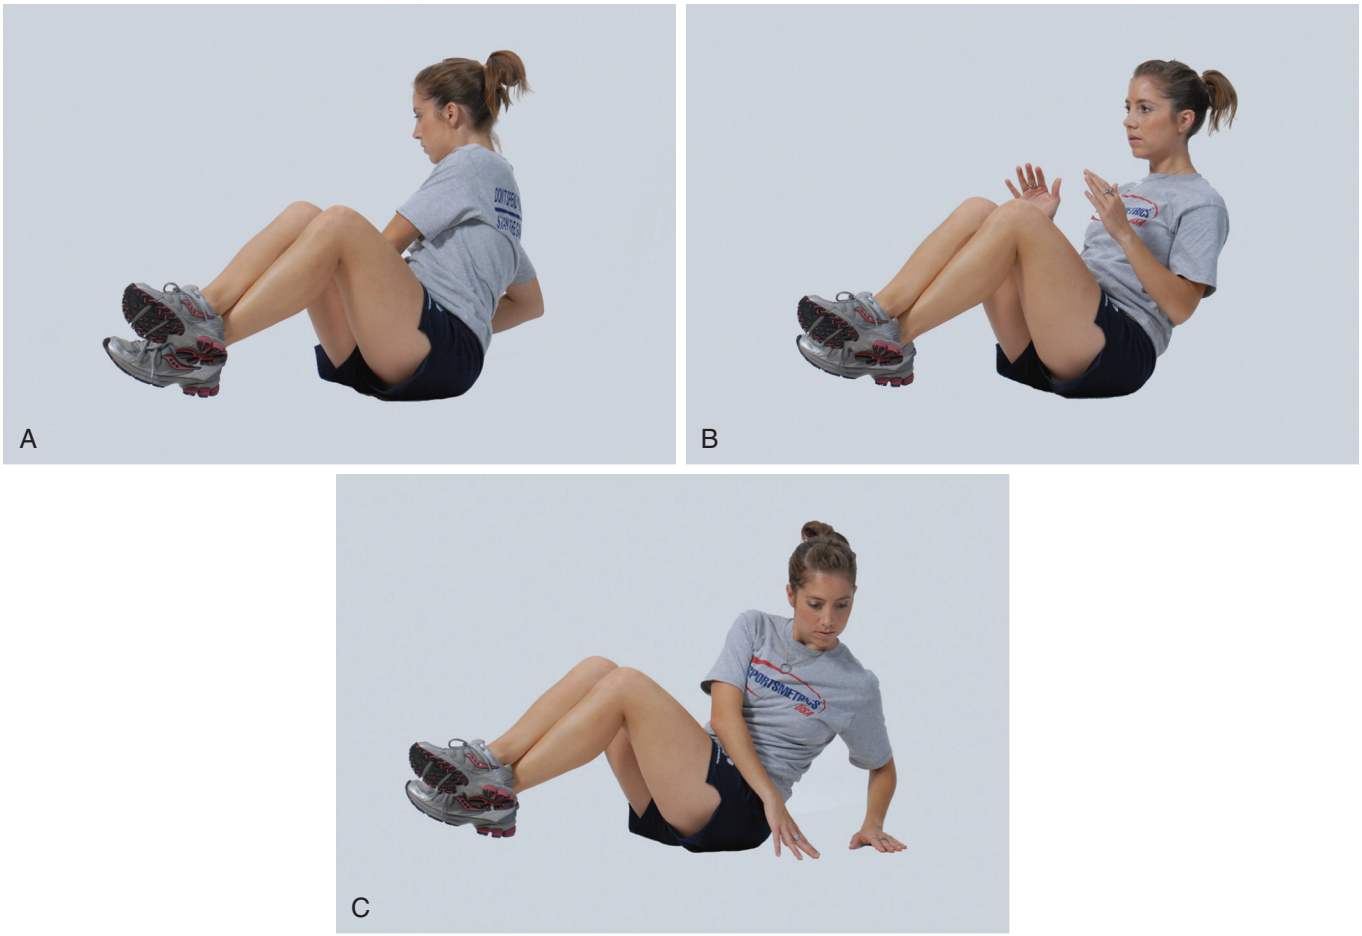

FIG 14-23 Abdominals (Russian twists).

Mistakes to correct include not keeping the arms at a 90-degree angle through the full range of motion, locking the knees, and twisting the torso. The athlete should be told to keep the head up and shoulders back, maintain an upright, neutral spine; and keep the abdominals tight.

8. **Superman (alternating arms and legs).** The athlete lies face down and places the forehead on top of the back of one hand. The other arm is extended out on the ground. The abdominal muscles are tightened, and the upper body is raised to lift the extended arm. At the same time, from the hip and gluteals, the leg opposite the extended arm is raised. The toes and fingers on the lifted leg and arm are extended. The abdominals remained tightened. This exercise is done for 30 seconds during weeks 1 to 3 and for 60 seconds during weeks 4 to 6.
   Mistakes to correct are lifting the head up, overly arching the back, and lifting the leg to the side. The athlete should be told to keep the spine as neutral as possible, focusing the eyes on the mat and/or ground directly below; lift from the trunk; lift the leg and arm only to the point of tension in the lower back; and keep the abdominals tight.
9. **Abdominals (Russian twists).** The athlete lies on the ground, bends the knees, and places the heels on the floor. The athlete bends at the hips, not at the waist, to bring the upper body to a 45-degree angle and holds this position. Moving the trunk as a unit, the athlete rotates the upper body side to side, allowing the hands to touch the ground next to the hip with each rotation (Fig. 14-23). This exercise is done 1 day each week for 30 seconds in phase 1, 60 seconds in phase 2, and 90 seconds in phase 3.
   Mistakes to correct are slouched posture, rounded shoulders, and twisting only the shoulders and not the torso. The athlete should be told to keep the back straight and shoulders relaxed, keep the upper body at a 45-degree angle, and move the trunk as a unit, making sure that both hands are touching the ground with each rotation.
10. **Abdominals (plank).** The athlete lies face down and places the elbows under the shoulders with the forearms on the floor (Fig. 14-24, *A*). The legs are placed hip distance apart, and the toes are curled under. The athlete lifts the body up onto the elbows and toes (Fig. 14-24, *B*). A neutral posture is maintained. The position is held with tight abdominals. This exercise is done 1 day each week for 30 seconds in phase 1, 60 seconds in phase 2, and 90 seconds in phase 3.
    Mistakes to correct include maintaining a slouched or arched midsection, placing the head down with the chin resting on the chest, and keeping the elbows and/or toes too close together. The athlete should be told to maintain a neutral posture, keep the neck and shoulders relaxed, keep the body in a straight line parallel to the ground, maintain the head in a neutral position, and keep the abdominals tight at all times.
11. **Abdominals (bicycle kicks).** The athlete lies on the back with the knees bent into the chest, placing the fingertips on the back of the head. The upper body is raised off the ground until the shoulders

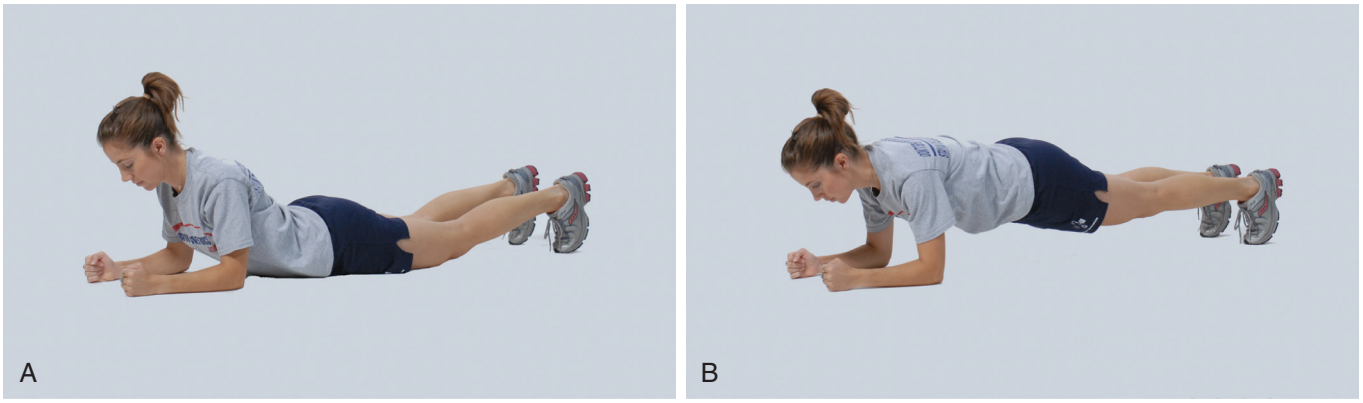

FIG 14-24 Abdominals (plank).

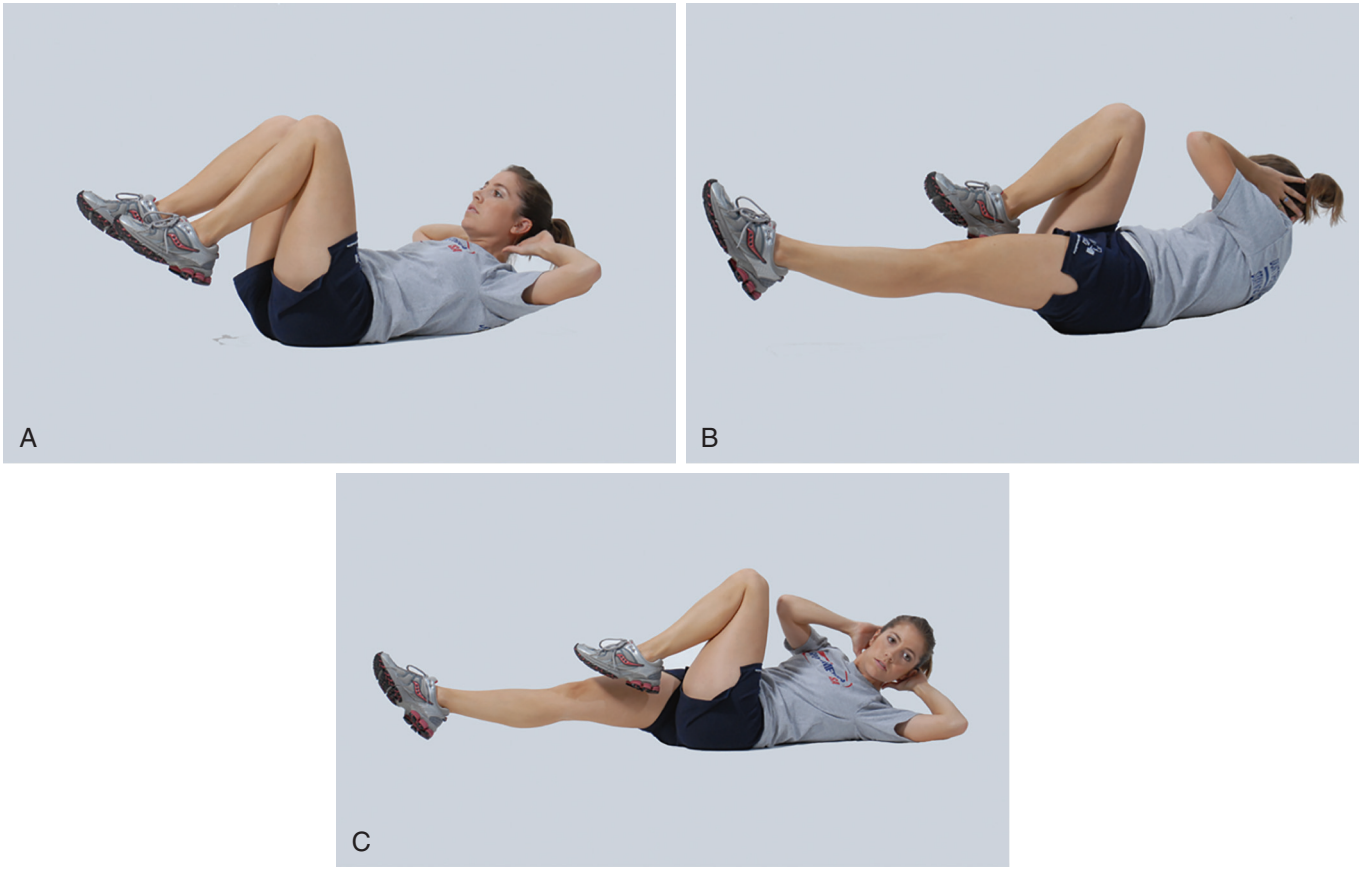

FIG 14-25 Abdominals (bicycle kicks).

no longer touch the ground, and then this position is held. The legs are moved in a cyclic motion, with the heels brought into the gluteus maximus and the legs extended out as close to the floor as possible (Fig. 14-25). This exercise is performed 1 day each week for 30 seconds in phase 1, 60 seconds in phase 2, and 90 seconds in phase 3.

Mistakes to correct include not keeping the upper body off the ground, rotating the upper body, and cycling the legs close to the body. The athlete should be told to keep the chest open and lift from the waist, keep the elbows open and upper body stationary, and fully bend and straighten the legs close to the ground.

12. **Hip flexor resistance band kicking.** The athlete places one end of a piece of a resistance band around the ankle, with the other end around the ankle of a partner or anchored to a stationary object. With the back faced to the partner or stationary object, the athlete steps forward to produce moderate tension in the band while the leg with the resistance band around it is in approximately 15 degrees of hip extension (Fig. 14-26, *A*). Then, the athlete drives the knee that is in back up and forward with maximal effort against the resistance of the band until the thigh is parallel to the ground (see Fig. 14-26, *B*). The leg is returned to a slightly extended position after each exertion. This exercise consists of 2 sets of 10 repetitions, with 30 seconds of rest between each set. A third set

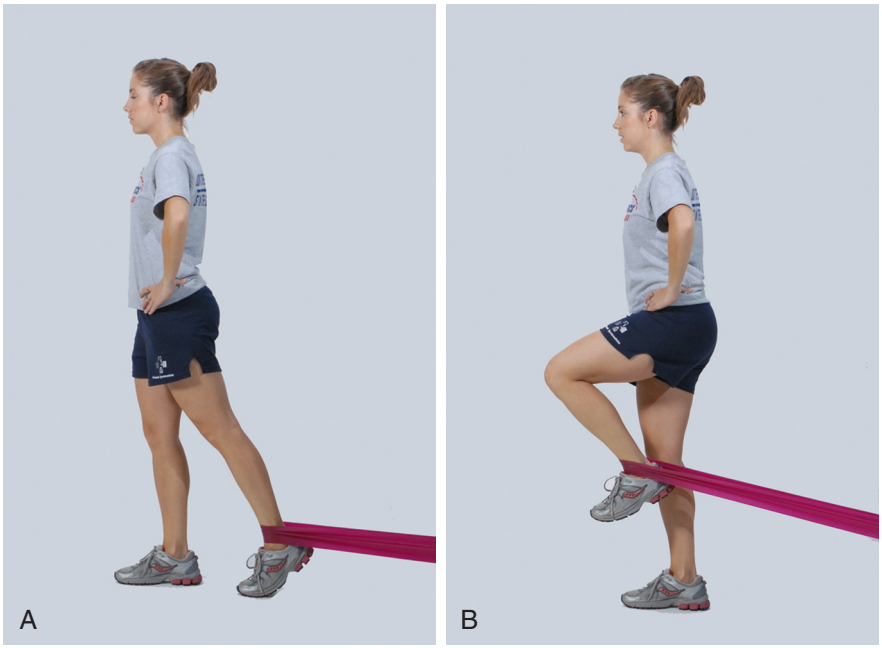

FIG 14-26 Hip flexor TheraBand kicking.

is performed of 20 repetitions in phase 1, 30 repetitions in phase 2, and 40 repetitions in phase 3.

Mistakes to correct include swinging the leg up and back, hiking the hip, and moving the torso. The athlete should be told to keep head and neck straight, look straight down, keep the shoulders and hips square, keep the upper body stationary, and always return the working leg to a slightly extended position before kicking forward again.

13. **Steamboats (hip flexion).** The athlete places a resistance band around the thighs, halfway between the hips and the knees. The exercise is begun with the feet shoulder width apart and one knee bent slightly so that the foot is off the ground. The athlete balances on the one leg that is on the ground and begins kicking forward and backward with the bent leg at the hip. The upper body is kept still and does not sway. This exercise is done for 30 seconds on each leg during weeks 1 to 3 and for 60 seconds during weeks 4 to 6. It may replace hip flexor TheraBand kicking.

    Mistakes to correct include flexing or extending at the knee, simply bending and straightening the knee and not moving at the hip, swaying the upper body back and forth with kicking movements, and not kicking forward or backward far enough to feel resistance of the band. The athlete should be told to keep the back straight, the shoulders back, and the head and eyes up; maintain a slight bend in both knees at all times; keep the upper body stationary; kick the leg back and forth through full range of motion; keep the hips level at all times; and not to hike the hip with motion.

14. **Hip abductor resistance band kicking.** The athlete places one end of a piece of a resistance band around the ankle and the other end around the ankle of a partner or anchored to a stationary object. The athlete stands in line with the partner or stationary object so that the leg with the resistance is farthest away from the partner or object (Fig. 14-27, *A*). The athlete steps sideways to produce moderate tension in the band, kicks the outside leg out sideways against the resistance of the band (see Fig. 14-27, *B*), and returns to the starting position. This exercise consists of 2 sets of 10 repetitions, with 30 seconds of rest between sets. A third set is performed of 20 repetitions in phase 1, 30 repetitions in phase 2, and 40 repetitions in phase 3. This activity is performed 2 days per week.

    Mistakes to correct are swinging the leg out and back without control and leaning the upper body to the side while kicking. The athlete should be told to keep the head and neck straight, look straight ahead, keep shoulders and hips square, keep the upper body stationary, and keep movements slow and controlled.

15. **Lateral walking with resistance band.** The athlete places a resistance band around the thighs, halfway between the hips and knees. The exercise is begun with the feet shoulder width apart. The athlete steps out to the side approximately 2 to 3 feet. Slowly and under control, the athlete follows with the other foot to regain the feet shoulder width apart position. Once finished, the athlete reverses direction so that the opposite foot leads the exercise. This exercise is done for 30 seconds during weeks 1 to 3 and for 60 seconds during weeks 4 to 6. It may replace hip abduction resistance band kicking.

    Mistakes to correct include allowing the feet to come together between steps, allowing the leg that follows to snap back to the starting position, walking with the knees locked in the straight position, bending forward at the waist, rounding the shoulders, and looking down at the feet and ground. The athlete should be told to keep the back straight, the shoulders back, and the head and eyes up; keep the steps to a distance that allows for leg control throughout the activity; keep motion slow and under control at all times; and to make sure that all motion is coming from the hips and legs.

Flexibility

Passive stretching is done at the conclusion of training, with each stretch held for 20 to 30 seconds and repeated twice on each side. Stretching is considered essential to achieving maximum muscle length to allow muscles to work with power through a complete range of

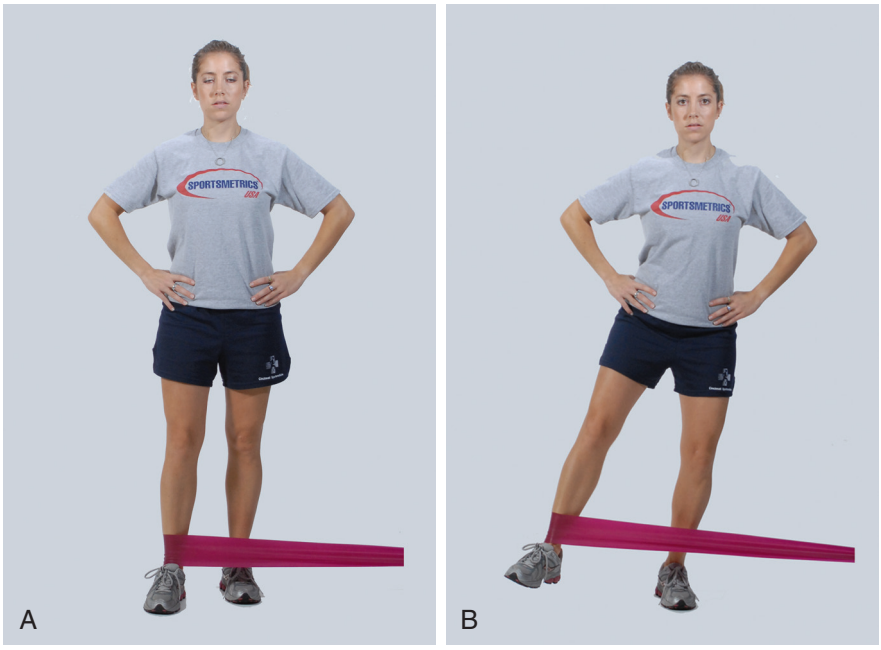

FIG 14-27 Hip abductor TheraBand kicking.

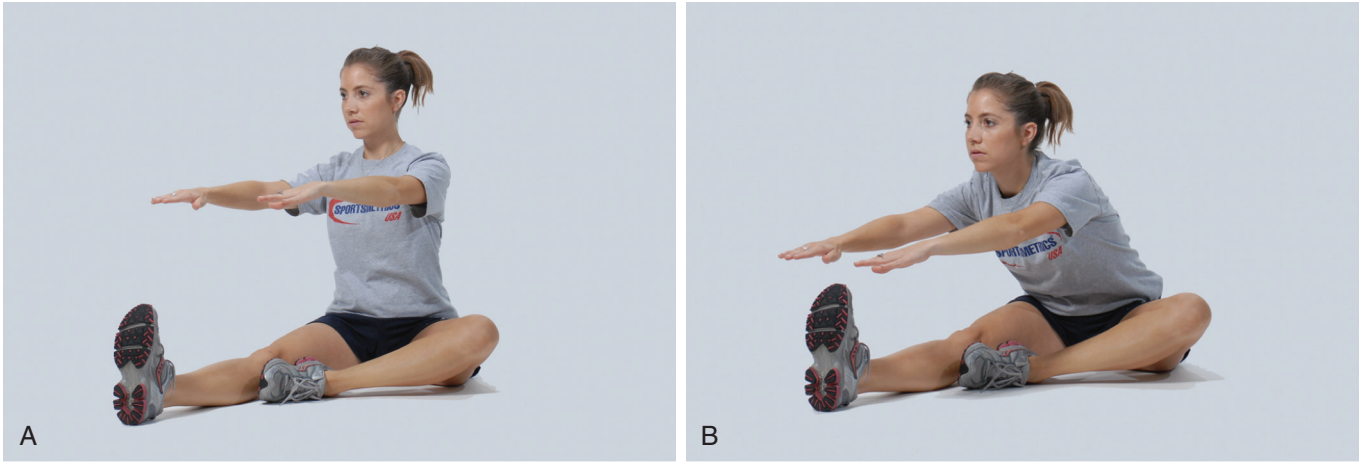

FIG 14-28 Hamstrings stretch.

motion. The major muscle groups targeted are the hamstrings, iliotibial band, quadriceps, hip flexor, gastrocnemius, soleus, deltoid, triceps, biceps, pectoralis, and latissimus dorsi.

1. **Hamstrings.** While seated, the athlete extends the right leg fully and bends the left leg, placing the inside of the foot along the left calf (Fig. 14-28, *A*). The back is kept straight, and the chest is brought toward the knee. The athlete reaches with both hands toward the toes (see Fig. 14-28, *B*). The hands are either placed on the floor alongside the legs or held on the toes.
   Mistakes to correct are rounding the shoulders when leaning into a stretch, bringing the chin into the chest when stretching, allowing the knee of the leg on the ground to bend, and bouncing into the stretch. The athlete should be told to keep the back straight when leaning forward into the stretch, bend forward at the waist, and keep the shoulders back and head up for the duration of the stretch.
2. **Iliotibial band.** While seated, the athlete bends the right knee and places the right foot flat on the floor. The left foot and ankle are placed on the right thigh just above the knee. Both hands are placed on the floor behind the hips, and the chest is pressed toward the knee and foot. The upper torso, neck, and shoulders remain neutral and open, and the upper back is not rounded (Fig. 14-29). This stretch may be performed while lying on the back to support the spine and neck.
3. **Quadriceps.** While standing, the athlete grabs the foot or ankle and lifts it up behind the body. The lower leg and foot are gently pulled up, directly behind the upper leg, with no twisting inward or outward (Fig. 14-30). The stretch is held for 20 seconds, released, and repeated.
   Mistakes to correct include allowing the foot to rest on the buttocks, pulling the leg and/or foot inward or outward, and locking the knee of the leg being used for balance. The athlete should be told to pull straight up on the foot and leg and to keep the back straight, shoulders back, and head and eyes up.
4. **Hip flexor.** The athlete stands with the feet in a lunge position and the front knee slightly bent. The athlete pushes up on the rear toe.

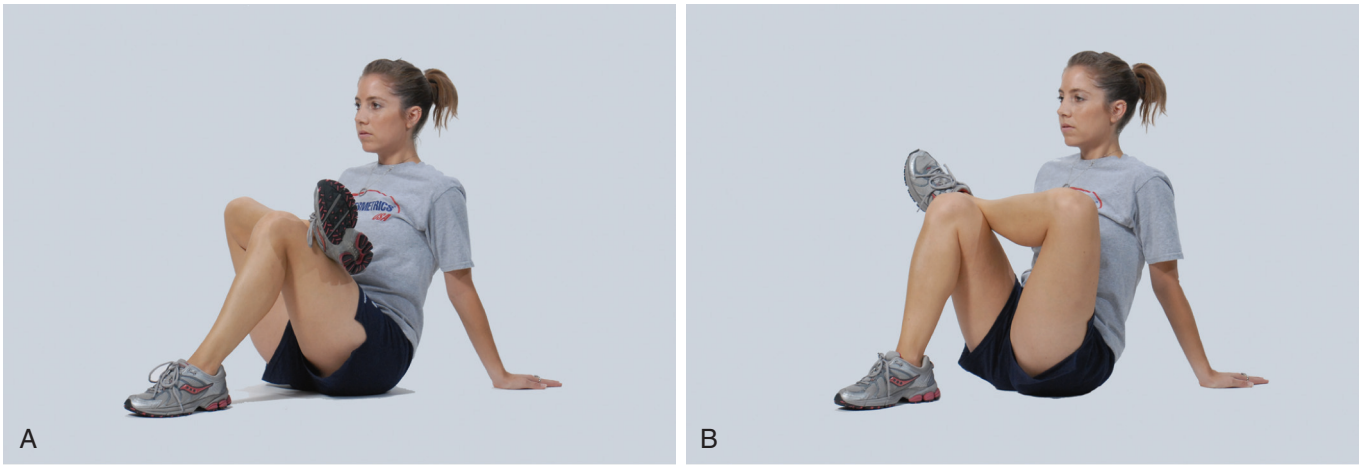

FIG 14-29 Iliotibial band stretch.

FIG 14-30 Quadriceps stretch.

The hips are pressed forward while the buttocks are tightened until a stretch is felt in the front of the hip. The upper torso remains upright and centered directly over the hips (Fig. 14-31).

Mistakes to correct include leaning the upper body forward, not pressing the hips forward, and bouncing into the stretch. The athlete should be told to keep the upper body upright and centered directly over the hips, press or rock the hips forward to initiate the stretch, and keep the back straight, shoulders back, and head and eyes up.

5. **Gastrocnemius.** The athlete stands in a long lunge position with the front knee slightly bent, but not extended past the ankle. The hands are placed on the front of the thigh, and the body is leaned forward while the back leg is kept straight. The rear heel is pressed down (Fig. 14-32). This stretch may also be done by placing both hands against a wall and leaning forward. The stretch is held for 20 seconds, released, and repeated.

   Mistakes to correct are allowing the back heel to raise off the ground, bouncing into the stretch, allowing the knee of the back leg to bend, and not maintaining upper body posture. The athlete should be told to keep the back straight, the shoulders back, and head and eyes up; keep the back leg straight; and keep the heel on the ground at all times.

6. **Soleus.** The athlete stands with one foot forward and one foot back in a short lunge position. Both knees are bent, and the athlete is instructed to sit the hips down into the back heel, with the majority of the body weight on the back leg (Fig. 14-33). The heel is kept on the floor. This stretch may be performed by placing both hands against a wall for balance.
7. **Deltoid.** While either standing or sitting, the athlete brings the left arm across the body, placing the elbow close to the chest. The palm of the hand faces the rear. The arm is clasped at the elbow and gently pressed into and across the body (Fig. 14-34). Both shoulders stay relaxed and low. The head, neck, and spine all remain neutral.
8. **Triceps, latissimus dorsi.** While either standing or sitting, the athlete extends the right arm above the head. The elbow is bent

FIG 14-31 Hip flexor stretch.

FIG 14-33 Soleus stretch.

FIG 14-32 Gastrocnemius stretch.

FIG 14-34 Deltoid stretch.

behind the head while the palm of the hand is brought toward the center of the upper back. The elbow is grasped with the left hand and gently pressed down and back (Fig. 14-35).

9. **Pectoralis, biceps.** While standing, the athlete clasps the hands behind the back. With the shoulders and neck relaxed, the elbows are extended, the chest opened, and the hands lifted up. The posture should remain upright and neutral and the knees slightly flexed (Fig. 14-36).
10. **Low back.** The athlete kneels on the floor with the hands close to the buttocks. The athlete bends forward with the arms fully extended, reaching out onto the floor. The head is lowered between the arms, with the forehead close to or resting on the floor. The hands are gradually moved out farther from the body without the athlete rising up from the heels (Fig. 14-37).

SPORTSMETRICS TRAINING PROGRAM OPTIONS

Sportsmetrics Warmup for Injury Prevention and Performance

Designed as a maintenance program, WIPP is recommended upon completion of the formal Sportsmetrics training to continue to instill the skills and techniques learned for the athlete's entire sports season. WIPP training is conducted in place of the normal warmup before a practice or game and lasts approximately 20 minutes. The program

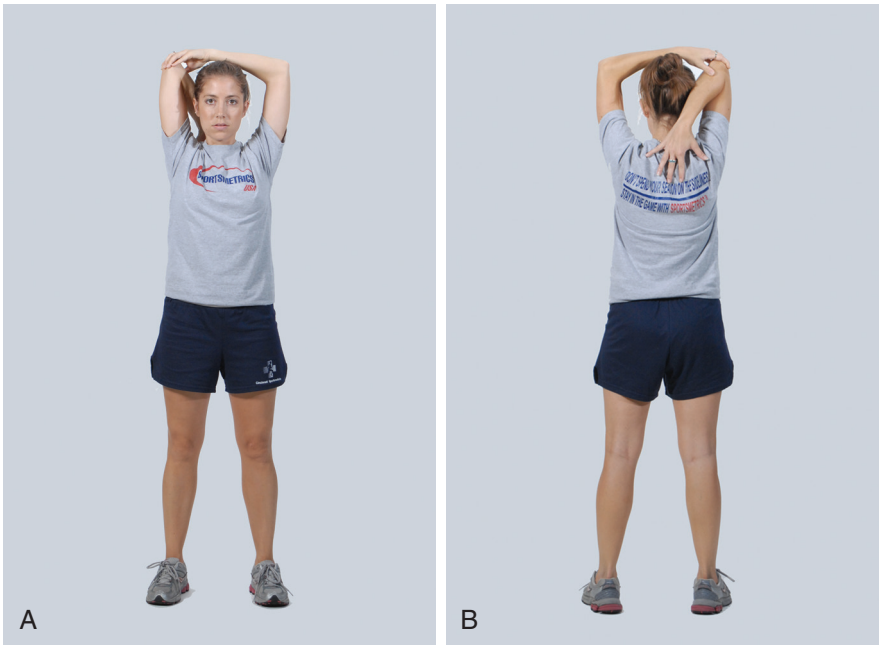

FIG 14-35 Triceps, latissimus dorsi stretch.

FIG 14-36 Pectoralis, biceps stretch.

FIG 14-37 Low back stretch.

integrates select elements from the four basic components of Sportsmetrics and focuses on the essential training concepts of control of the upper body, trunk, and lower body position on landing; increased hip and knee flexion angles on landing; and techniques to land softly to decrease ground reaction forces (Table 14-3).

Sportsmetrics Soccer, Sportsmetrics Basketball, Sportsmetrics Volleyball, Sportsmetrics Tennis

One common problem with the implementation of ACL injury prevention training is that many athletes, parents, and coaches are interested only in performance enhancement programs. In addition, coaches frequently do not want to take time away from practices, either in the preseason or during the season, solely for an injury prevention program. Therefore several sport-specific Sportsmetrics programs were created that include both the essential components of Sportsmetrics and additional exercises and drills designed to improve dynamic balance, agility, speed, strength, and aerobic conditioning. These programs begin with the dynamic warmup and plyometrics previously described. Then, sport-specific agility, speed, and aerobic conditioning exercises are performed, followed by strength and flexibility exercises. Sportsmetrics Soccer,[50] Sportsmetrics Basketball,[49] Sportsmetrics Volleyball,[48] and Sportsmetrics Tennis[3,4] have improved neuromuscular and athletic performance indices and are commonly preferred by coaches and athletes over the standard Sportsmetrics program. For all of these programs, athletes are taught techniques for agility and reaction drills that are believed to reduce the risk of a noncontact ACL injury.[1,6,12,15,38,69,73] These techniques are as follows:

1. Regardless of the direction, the first step should be short. Keep the toes pointed forward.

TABLE 14-3 Sportsmetrics Warmup for Injury Prevention and Performance Training Program

Component	Exercise	Duration (sec)	Comments	Transition Between Exercises (sec)
Dynamic warmup	Straight-leg march	20		5
Dynamic warmup	Hand walk	20		10
Dynamic warmup	Cradle walk	20		5
Dynamic warmup	Hip rotator walk	20		20
Jump training	Tuck jump	30		10
Jump training	Squat jumps	30		10
Jump training	180-degree jump	30		10
Jump training	Scissors jump	30		10
Jump training	Barrier hop side to side	30	15 sec each leg	75
Strength training	Steamboats	60	30 sec each leg	10
Strength training	Lateral step	60	30 sec each direction	40
Strength training	Supine hamstring	60	30 sec each leg	15
Strength training	Abdominal crunch	60		10
Strength training	Modified plank	60		15
Flexibility	Hamstring stretch	40	20 sec each leg	15
Flexibility	Hip flexor stretch	40	20 sec each leg	15
Flexibility	Quadriceps stretch	40	20 sec each leg	25
Flexibility	Calf stretch	40	20 sec each leg	20
Agility	Quick feet	60	30 sec each direction	20
Agility	Nebraska drill	60	30 sec each run	—

2. Maintain control of the body's center of gravity throughout the drill.
3. Keep an erect posture with a stable trunk, and avoid excessive anterior pelvic tilt and rounded shoulders.
4. Keep the head and eyes up, and look straight ahead.
5. Keep the body weight evenly distributed over the balls of the feet.
6. Maintain the same angle of hip, knee, and ankle flexion throughout the drill, including during changes in direction. Knee flexion should be greater than 30 degrees.
7. Avoid a valgus lower limb position.
8. Keep the knees over the ankles, and do not allow them to extend over the toes.
9. During deceleration, use three short steps to reduce speed instead of one step.
10. During a sidestep cut, bring the foot to the midline to plant and keep the torso upright, with no rotation, pointed in the general direction the athlete wishes to travel.[11]
11. Videotape the athlete while she or he perform drills and exercises to show techniques that require correction.
12. Use external focus cues such as cones to teach proper form.

The agility/reaction, acceleration/speed/endurance, additional jumps, and strength training components are shown in Table 14-4 for Sportsmetrics Soccer, in Table 14-5 for Sportsmetrics Basketball, in Table 14-6 for Sportsmetrics Volleyball, and in Table 14-7 for Sportsmetrics Tennis. These components have been described in detail elsewhere.[6] The effectiveness of all of these programs in improving neuromuscular and athletic performance indices has been published previously and is described briefly next. All training was accomplished by certified Sportsmetrics trainers. In addition, in the Sportsmetrics Tennis program, a tennis professional certified by the U.S. Tennis Association (elite level) was also involved.

The effectiveness of the Sportsmetrics Soccer program was tested in two phases.[50] Phase 1 consisted of a group of 62 high school female athletes who underwent the video drop-jump test, the agility *t* test, two vertical jump tests, and a 37-meter sprint test before and after 6 weeks of training. Phase 2 consisted of 62 other athletes who underwent an MSFT before and after training. There were significant improvements in the drop-jump test in the mean absolute millimeters of knee and ankle separation distance, as well as in the normalized knee separation distance (Table 14-8). There were also significant improvements in the agility *t* test, MSFT estimated maximal aerobic power, sprint test, and two-step approach vertical jump test.

Sportsmetrics Basketball was tested in 57 female high school athletes who underwent the video drop-jump test, MSFT, vertical jump test, and an 18-meter sprint test before and after 6 weeks of training.[49] There were significant improvements in the drop-jump test in the mean absolute millimeters of knee separation distance and the normalized knee separation distance, the MSFT, and the vertical jump test (Table 14-9). Improvement was noted in 91% of the subjects in the normalized knee separation distance, in 89% of the subjects in the MSFT, and in 70% of the subjects in the vertical jump test.

Sportsmetrics Volleyball was completed by 34 high school female athletes who underwent the video drop-jump test, the MSFT, the vertical jump test, and a sit-up test before and after training.[48] Significant improvements were found after 6 weeks of training in these athletes in all of the tests (Table 14-10). Improvement was found in 73% of the subjects in the MSFT and in 68% of the subjects in the vertical jump and sit-up tests.

The Sportsmetrics Tennis training program was tested in 42 players (31 females, 11 males; mean age: 14 ± 2 years).[3] Statistically significant improvements were found for all of the tests conducted, shown in Table 14-11. The percentages of the players whose test scores improved were 98% in the one-court suicide, 90% in the abdominal endurance test, 76% in the service line and single-leg hop tests, 69% to 74% in the baseline tests, and 59% to 65% in the single-leg triple-crossover hop test. There were no differences between the sexes regarding the absolute or percentage improvement in any of the tests. A subgroup of 15 players voluntarily participated in more than 1 training program to

TABLE 14-4 Sportsmetrics Soccer

Component	Sessions	Exercise	Duration
Agility, reaction	1-3	Serpentine run	¼ field, 3 reps
	1-3	Wheel drill: listen to instructor	30 sec, 2 reps
	4-6	Modified shuttle	¼ field, 3 reps
	4-6	Sprint/stop feet: listen	30 sec, 2 reps
	7-9	Square drill	30 ft × 30 ft (9.1 m × 9.1 m) box, 2 reps
	7-9	Sprint/quick feet: listen	45 sec, 2 reps
	10-12	Nebraska drill	30 ft (9.1 m) long, 4 reps
	10-12	Reaction drill: watch instructor point	45 sec, 2 reps
	13-15	Illinois drill	15 ft × 10 ft (4.6 m × 3.0 m), 4 reps
	13-15	Reaction mirror drill, pressing	60 sec, 2 reps
	16-18	Agility *t* test: 5-10-5	4 reps
	16-18	Advanced wheel drill: listen to instructor	60 sec, 2 reps
Acceleration, speed, endurance	1-3	Partner push-offs, hold 5 seconds	5 reps
	1-3	Sprint/backpedal	½ field or 50 yards (45.7 m), 5 reps
	1-3	Jog	4 laps around field (1280 yards, 1170 m)
	4-6	Acceleration with band	Go to 10-yard line (9.1 m)
	4-6	Sprint with ground touches/backpedal	½ field or 50 yards (45.7 m), 5 reps
	4-6	100 yards (91.4 m) shuttle	3 × 100 (300 yards, 274 m), 4 reps
	7-9	Partner push-offs, hold 10 sec	5 reps
	7-9	Half-eagle into sprint, jog back	½ field or 50 yards (45.7 m), 6 reps
	7-9	50-yard (45.7-m) shuttle	Up and back × 3 (300 yards, 274 m), 4 reps
	10-12	Acceleration with band	Go to 20-yard line (18.3 m)
	10-12	Box drill, sprint/90 degrees/backpedal	½ field, 3 reps
	10-12	50-yard (45.7-m) cone drill: 10 yards (9.1 m) and back, 20 yards (18.3 m) and back, 30 yards (27.4 m) and back, 40 yards (36.6 m) and back, 50 yards (45.7 m) and back	4 reps
	13-15	Partner push-offs, hold 15 sec	5 reps
	13-15	Sprint/180 degrees/backpedal	½ field or 50 yards (45.7 m), 7 reps
	13-15	Jingle-jangle, 20 yards (18.3 m)	Up and back × 5 (200 yards, 183 m), 5 reps
	16-18	Acceleration with band	Go to 30 yard (27.4 m) line
	16-18	Sprint/360 degrees/sprint	½ field or 50 yards (45.7 m), 7 reps
	16-18	Jingle-jangle, 10 yards (9.1 m)	Up and back × 5 (100 yards, 91 m), 6 reps
Ladders, quick feet, additional jumps	1-3	Ladder: up-up and back-back	2 reps
	1-3	Dot drill: double-leg jumps	5 reps ×3
	4-6	Ladder: toe touches	2 reps
	4-6	Dot drill: add split-leg jumps	5 reps ×3
	7-9	Ladder: outside foot in	2 reps
	7-9	Dot drill: add 180-degree split-leg jump	5 reps ×3
	10-12	Ladder: in-in, out-out	2 reps
	10-12	Dot drill: add single-leg hops	5 reps ×3
	13-15	Ladder: up-up and back-back	2 reps
	13-15	Dot drill: combination of all jumps	5 reps ×3
	16-18	Ladder: 1 foot forward, 1 foot backward	2 reps
	16-18	Dot drill: combination of all jumps	5 reps ×4
Strength training	1-18	Resistance band: squats	30 sec all exercises: sessions 1-6

	1-3	Dot drill: double-leg jumps	5 reps ×3
	4-6	Ladder: up-up/back-back	4-6 reps
	4-6	Sprint/stop feet/listen to instructor	30 sec, 2 reps
	4-6	Suicides/forward/backward, volleyball court ×2	2 reps
	5-7	Dot drill: add split-leg jumps	5 reps ×3
	7-9	Ladder: outside foot in	4-6 reps
	7-9	Sprint/quick feet/listen to instructor	30 sec, 2 reps
	7-9	Suicides/lateral shuffle, volleyball court ×2	2 reps
	7-9	Dot drill: add 180-degree jumps	5 reps ×3
	10-12	Ladder: in-in/out-out	4-6 reps
	10-12	Reaction drill/watch instructor point	45 sec, 2 reps
	10-12	Jingle-jangle	10 yards (9.1 m) up-back, 4-6 reps
	10-12	Dot drill: add single-leg hops	5 reps ×3
	13-15	Ladder: scissors	4-6 reps
	13-15	Reaction mirror drill/partner pressing	45 sec, 1 reps
	13-15	Jingle-jangle	20 yards (18.3 m) up-back, 4-6 reps
	16-18	Ladder: "Ickey shuffle"	4-6 reps
	16-18	Reaction instructor pointing/quick feet + up/down with pushup	45 sec, 2 reps
	16-18	Power rebounds relay	1 set
Strength training, on the court	1-18	Squats with resistance band	30 sec all exercises: sessions 1-6
		Power lunges (pulsating)	45 sec all exercises: sessions 7-12
		Single-leg heel raises	60 sec all exercises: sessions 13-18
		Supine hamstring bridge, single leg	
		Seated scapular retraction	
		Seated latissimus pull with resistance band	
		Seated scapular protraction with resistance band	
		Seated external rotation with resistance band	
		Partner internal rotation with resistance band	
		Abdominals of choice	
		Hip flexor resistance band kicking with partner	
		Steamboats (hip flexion)	
		Hip abductor resistance band kicking with partner	
		Lateral walking with resistance band	

Reps, Repetitions.

TABLE 14-7 Sportsmetrics Tennis

Component	Session no.	Exercise	Duration
Agility, reaction	1-3	Shadow swing baseline: forehand, backhand	2 sets × 10 reps each side
	1-3	Alternating short and deep balls: forehand, backhand	1 set × 10 reps each side
	4-6	Alternating short and deep balls: forehand, backhand	2 sets × 8 reps each side
	4-6	Resistance belt forehand and backhand	1 set × 10 reps each side
	7-9	Alternating short and deep balls: forehand, backhand	2 sets × 8 reps each side
	10-12	Rapid drop feed: forehand, backhand	2 sets × 8 reps each side
	13-15	Forehand, backhand reaction: facing net	2 sets × 8 reps each side
	13-15	Forehand, backhand reaction: facing fence	2 sets × 10 reps each side
	13-15	Rapid return serve feeds: forehand, backhand	2 sets × 8 reps each side
	16-18	Up-up, back-back, sprint to ground stroke, sprint to volley (forehand, backhand)	90 sec each side
Acceleration, speed, endurance	1-3	"Suicides," 1-court	2 reps
	4-6	Net zigzag	2 reps
	4-6	Partner push-offs	5 sec, 5 reps
	7-9	Forehand, backhand wide continuous hitting	8-6-6-8 reps
	7-9	Net zigzag	3 reps
	7-9	Partner push-offs	10 sec, 3 reps
	10-12	Baseline random feed: forehand, backhand	1 min, 2 min
	10-12	Net zigzag	3 reps
	10-12	Sprint/quick feet/listen to instructor	60 sec, 2 reps
	13-15	Suicides, 1-court	2 reps
	13-15	Suicides, 2 courts	1 rep
	13-15	Sprint/quick feet/listen to instructor	60 sec, 3 reps
	16-18	Forehand, backhand wide continuous hitting	6-4-4-6 reps
	16-18	Suicides, 1-court	4 reps
	16-18	Suicides, 2 courts	1 rep
Ladders, additional jumps	1-3	Up-up, back-back, sprint to cone, backpedal	2 reps
	4-6	Patterns 1 and 2	25 sec each
	7-9	Up-up, back-back, sprint to cone, backpedal	3 reps
	7-9	Patterns 3 and 4	25 sec each
	10-12	Up-up, back-back, sprint to cone, backpedal	2 reps
	10-12	Patterns 5 and 6	25 sec each
	13-15	Up-up, back-back, sprint to cone, backpedal	3 reps
	13-15	Patterns 7 and 8	25 sec each
	16-18	Patterns 9 and 10	25 sec each
Strength training, on the court	1-6	Medicine ball forehand	2 sets × 8 reps
	1-6	Medicine ball backhand	2 sets × 8 reps
	1-3	Medicine ball overhead	2 sets × 8 reps
	4-6	Medicine ball backwards, between legs	2 sets × 8 reps
	4-6	ETCH-Swing forehand and backhand	1 set × 10 shots each side
	7-9	ETCH-Swing forehand, backhand, serve	2 sets × 15 shots each side
	16-18	Medicine ball twisting lunges	2 sets × 16 reps
	1-18	Backward lunge, add hand weight day 4	1 full court × 2-4 reps
	1-18	Single-leg toe raise, add hand weight day 4	3 sets × 10-20 reps each leg
	1-18	Seated press-ups	10-20 reps
	1-18	Regular or wall pushups	3 sets × 10-20 reps
	1-18	Wall-sits	3 sets × 45-60 sec
	1-18	Wall-sits, ball pressed between legs	3 sets × 45-60 sec
	1-18	Abdominals, choose variety	150-300 reps
	1-18	Resistance band hip abduction, adduction	2-3 sets × 10-15 reps each side
	1-18	Tennis ball small circles	30-60 circles each arm
	1-18	Medicine ball overhead dribble	30-60 reps
	1-18	Medicine ball sideways core toss against wall	2 sets × 10-15 reps each side

Reps, Repetitions.

TABLE 14-11 Results of the Sportsmetrics Tennis Training Program

Test	Pretrain, Mean ± SD	Posttrain, Mean ± SD	Difference, Mean ± SD	*P* Value	Effect Size
One-court suicide(s)	18.55 ± 1.68	16.04 ± 1.23	–2.51 ± 1.18	<.0001	1.70
Abdominal endurance(s)	87 ± 56	162 ± 98	74 ± 75	<.0001	0.94
Baseline backhand (# reps)	8.5 ± 0.9	9.2 ± 0.7	0.7 ± 0.7	<.0001	0.88
Baseline forehand (# reps)	8.6 ± 1.0	9.3 ± 0.8	0.7 ± 0.9	<.0001	0.77
Baseline backhand distance (m)	42.8 ± 4.6	46.3 ± 3.6	3.5 ± 3.8	<.0001	0.85
Baseline forehand distance (m)	43.2 ± 5.1	46.8 ± 4.2	3.6 ± 4.7	<.0001	0.77
Service line (# reps)	22.4 ± 2.9	24.5 ± 2.2	2.1 ± 2.6	<.0001	0.82
Service line distance (m)	89.4 ± 11.8	97.8 ± 8.9	8.4 ± 10.9	<.0001	0.80
Single-leg hop, right leg (cm)	128.2 ± 28.5	141.8 ± 22.8	13.7 ± 21.3	.0004	0.53
Single-leg hop, left leg (cm)	129.5 ± 27.1	138.3 ± 26.0	8.9 ± 14.6	.0007	0.33
Single-leg triple-crossover hop, right leg (cm)	340.7 ± 71.9	373.6 ± 70.1	32.8 ± 68.9	.006	0.46
Single-leg triple-crossover hop, left leg (cm)	340.5 ± 77.6	374.3 ± 78.4	33.8 ± 67.2	.004	0.43

Positive values indicate improvements, except for the one-court suicide, where the negative mean difference represents improved speed.

TABLE 14-12 Improvements in Speed, Agility, and Abdominal Endurance in Players Who Completed Multiple Training Programs

	ONE-COURT SUICIDE(S)			BASELINE FOREHAND (M)			BASELINE BACKHAND (M)			SERVICE LINE (M)			ABDOMINAL ENDURANCE(S)		
Training Session	Mean ± SD	*P* Value	ES	Mean ± SD	*P* Value	ES	Mean ± SD	*P* Value	ES	Mean ± SD	*P* Value	ES	Mean ± SD	*P* Value	ES
First	2.56 ± 1.17	<.0001	1.63	4.6 ± 3.9	.0004	1.01	4.8 ± 3.2	<.001	1.07	12.3 ± 11.3	<.001	1.30	84 ± 98	.005	1.02
Second	1.11 ± 1.07	.0003	1.36	2.6 ± 3.5	.01	0.73	1.6 ± 4.2	NS	0.46	3.2 ± 9.9	NS	0.32	70 ± 89	.01	1.20
Third	0.96 ± .032	.004	0.73	3.8 ± 2.9	.02	1.33	2.7 ± 2.3	.02	0.89	11.6 ± 10.8	.03	0.73	111 ± 86	.02	0.95

Data represent the difference between tests conducted before and on completion of each training session. Positive values indicate improvements, except for the one-court suicide, where the negative mean difference represents improved speed.
ES, Effect size; *NS,* not significant; *SD,* standard deviation.

prepare for high school or tournament competition. Statistically significant improvements and large or moderate ESs were found for the speed and agility and abdominal endurance tests after the first, second, and third training programs among these players (Table 14-12).

Sportsmetrics Return to Play

The Sportsmetrics Return to Play program was developed as an end-stage component for rehabilitation in athletes who have sustained an ACL injury or undergone ACL reconstruction. The following are the indications to initiate the Return to Play program:

1. Negative pivot-shift test
2. Three millimeters or less increase anterior tibial translation on Lachman test
3. Less than 20% deficit peak torque hamstrings and quadriceps on isokinetic test
4. Less than 20% deficit in the distance hopped between the reconstructed and contralateral legs: single-leg hop for distance test and single-leg triple-hop for distance test
5. Successful completion *running program* with no pain, swelling, or giving-way
6. Successful completion *beginning plyometric training* with therapy staff: level surface box hops using both legs from front to back and side to side, diagonal hops using both legs, single-leg surface box hops using vertical box hops

In this program, the athlete conducts Sportsmetrics training at home using instructional videotapes but must see the physical therapist before training begins, 2 weeks later before the start of the second phase of Sportsmetrics, and then another 2 weeks later before the start of the third phase of training. In this manner, the therapist can watch and educate the athlete regarding proper form and positioning for each jump.

STRATEGIES FOR IMPLEMENTATION OF NEUROMUSCULAR TRAINING

Widespread Implementation of Neuromuscular Training

The widespread implementation of ACL injury prevention programs requires efforts at multiple levels and includes many disciplines. We identify the following as important areas to achieve success:

1. Disseminate and integrate information on ACL intervention programs to individuals directly involved with athletes, including coaches, physical education teachers, athletic trainers, strength and conditioning specialists, school administrators, primary care physicians, and pediatricians. Include the entire tier of the sports hierarchy, from local clubs and schools to national sports organizations.
2. Target governing bodies of sports organizations to facilitate or regulate the integration of ACL injury prevention training principles into routine team practices.
3. Request financial assistance from major sports organizations, sports industry for-profit companies, sports medicine organizations, national orthopedic and sports medicine research organizations, and individual philanthropists.
4. Target insurance and hospital organizations to participate in local prevention programs aimed at decreasing knee injuries in the communities they serve.
5. Continue to study risk factors and develop high-risk biomechanical profiles using findings from collaborative multisite studies. Develop screening procedures that can be used during routine preparticipation physical examinations.

To implement Sportsmetrics on a widespread basis, a formal course was devised at our institution to educate and certify health care professionals and coaches who wish to conduct training in their communities. The 13-hour formal course teaches the following:

1. The theories of why female athletes have an increased incidence of serious knee ligament injuries compared with males.
2. The scientific basis of Sportsmetrics.
3. The necessity for neuromuscular training versus plyometric performance enhancement training.
4. The verbal cues and methods required to teach the program to produce changes in landing mechanics and body positioning.
5. The differences between Sportsmetrics and other neuromuscular training programs.
6. Marketing strategies and ways to implement training in the community.
7. The necessity to conduct sports injury testing and produce research data.
8. For those involved in rehabilitation clinics, the implementation of Sportsmetrics as a component of rehabilitation after ACL reconstruction.

Participants are given a detailed demonstration of every jump and spend a few hours practicing the jumps themselves and conducting mock instructions for the teaching staff. Each participant is taken through the SIT and given step-by-step instruction on the video drop-jump test.[47] A formal written examination is conducted to ascertain that the participant has adequate knowledge of knee anatomy and strength training and plyometric concepts. A practical examination is done in which the participant trains a local athlete to demonstrate to our staff that they understand the correct verbal cues and training methodology to produce the desired result of proper body positioning and landing mechanics. Information regarding this course may be obtained at www.sportsmetrics.org.

Problems Encountered and Suggested Solutions

In our experience, young athletes are easily convinced to participate in performance enhancement training. However, unless they or someone they know has gone through a serious knee ligament injury, they simply do not comprehend the consequences of such an injury. It takes considerable effort on the part of the health care professional to educate and motivate athletes to undergo 6 weeks of training (3 times/week) to prevent an injury. In a similar manner, coaches are difficult to convince unless they have lost a number of athletes to ACL injuries. The development of the sport-specific Sportsmetrics programs, with their proven effectiveness in improving athletic performance indices, has helped this problem. The marketing strategy used involves the explanation of these improvements, with the added benefit of an ACL injury prevention component.

Because not all athletes have access to a certified instructor, a two-volume instructional DVD set and detailed manual are available. The first volume focuses on technique and teaching the proper form for body positioning and landing position. The second volume provides a step-by-step analysis of the training program and includes the dynamic warmup, jumps, and flexibility exercises.

Acknowledgments

We acknowledge Stephanie Tutalo Smith and Thomas Campbell for training in Cincinnati, OH; Tina Garrison for training in Alexandria, LA; Alex Hermeto and Michael Stamps for training in Fort Myers, FL; and Debbie Conley for training in Rogers, MN.

INTRODUCTION

This chapter provides a summary of the important biomechanic principles gained from our publications and other investigations regarding the posterior cruciate ligament (PCL) and posterolateral structures (PLSs). The primary PLSs of the knee joint are the fibular collateral ligament (FCL) and popliteus muscle-tendon-ligament unit (PMTL), including the popliteofibular ligament (PFL) and posterolateral capsule (PLC). Additional PLSs that may be injured and require repair are iliotibial band femoral and tibial attachments, meniscal tibial and femoral attachments (including fascicles), the fabellofibular ligament, and the lateral capsule, including the anterolateral ligament. All of these structures are illustrated in Chapter 2. Data from these investigations provide the basis for the diagnosis of abnormal knee motion limits in single and combined ligament injuries and allow the surgeon to plan the appropriate ligament repair and reconstructive procedures.

EFFECT OF SECTIONING THE PCL AND PLSs ON THE LIMITS OF KNEE MOTION

A series of studies were conducted in cadaveric knees to measure the limits of anteroposterior (AP) translation, internal-external tibial rotation, and varus-valgus rotation (using a six-degrees-of-freedom electrogoniometer) under specific forces and moments with a verified testing apparatus previously described.[10,29,30,36,75,115]

The PCL and PLSs were sectioned in 15 knees, first separately and then in combination, to measure the resultant abnormal knee motion limits to simulate isolated and combined ligament ruptures.[30] The PLSs in this investigation included the FCL, PMTL, and PLC. A 100-N force was applied to determine the AP limits; 5 N-m was used for internal-external rotation limits; and 20 N-m was used for adduction-abduction (varus-valgus) limits from 0 to 100 degrees of knee flexion.

In these ligament-cutting experiments, the popliteus tendon was sectioned from the femoral attachment, which effectively removed the entire popliteus muscle tendon and PFL static function. In other experiments to be described,[78] the PFL was sectioned independently of the popliteus tendon attachment to investigate the individual function of this ligament. The PLC was removed, including all soft tissue structures posterior to the FCL, to ensure that the individual soft tissue components were removed. This included, in addition to the PLC, other tissue components compromising the fabellofibular ligament and capsular arm of the biceps femoris short head.

Effect on Limits of Extension

The normal fully hyperextended knee position averaged 5.6 ± 3.8 degrees. After sectioning the PCL or PLS alone, only slight and clinically insignificant increases in hyperextension were noted (such as 2.6 ± 0.09 degrees when the PLS was cut). When both the PCL and PLS were sectioned, the increase in hyperextension was 4.0 ± 1.4 degrees.

CRITICAL POINTS Effect of Sectioning the Posterior Cruciate Ligament and Posterolateral Structures on the Limits of Knee Motion

Limits of AP translation, internal-external tibial rotation, varus-valgus rotation under specific forces and moments were measured in cadaveric studies.

100-N force applied to determine the AP limits, 5 N-m for internal-external rotation limits, 20 N-m for adduction-abduction (varus-valgus) limits from 0 degrees to 100 degrees of knee flexion.

Effect on Limit of Knee Extension

- No primary restraint to hyperextension, structures work together: entire posterior knee capsule, oblique popliteal ligament, fabellofibular ligament, PCL, and ACL.

Effect on AP Translation Limits

- PCL primary restraint to posterior tibial translation throughout knee flexion.
- Increased posterior translation at 30 to 45 degrees flexion associated with injury to PLS, medial ligament structures.

Effect on Internal-External Tibial Rotation Limits

- No increase in external tibial rotation PCL cut alone.
- PLS primary restraint external tibial rotation low knee flexion positions; test 20-40 degrees of flexion.
- Increases in external tibial rotation at 90 degrees indicate injury to PLS and PCL

Effect on Adduction-Abduction Rotation Limits

- PLS primary restraint adduction (varus) rotation limits.
- Loss PLS converts both cruciate ligaments into primary restraints for varus loading.
- Combined rupture PCL/PLS requires surgical restoration of all structures.
- Abnormal medial or lateral joint opening (gap test) at arthroscopy: concurrent medial or lateral ligament reconstruction.

The data indicate that there is no primary restraint in the knee that resists hyperextension. Many structures work in synergy to resist hyperextension, and it is therefore not surprising that sectioning the PLS or PCL results in only a small increase. Other structures anatomically positioned to resist hyperextension include the entire posterior knee capsule (femoral-meniscal tibial attachments), oblique popliteal ligament, fabellofibular ligament, and posterior fibers of the PCL and anterior cruciate ligament (ACL). A reconstructive procedure is described in Chapter 17 for knees with severe knee hyperextension. This procedure is performed in addition to other required ligament reconstructive procedures.

Effect on Anteroposterior Translation Limits

The normal anterior and posterior translation knee limits are shown in Figure 15-1, *A*. The increase in these limits when the PCL is cut are shown in Figure 15-1, *B*, and the further increase in these limits when the PLSs are also sectioned is shown in Figure 15-1, *C*. The values for the increase in motion limits are given in Table 15-1.

The data show that the PCL is a primary restraint to posterior tibial translation throughout knee flexion, with the exception of a small increase in posterior translation at full extension when the PLSs are cut. The clinical finding of a knee with increased posterior translation at 30 to 45 degrees of knee flexion, similar to the posterior translation limit at 90 degrees (Fig. 15-2), indicates associated injury to the PLSs and the medial structures.

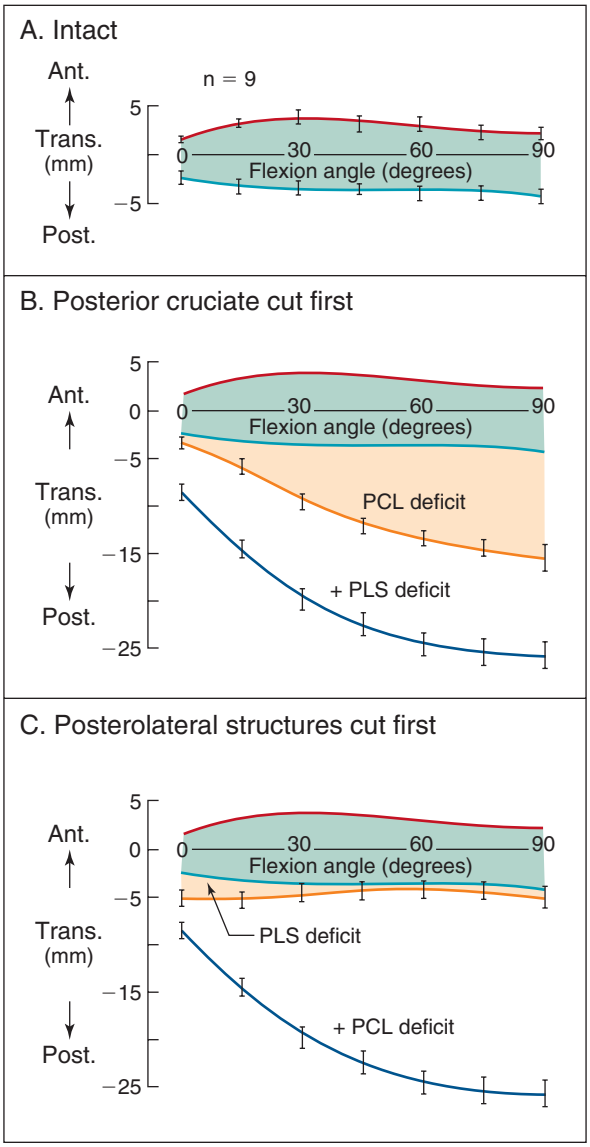

FIG 15-1 Limits of anterior *(ant.)* and posterior *(post.)* translation (vertical axis) when a 100-N anteroposterior (AP) force is applied. **A,** Intact knees. The curves show the average limits of motion and the standard deviation for nine knees. The range of total AP translation of the intact knee is shaded green. **B,** The posterior cruciate ligament (PCL) is cut first. The increase in posterior translation after cutting the PCL is shown in the area shaded in orange (PCL deficit). The limit of posterior translation, and therefore the amount of increase, is controlled by the remaining intact structures. The unshaded portion (+ posterolateral structure [PLS] deficit) shows the added increase when the PLSs (fibular collateral ligament, capsule, popliteus muscle-tendon-ligament) were cut after the PCL had first been removed. A concurrent external rotation took place with this cut. **C,** The PLSs are cut first. There was only a small increase (PLS deficit) in the posterior limit near full extension when the posterolateral structural elements were cut first. A concurrent external rotation was also present. (From Grood ES, Stowers SF, Noyes FR. Limits of movement in the human knee: effect of sectioning the posterior cruciate ligament and posterolateral structures. *J Bone Joint Surg Am.* 1988;70:88-97.)

It should be noted that a complete description of the translation limits requires an anatomic measurable point on the tibia, which is selected at the central coronal point on the tibia. The limits of posterior translation to the medial and lateral tibiofemoral joints are described in a subsequent study.[75]

FIG 15-2 Severe posterior tibial subluxation is shown in a chronic posterior cruciate ligament–deficient knee, which is caused either by physiologic laxity of the remaining secondary restraints or as the result of a traumatic injury.

TABLE 15-1 Increased Motion Compared With Normal Motion That Occurred When the Indicated Structures Were Sectioned

	ANGLE OF FLEXION (DEGREES)				
	0	15	30	60	90
Anterior Limit (mm)					
All cut	0.5 ± 0.8	0.6 ± 0.6	0.7 ± 0.7	0.4 ± 1.3	0.8 ± 1.0
Posterior Limit (mm)					
PCL cut	1.0 ± 1.6	3.6 ± 1.6	6.4 ± 1.5	9.6 ± 1.3	11.4 ± 1.9
PLS cut	3.1 ± 0.7	1.9 ± 0.8	1.4 ± 1.1	0.7 ± 0.8	0.5 ± 0.7
All cut	6.6 ± 2.7	11.3 ± 3.1	15.8 ± 3.0	20.7 ± 3.4	21.5 ± 3.4
External Rotation Limit (Degrees)					
PCL cut	0.4 ± 0.5	0.2 ± 0.5	0.2 ± 0.6	0.4 ± 0.9	0.6 ± 1.2
PLS cut	8.5 ± 2.6	11.8 ± 3.0	13.0 ± 2.3	5.2 ± 9.0	5.3 ± 2.6
All cut 1	10.5 ± 4.0	14.2 ± 3.7	18.0 ± 3.8	21.0 ± 3.1	20.9 ± 2.8
Varus Angulation Limit (Degrees)					
FCL cut	2.5 ± 0.4	4.5 ± 0.4	5.7 ± 0.2	5.5 ± 0.6	4.3 ± 0.9
PCL cut	0.4 ± 0.6	0.4 ± 0.6	0.4 ± 0.6	0.8 ± 0.6	1.4 ± 0.6
PLS cut	6.4 ± 2.3	7.9 ± 2.0	9.0 ± 2.0	8.3 ± 3.7	6.8 ± 4.5
All cut	8.1 ± 2.5	11.3 ± 3.0	14.2 ± 3.3	18.9 ± 3.4	21.2 ± 3.0
Valgus Angulation Limit (Degrees)					
PCL cut	0.3 ± 0.6	0.3 ± 1.0	0.5 ± 1.7	0.7 ± 1.9	0.5 ± 1.0

All values are given as mean ± standard deviation.
FCL, Fibular collateral ligament; *PCL,* posterior cruciate ligament; *PLS,* posterolateral structures (FCL, capsule, popliteus muscle-tendon-ligament).

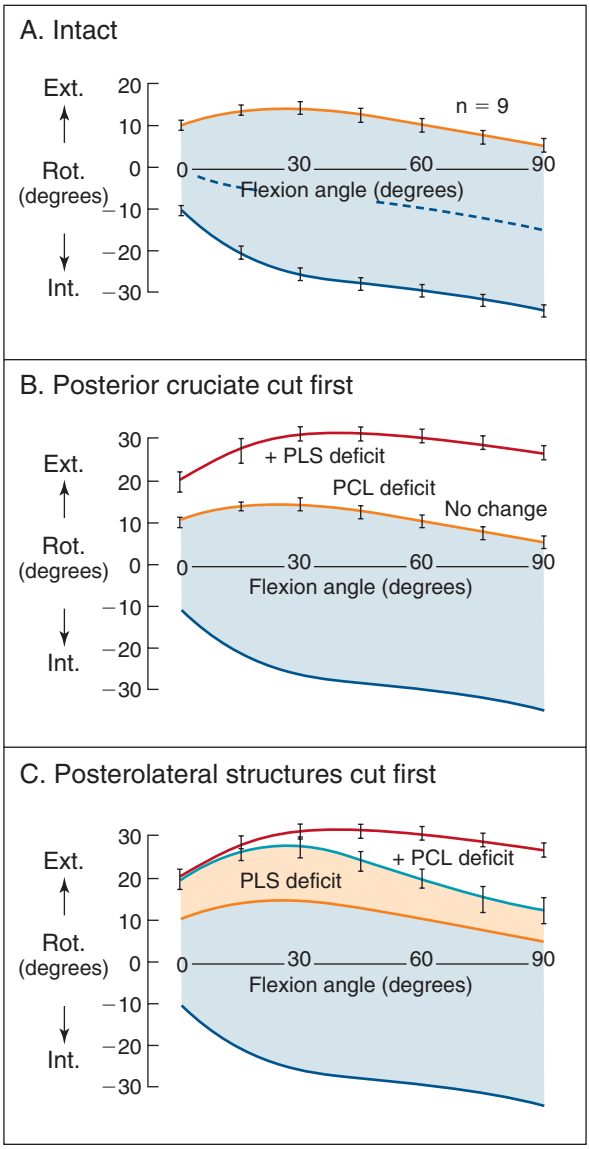

FIG 15-3 The limits of internal *(int.)* and external *(ext.)* rotation *(rot.)* of the tibia when a 5-N torque is applied. The fully extended position, measured in the intact knee, was used as the zero-rotation reference. **A,** Intact knees. The upper curve shows the limit of external rotation. The dashed line shows the average position of the knee during passive flexion with the tibia hanging freely. The range of tibial rotation in the intact knee is shaded. **B,** The posterior cruciate ligament (PCL) is cut first. No change was found in external tibial rotation. **C,** Posterolateral structures (PLS; fibular collateral ligament, capsule, popliteus muscle-tendon-ligament) are cut first. Increases in external tibial rotation occurred at low flexion angles. With added PCL sectioning, the increase in external tibial rotation occurred at high flexion angles. (From Grood ES, Stowers SF, Noyes FR. Limits of movement in the human knee: effect of sectioning the posterior cruciate ligament and posterolateral structures. *J Bone Joint Surg Am.* 1998;70:88-97.)

In a knee with a combined deficiency of the PCL and PLS, the abnormal posterior tibial translation is at least four to five times the normal limit throughout knee flexion.

Effect on Internal-External Tibial Rotation Limits

The normal knee motion limits to internal and external tibial rotation are shown in Figure 15-3, *A*. There is no increase in external tibial rotation when the PCL is cut alone (see Fig. 15-3, *B*). This finding demonstrates that the PLSs are the primary restraint for external tibial rotation throughout knee flexion. When only the PLSs are sectioned, an increase in external tibial rotation occurs (see Fig. 15-3, *C*), which is greatest at 30 degrees of knee flexion. The amount of external tibial rotation decreases as the knee is flexed, showing the influence of the PCL in limiting external tibial rotation after the PLSs are sectioned.

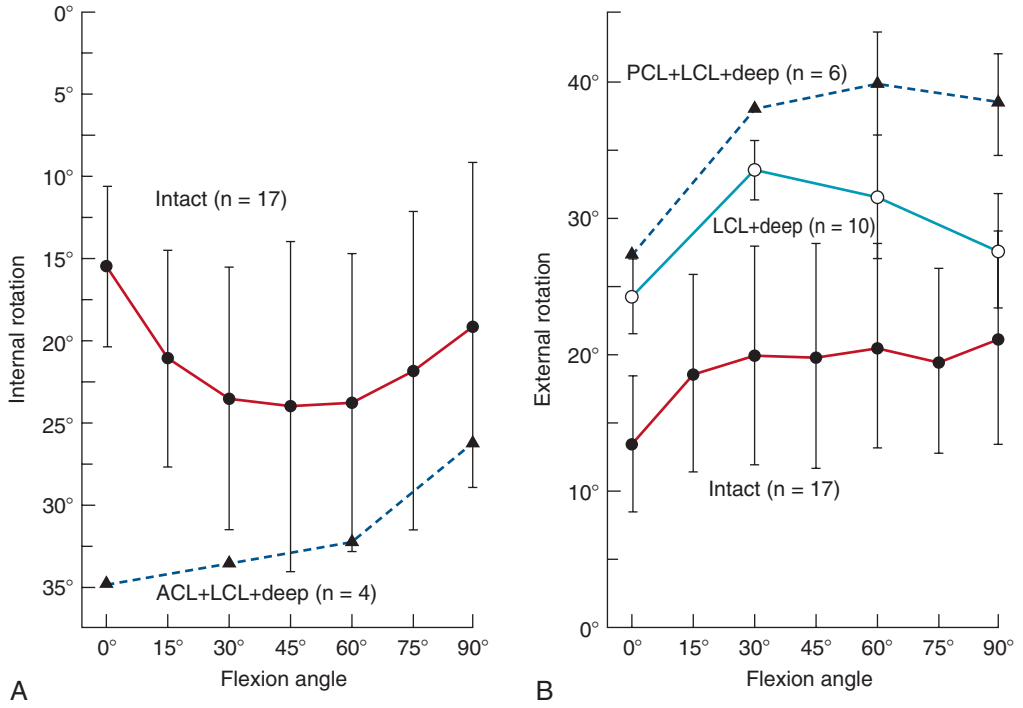

FIG 15-4 Primary internal and external tibial rotations resulting from 4.5 N-m of internal and external tibial torque in intact knees and after ligament sectioning. **A,** Increased internal rotation occurred only with combined section of the lateral collateral ligament (LCL), deep structures, and anterior cruciate ligament (ACL). **B,** Increased external rotation occurred at all angles of flexion with combined section of the LCL and deep structures, with additional increases at 60 degrees and 90 degrees when the posterior collateral ligament (PCL) was sectioned. The dashed lines indicate a lack of statistical difference from the adjacent curve unless otherwise stated. *(From Gollehon DL, Torzilli PA, Warren RF. The role of the posterolateral and cruciate ligaments in the stability of the human knee. A biomechanical study. J Bone Joint Surg Am.* 1987;69:233-42.)

These data indicate that the PLSs provide the primary restraint to external tibial rotation at low knee flexion positions and therefore should be tested in this range (20-40 degrees of flexion). Increases in external tibial rotation at 90 degrees indicate injury to both the PLS and PCL, consistent with the dial test (see Chapter 17). The data are in disagreement with the classic interpretation of the posterolateral drawer test at 90-degree flexion, indicating injury to only the PLS. The resisting function of the FCL, popliteus tendon, and PFL is described in separate studies mentioned later in this chapter.

Gollehon and coauthors[26] reported similar results showing an increase in external tibial rotation of 20-degree flexion after sectioning the PLS at 30 degrees of flexion. Sectioning of the PCL along with the PLS did not produce further significant increases in external tibial rotation (Fig. 15-4).

Effect on Adduction-Abduction Rotation Limits

The normal limits of adduction and abduction rotation are shown in Figure 15-5, *A*. Sectioning the PCL produces very small changes in these limits (see Fig. 15-5, *B*). When the PLSs are sectioned alone, large increases in adduction occur (see Fig. 15-5, *C*), indicating that these structures are the primary restraint to this knee motion. Once the PLSs are removed, the PCL becomes a primary restraint and large increases in the adduction limit occur with knee flexion.

The limits to adduction (varus angulation) after sectioning the FCL, the PLS (PMTL and PLC), and all structures (PCL, FCL, PMTL, and PLC) are graphed in Figure 15-6.[30] The data demonstrate that the FCL is the primary restraint for lateral joint opening, with further increases after the remaining PLSs are sectioned.

Markoff and associates[63] developed an in vitro system in cadaveric knees in which load transducers were used to measure ACL and PCL forces under different loading situations. After sectioning the FCL and the other PLSs, large increases were noted in resisting tensile forces in both cruciate ligaments under varus loading (Fig. 15-7) and in the PCL under posterior tibial loads and external tibial torques (Fig. 15-8). These findings are in agreement with prior studies, because the loss of the PLS converts both cruciate ligaments into primary restraints for varus loading, in which the ligaments are poorly positioned with small lever arms to resist this motion.

The importance of load-sharing of the PLS with the PCL has been demonstrated in many studies, which reinforces the need, in knees with combined PCL-PLS ruptures, to also perform posterolateral reconstructive surgery. An abnormal medial or lateral joint opening (gap test) to varus or valgus loading at arthroscopy indicates the necessity for concurrent medial or posterolateral ligament reconstruction. Otherwise, the majority of forces are placed on the ACL or PCL grafts, which may stretch out or fail postoperatively. The goal is to restore normal load-sharing in which the majority of varus-valgus loads and internal-external rotation torques are placed on the medial and lateral structures and not the cruciate ligaments.

One problem with cadaveric studies in which knee motion limits after ligament sectioning are measured is that the resulting millimeters of anterior or posterior translation (subluxation) of the medial and

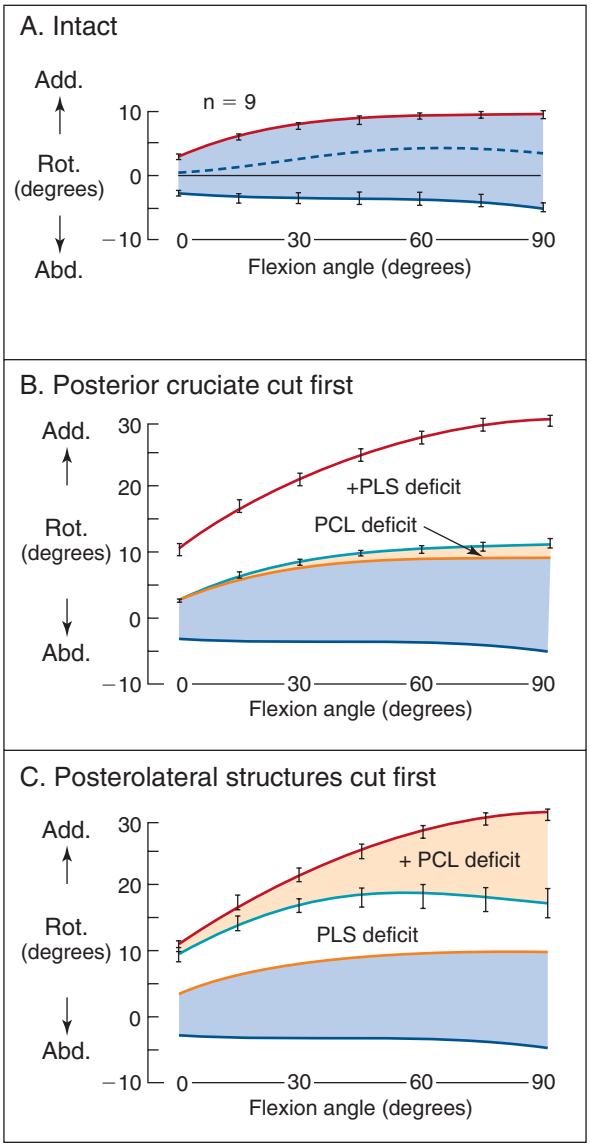

FIG 15-5 The limits of adduction *(add.)* and abduction *(abd.)* rotation *(rot.)* when a 20 N-m moment is applied. The fully extended position, measured in the intact knee, was used as the zero-rotation reference. **A,** Intact knees. The upper curve shows the limit of adduction rotation, and the lower curve shows the limit of abduction rotation. The dashed line shows the amount of adduction when the knee is passively flexed, with the tibia upside down to ensure tibiofemoral contact in both the medial and lateral compartment. **B,** The posterior cruciate ligament (PCL) is cut first. **C,** Posterolateral structures (fibular collateral ligament, capsule, popliteus muscle-tendon-ligament) are cut first. (From Grood ES, Stowers SF, Noyes FR. Limits of movement in the human knee: effect of sectioning the posterior cruciate ligament and posterolateral structures. *J Bone Joint Surg Am.* 1998;70:88-97.)

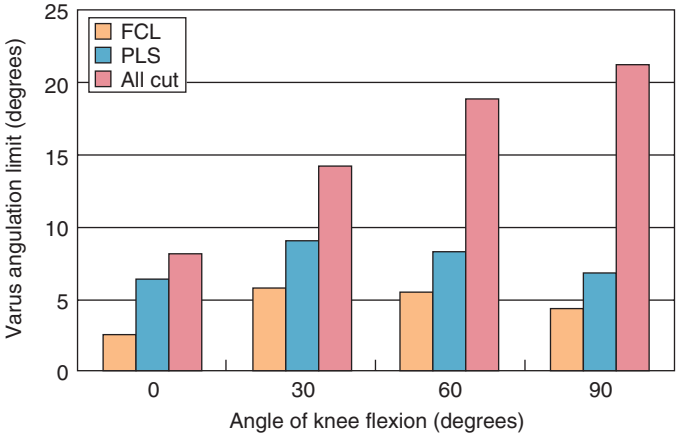

FIG 15-6 Increases in the limits to adduction (varus angulation) are shown after sectioning the fibular collateral ligament (FCL), the posterolateral capsule (PLC; popliteus muscle-tendon-ligament [PMTL] and posterolateral capsule [PLC]), and all structures (PCL, FCL, PMTL, and PLC). The data demonstrate that the FCL is the primary restraint for lateral joint opening, with further increases after the remaining posterolateral structures are sectioned. *PLS,* Posterolateral structures. (From Grood ES, Stowers SF, Noyes FR. Limits of movement in the human knee: effect of sectioning the posterior cruciate ligament and posterolateral structures. *J Bone Joint Surg Am.* 1998;70:88-97.)

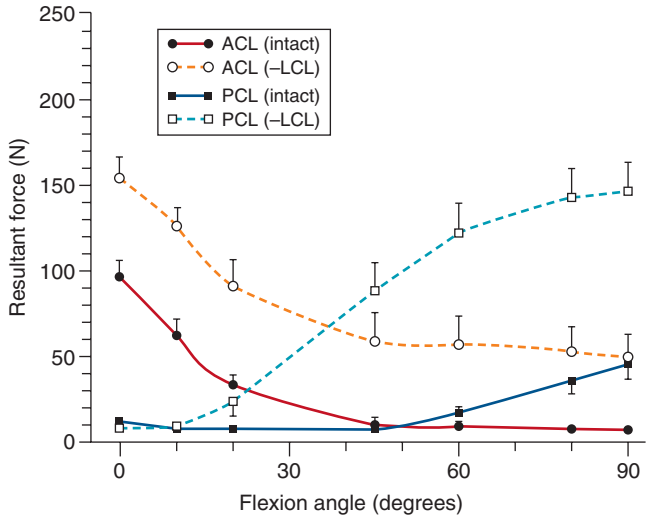

FIG 15-7 The forces generated in the anterior cruciate ligament (ACL) and posterior cruciate ligament (PCL) by 10.0 N-m of applied varus bending moment before (intact) and after sectioning of the lateral collateral ligament (LCL). The increases in the mean force in the ACL after ligamentous section were significant at all angles of flexion; the increases in the mean force in the PCL were significant from 45 to 90 degrees of flexion. The mean values for eight specimens are shown; the error bars indicate the standard error of the mean. (From Markolf KL, Wascher DC, Finerman GA. Direct in vitro measurement of forces in the cruciate ligaments. Part II: the effect of section of the posterolateral structures. *J Bone Joint Surg Am.* 1993;75:387-94.)

lateral tibiofemoral compartments are not measured or described. For example, when 15 degrees of increased external tibial rotation is measured after cutting the PLS, the resultant abnormal millimeters of posterior translation of the lateral tibial condyle are unknown. This is because it is also necessary to measure and compute the center of tibial rotation to determine the effect of the increase in degrees of external tibial rotation on the lateral and medial tibiofemoral compartment translation or position. Limited published data exist on tibial translations or subluxations of the medial and lateral compartments (rotatory subluxations) after knee ligament injuries, discussed in further detail in this chapter.[75]

ROLE OF THE POSTERIOR OBLIQUE LIGAMENT

Petersen and colleagues,[80] using a robotic testing system in a cadaveric study, examined the restraint of the superficial medial collateral

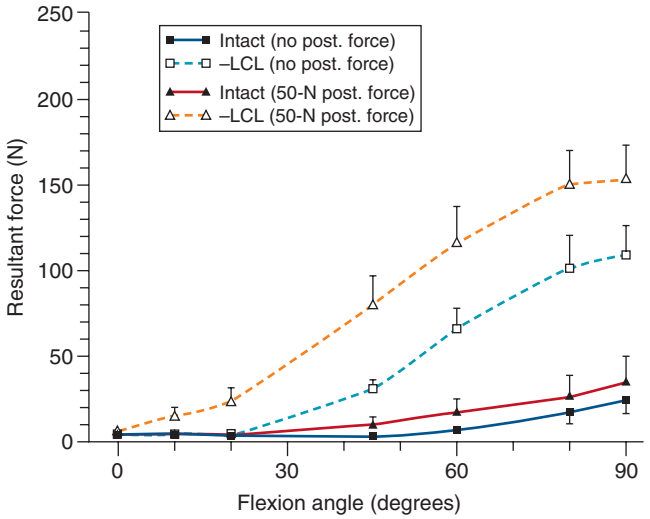

FIG 15-8 The forces generated in the posterior cruciate ligament (PCL) by 50 N of posterior *(post.)* tibial force, with the tibial rotated externally by 7 N-m of applied tibial torque. Application of the 50-N posterior tibial force had no significant effect on the mean force in the PCL in the intact specimens (intact). After ligamentous section (lateral collateral ligament [LCL], fibular collateral ligament), the posterior tibial force increased the mean force in the PCL at all angles except full extension. The mean values for eight specimens are shown; the error bars indicate the standard error of the mean. (From Markolf KL, Wascher DC, Finerman GA. Direct in vitro measurement of forces in the cruciate ligaments. Part II: the effect of section of the posterolateral structures. *J Bone Joint Surg Am.* 1993;75:387-94.)

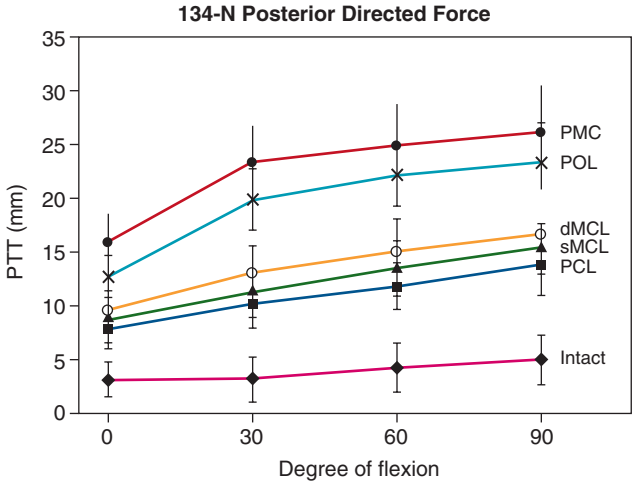

FIG 15-9 Posterior tibial translation (PTT) in response to a posterior load of 134 N (mean ± standard deviation). The effect of sectioning the secondary medial restraints resulted in a marked increase in posterior tibial translation. (From Petersen WJ, Loerch S, Schanz S, et al. The role of the posterior oblique ligament in controlling posterior tibial translation in the posterior cruciate ligament deficient knee. *Am J Sports Med.* 2008;36:495-501.)

ligament (SMCL), the deep medial collateral ligament (DMCL), the posterior oblique ligament (POL), and the posteromedial capsule (PMC) in resisting posterior tibial translation after PCL sectioning. The data shown in Figure 15-9 demonstrate the increase in posterior tibial translation after sequential ligament sectioning of the medial and posteromedial structures. The authors concluded that the POL has a much larger role than the SMCL and DMCL in resisting posterior tibial translation and internal tibial rotation. It should be noted that these two structures were first sectioned, and no studies were done when the POL was sectioned first. This indicates that there could be a sectioning artifact introduced in the study. Even so, there are posteromedial oblique capsular fibers from the medial femoral condyle to the tibia, just posterior to the SMCL, which resist internal tibial rotation and posterior tibial translation (after PCL sectioning). These authors concluded that discrete oblique fibers form the middle arm of the POL described by Hughston and Eilers.[41] Of interest in this cadaveric study was the finding that a valgus loading of the knee joint close to knee extension (with PCL deficiency) produced an increased posterior tibial translation of the medial compartment with absence of the POL and PMC.

Robinson and coworkers[85] conducted a cadaveric study of the medial and posteromedial structures and could not identify a distinct separate POL structure, but they did find an oblique portion of the PMC where fibers could be tensioned under internal tibial rotation loading. Robinson and associates[84] and Haimes and colleagues[36] studied the contribution of the PMC, which included the POL. Robinson and associates[84] reported that the PMC resisted 28% of the posterior tibial load when the tibia rotated freely in the extended knee, which rose to 42% when the tibia was subjected to internal rotation. These authors concluded the PMC resisted posterior tibial translation close to full extension and less so with knee flexion, which relaxes the PMC. With knee flexion, the SMCL resisted posterior tibial translation.

In knees with chronic PCL instability and associated medial and posteromedial ligament and capsular injury, the integrity of all the structures should be restored. Increased internal tibial rotation is assessed with the dial test. The problem is that the tibia drops posteriorly with PCL deficiency, and it is difficult to judge the added posterior subluxation on internal tibial rotation that tests the role of the PMC (including the POL).

FUNCTION AND ROLE OF THE PMTL

The PMTL includes (1) the muscular tibial origin, (2) the fibular origin (PFL), (3) the merging of both of these components to the popliteal tendon inserting on the lateral femoral condyle, (4) the inferior and superior popliteomeniscal fascicles forming the popliteal hiatus, and (5) the soft tissue attachments to the lateral meniscus and posterior tibia. The static stabilizing function of the PMTL that requires surgical reconstruction has been debated.[48,70,78] Studies from our laboratory advanced the hypothesis that the PFL has a secondary role in that it provides a functional attachment of the popliteus tendon to the fibula. However, removal of this fibular attachment has little effect on the limits of motion, as long as the popliteal tendon femoral and tibial attachments remain intact.[78] This hypothesis questions the success of operations in posterolateral rotational instability in which only the PFL is reconstructed, without attention to the FCL or popliteus tendon femoral and tibial attachments.[65,90,98]

As previously described, Grood and coauthors[30] reported increases in external tibial rotation (posterior subluxation lateral tibial plateau) that is highly dependent on the order of sectioning of the PLSs. The last remaining PLS sectioned will, in general, provide the largest effect in terms of increased knee motion limits after the other primary and secondary restraints have been sectioned. Therefore the experimental design on the order of ligament sectioning may induce an artifact and an incorrect assignment of a primary restraining role to a soft tissue structure. Shahane and associates,[90] in a cadaveric study, concluded that the PMTL was the primary restraint to external tibial rotation and

CRITICAL POINTS Function and Role of the Popliteus Muscle-Tendon-Ligament Unit

PMTL includes:

1. Muscular tibial origin
2. Fibular origin (PFL)
3. Merging of these components to popliteal tendon inserting on the lateral femoral condyle
4. Inferior and superior popliteomeniscal fascicles forming the popliteal hiatus.
5. Soft tissue attachments to lateral meniscus and posterior tibia

All PLSs provide restraint to external tibial rotation.

PFL has a secondary role; removal has little effect on the limits of motion (popliteal tendon femoral and tibial attachments intact).

Application to Surgical Reconstruction

- FCL, PMTL, posterolateral capsular structures function as a unit to resist external tibial rotation and varus rotation.
- FCL, PMTL act together at low- to mid-flexion positions.
- Reconstructing only PMTL can lead to failure if FCL is deficient.
- Reconstructing only FCL can lead to failure if PMTL is deficient.

the FCL was a secondary restraint. However, their study did not include sectioning the FCL first to determine whether increases in external tibial rotation occurred before sectioning the PMTL. In contrast, Veltri and colleagues[108,109] reported that sectioning the PFL (after first sectioning the FCL, popliteus tendon intact) resulted in only small and minor increases in external tibial rotation.

In their cadaveric study, Pasque and coworkers[78] implemented an experimental system similar to that already described,[29,30] in which an instrumented spatial linkage and loading of the knee joint was used with a 100-N posterior force, a 10 N-m varus force, and a 5 N-m external moment from 0 to 120 degrees of knee flexion. The ligament sectioning of the PLS was varied to more precisely define the restraining function of the individual structures. The results are shown in Figures 15-10 and 15-11. Sectioning the PFL in the intact knee produced no statistically significant changes in motion limits, whereas sectioning both the popliteus tendon and PFL together (removing the function of the PMTL) produced a small increase in external rotation from 3 to 5 degrees.

In another group of knees, the PCL, FCL, and PLC were first sectioned, followed by the PFL and then the popliteus tendon. Only small increases were noted after sectioning the PFL, as long as the popliteus tendon attachments remained intact.

In a separate study, Wroble and associates[115] reported the effect on external tibial rotation when only the popliteus tendon was sectioned in ACL-deficient knees (Fig. 15-12) and when only the FCL was sectioned along with the iliotibial band and lateral capsule (Fig. 15-13). Consistent with the studies previously discussed, only small increases in external tibial rotation were found when individual PLSs were sectioned.

All of the PLSs provide important restraints to external tibial rotation, whereas the PFL serves as a secondary restraint in providing a fibular origin to the PMTL. In acute knee injuries, all of the soft tissue structures including this fibular attachment should be repaired in addition to an FCL graft reconstruction (see Chapter 17). The FCL functions to limit external tibial rotation, particularly at low knee flexion angles, and is an important structure to reconstruct in posterolateral injuries. Sugita and Amis[99] measured the orientation of the FCL and PFL in cadaveric knees and reported that the

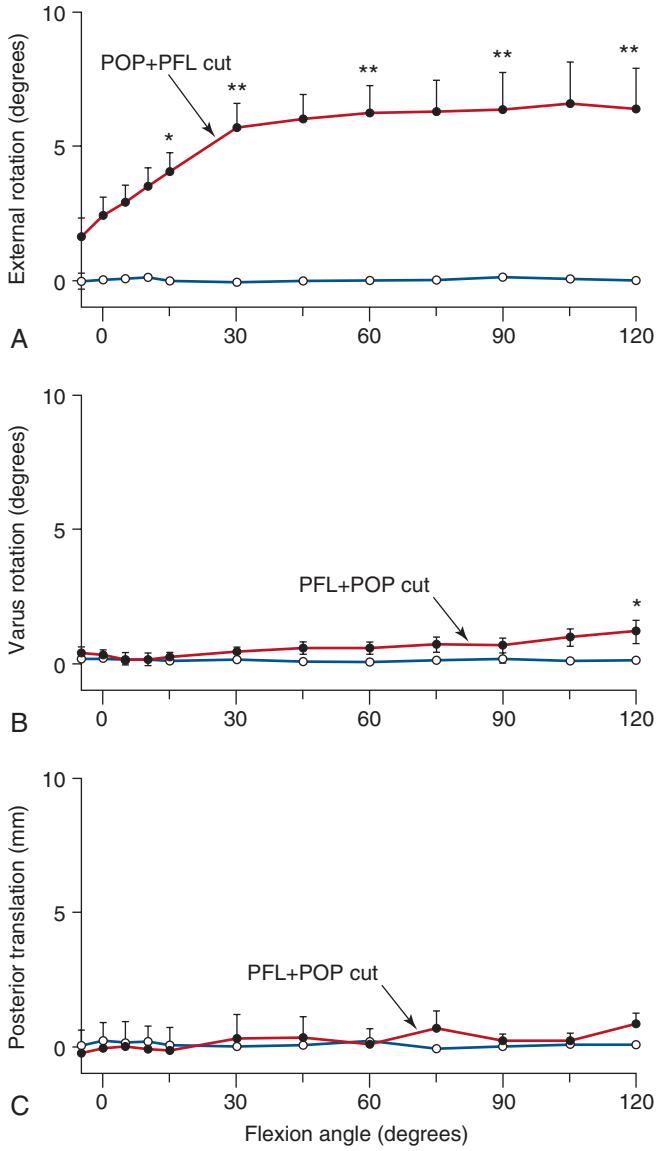

FIG 15-10 The increase in external rotation (**A**), varus rotation (**B**), and posterior translation (**C**) from the intact knee when the popliteofibular ligament (PFL) and popliteus (POP) tendon were sectioned. The data are given as the mean ± standard error of the mean. $*P < .05$, $**P < .001$ by one-tailed test after correction of multiple comparisons. (From Pasque C, Noyes FR, Gibbons M, et al. The role of the popliteofibular ligament and the tendon of popliteus in providing stability in the human knee. *J Bone Joint Surg Br.* 2003;85:292-298.)

FCL slackened with increasing knee flexion, achieving a vertical position at 70 degrees of flexion, which decreased its ability to resist external tibial rotation. The PTML maintained an oblique orientation, which allowed effective resistance of external tibial rotation with increasing knee flexion, indicating the importance of restoring PTML function.

LaPrade and coworkers[49] conducted an in vitro cadaveric knee study in which a specially designed buckle transducer was attached to the FCL, popliteus tendon, and PFL. The knee joints were subjected to AP forces (67 N), varus-valgus torques (12 N-m), and internal-external rotation torques (6 N-m). A reciprocal relationship of load-sharing with knee flexion was found, because the FCL had higher loads resisting the external rotation torque at low flexion positions and the

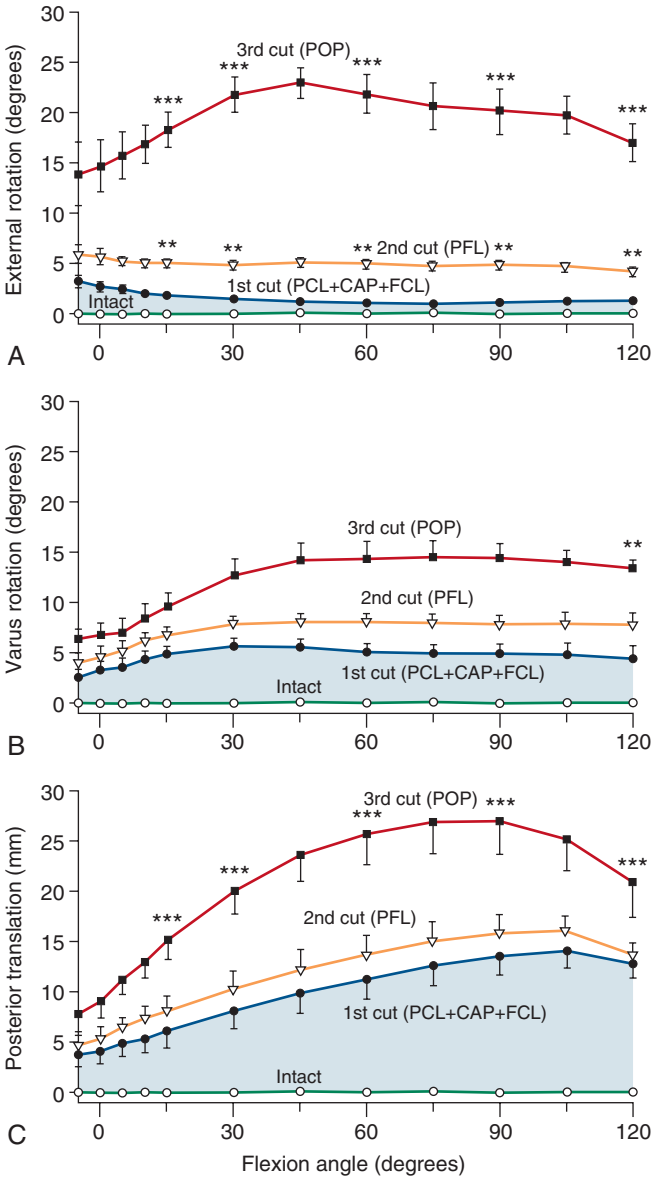

FIG 15-11 The increase in motion limits from the intact knee after external rotation (**A**), varus rotation (**B**), and posterior translation (**C**). The open circles represent the intact knee. The solid circles represent sectioning of the posterior cruciate ligament (PCL), fibular collateral ligament (FCL), and posterolateral capsule (CAP). This denotes that multiple ligaments have been sectioned, leaving only the popliteofibular ligament (PFL) and popliteus tendon (POP) structures remaining. Only small increases were noted after the PFL had been cut (triangles). Subsequent sectioning of the POP (squares) resulted in large increases in movement limits. Data are given as the mean ± standard error of the mean. $*P \leq .01$ and $***P \leq .001$ after correction for multiple comparisons (one-tailed *t* test). (From Pasque C, Noyes FR, Gibbons M, et al. The role of the popliteofibular ligament and the tendon of popliteus in providing stability in the human knee. *J Bone Joint Surg Br.* 2003;85:292-298.)

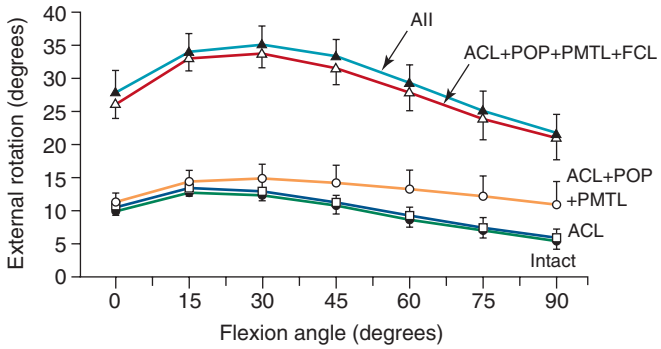

FIG 15-12 Limits of external rotation with 5 N-m moment for intact specimens and with structures cut. "All" included the anterior cruciate ligament (ACL), popliteus tendon (POP), popliteus muscle-tendon-ligament unit (PMTL), fibular collateral ligament (FCL), and iliotibial band and anterolateral capsule (ALS). Statistically significant increases in external rotation were found in the ACL + POP + PMTL cut state at 60 degrees of flexion and higher. Statistically significant increases in external rotation were found at all flexion angles for the ACL + POP + PMTL + FCL and the "all" cut states. The intact FCL limits external rotation at all flexion angles after the ACL + POP + PMTL was sectioned. (From Wroble RR, Grood ES, Cummings JS, et al. The role of the lateral extraarticular restraints in the anterior cruciate ligament-deficient knee. *Am J Sports Med.* 1993;21:257-263.)

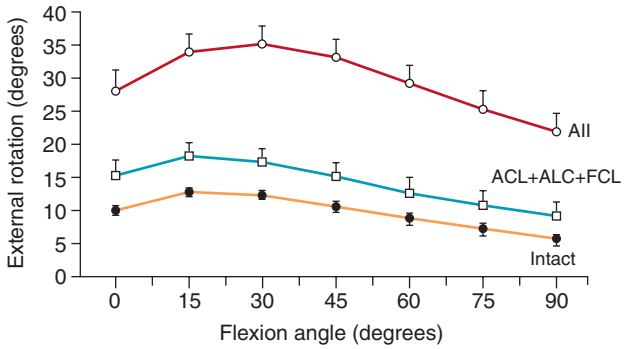

FIG 15-13 Limits of external rotation with 5 N-m moment for intact specimens and with anterior cruciate ligament (ACL) + iliotibial band and anterolateral capsule (ALC) + fibular collateral ligament (FCL) and "all" structures (ACL + ALC + FCL + popliteus muscle-tendon-ligament unit [PMTL] + popliteus tendon [POP]) cut. Statistically significant increases were found at all flexion angles for both cut states. The difference between the ACL + ALC + FCL and "all" curves represents the restraining function of the PMTL and POP toward external rotation. Note that increases occur at all flexion angles. (From Wroble RR, Grood ES, Cummings JS, et al. The role of the lateral extraarticular restraints in the anterior cruciate ligament-deficient knee. *Am J Sports Med.* 1993;21:257-263.)

popliteus complex had higher loads at 60 degrees and 90 degrees of knee flexion (Fig. 15-14). Even though buckle transducers have inherent problems in truly measuring ligament tensile-resisting loads, the results show that all three structures are important in resisting external tibial rotation loads and the importance of anatomic reconstruction of these structures when deficient.

Application to Surgical Reconstruction

These studies provide the surgeon with important principles for the surgical restoration of function in acute and chronic injuries to the PLS. The FCL, PMTL, and PLC function as a unit in resisting external tibial rotation and varus rotation. As such, no individual structure is the primary restraint in resisting these motions. The PLC slackens with knee flexion, providing less of a contribution to resisting these motions. The FCL and PMTL provide important contributions and act together at low- to mid-flexion positions. The FCL provides a higher contribution to varus rotation, and the PMTL provides a higher contribution

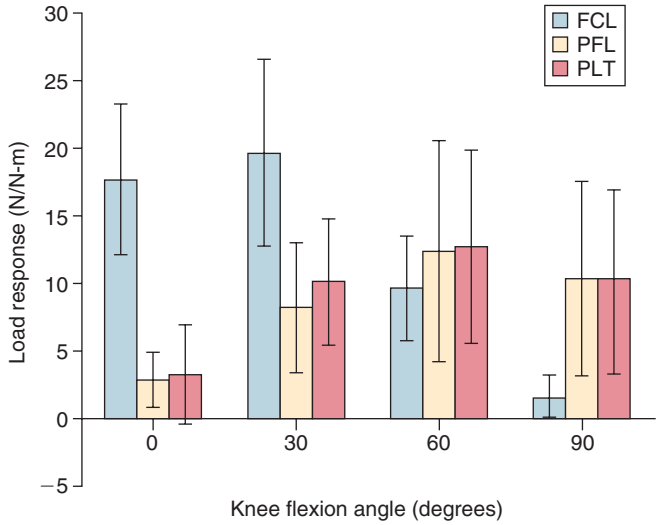

FIG 15-14 Forces in the fibular collateral ligament (FCL), popliteus tendon (PLT), and popliteofibular ligament (PFL) during application of an external rotation torque of 6 N-m. (From LaPrade RF, Tso A, Wentorf FA. Force measurements on the fibular collateral ligament, popliteofibular ligament, and popliteus tendon to applied loads. *Am J Sports Med.* 2004;32:1695-1701.)

to resisting external tibial rotation and posterior tibial translation with knee flexion.

We have encountered knees requiring revision of a failed posterolateral surgical procedure in which only the PMTL was reconstructed, leaving a partially or completely insufficient FCL. The abnormal lateral joint opening places high tensile forces on the PMTL, which is not designed to resist varus moments (in the absence of a functional FCL). Similarly, performing only an FCL reconstruction in knees with a complete PMTL disruption subjects the FCL graft to external tibial rotation moments without the added load-sharing of the PMTL. At surgery, there may exist a false sense of restoring stability when reconstructing only the FCL or PMTL that will initially eliminate the abnormal motions of lateral joint opening and external tibial rotation. However, the single reconstruction will be subjected to much higher in vivo loading conditions without the added load-sharing of the other PLSs, and there is an increased risk of failure and a return of knee instability. An anatomic reconstruction of the PLS (with the goal of restoring the PLC and meniscus attachments, PMTL, and FCL) is described in Chapter 17.

All of the biomechanic studies show the effects of the PLS at the maximum limits of internal-external rotation under defined torques. Within this envelope of motion, the resisting effect of the FCL and other PLS changes as already described, depending on many factors, including degrees of internal-external rotation, the AP tibiofemoral displacements with knee flexion, and imposed loads that lead to an increase or decrease in femoral-fibular attachment distances and tensioning or slackening of the ligament structures. Normal anatomic variations in the position of the tibiofibular joint may occur with a more posterior fibula position, increasing the FCL orientation. These variables produce subtle differences in measured FCL function in cadaveric studies and account for the large standard deviations commonly found.

POSTERIOR SUBLUXATION OF THE MEDIAL AND LATERAL TIBIOFEMORAL COMPARTMENTS

The millimeters of posterior subluxation of the medial and lateral tibiofemoral compartments after sectioning the PCL and PLS were measured in whole cadaver lower limbs in a testing apparatus previously described.[75] The position of the lateral and medial tibial plateaus was determined by three reference points: the AP translation of a point located at the center of each plateau, and the medial and lateral locations of points located midway between the tibial edges and joint centers.

The purposes of this investigation were, first, to determine the AP position of the medial and lateral tibia plateaus when a known external rotation torque was applied at 30 degrees and 90 degrees of knee flexion and, second, to measure how the positions of the lateral and medial tibial plateaus change and the magnitude of this change (subluxation) after sectioning the PLS alone and in combination with the PCL. The anterior meniscofemoral ligament (AMFL) and posterior meniscofemoral ligament (PMFL) were also sectioned when present. Studies have shown that these structures are not the primary restraints for posterior tibial translation or external rotation and provide a restraint only after the PCL has been removed.[34,39,50] The study also determined the effect of physiologic joint laxity, or preexisting ligament laxity, on the magnitude of rotatory subluxation

CRITICAL POINTS Posterior Subluxations of the Medial and Lateral Tibiofemoral Compartments

Posterior subluxation medial and lateral tibiofemoral compartments measured after sectioning PCL, PLSs.

Sectioning only PLSs: mean increase posterior translation lateral tibial plateau, 8.0 mm (30 degrees of flexion) over intact state.

Posterior Tibial Translation

- Sectioning PCL and PLSs: increases posterior translation medial and lateral tibial plateaus (30 degrees, 90 degrees of flexion).
- Sectioning PLSs: significant increases external tibial rotation (30 degrees, 90 degrees of flexion).
- Sectioning PCL and PLSs: further increase in external tibial rotation (30 degrees, 90 degrees of flexion).

External Tibial Rotation

- Classification of rotatory subluxations is based on final position (translation, millimeters) of medial and lateral tibial plateaus under defined loading conditions.
- In normal knees (5 N-m external tibial rotation, 100-N posterior force, 30 degrees of flexion), lateral tibial plateau displaces mean 7.5 ± 2.9 mm. PLSs sectioned: further increase to 15.5 ± 3.5 mm.
- PCL, PLSs sectioned: mean posterior translation, 25.3 ± 5.2 mm.

Effect of Physiologic Laxity

- Substantial differences in clinical tests "tight-jointed" versus "loose-jointed" knees. Determines amount of displacement before other secondary ligament restraints block further joint displacements.
- Some "tight" knees may have substantial damage to PLSs, demonstrate minimal increases in posterolateral tibial subluxation on external tibial rotation owing to secondary resistance provided by PCL.
- In knees with physiologic laxity, large increases in posterior tibial plateau subluxation may be detected after isolated PLS rupture because there is little resistance provided by the PCL.
- Diagnosis of injury to PLSs based on the final posterior position of the lateral tibial plateau, not on the degrees of external tibial rotation.
- Examiner palpates the position of the medial and lateral tibial plateaus to qualitatively determine the anterior and posterior position of the medial and lateral tibial plateaus with tibial rotation.

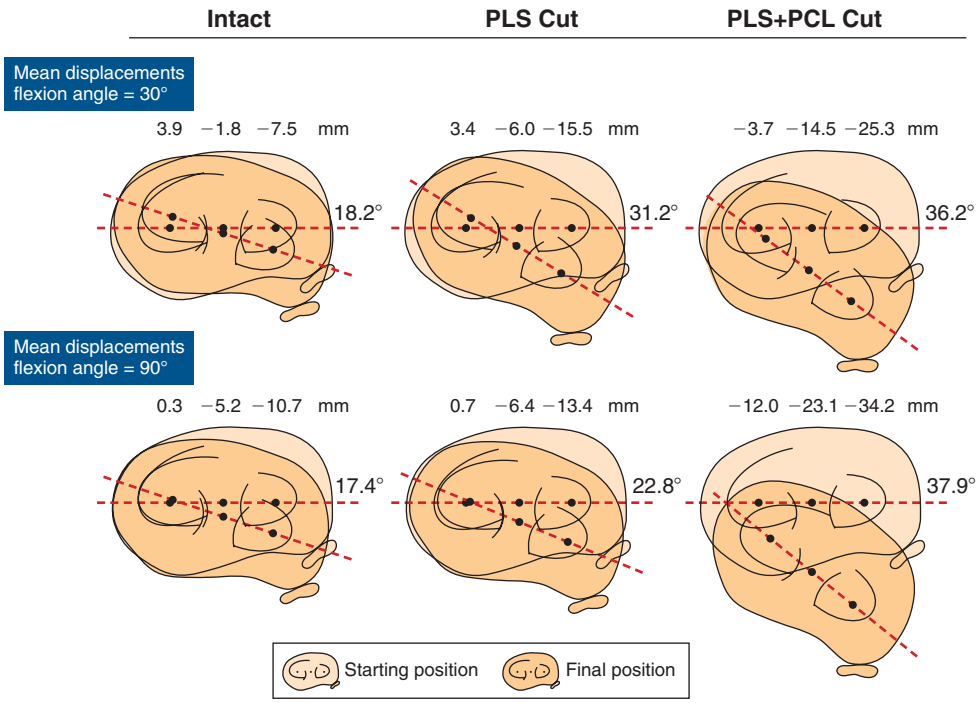

FIG 15-15 The mean values of external tibial rotation and the millimeters of anteroposterior (AP) translation for medial, central, and lateral tibial reference points are shown for 30 degrees and 90 degrees of knee flexion under the predetermined loads applied to the knee joint (100-N posterior load, 5 N-m external rotation torque). The neutral position (0-degree rotation, 0-mm AP translation) was determined in the intact knee by allowing the tibia to hang vertically by its own weight. *PCL,* Posterior cruciate ligament; *PLS,* posterolateral structures. (From Noyes FR, Stowers SF, Grood ES, et al. Posterior subluxations of the medial and lateral tibiofemoral compartments. An in vitro ligament sectioning study in cadaveric knees. *Am J Sports Med.* 1993;21:407-414.)

of the tibia after sectioning the PLS alone and in combination with the PCL.

Posterior Tibial Translation

The mean values of AP translation and external tibial rotation are shown in Figure 15-15 for intact knees and after sectioning the PLS and PLS/PCL. Sectioning only the PLS resulted in a mean increase in posterior translation of the lateral tibial plateau of 8.0 mm at 30 degrees of flexion over the intact state ($P < .01$) and a smaller increase of 2.7 mm at 90 degrees of flexion. There was no significant increase in posterior translation of the medial tibial plateau at either flexion angle. There was a large range of posterior tibial subluxations at both 30 degrees (Fig. 15-16) and 90 degrees (Fig. 15-17) of knee flexion.

Sectioning both the PCL and PLS caused significant increases in posterior translation of both the medial and lateral tibial plateaus at 30 degrees and 90 degrees of flexion ($P < .01$). The increase in posterior translation of the lateral tibial plateau compared with the intact state averaged 17.8 and 23.5 mm at 30 and 90 degrees of flexion, respectively. The increase in posterior translation of the medial tibial plateau over the intact state averaged 7.6 and 12.3 mm at 30 and 90 degrees of flexion, respectively.

External Tibial Rotation

The mean values of the external tibial rotation limits for the intact knees and after sectioning the PLS and PLS/PCL are shown in Table 15-2. Cutting the PLS caused a significant increase ($P < .01$) in external tibial rotation at both 30 degrees (mean increase, 13.0 degrees) and 90 degrees (mean increase, 5.4 degrees) of flexion. Sectioning the PCL along with the PLS caused a further increase in external tibial rotation at 30 degrees (mean increase, 5.0 degrees; not significant) and at 90 degrees of flexion (mean increase, 15.1 degrees; $P < .01$). Considerable variability was present among specimens in the amount of measured external tibial rotation at 30 degrees (see Fig. 15-13) and 90 degrees (see Fig. 15-14) of flexion.

On the basis of these data, a classification system of rotatory subluxations was devised based on two concepts: the final position of the medial and lateral tibial plateaus under defined loading conditions (such as with either internal or external tibial rotation at a defined knee flexion angle) and the position of each plateau. There are three possible positions for each plateau: anterior subluxation, normal position, or posterior subluxation. For each of these positions of the lateral tibial plateau, there exists three corresponding positions for the medial tibial plateau (Fig. 15-18).

This study showed that in normal knees under the conditions of external tibial rotation (5 N-m) and a posterior force (100 N) at 30 degrees of flexion, the lateral tibial plateau displaced a mean of 7.5 ± 2.9 mm. After sectioning the PLS, a further increase to 15.5 ± 3.5 mm was noted, representing an increase of 8 mm of posterior tibial subluxation of the lateral tibia plateau from normal. This is the amount that the clinician may palpate on the lateral tibiofemoral step-off with external tibial rotation in knees with ruptures to the PLS (compared with the opposite knee). After sectioning the PCL (in addition to the PLS), a mean posterior translation of 25.3 ± 5.2 mm was demonstrated, representing a 17.8-mm increase from normal.

Under the same loading conditions at 90 degrees of flexion, sectioning only the PLS resulted in a small (2.7-mm) increase in posterior translation of the lateral tibial plateau. These data agree with the external tibial knee motion limits previously reported,[30] where small and

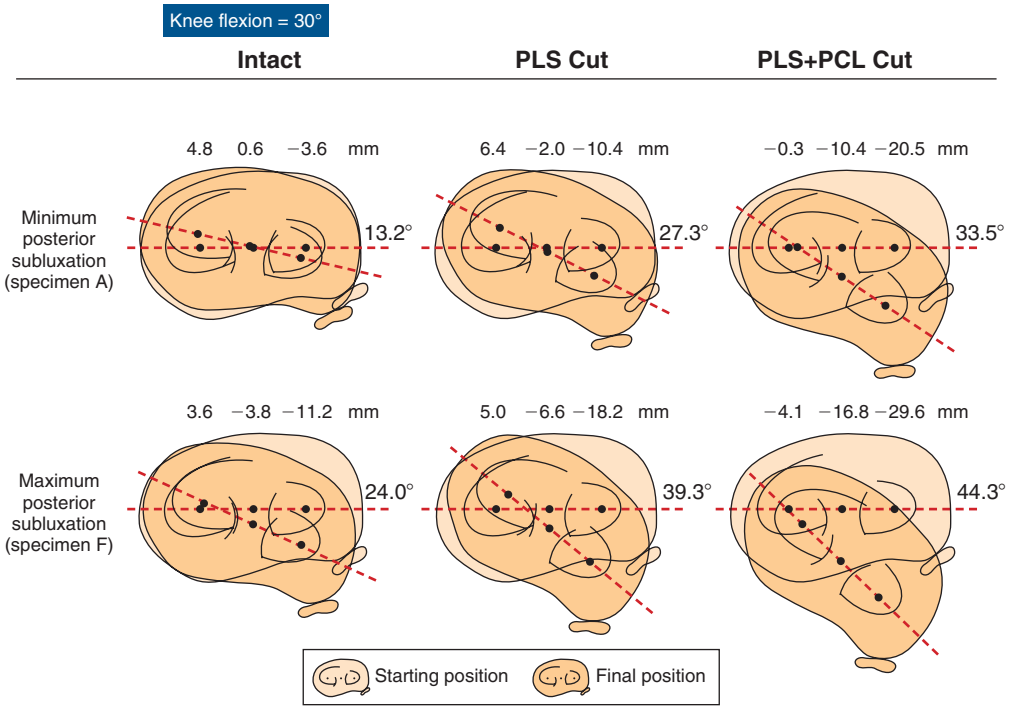

FIG 15-16 Tibiofemoral position at 30 degrees of knee flexion. The degrees of external rotation and the millimeters of anteroposterior translation for the medial, central, and lateral points are shown for two specimens, one with the least posterior tibial subluxation and one with the greatest posterior tibial subluxation (100-N posterior load, 5 N-m external rotation torque). *PCL,* Posterior cruciate ligament; *PLS,* posterolateral structures. insignificant increases in external tibial rotation occurred at 90 degrees after PLS sectioning. When the PCL was also sectioned, the lateral tibial plateau demonstrated a gross posterior subluxation, with a mean posterior translation of 34.2 ± 3.5 mm (23.5 mm from normal).

Effect of Physiologic Laxity

Normal knees that had greater physiologic laxity (greater posterior tibial translation and degrees of external rotation) had larger amounts of posterior subluxation of the lateral tibial plateau when the PLSs were sectioned. It is important to note that the posterior subluxation of the lateral tibial plateau varied from 10 mm to 18 mm at 30 degrees of flexion and from 9 mm to 18 mm at 90 degrees of flexion. This represents the displacement required to tense the PCL to resist further posterior subluxation of the lateral tibial plateau. In intact knees that had low values for posterior tibial displacements, ligament cutting resulted in a small increase in posterior subluxation, which was often lower than that measured in the normal "physiologically loose" knees.

From a clinical standpoint, knees that normally have low values for posterior subluxation that have substantial damage to the PLS may demonstrate only minimal increases in posterior tibial subluxation on external tibial rotation because of the secondary resistance provided by the PCL. Conversely, in knees with physiologic laxity, large increases in posterior tibial plateau subluxation may be detected after isolated PLS rupture because there is little resistance provided by the PCL. This finding explains the importance of individualizing the examination to each patient and determining his or her laxity profile. The surgeon should expect substantial differences in ligament stress tests in "tight-jointed" versus "loose-jointed" knees, which determines the amount of displacement before other secondary ligament restraints block further joint displacements.

The data in this experiment confirm the significant increase in posterior subluxation of the lateral tibial plateau at 30-degree knee flexion after sectioning the PLS, but not at 90-degree flexion. In addition, the data show that there is no significant increase in external tibial rotation after the PCL is sectioned and the PLSs are intact. The data also confirm that the diagnosis of injury to the PLS is based on the final posterior position of the lateral tibial plateau and not on the degrees of external tibial rotation. This is because an increase in external tibial rotation may occur with anterior subluxation of the medial tibial plateau when damage to the medial ligamentous structures is present.

In a prior study, the senior author and others[73] reported that the clinician may diagnose a posterolateral ligament injury when the increase in external tibial rotation is caused by a medial collateral ligament injury. For this reason, during clinical testing with the dial test for tibial rotatory subluxation, the examiner must palpate the position of the medial and lateral tibial plateaus to qualitatively determine if an anterior position of the medial plateau or a posterior position of lateral tibial plateau occurs with external tibial rotation. This is why the dial rotation test should be performed with the patient in the supine position (not in the prone position) as the senior author described to

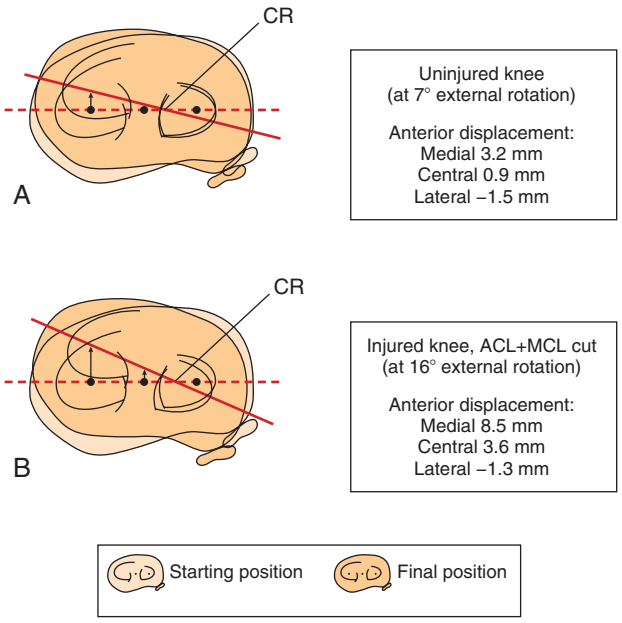

FIG 15-19 The external rotation dial test in the normal uninjured knee (**A**) and after sectioning the anterior cruciate ligament (ACL) and medial collateral ligament (MCL) (**B**). The increase in external tibial rotation from 7 degrees to 16 degrees is shown, along with an increase in anterior translation of the medial tibial plateau and shift in the axis of tibial rotation. *CR,* Center of rotation. (From Noyes FR, Cummings JF, Grood ES, et al. The diagnosis of knee motion limits, subluxations and ligament injury. *Am J Sports Med.* 1991;19:163-171.)

enable the examiner to observe and palpate the relative step-off of the medial and lateral tibial plateaus at 30 degrees and 90 degrees of flexion. Still, it may be difficult to quantify the amount of posterior subluxation of the lateral tibial plateau with PLS injuries, and additional tests such as lateral joint opening under varus loading and varus recurvatum are needed to confirm the diagnosis.

In Figure 15-19, the external rotation dial test is shown for a cadaveric knee measured with a 3-dimensional goniometer with 5 N-m load under conditions already described.[73] The increase in the external rotation limit and anterior translation of the medial tibial plateau is shown in the normal knee and then after sectioning the ACL and SMCL. The tibial rotation increased from 7 to 16 degrees and was associated with a lateral shift in the axis of tibial rotation. This resulted in an increase in anterior translation of the medial tibial plateau from 3.2 to 8.5 mm (anteromedial subluxation). In this study, examinations of cadaveric knees were performed by 11 experienced knee surgeons who were blinded as to the sectioned ligaments and asked to determine a diagnosis. More than one-half of the surgeons misinterpreted the increase in external tibial rotation as an injury to the PLS. This indicates that tests for rotatory subluxations of the knee joint are limited by the ability to quantitatively determine the millimeters of AP translation of the medial or lateral tibiofemoral joint under external rotation loads, and variability among examiners should be expected.

EFFECT OF PCL AND POSTEROLATERAL RECONSTRUCTION ON RESTORING NORMAL KNEE MOTION LIMITS

Isolated Posterior Cruciate Ligament Reconstructions

There still exist few studies and incomplete data to completely guide the surgeon on time-zero kinematics of single- and double-bundle PCL grafts (Table 15-3). As already discussed, there is a theoretic advantage of using two PCL grafts, owing to the substantial collagen material that is required, given the total cross-sectional area of the native PCL attachment. In addition, a second graft decreases the total forces a single graft is subjected to, because both grafts share the load (although in different percentages). The data presented show the difference in load-sharing between two grafts placed in the distal two-thirds of the PCL attachment compared with grafts placed in a distal and proximal manner. Other unanswered questions concern the amount of tension to be placed on PCL grafts and the appropriate knee flexion angle.

Kennedy and associates[45] performed a biomechanic study on a single-bundle anterolateral PCL reconstruction in nine cadaveric knees in which the graft was tensioned to 88 N and fixed at 75, 90, and 105 degrees. A posterior load of 134 N was applied, and knee laxity was determined at 0 to 120 degrees and 5 N-m external, 5 N-m internal, and 10 N-m valgus rotation torques. Each fixation angle had comparable time-zero loads; however, a residual average of 4.1 mm of posterior translation occurred. The authors did not provide a justification for selecting the 88-N initial graft tension, and the observation is made that a higher initial graft tension would most likely be necessary, as shown in published data already presented. The difference in methodology regarding the initial graft tension is important. Rather than selecting an arbitrary graft tension, an alternative approach is to tension the graft to a certain knee flexion angle (e.g., 90 degrees), which provides data on the amount of graft tension required to restore time-zero stability, and then examine the change in graft forces at different knee flexion positions.

In a second study, Kennedy and colleagues[46] performed an anatomic double-bundle PCL reconstruction to examine time-zero graft forces. In this study, the investigators used a higher overall total graft tension (initial tension anteromedial bundle of 88 N, posterolateral bundle at 67 N, total of 135 N) and reported a mean residual posterior translation of 1.5 mm at 90 degrees of flexion. Difficulties arise in comparing these results with single-bundle anterolateral bundle PCL data previously described (overall graft tension of 88 N), owing to the overall higher graft tension in the double-bundle study. The study recommended that the posterolateral bundle graft be tensioned at 0 degrees instead of 15 degrees and that the anterolateral bundle graft be tensioned at 90 to 105 degrees (compared with 75 degrees) to minimize higher graft tensions with knee flexion.

In two cadaveric knee studies,[57,61] Markolf and coworkers reported that a single-bundle PCL graft placed in the anterolateral femoral attachment produced a laxity profile that better replicated the normal knee, had better graft isometricity, and resulted in lower PCL graft forces than a double-bundle reconstruction (Fig. 15-20). The posteromedial graft overconstrained the knee from 30 degrees to 0 degrees (Fig. 15-21) and did not provide resistance to posterior tibial translation at higher flexion angles. Note that Markolf and coworkers used a

CRITICAL POINTS Effect of Posterior Cruciate Ligament and Posterolateral Reconstruction on Restoring Normal Knee Motion Limits

- Studies show the dependence of posterolateral reconstructions on a functional PCL or PCL reconstruction.
- PCL reconstruction may fail if concurrent injury to the PLS is not diagnosed and surgically addressed.
- All functional components of the posterolateral structures should be restored at surgery.

TABLE 15-3 Effect of Posterior Cruciate Ligament Reconstruction on Biomechanical Properties and Knee Motion Limits

Study	No. Specimens, Patient Age	Grafts, How Placement Was Determined	Results	Conclusions
Benedetto et al[5] (2014)	5 pairs, 65-85 yr	QT-PB, arthroscopic inlay. Anatomic PCL tibia footprint marked, remnants fibrous attachments left intact. Group A: tibial footprint positioned onto center of proximal margin of remnants (ALB). Group B, footprint center placed at most distal edge of remnants (PMB).	No difference in displacement at 5, 500, 1000 cycles. Significant difference in yield strength (N): group A, 201 ± 35; group B, 500 ± 186. Failure load (N): group A, 338 ± 130; group B, 564 ± 212. Stiffness (N/mm): group A, 74 ± 16; group B, 56 ± 13 ($P < .05$ all comparisons).	Replicating anatomic PCL footprint at posterior edge of the posterior tibial facet results in higher pullout strength compared with tunnel position at center of tibial facet. Bias of added backup fixation in group B.
Kennedy et al[45] (2014)	9, 29-63 yr	AT allograft, single strand, transtibial. Tibial tunnel: 1 cm medial to tibial tuberosity, 6 cm distal to joint line. ALB femoral footprint, centered, fixed at 75 degrees, 90 degrees, 105 degrees.	No difference in posterior translation for 3 fixation methods, but all residual increases compared with intact (5.3-5.4 mm). No difference in IR, ER, valgus rotation for 3 fixation methods.	All fixation angles significantly reduced posterior translation compared with intact, but residual translation existed.
Kennedy et al[46] (2014)	9, 29-63 yr	AT (ALB), anterior tibialis (PMB) allografts. Two strands. Fixation options (PMB/ALB): • 0 degrees/75 degrees • 0 degrees/90 degrees • 15 degrees/75 degrees • 15 degrees/90 degrees • 15 degrees/105 degrees	All methods significantly reduced posterior translation; mean residual laxity = 1.5 mm. Fixation PMB at 15 degrees resulted in significantly larger graft forces compared with fixation at 0 degrees during posterior, IR, ER, valgus rotation loading. Fixation ALB at 75 degrees resulted in larger forces than at 90 degrees or 105 degrees.	Fix PMB at 0 degrees and ALB at 90 to 105 degrees to reduce posterior translation to intact state and not result in increased graft loads.
Tompkins et al[100] (2013)	10 pairs, age unknown	OI vs. IO femoral drilling. CT scans used to compare 2 techniques; goal to place femoral tunnel aperture within anatomic femoral PCL footprint, determine tunnel orientation within medial femoral condyle.	OI technique placed 70.4% of the tunnel within native femoral footprint; IO placed 79.8%. IO technique created femoral tunnels with more vertical and anterior orientation.	Either technique can be used, but IO technique with knee hyperflexed during drilling likely produces "gentler graft bending angles."
Tsukada et al[112] (2012)	8, 52-77 yr	Two-strand (2 femoral, 2 tibial tunnels) reconstruction compared with single-strand AL reconstruction and single-strand PM reconstruction. STG for AL, ST for PM. AL fixed on tibia 90 degrees of flexion, PM bundle fixed at 0 degrees.	At 60 and 90 degrees, posterior translation single-strand PM reconstruction significantly greater than other 2 reconstructions, but no difference at 0 and 30 degrees flexion. No difference for all 3 reconstructions in posterior load + ER for all flexion angles.	Recommend 2-strand reconstruction; however, "cannot confirm superiority."
Weimann et al[113] (2012)	10, 55-78 yr	Single-strand STG. MCL and POL reconstructed with ST graft. 134 N posterior load, 10 N-m valgus torque, 5 N-m internal torque 0, 30, 60, 90 degrees of flexion. PTT measured robotic system.	PCL + posteromedial structures cut, PTT significantly increased all flexion angles. Knees with PCL + PM injuries had decreased PTT over PCL alone; however, still residual abnormal PTT (~5 mm).	Reconstruction POL contributed to normalizing PTT in knees with combined PCL-PM injuries. However, experimental bias of residual abnormal PTT.

TABLE 15-3 Effect of Posterior Cruciate Ligament Reconstruction on Biomechanical Properties and Knee Motion Limits—cont'd

Study	No. Specimens, Patient Age	Grafts, How Placement Was Determined	Results	Conclusions
Markolf et al[61] (2010)	10, 21-45 yr	Single-strand, 2-strand (narrow tunnel separation), 2 femoral tunnels, 1 tibial tunnel; 2-strand (wide tunnel separation) 2 femoral tunnels, 1 tibial tunnel; AT allograft.	Tunnel separation distance no difference in mean laxities, graft forces, tibial rotations. PM graft tightened from 30 to 0 degrees and developed high graft forces.	Need for PM graft questioned; high graft forces at 0 degrees may cause elongation with time. No biomechanic advantage to 2-strand reconstruction in making bone bridge between tunnels <3 mm.
Ahn et al[2] (2009)	20, 49-78 yr	Single-strand AT. Anteromedial cortex tibial tunnel (tip guide pin aimed 2.5 cm inferior from tibial tuberosity) vs. AL cortex tibial tunnel (1.5 cm lateral to tibial tuberosity). Both transtibial tunnel technique, 10-mm reamer drilled to tibial PCL insertion site.	Mean cortex-tunnel angles: 47.5 ± 9.3 degrees anteromedial vs. 28.3 ± 7.4 degrees AL ($P < .01$). Mean long tunnel diameter 10.6 ± 1.0 mm anteromedial vs. 14.0 ± 1.5 mm AL ($P < .01$). Maximal load at failure 385.4 ± 139.7 N anteromedial vs. 225.1 ± 144.1 N anterolateral ($P < .05$).	Anterolateral approach resulted in tunnel with wider entrance, more acute cortex-tunnel angle, and lower maximal load at failure. May require additional fixation.
Schoderbek et al[88] (2009)	8, 42-65 yr	3 femoral tunnel techniques compared: OI, IO at 90 degrees, IO at 120 degrees.	Mean graft-femoral tunnel angle: OI, 34.4 ± 14.4 degrees; IO, 120 degrees flexion, 52.3 ± 14.1 degrees; IO 90 degrees flexion, 74.4 ± 11 degrees. Angle smaller OI technique vs. both IO techniques ($P < .05$).	IO at 90 degrees produced high graft/femoral tunnel angle. OI produced lowest critical corner angle.

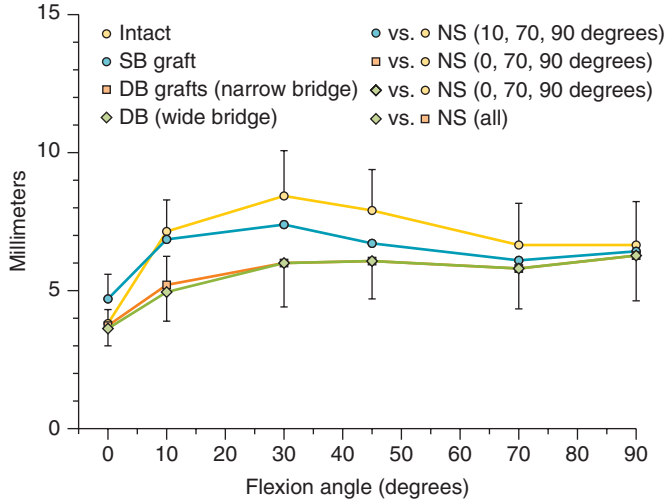

FIG 15-20 Mean anteroposterior (AP) laxities (at ±100 N) vs. knee flexion angle for the intact knee and after a single-bundle (SB) reconstruction and double-bundle (DB) reconstructions with narrow and wide bone bridges. Mean laxities are shown, and error bars indicate 1 standard deviation. Mean values are significantly different at each flexion angle unless indicated by *NS* (not significant). (From Markolf KL, Jackson SR, McAllister DR. Single- versus double-bundle posterior cruciate ligament reconstruction. Effects of femoral tunnel separation. *Am J Sports Med.* 2010;38:1141-1146.)

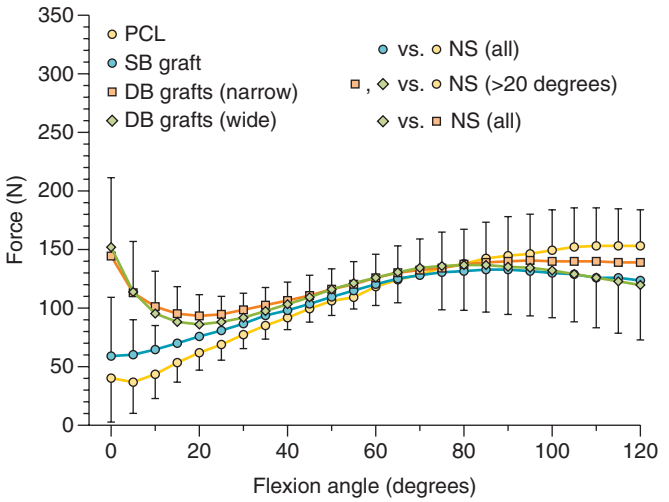

FIG 15-21 Mean curve of 100 N posterior tibial force vs. knee flexion angle for the intact posterior cruciate ligament (PCL), single-bundle anterolateral graft (SB), and double-bundle (DB) grafts with narrow and wide bone bridges; sample standard deviations are indicated by error bars. All mean graft forces are significantly different from corresponding PCL forces unless indicated by NS (not significant). (From Markolf KL, Jackson SR, McAllister DR. Single- versus double-bundle posterior cruciate ligament reconstruction. Effects of femoral tunnel separation. *Am J Sports Med.* 2010;38:1141-1146.)

PCL graft tensioning technique in which the graft was tensioned under measured loads to restore posterior knee translation to normal values at 90-degree knee flexion, in contrast to the studies of Kennedy and colleagues.[45,46] More conclusive studies regarding PCL graft positioning and tensioning are necessary in the future from both laboratory kinematic and clinical standpoints.

Combined Posterior Cruciate Ligament-Posterolateral Reconstructions

Sekiya and coworkers[89] conducted an in vitro cadaveric study using a robotic testing system in which the PCL was reconstructed with a two-strand construct (Achilles and semitendinosus tendons), the PFL was reconstructed with a gracilis tendon, and the popliteus tendon was reattached to its femoral origin. The specimens were subjected to a 134-N posterior tibial load and a 5 N-m external tibial torque at multiple flexion angles. The authors reported that the forces in the posterolateral grafts were significantly higher than those in the native PLS. A possible explanation for the increased loads on the posterolateral reconstruction is the fact that the two-strand PCL reconstruction did not restore normal posterior tibial translation, because significant increases in posterior tibial translation were detected from 0 to 90 degrees of flexion compared with intact knees. The PCL grafts were tensioned to a defined load, but not to the load required to reduce posterior tibial translation to normal; therefore the PCL reconstruction forces were low after the reconstruction. For this reason, additional loads were placed on the posterolateral grafts.

The data from the investigation by Sekiya and coworkers[89] and a subsequent study[37] show the dependence of posterolateral reconstructions on a functional PCL reconstruction. Harner and associates[37] studied the effect of deficiency of the PLSs on PCL Achilles tendon graft reconstructions in 10 cadaveric knees. The authors reported that a functional PCL reconstruction (posterior tibial translation restored to within 2.4 ± 1.4 mm of the intact knee, 90 degrees of flexion) subjected to sectioning of the PLS resulted in a significant increase in posterior tibial translation (6.0 ± 2.7 mm at 30 degrees, 4.6 ± 1.5 mm at 90 degrees; $P < .05$). In addition, the forces in the PCL graft were significantly increased for posterior tibial load, external tibial torque, combined posterior and external torque, and varus torque. These data support other studies in which researchers have concluded that a PCL reconstruction may stretch out or fail if a concurrent injury to the PLS is not diagnosed and concurrently surgically addressed.[63,71]

LaPrade and colleagues[48] conducted a biomechanic analysis of an anatomic posterolateral reconstruction in which a two-graft technique was used to replace the FCL, popliteus tendon, and PFL. The reconstructions were performed using Achilles tendon-bone constructs in 10 cadaveric knees aged 62 to 74 years (Fig. 15-22). It should be noted that in the reconstruction described by LaPrade and colleagues,[48] the PFL does not attach to the popliteus tendon at its normal anatomic attachment, and therefore this represents an anatomic reconstruction of the popliteus tendon and FCL. The knees were tested under a 5 N-m varus moment and 5 N-m external rotation torque, first with the PLSs intact; second with the FCL, popliteus tendon, and PFL sectioned; and

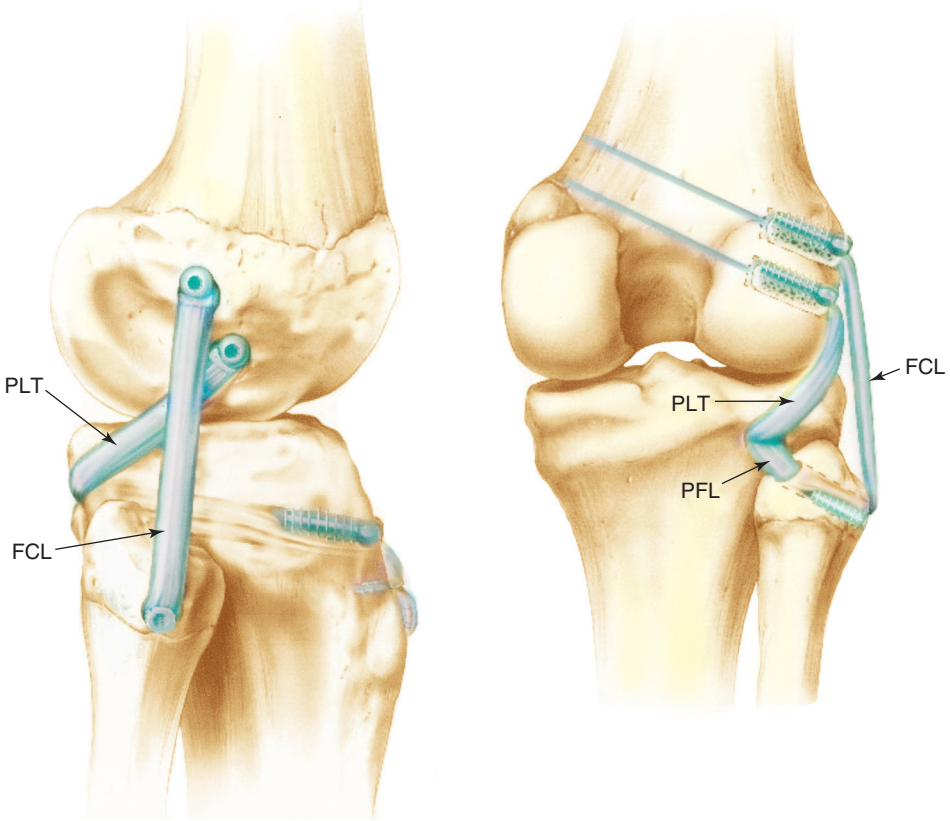

FIG 15-22 The posterolateral knee reconstruction described by LaPrade. *Left,* Lateral view, right knee. *Right,* Posterior view, right knee. *FCL,* Fibular collateral ligament; *PFL,* popliteofibular ligament; *PLT,* popliteus tendon. (From LaPrade RF, Johansen S, Wentorf FA, et al. An analysis of an anatomical posterolateral knee reconstruction. An in vitro biomechanical study and development of a surgical technique. *Am J Sports Med* 2004;32:1405-1414.)

third after the posterolateral reconstruction. There was no significant difference between the intact and reconstructed knees for varus translation at 0, 60, or 90 degrees of flexion or for external tibial rotation at 0, 30, 60, or 90 degrees of flexion. The authors concluded that this technique restored static stability and provides the scientific basis for patient outcome studies. We agree with this conclusion, because both the popliteus tendon (static attachments) and FCL were reconstructed.

Apsingi and coworkers[3] reported on the kinematics of cadaveric knees with a combined PCL and posterolateral ligament deficiency. The authors used both a single-bundle and double-bundle PCL reconstruction that was combined with a femoral-fibular graft reconstruction for the PLS. The combined PCL and posterolateral reconstruction restored all the laxity limits to normal, and the double-bundle PCL reconstruction was not reported to have an advantage over the single-bundle reconstruction. Of importance, the nonanatomic femoral-fibular reconstruction involved two femoral tunnels with the graft passed in an anterior-to-posterior direction through the fibula. The location of the two femoral tunnels was determined by selecting isometric points on the lateral femoral condyle and not by attaching the two graft arms to any specific anatomic location. The two graft ends passed through the two femoral tunnels were tensioned independently to restore the adduction and external rotation limits to normal. The anterior limb was tensioned at 20 degrees of flexion to match the laxity of the intact knee to varus loading. The posterior limb was tensioned at 90 degrees of flexion to match the intact knee motion limit to external rotation torque. Each graft arm was only 5 mm in diameter. The data from this study and others on femoral-fibular reconstructions may suggest that the more simplified femoral-fibular reconstruction is all that is required for posterolateral insufficiency, instead of the more complex anatomic reconstruction recommended by the senior author (F.R.N.) and LaPrade and colleagues.[48] It is true that in a time-zero cadaveric study, a single graft appropriately tensioned will restore varus and external rotation motion limits to normal.

Two points are worthy of emphasis. First, Apsingi and coworkers[3] did not measure the effects of the femoral-fibular reconstruction on decreasing or unloading the PCL graft. Markolf and associates[60] showed that an FCL reconstruction alone was insufficient to decrease or unload PCL graft forces. The Markolf and associates[60] data provide added support to the concept of restoring all of the functional components of the PLS at the time of surgery. Second, a small-diameter graft passed through the fibula and secured to the femoral condyle may be insufficient to resist the large adduction and external rotation loads that occur postoperatively. The anatomic reconstruction advocated by Noyes[72] and LaPrade[48] places two larger-diameter grafts at both the femoral, fibular, and tibial attachment sites of respective PLSs. The graft function therefore does not depend only on a fibular attachment site, and the popliteus tendon graft is passed through a distal tibial tunnel.

A third point on the application of biomechanic studies to clinical cases involves whether to select an isometric point on the femur for the FCL and popliteus tendon[60,94] or, as described by some authors, to select the anatomic attachment site to restore native anatomy.[48,72] Sigward and associates[94] reported, on the basis of a cadaveric knee study, the femoral fixation sites for isometry of posterolateral reconstructions. A coordinate grid system was located across the lateral femoral condyle, permitting the placement of 21 holes in the femur, 5 mm apart, for the measurement of suture length changes with knee flexion. The authors did compute a mean location for the FCL and popliteus tendon attachment; however, the femoral isometric points showed major differences among knees. This wide variability among specimens indicates that one mean value for the ideal isometric point for a graft placement would most likely be incorrect for knees undergoing surgery. Future clinical studies are necessary to determine the ideal success rates for knees in which either an isometric point is selected at surgery or an anatomic attachment site is selected. Until these studies are available, we recommend anatomic attachment points and an anatomic reconstruction for posterolateral instability as described in Chapter 17.

CLINICAL EFFECTS OF POSTERIOR TIBIAL SUBLUXATION OF THE PCL-DEFICIENT KNEE

Morrison[69] and Denham and Bishop[19] estimated that PCL forces up to 50% body weight occur during level walking. Even higher PCL forces have been calculated during stair-climbing, ascending stairs, and descending stairs.[6] (See Chapter 18 for other studies on estimated PCL forces during activity.) In a study done at our laboratory and involving 10 patients with complete PCL ruptures, the amount of posterior tibial translation that occurred during a double-stance static squat test was measured.[12] A lateral radiograph was obtained of both lower limbs, which was used to compute the amount of posterior tibial translation and sagittal plane forces on the PCL-deficient knee and a normal knee. A stress radiograph was taken with an 11-kg (108-N) posterior force to provide an objective measurement of the amount of posterior translation in the PCL-deficient knee compared with the opposite, normal knee. In low knee flexion angles, only 3 of the 10 knees had a posterior subluxation (from 5 to 9 mm) during the squat test. However, in high knee flexion positions, nine knees had an abnormal posterior tibial subluxation (mean, 5.9 ± 2.8 mm; range, 3-12 mm).

Logan and coworkers[52] used an open-access magnetic resonance imaging (MRI) system that allowed full weight bearing (squatting) by six patients with isolated PCL ruptures and measured tibiofemoral motion from 0 to 90 degrees of flexion (Table 15-4). The investigation found significantly increased, persistent posterior subluxation (~5 mm) of the medial tibia throughout knee motion. The authors concluded that the "fixed" anterior subluxation of the medial femoral condyle and posterior subluxation of the medial tibial plateau could explain the clinical observation of medial compartment osteoarthritis in PCL-deficient knees.

In several investigations, researchers have found significant differences in knee kinematics at higher knee flexion angles during a

CRITICAL POINTS Clinical Effects of Posterior Tibial Subluxation of the Posterior Cruciate Ligament-Deficient Knee

- PCL forces up to 50% of body weight occur during level walking.
- Higher PCL forces occur during stair-climbing, ascending stairs, descending stairs.
- Posterior tibial subluxation occurs in PCL-deficient knees during activities of daily living in high knee flexion positions, but not at low flexion positions in which smaller posterior shear forces are present.
- High PCL forces occur during a single-leg lunge between 60 and 120 degrees of flexion.
- Quadriceps neutral angle may vary from 60 to 90 degrees between knees; not objective measurement diagnosis of posterior tibial subluxation.
- PCL-deficient patients frequently note an anterior shifting of the tibia, as the tibial moves forward from its subluxated position, when they attempt to stand from a seated position.
- Significantly increased contact pressures in medial tibiofemoral and patellofemoral compartments occur in PCL-deficient knees.

TABLE 15-4 In Vivo Effects of Posterior Cruciate Ligament Deficiency

Study	Subjects	Methods	Results	Conclusions
Chandrasekaran et al[13] (2012)	10 isolated PCL injured knees, 10 controls	Supine leg press, 150-N load, MRI sagittal images 0-90 degrees. Tibiofemoral contact, flexion facet center measured from posterior tibial cortex.	Significant difference in medial compartment PCL-deficient compared with controls for contact pattern (greatest differences occurred at 75 degrees flexion of 4 mm and 90 degrees flexion of 5 mm) and flexion facet center (75 degrees flexion, 3 mm).	Significant difference medial compartment in sagittal plane articulation of TF joint in subjects with isolated PCL injury. TF contact and flexion facet center move more anteriorly on the tibia as the knee flexes in PCL-deficient knees.
von Eisenhart-Rothe et al[110] (2012)	12 isolated PCL injured knees, 20 controls	MRI supine, with and without isometric muscle contractions, 0 to 90 degrees of flexion.	Significant differences at 90 degrees, femur anterior in relation to tibia, patellar tilt and patellar shift positioned laterally. Isometric muscle contractions caused anterior translation of femur compared with muscle relaxation.	Significant changes in TF and patellofemoral joint kinematics occur in patients with isolated PCL deficiency >30 degrees flexion; may explain development of OA.
Goyal et al[27] (2012)	9 isolated PCL grade II injured knees, contralateral normal knees	Level running, stair ascent. Dynamic stereo x-rays taken, 3-D reconstruction knee anatomy created from CT scans. Model-based tracking used to align x-ray with CT bone models.	Running: swing phase: PCL-deficient tibia 2 mm posteriorly subluxated, had anterior velocity relative to the femur 40 mm/s greater than contralateral knee. Stair ascent: terminal swing and early stance phases: PCL-deficient tibia 4 mm posteriorly subluxated. Between foot strike and time of peak ground reaction force, tibia translated anteriorly relative to femur with velocities 3-4 times greater than contralateral knee.	Significant changes in knee kinematics during stair ascent may result in high shear forces that may expose the joint to potentially damaging forces.
Gill et al[25] (2009)	7 isolated PCL injured knees, contralateral normal knees, 2-year post-PCL single-bundle AT allograft reconstruction	Single-leg lunge, MRI and dual fluoroscopy used to create series of knee models to assess tibiofemoral and patellofemoral kinematics from 0 to 120 degrees of flexion.	TF: 75 to 120 degrees of flexion: both PCL-deficient and PCL-reconstructed knees significantly increased lateral tibial translation, abnormal patellar rotation, and tilt.	Single-bundle reconstruction restored normal anteroposterior translation; however, was not able to restore normal mediolateral tibial translation (small changes, 1-15 mm), patellar rotation, and patellar tilt.
Kozanek et al[47] (2009)	14 isolated PCL injured knees, contralateral normal knees	Single-leg lunge, MRI and dual fluoroscopy used to create series of knee models from 0 to 120 degrees. Length of posterolateral structures measured from models.	Significant increases in length of FCL, greatest at 120 degrees (injured, 51.6 ± 6.1 mm; normal, 48.2 ± 6.1 mm) and PMT unit, greatest at 30 degrees flexion (injured, 110.4 ± 10.2 mm; normal, 101.2 ± 9.3 mm).	PCL deficiency increases length patterns of FCL, PMT during weight-bearing flexion.
Van de Velde et al[104] (2009)	14 isolated PCL injured knees, contralateral normal knees	Single-leg lunge, MRI and dual fluoroscopy used to create series of knee models to assess location and magnitude of peak cartilage deformation in the tibiofemoral compartments from 0 to 120 degrees flexion.	Medial compartment: more anterior and medial location of peak cartilage deformation on tibial plateau compared with normal knees between 75 and 120 degrees flexion. Greater deformation of cartilage in medial compartment from 75 to 120 degrees flexion. No differences in lateral compartment.	PCL deficiency results in shift of TF contact and an increase in cartilage deformation in the medial TF compartment beyond 75 degrees of flexion.

TABLE 15-4 In Vivo Effects of Posterior Cruciate Ligament Deficiency—cont'd

Study	Subjects	Methods	Results	Conclusions
Van de Velde et al[105] (2009)	10 isolated PCL injured knees, contralateral normal knees	Single-leg lunge, MRI and dual fluoroscopy used to create series of knee models to assess patellofemoral kinematics and cartilage contact from 0 to 120 degrees flexion.	Significant differences 90 to 120 degrees of flexion: patellar flexion angle (mean, 10.7 degrees), decreased lateral shift (mean, –1.9 mm), decreased patellar tilt (mean, –2.7 degrees), decreased valgus rotation (mean, –1.8 degrees). Significant changes patellofemoral cartilage contact: distal (mean, –3.3 mm) and medial (mean, 2.7 mm) shift.	Significant differences occurred between 90 and 102 degrees flexion that might predispose patellofemoral joint to degeneration. Avoid deep squats in patients with PCL deficiency.
Li et al[51] (2008)	8 isolated PCL injured knees, contralateral normal knees	Single-leg lunge, MRI and dual fluoroscopy used to create series of knee models to assess translation and rotation from 0 to 105 degrees flexion.	≥90 degrees PCL-injured knees had significantly less anterior tibial translation (3.5-4.3 mm), greater lateral tibial translation (1.1 mm), lower varus rotation (mean, 0.6 degrees). All flexion angles >30 degrees, increased posterior tibial translation.	PCL functions to constrain posterior tibial translation, lateral tibial translation, and tibial rotation during weight-bearing flexion.
Logan et al[52] (2004)	6 isolated PCL injured knees, contralateral normal knees	Weight-bearing squats (0, 20, 45, 90 degrees flexion) and non-weight-bearing images (90 degrees flexion), vertical open double-doughnut MRI configuration.	Weight bearing: 5-mm increased posterior subluxation medial tibial plateau and anterior subluxation medial femoral condyle throughout arc of flexion.	During weight bearing, tibia subluxated posteriorly on femur in medial compartment.

AT, Achilles tendon; *CT,* computed tomography; *FCL,* fibular collateral ligament; *MGH,* Massachusetts General Hospital; *MRI,* magnetic resonance imaging; *OA,* osteoarthritis, *PCL,* posterior cruciate ligament; *PMT,* popliteus-muscle-tendon; *TF,* tibiofemoral.

single-leg lunge between PCL-deficient and contralateral normal knees using knee models created by MRI and dual fluroscopy.[25,47,104,105,110] For instance, Gill and colleagues[25] reported that PCL-deficient knees had significantly increased posterior tibial translation between 60 and 120 degrees of flexion compared with normal knees (mean difference, 3.5 ± 1.1 mm; $P < .05$). Significant decreases in patellar rotation and tilt were also observed between PCL-deficient knees and normal knees between 75 and 120 degrees of knee flexion.

These data support the concept that posterior tibial subluxation occurs in PCL-deficient knees during activities of daily living in high knee flexion positions, but not usually at low flexion positions, where smaller posterior shear forces are present. In strenuous activities such as sudden stopping, deceleration, or walking down a ramp, a posterior subluxation of the tibia is expected to occur. If the subluxation reaches 8 to 10 mm, minimal function of the menisci occurs (particularly the medial meniscus) and increased tibiofemoral stresses may be expected. As the tibia becomes more vertical with knee flexion, an increase in tibiofemoral compressive forces occurs from increased quadriceps and patellar tendon forces. However, the increased tibiofemoral compressive forces are not sufficient to overcome the posterior tibial shear forces, and a resultant abnormal posterior tibial translation occurs.

As noted by Daniel and colleagues,[17] the quadriceps neutral angle is the angle of knee flexion at which the course of the patellar tendon is perpendicular to the articular surface of the tibia. The neutral knee flexion angle may vary from 60 to 90 degrees, with a mean of 71 degrees. Below this angle, the patellar tendon lies anterior to the tibial tubercle and produces a posterior tibial shear force. Conversely, at a greater flexion angle, the patellar tendon has a line of action coursing posterior to the attachment to the tibial tubercle, producing an anterior tibial shear force. The quadriceps neutral angle varies sufficiently among knees and is not an objective measurement in terms of the diagnosis of posterior tibial subluxation. However, patients with PCL-deficient knees frequently note an anterior shifting of the tibia from its posterior subluxated position when they attempt to stand from a seated position, which can easily be demonstrated in the clinic.

Experimental studies have documented significantly increased contact pressures in the medial tibiofemoral and patellofemoral compartments after PCL sectioning.[24,53,96] Skyhar and coworkers[96] reported that PCL sectioning caused significant increases in contact pressure on the medial tibiofemoral compartment at all knee flexion angles compared with intact specimens (29.1 ± 11.6 Pa and 19 ± 3.4 Pa, respectively; $P < .05$). A significant elevation in contact pressure in the patellofemoral compartment was found only at 60 degrees of flexion. Gill and associates[24] analyzed patellofemoral contact pressures under simulated muscle loads in both PCL-sectioned and PCL-reconstructed cadaver knees (Achilles tendon single-bundle allograft). Significantly greater peak contact pressures were measured in the PCL-deficient knees than in the intact knees under both an isolated quadriceps (400 N) and a combined quadriceps and hamstrings (400 N/200 N) load. The PCL-reconstructed knees also had elevated pressures, which were not significantly different from those measured in the PCL-deficient specimens. There was no effect of knee flexion angle on these findings.

More recently, the location and magnitude of articular cartilage deformation in the tibiofemoral compartment was measured by Van de Velde and coworkers in 14 patients with isolated PCL deficiency

during a single-leg lunge.[104] Three-dimensional knee models of the bone and cartilage were derived from MRI sequences and were used to reproduce in vivo knee positions from 0 to 120 degrees of flexion. The location and magnitude of peak cartilage deformation were significantly altered in the PCL-deficient knees between 75 and 120 degrees of flexion. There was a more anterior (mean, 2.4 ± 0.4 mm) and medial (mean, 1.9 ± 0.4 mm) location of cartilage deformation on the tibial plateau, as well as increased deformation. There were no significant differences in the lateral tibiofemoral compartment for these values. In another investigation by Van de Velde and colleagues,[105] changes in patellofemoral joint kinematics and cartilage deformation were measured in 10 patients with isolated PCL ruptures during a single-leg lunge. Between 90 and 120 degrees of flexion, the PCL-deficient knees had a significantly increased patellar flexion angle (mean, 10.7 degrees), decreased lateral shift (mean, –1.9 mm), decreased patellar tilt (mean, –2.7 degrees), and decreased valgus rotation (mean, –1.8 degrees). There was a distal (mean, –3.3 mm) and medial (mean, 2.7 mm) shift of cartilage contact from 75 to 120 degrees of knee flexion. Chandrasekaran and associates[13] reported significant differences in medial compartment contact points and flexion facet centers (measured from the posterior tibial cortex) in 10 PCL-deficient knees compared with healthy knees during a supine leg press against a 150-N load. The tibiofemoral contact points and the flexion facet centers moved more anteriorly in the PCL-deficient knees, which were significantly increased compared with the healthy knee from 45 to 90 degrees of flexion. At 90 degrees of flexion, the mean difference in the tibiofemoral contact points was 5 mm and the mean difference in the flexion facet centers was 2 mm.

MENISCOFEMORAL LIGAMENTS

Gupte and colleagues[33] conducted an analysis of 16 anatomic studies involving 1022 cadaveric knees and reported that 91% had at least one MFL. The AMFL was identified in 390 knees (48%); the PMFL was identified in 569 knees (70%); and both the AMFL and PMFL were found in 257 knees (32%). It is important to identify the AMFL and PMFL (when present) to determine the PCL anatomic footprint for graft placement, particularly when a two-strand graft construct is used.[35] The anatomic attachment of the AMFL is distal to the PCL attachment (Fig. 15-23), which gives the appearance that the PCL footprint is adjacent to the articular cartilage when, in fact, the true PCL attachment is a few more millimeters proximal.

The cross-sectional area of the AMFL ranges from 6.8 to 7.8 mm^2, and the cross-sectional area of the PMFL ranges from 6.7 to 12.7 mm^2.[33]

CRITICAL POINTS Meniscofemoral Ligaments

- Most knees have at least one MFL.
- One-third of knees have both MFLs.
- Insufficient data to support a functional role of these structures.
- Identify AMFL and PMFL (when present) to determine true PCL anatomic footprint for graft placement.
- In some knees with isolated PCL ruptures, secondary ligament restraints including the MFL structures resist posterior tibial subluxation, particularly at low knee flexion angles.
- 90 degrees of knee flexion, neutral tibial rotation best position to test for maximum posterior translation.
- Amount of posterior translation determined by secondary restraints will vary depending on physiologic laxity.

For the surgeon, this indicates that these structures will be encountered at the time of PCL surgery. The mean ultimate loads of the AMFL and PMFL have been reported to be 265 ± 152 N and 443 ± 287 N, respectively.[43] A comparison of the ultimate strength of the MFLs and the PCL is not possible, because published cadaveric data are from older specimens tested at failure loads less than expected.

Gupte and colleagues[33] reviewed the numerous theories and evolutionary perspectives on the function of the MFL and concluded that there are insufficient data to support a functional role of these structures in humans. In animals such as sheep, horses, and dogs, the lateral meniscus posterior horn is attached by virtue of the PMFL without a separate posterior tibial attachment. In humans, the posterior horn of the lateral meniscus has two separate attachments into the tibia and, when the PMFL is present, an additional attachment into the femur. In rare cases, the posterolateral meniscus tibial attachment is absent and attaches only by the femoral PMFL, which must be preserved with any surgical procedure such as PCL reconstruction. The Wrisberg-type discoid lateral meniscus may have the PMFL as the only attachment, with an absent posterior tibial attachment. Gupte and colleagues[33]

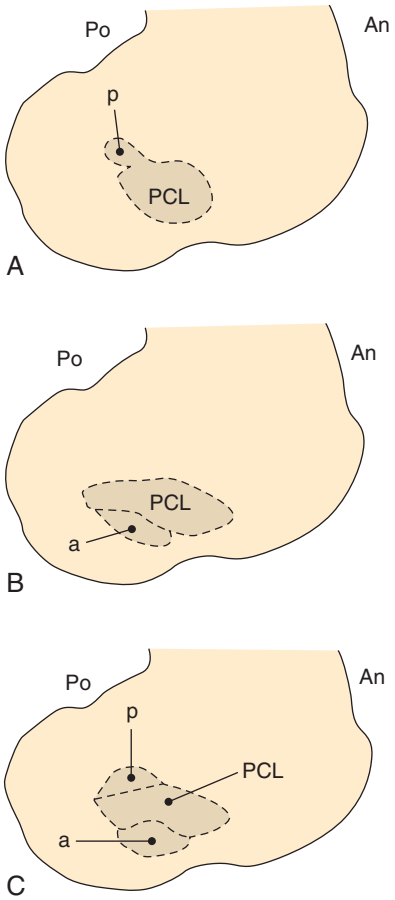

FIG 15-23 Femoral insertions of the meniscofemoral ligaments in relation to the insertion of the posterior cruciate ligament (PCL). Diagrammatic views of the left lateral femoral condyle in sagittal section demonstrate its anterior (An) and posterior (Po) aspects. **A,** Specimen with posterior meniscofemoral ligament (p) and PCL. **B,** Specimen with anterior meniscofemoral ligament and PCL. **C,** Specimen with PCL and coexisting anterior and posterior meniscofemoral ligaments. (From Gupte CM, Bull AM, Thomas RD, Amis AA. A review of the function and biomechanics of the meniscofemoral ligaments. *Arthroscopy.* 2003;19:161-171.)

noted that the PMFL is tight in both knee extension and deep knee flexion. It has been theorized that the PMFL may pull the lateral meniscus into the joint during flexion, causing clicking and snapping symptoms and leading to meniscus deteroriation.[20] It is possible that the PMFL provides additional resistance to posterior displacement of the lateral meniscus posterior horn during maximum external rotation tibia; however, this has not been experimentally proven.

The effect of the MFLs acting as a secondary restraint to posterior tibial translation was investigated by Gupte and coworkers[32] in cadaveric knees. The authors postulated that the MFLs provide to the PCL a "synergistic reinforcement" in resisting posterior tibial translation. In this study, the PCL was first divided and the increase in posterior tibial translation measured; then the MFLs were divided (Figs. 15-24 and 15-25). The data showed that the MFLs contributed 28% of the restraining force at 90 degrees of knee flexion without any restraint for rotatory subluxations. The data show that partial or isolated tears of the PCL may be supported in part by intact MFL structures, resulting in less overall posterior tibial translation. This

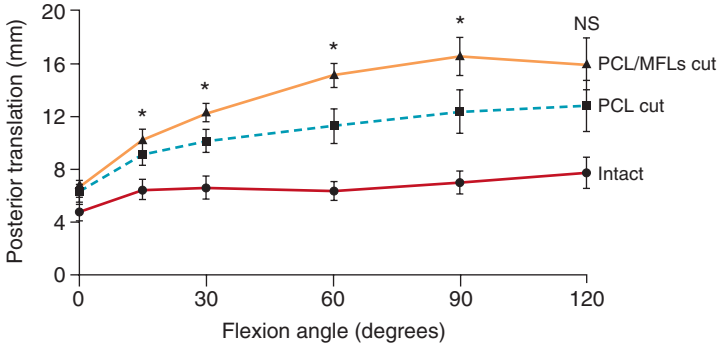

FIG 15-24 The effect of division of the posterior cruciate ligament (PCL) on posterior laxity in the intact knee, and the effect of division of the meniscofemoral ligaments (MFLs) in the PCL-deficient knee. Division of the PCL resulted in an increase in posterior translation at all angles of flexion in the intact knee (paired *t* test and analysis of variance; $P < .005$). Division of the MFLs resulted in an increase in posterior translation in the PCL-deficient knee between 15 and 90 degrees of flexion (*$P < .005$). Bars are standard error of the mean. *NS*, not significant. (From Gupte CM, Bull AM, Thomas RD, Amis AA. The meniscofemoral ligaments: secondary restraints to the posterior drawer. Analysis of anteroposterior and rotatory laxity in the intact and posterior cruciate-deficient knee. *J Bone Joint Surg Br.* 2003;85:765-773.)

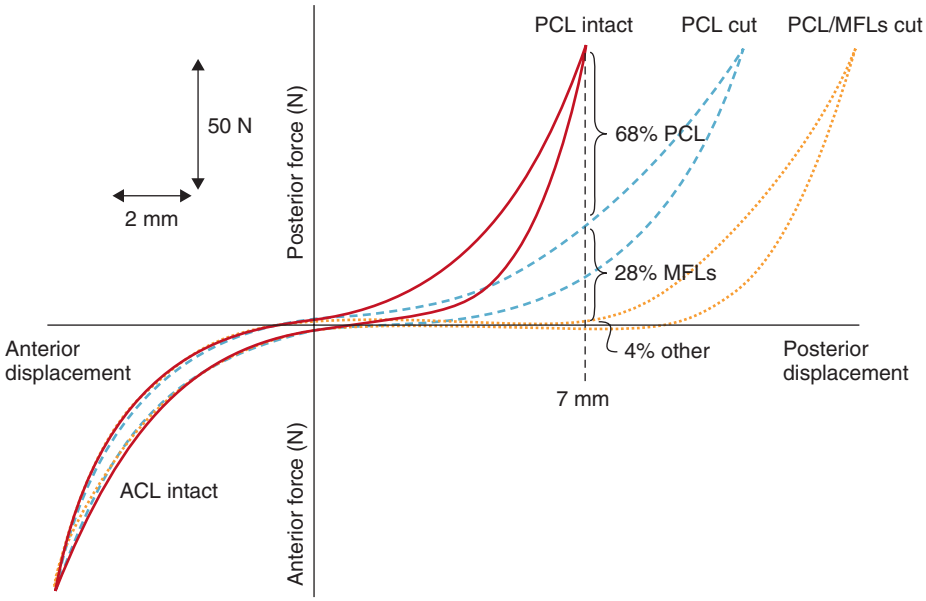

FIG 15-25 Mean load-displacement curves for intact, posterior cruciate ligament (PCL)-deficient and PCL/meniscofemoral ligament (MFL)-deficient knees tested at 90 degrees of flexion. Note the hysteresis effect of the anteroposterior (AP) drawer cycle. Note also the relative percentage contributions of the PCL and MFLs to resisting posterior drawer at displacement of 7 mm. The crossed hairlines mark the assumed AP neutral and zero load. (From Gupte CM, Bull AM, Thomas RD, Amis AA. The meniscofemoral ligaments: secondary restraints to the posterior drawer. Analysis of anteroposterior and rotatory laxity in the intact and posterior cruciate-deficient knee. *J Bone Joint Surg Br.* 2003;85:765-773.)

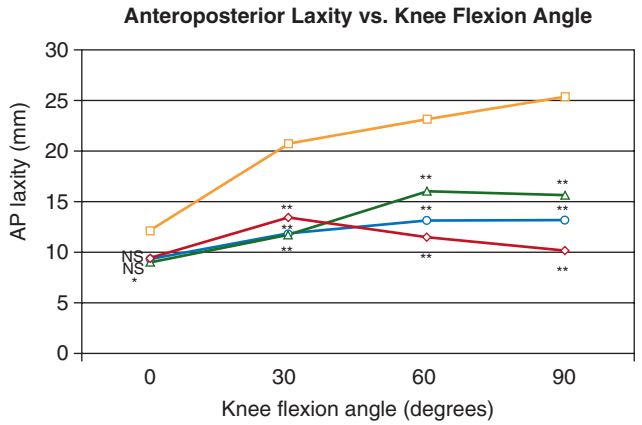

FIG 15-26 Anteroposterior (AP) laxity with the knee in 0, 30, 60, and 90 degrees of flexion. The test was performed under four conditions: with the posterior cruciate and meniscofemoral ligaments intact (diamonds), with the ligaments transected and the tibia in neutral rotation (squares), with the ligaments transected and the tibia in internal rotation (circles), and with the ligaments transected and the tibia in external rotation (triangles). **Significant difference at $P \leq .001$; *significant difference at $P \leq .05$; NS indicates no significant difference ($P > .05$) compared with the laxity measured with the ligaments transected and the tibia in neutral rotation. (From Bergfeld JA, McAllister DR, Parker RD, et al. The effects of tibial rotation on posterior translation in knees in which the posterior cruciate ligament has been cut. *J Bone Joint Surg Am.* 2001;83:1339-1343.)

TABLE 15-5 Anteroposterior Laxity for Each Condition at Each Knee Flexion Angle

	ANTEROPOSTERIOR LAXITY (mm)			
Condition	0 Degrees Flexion	30 Degrees Flexion	60 Degrees Flexion	90 Degrees Flexion
PCL and MFL intact	9.4	13.5	11.5	10.2
PCL and MFL transected				
Neutral tibial rotation	12.1*	20.8†	23.3†	25.5†
Internal tibial rotation	9.3*‡	11.8*‡	13.2*§	13.2§¶
External tibial rotation	9.0*	11.7*	16.1†	15.7†

*$P < .05$ compared with the intact condition.
†$P < .001$ compared with the intact condition.
‡$P > .05$ compared with the test performed with the ligaments transected and the tibia in external rotation.

MFL, Meniscofemoral ligament; *PCL,* posterior cruciate ligament.

suggests the potential benefit of preserving the function of the MFLs when possible at surgery, which is often difficult in double-bundle PCL reconstructions. This also provides the rationale for protecting knees with isolated PCL ruptures, using a postoperative brace at full extension with a calf pad for 4 weeks to allow initial healing. The secondary ligament restraints maintain a normal tibiofemoral joint position at full extension, keeping a normal PCL tibiofemoral attachment distance.

Bergfeld and associates[7] conducted a cadaveric study on 20 knees in which total AP translation was measured in four different flexion angles after cutting the PCL and MFLs. Testing was performed with the tibia in neutral, internal, and external rotation (5 N-m torque). Statistically significant decreases in posterior tibial translation occurred with internal and external tibial rotation (Fig. 15-26 and Table 15-5). The authors concluded that 90 degrees of knee flexion and neutral tibial rotation was the best position to test for maximum posterior translation and that the medial and lateral secondary restraints were tensioned to reduce the posterior limit with internal-external tibial rotation. Because the MFLs were cut, other structures limited posterior translation in internal tibial rotation and not the MFLs, as had been reported previously.[14] Note in Chapter 3, after sectioning the PCL, that the posterior tibial translation increased 12.1 ± 0.6 mm and that 15 of 22 specimens had increases greater than 10 mm. This indicates that the amount of posterior translation determined by secondary restraints will vary depending on their physiologic laxity. Therefore the frequently reported value of greater than 10-mm posterior translation, indicating injury to the secondary restraints cannot be used. The secondary restraints may be lax owing to either physiologic laxity or injury.

Gupte and colleagues[31] introduced the concept of a "meniscal tug test" at arthroscopy, which involves placing tension on the AMFL with a nerve hook and observing movement in the posterior horn of the lateral meniscus. The AMFL was confirmed in 88% of 68 knees, whereas the PMFCL was identified in only 9%. The authors concluded that this test could be used to distinguish between fibers of the PCL and MFLs, which is helpful in avoiding a misdiagnosis of a partial versus a complete PCL tear.

POPLITEOMENISCAL FASCICLE ATTACHMENTS

Staubli and Birrer[97] conducted anatomic dissections of the popliteus tendon and its fascicles and described the relationship of these to the lateral meniscus attachments in cadaveric knees. These authors also compared arthroscopic examinations of the popliteus-lateral meniscus attachments in a normal control group of 107 patients with those of 68 patients with acute and chronic ACL disruptions. Structural lesions of the popliteus meniscus attachments were observed in approximately 19% of control knees compared with 86% to 95% of ACL-deficient knees. The authors concluded that the surgeon should determine whether an anterior subluxation and disruption of lateral meniscus attachments is present, requiring operative repair at the time of ACL reconstruction.

Simonian and coworkers,[95] in a cadaveric study, transected the anteroinferior fascicle and then the posterosuperior fasciculi to determine the contribution of these structures to lateral meniscus stability. The mean lateral meniscal motion under a 10-N load was 3.6 mm. After the anteroinferior fascicle was cut, an increase in anterior displacement of the posterior horn of the lateral meniscus of 1.8 mm (50%) occurred, and when both fasciculi were cut, an increase of 2.8 mm (78%) was found. The authors concluded that the popliteomeniscal fasciculi contributed to lateral meniscus stability and acknowledged the difficulty in objectively determining abnormal meniscus displacements at the time of arthroscopic surgery. Tests for abnormal lateral meniscus displacement at the time of arthroscopic surgery and the repair of the popliteomeniscal fascicles are discussed in Chapter 23.

CRITICAL POINTS Popliteomeniscal Fascicle Attachments

- Structural lesions of the popliteus system observed in approximately 19% of control knees compared with 86% to 95% of ACL-deficient knees in one study.
- Popliteomeniscal fasciculi contribute to lateral meniscus stability, difficult to objectively determine abnormal meniscus displacements at arthroscopy.
- Surgeon determines whether an anterior subluxation of the posterior horn lateral meniscus is present with partial disruption of meniscus attachments, requiring operative repair. This is common with ACL ruptures.

PCL FIBER FUNCTION: SCIENTIFIC BASIS FOR PLACEMENT OF PCL GRAFTS AT TIBIOFEMORAL LOCATIONS

The anatomy of the cruciate ligaments has been described for over a century in qualitative terms as having two major bundles or bands. The Weber brothers in 1836[111] and Fick in 1911[23] published some of the first anatomic descriptions of the ACL and PCL; however, these authors did not conduct biomechanic studies to support their descriptions. The PCL has been classically described as a structure composed of an anterolateral bundle that is tense in flexion and a posteromedial bundle that is tense in extension. This nomenclature is still used today; however, we advance the concept that this classical description does not describe the function of the PCL fibers or provide the surgeon with adequate data for determining placement of PCL graft strands (see Chapter 16).

Inderster and associates[42] divided the PCL into three bundles: anterolateral, posteromedial, and posterior oblique. These authors reported that the femoral-to-tibial distances of the anterolateral and posteromedial bundles increased with knee flexion from 0 to 90 degrees, whereas the length of the posterior oblique bundle remained the same. Accordingly, they recommended a more posterior position of a PCL reconstruction at the femoral attachment of the posterior oblique bundle. The authors did not induce posterior loads on the tibia to determine femoral-tibial length changes under loading conditions, nor did they measure tibial displacements after PCL reconstruction.

Covey and colleagues[15,16] described a fiber continuum of the PCL consisting of four regions: anterior, central, posterior longitudinal, and posterior oblique. This four-fiber region classification was confirmed by Makris and coworkers[54] according to fiber orientation and osseous sites of attachment visualized in 24 cadaveric knees. The anterior fiber region attachment was located at the most anterior portion of the femoral attachment and inserted into the anterior portion of the tibial attachment. The central fiber region was the widest portion, representing the middle part of the femoral attachment, and inserted into the middle and slightly lateral aspect of the tibial attachment. The anterior and central fiber regions represented nearly 80% of the PCL, with the posterior fiber regions accounting for the remaining 15% to 20%. The posterior fiber region consisted of a posterior longitudinal attachment to the tibia medially and a posterior oblique region attachment to the tibia laterally.

In these investigations, the researchers reported that, under operative conditions, most of the PCL's attachment sites exhibit nonisometric behavior. Only the small posterior fiber attachment sites (which account for 15% of the PCL)[54] demonstrate near isometry. In addition, Covey and colleagues[15] reported marked loosening of most PCL fibers by an applied quadriceps force at knee flexion angles less than 75 degrees when compared with an unloaded state. Internal tibial rotation slackened certain fibers (anterior, central) near extension, but significantly tightened others (central, posterior) with flexion. The authors concluded that the joint angle and type of load applied to the knee joint produce different functional roles to the four fiber regions of the PCL.

CRITICAL POINTS Posterior Cruciate Ligament Fiber Function: Scientific Basis for Placement of Posterior Cruciate Ligament Grafts at Tibiofemoral Locations

- PCL classical description: anterolateral bundle tense in flexion, posteromedial bundle tense in extension. Does not describe function of PCL fibers, gives surgeon inadequate data for determining placement and tensioning PCL grafts.
- PCL ligament length pattern is highly dependent on a proximal-to-distal direction of the femoral attachment.
- Transitional zone in proximal one-third of PCL femoral attachment, approximately 11 mm from the articular cartilage distally, extending approximately 10 mm from the roof in a posterior direction.
- The bulk of the PCL lengthens with knee flexion, approximately one-third of the posterior fibers lengthen with knee extension.
- Graft placed within PCL attachment will have portions that undergo different elongations along every 2-3 mm in graft diameter, progressing in a proximal-to-distal direction.
- One- and two-strand reconstructions attached in three difference locations within PCL femoral footprint in a cadaveric investigation. Central tibial tunnel used.
  - One strand (distal and middle position) restored posterior translation limits to normal.
  - One strand (deep and proximal) abnormal increase in posterior translation.
  - Two strands (distal locations, tensioned at 90 degrees) shared applied load.
  - Two strands (one strand anterior, one proximal): reciprocal loading relationship.
  - Tension in single-strand PCL graft nearly doubles with knee flexion.
  - Placement of second graft strand in either distal or middle position most ideal.
- All graft constructs capable of restoring posterior translation limit to normal. However, the constructs do so by inducing high tensile forces in the graft that may be deleterious, producing eventual graft elongation.

Quantitative data have been reported by many investigators who have used a variety of techniques to determine the length-tension behavior of the PCL fibers under loaded conditions. These measurement conditions include the use of force measurement sensors,[4,58,63] wire cables,[21] mercury strain gauges,[22,44] and photogrammetric techniques.[18,101,106,107] Ahmad and associates[1] performed an analysis of PCL bundle length change and angle of orientation with knee flexion and extension. The anterolateral bundle was observed to become more vertical with increased knee flexion and the posteromedial bundle to become more horizontal. Therefore the posteromedial bundle has a better orientation to resist posterior tibial translation, owing to its horizontal position. The study data are in agreement with other studies showing the marked changes in the length of PCL fibers with knee flexion and extension based on their femoral attachment.

The use of an instrumented spatial linkage during application of joint loads (followed by digitization of the tibia and femoral surfaces and ligament attachment locations) allows the length of discrete fiber strands or regions within a ligament to be measured based on

tibiofemoral attachment sites and the change in distance (fiber length) with knee motion.[28,38,87] This information is required to determine locations of graft attachments whose tibiofemoral length changes the least with knee flexion or, alternatively, graft attachment locations at which the fiber length changes the most. The surgeon should select graft attachment locations that have the least amount of change in tibiofemoral length and tension the graft at the knee flexion position where the graft length is the longest (and therefore functional). For example, if a graft is tensioned at a knee flexion angle where the tibiofemoral fiber length is at its shortest, the graft will initially constrain knee flexion or extension and fail as the graft construct (tibiofemoral distance) lengthens with further knee flexion or extension.

The PCL ligament length pattern is highly dependent on a proximal-to-distal direction of the femoral attachment, and not on an anterior-to-posterior direction, as proposed by the anterolateral-posteromedial bundle concept previously discussed. In Figure 15-27, the tibiofemoral separation distances are shown for a number of proximal-to-distal locations that pass through the PCL femoral attachment. A transitional zone (<2-mm length change) adjacent to the center of rotation is shown. All attachment locations distal to line A-A lengthen with knee flexion, and all fibers proximal to this line shorten with knee flexion. In Figure 15-28, the average tibiofemoral separation length is shown along three femoral attachment site locations. Two sites are within the PCL femoral attachment, and one is outside the PCL attachment. These data demonstrate that the fiber length change is minimal in an anterior-to-posterior direction within the PCL attachment. These experimental findings were corroborated by Sidles and colleagues,[93] Ogata and McCarthy,[76] and Trus and coworkers.[102]

The changes in tibial attachment location show only a small effect on the tibiofemoral separation distance, as demonstrated in Figure 15-29. These experimental conditions are valid if one assumes a PCL fiber follows a straight path between attachment sites. Native PCL fibers do not follow straight paths but may have curvatures induced by other fibers. As yet, there is no description of fiber anatomy suggesting major PCL fiber curvature from one attachment site to another.

A simplified planar model may be used to explain the larger effect of the femoral attachment on PCL fiber length change in comparison with the tibial attachment. The model is shown in Figure 15-30, where the tibia is stationary and the femur rotates about a fixed center. The femur is positioned at 45 degrees, and the change in tibiofemoral distance is shown relative to the center of rotation with knee extension and flexion to 90 degrees. The planar model does not describe the true

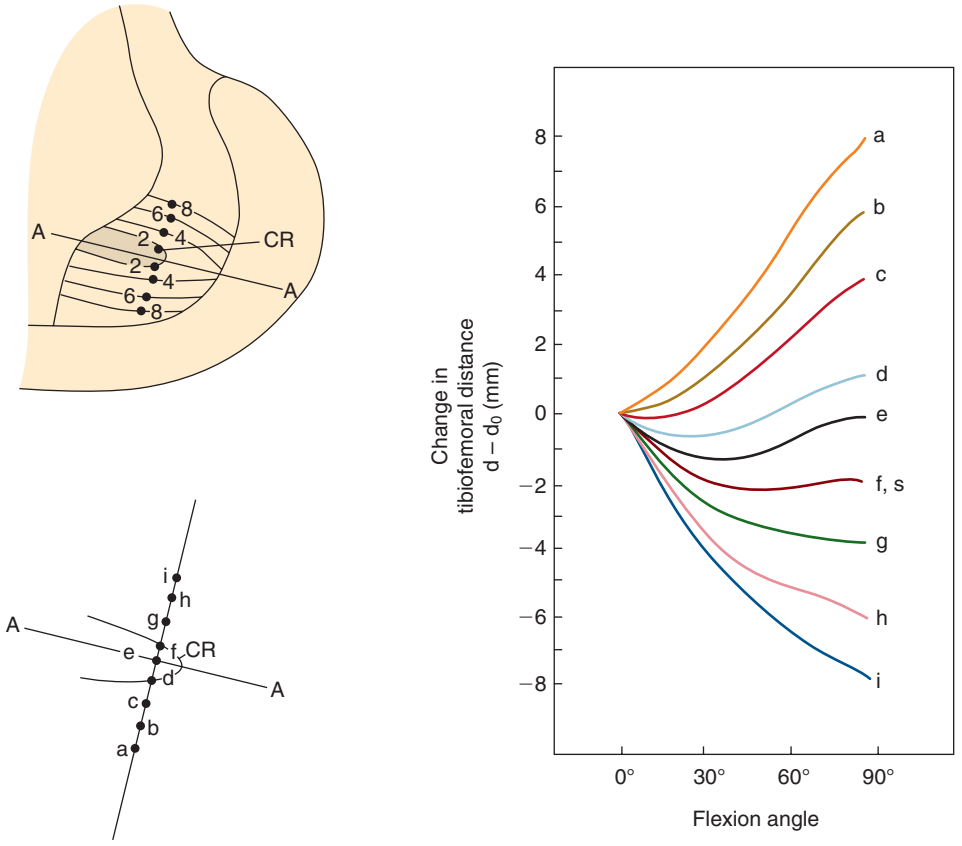

FIG 15-27 Contour map for one typical knee. The number on each contour line indicates the magnitude of the maximum length change. Line A-A represents the most isometric line and runs almost in the anteroposterior direction. Point CR indicates the intersection of the best-fit flexion axis with the lateral surface of the medial femoral condyle. Note that line A-A passes near point *CR*. The curves at the right show the changes in the tibiofemoral separation distances that occurred for selected femoral attachments. Attachments proximal to the isometric line were shorter at 90 degrees than at full extension. Attachments distal to the line were longer at 90 degrees. Attachments along line A-A had a length at 90 degrees that was nearly identical to its length at 0 degrees. (From Grood ES, Hefzy MS, Lindenfeld TN. Factors affecting the region of most isometric femoral attachments. Part I: the posterior cruciate ligament. *Am J Sports Med.* 1989;17: 197-207.)

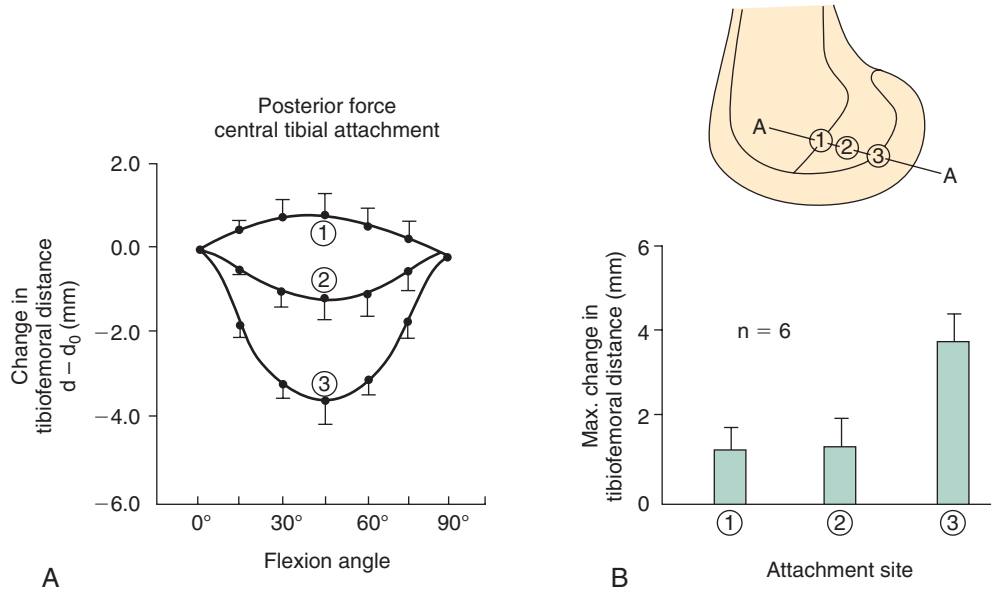

FIG 15-28 **A,** Average tibiofemoral separation distance vs. knee flexion for three femoral attachment sites located along the most isometric line. **B,** The average and standard deviation (shown by bars) of the difference between the maximum and minimum tibiofemoral separation distance for each of the three femoral attachment sites. (From Grood ES, Hefzy MS, Lindenfeld TN. Factors affecting the region of most isometric femoral attachments. Part I: the posterior cruciate ligament. *Am J Sports Med.* 1989;17:197-207.)

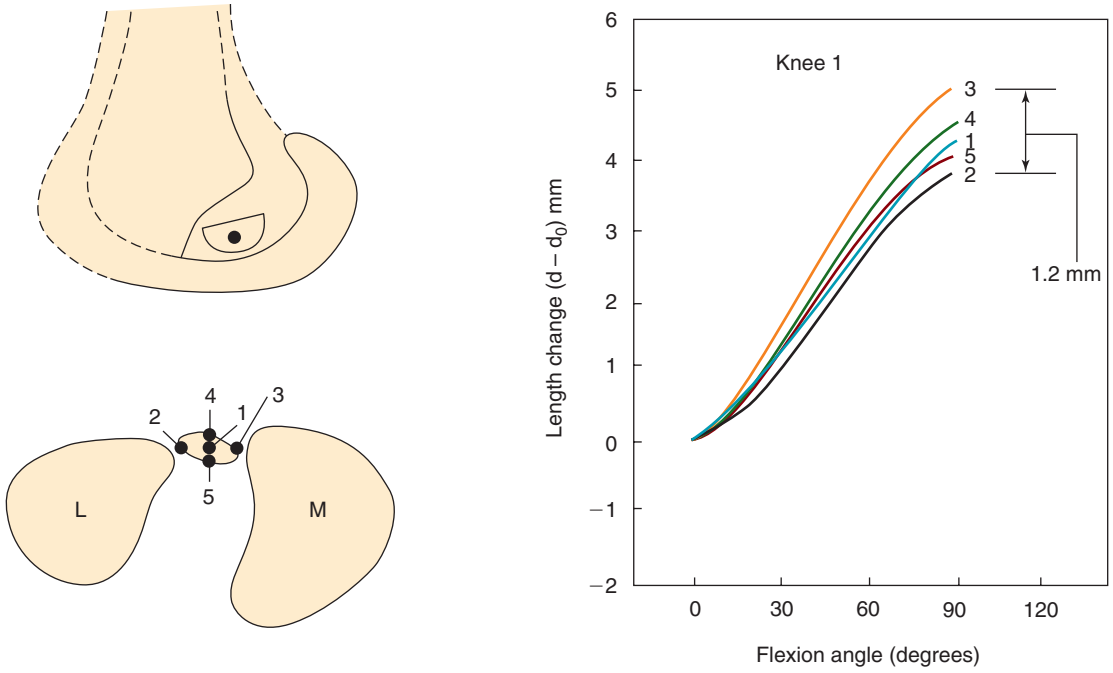

FIG 15-29 Relation between the change in the tibiofemoral separation distance and that at full extension and flexion angle for five tibial attachment sites in one typical knee. (From Grood ES, Hefzy MS, Lindenfeld TN. Factors affecting the region of most isometric femoral attachments. Part I: the posterior cruciate ligament. *Am J Sports Med.* 1989;17:197-207.)

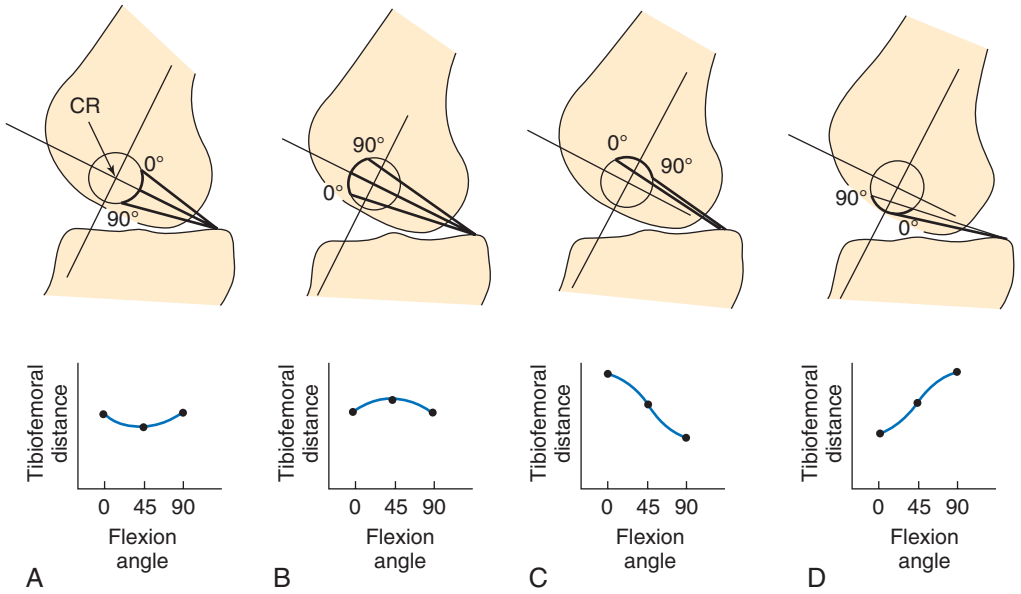

FIG 15-30 The mechanism governing the sensitivity of the length patterns of the fibers within the posterior cruciate ligament to their femoral attachments. **A,** Fiber is attached posterior to the center of rotation (CR) and has a concave length pattern. **B,** Fiber is attached anterior to the CR and has a convex length pattern. **C** and **D,** Length patterns of fibers with femoral attachments located proximal and distal to the CR. The fiber with proximal attachment (**C**) becomes longer with flexion, whereas the fiber with distal attachment (**D**) becomes shorter with flexion. (From Grood ES, Hefzy MS, Lindenfeld TN. Factors affecting the region of most isometric femoral attachments. Part I: the posterior cruciate ligament. *Am J Sports Med.* 1989;17: 197-207.)

3-dimensional behavior of the PCL fibers, which is more complex. However, the model does show how the fiber length change is dependent on its femoral attachment relative to the center of femoral rotation, which is simplified to a fixed point. Refer to Chapter 3 for further information on ACL and PCL fiber function.

The contour map showing the length change of PCL fibers based on their femoral attachment from 0 to 90 degrees is shown in a planar manner in Figure 15-31. A previous study showed that a graft placed into a nonisometric location, just distal to the transitional zone, demonstrated a few millimeters' increase in the tibiofemoral distance with knee flexion, providing greater control of posterior tibial displacement than a graft placed in a so-called isometric zone.[28] These data show that any graft placed within the PCL attachment will have portions that undergo different elongations along every 2 to 3 mm in a graft cross-sectional area, progressing in a proximal-to-distal direction.

In a second investigation at our laboratory,[87] several attachment sites at the proximal and distal origins located around the circumference of the PCL femoral attachment were studied. The peripheral attachment sites originated on the proximal border of the PCL (anterior, middle, posterior, and posterior oblique) and on the distal border (anterior, middle, and posterior). The limbs were loaded to 100 N, and the knees were flexed from 0 to 120 degrees. This was one of the first studies to examine PCL fiber length changes at knee flexion angles greater than 90 degrees. The changes in tibiofemoral length for the seven selected peripheral attachment points are shown in Figure 15-32. These data confirm that proximal PCL fibers lengthen with knee extension, whereas distal fibers lengthen with knee flexion. In Figure 15-33, the flexion angles in which the fiber length elongations were the least (within 5% of the maximum length and therefore the functional zone) are graphed for each attachment point. The data as a whole show a progressive loading of fibers from distal to proximal within the PCL

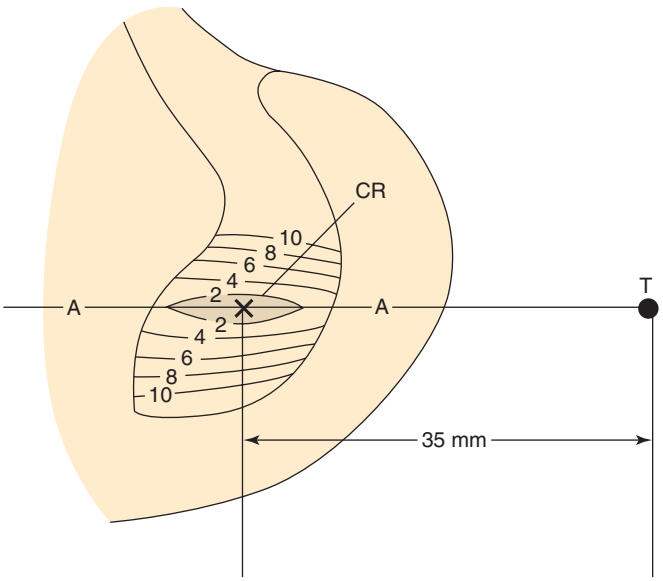

FIG 15-31 Contour map obtained from the single-hinge model in which the knee rotates around a single axis of rotation. A tibial attachment site (T) 35 mm away from this axis was used in the analysis. The number on each contour line indicates the magnitude of the maximum length change found as the knee was rotated from 0 degrees to 90 degrees. Line A-A represents the "most isometric" line. This line, besides being an axis of symmetry for the contour map, passes through the center of rotation (CR) and the tibial attachment site when the knee is positioned midway between the limits of flexion. Shading represents the region within which a maximum length change of less than 2 mm was found. (From Grood ES, Hefzy MS, Lindenfeld TN. Factors affecting the region of most isometric femoral attachments. Part I: the posterior cruciate ligament. *Am J Sports Med.* 1989;17:197-207.)

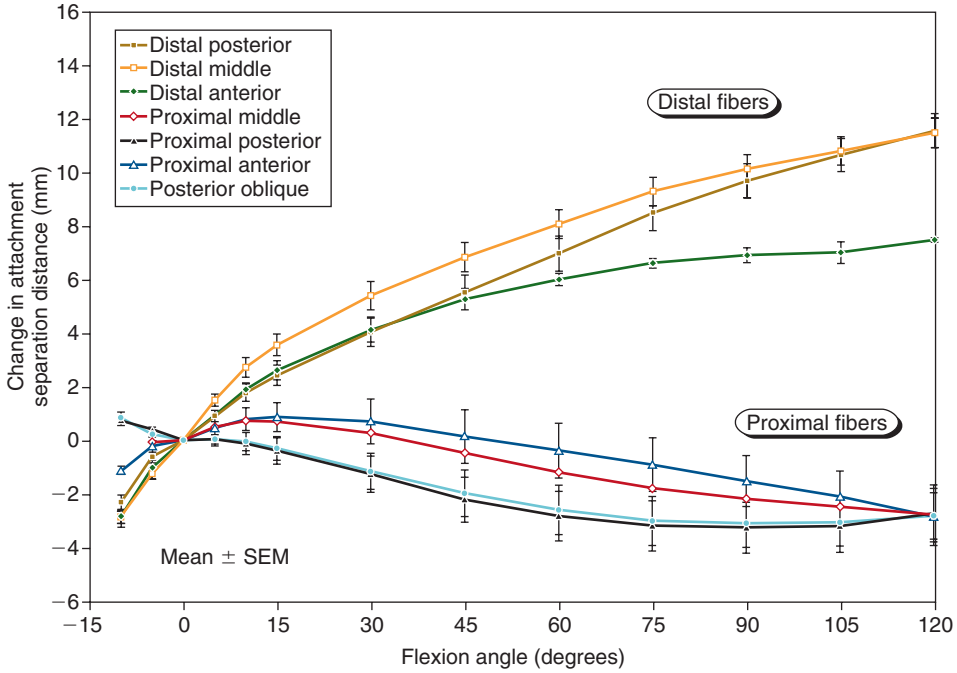

FIG 15-32 Changes in attachment separation distance in millimeters are measured with progressive knee flexion under a 100 N posterior load. Distal fibers lengthen with knee flexion, and proximal fibers shorten with knee flexion. (From Saddler SC, Noyes FR, Grood ES, et al. Posterior cruciate ligament anatomy and length-tension behavior of PCL surface fibers. *Am J Knee Surg*. 1996;9:194-199.)

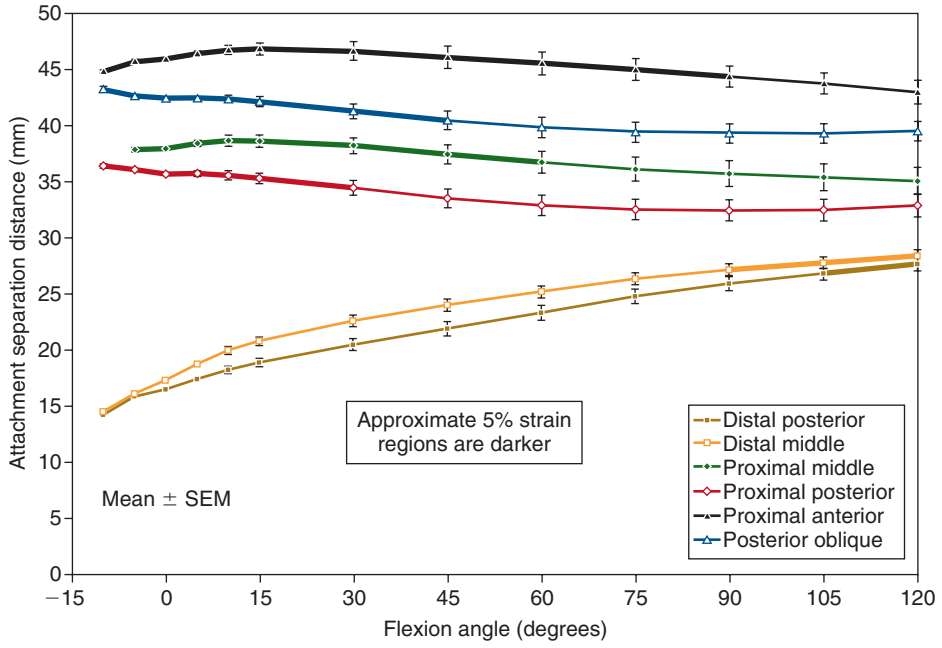

FIG 15-33 The change in attachment separation distance curves has been shifted to begin at the measured absolute length of each fiber. The darker area for each curve represents the 5% strain for each fiber. This, in theory, represents the functional range of knee flexion for each fiber. Note that this model predicts that the proximal anterior fiber will function over the longest functional range. (From Saddler SC, Noyes FR, Grood ES, et al. Posterior cruciate ligament anatomy and length-tension behavior of PCL surface fibers. *Am J Knee Surg*. 1996;9:194-199.)

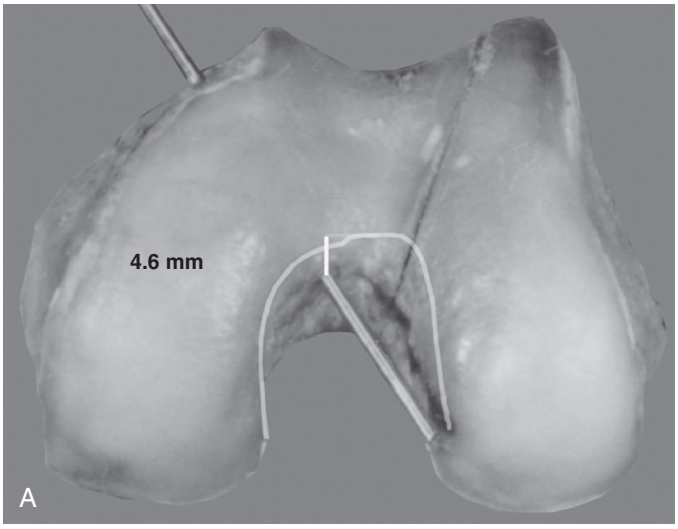
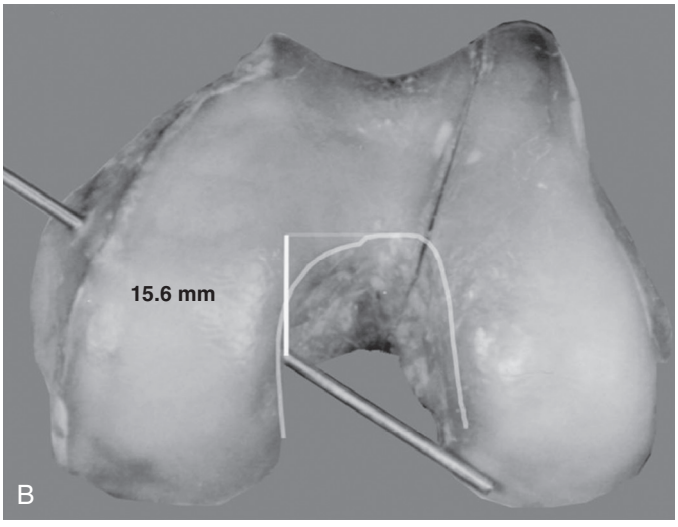
Test Performed	Measurements
I. Intact knee (N = 12) a. 50-N posterior force b. 100-N posterior force	Six-degrees-of-freedom knee kinematics
II. PCL and MFL sectioned (N = 12) Same as in I	Same as in I
III. One-strand PCL reconstructions S_1 (N = 12), S_2 (N = 7), D (N = 5) 50 N posterior force	Six-degrees-of-freedom knee kinematics Strand tension
IV. Two-strand PCL reconstructions S_1–S_2 (N = 7), S_1–D (N = 5) 100 N posterior force	Six-degrees-of-freedom knee kinematics Tension in both strands

FIG 15-34 Tests performed and measurements made using six-degrees-of-freedom knee kinematics that include the three rotations (flexion/extension, adduction/abduction, and external/internal) and three translations (anterior/posterior, medial/lateral, and proximal/distal). (From Mannor DA, Shearn JT, Grood ES, et al. Two-bundle posterior cruciate ligament reconstruction. An in vitro analysis of graft placement and tension. *Am J Sports Med.* 2000;28:833-845.)

attachment with progressive knee flexion. There is a smaller effect proceeding from anterior to posterior. These data contradict the description of PCL fiber function that divides the PCL into an anterolateral bundle (which is tight in flexion) and posteromedial bundle (which is tight in flexion).



The surgeon has the option of placing a PCL graft strand in different regions of the PCL femoral attachment site that determines the functional range of the graft with knee flexion and the knee flexion position to tension the graft. This was investigated in a third cadaveric study in our laboratory in 12 cadaveric knees (Fig. 15-34).[55] The one-strand and two-strand reconstructions were attached in three different locations within the PCL femoral footprint (Figs. 15-35 to 15-37). A bone-patellar tendon-bone (B-PT-B) graft was used to provide secure fixation and prevent slippage in the fixture apparatus. The shallow edge of the graft was placed 2 mm from the articular cartilage margin. The center of the deep proximal strand was within 1 to 2 mm of the proximal edge of the PCL attachment. Within the femoral tunnels, the graft orientation was chosen to place the fibers on either the shallow or distal side of the tunnel, with the bone placed along the deep side. A central tibial tunnel was chosen. A 50-N posterior force was applied to the tibia for the single-strand constructions, and a 100-N force was applied to the two-strand PCL reconstructions. The tension in the graft strand was adjusted to restore posterior translation to within ±1 mm of the intact knee. The graft tensioning was performed at 90-degree flexion for all grafts except the proximal (deep) graft, which was tensioned at 30-degree knee flexion. This was done to remain consistent with prior data on the increased tibiofemoral separation distance of a graft placed at this location.



In Figure 15-38, the increase in graft tension with knee flexion is shown along with the posterior translation limit. The one-strand graft restored the knee joint to a normal posterior translation limit, with a more than doubling of graft tension with knee flexion (maximum, 118 ± 15 N; $P < .001$). In Figure 15-39, the one-strand reconstruction placed at the distal and middle (S_2) position shows a similar tension relationship with knee flexion and also restored knee posterior translation limits to normal. In contrast, the single-graft strand placed into a deep and more proximal position (Fig. 15-40) showed less overall graft tensile loading and an abnormal increase in posterior translation with knee flexion. The difference in the behavior from the two shallow grafts was significant ($P < .001$). The more proximal graft position and graft tensioning did not restore normal posterior translation limits and therefore is not a position recommended for PCL reconstruction.

The more complex behavior of a two-strand PCL reconstruction is shown in Figure 15-41, where the two strands were both placed into the more distal locations and tensioned at 90 degrees. Both strands shared the applied load, as shown. In contrast, a two-strand construct in which one strand was placed anterior and a second was placed more proximal resulted in a marked difference in load-sharing, with a reciprocal loading relationship found between strands (Fig. 15-42). In both situations, posterior translation limits were restored to normal. Similar results were reported by Carson and associates,[11] who conducted an in vitro study of cadaveric knees using a two-bundle (two femoral tunnels) and tibial inlay graft and measured forces in the anterolateral and posteromedial bundles. A reciprocal loading pattern was reported when the anterolateral bundle was placed anterior and the posteromedial bundle posterior to the center of femoral rotation. These authors recommended that tensioning and fixation of the anterolateral and posteromedial bundles be performed at 90 and 0 degrees, respectively.

To further investigate these findings, a fourth cadaveric study was conducted on 19 lower limbs to determine the tension that develops in various two-strand PCL graft constructs.[91] The test conditions are shown in Figure 15-43 for the graft strand configurations. A one-strand PCL reconstruction was performed, and the measured graft tension compared with three different two-strand reconstructions. The location of the single- and two-strand graft configurations are shown in Figure 15-44. The one-strand graft was placed in the anterior one-third and middle of the PCL femoral attachment. In the two-strand PCL graft reconstructions, one strand was placed in the anterior femoral region (AD_2) and the second in either the distal, middle, or proximal one-third of the PCL attachment. The reconstructions were tensioned (with a custom-designed instrumented spatial linkage) to restore posterior translation to ±1 mm of the intact knee (90 degrees flexion, 100-N posterior load). The two-strand graft configurations were all tensioned to share load, with the exception that the proximal strand (MP) was tensioned to carry 20%

of the load and the anterior strand was tensioned to carry 80%. The tension in each graft strand was directly measured during knee motion using strain-gauge load cells following a methodology previously described.[91]

The relationship between graft strand placement within the PCL femoral attachment and the tension and function of the graft strand is shown in Table 15-6. In Figure 15-45, the tension in the single-strand PCL graft is shown to nearly double with knee flexion. Under a 100-N posterior load, the graft tension reached over 200 N. This doubling of the tensile load as a multiple of the applied posterior load has been shown in numerous experiments conducted in laboratory studies. With the knee at 90 degrees of flexion, the PCL is elevated approximately 60 degrees from the sagittal AP plane. At this flexion position, the PCL resists nearly all (95%) of the applied posterior force. In this study, the graft tensions required to restore normal posterior translation limits ranged from 230 to 300 N.

TABLE 15-6 Posterior Translation With Graft Tensioning

Reconstruction	No. Knees	Change in Posterior Translation (mm)*	Anterior-Distal Strand Tension (N)	Second Strand Tension (N)	Total Strand Tension (N)
One-strand (anterior-distal)	5	–0.7 ± 0.3	230.3 ± 23	NA	230.3 ± 23
Two-strand (anterior-distal, middle-distal)	5	–0.1 ± 0.3	123.3 ± 6	152.3 ± 14	275.6 ± 19
Two-strand (anterior-distal, middle-middle)	5	–0.1 ± 0.4	148.0 ± 12	155.1 ± 15	303.1 ± 22
Two-strand (anterior-distal, middle-proximal)	4	0.6 ± 0.5	246.9 ± 20	40.8 ± 16	287.7 ± 25

Data are for 90 degrees of flexion with a 100-N posterior force applied to the proximal part of the tibia. The values are given as the mean ± standard error of the mean.
*Compared with the intact knee.

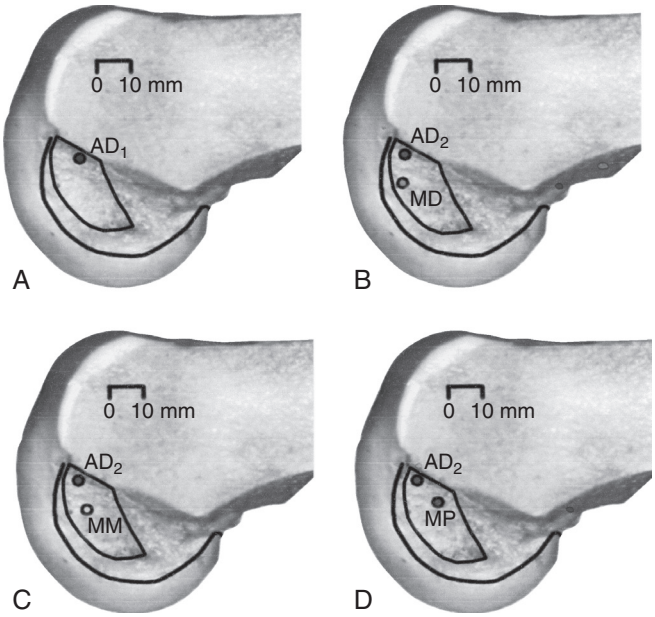

FIG 15-44 Sagittal views of the femur in 90 degrees of flexion. **A,** One-strand anterior-distal (AD) reconstruction. The AD_1 attachment is 6.7 mm from the trochlear groove and 10.6 mm from the cartilage edge. **B,** Two-strand AD, middle-distal reconstruction. The AD_2 attachment is 5.2 mm from the trochlear groove and 6.3 mm from the cartilage edge. **C,** Two-strand AD, middle-middle reconstruction. The middle-middle attachment (MM) is 14.8 mm from the trochlear groove and 9.5 mm from the cartilage edge. **D,** Two-strand AD, middle-proximal reconstruction. The middle-proximal attachment (MP) is 12.1 mm from the trochlear groove and 13.3 mm from the cartilage edge. (From Shearn JT, Grood ES, Noyes FR, Levy MS. Two-bundle posterior cruciate ligament reconstruction: how bundle tension depends on femoral placement. *J Bone Joint Surg Am.* 2004;86:1262-1270.)

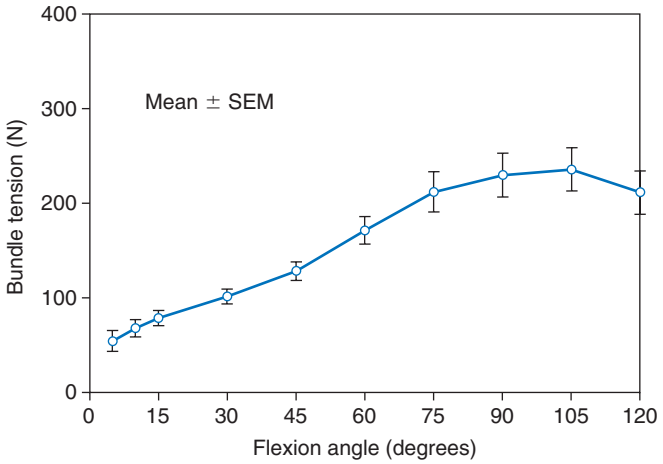

FIG 15-45 Strand tension for the one-strand reconstruction. *SEM,* Standard error of the mean. (From Shearn JT, Grood ES, Noyes FR, Levy MS. Two-bundle posterior cruciate ligament reconstruction: how bundle tension depends on femoral placement. *J Bone Joint Surg Am.* 2004;86:1262-1270.)

The graft strand tensions for the two-strand PCL reconstructions are shown in Figures 15-46 to 15-48. The average tension and the peak tension decreased for the two-strand reconstructions in which the second graft strand was placed in either a distal or a middle position and was able to share the posterior resisting load (Table 15-7). This represented the most ideal arrangement for the two graft strands, particularly when the second graft strand was placed in the middle third of the PCL attachment. In contrast, placement of the second graft strand in a more proximal location resulted in a reciprocal loading behavior between both graft strands, with higher loads placed on the anterior graft strand in comparison with those in the other two-strand configurations.

The data in this experiment support the conclusions of prior studies previously described that small changes in graft position in a proximal-to-distal direction within the PCL attachment have a pronounced effect on graft tension behavior. The hypothesis of this study is that load-sharing between two-strand PCL reconstructions is more ideal in terms of graft function in the long term in preventing posterior tibial subluxation with increasing knee flexion. In addition, the lower graft strand loads in a load-sharing configuration would be more protective against deleterious graft elongation that would be expected to occur under higher loads. It should be noted that, under the conditions of the experiment, all of the two-strand reconstructions restored the posterior translation limit to within ±1 mm of the intact knee, whereas the single-strand reconstruction resulted in a slight overconstraint of 2 mm (which occurred at the 30-degree flexion position; Fig. 15-49).

Petersen and associates,[79] in a cadaveric study, examined the effect of the femoral tunnel position of a two-bundle PCL reconstruction using a robotic testing system. These authors reported a significant effect of the femoral tunnel position in fiber tension behaviors. An

anterior position of the two tunnels (anterolateral 7 mm, posteromedial 4 mm from femoral articular cartilage) was recommended. A more posterior (deep) placement of the tunnels was not recommended. One problem should be noted in that the PCL reconstructions (80-N tension at 90 degrees of knee flexion) resulted in a residual posterior tibial translation (7-10 mm at 90 degrees of knee flexion). It is preferred that biomechanic experiments tension grafts until the abnormal posterior translation is eliminated and not to an arbitrary graft tension, as in this study.

Markolf and colleagues[56] conducted a cadaveric study in which one- and two-strand PCL reconstructions were performed to determine whether the second graft strand placed in a posterior position (two placements, center and proximal PCL footprint) provided an advantage in terms of tensile load-sharing between graft fibers. The posteriorly placed grafts provided a resistance to posterior tibial translation, developed tension in the low knee flexion range, and developed greater than the normal PCL forces measured before PCL reconstructions. One problem not explained in the study is that, under 100-N posterior tibial load, the PCL would be expected (as the primary restraint in an oblique position) to develop close to or greater than the 100-N applied posterior forces. In the experimental results, the PCL developed forces of only approximately 30 to 50 N in the 20- to 40-degree flexion range, which is considerably lower than would be expected. Therefore it is difficult to interpret the data because the PCL and graft forces were less than expected.

Race and Amis[82] examined the separate functions of the anterolateral PCL (APCL) and posteromedial PCL (PPCL) bundles under loaded conditions in cadaveric knees. The results showed that approaching knee extension, ligamentous restraints other than the PCL contribute significantly to resisting posterior tibial translation (Fig. 15-50). With increasing knee flexion, the APCL and the PPCL provide a posterior resisting force. These results question the traditional concept that the PPCL provides a posterior resistance close to knee extensions, because the PPCL is aligned nearly perpendicular to a posterior loading direction. Further, with knee flexion, the PPCL is oriented in a more advantageous position because it is less vertical in terms of resisting posterior tibial displacement. These data support those of the senior author,[55] as already discussed. In addition, surgical reconstruction of the knee with significant posterior instability at low flexion angles implies damaged medial structures and PLSs described in the bumper model analogy in Chapter 3.

Race and Amis[81] demonstrated, in a cadaveric study, that a single anterolateral bundle reconstruction alone would not prevent abnormal posterior tibial translation at high flexion angles. Markolf and coworkers,[57] in a cadaveric study, evaluated the effect of a single PCL graft placed in three tunnels (anterior, central and posterior) within the PCL femoral footprint. They reported that if a single graft is used, a central location provides the best match for the PCL. The anterolateral and posterolateral tunnel positions did not control posterior tibial translation and underwent potentially deleterious high forces. A problem in the experimental design was that the posteromedial graft was tensioned at 90 degrees of knee flexion (its shortest position) and therefore underwent very high tensile loads as the knee approached full extension. It is important at surgery to determine the length change of the graft construct (tibiofemoral separation distance during knee flexion-extension), as will be discussed.

In a cadaveric study, Wiley and associates[114] examined the effect of single- and double-bundle PCL grafts and reported that the double-bundle reconstruction had statistically lower posterior tibial translation. Both graft constructs were placed into the distal two-thirds or shallower. PCL femoral attachment (avoiding a posterior or deep graft placement) and both grafts were tensioned at 90 degrees of knee flexion. The single-bundle PCL reconstruction was placed more proximal in the PCL attachment.

The primary conclusion of these studies is that most of the graft constructs are capable of restoring the posterior translation limit to normal after PCL sectioning. However, the constructs do so by inducing high tensile forces in the graft that may be deleterious and result in graft elongation and failure. To the extent that the in vitro data apply to in vivo graft function, the surgeon may select a position of the second graft strand that induces either load-sharing or reciprocal loading. Placement of the two graft strands in the middle region avoids the large tibiofemoral separations and resultant graft tensions that affect grafts placed closer to the periphery of the PCL attachment. These findings contradict those of other studies that recommend that the second graft strand be placed distal or proximal to the PCL attachment.[82,83] Even though the surgeon may select a more ideal graft placement in regard to load-sharing between graft strands, or the more ideal placement of a single graft strand, the data show that, owing to the diameter of the graft, there will be asymmetrical graft loading with portions of the graft at the outside diameter undergoing different elongation and tension than other portions. This makes it difficult for

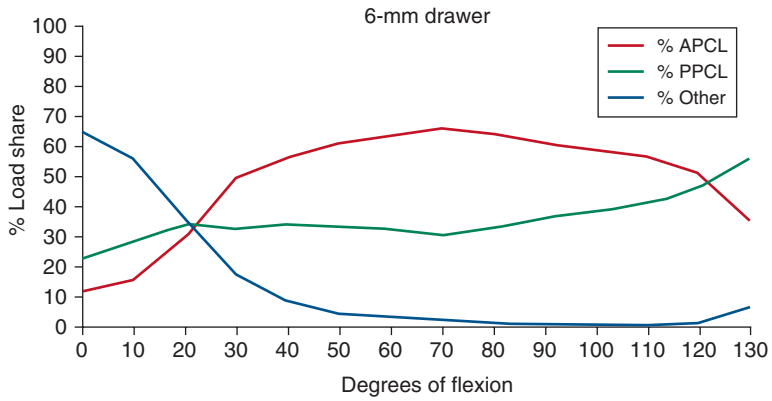

FIG 15-50 Graph of average percentage contribution to resisting posterior displacement against flexion angles for the anterolateral posterior cruciate ligament (APCL), the posteromedial posterior cruciate ligament (PPCL), and combined other structures ($n = 9$). (From Race A, Amis AA. Loading of the two bundles of the posterior cruciate ligament: an analysis of bundle function an A-P drawer. *J Biomech.* 1996;28:873-879.)

any graft strand to reproduce the complex microgeometry of the PCL in which different lengths of collagen fibers are brought into the loading sequence as knee flexion occurs.

Data are not currently available from clinical studies to determine whether two-strand PCL grafts are more successful in restoring posterior tibial translation than single-strand PCL grafts. There are no clinical data comparisons of two-strand PCL grafts implanted in an equal load-sharing configuration versus a reciprocal load-sharing (proximal-distal grafts) configuration. These are important areas for future study to improve the success rate of PCL reconstructions.

CYCLIC FATIGUE TESTING OF ONE- AND TWO-STRAND PCL GRAFT CONSTRUCTS

Several potential mechanisms exist for failure of a PCL graft after implantation, and it is important to design operative techniques and a postoperative rehabilitation program that diminish high tensile forces when possible. Because the PCL is the primary restraint to posterior tibial subluxation, any activities that involve high knee flexion or hamstring activation (descending stairs, walking down a ramp, squatting) may induce deleterious graft tensile forces.[6,12,62,77] In the early postoperative period, before graft maturation occurs and an adequate quadriceps muscle force production is able to counteract these forces, graft elongation or failure may occur. All of the muscles that cross the knee joint are involved in increasing joint contact forces by allowing normal knee joint geometry to decrease high tibial shear forces (see Chapter 18).[12,59,68] Improper graft tensioning (at the knee position of the shortest length) will produce high tensile forces as the graft elongates with knee flexion or extension. Abrasion of collagen strands against bone tunnels is a known cause of graft thinning and rupture.[8,64,92]

The cyclic fatigue of a PCL graft after implantation has been reported in only a few studies.[8,64,92] The failure mechanism of cyclic fatigue involves the nonuniform distribution of loads. For example, a single graft strand placed into the PCL femoral attachment with knee flexion-extension would subject the individual graft fibers to different tensions and lengths. The native PCL has different fiber lengths that are brought into the loading profile; however, a single-diameter graft of a fixed length does not function as a native PCL fiber. This means that individual fibers would, at certain periods, be carrying the majority of the applied load, potentially resulting in an overload and graft fiber elongation. The biomechanic studies already presented show that a proximal-to-distal change in graft position of 2 to 3 mm results in significant changes in graft tension-length relationships. As well, a PCL graft strand may be subjected to angulation (bending) or torsional forces at the bone insertion site. A native ligament has two fibrocartilaginous zones[74] owing to diffuse insertional forces over a wide area and decreased stiffness that prevents stress concentration effects. It is theorized that collagen graft fibers placed into a bone tunnel do not undergo remodeling to restore a normal attachment site[9,112] and that stress concentration effects are therefore always present, particularly at higher in vivo loads when activity is resumed. There is evidence that the bone-tendon junction does remodel to a normal attachment site with a B-PT-B graft.[86]

In studies of cyclic fatigue testing of PCL grafts after implantation, researchers have reported a marked effect of this loading that produced premature graft failure. In three studies, the flexion angle of the graft construct was fixed and a load applied in a cyclic manner to test a one-strand B-PT-B graft.[8,64,66] This type of loading is less ideal in terms of understanding graft cyclic fatigues properties, because single tensile loading does not reproduce the loading profile that a graft would be subjected to with knee flexion-extension motion. Mehalik[67] studied the cyclic behavior of a one-strand Achilles tendon graft in knees cycled to 90 degrees of flexion and reported an increase in posterior translation of approximately 1.7 mm after 1000 cycles (posterior load 50 N; flexion limit, 105 degrees).

Markolf and colleagues[64] performed a cyclic loading study of a B-PT-B allograft using a tibial tunnel and a tibial inlay technique. After 2000 cycles, the graft length of the inlay and tunnel methods increased by 5.9 and 9.8 mm, respectively (load level, 50-300 N). The authors concluded that grafts undergo thinning and increase in length with both fixation techniques. There was greater thinning and degradative effects of the angulated grafts in tibial tunnels compared with the tibial inlay grafts. For example, 10 (32%) of 31 grafts failed at the acute angle of tibial attachment before 2000 cycles, whereas all of the 31 tibial inlay graft constructs survived the testing procedure. The data suggest that a 10-mm-wide B-PT-B graft replacement for PCL reconstruction, with either a tunnel or inlay technique, may result in unacceptable graft elongation under the loading profile. However, the relationship of the cyclic loading behavior to the other mechanic properties of the graft was not studied, and it is possible that significant disuse and age effects resulted in increased elongation or premature failure.

Bergfeld and coworkers[8] compared a tibial tunnel graft technique with a tibial inlay technique using a 10-mm central third B-PT-B graft in cadavers. Both reconstructions restored posterior translation limits to within 2 mm (150-N loading). A tensile load of 89 N on the PCL graft at the femoral site was used. After 72 cycles (from 0 to 90 degrees), the "laxity" of both reconstructions increased as a result of graft stretching, with thinning of the graft found at the tibial tunnel exit but not in the tibial inlay group. The authors acknowledged that the conditions of tensioning may have overconstrained knees in the inlay group.

In a study done at our laboratory,[92] the cyclic behavior of a PCL B-PT-B graft was reported using cadaveric knee joints cycled from 5 degrees to 120 degrees under 100-N posterior loading. The conditions of the experiment were already described, and four graft constructs used are shown in Figure 15-43. The behavior of a normal PCL under cyclic loading is shown in Figure 15-51 where, at 2048 cycles, the increase in posterior translation under loading was less than 1 mm.

CRITICAL POINTS Cyclical Fatigue Testing of One- and Two-Strand Posterior Cruciate Ligament Graft Constructs

- Design operative techniques and postoperative rehabilitation program that diminish high tensile forces.
- High knee flexion activities, hamstring activation (descending stairs, walking down a ramp, squatting) produce deleterious graft tensile forces.
- In the early postoperative period, before adequate quadriceps muscle force able to counteract forces, graft elongation or failure may occur.
- A single-diameter graft of a fixed length does not function as a native PCL.
- A proximal-to-distal change in graft position of only a few millimeters results in significant changes in graft tension-length relationships.
- Cyclic fatigue testing of PCL grafts shows a marked effect, producing premature graft failure after a few hundred knee flexion cycles.
- All graft configurations show marked sensitivity to cyclic loading.
- Only the two-strand construct (one anterior strand, one central strand) showed a two- to threefold increase in number of cycles to graft failure.
- Number of cycles to failure would be reached in the first 2 weeks of rehabilitation unless appropriate measures were taken to limit posterior translation loads and number of flexion-extension cycles.
- In vitro data indicate need to build into protocols measures to protect PCL grafts early postoperatively.

TABLE 15-8 Cyclical Data for the Reconstructed Knees

Reconstruction	Number	Cycle Number to 2.5 mm	Rate of Posterior Translation Return for 2.5 mm*	Cycle Number to 7.5 mm	Rate of Posterior Translation Return for 7.5 mm*
AD_1	4†	137 ± 44	2.3 ± 0.7	267 ± 52	2.5 ± 0.4
AD_2 – MD	4	171 ± 15	1.5 ± 0.2	347 ± 63	2.1 ± 0.5
AD_2 – MM	4†	158 ± 21	1.5 ± 0.1	694 ± 188	1.2 ± 0.3
AD_2 – MP	4‡	80 ± 10	3.1 ± 0.5	176 ± 14	4.0 ± 0.4

*Mean ± standard error of the mean in millimeters/100 cycles.
†Specimen excluded from 7.5-mm group.
‡Specimen excluded from 2.5-mm group.
AD_1, One-strand anterior-distal; *AD_2 – MD,* two-strand anterior-distal, middle-distal; *AD_2 – MM,* two-strand anterior-distal, middle-middle; *AD_2 – MP,* two-strand anterior-distal, middle-proximal.

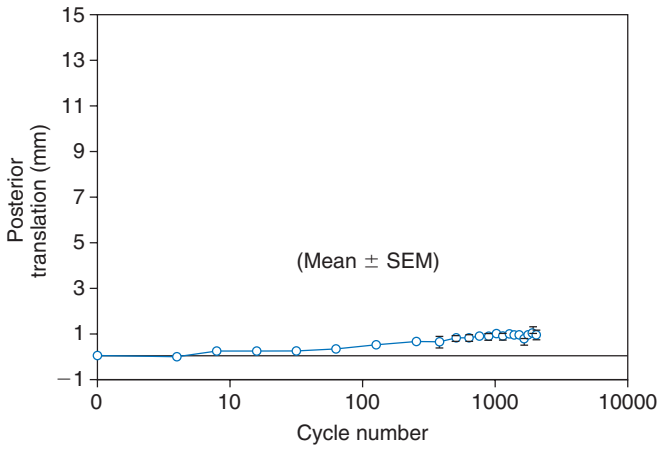

FIG 15-51 For an intact knee, the posterior translation increased during a cyclic fatigue test at 90-degree flexion ($n = 8$ for cycle numbers 384, 640, 896, 1152, 1408, 1664, 1920; $n = 12$ for the other cycle numbers). *SEM,* Standard error of the mean. (From Shearn JT, Grood ES, Noyes FR, Levy MS. One and two-strand posterior cruciate ligament reconstructions: cyclic fatigue testing. *J Orthop Research*. 2005;23:958-963.)

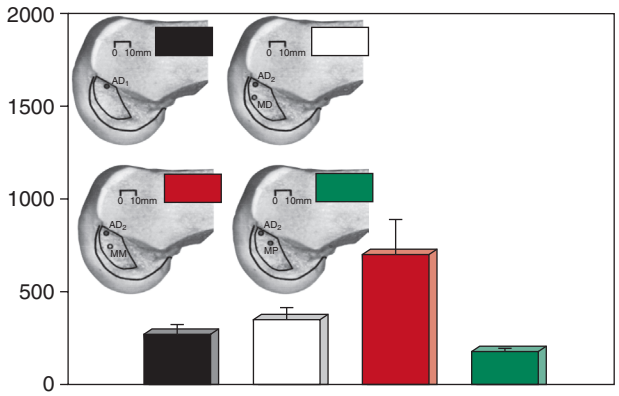

FIG 15-52 Cycle number corresponding to a 7.5-mm posterior translation increase. (From Shearn JT, Grood ES, Noyes FR, Levy MS. One and two-strand posterior cruciate ligament reconstructions: cyclic fatigue testing. *J Orthop Research*. 2005;23:958-963.)

The return of 2.5 mm of posterior translation for the four PCL reconstruction techniques is shown in Table 15-8. All of the graft configurations showed a marked sensitivity to cyclic loading. The return of 7.5 mm of posterior translation was also low in terms of the numbers of cycles. Only the two-strand construct with one anterior graft strand and a second strand placed in the middle configuration showed a two- to threefold increase in the number of cycles to graft failure (Fig. 15-52). Even so, this number of cycles to failure would be reached within the first 2 weeks of rehabilitation unless appropriate measures were taken to limit flexion-extension cycles or the maximum of 120 degrees. The results further showed that 76% of the grafts failed at or adjacent to the femoral attachment region (19 of 25 grafts), with 20% (5 of 25 grafts) in the mid susbstance and 4% (1 of 25 grafts) at the tibial attachment ($P < .001$).
